To address aspects of these issues, an exhaustive series of U L_3 -edge EXAFS measurements have demonstrated that the perchlorate anion does not coordinate directly to the $[\text{UO}_2]^{2+} \cdot 5\text{H}_2\text{O}$ aquo cation even in 11.5 M HClO_4 (Sémon *et al.*, 2001). The average, equatorial $\text{U}-\text{OH}_2$ distances (2.40–2.43 Å) for the $[\text{UO}_2]^{2+}$ aquo ions in perchloric acid are independent of concentration, and are at the short end of the range of distances for the mineral acid aquo ion systems of Table 28.2. In contrast, the systematic U L_3 EXAFS studies of the $[\text{UO}_2]^{2+}$ ion in 0–10 M solution concentrations of HCl reveal inner-sphere Cl^- complexation at and above 4 M, which is accompanied by expansion of the $\text{U}-\text{OH}_2$ bond lengths (Allen *et al.*, 1997). The total equatorial coordination number remained constant at five, suggesting a simple replacement of H_2O with Cl^- as the concentration of HCl increased. Subsequent treatments of the ten EXAFS spectra in the $[\text{Cl}^-]$ series through principal component (factor) analysis revealed the presence of three distinct species (Wasserman *et al.*, 1999). Two of these reflect the inner-sphere replacement of H_2O by Cl^- at the equatorial position in the 1–10 M HCl solutions. The third species, significant only for the $[\text{UO}_2]^{2+}$ ion in 12 and 14 M solutions of LiCl, was attributed to a product resulting from the use of the Dowex anion-exchange resin for the preparative chemistry.

In acidic solutions (pH \approx 5) of 0.052 M $[\text{UO}_2]^{2+}$ with excess fluoride ion (0.21 and 0.45 M), the equatorial coordination number was also found to be five, consisting of a combination of U–F and U–OH₂ interactions that were not resolved in the FT data (Vallet *et al.*, 2001). The F[−] and H₂O coordination numbers were determined from the combined results of equilibrium measurements and the U L₃-edge EXAFS analysis to reveal tri- and tetrafluoride complexation, $[\text{UO}_2\text{F}_3(\text{H}_2\text{O})_2]^-$ and $[\text{UO}_2\text{F}_4(\text{H}_2\text{O})]^{2-}$, with average U–F and U–OH₂ distances of 2.25–2.26 and 2.47–2.48 Å, respectively. At 3 M [F[−]], water does not participate in the equatorial coordination, which was shown to consist of five F[−] anions at 2.26 Å, of the uranyl(vi) pentafluoride complex, $[\text{UO}_2\text{F}_5]^{3-}$ (Vallet *et al.*, 2001). Solution EXAFS and quantum chemical methods have been brought to bear upon the nature of aqueous uranyl(vi) complexes with fluoride and oxalate, $[\text{C}_2\text{O}_4]^{2-}$, ligands (Vallet *et al.*, 2003). At pH=4.2 in the absence of F[−], the equatorial bonding in the $[\text{UO}_2(\text{O}_2\text{C}_2\text{O}_2)_2\text{H}_2\text{O}]^{2-}$ complex was determined to consist of five O atoms of which four are attributable to the two symmetric oxalate ligands, wherein each carboxylate group chelates to U in a monodentate fashion with one O, and the fifth is from H₂O. In this molecular complex, whose structure is illustrated below (left), the average equatorial U–O distance is 2.38 Å. Upon the addition of F[−] at a concentration slightly in excess of that (0.06 M) for $[\text{UO}_2]^{2+}$, the fluoride ion displaces the water molecule without any effect on the nature of the oxalate chelation, thereby maintaining the five-coordinate equatorial ligation, $[\text{UO}_2(\text{O}_2\text{C}_2\text{O}_2)_2\text{F}]^{3-}$. With excess (1.68 M) oxalate at pH=6.5, a five-coordinate complex with three oxalate ligands, $[\text{UO}_2(\text{O}_2\text{C}_2\text{O}_2)_3]^{4-}$, is formed. In this structure (illustrated below, right) two of the oxalates are chelate-bonded exactly as in the aquo and fluoride complexes and the third is bound to U through a single carboxylate O.

The early EXAFS experiments indicated that the dissolution of solid uranyl nitrate, $\text{UO}_2(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, and sodium uranyl acetate, $\text{NaUO}_2(\text{CH}_3\text{CO}_2)_3$, at concentrations of 0.25 M and less in acidic media leads to their complete dissociation and formation of the pentahydrate aquo ion, $[\text{UO}_2]^{2+} \cdot 5\text{H}_2\text{O}$ (Charpin *et al.*, 1985). In subsequent concentration- and temperature-dependent U L₃-edge EXAFS measurements (Schofield *et al.*, 1999), no evidence was found for equatorial ligand replacement of H₂O with $[\text{NO}_3]^-$ in acidic solutions of 1 M nitrate and less at 150°C and below. In related *in situ*,

temperature-dependent U L₃-edge EXAFS studies of the uranyl ion speciation in acidic acetate solutions with different concentration ratios, [CH₃CO₂⁻] : [UO₂²⁺], (Mosselmans *et al.*, 2001), little direct evidence was apparent in the FT data for [CH₃CO₂]⁻ coordination to the pentahydrate [UO₂]²⁺ cation at low ratios. Whereas the equatorial coordination number was also found to be five at high ratios, the evidence for distant U–C backscattering suggests the coordination of at least two bidentate acetate ligands even at temperatures as high as 250°C. The presence of one H₂O molecule is presumed to complete the equatorial O coordination in a neutral aquo species, [UO₂(CH₃CO₂)₂H₂O].

For the binary, aqueous [UO₂]²⁺–[SO₄]²⁻ system in acidic solution pH ≤ 2, bidentate O coordination of the sulfate ligand to [UO₂]²⁺ was evident through observation of distant S backscattering in the U L₃-edge EXAFS data for each of two solution species identified as UO₂SO₄(aq) and [UO₂(SO₄)₂]²⁻ in the equilibrium distribution diagram (Moll *et al.*, 2000a). Both were shown to have an equatorial O coordination number of five, meaning that in addition to the two O atoms from the bidentate [SO₄]²⁻ groups, the former has three H₂O molecules, i.e. [UO₂SO₄(H₂O)₃], and the latter has one H₂O molecule, i.e. [UO₂(SO₄)₂H₂O]²⁻, in the inner-sphere equatorial coordination environment of [UO₂]²⁺. At the higher pH of 5.25, obtained by adjustment with NaOH, the EXAFS metrical results showing bidentate sulfate chelation in the [UO₂]²⁺–[SO₄]²⁻–[OH]⁻ system were used to verify the previously proposed structure models for the tri- and pentanuclear complex anions, [(UO₂)₃O(OH)₂(SO₄)₃(H₂O)₂]⁴⁻ and [(UO₂)₅O₃(OH)₂(SO₄)₄(H₂O)₂]⁶⁻, respectively. For a related sulfur-bearing oxoanion in acidic aqueous solutions, the triflate anion, [CF₃SO₃]⁻, was found to act as a monodentate ligand by inner-sphere coordination to U through one O atom at high (>8M) concentrations of the anion (Sémon *et al.*, 2001). The total equatorial O coordination number is approximately five, suggesting the displacement of one H₂O molecule from the pentahydrate aquo species and the formation of [UO₂(CF₃SO₃)₁(H₂O)₄]⁺.

(ii) *Neptunyl(v)*

Although there are, as yet, no experimental structural details for the aqueous uranyl ion of U⁵⁺, [UO₂]⁺, the calculated structure (Hay *et al.*, 2000) using DFT methods is, not surprisingly, a pentagonal bipyramid with U=O and U–OH₂ bond lengths of 1.810 and 2.616 Å, respectively. Unlike U, the most stable form of Np in acidic aqueous solution is the pentavalent neptunyl ion, [NpO₂]⁺·*n*''H₂O. It can be conveniently and reversibly interconverted to the hexavalent form, [NpO₂]²⁺·*n*'''H₂O, by electrochemical means, suggesting that the one-electron redox reaction is either independent of possible differences in the hydration of Np or, alternatively, that the hydration numbers *n*'' and *n*''' for [Np⁵⁺O₂]⁺ and [Np⁶⁺O₂]²⁺, respectively, are equivalent. This has been an issue of some controversy since the 1970s, when original work involving NMR

studies of perchlorate salt solutions of $[\text{NpO}_2]^{2+}$ was interpreted to provide a mean number of six-coordinated water molecules (Shcherbakov *et al.*, 1974; Mashirov *et al.*, 1975; Shcherbakov and Iorga, 1975). Similarly, based upon ^1H NMR experiments, a hydration number of six was proposed for $[\text{NpO}_2]^+$ (Glebov *et al.*, 1977). Recent interpretations of electronic absorption spectra suggest that the hydration number for both neptunyl species, $[\text{NpO}_2]^+$ and $[\text{NpO}_2]^{2+}$, is five and, furthermore, that their coordination polyhedra are pentagonal bipyramids (Garnov *et al.*, 1996). This interpretation is consistent with the accepted coordination of the pentahydrate, hexavalent uranyl ion, $[\text{UO}_2]^{2+} \cdot 5\text{H}_2\text{O}$.

As shown in Table 28.4, the first Np L_3 -edge EXAFS brought to bear upon the $[\text{NpO}_2]^+ \cdot n\text{H}_2\text{O}$ ion indicated that $^{237}\text{Np}^{5+}$ has an equatorial coordination of five H_2O molecules at 2.52(2) Å (Combes *et al.*, 1992). Two subsequent, independent EXAFS investigations (Allen *et al.*, 1997; Antonio *et al.*, 2001) as well as the results from two theoretical calculations (Hay *et al.*, 2000; Tsushima and Suzuki, 2000) confirmed the hydration number of five. A lower value of four H_2O molecules was extracted from the analysis of the EXAFS data for an aqueous solution of 0.05 M $[\text{NpO}_2]^+$ in 0.1 M HNO_3 , the sole exception (Reich *et al.*, 2000). Although the exact reasons for the variance are not known, the complex hydrolytic behavior of Np^{5+} , particularly at $\text{pH} \approx 1$, might have some bearing upon this as well as the unusually large (0.08 Å) range of average interatomic distances, 2.44–2.52 Å, involving the equatorial coordination of water molecules. Alternatively, it may suggest that the hydration sphere of $[\text{NpO}_2]^+$ has substantial sensitivity to experimental conditions, such as pH, counter-anion, ionic strength, etc., whereas the axial $\text{Np}=\text{O}$ interactions (1.80–1.85 Å) are less sensitive. In either case, complicating chemical behaviors, e.g. hydrolysis, disproportionation, complexation, oligomerization, precipitation, etc., are generally suppressed in a highly acidic ($\text{pH} \approx 0$) non-complexing perchloric acid medium. The EXAFS experimental conditions cover a range of pH values starting from effectively 0 in 1 M HClO_4 (Antonio *et al.*, 2001) to $\text{pH} \approx 1$ in 0.1 M HNO_3 (Reich *et al.*, 2000), to $\text{pH} \approx 2$ in perchloric acid (Combes *et al.*, 1992) and, finally, to $\text{pH} \approx 3$ in hydrochloric acid with excess (3 M) chloride as LiCl (Allen *et al.*, 1997). At Cl^- concentrations of ca. 6 M and above, the equatorial coordination number remains constant at five, but whereas one (or more) Cl^- ions displace and replace an equal number of H_2O molecules about $[\text{NpO}_2]^+$ (Allen *et al.*, 1997). This is accompanied by an elongation of the $\text{Np}-\text{OH}_2$ bond lengths.

(iii) *Neptunyl(vI)*

The two independent Np L_3 -edge EXAFS studies (Reich *et al.*, 2000; Antonio *et al.*, 2001) and the two independent theoretical studies (Hay *et al.*, 2000; Tsushima and Suzuki, 2000) of the hexavalent neptunyl ion are in consensus

about the hydration number (five). The EXAFS results reveal axial Np=O bond lengths (1.73–1.75 Å) and equatorial Np–OH₂ bond lengths (2.36–2.41 Å) that are consistently shorter (ca. 0.03–0.16 Å) than the corresponding interactions for the pentavalent neptunyl aquo ion [NpO₂]⁺·5H₂O. The shorter bond distances for the hexavalent species [NpO₂]²⁺·5H₂O are consistent with the expected decrease in the Np IR with increasing oxidation state. The well-known ionic radii (IR) tabulations of Shannon (1976) are limited to the comparison between Np⁵⁺ (0.75 Å) and Np⁶⁺ (0.72 Å) for CN = 6. The 0.03 Å difference is considerably smaller than the corresponding IR contraction of 0.14 Å between Np³⁺ (1.01 Å) and Np⁴⁺ (0.87 Å), which is clearly borne out in the Np–OH₂ distances of Table 28.4 for the Np³⁺·*n*H₂O and Np⁴⁺·*n*'H₂O systems. The absence of experimental detail for the pentavalent uranyl aquo ion prevents the analogous metrical comparisons between it and the hexavalent uranyl aquo ion. Because the Pu aquo system has stable pentavalent and hexavalent plutonyl ions, additional comparisons, both absolute and relative, can be drawn with regard to the data of Table 28.5.

(iv) *Plutonyl(vI/v)*

Two reports of Pu L₃-edge EXAFS measurements (Ankudinov *et al.*, 1998; Conradson, 1998) constitute the full extent of experimental investigation of the [Pu⁵⁺O₂]⁺·*n*"H₂O system and the majority of that for [Pu⁶⁺O₂]²⁺·*n*"'H₂O. For plutonyl(v), the curve-fitting analysis furnished axial Pu=O bond lengths of 1.81–1.84 Å and an equatorial coordination number of four with Pu–OH₂ bond lengths of 2.45–2.47 Å. This hydration number (four) stands in contrast to that (five) obtained from the results of two different levels of calculation with DFT (Hay *et al.*, 2000) and Hartree–Fock (Tsushima and Suzuki, 2000) methods. The theoretical investigations of the hexavalent plutonyl aquo ion reach the same conclusion, namely that [PuO₂]²⁺ forms the most stable and strongly bound complexes with five H₂O molecules in the equatorial coordination (Spencer *et al.*, 1999; Hay *et al.*, 2000; Tsushima and Suzuki, 2000). Whereas the optical spectroscopy (Garnov *et al.*, 1996) and the early EXAFS experiments (Runde *et al.*, 1997) are in agreement, showing an O coordination number of five, the later EXAFS work (Ankudinov *et al.*, 1998; Conradson, 1998) provides an O coordination number of six. The fact that the average Pu–OH₂ distances of 2.45 Å (Runde *et al.*, 1997) for the pentahydrate plutonyl(vI) and 2.40–2.45 Å (Ankudinov *et al.*, 1998; Conradson, 1998) for the hexahydrate plutonyl(vI) species are overlapping despite the unit difference in hydration number remains something of a quandary. In strongly acidic (1 M HClO₄ and 1 M HCl) [PuO₂]²⁺ solutions with aqueous chloride concentrations of 5 M and above, Pu EXAFS data reveal the formation of plutonyl(vI) chloro complexes, wherein some number of inner-sphere H₂O are replaced by Cl[–] ions (Runde *et al.*, 1997). Although the exact extent of the

Cl⁻ substitution was not determined, the effects include a weakening and elongation (0.01 to 0.06 Å) of the remaining equatorial Pu–OH₂ interactions as well as the axial Pu=O bonds.

According to the data of Table 28.5, the axial Pu–O interatomic distance contraction between the plutonyl(v) and (vi) aquo ions amounts to 0.06–0.10 Å. This is more than twice that expected based upon the difference in the Pu⁵⁺ (0.74 Å) and Pu⁶⁺ (0.71 Å) IR for CN=6 (Shannon, 1976). As mentioned previously, the same phenomenon was observed for the neptunyl(v) and (vi) aquo ions. This behavior is to be contrasted with that between the aquo ions of Pu³⁺ and Pu⁴⁺, which exhibit a 0.09–0.12 Å Pu–OH₂ interatomic distance contraction that is consistent in magnitude with the 0.14 Å difference of IR for CN = 6. In view of the apparent difference in the equatorial coordination number between [PuO₂]⁺ and [PuO₂]²⁺, it is difficult to ascribe any significance to the 0.0–0.07 Å difference between the Pu–OH₂ distances of Table 28.5. Comparisons with corresponding Am species, [AmO₂]⁺ and [AmO₂]²⁺, would be informative but are not possible because of the present lack of metrical information for these two aquo ions.

28.2.3 Base redox speciation

The aqueous actinide chemistry of the four oxidation states – III, IV, V, and VI – described above for acidic solutions have been complemented by studies, albeit far fewer in number, of the same four states plus the heptavalent (VII) one in alkaline and carbonate solutions (Shilov and Yusov, 2002). In particular, the An⁷⁺ ions of Np, Pu, and Am are extremely unstable species under all but the most alkaline of conditions. Concentrated carbonate solutions too have been shown to facilitate studies of the otherwise unstable Am⁴⁺, Cf⁵⁺, and Cm⁶⁺ ions. Aspects of An redox speciation in hydroxide and carbonate media as obtained by use of EXAFS spectroscopy are surveyed in this section.

(a) Hydroxide solution systems

(i) Neptunium(vii/vi)

A longstanding problem in actinide science about the nature of the Np⁷⁺ species in aqueous, basic solutions was resolved through use of EXAFS and quantum chemistry. Since the first report of its preparation (Krot and Gelman, 1967), the coordination environment of Np⁷⁺ has remained controversial, in part because of the technical difficulties associated with the stabilization of the high-valent ion. The existence of an anionic species of Np⁷⁺ in alkaline solution was proposed early on (Spitsyn *et al.*, 1969), “. . .and its formula is believed by most researchers to be NpO₅³⁻” (Fahey, 1986). Still, equally probable trianionic

forms include $[\text{NpO}_4(\text{OH})_2]^{3-}$ (Burns *et al.*, 1973) and $[\text{NpO}_2(\text{OH})_6]^{3-}$, among others. In order to address this speciation issue, Np L_3 -edge EXAFS was brought to bear upon a 0.03 M solution of Np^{7+} in 2.5 M NaOH prepared by ozonation of the neptunyl(vi) hydroxide, $\text{NpO}_2(\text{OH})_2$ (Clark *et al.*, 1997). The analysis provided evidence for a linear, *trans*-dioxo species of Np^{7+} , which has an overall pentagonal bipyramidal coordination consisting of the two axial O atoms at 1.85(2) Å and five equatorial O atoms attributed to four OH^- at 2.18(3) Å and one H_2O at 2.43(3) Å. This environment is consistent with the formation of a monoanionic neptunyl(vii) species, $[\text{NpO}_2(\text{OH})_4(\text{H}_2\text{O})]^-$, whose coordination polyhedron is similar, albeit with different Np–O distances, to those for the *bona fide* dioxo species of $[\text{Np}^{5+}\text{O}_2]^+$ and $[\text{Np}^{6+}\text{O}_2]^{2+}$ that are ubiquitous in acid solution.

In contrast, two subsequent Np EXAFS and DFT studies (Bolvin *et al.*, 2001; Williams *et al.*, 2001) of the coordination geometry of Np^{7+} in alkaline solution came to the conclusion that Np^{7+} has a tetraoxo square planar coordination environment. The presence of two distant, axial O atoms, presumably hydroxide ligands, completes the coordination sphere, which has a square bipyramid structure. In one study (Williams *et al.*, 2001), bulk electrolysis techniques in simultaneous combination with ozonation were utilized to control the Np valence in a freshly prepared suspension of Np^{5+} (0.0065 M) in 1 M NaOH for *in situ* Np L_3 -edge EXAFS of the Np^{7+} and Np^{6+} ions, whose electrochemical interconversion is facile (Zielen and Cohen, 1970). The Np^{6+} EXAFS was fit to reveal a typical *trans*-dioxo species with two close, axial O atoms at 1.82(2) Å and an equatorial coordination of four distant O atoms at 2.21(3) Å, in what would likely be a square bipyramidal polyhedron, $[\text{NpO}_2(\text{OH})_4]^{2-}$. Geometry optimizations at the B3LYP level using a CPCM solvent model confirm this neptunyl(vi) structure and stoichiometry (Bolvin *et al.*, 2001). In contrast, the Np^{7+} EXAFS was fit to reveal four close O atoms at 1.87(1) Å and two distant ones at 2.24(4) Å, consistent with a polyhedron that could also be a square bipyramid. The accompanying DFT calculations predicted a slightly distorted square-planar geometry for the tetraoxo, $[\text{NpO}_4]^-$, anion (Williams *et al.*, 2001). The geometry was further elucidated at the DFT level using the hybrid functional B3LYP and a CPCM solvent model to reveal a six-coordinate Np^{7+} in the square bipyramid polyhedron, $[\text{NpO}_4(\text{OH})_2]^{3-}$ (Bolvin *et al.*, 2001). The associated Np L_3 -edge EXAFS acquisition and analysis for a solution of Np^{7+} (0.015 M) in 2.5 M NaOH revealed a coordination of 3.6 ± 0.3 O atoms at 1.89 Å and 3.3 ± 1.3 O atoms at 2.33 Å. The large error on the distant O coordination number was attributed to the low backscattering amplitude and the interference from the four close O atoms. From the combination of theoretical results and experimental data (including solid-state structural and solution electrochemical information) (Shilov, 1998), it was concluded “. . . that the predominant Np(vii) complex found in solutions with high concentration of OH^- is indeed $\text{NpO}_4(\text{OH})_2^{3-}$ ” (Bolvin *et al.*, 2001).

(ii) Plutonium(vii/vi)

Although no EXAFS results have been published about the corresponding Pu⁷⁺/Pu⁶⁺ and Am⁷⁺/Am⁶⁺ redox speciation in alkaline solutions, the plutonium electrochemical behavior as a function of hydroxide ion activity is very much like that for neptunium, except for the more positive electrode potentials for Pu (Shilov, 1998). This suggests that the six O, tetragonal bipyramidal coordination environments for both Np⁷⁺ and Np⁶⁺ are likely to be obtained for the corresponding Pu species. In these, the absence of a substantial structural rearrangement between the hexa- and heptavalent species would explain the reversible and generally facile redox reaction:

The formulas shown in this equation are presently accepted by actinide electroanalytical chemists in general (for An \equiv Np, Pu, and Am) and this An⁷⁺/An⁶⁺ redox speciation appears, exactly as written, in contemporary compilations of standard electrode potentials (Bratsch, 1989). The estimated potential for the Pu⁸⁺/Pu⁷⁺ couple (> 3V) (Shilov and Yusov, 2002) is well beyond the polarization window of aqueous solutions. The existence of Pu⁸⁺ will have to be confirmed in other solvents, such as newly designed ionic liquids with immense (ca. 5V) polarization windows (Quinn *et al.*, 2002), or in the solid-state.

(iii) Uranyl(vi)

Because of practical and technological issues in nuclear waste storage and processing, the speciation and structure of U⁶⁺ complexes in strongly alkaline solutions has been investigated with U L₃-edge EXAFS, quantum chemical calculations, and other spectroscopic and physical methods (Moll *et al.*, 1998; Schreckenbach *et al.*, 1998; Clark *et al.*, 1999; Wahlgren *et al.*, 1999; Moll *et al.*, 2000b; Vallet *et al.*, 2001). Driven by implications of serious environmental concern, i.e. aging tanks of alkaline high-level waste, the original work (Clark *et al.*, 1999) on [UO₂]²⁺ (≈ 0.10 M) in a 3.5 M tetramethylammonium hydroxide, [(CH₃)₄N]OH, solution sparked interest of theoretical, applied, and fundamental importance. The FT data revealed a single asymmetric peak, which was shown to include backscattering contributions from axial and equatorial O coordination. The k³χ(k) EXAFS was fit to expose two nearest O atoms at 1.79(1) Å, attributed to axial U=O bonding, and 5.2(5) Å O atoms at 2.22(1) Å, attributed to equatorial U–OH bonding. This seven O pentagonal bipyramidal coordination of U⁶⁺ is not unusual on its own and, except for the relatively long and short axial and equatorial bonds, respectively, it is the prevalent structure in acid solution. Yet, comparison of the solution environment with that for the solid uranyl(vi) salt, [Co(NH₃)₆]₂[UO₂(OH)₄]₃·H₂O, crystallized from 3.5 M [(CH₃)₄N]OH revealed unexpected detail that has been the source of multinational debate. The single-crystal structure shows a six O pseudo-octahedral

coordination of U^{6+} with two *trans*-oxo atoms at 1.82(1) Å and four OH^- ligands at 2.26(2) Å. The corresponding EXAFS data for the crystalline compound, collected and analyzed in the same manner as for the solution sample, are in agreement with the X-ray diffraction data. The $k^3\chi(k)$ EXAFS were best fit with two O atoms with an average U=O distance of 1.81(1) Å and 3.9(5) O atoms with an average U–O distance of 2.21(1) Å (Clark *et al.*, 1999). The pivotal difference between the solid and solution structures is the OH^- coordination number, which is four in the solid and five in solution.

Although such differences in coordination upon dissolution of a solid are not extraordinary, the remarkable aspect here is the observation of essentially identical, within experimental error, average U=O and U–OH distances despite the coordination number difference in the solution (7) and solid (6) uranyl hydroxide complexes. Based upon a comparison of the U^{6+} IR for CN=6 and 7 (0.73 and 0.81 Å, respectively) (Shannon, 1976), the U–O distances for the seven-coordinate solution sample are anticipated to be 0.08 Å longer than those for the corresponding six-coordinate solid sample. An expansion of this magnitude is not evident, suggesting that a simple ionic, electrostatic model of the U=O and U–OH interactions is inappropriate for these systems. Alternatively, it may be an indication of some degree of covalency and the participation of f-electrons in the U–O bonding, or that the solution coordination number is in error because of, for example, the effects of an equilibrium distribution of two monomeric uranyl(VI) species, a pentahydroxide, $[UO_2(OH)_5]^{3-}$, and a tetrahydroxide, $[UO_2(OH)_4]^{2-}$ (Clark *et al.*, 1999). These intriguing results, in particular, the equatorial coordination number (5) in highly alkaline solution conditions, have been experimentally confirmed through EXAFS (Moll *et al.*, 1998; Wahlgren *et al.*, 1999). Yet, remarkably, and as developed below, the EXAFS-determined value was set aside in favor of that (4) from bond length comparisons and theoretical and geometrical optimizations.

Uranium $L_{3\text{-edge}}$ EXAFS was used to elucidate the coordination of $[UO_2]^{2+}$ (0.055 M) in solutions of $[(CH_3)_4N]OH$. The results obtained from the curve-fitting analyses are indistinguishable and reveal two axial O atoms at 1.82 Å as well as 5.0 ± 0.5 and 5.2 ± 0.5 equatorial O atoms at 2.24 Å in 1 and 3 M $[(CH_3)_4N]OH$, respectively (Moll *et al.*, 1998; Wahlgren *et al.*, 1999). This latter coordination number was subsequently reevaluated to be 4.6 ± 0.6 (Moll *et al.*, 2000b). A number of factors combine to cast doubt on the EXAFS result for the equatorial coordination number, including the general difficulty and large uncertainty associated with such determinations for uranyl complexes at ambient temperature. (Thompson *et al.*, 1995, 1997; Barnes *et al.*, 2000) Insofar as bond lengths generally increase with coordination number (Shannon, 1976), it is also peculiar that the average U–OH distance (2.24 Å) for a purportedly five-coordinate hydroxo anion of $[UO_2]^{2+}$ in solution is the same as that (2.26(2) Å) for the four OH^- -coordinated $[UO_2]^{2+}$ complex anion, $[UO_2(OH)_4]^{2-}$, in a crystallographically characterized solid (Clark *et al.*, 1999). Despite the higher coordination number indicated by the EXAFS data, it was concluded "...that

the coordination number of uranyl(vi) ion in strongly alkaline solution is four, not five. . .” and that the mononuclear, tetrahydroxide species, $[\text{UO}_2(\text{OH})_4]^{2-}$, is the dominant complex in strongly alkaline solutions (Wahlgren *et al.*, 1999). This suggestion was corroborated by the results of geometry optimizations obtained through a number of *ab initio* quantum chemical calculations (Moll *et al.*, 1998; Schreckenbach *et al.*, 1998; Wahlgren *et al.*, 1999; Vallet *et al.*, 2001).

At the time of this publication, issues about the form of $[\text{UO}_2]^{2+}$ in alkaline solution were most recently revisited with regard, again, to its speciation in 0.5 and 3 M $[(\text{CH}_3)_4\text{N}]\text{OH}$ by use of U L_3 -edge EXAFS and ^{17}O NMR (Moll *et al.*, 2000b). The results serve to resolve, in part, the controversy generated by the watershed report (Clark *et al.*, 1999), whose experimental evidence indicated the formation of a pentahydroxide species, and the approximately coincident work (Wahlgren *et al.*, 1999), whose evidence was interpreted in favor of a tetrahydroxide species. The latest research has found evidence for the latter, $[\text{UO}_2(\text{OH})_4]^{2-}$, species from the primary EXAFS analysis of data obtained in a dilute (0.05 M) solution of $[\text{UO}_2]^{2+}$ in 0.5 M $[(\text{CH}_3)_4\text{N}]\text{OH}$ at pH=13.7 (Moll *et al.*, 2000b). The pseudo-octahedral environment of U^{6+} was shown to consist of 1.8 ± 0.3 O atoms at 1.83 Å and 4.2 ± 0.6 O atoms at 2.26 Å. In the concentrated, 3 M solution of $[(\text{CH}_3)_4\text{N}]\text{OH}$ of the original studies (Clark *et al.*, 1999), the presence of a fifth OH^- ligand in association with $[\text{UO}_2(\text{OH})_4]^{2-}$ was unambiguously established by use of ^{17}O NMR (Wahlgren *et al.*, 1999). A $[\text{UO}_2(\text{OH})_5]^{3-}/[\text{UO}_2(\text{OH})_4]^{2-}$ ratio of ≈ 0.3 in a 3 M solution of $[(\text{CH}_3)_4\text{N}]\text{OH}$ was calculated based upon an estimation of the equilibrium constant for the aqueous reaction,

The EXAFS results for this mixture of solution species provide a site-averaged coordination environment of 1.8 ± 0.3 O at 1.83 Å and 4.6 ± 0.6 O at 2.25 Å (Wahlgren *et al.*, 1999).

Since the publication of the results from the pioneering X-ray scattering experimentation (Aberg, 1970; Musikas and Narten, 1978), metrical details about the solution structures of polynuclear hydrolysis products of uranyl(vi) have been few and far between. At least, there is a dearth of EXAFS research, other than the investigation of an acidic solution (pH=4.1) of dilute (0.05 M) $[\text{UO}_2]^{2+}$ in 0.05 M $[(\text{CH}_3)_4\text{N}]\text{OH}$ (Moll *et al.*, 2000b). In these conditions, the formation of the triangular, trinuclear complex, $[(\text{UO}_2)_3(\text{OH})_5]^+$, was confirmed on the basis of the 3.80 Å U–U interatomic distance. The U coordination number for a pure specimen of this trinuclear hydrolysis complex is two. The lower, EXAFS-determined values of $1.3\text{--}1.4 \pm 0.4$ are consistent with an admixture of the trinuclear complex and the binuclear one, $[(\text{UO}_2)_2(\text{OH})_2]^{2+}$, whose structure has been optimized at several levels of theory (Tsushima and Reich, 2001) and which is presumed to have the core structure of the solid-state hydroxo compound $[(\text{UO}_2)_2(\text{OH})_2\text{Cl}_2(\text{H}_2\text{O})_4]$, with a U coordination number of one and a U–U interatomic distance of 3.94 Å (Aberg, 1970).

The EXAFS-measured distribution of equatorial U–O interactions, which involve a combination of bridging as well as terminal oxo and hydroxide ligation and bond lengths, are also consistent with a mixed speciation of polynuclear complexes. The site- and species-averaged, axial U=O bond length of the uranyl ion was 1.79 Å (Moll *et al.*, 2000b).

(iv) *Thorium(IV)*

The hydrolysis of the tetravalent actinides leads to a complicated distribution of species with different degrees of aggregation, the exact extent of which hinges upon the solution conditions (Neck and Kim, 2001). For example, even below the onset of oligomerization, in the narrow (2 unit) pH range of 3–5, the calculated Th⁴⁺ speciation already indicates appreciable amounts of bi- and tetranuclear species, such as [Th₂(OH)₂]⁶⁺ and [Th₄(OH)₈]⁸⁺, in addition to the mononuclear ones, e.g. [Th(OH)]³⁺, [Th(OH)₂]²⁺, [Th(OH)₃]⁺ (Neck *et al.*, 2002). In view of the complexity for such an assortment of multi-site, polynuclear complexation, the use of EXAFS for studies of the aqueous speciation of suspended colloids above the onset of hydrolysis has been limited. The available studies concern the use of Th L₃-edge EXAFS for coulometrically titrated solutions (pH=1.38–3.67) of 0.0043–0.028 M Th⁴⁺ in 0.5 M NaCl (Neck *et al.*, 2002; Rothe *et al.*, 2002). The FT data for the aqueous solutions of pH ≤ 3 (below the onset of colloid formation) exhibit a strong, nearly symmetric peak due to O backscattering, fit as 11.6–12.7 O at 2.45–2.46 Å, that is typical of the Th⁴⁺ aquo ion. In contrast, the FT data for the aqueous suspension of colloidal species at pH=3.50 and 3.62 exhibit a weak, highly asymmetric peak due to O backscattering, fit as 10.5–10.6 O at 2.51 Å, that is expected for a broad distribution of Th–O interactions arising from the presence of a mixture of ultrafine (i.e. nanosize), polynuclear species and amorphous Th⁴⁺ colloids. The EXAFS data for the aqueous suspension at pH=3.67 also reveals a weak, distant peak attributed to Th–Th interactions. The structural parameters and Th⁴⁺ coordination environment for this specimen are similar to those for the carefully prepared amorphous hydrated oxyhydroxide solid, ThO_n(OH)_{4–2n}·xH₂O (Neck *et al.*, 2002; Rothe *et al.*, 2002).

(b) **Carbonate solution systems**

A large part of the interest and activity in environmental and molecular sciences of the actinide elements concerns their interactions with carbonate, [CO₃]²⁻, and bicarbonate, [HCO₃]⁻, anions in hydrologic and geochemical processes. Besides H₂O (including hydroxide) itself, these are the predominant ligands for An-ion complexation found in fresh and saline waters alike. Of the Earth's estimated total water volume, approximately 97% or 317 × 10⁶ mi³ is attributed to seawater alone (Nace, 1967), which is known to contain an essentially uniform, worldwide distribution of uranium at 3.35 ± 0.2 × 10⁻⁹ g/cm³ (Ku *et al.*, 1977).

An estimate of the total amount of dissolved U in the oceans (4.43×10^{12} kg) provides a glimpse of the enormity of scale and the correspondingly keen interest in its aqueous speciation. From decades of experimental study, it is generally accepted that U takes the form of the mononuclear anionic, uranyl(vi) tris(carbonato) complex, $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, in the slightly alkaline ($\text{pH} \approx 8$) ocean waters (Djogic and Branica, 1991). Despite comprehensive studies of actinide carbonate chemistry, which are very well reviewed elsewhere (Clark *et al.*, 1995), the field of synchrotron radiation research of An carbonate complexes was late to break open with the report on uranyl carbonate complexes in near-neutral aqueous solution (Allen *et al.*, 1995). In this section, we describe the results obtained from EXAFS studies of the carbonate solution chemistry of the trivalent and tetravalent An ions as well as for the actinyl, $[\text{AnO}_2]^{n+}$, carbonates of the pentavalent ($n=1$) and hexavalent ($n=2$) An ions.

(i) *Uranyl(vi)*

The apparent simplicity of the $[\text{CO}_3]^{2-}$ anion belies its flexibility in the formation of coordination compounds with $[\text{UO}_2]^{2+}$ in various degrees of polynuclear association. In addition to serving conventional mono- and symmetrical bidentate structural roles, it may serve to bridge and link metal-ions. Although some 14 modes of carbonate ligation with two, three, four, and six metal-ions are known (Cotton *et al.*, 1999), its service as a molecular bridge between uranyl cations is relatively rare (Allen *et al.*, 1995; Clark *et al.*, 1995). To elucidate aspects of such aggregation behavior, a multipronged approach was taken to unravel the solution species distribution of the monomeric tris(carbonato) complex, $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, and the trimeric complex, $[(\text{UO}_2)_3(\text{CO}_3)_6]^{6-}$. The unusual structure of the trimer, schematically illustrated below without the axial O atoms, is built up of three bis(carbonato) monomers of empirical formula

$[\text{UO}_2(\text{CO}_3)_2]^{2-}$ with three bridging carbonate ligands linking three U^{6+} ions in a fashion (i.e. six-bond $-(\text{U}-\text{O})_3-$ ring) not depicted in Cotton *et al.* (1999).

A 0.2 M aqueous solution (pH=5.7) of this crystallographically characterized triangular, trinuclear uranyl(VI) carbonate, $[(\text{UO}_2)_3(\text{CO}_3)_6]^{6-}$ as the guanidinium salt $[\text{C}(\text{NH}_2)_3]^+$, was studied by U L_3 -edge EXAFS (Allen *et al.*, 1995). The data analysis provided O, C, and U coordination numbers and interatomic distances consistent with the trimeric structure of the solid salt, $[\text{C}(\text{NH}_2)_3]_6[(\text{UO}_2)_3(\text{CO}_3)_6] \cdot 6.5\text{H}_2\text{O}$, suggesting that the oligomeric anionic unit is maintained upon dissolution of the solid under the selected conditions. The analysis was confirmed by the presence of a distant, 4.92 Å U–U interaction that was not evident in the EXAFS data for the corresponding monomeric species, $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, which has an otherwise identical, eight O coordination of U^{6+} in a hexagonal bipyramid polygon (Reeder *et al.*, 2000). The two closest, axial O atoms are bonded at 1.79 Å in both the monomeric and trimeric anions. The six equatorial O atoms arise from the symmetrical bidentate coordination of three carbonate groups, with an average U–O distance of 2.42 Å for the monomer and 2.45–2.46 Å for the trimer. The EXAFS data for the trimer and the monomer alike provide evidence for distant backscattering that was fit to reveal three C at 2.89–2.90 Å as well as three O at 4.12 Å (monomer) and at 4.16–4.17 Å (trimer), which are attributed to the terminal O atoms of the three carbonate ligands.

The recent discovery and characterization of the aqueous, neutral dicalcium uranyl(VI) tris(carbonato) complex, $[\text{Ca}_2\text{UO}_2(\text{CO}_3)_3]$, in natural, mining-related waters (Bernhard *et al.*, 1996) reinvigorates interest with the ages-old anionic species, $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, particularly with regard to issues of ion-pairing. The combination of experimental (Bernhard *et al.*, 2001) and theoretical (Tsushima *et al.*, 2002) results reveal that counter-cations can play a significant role in the aqueous speciation and structure of the otherwise ordinary $[\text{UO}_2(\text{CO}_3)_3]^{4-}$ complex anion. The solution (pH=8) U L_2 - and L_3 -edge EXAFS for $[\text{Ca}_2\text{UO}_2(\text{CO}_3)_3]$ (0.0005 M) and $[\text{UO}_2(\text{CO}_3)_3]^{4-}$ (0.001 M) do not differ significantly and, moreover, the carbonate coordination of uranyl(VI) in both is the same as that for the natural mineral liebigite, $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3 \cdot 10\text{H}_2\text{O}$, which has two axial O at 1.78 Å, six equatorial O at 2.43 Å, three C at 2.86, and three O at 4.12 Å. In addition, the crystallographic structure of liebigite reveals a 4.07 Å U–Ca interaction arising from two Ca–O polyhedra in the equatorial plane. These distant Ca interactions are difficult to identify in the U EXAFS data of the $[\text{Ca}_2\text{UO}_2(\text{CO}_3)_3]$ aqueous species and solid mineral specimens at ambient temperature because of spectral congestion and overlap with the nearly equidistant interactions of the terminal O atoms (3) of the symmetrical, bidentate carbonate ligands. Nevertheless, based upon a rigorous analysis of the available EXAFS and in combination with other physical and spectroscopic evidence, Bernhard *et al.* (2001) concluded “. . . that the calcium atoms are likely to be in the same positions both in the solution complex and in the solid.” Structure optimizations of the neutral $[\text{Ca}_2\text{UO}_2(\text{CO}_3)_3]$ aquo species were subsequently

calculated at different levels (HF, MP2, and B3LYP) of theory with and without Ca^{2+} , i.e., $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, and with and without hydration (Tsushima *et al.*, 2002). The calculated structure that included two Ca^{2+} and ten H_2O molecules is in good agreement with that deduced by EXAFS measurement and, thereby, demonstrates the need to explicitly incorporate counter-cations and water molecules to obtain accurate geometrical structures from theory.

Uranium L_3 -edge EXAFS was used to probe the coordination environment of the uranyl(VI) tris(carbonato) complex, $[\text{UO}_2(\text{CO}_3)_3]^{4-}$, before and after a stoichiometric, one-electron electrochemical reduction (Docrat *et al.*, 1999). In aqueous electrolytes of 1 M Na_2CO_3 at pH=11.95 (Docrat *et al.*, 1999) and 0.1 M $\text{Na}_2\text{CO}_3/0.1$ M NaNO_3 at pH=11.3 (Morris, 2002), the cyclic voltammetry data for $[\text{UO}_2(\text{CO}_3)_3]^{4-}$ (0.0022–0.010 M) show one electrochemically irreversible couple attributed to $\text{U}^{6+}/\text{U}^{5+}$ redox activity. The metastable reduced species formed by controlled potential coulometry was ascribed to the uranyl(V) tris(carbonato) complex, $[\text{UO}_2(\text{CO}_3)_3]^{5-}$. The U L_3 -edge position for the reduced species was 2.4 eV lower than that for the oxidized form, consistent with the reduction of $[\text{U}^{6+}\text{O}_2]^{2+}$ to $[\text{U}^{5+}\text{O}_2]^+$. The EXAFS analysis revealed that the basic geometry of the U coordination environment is essentially the same for both solution complexes, except for the expected variation of interatomic distances with change of U oxidation state. The average axial dioxo distance increases by 0.10 Å from 1.80(2) to 1.90(2) Å upon reduction. Elongations of similar magnitude (0.05–0.10 Å) are found for the six equatorial O bonds, the three C, and the three terminal O interactions with the carbonate ligands. These three distances increase, in order, from 2.43(2), 2.89(4), and 4.13(4) Å in the oxidized form to 2.50(2), 2.94(4), and 4.23(4) Å, respectively, in the reduced form. The absence of significant conformational variation between $[\text{UO}_2(\text{CO}_3)_3]^{4-}$ and $[\text{UO}_2(\text{CO}_3)_3]^{5-}$ makes it difficult to rationalize the less than ideal electrochemical response and the relative instability of the reduced species (Docrat *et al.*, 1999).

Four different isomers have been proposed for the binuclear complex anion, $[(\text{UO}_2)_2(\text{CO}_3)(\text{OH})_3(\text{H}_2\text{O})_n]^-$, in solution (Szabo *et al.*, 2000). This variety of bridge isomers is largely attributable to the assortment of different carbonate bonding modes (Cotton *et al.*, 1999) that can be envisioned to link the two $[\text{UO}_2]^{2+}$ groups in this ternary species. Although the use of U EXAFS alone is not sufficient to provide an unambiguous identification of the predominant isomer, the EXAFS results in combination with multinuclear (^{13}C and ^{17}O) NMR measurements have provided conclusive insight about the speciation. The U L_3 -edge EXAFS of a 0.05 M solution of $[(\text{UO}_2)_2(\text{CO}_3)(\text{OH})_3(\text{H}_2\text{O})_n]^-$ (pH \approx 7–8) was analyzed with multi-shell models of axial and equatorial O, U–C, and U–U interactions (Szabo *et al.*, 2000). The pivotal aspect of the analyses was the identification of terminal, equatorial OH^- bonding (1.3 ± 0.3 at 2.26 Å) and distant U interactions (0.5 ± 0.1 at 3.90 Å). The equatorial coordination sphere is completed by 3.9 ± 0.6 O atoms at 2.47 Å. This is consistent with a pentagonal bipyramidal uranyl(VI) environment, wherein the two axial O atoms are bonded

at 1.81 Å. The isomer structure consistent with the combined EXAFS and NMR data is suggested to consist of two $[\text{UO}_2]^{2+}$ groups that are bridged by two O atoms, one from hydroxide and one from the lone carbonate ligand that is in bidentate coordination with one uranyl unit. The terminal equatorial coordination is completed by a combination of the two remaining hydroxide ligands and three water molecules, $[(\text{H}_2\text{O})(\text{OH})_2\text{UO}_2(\text{OH})(\text{CO}_3)\text{UO}_2(\text{H}_2\text{O})_2]^-$, as illustrated below.

(ii) *Neptunyl(v)*

The study of neptunium in aqueous carbonate solutions provides fundamental information that can be applied to intricate environmental problems and to solving difficult issues with regard to the treatment of alkaline, high-level tank waste. Concerns about pentavalent neptunyl carbonate complexation, particularly the aqueous speciation, solubility, redox, and sorption behaviors, also relate to its fate and transport in subsurface geologic repositories (Efurd *et al.*, 1998; Kaszuba and Runde, 1999).

Three environmentally relevant neptunyl(v) carbonate complexes of general composition $[\text{NpO}_2(\text{CO}_3)_n]^{(2n-1)-}$ for $n=1$ $[\text{NpO}_2(\text{CO}_3)]^-$, $n=2$ $[\text{NpO}_2(\text{CO}_3)_2]^{3-}$, and $n=3$ $[\text{NpO}_2(\text{CO}_3)_3]^{5-}$, have long been of interest. Information about their molecular structures and the extent of hydration became available through Np L_3 -edge EXAFS and complementary spectroscopic work on single-component solutions of the anions with unprecedented solubilities (0.001 M) achieved by use of the large, bulky tetra-*n*-butylammonium, $[(n\text{-Bu})_4\text{N}]^+$, counter-cations in place of alkali-metal cations (Clark *et al.*, 1996a,b). For the tris(carbonato) complex ($n=3$) in a Na_2CO_3 solution (of unspecified concentration), the EXAFS spectra show "...unequivocally that the carbonate ligands must be coordinated in a bidentate fashion due to the combination of six Np–O and three Np–C distances of 2.52 and 2.98 Å", (Clark *et al.*, 1996a) respectively. The overall eight-coordinate geometry of Np^{5+} is hexagonal bipyramidal, in which the two *trans*-neptunyl O atoms at 1.86(2) Å occupy the usual axial positions with respect to the six equatorial O atoms. Much less definitive information about the equatorial coordination was provided for the mono- and bis

(carbonato) species, $n=1$, and 2, respectively, in $[(n\text{-Bu})_4\text{N}]_2\text{CO}_3$ solutions (unspecified concentrations) because of curve-fitting difficulties and metrical uncertainties. What seems clear “. . . is a distinct change in coordination geometry about the neptunyl ion, from six O atoms in the tris- and bis-carbonato complexes, to five O atoms in the mono(carbonato) complex” (Clark *et al.*, 1996b). The five O atoms of the equatorial ligation for the mono(carbonato) complex are attributed to the coordination of three H_2O molecules and two O atoms from the $[\text{CO}_3]^{2-}$ anion in a symmetrical bidentate mode. The overall stereochemistry of Np^{5+} is expected to be a pentagonal bipyramid that has an average Np-O equatorial distance of 2.49(3) Å. This bond length is shorter than that (2.53(3) Å) for the 6-O equatorial coordination of the tris(carbonato) species, a detail that is consistent with the 5-O equatorial coordination of $[\text{NpO}_2]^+$ in $[\text{NpO}_2(\text{CO}_3)(\text{H}_2\text{O})_3]^+$. Similarly, the six O atoms of the equatorial ligation for the bis(carbonato) complex are attributed to the coordination of two H_2O molecules and four O atoms from the two bidentate $[\text{CO}_3]^{2-}$ anions, as $[\text{NpO}_2(\text{CO}_3)_2(\text{H}_2\text{O})_2]^{3-}$, with an average distance of 2.48(3) Å. It seems counter-intuitive that the higher coordination number for the bis(carbonato) complex does not correlate with a larger average equatorial Np-O distance, e.g. like that for the unequivocally characterized tris(carbonato) neptunyl(v) complex with six O atoms in the equatorial plane.

(iii) *Plutonyl(vi)*

The aqueous speciation of the plutonyl and americyl cations, $[\text{AnO}_2]^{n+}$ for $n=1$ and 2, in carbonate media has not been examined through XAS. Solid-state EXAFS studies of actinyl carbonates are similarly absent, except for the sole work in which $^{239}\text{Pu}^{6+}$ was precipitated from an acid solution of $\text{pH}=4$ with CO_2 over the course of 3–5 days (Runde *et al.*, 1999). The washed solids, identified as PuO_2CO_3 from powder X-ray diffraction measurements, were examined by Pu EXAFS to reveal the typical FT data with contributions from axial (1.74 Å) and equatorial O atoms (2.45 Å) as well as a distant, 4.2 Å Pu–Pu interaction. No coordination numbers were reported for this monocarbonate phase.

(iv) *Tetravalent An*

The tetravalent An carbonate series, $[\text{An}(\text{CO}_3)_n]^{4-2n}$ for $\text{An} \equiv \text{Th}, \text{U}, \text{Np},$ and Pu , has been the subject of systematic and comprehensive EXAFS investigations. In this collection of results, the predominant aqueous species is, by far, the pentacarbonato ($n=5$) complex, $[\text{An}(\text{CO}_3)_5]^{6-}$. For example, the extensive L_3 -edge EXAFS measurements of U^{4+} , Np^{4+} , and Pu^{4+} in the aqueous $\text{K}^+ - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system (Rai *et al.*, 1998, 1999a,b) can be succinctly summarized as follows: The aqueous An^{4+} complexes in carbonate (5.4–6.0 M K_2CO_3) and bicarbonate (0.9–1.0 M) solutions were found to be

$[\text{An}(\text{CO}_3)_5]^{6-}$. Despite the excess concentrations of $[\text{HCO}_3]^-$, with respect to $[\text{An}^{4+}]$, no evidence was ever found for its complexation. This may reflect an inherent limitation of the technique, wherein the effects of protonation on the average An–O and An–C distances would be insignificant in comparison with the measurement error, and therefore extremely difficult to determine. In this regard, the detection of appreciably more coarse and substantial structural variations, especially the equatorial O coordination number, can be problematic and fraught with uncertainty. This, in turn, can make it difficult to determine the exact number of bicarbonate and carbonate groups, as well as their identity, involved in the complexation of tetravalent An ions.

(v) *Neptunium(IV)*

A case that illustrates this complicated issue as regards An^{4+} EXAFS in general concerns the investigation of the pure Np^{4+} ion (of unspecified milli-molar concentration) in 0.93 M KHCO_3 (Rai *et al.*, 1999a). In the FT data, the Np–O and Np–C interactions are not resolved, and correlation effects in the curve-fitting leads to metrical parameters that are not diagnostic of a unique structure. For example, from the nearest O and C coordination numbers, 11.0 ± 2.8 and 5.8 ± 1.8 , respectively, alone, it is difficult to establish the presence of tetra-, penta-, hexa-, or heptacarbonato complexation. In this situation, fortunately, the magnitude of the average Np–O and Np–C interatomic distances, 2.43(2) and 2.84(2) Å, respectively, is known to be diagnostic of bidentate carbonate coordination (Denecke *et al.*, 1997b). To provide added quantitative insights about the Np carbonate species, a distant and well-resolved peak in the FT data attributed to the distal O atoms of the bidentate $[\text{CO}_3]^{2-}$ groups was subjected to analysis. The coordination number obtained, 5.4 ± 1.6 O atoms, is a conclusive indicator “...that five carbonate groups were involved, and the complexed Np^{4+} species therefore is $\text{Np}(\text{CO}_3)_5^{6-}$ ” in 0.93 M KHCO_3 (Rai *et al.*, 1999a).

The structure is illustrated above in which two of the five distal O atoms at 4.16 (2) Å are identified. For the corresponding 5.4 M K_2CO_3 solution, the unintended, partial oxidation of Np^{4+} leads to neptunyl(v) contamination and additional uncertainties with the EXAFS analyses. Nevertheless, the data are consistent with the suggestion that $[\text{Np}(\text{CO}_3)_5]^{6-}$ is the dominant species in carbonate solution.

(vi) *Uranium(IV) and plutonium(IV)*

From EXAFS acquisition and analyses (Rai *et al.*, 1998, 1999b), the speciation of U^{4+} and Pu^{4+} (of unspecified milli-molar concentrations) in 0.9 and 1.0 M KHCO_3 solutions, respectively, was shown to be like that for Np^{4+} . Namely, the three An^{4+} solution species are the anionic (6-) penta(carbonato) complexes, wherein the five carbonate groups are in bidentate coordination consisting of 9.5 O at 2.46 Å and 5.2 C at 2.90 Å for U (Rai *et al.*, 1998) and 9.8 ± 2.5 O at 2.41(2) Å and 5.5 ± 1.7 C at 2.88 Å for Pu (Rai *et al.*, 1999b). The corresponding distal O interactions consist of 4.1 O at 4.18 Å for U and 5.0 ± 1.5 O at 4.14(2) Å for Pu. Because of the presence of oxidation state impurities, e.g. uranyl(vi) and plutonyl(v), and the low S/N ratio of the primary data due to minuscule solubility, the EXAFS spectra for the U^{4+} and Pu^{4+} carbonate species in 5.4–6.0 M solutions of K_2CO_3 were not adequate for detailed analysis. Despite the uncertainties with the available EXAFS, it was concluded largely based upon other comparisons that $[\text{An}(\text{CO}_3)_5]^{6-}$ is the dominant An^{4+} species in concentrated carbonate solutions. Other complementary research (Clark *et al.*, 1998) provides thorough and convincing evidence in this regard. The Pu L_3 -edge EXAFS of the limiting $^{242}\text{Pu}^{4+}$ (ca. 0.1 M) ion in an aqueous solution of 2.5 M Na_2CO_3 was fit to reveal 10.0 ± 1.2 O atoms at 2.42(1) Å; 5.0 ± 0.6 C atoms at 2.88(2) Å; 5.0 ± 0.6 O atoms at 4.16(2) Å. These values are consistent with the formation of a monomeric penta(carbonato) anion, $[\text{Pu}(\text{CO}_3)_5]^{6-}$, that is essentially identical to the one found in the solid-state, single-crystal X-ray structure of $[\text{Na}_6\text{Pu}(\text{CO}_3)_5]_2 \cdot \text{Na}_2\text{CO}_3 \cdot 33\text{H}_2\text{O}$ (Clark *et al.*, 1998). In this anion, each of the five $[\text{CO}_3]^{2-}$ groups has bidentate coordination in a pseudo-hexagonal bipyramid polygon about Pu^{4+} with three in equatorial positions and two in axial ones. This definitive structure sets to rest a decade-long debate about the molecular structure of the limiting complex in the Pu^{4+} carbonate system under high $[\text{CO}_3^{2-}]$ in both solution- and solid-states.

(vii) *Thorium(IV)*

EXAFS investigations of the Th^{4+} carbonate system show that a penta(carbonato) $[\text{Th}(\text{CO}_3)_5]^{6-}$ solution species is obtained at high concentrations of carbonate (1–2 M Na_2CO_3 with 0.1–1.0 M NaOH) and bicarbonate (0.17–1.0 M NaHCO_3) (Felmy *et al.*, 1997; Hess *et al.*, 1997). Curve-fitting analysis of Th

L₃-edge EXAFS data for solutions of 0.001–0.009 M Th⁴⁺ reveals ten O atoms at 2.49–2.50 Å, a distance that is consistent with bidentate coordination of [CO₃]²⁻. Because the C backscattering is weaker than that for the nearer O and because the Th–C peak cannot be resolved from the Th–O peak in the FT data, the Th–C metrical parameters are subject to large uncertainties. For example, coordination numbers of 3.1–5.2 and distances of 2.97–3.01 Å make it difficult to be specific about the character of the carbonate complexation. The number of coordinated carbonate groups was determined through the analysis of the signal for the well-resolved distal O peak in the FT data to reveal 5±1 O atoms at 4.21–4.26 Å, as expected for the [Th(CO₃)₅]⁶⁻ anion. In contrast, for solutions with a bicarbonate concentration of 0.1 M and less, “. . .the thorium speciation changes dramatically” (Felmy *et al.*, 1997; Hess *et al.*, 1997). The specific and exact nature of this change was not conclusively established from the EXAFS analysis because of data quality limitations, i.e. low S/N ratio, of the primary spectra for the dilute (≤0.0001 M) Th⁴⁺ solutions at pH=9.39–9.43. Although the issue is open to question, the initial EXAFS results suggest a contraction of the Th–O bond length (from ca. 2.50 Å for [Th(CO₃)₅]⁶⁻ to 2.46 Å) accompanied by a decrease in the number of nearest O atoms (from 10 for [Th(CO₃)₅]⁶⁻ to 8). Based upon this information, a mixed carbonate hydroxide species was proposed (Felmy *et al.*, 1997), wherein three [CO₃]²⁻ groups are in bidentate coordination around Th⁴⁺ along with two OH⁻ groups (Hess *et al.*, 1997).

28.2.4 Organic acids

EXAFS analyses provide an average structure of all the element-selected An ions in solution, regardless of their state of speciation – monomer, dimer, trimer, . . ., polymer – and their possible combined and simultaneous presence as hydrolysis products, intermediates, non-complexed aquo ions, etc. As such, the short-range metrical results for An materials containing an assortment of bonding sites and mixtures of phases are difficult to use for definitive comparisons with individual structures proposed in speciation diagrams. In these cases, additional spectroscopic information, such as from, for example, NMR, optical, vibrational, fluorescence, etc., experiments is necessary to confirm the available EXAFS results. For example, the use of EXAFS alone to study the coordination and binding stoichiometry of An ions in natural materials like organic macromolecules known as humic substances, which contain multiple coordination sites, different functional groups (i.e. carboxyl, carbonyl, hydroxyl, thiol, amido, etc.), and bonding modes, can be a difficult and intricately complicated problem. Fortunately, the carboxylate anions, –COO⁻, of organic acids are the most important and widespread functional group for An complexation in the surface-waters and in the subsurface geologic fluids of the terrestrial aquatic environment (Pittman and Lewan, 1994). Moreover, the use of EXAFS has been developed for such challenging environmental research thorough analysis and understanding of the spectra for smaller, molecularly characterized

An carboxylate complexes of common organic, carboxylic acids both aliphatic (R-COOH) and aromatic (Ar-COOH), including the di- and tricarboxylic acids.

Tables 28.7 and 28.8 contain the structures of the mono-, di-, and tricarboxylate ligands as well as several phenolate ligands that are relevant with regard to their presence in natural waters and materials. Except for two publications, one about Th⁴⁺ (Denecke *et al.*, 1999) and the other on Np⁴⁺ (Denecke *et al.*, 2002), the EXAFS research available in time for this publication is exclusively focused on the uranyl(vi) ion, [UO₂]²⁺, complexes of these organic anions. Though large, the extent of the EXAFS structure investigations is dwarfed by the number of crystal and molecular structures studies that have been completely reviewed and discussed in the light of the complexation of radionuclides with humic substances, particularly the humic and fulvic acids, elsewhere (Leciejewicz *et al.*, 1995; Denecke *et al.*, 1997a).

(a) Model systems

Despite early success at probing the bonding of [UO₂]²⁺ with the aliphatic, monobasic acetate ligand through use of U L₃-edge EXAFS (Charpin *et al.*, 1985), research on An complexes of organic acids was not immediately impacted by the method. More than a decade later, three EXAFS studies were reported (Allen *et al.*, 1996a; Pompe *et al.*, 1996; Reich *et al.*, 1996a) with results for uranyl(vi) solutions and solids containing organic carboxylate ligands that set the groundwork for EXAFS measurements that continue today. A pivotal development was realized when the results from EXAFS were demonstrated to be diagnostic of carboxylate coordination (Denecke *et al.*, 1997a,b, 1998a,b). In particular, the distinction between mono- and bidentate O coordination is plainly reflected in the U–O interatomic distance, wherein long U–O distances of ca. 2.5 Å are indicative of bidentate coordination and shorter ones of ca. 2.3 Å suggest monodentate coordination. Oftentimes, the bidentate mode of coordination is corroborated by the appearance of either one or two U–C interactions. The first one with a U–C interaction of ca. 2.85 Å arises from the nearest C atom that is bonded to the two O atoms and the second oftentimes weak one at ca. 4.4 Å arises from the next nearest, the so-called distal C atom that is collinear with the nearest C and absorbing An atoms. Because these two U–C interactions occur at significantly longer distances for the monodentate-bonding mode, e.g. the first and closest U–C distance is ca. 3.5 Å, they are rarely observed in the FT data of An EXAFS. A schematic representation of these two binding forms is shown below. Similar schemes and interatomic distances apply for the bidentate and monodentate coordination of the carbonate ligand discussed above.

Despite the extensive research with the model ligands (L) of Tables 28.7 and 28.8, the results from EXAFS are not sufficient on their own to provide conclusive speciation information about the equatorial coordination of [UO₂]²⁺ and other An moieties. The An:L complexation ratio, e.g. 1:1, 1:2,

1:3, and 2:2, 2:3, etc., is especially difficult to determine from one-dimensional metrical information largely because of spectral congestion. For example, the identification of typically weak and distant U–U interactions that are expected for the 2:2 complexes is oftentimes complicated. Peaks that are purported to arise from U–U interactions can be essentially identical to the O–O peak (i.e. the U–O–U–O–U backscattering pathway) that arises from multiple-scattering within a single uranyl group, which is a common structural feature of the monomeric (1:1, 1:2, ...) and dimeric (2:2, 2:3, ...) complexes. Fortunately, in this regard, the U–U assignment can be convincingly made by use of low-temperature EXAFS (Thompson *et al.*, 1995, 1997; Barnes *et al.*, 2000; Hennig *et al.*, 2001b). Another difficulty arises in the identification of all of the equatorial O ligands in the molecular complexes of $[\text{UO}_2]^{2+}$ that contribute to the total coordination number of which five is the most common one of all the entries of Tables 28.7 and 28.8. For example, the O equatorial responses from carboxylate, phenolate, water, and hydroxide are difficult, oftentimes impossible, to distinguish from EXAFS alone. The use of vibrational spectroscopies, particularly FT-infrared, is especially useful with regard to information about the coordination of R–COO[−] and Ar–COO[−] moieties.

(b) Natural systems

Both humic and fulvic acids play key roles that are not very well understood in the biological and environmental sciences. Humic acid is, in large part, responsible for the immobilization of An ions and heavy metals in soils. The complexation of metals with reactive functional groups is an important regulatory

process of the solubility and fate of soil contaminants. As such, the identity of potential binding sites of 'hard' and 'soft' functional groups, including ligands of N (e.g. amino), O (e.g. hydroxyl, carboxyl, carbonyl), and S (e.g. thiol, sulfide, thiol-ether, sulfonyl) on the outer and inner surfaces of humic acid that would accommodate An ions with different charge/IR ratios has been a subject of practical concern. The difficulties in this area of research stem from uncertainties about the nature of humic acid itself. The diversity of the chemical building blocks that combine in their assembly to form humic acid is well-known and remains a matter of significant interest (Giordano, 1994; Silva and Nitsche, 1995; Nitsche, 1997; Paciolla *et al.*, 1999). In particular, the primary and secondary molecular and crystal structures of humic acid and its conformers, which are believed to vary with ancestry, are not known. Yet, despite the existing gap in knowledge about the specific formula and stereochemistry of humic acid, in general, and about the metal-binding sites of humic acid, in particular, the obvious strength of the EXAFS work is that it provides direct insight about the An coordination. The results of exhaustive U L₃-edge EXAFS data acquisition and analysis of humic and fulvic acids of both natural and synthetic origin, and under the neutral to slightly acidic conditions of pH and Eh that are of environmental relevance, are in consensus (Denecke *et al.*, 1997a, 1998a,b; Reich *et al.*, 1998a; Nitsche *et al.*, 1999; Schmeide *et al.*, 2003). The bonding of the uranyl ion is predominantly associated with carboxylate functional groups. Moreover, the U–O interatomic distances are consistent with the monodentate coordination structure shown above. Under alkaline conditions, the bonding appears to involve some degree of interaction with phenolic –OH groups (Reich *et al.*, 1996a), which are deprotonated at $8 \leq \text{pH} \leq 10$. The pH-dependent bonding of $[\text{UO}_2]^{2+}$ to carboxylate and phenolate functionalities has been demonstrated in several model systems (Rossberg *et al.*, 2000, 2003; Moll *et al.*, 2003). Additional work has been proposed to clarify this possibility with natural humic acids (Reich *et al.*, 1996a; Schmeide *et al.*, 2003).

28.3 SORPTION STUDIES

Chemical reactions that take place at the particle–water interface play a large role in controlling environmental speciation, bioavailability, and transport of ions. For example, adsorption/desorption equilibria and redox reactions can be significantly influenced by the nature of the surfaces seen by the solution. Simple solution solubilities may be altered in the presence of a mineral surface that can preferentially adsorb, and thereby concentrate and precipitate metal-ions at solution concentrations well below their solubility limits. In addition, surface redox reactions can also reduce metal solubility and result in mineral incorporation or crystallization reactions that would not occur in the absence of the active surface (Breit, 1995). In this manner, the mobility of radionuclides through the environment is strongly influenced by their interactions at water–mineral

Table 28.7 Uranyl(vi) complexes of low-molecular weight aliphatic carboxylate ligands (L) with axial (ax.) oxygen coordination numbers and U=O distances as well as equatorial (eq.) coordination numbers and U-O bond lengths. The L stick structures do not represent the true stereochemistry. Estimated standard deviations, where available, are obtained from the primary sources and are given after the ± sign or within parentheses.

interfaces. For example, uranium mobility in oxic groundwater is dominated by adsorption of U(VI) onto mineral surfaces. The sorption of uranyl on to organic and inorganic surfaces plays a major role in preconcentrating low-temperature sedimentary uranium and the formation of uranium-bearing minerals, such as uraninite, through reduction following adsorption from groundwater. To predict mobility, it is necessary to have a fundamental understanding of interaction processes including surface complexation and precipitation as well as radionuclide incorporation into mineral phases. Among physical factors that influence partitioning between solution and metal surface are the specific actinide involved, its concentration, coordinating ligands such as dissolved carbonate, phosphate, and other complexing ions, solution pH, and mineral surface contamination.

Published synchrotron studies examining actinide interactions on mineral surfaces focus on valence and structural details of binding. Questions to be answered have centered on the valence state of the actinide and its coordination environment, including the presence of mineral-phase atoms visible in the coordination sphere that may help to distinguish inner- from outer-sphere interactions. The presence of actinide-actinide interactions may indicate clustering or the formation of oligomers on the mineral surface. Such oligomers may represent precursors to mineral-phase formation.

Synchrotron work to date has focused on XAS and microprobe studies of U, Np, or Pu adsorption onto silicate, phosphate or iron-based mineral phases and onto more complex soil samples. Work has also been published that looks at sorption onto bacterial surfaces as well as incorporation into mineral phases. These topics will be reviewed in the following subsections.

28.3.1 Silicates

Silicates are the largest and most complicated class of minerals, with estimates that as much as 90% of the Earth's crust is composed of silicates. These complicated structures can form as single units, double units, chains, sheets, rings, and frameworks. Phyllosilicates are a silicate subclass in which rings of tetrahedra are linked by shared oxygens to other rings in a two-dimensional plane that produces a sheet-like structure. The silicon to oxygen ratio is generally 2:5, with the sheets typically connected to each other by cation layers. The cation layers are weakly bound and often have water and other moieties trapped between the sheets. Clays are a group of phyllosilicates that contain large percentages of water trapped between the silicate sheets. Most clays are chemically and structurally analogous to other phyllosilicates but contain varying amounts of water and allow facile ion-exchange of interlayer ions. It is the physical characteristics of clays, more so than their chemical and structural characteristics, which defines this group.

Clay minerals are further divided into four groups, one of which is the montmorillonite/smectite group. Montmorillonites differ mostly in chemical

content. The general formula is $(\text{Ca,Na,H})(\text{Al,Mg,Fe,Zn})_2(\text{Si,Al})_4\text{O}_{10}(\text{OH})_2 \cdot n\text{H}_2\text{O}$. The water content is variable, and in fact when water is absorbed, the crystals tend to swell to several times their original volume. The effect of montmorillonite is to slow the progress of water through soil or rocks.

There have been several studies of the adsorption of actinide ions onto silicate surfaces, as summarized in Table 28.9. These studies are driven by the realization that the surfaces of these mineral phases have a discernable influence on the migration of ions in natural environments. Silicates have been proposed to have two surface sites onto which an adsorbed ion can bind. Numerous experiments explore specific models which address these two broad classes of binding sites: external amphoteric 'edge' sites whose properties are pH-dependent, and fixed-charge, basal-plane 'exchange' sites whose reactivity is independent of pH (Sposito, 1984, 1990; Weiland *et al.*, 1994). Unlike many transition-metal mineral phases, the silicate surface itself shows no redox chemistry. This simplifies the types of interactions that can be expected on the surface to complexation,

precipitation, and incorporation, and thereby providing simple model for study. The main question that has been addressed to date is the mechanism by which the ion binds to a silicate surface. As demonstrated in Fig. 28.7 for an actinyl ion, surface binding can include mononuclear or polynuclear inner- or outer-sphere complexation. Inner-sphere complexes can bind with either monodentate or bidentate ligation with surface sites.

The simplest of the silica phases to be studied are silica gels, amorphous $\text{SiO}_2 \cdot n\text{H}_2\text{O}$. Non-porous pyrogenic silica samples, consisting of spherical particles amorphous by X-ray diffraction, were used in a study of Th adsorption in order to determine the molecular details of the adsorption (Oesthols *et al.*, 1997). Wet samples of Th sorbed onto amorphous silica were studied using Th L_3 -edge EXAFS. Solution pH values in the study were in the range of 2.8–4.0, which corresponded to the adsorption edge in the pH region of 2–3 that had previously been determined potentiometrically (Oesthols, 1995). Th surface coverages were

Fig. 28.7 Binding modes for a metal-ion to a mineral surface. The binding can be (a) outer sphere, in which the metal ion's first coordination sphere is not a bulk-surface ion; (b) a mononuclear, monodentate, inner-sphere complex, in which the metal-ion's first coordination sphere includes an ion from the bulk-surface; (c) mononuclear, bidentate coordination, in which the complexing metal-ion shares two ligands with the surface; and (d) polynuclear, bidentate coordination, in which the metal-ion has coordination to other metal-ions as well as the surface.

determined to be 3.8–230%. The spectra showed a decrease in structural order with increasing surface coverage. For lower surface coverage, 3.8–75.5%, two oxygen coordination shells were seen at approximately 2.28 and 2.54 Å with coordination numbers of about 2–2.7 and 5, respectively. These samples also showed about 2(1) Th–Si interactions at 3.85 Å. Samples with higher Th surface coverage, that is 92.7 and 230%, also showed two oxygen shells, with about two O at 2.33 Å and 4.5 O at 2.54 Å and 2.3 and 1.3 Th–Si interactions at 3.84 and 3.79 Å, respectively. None of the samples showed evidence of any Th–Th interactions, even the sample reported to have 230% surface coverage, suggesting that the surface layer resembles amorphous thorium hydroxide, which also shows no significant Th–Th correlations. The absence of Th–Th correlations, even in amorphous Th(OH)₄ was attributed to a high degree of disorder (Oesthols *et al.*, 1997). The EXAFS data were consistent with Th adsorption onto the amorphous silica surface via bidentate inner-sphere complexation, in which Th has a double corner-sharing bond with two different SiO₄ surface tetrahedra. Four to eight oxygen atoms are shared with coordinated solution–water molecules, which account for the longer Th–O correlations at 2.55 Å.

Uranium sorption by silica gels has also been shown to be pH sensitive (Michard *et al.*, 1996), increasing with increasing pH over the range of about 3–5. This pH interval corresponds approximately to that over which there are hydrolyzed uranyl species present in solution. A two-phase process has been proposed that involves an external mass transfer and an intra-particle mass transfer, of which only the former is strongly pH-dependent. Earlier, Raman studies had suggested that uranyl sorbs as an inner-sphere surface complex (Maya, 1982). This suggestion has been confirmed by EXAFS studies of UO₂²⁺ sorption products for samples prepared at pH 3 and 5 (Dent *et al.*, 1992), which were noted to be indistinguishable, but no detailed analysis was provided. Coordination information of uranyl sorbed to silicic acid and silica gel samples prepared at pH 4 was determined by EXAFS (Reich *et al.*, 1996b). The two materials are distinguished by different surface areas, 80 vs 470 mg/g for silicic acid and silica gel respectively, as determined by BET measurements. An analysis of EXAFS data showed the expected dioxo coordination with a U–O_{ax} distance of 1.78 Å for both samples. Two silicic acid samples, prepared with different solution uranyl concentrations, were examined. The sample, obtained from a 0.01 M UO₂²⁺ solution, has two resolvable O coordination shells in the equatorial plane with 2.6(4) O at a distance of 2.27 Å and 1.8 O at a distance of 2.50 Å. The sample obtained from a more concentrated uranyl solution, 0.05 M, has 2.1(4) equatorial O at a distance of 2.27 Å and 2.25 O at a distance of 2.48 Å. Both samples show a total equatorial O coordination of slightly less than 5. These results compare to those determined for silica gel samples obtained from a 0.05 M uranyl solution, which also have two equatorial O shells, one with 4(1) O at 2.29 Å and the other with 1.6(7) O at a distance of 2.50 Å, for a total O coordination greater than five. Similar results were determined for a sample prepared at pH 3.4 (Sylwester *et al.*, 2000).

The observation of two O coordination shells separated by about 0.2 Å, coupled by the absence of an EXAFS feature attributable to U–U interactions, is strong evidence that, at pH values 3.4 and 4, uranyl undergoes inner-sphere, mononuclear, bidentate surface complexation (Reich *et al.*, 1996b; Sylwester *et al.*, 2000). In contrast, samples prepared at higher pH values show additional U–Si and U–U coordination shells (Allard *et al.*, 1999; Sylwester *et al.*, 2000). For example, at pH 6.24 additional coordination shells are observable in the data, with one Si at 3.1 Å and about two U at 4 Å (Sylwester *et al.*, 2000). This result indicates some form of oligomeric uranyl phase, either a surface complex or a precipitate. The U–Si atomic distance and coordination number would imply a surface adsorption via bidentate complexation to two surface O associated with the same Si. Monodentate complexation with surface O would be expected to result in a longer U–Si distance of about 3.8 Å (Burns *et al.*, 1997).

EXAFS spectra of uranyl-loaded montmorillonite, which contains aluminol as well as silanol sites, are clearly different from that of the metal adsorbed onto silica (Chisholm-Brause *et al.*, 1992, 1994; Thompson *et al.*, 1997; Sylwester *et al.*, 2000; Hennig *et al.*, 2002). The degree of complexation at the edge aluminol or silanol sites should rise with increasing pH because these sites become increasingly deprotonated and therefore available for cation complexation. In studies with pH values in the range of about 3 (Chisholm-Brause *et al.*, 1994) to 5 (Dent *et al.*, 1992; Sylwester *et al.*, 2000), the data contain an unresolvable single-shell structure similar to those seen in aqueous solution and consistent with outer-sphere coordination. The observed U–O_{eq} bond distances of 2.41–2.43 Å support this finding. In contrast, studies at higher pH (5–7) indicate that an inner-sphere complexation process dominates the sorption. Although the short data range (3.1–11.4 Å⁻¹) prohibited the observation of a splitting in the shell attributed to equatorial ligation, large Debye–Waller factors (0.013–0.017 Å²) together with much shorter bond distances observed at higher pH, 2.34–2.38 Å, were used to support models for binding to amphoteric surface hydroxyl sites (Hennig *et al.*, 2002).

Another interesting study was published concerning the role of montmorillonite surface coverage on the local structure about the uranyl (Chisholm-Brause *et al.*, 1994). There were three samples studied whose final pH values decreased with increasing surface coverage, from 5.6 to 4.4 and finally to 3.4. At low surface coverage, 0.0103 mmol/g, the ratio of the integrated EXAFS amplitude from the equatorially bound O to that found in solution is only 0.58. The bond distance is also short at 2.391 Å. As the solution concentration was increased, the surface coverage also increased from 0.044 to 0.208 mmol/g, there was a higher ratio of uranyl ligation in the equatorial plane (0.65 and 0.77) and these O occurred at longer distances, specifically 2.414 and 2.444 Å, respectively. This same observation has been previously quantified in terms of significant differences in equatorial O coordination as a function of solution U concentration (Chisholm-Brause *et al.*, 1992; Dent *et al.*, 1992). The authors argue that these data suggest that uranyl forms at least three distinct sorption

complexes on montmorillonite, a result that is consistent with previously published modeling (Zachara and McKinley, 1993). Using simple bond-length to coordination-number correlations, it was also argued that the observed increase in amplitude of the EXAFS spectra with increasing surface coverage must be due, at least in part, to decreasing disorder, and not just an increase in the number of coordinating ligands (Chisholm-Brause *et al.*, 1994). An independent study (Hennig *et al.*, 2002) on samples with uranium loading of 1751–2473 ppm did not support this finding. These EXAFS data show no evidence of U–U interactions, even at pH values >5.4, where thermodynamic modeling predicts the formation of solid-hydrated uranyl oxides, indicating that surface complexation may be kinetically favored relative to precipitation under the conditions employed. It should be noted that molecular dynamics simulations of uranyl sorption onto a quartz surface find that water oxygen atoms and surface oxygen atoms are equidistant to the metal-ion. Equatorial splitting of the bond distances is caused not by inner-sphere coordination, but instead by the presence of other ligands in the first coordination sphere of the UO_2^{2+} , such as the carbonate anion (Greathouse *et al.*, 2002).

Uranyl sorption complexes on two related phyllosilicates, vermiculite, which is a montmorillonite, and hydrobiotite, which is a mica, were studied to gain further information on binding to different surface sites (Hudson *et al.*, 1999). Samples were prepared that favored fixed-charge, ion-exchange sites, or amphoteric surface hydroxyl sites. Samples made under conditions that significantly favored the ion-exchange sites had EXAFS spectra with one resolvable equatorial O distance, consistent with outer-sphere uranyl complexation. Upon dehydration, the EXAFS data are consistent with inner-sphere uranyl coordination. In addition to the standard EXAFS experiments, the local structure about the uranyl ion in the hydrated sample was also studied using polarized L_1 - and L_3 -edge XANES. Polarized X-ray absorption data have been demonstrated to yield information about the spatial orientation of the linear dioxo group (Hudson *et al.*, 1996). Polarization data were used to probe the orientation of the linear dioxo-groups with respect to the silicate surface in the vermiculite sample (Hudson *et al.*, 1999). The ion-exchanged sites, with outer-sphere coordination, showed a preferred orientation of the dioxo moiety parallel to the silicate layers. Samples that significantly favored the hydroxy sites have EXAFS spectra that show the uranyl ion in a highly distorted equatorial shell with the detection of a U–U interaction, which suggests the formation of surface precipitates and/or oligomeric complexes.

The reports on sorption onto montmorillonite have been extended by experiments on uptake at initial Th concentrations representing undersaturation (pH 2 and 3) and oversaturation (pH 5) with respect to amorphous ThO_2 (Daehn *et al.*, 2002). The sorption experiments were conducted with Th concentrations in the range of 2.7×10^{-6} to 4×10^{-4} M and under an N_2 atmosphere. At low and intermediate surface coverage, 1–34 and 157 $\mu\text{mol/g}$, two coordinating oxygen shells were observed, with about three O at 2.24 Å, six to

eight O at 2.45–2.48 Å, and one Si shell at 3.81–3.88 Å. Any attempt to include Th–Th interactions into the fit failed. The same coordination environment was observed for both pH values. The pH=5 samples had Th–O coordination similar to those observed at the lower pH. For the samples with lower Th loading (14 and 40 µmol/g), data analyses suggested a reduced number of Th–Si pairs, 1.4–1.7 at a distance of 3.87 Å, compared to the sorption samples prepared at pH=3, which had 2.5–2.9 Si at 3.83 Å. The reduced Th–Si coordination number at the higher pH could be explained by assuming that a fraction of Th is no longer directly bonded to the montmorillonite surface, but instead forms an outer-sphere complex. It could also indicate destructive interference with the EXAFS generated by the Th–Si pairs at 3.9 Å (Daehn *et al.*, 2002). This latter hypothesis is supported by the data from the pH=5 sample with the highest Th loading (166 µmol/g), which was satisfactorily fit with neither a Th–Si nor a Th–Th interaction. However, the similarity of EXAFS data from this sample with those obtained from a Th amorphous precipitate suggests the surface formation of similar precipitates at high Th concentrations and high pH.

Polarized EXAFS measurements were also obtained from Th-treated oriented films, prepared at pH values of 2 and 3, to investigate whether the sorbed Th was oriented with respect to the octahedral sheets of the clay (Daehn *et al.*, 2002). The spectra were recorded with an electric field vector at 10°, 35°, 55°, and 80° with respect to the clay-film plane. No significant polarization effects were observed in the spectra obtained from the pH=2 or 3 samples. It was postulated that Th adsorbs to the montmorillonite at its edge sites, by sharing double corners with Si tetrahedra, and that these sites are saturated when the concentration of Th is greater than 32 µmol/g. This hypothesis is supported by the observed difference in EXAFS spectra of the lower concentration samples compared with the higher surface-coverage samples, which look more similar to solution Th spectra. This result may indicate that Th is sorbed as an outer-sphere complex after the clay edge sites are saturated.

Studies on Th- (Giaquinta *et al.*, 1997a) and uranyl-exchanged bentonite (Giaquinta *et al.*, 1997a,b), a smectite clay, and zeolite (Wasserman *et al.*, 2000) samples extended previous work on two aspects: (1) the exchanged clays were coated with hydrophobic silanes in order to inhibit interlayer-water exchange and (2) uranyl-exchanged samples were subjected to hydrothermal conditions. The uranyl-ion-exchanged samples were thoroughly washed in an effort to produce samples with single-interlayer binding sites. The EXAFS from the simple, untreated samples were analyzed, assuming only one site. The results from Th L₃-edge EXAFS (Giaquinta *et al.*, 1997a) showed that Th had a single hydration sphere with approximately 11 O at a distance of 2.49 Å and 2.7(6) Å at 3.66 Å. In contrast, EXAFS spectra from the hydrothermally treated samples were similar to that obtained from ThO₂. The first O shell shifted to a slightly shorter distance, 2.39 Å and there were two additional peaks present. The peak at 3.93 Å, present only in the treated sample, was attributed to a Th–Th

interaction and consistent with the formation of a thoria-like hydrous polymer (Baes and Mesmer, 1976). The EXAFS from the UO_2^{2+} exchanged sample, before treatment, was analyzed with 2.2 O at 1.77 Å, 5 O at 2.43 Å, and 2.6 O at 3.45 Å (Giaquinta *et al.*, 1997b). This result is consistent with outer-sphere uranyl complexation as seen for other montmorillonite samples.

In contrast to the Th samples, the uranyl-loaded clays from hydrothermally treated samples produced EXAFS spectra that were different from those obtained before treatment. The silane-treated uranyl samples also showed no change to the uranyl environment compared to those obtained before hydrothermal treatment, except that the spectra showed that the coordination shells were at longer distances. The methoxysilane data revealed dramatic changes in the uranium environment. The dioxo coordination environment disappeared and was replaced by a single oxygen shell at 2.33 Å. There was also an additional peak observed at 3.36 Å and another at 3.92 Å, determined to be a U–U interaction. This coordination is suggestive of small particle uraninite formation, which implies the reduction of U(VI) to tetravalent U. This suggestion was confirmed by U L_3 XANES experiments. The observation of uranyl reduction in the presence of an organic and under elevated temperature and pressure is important in terms of uranium migration under geological conditions.

Dissolved CO_2 is also believed to significantly influence uranium adsorption on mineral surfaces with a maximum at near-neutral pH, and decreasing sharply toward more acidic (pH < 6) and more alkaline (pH > 7) conditions. The mechanism behind this influence was studied using EXAFS to probe uranyl sorption onto the clay-mineral kaolinite (Thompson *et al.*, 1998). The combination of uranium concentrations and pH values used in these experiments were such that complex uranyl oxyhydroxides would be expected. Indeed U–U interactions were observed.

In addition to the work on the aluminosilicate clays, there have been limited EXAFS studies of actinide sorption onto aluminates, specifically uranyl onto $\gamma\text{-Al}_2\text{O}_3$ and $\alpha\text{-Al}_2\text{O}_3$. The former study was done on two samples with contact solution pH values of 3.48 and 6.50 (Sylwester *et al.*, 2000). EXAFS data from both samples demonstrated the standard dioxo uranium(VI) coordination at 1.78 Å. There were also two equatorial shells, the first with about 2.8 O at 2.37 Å and about 2.0 O at 2.53 Å, whereas the second had about 2.6 O at 2.34 Å and 3.1 O at 2.50 Å. The splitting of the equatorial coordination shell is again used as evidence for inner-sphere coordination to the alumina surface. The sample at near-neutral pH also showed a U–U interaction at 4.10 Å corresponding to about 0.5 U near-neighbors, which indicated the coordination of a mixture of mononuclear and polynuclear surface complexes. The study of uranyl sorption on $\alpha\text{-Al}_2\text{O}_3$ (Denecke *et al.*, 2003) examined the polarization dependence of uranyl ions sorbed onto a single-crystal (110) surface under different loading conditions. Although the authors indicate the potential of polarization experiments, no definitive information about uranyl coordination to the $\alpha\text{-Al}_2\text{O}_3$ surface was provided.

28.3.2 Carbonate incorporation

Carbonate minerals are among the most common secondary phases that form in near-surface environments. There are three main sedimentary carbonate minerals: calcite, aragonite, and dolomite, as listed in Table 28.10. Of these mineral phases, calcite is one of the most abundant of the non-silicate minerals, comprising about 4% by weight of the Earth's crust. Aragonite is a less common polymorph of calcite and is a major constituent of invertebrate skeletons that, in most environments, eventually converts to calcite. Carbonate minerals are known to incorporate trace amounts of uranium, an attribute that has been utilized for the U-series age determinations of ancient calcites and as marine paleoenvironmental (Brannon *et al.*, 1996) and diagenetic indicators (Russell *et al.*, 1994). In addition, the carbonate mineral class itself includes a variety of stable uranyl carbonates (Reeder, 1983). The studies of actinide interactions with carbonate phases have focused on incorporation studies.

It is important to develop a molecular level understanding of the speciation of actinides sequestered in carbonate phases in order to assist in the assessment of these ubiquitous minerals in actinide mobility and sequestration. The mechanism(s) of actinide incorporation into carbonates, particularly calcium carbonates, for which the actinide can substitute for Ca^{2+} , has been the source of significant recent study when the substituting ion is uranium (Shen and Dunbar, 1995). The structural work published to date has focused on uranium substitution and has not directly addressed the issue of transuranic substitution into a calcium carbonate lattice. U^{4+} is approximately the right size to substitute for Ca^{2+} in the calcite lattice, but there are two problems to this simple ion replacement. First, the substitution of a tetravalent ion for a divalent one requires some stable charge-balance mechanism available in the lattice. Second, U^{4+} has a low groundwater solubility because of the precipitation of insoluble uranous phases and as a result U is present in most natural waters as the dioxo uranium(vi) ion. Although $\text{U}(\text{vi})\text{O}_2^{2+}$ is divalent, its configuration and size would be expected to cause significant local structural disruption if it were to substitute directly for Ca^{2+} (Langmuir, 1978; Reeder, 1983).

The structural details of uranium incorporation into calcite and dolomite were first probed by performing EXAFS experiments on powdered samples exposed to a uranyl perchlorate solution (Geipel *et al.*, 1997). The adsorption experiments were done with no external pH control and under atmospheric conditions, that is, without excluding CO₂. The final solution pH values, after equilibration, were measured to be between 8 and 9 and the final samples had loadings of about 12.8 to 66.3 mg U/g. XPS studies on the samples indicated that the uranyl ions displace Ca at the mineral surface. There was no chlorine-containing surface species detected, indicating that the perchlorate anion did not participate in the surface reaction. The U EXAFS of all the samples studied were indistinguishable and consistent with uranyl coordination. The uranyl equatorial shell was characterized by a broad distribution of U–O distances, with an average of 2.34(2) Å. These results support conclusions of earlier studies that uranyl carbonates and hydroxides form at the grain surfaces of calcite (Carroll and Bruno, 1991; Carroll *et al.*, 1992).

More recent studies have focused on the incorporation of uranyl into synthetic aragonite (Reeder *et al.*, 2000) and calcite (Reeder *et al.*, 2000, 2001). Several previous studies have shown uranyl to be preferentially taken up by aragonite relative to calcite (Kitano and Oomori, 1971; Meece and Benninger, 1993), which points to underlying important mechanistic or structural differences for its incorporation into these two polymorphs. This issue was directly examined by comparing synthetic samples of the two phases (Reeder *et al.*, 2000) that were formed under similar conditions, that is U concentrations were held in the range 10–82 mM, the pH values were maintained at about 8.2–8.3, and air was bubbled through the solutions. Because of the deleterious effects of Sr incorporation on XAS data collection, efforts were made to ensure its exclusion during sample preparation. The final aragonite samples had 985 and 10810 ppm U whereas the calcite samples had 700 and 1890 ppm U in agreement with previous findings that uranyl is preferentially taken up by the orthorhombic phase. U L₃ XANES data indicate the presence of uranyl(VI) in the samples. Fits to the EXAFS data for all uranyl-containing aragonite and calcite samples showed the typical dioxo-coordination environment.

The results of a detailed analysis of the EXAFS data are given in Table 28.11. The most significant differences between U in the two mineral phases were evident in the first equatorial shell. For the aragonite sample, a fit to the data determined that the uranyl ion in aragonite has the same coordination environment as the uranyl triscarbonato solution complex, which was also measured during the same experiment (Reeder *et al.*, 2000, 2001). The O_{eq} distances from aragonite compare to the U–O average distance of 2.47 Å determined for the uranyl coordination by six equatorial oxygens (Burns *et al.*, 1997). In addition to oxygen scattering, a correlation attributed to U–C₃, from carbonate at 2.89 Å is in the range characteristic of bidentate coordination by three carbonate groups (Allen *et al.*, 1995). A further correlation attributed to distal oxygens of carbonate groups at 4.1 Å was also observed, as was a linear

Table 28.11 Comparisons of coordination numbers (CN), distance from uranium (R), and Debye-Waller factor (σ^2) determined for the best fits of U L_3 EXAFS data from synthetic aragonite and calcite that were precipitated from solutions containing the uranyl ion (Reeder *et al.*, 2000). Multiple values for one parameter indicate fits from different samples. Underlined values indicate that the parameter was fixed during fitting.

three-legged multiple-scattering path (O_{dist}–C–U) at essentially the same distance. The observation of bidentate coordination of U by three carbonate ions was supported by Raman and luminescence spectroscopies. There was no unambiguous evidence of any U–U interactions that would indicate clustering or co-precipitation of a uranyl mineral phase. In addition, evidence of U–Ca correlation was observed that was dependent on U concentration.

The same basic structural unit was determined for the uranyl incorporation into aragonite as was observed in the growth solution, which was also measured and analyzed (Reeder *et al.*, 2000). The EXAFS results, supported by Raman data, were used to postulate an incorporation mechanism for uranyl into aragonite. EXAFS show that the predominant aqueous uranyl species is UO₂(CO₃)₃⁴⁻ and that this configuration is preserved in aragonite. The authors suggest that the entire solution species is incorporated into the mineral phase essentially intact (Reeder *et al.*, 2000).

In contrast to the well-defined coordination environment observed for uranyl in aragonite, the coordination environment of uranyl in calcite appears significantly more disordered (Reeder *et al.*, 2000, 2001). The second FT peak from the U EXAFS data, attributable to U–O_{eq}, is significantly less intense and at a smaller U–O distance, relative to the dioxo peak, in the calcite sample. This observation is manifested in the fit, which has fewer, about five, equatorial O with significantly larger Debye–Waller factors (0.009–0.010 Å²). Weak peaks in the FT suggest that there are carbon atoms coordinated at 2.9 and 3.2 Å with more than one type of U coordination by carbonate, indicating both mono and bidentate interactions. The luminescence data are also different for calcite, indicating the possibility of uranyl hydroxide formation on mineral surfaces, a postulate previously made from an independent study (Geipel *et al.*, 1997).

The work on powder-samples of calcite has been augmented by further work, on single-crystals, designed to address the issue of whether incorporation occurs at structurally distinct surface sites (Reeder *et al.*, 2001). The single crystals were grown at slightly lower pH values (7.5–7.6) than were the powder samples. Luminescence lifetime measurements indicated that more than one solution species was present in the growth solution. The average U concentrations in the crystals were rather low, about 15 and 225 ppm. Micro synchrotron X-ray fluorescence (μ -SXRF) and micro X-ray absorption near-edge structure (μ -XANES) data were obtained from the single-crystals using a monochromatic beam with spot size $15 \times 15 \mu\text{m}^2$ or $5 \times 6 \mu\text{m}^2$. The as-grown $(10\bar{1}4)$ face was examined, and had a single, polygonized growth hillock composed of four uniform vicinal faces that differed by the orientation of their growth steps and the direction of their advancement during growth. The presence of this hillock is significant because uranyl species can become incorporated into structurally distinct steps of the non-equivalent vicinal faces during crystal growth processes. The μ -SXRF data reveal a striking difference in the distribution of uranium corresponding precisely to the non-equivalent vicinal faces. The $[4\bar{4}1]_+$ and $[4\bar{4}1]_-$ surfaces were highly enriched in uranium relative to the $[48\bar{1}]_+$ and $[48\bar{1}]_-$ surfaces. The magnitude of differential uptake was approximately a factor of 6 to 10. The implications of these findings are that surface controls are significant and therefore that the relative proportions of crystal surface morphologies can strongly influence uranyl incorporation. Polarized μ -XANES revealed neither a discernible difference between the spectra obtained from the non-equivalent vicinals nor any orientational dependence. Fits to the EXAFS data were similar to those from the powder samples, listed in Table 28.11, with two axial O at 1.80 Å, 5.7 O at 2.36 Å, and 3.2 C at 2.92 Å. Weak features observed at higher r could be fit with minor contributions from a distal oxygen and a multiple-scattering path at 4.15 and 4.18 Å, respectively. The results indicate that there is no preferred orientation of the uranyl moiety within the single-crystal, and would be consistent with multiple uranium species, as suggested by luminescence and supported by the apparent disorder seen by EXAFS beyond the first coordination shell.

The uranyl concentrations in the synthetic calcite and aragonite samples far exceed that normally found in natural samples, raising the possibility that the obtained coordination environments do not reflect the environments seen in natural samples, which equilibrate over long time frames, and may undergo repeated dissolution/precipitation or structural transformations. Unfortunately, the low concentrations of U typically found in natural calcium carbonate mineral samples, combined with the presence of large amounts of Sr^{2+} , either substituting directly for Ca^{2+} ion in the lattice or as partially segregated into strontianite (Gregor *et al.*, 1997) complicate the acquisition of EXAFS data with adequate statistics for useful analyses. One study looked at U incorporation into natural coral skeletal aragonite (Pingitore *et al.*, 2002). Two live coral samples, collected from the Galapagos Islands, and one dead sample,

obtained from an exposed reef terrace on Guadeloupe were used in the study. Radiocarbon dating from nearby reefs yielded the age of the Guadeloupe sample as about 25000–30000 years old. The U content, determined from inductively coupled plasma-mass spectrometry (ICP-MS) was low, approximately 3 ppm. In contrast, the Sr concentrations were approximately 7000 ppm in all three samples, requiring XAS data acquisition at the U L₂-edge. XANES edge energies and shapes were used to infer that the U in the two live samples was present as uranyl(vi) whereas that in the dead sample from the exposed reef on Guadeloupe was predominately U⁴⁺. Unfortunately, the EXAFS data were not of sufficient quality to confirm this observation and furthermore it should be noted that XANES data can sometimes be misleading when distinguishing between tetra- and hexavalent U (Eller *et al.*, 1985; Calas *et al.*, 1987; Greaves *et al.*, 1989; Biber *et al.*, 1997; Hess *et al.*, 1998; Sturchio *et al.*, 1998).

There have been two reports published on natural calcite samples that contain uranium. The first looked at a natural sample of spar calcite from a Mississippi Valley-type zinc ore deposit (Sturchio *et al.*, 1998). This sample has a relatively high U concentration (5–35 ppm). The sample also included a high concentration of Sr, necessitating data collection at the U L₂-edge. The XANES data are inconclusive with respect to the U oxidation state. In contrast, the EXAFS data fit well with a single coordination environment. The missing peak at 1.8 Å in the FT confirms the absence of a uranyl ion and the overall coordination environment confirms the incorporation of tetravalent U into the calcite lattice. Although the EXAFS results show an important difference for the U coordination over that of Ca²⁺, it is clear that the U does directly substitute for Ca²⁺ in the lattice. In calcite, the Ca²⁺ has a first coordination shell of octahedral O about Ca²⁺ at a distance of 2.36 Å (Effenberger *et al.*, 1981). In contrast the incorporated U is best fit with two shells: one at 2.21 and one at 2.78 Å. More distant shells were also observed, including six C at 3.26 Å, six Ca²⁺ at 4.02 Å, and six Ca²⁺ at 4.98 Å. These distances are indistinguishable from those observed in calcite itself. An X-ray synchrotron microprobe analysis of the same sample confirms the substitution of U into the calcite structure and is inconsistent with inclusions of distinct U-rich phases. The simultaneous presence of sulfide minerals and hydrocarbon inclusions indicates that this calcite sample was formed in a reducing environment. This may explain the high concentration of U in this sample, and indicates that U⁴⁺ is preferentially incorporated into calcite in such environments. In contrast, U⁶⁺ is generally excluded from calcite. These results provide insight into the geochemical cycle of U in deep groundwater aquifers and anoxic lacustrine and marine basins. The incorporation of U into calcite gives a potentially stable host for dispersed U⁴⁺ over geological time scales.

The second report of an XAS study of uranium in natural calcite (Kelly *et al.*, 2003) involved the use of XAS and X-ray microprobe to look at a sample relatively rich in U (about 360 µg/g) from a 13700-year-old speleothem deposit

in northern Italy (Spoetl *et al.*, 2002). X-ray fluorescence (XRF) mapping was done with a monochromatic beam (17.3 keV) focused to $5 \times 5 \mu\text{m}^2$. Fluorescence emission from U, Sr, and Ca were monitored. XRF mapping indicated that uranium concentrations vary between 80 and 500 ppm that were homogeneous on the 100- μm scale. The data were considered consistent with a dilute solid solution. It is interesting to note that there is petrographic evidence that this natural sample of calcite formed by recrystallization of a U-rich aragonite sample, which may explain the high uranium substitution. In contrast to the previous data on the natural calcite sample from the Mississippi valley, the XANES data from the northern Italy calcite sample indicated uranium is predominately hexavalent. The EXAFS data confirmed a hexavalent, dioxo-uranyl coordination that is monodentate to four carboxylates with U–O distances from the EXAFS fit of 2.41 Å. These results are similar, although more detailed, than those previously reported for synthetic calcite samples (Reeder *et al.*, 2000, 2001) but the interpretation is different. The authors of the paper, reporting uranyl incorporation into natural calcite (Kelly *et al.*, 2003), propose a direct substitution into the calcite lattice that involves the replacement by UO_2^{2+} of one Ca and two carbonate anions. Charge balance then requires the non-local substitution of excess Na^+ , which is observed in the chemical analysis. Overall, the reported EXAFS analyses are not inconsistent with their proposed model, although the complexity of the uranyl site requires eight scattering contributions with 19 variable parameters to adequately fit the data. Considering the reported k -range, only 15 parameters should have been used in the fit (Teo, 1986). Thus, although the proposed model for uranyl substitution into calcite is interesting, further experimental work is required for its confirmation.

The overall conclusion that the uranyl ion is more effectively incorporated into the aragonite than the calcite structure raises an environmental issue (Reeder *et al.*, 2000). Prevalent geological conditions at or near the Earth's surface favor the transformation of aragonite, which is metastable, into calcite. However, the uranyl ion does not fit into the calcite lattice as well as it does into the aragonite lattice. The UO_2^{2+} coordination environment is more clearly defined in the latter material, which is known to incorporate a significantly higher concentration of uranyl. Therefore the transformation of aragonite into calcite destabilizes the uranyl incorporated into the phase. As a result, CaCO_3 may not be an effective sequestering agent for U(VI) under geologic conditions and over long timescales.

28.3.3 Fe-bearing mineral phases

Iron and its compounds play an important environmental role in both biotic and abiotic processes. Its complex redox and solubility behavior is a function of solution Eh and pH, as sketched in Fig. 28.5 (Hem, 1985). Fe^{2+} is generally soluble in groundwater systems whereas most iron minerals and insoluble complexes contain Fe^{3+} . Iron oxides in particular are ubiquitous in soils and

sediments where they play an important, although not well understood, role in regulating metal-ion distribution through chemical, adsorption, and redox mechanisms. Iron sulfides also play a role in more anoxic environments. Oxidation state properties of Fe can play an important role in actinide speciation and transport, especially in reducing environments. Simple solution redox reactions may be directly affected by the presence of a redox-active surface, or they may be altered in the presence of a mineral surface that can preferentially adsorb, and thereby concentrate metal-ions at solution concentrations that are well below their solubility limits.

In order to understand the results of experiments designed to study actinide speciation on Fe surfaces, which are conducted at a macroscopic level, it is necessary to elucidate a molecular level model for the solid/surface reactivity. Several studies, using EXAFS spectroscopy, have been undertaken to probe actinide speciation on carefully prepared Fe samples, as listed in Table 28.12. Most, although not all of these experiments have focused on uranyl adsorption onto mineral phases, although the occlusion of U by Fe-oxide mineral coatings has also been reported (Jenne, 1977). In the absence of high solution concentrations of complexing ligands, U has been shown to complex to Fe minerals such

Table 28.12 Published studies of uranium and neptunium binding to Fe mineral surfaces. These studies focus on inner- versus outer-sphere coordination of actinide with mineral surface as well as any evidence of redox chemistry.

as hematite and goethite over a wide range of solution pH conditions (Hsi and Langmuir, 1985; Waite *et al.*, 1994; Duff and Amrhein, 1996), making these reactions of significant importance to its environmental behavior. For the most part, these studies involve Fe(III) phases and are therefore unlikely to involve redox activity because the studies have utilized the fully oxidized UO_2^{2+} ion in solution.

Among the relevant experiments are those that probe the interaction of uranyl with hydrous ferric oxide (HFO) because the enrichment factor for uranyl on the HFO surface is about 500 times greater than on well-crystallized goethite, and about 10^5 times greater than on clay surfaces (Szalay, 1991). EXAFS data, obtained from samples prepared at pH 5 with an 8.2% surface coverage (Manceau *et al.*, 1992), show uranyl coordination with about five equatorial oxygens at 2.2–2.4 Å and an additional broad peak corresponding to one Fe at about 3.4 Å and another 0.5 Fe at about 3.3 Å. These distances are consistent with uranyl bonding as a mononuclear bidentate inner-sphere complex, sharing edges with the Fe–O, OH surface octahedra. The authors note the excellent match between the unshared edges of the Fe–O octahedra and of the O–O distance of the equatorial uranyl ligands. They use this match to explain the unusually high affinity of uranyl for HFO as compared to crystalline phases such as goethite. The structural relationship between the sorbent and the sorbate is used to explain, at a molecular level, why uranyl complexes inhibit the HFO to crystalline oxide transformation (Manceau *et al.*, 1992).

A related study involved U L_3 -XAFS studies of U(VI) adsorption onto ferrihydrate over a wide range of solution and adsorption conditions (Waite *et al.*, 1994). Ferrihydrate is an amorphous or poorly crystalline hydrous Fe(III) oxide that exhibits a stoichiometry near $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. EXAFS experiments were performed on ferrihydrite samples that had been aged for 65 h at 25°C and pH 6, after which the pH was adjusted to 5 or 5.5 and held for a further 24 h before adding U(VI). There were two samples made with U/Fe molar ratios of 0.044 and 0.077. Data, collected over a k -range of 3–16 Å⁻¹, required three U–O and one U–Fe shells to obtain the best fit. The results, using integral coordination numbers for the U–O fits, were two axial O at 1.80 Å, three equatorial O at 2.34 Å, two O at 2.52 Å, and about 0.5–1 Fe at a distance of approximately 3.4 Å. The authors conclude from their fits that the O at 2.52 Å is an inner-sphere O sorbed to the ferrihydrate surface. The Fe is coordinated in a bidentate fashion with the U, and, within a 10% error margin, there are no sorbed multinuclear uranyl complexes. These results are very similar to those reported in the previous study (Manceau *et al.*, 1992), although the latter study shows a split equatorial oxygen shell. The EXAFS results, supported by model simulations, suggest that the major U(VI) species at the ferrihydrite surface in the acidic pH range is an inner-sphere, bidentate complex that involves two surface hydroxyls of an Fe octahedral edge and the uranyl cation. Later work on very similar samples (Reich *et al.*, 1998b) failed to confirm the split oxygen shells at 2.34 and 2.52 Å, but instead found a single shell with five O coordinating at 2.36–2.39 Å

with a large Debye–Waller factor, consistent with the earlier work (Manceau *et al.*, 1992). Despite the absence of evidence for a split equatorial oxygen shell, inner-sphere complexation was proposed (Reich *et al.*, 1998b), and the authors noted that the difference in the equatorial oxygen coordination cannot be explained by the shorter k -range of their data.

Uranium uptake was studied from solutions at various pH values in the presence of the iron-bearing mineral phases goethite, lepidocrocite, and mackinawite (Moyes *et al.*, 2000). Refinements of EXAFS data show the U coordination at the surface to be very similar to those reported previously for U bound to other Fe–O and Fe–S mineral surfaces (Waite *et al.*, 1994; Reich *et al.*, 1998b). Binuclear, bidentate surface complexes are present together with monodentate, mononuclear coordination to the structural sulfate for the FeSO₄ oxide, schwertmannite (Walter *et al.*, 2003).

The EXAFS results from uranyl adsorbed on HFO and other mineral samples, together with modeling, show that the adsorbed complex is a unique product of the coordination environment at the surface, and appears independent of the predominant U(vi) speciation in solution, as was previously suggested (Waite *et al.*, 1994). A diffuse double-layer, two-site model with two proposed surface species provided excellent agreement with all data over a range of pH, U(vi) concentration, and two dissolved CO₂ concentrations. This conclusion contradicts several previously published modeling approaches to uranyl surface speciation (Hsi and Langmuir, 1985).

It has been previously reported that dissolved carbonate, ubiquitous in groundwater, plays a crucial role in the distribution of U(vi) between solution and Fe oxide surfaces (Ho and Doern, 1985; Hsi and Langmuir, 1985). EXAFS studies have focused on the molecular influence of carbonate complexation on U sorption onto Fe oxide surfaces. U complexed to ferrihydrite shows a U–C distance of 2.93(2) Å (Reich *et al.*, 1998b), which matches the U–C distance previously reported for a bidentate coordination of the CO₃²⁻ group to uranyl (Coda *et al.*, 1981; Allen *et al.*, 1995), and is consistent with the proposed formation of (=FeO₂)UO₂CO₃²⁻ (Waite *et al.*, 1994), an inner-sphere structure. U coordinated to hematite shows a similar behavior (Bargar *et al.*, 1999a,b). EXAFS fits indicate that U(vi) has five to six equatorial oxygens. Since two of these should be hematite-surface oxygens, it is argued that there are at most two carbonate ligands and the complex should have a composition similar to FeO₂UO₂(CO₃) _{x} , where $x \leq 2$. The absolute coordination numbers for carbonate in all samples imply that $\geq 50\%$ of adsorbed U was complexed, even at pH 4.75. This finding contradicts predictions that U(vi)–carbonate ternary complexes should predominate only above pH 6 (Waite *et al.*, 1994). In addition, at pH values ≤ 6.5 , there was no evidence from the EXAFS data for second-neighbor U(vi), indicating that the adsorbates were monomeric (Bargar *et al.*, 2000).

Also ubiquitous in the environment is the citrate anion. EXAFS was used to characterize the coordination environment of uranyl adsorbed onto goethite in

the presence of citrate under aqueous conditions where uranyl is strongly sorbed (Reddon *et al.*, 2001). A PCA showed that two major constituents should account for all the data. Unlike other Fe-mineral adsorption studies, there was no evidence of a Fe-neighbor in the U EXAFS. The authors concluded that the adsorption of uranyl does not follow a simple, stoichiometric relationship between the total U and citrate in the sample, and that under the conditions employed the adsorption of citrate on goethite appears to be favored over the formation of a uranyl–citrate–goethite complex.

In addition to the adsorption of uranyl onto mineral phases, EXAFS structural data were reported for U trapped in Fe-rich gels that are formed during the oxidative weathering of a granitic U deposit in the context of acid-mine drainage (Allard *et al.*, 1999). These natural samples, from the Massif Central in France, were in water that was close to saturation with respect to amorphous silica and crystalline-hydrated U-hydroxides and silicates. This effort addressed the elementary processes implied in U sorption and the trapping mechanism of U by natural short-range ordered phases. They investigated samples obtained at the fissure outlets on the walls of the galleries. These include hydrated amorphous products that are referred to as gels. XANES data confirm that the U was found to be present as hexavalent uranyl. The EXAFS on the Fe-rich gels found that uranyl is mainly present either as an outer-sphere complex or as an inner-sphere complex unresolved by EXAFS. No U–Fe, U–Si/Al, or U–U interactions were evident from the gel samples. The absence of U–Fe contributions to the data, despite the high affinity of uranyl for hydrous Fe oxides, suggests that U may be trapped in a two-step process involving the early complexation of U and Si/Al followed by the transport of Fe as ferrous in fissure water, with the ultimate precipitation of Fe in Si/Al-containing solutions at a redox front.

Green rusts, which are mixed Fe(II)/Fe(III) hydroxides, are formed by a number of abiotic and biotic processes under circumneutral to alkaline conditions in suboxic environments. The interaction of hydroxysulfate green rust, in which SO_4^{2-} is an interlayer anion was studied to examine its influence on the redox behavior of U(VI) (O'Loughlin *et al.*, 2003). L_3 -edge XANES spectra show that U(VI) was readily reduced to U(IV) at a pH of 7.3 in the presence of green rust. EXAFS data indicate an average U local environment similar to that in UO_2 . The decreased FT amplitude in the green rust sample compared to a UO_2 standard probably indicates small particle size and/or increased disorder.

The co-precipitation of uranium with iron-oxide minerals was studied with a series of co-precipitates with mole fractions of U in the range of 0.35–5.4% (Duff *et al.*, 2002). Although the XANES spectra are consistent with U(VI), EXAFS results show U to be in a highly distorted environment, in agreement with XRD, FT-infrared, XANES, and luminescence studies. Fits to the data for samples with <1 mol% U indicate no axial O, instead there are about four O at 2.21–2.36 Å. The model fits also indicate that at least one Fe atom exists in the uranium second-coordination shell at 3.19 Å. However, details of the fit suggest that there are multiple shell environments. Overall, the results are interpreted as

consistent with the incorporation of U(VI), minus the dioxo coordination, into the Fe oxides. This situation does not apply for co-precipitated samples with > 1 mol% U, which exhibit uranyl coordination and evidence of a second shell U backscatterer. These data are consistent with XRD, FT-infrared and luminescence data, which taken together show evidence of a U(VI) oxide hydrated phase such as schoepite, $\text{UO}_2(\text{OH})_2 \cdot 2\text{H}_2\text{O}$.

There have been few reports of synchrotron studies centered on the sorption of transuranics onto Fe-bearing mineral phases. Despite its low affinity for complexation, Np(V) has been reported to sorb onto mineral surfaces with the decreasing affinity: calcite > goethite >> $\text{MnO}_2 \approx$ clays. The sorption of Np(V) onto these phases may involve its reduction to yield the much less soluble Np^{4+} , which has much high binding affinities and generally lower solubility. An early study of Np(V) on an iron-bearing mineral involved goethite, which has fully oxidized Fe (Combes *et al.*, 1992). XANES spectra confirm the presence of neptunyl groups. Fitting the EXAFS data results in 2.2 O at 1.85 Å and 5.5 O at 2.51 Å for Np adsorbed onto goethite, compared with the fit obtained from Np(V) in solution of 1.6 O at 1.83 Å and 5.2 O at 2.52 Å. This coordination environment for solution Np(V) compares with more recent comparative studies of Np coordination in solution, which are listed in Table 28.4. The only observed difference between the spectra obtained directly from solution and the goethite-sorbed spectrum is the presence of high-amplitude structure between 2.5 and 4 Å in the FT of the latter. Although these data may indicate Np-Fe interactions, the short *k*-range prohibits a full analysis. The authors claim that their data rule out diffusion into the solid and precipitation or coprecipitation of ordered solids onto the goethite surface. A more recent study (Moyes *et al.*, 2002) looked at solution Np(V) sorption onto microcrystalline mackinawite (FeS) at pH values in the range 7–8 and 3, and Np solution concentrations of 0.27, 0.68, and 2.74 mM. XANES spectra indicate limited sorption coupled with a reduction to Np(IV) that is confirmed by EXAFS. The coordination environment of Np in all samples is indistinguishable, with four O at 2.25 Å, three S at 2.63 Å, two Fe at 3.92 Å, and six Fe at 4.15 Å. The absence of two axial O atoms at about 1.85 Å supports the XANES finding for the reduction of Np(V). The short Np-S distances suggest a direct coordination with mineral surface S.

28.3.4 Phosphates

The phosphate class of minerals are made up of $(\text{MO}_4)^{3-}$ units in which M^{5+} can be P, As, Sb, or V (Deer *et al.*, 1992). Although apatites are the most common subclass of the phosphates, monazites are important here because of the insolubility of rare-earth and actinide phases. Thorium and uranium are common impurity phases in monazite.

Uranium sorption on the surface of hydroxyapatite, $\text{Ca}_5(\text{PO}_4)_3\text{OH}$, was studied as a removal mechanism for heavy metals from groundwater, either

by precipitating as a phosphate or by ion-exchange for Ca^{2+} (Fuller *et al.*, 2002). Samples with less than 4700 ppm surface-sorbed uranium(vi) were studied by EXAFS and found to have the standard axial dioxo coordination. In addition, a broad equatorial shell was observed that, for two of the three samples studied could not be resolved by the fit. The single, unresolved shell was fit to a distance of about 2.313 Å by employing large Debye–Waller factors and fixing the coordination number to six. The most concentrated sample (4700 ppm) showed a resolvable two-shell equatorial coordination with 3.6(6) O at 2.338(8) Å and 2.1(2) O at 2.51 Å. Two of the three samples also had U–Ca interactions that fit to about one Ca at 3.8 Å, a distance consistent with bidentate edge sharing and/or monodentate corner-sharing coordination between the equatorial oxygens of the uranyl ion and the Ca–O polyhedra on the hydroxyapatite surface. In contrast, the U(vi) coordination environment is inconsistent with its incorporation into the mineral phase. One of the samples, exposed to dissolved carbonate, showed a U–C interaction implying U–carbonate ternary complexes. There were also indications of a more distant coordination shell that was fit as either a Ca atom at 4.55 Å or a U atom at 4.09 Å, with no independent evidence presented that could distinguish between the two fits. As the uranyl coverage on the hydroxyapatite surface increased above 4700 ppm, the EXAFS spectra began to resemble that of a U(vi) phosphate, notably chernikovite, $(\text{H}_3\text{O})_2(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$. The uranyl uptake at the onset of chernikovite precipitation corresponds to a surface coverage of about 6% of a monolayer.

An independent study was also conducted on the incorporation of U(vi) into synthetic fluorapatite (Rakovan *et al.*, 2002). XAS together with luminescence and diffuse reflectance were used to determine the local structure of U(vi) in a powder sample. The sample had a concentration of 2.3 wt% U. Optical luminescence data, including lifetime measurements, combined with diffuse reflectance data indicate that although the U appears hexavalent in the fluorapatite sample, it does not have the standard dioxo coordination environment. This finding is supported by U L_3 -edge XANES spectra, which confirms that uranium is hexavalent. However, the XANES data do not show the small shoulder feature indicative of dioxo coordination about uranium (Hudson *et al.*, 1995a), but instead are similar to the spectra observed for U(vi) in Li_4UO_5 (Locock and Burns, unpublished) and Np(vii) in solution (Williams *et al.*, 2001). Both of these ions exhibit an unusual tetraoxo coordination environment of four short and two longer oxygen distances. This coordination environment is confirmed by a simple inspection of the U EXAFS data, which are also inconsistent with a dioxo coordination environment. An analysis revealed that U is coordinated to six equidistant oxygens at 2.06 Å. With respect to the host fluorapatite sample, the U EXAFS fit shows a similarity to the coordination environment of the Ca1 site (space group $P6_3/m$, No 176; Wyckoff position 4f; 3 symmetry) (Comodi *et al.*, 2001). Attempts to fit the data assuming Ca2 substitution (Wyckoff position 6h, m symmetry) were unsuccessful. The finding of 6 oxygen at 2.06 Å is in agreement with the average U–O distances for

six-coordinate, tetraoxo- (Hoekstra and Siegel, 1964) or near-cubic (Bawson *et al.*, 1956) coordination. This work clearly demonstrates that fluorapatite can accommodate large concentrations of U(VI) into the lattice, with a coordination environment that is very similar to that found in perovskites, another common mineral class. Therefore, the determination of significant uranium incorporation into fluorapatite may point to an important sequestration mechanism for high-valent actinides in the environment.

Uranyl sorption onto the lanthanide phosphates LaPO_4 and $\text{La}(\text{PO}_3)_3$ has also been studied as a function of pH (Ordóñez-Regil *et al.*, 2002). The study included pH values of 1, 2, and 3, which compare to the isoelectric point of about 4 for LaPO_4 and 3 for $\text{La}(\text{PO}_3)_3$. The fitted parameters for the EXAFS spectra from the two samples were statistically indistinguishable. In addition to the dioxo-shell, there were two equatorial O shells, with 2.4 O at 2.31 Å, and 1.8 O at 2.47 Å, distances consistent with bidentate, inner-sphere coordination. The observation of a U–P interaction at 2.74 Å is used to argue that the uranyl is complexed to a single surface phosphate group.

28.3.5 Natural soil samples

The understanding and prediction of actinide speciation in natural soil samples comes from a synthesis of the published studies of actinide speciation and coordination under laboratory conditions. The challenge encountered when characterizing naturally occurring samples is the length scale of potential inhomogeneities. Depending on their origins, soil samples can have fine grain sediments that present chemical inhomogeneities on the micron or smaller length scale. Micro techniques that have been used to study such samples, including scanning tunneling microscopy (STM) (Yanase *et al.*, 2002) uranyl fluorescence (Joergensen, 1977) and micro-Raman (Allen *et al.*, 1987; Biwer *et al.*, 1990; Palacios and Taylor, 2000) that produce important, but limited, information about uranium speciation.

Until the development of specialized μ -XAS and μ -SXRF capabilities, synchrotron-based spectroscopic studies were limited by beam sizes on the order of mm^2 or larger. Various micro-focusing techniques have reduced the beam size to about $50 \times 50 \mu\text{m}^2$ or larger, depending on energy ranges and flux requirements. Unfortunately, the focusing optics work over limited energy ranges, so that for work on the actinide L_3 -edges, XAS energy scans are limited to 200–300 eV, sufficient only for XANES spectroscopy. Nevertheless, information has been obtained by these μ -XAS techniques that have significantly broadened the knowledge of actinide speciation in these complex samples.

A conventional XAS study on uranium-contaminated soil samples showed the potential for XAS to contribute information necessary to the development of a rational remediation scheme (Morris *et al.*, 1996). This study examined samples from the Fernald Environmental Restoration Management Company, a U.S. DOE facility that once served as one of the principal processing centers

for uranium. The soil matrix consists primarily of quartz, calcite, dolomite, and the clay minerals illite and chlorite, with the pH of the topsoils in the range of about 5.4–6.3 (Elless and Lee, 1994). Background levels of U in uncontaminated reference topsoils near the production facility are typically about 3–5 ppm. There were many different source terms for the contaminants including both aqueous waste and airborne particulate. U concentrations from production range from about 10 to 8000 ppm at pH values of 7–8.5. Only about the top 0.25–0.3 m were contaminated.

XANES studies of both bulk and size-selected samples showed that most of the U exists in the hexavalent oxidation state, a finding that was confirmed by EXAFS. EXAFS data showed that the equatorial uranyl coordination varied significantly between samples and indicated variation in speciation. Independent optical, microscopy, and diffraction (Elless and Lee, 1994) data indicated the presence of autunite-like, $\text{Ca}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 2\text{--}6\text{H}_2\text{O}$, and schoepite-like, $\text{UO}_3 \cdot 2\text{H}_2\text{O}$, phases in the samples, consistent with the variation in EXAFS coordination. The goethite (FeOOH) that is naturally present in the soil should require U(vi) if equilibrium is reached because the Fe(III)/Fe(II) reduction potential is considerably lower than the corresponding U(VI)/U(IV) potential. The XAS used in this study, together with other spectroscopies, confirmed that 75–95% U was hexavalent. Based on this speciation, the authors were able to make specific recommendations about site remediation, including the need for near-term action based on the solubility and mobility of U(vi). A later study, in which U was added to natural subsurface soil samples from Hanford, SRS, and Oak Ridge produced similar results (Bostick and Fendorf, 2002).

Micro-XAS and synchrotron X-ray fluorescence (SXRF) studies on soil and sediment samples from Fernald and the Savannah River Site (SRS) offer a different perspective (Bertsch *et al.*, 1994; Hunter and Bertsch, 1998). The samples from the SRS differ from those of Fernald in that the U contamination was discharged as aqueous waste. This study used a micro-focused synchrotron beam with spot sizes that varied from 50×50 to $300 \times 300 \mu\text{m}^2$. The focusing optics utilized limit the energy range over which data was collected to approximately 200–300 eV, which restricted spectra to the XANES region only. Under the experimental configuration employed, it was possible to simultaneously collect a full SXRF spectrum to provide specific information on associated elemental distributions that is coupled to speciation data from XAS. The objective of the study was to determine U speciation in localized regions within inhomogeneous samples. XANES of clay fractions from both sites indicated > 90% hexavalent U, with no evidence of spatial variability of the U speciation within the clay fraction. This result was expected because the beam size was much bigger than individual clay particles and was consistent with the large number of size-fractionated sediment samples from SRS even though some of these latter samples were collected in seasonally reduced environments from wetland areas. No observation of significant biotic or abiotic U reduction was observed, as had been previously suggested (Lovley *et al.*, 1991; Nagy *et al.*, 1991), from samples

with high organic content that were in reducing environments. In contrast, sand and sediment fractions showed significant spatial variation using a 50 μm beam. The XRF signal was monitored, looking for areas concentrated in U, and then XANES spectra collected. Two types of populations were discernable: (1) those highly enriched in U and depleted in other elements such as Fe and Mn. For Fernald soil samples, U-rich regions were often relatively enriched in Ca, Cu, and Zn, whereas for SRS sediment these regions were highly enriched in Ni, and (2) U was concentrated and co-associated with regions relatively enriched in Fe and Mn. The U-rich region represented about 25% of the observations and may represent discrete U-containing phases either originally deposited as a component of the source term, or subsequently precipitated as a secondary phase. The zones of lower U concentration may represent either U co-precipitated with or sorbed to the Fe, Al, and Mn oxyhydroxides indigenous to the samples. XANES data, obtained using a 50 μm beam, from various regions within the sand fraction of Fernald soils provided evidence of varying oxidation states. Two of the 22 regions sampled showed predominantly U(IV) whereas other regions showed U(VI). There appeared to be discrete regions of U(IV) surrounded by a larger number of U(VI)-containing particles or surface-associated U(VI) phases. In contrast, when operating with a beam size of 300 μm , there was no evidence of pure or predominantly U(VI) speciation because of spatial averaging, pointing out the clear advantage of microprobe studies of natural, spatially inhomogeneous samples. The sand fractions from SRS did not display spectral differences indicative of varying oxidation states and were consistent with U(VI). However, post edge features indicated significant differences in the coordination environments within various regions of the sample.

During the 1999 global conflicts in the Balkan states, ammunitions were expended containing large amounts of depleted uranium (DU) that remains as an environmental pollutant with unknown health risks (Fetter and von Hippel, 1999; Priest, 2001; Bleise *et al.*, 2003). A series of studies was devised to investigate the oxidation state of particles dispersed into the geosphere in order to assess the fate and transport of this introduced pollutant (Shaughnessy *et al.*, 2003). The samples used in the analyses were collected at Ceja Mountain, Kosovo. Analytical results revealed U in soils with concentrations exceeding 2–3 ppm. Scanning electron microscopy (SEM) showed that most of the particles were present in the respiratory fraction, that is less than 5 μm (Danesi *et al.*, 2003). Micro-XANES data from the samples, obtained over an energy range of 300 eV using an X-ray beam spot size of $20 \times 20 \mu\text{m}^2$, were compared with U standards. SXRF data indicated the simultaneous presence of U and Ti, in accord with other analytical techniques and the known sample histories. The U L_3 -edge data from the samples indicated that the U was oxidized, i.e. that there was no metal present. Depending on sample details, the U was consistent with either tetravalent U, as UO_2 , or U_3O_8 , or mixed samples. Hexavalent U was not observed. This finding is interpreted as DU particles with tetravalent

cores and oxidized surfaces, indicating weathering. This study revealed important factors for further assessing the environmental and health impacts of munitions-generated depleted U.

Elevated levels of U occur in natural soils and evaporation ponds that are associated with agricultural irrigation activities in the southwestern U.S. Evaporation ponds are periodically filled and evaporated to dryness, a process that can significantly influence redox processes. Most soils in the area are derived from marine Cretaceous shale that is known to contain high levels of U, with total concentrations as high as 280 ppm. A synchrotron-based study has been published that focuses on natural uranium speciation in evaporation ponds located in the San Joaquin Valley (SJV), CA (Duff *et al.*, 1997). Sediment samples, obtained from depths of 0–5 cm, were collected on two different occasions, one when the pond was nearly dry and the other when it was partially filled with drainage water. Suspension pH and Eh measurements were obtained at the time of sampling. There were no observable trends in U concentration with depth of sample, however the aqueous concentrations of U(IV) decreased with increasing Eh whereas dissolved U(VI) concentrations increased greatly with increasing Eh.

Micro-XANES data were obtained over a 130 eV range with a $200 \times 200 \mu\text{m}^2$ beam size and SXRF data were collected at the U L₃-edge energy. XANES spectra were fitted using those obtained from standard spectra to assess relative ratios of reduced to oxidized U. These data showed that the amount of reduced U relative to oxidized U increases with increasing sample depth. The deepest samples (about 5 cm) showed that about 25% of the U in the measured samples was tetravalent. No changes were observed in the U concentration as the beam was scanned across the sample. Whereas the samples did not appear to contain any U hotspots, it should be noted that the particle sizes less than 2 μm were considerably smaller than the beam size, which was about 200 μm . A scenario for the fate of U in the SJV evaporation pond was proposed based on XANES and SXRF data that were complemented by other analytical techniques. It was proposed that U enters the pond in the drainage water, probably as a carbonate anionic species. Some of the U is accumulated by algae that creates a biomass with reducing conditions in which U(VI) reduction takes place. The precipitation of mixed U(VI)/U(IV) in organic matter then brings the U into the sediment. Over time, with increasing burial, the increasingly anoxic environment further reduces the U(VI). As the ponds drain, the soil aerates and the reduced U is reoxidized, resolubilized, and thus remobilized. A follow-up study was published that addressed samples obtained over a wider depth range, 0–40 cm (Duff *et al.*, 2000). Microprobe (300 μm^2 spot size) XANES measurements, over a 140 eV range, were used to infer the relative amount of U(VI) by comparing edge position with known standards. This study found that the relative percentage of U(VI) appeared to decrease with increasing sampling depth and correlated with a decreasing total organic content.

The power of synchrotron-based microprobe spectroscopies to provide unique speciation information was clearly demonstrated in a series of experiments designed to probe plutonium adsorbed to natural tuff samples from the Yucca Mountain site (Duff *et al.*, 1999a,b, 2001). Tuff is rock composed of compacted volcanic ash that varies in size from fine particulate to gravel. These studies were performed to assist in the modeling of Pu speciation and groundwater transport in the event of a release of stored radioactive waste into the environment. The solubility of Pu in groundwater varies greatly, with 3+ and 4+ states being significantly more sorptive and less soluble than their higher valent counterparts. This discrepancy occurs because the higher valent ions form dioxo moieties, which have lower overall ionic charges. Under acidic conditions, Pu(v) undergoes disproportionation, to form Pu(IV) and Pu(VI), whereas in neutral to basic oxic solutions Pu(V)O₂⁺ dominates speciation. The synchrotron microprobe studies were designed to determine what Pu species are adsorbed to natural tuff samples using spatially resolved μ -SXRF to determine Pu distribution and μ -XANES to determine oxidation states. All oxidation states of Pu have been reported to sorb to smectites and iron- and manganese-bearing oxyhydroxides (Keeney-Kennicutt and Morse, 1985; Sanchez *et al.*, 1985). A question addressed by these studies is whether minerals, particularly those with redox-active surfaces, can influence the redox chemistry of Pu in solution. The tuff samples, analyzed by X-ray diffraction, were predominantly zeolitic phases, specifically clinoptilolite 80 wt%, smectite 2%, opal 8%, feldspar 7%, and quartz 3%. Further work on the smectite isolates showed them to contain rancieite, a mineral with mixed manganese content, (Ca, Mn²⁺)Mn₄⁴⁺O₉ · 3H₂O.

Information on the average oxidation state of sorbed Pu on tuff was obtained on the spatial scale of about 140 μm^2 . The Pu-sorbed samples were prepared using 10⁻⁴ M, ²³⁹Pu(v) spiked, synthetic groundwater meant to mimic deep tuffaceous aquifers such as those found below Yucca Mountain. About 92–98% of the initial Pu(v) in solution was sorbed to the samples. SXRF was done for elements with absorption energies below 18.5 keV. The problem in resolving the Pu and Sr signals was circumvented by obtaining one elemental map just below the Pu L₃-edge and another just above the edge. The Pu elemental map was then obtained by subtracting the images. Contrary to expectations based on previous work (Triay *et al.*, 1997), the mapping showed that Pu is predominately associated with manganese oxides, specifically rancieite, and smectites but not with iron oxides. Fractures and pore spaces from Yucca Mountain tuff samples contain highly reactive surfaces that can sorb a variety of differently charged and sized ions from fracture- and pore-space fluids. Rancieite comprises less than a percent of the mineral distribution in the tuff, but its presence at primary flow paths makes it highly accessible to dissolved species in the groundwater (Duff *et al.*, 2001). Several other elements in addition to Pu were co-associated with the manganese oxide and not with hematite. It is postulated that the iron mineral surfaces appear to be passivated and thus inaccessible to sorption.

Why the iron oxide, and not the manganese oxide, surfaces were passivated is not understood. Modeling and surface calculations based on experimentally determined concentrations suggest that multiple binding sites are present on the Mn–O/smectite phase.

μ -XANES was obtained from the same samples at two different $10 \times 15 \mu\text{m}^2$ spots that appeared to contain the highest level of Pu as determined by the SXRF mapping. Unfortunately, XANES was not definitive in determining the oxidation state. Although the Pu L_3 -edge position indicates the presence of primarily Pu(VI), the post edge feature associated with multiple-scattering from the plutonyl was not observed. The FT of a short EXAFS spectrum ($k_{\text{max}} = 8 \text{ \AA}^{-1}$) did not show evidence of the two-shell first coordination sphere that is expected for plutonyl coordination (Duff *et al.*, 1999b). A single peak at 1.65 \AA (uncorrected for phase shift) was observed but not fit. In addition, there was no evidence of a Pu–Pu interaction, which would have signaled Pu precipitation on the tuff surface. The authors conclude only that there may have been some oxidation of their Pu upon sorption to the Mn^{4+} -rich phase. It should be noted that tuff samples have been shown to oxidize Ce(III) to Ce(IV) (Vaniman *et al.*, 2002), an oxidation that was attributed to its association with rancieite, which contains an oxidized fraction of Mn.

These seminal papers clearly demonstrate the importance of a molecular level understanding of sorption on natural samples. That Pu should sorb preferentially to a Mn-oxide phase was not expected. Such information is very important in modeling actinide migration through the geosphere. In addition, it supports previous findings that actinide sorption is governed by the solid–water interface rather than solution speciation (Waite *et al.*, 1994). The results show that predictive remediation requires a more comprehensive understanding of Mn–Pu interactions.

Toward this end, a study was undertaken (Shaughnessy *et al.*, 2003) of interfacial reactions between aqueous Pu(VI) species and Mn oxyhydroxide mineral surfaces, notably manganite (MnOOH) and hausmannite (Mn_3O_4), which serve as representative examples of Mn phases typically found in the vadose zone. Note that manganite has a rutile-related structure, with trivalent Mn whereas hausmannite is a spinel-related structure with mixed di- and trivalent Mn. These two phases were from commercial stock and size selected for particles in the range of 63 – $212 \mu\text{m}$. The pH of the point of zero surface charge (pH_{pzc}) was determined to be $7.4(3)$ for manganite and greater than 10 for hausmannite. Sorption studies were done as a function of pH over the range 3 – 10 , a function of Pu concentration, and as a function of solution exposure time at a fixed pH. Pu solution concentrations ranged from 1×10^{-7} to 1×10^{-4} M. There was an initial rapid sorption step that occurred within the first 24 h of contact, followed by a much slower sorption process. This two-step process for actinide adsorption onto mineral phases has been previously reported (Keeney-Kennicutt and Morse, 1985; Waite *et al.*, 1994). All XAS data reported in the Mn work were limited to samples that had a 24 h contact time with the soak-Pu

solutions. The sorbed Pu oxidation states were determined by a combination of optical absorption methods and XAS. A comparison of the Pu L₃-edge XANES data from the mineral-adsorbed phase with those from oxidation-state specific solution phases showed that the Pu sorbed to the Mn phases had been reduced from Pu(vi) in the initial solutions to Pu(iv) on the sorbed surface. Optical spectra on the remaining solutions determined the presence of Pu(v). In other words, all of the initial solution phase Pu(vi) had been reduced to either Pu(v), which remained in solution, or Pu(iv), which remained sorbed on manganite or hausmannite. There was no reduction observed for a blank Pu(vi) solution over the same time frame. The reductant in this redox reaction was not clearly evident from the experiment, but the authors conjecture that there may have been dissolved Mn(II) in solution. It should be noted that the reduction of Pu(vi) observed in this study is in contrast to the work on natural tuff, in which Pu(v) was seen to oxidize (Duff *et al.*, 1999a,b, 2001). The similarity in redox couples for Pu(iv), Pu(v), and Pu(vi) clearly complicates the chemistry in these redox-active mineral systems. EXAFS data from the same Mn samples (Shaughnessy *et al.*, 2003) were analyzed to determine the Pu coordination onto the mineral surfaces. The data were analyzed over a short *k*-range (2.5–10 Å⁻¹), significantly limiting the allowable number of variable parameters in the fitting. The data do not indicate dioxo coordination of the Pu, supporting the XANES interpretation of Pu reduction to tetravalent. The best fit was consistent with a single O shell at distances of 2.28–2.36 Å and with coordination numbers in the range of 7–9. The values may vary with the pH of the soak solution used for the sorption experiments. The fitted distances compare well with those expected for Pu(iv)–O interactions, as exemplified by the 2.337 Å one found in PuO₂ (Haschke *et al.*, 2000). In addition, Pu–Mn interactions were observed at about 3.37 Å for all samples, indicating that, like other adsorbed actinides, the sorbed Pu has an inner-sphere coordination with the mineral surface. These results support the finding that Mn-based mineral phases may serve to sequester Pu under natural groundwater conditions.

28.3.6 Bacterial interactions

It has been recently realized that microbes can actively influence actinide chemistry in the environment. Although much less studied than processes involving inorganic constituents, biotic interactions can have a marked influence on actinide speciation. Microbes are ubiquitous in the environment and therefore their influence must be included when developing predictive modeling for actinide fate and transport. Microbial processes can cause either mobilization or immobilization of radionuclides, that is actinides may be stabilized in solution or precipitated by direct processes, such as respiration, or indirect processes, such as the biotic modification of solution constituents.

XAS is developing into a cornerstone technique for discerning the influence of bacteria on actinide speciation, as indicated by the published work referenced in

Table 28.13. XAS is often used together with other physical techniques, such as optical and/or infrared spectroscopies, X-ray diffraction, microscopy (TEM, SEM), EDS (energy dispersive X-ray spectroscopy). These results augment the standard chemical analyses, such as titrations and solvent extraction. The advantage afforded by XAS is that it can probe metal-ion speciation *in situ*, that is in the presence of bacterial cells, cell growth media, and other metal-ions, with no necessity for chemical pretreatment. Its sensitivity to oxidation state is particularly important for probing redox effects of microbial interactions. Among its most significant disadvantages are its sensitivity, often requiring ppm or higher concentrations for meaningful data acquisition, and the propensity for beam-induced redox chemistry (Skanthakumar *et al.*, 2004) that can vitiate speciation, especially at low metal concentrations.

There are several questions that arise concerning microbial influence on actinide speciation. These all center on solubility and transport issues, and include precipitation, adsorption to the bacterial surface, incorporation into the cell, and solubilization of mineral phases. Precipitation can occur either through a change in redox state or through chelation. Generally, the higher oxidation states, including U(vi), Np(v), and Pu(v), (vi) are soluble in acidic and near-neutral pH, whereas their tetravalent analogs are relatively insoluble. Therefore, processes that control oxidation state are particularly important to quantify. Compounds or ions in solution may be used as electron acceptors in energy metabolism, a process referred to as dissimilative metabolism. The reduced species is excreted in the environment. Microbes are known to involve metal-ions, such as Fe(III) or Mn(III,IV), directly in their respiratory processes as electron acceptors. Aerobic respiration involves O₂ as the electron acceptor. Some microbes are capable of anaerobic respiration, in which they use nitrate, sulfate, carbonate, ferric iron or even certain organic compounds as the electron acceptor. Because these ions have lower reduction potentials than O₂, less energy is released. However, the use of alternate electron acceptors in their respiratory process allows microorganisms to live in environments that contain too little oxygen to support life.

Dissimilatory metal-reducing bacteria (DMRB) are able to couple the oxidation of organic matter to the reduction of Fe(III) or Mn(III/IV). Under anoxic conditions, DMRB have been shown to readily reduce U(vi) to precipitate UO₂ solid (Lovley *et al.*, 1991; Gorby and Lovley, 1992). XANES spectroscopy was used to probe U(vi) reduction, either as an aqueous species [UO₂(CO₃)_{3(aq)}]⁴⁻ or as metaschoepite [UO₃·2H₂O_(s)] (Fredrickson *et al.*, 2000). The results showed that the DMRB bacterium *Shewanella putrefaciens* reduced UO₂²⁺ in complex mineral suspensions via a combination of direct enzymatic or indirect mechanisms to insoluble U(IV) species. U reduction occurred whether the U(vi) was in solution or associated with a solid phase. The studies further showed that *S. putrefaciens* could reduce U(vi) in complex suspensions that included Fe(III) as an alternative electron acceptor, despite the lower standard potential of the U (vi) couple, as shown in Table 28.1. Further experiments, involving Mn K-edge

Table 28.13 Published studies of actinide-ion sorption onto bacterial surfaces. These studies involve actinide redox speciation studies and efforts to define active binding sites on bacterial surfaces.

XANES, showed that the presence of Mn(III/IV) oxides may impede the reduction of U(VI), by *S. putrefaciens* (Fredrickson *et al.*, 2002), in soils. Independent studies use U L₃ XANES to determine that *Desulfosporosinus* ssp, a Gram positive sulfate reducer, is able to reduce U(VI) to U(IV) (Suzuki *et al.*, 2002, 2003). These studies used organic substrates to create anaerobic conditions to stimulate growth of *Desulfosporosinus* ssp in natural U-contaminated sediments from the Midnight Mine, WA, USA. After 1 month, the U concentrations were reduced from 20 to 0.3 ppm. EXAFS-determined coordination numbers were used to infer an average particle size of about 1.5 nm. XAS, together with TEM data show the particles to be uraninite. The authors conclude that the small particle size of biogenic UO₂ may not significantly limit its mobility. This has important implications for the use of bacteria in environmental remediation.

A review of the standard reduction potentials listed in Table 28.1 shows that both Np(V) and Pu(VI), (V) are more easily reduced than is U(VI), suggesting that microbial reduction may play an important role in the aquatic environmental chemistry of dissolved or sorbed actinide ions. In addition, bacteria can be viewed as generating a biopotential through their surfaces and through enzymes, such as siderophores, that they excrete into their environment. In this way, bacteria compete with dissolved ions to influence the solution's effective reduction potential, or Eh. There are very few studies focused on their microbial reduction, even though Pu(VI) and (V) are both more easily reduced than Fe(III). Published work investigating Np(V) reduction by *Desulfovibrio desulfuricans* (Soderholm *et al.*, 2000) and by an anaerobic methanogenic microcosm (Banaszak *et al.*, 1999) indicate that Np(V) is reduced abiotically in the growth medium necessary to sustain the organism.

The solubility and mobility of actinide ions can also be significantly influenced by biosorption. In addition to living cells and spores, dead and decomposed cells are present in natural systems, and can play a role in complexation. Actinides can be complexed with the amino, carboxylate, hydroxyl, and phosphate functional groups that are present on the cell surface. These negatively charged groups are capable of complexation with actinide cations to form biocolloids that have their own chemistry and transport properties. EXAFS spectroscopy has been used to develop an understanding of the functional groups responsible for complexation. XAS studies of actinide biocolloid formation are largely limited to L₃-edge U data. EXAFS of biocolloids formed in brine by halophilic bacteria (WIPP 1A) indicate that bulk samples contain more than one U-containing phase (Francis *et al.*, 1998). TEM and EDS analyses supported this result, showing that U was accumulated intracellularly in addition to being bound to the cell surface. In another study (Hennig *et al.*, 2001a), Gram-positive strains of *Bacillus cereus* and *Bacillus sphaericus* were recovered from a U waste pile, the 'Haberlandhalde' in Germany. The vegetative cells and spores of these isolates were compared with cells and spores of two reference strains, *B. cereus* 4415 and *B. sphaericus* 9602. The structure of the spore coat is completely different from that of the cell wall. The studies showed that the

bacteria selectively accumulate a large variety of heavy metals, specifically these strains accumulate large amount of U. L_{3-} and L_{2-} edge XANES spectra obtained from all the bacilli samples were consistent with U(VI). The EXAFS parameters from all the samples, including both vegetative cells and spores, were very similar, indicating that a structurally similar U complex is formed in all cases. The structural parameters exclude the presence of hydrolysis species but coordination numbers and bond lengths compare well with inorganic 1:1 uranyl phosphate phases. U–P interactions at 3.61–3.63 Å in all samples, which are typical distances for monodentate-bound phosphate phases. After 8 weeks, vegetative cells of *B. sphaericus*, lysing cells, and the activity of enzymes lead to the release of $H_2PO_4^-$ that caused quantitative precipitation of bacterial U(VI) as $UO_2(H_2PO_4)_2$ (Panak *et al.*, 2002b). This complex differs significantly from those of the bacterial surface complexes. The results confirm that surface complexes are formed without metabolic activity.

Similar results were obtained from studies of U complexes formed by *Acidithiobacillus ferrooxidans* (Merroun *et al.*, 2002a), which accumulate U as phosphate compounds. EXAFS data, supported by EDX and infrared spectroscopy (Merroun *et al.*, 2002b) were used to suggest that U accumulates within extracellular polysaccharides and as dense granules in the cell cytoplasm. On the basis of these results it was suggested that these bacteria use polyphosphates to detoxify and remove U when it enters the cells and is present at toxic levels.

In order to quantitatively assess the effects of changing chemical conditions on actinide adsorption/desorption on bacterial surfaces, a surface complexation model for U complexation for Gram-positive cells has been developed (Fein *et al.*, 1997). This model treats surface complexation as a series of thermodynamic equilibria that are dependent on binding geometry and may be pH-dependent. XAS spectroscopy has been used to test this uranyl–bacterial surface speciation model (Kelly *et al.*, 2002). In general, the data are consistent with the model, although a large number of parameters were used to treat the EXAFS data.

Np(V) was determined to adsorb on the facultative, gram negative soil bacterium *Pseudomonas fluorescens* without significant reduction (Songkasiri *et al.*, 2002). The adsorption of 15–20% of the available NpO_2^+ onto the bacterial surface at pH 7 is contrary to expectations based on solution Np(V) chemistry. The situation is more complex for Pu. Sorption studies with Pu(VI) on aerobic soil bacteria showed the reduction of Pu upon complexation, as determined by optical absorption spectroscopy and solvent extraction techniques (Panak and Nitsche, 2001). Follow-up studies, employing XANES spectroscopy in conjunction with solvent extraction, showed that after 9 days of contact with *B. sphaericus*, 32(10)% of the Pu(VI) remained, whereas 28(12)% and 40(6)% were reduced to Pu(V) and Pu(IV), respectively (Panak *et al.*, 2002a). EXAFS data were used to show that Pu(VI) forms strong surface complexes with *B. sphaericus*. These complexes mainly involve phosphate groups, similar to earlier U work (Panak *et al.*, 2000). These results are consistent with a model of

the different interaction processes of Pu(vi) with aerobic soil bacteria (Panak and Nitsche, 2001). This process involves (i) the complexation of Pu(vi) with phosphate groups on the cell wall, (ii) reduction of Pu(vi) followed by the dissolution of Pu(v), and (iii) disproportionation of Pu(v) to tetravalent and hexavalent Pu, followed by the complexation of Pu(iv) with the biomass. These interactions may have important implications for the migration behavior of Pu in natural systems.

Overall, the role of bacteria on the chemistry of actinides and their impact on speciation and transport remains unclear. There is certainly evidence of actinide reduction and precipitation; it remains unclear if these small particles remain mobile through some biocolloid transportation mechanisms. In addition, the particles are so small that re-dissolution reactions may be important. The development of predictive models for the mechanisms of actinide complexation with bacterial surfaces (Fein *et al.*, 1997) and actinide redox reactions (Panak and Nitsche, 2001) are important steps toward a predictive understanding of bacterial influences on actinide mobility. XAS is playing a crucial role in the development and testing of these models.

28.4 FUTURE DIRECTION

XAS and μ -SXRF capabilities have proven to be important synchrotron tools applied to the study of actinide chemistry. The information obtained has significantly improved, and is still improving, our understanding of environmental actinide chemistry. The direction of future actinide studies is closely tied with the operation of existing synchrotrons and with the development of the so-called fourth generation facilities. The availability of new beamlines will open scientific vistas heretofore unavailable with regard to time, energy, and spatial resolution, including the study of dynamic processes and reactions with unprecedented temporal sensitivity; high-energy resolution measurements throughout the electromagnetic spectrum from the infrared through the visible, vacuum ultraviolet, and deep into the X-ray region; and microanalysis of materials on the nanometer length scale.

There are a variety of other synchrotron techniques that are currently under development and are beginning to find use for answering outstanding issues in environmental science (Fenter *et al.*, 2002). Although XAS and microprobe experiments are expected to continue playing a central role in discerning actinide speciation, several relatively new synchrotron techniques, including small-angle X-ray scattering (SAXS), high-energy X-ray scattering (HES), standing wave, and reflectivity measurements are expected to play a growing role in unraveling ever more complex problems posed by actinides in the environment.

Although it is always more convenient to conduct experiments in one's own laboratory than at a synchrotron radiation facility, conventional tube-sources

of X-rays do not provide properties, such as polarization and pulsed-time structure to name just two, that arise naturally from the continuum radiation produced at bending magnets and from the tuned radiation produced from insertion devices. Without exception, synchrotron light is a probe with which actinide science will advance in ways that would be impossible otherwise.

ACRONYMS, ABBREVIATIONS, AND SYMBOLS

An	actinide
Ar	aromatic/aryl functional group
ATCC	American-Type Culture Collection
B	empirical constant, 0.37, in Brown's BVS equation
B3LYP	hybrid Hamiltonian of Becke's 3 parameter exchange functional and correlation functional of Lee-Yang-Parr
BET	Brunauer-Emmett-Teller, adsorption method for surface area measurement
BVS	bond-valence sum
COSMO	conductor-like screening model
CPCM	conductive polarizable continuum model
CN	coordination number
DFT	density functional theory
DMRB	dissimilatory metal-reducing bacteria
DU	depleted uranium
e^-	electron
E	X-ray energy, eV
E_p	applied/controlled electrode potential, V
E°	standard electrode potential, V
$E^{\circ'}$	formal electrode potential, V
E_0	energy threshold for k -space conversion, eV
ΔE_0	energy scale parameter
Eh	redox potential
EDS	energy dispersive X-ray spectroscopy
EDX	energy dispersive X-ray analysis
EXAFS	extended X-ray absorption fine structure
F	Faraday's constant
$F(k, r)$	back-scattering amplitude function
FEFF	effective curved-wave scattering amplitude, $F_{\text{eff}}(k, r)$, computer code
FT	Fourier transform
\hbar	Planck's constant
HES	high-energy X-ray scattering
HFO	hydrous ferric oxide

ICP-MS	inductively coupled plasma-mass spectrometry
IR	ionic radius/radii
k	photoelectron wave vector, \AA^{-1}
λ_e	photoelectron wavelength
m	electron mass
MCD	magnetic circular dichroism
MP2	2 nd order Moller Plesset perturbation theory
n	number of electrons
N	coordination number
N_p	number of independent parameters
μ -SXRF	micro synchrotron-X-ray fluorescence
μ -XANES	micro X-ray absorption near-edge structure
$\varphi(k, r)$	backscattering atom phase function
$\varphi_c(k)$	central atom phase function
pH	negative log of the hydrogen ion concentration
PCA	principal component analysis
R	aliphatic/alkyl functional group
r	interatomic distance
R	gas constant
R_0	empirical radius parameter in Brown's BVS equation
\mathfrak{R}_{ox}	oxidized form of reagent
\mathfrak{R}_{d}	reduced form of reagent
σ	Debye-Waller factor
S_0^2	amplitude reduction factor
SJV	San Joaquin Valley
SRS	Savannah River Site
SEM	scanning electron microscopy
S/N	signal to noise
SAXS	small-angle X-ray scattering
SHE	standard hydrogen electrode
SXRF	synchrotron X-ray fluorescence
T	temperature
TEM	transmission electron microscopy
WIPP	waste isolation pilot plant
XANES	X-ray absorption near-edge structure
XAS	X-ray absorption spectroscopy
$\chi(k)$	EXAFS signal

29.1 INTRODUCTION

The need to address topics of handling, storage, and disposal of plutonium and uranium is driven by concern about hazards posed by the element and by the worldwide quantity of civilian and military materials. The projected inventory of separated civilian plutonium for use in fabricating mixed-oxide (MOX) reactor fuel during initial decades of this century is constant at about 120 metric tons and a comparable amount of excess military plutonium is anticipated from reductions in nuclear weapon stockpiles (IAEA Report, 1998). Although inventories of civilian material are in oxide form, Pu from weapons programs exists primarily as metal. Plutonium is a radiological toxin (Voelz, 2000); its management in a safe and secure manner is essential for protecting workers, the public, and the environment.

The focus of this chapter is on plutonium handling and storage, which are operations required for both civilian and weapons materials. Plutonium dioxide for MOX fabrication is processed and stored on an interim basis. The spent fuel formed during power generation is considered suitable for disposal. Excess Pu from military sources must be extracted, prepared, and stored until disposal options are investigated and evaluated. Storage periods of several decades may

be required until disposal methods are selected and implemented. This chapter centers on handling and storage of plutonium metal and oxide, and where information is available, on handling and storage of uranium metal and oxide.

Hazards associated with Pu and U strongly depend on the material form and are substantially altered by chemical reaction. Atmospheric dispersal of particles is the primary mechanism for large-scale environmental distribution of actinide-containing materials such as oxide (Mishima and Pinkston, 1994). Entrainment and dispersal of oxide particles with geometric dimensions less than 10 μm is anticipated under normal aerodynamic conditions. The source term for environmental release is determined by the mass fraction of particles within the aerosolizable size range. Oxide particles in the respirable fraction have geometric dimensions less than 3 μm and are retained in a human respiratory system if inhaled. Metal is not highly dispersible, but its release is facilitated by corrosion reactions that transform metal into powdered forms and contribute to loss of containment by generating heat and pressure. Therefore, corrosion reactions of Pu and U are important considerations, especially in light of pyrophoric tendencies exhibited by metal fines and corrosion products such as the hydrides.

In addition to an inherent source term for dispersal, oxides of Pu and U chemically interact with environmental gases during handling and storage in ways that significantly alter the potential hazard. This statement conflicts with the widely held view that PuO_2 is stable and unreactive. Because oxides and other compounds exist as adherent layers on the surfaces of Pu and U, a thorough understanding of the chemistry is necessary to determine their properties and influence on behavior of the metals. Some product layers are protective and slow the corrosion of the metal, but others catalyze rapid reaction. Such a 'runaway' reaction occurred during a seemingly routine operation in which a failed storage vessel containing a Pu casting was examined in a gloved box filled with a nitrogen-rich atmosphere normally used for handling metal (Haschke and Martz, 2000). After the partially disassembled package had been exposed to that atmosphere for 3 h, workers discovered that the vessel was hot and that its diameter had increased by 50% in the region around the metal. Subsequent investigation showed that a spontaneous reaction had advanced into the metal at more than 1 cm h^{-1} , a rate that is 10^{10} faster than normal corrosion of Pu in dry air at room temperature.

Unanticipated behavior is a consistent feature of plutonium chemistry. As described in a review by Waber (1980) early experience with handling and storage of plutonium and uranium revealed perplexing and unexplained observations. Reports suggest that corrosion rates of metal are markedly enhanced by moisture, by storage in Ar, or other inert gases with low oxygen content, and by confinement in a sealed vessel, but are slow in open air or a large amount of oxygen. Pyrophoric products are often present on Pu after extended storage in a closed container. Metal pyrophoricity and ignition behavior are unpredictable.

In a later review (Stakebake, 1971), proposed corrosion mechanisms and possible involvement of hydrogen are described, as well as instances of container pressurization that correlate with adsorption of atmospheric gases such as H₂O and CO₂ and with their subsequent radiolysis or thermal desorption. Other reviews describe kinetics (Colmenares, 1975) and mechanisms (Colmenares, 1984) of U and Pu oxidation, as well as physicochemical properties of the oxides. Material properties and kinetics, as well as conditions for safe handling and storage of plutonium metal and oxide, are discussed in more recent reviews (Haschke and Martz, 1998a; IAEA Report, 1998).

In this chapter, we describe relevant chemistry of plutonium metal, oxide, hydride, and other compounds and apply observations in interpreting the complex behavior of Pu and PuO₂ during handling and storage. Recent identification of key gas–solid and solid-state reactions that were not recognized in early studies show the importance of both rapid and slow reactions. Processes occurring over periods of years form highly catalytic surfaces that promote metal corrosion. The importance of minor chemical constituents such as water, of catalytic cycles, and of synergistic reactions is recognized. We describe and evaluate incidents involving containment failure and release of nuclear material with the objective of identifying conditions that alter chemical reactivity and the potential hazard. Existence of multiple hazards and multiple paths to the same potentially hazardous state suggests that unrecognized pathways probably exist and that knowledge is incomplete. Although current understanding of behavior is adequate for recommending procedures that significantly increase safety during handling and extended storage of metals and oxides, definition of general comprehensive requirements is precluded by substantial uncertainty about behavior of Pu-containing residues.

29.2 KINETIC CONSIDERATIONS

29.2.1 Scope of concerns

Chemical reactions that create hazards during handling differ in one important way from those encountered during storage. Reactions during handling are typically of concern only if they are rapid enough to create a direct hazard, such as pyrophoric ignition, during that operation. In contrast, reactions of concern during extended storage may occur slowly with cumulative effects resulting in a hazard such as progressive pressurization and containment failure over time. Gas–solid and liquid–solid reactions are of primary concern because rates of solid–solid reactions are typically insignificant, but exceptions to this general rule cannot be excluded.

The scope of the review is confined to hazards associated with separated plutonium and uranium, not those posed by spent fuel. Three material

categories are identified and addressed: metals, oxides, and residues. Metallic forms are typically from weapons sources. They generally include unalloyed and Ga-containing alloys of typical weapons-grade Pu (initially 0.04% ^{238}Pu , 93.3% ^{239}Pu , 6.0% ^{240}Pu , 0.6% ^{241}Pu , 0.04% ^{242}Pu) (IAEA Report, 1998), as well as highly enriched ($>90\%$ ^{235}U) and depleted ($<0.72\%$ ^{235}U) U. Oxides are derived from both weapons and civilian sources. The isotopic distribution of Pu depends on the level of fuel burnup and is typically about 1% ^{238}Pu , 60–70% ^{239}Pu , 20–25% ^{240}Pu , 5–10% ^{241}Pu , and 1–5% ^{242}Pu for civilian sources (IAEA Report, 1998). Unirradiated MOX fuel for light-water reactors typically contains 5–7% Pu. Residues are poorly defined and include a broad spectrum of wastes produced by processing activities.

29.2.2 Rate-controlling factors and mechanisms

A negative Gibbs energy change is necessary for any reaction, either rapid or slow. The potential hazard existing during handling depends on both the rate and the enthalpy of reaction. Factors that determine the reaction rates of liquids and gases with metals or ionic compounds are suggested by consideration of likely mechanistic steps. Reacting molecules must (1) reach the solid interface, (2) adsorb on that surface, and (3) dissociate to form a monatomic anion by interaction with electrons from the solid. Resulting anions must (4) enter the solid lattice, (5) be transported through the layer of product solid while electrons move toward the surface, and (6) ultimately react at the product–reactant interface. The rate of reaction is determined by the slowest step or the combined effect of steps.

A general expression for the rate, R , of a gas–solid reaction includes dependencies on temperature and on partial pressures P_1, P_2, P_3, \dots of gaseous reactants 1, 2, 3, \dots .

$$R = k \exp(-E_a/R^*T)(P_1)^{n_1}(P_2)^{n_2}(P_3)^{n_3} \dots$$

This equation includes the proportionality constant (k) and an Arrhenius term defined by the activation energy (E_a), the gas constant (R^*), and temperature. The rate is normalized for surface area of the reacting solid using geometric areas of massive solids or molecular-scale (BET) areas of powders. Dependencies of R on gas concentrations are described by the pressure exponents n_1, n_2, n_3, \dots . Experimental valuation of k , E_a , and n are important in identification of rate-determining steps.

Different rate-controlling steps are encountered during corrosion of solids at different conditions (Haschke *et al.*, 2000a). During reaction of a mixture of reactive and inert gases, the rate may be controlled by transport of reactive gas through a layer of unreactive gas that accumulates at the gas–solid interface. In some cases, the rate is determined by the concentration of reactant molecules adsorbed on the surface. In other cases, R is determined by diffusion of the reacting anion through an adherent product layer on the reacting solid, as

indicated by a parabolic time dependence of the extent of reaction. Parabolic dependence is observed only as long as the product adheres and the thickness of the diffusion barrier increases. If spallation of product particles begins, the layer is thin in some locations and the rate increases at those sites. Although rates vary across the surface, continuing reaction and spallation maintain a constant average thickness and results in a linear dependence of extent on time. The combined process of parabolic and linear steps is described as 'paralinear' behavior. In the linear step, the diffusion-controlled rate is constant at fixed temperature and reactant pressure. The diffusion rate is usually increased by increasing temperature or by increasing pressure until the surface becomes saturated with reactant molecules. The reaction rate is dramatically increased and becomes temperature independent if the surface layer catalytically dissociates and transports reactant to the product-reactant interface. In that case, the rate is determined solely by the concentration of adsorbed reactant and depends only on gas pressure.

The preceding discussion of rate-controlling processes implies that the product layer on the surface of a reacting solid may be protective or catalytic depending on its ability to form and transport the diffusing species. The structure of the product formed on the reacting solid (metal or compound) is important in determining its nature. A surprising feature of plutonium compounds formed by atmospheric constituents is the pervasive presence of plutonium in cubic ($Fm\bar{3}m$ symmetry) structures in which Pu occupies face-centered cubic (fcc) positions (Haschke *et al.*, 2000a). The fcc cation lattice has two tetrahedral interstitial sites per cation and one interstitial octahedral site per cation, features that allow for a variety of compositions and accommodation of up to three anions per Pu. Maintenance of charge balance in the lattice is enhanced by the ability to include anions with different charges and Pu cations in different oxidation states in solids.

This structural flexibility facilitates formation of various products at low temperature by decreasing or increasing the anion/cation ratio or by replacing existing anions. Such reactions of solid phases usually occur at elevated temperatures because of the high activation energies associated with rearrangement of the cationic lattice. The NaCl-type structure is formed by anion occupation of octahedral sites in the fcc lattice, the CaF_2 -type structure is formed by occupation of the tetrahedral sites, and the anti- Fe_3Al structure is formed by occupation of both sites. Extended solid solutions form as the anion/cation ratio and the average oxidation state of Pu progressively change.

Transport rates of reactant ions in the product layer appear strongly dependent on deviations from ideal stoichiometry (Haschke *et al.*, 2000a). At low temperatures, transport of ions through a rigid CaF_2 -type lattice like PuO_2 or UO_2 occurs by hopping of reactant ions between octahedral sites. Vacant tetrahedral sites formed in substoichiometric compounds share faces with normally vacant octahedral sites and create channels that facilitate anion movement. In a similar way, occupation of octahedral sites in compositions with

anion:cation ratios greater than 2 tends to hinder anion movement because diffusion channels are occupied. However, markedly different behavior is encountered with superionic conductors in which the cation lattice is rigid and the anions (e.g. O^{2-} , F^- , Cl^- , I^-) are highly mobile (Boyce and Huberman, 1979). These solids frequently have NaCl-type, CaF_2 -type, or related structures; their ionic conductivities are comparable to those of molten salts and typically exceed those of ordinary ionic solids by more than 10^8 .

In large measure, plutonium reactivity and its perplexing behavior are determined by fundamental properties of the product compound(s) existing on the metal surface, not by the properties of Pu. The only important property of plutonium is its chemical potential that drives reaction. Interpretation of Pu corrosion hinges on understanding the behavior of hydride, oxide, and other surface compounds. Therefore, relevant fundamental properties of these materials are reviewed as a basis for describing reactivities of metals and compounds.

29.3 FORMATION AND PROPERTIES OF COMPOUNDS

29.3.1 Plutonium hydrides

As shown by the phase diagram in Fig. 29.1, the complex plutonium–hydrogen system is dominated by the existence of a fcc PuH_x solid solution that is stable from $PuH_{1.95}$ to $PuH_{2.7}$ at room temperature and extends to PuH_3 above $300^\circ C$. This simplified diagram does not indicate regions of apparent structural ordering outlined in comprehensive reviews of hydride properties (Flotow *et al.*, 1984; Haschke *et al.*, 1987; Ward and Haschke, 1994). At high compositions, the fcc CaF_2 -related hydride coexists with the PuH_y ($2.8 < y < 3.0$ at $25^\circ C$) solid solution, a substoichiometric phase derived from the hexagonal LaF_3 -related PuH_3 phase by formation of anion vacancies. Hydrides are obtained by reaction of metal with H_2 or with elemental hydrogen derived from other sources. Hexagonal hydride is formed by reaction of Pu with H_2 at several bar pressure and temperatures above $400^\circ C$ (Haschke *et al.*, 1987) and its appearance is unlikely unless these conditions exist. Transformation of the Pu cations from the fcc arrangement of PuH_x to the hcp arrangement of PuH_y at low temperatures is apparently precluded by a high activation energy. Therefore, metastable PuH_x forms beyond the $PuH_{2.7}$ composition as hydrogen occupies vacant octahedral sites in the cubic structure. The value of x exceeds 2.9 as the H_2 pressure is increased to 1 bar (Haschke *et al.*, 1980). The cubic PuH_x powder formed by slow reaction at low temperatures is pyrophoric in air at room temperature, but the hexagonal PuH_y only ignites in air when heated above $270^\circ C$ (Haschke *et al.*, 1987).

Stoichiometric PuH_2 is frequently formulated as a distinct binary phase, but reference to Fig. 29.1 shows that the dihydride exists only as a composition within the PuH_x continuum. The hydride at the lower phase boundary has a

Fig. 29.1 Proposed phase diagram of the Pu-H system. Data are from Flotow *et al.* (1984).

progressively decreasing x with increasing temperature and coexists with hydrogen-saturated metal (Allen, 1991). Temperatures and corresponding equilibrium H_2 pressures within the two-phase region (Fig. 29.1) show that the hydride decomposes to metal upon heating in vacuum. The extrapolated equilibrium hydrogen pressure at room temperature is 10^{-21} bar (Flotow *et al.*, 1984) and the estimated H/Pu ratio in the metal is 10^{-9} (Allen, 1991). ΔH_f° (298 K) and ΔG_f° (298 K) for cubic PuH_x vary regularly with x between values for terminal compositions in Table 29.1 (Flotow *et al.*, 1984).

Electrical properties of PuH_x are inconsistent with those of ionic insulators having CaF_2 -type structures (Haschke *et al.*, 1987; Ward and Haschke, 1994). Whereas compositions less than PuH_2 are consistent with forming vacancies on anion sites, x values in the 2–3 range are apparently attained by progressive occupation of additional anion sites by H^- . The PuH_2 formula implies that plutonium is present as the divalent cation, an unknown oxidation state of Pu in solids. The color of PuH_x changes from silver at $x = 2$ to black at high x ; hydride conductivity is comparable to that of α -phase Pu at x near 2 and decreases to the semiconductor range at high x . Magnetic data show that Pu in PuH_x is present in the trivalent state. PuH_2 is most easily viewed as a Pu(III) lattice in which anion sites are occupied by H^- in a 2:1 H/Pu ratio and a

conduction band is occupied by one electron per Pu (Haschke *et al.*, 1987). The hydride color changes from silver to black with increasing PuH_x composition as conduction electrons are progressively bound as H⁻ on anion sites.

High mobility of hydrogen in PuH_x is indicated by proton nuclear magnetic resonance (NMR) data showing that resonance lines are motionally narrowed and the diffusion of hydrogen is 'too fast' for measurements at room temperature (Cinader *et al.*, 1976). At and below 190 K (-83°C), line shapes of PuH_x correspond to a rigid lattice with hydrogen occupying all tetrahedral sites and the appropriate fraction of octahedral sites required by *x*. A previously unexplained broad peak in the C_p curve for hydride (Flotow *et al.*, 1984) at 200–270 K coincides with freezing-in of H⁻ on lattice sites. This peak is identified as the transition from ionic to superionic conduction above 0°C (Haschke and Allen, 2001) and implies that hydrogen transport in PuH_x is extremely rapid at 25°C and higher temperatures.

29.3.2 Plutonium oxides

The partial plutonium–oxygen phase diagram in Fig. 29.2 is based on phase relationships presented in prior reviews of oxide chemistry (Colmenares, 1975; Weigel *et al.*, 1986) and in a more recent assessment of high-temperature data (Wriedt, 1990). Three oxides are stable at room temperature: hexagonal La₂O₃-type sesquioxide (identified as β -Pu₂O₃), bcc Mn₂O₃-related PuO_{1.515} (identified as α -Pu₂O₃), and PuO₂. According to the diagram, β -Pu₂O₃ coexists with oxygen-saturated Pu and α -Pu₂O₃ coexists with PuO₂ below 335°C with a narrow two-phase region separating the PuO_{1.50} and PuO_{1.515} compositions at low temperatures. Assignment of this unusual relationship is based on coexistence of the two phases, failure to observe the hexagonal to cubic transition, and a reported lack of overlap in their compositions (Wriedt, 1990). This basis seems tenuous because dimorphic relationships of hexagonal and cubic oxides exist for

Fig. 29.2 Partial Pu–O phase diagram based on high-temperature studies with O₂.

lanthanide analogs (Eyring, 1979) and transformation is likely to be slow at low temperatures. The composition of the cubic oxide (PuO_{1.46 ± 0.04}) formed during slow oxidation of Pu by water at room temperature (Haschke *et al.*, 1983) suggests that composition ranges of the two oxides are not significantly different. A reason to expect enhanced stability for a stoichiometric Mn₂O₃-related phase at the Pu₂O₃ composition with 3% occupancy of the cation sites by Pu(IV) is not apparent. In addition, both α - and β -forms of the sesquioxide are reportedly prepared by carbon reduction of PuO₂ at 1500–2000°C (Haire and Haschke, 2001), a temperature range in which α -Pu₂O₃ is unstable (Fig. 29.2) (Weigel *et al.*, 1986; Wriedt, 1990).

Concern about the precise phase relationships of sesquioxide may seem unmerited, but the nature of the oxide layer on Pu is apparently a key factor in determining metal reactivity. Data in Fig. 29.2 imply that β -Pu₂O₃ should exist on the metal surface, but analysis of Pu surfaces shows that only PuO₂ is detectable after exposure to air at room temperature (Terada *et al.*, 1969; Stakebake, 1971; Colmenares, 1984). Kinetic control of oxidation is implied (Haschke, 1992a) and supported by X-ray diffraction (XRD) measurements showing that heating of dioxide-coated Pu in vacuum results in reduction of the PuO₂ surface layer to α -Pu₂O₃ by the underlying metal (Terada *et al.*, 1969). The α -Pu₂O₃ readily appears at 150°C, is completely formed within minutes at 200°C, and persists when heated at 420°C. Appearance of a NaCl-type phase

at higher temperatures is attributed to formation of PuO (Cleveland, 1979). Subsequent X-ray photoelectron spectroscopy and atomic emission spectroscopy (XPS/AES) investigation confirms the facile reduction of PuO₂ to Pu₂O₃ at 200°C, but shows that the product observed at high temperatures is an oxide carbide (nominally Pu(III)O_{0.5 ± 0.1}C_{0.5 ± 0.1}) formed by reaction of free carbon with oxide and metal (Larson and Haschke, 1981). The spectroscopic data also show that plutonium oxide is extensively contaminated with unbound C after exposure to air or CO₂ and that the C(1s) peak shifts to a lower binding energy characteristic of carbide (C⁴⁻) at temperatures in the range reported for PuO formation. Although plutonium monoxide is frequently reported in the literature, those products are most likely ternary compounds stabilized by carbon or nitrogen (Larson and Haschke, 1981; Weigel *et al.*, 1986).

Formation of an α -Pu₂O₃ layer on Pu at 200°C does not agree with phase relationships in Fig. 29.2, but is consistent with facile movement of oxide ions in fcc Pu cations lattice. The bcc Mn₂O₃-type structure (Wells, 1975) is derived by ordered removal of O²⁻ from one-fourth of the tetrahedral sites of CaF₂-type PuO₂ and occupation of all cation sites by Pu(III). The superstructure of anion vacancies results in a doubled cubic cell ($a_0 \text{ bcc} = 2 a_0 \text{ fcc}$). Electrons move into the PuO₂ layer and reduce Pu(IV) to Pu(III) as O²⁻ ions move from the oxide layer to the oxide-metal interface and form additional α -Pu₂O₃.

In air or O₂, the steady-state chemical composition of the oxide layer on the Pu surface is determined by the relative rates of competing reactions (Haschke and Allen, 2001). Formation of α -Pu₂O₃ at the oxide-metal interface is countered by its oxidation to PuO₂ by oxygen. The relatively rapid rate of PuO₂ formation at 25°C yields a layer that is primarily dioxide, even though a thin sesquioxide layer must exist at the oxide-metal interface. These reactions have different activation energies and the rate of reduction increases more rapidly with increasing temperature than the rate of oxidation, as demonstrated by XRD and XPS analysis of the product layer formed in water vapor at 250°C (Stakebake *et al.*, 1993). The α -Pu₂O₃ layer is detectable beneath a relatively thin double layer composed of an inner PuO₂ layer and an outer layer of a previously unidentified higher oxide with a CaF₂-related structure. The dominant oxide layer on Pu surface in air progressively changes from PuO₂ at 25°C to α -Pu₂O₃ with increasing temperature (Haschke and Allen, 2001). The rate reduction becomes increasingly rapid with increasing temperature and formation of sesquioxide is kinetically favored above 500°C.

Additional complexity of the Pu-O phase diagram is suggested by results of water titration measurements in which Pu was submerged in salt solution at room temperature (Haschke *et al.*, 1983; Haschke, 1992a). Ionic radii of Pu(III) and Pu(IV) and relative free energies of Pu₂O₃ and PuO₂ correspond closely with those of Pr, suggesting that stable mixed-valence intermediate oxides like the CaF₂-related phases in the Pr-O system (Eyring, 1979) are to be expected for Pu. The titration (Haschke *et al.*, 1983), which is monitored by measuring hydrogen production, shows that the H₂ generation rate progressively decreases

Table 29.2 Sequence of reactions derived from cumulative H_2/Pu ratios at intersection points of linear segments during reaction of Pu with water at 23°C (Haschke, 1992a).

Reaction	Cumulative H_2/Pu ratio ^a	
	Theoretical	Experimental
$Pu + H_2O \rightarrow PuOH + 1/2H_2$	0.500	0.507(6)
$PuOH + 2/7H_2O \rightarrow 1/7Pu_7O_9H_3 + 4/7H_2$	1.071	1.078(23)
$1/7Pu_7O_9H_3 + 3/14H_2O \rightarrow 1/2Pu_2O_3 + 3/7H_2$	1.500	1.455(38)
$1/2Pu_2O_3 + 3/14H_2O \rightarrow 1/7Pu_7O_{12} + 3/14H_2$	1.714	1.716(170)
$1/7Pu_7O_{12} + 4/63H_2O \rightarrow 1/9Pu_9O_{16} + 4/63H_2$	1.778	1.763(118)
$1/9Pu_9O_{16} + 1/45H_2O \rightarrow 1/10Pu_{10}O_{18} + 1/45H_2$	1.800	1.803(2)
$1/10Pu_{10}O_{18} + 1/30H_2O \rightarrow 1/12Pu_{12}O_{22} + 1/30H_2$	1.833	1.831(181)
$1/12Pu_{12}O_{22} + 1/6H_2O \rightarrow PuO_2 + 1/6H_2$	2.000	1.993(16)

^a Uncertainties in measured values are given in parenthesis.

over a year-long period in a sequence of constant-rate steps with intersection points at well-defined molar ratios of H_2/Pu associated with completion points of successive reactions. Intersection points corresponding to changes in rate (Table 29.2) are assigned to formation of oxide hydrides ($PuOH$ and $Pu_7O_9H_3$), Pu_2O_3 , members of the Pu_nO_{2n-2} homologous series with $n = 7, 9, 10,$ and 12 , and PuO_2 . Continued generation of pure H_2 beyond the dioxide composition could not be explained. XRD data for initial and terminal products show CaF_2 -related structures and imply that all intermediate products have fcc Pu lattices that do not transform at 25°C. Members of the homologous series presumably have CaF_2 -related structures like those of intermediate praseodymium oxides (Eyring, 1979).

Formation of a high-composition plutonium oxide, PuO_{2+x} , by reaction of PuO_2 with H_2O or with O_2 in the presence of water is indicated by microbalance and pressure–volume–temperature measurements at 25–250°C (Haschke *et al.*, 2000b). The oxide–water reaction proceeds with H_2 formation and a mass increase corresponding to stoichiometric incorporation of oxygen in the solid:

Dry O_2 (air) does not react with PuO_2 at a detectable rate, but is preferentially consumed in forming PuO_{2+x} via a water-catalyzed cycle if water is present. Catalyzed reaction of O_2 forms PuO_{2+x} at the same rate as the oxide–water reaction, but H_2 is not formed. The catalytic cycle is established as water reacts with the oxide at its characteristically more rapid rate and atomic H formed on the surface combines with dissociatively adsorbed oxygen to re-form water. In the absence of O_2 , high-purity (>99.99%) H_2 is produced according to the above reaction as H atoms associate and desorb.

XRD data for solid products of the oxide–water reaction show a single CaF_2 -related phase with a lattice parameter that increases by 0.4 pm as reaction

initiates and thereafter has a linear dependence on composition, a_0 (nm) = $0.53643 + 0.001764(2+x)$, consistent with the formation of an extended solid solution. Results account for earlier observations of H₂ generation beyond the PuO₂ composition in liquid water (Haschke *et al.*, 1983; Haschke, 1992a) and show that oxide stoichiometries approach PuO_{2.3} (Haschke *et al.*, 2000b), but do not define the upper phase boundary of PuO_{2+x}. The area-normalized rate of H₂ formation by the PuO₂-water reaction is temperature-dependent ($E_a = 39.3$ kJ mol⁻¹), implying that the reaction is chemical, not radiolytic. Self-induced radiation damage does not account for the expansion of a_0 (Haschke and Allen, 2002) and radiolysis of H₂O fails to account for either the observed H₂ formation rate or for absence of O₂ as a gaseous product (Haschke *et al.*, 2001a).

As implied by extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES) results showing Pu(v) in PuO_{2+x} (Conradson *et al.*, 2003, 2004; Paffett *et al.*, 2003a), formation of this UO_{2+x} analog occurs by substitution of Pu(v) for Pu(IV) on cation lattice sites and accommodation of additional O²⁻ on octahedral interstices of the lattice (Haschke *et al.*, 2000b). EXAFS results show nearest-neighbor Pu-O distances of 0.183–0.193 nm for a range of PuO_{2+x} compositions (Conradson *et al.*, 2003, 2004). This value is significantly shorter than the characteristic Pu-O distance of 0.233 nm for O in tetrahedral sites of PuO₂. Evaluation of parameters affecting XANES edge energies indicates that observations are most consistent with the presence of Pu(v) in PuO_{2+x}.

The highest PuO_{2+x} possible composition is identified as PuO_{2.5}, the maximum attainable stoichiometry of the Pu(IV)_{1-2x}Pu(V)_{2x}O_{2+x} solid solution (Haschke and Allen, 2002). Lattice parameters of steady-state solids formed after placing Pu(IV) hydrous oxide in aqueous solution are consistent with formation of cubic PuO_{2+x} with x -values that vary from 0 near pH 10 to 0.5 near pH 3 (Haschke and Oversby, 2002). Stability of PuO_{2+x} is demonstrated by extraction of oxygen from water during formation and is supported by thermodynamic assessment (Haschke and Allen, 2002). Results indicating that the phase is stable to $x = 0.5$ in air at temperatures of 350–400°C and that x approaches zero at 600°C are not confirmed by experiment. ΔH_f° (298 K) and ΔG_f° (298 K) for α -Pu₂O₃, PuO₂, and selected PuO_{2+x} compositions are given in Table 29.1.

Further EXAFS investigation of hydrothermal products and other compounds formed by aging precipitates from neutral Pu(IV) and Pu(VI) solutions shows the 0.183–0.193 nm Pu-O distances characteristic of PuO_{2+x} (Conradson *et al.*, 2004). These compounds, as well as those formed by reaction of PuO₂ with water vapor, have slightly increased fcc lattice parameters relative to PuO₂ and are identified as PuO_{2+x-y}(OH)_{2y}. Interpretation of EXAFS and XANES results leads to a structure described as a conglomeration of oligomerized Pu(IV) and PuO₂⁺ oxo-hydroxide-aquo moieties with the same average Pu sublattice locations as in PuO₂. Other workers suggest that additional oxygen is

accommodated in the lattice predominately as hydroxyls, not as oxide and describe the phase as $\text{PuO}_{2+x} \cdot \text{H}_2\text{O}$ (Paffett *et al.*, 2003a).

Results of thermal decomposition and chemical analyses (Haschke, 1992a) of the product subsequently identified as $\text{PuO}_{2.27}$ on the basis of H_2 generation (Haschke *et al.*, 2000b) are most consistent with an anhydrous product, but stabilization of the higher oxide by hydroxide cannot be excluded. A first-principles quantum mechanical calculation of the PuO_{2+x} electronic structure (Petit *et al.*, 2003) indicates that a delicate energy balance does not favor PuO_{2+x} formation, but might be altered if interstitial species other than O^{2-} are present. The predicted composition dependence of the cubic PuO_{2+x} lattice parameter is consistent with the observed insensitivity of a_0 to x . Incorporation of hydroxyl in the lattice during exposure of oxide to moisture may account for the mass loss observed above 700°C during calcination (Stakebake, 1973).

Although behavior of plutonium oxides is generally consistent with a recently proposed Pu–O phase diagram (Haire and Haschke, 2001), the alternative diagram in Fig. 29.3 shows overlapping compositions for α - Pu_2O_3 and β - Pu_2O_3 . Transformation of α into β near 450°C (Wriedt, 1990) is consistent with behavior of lanthanide oxides (Eyring, 1979). Thermodynamic data do not resolve the issue because the difference in free energies of formation of the two oxides is small. The $\Delta G_f^\circ(298\text{ K})$ of -1580 kJ mol^{-1} recommended for β - Pu_2O_3

Fig. 29.3 Partial Pu–O phase diagram based on studies with O_2 at high temperatures and on studies with H_2O at low temperatures.

(Morss, 1986) overlaps with the composition-adjusted value $(-1574 \pm 11) \text{ kJ mol}^{-1}$) for stoichiometric $\alpha\text{-Pu}_2\text{O}_3$. Formation of $\alpha\text{-Pu}_2\text{O}_3$ in water at low temperatures may result from favorable kinetics of a preexisting fcc Pu lattice, but the reported preparation of bcc $\text{PuO}_{1.515}$ by reduction of PuO_2 above 1600°C (Weigel *et al.*, 1986) cannot be explained because that composition is within the phase field of $\beta\text{-Pu}_2\text{O}_3$ (Figs. 29.2 and 29.3), a solid that apparently does not transform into $\alpha\text{-Pu}_2\text{O}_3$ on cooling (Wriedt, 1990).

A major difference between Figs. 29.2 and 29.3 is the existence of homologous series oxides containing fixed ratios of Pu(III) and Pu(IV) (Haschke, 1992a). Observed compositions correspond to those of Pr–O (Eyring, 1979) plus an additional member at $n = 5$ ($\text{PuO}_{1.6}$). Intermediate oxides apparently form during reaction of $\alpha\text{-Pu}_2\text{O}_3$ with water at room temperature because rates of the oxide–water reactions are sufficiently slow that conditions are isothermal and differences in rates of successive reactions are resolved (Haschke *et al.*, 1983; Haschke, 1992a). Failure to observe intermediate oxides in studies with O_2 is attributed to the catalytic nature of $\alpha\text{-Pu}_2\text{O}_3$ and rapid exothermic reaction of the bcc oxide with oxygen (Haschke and Allen, 2001). Rapid reaction heats the oxide beyond the stability ranges of the $\text{Pu}_n\text{O}_{2n-2}$ phases and terminates at PuO_2 . Unlike the dioxides of Ce, Pr, and Tb (Eyring, 1979), PuO_2 does not desorb oxygen and equilibrate with $\text{Pu}_{12}\text{O}_{22}$ when heated to 500°C , but vaporized incongruently at $1500\text{--}2000^\circ\text{C}$ with the formation of PuO_2 (g), PuO (g), O (g), and O_2 (g) (Cleveland, 1979; Weigel *et al.*, 1986).

As defined by estimated equilibrium oxygen pressures (Haschke and Allen, 2001), the phase boundary of the PuO_{2+x} solid solution is indicated in Fig. 29.3. Data suggest that the stable solution extends to $\text{PuO}_{2.5}$ at temperatures up to 400°C and imply that a very narrow two-phase region exists between PuO_2 and PuO_{2+x} . Behavior is uncertain and additional work is needed to resolve the controversy over existence of PuO_{2+x} (Ronchi *et al.*, 2000) and define equilibria in the Pu–O and Pu–O–H systems.

29.3.3 Other plutonium compounds

As the major constituent of air, nitrogen is an important potential reactant in corrosion. The only binary compound of plutonium is the mononitride, PuN , which has a variable composition ($\text{PuN}_{1-\delta}$) attributed to formation of anion vacancies in the fcc NaCl-type structure (Cleveland, 1979; Weigel *et al.*, 1986). Reaction of N_2 with Pu initiates at about 300°C , but is slow and only 80% complete after 17 h at 1000°C (Brown *et al.*, 1955). The nitriding rate is markedly increased by reacting N_2 with PuH_x in a process that initiates at temperatures as low as 230°C . A rapid initial reaction is about 60% complete and followed by a slower second step that results in 97% of theoretical PuN formation after several hours. Nitriding of Pu is promoted if the metal is coated with hydride and then exposed to N_2 at 250°C (Cleveland, 1979). The reaction apparently proceeds as nitrogen displaces hydrogen in the fcc Pu lattice of PuH_x .

and as product H atoms advance into the metal to re-form hydride (Haschke and Allen, 2001). Values of ΔH_f° (298 K) and ΔG_f° (298 K) for PuN are given in Table 29.1 (Lemire *et al.*, 2001).

Reaction of plutonium metal with water in near-neutral solutions at room temperature proceeds by a stoichiometric reaction that forms 0.5 mol H₂ per mol of Pu and a hydridic black solid identified as plutonium monoxide monohydride, PuOH (Haschke *et al.*, 1983; Haschke, 1992a). Formation of this compositional analog of PuOCl is suppressed at high pH (Haschke, 1995) and catalyzed by chloride and other salts in solution, but those anions are not incorporated in the solid (Haschke, 1992a). The product forms an adherent layer on the metal and spalls as particles with average dimensions of about 7 nm (Haschke *et al.*, 1983). PuOH crystallizes in a CaF₂-related structure and XPS data indicates that plutonium is trivalent, implying that cation sites are occupied by Pu(III) and anion sites are occupied by O²⁻ and H⁻. Thermal decomposition of PuOH at 105–195°C in vacuum results in stoichiometric loss of hydrogen and formation of a violently reactive solid at the PuO composition. The oxide hydride is insoluble in dilute HCl and continued exposure to liquid water produces additional H₂ and a sequence of solid products identified in Section 29.3.2.

29.3.4 Plutonium alloys

As shown by phase diagrams for binary and higher systems of plutonium (Ellinger *et al.*, 1968), formation of intermetallic compounds is an extensive and important aspect of Pu chemistry. Alloying of Pu with 3–9 at% (1–3 wt%) Ga expands the thermal stability range of the fcc δ -phase from the 310–452°C span of pure metal to a range extending from about 100 to 600°C (Hecker, 2001) and substantially reduces the corrosion rate in air (Waber, 1980). Although the Ga alloy is apparently unstable at room temperature, the rate of transformation is extremely slow. Addition of Al has comparable effects on δ -phase stability and corrosion, and forms a PuAl₂ intermetallic compound that melts congruently at 1540°C (Ellinger *et al.*, 1968). Alloying with Fe forms a eutectic composition (10 at% Fe) that melts at 410°C and Pu₆Fe, an intermetallic phase that melts at 428°C (Ellinger *et al.*, 1968). Other metals, such as Nb and V, do not form compounds with Pu and are relatively insoluble in molten Pu (Ellinger *et al.*, 1968). At 1200–1300°C, the saturated Pu-rich liquid contains about 10 at% of these metals.

29.3.5 Uranium compounds

Like plutonium, uranium forms compounds with constituents of the atmosphere and of environments for handling and storage. A single stoichiometric hydride, UH₃, formed by reaction of the elements exists in two cubic modifications (Ward, 1985). The low-temperature α -UH₃ is difficult to prepare and is not expected to form during routine operations. The β -UH₃ phase crystallizes in a

structure identified as β -tungsten-type, but the correct structure is apparently anti-type W_3O (Wells, 1975). All H-atoms occupy distorted tetrahedral sites that are formed by four U-atoms and share a face with another occupied tetrahedron and edges with three occupied tetrahedra. Edge-shared octahedral vacancies formed by six edge-shared tetrahedra provide the most likely pathway for H-transport. The measured activation energy for hydrogen self-diffusion in β - UH_3 is $(30 \pm 5) \text{ kJ mol}^{-1}$ (Ward and Haschke, 1994). The electrical conductivity at 25°C ($1 \times 10^{-3} \text{ ohm}^{-1} \text{ cm}^{-1}$) indicates metallic behavior. The hydride is highly reactive and ignites spontaneously when exposed to air. Thermodynamic properties of the hydride are reviewed (Flotow *et al.*, 1984; Grenthe *et al.*, 1992): $\Delta H_f^\circ(298 \text{ K})$ and $\Delta G_f^\circ(298 \text{ K})$ for β - UH_3 are -127 and -73 kJ mol^{-1} , respectively.

The U- O_2 system is also complex (Keller, 1973; Colmenares, 1975). Studies cited in these reviews indicate that reaction of U with O_2 successively forms UO_2 , UO_{2+x} ($x < 0.2$), U_4O_9 , U_3O_7 , U_2O_5 , and U_3O_8 , the stable oxide in air with U in U(IV) and U(VI) oxidation states. UO_2 is prepared by reducing higher oxides with H_2 (Anderson *et al.*, 1955). The highest oxide, UO_3 , is obtained in five crystallographic forms by heating U_3O_8 in 40 bar O_2 at 500°C or in NO_2 at $(115 \pm 60)^\circ\text{C}$ and by ignition of oxygen-rich precipitates such as the hydrated nitrate ($UO_2(NO_3)_2 \cdot 6H_2O$) at 400 – 600°C (Hoekstra *et al.*, 1961). UO_{2+x} forms by accommodating oxygen on octahedral sites of CaF_2 -type UO_2 . UO_{2+x} is stable only at temperatures above 300°C , but may form as a metastable phase at lower temperatures. The CaF_2 -related structure of U_4O_9 results from long-range ordering of oxygen on octahedral sites. The structure of low-temperature orthorhombic α - U_3O_8 (Wells, 1975) contains chains of vertex-shared pentagonal-bipyramidal (UO_7) coordination polyhedra. The structure, which is formed by sharing edges of polyhedral chains, has narrow channels that may restrict oxygen transport (Haschke *et al.*, 2001b). $\Delta H_f^\circ(298 \text{ K})$ and $\Delta G_f^\circ(298 \text{ K})$ for UO_2 , U_4O_9 , and U_3O_8 are -1085 and $-1032 \text{ kJ mol}^{-1}$, -4511 , and $-4276 \text{ kJ mol}^{-1}$, and -3575 and $-3369 \text{ kJ mol}^{-1}$, respectively (Grenthe *et al.*, 1992).

Hydrothermal studies indicate that U_3O_7 , U_2O_5 , and $UO_3 \cdot nH_2O$ form by spontaneous reaction of UO_2 with water at 130 – 200°C (Matzke and Turos, 1991). Rutherford backscattering (RBS) and elastic recoil detection analysis (ERDA) show that a layer of hydrogen-free higher oxide forms on the dioxide surface and imply that H_2 is produced.

Experimental conditions preclude the presence of significant amounts of O_2 . Hydrated UO_3 ($UO_3 \cdot nH_2O$) apparently forms at 200°C via a complex process involving oxidation of UO_2 , leaching of U(VI) from the higher oxide product, and precipitation of hydrated UO_3 . However, thermodynamic data for uranium oxides (Grenthe *et al.*, 1992) indicate that oxidation of UO_2 by H_2O is unfavorable at standard conditions. Because changes in heat capacities are small over a limited temperature range, ΔG° for the reaction at 130°C is approximately equal

to that for 25°C (+92 kJ mol⁻¹) and ΔG at 2.7 bar H₂O pressure remains positive unless the H₂ pressure is less than 10⁻¹² bar, a condition that is difficult to maintain in an autoclave system as H₂ is apparently produced. Behavior parallels that for PuO₂-H₂O (see Section 29.3.2) and additional work is needed.

Uranium reacts with N₂ or NH₃ to form sesquinitride, U₂N₃, at temperatures above 400°C (Dell, 1973). The phase is non-stoichiometric with compositions typically ranging from UN_{1.6} to UN_{1.7}. Below 1100°C, the α -U₂N₃ product has the bcc Mn₂O₃-related structure like that of α -Pu₂O₃ (Wells, 1975). The NaCl-type mononitride, UN, obtained by decomposing the sesquinitride in vacuum above 1100°C has a room-temperature conductivity (6.7×10^{-3} ohm⁻¹ cm⁻¹) similar to that of Bi and Pb (Keller, 1973). The tendency to form sesquinitride during reaction of the elements is consistent with autocatalysis of nitriding by UN. Behavior appears similar to autocatalysis of hydriding by PuH_x and to the catalyzed oxidation of α -Pu₂O₃ by O₂. Values of ΔH_f° (298 K) and ΔG_f° (298 K) for UN and α -U₂N_{3,18} are -290 and -265 kJ mol⁻¹ and -758 and -676 kJ mol⁻¹, respectively (Grenthe *et al.*, 1992).

29.4 REACTION KINETICS OF PLUTONIUM COMPOUNDS

29.4.1 Hydride reactions

(a) Relevant hydride properties

Reaction rates of PuH_x (1.95 < x < 3) with gases and liquids depend on the size distribution of hydride particles and are proportional to surface area (Haschke, 1991). Size distributions of PuH_x vary with preparative conditions; fine powders are formed during slow reaction at low temperatures (Stakebake, 1981a,b) and coarse particles with dimensions up to 1 cm are produced during rapid reaction at temperatures above 400°C (Haschke *et al.*, 1980). Specific surface areas of the low-temperature hydride are in the 0.15–0.25 m² g⁻¹ range and equal those (0.1–0.2 m² g⁻¹) of Pu powders prepared by thermal dehydriding of the powder (Stakebake, 1981c). Therefore, the size distribution of metal particles prepared by a hydride-dehydride process is adopted for low-temperature PuH_x (Haschke, 1992b). Geometric areas of a few cm² per gram for hydride prepared at high temperatures are comparable to those of massive Pu.

(b) Reaction of PuH_x with hydrogen

The reaction of PuH_x with H₂ is an important process in ignition and corrosion of Pu metal, but has not been extensively studied. Compositions measured by microbalance methods at constant pressures in the 1–400 mbar range as PuH_x was heated at 2°C min⁻¹ in the 25–500°C range agree with isothermal x-values at equilibrium (Haschke, 1981). In addition to indicating that the rates of

hydrogen absorption and desorption by cubic PuH_x are rapid, these results imply that formation of atomic H at the gas–solid interface and transport of hydrogen in the hydride are facile, even at room temperature. The rate of hydrogen absorption by PuH_x is comparable to the rate of the Pu-H_2 reaction and is essentially constant for compositions in the $\text{PuH}_{1.9}$ – $\text{PuH}_{2.7}$ range (Haschke *et al.*, 1980). After adjustment of the surface area to account for a two- to three-fold increase during hydriding, the area-normalized rate at 1 bar H_2 pressure is 1–3 $\text{mmol H}_2 \text{ cm}^{-2} \text{ min}^{-1}$ (geometric area).

Accommodation of additional hydrogen in the hydride structure is facile and has important kinetic consequences (Haschke and Allen, 2001). Product hydrogen accumulates in the solid and is released as H_2 after x of the PuH_x cores inside reacting hydride particles approach 3. Therefore, reactions of PuH_x with liquids and gases initiate without counter-current flow of hydrogen out of the solid or formation of H_2 at the gas–solid interface.

(c) Reaction of PuH_x with oxygen

Because exposure of hydride to oxygen is expected to result in pyrophoric reaction, observations made during microbalance studies in which PuH_x ($2.0 < x < 2.7$) at 50–360°C was exposed to O_2 at 13.3 mbar are perplexing (Stakebake, 1981a,b). Reaction initiated immediately at 50°C, essentially ceased after 2 min (20% completion), and completely transformed the hydride to PuO_2 only after the temperature was increased to 315°C in several steps. After each step, the microbalance system was evacuated and the sample temperature was increased before O_2 was reintroduced. During the initial stage of each step, the oxidation rate of oxide-coated hydride was similar to that observed during initial exposure of PuH_x to O_2 . Within each step, the rate progressively decreased during an intermediate stage and continued at a slow temperature-dependent rate after entry into a final stage. Results show that reaction at 360°C proceeds via these stages with 95% transformation to PuO_2 after 90 min. XRD data verify that PuO_2 is the product layer on the hydride during the final stage. Kinetic analysis shows that E_a for the initial spontaneous PuH_x – O_2 reaction is negative (-9 kJ mol^{-1}), a result that is inconsistent with the expectation of high activation energies for autothermic processes. Evaluation of linear rates R , in $\text{mg O}_2 (\text{mg PuH}_x)^{-1} \text{ min}^{-1}$, for the final stage shows an Arrhenius dependence ($\ln R = 8.75 - 5050/T$) and an E_a (42 kJ mol^{-1}) consistent with diffusion control of oxygen through a protective PuO_2 film.

In a more recent study of hydride pyrophoricity and catalysis (Haschke and Allen, 2001), the stages of PuH_x oxidation observed in earlier work (Stakebake, 1981a,b) are correlated with chemistry of the oxide layer on the hydride. During heating in vacuum, PuH_x spontaneously reduces the PuO_2 layer to $\alpha\text{-Pu}_2\text{O}_3$, a product that rapidly dissociates O_2 , and transports oxygen to the oxide–hydride interface. The initial linear oxidation rates of PuH_x and $\alpha\text{-Pu}_2\text{O}_3$ -coated PuH_x form a single data set with values ($88 \mu\text{g Pu cm}^{-2} \text{ min}^{-1}$ at 50°C to

21 $\mu\text{g Pu cm}^{-2} \text{ min}^{-1}$ at 360°C, BET area) and yield an E_a of -8 kJ mol^{-1} . Results imply that $\alpha\text{-Pu}_2\text{O}_3$ and PuH_x are equally reactive toward O_2 . A negative E_a is consistent with a decrease in concentration of adsorbed reactant on a catalytic ($E_a = 0$) solid as temperature increases at constant pressure. Oxidation of the Pu_2O_3 surface to PuO_2 competes with reduction of PuO_2 by hydride during the intermediate stage, a process apparently triggered as x in PuH_x approaches 3 and product hydrogen flows out of the solid. The diffusion-controlled final stage is entered as the surface is covered by protective PuO_2 .

The $\text{PuH}_x\text{-O}_2$ reaction is not autothermic, but is controlled by the oxygen pressure, P_{O_2} (Haschke and Allen, 2001). The rate equation is based on data for a range of temperatures because E_a is essentially zero:

$$R \text{ (in g Pu cm}^{-1} \text{ min}^{-1}) = 0.37(P_{\text{O}_2})^2 \text{ (BET area, } P \text{ in bar).}$$

The reason for a squared pressure dependence is unknown. The equation accurately predicts temperature-independent rates and is applied in interpreting hydride pyrophoricity and its dependence on temperature. Oxidation is rapid when the hydride is covered by $\alpha\text{-Pu}_2\text{O}_3$ and is markedly slowed by a layer of PuO_2 . Contrary to expectation, increasing the O_2 pressure does not favor formation of PuO_2 . As with the oxide layer on Pu, high temperatures result in reduction of PuO_2 to $\alpha\text{-Pu}_2\text{O}_3$ on PuH_x instead of PuO_2 formation (see Section 29.3.2). The large increase in the rates of oxidation and heat generation induced by a small increase in P_{O_2} drives up the temperature, promotes transformation of the oxide surface into catalytic $\alpha\text{-Pu}_2\text{O}_3$, and results in continued oxidation at a rate equal to that of freshly prepared PuH_x . E_a for the $\text{PuH}_x\text{-O}_2$ reaction is zero, but pyrophoric oxidation of hydride depends indirectly on temperature as the pressure-dependent reaction heats the solid and maintains the catalytic surface.

Consistent failure of PuH_x to oxidize completely upon exposure to 13 mbar O_2 (Stakebake, 1981b) suggests that this P_{O_2} is below a threshold ignition pressure required for generating heat at a rate sufficient to form Pu_2O_3 and sustain rapid oxidation (Haschke and Allen, 2001). Complete oxidation of hydride within minutes at 0.13 bar O_2 (Stakebake, 1981a) implies that the threshold ignition pressure is 13–130 mbar, a range consistent with spontaneous ignition in air (0.21 bar O_2). The estimated threshold O_2 pressure for ignition of PuH_x is 40 mbar.

(d) Reaction of PuH_x with N_2

A facile $\text{PuH}_x\text{-N}_2$ reaction is implied by the use of hydride as an intermediate in preparing PuN (see Section 29.3.3), but kinetic data are limited. In an early study, nitriding initiated abruptly at 230°C during heating at $2.7^\circ\text{C min}^{-1}$ in 1 bar N_2 , transformed 60% of the PuH_x to PuN within minutes, and continued in a slow stage that approached completion (97%) after several hours (Brown *et al.*, 1955). XRD analysis of PuN products showed the presence of PuO_2 that

may have formed on the PuH_x before nitriding or on the nitride during handling. Effects of surface oxide in preventing reaction at temperatures below 230°C are uncertain.

A microbalance investigation of the $\text{PuH}_x\text{-N}_2$ reaction (Muromura and Ouchi, 1974) shows that rapid initial reactions of PuH_2 and PuH_3 at 282°C and 1 bar N_2 pressure are followed by progressively slower reactions that are about 60% complete after 2 h. Data for the initial stage at $225\text{--}268^\circ\text{C}$ and $10^{-3}\text{--}1$ bar N_2 are evaluated using a model based on rate control by chemisorption of nitrogen or hydrogen. Results indicate that the initial rate is controlled by slow association of product H-atoms at the gas–solid interface, a conclusion that seems inconsistent with measured E_a values of $150\text{--}297\text{ kJ mol}^{-1}$ for the initial stage of reaction.

Subsequent microbalance results for $\text{PuH}_x\text{-N}_2$ at 67 mbar (Stakebake, 1988) are consistent with early observations (Brown *et al.*, 1955). Mass–time data for reaction at 275°C show an initial linear rate ($0.2\text{ mg Pu cm}^{-2}\text{ min}^{-1}$, BET area) stage resulting in 30% reaction, an intermediate stage in which the rate became progressively slower over time, and a slow constant-rate final stage entered after 85% reaction. Linear rates for the slow stage at $270\text{--}445^\circ\text{C}$ ($0.14\text{--}0.37\text{ }\mu\text{g Pu cm}^{-2}\text{ min}^{-1}$, BET area) yield an activation energy of 18 kJ mol^{-1} . Each temperature increase was followed by a brief, but rapid initial reaction. The initial rate at 275°C ($1.6\text{ mg Pu cm}^{-2}\text{ min}^{-1}$) is comparable to that for the $\alpha\text{-Pu}_2\text{O}_3$ -catalyzed $\text{PuH}_x\text{-O}_2$ reaction at 67 mbar.

(e) Reaction of PuH_x with air

Exposure of PuH_x to air at 25°C results in spontaneous reaction of O_2 and N_2 and a thermal spike (Haschke *et al.*, 1998a). PuH_x was exposed to air supplied from a reservoir connected to a reactor. After reaction ceased, the residual gas was 50–75% H_2 plus 25–50% N_2 . Product mole fractions in the solid were 0.80–0.95 PuH_x , 0.03–0.15 PuN , and 0.20–0.5 Pu_2O_3 . N_2 and O_2 were consumed in a (1.6 ± 0.5) ratio (3.71 N_2/O_2 ratio in air) during reaction, showing that temperatures generated by hydride oxidation were sufficient to initiate the $\text{PuH}_x\text{-N}_2$ reaction. Product hydrogen accumulated in the hydride cores of reacting particles until x approached 3 and was thereafter released as H_2 , a product that pressurized the reactor and subsequently prevented access of additional O_2 .

The preceding results show that pyrophoric $\text{PuH}_x\text{-air}$ reaction involves both O_2 and N_2 , but are skewed by an experimental configuration in which accumulation of H_2 prevents continuing access of air (O_2) to the sample. Experience shows that unconfined reaction of hydride in air typically continues to completion and is accompanied by burning of H_2 as a pale flame above the solid. Water may have existed as a transient species in the closed system, but is probably formed in open systems. Unlimited access to air may also result in a secondary reaction in which the Pu_2O_3 and PuN products are oxidized to PuO_2 .

(f) Reaction of PuH_x with H₂O

Reaction of PuH_x with liquid water at 25°C proceeds at a surprisingly slow rate (Haschke, 1995). The proposed reaction is based on simultaneous generation of H₂ and increase in composition of hydride cores of reacting particles until $x+\delta$ approaches 3:

Production of H₂ is observed and XRD data for the product show an increase in hydride composition, but the oxidation product is not identified. Formation of PuOH is assumed by analogy to the reaction of liquid water with Pu metal.

Measurements of the H₂ formation rate show that a moderately rapid reaction occurs during the 0.5 h period after immersion of PuH₂ in 1 M CaCl₂ solution (Haschke, 1995). This initial stage is followed by one in which the rate has a parabolic time dependence, characteristic of a diffusion-controlled reaction. Based on H₂ generation and the above equation, the derived linear rate for the initial stage (0.3 μg Pu cm⁻² min⁻¹, BET area) is 100-fold less than that for corrosion of Pu in 1 M CaCl₂ (Haschke, 1992a).

29.4.2 Oxide reactions**(a) Reactions of α-Pu₂O₃**

Contrary to early reports that describe the bcc sesquioxide as protective and the source of parabolic oxidation kinetics during metal corrosion (Schnizlein and Fischer, 1967; Lindsay *et al.*, 1972), recent studies suggest that α-Pu₂O₃ is highly reactive and catalyzes reactions of Pu with H₂, O₂, and N₂ (Haschke and Allen, 2001). Kinetic data are available for the reaction of sesquioxide with liquid water (Haschke *et al.*, 1983; Haschke, 1992a). During formation of Pu₇O₁₂ at 25°C, α-Pu₂O₃ reacts with H₂O at a slow constant rate of 10 nmol H₂ per g Pu₂O₃ per min or about 2 pg Pu₂O₃ cm⁻² min⁻¹ (BET area) according to the reaction shown in Table 29.2.

(b) Reactions of PuO₂

Reactions of PuO₂ with liquids and gases also depend on surface area, a property that varies substantially depending on the oxide source and preparative conditions (Haschke and Ricketts, 1995). Specific areas of oxides obtained by firing oxygenated precipitates at 400–500°C vary from 10 m² g⁻¹ for nitrate to as much as 60 m² g⁻¹ for oxalate and those from oxidation of Pu are 5–15 m² g⁻¹. Specific areas decrease upon firing above 600°C and consistently fall to 1–5 m² g⁻¹ during calcining at 950°C.

Chemical behavior of plutonium dioxide is altered over broad ranges of temperature and humidity by chemisorption and physisorption of water

(Stakebake and Steward, 1973; Benhamou and Beraud, 1980, Haschke and Ricketts, 1997). Dissociative chemisorption occurs at low humidity by reaction of H_2O with O^{2-} ions to form two OH^- ions that bind strongly to the surface (Haschke and Ricketts, 1997). This reaction occurs at low H_2O concentrations (<300 ppm or <0.3 mbar H_2O) via two first-order steps that each adds one monolayer of hydroxide corresponding to a mass gain of 0.11 mg $\text{H}_2\text{O m}^{-2}$ of oxide surface ($3 \mu\text{mol H}_2\text{O m}^{-2}$) and transforms the surface stoichiometry to $\text{PuO}(\text{OH})_2$. Measurements with $\text{U}_{0.75}\text{PuO}_{0.25}\text{O}_{2-x}$ ($0.02 < x < 0.05$) suggest that the oxide surface is saturated by chemisorbed water at a gas-phase concentration of $10\text{--}20$ ppm H_2O (Woodley and Gibby, 1973). Adsorbate-free (calcined) oxide tenaciously getters water and maintains a low H_2O pressure at 25°C and $10\text{--}15\%$ coverage by the initial hydroxide layer (Haschke *et al.*, 2001b). The chemisorption rate in air at 25°C and 0.3 mbar H_2O (1% relative humidity at 25°C) is approximately $10 \mu\text{mol H}_2\text{O m}^{-2} \text{h}^{-1}$ (Haschke *et al.*, 2001a).

Additional water physisorbs on the $\text{PuO}(\text{OH})_2$ surface of the oxide at progressively slower rates in discrete first-order steps corresponding to layers of molecular H_2O (0.22 mg $\text{H}_2\text{O m}^{-2}$ per layer) as water pressure increases (Haschke and Ricketts, 1997). At 25°C and relative humidities in the $10\text{--}60\%$ range, the equilibrium water concentration, $[\text{H}_2\text{O}]$, is (0.4 ± 0.1) mg $\text{H}_2\text{O m}^{-2}$, corresponding to two OH^- layers plus approximately one H_2O layer. The $[\text{H}_2\text{O}]$ increases sharply above 70% relative humidity and approaches a total of ten layers at saturation. The water content of oxide equilibrated with moist air at a given temperature and relative humidity is readily estimated if the specific surface area of the oxide is known. Although the distribution of water between adsorbed and gaseous states in a closed container depends on specific conditions, more than 99% of available H_2O resides on the oxide surface in a typical storage configuration at $25\text{--}75^\circ\text{C}$ (Haschke *et al.*, 2001a).

Thermal studies show that water desorbs from PuO_2 in two temperature ranges (Stakebake, 1973). Desorption enthalpies derived from kinetic data for removal of water in the $100\text{--}150$ and $300\text{--}350^\circ\text{C}$ ranges are 84 and 285 kJ mol^{-1} , respectively, if reversible adsorption is assumed to be a nonactivated process. Gravimetric data show a third mass loss above 700°C , but that process is not characterized. Adsorption–desorption measurements in a closed system at $25\text{--}260^\circ\text{C}$ indicate that desorption is complete within that temperature range (Paffett *et al.*, 2003b). Desorption enthalpies derived from non-isothermal adsorption data vary from 51 to 44 kJ mol^{-1} depending on adsorbate coverage and are consistent with values for UO_2 and other metal oxides. Further work is needed to resolve the differences between results of these studies and to account for a significant mass loss at $700\text{--}1000^\circ\text{C}$ (Stakebake, 1973).

Slow reaction of PuO_2 with liquid or gaseous water forms PuO_{2+x} and H_2 via a temperature-dependent process (see Section 29.3.2). The rate of H_2 formation (or oxygen accommodation in the dioxide structure) is described by an Arrhenius equation derived from data for gaseous and liquid water at $25\text{--}350^\circ\text{C}$ (Haschke *et al.*, 2000b):

$$\ln R \text{ (mol H}_2 \text{ m}^{-2} \text{ h}^{-1}) = -6.441 - (4706/T) \text{ (BET area).}$$

This reaction also defines R (in mol O m⁻² h⁻¹) for PuO_{2+x} formation by water-catalyzed reaction of O₂. The rate is independent of water concentration at room temperature (Haschke *et al.*, 2001b), but behavior at high temperatures is unknown.

Radiolytic decomposition of adsorbed water by alpha particles from decay of Pu isotopes occurs simultaneously with the formation of PuO_{2+x} and H₂. As with gamma radiolysis of liquid water (Draganić and Draganić, 1971), alpha radiolysis (Christensen, 1998) proceeds with formation of free radicals such as hydroxyl (OH) and atomic hydrogen (H). Association of radicals leads to formation of H₂ and H₂O₂, a product that accumulates in solution and decomposes with the formation of O₂. The radiochemical yield (G_{H_2}) for hydrogen production is 0.45 H₂ per 100 eV of energy absorbed by water for gamma radiation and approximately 1.3 H₂ per 100 eV of energy absorbed by water for alpha particles. If water is irradiated in a closed system, a steady-state pressure of 1–2 atm is established as rates of radiolysis and re-formation of water become equal (Allen *et al.*, 1952). Similar dissociation reactions occur during radiolysis of adsorbed water, but differences are expected because absence of a liquid phase prevents formation and accumulation of products in solution. A review of observations during gamma irradiation of water adsorbed on non-radioactive oxides (Haschke *et al.*, 2001a) shows variable behavior and imbalance in the hydrogen–oxygen inventory, a condition attributed to reaction of gaseous product (usually loss of oxygen) with substrate solids. Radiochemical yields of adsorbed H₂O are reduced by factors of 10³ in some cases and increased by up to 10² in others. Difficulties in balancing the radiolytic inventory and determining the radiolysis rate for H₂O on PuO₂ are likely because radiolytic oxygen is scavenged by PuO_{2+x} formation and because H₂ is independently produced by the oxide–water reaction (Haschke *et al.*, 2001a).

Studies of alpha-particle radiolysis of water by ²⁴⁴Cm in solution show a H₂/O₂ ratio of 1.86 in the product gas (Kalinichenko *et al.*, 1987). Results of companion studies with ²³⁸PuO₂ immersed in water or exposed to steam at 60–140°C (0.2–3.6 bar H₂O pressure) imply that H₂ is the only gaseous product because G_{H_2} values for alpha radiolysis of water (1.05 and 5.8 H₂/100 eV absorbed by liquid and vapor, respectively) are based on measured (total) rates of gas evolution. The chemical fate of oxygen is not addressed. H₂ generation rates measured during exposure of mixed residues containing PuO₂ and MgO, Ca(OH)₂, or CaF₂ to moist air in closed containers at ambient temperature and 90°C are compared with predictions based on the rate of energy release by alpha decay, G_{H_2} , and composition-weighted stopping powers of water in the mixture (Livingston, 1999). On average, observed rates exceed predictions by a factor of 10. Evaluation (Haschke *et al.*, 2001a) of data from tests with only PuO₂ (Livingston, 1999) shows consumption of O₂, formation of N₂, and a temperature-dependent process that is inconsistent with radiolysis.

An estimate of the radiolysis rate ($(9 \pm 4) \text{ pmol H}_2 \text{ m}^{-2} \text{ h}^{-1}$) for oxide exposed to 50% humid air at 25°C (Haschke *et al.*, 2001a) indicates that radiolysis neither accounts for observed H₂ generation rates during exposure of PuO₂ to H₂O nor for a temperature dependence of the rate (Haschke *et al.*, 2000b). Particle-size distribution and self-absorption of alpha energy by the oxide, specific area of the oxide, thickness and alpha particle range of the absorbed water layer, and G_{H_2} for liquid H₂O are included in the derivation. Observed rates exceed estimated values by factors of 10 at 25°C and 10⁵ at 350°C. A rate equation is derived assuming a linear dependence on water concentration and a zero rate in the absence of water:

$$R (\text{pmol H}_2 \text{ m}^{-2} \text{ h}^{-1}) = 0.37 (\text{mol H}_2 (\text{mol H}_2\text{O})^{-1} \text{ h}^{-1}) [\text{H}_2\text{O}] (\mu\text{mol H}_2\text{O m}^{-2}).$$

Observations with CeO₂-H₂O show that G_{H_2} is strongly dependent on [H₂O] if less than—two to three water layers are adsorbed and remains essentially constant if more than three layers are adsorbed (LaVerne and Tandon, 2002). Therefore, proportionality of R and [H₂O] may be limited to water concentrations less than 15 μmol H₂O m⁻².

Exposure of H₂-O₂ mixtures to calcined (water-free) PuO₂ at 25–300°C results in surface-catalyzed combination as H₂O (Haschke *et al.*, 1996, 2001b; Morales, 1998). The spontaneous reaction apparently proceeds by dissociative adsorption of H₂ and O₂ and combination of the atomic species. Behavior at 25°C is consistent with first-order kinetics controlled by the concentration of active sites on the oxide surface and progressive blockage of those sites by chemisorption of product water as OH⁻ (Haschke *et al.*, 2001b), but R is less sensitive to [H₂O] at 100–300°C (Morales, 1998). Combination rates on water-free PuO₂ at 25 and 100–300°C are 30 nmol H₂O m⁻² h⁻¹ and 50 μmol m⁻² h⁻¹ (BET areas), respectively (Haschke *et al.*, 2001a). Adsorption of product H₂O sharply reduces the rate at 25°C, but only causes a 50-fold reduction above 100°C. The combination rate on stainless steel at 25°C (100 nmol H₂O m⁻² h⁻¹, geometric area) is comparable to that for PuO₂ (Haschke *et al.*, 2001a). The combination reactions on both solids compete with radiolytic decomposition of water, but the extent of reaction on the relatively small area of steel in a typical storage configuration is negligible compared to that on calcined oxide ($(3 \pm 2) \text{ m}^2 \text{ g}^{-1}$).

29.4.3 Nitride reactions

Plutonium nitride is readily oxidized to hydrous oxide (PuO₂ · xH₂O) by water and reacts more slowly with oxygen to form dioxide (Brown *et al.*, 1955). The oxidation rate in O₂ is increased by moisture (Cleveland, 1979). Reaction with O₂ in air initiates below 100°C and rapidly goes to completion by 150°C with apparent formation of a hydrous intermediate that decomposes on heating above 800°C (Brown *et al.*, 1955). An effect of residual hydrogen on the reactivity of PuN formed via hydride is suggested by absence of pyrophoric

behavior after the product was heated in vacuum and N₂ at 700°C (Leary *et al.*, 1967). This result is confirmed by a study in which nitride from a PuH_x-N₂ reaction was heated at 700°C in N₂ atmospheres that were repeatedly replaced until H₂ could not be detected (<0.01%) in the static gas (Allen, 2001). The product was unreactive in 1 bar O₂ at temperatures up to 700°C, suggesting that residual hydrogen or moisture formed by hydrogen is involved in promoting oxidation of PuN.

29.5 CORROSION KINETICS OF PLUTONIUM METAL

29.5.1 Reaction of Pu with hydrogen

As with the U-H₂ reaction (Haschke, 1991), hydriding of PuO₂-coated Pu proceeds through several stages that culminate in rapid corrosion of the metal (Haschke *et al.*, 2000a). Pu is inherently coated with oxide unless the surface is prepared in ultra-high vacuum by abrasion/scraping or sputter etching. At room temperature, a variable induction period, during which reaction is not detected, is followed by nucleation and growth of reactive hydride sites that ultimately cover the metal surface and induce the maximum hydriding rate. Kinetic studies are facilitated using Pu samples that are covered by PuH_x before testing (Ogden *et al.*, 1980; Haschke and Allen, 2001). Uncertainty is inherent in rate measurements because variation in *x* of the PuH_x product alters the amount of Pu consumed by a given quantity of H₂. Although PuH₂ is not a distinct phase, use of that hydride composition facilitates evaluation.

Data from pressure–volume–temperature (PVT) in Fig. 29.4 show the dependence of the Pu hydriding rate, *R*, on H₂ pressure between –18 and 300°C (Haschke and Allen, 2001). The ln *R*–ln *P*_{H₂} slopes define the pressure exponents, *n*, of H₂ (see Section 29.2.2). The dependence of *R* on temperature and *P*_{H₂} are described by a general rate equation:

$$R (\text{g Pu cm}^{-2} \text{ min}^{-1}) = 0.0567 \exp(805/T) (3.75 P_{\text{H}_2})^n \text{ (geometric area, } P \text{ in bar)}.$$

The pressure exponent is 1 for *P*_{H₂} less than 0.27 bar and 0.5 for higher pressures. These pressure exponents are consistent with the Langmuir model and control of the rate by the concentration of adsorbed hydrogen at the gas–hydride interface. The progressive decrease in the rate with increasing temperature in Fig. 29.4 gives an *E*_a of –7 kJ mol^{–1}, a result attributed to a decrease in the concentration of adsorbed hydrogen with increasing temperature at constant *P*_{H₂}. The hydriding rate is 1–2 g Pu cm^{–2} min^{–1} or 4–8 mmol H₂ cm^{–2} min^{–1} at 1 bar H₂ (geometric area), a value that is close to the rate (1–3 mmol H₂ cm^{–2} min^{–1}) of the PuH_x-H₂ reaction.

Results for reaction of H₂ with metal powder (0.1–0.3 m^{–2} g^{–1}) from unalloyed Pu (Stakebake, 1992a) and the δ-phase Ga alloy (Stakebake, 1981c) are consistent with findings for massive metal. The pressure exponent is 1 at low

Fig. 29.4 Dependence of $\ln R$ on $\ln P_{H_2}$ for the $Pu-H_2$ reaction at selected temperatures between -18 and $300^\circ C$.

P_{H_2} , but the transition to $n = 1/2$ occurs near 5 mbar H_2 . Activation energies are negative (-0.2 to -0.6 kJ mol^{-1}). The initial linear hydriding rate at $30^\circ C$ and 10.6 mbar H_2 (1.7 $\text{mg Pu cm}^{-2} \text{min}^{-1}$, BET area) is less than calculated for massive Pu (32 $\text{mg cm}^{-2} \text{min}^{-1}$, geometric area) by the above equation. The ratio of the rates implies that the true (BET) area of hydride surface on massive metal is 20 times greater than the geometric area (Haschke and Allen, 2001).

In early hydriding rate measurements, massive metal was attached to heat sinks and the extent of reaction was controlled in an effort to limit thermal excursion and minimize error in the E_a determination. Pressure exponents of 0.6 (Bowersox, 1977) and 0.7 (Ogden *et al.*, 1980) are determined for experimental P_{H_2} ranges spanning the transition pressure from $n = 1$ to 0.5 in Fig. 29.4, but Arrhenius evaluations give positive E_a values of 8 kJ mol^{-1} (Ogden *et al.*, 1980) and 25 kJ mol^{-1} (Bowersox, 1977) inconsistent with negative values obtained without thermal control. A negative activation energy cannot result from auto-thermic effects. Self-heating always drives E_a to more positive values regardless

of its sign and cannot cause E_a to be negative, only less negative. Mass-time data for an extended test at 40°C and 9.0 bar H₂ (Ogden *et al.*, 1980) are inconsistent with a positive E_a . The temperature of the sample and sink rose by about 100°C during the measurement. Although a two-fold rate increase is anticipated if E_a is 8 kJ mol⁻¹ as a result of the temperature increase, microbalance data show a two-fold rate decrease consistent with -8 kJ mol⁻¹.

Kinetics of the Pu-H₂ reaction are altered by the type of oxide on the metal surface (Haschke and Allen, 2001). Induction periods are absent and maximum hydriding rates are observed immediately upon exposure of the metal to H₂ at all temperatures if the PuO₂ layer is reduced to α-Pu₂O₃ by heating to 200°C in vacuum before reaction. Catalytic properties of PuH_x and α-Pu₂O₃ are implied by the rates at which those materials dissociate and transport hydrogen. At room temperature and 1 bar H₂, the corrosion rates of unalloyed and alloyed Pu are about 1.7 g Pu cm⁻² min⁻¹ and correspond to advancement of the reaction front into the metal at about 6 cm h⁻¹, a rate that is unusually rapid for a gas-solid reaction. The rate is essentially independent of temperature, but goes to zero if equilibrium conditions in the Pu-PuH_x two-phase region (Fig. 29.1) are satisfied. As indicated by curve 11 in Fig. 29.5, corrosion of Pu by H₂ at 1 bar ceases at the 850°C equilibrium point (Flotow *et al.*, 1984).

29.5.2 Reaction of Pu with oxygen, water, and air

(a) Overview of kinetic behavior

Plutonium ignites in air and oxidizes via a self-sustaining reaction if the temperature exceeds 500°C or the corrosion rate exceeds 0.07 g Pu cm⁻² min⁻¹, the approximate R required for self-heating of Pu to that autothermic temperature (Haschke and Allen, 2001). The Arrhenius evaluation of Pu corrosion reactions in Fig. 29.5 shows three sets of rate curves. Curves 1-7 show strong temperature dependence characteristic of rate control by diffusion of reactant through a protective PuO₂ layer. Curves 8 and 9 are consistent with onset of self-sustaining oxidation at high temperatures. Reaction becomes self-sustaining when the metal is heated above the ignition temperature, T_i , by an external or internal heat source. The set formed by curves 10-12 are independent of temperature and rates of these catalyzed reactions inherently exceed that required for ignition, regardless of initial temperature. Equations (Haschke *et al.*, 1998a; Haschke and Allen, 2001) for the curves in Fig. 29.5 are given in Table 29.3.

A variety of parameters participate in controlling the corrosion rate of thermally driven processes described by curves 1-6 in Fig. 29.5 (Haschke *et al.*, 1996, 1998a). Reactions in this set are temperature-dependent and exhibit parabolic behavior, implying that rates are controlled by diffusion of reactant through the product layer on the metal (Haschke *et al.*, 2001b). Parabolic kinetics are observed only during the formation of the initial oxide layer at temperatures below 400°C and are typically not encountered during routine

Fig. 29.5 Arrhenius curves for corrosion of unalloyed Pu and δ -phase Ga alloy. Curves 1 and 2 describe the oxidation rates of unalloyed metal and alloy in dry air, respectively. Curves 3–5, and a–d describe oxidation of unalloyed Pu in moist air or water vapor. Curves a, b, c, and d are for 10, 10^2 , 10^3 , and 10^4 ppm H_2O , respectively. Curve 6 describes the oxidation of alloy by water vapor. Curve 7 defines behavior in a region where effects of alloying and water are absent. Curves 8 and 9 describe behavior of static metal in air and of ignited Pu droplets during free fall in air, respectively. Curves 10, 11, and 12 describe catalyzed corrosion of hydride-coated Pu by air, H_2 , and O_2 , respectively. Detailed descriptions of the curves are given in the text and in Tables 29.3 and 29.4.

handling and storage. Rates indicated by curves 1–6 in Fig. 29.5 are for the linear (constant-rate) stage of corrosion maintained by continuous spallation of product and diffusion of reactant through a product layer of constant average thickness. Assessment of behavior in air is facilitated by normalization of data to 0.21 bar oxidant (O_2 or H_2O) pressure.

Influence of parameters other than temperature is shown by effects of moisture and alloying on corrosion rates described by curves 1–6. Therefore, corrosion kinetics of unalloyed and alloyed Pu in dry air, water vapor, and moist air are discussed separately. Attainment of moisture levels at which the corrosion

^d Dry conditions are less than 0.5 ppm H₂O at 1 bar pressure.

^e P_e is the equilibrium pressure of H₂O at T.

^f The value of A has been changed to correct an error (Haschke *et al.*, 1996).

^g The Pu surface is coated with PuH_x or a double layer of α-Pu₂O₃ and PuH_x.

rate of unalloyed Pu in air or oxygen is insensitive to water concentration at low temperatures is difficult. Results of many studies with 'dry' gases appear inaccurate because residual H₂O concentrations exceeded the 0.5 ppm level required to avoid moisture enhancement of corrosion (Haschke *et al.*, 1996).

(b) Dry oxidation of unalloyed and alloyed Pu

Linear oxidation of unalloyed Pu in dry (<0.5 ppm H₂O) air or 0.21 bar O₂ proceeds as described by curve 1 in Fig. 29.5 and Table 29.3 (Haschke *et al.*, 1996, 1998a). Behavior is defined by a single Arrhenius curve for temperatures up to 400°C, implying that the same reaction occurs over that range (Haschke *et al.*, 2001b). Oxidation of Pu in dry air forms PuO₂ (Colmenares, 1984), a product that persists at the gas–solid interface even though the thickness of the α-Pu₂O₃ layer at the product–metal interface increases with increasing temperature. The E_a for oxidation is 75 kJ mol⁻¹ (Haschke *et al.*, 1996), but the temperature dependence for autoreduction at the interface is unknown. The penetration rate by oxidation in dry air at 25°C is about 20 pm h⁻¹.

Control of oxidation by the rate of O²⁻-ion diffusion through the dioxide layer is supported by parabolic kinetics and agreement of E_a values for oxidation and oxygen self-diffusion in nonstoichiometric dioxide (Haschke *et al.*, 1996, 2001b). Dependence of electrical conductivity on P_{O₂}, positron annihilation data for UO₂ (Colmenares, 1984), and close correspondence of the Pu and

U systems suggest that the oxidation is a concerted process in which electrons move toward the gas–solid interface as Pu(v) ions simultaneously migrate toward the product–metal interface. Data suggest that O^{2-} ions form clusters by associating with Pu(v) and move by hopping between octahedral sites in the fluorite structure. Migration of O^{2-} through the oxide layer is driven by the gradient in oxygen concentration between the gas–oxide and oxide–metal interfaces.

Arrhenius results for oxidation of δ -phase Ga alloy in dry air or O_2 are shown by curve 2 in Fig. 29.5 and Table 29.3 (Stakebake and Saba, 1990; Haschke *et al.*, 1998a). The pressure exponent of O_2 varies from near zero to 0.5 (Stakebake and Lewis, 1988). The activation energy (79 kJ mol^{-1}) agrees with that (75 kJ mol^{-1}) for unalloyed Pu, suggesting that the oxidation mechanism is essentially identical for the two metals. The only obvious difference is that oxidation of the alloy is a factor of 70 slower than that of unalloyed Pu. Because the rate is apparently controlled by diffusion of oxygen through the oxide layer in both cases, the slower oxidation rate of the alloy apparently results from a reduced rate of oxygen transport through PuO_2 formed by that metal. The chemical fate of gallium during oxidation of the alloy is uncertain. Ga may occupy octahedral anion sites in the PuO_2 structure and slow diffusion of oxygen or reside on cation sites and restrict the flow of electrons to the surface.

In addition to the parabolic and linear stages of reaction, a second linear stage appears after 1–2 days during oxidation of alloyed Pu at $275\text{--}300^\circ\text{C}$ (Stakebake, 1986; Stakebake and Lewis, 1988). A similar rapid third stage is observed for unalloyed Pu (Stakebake, 1992b). This more rapid corrosion results in 1.5- to three-fold rate increases and is attributed to the formation of cracks in the adherent surface layer of oxide.

(c) Oxidation of unalloyed and alloyed Pu by water vapor

As shown by curves 3–5 in Fig. 29.5, the corrosion rate of unalloyed Pu in water vapor at temperatures below 200°C is more rapid than that in dry air (Haschke *et al.*, 1996, 1998a; Haschke and Allen, 2001). Curves 3 and 4 differ slightly because P_{H_2O} is fixed at 0.21 bar above 61°C and equals the value for liquid–gas equilibrium at lower temperatures. As shown by curve 5, the progressive decrease in R between 110 and 200°C is consistent with a mechanism change in which effects of moisture enhancement are lost (Haschke and Allen, 2001). At temperatures above 200°C , the corrosion rate in water at 0.21 bar is indistinguishable from that in dry air. Moisture enhancement of the Pu corrosion rate is confined to the envelope bounded by curves 1, 3, and 5. Relative to dry oxidation, R is increased by 10^2 at room temperature and by 10^4 at 100°C .

Kinetic data show that the corrosion rate of unalloyed Pu by water depends on temperature and is proportional to $(P_{H_2O})^{1/2}$ (Haschke *et al.*, 1996). As shown by data in Table 29.4, experimental E_a values are a linear function of $\ln P_{H_2O}$. The systematic set of Arrhenius equations derived from these data

Table 29.4 Arrhenius equations^a for reaction of unalloyed Pu with water vapor at selected pressures or with air at 1 bar pressure and the corresponding partial pressures of water (Haschke *et al.*, 1996).^b

$P_{\text{H}_2\text{O}}$ (bar)	H_2O concentration (ppm)	E_a (kJ mol ⁻¹)	A	B
4.7×10^{-7}	0.46	75	8.90	9050
1×10^{-6}	1	79	10.72	9480
1×10^{-5}	10	89	16.16	10760
1×10^{-4}	10^2	100	21.58	12030
1×10^{-3}	10^3	111	27.29	13310
1×10^{-2}	10^4	121	32.43	14580
0.1	10^5	132	37.89	15850
1	10^6 , $(P_{\text{H}_2\text{O}})_e$ ^c	142	42.76	17130

^a The form of the Arrhenius equations is $\ln R$ (g Pu cm⁻² min⁻¹) = $A - B/T$ (T in K, geometric area of Pu). Note that rate units are mg O cm⁻² min⁻¹ in the original report, but are reported here as g Pu cm⁻² min⁻¹ to facilitate comparison with data in Table 29.3.

^b Each equation is valid for T between 383 K and the point at which $P_{\text{H}_2\text{O}}$ equals the equilibrium pressure $(P_{\text{H}_2\text{O}})_e$.

^c The maximum $P_{\text{H}_2\text{O}}$ at each T is $(P_{\text{H}_2\text{O}})_e$ below 373 K and equals 1 bar at higher temperatures.

describes the dependence of R on T within the envelope. Curves a, b, c, and d in Fig. 29.5 indicate behavior at 0.01, 0.1, 1, and 10 mbar H₂O, respectively. Rate equations for any water concentration within the envelope are readily derived by interpolation of equations in Table 29.4. Values in the region of decreasing rates between 110 and 200°C may be estimated using curves in the figure.

Although formation of PuO₂ and PuH₂ is reported in early studies of the Pu–H₂O reaction, PuO₂ and H₂ are the only detectable products below 100°C (Stakebake, 1971; Colmenares, 1984). Because production of hydride is thermodynamically favorable in the presence of metal, formation of H₂ implies that hydrogen is not readily transported through the oxide product layer at low temperatures (Haschke *et al.*, 2001b). Increasingly larger amounts of hydrogen are apparently transported with increasing temperature, but the observed product fraction of about 0.15 PuH_x after extended reaction of H₂O at 250°C (Stakebake *et al.*, 1993) is substantially less than the 0.67 fraction expected for complete reaction of hydrogen. As described in Section 29.5.2(d), stoichiometric amounts of PuH_x form at all temperatures via a secondary reaction if excess metal and H₂O are confined in a closed system for an extended period.

The oxide product of the Pu–H₂O reaction is chemically identical to that formed by dry O₂ and kinetics are parabolic, implying diffusion control of O²⁻ transport through an oxide layer (Haschke *et al.*, 2001b). The rapid oxidation rate (curve 3) relative to that by dry air/O₂ (curve 1) is attributed to the combined effect of a high concentration of chemisorbed OH⁻ at the gas–solid

interface, to facilitate formation of O^{2-} by interaction of OH^- ions with electrons, and the resulting increase in oxide concentration that produced PuO_{2+x} at the surface (Stakebake *et al.*, 1993). The oxidation rate is enhanced by H_2O because the steady-state oxygen gradient across the constant thickness oxide layer is larger than with dry oxygen. Whereas O^{2-} is formed by transferring one electron to OH^- , the probability of transferring two electrons to dissociatively adsorbed O atoms is low and results in slow oxidation. Enhancement of the Pu oxidation rate by H_2O is attributed to the relatively rapid rates of forming oxide ions from hydroxide ions at the gas–oxide interface. Closure of the rate–temperature envelope (curve 5) is consistent with progressive desorption of water at 110–200°C.

Comparison of curves 6 and 2 in Fig. 29.5 shows the oxidation rate of δ -phase Ga alloy in 0.21 bar water vapor is about a factor of 10 faster than in dry air (Stakebake and Saba, 1990; Haschke *et al.*, 1996). Kinetics of the alloy–water reaction are parabolic and the linear stage is followed by a third stage. At 305°C, the third-stage rate progressively increases by 100 fold and results in complete reaction of 1-mm-thick unalloyed Pu over a 10 h period (Stakebake, 1992b). At that temperature and 20 mbar H_2O , the maximum rate is about 0.01 g Pu $cm^{-2} min^{-1}$ (geometric area). The activation energy (65 kJ mol^{-1}) and the pressure exponent ($n = 0.15–0.23$) of the linear stage are similar to those for oxidation in dry conditions, but E_a is low (11 kJ mol^{-1}) and $n = 1$ for the third stage. Behavior parallels that encountered with hydride-catalyzed oxidation of metal by air (see Section 29.4.1b), suggesting that more rapid diffusion of hydrogen through the oxide layer at elevated temperatures results in the accumulation of hydride at the product–metal interface and catalytic enhancement of reaction by α - Pu_2O_3 and PuH_x layers (Haschke and Allen, 2001). Formation of cracks in the oxide product should enhance this process.

Mixtures of oxide and hydride are formed during reaction of Pu skulls and turnings with flowing mixtures of 25% steam and 75% Ar at 400–800°C (Smith, 1960). After initiation by external heating, reaction becomes self-sustaining and is controlled by adjusting the steam–argon ratio at 1 bar total pressure. The reported corrosion rate of 250 g Pu h^{-1} and the approximate specific area (10 $cm^2 g^{-1}$) of turnings (Martz *et al.*, 1994) yield an area-normalized value of 0.4 g Pu $cm^{-2} min^{-1}$ (geometric area). Prediction of the third-stage rate at 0.25 bar H_2O pressure using the rate based on data for at 305°C (Stakebake, 1992b) and first-order dependence on P_{H_2O} (Stakebake and Saba, 1990) yields 0.1 g Pu $cm^{-2} min^{-1}$. Similarity of the rates suggests that the self-sustaining process corresponds to the third stage of the Pu– H_2O reaction, that E_a is zero, and that rate is controlled by P_{H_2O} after a hydride layer is formed at the product–metal interface. As observed during oxidation of PuH_x , a protective PuO_2 layer apparently forms unless the water pressure, heat-generation rate, and resulting temperature are adequate to maintain an α - Pu_2O_3 surface that catalyzes the reactions of H_2 and O_2 .

(d) Oxidation of unalloyed Pu by moist air

At a given water pressure and temperatures less than 110°C, the corrosion rate of unalloyed Pu in moist air is more rapid than in dry air and indistinguishable from that observed during oxidation in water vapor at corresponding conditions (Haschke *et al.*, 1996). The pressure exponent for H₂O is 0.5; activation energies and Arrhenius equations vary with humidity as defined by data for water vapor in Table 29.4. Curves a, b, c, and d in Fig. 29.5 indicate corrosion behavior in 1 bar air at 10, 100, 10³, and 10⁴ ppm H₂O. The effect of 1 ppm water is clearly evident and reliability of many kinetic studies at 'dry' conditions appears doubtful.

Although corrosion kinetics in moist air and water vapor are indistinguishable, the chemistry of moisture-enhanced oxidation in moist air below 110°C is different from that for water vapor because O₂ is consumed and H₂ is not produced. Failure to observe H₂ has apparently resulted in proposal of various mechanisms to account for moisture enhancement of corrosion in air. As discussed in a review of proposed mechanisms (Haschke *et al.*, 2001b), two primary explanations are suggested: (1) disruption of the protective oxide layer by formation of hydride or hydrogen at the product-metal interface and (2) rapid transport of oxygen through the oxide as OH⁻ or H₂O. The validity of such mechanisms is questioned because formation of PuO₂ as the only product at low temperatures requires that product H either form PuH_x or return to the gas-solid interface and re-form H₂O. Because hydride is not observed and decomposition back to metal and hydrogen is prevented by thermodynamic stability of PuH_x, mechanisms involving migration of hydrogen or hydrogen-containing species through the oxide layer appear unlikely.

Modification of the mechanisms for oxidation in dry air and water vapor (see Sections 29.5.2(b) and 29.5.2(c)) accounts for all observations with moist air, including appearance of linear kinetics and absence of physical disruption of the oxide layer (Haschke *et al.*, 2001b). As shown by the following sequence of reactions, chemical behavior is described by a water-catalyzed cycle like that for formation of PuO_{2+x} in air (Haschke *et al.*, 2000b):

Adsorbed water reacts at the relatively rapid rate of Pu-H₂O reaction. In the presence of O₂, product H-atoms combine with dissociative adsorbed oxygen to re-form H₂O instead of associating as H₂. The net reaction accounts for the disappearance of O₂, formation of PuO₂, and absence of PuH_x or H₂ products. As with reaction of Pu with water vapor, adsorption of H₂O and formation of PuO_{2+x} at the gas-solid interface apparently create an oxygen gradient that

enhances corrosion by driving more rapid transport of oxide ions through the PuO_2 layer.

Mixtures of oxide and hydride are formed by reaction of Pu (and U) with water vapor or moist air at low temperatures if three conditions are satisfied: the system is closed, the time period is sufficiently long, and excess metal is present. In moist air, O_2 is first consumed by the above cycle and H_2O then reacts via the second step to form additional oxide and H_2 (Haschke *et al.*, 2001b). Oxide is formed at equal rates during those reactions. If the system remains closed, H_2 produced by the second step reacts with available Pu (U) to form hydride after H_2O is depleted. Hydriding of Pu is facile if the oxide surface on the metal is transformed to $\alpha\text{-Pu}_2\text{O}_3$ by autoreduction.

(e) Thermal ignition and self-sustained oxidation of Pu

As shown by curves 1, 2, and 6 in Fig. 29.5, all effects of water vapor and alloying cease abruptly near 400°C (Haschke *et al.*, 1996; Haschke and Allen, 2001). The origin of the rate decrease for unalloyed Pu and of the convergence of Arrhenius curves for all metal forms is uncertain. A reasonable suggestion consistent with the sharpness of the step is the stoichiometry-dependent transition of $\text{PuO}_{2-\delta}$ from n-type to p-type semiconduction (Stakebake and Lewis, 1988). The ensuing rate increase indicated by curve 7 leads to self-sustained oxidation reactions defined by curves 8 and 9.

A sharp increase in corrosion rate at $400\text{--}500^\circ\text{C}$ is shown by measurements with the Ga alloy in 0.67 bar air (Stakebake and Lewis, 1988). High E_a values ($205\text{--}226\text{ kJ mol}^{-1}$) are observed during both the second and third stages of reaction. As indicated by the average oxide thickness at which kinetic behavior deviates from parabolic behavior, the PuO_2 diffusion barrier progressively decreases in thickness over the $400\text{--}450^\circ\text{C}$ range and is not discernable at higher temperatures. Behavior implies that the rate of sesquioxide formation by the Pu– PuO_2 reaction at the product–metal interface approaches and exceeds that for dioxide formation at the gas–solid interface as temperature increases (Haschke and Allen, 2001). The proposed transformation of surface oxide to $\alpha\text{-Pu}_2\text{O}_3$ near 500°C is consistent with the onset of self-sustained corrosion in air at $(500 \pm 25)^\circ\text{C}$ (Martz *et al.*, 1994). The high E_a (298 kJ mol^{-1}) for curve 7 (Fig. 29.5 and Table 29.3), which is based on well-defined rates at 400 and 500°C (Haschke *et al.*, 1998a), agrees with measured results and reflects the change from a protective to a catalytic surface.

Ignition and onset of self-sustained oxidation of unalloyed and alloyed Pu at 500°C are shown by results of several studies cited in a review of plutonium pyrophoricity (Martz *et al.*, 1994). If determined under conditions of dynamic heating, the ignition temperature, T_i , is correlated with geometric specific area, S , of the metal as shown in Fig. 29.6. Whereas Pu powder, chips, turnings ignite at $(150 \pm 50)^\circ\text{C}$, foil and bulk metal with thicknesses greater than 0.2 mm ignite at $(500 \pm 25)^\circ\text{C}$. As outlined in the preceding paragraph, T_i apparently corresponds

Fig. 29.6 Correlation of reported ignition temperatures, T_i , for Pu and U with specific surface area, S , of the metal.

to the temperature at which autoreduction transforms the oxide layer to α - Pu_2O_3 , but low-temperature ignition of powder and turnings seems inconsistent with that interpretation. Appearance of large pre-ignition exotherms at 200–300°C during studies with bulk metal samples (Pitts, 1968; Schnizlein and Fischer, 1968) suggests that substantial amounts of heat are generated by a rapid chemical reaction at the Pu surface. If a fixed amount of heat is produced per unit area of metal, the self-heating effect is much larger for powders and turnings with high specific area than for massive pieces of Pu. A likely exothermic source is rapid re-oxidation of the Pu_2O_3 layer at the oxide–metal interface. A thermal model based on this concept and retention of all heat by the metal and reaction products predicts ΔT for rapid reoxidation of the Pu_2O_3 layer (5 μm thick) formed in the oxide–metal interface at 150°C (Martz *et al.*, 1994). ΔT values equaling or exceeding the 350° increment required to reach 500°C are predicted for spherical Pu particles with diameters less than 0.25 mm and foils

with thicknesses less than 0.088 mm, agreeing with the observed specific area for transition from $T_i = 150^\circ\text{C}$ to $T_i = 500^\circ\text{C}$ in Fig. 29.6.

The thermal model for low-temperature ignition (Martz *et al.*, 1994) accounts for unanticipated observation of lower T_i values in air than in 1 bar O_2 (Schnizlein and Fischer, 1968). Although conventional logic suggests that foils and powders should oxidize more readily in oxygen than in air, an increase in P_{O_2} favors formation of protective PuO_2 while suppressing Pu_2O_3 formation and onset of ignition. This explanation seems to contradict the conclusion that increasing P_{O_2} promotes Pu_2O_3 formation during oxidation of PuH_x (see Section 29.4.1(b)) and PuH_x -coated Pu (see Section 29.5.2(f)), but differences in the dependence of rate on P_{O_2} must be considered. Rates of reaction and heat production are proportional to $(P_{\text{O}_2})^n$ with $n = 2$ for the $\text{PuH}_x\text{-O}_2$ reaction and with $0 < n < 0.5$ for the Pu-O_2 reaction (see Section 29.5.2(b)). If PuH_x is present, increasing P_{O_2} from 0.2 to 1 bar increases the rate of heat production by a factor of 25. In the absence of PuH_x , the resulting rate change is less than two-fold.

Effects of other counter-intuitive observations (Pitts, 1968) are also consistent with Pu_2O_3 formation at the ignition point. T_i values for Pu powder (100–250 μm diameter) are 392, 189, and 152°C for 0.03, 0.12, and 0.60 g specimens, respectively. The steady-state O_2 concentration within the porosity of a powder bed decreases with increasing sample size because the area of reactive surface is larger and oxygen diffusion into the powder is increasingly restricted. Low P_{O_2} in the bed promotes formation of catalytic $\alpha\text{-Pu}_2\text{O}_3$ and reduces T_i . Similar decreases in T_i of foil (0.06 mm thick) after folding and compressing are probably not due to stress in the metal, but to fracture of the PuO_2 layer during deformation and to reduction of the O_2 concentration within folds of the sample. A decrease in T_i with increasing extent of surface oxidation before testing is consistent with formation of a thicker Pu_2O_3 layer and a larger ΔT during reoxidation (Martz *et al.*, 1994).

The 500°C ignition point of Pu is observed under dynamic conditions in which heat is supplied at a rate that causes a temperature increase in excess of $10^\circ\text{C min}^{-1}$ (Pitts, 1968; Schnizlein and Fischer, 1968; Musgrave, 1971). Studies show that T_i of massive Pu is progressively decreased by reducing the heating rate and reaches 355°C at about $0.1^\circ\text{C min}^{-1}$ (Pitts, 1968). During constant-temperature experiments, samples ignited after 0.5 h at 400°C and after 3 h at 375°C , but oxidized completely without igniting at 350°C . Results are consistent with thermal calculations indicating that the static ignition point of massive Pu is near 300°C , the temperature at which the rates of heat generation by the Pu oxidation in air and heat loss from the metal surface are equal (Haschke *et al.*, 2000c). Autothermic behavior is possible above 300°C , but experiments suggest that static ignition is likely to occur only at above 350°C .

As indicated by curve 8 in Fig. 29.5, self-sustained oxidation of Pu in static air is independent of temperatures above 500°C (Haschke and Martz, 1998b). The average rate at $500\text{--}1000^\circ\text{C}$ is $(0.14 \pm 0.07) \text{ g Pu cm}^{-2} \text{ min}^{-1}$, corresponding to a

linear corrosion rate of about 5 mm Pu per hour. E_a for the process (9.6 ± 6.3 kJ mol⁻¹) is effectively zero, but the dependence on P_{O_2} is unknown. The zero E_a is attributed to the formation of an O₂-depleted boundary layer of unreactive N₂ that controls the oxidation rate by limiting the O₂ flux to the metal surface, causing the burning metal to glow with a steady charcoal-like orange color during reaction (Haschke *et al.*, 2000a). However, analogy to results for other reactions involving catalytic α -Pu₂O₃ (Haschke and Allen, 2001) suggests that the rate might be invariant because E_a is zero and P_{O_2} of air is constant.

Curve 9 in Fig. 29.5 shows the Arrhenius relationship derived for dynamic Pu in air after ignition (Martz and Haschke, 1998). The kinetic assessment is based on studies in which laser-ignited metal particles (0.07–0.6 mg) incandescenced with increasing brightness and ultimately ‘exploded’ during free fall in air (Nelson, 1980). The time in free fall before explosion increased with increasing particle mass. Vaporization and oxidation of residual Pu during the nonviolent explosions produced hollow oxide spherules with one or more vent holes plus an aerosol that accounted for up to 77% of the Pu. Conceptually, oxide-coated metal spheres form upon melting of the Pu at 640°C and react at an increasing rate during free fall because an O₂-depleted layer cannot form (Martz and Haschke, 1998). Progressive heating increases the particle temperature, melts the oxide coat at 2300–2400°C, and results in venting of residual metal as vapor above the 3230°C boiling point of Pu. The ‘explosion’ results from rapid oxidation of vented Pu vapor in air.

A quantitative thermal model based on the above concept includes correction for thermal losses by the falling particle and fitting of the activation energy (Martz and Haschke, 1998). The model accurately predicts time intervals to explosion and fractions of aerosolized Pu as a function of Pu particle size. The effective E_a (40 kJ mol⁻¹) for reaction of ignited Pu in free fall suggests a temperature-dependent process that is evident for dynamic conditions in which the N₂ boundary layer is swept away. However, self-sustained oxidation of α -Pu₂O₃-coated PuH_x by O₂ (see Section 29.4.1(b)) and of Pu by H₂O (see Section 29.5.2(c)) has zero activation energy. Because α -Pu₂O₃-coated Pu may behave in a similar way, the apparent E_a might be a consequence of P_{O_2} dependence and the increasing O₂ impingement rate as the particle accelerates during free fall.

Ignition studies with samples of Pu powder are relevant to anecdotal reports that kilogram-sized pieces (Martz *et al.*, 1994), as well as chips and turnings (Stakebake, 1992c), spontaneously ignite in air at room temperature. Specimens of Pu powder (50–100 μ m size) used in ignition studies were prepared by filing metal and sieving the fines in dried (200–700 ppm H₂O) air (Musgrave, 1971). If fine Pu particles were pyrophoric, they would ignite during this preparation. The filings apparently oxidized slowly in air at room temperature and ignited only upon heating to 175–200°C, suggesting that other reactive materials such as α -Pu₂O₃ and PuH_x participate in initiation of self-sustained reactions of both finely divided and massive metal at room temperature (see Section 29.8.4b).

(f) Catalyzed ignition and self-sustained reaction of Pu

Involvement of reactive materials in initiating self-sustained oxidation of Pu is supported by results of kinetic studies with Ga alloy coated with PuH_x or a double layer of α-Pu₂O₃ and PuH_x (Haschke *et al.*, 1998a; Haschke and Allen, 2001). Oxidation of a 1.5 mm thick Pu sample coated with the double layer was complete in less than 1 s and produced gas-phase temperatures in excess of 1000°C after exposure to O₂ at a median pressure of 3.2 bar (Haschke *et al.*, 2000a). The solid product expanded in the shape of the Pu sample during reaction and consisted of a PuH_x core surrounded by a thick Pu₂O₃ layer. Product hydrogen was accommodated as PuH_x during advancement of oxidation into the metal and was not detectable in the gas phase after reaction. As with the PuH_x-O₂ reaction, oxidation of hydride-coated metal has zero activation energy, a property that allows the dependence of rate on P_{O₂} to be evaluated without regard for the temperature.

Rate data for oxidation of Pu coated with the α-Pu₂O₃-PuH_x double layer are consistent with those for reaction of O₂ with PuH_x and α-Pu₂O₃-coated PuH_x (Haschke and Allen, 2001). If the factor of 20 between geometric and BET areas of the metal is included, evaluation shows that the oxidation rate of hydride-coated Pu with O₂ is proportional to P_{O₂} squared as indicated by the following equation.

$$R \text{ (in g Pu cm}^{-2} \text{ min}^{-1}) = 7.4(P_{\text{O}_2})^2 \text{ (geometric area, } P \text{ in bar).}$$

The rate in 1 bar O₂ is indicated by curve 12 in Fig. 29.5. Hydride-catalyzed oxidation is apparently independent of alloying and penetrates the metal at more than 25 cm h⁻¹ at 1 bar O₂ and by almost 3 m h⁻¹ at 3 bar O₂, a value corresponding to the interfacial hydriding rate expected for the metal-hydrogen reaction at 1 kbar H₂. Rapid oxidation of Pu is attributed to a two-part catalytic process in which α-Pu₂O₃ dissociatively adsorbs and transports oxygen to the oxide-hydride interface and PuH_x transports product hydrogen to the hydride-metal interface. Transport of anions in the fixed fcc Pu lattice of product compounds and formation of PuH_x at the product-metal interface are extremely rapid. Zero activation energy and the dependence of R on P_{O₂} imply that the corrosion rate is controlled by dissociative adsorption of O₂.

Exposure of PuH_x-coated Pu or PuOH-coated Pu to air at room temperature results in rapid corrosion that parallels behavior of the PuH_x-air reaction (see Section 29.4.1c) and indiscriminately consumes N₂ and O₂ at the 3.7:1 ratio of air (Haschke *et al.*, 1998a; Haschke and Allen, 2001). Stoichiometry data show that reaction is described by formation of PuN:Pu₂O₃ in a 5.57:1 ratio plus PuH_x with x near 3 and consumes 1.86 moles of Pu per mol of air. The solid product may be a mixture of nitride and sesquioxide or contain a NaCl-related oxide nitride, PuN_{1-ν}O_ν, having a maximum ν of 0.13 (Jain and

Ganguly, 1993). Reaction continues until all Pu is consumed and forms solids with PuH_x cores similar to those observed during reaction of O₂. H₂ is produced if spalled hydride powder is present (Haschke *et al.*, 1998a). Reaction of PuOH-coated metal apparently proceeds through an initial stage in which the surface layer reacts with metal to form α-Pu₂O₃ and PuH_x (Haschke and Allen, 2001).

Kinetic data for substantial ranges of air pressure, P_a , and temperature show that the corrosion rate of Pu coated by the α-Pu₂O₃-PuH_x double layer is independent of temperature and proportional to P_a squared (Haschke and Allen, 2001).

$$R \text{ (in g Pu cm}^{-2} \text{ min}^{-1}\text{)} = 1.72(P_a)^2 \text{ (geometric area, } P_a \text{ in bar).}$$

Behavior is indicated by curve 11 in Fig. 29.5. Fortuitously, the corrosion rate in 1 bar air is coincident with that for the Pu-H₂ reaction at 1 bar pressure (see Section 29.5.1) and advances into the metal at about 6 cm h⁻¹. Dissociation and transport of nitrogen and oxygen are catalyzed by the PuN-α-Pu₂O₃ corrosion product covering the PuH_x layer. Involvement of PuH_x in catalyzing the Pu-N₂ reaction is evident because N₂ does not react with Pu₂O₃-coated Pu following thermal ignition (see Section 29.5.2(e)). Reactions of PuH_x-coated Pu and PuH_x in air are similar and suggest that involvement of N₂ is contingent on generation of sufficient heat by the initial PuH_x-O₂ reaction to form Pu₂O₃ and to initiate the PuH_x-N₂ reaction. Both the amount and partial pressure of O₂ are important factors in hydride-catalyzed ignition of self-sustained corrosion in air.

The importance of O₂ in initiating and sustaining catalyzed corrosion of Pu in air is shown by derivation of the rate equation for reaction in air from that for oxidation of PuH_x in O₂ (Haschke and Allen, 2001). That relationship is obtained by assuming that the oxidation kinetics of hydride (see Section 29.4.1(c)) and hydride-coated plutonium by O₂ are identical. If reaction of N₂ is driven by the thermal effect of O₂ reaction, the squared dependence of R on P_a arises only from the partial pressure of O₂, while the pressure exponent for N₂ is zero. The rate equation for air is derived from that for oxidation in O₂ by including the metal consumption ratio (5.57:1) for indiscriminate reaction of air and by substituting 0.21 P_a for P_{O_2} .

$$R \text{ (in g Pu cm}^{-2} \text{ min}^{-1}\text{)} = 1.8(P_a)^2 \text{ (geometric area, } P_a \text{ in bar).}$$

Agreement of this derived equation with the experiment result presented above supports the conclusion that the kinetics the PuH_x-air and hydride-catalyzed Pu-air reactions are controlled by the O₂ partial pressure. As with the PuH_x-O₂ reaction, oxygen pressures below a threshold value have an insufficient heat generation rate for maintaining a catalytic α-Pu₂O₃ surface and result in the formation of a protective PuO₂ layer.

(g) Salt-catalyzed corrosion of Pu in liquid water

Formation of PuOH by reaction of Pu with water is strongly dependent on the anion concentration, [X], in solution (Haschke, 1992a). Data for [X] in the 10^{-7} ([OH⁻] in distilled H₂O) to 2 M ([Cl⁻] in CaCl₂ solution) at 25°C (Haschke, 1995) show that $\ln R$ is a linear function of $\ln[X]$ as described by the dependence of corrosion rate, R , on salt concentration in moles per liter.

$$R \text{ (in g Pu cm}^{-2} \text{ h}^{-1}\text{)} = 0.0073[X]^{0.43} \text{ (geometric area).}$$

Measured corrosion rates in distilled water, typical tap water, and synthetic seawater are 7×10^{-3} , 0.52, and 6.3 mg Pu cm⁻² h⁻¹, respectively. If a 1 mm thick piece of Pu is submerged in seawater at room temperature, corrosion on both surfaces results in transformation to PuOH powder within 5–6 days. The dependence of R on salt concentration suggests that anions catalyze the reaction by facilitating electron transfer at the surface.

Data indicate that the corrosion rate in water is sensitive to pH and temperature (Haschke, 1995). The corrosion rate at pH 10 is 10^4 slower than at pH 7 and freshly burnished metal is untarnished after 3 weeks in solution at pH 13.7. Relative to the corrosion rate in 1 M CaCl₂ solution, the 50-fold more rapid rates in 1 M FeCl₃ and NiCl₂ solutions are attributed to H⁺ formation by cation hydrolysis. Evaluation of limited data gives an E_a of 25 kJ mol⁻¹ for corrosion in near-neutral solutions.

29.5.3 Reaction of Pu with steel

Molten plutonium aggressively dissolves all types of iron and steel (Haschke and Martz, 1998a). If excess Pu is present, corrosion penetrates a 1.5 mm thick stainless steel barrier within a few minutes at 700–900°C. Although a eutectic near the Pu₆Fe composition melts at 410°C, the Pu–Fe reaction is slow below the 640°C melting point of Pu because reaction proceeds by inter-diffusion of the solid metals. The intimate contact required for that process is further hindered by the presence of oxide layers on the metals.

The extent of corrosion at temperatures below the 1230°C melting point of PuFe₂ is limited by the equilibrium composition of the Pu-rich liquid coexisting with that intermetallic compound (Ellinger *et al.*, 1968). At 1000°C, the iron-saturated solution contains 33 at% Fe, the composition formed by reaction of 6.8 g Pu with a 1 cm² area of 1 mm thick steel. Complete dissolution of Fe is expected at 1000°C if the thickness-normalized ratio of g Pu per cm² of steel surface approaches or exceeds 6.8 at any point of contact. The corrosion rate decreases as the molar ratio of Fe:Pu exceeds 1:2 (33 at% Fe) and reaction of residual Fe is slowed by formation of a protective PuFe₂ layer. The likelihood of penetration is low if the Fe:Pu ratio exceeds 2:1, but failure of a steel container is possible at high Fe:Pu ratios if corrosion of the steel is localized. In typical storage configurations, the Fe:Pu ratio is low and rapid loss of containment is likely if the temperature exceeds 700°C.

29.6 CORROSION KINETICS OF URANIUM COMPOUNDS AND URANIUM METAL

29.6.1 Reaction of UO_2 with water

Formation of higher-oxide layers on the surface of UO_2 during exposure to water and aqueous solutions in the absence of O_2 at 130–200°C (Matzke and Turos, 1991) implies that H_2 is produced by chemical reaction. The kinetics in pH 10 solution are parabolic over the 170–200°C range as indicated by proportionality of the product layer thickness (τ in nm) to the square root of reaction time (t in hours) at constant temperature: $\tau = kt^{1/2}$. Arrhenius evaluation of published data shows that $2\ln k (\text{nm h}^{-0.5}) = 31.75 - (10100/T)$ and that E_a (84 kJ mol⁻¹) is consistent with self-diffusion of oxygen in the oxide. If the product layer is U_3O_7 , each nm of oxide thickness formed by reaction of H_2O corresponds to generation of 1.4 nmol H_2 per cm² of oxide (BET area).

The corrosion rate and the mechanism of the UO_2 – H_2O reaction are sensitive to solution pH and temperature (Matzke and Turos, 1991). The rate is apparently not controlled by diffusion below 170°C or in neutral solutions because the layer growth is linear with time at those conditions. Although kinetic data are not reported for the linear regime, reaction apparently proceeded with formation of higher oxide and H_2 over a broad parametric range. Consequences of the UO_2 – H_2O reaction during storage of uranium oxide merit consideration and further evaluation even though thermodynamic data indicate that the process is not favorable.

29.6.2 Reaction of U with hydrogen

Kinetics of the U– H_2 reaction are outlined in earlier reviews describing quantitative rate data and models for hydriding are proposed (Haschke, 1991; Ward and Haschke, 1994). Hydriding of oxide-coated U proceeds sequentially through induction, nucleation, and acceleration stages as localized hydride sites initiate and grow. Under certain conditions, a parabolic stage appears in the window bounded by complete surface coverage by UH_3 and onset of the final linear (constant-rate) stage. As with Pu, nucleation of hydride sites on U is slowed by oxide on the metal surface and preferential site growth implies that hydriding is promoted by UH_3 . Appearance of a parabolic stage indicates the rate is controlled by diffusion of hydrogen through a UH_3 layer and that the hydriding mechanisms of U and Pu differ.

Adequate kinetic data are available only for the terminal constant-rate stage of hydriding with a fully active surface covered by UH_3 . The $\ln R - \ln P_{\text{H}_2}$ isotherms in Fig. 29.7 derived (Ward and Haschke, 1994) from measurements at low (10^{-7} –0.1 bar) (Powell *et al.*, 1991) and high (0.01–50 bar) (Block and Mintz, 1981) H_2 pressures show that the area-normalized rate during the linear stage of the U– H_2 reaction depends on both T and P_{H_2} as described by $R = k \exp(-E_a/R^*T)(P_{\text{H}_2})^n$. Three regions with distinctly different pressure

Fig. 29.7 Dependence of $\ln R$ on $\ln P_{H_2}$ for the $U-H_2$ reaction at selected temperatures between -10 and 380°C .

exponents consistent with Langmuir adsorption theory are identified: a low-pressure region in which the surface concentration of adsorbed hydrogen, θ , is negligible and proportional to P_{H_2} ($n = 1$); an intermediate-pressure region in which θ is proportional to $(P_{H_2})^n$ ($n = 0.5 \pm 0.1$), and a high-pressure region in which θ is 1 and independent of P_{H_2} ($n = 0$). At low P_{H_2} and temperatures below 200°C , rates for all temperatures converge to a single line with a slope of 1 (curve 1 in Fig. 29.7) consistent with rate control by impingement of H_2 on the surface. In the absence of a dependence on T , $E_a = 0$ and $R = kP_{H_2}$. As shown by data in Table 29.5, the general equation also applies to curves 2–5 with n values near 0.5, implying that R depends on the concentration of adsorbed H_2 and that reaction involves dissociation into atomic H. Pressure independence at high P_{H_2} is attributed to hydrogen saturation of the surface.

Arrhenius results in Table 29.6 show that the hydriding rate is dependent on temperature at intermediate and high P_{H_2} (Ward and Haschke, 1994). In the pressure-independent ($n = 0$) region, R depends only on temperature. As shown by E_a values in Table 29.6, activation energies coincide with the

Table 29.5 Rate equations describing the dependence of the U hydriding rate on H_2 pressure for curves in Fig. 29.7.^a

Curve	T (°C)	Applicable P_{H_2} range (bar)	k	n
1	<200	– ^b	0.75	1.0
2	200	5×10^{-3} –5	0.067	0.61
3	85	2×10^{-4} –3	0.012	0.53
4	23	2×10^{-5} –1	1.7×10^{-3}	0.46
5	–10	2×10^{-6} –0.7	3.2×10^{-4}	0.40

^a Rate equations have the form $R(\text{in g U cm}^{-2} \text{ min}^{-1}) = k(P_{H_2})^n$ (P_{H_2} in bar, geometric area of U). Reference to Fig. 29.7 may be necessary to verify validity of the equation.

^b The applicable P_{H_2} range of curve 1 depends on temperature and expands to higher pressures with increasing temperature. Curve 1 is not applicable above 200°C because the required P_{H_2} approaches P_e for UH_3 formation. Reference to a detailed analysis of applicable kinetic regimes (Ward and Haschke, 1994) may be necessary.

Table 29.6 Arrhenius equations^a for hydriding of U along selected H_2 isobars in Fig. 29.7 (Haschke, 1998).

P_{H_2} (bar)	Applicable T range ^b (°C)	E_a (kJ mol ^{–1})	A	B
10	<425	32	6.40	3815
1	0–325	27	4.32	3270
0.1	–50 to 250	25	2.36	2995
10^{-2}	<200	24	0.82	2865
10^{-3}	<70	23	–0.49	2730

^a Rate equations have the form $\ln R$ (R in g U cm^{–2} min^{–1}) = $A - (B/T)$ (T in K, geometric area of U).

^b Temperature limits are based on kinetic regimes defined in a $P_{H_2} - T$ diagram (Ward and Haschke, 1994).

(30 ± 5) kJ mol^{–1} E_a for hydrogen self-diffusion in UH_3 (see Section 29.3.4), implying that R is controlled by diffusion of hydrogen through the adherent hydride layer at high P_{H_2} and is determined by the combined effects of the adsorbed H_2 concentration and diffusion at intermediate pressures. Rates in the intermediate-pressure ($n \sim 0.5$) region vary with T , as well as with P_{H_2} , showing that R depends on both parameters. Systematic variations of n with T (Table 29.5) and E_a with P_{H_2} (Table 29.6) suggest that parameters are not independent. In part, the dependence of E_a on P_{H_2} accounts for the large range of activation energies (8–33 kJ mol^{–1}) cited in early studies (Haschke, 1991); the observed value depends on the isobaric H_2 pressure present during measurement.

Involvement of thermodynamic rate control is shown in Fig. 29.7 by abrupt decreases in rate as P_{H_2} approaches the equilibrium pressure, P_e , for UH_3 formation at 85, 200, and 380°C. Values of R consistently deviate from control by other parameters for $P_{H_2} < 10P_e$. Values of P_e are defined by $\ln P_e$ (in bar) = $14.54 - (10233/T)$ (Flotow *et al.*, 1984). A diagram identifying the

$P_{\text{H}_2} - T$ regimes in which different parameters determine the rate of U–H₂ reaction (Ward and Haschke, 1994) shows that impingement control is not possible above 200°C because the P_{H_2} required to drive that process is greater than P_e . In a similar way, existence of the regime involving combined effects of P_{H_2} and T is precluded by thermodynamic control above 400°C. The 85°C isotherm in Fig. 29.7 exhibits all four types of control. Although several models have been proposed to describe and predict the hydriding kinetics of U (Haschke, 1991), results suggest that accounting for behavior over the full parametric range with a single model is unlikely unless all control mechanisms and their relationships are included.

Kinetic studies with high surface area ($0.5\text{--}3\text{ m}^2\text{ g}^{-1}$) U prepared by hydriding and dehydriding cycles (Condon and Larson, 1973; Stakebake, 1979) suggest that reaction of H₂ with powdered metal differs from that of massive uranium. Studies with U-powder at 75–200°C and 5×10^{-4} –0.13 bar H₂ show that $n = 0.5$ (Condon and Larson, 1973), that E_a is -7 kJ mol^{-1} (Condon and Larson, 1973; Stakebake, 1979), and that R depends on the amount of unreacted metal, not on the surface area. Proposed models in both studies are based on rapid diffusion of hydrogen and formation of hydride within the U-particles. Mass–time data for reaction of U-powder ($0.6\text{ m}^2\text{ g}^{-1}$) with H₂ at 0.13 bar and 100°C (Stakebake, 1979) yield a linear rate of $2 \times 10^{-4}\text{ g U cm}^{-2}\text{ min}^{-1}$ (BET area). The value of R calculated for massive U at 100°C using the equation for 0.1 bar in Table 29.6 and a specific area that is 10–20 times the geometric value yields a rate of $(2 \pm 1) \times 10^{-4}\text{ g U cm}^{-2}\text{ min}^{-1}$ (BET area), suggesting that hydriding kinetics of powdered and massive U are similar.

Compared to the penetration rate of Pu by H₂ at 1 bar and 25°C (6 cm h^{-1}), corrosion of massive U by H₂ at those conditions is relatively slow ($40\text{ }\mu\text{m h}^{-1}$) and is consistent with differences in hydrogen-transport properties of the hydrides. Although the corrosion rate of finely divided uranium appears to be indistinguishable from that of massive metal, the rate of heat generation is enhanced because of the larger surface area. The UH₃ product has a specific area of about $1\text{ m}^2\text{ g}^{-1}$ (Condon and Larson, 1973) and is pyrophoric in air. Studies of the reaction between UH₃ and saturated H₂O vapor at 100°C show that UO₂ and H₂ form at a constant rate until the process is approximately 65% complete after 20 h (Baker *et al.*, 1966). Subsequent reaction continues at a progressive slower rate and becomes immeasurably slow at about 80% completion after 50–60 h.

29.6.3 Reaction of U with oxygen, water, and air

As shown in a recent review (Haschke, 1998), oxidation kinetics of U in dry air and water vapor closely parallel those of Pu, but diverge in moist air below the ignition point and in static air at temperatures above the ignition point. The kinetic behavior of U (Fig. 29.8) is similar to that of unalloyed Pu in Fig. 29.5. Arrhenius curves for U form an envelope bounded by slow rates in dry air and

Fig. 29.8 Arrhenius curves for corrosion of U in air and water vapor. Curve 1 describes behavior in dry air. Curves 2, 3, and 4 are for corrosion in water vapor at the equilibrium pressure below 100°C and in 1 bar steam at higher temperatures. Curve 5 shows behavior in air at all humidity levels and curve 6 describes the behavior at 0.053 bar water pressure. Curve 7 describes the corrosion in air above 500°C. Detailed descriptions of the curves are given in the text and in Table 29.7.

rapid rates in water vapor at low temperatures and closed by convergence of rates at high temperatures. Respective rates for U and Pu in dry air at 25°C are 8 and 5 ng metal cm⁻² min⁻¹. The oxidation rates of both metals in saturated water vapor are approximately 250 times faster than in dry air at room temperature.

Oxidation of uranium in dry air proceeds with formation of an adherent product layer on the metal surface and with parabolic kinetics (Haschke *et al.*, 2001b). The chemical composition of the layer during the linear stage was identified as UO₂ below 275°C and an outer layer of U₃O₈ was observed in air at higher temperatures (Colmenares, 1975). Spalled oxide continues to react and form U₃O₈ in air. Curve 1 in Fig. 29.8 for the constant-rate stage of oxidation (Haschke, 1998) is based on measurements in dry air at 40–350°C (McGillivray

Table 29.7 Arrhenius equations^a for corrosion of U in air and H₂O vapor.

Curve	Reaction	Applicable range		A	B	References ^b
		T (K)	P _{H₂O} (bar)			
1	U + dry air	<773	0	6.19	8 077	A,B
2	U + H ₂ O vapor	<373	P _e ^c	10.64	7 725	A,C
3	U + H ₂ O vapor	373–623	1.01	8.33	6 860	A,D
4	U + H ₂ O vapor	623–773	1.01	–4.92	0	A,D
5	U + humid air	<373	0.003–0.5	22.96	13 285	A,C,E
6	U + humid air	372–673	0.053 ^d	5.09	6 765	A,B,C
7	U + dry/humid air	>773	1.01	1.21	4 655	A,F

^a Arrhenius equations have the form R (in g U cm⁻² min⁻¹) = $A - B/T$ (T in K, geometric area).

^b References: A, Haschke (1998); B, McGillivray *et al.* (1994); C, Colmenares (1984); D, Huddle (1953); E, Ritchie *et al.* (1986); F, Hilliard (1958).

^c P_e is the H₂O pressure in equilibrium with water at T .

^d The 0.053 bar H₂O pressure corresponds to a median value of the measurements. Rates at other conditions are derived using the temperature-dependent exponent of P_{H₂O}, n , which varies from 0 at 100°C to a maximum of 1 at 250°C and decreases to 0.6 at 350°C (Haschke, 1998).

et al., 1994). The Arrhenius equation describing curve 1 appears in Table 29.7. E_a (67 kJ mol⁻¹) is consistent with rate control by diffusion of oxygen through the adherent oxide layer. As shown by curves 2 and 3 in Fig. 29.8, corrosion of uranium in water vapor is more rapid than in dry air (curve 1). Contrary to reports that UH₃ is formed by the U–H₂O reaction, products are identified as H₂ and UO_{2+x} with values of x varying from 0 to 0.2 (Haschke *et al.*, 2001b). Curve 2 (Table 29.7) describes the reaction rate for equilibrium vapor pressures, P_e, of water at temperatures up to 100°C (Haschke, 1998). The pressure exponent is 0.5 and E_a is 64 kJ mol⁻¹, implying that the rate is controlled by diffusion of oxygen through the product layer of constant average thickness (Haschke *et al.*, 2001b). The derived rate equation for 100–250°C given by curve 3 in Fig. 29.8 and Table 29.7 is derived using R at 100°C and 1.01 bar H₂O and on experimental data (curve 4) for the uranium-steam reaction at 200–500°C (Huddle, 1953). Those data describe a temperature-independent process that results in closure of the rate envelope near 500°C and absence of moisture-enhanced corrosion above that point.

Curves 5 and 6 in Fig. 29.8 and Table 29.7 describe the corrosion of uranium in moist air (Ritchie *et al.*, 1986; McGillivray *et al.*, 1994; Haschke, 1998). At 100°C, R for U at O₂ concentrations less than 20 ppm is proportional to (P_{H₂O})^{0.5} (Colmenares, 1984). This behavior is like that observed for Pu at all O₂ pressures (see Section 29.5.2(c)). If P_{O₂} exceeds 0.15 mbar (150 ppm), R exceeds the rate in dry air, but remains fixed as P_{H₂O} is varied from 3 to 130 mbar. Curve 5 describes the humidity-independent corrosion rate (E_a = 110 kJ mol⁻¹) in air at 40–100°C. At 100–400°C, the corrosion rate is dependent on H₂O pressure with values of n increasing linearly from 0 at 100°C to a maximum

of 1 at 250°C and decreasing linearly to 0.6 at 350°C (Haschke, 1998). Curve 6 defines R for a median H_2O pressure of 0.053 bar and an E_a equal to 56 kJ mol⁻¹. Rates, $R(P_{\text{H}_2\text{O}})_T$, at other values of T and $P_{\text{H}_2\text{O}}$ are derived using $R(0.053)_T$ from curve 6 and the equation: $R(P_{\text{H}_2\text{O}})_T = R(0.053)_T ((P_{\text{H}_2\text{O}})^n / 0.053^n)$. Enhancement of the rate in moist air is attributed to the same water-catalyzed cycle as proposed for plutonium (see Section 29.5.2d) (Haschke *et al.*, 2001b). Attenuation of enhancement by O_2 suggests that the oxide surface is chemically altered by the formation of a higher oxide or other change that reduces the rate of O^{2-} formation or transport. Convergence of curves 5 and 1 at 35–40°C indicates that corrosion of U in air is insensitive to humidity at room temperature or that curve 1 describes the corrosion rate in air with significant residual moisture.

At temperatures above 500°C, the corrosion rate of U is humidity-independent and described by curve 7 (Hilliard, 1958; Haschke, 1998). The convergence of curves 1, 4, and 7 in Fig. 29.8 at this temperature suggests that measurements are consistent and implies a significant change in chemical behavior. Corrosion rates exceed that required to form a N_2 -rich boundary layer with Pu (curve 8, Fig. 29.5) (Haschke and Martz, 1998b), are insensitive to an increase of 10^4 in the flow rate of air during reaction, and show that reaction slows slightly after O_2 is depleted from static air at 805°C (Hilliard, 1958). Unlike Pu, corrosion of U at high temperatures apparently proceeds with facile reaction of both O_2 and N_2 . E_a (39 kJ mol⁻¹) is comparable to that (40 kJ mol⁻¹) observed for ignited Pu during free fall in air.

29.6.4 Thermal ignition and self-sustained oxidation of U

The ignition behavior of U is uncertain because of conflicting observations. Reported ignition temperatures of U in air (Fig. 29.6) indicate that the ignition behavior is similar to that of Pu. Ignition temperatures, T_i , extracted from an early review (Wilkinson, 1962) show that powder, chips, and foils with dimensions less than 1 mm ignite at 250–325°C and that pieces with larger dimensions ignite at 500–600°C. Behavior suggests that rapid reoxidation of a UO_2 layer at the oxide–metal interface to U_3O_8 might provide sufficient heat to raise the temperatures of powder and chips to the ignition point in a process similar to that described for Pu (see Section 29.5.2(e)).

Questions about the T_i data in Fig. 29.6 are raised by results of other studies (Hilliard, 1958). Exposure of burnished and preheated U samples to flowing air resulted in three types of behavior depending on initial temperature. At temperatures below 400°C, attainment of a stable temperature after 1–2 h is followed by a continuing reaction at a constant rate. At temperatures of 400–650°C, an initial thermal spike is followed by a period in which the sample temperature remained near the furnace temperature. Successive periods (0.3–0.5 h) of such slow reaction were followed by a thermal spike that exceeded 1000°C in some cases. This cyclic process continued until the metal was consumed.

At initial temperatures above 650°C, a sharp initial thermal spike was followed by a period (0.5–1 h) in which the sample temperature remained relatively constant at a value above the furnace temperature.

Thermal excursions attributed to ignition may correspond to spikes induced by periodic spallation of a thick oxide layer (Hilliard, 1958), not with onset of autothermic reaction. That possibility is supported by failure of samples at 1250°C to continue reacting in air after removal from the furnace (Hilliard, 1958). Corrosion rates derived for isothermal reactions during extended (>1 h) tests at 440 (365°C furnace) and 810°C (710°C furnace) are 0.006 and 0.05 g U cm⁻² min⁻¹, respectively. The corresponding rates calculated for curves 1 and 7 (Table 29.7) are 0.0059 and 0.045 g U cm⁻² min⁻¹. Observation of a stable rate over a long time period at 810°C is inconsistent with onset of autothermic behavior at 500–600°C. The autothermic behavior of U remains uncertain.

29.6.5 Reactions of U and UH₃ with water

A review and assessment of chemistry and reaction kinetics for reactions of U and UH₃ with water (Haschke, 1995) suggest that the solid products may be oxide hydrides (UO_{1.5 ± 0.3}H_{0.5 ± 0.2}), not mixtures of UO₂ and UH₃. The corrosion rate of U in distilled water at 25°C (0.5 μg U cm⁻² min⁻¹, geometric area) is similar to that for Pu, but the U–H₂O rate in synthetic seawater is a factor of 20 slower than in distilled water. The reaction rate of UH₃ (2 μg U cm⁻² min⁻¹, BET area) is modest for small samples, but violent exothermic reaction is reported for samples greater than 25 g (Newton *et al.*, 1949).

29.7 RADIOLYTIC REACTIONS

Radiolysis of organic and molecular compounds in close proximity to radioactive materials provides an important source of chemical reactants capable of altering properties and behavior of materials, especially during periods of extended storage. The extent of radiolysis is a function of specific alpha activity, which is negligible for ²³⁸U and varies significantly for the common Pu isotopes (IAEA Report, 1998). Respective values for ²³⁸Pu, ²³⁹Pu, ²⁴⁰Pu, ²⁴¹Pu, and ²⁴²Pu are 600, 2, 8, 3700 (beta decay), and 0.1 GBq g⁻¹. The alpha activity of ²⁴¹Am formed by beta decay of ²⁴¹Pu is 120 GBq g⁻¹. The isotopic distribution of Pu varies markedly with the level of fuel burnup. An activity of 8 × 10⁻⁵ GBq g⁻¹ for ²³⁵U indicates that radiolytic processes are relatively insignificant for highly enriched uranium.

Formation of H₂, CH₄, and other gaseous products by alpha-induced radiolytic decomposition of hydrocarbons (–CH₂–) and other organic materials is especially important:

Hydrocarbon oils polymerize and polyethylene plastics are embrittled by this reaction. Alpha radiolysis of oxygenated organic compounds also generates CO and CO₂ (Kazanjian, 1976). Radiolysis of polyvinyl chloride (PVC) and chlorinated solvents produces HCl. Rates progressively decrease over time from 'burnout' as a layer of carbon-rich residue forms adjacent to the Pu-containing source. Studies in which liquid and solid organic materials (oil, ethylene glycol, silicone rubber) were placed in contact with oxide-coated Pu show that H₂ is the primary (>99%) gaseous product and that gas generation rates are surprisingly similar for all organic materials in the tests (Haschke *et al.*, 2001c). Respective rates after 0.01, 0.5, and 2.5 years are 4, 0.07, and 0.04 nmol H₂ cm⁻² min⁻¹ (geometric Pu area). Corresponding H₂-generation rates for plutonium oxide powders in contact with organic materials are expected to vary from 0.2 to 0.002 nmol H₂ cm⁻² min⁻¹ (BET area).

Formation of gaseous products is reported for tests in which cellulose, plastics, hydrocarbon oils, latex rubber, and chlorocarbon solvents were exposed to ²³⁸PuO₂ or ²³⁹PuO₂ in closed containers with air atmospheres (Kazanjian, 1976). Derived *G*-values for total gas generation vary from 0.4 to 3 molecules per 100 eV of absorbed energy. As shown by a linear time dependence of moles H₂ produced, rates of hydrogen production were essentially constant over 1-year test periods and show no evidence for decreases associated with burnout. O₂ was consumed at a constant rate over a period of 20–60 days, suggesting that observed rates of H₂ production during the initial period were reduced by formation of H₂O. These results and consistent evidence for water in gas analyses indicate that H₂ does not accumulate as predicted by *G*-values if O₂ is present, but that water is formed by surface-catalyzed combination of the elements. Continuing formation of CO₂ after depletion of O₂ suggests a radiolytic or catalytic reaction of H₂O with C-rich residues.

Radiolytic reactions of Pu also form highly reactive and corrosive products in other systems. In the absence of organic compounds, radiolysis of air in a confined volume produces mixtures containing up to 10% N₂O and NO₂ within 2–3 years (Haschke and Martz, 1998a). NO₂ is corrosive to steel at moisture levels above 3% relative humidity. Radiolysis of air-exposed aqueous solutions produces HNO₃ (Rai *et al.*, 1980; Rai and Ryan, 1982). The pH of a solution containing about 1 mg ²³⁸PuO₂ per ml decreased from neutral to 1.5 within a 3.5-year period. N₂ atmospheres are not inert if aqueous solutions are present because HNO₃ is formed from oxygen produced by radiolysis of water. Radiation-promoted nitration of organic materials such as ion-exchange resins in nitric acid solution forms solids that may react violently when dry (Cleveland, 1979).

Mention of an important nonradiolytic process related to alpha decay of Pu isotopes is merited because of its apparent involvement in movement of submicrogram-size oxide particles. Observation indicates that spreading of radioactive contamination occurs spontaneously during operations with oxide. Movement of ²³⁸PuO₂ is noticeably more rapid than in similar operations with ²³⁹PuO₂. The unquantified process, which is attributed to air entrainment

of small particles by recoil energy from alpha decay, is apparently an important factor in transport of finely divided powders and spread of contamination over time.

29.8 HAZARD ASSESSMENT

29.8.1 Synergistic reactions

The chemistry of Pu metal and oxide, and to a lesser extent that of U, is unusually complex and reactivities of systems containing those materials may be dramatically altered by changes in surface chemistry. Slow processes that normally do not merit consideration may become important during an extended storage period. Trace amounts of hydrogen, water, and other gases are important constituents because of their chemical properties. For example, H₂ reacts with O₂ to form water and with Pu to form hydride. Both products catalyze specific reactions. In some cases, transport of oxide particles is a key step in radiolytic formation of H₂. Entrainment of submicrogram-size particles is promoted by alpha recoil. Synergistic convergence of several processes like these may produce unanticipated behavior.

Synergistic interaction is demonstrated by considering a hypothetical storage configuration in which oxide-coated Pu metal and a high-purity Ar atmosphere are sealed for an extended period in a steel container with an elastomeric *o*-ring closure. A potentially hazardous situation is created by occurrence of parallel and sequential reactions. In the absence of oxygen, the oxide layer is reduced to α -Pu₂O₃ over time. Small oxide particles entrained by alpha recoil are simultaneously dispersed throughout the container via thermal currents created by heat from radioactive decay. Hydrogen formed by radiolytic decomposition of elastomer by alpha particles from oxide particles deposited on the *o*-ring reacts with the sesquioxide-coated Pu to form a Pu₂O₃-PuH_x double layer. Catalytic initiation of self-sustained oxidation and nitriding (see Section 29.5.2(f)) is possible and likely upon exposure of the metal to air.

A significant constraint on assessment of hazards for Pu exists because all pathways that lead to potentially hazardous situations are not defined. In light of limited understanding of synergistic interactions, subsequent discussions of hazards cannot be considered exhaustive.

29.8.2 Potential hazards

(a) Formation of gases

Concern focuses on the formation of potentially explosive gases and generation of static pressures that might result in loss of containment and dispersal of Pu-containing particles. H₂ produced by chemical or radiolytic processes is

highly reactive and forms explosive mixtures with O₂. Gas pressures generated by chemical reaction, radiolysis, or thermal decomposition may rupture a container.

Contrary to widely held views that PuO₂ is inert and the ideal storage form for plutonium, observations (see Sections 29.3.2 and 29.4.2) show that dioxide tenaciously adsorbs water and reacts with H₂O to form PuO_{2+x} and H₂. If air or O₂ is sealed in the storage container with moisture-equilibrated oxide, the water-catalyzed PuO₂-O₂ reaction (Haschke *et al.*, 2000b) proceeds via a mechanism like that for water-catalyzed oxidation of Pu by O₂ (see Section 29.5.2d).

Occurrence of this process in storage is shown by initial disappearance of O₂ from air-filled storage containers at the rate predicted for kinetic control by the first step of this cycle (Haschke *et al.*, 2001a). Calculations indicate that O₂ in a typical air-filled container is consumed after about 1.5 years. After O₂ is depleted, H₂O reacts via the initial step with association of H atoms as H₂.

The maximum H₂ pressure from chemical reaction of water in a closed, air-filled system is determined by several factors: amount of oxide, specific area of the oxide, initial concentration of adsorbed water, oxide mass, free volume of the container, and rate of the oxide-water reaction. These factors are included in a quantitative model for calculating the time dependence of pressure in a sealed oxide container (Haschke *et al.*, 2001a). Thermodynamic assessment indicates that reaction of water is not limited by attainment of the equilibrium H₂ pressure and that the oxide-water reaction proceeds to completion (Haschke and Allen, 2002).

An important consequence of the water-catalyzed cycle is the sequential nature of the catalytic cycle. Depletion of O₂ before onset of H₂ formation is observed for water-enhanced oxidation of Pu and U, implying that corrosion is controlled by the oxide surface. Therefore, formation of H₂-O₂ mixtures by chemical reaction is apparently precluded. That assessment is tempered by the requirement that formation of H₂ by radiolysis of H₂O or some other process is slow relative to the rate of O₂ consumption (Haschke *et al.*, 2001a). Although formation of H₂ by weapons-grade plutonium oxide appears sufficiently slow, the radiolysis rate must be considered in each case because rapid formation of H₂ may result in the formation of a transient explosive mixture.

As implied by preceding discussion, H₂ is produced by radiolysis of organic materials in close proximity to oxide or metal. The process is under kinetic control and is capable of generating high pressures. Formation of H₂ is limited only by the amount of organic material available, but its rate of formation is slowed by kinetic factors such as 'burnout' around the radiation source

(see Section 29.7) and by formation of H_2O in the presence of O_2 . The rates at which H_2 and O_2 dissociatively adsorb and form H_2O on various surfaces are unknown, but may be important in determining the H_2 inventory and pressure.

H_2 is also generated by reaction of H_2O with metallic Pu and U. Measurements with Pu in moist air show that the pressure in a sealed container decreases as O_2 is consumed and then increases at essentially the same rate as H_2 is formed (Haschke *et al.*, 2001b). However, as discussed in Section 29.5.2d, hydrogen is a transient species in the presence of Pu and is expected to ultimately react with available metal to form PuH_x . Measurements show that the reaction proceeds as expected if H_2O is the only source of H_2 or if solid organic materials are radiolyzed. Hydride formation does not initiate immediately and the H_2 pressure may continue to increase over time if volatile organic liquids are present.

The course of the Pu– H_2O reaction in low- O_2 atmospheres is altered and the rate of H_2 generation is increased if small amounts of gaseous HCl are present (Haschke *et al.*, 1998b). PuCl_3 formed by rapid Pu–HCl reaction is deliquescent, forms a concentrated chloride solution on the metal surface, and apparently catalyzes the formation of PuOH plus H_2 , as observed in aqueous chloride solution (see Section 29.5.2(g)). Chloride catalysis increases the H_2 formation rate of alloyed Pu by approximately 10^3 at room temperature.

Thermodynamic data derived for PuO_{2+x} suggest that the higher oxide is a thermally activated source of high- O_2 pressure (Haschke and Allen, 2002). Results indicate that $\text{PuO}_{2.2}$ is the equilibrium composition formed by calcination of oxalate, peroxide, nitrate, or other oxygenated solids at 400–450°C in air and that PuO_2 is stable above 650°C. Predictions are consistent with formation of $\text{PuO}_{2.3}$ during heating of $\text{PuO}_3 \cdot 0.7\text{H}_2\text{O}$ in vacuum at 200–250°C. Pressurization of storage containers may result from decomposition of PuO_{2+x} upon heating to 450–500°C (Bagnall and Laidler, 1964), as well as from generation of gases by pyrolysis of anion residues in low-fired solids (see Section 29.8.3(b)). Generation of O_2 pressures approaching 50 bar is possible if a typical sealed storage vessel containing low-fired (400–450°C) $\text{PuO}_{2.2}$ is heated above 650°C. Formation of O_2 – H_2 mixtures is possible during heating if higher oxide was formed *in situ* by reaction of adsorbed H_2O .

Other possible methods of generating O_2 and other noncondensable gases exist if the storage container for low-fired oxide is involved in a fire. Pressurization may occur as gases are formed by thermal decomposition of residual oxygen-containing anions or anion fragments remaining in the oxide.

A minor contribution to the pressure is made by accumulation of helium produced by alpha decay in oxide. For short time periods (several hundred years) compared to the half-life of ^{239}Pu , the He production rate is approximately constant at 0.10 mmol He per kg $^{239}\text{PuO}_2$ per year. Although a comparable rate of 0.11 mmol He per kg ^{239}Pu per year exists for Pu, He is retained in the metal (Hecker and Martz, 2000) and is released only upon heating. Results

indicate that, except for a near surface layer from which alpha particles escaped, all He produced in bulk ^{239}Pu over a 40 year period remains in the metal.

Although generation of gas pressures during storage of UO_2 has not been of concern, questions are raised by the reported reaction of UO_2 with liquid water and solutions (Matzke and Turos, 1991). Additional investigation is needed to determine if uranium dioxide reacts with water vapor and adsorbed water, to define kinetic behavior over a broad range of conditions, and to assess potential consequences for handling and storage.

(b) Thermal hazards

In addition to the thermal hazard posed by reaction of hydrogen from radiolytic and chemical interactions, large amounts of heat are produced over short time periods by rapid, self-sustained corrosion of Pu metal. As described in Sections 29.5.2e and 29.5.2f, autothermic reactions are initiated in two ways: thermally and catalytically. Thermal sources may be external or exist within the chemical system. As discussed in Section 29.5.2e, Pu powder does not spontaneously ignite in air at room temperature, implying that spontaneous ignition of the metal at 25°C is driven by reaction of coexisting pyrophoric or catalytic materials. Formation of catalytic surface layers on Pu may result in spontaneous ignition upon exposure to air at room temperature. Self-sustained reaction during both thermal and catalytic processes is apparently contingent on attainment of a temperature required to maintain an $\alpha\text{-Pu}_2\text{O}_3$ surface, but PuH_x is also necessary for catalyzed reaction and results in simultaneous reaction of both O_2 and N_2 .

Highly reactive and pyrophoric compounds of plutonium are potential thermal sources for heating Pu above the 500°C ignition point. The $\alpha\text{-Pu}_2\text{O}_3$ layer formed on Pu by autoreduction of the oxide surface is identified as the ignition source for Pu chips and fines (Martz *et al.*, 1994). PuH_x is considered pyrophoric because of its unique ability to accommodate product H_2 and consume N_2 (Haschke and Allen, 2001). In concert, these processes promote pyrophoric reaction by facilitating transport of O_2 to the hydride surface and preventing formation of a N_2/H_2 boundary layer at the hydride surface. The heat-generation rate of $10\text{--}15\text{ kJ g}^{-1}\text{ PuH}_x$ per min for the hydride-air reaction is substantially larger than the $0.1\text{--}0.5\text{ kJ g}^{-1}\text{ Pu}$ per min rate required for self-sustained reaction of massive metal in air because the hydride surface area is relatively high. Thermal calculations show that more than 30 mass% of a hypothetical mixture containing substoichiometric dioxide ($\text{PuO}_{1.98}$), 5% hydride, and 0.5% Pu powder must be present and react to adiabatically heat the co-existing metal (70 mass%) to 500°C (Haschke and Allen, 2001).

Catalyzed corrosion of Pu by H_2 is initiated by an $\alpha\text{-Pu}_2\text{O}_3$ surface layer, as well as by a layer of PuH_x . As discussed in Section 29.5.2f, Pu coated with an $\alpha\text{-Pu}_2\text{O}_3\text{-PuH}_x$ double layer spontaneously reacts with O_2 and N_2 upon exposure

to air at room temperature. The catalytic double layer forms on the Pu surface via several pathways, including exposure of PuH_x-coated metal to air or O₂. Other known routes to the catalytically active surface include exposure of α-Pu₂O₃-coated Pu to a small amount of H₂ and formation of a PuOH precursor by immersion of the metal in water (Haschke and Allen, 2001). When altered by traces of gaseous HCl, the water vapor–metal reaction also produces a reactive PuOH surface (see Section 29.8.2a). Existence of additional routes to the catalytically active surface is likely. On the basis of rate equations and enthalpy data, rates of heat generation by self-sustained oxidation of static Pu in air, by the autocatalytic Pu–H₂ (1 bar H₂) reaction, and by the catalyzed Pu–air reaction are 0.5, 1.1, and 2.7 kJ cm⁻² min⁻¹, respectively. If the surface of a 2 kg Pu casting (5 cm diameter, 1.3 cm high) is fully active and all heat is retained in the metal, a 1.0 kJ cm⁻² min⁻¹ generation rate produces a temperature increase of 490° per min.

Secondary consequences of thermal excursions of internal or external origin are also of concern because temperatures frequently exceed the 640°C melting point of Pu. If the metal is in a steel container, rapid corrosion of the vessel by molten Pu (see Section 29.5.3) may result in catastrophic release to the environment (Haschke and Martz, 1998a). A substantial increase in the surface area of the metal is possible upon release and may cause a noticeable increase in the corrosion rate.

As discussed in Section 29.6.2, the ignition characteristics of U are uncertain. Behavior seems most consistent with rate control by a protective UO₂ product layer that is not capable of forming a catalytic oxide like α-Pu₂O₃. If sharp thermal spikes are caused by periodic spallation of the uranium oxide, onset of self-sustained reaction of massive metal is unlikely. However, exposure of UH₃ powder to air is likely to result in pyrophoric ignition and a large thermal excursion.

(c) Release and dispersal of nuclear material

For humans, the primary health hazard of plutonium is radiation exposure from small Pu-containing particles retained in the respiratory system (Voelz, 2000). Airborne particles with aerodynamic diameters, D_A , less than 10 μm are deposited in significant quantities in the lungs (Luna *et al.*, 1971). D_A is the diameter of a unit-density (1 g cm⁻³) sphere with the same terminal velocity in air as a particle of arbitrary size, shape, and density. Because effects of shape and air resistance are small, $D_A \sim (\rho_p)^{0.5} D_G$, where D_G is the geometric diameter of a particle with density ρ_p (Mishima and Pinkston, 1994). The density of PuO₂ is 11.46 g cm⁻³ and the combined mass of oxide particles with geometric diameters less than 3 μm constitutes the respirable release fraction (RRF) of an oxide powder. The aerosol release fraction (ARF) is the mass fraction of powder comprised of particles that are likely to become airborne. Because aerodynamic diameters of particles in ARF are less than 30 μm, PuO₂ particles

in this mass fraction typically have geometric diameters less than 10 μm , but entrainment studies during metal oxidation suggest that D_G may extend to 20 μm (Stewart, 1963).

The source term (ST) for the airborne release of respirable particles is usually defined by the source strength of aerosolizable particles in units of grams (Luna *et al.*, 1971). ST is a function of the quantity, Q , of material at risk, ARF, and RF, the respirable fraction of ARF:

$$\text{ST} = Q \times \text{ARF} \times \text{RF} = Q \times \text{RRF}.$$

Note that RF is a fraction of ARF and that RRF is a fraction of Q because these quantities are easily confused.

The risk of releasing and dispersing respirable particles is significantly enhanced by corrosion reactions that simultaneously transform metal into powder and promote loss of containment (Haschke *et al.*, 1998a). Reactions of oxide do not detectably alter the source term, but generate gases that pressurize the container. Consequences of solid expansion during metal corrosion are surprising because solid products do not move to occupy free volume within the container. After the solid product expands to the container wall, further reaction compresses the product, prevents movement that would relieve radial pressure, and leads to rupture of the container (Haschke and Martz, 1998a).

Assessment of the dispersal hazard is contingent on availability of source-term data, and in some cases, on the corrosion rate, R , of metal at conditions of interest (Haschke and Martz, 1998b). If corrosion continues during the dispersal incident, the material at risk increases as metal is progressively transformed into product. The dependence of ST on R , surface area of metal involved, and time period of the incident are incorporated into the above source-term equation by replacing Q with the product of R , surface area, and time. Values of R are defined for Pu and U in Sections 29.5 and 29.6. Alternatively, the measured airborne release rate, which inherently equals $R \times \text{ARF}$, may be included along with SA and time to define the source term for a dynamic event.

Cumulative mass fractions of particles with geometric sizes less than 3, 10, and 30 μm for oxides from corrosion of Pu and calcination of precipitates are listed in Table 29.8 (Pritchard *et al.*, 1963; Stewart, 1963; Stakebake and Robinson, 1977; Giacomini, 1985; Ricketts, 1995; Machuron-Mandard and Madic, 1996; Haschke *et al.*, 1998a; Martz and Haschke, 1998c; Szempruch, 2001). Respirable release fractions are indicated by cumulative fractions for 3 μm size particles. Because RRF varies by as much as 10^5 depending on preparative method, reliable assessment of the dispersal hazard is unlikely unless the oxide source is considered. RRF for oxide from corrosion of metal is decreased by increasing temperature and humidity or by the presence of hydride catalyst, but is increased by alloying (Stewart, 1963; Haschke *et al.*, 1998a). These correlations suggest that the size distribution of a spalled corrosion product is determined by the relative rates of corrosion and crack formation in the density-stressed product layer on the metal surface (Haschke *et al.*, 1998a). Nucleation

Table 29.8 Size distribution data for plutonium oxide prepared at different conditions.^{a,b}

Preparative history of PuO ₂	Cumulative mass fraction at specified size (μm)			References ^c

and propagation of cracks appear rather insensitive to parameters that increase the corrosion rate; slow reaction at room temperature promotes formation of small particles by allowing time for extensive crack formation and spallation before a thick product layer is formed. Size distributions of products formed at temperatures above the 500°C ignition point of Pu and by rapid catalyzed reactions are bimodal, suggesting that particles form by two processes (Haschke, 1992b). A second distribution of small fragments is apparently produced during spallation of large particles. A bimodal distribution also results from formation of small oxide particles during oxidation of PuH_x.

The RRF for ignited Pu droplets (Table 29.8) is approximately 0.7 for all droplets with diameters greater than 100 μm if the free-fall period is sufficient for the temperature to exceed the boiling point of Pu (Martz and Haschke, 1998). Electron micrographs of oxide formed by oxidation of the vapor show a fume aerosol containing web-like chains of particles with diameters of 5–100 nm (Raabe *et al.*, 1978). *In vitro* dissolution rates of the fume aerosol are higher than normally observed for PuO₂. Data from tests to simulate dispersal of Pu by accidental detonation of high explosive show that particles collected in downwind air samplers were primarily spheres or spheroids with average densities of ~2.8–4.9 g cm⁻³ (Friend and Thomas, 1965), suggesting that metal particles

were heated above the melting point during detonation and that hollow oxide spherules were formed by venting of metal vapor (see Section 29.5.2(e)). Size distribution data for collected particles show that RRF is approximately 0.2 and that the mass fraction of particles with aerodynamic diameters below $0.1\ \mu\text{m}$ (geometric diameter $<0.03\ \mu\text{m}$) is less than 0.005 (Friend and Thomas, 1965; Luna *et al.*, 1971; Stephens, 1995). Trimodal distributions correlate with three size-determining processes: fragmentation of metal, surface oxidation of fragments, and oxidation of Pu vapor. Average spherule densities of $3\text{--}5\ \text{g cm}^{-3}$ correspond to release of 55–75% of the mass as fume aerosol and suggest that the aerosol release fraction may far exceed the 0.5% value derived from collection data.

RRF values for PuO_2 prepared by calcination of precipitates such as oxalate and peroxide in Table 29.8 vary by a factor of 10^2 , even for the same chemical process. Although differences are inherently introduced by different methods of size measurement, that possibility is unlikely to account for these observations and suggests that specific preparative procedures are important in determining the source term of the oxide product. Adoption of a single conservative value of RRF for all situations seems inappropriate. Characterization of the specific material at risk appears necessary for a meaningful assessment of the dispersal hazard.

Uranium oxide particles produced by oxidation of U in a fuel fire are significantly larger than those from oxidation of Pu under similar conditions (Stewart, 1961; Haschke, 1998). Size data are described by a bimodal distribution and estimated cumulative mass fractions with dimensions less than 3, 10, and $30\ \mu\text{m}$ are 1×10^{-4} , 5×10^{-4} , and 5×10^{-3} , respectively.

(d) Uncertainty of chemical properties

A serious hazard associated with the variety of Pu-containing materials is uncertainty about chemical composition and reactivity. Certain process residues such as chloride-rich pyrochemical salts have been characterized (Haschke and Phillips, 2000) and their chemical reactivity has been evaluated (Haschke *et al.*, 2000c). However, numerous potential vulnerabilities cited in an assessment of weapons-related facilities (DOE Report, 1994) derive from lack of knowledge about properties of residues containing several metric tons of Pu. Vulnerabilities are likely to exist worldwide for residues from both military and civilian operations.

(e) Nuclear criticality

Radiation levels produced by fission of ^{239}Pu or ^{235}U in a nuclear chain reaction present a severe potential hazard during operations involving these isotopes. Criticality is controlled by complex relationships that depend on the amount, density, and geometry of fissionable isotopes, as well as on moderation and

reflection of neutrons and interactions with other neutron sources. Criticality assessment is beyond the scope of this review and must be made by expert evaluation for each specific handling or storage configuration.

29.8.3 Case studies

(a) Incidents with metal

Several incidents involving spontaneous ignition and reaction of kilogram-size Pu metal castings have resulted in contamination of workers and facilities by nuclear materials (Haschke and Martz, 1998a, 2000). In at least two cases, storage of metal in unsealed storage containers and sealed plastic contamination barriers resulted in rupture of the container by expansion of the solid and release of material to the environment. Assessment of the previously mentioned incident (see Section 29.1) (Haschke *et al.*, 2000a) is especially useful because the package involved in the incident appeared stable over an 11-year storage period. The package consisted of an inner cylindrical steel container with 2.5 kg of rod-shaped Pu castings and welded closures at both ends, two sealed plastic contamination barriers, and an outer steel can with a slip-lid closure covered by plastic tape. A worker became highly contaminated with Pu-containing particles during routine handling of the package.

Inspection of the package in a nitrogen-rich gloved box atmosphere routinely used for handling Pu metal showed that the outer can contained a fine oxide-like powder, that the plastic barriers had embrittled and failed surrounding the lower weld, and that the end of the inner can had been torn open by formation and expansion of a solid reaction product around the Pu castings. Product particles had apparently been released as air was expelled by flexing and volume change as the can was handled. During a 3 h period after exposure of the inner container to the gloved box atmosphere, a rapid reaction caused significant bulging and heating of the inner container. Reaction ceased after the container was transferred to an argon-filled gloved box.

Assessment suggests the occurrence of two important processes: (1) autoreduction of oxide on the metal surface to α -Pu₂O₃ over a period of years and (2) simultaneous transport and deposition of oxide particles on the plastic bagging, resulting in radiolytic production of H₂ and embrittlement of the plastic. Movement of oxide from the inner container, through the constriction of a faulty weld, and onto the plastic barrier is attributed to recoil entrainment of small particles and pumping of gas by action of atmospheric pressure changes on the plastic bagging. Reaction of hydrogen with the activated metal surface produced a Pu₂O₃-PuH_x double layer and resulted in catalyzed reaction of O₂ and N₂ after the plastic failed and air entered the package. This reaction led to failure of an inner metal container. The rate of rapid corrosion observed after the inner container was placed in a reduced-oxygen gloved box corresponds to that for indiscriminate reaction of Pu with air (Haschke *et al.*, 1998a).

Formation of the catalytic double layer by different pathways is suggested by observations with other massive samples (Martz *et al.*, 1994). Spontaneous ignition of a massive Pu casting in air after exposure to hydrocarbon oil in a closed container is consistent with reaction of radiolytic H₂ to form a PuH_x surface layer followed by catalyzed reaction upon exposure to air. Similar reaction of Pu after opening of a container that had been immersed in water during criticality measurements is consistent with formation of PuOH on the metal surface and ignition in air (see Section 29.5.2(f)). Water apparently entered the steel container through a faulty seal.

Involvement of catalytic surfaces is also suggested by exothermic reaction of a Ga alloy casting during annealing in a N₂ atmosphere at temperatures in the δ-phase stability range (Haschke, 1986). As the alloy was heated during the initial processing operation in a newly constructed annealing furnace, the temperature greatly exceeded the programmed value and continued to rise after the furnace had been shut down. Exothermic reaction ceased after the casting was consumed, but resumed when the furnace was opened to air. The initial exothermic reaction is attributed to PuH_x-catalyzed nitriding. Surface hydride was apparently formed by high-temperature reaction of water driven from a furnace hearth plate of asbestos fiberboard containing hydrated aluminosilicates. The second exotherm resulted from oxidation of the nitride. In addition to showing that hydrogen originates from unexpected sources, these observations demonstrated that N₂ is not an inert gas for operations with Pu metal at elevated temperatures. Inertness is unlikely even at room temperature where nitriding of PuH_x-coated metal is documented (Haschke *et al.*, 2001c).

(b) Incidents with oxide

The hazard associated with organic material in contact with oxide is shown by violent rupture of a sealed container with only 225 g of PuO₂ after less than 2 years in storage (Haschke and Martz, 1998a). The oxide compact was contaminated with a die lubricant containing aluminum stearate and dodecane. When the package failed, it was propelled out of a criticality well and onto the floor of the storage vault, resulting in extensive contamination of the facility. Examination of a companion container showed that high H₂ pressures were generated by radiolysis of the organic material.

In another incident (Haschke and Martz, 1998a), a storage container of oxide with a relatively high ²³⁸Pu content ruptured during transport in an insulated shipping container certified for the existing heat load. The multi-kilogram charge had been prepared by calcination of plutonium nitrate. Alpha contamination was discovered in the shipping container during unpacking. Inspection showed that an inner slip-lid container, a sealed plastic contamination barrier, and an outer rim-seal can had all failed due to internal pressure. Pressurization was attributed to thermal desorption of water and other gases from the oxide, but a high adsorbate concentration would have been necessary. As outlined in

Section 29.8.2a, formation of O₂ by thermal decomposition of PuO_{2+x} and of anion residues may also have contributed to pressurization.

The possibility for PuO_{2+x} involvement in pressurization is supported by analytical data for the Pu and O content of oxides prepared by calcination of oxalate, peroxide, and nitrate precipitates using production procedures (Moseley and Wing, 1965). Materials were heated to the indicated temperatures, but heating periods are not specified. Results (Table 29.9) derived from reported analytical data show that O/Pu ratios in the products generally decrease with increasing temperature and that mass fractions of Pu plus O approach 1.00, suggesting that other constituents remain after calcination at low temperatures. Oxide compositions in excess of the PuO₂ are consistently indicated and are likely to be present unless oxides are thoroughly calcined at high temperature.

(c) Incidents with residues

Although photographs of numerous corroded and failed containers of Pu metals and compounds are presented in a U.S. DOE vulnerability study (DOE Report, 1994), information and documentation of the failures are unavailable. The difficulty associated with residues is demonstrated by severe bulging of rim-seal cans containing reacted ash, a residue produced by firing hydroxide precipitates of Pu and other metals with filter paper and other organic materials at 400–450°C (Van Konynenburg *et al.*, 1996). Residues prepared over a period of 20 years before repackaging were removed from storage in unsealed containers with plastic contamination barriers, homogenized by blending in air, and sealed in food-pack cans. Bulging of cans was observed after 13 months and subsequent analysis of several containers showed that pressure increases up to 5 bar resulted from two distinctly different processes (Haschke and Martz,

Table 29.9 Analytical data for oxides prepared by calcination of plutonium-containing precipitates (Moseley and Wing, 1965).^{a,b}

Initial precipitate	Calcination temperature (°C)	(g Pu + g O)/g	O/Pu ratio
Pu(III) oxalate	400	0.893	3.21
	600	0.983	2.48
	800	0.991	2.06
	1000	1.000	2.09
Pu peroxide	400	0.961	2.33
	600	0.983	2.17
	1000	1.000	2.04
Pu nitrate	600	0.997	2.06
	800	0.974	2.18
	1000	0.999	2.14

^a Calcination times are not specified and may vary.

^b Pu contents were determined by Ce titration and emission spectrography; O contents were determined by vacuum fusion with carbon.

1998a). For cases in which large amounts of free C was apparently present, N₂ appeared stable, O₂ was depleted, H₂ and CO₂ were formed, and a pH of 4 was measured after the solid residue was placed in water. In other cases, N₂ plus O₂ were formed and the observed pH was 10. A qualitative explanation for some observations is proposed (Van Konynenburg *et al.*, 1996), but proposed processes do not account for production of N₂ and O₂. Formation of N₂ parallels that observed with air-exposed oxide in radiolysis studies (Livingston, 1999) and suggests involvement of radiolytic nitrogen oxides that form on the oxide surface during exposure to air (Stakebake *et al.*, 1970).

Large variations in the chemistry of a relatively well-characterized residue such as reacted ash are surprising. Confidence in estimation of the potential hazard must be tempered by recognition of uncertainty and lack of knowledge. Assessment of hazards for poorly characterized plutonium-bearing residues is especially difficult.

29.9 MITIGATION OF HAZARDS

29.9.1 Atmospheres for safe handling of plutonium

Control of oxygen and moisture levels in the gloved box atmosphere is essential for preventing excessive corrosion of Pu metal and adsorption of water on the oxide. As shown by retention of H₂O formed by combination of H₂ and O₂ on PuO₂ (Haschke *et al.*, 2001b), water tenaciously adsorbs on oxide and oxide-coated metal. Use of an argon atmosphere is desirable because radiolytic formation of nitrogen oxides and nitrates is curtailed, but maintenance of low (<10 ppm) O₂, H₂O, and N₂ concentrations is challenging. Use of nitrogen atmospheres is less desirable because N₂ is not radiolytically (see Section 29.7) or chemically (see Sections 29.4.1(e) and 29.8.3(a)) inert at room temperature.

A perplexing observation reported by early workers is that corrosion of Pu by moisture is as much as 60 times more rapid in argon or helium than in air at the same humidity level (Waber, 1980). Suggestions that this behavior parallels that of U and that H₂O corrosion is suppressed by O₂ are not supported by results for the Pu-H₂O reaction (Haschke *et al.*, 1996). Another possibility is suggested by enhancement of Pu corrosion by traces of HCl in an Ar atmosphere (Haschke *et al.*, 1998b). At 25°C, the estimated corrosion rate of alloyed Pu in saturated H₂O is 0.2 ng Pu cm⁻² min⁻¹; the derived rate with ppm levels of HCl and P_{H₂O} less than 0.1 mbar is 0.5 µg Pu cm⁻² min⁻¹ (Haschke *et al.*, 2001c). The likely source of HCl is radiolysis of polymerized residues formed during prolonged use of chlorinated organic solvents in the gloved box. Enhanced corrosion in He or Ar atmospheres during early studies may have resulted from a similar synergistic interaction.

Dry air is suitable for handling plutonium metal and oxide if adequate controls are exercised. Metal powder and chips do not spontaneously ignite in

air at room temperature (see Section 29.5.2e) and corrosion of Pu is suppressed by formation of a protective PuO₂ layer, but ignition is likely if reactive and catalytic compounds such as PuH_x and Pu₂O₃ are present. Effects of water concentration on the corrosion rate of unalloyed Pu are evident at 1 ppm H₂O and maintenance of 0.5 ppm is apparently necessary to prevent moisture enhancement (Haschke *et al.*, 1996). The water-catalyzed cycle for the Pu–O₂ reaction (see Section 29.5.2d) is almost insidious. H₂O is not consumed during corrosion as long as O₂ is present, but remains tenaciously adsorbed and accumulates on the oxide surface over time at low equilibrium pressure. The surface of freshly calcined PuO₂ has a stronger affinity for water than many commonly used desiccants (molecular sieves, CaSO₄, and CaCl₂) and will extract water from them.

Use of dry N₂-enriched atmospheres containing less than 3–5% O₂ is advantageous because pyrophoric materials such as PuH_x do not spontaneously ignite at this condition (Haschke and Allen, 2001). Experiments show that preheated (>500°C) Pu specimens rapidly cool instead of oxidizing when exposed to N₂–O₂ mixtures with 7–9% O₂, but burn in a self-sustaining reaction when exposed to mixtures containing 10% or more O₂ (Musgrave, 1971). Predictions based on corrosion rates show that thermal ignition of Pu is prevented by maintaining the O₂ percentage below 9.6% and that pyrophoric reactions of PuH_x and PuH_x-coated Pu are prevented by maintaining the O₂ percentage below 4.2% (Haschke and Allen, 2001). Results are consistent with observations indicating that the threshold O₂ pressures for self-sustained reactions of Pu and PuH_x are 90 and 40 mbar, respectively.

29.9.2 Conditions for safe storage of metals and oxides

(a) Packaging and storage of plutonium

General requirements for storage of plutonium metals and oxides are outlined in safety guidelines (IAEA Report, 1998) and in a recent review (Haschke and Martz, 1998a). Specific recommendations for storage periods up to 50 years are presented in a U.S. DOE standard (DOE Standard, 2000a). In addition to outlining criteria for design, construction, and testing of storage containers, the DOE publication includes recommendations for material stabilization, packaging, quality assurance, documentation, and surveillance. The standard applies to Pu-containing metals and oxides containing at least 30 mass% Pu plus U and unirradiated MOX fuel, but not to residues, wastes, spent nuclear fuels, radiation sources, or solutions.

Packaging recommendations in the DOE standard include double confinement of materials in nested cylindrical containers constructed of a durable, corrosion-resistant metal such as 300 series stainless steel (Fig. 29.9) and sealed by welding (DOE Standard, 2000a). An unsealed convenience can be used to facilitate loading without contamination of the inner container or the weld

Fig. 29.9 Plutonium storage containers fabricated in accordance with DOE Standard 3013. Convenience can (left), inner welded can (center), and outer welded can (right) are shown.

zone. The inner container is designed to deform if the internal pressure reaches 8 bar; the minimum design pressure of the outer container is 50 bar. Welds are certified to have leak rates less than 10^{-7} std $\text{cm}^3 \text{s}^{-1}$ using standard leak-test procedures. Rigorous exclusion of organic materials such as elastomeric gaskets, organic coatings, and plastic contamination barriers from the storage package is essential to prevent formation of radiolytic gases during storage.

Recommendations for stabilization of metals are simple compared to those for oxides (DOE Standard, 2000a). Metal pieces weighing more than 50 g are considered suitable for storage because ignition at 150–200°C is unlikely (see Section 29.5.2(e)). Metal surfaces should be visibly free of non-adhering corrosion products (including oxide) and organic materials. Stabilization of oxides is

accomplished by calcination at 950°C in an oxidizing atmosphere such as air for a minimum of 2 h or until the loss-on-ignition (LOI) criterion or other suitable method indicates that residual moisture level is sufficiently low. LOI is a gravimetric analysis that measures the loss of volatile species from a calcined oxide sample during heating at 1000°C for 1 h. The acceptance criterion for oxide at the time of packaging is a maximum LOI of 0.5 mass%, a level that limits the H₂ pressure from the oxide–water reaction (see Sections 29.3.2 and 29.4.2b) to a value below the design pressure of the package. In addition to removing moisture, calcination at 950°C consistently reduces the specific area of PuO₂ to below 5 m² g⁻¹ (Haschke and Ricketts, 1995; Machuron-Mandard and Madic 1996), an area that prevents re-adsorption of H₂O in excess of the 0.5 mass% criterion during exposure to air (Haschke and Ricketts, 1997).

The combined mass of Pu and other fissile materials such as ²³⁵U stored as metal or oxide in each package is limited to 4.40 kg (DOE Standard, 2000a). The container may be filled with any gas (air, argon, or a He-rich mixture for leak testing) that does not react adversely with the container or contained materials. Surveillance is based on initial and periodic measurements of package properties. Onset of pressurization may be detected by radiographic indication of a deformed inner container. Recommended non-destructive surveillance activities also include periodic verification of package mass and leak rate.

(b) Packaging and storage of uranium

The standard for storage of ²³³U (DOE Standard, 2000b) is similar to that for plutonium, but is much less restrictive.

29.10 DISPOSITION OPTIONS

29.10.1 Issues

Reduction in nuclear arsenals and dismantlement of nuclear weapons creates the problem of what to do with excess plutonium and enriched uranium. In addition to issues of environmental aspects, safety, and health, the proliferation risk posed by surplus nuclear material is of concern. An ideal disposition method would eliminate the possibility of reusing such materials in weapons applications. Because total elimination is unrealistic, the U.S. National Academy of Sciences has proposed the ‘spent-fuel standard’ as a concept for minimizing accessibility to plutonium and uranium (National Academy of Sciences Report, 1994). The concept, which has been accepted by the U.S., Russia, and seven other stakeholder nations, defines ‘minimized accessibility’ as equivalent to that of Pu in spent reactor fuel. In cooperative agreements endorsed by other countries, the U.S. and Russia will investigate and demonstrate disposition technologies for use in subsequent disposal of 68 metric tons of weapons-grade Pu.

Studies to define the best disposal options for excess fissile materials are concentrated in three main areas:

- immobilization with high-level waste (HLW) (treating plutonium as waste);
- conversion to a mixed oxide (MOX) for burning in existing reactors;
- use in fueling fast-neutron reactors.

Russia, for example, is focusing on disposal of surplus Pu by burning MOX fuel in reactors. The hybrid United States strategy attempts to insure against possible difficulties by including both irradiation of MOX and immobilization (DOE, 1996, 1997a,b). The approach allows for immobilization of some relatively impure Pu in glass or ceramic material and disposal in a geologic repository, as well as for burning MOX in existing commercial reactors with subsequent geologic disposal as spent fuel. Low-grade Pu-containing materials may be disposed of as nuclear waste. As implied in following sections, implementation of disposal options will require extensive processing capability to separate and prepare materials for disposal. Construction of dedicated facilities to accomplish these tasks will probably be necessary.

29.10.2 Disposition of metals and oxides

(a) Disposition of plutonium metal

Implementation of disposal options requires that Pu metal be converted to oxide. Consideration has been given to pyrochemical processes in which preparation of plutonium hydride is followed by direct conversion to the oxide or by a two-step method involving formation of nitride and subsequent oxidation to PuO_2 . In an alternative method, oxide can be produced directly by somewhat slower oxidation of metal, but hazards associated with handling hydrogen and plutonium hydride are avoided. An intriguing one-step process for separation and oxidation employs formation of the $\alpha\text{-Pu}_2\text{O}_3\text{-PuH}_x$ double layer on the metal and controlled oxidation with O_2 (see Section 29.5.2f). An advanced recovery and integrated extraction system (ARIES) is being developed to demonstrate requisite process technologies (Rofer *et al.*, 2000).

(b) Disposition as plutonium as MOX fuel

One disposal pathway for plutonium is irradiation of MOX fuel ($\sim 5\% \text{PuO}_2$) in commercial light-water reactors. The fissile content is similar to that of enriched uranium fuels in which the Pu content reaches about 1% during normal operation. Civilian plutonium is currently being recycled in European light-water reactors in this way, and MOX usage is expected to expand to Japan and other countries. Burning military plutonium as MOX fuel minimizes accessibility in two important ways: (1) formation of the Pu-containing matrix of highly

radioactive fission products and (2) alteration of the isotopic distribution from weapons-grade to reactor-grade plutonium.

Opponents of using military Pu in MOX fuels contend that substantial proliferation risk exists because the plutonium is considered 'weapons-usable' after irradiation. As noted in Section 29.2.1, weapons-grade plutonium typically contains 93–94% of the fissile ^{239}Pu isotope, whereas reactor-grade plutonium usually contains less than 70% ^{239}Pu . Irradiation of 'weapons-grade' plutonium as MOX fuel increases the difficulty of using high-burnup material in weapons applications by increasing the fraction of non-fissile Pu isotopes. Burning weapons Pu as MOX has limited effect on the proliferation risk because extensive spent-fuel sources of Pu exist worldwide.

(c) Plutonium immobilization

Immobilization of plutonium oxide in a suitable glass or ceramic material and placement in a geological repository achieves the spent-fuel standard by encapsulating plutonium in a waste form with a radiological barrier to reduce accessibility. The radiological barrier can be either internal or external to the plutonium packages. 'Homogeneous' and 'can-in-can' (CIC) are two types of immobilization packaging concepts that have been evaluated (Gray and Gould, 1997). In both concepts the fission products in the canister generate a radiation barrier of at least 100R per hour at a distance of 1 m from the package over 30 years and would mimic the characteristics of spent fuel.

The homogeneous package is formed by incorporating HLW or ^{137}Cs as an internal radiation barrier along with Pu in a glass or ceramic. In a batch process, plutonium oxide is melted directly with fission products such as ^{137}Cs or HLW to form a single highly radioactive glass product that is placed in a large stainless steel canister. This type of package may also be prepared in a two-stage process that first forms a Pu-containing glass. In the second step, glass and fission products are heated and the molten mixture is poured into the storage canister.

The CIC package has a radiation barrier that is external to the plutonium-bearing material (Gray and Gould, 1997). Small cans of Pu-containing glass or ceramic matrix are placed in a rack within a large (0.6 m in diameter, 3 m high) stainless steel canister that is then filled with HLW glass as an external radiation barrier. Although the homogeneous concept has a slight advantage from a non-proliferation standpoint because of the intimate mixing of the plutonium with fission products, the CIC option is preferred over the homogeneous designs from an operational perspective because of higher technical viability and ease of implementation. Both concepts meet the 'spent fuel' criterion, but extensive fabrication facilities and potentially hazardous process operations are required to produce a form that is inherently obtained by burning MOX fuel.

(d) Immobilization of plutonium by vitrification

Vitrification of HLW and placement in a packaging configuration is a disposal option that has been extensively studied and evaluated for 30 years (McKibbin and Wicks, 1995). Early studies show that plutonium can be safely incorporated into a high-level plutonium borosilicate glass at concentrations up to at least 4–5 wt% (Matzke and van Geel, 1995). Another candidate matrix is an alkali–tin–silicate (ATS) glass for incorporating ^{137}Cs as an internal radiation barrier. However, work on this glass has essentially stopped because of interest in the CIC option.

The glass proposed for the CIC option is similar to commercial Löffler optical glasses that contain up to 55 wt% rare-earth oxide. This glass is a single-phase lanthanide borosilicate (LaBS) formulated to accommodate up to 16 wt% actinide (Gould *et al.*, 1988). Highly volatile cesium cannot be incorporated as an internal radiation barrier because of the high melting temperature (1500°C) of these glasses (Science and Technology Review, 1997). Leaching tests show that LaBS is more durable than typical borosilicate glass and has outstanding chemical resistance. Excellent performance of glass systems and general improvement with time were observed in laboratory tests and actual field experiments in Sweden, Belgium, England, and the U.S. (Wicks, 1999).

(e) Immobilization of plutonium by ceramification

Ceramic waste forms have been considered for use in immobilizing HLW since the late 1970s. The most advanced ceramic formulation to date is a synthetic rock (Synroc) developed by the Australian Nuclear Science and Technology Organization (ANSTO) in 1978 (Jostons, 1994). A demonstration plant completed in 1987 operated at a commercial scale of approximately 10 kg of Synroc per hour. The proposed plutonium immobilization ceramic form is Synroc-F, a pyrochlore-rich ceramic that also contains zirconolite, brannerite, and rutile as secondary and tertiary phases (Gould *et al.*, 1988). This titanate ceramic was chosen for Pu immobilization to accommodate high loadings of plutonium and uranium, as well as the neutron absorbers gadolinium and hafnium that are added to ensure criticality control in the repository. Plutonium and uranium are interchangeable in pyrochlore with nominal actinide loadings of 10 wt% Pu and 20 wt% U. The preferred titanate-based ceramic can be formulated as ABTi_2O_7 where Ca and half of the Gd are in the A-position, and Pu, U, Hf, and the remainder of the Gd occupies the B-position. Calcium and titanium oxide are the mineral formers. Natural pyrochlore is calcium zirconate titanate ($\text{CaZrTi}_2\text{O}_7$), but the pyrochlore selected for immobilizing Pu has the chemical formula: $(\text{Ca}_{0.89}\text{Gd}_{0.11})(\text{Hf}_{0.23}\text{U}_{0.44}\text{Pu}_{0.22}\text{Gd}_{0.11})\text{Ti}_2\text{O}_7$. The molar ratio of neutron poison to Pu is 1:1; the molar ratio of U to Pu is 2:1 (Rankin and Gould, 1999).

Assessment of current information indicates that both ceramic and glass are acceptable forms for Pu immobilization. Ceramic technology is recommended for the CIC packaging option because of superior proliferation resistance, repository performance and acceptability, potential worker dose, and cost effectiveness (Cohran *et al.*, 1997; Macfarlane, 1998).

29.10.3 Interim storage

At the present time, the path forward for disposition of weapons plutonium is uncertain. In some cases, the method of disposition has not been conclusively determined and/or requisite processing facilities do not exist. Placing these materials in a final disposition condition (either by immobilization or burning as MOX fuel) will most likely take longer than weapons dismantlement. Therefore, safe interim storage of excess plutonium must be considered for both short and extended periods.

Likewise, interim storage of highly enriched uranium and separated reactor-grade plutonium oxide for use in MOX fuel fabrication will be necessary. It is hoped that use of the fundamental and applied information presented in this chapter will facilitate safe handling, storage, and disposition of these nuclear materials.

30.1 INTRODUCTION

Actinide elements are ubiquitous in nature. Uranium and thorium are present in the Earth's crust with average concentrations of 1–10 $\mu\text{g g}^{-1}$, making them more abundant than Ag, Sb, Cd, or Hg. While U and Th can even be found as major or minor mineral constituents in a variety of geochemical environments, typically they are highly dispersed and present only at trace or ultra-trace concentrations in most natural materials. Because ^{238}U , ^{235}U , and ^{232}Th are the parents of the three naturally occurring non-extinct radioactive decay chains, they are always accompanied by lower concentrations of their radioactive progeny, many of which are also actinides (Table 30.1). The chemical behavior of ^{238}U , ^{235}U , ^{232}Th , and their progeny have been studied for years because accurate determination of their relative abundances can provide geochronological information on a variety of geological/environmental processes. Careful analyses have revealed that trace amounts of the transuranic actinides ^{237}Np and ^{239}Pu occur naturally and are present in U ores with mass ratios of

Table 30.1 Nuclear data for naturally occurring actinides, their decay products, as well as nuclides used as analytical isotopic tracers. The abundances, half-life ($t_{1/2}$), and primary decay mode data are taken from Firestone and Shirley (1996). The thermal-neutron cross section (σ_n) data are taken from Erdtmann (1976).

Nuclide	Abundance	$t_{1/2}$	Specific activity (Ci g ⁻¹)	Decay modes	σ_n (b)	Comments
²²⁷ Ac		21.773 y	72.328	β^- (98.620%) α (1.380%)	(n, γ) 762 ± 29 (n,f) <0.002	b

$<2 \times 10^{-12}$ and $<1 \times 10^{-11}$ for $^{237}\text{Np}/\text{U}$ and $^{239}\text{Pu}/\text{U}$, respectively (Levine and Seaborg, 1951; Peppard *et al.*, 1952). Once considered extinct, the long-lived plutonium isotope ^{244}Pu was first proposed to have existed in the early solar system by Kuroda (1960). The presence of this nuclide in the early solar system was first confirmed via its signature of fissionogenic Xe isotopes (Rowe and Kuroda, 1965). The nuclide was eventually found to be non-extinct by direct detection in Precambrian bastnasite (Hoffman *et al.*, 1971).

Although the existence of some of the naturally occurring actinides has been known for more than two centuries, the use of actinides reached a new era with the discovery of nuclear fission in 1938. The development of nuclear fission as an energy source and weapon have led to the production and subsequent global spread of both natural and artificial actinide elements in the environment at ultra-trace levels. Fallout from nuclear weapon testing represents the highest contributor to the global spread of transuranic actinides with cumulative levels of the most abundant transuranic actinide Pu averaging approximately 1 mCi km^{-2} (Kim, 1986, and references therein). For the transuranic actinides, of particular concern are the nuclides that will linger in the environment due to long half-lives (Table 30.2). The more than 50 years of nuclear weapons production, testing, and energy generation has left a worldwide legacy of environmental contamination. As strategies for environmental remediation and disposal of actinide-contaminated materials are developed and implemented, the ability to perform accurate and precise determinations of trace level actinides in a variety of natural matrices has become increasingly important.

Accurate determination of trace actinides in geological, environmental, and biological materials represents a significant challenge due to their extremely low concentrations and the diverse matrix chemistry of these samples. Concentrations of the environmental transuranic actinides are frequently $<1 \text{ fg g}^{-1}$ sample and require accurate determination of less than 10^6 atoms of actinide. To perform these types of measurements, the modern analytical chemist can select from a variety of procedures and techniques encompassing sample decomposition, chemical separation, as well as analytical instruments, and calibration methods for the determination of concentration. The specific approach selected is dependent on several factors: sample matrix, sample size, analyte concentration, the need to determine multiple analytes, cost of analysis, time of analysis, equipment available, and the skill and training of the analyst. Any of these factors can influence the selection of an analytical method. The purpose of this chapter is to review and assess those procedures and techniques that are currently the state-of-the-art for trace actinide determination in geological, environmental, and biological matrices. This chapter emphasizes the procedures and techniques that are used specifically for the determination of the naturally occurring actinides and the long-lived environmental transuranic actinides at concentrations $<1 \text{ } \mu\text{g g}^{-1}$.

Table 30.2 Nuclear data for the environmental transuranic nuclides as well as nuclides used as analytical isotopic tracers. The half-life ($t_{1/2}$) and primary decay mode data are taken from Firestone and Shirley (1996). The thermal-neutron cross section (σ_n) data are taken from Erdmann (1976).

30.2 CHEMICAL PROCEDURES

30.2.1 Sample decomposition

Most modern instrumental analytical techniques first require the preparation of a homogeneous, stable, aqueous solution that possesses a known matrix. For aqueous samples, the actinides may be present as dissolved species or adsorbed on the surfaces of suspended solid materials. In many cases these actinides can be solubilized and stabilized via acidification. Environmental aqueous samples such as natural waters are simply acidified with HNO_3 or HCl soon after collection to eliminate and/or prevent the formation of Fe or Al hydroxides (Lally, 1992). Simple acidification, however, may not decompose all suspended solid materials. Urine samples are acidified and decomposed with heat after addition of an inactive carrier and isotopic spikes (Wyse *et al.*, 1998). For solid samples, complete decomposition of the sample matrix is typically performed; this requires more aggressive chemical treatment. Samples possessing organic matrices are typically dried thermally and ashed as a first step. Complete dissolution of actinides in solid samples may be complicated due to the presence of refractory oxide actinide phases. Selection of the appropriate sample decomposition method is an important factor in performing an accurate determination of actinide concentration. Selection of a sample decomposition method is dependent on the sample matrix, the chemical state of the actinide, and the chosen method of actinide determination. The decomposition step may be followed by separation, purification, and conversion of the actinide to a chemical form that is appropriate with the requirements of the method of determination. Decomposition of solid materials can be accomplished by either fusion or acid decomposition.

(a) Fusion decomposition

Fusion decomposition is extremely aggressive and is used primarily for decomposition of geological and solid environmental materials. Fusions are performed by heating a mixture of the sample with a flux reagent at atmospheric pressure in a graphite, zirconium, or platinum crucible. The method is well suited for large samples (several grams). The wide variety of sample matrices in each case requires a careful selection of the flux reagent. Selection of the appropriate flux material can result in both acid–base and oxidation–reduction-based decompositions (Dolezal *et al.*, 1968). Common fluxes are hydroxides, peroxides, carbonates, bisulfates, hydrosulfates, pyrosulfates, tetraborates, and metaborates (Dean, 1995). For fusion decompositions, 0.1–10 g of a dried, homogenized, and powdered solid sample is mixed with flux at a sample to flux ratio ranging from 1:2 to 1:20. Isotopic spikes and elemental carriers, if required, are added at this stage. The mixture is heated to a temperature above the melting point of the flux over a Meker burner or in a muffle furnace until the

mixture forms a well-mixed molten mass. After cooling, the resulting fusion bead is dissolved with a dilute acid such as HNO₃ or HCl.

Fusion with NaOH–Na₂O₂ is a standard geochemical procedure that is extremely effective in decomposing silica-containing matrices. The effectiveness of the method is due to the high temperatures and oxidizing conditions that can be achieved. This method was used to decompose gram quantities of U-ore materials for determination of naturally produced Pu and Tc (Dixon *et al.*, 1997). The oxidizing conditions of the fusion mixture ensured reproducible decomposition and equilibration of a ²⁴²Pu isotopic spike. The method yielded a precision of 1.6% and a blank of (0.17 ± 0.15) pg for ²³⁹Pu in Canadian Reference Material BL-5. Comparison of ²³⁹Pu results with results from acid-decomposed samples (Attrep *et al.*, 1992) indicates that the fusion method may be more effective in totally dissolving trace Pu in U ore samples than acid decomposition. Croudace *et al.* (1998) used a metaborate–tetraborate flux for fusion of soil and sediments contaminated with weapons Pu and U. The American Society for Testing and Materials (ASTM) has published a standard procedure for fusion decomposition of solid materials (ASTM C1342-96, 1996b).

The major disadvantage to fusion decomposition is that the large mass of flux material yields a solution with high total dissolved solids (TDS). Chemical separation of the analyte from the dissolved flux material is typically required. Additionally, trace analysis of naturally occurring actinides may be complicated due to trace impurities in the flux. The aggressiveness of the reaction can also result in the attack of the mass of the crucible, leading to contamination of the sample. Despite these disadvantages, fusion decomposition is one of the most effective methods of decomposing refractory mineral phases in geological and environmental samples.

(b) Acid decomposition

Acid decompositions have been adapted for virtually all sample matrices. Acid decompositions yield solutions with low TDS that can be used for direct determination of many elements, including actinides, without subsequent chemical treatment. The availability of ultrahigh purity acids makes acid decomposition ideal for determination of trace U and Th. Acid decompositions are performed in a chemically resistant beaker on a hotplate at atmospheric pressure or in a closed digestion bomb at elevated pressures and temperatures in a convection or microwave oven.

For open-vessel acid decompositions a dried, homogenized, and powdered solid sample is mixed with several milliliters of one or more concentrated acids in a glass, polytetrafluoroethylene (PTFE), or perfluoroalkoxy (PFA) beaker and heated in a fume hood on a hotplate at atmospheric pressure. Several grams of material can be decomposed in an open vessel. For closed-vessel acid decompositions, the sample and acids are mixed in a PTFE-lined pressure vessel.

Water can be added to increase the solubility and prevent temperature spikes due to exothermic reactions. The vessel is sealed tightly and heated in a convection oven. The effectiveness of closed-vessel system results from the higher pressures and temperatures under which the decomposition takes place. Closed-vessel decompositions are typically restricted to <1 g of inorganic material or <0.1 g of organic material for a 23 mL closed vessel (Dean, 1995).

The types of acids selected depend on the chemical properties of the sample matrix as well as the elements to be determined. Actinides are soluble in HNO_3 and HCl so most procedures for the decomposition of actinide-containing samples utilize these acids. The ASTM has published a set of standard procedures for hotplate and convection-oven digestion of water and solid samples with HNO_3 and HCl (ASTM D1971-95, 1995a). These procedures are applicable to wastewaters, sludges, river and lake waters, and plant and animal tissues.

A HF-HNO_3 mixture is required for acid decomposition of silicates. After decomposition, HF must be removed so that insoluble actinide fluorides are converted to a soluble form either by fuming with HClO_4 or H_2SO_4 or by complexation with H_3BO_3 . Beasley *et al.* (1998) used open vessels for the decomposition of soil samples for U, Np, and Pu determinations. Samples weighing 1–3 g were ash dried at 600°C to remove organic matter and were dissolved in a mixture of HF-HCl . The residue was fumed to dryness in an open vessel three times to remove residual HF and then dissolved in 6 M $\text{HCl-H}_3\text{BO}_3$ mixture to solubilize actinide fluorides.

The addition of H_2O_2 in small or catalytic quantities aids in oxidizing organic matter. A $\text{HNO}_3\text{-H}_2\text{O}_2$ mixture has been used for decomposition of plant material (Testa *et al.*, 1998) as well as animal and human whole organs and bones (USTUR 100, 1995; Glover *et al.*, 1998b).

Recently, specially designed microwave sample decomposition systems have become a routine analytical tool for decomposition of geological, environmental, and biological samples (Lamble and Hill, 1998). Microwave systems provide high-heating efficiency and programmability for unattended operation. The resulting decomposition procedures are reproducible and rapid. Specially designed closed PTFE or PFA vessels minimize sample contamination. Standard procedures for microwave-heated, closed-vessel decomposition with HCl and HNO_3 for the determinations of metals in groundwater have been published (ASTM D4309-91, 1991a). These procedures are applicable for digestion of suspended solids in water and leaching elements from most solid materials but would not yield total dissolution of silica-containing materials. The United States Environmental Protection Agency (U.S. EPA) has developed Method 3052 (U.S. EPA, 1996) for total microwave-heated, closed-vessel decomposition of ashes, biological tissues, oils, oil-contaminated soils, sediments, sludges, and soils. This method has been validated for U determinations on the Standard Reference Material (SRM) 2704 Buffalo River Sediment. Attrep *et al.* (1992) used a microwave system for the decomposition of U-ore materials for the determination of naturally produced Pu and Tc. Alvarado *et al.* (1996) have

developed a microwave procedure for the rapid decomposition of plant tissue for the purpose of actinide analysis using a $\text{HNO}_3\text{--H}_2\text{O}_2$ mixture. An overview of microwave digestion techniques can be found in Kingston and Haswell (1997).

30.2.2 Chemical separation

The accuracy and precision of most methods of actinide determination are influenced both by nonspecific interferences from more abundant sample matrix species and by specific spectroscopic or isobaric interferences from other actinides. These interferences often necessitate chemical separation of the actinide from the interfering species before determination. Additionally, chemical separations preconcentrate the analyte. Preconcentration is especially useful for actinides because of their ultralow concentrations in the environment. Chemical separations can enhance the sensitivity, accuracy, and precision of the overall analytical method.

Actinides are amenable to a variety of chemical separation methods including: coprecipitation, adsorption, chelation, liquid–liquid extraction, column ion-exchange chromatography, column extraction chromatography, or a combination of two or more of these methods. Procedures for the separation and purification of environmentally important actinides have been compiled (Kirby, 1959; Hyde, 1960; Penneman and Keenan, 1960; Stevenson and Nervik, 1961; Gindler, 1962; Coleman, 1965; Burney and Harbour, 1974). Many of these methods are applicable here. Recently, flow injection (FI) analysis and high-performance liquid chromatography (HPLC) have been utilized for online actinide separation with radiometric or mass spectrometric detection. In this section, we review the methods that have been used specifically for analytical-scale separations of trace actinides for the purpose of concentration determination. Because of the common desired goal, i.e. separation of the actinide from more abundant matrix elements and/or other actinides, most of the procedures below can be adapted to geological, environmental, and biological samples.

(a) Coprecipitation

Actinides can be preconcentrated from a large solution volume by coprecipitation. The most frequently used anions for actinide coprecipitation are fluorides, hydroxides, and phosphates. Actinides in the trivalent and tetravalent states are efficiently scavenged from solution by addition of a rare-earth element carrier with precipitation as a fluoride (Magnusson and LaChapelle, 1948). Actinides can also be coprecipitated as a group with $\text{Fe}(\text{OH})_3$ (Lally, 1992) from a carbonate-free solution. Carbonate must be removed by boiling under acidic conditions due to its ability to complex with actinides and prevent quantitative precipitation. Coprecipitation is performed by adding a macroscopic amount of FeCl_3 to an acidified sample digest solution and adjusting the solution pH to basic by the addition of NH_4OH . The precipitate can then be filtered, washed,

and dissolved with HCl or HNO₃ before further separation and purification of the actinides. Coprecipitation of actinides can also be performed with Ca(II) as Ca₃(PO₄)₂ from an acidic digest solution with the addition of NH₄OH to a pH 8–9. This procedure is used for group actinide precipitation from digested soils (Kim *et al.*, 2000) and from urine for bioassay (Maxwell and Fauth, 2000). Direct coprecipitation with MnO₂(s) and adsorption onto MnO₂(s) have been extensively used for preconcentration of actinides from large-volume freshwater and seawater samples (Wong *et al.*, 1978; Bowen *et al.*, 1980). Sidhu and Hoff (1999) describe a procedure in which Pu was preconcentrated *in situ* from 2001 samples of fresh- and seawater. In this method, KMnO₄ solution was added to an acidified water sample and MnO₂(s) was precipitated with the addition of NaHSO₃. The resulting solid was filtered and the Pu was further purified before determination.

(b) Liquid–liquid extraction

Liquid–liquid extraction of actinides can be accomplished with a wide range of organic acids, ketones, ethers, esters, alcohols, and phosphoric acid derivatives (Lally, 1992). Methyl isobutyl ketone has been used to extract U(VI) from aqueous solutions. U(IV) can be extracted with ethyl acetate after treatment of an acidified solution with Al(NO₃)₃·9H₂O (Guest and Zimmerman, 1955). U(VI) can be extracted with 25% tributylphosphate (TBP) in toluene (Mair and Savage, 1986). A standard test method for the determination of U in water by high-resolution α -liquid-scintillation spectrometry utilizes a selective extractive scintillator solution containing dialkylphosphoric acid (ASTM D6239-98, 1998). Interfering radionuclides (Am, Pu, Po, Ra, Rn, and Th) are masked from extraction by diethylenetriaminepentaacetic acid (DTPA). Attrep *et al.* (1992) described a method for the determination of ultralow levels of natural ²³⁹Pu in U ores in which Pu was extracted with 0.5 M thenoyltrifluoroacetone (TTA) in *o*-xylene and back-extracted into 8 M HNO₃. Bis(2-ethylhexyl)phosphoric acid (HDEHP) in toluene and dibutyl-*N,N*-diethylcarbamylphosphonate (DDCP) have both been used to separate Am from Pu for bioassay measurements (Filipy *et al.*, 1998). Triisooctylamine (TIOA) in xylene has been used to selectively extract Np from U and Pu (Novikov *et al.*, 1972). Whereas liquid–liquid extraction methods are very effective, in general they are being replaced due to the volume and classification of waste products that are produced by their use.

(c) Ion exchange

Ion-exchange resins are typically high-molecular-weight organic polymers containing a large number of functional groups that provide the basis for the separation of the analyte from undesired species. Cation exchange can be performed on resins possessing functional groups such as the strongly acidic

sulfonate group $-\text{SO}_3^-$. A cation-exchange resin composed of spherical polystyrene-divinylbenzene polymer substrate containing geminally substituted diphosphonic and sulfonic groups capable of selectively binding actinides and lanthanides from common matrix elements has been developed. This resin, Diphonix, allows preconcentration of actinides from large samples (Horwitz *et al.*, 1993a). Actinides can be recovered from Diphonix resin by elution with 1-hydroxyethylidenediphosphonic acid (HEDPA) or by complete decomposition of the resin (Chiarizia *et al.*, 1997). This method has been applied to separations of transuranic radionuclides in urine (Eikenberg *et al.*, 1999a) and for separation of Th from dietary samples, urine, and feces (Eikenberg *et al.*, 1999b).

Most ion-exchange methods for the separations of actinides utilize anion exchange. Anion exchange is performed on resins possessing functional groups such as the strongly basic quaternary ammonium salt $-\text{NR}_3^+$. Uranium can be separated from a variety of ions by the use of basic anion-exchange resins such as Bio-Rad AG1X8. Uranyl ions form strong anionic sulfate and chloride complexes that can be the basis for U separations. A standard test method for the determination of U in water uses coprecipitation of U spiked with ^{232}U -tracer with $\text{Fe}(\text{OH})_3$ (ASTM D3972-90, 1990). After dissolution of the precipitate, U is separated from Th, Po, Pu, and Am by adsorption from a HCl solution onto an anion-exchange resin. Separation of ^{231}Pa is not achieved by this method and this nuclide could potentially cause spectroscopic interference with ^{234}U when alpha spectrometry is employed for U determination.

Anion exchange is also used for the separation of Pu from solution. Determination of Pu in water can be performed by coprecipitation of Pu and ^{242}Pu -tracer with Fe(III) as $\text{Fe}(\text{OH})_3$ (ASTM D3865-97, 1997a). After dissolution of the precipitate, Pu is separated from Th and Am by anion exchange. Separation of ^{238}Pu from ^{228}Th and ^{241}Am is necessary due to α -spectroscopic interference.

A specialized anion-exchange resin called TEVA-Resin (EIChroM Industries Inc., Darien, IL, USA) is capable of separating actinides in different oxidation states from common matrix elements. The resin is composed of a liquid aliphatic quaternary amine incorporated onto an inert polymeric substrate, Amberchrom CG-71ms. Specifically, this resin allows the separation of the tetravalent actinides Pu(IV), Np(IV), and Th(IV) from hexavalent U(VI) and trivalent Am(III) in HNO_3 solutions (Horwitz *et al.*, 1995). Th(IV) that has sorbed onto TEVA-Resin can be preferentially eluted with 3 M HCl. Separation of Pu from Np is also feasible with this material. Addition of hydroquinone reduces Pu(IV) to Pu(III), allowing Pu elution with 9 M HCl whereas Np is retained. Np can then be eluted with 0.5 M HCl or 0.02 M HNO_3 –0.02 M HF. Lanthanide elements are difficult to separate from Am(III) and may interfere with preparation of a sample for α -spectrometric analysis. Am can be separated from lanthanide elements on TEVA-Resin by complexation with thiocyanate.

(d) Extraction chromatography

Several extraction chromatographic resins have been developed specifically for the separation and preconcentration of actinides from acidic matrices such as acid-stabilized groundwaters and dissolved environmental and geological solids. These resins are composed of an inert support material that has been impregnated with an actinide-selective organic extractant. Whereas these resins function by passing actinide-containing solutions down to an exchange column containing the material, the separation is based on liquid-liquid extraction. These commercially available extraction resins named Actinide-CU, UTEVA-Spec, and TRU-Spec (EiChroM Industries Inc.) provide an extremely valuable tool for the preconcentration and separation of actinide elements from elements common to natural matrices and for separation of individual actinide elements from each other.

Preconcentration of Am and Pu from human tissue samples has been performed using Actinide-CU resin (Qu *et al.*, 1998). This resin is composed of bis(2-ethylhexyl)methanediphosphonic acid ($H_2DEH[DMP]$ or DIPEX) supported by an inert polymeric substrate, Amberlite XAD-7. This resin has a strong affinity for actinides in strongly acid solutions and, thus, stripping of the actinide-organophosphonate complex with isopropanol is required to recover the actinides. This resin is appropriate only for preconcentration of actinides and not separation of individual elements.

The resin U/TEVA-Spec demonstrates specificity for U and tetravalent actinides. It is composed of diamylamylphosphonate (DAAP) sorbed on Amberlite XAD-7 (Horwitz *et al.*, 1992). Preconcentration and separation of U from common geological and environmental matrix elements such as Fe, Ca, Al, Na, and K and other actinides can be achieved from HNO_3 solutions. Separation of U from Th can be accomplished with a 2 M HNO_3 whereas separation of U from Np or Pu can be accomplished with a HNO_3 -oxalic acid mixture.

TRU-Spec resin demonstrates high retention of tri-, tetra-, and hexavalent actinides. It is composed of octyl(phenyl)-*N,N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) in TBP supported by Amberlite XAD-7 (Horwitz *et al.*, 1993b). In HNO_3 solutions, preconcentration and separation of all actinides from matrix elements common to geological and environmental samples can be achieved with TRU-Spec. Additionally, TRU-Spec allows for sequential elution of Am, Pu, Th, Np, and U using a scheme that incorporates HNO_3 and HCl rinse steps in combination with complexation and oxidation-state adjustments. Common matrix elements can be eluted before the actinides, providing for separation of these matrix elements. A method for preconcentration and separation of actinides from urine by this method was first described by Horwitz *et al.* (1990). Separations with applications to geochemistry have also been developed. TRU-Spec resin has been used for the separation of Th and U from geological samples (Pin and Zalduogui, 1997) and for the separation of

U and Th, from Pa in shells and minerals for geochronological measurements (Burnett and Yeh, 1995).

Many highly effective, flexible, and efficient methods for the separation of actinides from their sample matrix, as well as from each other, have been devised by combining anion exchange with one or more extraction chromatography steps. Croudace *et al.* (1998) described a procedure for the determination of Pu and U in soils and sediments that utilizes a combination of anion exchange and extraction chromatography (U/TEVA·Spec) to isolate Pu and Th from U and purify the U fraction. Maxwell (1997) devised a rapid-actinide separation method for environmental samples that utilizes anion exchange with TEVA·Spec resin and extraction chromatography with U/TEVA·Spec resin for the separation of U, Np, Pu, Am, and Cm.

Yokoyama *et al.* (1999) used extraction chromatography with U/TEVA·Spec resin and anion exchange with TEVA·Spec resin to separate Th and U before mass spectrometric determination of Th/U isotopic content of silicate rock samples. The recovery yields for Th and U were >90% and the total blanks were <19 pg for Th and <10 pg for U. Dual sequential columns and vacuum extraction were used to increase sample throughput. Separations by anion exchange with TEVA·Spec resin and extraction chromatography with TRU·Spec have been applied to separation of actinides from urine (Maxwell and Fauth, 2000), soil (Smith *et al.*, 1995), and soft human tissue (Moody *et al.*, 1998). A general radiochemical method that utilizes anion exchange and extraction chromatography for separating Th, U, Np, Pu, and Am from each other and matrix elements is shown in Fig. 30.1.

The use of extraction chromatographic resins configured as a continuous low-pressure FI or HPLC system, in series with the appropriate detector, can potentially enhance the selectivity, sensitivity, and speed of the detection method. Egorov *et al.* (1998) have developed a multieluant FI scheme utilizing TRU·Spec resin and off-line radiometric counting for quantitation. This system is capable of performing automated separations of Am from Pu including on-column Pu oxidation and reduction. FI has also been used with mass spectrometric detection of actinides (ASTM C1310-95, 1995c).

(e) Speciation separations

The most commonly used method for the determination of concentrations of actinides with oxidation-state specificity is direct spectrometric analysis in the visible and near IR spectral regions (see Chapter 27, section 27.3.2, of this book). Spectroscopic methods, however, typically require actinide concentrations that are higher than those found in most environmental and biological samples. To solve the problem of low concentration, indirect methods have been developed. These indirect methods use oxidation-state selective chemical separation of actinide species followed by radiometric or mass spectrometric

Fig. 30.1 Schematic representation of a method for sequential separation of Th, Np, U, Am, and Pu using sequential anion exchange and extraction chromatography (after Horwitz et al., 1995). In this procedure analyte and yield tracers are initially co-precipitated as a group from a dissolved or digested sample using one of the common carriers such as Ca(II). The precipitate is separated, washed, and dissolved with 3 M HNO₃-1.0 M Al(NO₃)₃ and loaded on the first column. The method is applicable to geological, environmental, and biological materials.

determination. These chemical separation methods are based on the same fundamental principles of actinide separation used for interference removal.

Solvent extraction has been used for separating trace actinides possessing different oxidation states (Foti and Freiling, 1964). Saito and Choppin (1983) developed a solvent extraction-based methodology for the separation of trace level actinide elements in the III, IV, V, and VI oxidation states in solutions possessing pH 6–8. Dibenzoylmethane (DBM) in benzene was used as an extractant for actinides in 0.7 M NaCl aqueous solutions. The pH dependence of the extraction was determined for Am(III), Th(IV), Np(V), U(VI), and the method was demonstrated on systems containing mixtures of Pu(IV) and Pu(VI). The solvent extraction method can be applied to solutions possessing pH < 4 by using thenoyltrifluoroacetone (TTA) as the extractant (Bertrand and Choppin, 1982). Actinides in the V oxidation state were extracted from 0.1 M acetate buffer whereas actinides in the VI state were extracted from 0.6 M perchloric acid.

Oxidation state-specific adsorption has been used for separating trace actinide species. Inoue and Tochiyama (1977) used adsorption on silica gel to distinguish between Np(V) and Np(VI). Bondiotti and Trabalka (1980) used differential adsorption to TiO₂ as a method to determine Pu(V) in natural waters with pH 9–11. Orlandini *et al.* (1986) used selective adsorption of Pu(VI) on silica gel and adsorption of Pu(V) on CaCO₃ for the determination of Pu oxidation state in Lake Michigan Water.

Coprecipitation has also been used to separate actinides possessing different oxidation states. The most widely used adsorption and coprecipitation method is the rare-earth fluoride technique that was adapted from the classical separation of reduced Pu(III + IV) from oxidized Pu(VI) by the coprecipitation of the former on a rare-earth fluoride (Magnusson and LaChapelle, 1948). This method was used for the determination of the oxidation state of Pu in filtered and unfiltered seawater samples from the Irish Sea (Nelson and Lovett, 1978a; Nelson *et al.*, 1984) and the Pacific Ocean (Nelson and Lovett, 1978b). Samples were made 0.8 M in HNO₃, 0.25 M in H₂SO₄, 0.5 mM in K₂Cr₂O₇, and 0.7 mM in Nd(NO₃)₃. Sufficient HF was added to raise the total fluoride concentration to 0.25 M and the precipitated NdF₃, along with the coprecipitated Pu(III + IV), was filtered. The unprecipitated Pu(V) and Pu(VI) was treated with (NH₄)₂SO₄ · FeSO₄ · 6H₂O to reduce the remaining Pu and a second NdF₃ step was performed. The Pu in each fraction was purified by anion exchange and Pu isotopes were quantified by alpha spectrometry.

The association of actinides with organic and inorganic aqueous colloidal materials is an important factor that controls the mobility of the actinide in the environment. The determination of the concentrations of actinides associated with aqueous colloids is typically performed by physically separating aqueous colloids by ultrafiltration with subsequent analysis of the filtrate. Ultrafiltration separation of actinide-associated colloidal materials in natural waters has been performed by passing solutions through flat membrane filters possessing specific nominal pore sizes (Nelson and Lovett, 1978a; Nelson *et al.*, 1984), by

tangential-filtration with hollow-fiber cartridge filters (Marley *et al.*, 1991; Kaplan, *et al.*, 1994), and by size-exclusion chromatography (SEC) (Cooper *et al.*, 1995). Porcelli *et al.* (1997) used the tangential-flow hollow-fiber technique to separate U and other elements associated with colloids >10 kDa and >3 kDa in a study of the transport of U isotopes through the Kalix River watershed and Baltic Sea. Kersting *et al.* (1999) characterized Pu-associated colloidal material in groundwater from the Nevada Test Site by sequentially filtering aqueous samples with 1000, 50, and approximately 7 nm pore size filters. Tangential filtration was employed for the 7 nm size filtration. The $^{240}\text{Pu}/^{239}\text{Pu}$ ratio of the collected particulate material (>1000 nm), two colloidal fractions (1000–50 nm and 50–7 nm), and the ultrafiltrate (<7 nm) was determined by mass spectrometry. The measurements had a reported precision of $\pm 1.5\%$ and a procedural blank of <2 pg Pu. The Pu isotopic signature allowed the identification of the source of the Pu as a specific nuclear event. The authors noted, however, that the high pumping rates employed could potentially generate higher colloidal concentrations due to shear stress. The chemical form of the colloid could not be identified by this method.

30.3 NUCLEAR TECHNIQUES

The radioactive properties intrinsic to all actinides allow their direct detection by using radiometric techniques. In principle, the α -particles, β -particles, and γ -rays emitted by any radionuclide can be used for quantitative analysis (see Chapter 27, section 27.3.1, of this book). An examination of the radioanalytical literature reveals that a variety of mathematical criteria have been used to establish levels at which a radionuclide can be considered to be qualitatively detected or quantitatively determined with a given relative standard deviation (RSD). The minimum concentration level that leads to detection is generally defined as the minimum detection limit (MDL). The minimum concentration level that leads to quantitative determination with satisfactory precision is generally defined as the limit of quantitation (LOQ). Currie (1968) developed working expressions for the MDL as 3.29σ and the LOQ as 10σ where σ is the statistically defined standard deviation for the well-determined blank of the method. The confidence limits are assumed to be 95% for these values. These expressions have been widely adopted by the analytical community.

The natural abundances, half-lives ($t_{1/2}$), specific activities, modes of decay, and thermal-neutron capture cross sections (σ_n) for the naturally occurring actinides, their decay products, and several isotopic tracer nuclides are given in Table 30.1. The half-lives, specific activities, modes of decay, and thermal-neutron capture cross sections, for the environmental transuranic actinides and several of their tracers are given in Table 30.2.

Neutron activation analysis (NAA) techniques are based on the transmutation of nuclei to radionuclides or excited nuclear states by capture of neutrons.

Qualitative and quantitative analysis can be performed by detecting the α -particles, β -particles, γ -rays, delayed neutrons, or fission products that are produced as the excited nuclei relax. The emitted radiation or particles can be measured during irradiation or after a delay. Because all actinides are already radioactive the objective of NAA is to produce radionuclides with higher activities thus, improving the measurement sensitivity relative to alpha, beta, or gamma spectrometry of the unirradiated actinide.

Because quantitative analysis using radiometric and NAA techniques are based on the measurement of disintegration rates of radionuclides, the MDL is related to the specific activity of the determined radionuclide, the number of atoms of the radionuclide, counting time, and detection efficiency. The long half-lives and, therefore, low specific activities of the parents of the three non-extinct natural decay chains as well as several of the environmental transuranic nuclides complicates determination using radiometric techniques. Samples containing low concentrations of an actinide need to be counted for relatively long times on extremely stable spectrometers possessing low backgrounds to obtain precision adequate for detection and accurate determination. Whereas there are many radiometric procedures that are amenable to the determination of actinides at trace concentrations, the procedures that are the most generally applicable and commonly used are high-resolution alpha and gamma spectrometries.

30.3.1 Alpha spectrometry

Alpha spectrometry allows the analyst to identify and quantify individual α -emitting radionuclides based on the detection of emitted α -particles and determination of α -particle energies specific to the radionuclide of interest. Detection of α -particles with specific energies allows isotopic discrimination for most actinides. Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in α -spectrometric determinations are given in Table 30.3.

Despite the short range of α -particles through matter, analyses based their detection possess advantages as compared to the detection of β -particles and γ -rays due to the extremely low backgrounds that are achievable. However, accurate and precise α -spectrometric analysis typically requires chemical separation of actinide to eliminate sources of α -particles with energies similar to the analyte, correction for the recovery of the chemically separated actinide with an isotopic spike, and preparation of a thin source. Despite the necessity of these chemical procedures, alpha spectrometry is one of the most frequently utilized techniques for the routine determination of actinides in geological, environmental, and biological samples. The requirement of chemical separations can be used to the analyst's advantage by performing preconcentration from large samples. The instrumentation used in high-resolution alpha spectrometry is not extremely complex or expensive and

Table 30.3 Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in alpha-spectrometric determinations. The principal α -particle energies (E_α) and yields (I_α) are taken from Firestone and Shirley (1996).

can be used on a routine basis. Alpha spectra are reasonably simple and allow straightforward quantitative analysis.

(a) Alpha-spectrometry fundamentals

Alpha spectrometry can be performed using ionization chambers, magnetic spectrometers, scintillation detectors, and semiconductor detectors. Because of the combination of high resolution, sensitivity, compactness, and relative ease of use, alpha spectrometry is most frequently performed utilizing spectrometers that incorporate ion-implanted Si semiconductor detectors.

A typical alpha spectrometer with a 450 mm² ion-implanted Si detector has an energy resolution <20 keV, an efficiency >25% for source-to-detector spacing >1 cm, an energy range from 3 to 8 MeV, and a background <1 × 10⁻⁴ Bq. The detector is part of an integrated spectrometer that includes a vacuum chamber, bias supply for the detector, complete amplification system (preamplifier and amplifier), and calibration pulser. Data acquisition is controlled by a personal computer equipped with a multichannel analyzer for pulse height analysis along with data acquisition and processing software. A schematic diagram of a typical alpha-spectrometry system is illustrated in Fig. 30.2. A more detailed discussion of the theory and operation of alpha spectrometers can be found in Ehman and Vance (1991) and in Ivanovich and Murray (1992).

For accurate determination by high-resolution alpha spectrometry the α -emitting radionuclide must be prepared as a thin, flat, uniform source. To minimize the inelastic scattering of α -particles that degrade peak resolution the ideal source consists of a monolayer of the actinide. Three methods have generally been used for source preparation: evaporation, microprecipitation with a rare-earth fluoride, and electrodeposition (ASTM D3084-95, 1995b). The method most often employed is electrodeposition. In this method actinides are electrochemically deposited quantitatively from an electrolyte solution onto a polished stainless steel or platinum cathode planchet. The deposition is non-selective. Prior chemical separation of the actinides from matrix elements may be required so that the total mass of electrodeposited material is <10 $\mu\text{g cm}^{-2}$. Additionally, chemical separation of the analyte from other

Fig. 30.2 Schematic diagram of an alpha-spectrometry system.

actinides that decay with similar α -particle energies is required to minimize spectroscopic interferences. A variety of electrolytes have been used in the preparation of electrodeposited actinide sources: $\text{NaHSO}_4\text{-Na}_2\text{SO}_4$, KOH-KCO_3 , NH_4HCOO_2 , $\text{NH}_4\text{Cl-HCl}$, $\text{NH}_4\text{Cl-NH}_4\text{I}$, $\text{NH}_4\text{Cl-H}_2\text{C}_2\text{O}_4$, $(\text{NH}_4)_2\text{SO}_4$, $(\text{NH}_4)_2\text{SO}_4\text{-H}_2\text{SO}_4\text{-NH}_4\text{OH}$, isopropanol, and dimethyl sulfoxide (DMSO) (Kressin, 1977 and references therein). The anode is typically Pt wire or gauze. Rotating the anode provides stirring for a more uniform deposit. Electrodeposition is performed at a constant current density (0.5 A cm^{-2}) and low voltage for approximately 2 h. Recent work on optimizing the $(\text{NH}_4)_2\text{SO}_4\text{-H}_2\text{SO}_4\text{-NH}_4\text{OH}$ buffer system by Glover *et al.* (1998c) has demonstrated nearly 100% recoveries of Th, U, Pu, and Am in only 1 h. A standard procedure for electrodeposition of actinides from a solution of $(\text{NH}_4)_2\text{SO}_4$ has been published (ASTM D1284-00, 2000b).

Alpha-spectrometric measurement is performed by placing the actinide-containing planchet in a vacuum chamber at a fixed distance from a detector with a known background and efficiency. The air in the chamber is evacuated and the sample is counted for a time sufficient to attain desired statistical uncertainty. A total of 10000 counts would be required for 1% uncertainty (1σ) due to counting statistics alone (Friedlander *et al.*, 1981). The background is determined by separately counting a chemically prepared experimental blank. The efficiency of the detector for a given geometry is determined by counting a calibrated source at the same geometry that samples are counted. After counting the sample, the alpha spectrum is corrected for background and detector efficiency. Correction for losses incurred during radiochemical procedures are made based on the recovery of the isotopic spike. Spike recovery can be determined as determined from the alpha spectrum or by separate alpha-spectrometric analysis. The number of counts per second (cps) of each nuclide can then be related to the activity of the sample according to the following equation:

$$a = \frac{N}{\epsilon_d r t_s d_s} \quad (30.1)$$

where a is the activity of the nuclide of interest (Bq), N is the total number of counts in the energy region of interest, ϵ_d is the detector efficiency, r is the fraction of isotopic tracer recovered, t_s is the analysis live-time (s), and d_s is the sample decay fraction from the time of sample collection to the midpoint of the counting period.

(b) Alpha-spectrometry applications

Because the analyte elements have typically been chemically separated (see Section 30.2.2) and prepared as a thin-layer source on a planchet before alpha-spectrometric analysis, the details of the actual analysis by alpha-spectrometric measurement are essentially independent of the initial source

matrix material. The nature of the source of the actinides (natural and/or anthropogenic) will dictate what spectral interferences may be present in the sample. There are numerous examples in the literature of applications of alpha spectrometry for the determination of trace actinide content in a variety of matrices. The following examples describe some specific details of these applications and give an overview of the breadth of applications.

Alpha spectrometry has historically been one of the most frequently utilized techniques for uranium-series disequilibria measurements particularly for ^{234}U and ^{238}U (Ivanovich and Murray, 1992). Complete isotopic analysis of the naturally occurring isotopes ^{238}U , ^{235}U , and ^{234}U can be performed with ion-implanted Si detectors because of complete resolution of their peaks. Uranium-232, a commonly used recovery spike, can also be completely resolved. ^{236}U has also been used as a recovery spike. However, tailing from the higher energy ^{236}U α -particles can potentially overlap with those of ^{235}U and a correction for this contribution may need to be performed. Samples must be counted soon after chemical separation due to the ingrowth of short-lived daughters whose α -particle energies overlap with U isotopes. To achieve a 1% counting uncertainty U isotope determination using a 7 day count and a 25% efficiency detector would require a sample containing 5.3 μg , 830 ng, and 290 pg of ^{238}U , ^{235}U , and ^{234}U , respectively. Alpha-spectrometric determination of U in geological and environmental samples require, therefore, long counting times and/or preconcentration from large samples to obtain sufficient amounts of U (see Section 30.2.2). For these reasons there has been great impetus for development of mass spectrometric methods for U isotopic analysis.

Maxwell and Fauth (2000) have recently demonstrated that alpha spectrometry possesses the sensitivity and low background sufficient for U isotope bioassay. By utilizing appropriate chemical procedures and a ^{232}U spike, they demonstrated analytical biases of +7.8% and +1.5% for ^{234}U and ^{238}U , respectively. Typical U levels in urine were found to be 0.003–0.03 Bq L $^{-1}$ and 0.002–0.05 Bq L $^{-1}$ for ^{234}U and ^{238}U , respectively. The method demonstrated blanks of 0.1 mBq L $^{-1}$ for ^{234}U and 0.4 mBq L $^{-1}$ for ^{238}U , sufficiently low for routine assay.

The determination of Th isotopes, specifically ^{230}Th and ^{232}Th , is an important component of uranium-series disequilibria measurements (Ivanovich and Murray, 1992). For the determination of ^{230}Th and ^{232}Th , chemical separation of Th from U is required due to the spectral interference between ^{230}Th and ^{234}U (Table 30.3). As with U, complete isotopic analysis of the naturally occurring Th isotopes ^{232}Th , ^{230}Th , and ^{228}Th can be performed because their peaks can be completely resolved using an ion-implanted Si detector. ^{229}Th , a commonly used recovery spike, can also be completely resolved. Alpha-spectrometric determination of Th isotopes can be complicated due to the ingrowth of ^{224}Ra interfering with ^{228}Th determination (Ivanovich and Murray, 1992). This parent–daughter relationship can be exploited for the determination of ^{224}Ra via alpha-spectrometric determination of ^{228}Th (Noyce, 1981). Eikenberg *et al.* (1999b) have recently utilized alpha spectrometry for the determination of Th

isotopic ratios in human diet as well as urine and feces achieving MDLs as low as 0.04 mBq L^{-1} for ^{232}Th , ^{230}Th , and ^{228}Th .

Protactinium-231 is a daughter product of ^{235}U that is used in soil and sediment dating (Ivanovich *et al.*, 1992). ^{231}Pa is typically determined via isotope dilution with ^{233}Pa followed by chemical separation and alpha-spectrometric determination. Chemical recovery is determined via gamma-spectrometric determination of ^{233}Pa (Lally, 1992). High radiochemical purity is required to minimize spectral interferences from the typically more abundant ^{230}Th and ^{234}U (Table 30.3).

High-resolution alpha spectrometry is one of the most common methods for the determination of the environmental transuranic actinides in environmental and biological samples. When chemically separated as a group, the transuranic actinides can be determined with only a few spectral interferences, most notably: ^{240}Pu – ^{239}Pu , ^{238}Pu – ^{241}Am , and ^{243}Cm – ^{244}Cm . Fig. 30.3 shows an alpha spectrum from a sample containing long-lived actinide and transuranic nuclides produced by the irradiation of UO_2 nuclear fuel.

Neptunium-237 is essentially free of spectral interferences from other transuranic actinides although separation from U and Th isotopes is required due to potential spectral interferences (Table 30.3). Neptunium-237 determination is complicated because it possesses a long half-life and is typically at much lower concentrations in nuclear fuel cycle source materials (Wolf, 1998). The general

Fig. 30.3 An alpha spectrum from the author's laboratory of an electrodeposited source containing actinides with E_α between 3700 and 6100 keV that are present in irradiated UO_2 nuclear fuel after a cooling period of 20 years. The spectrum contains prominent peaks from $^{243}\text{Cm}+^{244}\text{Cm}$, $^{238}\text{Pu}+^{241}\text{Am}$, and $^{240}\text{Pu}+^{239}\text{Pu}$ (listed from high to low energy). Also detectable at lower energies are minor contributions from long-lived nuclide $^{234}\text{U}+^{237}\text{Np}$, ^{235}U , and ^{238}U .

reverse relationship between radionuclide half-life and α -particle energy (the Geiger–Nuttall relationship) complicates ^{237}Np determination when higher activities of high-energy α -emitters are present. High-accuracy alpha-spectrometric determination of ^{237}Np can be achieved via isotope dilution with ^{239}Np followed by chemical separation (Horwitz *et al.*, 1995). Chemical recovery is determined via gamma-spectrometric determination of ^{239}Np . Examples of the routine application of alpha spectrometry to the determination of ^{237}Np in environmental and biological samples are given by Maxwell (1997) and Maxwell and Fauth (2000). Levels as low as 0.017 mBq of ^{237}Np were measured in Irish Sea sediment (Yamamoto *et al.*, 1998). Analogous to natural U and Th isotopes, the low specific activity of ^{237}Np complicates determination via alpha spectrometry and this has led to an effort to develop mass spectrometric methods of determination.

Alpha spectrometry is routinely used for the determination of Pu isotopes in environmental and biological samples. Plutonium-238 is particularly amenable to alpha-spectrometric determination because of its relatively high specific activity (for example, Cooper *et al.*, 2000). Chemical separation of Pu from Am must be performed due to spectral interferences between ^{238}Pu and ^{241}Am (Table 30.3). Thorium-228 will also interfere if present at sufficient concentrations. Unambiguous determination of both ^{240}Pu and ^{239}Pu cannot be performed due to near identical α -particle energies. For this reason it is common to report the combined $^{240+239}\text{Pu}$ activity. Determination of individual ^{239}Pu and ^{240}Pu activities from an alpha-spectrometric measurement requires an independent mass spectrometric analysis determination of the $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio. Complete resolution of the ^{236}Pu , ^{238}Pu , $^{240+239}\text{Pu}$, and ^{242}Pu can be achieved with ion-implanted Si detectors. Plutonium-241 is not determined via alpha spectrometry because it does not decay by α -emission (Table 30.2). Standard methods for the determination of Pu in water (ASTM D3865-97, 1997a) and soil (ASTM C1001-00, 2000a) by alpha spectrometry have been published. These methods utilize either ^{236}Pu or ^{242}Pu as isotopic spikes. The procedure for determination of Pu in water demonstrates biases of less than $\pm 10\%$ whereas the procedure for determination of Pu in soil demonstrates biases of less than $\pm 26\%$ for soil samples containing 0.00188–0.150 Bq Pu g^{-1} .

Americium-241 is similar to ^{238}Pu in that it also possesses a relatively high specific activity compared to many of the environmental transuranic actinides. Frequently, Americium-241 is determined concurrently in a chemically separated aliquot of a sample. Americium-241 must be separated chemically from ^{238}Pu and ^{228}Th to remove spectral interferences. Accurate and precise determination of ^{241}Am via alpha spectrometry is performed using ^{243}Am as an isotopic spike. A routine procedure for ^{241}Am determinations in soil has been published (ASTM C1205-97, 1997b). Alpha spectrometry has been used extensively for the determination of anthropogenic Pu and Am isotopes in the environment including seawater (see for example, Nelson and Lovett, 1978a, 1978b; Bowen *et al.*, 1980; Nelson *et al.*, 1984; Plutonium in the Environment, 1995), Antarctic

snow (Holm and Persson, 1978), and plant samples grown in a contaminated lake bed (Whicker *et al.*, 1999). Alpha spectrometry has been used for the determination of Pu and Am isotopes in biological samples such as human tissue (Moody *et al.*, 1998; Qu *et al.*, 1998), and urine (Maxwell and Fauth, 2000). It has also been used to determine concentrations of natural ^{239}Pu in geological samples (Ganz *et al.*, 1991).

The short half-lives of ^{243}Cm and ^{244}Cm essentially preclude their determination by any method other than alpha spectrometry at environmental levels. Spectral deconvolution is required to separate the ^{243}Cm and ^{244}Cm α -peaks due to low concentrations and similar energies (Mitchell *et al.*, 1998). Studies have utilized alpha spectrometry to search for $^{242\text{m}}\text{Am}$ via detection of daughter ^{242}Cm as well as ^{243}Cm and ^{244}Cm in lichen samples (Murray *et al.*, 1979).

A recent study of the application of alpha spectrometry to the transuranic actinides by Wolf (1998) achieved 10σ LOQ for ^{237}Np , ^{239}Pu , ^{241}Am , and ^{244}Cm of 40, 0.4, 0.008, and 0.0003 pg, respectively (1 mBq). These analyses were performed using relatively short counting periods (<48 h) under routine conditions with 450 mm² ion-implanted Si detectors possessing 25% relative efficiency and backgrounds (1×10^{-4} Bq). Activities over an order of magnitude have been quantified with dedicated low-level detectors and extremely long (>30 days) counting periods (Yamamoto *et al.*, 1998; Eikenberg *et al.*, 1999b; Cooper *et al.*, 2000; Maxwell and Fauth, 2000). The U.S. EPA and ASTM have published standard methods for the determination of actinides in water (U.S. EPA, 1979; ASTM D3084-95, 1995b).

30.3.2 Gamma spectrometry

Gamma spectrometry allows the analyst to identify and quantify individual actinide nuclides based on the detection of emitted γ -rays possessing energies that are specific to nuclear transitions in the actinide of interest. γ -Rays are highly penetrating and their measurement is relatively straightforward because essentially all γ -ray peaks can be individually resolved by high-resolution detectors. X-ray spectrometry is a related technique in which X-rays produced by a daughter atom after decay is detected. These X-rays are element-specific. Lower photon energies, sample self-shielding, lack of isotope specificity, and difficulty in calibrating efficiency curves at low energies complicate X-ray spectrometric determination. For these reasons, gamma spectrometry is a more commonly used than X-ray spectrometry for quantitation of specific actinide nuclides.

Gamma spectrometry requires minimal sample preparation, particularly when compared to the chemical procedures required for the preparation of a source for alpha spectrometric analysis. Gamma spectrometry is non-destructive and multiple radionuclides can be measured simultaneously. In some cases quantitation of actinides by gamma spectrometry can be performed based on the activity of one or more daughter products of the parent actinide. Quantitation based on daughter product activity requires an assumption of

radioactive equilibrium in the sample. However, daughter product analysis is the only route for determining ^{238}U and ^{232}Th by gamma spectrometry at their naturally occurring concentrations. Gamma spectrometry is frequently employed to measure recovery of long-lived actinides by way of spiking with a short-lived, γ -ray-emitting isotope. The sensitivity of the technique is dependent primarily on the half-life of the radionuclide and the percent γ -ray intensity (I_γ). Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in gamma-spectrometric determinations are given in Table 30.4.

(a) Gamma-spectrometry fundamentals

Several types of detectors can be used for gamma spectrometry. They can be classified as gas-filled, scintillation, and semiconductor. Gas-filled detectors are essentially a chamber filled with a gas mixture, such as 90% Ar–10% CH_4 , that contains a positively biased anode. Depending on the bias voltage of the anode, gas-filled detectors can function as ionization chambers, proportional counters, or Geiger–Müller counters. Ionization chambers are used for high-radiation fluxes and are typically not suitable for trace analysis. Proportional counters are used for X-ray measurements where only moderate resolution is required (>1 keV at 5.9 keV). Geiger–Müller counters do not allow the energy of the γ -ray to be determined. Scintillation detectors function because γ -rays interacting with a scintillator produce a pulse of light that can be detected by a photomultiplier tube. A variety of plastics as well as Tl-activated NaI and CsI crystals are capable of detecting γ -rays with energies >1000 keV and have found applications as γ -ray detectors. The 7.6×7.6 cm NaI(Tl) detector is the benchmark standard for the calculation of efficiency of γ -ray detectors. These detectors possess absolute efficiencies between 20 and 40% for the energies typical for most actinide γ -rays. Most analytically important actinide γ -rays and X-rays are in the 3–300 keV region. The low cost-to-size ratio of NaI and its ability to be configured into extremely large detector systems has enabled its use as anti-coincidence shields. One such environmental radionuclide detector system is described by Wogman (1970). However, the energy resolution of scintillator detectors (>10 keV at 100 keV) is typically insufficient to allow deconvolution of complex actinide γ -ray spectra.

Because of their superior resolution, most gamma-spectrometry systems currently utilize a high-purity germanium (HPGe) detector biased with a power supply, a preamplifier, spectroscopy amplifier, and pulse height analyzer. Most HPGe detectors are configured as a junction between n- and p-type semiconductor materials and come in a variety of geometries, sizes, and shapes. The selection of a specific detector depends on the types of samples measured. The most common geometry is a coaxial HPGe detector. Typical HPGe detectors used in geochemical and environmental analysis have volumes 100–200 cm^3 , possess efficiencies of approximately 30–40% relative to a 7.6×7.6 cm NaI

Table 30.4 Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as daughter nuclides and isotopic tracers utilized as in γ -spectrometric determinations. The principal γ -ray energies (E_γ) and yields (I_γ) are taken from Firestone and Shirley (1996).

(TI) detector, and have resolutions <1 keV at 122 keV. These systems are useful for a wide spectrum of applications and are normally calibrated in the range from approximately 50 to 2000 keV. Larger detectors with relative efficiencies $>150\%$ are available but at the expense of slightly lower relative resolutions (<2 keV at 122 keV). These high-efficiency detectors are useful for counting larger-volume, low-activity environmental samples. Another approach to high-efficiency gamma spectrometry is to use a well-type HPGe. Well-type detectors offer the ultimate absolute counting efficiency for small samples. The name 'well type' is given because this type of detector possesses a cavity that can surround a small sample. A typical well only has an available volume of <10 cm³, which precludes the analysis of very large-volume samples. Finally, thin planar HPGe detectors equipped with a beryllium window offer high resolutions for the measurement of γ -rays and X-rays with energies between 3 and 300 keV. The thin beryllium window minimizes attenuation of these low-energy photons. These thin detectors have the additional benefit of being transparent to higher energy γ -rays and thus possess lower background from Compton scattering of high-energy γ -rays.

HPGe detectors are required to be at liquid-nitrogen temperature when they are under high-voltage bias and are connected to a liquid N₂-containing Dewar via a cryostat. The detector and sample are normally shielded with alternating layers of lead, copper, and a low-Z material such as plastic. This graded shielding system minimizes the X-rays scattered from the lead shielding and shields the detector from external sources. Data acquisition and spectral analysis can be controlled by a personal computer equipped with data acquisition and processing software for quantitative analysis. A schematic diagram of a typical gamma-spectrometry system is illustrated in Fig. 30.4. A more detailed discussion of gamma-spectrometry systems can be found in Friedlander *et al.* (1981) and Ehman and Vance (1991).

Typically, all that is required is that the sample be placed in front of the detector of a calibrated gamma-spectrometry system. The detector needs to be

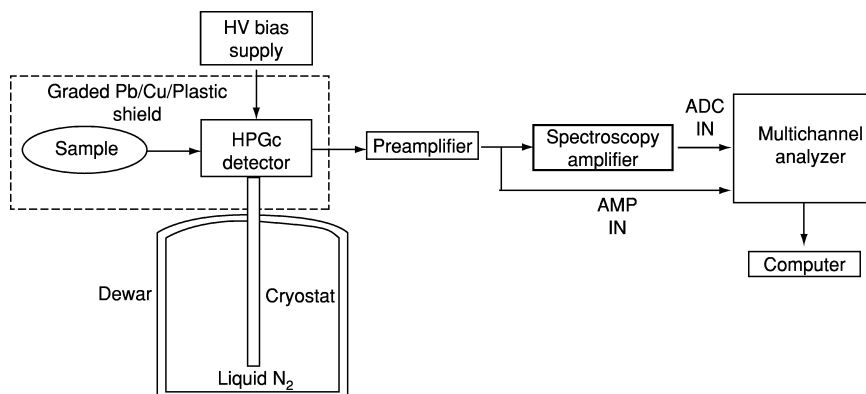

Fig. 30.4 Schematic diagram of a gamma-spectrometry system (after Wolf, 1999).

calibrated for energy and efficiency at the geometry at which the sample is counted. Additionally, the sample size and matrix of the sample need to be similar to that of the standardization source. This is typically achieved by preparing a mock-up sample that has been spiked with known amounts of radionuclides that emit γ -rays with energies comparable to those of interest.

(b) Gamma-spectrometry applications

Extensive work has been performed to develop gamma-spectrometric analysis methods for the determination of the naturally occurring long-lived actinides ^{238}U , ^{235}U , ^{232}Th , and their progeny for both environmental and geochemical studies. A review of this application of gamma spectrometry to U-series disequilibria has been published (Ivanovich and Murray, 1992).

In the ^{238}U -series nuclides, determination of ^{238}U is usually based on the measurement of short-lived daughter ^{234}Th due to the lack of an intense γ -ray for ^{238}U (Harbottle and Evans, 1997). ^{234}Th is essentially always in equilibrium with ^{238}U in geological and environmental samples such as minerals and soils unless the material has been recently chemically treated or the U has been recently deposited. Determination is typically based on the measurement of the 92.6 or the 63.3 keV γ -ray doublets. Measurement of the 63.3 keV γ -ray generally can be improved by using a planar HPGe with a thin Be window. A gamma spectrum of a UO_2 sample collected on a high-resolution planar HPGe detector is given in Fig. 30.5. Determination of ^{238}U can also be performed by measurement of the 1001 keV γ -ray from the decay of $^{234\text{m}}\text{Pa}$. The low I_γ for this γ -ray precludes its use for samples with U concentrations $< 10 \mu\text{g g}^{-1}$. A recently published example of the application of gamma spectrometry for the determination of actinides is that of Gu *et al.* (1997). In a study of the deposition of dust in the Chinese loess plateau, activities of ^{238}U , as well as ^{232}Th and several of their daughter products were determined non-destructively using a low background well-type HPGe detector. Uranium-234 can potentially be determined by measuring its 53.23 keV γ -ray; however, this line is weak and spectral interference from ^{214}Pb at 53.2 keV essentially precludes direct determination of ^{234}U via gamma spectrometry. Determination of the ^{238}U daughter ^{230}Th can be accomplished by measuring its 67.8 keV emission. The low I_γ of this transition precludes its measurement in samples with only trace ^{238}U content. Harbottle and Cumming (1994) report a MDL of 4.4 μg for ^{238}U in 3 g environmental samples using a Compton suppression well counter.

In the ^{235}U -series, identification and quantitation can be performed directly on the parent nuclide via measurement of its strong 185.7 keV γ -ray. A correction for interference from the ^{238}U daughter ^{226}Ra is required for samples in secular equilibrium. However, this interference can be corrected by indirectly determining the contribution of ^{226}Ra based on measurement of γ -rays from ^{214}Pb and ^{214}Bi . The α -decay of ^{226}Ra produces ^{222}Rn ($t_{1/2} = 3.8235$ days), which rapidly establishes equilibrium with both ^{214}Pb and ^{214}Bi . The short

Fig. 30.5 Gamma spectrum of an isotopically enriched U sample counted for 1 day. The spectrum was collected on a high-resolution planar HPGe detector possessing a thin Be window. The spectrum illustrates prominent peaks from ^{234}Th and ^{235}U (after Wolf, 1999).

half-lives and abundance of γ -rays emitted by these two progeny make it possible to correct for ^{226}Ra in samples containing total U at concentrations $<1 \mu\text{g g}^{-1}$ when secular equilibrium can be assumed (Harbottle and Evans, 1997). The total mass of U in the sample can be calculated from the determination of ^{235}U if a natural or other known isotopic distribution is assumed. Harbottle and Cumming (1994) report a MDL of 50 ng for ^{235}U in 3 g environmental samples using a Compton suppression well counter.

Direct determination of ^{231}Pa is difficult due to its complex γ -ray spectrum at relevant higher energies (280–300 keV). Indirect determination via the 50.14 keV γ -ray of short-lived daughter ^{227}Th is complicated due to sample shielding at lower energies. The availability of commercially available gamma-spectrometry software to enable the deconvolution of the 235.97 keV ^{227}Th peak from a quartet of peaks due to the presence of ^{212}Pb , ^{224}Ra , and ^{214}Pb (Harbottle and Evans, 1997). ^{233}Pa , an isotopic tracer for ^{231}Pa determinations, can be quantified directly by gamma spectrometry.

In the ^{232}Th -series, ^{232}Th cannot be determined directly via gamma spectrometry due to its long half-life and lack of an intense γ -ray. ^{232}Th can be determined indirectly by measuring one of several γ -rays emitted by short-lived daughters ^{228}Th , ^{228}Ac , or ^{212}Pb provided that equilibrium can be assumed.

In the transuranic actinides ^{237}Np , ^{239}Pu , ^{240}Pu , and ^{241}Am , typically only ^{241}Am is determined via gamma spectrometry. Americium-241 is a daughter of

^{241}Pu , a minor isotope of weapons-grade Pu, and has been used as a convenient qualitative signature for the presence of Pu (Burns *et al.*, 1995; Jerome *et al.*, 1995; Wolf *et al.*, 1997). Americium-241 can be readily be determined directly through measurement of its 59.54 keV γ -ray. Use of ^{241}Am as a signature for Pu, however, requires subsequent laboratory determination of Pu by other techniques to ensure that chemical fractionation of Am and Pu has not occurred in the environment.

Neptunium-237 can be determined directly via measurement of a pair of low-energy γ -rays at 29.4 and 86.5 keV or indirectly via daughter product ^{233}Pa after secular equilibrium has been achieved. The low specific activity of ^{237}Np essentially precludes its determination in environmental samples by gamma spectrometry. Chemical recovery of ^{237}Np can be monitored with the isotope spike ^{239}Np . Neptunium-239 can be determined directly by gamma spectrometry via any of its relatively intense γ -rays.

Plutonium isotopes ^{239}Pu and ^{240}Pu have numerous γ -rays that potentially allow their determination by gamma spectrometry (Gunnick, 1991). Most of these γ -rays have $I_{\gamma} < 1 \times 10^{-3}$, making their direct determination in environmental samples impossible. Alternatively, Pu can be determined by measuring U L-shell X-ray emissions associated with its decay. This method has been applied to chemically pure Pu standards achieving MDLs of 20 pg (Nitsche *et al.*, 1992). A recent study of the application of gamma spectrometry to the transuranic actinides by Wolf (1998) achieved LOQs for ^{237}Np , ^{239}Pu , and ^{241}Am of 100 ng, 1500 ng, and 5 pg, respectively. These analyses were performed under routine conditions using a 104% relative efficiency HPGe detector. These results correspond to LOQs of 1.0, 3500, and 0.5 Bq and MDLs of 0.3, 1100, and 0.2 Bq for ^{237}Np , ^{239}Pu , and ^{241}Am , respectively.

A standard method for the determination of γ -ray emitters in water has been published (ASTM D3649-91, 1991c). This method reports that with typical gamma spectrometers activities of approximately 40 Bq can be measured under routine conditions and activities of 0.4 Bq can be determined for many nuclides. Application of gamma spectrometry to most naturally occurring actinides and the environmentally important transuranic actinides, however, are limited by typical long half-lives and/or low intensities for emitted γ -rays. The limitations of radiometric determination via gamma spectrometry are particularly apparent when sensitivity is considered on a mass basis.

30.3.3 Neutron activation analysis

(a) NAA fundamentals

Analysis of trace actinide content by NAA has been performed on the naturally occurring actinides as well as on transuranic actinides (see Chapter 27, section 27.3.5, of this book). The most frequently used method of NAA is activation with thermal neutrons. Typically, NAA is performed using neutrons produced in a nuclear reactor or by an isotopic source such as ^{252}Cf and subsequently

thermalized (most probable energy of 0.025 eV). Samples and flux monitor standards are typically irradiated simultaneously and analyzed for high-precision quantitative analysis. After the irradiation, measurement of the α -particles, β -particles, γ -rays, delayed neutrons, or fission products are performed using an appropriate spectrometer. If no chemical treatment is performed after irradiation, the technique is called instrumental neutron activation analysis (INAA). If chemical separations are performed after irradiation, the technique is called radiochemical neutron activation analysis (RNAA). If chemical methods are used to preconcentrate the element of interest before activation the technique is called preconcentration neutron activation analysis (PCNAA). NAA employing epithermal neutrons, i.e. neutrons with energies of 0.1–1 eV, is called epithermal neutron activation analysis (ENAA). Finally, if the concentration of the nuclide is determined by using an isolated solid detector to quantify the number of tracks produced by neutron-induced fission, the method is known as fission track analysis (FTA).

The basic equation that governs all NAA methods is:

$$R = \frac{m}{M} N \phi \sigma_n \varepsilon (1 - e^{-\lambda t}) \quad (30.2)$$

where R (Bq) is the count rate of a sample containing a mass m (g) of a given nuclide with molecular weight M (g mol^{-1}) at the end of irradiation, and N is Avogadro's constant. The thermal-neutron flux density (ϕ) is the number of thermal neutrons incident on a unit area of sample per unit time ($n \text{ cm}^{-2} \text{ s}^{-1}$). The thermal-neutron capture cross section (σ_n) is a measure of the probability that the nuclide of interest will capture a neutron and be activated and has unit surface area (cm^2). The term ε is the efficiency of the detector measuring the count rate (absolute number of decays per number of decays counted) for the decaying radionuclide. The final set of terms in parentheses corrects the activity for the duration of irradiation t (s) and the decay constant λ (s^{-1}) of the specific nuclide. This equation is valid for samples thin enough that attenuation of the neutron flux can be ignored. Examination of equation (30.2) shows that the absolute sensitivity of NAA is dependent on the flux ϕ , the cross section σ_n for the nuclear reaction, the decay constant λ of the nuclide of interest, and the irradiation duration t . An overview of the fundamentals of NAA can be found in texts such as Friedlander *et al.* (1981) and Ehman and Vance (1991).

(b) INAA applications

Non-destructive INAA determination of U in geological and environmental materials can be performed in several ways (Parry, 1991). One approach is NAA with subsequent detection of delayed neutrons. This method possesses a high specificity for U and has been used for many years in the exploration of U ores. The method is based on the measurement of delayed neutrons following a short irradiation with thermal neutrons. Uranium-235 undergoes thermal-neutron-induced fission. The resulting neutron-rich fission products undergo β^- decay.

While most of the fissiogenic daughter nuclei are in excited states and relax via γ -ray emission, some daughter nuclei possess sufficient energy for relaxation to occur via delayed-neutron emission. The delayed neutrons are emitted instantaneously after β^- -decay with the half-life of the β^- -decaying parent. The neutrons are detected with polyethylene-moderated BF_3 proportional counter systems. The BF_3 detector is extremely sensitive to neutrons and insensitive to the γ -rays and β^- -particles emitted by other activated elements in the sample. The technique, therefore, is highly selective with respect to ^{235}U . If the sample is irradiated with a neutron flux possessing an appreciable fast-neutron component, there will be a contribution from fast-neutron fissions of ^{238}U . This condition is not problematic because this nuclide is still U. If the sample contains significant amount of ^{232}Th , a correction for fast-neutron fissions is required for accurate U determination. The dominant ^{235}U fission products that decay via delayed-neutron emission are ^{89}Br ($t_{1/2} = 4.4$ s), ^{87}Br ($t_{1/2} = 55.6$ s), ^{94}Rb ($t_{1/2} = 2.8$ s), ^{137}I ($t_{1/2} = 24.5$ s), and ^{135}Sb ($t_{1/2} = 1.7$ s). For example, the decay scheme for ^{87}Br is

NAA with delayed-neutron detection can be automated for online and unattended determination of U content in solid and liquid samples. A system described by Rosenberg *et al.* (1977) determines the U content in 10 g samples that have been packed in polyethylene containers and irradiated for 60 s in a flux of $10^{16} \text{ n cm}^{-2} \text{ s}^{-1}$. Samples are counted for 60 s after a 20 s decay. Even though natural U is only 0.720% ^{235}U , and less than 1% of the neutrons released in the fission are from delayed-neutron emitters, the thermal cross section of ^{235}U is so large that the technique possesses sufficient sensitivity for routine analysis of U-containing materials with a reported MDL of $0.6 \mu\text{g g}^{-1}$. This method can also be coupled with gamma spectrometry for the determination of additional elements in the sample.

A second and more common pathway for INAA of U is use of the (n,γ) reaction. For ^{238}U this method consists of determining the intensity of the 105 keV γ -ray from the decay of ^{239}Np . ^{239}Np is produced from the decay of ^{239}U that results from thermal-neutron capture by ^{238}U according to the following reaction:

The amount of ^{239}U and ^{239}Np produced is directly related to, and therefore a measure of, the amount of ^{235}U present in the original sample. At high concentrations U can be determined by measurement of the 74 keV γ -ray from the decay of ^{239}U immediately after sample irradiation. MDLs are enhanced with the use of a detector sensitive to low-energy photons such as a planar HPGe with a thin Be window. Both of these methodologies are enhanced with a higher ratio of epithermal neutrons. INAA of ^{232}Th is based on gamma-spectrometric

determination of ^{233}Pa produced by the following reaction:

INAA determination of trace U and Th is that the analysis can be performed simultaneously with a suite of other elements. Routine applications of INAA for the determination of trace elements including U and Th in the recent literature include the analysis of oceanic basalts (Joron *et al.*, 1997) and precious and common opals (McOrist and Smallwood, 1997). Joron *et al.* (1997) reported detection limits of 6.9 and 1.7 ng g⁻¹ for U and Th, respectively. Samples weighing 150 mg were irradiated for 8–15 h at a flux of 1.1×10^{13} n cm⁻² s⁻¹ followed by a 1-week sample cooling and 3000 s count time for U determination. Samples were counted second time for 40000 s after a 30-day cooling period for the Th determination.

The high sensitivity of INAA makes this technique ideal for the analysis of minute amounts of material such as individual phases, minerals, and crystals separated from bulk material. Schrauder *et al.* (1966) used INAA to determine U and Th along with a suite of trace elements in 13 micro-inclusion-bearing fibrous diamonds from Botswana to constrain the composition of fluids in the mantle (Schrauder *et al.*, 1996). Raimbault *et al.* (1997) developed a technique to extract single crystals and perform multielemental analysis, including U and Th, with INAA. The INAA technique required only a few micrograms of mineral and facilitated the measurement of more than 30 elements in multiple samples from the Oklo U deposit in Gabon. This work utilized the presence of epithermal neutrons in the reactor flux producing (n,p) reaction products, extending the number of elements determined. This methodology was able to detect low µg g⁻¹ concentrations of U and Th in single-crystal samples in a variety of minerals.

A non-destructive method for the determination of ^{239}Pu by INAA in contaminated soils has been developed by Fuller *et al.* (1965). This method utilized the fission product ^{140}La to quantify ^{239}Pu . Because ^{140}La is produced by the fission of both ^{239}Pu and ^{235}U , the ^{235}U contribution needs to be subtracted from the total activity. This was accomplished by first directly determining the ^{235}U content of the unirradiated soil via gamma spectrometry. Soil samples were irradiated with thermal neutrons for 60 s and counted twice after decay periods of 3–4 and 10–14 days. The ^{238}U content was determined after the first cooling period via the ^{239}Np 74 keV γ -ray. Lanthanum-140 was determined after the second cooling period by measuring its 1.6 MeV γ -ray. The MDL for ^{239}Pu in soil sample was reported to be 5 ng.

(c) RNAA applications

With respect to NAA techniques, RNAA offers lower MDLs for actinides than INAA due to virtual elimination of activated matrix elements. RNAA has traditionally been used for trace U and Th determinations in a variety of

matrices (Parry, 1991) from the first lunar samples (Wänke *et al.*, 1970) to biological materials (Picer and Strohal, 1968). Typically, the irradiated sample is decomposed and equilibrated with a milligram amount of the element of interest known as the carrier. The carrier element, along with the radionuclide produced during sample irradiation, is then chemically separated and purified. The amount of radionuclide recovered from the chemical separation is determined gravimetrically from the amount of carrier element recovered. For RNAA determination of U, the quantitation is based on the radiochemical analysis of one or more fission products arising from the thermal-neutron-induced fission of ^{235}U . RNAA determination of ^{232}Th is complicated due to lack of a stable isotopic carrier for the determination of the recovery yield. In this case, ^{231}Pa can be used as a recovery tracer for the activation product ^{233}Pa (Glover *et al.*, 1998a and references therein). The purified elemental sample can then be radiometrically assayed by gamma spectrometry. RNAA is a destructive technique that is more time-consuming and requires greater analytical and chemical laboratory skills than does INAA. The chemical separation of the element of interest, however, results in a sample possessing a gamma spectrum with virtually no background from other γ -ray-emitting species. Procedures for the determination of trace U in geological materials via the $^{235}\text{U}(\text{n},\text{f})^{132}\text{Te}$ reaction are given in Anders *et al.* (1988). Using a thermal-neutron flux of $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$, this methodology can achieve MDLs as low as 10 pg g^{-1} for U. Filby (1975) used the $^{235}\text{U}(\text{n},\text{f})^{135}\text{I}$ reaction to determine U in human lung samples, coal dust, coal filters, rat lung tissue, animal diets, and minerals. The reported MDLs for U in these matrices were as low as 5 ng g^{-1} depending on the sample matrix and final radiochemical purity.

A comparison of INAA and RNAA analyses for ^{232}Th show that up to two orders of magnitude improvement in MDLs can be achieved when RNAA is employed. RNAA has been used for the analysis of ^{232}Th in human tissue samples with a MDL of 10 pg (Picer and Strohal, 1968).

Recently, a procedure for PCNAA of ^{232}Th in human tissues has been developed (Glover *et al.*, 1998a). The method used ^{227}Th to determine the yield of the preconcentration process. Removal of the matrix elements before irradiation greatly lowers the dose to the radiochemist processing the sample. This method resulted in a MDL of 10^{-4} Bq per sample ($\sim 20 \text{ ng } ^{232}\text{Th}$), an order of magnitude lower than the MDL for direct alpha-spectrometric determination. PCNAA has the advantage in that very large samples can be processed. Th isotopic composition (^{228}Th , ^{230}Th , and ^{232}Th) can be determined when this PCNAA procedure is combined with alpha spectrometry (Glover *et al.*, 1998b). Thorium isotopes ^{228}Th and ^{230}Th can be determined before irradiation by electroplating the separated Th onto a V planchet and counting it on an alpha spectrometer. The electroplated sample can then be irradiated for ^{232}Th determination. This method has been used to measure the Th isotopic composition of human tissues with MDLs of 1×10^{-8} , 4×10^{-4} , and 1 ng for ^{228}Th , ^{230}Th , and

^{232}Th , respectively. A PCNAA method has been adapted for the determination of ^{237}Np via the $^{237}\text{Np}(n,\gamma)^{238}\text{Np}$ reaction (Byrne, 1986). This method was used to determine ^{237}Np in contaminated sediments from the Esk estuary and the foreshore at Grange-over-Sands, Cumbria. The sediment samples were ashed and the Np separated by ketone extraction. Recovery of the ^{237}Np was monitored with a ^{239}Np isotopic spike. The reported MDL for ^{237}Np was 4 pg g^{-1} for a 5 g sample. This MDL could be improved to $<0.4\text{ pg g}^{-1}$ if higher neutron fluences were used.

(d) FTA applications

If a sample is irradiated in close proximity to a glassy or plastic material, the heavy nuclides generated from thermal-neutron-induced fission will produce submicroscopic tracks in the material. The measurement of these tracks after etching is the basis for FTA and was first reported in 1958 by Young (1958). Moorthy *et al.* (1988) describe the application of FTA to the analysis of ^{239}Pu in urine. Because ^{235}U will also undergo thermal-neutron-induced fission the Pu is first isolated by anion-exchange chromatography. An aliquot of the separated sample was transferred to a fused silica slide. Samples and standards were irradiated for 10 min for a neutron fluence of 10^{17} n cm^{-2} . After cooling for 2 days the slide is washed and etched with HF. Fission track density is determined under a bright-field microscope. The reported LOQ was $5\text{ fg }^{239}\text{Pu}$ per sample. Recently FTA has been used for the measurement of U in pore water (Barnes and Cochran, 1990). The FTA method can be performed with small samples but generally only gives precisions of 6–15%. Love *et al.* (1998) recently have described a novel approach to determine $^{240}\text{Pu}/^{239}\text{Pu}$ ratios in human tissue samples by combining alpha spectrometry and FTA.

30.4 ATOMIC SPECTROMETRIC TECHNIQUES

Atomic spectrometric techniques are based on the absorption and emission of electromagnetic radiation from atoms or ions. Information specific to the electronic structure of individual elements is manifested in the ultraviolet and X-ray regions (see Chapter 27, section 27.3.2, of this book) of the electromagnetic spectrum. Each element possesses a unique electronic structure and, therefore, unique atomic spectra. The absorption and emission of electromagnetic radiation of a wavelength specific to an electronic transition of a particular element can serve as the basis for analysis and determination of that element. The actinides are amenable to analysis and determination via several atomic absorption/emission-based techniques including atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), flame emission spectrometry (FES), and inductively coupled plasma atomic emission spectrometry (ICPAES). The

application of these techniques for U determination has recently been reviewed (Wolf, 1999). The application of these techniques to trace analysis of actinides has been limited due to the complexity of actinide ultraviolet absorption/emission spectra, lack of sensitivity, and lack of isotopic specificity. Atomic spectrometric methods based on fluorescence or phosphorescence generally possess lower MDLs. The actinides U, Am, and Cm are relatively unique among most elements in that they can be determined directly via fluorometry without the addition of a fluorescent chelating agent. Even lower MDLs can be achieved by utilizing the ability of uranyl ions to phosphoresce when excited to a triplet state. Because of this, the techniques of fluorometry, and phosphorimetry, have been employed for trace U determination.

30.4.1 Fluorometry

(a) Fluorometry fundamentals

In the fluorometric determination of U, an aliquot of a decomposed solid sample or digested aqueous liquid sample is pipetted onto a Pt disk containing a NaF–LiF flux and is evaporated and fused in a furnace. The fused disk is then exposed to an ultraviolet source such as a mercury-arc lamp in combination with a filter or monochromator at 365 nm. Laser excitation with time-resolved detection can increase the sensitivity of the technique by two orders of magnitude. The intensity of the fluorescence is measured at 560 nm. The presence of ionic species of Cd, Cl, Cr, Co, Cu, Fe, Mg, Mn, Ni, Pb, Pt, Si, Th, and Zn quench U fluorescence and lower the sensitivity of the technique. Nb and Ta are reported to enhance U fluorescence. In samples containing significant quantities of these elements, analyses can be performed after chemical separation of the U or dilution of the sample if sufficient concentrations of U are present. The fluorometric method is a single-element method dedicated to the determination of U.

(b) Fluorometry applications

Fluorometry has also been applied to the determination of U in geological, environmental, and biological materials. The ASTM has published a standard test method for determining traces of U in water by fluorometry (ASTM D2907-91, 1991b). This method can determine U concentrations as low as 5 ng mL^{-1} . A procedure has recently been developed for the determination of trace U rocks, minerals, and soils by laser fluorometry after low-temperature dissolution with a HF–HNO₃ mixture for economical high-throughput analyses (Ramdoss *et al.*, 1997). Time-resolved laser fluorometry can attain MLDs as low as 50 pg mL^{-1} (Ghods-Esphahani *et al.*, 1990 and references therein).

30.4.2 Phosphorimetry

(a) Phosphorimetry fundamentals

The uranyl ion can be directly determined phosphorimetrically in a H_3PO_4 or H_2SO_4 solution. The acid is added to protect the uranyl ion from various intermolecular mechanisms that quench luminescence. The sample is excited at 254 nm, and the intensity of the yellow-green emission can be measured in a fluorimeter and related to concentration. Use of a pulse-laser excitation source can increase the sensitivity of this method greatly. In the pulsed-laser phosphorimetric method, an aliquot of sample is pipetted into a glass vial, mixed with HNO_3 and H_2O_2 , and taken to dryness. The residue is dissolved in HNO_3 and a complexant such as H_3PO_4 . The phosphorimetric method is a single-element method dedicated to the determination of U. The technique determines total U concentration independent of the specific isotopic composition of U.

(b) Phosphorimetry applications

The ASTM has published a standard test method for determining trace U in water by pulsed-laser phosphorimetry (ASTM D5174-91, 1991d). This technique can be used to determine U concentrations as low as 50 pg mL^{-1} .

30.5 MASS SPECTROMETRIC TECHNIQUES

In contrast to radiometric techniques, quantitative analysis by mass spectrometry is based only on counting the number of atoms of the nuclide of interest as opposed to counting randomly occurring radioactive decay events (see Chapter 27, section 27.3.3, of this book). The precision of the measurement is, therefore, independent of the specific activity of the radionuclide. The long half-lives and low specific activities of the parents of the three non-extinct natural decay chains and several of the environmental transuranic nuclides (^{231}Pa , ^{237}Np , ^{239}Pu , ^{240}Pu) make them ideal candidates for determination by mass spectrometry. Mass spectrometric techniques are based on the separation of gas-phase analyte ions (either molecular or atomic) on the basis of their mass-to-charge ratio (m/z) so that they can be separately detected. The technique can, therefore, provide isotopic information of the element of interest. The first mass spectroscopic measurement of a U compound was demonstrated by F. W. Aston in 1931 (Aston, 1931). The first accurate mass spectrometric measurement of the isotopic composition of U was performed by A. O. Nier in 1939 (Nier, 1939). Technological advancements have since resulted in highly automated, commercially available inorganic mass spectrometers that, in many laboratories, have

replaced radiometric and other nuclear-based techniques for the trace analysis of actinides.

Mass spectrometric measurements require the atomization and ionization of the analyte from a solid sample or solution in the ion source. Ions are electrostatically extracted from the source and focused with a system of electrostatic ion lenses into the mass analyzer. The mass analyzer disperses the ions in space or time based on m/z . Several types of mass analyzers have been utilized for inorganic mass spectrometry including single focusing static magnetic sectors, double focusing tandem magnetic/electrostatic sectors, dynamic time-of-flight (TOF) mass analyzers, and quadrupole mass analyzers (Becker and Dietze, 1998). A limitation to the magnetic-sector mass analyzer is that it does not focus on the basis of velocity for an ion with a given mass. Velocity focusing can be achieved with the addition of an electrostatic sector to form a double focusing tandem magnetic/electrostatic sector mass analyzer. The dynamic TOF mass analyzer functions by accelerating all ions to the same kinetic energy and allowing ions with different masses to disperse along a flight tube. Quadrupole mass analyzers function as a high-pass, low-pass mass filter. This is achieved by placing a direct current (dc) voltage and a radiofrequency (rf) voltage on two pairs of parallel rods. For a given set of dc and rf voltages, only ions with a specific m/z possess a stable path through the filter. A m/z scan can be performed by varying the dc and rf voltages. After dispersion by the mass analyzer ions are detected. High precision can be achieved on systems that disperse the ions in space by configuring multiple detectors to simultaneously detect ions with different m/z (multicollector systems). The detector and mass analyzer are both pumped to a very low pressure so that collisions with gas molecules are minimized. More details of the various configurations of sources, mass analyzers, and detectors can be found in Platzner *et al.* (1997).

Mass spectrometric techniques are defined primarily by the ion source. Mass spectrometers utilized for inorganic trace analysis include the spark source mass spectrometer (SSMS), the glow discharge mass spectrometer (GDMS), the laser ablation mass spectrometer (LAMs), the resonance ionization mass spectrometer (RIMS), the accelerator mass spectrometer (AMS), the secondary ion mass spectrometer (SIMS), the thermal ionization mass spectrometer (TIMS), and the inductively coupled plasma mass spectrometer (ICPMS). Mass spectrometric determination of trace actinides requires the spectrometer to produce actinide ions with high efficiency, and the capability of selectively separating the nuclide of interest from interfering isobars, molecules, and backgrounds caused by higher abundance isotopes. The most commonly used mass spectrometric techniques for trace actinide analysis are TIMS and ICPMS. AMS, and RIMS, although less routine than TIMS and ICPMS, have the potential for ultrahigh-sensitivity determination of actinides. Fundamentals and application of TIMS, AMS, RIMS, and ICPMS for trace actinide determinations are discussed below.

30.5.1 Thermal ionization mass spectrometry

Thermal ionization sources produce an extremely stable, relatively intense supply of ions with a minimal energy spread, and minimal molecular and atomic interferences. When coupled with an appropriate mass analyzer and multicollector detector system, the resulting TIMS instrument is capable of measuring elemental isotopic ratios with precisions $<0.01\%$ while requiring only nanograms of material (Becker and Dietze, 1998). However, the high first ionization potential for the actinides complicates their determination by TIMS due to the lower efficiency of the thermal ionization process. Despite this, methods have been developed so that as little as 40 fg of an actinide can be determined (Chen and Wasserburg, 1981). The main disadvantage of TIMS is that extensive sample preparation is required. Whereas the thermal ionization source is moderately selective with respect to some interfering atomic and organic molecular species, chemical procedures are required to separate individual actinides to minimize the presence of interfering isobars. Additionally, TIMS is typically used to determine only one element per prepared sample. Despite these disadvantages, TIMS has been used nearly exclusively in geochronological studies where high-precision isotope ratio determinations are required (Chen *et al.*, 1992). In some cases TIMS has been replacing alpha spectrometry in environmental studies where extremely low concentrations of long-lived transuranic actinides are being determined (Cooper *et al.*, 2000). TIMS analysis of actinides is also applicable for the purpose of bioassay (Maxwell, 1997).

(a) TIMS fundamentals

TIMS instruments that are used for actinide analysis consist of the following principal components: a thermal ionization source that produces positively charged actinide ions; ion extraction and focusing optics and source slit; mass analyzer; collector slit and detection system (Platzner *et al.*, 1997). These components and their arrangement are illustrated in Fig. 30.6.

Trace analysis of an element by TIMS first requires sample dissolution and chemical separation of the analyte element from sample matrix components as well as potentially interfering isobars (see Section 30.2.2). A small aliquot of solution containing the chemically separated actinide (typically $<1\ \mu\text{g}$ of actinide) is deposited onto a filament composed of a clean, degassed refractory metal such as Re or W that possesses a high-electron work function. The most frequently used method utilizes two filaments arranged opposite to each other. Single, double, and triple filament designs have been utilized. In a double filament configuration, one filament is used for evaporative heating of the atoms and the second for ionization. Arden and Gale (1974) and Chen and Wasserburg (1981) have developed a method using graphite to enhance U^+ emission by loading an aqueous colloidal suspension of graphite onto a Re filament. The solution is evaporated, producing a thin graphite film. The

Fig. 30.6 Schematic representation of a 90° single-collector TIMS (after Platzner *et al.*, 1997).

separated U sample is loaded onto the filament, evaporated, and a second graphite film is applied. The geometry of the filament was either V-shaped or dimpled. The ionization efficiencies with this method were determined to be 0.6–1.2% for standards and the source produced very stable ion beams. This method has also been utilized for the preparation of a ^{231}Pa source yielding efficiencies of 0.7% (Pickett *et al.*, 1994). A second method of source preparation directly uses an anion-exchange resin bead onto which U, Th, or Pu has been adsorbed (Walker *et al.*, 1974). This resin bead source has also been used for the determination of Am and Cm by TIMS (Poupard and Jouniaux, 1990). Perrin *et al.* (1985) developed a surface ionization-diffusion-type ionization (SID) source for the analysis of Pu, which uses a Re filament onto which Pu has been electroplated followed by an overplating with Pt.

Ions produced in the source are accelerated to approximately 10 kV, focused with a series of ion lenses, and pass through a source slit to enter the mass analyzer. The most common method of mass analysis for TIMS measurements of actinides is the single-focusing static magnetic sector (Chen *et al.*, 1992). The magnetic-sector mass analyzer disperses ions by m/z according to the following equation:

$$\frac{m}{z} = \frac{H^2 r^2}{2V} \quad (30.3)$$

where m is the ion mass, z is the ion charge, V is the potential to which the ion has been accelerated, H is the strength of the magnetic field, and r is the radius of the circular path followed by the ion. A magnet with a radius of 30 cm requires a field strength of 0.7 T to achieve beam separation of 0.255 cm for m/z 236 and 235 (Platzner *et al.*, 1997). Double focusing tandem magnetic/electrostatic sector instruments (Palacz *et al.*, 1992) as well as three-stage instruments (Lagergren and Stoffels, 1970) have also been utilized for actinide determination. In a single detector system, after dispersion by the magnetic sector, the ion beam is scanned across the collector slit so that only one isotope reaches the detector at any one time. Because of the low ion currents generated during trace analysis a detector that enhances the signal at each m/z such as a secondary electron multiplier (SEM) or Daly detector is used. Larger currents from major isotopes are measured with Faraday ion collectors. On a typical modern system, instrument control, data acquisition and analysis are computer-controlled.

Quantitative trace analysis by TIMS is typically performed via isotope dilution (ID). Accurate results require corrections for time-dependent and time-independent biases in the ion source, mass analyzer, and detector system. The rate of evaporation of isotopes of an element from any thermal ionization source is mass dependent so bias corrections are required. These mass fractionation discrimination effects limit the accuracy of determination. Correction for biases can be made in part by the use of internal isotopic standards and performing analysis of well-determined standards.

(b) TIMS applications

The analysis of trace concentrations of actinides by TIMS has been demonstrated for essentially all of the long-lived actinides including ^{234}U , ^{235}U , ^{238}U , ^{230}Th , ^{232}Th , ^{231}Pa , ^{237}Np , ^{239}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , and ^{241}Am and has been utilized for measurements of geological, environmental, and biological samples. TIMS is currently one of the most frequently utilized techniques for U-series disequilibria measurements. Procedures and applications of TIMS to U measurements are summarized in Chen *et al.* (1992) and references therein. Chen and Wasserburg (1981) utilized their graphite-coated filament in a methodology for the determination of ^{238}U abundances, $^{238}\text{U}/^{235}\text{U}$ ratios, and $^{234}\text{U}/^{238}\text{U}$ ratios in small cosmochemical samples. The method utilized a ^{233}U - ^{236}U double spike to correct for instrumental fractionation, high-yield, low-background chemical separation procedures, and filament-loading techniques. This methodology could determine $^{234}\text{U}/^{238}\text{U}$ ratios with a precision of 0.5% (2σ) for a sample size of 5×10^9 ^{234}U atoms and accurate U concentration measurements could be made with as little as 20 fg of U. This method has also been adapted for the determination of Th isotopes (Cheng *et al.*, 2000). The high-precision and

sensitivity of TIMS has been used to redetermine the half-lives of ^{234}U and ^{230}Th by precisely determining $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ ratios in many geological materials that have behaved as closed systems $>10^6$ years (Bourdon *et al.*, 1999).

Naturally occurring ^{231}Pa , a nuclide that has traditionally been determined radiometrically, has recently been determined in geological and seawater samples by TIMS. Pickett *et al.* (1994) determined ^{231}Pa in geological samples by ID-TIMS. ^{233}Pa was separated from a ^{237}Np source and was utilized as the isotopic spike. The authors estimated that as little as 30 fg of ^{231}Pa under routine analysis conditions and achieved an external reproducibility better than $\pm 1\%$. The preferred sample size was stated to be >100 fg ^{231}Pa . A similar method has been developed by Bourdon *et al.* (1999) that utilizes a ^{233}Pa spike produced *in situ* from neutron activation of ^{232}Th . The application of TIMS to ^{231}Pa , ^{230}Th , and ^{232}Th determination in seawater yielded decreased sample size (100–1000-fold), increased precision (5–10% vs. 20–40%), and decreased measurement time (hours vs. weeks) when compared to traditional alpha-spectrometric determination (Edmonds *et al.*, 1998).

A typical TIMS system and method used for the determination of transuranic actinides has been described by Perrin *et al.* (1985). The method utilized a modified instrument developed at the National Bureau of Standards (NBS, currently National Institute of Standards and Technology, NIST). This spectrometer is a 30.5 cm radius 90° deflection magnetic-sector mass analyzer equipped with a 17-stage electron multiplier. The dark current of the detector system is 0.05 cps. Application to Pu isotopic determination demonstrated the capability of measuring the $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio in samples of 0.5–2 ng with 0.07% precision and accuracy at the 95% confidence level. Chemical separation of Pu from U and Am is required to minimize isobaric interferences from ^{238}U and ^{241}Am on ^{238}Pu and ^{241}Pu , respectively. Plutonium-242 (Cooper *et al.*, 2000) is typically used as an isotope spike in the ID-TIMS determination of Pu. Plutonium-244 has also been used as an isotope spike in an investigation of sources of transuranic elements in arctic marine sediments where ^{242}Pu was one of the target analytes (Curtis *et al.*, 1999). When combined with the appropriate analytical separations and clean room techniques the TIMS methodology has a ^{239}Pu blank of (17 ± 0.15) pg and MDL of 440 fg (Cooper *et al.*, 2000). This method has been used to determine concentrations of naturally occurring ^{239}Pu in U ores (Attrep *et al.*, 1992; Dixon *et al.*, 1997) as well as measure colloidal transport of Pu in groundwater that originated from the testing of nuclear weapons at the Nevada Test Site (Kersting *et al.*, 1999). The groundwater measurements had a reported precision of $\pm 1.5\%$ and a procedural blank of <2 pg Pu. These figures of merit allowed the identification of the source of the Pu as a specific nuclear event. A related ID-TIMS procedure for ^{237}Np in soil and in human tissue samples has been developed (Efurd *et al.*, 1986). This ID-TIMS method used ^{236}Np was used as an isotope spike and is optimized for samples containing 100 pg ^{237}Np . Although ^{237}Np does not possess any isobaric interferences, chemical separation must be performed to

minimize the amount of ^{238}U in the sample due to the tail of the ^{238}U peak adding counts at $m/z = 237$. This type of interference results from limitations in a performance characteristic called abundance sensitivity. Abundance sensitivity is defined as the ratio of the signal at the mass of interest resulting from the presence of a major abundance peak to the signal of the major peak. This characteristic is inherent to each individual mass spectrometer. Interference is caused when ions possessing a higher m/z inelastically scatter with components of the spectrometers or residual gas in the spectrometer. This scattering causes ions to have decreased kinetic energies and produces a signal in the low m/z region of tail of the higher-mass isotope peak. The contribution of this signal becomes increasingly significant as the ratio of the minor to the major isotope decreases. Lagergren and Stoffels (1970) describe a three-stage TIMS that has been used for the low-level determination of actinides. This instrument is equipped with a sliding-shaft vacuum lock for precise positioning of the ion source, two magnetic sectors followed by an electrostatic sector, and a pulse-counting ion detection system. The instrument has good sensitivity for minor isotope determination and is capable of determining even the minor Pu isotopes ^{241}Pu and ^{242}Pu in environmental samples. This TIMS instrument has been used to assess the production of ^{237}Np from above-ground nuclear testing by determining $^{237}\text{Np}/^{239}\text{Pu}$ ratios in northern hemisphere soil samples. An essential component to this work is that it was performed in a dedicated low-level laboratory. Laboratory blank levels did not exceed approximately 10^4 atoms. Highly reproducible and accurate results were achieved at $<10^6$ atoms of transuranic actinide (^{237}Np , ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu).

Extremely high sensitivity and the capability of providing isotopic information makes TIMS an extremely effective tool for trace actinide determination. In general TIMS can be applied to actinide determination in geological, environmental, and biological samples. The technique can also be applied to routine actinide bioassay determination (Maxwell, 1997) although alpha spectrometry and ICPMS are typically used due to their greater cost effectiveness. The technique is highly selective due primarily to chemical procedures performed before analysis. The technique is applicable to isotopes of all the naturally occurring actinides and environmental transuranic actinides. Calculations based solely on counting statistics indicate that under routine conditions radionuclides with half-lives ~ 70 years and greater can be determined more precisely by TIMS (Chen *et al.*, 1992). These calculations indicate that ^{238}Pu is the actinide with the half-life that is the lower limit for which TIMS is more precise than alpha spectrometry.

30.5.2 Accelerator mass spectrometry

Accurate determination of trace concentrations of any nuclide by mass spectrometric techniques requires the ability to discriminate between the analyte signal and the signal from interfering species possessing near-identical m/z ratios.

These interfering species may either be molecules, isobars, or species resulting from inelastic scattering of ions possessing higher m/z ratios. Theoretically, discrimination of molecules and isobars possessing near-identical m/z ratios may be achieved by increasing the resolution of the spectrometer to a level sufficient for discrimination on the basis of m/z . This approach, however, decreases ion transmission efficiency and thus, instrumental sensitivity. The determination of a minor isotope can be complicated if it possesses a lower mass than the most abundant isotope due to limitations in abundance sensitivity. All of these interferences result in limiting the ability of a mass spectrometer to precisely and accurately determine concentrations of trace elements and trace isotopes of elements. Acceleration of analyte ions to potentials >1 MV offers several unique mechanisms that together allow for the elimination of both of these types of interfering species. The utilization of high-energy accelerators for ultrahigh-sensitivity mass spectrometric analysis is called AMS.

(a) AMS fundamentals

The high sensitivity and specificity of AMS is achieved with control and manipulation of a combination of experimental parameters depending on mass (m), charge (z), and energy (E) of the analyte ion combined with unique advantages that high-energy acceleration introduces. The first significant experiment using AMS was reported by Alvarez and Cornog (1939) who used a cyclotron to assist in the discovery of ^3He in He. The AMS technique was reintroduced in the 1970s and developed for the measurement of long-lived ($t_{1/2} = 2.73 \text{ y} - 16 \text{ My}$) cosmogenically produced radionuclides such as ^3H , ^{10}Be , ^{14}C , ^{26}Al , ^{32}Si , ^{36}Cl , ^{41}Ca , ^{53}Mn , $^{55,60}\text{Fe}$, $^{59,63}\text{Ni}$, $^{81,85}\text{Kr}$, and ^{129}I (Vogel *et al.*, 1995). The primary strength of the AMS technique is the ability to measure the abundance of minor isotopes in the presence of major isotopes in the range 10^{-12} to 10^{-15} . Modern AMS instruments that have used for actinide analysis typically consist of the following components: a pre-accelerator system consisting of a negative ion source, pre-accelerator, and a mass analyzer; a tandem-based accelerator with a gas-based or foil-based electron stripper; and a post-accelerator analysis and detection system (Litherland, 1987). These components and their arrangement are illustrated in Fig. 30.7. Negative ions, either atomic or molecular, are extracted from the ion source at a potential of several kV. This potential allows the initial energy distribution of the ions extracted from the source to be sufficiently overwhelmed so that unit mass resolution analysis of the ions may be achieved before introduction into the accelerator. The ions accelerate toward the terminal of the accelerator that is at a high-positive electrostatic potential of several MV. At the terminal the ions pass through either a low-pressure gas or thin foil that strips one or more electrons from the ions. Typically beam conditions are optimized so that two or more electrons are stripped from the analyte ions. Multiply charged molecular ions fragment due to coulombic repulsion. Thus, essentially all molecules can be destroyed. These positively charged ions now

Fig. 30.7 Schematic representation of the AMS based on the 14UD Pelletron accelerator at the Australian National University (after Fifield et al., 1996).

accelerate away from the terminal with an increased energy. These ions, which can possess energies as high as several GeV, are subjected to further mass analysis and detection. The high energies that can be achieved in such a system allows utilization of rate of energy loss-range detection, a detection system that allows separation of isobars due to differing average nuclear charge as ions pass through a gas.

An important requirement for an AMS ion source is the ability to produce an intense beam of negative ions ($>1 \mu\text{A}$) with low memory effect. The most common ion source utilized for AMS is a Cs sputter ion source. Zhao *et al.* (1994a) studied the production of negative atomic and molecular ions from a Cs sputter ion source for introduction of ions into the accelerator for subsequent analysis and detection of the isotopes of interest. Samples were prepared as compressed as either mixtures of original sample material (Th metal or U ore); mixtures of actinide, C, and Al; or a mixture of actinide oxide and Nb. The authors concluded that a dicarbide was an effective molecule for the analysis of Th and Pa whereas a monoxide was superior for U and Pu.

Many of the facilities that developed AMS for the determination of these radionuclides utilized tandem-based accelerators originally constructed for nuclear physics experiments. However, the analysis of actinides by AMS was initially restricted due to limitations in the maximum achievable terminal potential of most tandem-based accelerators. Lower terminal potentials result in substantially higher backgrounds due to the higher cross sections of both elastic scattering and charge-changing collisions at these energies. Background can be particularly problematic for actinide analysis due to the large number of mass combinations of lighter atoms at heavier masses. Lower terminal potentials also result in decreased transmission efficiencies due to the lower yield of higher

charge states of heavier ions during charge-changing collisions. However, several instrumental advances resulting in improved background control now allow the analysis of actinides with tandem-based accelerators at moderate (1–3 MeV) energies (Kilius *et al.*, 1990).

(b) AMS applications

AMS has been demonstrated for several actinide elements, in particular Th, Pa, U, and Pu. The first detection of the naturally occurring U isotope ^{236}U by AMS was achieved by Zhao *et al.* (1994b) at the IsoTrace Laboratory in Ontario, Canada. This nuclide is produced by the (n,γ) reaction on ^{235}U in U ore deposits. The production of ^{236}U can be significantly increased in U ore deposits saturated with water due to the production and subsequent thermalization of MeV neutrons from the fission of ^{238}U . Analysis of ^{236}U by conventional low-energy mass spectrometric methods is problematic due to the background resulting from elastic scattering of the intense ^{238}U signal and the molecular species ^{235}UH . The AMS instrument used in this work was composed of a Cs sputter source; an injection system consisting of a 45° electrostatic analyzer ($E/\Delta E \sim 400$) and a 90° magnet ($m/\Delta m \leq 400$); a tandem accelerator operating at a potential of $\leq 2\text{MV}$; a post-accelerator system consisting of a 15° electrostatic analyzer ($E/\Delta E \sim 300$), a 90° magnet ($m/\Delta m \leq 2600$), a 45° electrostatic analyzer ($E/\Delta E \leq 900$); and an ionization chamber detection system. Molecular interferences were minimized by selecting an ion charge state of +5. This system determined a $^{236}\text{U}/^{234}\text{U}$ ratio of $(1.0 \pm 0.27) \times 10^{-5}$ in a sample of U ore from Cigar Lake, Saskatchewan, Canada. This ratio corresponds to a $^{236}\text{U}/^{238}\text{U}$ ratio of $(5.6 \pm 0.15) \times 10^{-10}$ under the assumption of secular equilibrium. This measurement demonstrated the capability of small tandem-based AMS systems for analyzing actinides.

Purser *et al.* (1996) proposed the configuration of a broad-range precision AMS system for the measurement of ^{229}Th , ^{230}Th , ^{233}U , and ^{236}U . The authors proposed using ^{236}U as a thermal-neutron monitor with an integration period >100 My. The AMS instrument proposed by the authors consists of a Cs sputter source; an injection system consisting of a 90° magnet ($m/\Delta m \sim 800$) and a 90° electrostatic analyzer ($E/\Delta E \sim 120$); a tandem accelerator with a terminal stripping tube operating at a potential of 3 MV; a post-accelerator system consisting of two electrostatic analyzers, a second stripper to remove E/z ambiguities, a 90° magnet ($m/\Delta m > 1000$) equipped so that the energy of the ions can be bounced at the source to select individual masses, and a focal-plane detection system.

The measurement of Pu isotopes by AMS has been demonstrated by Fifield *et al.* (1996). A simplified schematic representation of the AMS system is shown in Fig. 30.7. The instrument consisted of a high-intensity negative ion source that produced PuO^- ; an injection system consisting of a 125 kV preaccelerator and a 90° magnet; a 14 UD Pelletron accelerator operating with a terminal

voltage of 3.5 MV with a gas stripper; a post-accelerator system consisting of a 90° magnet and a switching magnet; and a longitudinal-field ionization heavy-ion detector. This instrument had a limit of detection of approximately 10^6 atoms of Pu and was capable of determining $^{240}\text{Pu}/^{239}\text{Pu}$ ratios.

The ability to measure isotopic ratios in the range 10^{-12} to 10^{-15} potentially makes AMS an extremely powerful technique, particularly for the determination of naturally occurring minor actinide isotopes such as ^{230}Th in the presence of ^{232}Th and ^{236}U as well as in the presence of the more abundant isotope ^{238}U . Despite the demonstrated high sensitivity of AMS it has not become a widely used method for the determination of trace levels of actinide elements. AMS requires dedicated accelerator facilities and personnel. Whereas several AMS user facilities exist, none of these facilities perform trace actinide analyses routinely.

30.5.3 Resonant ionization mass spectrometry

High ionization efficiency and extremely low interferences from isobars and molecular ions are important factors for the measurement of low concentrations of actinides by mass spectrometric techniques. The availability of high-intensity narrow-bandwidth tunable lasers has enabled the application of laser spectroscopic techniques for highly efficient and selective ionization of specific elements. RIMS is the name given for the technique in which photons from laser light sources are used to selectively excite and ionize atoms before mass spectrometric analysis. The resonant ionization process is theoretically achievable for every actinide element (Hurst, 1987).

(a) RIMS fundamentals

Ambartzumian and Letokhov (1972) were the first to describe the process by which neutral atoms are selectively excited and ionized via a two-step photon absorption process. The primary strength of this technique as a source of ions for mass spectrometric analysis is the high selectivity in which atoms of a selected element are ionized. A laser is tuned to a wavelength that will promote a valence electron in a *Z*-selected atom from its ground state to an excited state. Additional resonance or non-resonance steps are then used to achieve nearly 100% ionization efficiency. Hence, by selecting a laser or lasers with energies matching specific bound electronic transitions of the atoms of interest, saturated resonant excitation and ionization can be achieved provided that the sum of the energies of the photons exceed the ionization potential of the element. Two simplified resonance ionization schemes that have been used for RIMS analysis of actinides are illustrated in Fig. 30.8. These discrete resonant transitions are critical for the RIMS technique because they are highly specific and extremely efficient processes, as high as 10^9 times as that for non-resonant background

Fig. 30.8 Simplified energy diagrams for two pathways that have been used for RIMS analysis of actinide elements (after Krönert *et al.*, 1985; Peuser *et al.*, 1985; Trautmann, 1992). Pathway A is a two-photon transition followed by photoionization by a photon of the same energy. This resonance ionization pathway has been demonstrated for U (Krönert *et al.*, 1985). Pathway B shows a three-step excitation and photoionization process using three photons possessing different energies. Pathway B has been demonstrated for Pu (Peuser *et al.*, 1985) and Np (Trautmann, 1992).

nuclides (Fassett *et al.*, 1983). In a typical two-photon process, an atom is first resonantly excited from the ground state to an excited electronic state and then subsequently ionized by absorbing a second photon. Some elements require a three-photon process: two photons for excitation to consecutive excited electronic states followed by a third photon for ionization. Multiple isotopes of a given element may be excited and ionized simultaneously, but not equally, by selecting broad bandwidth lasers. In RIMS, ionization is followed by mass spectrometric analysis for unambiguous identification on the basis of m/z . Mass analysis is typically performed using either magnetic sector or TOF mass spectrometers. Detection of ions is typically performed by a secondary electron multiplier or channel plate detectors.

(b) RIMS applications

Analysis by RIMS has been demonstrated for several actinides including Th, U, Np, and Pu. Detection of Pu isotopes by RIMS was first demonstrated by Donohue and Young (1983). A sample consisting of a mixture of NBS SRM 947e (^{238}Pu , ^{239}Pu , ^{240}Pu , and ^{241}Pu) and a ^{242}Pu standard was loaded onto a single Re thermal ionization source filament, atomized, and then excited and ionized with a nitrogen pumped dye-laser system. Several potential two-photon RIMS-active wavelengths in the excitation range of 431–451 nm were identified. After ionization, Pu ions were analyzed with a single-stage magnetic sector mass spectrometer that was scanned across the 238–250 amu mass range. The mass spectrum of this sample appeared with approximately the same abundances as it did when ionized by thermal ionization demonstrating that resonance ionization of Pu. This initial work with Pu did not, however, have sufficient sensitivity to achieve precision sufficient for analysis within a reasonable time. Further development of this method resulted in a methodology that, in addition to virtually eliminating isobaric interferences, demonstrated the potential of being at least as precise as TIMS (Donohue *et al.*, 1984). Improvements included the use of a single-wavelength RIMS process that used low-energy photons in the 590 nm region for resonant ionization of both U and Pu. A pulsed-heated filament synchronized with a 30 Hz pulsed-laser system resulted in a ten-fold improvement in sensitivity. Analysis was performed with a high-sensitivity tandem magnetic sector mass spectrometer.

Continued development and improvements in pulsed-laser systems have resulted in the ability to detect trace amounts of Pu by RIMS (Krönert *et al.*, 1985; Peuser *et al.*, 1985). Sensitivity was improved by applying a high-repetition pulsed-laser three-photon excitation and ionization scheme. A laser system was developed that consisted of a 6.5 kHz 30 ns pulse width Cu vapor laser for simultaneously pumping of three dye lasers. The dye lasers were scanned for the first two steps $\lambda_1 = 586.5$ nm and $\lambda_2 = 688.2$ nm using wavelength intervals of 0.05 nm whereas the third was made with part of the laser pump beam at $\lambda_3 = 578.2$ nm. TOF mass spectrometry was used for mass analysis and to minimize the background from non-resonantly produced ions. These improvements resulted in the ability to detect as few as 10^8 Pu atoms by RIMS and also demonstrated the capability to detect ^{237}Np (Trautmann, 1992). More recently RIMS has been applied to Pu and transplutonium elements with the potential of detecting 10^6 atoms in environmental samples (Erdmann *et al.*, 1998).

The RIMS method has been used for the measurement of U isotope ratios in several NBS standards. The $^{234}\text{U}/^{235}\text{U}$ ratio of NBS U930 and $^{235}\text{U}/^{238}\text{U}$ ratios of natural U, NBS U930, NBS U500, and NBS U750 were measured via resonant ionization followed by TOF mass spectrometry with a gated pulse counter designed specifically for the processing transient signals generated by the pulsed multiphoton ionization process. Replicate measurements of $^{235}\text{U}/^{238}\text{U}$ ratios in NBS U500 demonstrated accuracy and precision of 0.4%

(Green and Sopchyshyn, 1989). This work, however, was performed on relatively high concentrations of pure U samples.

Fearey *et al.* (1992) have developed a RIMS method for the determination of $^{230}\text{Th}/^{232}\text{Th}$ ratios for application in U-disequilibrium dating of geological samples. The use of both a broadband standing wave dye laser to excite both isotopes simultaneously and a scanned narrowband Ti:sapphire laser for excitation of each individual isotope was investigated. Mass spectrometry was performed with a single magnetic sector mass analyzer. Results indicated that the superior frequency stability of the narrowband Ti:sapphire laser compared to the broadband dye laser resulted in both higher accuracy and precision of the $^{230}\text{Th}/^{232}\text{Th}$ ratio determination. The method demonstrated a higher ionization efficiency than thermal ionization.

The extremely high efficiency and specificity of the resonant ionization process possesses enormous potential for high-sensitivity analysis of actinide elements. Single atom counting would be possible providing that suitably sensitive detection technologies could be developed and applied. The primary drawback of the technique is that ion signals generated by pulsed multiphoton ionization processes are inherently difficult to quantify with high precision. Despite its potential for high sensitivity RIMS has not become a widely used method for the determination of trace levels of actinide elements. The instrumentation for RIMS analysis is complex and is not well suited for routine analysis of geological, environmental, and biological samples. Further development of laser technologies may provide for less complex and less expensive RIMS instruments for routine analysis in the future. Application to complex geological, environmental, and biological samples will require utilization of chemical sample preparation procedures.

30.5.4 Inductively coupled plasma mass spectrometry

The ICP source is an effective and efficient atomization and ionization source that allows convenient introduction of aqueous samples. The high temperature of the ICP source efficiently ionizes actinide elements. When coupled with a quadrupole mass analyzer, the large dynamic range, nominal resolution, high-sample throughput and relatively simple spectra make ICPMS an extremely useful analytical tool for performing rapid trace analysis with <1 pg of an actinide. ICPMS instruments equipped with quadrupole mass analyzers became commercially available in the early 1980s and have since gained wide acceptance as a sensitive and accurate method for geoanalytical and environmental chemists. Actinides can be determined along with a suite of other trace elements simultaneously. Most aqueous samples can be analyzed with minimal pretreatment. ICPMS has rapidly emerged as one of the most versatile analytical techniques for trace actinide analysis.

(a) ICPMS fundamentals

Analysis by ICPMS typically requires a liquid sample. Bulk elemental analysis of solid materials by ICPMS requires the dissolution of the material followed by direct analysis. Acid dissolutions are usually performed so that the TDS values do not exceed 0.2%. In many cases ICPMS analysis can be performed directly on aqueous samples such as water and urine. Chemical preconcentration and separation of the actinides of interest from matrix elements can also be performed before analysis. Laser ablation (LA) has been used for direct sampling of solid materials. The analytical capabilities of LA-ICPMS have been described in Longerich *et al.* (1996). The focus of this section is aqueous sample ICPMS.

In ICPMS, a solution of the sample is introduced as an aerosol into the ICP source by a nebulizer in combination with spray chamber. Nebulization converts the liquid sample to an aerosol with a stable and reproducible size distribution. Because instrumental sensitivity and background values in ICPMS are dependent on the method of sample introduction, a variety of approaches have been designed to increase efficiency, reduce sample volume requirements, and reduce the effect of solvent loading on the plasma (Montaser *et al.*, 1998). Several types of nebulizers have been utilized with ICPMS including pneumatic, ultrasonic (USN), and electrothermal vaporization (ETV). Matrix reduction methods include FI as well as desolvation. The most common sample introduction method is pneumatic nebulization. Crain and Mikesell (1992) demonstrated that the higher efficiency of the USN system yielded improved sensitivity of ICPMS for the determination of U in industrial wastewater by an order of magnitude. FI preconcentrates analyte elements and reduces matrix effects. FI-ICPMS has been demonstrated for U analysis in environmental samples (Aldstadt *et al.*, 1996).

The aerosolized sample is swept into the ICP with a stream of Ar called the sample carrier gas. A typical ICP source contains a torch that is configured as three concentric quartz tubes through which Ar is flowing. The diameter of the largest tube is approximately 2 cm, and the Ar that flows through it at a rate of approximately 14 L min⁻¹ is called the cooling gas. The middle tube contains Ar flowing at a rate of 0–1 L min⁻¹. This auxiliary flow can be used to affect the shape of the plasma and extend the torch life. The aerosol sample and carrier gas is introduced into the center tube with a flow of approximately 1 L min⁻¹. The torch is surrounded by a water-cooled induction coil that is powered by a radio frequency generator that creates the plasma. Typical frequencies are 27.5 and 40 MHz with a power of 1.3 kW. An impedance matching circuit is used to maintain a stable plasma. The source is called an inductively coupled plasma because the coil acts as an inductor. The ICP atomizes molecular species and ionizes the atoms.

The most critical component of an ICPMS is the interface that samples these ions and allows their transfer to a lower pressure region without significant bias.

Sampling is achieved by a sampling cone with an orifice approximately 1 mm in diameter. Ions flow through this orifice into an expansion chamber that is mechanically pumped to lower the pressure. The sampled material forms a supersonic jet. The jet flows through a skimmer cone also with an approximately 1 mm diameter orifice. Ions are extracted and focused toward the mass analyzer with a series of electrostatic ion lenses. Most commercial ICPMS instruments use a fast-scanning quadrupole mass analyzer operated at nominal mass resolution. Typical multielemental survey scan rates are 100 ms for a continuous scan from ${}^6\text{Li}$ to ${}^{238}\text{U}$. Dedicated trace actinide analysis use programmed peak jumping with longer dwell times. Ions transmitted through the mass analyzer are typically detected with a channel electron multiplier. A schematic diagram of typical ICPMS instrumentation is given in Fig. 30.9. A thorough description of the principles of ICPMS operation and instrumentation can be found in Jarvis *et al.* (1991). Instrument control and data acquisition is controlled with a personal computer equipped with a software interface. For transuranic actinide analysis, the ion source or the entire instrument may be contained in a fume hood or gloved box.

Spectra generated by ICPMS are relatively simple, primarily singly charged ions with some additional doubly charged ions, oxides, and hydrides. The doubly charged ions, hydrides, and oxides can be minimized to approximately $<1\%$ of the parent ion. Actinide determination is straightforward due to the virtual absence of isobaric or molecular interferences in typical environmental and geological samples. Modern state-of-the-art ICPMS instruments possess $100\text{ MHz } \mu\text{g}^{-1}\text{ mL}^{-1}$ sensitivity with backgrounds $<0.5\text{ cps}$. These figures correspond to a MDL $<100\text{ fg mL}^{-1}$ for an actinide in solution, approximately 2.5×10^8 atoms in a 1 mL sample, or 50 pg g^{-1} in solid samples assuming a typical 0.2% TDS sample dissolution. Equivalent MDLs are readily achievable for all other actinides.

Perhaps the technique that shows the most promise for improvements in routine actinide analysis is high resolution (HR)-ICPMS. This technique

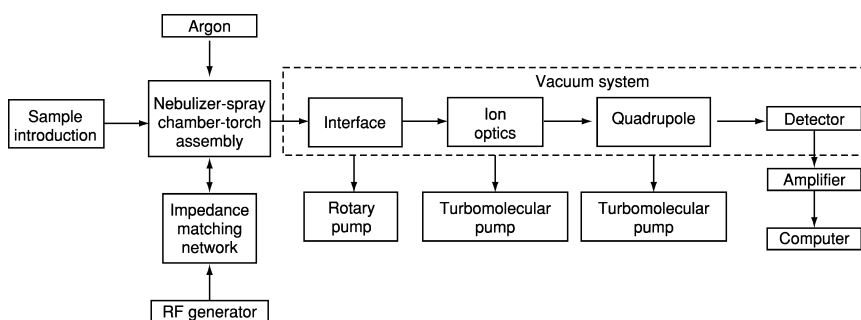

Fig. 30.9 Schematic diagram of an ICPMS (after Wolf, 1999).

combines an ICP source with a high-precision, double-focusing, mass analyzer. A review of HR-ICPMS instrumentation and applications has been published by Moens and Jakubowski (1998). The technique was first introduced in 1988 and the availability of commercial second- and third-generation HR-ICPMS instruments has made a significant impact on planetary, earth, and environmental chemistry. Commercial HR-ICPMS instruments, when operated at resolutions >2000 , are capable of separating many interfering polyatomic ions from isotopes of interest. However, when operated at lower resolutions, a HR-ICPMS equipped with a single detector is capable of measurement with higher sensitivities, lower backgrounds, and higher precisions than typical quadrupole-based ICPMS instruments. A mass spectrum of a 1 ng mL^{-1} U- and Th-containing solution measured on a VG Elemental Axiom HR-ICPMS is given in Fig. 30.10. The spectrum was collected by the author using instrumental resolution setting of 460. Essentially all of the U and Th isotopes are isobar-free; however, ^{232}ThH and ^{238}UH can potentially bias ^{233}U and ^{239}Pu determinations if high ^{232}Th and ^{238}U concentrations are present. This instrument possesses a $2 \text{ GHz } \mu\text{g}^{-1} \text{ mL}^{-1}$ sensitivity and a $<0.1 \text{ cps}$ background corresponding to a MDL of $<1 \text{ fg mL}^{-1}$ for U in solution, approximately 2.5×10^6 atoms of

Fig. 30.10 Spectrum of a 1 ng mL^{-1} U- and Th-containing sample. The spectrum was analyzed using conventional liquid sample introduction, pneumatic nebulization and a HR-ICPMS in the author's laboratory. The sample was prepared from NIST SRM 3164 and NIST SRM 3159. Note that even at these low concentrations, peaks from naturally occurring minor U isotopes ^{234}U and ^{236}U are evident. Also apparent is the contribution from the major ^{238}U peak to $m/z = 237$ and the contribution of ^{238}UH to $m/z = 239$.

U in a 1 mL sample, or 1 pg g⁻¹ in solid samples with assuming a typical 0.2% TDS sample dissolution. Equivalent MDLs are readily achievable for all other actinides. In addition to higher sensitivities, superior precisions can be achieved on HR-ICPMS instrumentation designed in a multicollector (MC) configuration. In this configuration, the precision of MC-ICPMS is comparable to TIMS.

(b) ICPMS applications

ICPMS can be used to determine total actinide element concentration, concentration of individual nuclides, and isotope ratios. The technique has been applied to the analysis of all of the long-lived naturally occurring actinides and environmental transuranic actinides. Elemental analysis of U and Th in geological samples with ICPMS requires the determination of the concentration of at least one isobar-free isotope and known isotopic distribution for the element. This is accomplished by direct determination of $m/z = 232$ for Th and $m/z = 238$ for U. Total U is calculated using the natural isotopic composition of U. Quantitative trace analysis of U and Th can be performed using internal standardization, external calibration, or isotope dilution. The most common approach to calibration is external calibration followed by linear regression. Internal standards such as ²⁰⁹Bi (for ²³⁵U, ²³⁸U) (Wolf, 1998), another actinide (i.e. ²³²Th for U analysis) (Crain and Mikesell, 1992), or an isotopic spike (i.e. ²³³U, ²³⁵U, or ²³⁶U for U analysis) (Eggins *et al.*, 1997) have been used to compensate for variations in instrumental response. These calibration methods typically yield uncertainties less than ±10% for a wide variety of matrices even at ultra-trace concentrations.

Isotope dilution (ID) is commonly employed to improve the accuracy of elemental ICPMS determinations. The suitability of ID-ICPMS analysis was evaluated for U determinations (Joannon *et al.*, 1997). Uranium concentrations were measured in two separate solutions of six international rock reference materials, and the results differed by 1–3% for concentrations in the range of 10–400 ng g⁻¹. Isotope dilution ICPMS analysis can yield uncertainties less than ±1% in a wide variety of matrices.

Uranium and thorium isotope ratio measurements for U-disequilibrium studies using ICPMS and HR-ICPMS are straightforward because of the availability of the isobar-free nuclides ²³⁰Th, ²³²Th, ²³⁴U, ²³⁵U, and ²³⁸U. Typical precisions for quadrupole-based ICPMS instruments range from 0.1 to 1.0%. These precisions limit its usefulness for measurement of many of the geologically important isotopic systems. Despite these limitations, the ease at which ICPMS is able to measure isotope ratios makes it useful for a few selected isotopic systems that do not require precisions better than approximately 0.1%. Superior precision can be achieved on HR-ICPMS instrumentation designed in a multicollector (MC) configuration. When used in the MC configuration, the precision of ICPMS is comparable to that of TIMS. A review of MC-ICPMS

instrumentation and applications including U and Th isotopic analysis has been reported (Halliday *et al.*, 1998). This paper reviews results of replicate analysis of NIST SRM-906 measured by TIMS and MC-ICPMS. Precisions of approximately 1 δ unit (2σ), comparable to the best achievable TIMS precision, were achieved. The external reproducibility of MC-ICPMS was superior to TIMS. Multicollector ICPMS will undoubtedly be established as the preferred method for U and Th isotopic determinations due to its high precision, ease of sample introduction, high sample throughput, and user-friendly interface.

ICPMS has been used to determine concentrations of U and Th in geological, environmental, and biological materials. A review of applications of ICPMS to geological materials has been published (Lipschutz *et al.*, 2001). Environmental matrices such as wastewaters (Crain and Mikesell, 1992) and soils (Crain *et al.*, 1995) have been analyzed by ICPMS. Biological materials studied include plant tissues (Alvarado *et al.*, 1996), urine and lung fluid (Wyse *et al.*, 1998), and fecal material (Twiss *et al.*, 1994). Standard methods for the determination of ^{238}U and ^{232}Th in water (ASTM D5673-96, 1996a) and in soils (ASTM C1345-96, 1996c) have been published. The estimated MDLs for ^{238}U and ^{232}Th in water by ICPMS are 20 and 30 pg mL^{-1} , respectively. The ICPMS MDL for ^{238}U and ^{232}Th in soil are both 500 ng g^{-1} . These MDLs take into consideration a dilution factor of 200 from the soil dissolution procedures. A standard method for the determination of ^{234}U and ^{230}Th in soil by FI-ICPMS has also been published (ASTM C1310-95, 1995c). The estimated FI-ICPMS MDL for ^{234}U and ^{230}Th in soil are 2 and 5 pg g^{-1} , respectively.

The capabilities of both ICPMS and HR-ICPMS can easily be expanded to the determination of the transuranic actinides. In contrast to TIMS, direct analysis of actinides can be performed without any chemical separations. This approach can be complicated due to backgrounds caused by limitations in the mass analyzer, molecular interferences, and isobars. Chemical separation of U must be performed to minimize the contribution of ^{238}U to $m/z = 237$ during ^{237}Np determinations. ^{238}U can interfere with trace determinations of ^{239}Pu particularly when the U/Pu ratio is $>10^6$. Chemical separation of U from Pu minimizes this effect. Isobaric interferences complicate total Pu isotopic analysis: ^{238}U interferes with ^{238}Pu , and ^{241}Am interferes with ^{241}Pu . Essentially all of these interferences can be minimized by utilizing one of the chemical separation procedures outlined in Section 30.2.2.

Vance *et al.* (1998) have recently assessed and reviewed the application of ICPMS for the routine determination of ^{237}Np in a variety of matrices and found that ICPMS achieves MDLs 1–2 orders of magnitude lower than alpha spectrometry. Yamamoto *et al.* (1994) used HR-ICPMS to measure fallout ^{237}Np in soil samples with concentrations as low as 15 fg g^{-1} of soil. Chemical separations were used to preconcentrate ^{237}Np from 10–40 g samples and ^{239}Pu was used as a recovery spike. Crain *et al.* (1995) used ICPMS to determine concentrations of several long-lived actinides including ^{237}Np and ^{239}Pu in soil leachates with MDLs of 20 fg mL^{-1} of solution sample. These MDLs were

achieved using an USN and peak jumping for maximum sensitivity. ICPMS has also been used for the determination of ^{239}Pu in urine for bioassay (Wyse *et al.*, 1998). A recent study of the application of IDMS to the transuranic actinides achieved LOQs for ^{237}Np , ^{239}Pu , ^{241}Am , and ^{244}Cm of 20 pg for each nuclide (Wolf, 1998). These analyses were performed using pneumatic nebulization on a quadrupole-based ICPMS designed in a containment hood. Considering the sensitivities of modern state-of-the-art instruments, MDLs of <100 fg in a 1 mL sample are readily attained for isobar-free actinides by ICPMS (Brenner *et al.*, 1998). If 1 mBq is assumed to be the MDL for routine alpha-spectrometric actinide determination, then ICPMS should possess higher sensitivities than alpha spectrometry for actinides with $t_{1/2} > 1400$ years.

HR-ICPMS and MC-ICPMS are capable of even greater sensitivities and precisions for trace transuranic actinide determination. HR-ICPMS has been used for the determination of ^{239}Pu , ^{240}Pu , and ^{242}Pu isotope ratios in soils from the former Semipaltinsk nuclear test site in the former USSR (Yamamoto *et al.*, 1996). Ratio measurements with precision of 5% could be achieved with as little as 100 fg mL⁻¹ of solution. However, to discriminate between different source materials on the basis of Pu isotopic ratios requires precisions <1% at ultra-trace concentrations. Taylor *et al.* (2001) have determined Pu isotope ratios in solutions containing <100 fg mL⁻¹ with precisions of 1.4% (2σ). These high precisions were achieved utilizing a MC-ICPMS along with a $^{236}\text{U}/^{233}\text{U}$ double spike to correct for instrument drift. High sensitivity of MC-ICPMS allowed the determination of $^{242}\text{Pu}/^{239}\text{Pu}$ ratios. MDLs <1 fg mL⁻¹ that can be attained for isobar-free actinides by HR-ICPMS and MC-ICPMS. The addition of USN or other low-flow nebulizers to such systems could lower these MDLs by an order of magnitude. Again, if 1 mBq is assumed to be the MDL for routine alpha-spectrometric actinide determination, then HR-ICPMS should possess higher sensitivities than alpha spectrometry for actinides with $t_{1/2} > 14$ years.

30.6 SUMMARY

The development of standard methods, improvements in chemical procedures, and technological advances in instrumentation have significantly enhanced capabilities in trace actinide determination. There are many methods available for the determination of trace concentrations of actinides in geological, environmental, and biological materials. A substantial database of standard analytical methods for actinide determinations has been compiled and is maintained by the ASTM. In the area of chemical procedures, the development of actinide-specific anion and extraction chromatographic resins has greatly simplified actinide chemical separations. These procedures are used in most laboratories that specialize in the determination of actinides in geological,

environmental, and biological samples. The impact that improved chemical procedures have on the sensitivity, precision, and accuracy of analytical methods cannot be underestimated.

Because of the numerous and complex factors involved in the overall quality of an analytical approach, direct comparison of the different techniques is difficult. A few general observations can be made. The actinides are the only family of elements whose concentrations can be determined entirely by direct radiometric counting techniques. Gamma spectrometry has the advantage of being the only non-destructive radiometric technique but it is limited in general applicability to all the actinides due to the absence of intense γ -rays. Essentially all but a few of the naturally occurring actinides and environmental transuranic actinides can be determined by gamma spectrometry. Alpha spectrometry can provide complete isotopic information for U and Th. However, alpha spectrometry, like all radiometric techniques, is fundamentally limited by the low specific activity of most of the naturally occurring actinides and environmental transuranic. Despite this limitation, alpha spectrometry has been one of the most frequently utilized techniques for the routine determination of actinides in geological, environmental, and biological samples. The principal reasons for this are experimentally adequate sensitivity and selectivity as well as instrumentation well adapted to high-throughput routine analyses. In cases where higher sensitivity and higher precision are required, TIMS has typically been employed. The primary drawback to routine utilization of TIMS is that the instrumentation is more complex than in alpha spectrometry and is less suited to routine high-throughput analysis. In theory, both AMS and RIMS have the potential for improved sensitivity and selectivity over TIMS. In practice, however, the complexity of the instrumentation required for actinide determination by AMS and RIMS have so far prevented their adaptation as routine methods.

Perhaps the most significant technological advancement in the area of trace element analysis has been the continuing development of ICPMS and its application to actinide determinations. The strength of ICPMS resides in its high sensitivity, multielement capability, and high-sample throughput. ICPMS has replaced INAA as the standard method for trace element analysis of geological materials. Commercially available quadrupole-based ICPMS instruments are well suited for routine determination of actinides in a variety of sample matrices. The sensitivity and precision of ICPMS is comparable to that of alpha spectrometry for all but the shortest-lived actinides. When configured as a multicollector instrument the sensitivity and precision of MC-ICPMS is comparable to TIMS. The sensitivity of MC-ICPMS is comparable to, or superior to that of RNAA, for the determination of ultra-trace elements. Both ICPMS and MC-ICPMS are supplanting other methods in laboratories that need to determine trace actinide concentrations with isotopic specificity. Further development of applications of the more recently available HR-ICPMS and

MC-ICPMS instruments for ultra-trace actinide determinations will certainly improve our understanding of the chemistry of the actinide and transuranic actinide elements in the environment.

LIST OF ABBREVIATIONS

AAS	atomic absorption spectrometry
AES	atomic emission spectrometry
AMS	accelerator mass spectrometry
ASTM	American Society for Testing and Materials
Bq	Becquerel
CMPO	octyl(phenyl)- <i>N,N</i> -diisobutylcarbamoylmethylphosphine oxide
cps	counts per second
Da	Dalton, unified atomic mass unit
DAAP	diamylamylphosphonate
DBM	dibenzoylmethane
dc	direct current
DDCP	dibutyl- <i>N,N</i> -diethylcarbamylphosphonate
DTPA	diethylenetriaminepentaacetic acid
ENAA	epithermal neutron activation analysis
EPA	Environmental Protection Agency
ETV	electrothermal vaporization
FES	flame emission spectrometry
FI	flow injection
FTA	fission track analysis
GDMS	glow discharge mass spectrometry
HDEHP	bis(2-ethylhexyl)phosphoric acid
H ₂ DEH[DMP]	bis(2-ethylhexyl)methanediphosphonic acid
HEDPA	1-hydroxyethylidenediphosphonic acid
HPGe	high-purity germanium
HPLC	high-performance liquid chromatography
HR-ICPMS	high resolution-inductively coupled plasma mass spectrometry
ICPAES	inductively coupled plasma atomic emission spectrometry
ICPMS	inductively coupled plasma mass spectrometry
ID	isotope dilution
ID-ICPMS	isotope dilution-inductively coupled plasma mass spectrometry
ID-TIMS	isotope dilution-thermal ionization mass spectrometry
INAA	instrumental neutron activation analysis

LA	laser ablation
LA-ICPMS	laser ablation-inductively coupled plasma mass spectrometry
LAMS	laser ablation mass spectrometry
LOQ	limit of quantitation
MC-ICPMS	multicollector-inductively coupled plasma mass spectrometry
MDL	minimum detection limit
NAA	neutron activation analysis
NBS	National Bureau of Standards
NIST	National Institute of Standards and Technology
PCNAA	preconcentration neutron activation analysis
PFA	perfluoroalkoxy
PTFE	polytetrafluoroethylene
rf	radio frequency
RIMS	resonance ionization mass spectrometry
RNAA	radiochemical neutron activation analysis
RSD	relative standard deviation
SEC	size exclusion chromatography
SEM	secondary electron multiplier
SID	surface ionization diffusion
SIMS	secondary ion mass spectrometry
SRM	standard reference material
SSMS	spark source mass spectrometry
TBP	tributyl phosphate
TDS	total dissolved solids
TIMS	thermal ionization mass spectrometry
TIOA	triisooctylamine
TOF	time-of-flight
TTA	thenoyltrifluoroacetone
USN	ultrasonic nebulization
USTUR	United States Transuranium and Uranium Registries

ACKNOWLEDGMENTS

The author would like to thank his colleagues at Argonne National Laboratory for many informative discussions on the chemistry of actinide elements and his colleagues at Indiana State University for encouragement and support during the writing of this work. The author is especially grateful to his wife Heather for her assistance and support through the many evenings and weekends that were used to produce this work.

APPENDIX I

NUCLEAR SPINS AND MOMENTS OF THE ACTINIDES

Nuclear spins and nuclear moments are used to test the single-particle models and nuclear quadrupole moments provide the deformation of the nucleus. In the following table, we present measured values of ground state spin in units of \hbar , magnetic dipole moment (μ) in units of nuclear magneton, and spectroscopic quadrupole moment (Q) in units of barns. The data have been taken from Raghavan (1989) and Firestone and Shirley (1996).

<i>Nuclide</i>	<i>Nuclear spin</i> (\hbar)	<i>Nuclear magnetic moment</i> (nuclear magneton)	<i>Electric quadrupole moment</i> (barns)
²¹⁷ Ac	9/2	+3.825(45)	
²²⁷ Ac	3/2	+1.1(1)	+1.7(2)
²²⁹ Th	5/2	+0.46(4)	+4.3(9)
²²⁸ Pa	3	+3.48(33)	
²³⁰ Pa	2	+2.00(29)	
²³¹ Pa	3/2	+2.01(2)	-1.72(5)
²³³ Pa	3/2	+3.39(70)	-3.0
²³³ U	5/2	0.59(5)	3.663(8)
²³⁵ U	7/2	-0.38(3)	4.936(6)
²³⁷ Np	5/2	+3.14(4)	+3.886(6)
²³⁸ Np	2		
²³⁹ Np	5/2		
²³⁹ Pu	1/2	+0.203(4)	
²⁴¹ Pu	5/2	-0.683(15)	+5.6(20)
²⁴¹ Am	5/2	+1.61(3)	+4.2(13)
²⁴² Am	1	+0.3879(15)	-2.4(7)
^{242m} Am	5	+1.00(5)	+6.5(20)
²⁴³ Am	5/2	+1.61(4)	+4.30(3)
²⁴³ Cm	5/2	0.41	
²⁴⁵ Cm	7/2	0.5 (1)	
²⁴⁷ Cm	9/2	0.37	
²⁴⁹ Bk	7/2	2.0(4)	+5.79
²⁴⁹ Cf	9/2	-0.28	
²⁵³ Es	7/2	+4.10(7)	6.7(8)
^{254m} Es	2	2.90(7)	3.7(5)

APPENDIX II

NUCLEAR PROPERTIES OF ACTINIDE AND TRANSACTINIDE NUCLIDES

Irshad Ahmad

DISCUSSION

In this appendix, an elementary discussion of the nuclear properties of heavy elements is presented. For a better understanding of the subject, the reader should refer to nuclear chemistry textbooks (Krane, 1988; Choppin *et al.*, 2002) and for the information on decay data, the *Table of Isotopes* (Firestone and Shirley, 1996) or the *Table of Radioactive Isotopes* (Browne and Firestone, 1986) or *Nuclear Data Sheets* (Tuli, 2004) should be consulted.

Isotopes of all elements with $Z \geq 89$ are radioactive. The most common mode of decay for these nuclei is by the emission of alpha particles (^4He ions). Alpha decay energies have been experimentally measured (Browne and Firestone, 1986; Firestone and Shirley, 1996) for most nuclides and these can also be calculated from atomic masses (Wapstra *et al.*, 2003). The α decay of a nucleus with atomic number Z and atomic mass A produces a daughter nucleus with atomic number $Z-2$ and atomic mass $A-4$. During the α decay, about 2% of the available decay energy is imparted to the recoiling daughter nucleus and the remaining energy is carried off by the fast moving α -particle. Several groups of α -particles are emitted by a sample of a nuclide, each with a definite energy. For the actinide nuclides, α -particle energies range from about 4 to 11 MeV. As a rule, α -particle energy increases with increasing Z , and for a given element, it decreases with increasing mass number.

The α -decay half-life decreases exponentially with increasing energy. As a guide, every 50 keV increase in the decay energy reduces the half-life by a factor of ~ 2 . The dependence of the α -decay half-life on the decay energy is given by the well-known Geiger–Nuttall law and more recently by Viola–Seaborg formula. A very useful quantity that facilitates the understanding of the mechanism of α -decay is the concept of hindrance factor. It is defined as the ratio of the experimental partial α -decay half-life to the theoretical half-life calculated on the assumption that the α -particle pre-exists in the nucleus and during its emission, it carries no angular momentum. An alpha transition in which the

ground state configuration of the parent nucleus remains unchanged is called 'favored transition'. All alpha transitions between the ground states of even-even nuclei are favored transitions and are assigned a hindrance factor of one.

Like elements of lower Z , each actinide element has one or more β -stable isotopes. Isotopes heavier than the β -stable isotope decay by the emission of β^- particles (electrons) and isotopes lighter than the β -stable isotopes decay by electron capture (EC). Electron capture decay is usually accompanied by the emission of K x-rays of the daughter nuclide. These x-rays provide a signature of the decaying nuclide. In heavy nuclei, β^+/EC ratio is very small and, as a consequence, positron (β^+) emission has been observed only in a few nuclei. The β -decay energy increases as the mass of the isotope gets further away from the line of β -stability. A quantity denoted by $\log ft$ is very useful in classifying the β transitions and estimating the β -decay half-lives of unknown nuclei. The ft value, also called the reduced β transition probability, is the energy-independent transition rate.

Spontaneous fission is a decay process in which a nucleus breaks up into two almost equal fragments. Each fission event is accompanied by the release of about 200 MeV energy and the emission of two to four neutrons. More than hundred nuclides are produced in fission of a nuclide sample and the mass yields and charge distributions have been measured for many fissioning systems (Wahl, 1989; Ahmad and Phillips, 1995). The fission half-life depends on the fissility parameter Z^2/A and is the major decay mode for many isotopes of element 100 and beyond. Nuclides with reasonable fission branch and available for experiments and industrial use are ^{248}Cm ($t_{1/2} = 3.40 \times 10^5$ years) and ^{252}Cf ($t_{1/2} = 2.64$ years). The isotope ^{252}Cf is widely used as a neutron source in industry and research.

Another rare mode of decay for heavy elements is the decay by the emission of intermediate mass fragments. These fragments are heavier than α particles but smaller than fission fragments. The branching ratio for this kind of radioactivity is extremely small ($\sim 10^{-10}$). Examples of such radioactivity are the ^{24}Ne emission by ^{231}Pa and ^{232}U (Price, 1989).

Alpha and β transitions usually populate excited states in addition to the ground states of the daughter nuclei. The excited states then decay to the ground state by emission of γ rays and conversion electrons. Typical half-lives of the excited states range from 10^{-9} to 10^{-14} s. However, in some cases, the decay of an excited state is forbidden for fast magnetic dipole ($M1$), electric dipole ($E1$), or electric quadrupole ($E2$) transitions because of the angular momentum selection rule. Such states have half-lives between nanoseconds and years. An excited state that has a half-life value greater than a nanosecond is called a 'metastable' state or 'isomer'. The isomeric state either de-excites to the ground state of the same nucleus by an internal transition (IT) or it decays by the usual mode of disintegration.

Most isomers occur because of the large difference between the spins of the excited state and the ground state. However, there are isomers which result not

by the difference in the spins of the states but by the difference in the shapes. These isomers decay by fission and are called 'fission isomers' or 'shape isomers' and have half-lives between 10^{-9} and 10^{-3} s. These isomers have deformations that are twice as large as the deformations of the ground states. More than 50 fission isomers have been discovered (Vandenbosch, 1977).

Very neutron-deficient nuclides decay predominantly by electron capture (EC). In some of these nuclei, the EC decay energy is quite large (> 4 MeV) and hence states at high excitation energy are populated in the daughter nucleus and a small fraction of these excited states decay by fission. Delayed fission of many nuclei has been observed (Hall and Hoffman, 1992).

Nuclear structure studies of actinide nuclides have been performed using a variety of techniques. These include high-resolution alpha, electron and gamma-ray spectroscopy, charged-particle transfer reaction spectroscopy, and Coulomb excitation studies. These investigations have provided significant information on the shape, size, and single-particle potential of actinide nuclei. The available data establish a spheroidal shape for nuclei with $A \geq 225$, with major to minor axes ratio of ~ 1.25 . The intrinsic quadrupole moments of actinide nuclei have been measured to be about 10^{-23} e cm² and the nuclear radii are about 10^{-12} cm.

Although most actinide nuclei have spheroidal shapes, there are indications that some neutron-deficient Ac and Pa nuclei have small octupole deformation in their ground states. These nuclei are pear-shaped and are axially symmetric but they are reflection asymmetric. Examples of such nuclei are ²²⁹Pa and ²²⁵Ac (Ahmad and Butler, 1993).

In nuclei, nucleons (neutrons and protons) move in orbits under the influence of the central nuclear potential. Nilsson (1955) and others (Chasman *et al.*, 1977) have calculated the eigenvalues and eigenfunctions of nucleons in a deformed potential as a function of the deformation β . Plots of the eigenvalues versus the deformation, commonly known as Nilsson diagrams, are extremely useful in understanding the single-particle properties of actinide nuclei. Each Nilsson state is characterized by a set of quantum numbers Ω , π , N , N_z , and Λ . The quantum number Ω is the projection of the single-particle angular momentum on the nuclear symmetry axis and π is the parity of the wavefunction. The asymptotic quantum numbers N , N_z and Λ denote the oscillator shell number, the number of the oscillator quanta along the symmetry axis, and the projection of the orbital angular momentum on the symmetry axis, respectively. In heavy nuclei, neutrons (protons) fill each orbital above the closed shell of 126 (82) pairwise and thus the ground state of an odd-mass nucleus is simply the orbital occupied by the last unpaired nucleon. All even-even nuclei have ground state spin-parity of 0^+ .

A spheroidal nucleus rotates about an axis perpendicular to the nuclear symmetry axis. The projection, K , of the total angular momentum, I , on the symmetry axis is the same as Ω . The rotation of a spheroidal nucleus generates a rotational band with spin sequence $K, K+1, K+2, \dots$. The

rotational energy E_I of a level with spin I is given by the expression

$$E_I = \frac{\hbar^2}{2\mathfrak{S}} I(I + 1),$$

where \hbar is Planck's constant and \mathfrak{S} is the nuclear moment of inertia. Typical values of $\hbar^2/2\mathfrak{S}$ are 7.0 keV for even–even actinide nuclei and 6.0 keV for odd-mass nuclei. The ground state band of an even–even nucleus has spin-parity sequence $0^+, 2^+, 4^+ \dots$; odd spin values are not allowed.

Qualitative and quantitative analysis of actinide samples can be performed by using a variety of techniques (Knoll, 2000). Gross counting with a 2π (50%) geometry gas proportional counter can be used to determine the α or β^- count rate in a sample. These counters have very low background for α particles but somewhat higher background for electrons. Background of ~ 0.1 α count per minute can be easily achieved for these counters.

Alpha pulse height analysis can be used to identify nuclides in a sample. Alpha spectra are measured either by Au–Si surface barrier detectors or passivated implanted planar silicon (PIPS) detectors. For best resolution (full width at half maximum), which can be as low as 9.0 keV, extremely thin sources are required. Precise energies and intensities of alpha groups have been tabulated by Ritz (1991).

Gamma-ray spectroscopy with high-resolution germanium spectrometers provides a powerful technique for qualitative and quantitative analysis of actinide samples. For high-energy γ rays in the range of 200 keV to 1.5 MeV, large volume Ge detectors provide the best sensitivity. Resolutions (FWHM) of less than 2.0 keV at the ^{60}Co 1332.5 keV line are easily achieved. In actinide nuclei, K x-ray energies lie in the 80–160 keV range and can be measured with high-resolution low-energy planar spectrometers (LEPS). K x-rays are produced when a vacancy in the K shell of an atom, created by electron capture or internal conversion, is filled by an electron from a higher shell. These K x-rays energies depend on the atomic number and there is sufficient separation between the energies of adjacent elements for them to be clearly identified. The Cm K x-ray spectrum produced in the alpha decay of ^{251}Cf and measured with a high-resolution LEPS is displayed in Fig. A.2.1. The resolution (FWHM) of the spectrometer is about 500 eV. Measurements of gamma ray spectrum and K x-ray spectrum are very useful in identifying and quantifying odd-mass nuclei.

L x-rays of actinide nuclei, which are produced when a vacancy in the L subshell of an atom is filled by an electron from a higher shell, have energies in the 10–30 keV range. Spectra of L x-rays can be measured with lithium-drifted silicon, Si(Li), detectors with resolutions (FWHM) of ~ 300 eV. A Np L x-ray spectrum from ^{241}Am alpha decay, measured with a Si(Li) spectrometer, is shown in Fig. A.2.2. These spectra are also characteristic of the element but are more complex. The definition of x-ray components is given in (Firestone and Shirley, 1996). Even–even nuclei decay to excited levels of daughter nuclei which de-excite by highly L converted transitions generating L x-rays. Thus even–even

Fig. A.2.1 K X-ray spectrum of Cm, produced in the alpha decay of ^{251}Cf , measured with a $2\text{ cm}^2 \times 1\text{ cm}$ LEPS spectrometer.

nuclei, which do not have any intense γ rays, can be analyzed by L X-ray spectroscopy.

Fissioning nuclides like ^{252}Cf can be assayed by measuring the gamma-ray spectrum with large-volume Ge detectors and using the intensities of gamma rays emitted in the decay of the abundant fission fragments (Ahmad *et al.*, 2003).

Some actinide nuclides have very long half-lives and hence they occur in nature. These include ^{232}Th , ^{235}U and ^{238}U which decay through a series of isotopes terminating at stable Pb isotopes. Isotopes of Ac, Th, and Pa are usually separated from the parent nuclides and used in the chemical and nuclear studies of these elements.

Transuranium isotopes are produced by long irradiations in nuclear reactors. In the US, there is a national program for the production and isolation of transuranium isotopes utilizing the High Flux Isotope Reactor (HFIR) at the Oak Ridge National Laboratory. The heaviest nuclide produced in this program is the 100 day ^{257}Fm . Neutron-deficient actinide isotopes are usually produced by nuclear reactions in charged particle accelerators.

All data in the tables of nuclear properties given in the preceding chapters and in this appendix have been taken from Browne and Firestone (1986), Firestone and Shirley (1996), Nuclear Data Sheets (Tuli, 2004) and from the

Fig. A.2.2 *L* X-ray spectrum of Np, produced in the alpha decay of ^{241}Am , measured with a 1 cm diameter and 5 mm thick Si(Li) detector.

web sites at the Isotope Project, Lawrence National Berkeley Laboratory (<http://www.lbl.gov>) and at the Nuclear Data Center, Brookhaven National Laboratory (<http://www.nndc.bnl.gov>). For the heaviest elements, data were taken from Armbruster (2000) and Hofmann and Münzenberg (2000). The cut-off date for literature survey was June 2004.

The notations for decay modes in the tables are: α for alpha decay, β^- for β^- decay, β^+ for positron decay, EC for electron capture decay, IT for isomeric transition, and SF for spontaneous fission. The letter m after a mass number represents an isomer. Isomers with half-lives of less than 1 s (except for the heaviest elements) and fission isomers are omitted from the tables. Energies and intensities are given for the most abundant α groups and most intense γ rays; for β^- particles, the maximum energy β_{max} is given. In the last column of Table A2.1, only the convenient methods of production are given; 'nature' denotes that the nuclide occurs in nature and 'multiple neutron capture' means that the nucleus is produced by multiple neutron capture in a high-flux reactor such as HFIR.

The specific activity S in disintegrations per minute per microgram was calculated using the expression

$$S = \frac{4.17449 \times 10^{17}}{t_{1/2}A},$$

where $t_{1/2}$ is half-life of the nuclide in minutes and A is the atomic mass in atomic mass units. The half-lives and atomic masses were taken from the references mentioned earlier in this text.

TABLES

In the following tables we reproduce the tables in each of the chapters 2 through 14 that contain the nuclear properties of the actinide and transactinide isotopes. We then give a table of specific activities of these isotopes.

Nuclear properties of actinium isotopes.

<i>Mass number</i>	<i>Half-life</i>	<i>Mode of decay</i>	<i>Main radiations (MeV)</i>	<i>Method of production</i>
206	33 ms	α	α 7.750	$^{175}\text{Lu}(^{40}\text{Ar},9\text{n})$

114	287	α	5 s	1.7 × 10 ¹⁶	
	288	α	2.6 s	3.34 × 10 ¹⁶	
115	288	α	87 ms	1.00 × 10 ¹⁸	
116	292	α	53 ms	1.62 × 10 ¹⁸	

^a Decay modes are denoted by: α for alpha decay, β⁻ for beta decay, EC for electron capture, IT for isomeric transition, and SF for spontaneous fission. The decay mode given in this column represents either the major decay mode or the only observed decay mode.

^b 1 year = 365.243 days.

^c Specific activity is given in units of disintegrations per minute per microgram and contains one more significant figure than the half-life in order to avoid rounding-off errors.

^d For commonly used isotopes, specific activities are also given in units of Curies per gram. 1 Ci = 2.22 × 10¹² disintegrations per minute = 3.7 × 10¹⁰ Bq.

 formation of energy bands, 2313–2317
 one-electron band model, 2324–2325

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Actinide metals (*Contd.*)
 strongly hybridized 5f bands in,
 2333–2339
 Fermi surface measurements, 2334
 photoemission measurement
 background, 2334–2336
 strong correlations, 2341–2350
 UIr₃ PES, 2336–2339, 2337f
 weak correlations, 2339–2341
 structural chemistry of, 2384–2388
 actinium, 2385
 americium, 2386–2387
 berkelium, 2388
 californium, 2388
 curium, 2387–2388
 einsteinium, 2388
 neptunium, 2385–2386
 overview, 2384–2385, 2384f
 plutonium, 2386, 2387f
 protactinium, 2385
 thorium, 2385
 uranium, 2385
 superconductivity of, 2350–2353
 Actinide oxides, structure of, 2390
 Actinide oxyhalides, structural chemistry of,
 2421, 2422t, 2423, 2424t–2426t
 Actinide phosphates, structural chemistry of,
 2430–2433, 2431t–2432t
 Actinium
 applications of, 42–44
 as geochemical tracer, 44
 as heat sources, 42–43
 as neutron sources, 43
 for tumor radiotherapy, 43–44
 atomic properties of, 33–34
 compounds of, 35, 36t
 enthalpy of formation, 2123–2125,
 2124f–2125f, 2539, 2541t
 entropy of, 2539, 2542f, 2543t
 Gibbs formation energy of hydrated ion,
 2539, 2540t
 half-life of, 20
 heat capacity of, 2119t–2120t, 2121f
 history of, 19–20
 ionization potentials of, 33, 1874t
 isotopes of, 18–19, 22t–23t, 31–32
 lanthanide elements *v.*, 2
 lanthanum *v.*, 18, 40
 metallic state of, 34–35
 structure of, 2385
 nuclear properties of, 20–26
 actinium–225, 22t–23t, 24f, 25–26
 actinium–227, 20–24, 21f, 22t–23t,
 25f–26f
 actinium–228, 22t–23t, 23f, 24–25
 occurrence in nature of, 26–27, 162
 origin of, 162
 oxidation states of
 in aqueous solution, 1774–1776, 1775t
 ion types, 1777–1778, 1777t
 preparation and purification of, 27–33
 gram quantities, 32–33
 by ion-exchange chromatography, 30–32
 purification of, 28–30
 reduction potentials of, 1778, 1779f,
 2127–2131, 2130f–2131f
 solution and analytical chemistry of,
 37–42
 complexation, 40, 41t
 radiocolloid formation, 41–42
 redox behavior, 37–38
 solubility, 38–40, 39t
 sublimation enthalpy of, 2119t–2120t,
 2122–2123, 2122f
 from uranium–235, 42–44
 Actinium (III)
 detection of, limits to, 3071t
 energy level structure of, 2058, 2059f
 hydration of, 2528–2530, 2529f, 2529t
 in mammalian tissues, circulation clearance
 of, 3368f, 3370–3371
 Actinium (I), electron configurations of,
 2018–2019, 2018f
 Actinium sesquioxide
 formation enthalpy of, 2143–2146, 2144t,
 2145f
 structure of, 2390
 Actinium trihalides, structural chemistry of,
 2416, 2417t
 Actinium-225
 as bismuth-231 generator, 44
 decay series of, 24f, 25
 identification of, 42
 properties of, 22t–23t, 25–26
 from protactinium–233, 171
 in radiotherapy, 43–44, 1829
 synthesis of, 28
 actinium-227
 decay series of, 20, 21f
 detection of
 limits to, 3071t
 α S, 3029
 as geochemical tracer, 44
 identification of, 20–24, 25f–26f, 42
 from neutron irradiation, 1756
 nuclear properties of, 3274t–3275t,
 3298t
 occurrence in nature, 26–27
 properties of, 20–24, 22t–23t
 from protactinium–231, 164, 166f
 purification of, 28–31, 29f, 31f
 gram quantities of, 32–33
 synthesis of, 27
 Actinium-228
 decay series of, 23f, 24
 identification of, 42

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- nuclear properties of, 3274t–3275t, 3298t

 Einsteinium–255
 discovery of, 1580
 fermium–255 from, 1622
 half-life of, 1580
 production of, 1582–1583
 Eisenstein-Pryce theory, optical transitions to, 2227t
 Ekanite, structural data for, 113
 Elastic constants
 of plutonium, 942–943, 944t, 945f–946f
 role of, 943
 Elastic recoil detection analysis (ERDA), for environmental actinides, 3059t, 3065
 Eldorado mine, uraninite at, 274
 Electrical conductivity, of uranium, oxides, 368–369
 Electrical properties
 of plutonium hydrides, 3205
 of uranium metal, 324, 324f, 324t
 Electrical resistivity
 of actinide metals, 2309, 2310f, 2324
 of americium, 1298t, 1299
 of Fermi liquid, 2340–2341, 2341f
 of plutonium, 954–957, 954f–956f, 2345–2347, 2346f
 δ -phase, 955–957, 955f–956f
 unalloyed, 954–955, 954f
 of UBe_{13} , 2342, 2343f
 of uranium
 hydrides, 333
 metallic state, 322

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Electrochemical methods
for neptunium
 determination of, 790–792
 electrolysis, 761–762
for protactinium, 227
 gravimetric methods, 229–231
 polarographic, 227
 potentiometric and amperometric, 227
 spectrophotometric methods, 227–228
Electrochemical separation, of uranium, 632–633
Electrode potentials
 of actinide ions, 2127–2131, 2130f–2131f
 of americium, 1328–1330, 1329t
 of einsteinium, 1606
 of element 113, 1725
Electrodeless discharge lamp (EDL)
 for actinide spectroscopy, 1839
 design and construction of, 1839, 1885–1886, 1885f
Electrodeposition
 of neptunium, 717
 in RTILs, 2690–2691
Electrolysis
 of actinium, 38
 of neptunium, 761–762
 of protactinium, 220
 of thorium, 60–61
Electrolytes, plasma and urine concentrations of, 3356–3357, 3357t
Electrolytic behavior, of neptunium, 755–759
 coulometric behavior, 757–759, 758f
 voltammetric behavior, 755–757, 756t, 757f
Electromagnetic separation, of plutonium isotopes, 821–822
Electrometallurgical technology (EMT)
 overview of, 2693
 in pyroprocessing, 2694
Electron behavior
 in actinides, 1–2
 parameters for, 2054
Electron diffraction techniques, for einsteinium, 1595–1598, 1597f
Electron energy loss spectroscopy (EELS), for environmental actinides, 3049t, 3051–3052
Electron exchange reactions, of actinide complexes, 2597–2598
Electron microprobe analysis (EMPA), for environmental actinides, 3049t, 3050
Electron microscopy, for actinide element study, 14
Electron paramagnetic resonance (EPR)
 of $5f^1$ compounds, 2241
 of $5f^7$ compounds, 2265
 actinide ion measurements with, 2226
 of americium
 americium (iv), 2263
 dioxide, 2292
 of californium (iii), 2269
 of cyclopentadienyl complexes, trivalent, 2803
 of einsteinium, 1602
 einsteinium (ii), 2272

of uranium ore processing, 302
- Pi-bonded ligands, of plutonium, 1188–1191
cyclooctatetraene complexes, 1188–1189
cyclopentadienyl complexes, 1189–1191
- PIPS. *See* Passivated Ion-implanted Planar
Silicon detectors
- Pitchblende. *See also* Uraninite
actinide species in, 3014–3016
complexity of, 302–303
natural occurrence of, 1804–1805
plutonium in, 822
uranium in, 253
- PIXE. *See* Proton-induced X-ray emission
spectroscopy
- Plasma
actinide clearance from, 3367–3387
dioxo ions, 3379–3387
rates of, 3367–3369, 3368f–3375f
tetravalent and pentavalent, 3376–3379
trivalent, 3370–3376
actinide distribution in, 3357t–3358t,
3359–3361
albumin and globulins, 3362–3363
carbonate and bicarbonate, 3361
citric and other alpha-hydroxy
dicarboxylic acids, 3360–3361
with erythrocytes, 3366–3367
transferrin, 3363–3364
transferrin binding, 3364–3366
description of, 3358
electrolytes concentrations in, 3356–3357,
3357t
fluid volumes and protein and iron
concentration in, 3357, 3358t
neptunyl ion in, 3384–3386
plutonyl ion in, 3386–3387
uranyl ion in
complexes, 3381–3382, 3382t
complexes in bladder urine, 3383–3384
complexes in proximal renal tubular
fluid, 3382–3383
- Plasma protein, uranyl bonding to, 3380–3381
- Plutonium
allotropes of, 1, 877–890, 880f, 881t, 1787
 α phase, 879–882, 882f–884f, 884t,
2309–2310, 2310f
behavior of, 879, 880f, 881t
 β phase, 882, 882f–883f, 885t
 δ phase, 882–883, 882f–883f, 886f,
892–897, 899, 916–917, 2329–2330,
2329f

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Plutonium (*Contd.*)
 δ' phase, 882f–883f, 883
 discovery of, 877–879
 ϵ phase, 882f–883f, 883
 γ phase, 882, 882f–883f
 transformation of, 879, 882f
 ζ phase, 882f–883f, 883, 890, 891f
 americium separation from, 1269–1270
 in aqueous solution, 1110–1182
 complex ions, 1156–1182
 hydrolytic stability, 1146–1156
 overview of, 1110–1111
 oxidation and reduction reactions,
 1117–1146
 spectroscopic properties, 1113–1117
 stoichiometry and structure of ions,
 1111–1113
 atomic properties of, 857–862
 core-level spectra, 861
 ionization potentials, 859
 Mössbauer spectra, 861–862
 optical emission spectra, 857–859, 858f,
 860t
 x-ray spectra, 859–861
 in biological systems
 acute toxicity of, 1820–1821
 in bone, 1817
 health hazard of, 1814
 ingestion and inhalation of, 1818–1820
 in liver, 1815–1816
 long-term effects of, 1821–1822
 in organs, 1815
 removal of, 1822–1825
 transferrin bonding of, 1814–1815
 complexes of
 cyclopentadienyl, 2803
 tris-cyclopentadienyl, 2470–2476,
 2472t–2473t
 compounds of, 987–1108
 antimonides, 1022–1023
 arsenides, 1022
 borides, 996–1003
 bromides, 1092–1100
 carbides, 1003–1009
 carbonates, 1159–1166, 1160t–1161t
 carboxylates, 1176–1181, 1178t
 chalcogenides, 1023–1077
 chlorides, 1092–1100
 deuterides, 989–996
 fluorides, 1077–1092
 halides, 1077–1108, 1180t, 1181
 history of, 987–988
 hydrides, 989–996
 iodates, 1172–1173
 iodides, 1092–1100
 nitrates, 1167–1168
 nitrides, 1017–1021
 oxalate, 1173–1175
 oxides, 1023–1049
 oxyhalides, 1100–1102
 perchlorates, 1173
 peroxide, 1175–1176
 phosphates, 1170–1172
 phosphides, 1021–1022
 pnictides, 1016–1023
 reaction kinetics of, 3215–3223
 safety and handling of, 988
 selenides, 1049–1056
 silicides, 1009–1016
 sulfates, 1168–1170
 sulfides, 1049–1056
 tellurides, 1049–1056
 corrosion of
 catalyzed, 3236–3237
 dry, 3227–3228
 hydrogen- and hydride-catalyzed, 977–979
 kinetic behavior, 3225–3227
 metal and intermetallic compounds of,
 973–979, 3223–3238, 3226f, 3227t,
 3229t
 salt-catalyzed, 3238
 thermal ignition, 3232–3235
 unalloyed, 3231–3232
 by water vapor, 3228–3230
 crystal structure data for, 879, 881t
 curium *v.*, 935
 discovery of, 4, 5t, 8
 extraction of
 neptunium *v.*, 709
 Purex process for, 710–712, 710f
 THOREX process, 2745
 with TTA, 1701, 3282
 half-life of, 815
 handling of, 3201
 hazards of, 3200
 corrosion, 3204
 HF calculations of, 1857–1858, 1857f
 HFIR target preparation of, 1401
 history of, 4, 8, 814–815
 ionization potentials of, 859, 1874t
 isotopes of, 4, 8–10, 12, 815–817, 816t
 decay of, 1143–1146
 formation of, 821, 825–826, 825f
 from nuclear power reactors, 826,
 827t–828t, 828
 separation of, 821–822, 828–831
 laser spectroscopy of, 1873
 liquid, 960–963
 melting point of, 960–962
 properties of, 962–963
 magnetic properties of, 2229–2230, 2230t,
 2240–2263, 2355–2357
 intermetallic compounds, 2361
 man-made, 1805–1807
 nuclear fuel processing and storage,
 1806–1807, 1807t–1808t

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- nuclear weapons testing, 1805–1806
- satellite disintegration, 1806
- metal and intermetallic compounds of, 862–987
 - aging and self-irradiation damage, 979–987
 - alloys and phase transformations, 891–921
 - applications of, 862
 - corrosion kinetics of, 3223–3238
 - crystal structure data for, 899, 900t–915t
 - electronic structure, theory, and modeling, 921–935
 - hazards of, 3256–3257
 - history of, 862
 - hydrogen reaction with, 3223–3225, 3224f
 - mechanical properties, 968–973
 - metal preparation, 863–864
 - nature of, 863
 - oxidation and corrosion, 973–979, 3226f, 3227–3235, 3227t, 3229t
 - oxygen, water, and air reaction with, 3225–3238
 - phase stability, 877–890
 - physical and thermodynamic properties of, 935–968
 - pyrochemical preparation and refining, 865–877
 - safe storage, 3260–3262, 3261f
 - special case of, 2345–2347
 - structure of, 2386, 2387f
- natural occurrence of, 822–824, 1756, 1804, 3016
 - in marine organisms, 1809
 - states of, 3086
- neutron irradiation of, 1757
- nuclear properties of, 815–822
- oxidation states of, 814, 2525–2527, 2525f
 - in aqueous solution, 1774–1776, 1775t
 - ion types, 1777–1778, 1777t
 - sorbed, 3175–3176
- oxide-water reaction of, 3209–3210, 3209t
- production of, 814–815, 1757–1758, 2629
 - bismuth phosphate process, 2730
 - REDOX process, 2730–2731
 - TLA process, 2731–2732
- pyrochemical methods for
 - molten chlorides, 2698–2699, 2699f
 - molten fluorides, 2701
 - processing for, 2702
- quadrupole moments of, 1884, 1884f
- radial functions of, 895, 1897f
- radiolytic reactions of, 3246–3248
- reaction with steel, 3238
- reduction potentials of, 1778, 1779f, 2127–2131, 2130f–2131f, 2525, 2525f
- for RTGs, 43
- in RTILs, 2689
- rutherfordium extraction with, 1697–1699
- separation and purification of, 826–857
 - in aqueous alkaline solutions, 852
 - aqueous-based, 830–831
 - DDP, 2705–2706
 - ion-exchange processes for, 845–852
 - from irradiated nuclear fuel, 828–830
 - non aqueous processes, 853–857
 - oxalates in, 1173–1174
 - precipitation and crystallization, 831–839
 - solvent extraction processes, 839–845
- solution chemistry of, 1108–1203
 - aqueous, 1110–1182
 - electronic structure and bonding, 1191–1203
 - history of, 1108–1110
 - nonaqueous and organometallic, 1182–1191
- storage of, 3201
- studies on, 11
- sublimation enthalpy of, 2119t–2120t, 2122–2123, 2122f
- superconductivity of, 1789
- synthesis of, 4, 8–9
- thermodynamic properties of
 - enthalpy of formation, 2123–2125, 2124f–2125f, 2539, 2541t
 - entropy of, 2539, 2542f, 2543t
 - Gibbs formation energy of hydrated ion, 2539, 2540t

- Plutonium (III) (*Contd.*)
 preparation and stability of, 1125, 1131
 oxoplutonates of, alkaline earth metals, 1058
 precipitation with
 fluoride, 838
 oxalate, 836–837
 reduction potentials of, 2715, 2716f
 reduction to metal, 870–872, 873f
 speciation of, 3113t, 3117–3118
 structure of, 593
- Plutonium (IV)
 absorption spectrum of, 849
 adsorption of, *B. sphaericus*, 3182–3183
 anion-exchange chromatography for, 848–849, 848f
 in biological systems, 1819
 compounds of
 carbonate of, 1162–1163
 carboxylates, 1177–1180, 1178t
 hydroxide, 838
 iodates, 1172–1173
 nitrates of, 1167–1168
 oxalate, 837, 1174–1175
 peroxide, 837–838, 1175–1176
 perrhenates, 1068
 phosphates, 1171–1172
 sulfates of, 1169–1170
 vanadates, 1069
 coordination numbers of, 1112
 detection of, limits to, 3071t
 disproportionation of, 1119–1122
 distribution coefficients of, 842, 842t, 848, 848f
 extraction of, DHDECMP, 2737–2738
 free-ion parameters of, 2038–2039, 2038t
 hydrolytic behavior of, 1148t, 1149–1150
 ligands for, 3417–3420, 3420f
 magnetic properties of, 2261–2262
 magnetic susceptibilities, 2261–2262
 in mammalian tissues
 bone, 3403
 bone binding, 3407–3409
 circulation clearance of, 3368–3369, 3368f–3375f, 3378
 glycoproteins, 3410–3411, 3411t
 initial distribution, 3341t–3344t, 3346t, 3352–3353
 liver, 3398–3400
 transferrin binding to, 3364, 3365
 natural occurrence of
 in hydrosphere, 1807–1810
 sorption and mobility, 1810
 oligomerized, 3210–3211
 oxidation state
 equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
 preparation and stability of, 1131–1132
 oxoplutonates of
 alkali metals, 1056
 alkaline earth metals, 1058
 crystallographic data of, 1060t–1061t
 polymerization of, 1150–1154, 1151f, 1153f
 applications of, 1150
 characterization of, 1152–1153
 history of, 1151–1152
 precipitation with
 hydroxide, 838
 oxalate, 837
 peroxide, 837–838
 reduction of, 1139–1140
 rutherfordium extraction with, 1697–1698
 separation of
 HDEHP for, 2651, 2651f
 PUREX process, 2732
 from SNF, 2646
 solvating extractant system for, 2654–2655
 speciation of, 3108–3109, 3113t, 3136
- Plutonium (V)
 adsorption, *B. sphaericus*, 3182–3183
 compounds of
 carbonate of, 1163–1165
 carboxylates, 1178t, 1180–1181
 nitrates of, 1168
 oxalate, 1175
 peroxide, 1175–1176
 phosphates, 1172
 coordination numbers of, 1112
 disproportionation of, 1122–1123
 hydrolytic behavior of, 1154–1155
 in hydrosphere, 1807–1810
 magnetic properties of, 2257–2261
 oxidation state
 equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
 preparation and stability of, 1132
 oxoplutonates of
 alkali metals, 1056
 alkaline earth metals, 1058
 crystallographic data of, 1060t–1061t
 with pyrochemical processes, 2698–2699, 2699f
 reduction of, 1143
- Plutonium (VI)
 adsorption, *B. sphaericus*, 3182–3183
 compounds of
 carbonate of, 1165–1166
 carboxylates, 1178t, 1180–1181
 iodates, 1173
 nitrates of, 1167–1168
 peroxide, 1175–1176
 phosphates, 1172
 distribution coefficients of, 842, 842t
 hydrolytic behavior of, 1155–1156
 magnetic properties of, 2247–2257

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- manganite and hausmannite reactions with, 3176–3177
- oxidation state
equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
preparation and stability of, 1132
- oxoplutonates of
alkali metals, 1057
alkaline earth metals, 1058–1059
crystallographic data of, 1060t–1061t
oxygen exchange with solvent water, 1133
with pyrochemical processes, 2698–2699, 2699f
- reduction of, 1138–1139, 1142–1143
alpha-induced, 1145–1146, 1146t
kinetics, 760–761
- separation of, PUREX process, 2732
- speciation of, 3113t, 3126
- Plutonium (vii)
coordination numbers of, 1112–1113
hydrolytic behavior of, 1156
magnetic properties of, 2240–2247
oxidation state, preparation and stability of, 1132–1133
- oxoplutonates of
alkali metals, 1057
alkaline earth metals, 1059
crystallographic data of, 1060t–1061t
speciation of, 3113t, 3126
- Plutonium carbide
entropy of, 2196, 2197t
formation enthalpy of, 2195–2196, 2197t
high-temperature properties of, 2198, 2198f, 2199t
- Plutonium carbonates, structural chemistry of, 2426–2427, 2427t, 2428f

- Plutonium hexafluoride
absorption spectra of, 2084–2085, 2086f
chemical properties of, 1092
covalency in, 1193–1196
electronic structure of, 1194–1196, 1195f
energy level analysis of, 2083–2085, 2083t, 2085f
preparation of, 1080–1082, 1081f
properties of, 1086–1090, 1087t
radiation decomposition of, 1090–1092
structure of, 1083, 1084t, 2419, 2421, 2421t
studies of, 1938
thermodynamic properties of, 2160–2161, 2160t, 2162t–2164t
- Plutonium hydrides
air reaction with, 3218
electrical properties of, 3205
entropy of, 2188, 2189t
formation enthalpy of, 2187–2188, 2187t, 2189t, 2190f
high-temperature properties of, 2188–2190, 2190t
hydrogen reaction with, 3215–3216
nitrogen reaction with, 3217–3218
oxygen reaction with, 3216–3217
phase diagram of, 990, 991f–992f, 3204–3205, 3205f
reaction rates of, 3215
structure of, 2403–2404
thermodynamic properties of, 3205, 3206t
water reaction with, 3219, 3229
- Plutonium hydroxides, 3213
precipitation with, 838
- Plutonium monocarbide
chemical properties of, 1007–1008
structure of, 1004–1006, 1005t
- Plutonium monophosphide, 1021–1022
- Plutonium monosilicide, structure of, 1014, 1015f
- Plutonium monoxide
dissociative energy of, 2149–2150, 2150f
in gas-phase, 2148t, 2149
physical properties of, 1028
preparation of, 1028–1029
structure of, 2394–2395
- Plutonium nitride, 3212–3213
enthalpy of formation of, 2197t, 2200–2201
entropy of, 2197t, 2201–2202
high-temperature properties of, 2199t, 2202
reactions of, 3222–3223
- Plutonium oxalate, precipitation with, 837
- Plutonium oxides, 1023–1049, 3206–3212
applications of, 1023–1025
container material compatibility with, 1049
dioxide, 1031–1034
formation enthalpies of, 1971
hazards of, 3257–3258, 3258t
interface of, 976–977, 978f
monoxide, 1028–1029
phase diagram of, 1025, 1026f, 1039–1041, 1040f, 1071–1073, 1073f, 3206–3208, 3207f, 3211–3212, 3211f
phase equilibria, 1025–1026, 1026f
plutonium (VIII), 1932–1933
preparation of, 1028–1036, 3206–3207
higher oxides, 1034–1036
plutonium dioxide, 1031–1034
plutonium monoxide, 1028–1029
plutonium sesquioxide, 1029–1031
properties of
chemical, 1048–1049
melting behavior, 1045
oxygen diffusion, 1044–1045
thermodynamic properties, 1047–1048, 1047t
vaporization behavior, 1045–1047, 1046f
reaction rates of, 3219–3222
safe storage, 3260–3262, 3261f
sesquioxide, 1029–1031
sesquioxide phase with, 3208
solid-state structures of, 1027t, 1036–1044, 1038f–1040f, 1042f–1043f
stability of, 3207
structure of, 2394–2395
ternary
with actinides, 1070–1077
with lanthanide oxides, 1069–1070
thermal decomposition of, 3211
thorium oxides with, 1070–1071
uranium oxides with, 1070–1077
applications of, 1070–1071
phase diagram of, 1071–1073, 1073f
preparation of, 1073–1074
properties of, 1074–1077
- Plutonium oxyhalides, structural chemistry of, 2421, 2422t, 2423, 2424t–2426t
- Plutonium pentafluoride, preparation of, 1079–1080
- Plutonium peroxide, precipitation with, 837–838
- Plutonium phosphates, structural chemistry of, 2430–2433, 2431t–2432t
- Plutonium pnictides, structure of, 2409–2414, 2410t–2411t
- Plutonium sesquioxide
formation enthalpy of, 2143–2146, 2144t, 2145f
high-temperature properties of, 2139f, 2146–2147
layer formation, 3208
oxide phase with, 3208
phase relationships of, 3207
physical properties of, 1030
preparation of, 1029–1031
reactions of, 3219

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- structure of, 1027t, 1037–1038, 1038f–1039f, 2395
thermodynamic properties of, 1047–1048, 1047t
- Plutonium silicides, structural chemistry of, 2406t, 2408
- Plutonium sulfates, structural chemistry of, 2433–2436, 2434t
- Plutonium tetraboride, 999t, 1000–1001, 1001f
- Plutonium tetrachloride
preparation of, 1093–1094, 1094f
stabilization of, 1184
- Plutonium tetrafluoride
plutonium metal from, 866
from plutonium with americium–241, 1270
preparation of, 1078–1079
properties of, 1085–1086, 1087t
structure of, 1083, 1084t, 1085f
thermodynamic properties of, 2165–2169, 2166t
- Plutonium tetrahalides, structural chemistry of, 2416, 2418t
- Plutonium tribromide
organic-solvent soluble, 1182–1183
preparation of, 1095
properties of, 1087t, 1098–1100, 1099t
solid-state structure of, 1084t, 1096–1097, 1097f–1098f
structural chemistry of, 2416, 2417t
- Plutonium trichloride
magnetic properties of, 2262
organic-solvent soluble, 1182–1183
preparation of, 1092–1093
properties of, 1087t, 1098–1100, 1099t
solid-state structure of, 1084t, 1096, 1096f, 1098f
- Plutonium trifluoride
organic-solvent soluble, 1182–1183
preparation of, 1078
properties of, 1083–1085, 1087t
structure of, 1082, 1084t
thermodynamic properties of, 2169, 2170t–2171t
- Plutonium trihalides, structural chemistry of, 2416, 2417t
- Plutonium triiodide
organic-solvent soluble, 1182–1183
preparation of, 1095
solid-state structure of, 1084t, 1096–1097
- Plutonium tritelluride, structure of, 1053, 1053f
- Plutonium, Uranium, Reduction, Extraction process. *See* PUREX process
- Plutonium-231, discovery of, 815
- Plutonium-236
detection of, α S, 3295
from neptunium-237, 703
nuclear properties of, 3277t
ultrapure preparation of, 822
- Plutonium-237, ultrapure preparation of, 822
- Plutonium-238
applications of, 817–819
curium-242 and -244 v., 1400
detection of
limits to, 3071t
RIMS, 3321
 α S, 3295
discovery of, 814–815, 817
as energy production by-product, 1805
half-life of, 815, 817
as heat source, 703, 1758
Mössbauer spectroscopy of, 861
from neptunium–237, 703
from neptunium–238, 861
nuclear properties of, 3277t
for power generation, 1827–1828
uranium–234 from, 257
- Plutonium–239
absorption cross section of, 2233
americium–241 from, 1268, 1758
critical parameters of, 820–821, 821t
curium from, 1758–1759
detection of
AMS, 3062–3063, 3319
FTA, 3307
 γ S, 3302
ICPMS, 3327–3328
limits to, 3071t
RIMS, 3321
 α S, 3295
TIMS, 3314
discovery of, 815
environmental hazards of, 1807
half-life of, 820
heat capacity of, 945
importance of, 820
ionization potential of, 1875
IP of, 859
maximum allowed dose of, 1821
Mössbauer spectroscopy of, 861–862
natural occurrence of, 822–824, 823t, 1756
neutron capture formation of, 823–824
nuclear energy with, 815
nuclear properties of, 3277t
for nuclear weapons, 1805
production of
from neptunium–239, 861
in nuclear reactor, 1826
from uranium–239, 255, 1757
radioactivity of, 1765
security risk of, 1758
study with, 1765
toxicity of, 1820
transmutation products of, 984–985, 985f
- Plutonium–240
detection of
AMS, 3319

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

 - entropy of, 2137–2138
 - heat capacity of, 357–359, 359f, 2138–2141, 2139f, 2142t, 2272–2273, 2273f
 - vaporization of, 364–367, 366f
- Uranium dioxide dichloride, 567–569
 - physical properties of, 568–569
 - preparation of, 567–568
 - reactions of, 568–569
- Uranium dioxide monobromide, 527–528
 - preparation of, 527
 - properties of, 527–528
- Uranium disulfide, structure of, 2412t–2413t, 2414, 2414f
- Uranium fluorides
 - fluoro complexes, 445–446, 487–489, 520–521, 520t, 563–564, 564t
 - applications of, 563
 - disproportionation of, 520–521
 - melting behavior of, 487, 488t
 - phase diagram of, 487, 489f
 - physical properties of, 487–488, 521
 - preparation of, 446, 487, 520, 520t, 563–564
 - hexavalent oxide fluoride complexes, 566–567
 - physical properties of, 566–567
 - preparation of, 566
 - oxides and nitrides of, 489–490
 - pentavalent oxide fluorides and complexes, 521
 - absorption spectra of, 521
 - preparation of, 521
 - polynuclear, 579
 - uranium hexafluoride, 557–563
 - application of, 557, 561–562
 - phase diagram of, 563, 563f
 - physical properties of, 560–561
 - preparation of, 557–560, 558f, 560f
 - uranium oxide difluoride, 565–566
 - physical properties of, 565
 - preparation of, 565
 - uranium hexafluoride conversion of, 565–566
 - uranium oxide tetrafluoride, 564–565
 - physical properties of, 565
 - preparation of, 564–565
 - uranium pentafluoride, 518–520
 - characterization of, 519–520
 - preparation of, 518
 - properties of, 518–519, 519f
 - reduction of, 518
 - uranium tetrafluoride, 484–486
 - applications of, 484
 - physical properties of, 485–486
 - preparation of, 484–485
 - uranium hexafluoride preparation from, 485
 - uranium tetrafluoride hydrates, 486–487
 - physical properties of, 486–487
 - preparation of, 486
 - uranium trifluoride, 444–445
 - physical properties of, 445
 - preparation of, 444–445
 - structure of, 445
 - uranium trifluoride monohydrate, 445–446
 - preparation of, 445
- Uranium halides, 420–575
 - applications of, 420
 - chemistry of, 421
 - hexavalent and complex, 529–575
 - absorption spectra of, 529, 557
 - applications of, 529
 - ground state of, 557
 - mixed halogeno-complexes, 574–575
 - oxide bromides and oxobromo complexes, 571–574
 - properties of, 529, 530t–556t
 - uranium compounds with iodine, 574
 - uranium dioxide dichloride and related compounds, 567–570
 - uranium hexachloride, 567
 - uranium hexafluoride and complex fluorides, 557–564
 - uranium oxide fluorides and complex oxide fluorides, 564–567
 - uranium oxochloro complexes, 570

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Uranium halides (*Contd.*)
 uranium perchlorates and compounds, 570–571
intermediate, 528–529
 characterization of, 529
 equilibrium of, 528
 preparation of, 528–529
oxidation states in, 420–421
pentavalent and complex, 501–529
 absorption spectra of, 501
 physical properties of, 501, 502t–517t
 stability of, 501
 ternary and polynary oxide bromides and oxobromo compounds, 528
 uranium oxide bromides, 527–528
 uranium oxide chlorides, 524–525
 uranium oxochloride, 525–526
 uranium pentabromide and complex bromides, 526–527
 uranium pentachloride and complex chlorides, 522–524
 uranium pentafluoride and complex fluorides, 518–521
trivalent and complex, 421–456
 absorption spectra of, 442, 443f
 anhydrous uranium chloro complexes, 450–452
 electronic structure of, 422
 history of, 421–422
 magnetic properties of, 443–444
 oscillator strengths, 442–443
 oxide halides, 456
 properties of, 422, 423t–441t
 stability of, 422
 synthesis of, 422
 uranium tribromide and bromo complexes, 453–454
 uranium trichloride and chloro complexes, 446–452
 uranium trichloride hydrates and hydrated chloro complexes, 448–450
 uranium trifluoride and fluoro complexes, 444–445
 uranium trifluoride monohydrate and fluoro complexes, 445–446
 uranium triiodide and iodo complexes, 454–455
tetravalent and complex, 456–500
 absorption spectra of, 482–483, 483f
 band structure of, 483
 crystal-field strength of, 482–483
 history of, 456
 magnetic properties of, 483
 mixed halides and halogeno compounds, 499–500
 nitrogen-containing, 500
 physical properties of, 456, 457t–481t
 stability of, 456
 structure of, 456, 482
 uranium oxide dibromide and nitride bromides, 497
 uranium oxide diiodide and nitride iodide, 499
 uranium oxide fluorides and nitride fluorides, 489–490
 uranium oxochloride oxochloro complexes, 494
 uranium perchlorates, 494
 uranium tetrabromide and complex bromides, 494–497
 uranium tetrachloride and complex chlorides, 490–493
 uranium tetrafluoride and fluoro complexes, 484–489
 uranium tetraiodide and complex iodides, 497–499
Uranium hexachloride, 567
 magnetic susceptibility of, 2245–2246
 properties of, 567, 568f
 structural chemistry of, 2419, 2421, 2421t
 synthesis of, 567
 thermodynamic properties of, 2160–2161, 2160t, 2162t–2164t
Uranium hexafluoride, 557–563, 1933–1939
 application of, 557, 561–562
 bond lengths of, 1935–1937, 1937t
 compounds of, 576–577
 distillation of, 315–317, 316f, 317t
 energy levels of, 1934–1935, 1934f, 1936t
 enthalpy of formation of, 2159, 2160t
 magnetic properties of, 2239–2240
 phase diagram of, 563, 563f
 physical properties of, 560–561
 preparation of, 557–560, 558f, 560f
 structural chemistry of, 2419, 2421, 2421t
 studies of, 1935, 1938
 thermodynamic properties of, 2159–2161, 2160t, 2162t–2164t
 TIP and, 2239–2240
 uranium oxide difluoride conversion to, 565–566
 uranium tetrafluoride preparation of, 485
 vibrational frequencies of, 1935–1937, 1937t
Uranium hydride, uranium reactions with, 3246
Uranium hydrides, 3213–3214
 entropy of, 2188, 2189t
 formation enthalpy of, 2187–2188, 2187t, 2189t, 2190f
 high-temperature properties of, 2188–2190, 2190t
 structure of, 2403
Uranium iodides, 454–455, 497–500, 574
 complexes, 498–499
 with neutral donor ligands, 455

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- preparation of, 498
- properties of, 498–499
- oxide and nitride, 499–500
- uranium tetraiodide, 497–498
 - physical properties of, 498, 498f
 - preparation of, 497–498
- uranium triiodide, 454–455
 - physical properties of, 455
 - preparation of, 454–455
- Uranium monoxide
 - dissociative energy of, 2149–2150, 2150f
 - in gas-phase, 2148, 2148t
- Uranium nitride, 3215
 - enthalpy of formation of, 2197t, 2200–2201, 2201f
 - entropy of, 2197t, 2201–2202
 - high-temperature properties of, 2199t, 2202
- Uranium ores
 - actinium from, 27
 - plutonium in, 822
 - protactinium from, 172–178
- Uranium oxide difluoride, 565–566
 - physical properties of, 565
 - preparation of, 565
 - uranium hexafluoride conversion of, 565–566
- Uranium oxide tetrafluoride, 564–565
 - physical properties of, 565
 - preparation of, 564–565
- Uranium oxide tribromide, 527
- Uranium oxides, 3214–3215
 - alkali and alkaline-earth metals, 371–383
 - non-stoichiometry, 382–383
 - uranates (vi), 371–380
 - uranates (v) and (iv), 381–382
 - binary, 339–371
 - chemical properties of, 369–371, 370t
 - crystal structures of, 343–351, 345t–346t
 - diffusion, 367–368
 - electrical conductivity of, 368–369
 - oxygen potential, 360–364, 361f–363f
 - phase relations of, 351–357, 352f
 - physical properties of, 345t–346t
 - preparative methods of, 339–343, 341f
 - reactions of, 370, 370t
 - single crystal preparation, 343
 - thermodynamic properties, 360–364, 361f–363f
 - UO₂ heat capacity, 357–359, 359f
 - UO₂ vaporization, 364–367, 366f
 - from fuel fire, 3255
 - geometric parameters of, 1973, 1974t–1975t
 - infrared spectroscopy of, 1971
 - plutonium oxides with, 1070–1077
 - applications of, 1070–1071
 - phase diagram of, 1071–1073, 1073f
 - preparation of, 1073–1074
 - properties of, 1074–1077
 - safe storage, 3262
 - structure of, 2391–2394, 2393f
 - thermodynamic properties of, 2135, 2136t
 - transition metals, 383–389, 384t–387t
 - crystal structures of, 388–389
 - preparative methods of, 383, 388
 - properties of, 384t–387t
- U₂O₅
 - phase relations of, 354f, 355
 - preparative methods of, 340–341
- U₃O₇
 - crystal structure of, 347–349
 - phase relations of, 354f, 355
 - preparative methods of, 340
- U₃O₈
 - crystal structure of, 349–350, 349f
 - electrical conductivity of, 368–369
 - preparative methods of, 341
 - UO₂ oxidation to, 369–370
 - UO₃ reduction to, 369–370
- U₄O₉
 - crystal structures of, 344, 345t–346t, 347, 348f
 - phase relations of, 353–354, 354f
 - U₄O₉, preparative methods of, 340
 - U₈O₁₉, phase relations of, 354f, 355
- UO, preparative methods of, 339
- UO₂ solid solutions, 371–383
 - lattice parameter change, 390, 391t–392t
 - magnetic properties, 389–390
 - in oxidizing atmospheres, 394
 - oxygen potentials, 394–398, 395t
 - preparation of, 389–390
 - regions of, 390–394
- UO₃
 - crystal structure of, 350–351
 - hydrates, preparative methods of, 342–343
 - preparative methods of, 341–342, 341f
 - reduction to U₃O₈, 369–370
- Uranium oxyhalides, structural chemistry of, 2421, 2422t, 2423, 2424t–2426t
- Uranium pentabromide, 526
 - thermodynamic properties of, 2160t, 2161, 2164–2165, 2164t
- Uranium pentachloride, 522–523
 - preparation of, 522
 - properties of, 522–523
 - structural chemistry of, 2419, 2419f, 2420t
 - thermodynamic properties of, 2160t, 2161, 2164–2165, 2164t
- Uranium pentafluoride, 518–520
 - characterization of, 519–520
 - compounds of, 576–577
 - preparation of, 518
 - properties of, 518–519, 519f
 - reduction of, 518

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Uranium pentafluoride (*Contd.*)
structural chemistry of, 2416, 2419, 2419f, 2420t
thermodynamic properties of, 2160t, 2161, 2164–2165, 2164t
- Uranium pentahalides, structural chemistry of, 2416, 2419, 2420t
- Uranium perchlorate, 570–571
physical properties of, 571
preparation of, 570–571
- Uranium phosphates, structural chemistry of, 2430–2433, 2431t–2432t, 2433f
- Uranium pnictides, structure of, 2409–2414, 2410t–2411t
- Uranium selenolate, from cyclopentadienyl complexes, 2807–2808
- Uranium sesquioxide, formation enthalpy of, 2143–2146, 2144t, 2145f
- Uranium silicides, structural chemistry of, 2406t, 2408
- Uranium sulfates
magnetic susceptibilities of, 2252
structural chemistry of, 2433–2436, 2434t, 2435f
- Uranium tetrabromide, 494–495
absorption spectra of, 495
physical properties of, 495
preparation of, 494–495
- Uranium tetrachloride, 490–492
application of, 490–491
magnetic properties of, 491–492
covalency of, 2249–2251
crystal-field splittings of, 2249
magnetic susceptibility, 2248, 2249f
physical properties of, 490–491
preparation of, 490
reduction of, 319
thermodynamic properties of, 2165–2169, 2166t
- Uranium tetrafluoride, 484–486
absorption spectra of, 2068, 2069f
applications of, 484
coordination chemistry of, 600
hydrates, 486–487
physical properties of, 486–487
preparation of, 486
physical properties of, 485–486
preparation of, 484–485
reduction of, 319
thermodynamic properties of, 2165–2169, 2166t
uranium hexafluoride preparation from, 485
- Uranium tetrahalides, structural chemistry of, 2416, 2418t
- Uranium tetraiodide, 497–498
physical properties of, 498, 498f
preparation of, 497–498
thermodynamic properties of, 2166t, 2168
- Uranium thiocyanate, 602, 603t
- Uranium thiolate, from cyclopentadienyl complexes, 2807–2808
- Uranium tribromide, 453–454
hexahydrate, 453–454
physical properties of, 453–454
preparation of, 453
magnetic susceptibility of, 2257–2258, 2258t
physical properties of, 453
preparation of, 453
- Uranium trichloride, 446–448
absorption spectra of, 447
hydrates and hydrated complexes, 448–450
absorption spectra of, 449–450
structure of, 448–449
synthesis of, 448–450
magnetic properties of, 448
magnetic susceptibility of, 2257–2258, 2258t
with neutral donor ligands, 452
physical properties of, 446–447
preparation of, 446
structural chemistry of, 447, 447f, 2416, 2417t
thermodynamic properties of, 2170t, 2173t, 2176–2178
- Uranium trifluoride
magnetic susceptibility of, 2257, 2258t
monohydrate, 445–446
preparation of, 445
physical properties of, 445
preparation of, 444–445
structure of, 445
thermodynamic properties of, 2169, 2170t–2171t, 2176–2178
- Uranium trihalides, structural chemistry of, 2416, 2417t
- Uranium trihydride
magnetic properties of, 2257, 2362
structure of, 2403
- Uranium triiodide, magnetic susceptibility of, 2257–2258, 2258t
- Uranium trioxide
in gas-phase, 2148, 2148t
structure of, 2393–2394, 2393f
- Uranium tris-cyclopentadienyl, magnetic susceptibility of, 2259, 2259t
- Uranium X₁ (UX₁). *See* Thorium–234
- Uranium X₂ (UX₂). *See* Protactinium–234
- Uranium Y (UY). *See* Thorium–231
- Uranium–232
isolation of, 256
nuclear properties of, 3274t–3275t, 3290t
synthesis of, 256
- Uranium–233
detection of
AMS, 3062–3063, 3318
NMR, 3033
extraction of, 176

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- nuclear energy with, 255
- nuclear properties of, 3274t–3275t, 3290t
- as probe for isotopic exchange study, 621
- production of, 256–257
 - protactinium–233 in, 161, 167–169
 - from thorium–232, 53
- for thorium-uranium fuel cycle, 2734
- Uranium–234
 - detection of
 - AMS, 3318
 - γ S, 3300
 - ICPMS, 3327
 - limits to, 3071t
 - PERALS, 3066, 3067f
 - RIMS, 3321–3322
 - α S, 3293
 - TIMS, 3313–3314
 - nuclear properties of, 3274t–3275t, 3290t
 - occurrence in nature, 255, 256t, 257
 - separation of, 257
- Uranium–235
 - absorption cross section of, 2233
 - dating with protactinium–231, and, 170–171
 - detection of
 - FTA, 3307
 - γ S, 3300–3302, 3301f
 - INAA, 3303–3304
 - limits to, 3071t
 - NAA, 3055–3057, 3056t, 3058f
 - NMR, 3033
 - RIMS, 3321–3322
 - RNAA, 3306
 - α S, 3293
 - TIMS, 3313–3314
 - discovery of, 255
 - laser spectroscopy of, 1873
 - natural occurrence of, 3273, 3276
 - neptunium–237 from, 1757
 - nuclear energy with, 255, 826, 1826–1827
 - products of, 826, 827t–828t, 828
 - nuclear properties of, 3274t–3275t, 3290t
 - occurrence in nature, 26–27, 255–256, 256t, 823–824, 1804–1805
 - plutonium–239 regeneration of, 824
 - products of, 1756
 - security risk of, 1758
- Uranium–236
 - detection of
 - AMS, 3062–3063, 3318
 - α S, 3293
 - nuclear properties of, 3274t–3275t, 3290t
- Uranium–238
 - detection of
 - γ S, 3027–3028, 3028f, 3300–3302, 3301f
 - ICPMS, 3327
 - INAA, 3304–3305
 - limits to, 3071t
 - MBAS, 3043
 - MBES, 3028
 - NAA, 3055–3057, 3056t, 3058f

 - RIMS, 3321–3322
 - α S, 3029, 3293
 - TIMS, 3313–3315
 - natural occurrence of, 3273, 3276
 - neptunium–237 from, 1757
 - neptunium–239 from, 702, 704
 - nuclear energy with, 255
 - nuclear properties of, 3274t–3275t, 3290t
 - occurrence in nature, 255, 256t, 1804–1805
 - plutonium–238 from, 815
 - in THOREX process, 2735–2736
- Uranium–239
 - discovery of, 255
 - nuclear properties of, 3274t–3275t
- Uranium-actinium series ($4n + 3$), 21f, 166f
 - actinium–227 in, 20, 21f
 - protactinium–231 in, 164–166, 166f
 - thorium–227 from, 53
 - thorium–231 from, 53
 - uranium–235 in, 256
- UPt₃, superconductivity of, 2351
- Uranocene
 - covalency in, 2854, 2855f
 - crystal-field parameters of, 2253
 - cyclooctatetraenyl complexes derivatives of, 2851–2853, 2852f
 - electronic transitions in, 1951–1952, 1952t
 - magnetic susceptibility of, 2252–2253
 - structure of, 1943–1944, 1944t, 1945f, 2486, 2488t
 - synthesis of, history of, 1894, 2485–2486
 - uranium bis-cycloheptatrienyl v., 2246
- Uranophane
 - anion topology of, 284f–285f, 286
 - natural occurrence of, 292
 - at Peña Blanca, Chichuhua District, Mexico, 272–273
 - at Shinkolobwe deposit, 273
 - structures, of uranium phosphates and arsenates, 295
 - uranium in, 259t–269t
- Uranopilite
 - at Oklo, Gabon, 271–272
 - uranium in, 259t–269t
- Uranospathite, refinement of, 295
- Uranothorianite, thorium from, 55, 58
- Uranotungstite, uranyl tungstates in, 301
- Uranyl (v)
 - bonding of, 577–578
 - structure and coordination chemistry of, 588–589
- Uranyl (vi)
 - bonding of, 577–578, 577f
 - bond-valence of, 3093–3094, 3094f

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Uranyl (vi) (*Contd.*)
 carboxylates, EXAFS investigations of, 3137–3140, 3141t–3150t

THE CHEMISTRY OF THE
ACTINIDE AND
TRANSACTINIDE ELEMENTS

Joseph J. Katz

Glenn T. Seaborg

**This work is dedicated to
Joseph J. Katz and Glenn T. Seaborg,
authors of the first and second editions of
The Chemistry of the Actinide Elements
and leaders in the field of actinide chemistry.**

THE CHEMISTRY OF THE
ACTINIDE AND
TRANSACTINIDE ELEMENTS

THIRD EDITION

Volume 1

EDITED BY

Lester R. Morss

PREFACE

The first edition of this work (*The Chemistry of the Actinide Elements* by J. J. Katz and G. T. Seaborg) was published in 1957, nearly a half century ago. Although the chemical properties of thorium and uranium had been studied for over a century, and those of actinium and protactinium for over fifty years, all of the chemical properties of neptunium and heavier elements as well as a great deal of uranium chemistry had been discovered since 1940. In fact, the concept that these elements were members of an "actinide" series was first enunciated in 1944. In this book of 500 pages the chemical properties of the first transuranium elements (neptunium, plutonium, and americium) were described in great detail but the last two actinide elements (nobelium and lawrencium) remained to be discovered. It is not an exaggeration to say that *The Chemistry of the Actinide Elements* expounded a relatively new branch of chemistry.

The second edition was published in 1986, by which time all of the actinide elements had been synthesized and chemically characterized, at least to some extent. At this time the chemistry of the actinide elements had reached maturity. The second edition filled two volumes, with a chapter for each of the elements (the elements beyond einsteinium were combined in one chapter) and systematic treatment of various aspects of the chemical and electronic properties of the actinide elements, ions, and compounds due to the filling of the 5f subshell. Six transactinide elements had been synthesized by 1986 but their experimentally determined chemical properties occupied only 1.5 pages of text in the second edition.

This edition was initiated by the editors of the second edition (J. J. Katz, G. T. Seaborg, and L. R. Morss) in 1997. They realized that the study of the chemical properties of the actinide elements had advanced to produce distinct subdisciplines of actinide chemistry, for example actinide coordination chemistry, actinide X-ray absorption spectroscopy, itinerancy in actinide intermetallics, organoactinide chemistry, and actinide environmental chemistry. These fields had sufficiently matured so that scientists could make more substantial contributions to predicting and controlling the fate of actinides in the laboratory, in technology, and in the environment. We now understand and are able to predict with some degree of confidence the chemical bonding and reactivity of actinides in actinide materials, in actual environmental matrices and in proposed nuclear waste repositories. Most of the unique properties of the actinides are caused by their accessible and partly filled 5f orbitals. In addition to advances with the actinides, there have been research groups at nuclear research centers in several countries that have dedicated themselves to carry out significant and systematic experimental studies on the transactinide elements for several decades. For these reasons the editors initiated the writing of a third edition, with the

enlarged title *The Chemistry of the Actinide and Transactinide Elements* that is both broader and deeper than the second edition.

The third edition follows the plan enunciated by the authors of the first edition: "This book is intended to provide a comprehensive and uniform treatment of the chemistry of the actinide [and transactinide] elements for both the nuclear technologist and the inorganic and physical chemist." To fulfill this plan consistent with the maturity of the field, the third edition is organized in three parts.

The first group of chapters follows the format of the first and second editions by beginning with chapters on individual elements or groups of elements that describe and interpret their chemical properties. A chapter on the chemical properties of the transactinide elements is included.

The second group, chapters 15-26, summarizes and correlates physical and chemical properties that are in general unique to the actinide elements, because most of these elements contain partially-filled shells of 5f electrons whether present as isolated atoms or ions, as metals, as compounds, or as ions in solution.

The third group of chapters (chapters 27-31) focuses on specialized topics that encompass contemporary fields related to actinide species in the environment, in the human body, and in storage or wastes. There are also two appendices that tabulate important nuclear properties of all actinide and transactinide isotopes.

Each chapter has been written to provide sufficient background for the substantial parts of the readership that are not specialists in actinide science, nuclear-science-related areas (nuclear physics, health physics, nuclear engineering), spectroscopy, or solid-state science (metallurgy, solid state physics). The editors hope that this work educates and informs those readers who are scientists and engineers that are unfamiliar with the field and wish to learn how to deal with actinides in their research or technology.

The editors are deeply indebted to the contributors of each chapter, all of whom agreed enthusiastically to write their chapters and all of whom did so as a labor of love as well as a long-term professional responsibility. We take special pleasure in thanking Dr. Emma Roberts, Senior Publishing Editor of Springer, who provided the resources to turn more than thirty manuscripts into this attractive and useful professional series of volumes. We also thank Roger Wayman and Aaliya Jetha of Springer and all the other professional staff at Springer and SPI Publisher Services who brought this work to completion.

The editors dedicate this work to Joseph J. Katz and Glenn T. Seaborg, the first authors of the first edition and second editions of *The Chemistry of the Actinide Elements*. They provided inspiration for the generations of scientists who followed them and they set high standards in their research. Dr. Katz guided and motivated the editors and authors of the third edition to produce a work that followed the model of the first and second editions and provided leadership as this edition was unfolding. Because of his insights and leadership as an inorganic, physical, and actinide chemist, we have asked Dr. Katz to be

listed on the title page as honorary editor, and he has agreed to accept this role. The editors also dedicate this work to the memory of Professor Seaborg, the co-discover of plutonium and many other actinide and transactinide elements, and pioneer in actinide chemistry. We note with sadness that he participated in planning this edition but passed away before any of the chapters had been written. We believe that he would have been pleased to see how productive has been the research of the authors and many other actinide and transactinide scientists who follow his leadership.

All of us who have participated in the writing, editing, and publishing *The Chemistry of the Actinide and Transactinide Elements* express our hope that this new edition will make a substantive contribution to research in actinide and transactinide science, and that it will be an appropriate source of factual information on these elements for teachers, researchers, and students and for those who have the responsibility for utilizing the actinide elements to serve humankind and to control and mitigate their environmental hazards.

*Lester R. Morss
Norman M. Edelstein
Jean Fuger*

CHAPTER THIRTY ONE

ACTINIDES IN ANIMALS AND MAN

31.1 INTRODUCTION

Protection of workers and the public has been the main objective of actinide biology research since its beginning in early 1942. It was recognized even before the fission chain reaction was demonstrated that nearly all of the isotopes of the newly created elements heavier than radium would be radioactive and emit alpha particles, and that, if taken into the body, they would be as damaging in the tissues as radium (Stone, 1951). Biological research with the actinides concentrated on quantifying their uptake and retention in tissues after introduction into the body by ingestion, inhalation, or injection (biokinetics, metabolism); identifying the nature of the radiation and/or chemical damage in the tissues with the greatest initial uptake, concentration, and longest retention; defining the radiation dose-dependent relationships between toxicity and actinide intake to blood.

Actinide biokinetics studies now include many species and the actinide sequence from $^{227}\text{Ac}^{3+}$ to $^{253}\text{Es}^{3+}$. Whole-body retention of several actinides has been measured in long-lived animals, in some cases for life span. Microscopic localization of actinides in the tissues has been investigated autoradiographically. Significant advances in the methods of aerosol preparation and inhalation exposure allowed quantification of deposition and retention of inhaled actinide particles in the lungs. Most of the biological investigations of internally

deposited actinides were undertaken to define their dose-dependent chronic radiotoxicity, which is manifested mainly as functional impairment and/or cancer induction in bone, liver, kidneys, and lung (when actinide aerosols are inhaled). Many of the actinide biology studies have been summarized (Zirkle, 1947; Voegtlin and Hodge, 1949, 1953; Thompson, 1962, 1989; Stover and Jee, 1972; Thompson and Bair, 1972; Hodge *et al.*, 1973; Nenot and Stather, 1979; Stannard, 1988; Lloyd *et al.*, 1993, 1994). As they became available, the data generated by those investigations were used to set and refine protection limits for actinide intakes into the body, both for workers and the public (Chalk River, 1949; NBS, 1953; ICRP, 1959, 1979, 1980, 1986, 1993, 1995). An introduction to the actinide biology literature is provided as an Appendix.

The biokinetic and toxicological data have generally been considered sufficient for radiation protection purposes, and with the exception of uranyl ion, less attention was given to understanding the chemical reactions of the actinides in the special chemical environments of the blood, tissue fluid, and tissues of the mammalian body.

Some of the aspects of actinide chemistry relevant to their uptake, distribution, and retention in the tissues of mammals have been reviewed (Durbin, 1962, 1975; Gindler, 1973; Taylor, 1973a,b; Bulman, 1978, 1980; Raymond and Smith, 1981; Duffield and Taylor, 1986; Katz *et al.*, 1986).

The chemical reactions of actinide ions in warm (37°C), nearly neutral (pH 7.4), dilute saline fluids of the mammalian body are dominated by hydrolysis and complexation (ICRP, 1972, 1986; Durbin, 1975; Duffield and Taylor, 1986; Taylor, 1998). After intake of an actinide in solution into the blood, ligand competition and exchange, in some cases facilitated by changes in local pH, determine its distribution among the tissues, presumably favoring those tissues or structural elements that contain or display the most stably binding bioligands on their surfaces.

31.2 INITIAL DISTRIBUTION OF ACTINIDES IN MAMMALIAN TISSUES

Access of foreign metal ions, in this case actinides, is most likely to occur by absorption from inhaled particles deposited in the lungs and from ingested food and water. Less likely modes of intake are through a contaminated wound or the broken skin. Once solubilized and transported into the blood, deposition in tissues and excretion of the absorbed actinides are essentially independent of the route of entry, for example, tissue deposition is equivalent for injected, inhaled, or ingested $^{239}\text{Pu}^{4+}$ citrate (Ballou *et al.*, 1972) and for a wide variety of uranium compounds (Voegtlin and Hodge, 1949, 1953; Tannenbaum, 1951b; Durbin and Wrenn, 1975). Parenteral injection (intravenous, iv; intraperitoneal, ip; intramuscular, im; subcutaneous, sc) has been a useful tool for investigating the chemically related factors that determine the disposition of actinides in the animal body. By placing solutions of actinide salts or complexes directly into the

blood or tissue fluid the experimental variables introduced by the efficient lung and gastrointestinal (GI) tract barriers are avoided. Comparable studies of the same actinide in several animal species help to differentiate between the chemical factors that are common across species and the biological factors that are species- or age-specific.

The initial distribution and excretion of soluble forms of the first ten actinides (Th through Es) plus Ac have been defined, in some cases in several animal species. Those basic biological data are collected in Tables 31.1–31.6; seven trivalent actinides including Pu³⁺ (rats, Table 31.1); five actinides injected in oxidation states greater than trivalent (rats, Table 31.2); actinide ions representing the four major oxidation states (mature female mice, Table 31.3); seven actinides considered to be long-term health hazards or with special radiological characteristics (young adult beagle dogs, Table 31.4); actinides in four major

Table 31.1 Initial distribution of injected trivalent actinides in rats.^a

Nuclide	Mass injected ($\mu\text{g kg}^{-1}$)	Time (days)	Fractions of absorbed actinide (%) ^b				
			Tissues			Excreta	
			Skeleton	Liver	Other tissues ^c	Urine	Feces and GI tract
²²⁷ Ac ^{3+d}	0.019	4	27	56	4	5	8

²⁴¹ Am ^{3+f}	0.12	4	35	42	3	10	10
²⁴² Cm ^{3+g}	1.6×10^{-3}	4	31	36	8	1	24
²⁴⁹ Bk ^{3+h}	4×10^{-3}	5	54	16	9	15	6
^{249,252} Cf ³⁺ⁱ	0.02	4	64	14	4	7	11
²⁵³ Es ^{3+j}	2.2×10^{-3}	7	69	7	2	11	11

^a Investigators in the different laboratories used several strains of Wistar-derived albino rats. Ages at the time of injection were rarely stated; however, the reported body weights indicate a range of age from 60 to 150 days. For some incompletely reported studies, sex and body weight and/or age were obtained from archived data. Rats of both sexes are sexually mature at about 60 days, but this species does not achieve skeletal maturity. Because active growth centers remain at the ends of some long bones and vertebrae after 150 days of age, the skeletons of the rats used in these studies must be considered to be still growing (Simpson *et al.*, 1950).

^b Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.

^c Includes kidneys, range 0.6 to 2.2%; ²⁴⁹Bk and ²⁵³Es studies also include full GI tract.

^j Hamilton (1947a); 180 g males; im injection of ²³³UO₂²⁺ in 0.14 M NaCl (97% absorbed).

^k J. G. Hamilton (unpublished data); 200 g females; im injection of ²³⁸PuO₂²⁺ in 0.1 M Na citrate and 0.01 M Na bromate (71% absorbed).

^l Carritt *et al.* (1947); 225 g, young males; iv injection of ²³⁹PuO₂²⁺ in dilute HNO₃.

oxidation states (mature Macaque monkeys, Table 31.5; mature Kenya baboons, Table 31.6); isotopes of industrially important Pu⁴⁺ and UO₂²⁺ and results from a ²⁴¹Am³⁺ accident case (adult human males, Table 31.7).

The data sets selected for inclusion in Tables 31.1–31.7 met the following criteria: The actinide studied was injected as an ultrafilterable citrate complex or a chloride or nitrate solution sufficiently acidic to avoid hydrolysis and colloid

Table 31.3 Initial distribution of intravenously injected actinides in mice.^a

^a Macaque monkeys (*Macaca mulatta*, *Macaca fascicularis*) were caught in the wild. Both sexes were used (about 80% were females), and injected at 5 to 15 years of age (2.5–11 kg body weight). They were sexually and skeletally mature; skeletal maturity was verified roentgenographically (Van Wageningen and Asling, 1958).

^b Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.

^c Durbin (1973); im injection of ²⁴¹Am³⁺ in 0.08 M Na citrate buffer, pH 3.5 (98% absorbed); average dosage shown for monkeys given 0.03 to 0.17 $\mu\text{g kg}^{-1}$.

^d Durbin *et al.* (1985); iv or im injection of ²³⁸Pu⁴⁺ in 0.08 M Na citrate buffer, pH 3.5 (91% absorbed); average dosage shown for monkeys given 0.017 to 0.112 $\mu\text{g kg}^{-1}$.

^e Durbin *et al.* (1987); im injection of ²³⁷Np in 0.08 M Na citrate buffer, pH 3.5, probably a mixture of NpO₂⁺ and Np⁴⁺ (99% absorbed).

^f P. W. Durbin and N. Jeung unpublished data; im injection of ²³³UO₂²⁺ in 0.14 M NaCl (100% absorbed).

formation in the medium; values were reported for the actinide content of all soft tissues, the whole skeleton, and the separated urine and feces; the fraction retained at the wound site was reported for im injection studies.

The skeleton is a major deposition site for the actinides in all of the oxidation states that have been administered to animals. Liver is the most important soft tissue deposition site for all of the actinides except UO₂²⁺. Shortly after intake to blood, the skeleton and liver (skeleton and kidneys in the case of UO₂²⁺) account for about 90% of the actinide in the body (Tables 31.1–31.6; ICRP, 1972). It is clear that both bone and liver possess appropriate binding sites and ligands with high affinities for actinide ions, but the partitioning of the individual actinides between deposition in bone and liver varies with their chemical properties, most importantly electronic charge and ionic radius.

The initial partitioning of an actinide between deposition in bone and liver is likely to depend primarily on the relative affinities of the ligands on the anatomical surfaces of bone and on liver cell membranes for binding that actinide in competition with the ligands that transport it in the blood. The outcome of those competitions will be modulated by the relative abundances of ligands (binding sites) on the bone surfaces and hepatic cell membranes that are exposed

Table 31.6 Initial distribution of injected actinides in Kenya baboons.^a

^a Female Kenya baboons (*Papio anubis*, *Papio cynocephalus*) were caught in the wild. They were injected when 7 to 16 years old (12–15 kg body weight) and were sexually and skeletally mature. Skeletal maturity and ages were estimated from data on molar tooth eruption and wear, estrus cycles, and body weight (Guilmette *et al.*, 1980).

^b Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.

^c Guilmette *et al.* (1980); iv injection of ²⁴¹Am³⁺ in 0.08 M Na citrate, pH 3.5.

^d Lo Sasso *et al.* (1981); iv injection of ^{243,244}Cm³⁺ in 0.08 M Na citrate buffer, pH 3.5.

^e Includes kidneys.

^f Ralston *et al.* (1986); iv injection of ²³⁹NpO₂²⁺ in 0.01 M NaHCO₃.

^g Lipsztein (1981); iv injection of ²³⁷UO₂²⁺ in HNO₃, pH 1.6.

to the circulating fluids, the relative rates of blood flow through those tissues, and the concentrations of the transport ligands.

31.2.1 Trivalent actinides

The initial distributions of Am³⁺ in the tissues of the six mammals (Tables 31.1–31.7) agree well with one another, as do the overall distributions of Cm³⁺ in the rats, dogs, and baboons (Tables 31.1, 31.4, and 31.6), and those of Cf³⁺ and Es³⁺ in the rats and dogs (Tables 31.1 and 31.4). Bone and liver are the major initial deposition sites. The larger animals (dog, baboon) retained more Am³⁺, Cm³⁺, Cf³⁺, and Es³⁺ in the bulk soft tissues, mainly muscle and pelt, than did the rats and mice. Renal excretion of the trivalent actinides is limited. It tended to be somewhat greater for the heavier than for the lighter members of the series, and to be greater for the dogs, who were given iv injections of actinide solutions containing large excesses of citrate buffer. Impeded filtration through the kidneys into urine indicates that uptake of the trivalent actinides in the target tissues is rapid and/or that the major fraction of circulating actinide is bound to nonfilterable protein.

In both the rats (Table 31.1) and the dogs (Table 31.4), and similarly to the behavior of the lanthanides, the initial skeletal deposition of the trivalent actinides increases and the partitioning between deposition in bone and liver

Table 31.7 Initial distribution of absorbed actinides in adult men.

^a Robinson *et al.* (1983); 64-year-old man; accidental high-level skin burns and abrasions contaminated with ~ 3 mCi of ^{241}Am in hot 7 M HNO_3 ; 10 μCi absorbed and retained as estimated from external photon measurements.

^b Talbot *et al.* (1993); two male volunteers, average age 66 years, average body weight 73 kg; iv injection of $^{237}\text{Pu}^{4+}$ in 0.03 M Na citrate; tissue distribution estimated from collected excreta and external photon measurements.

^c Includes kidneys.

^d Original data of Bernard and Struxness (1957) normalized to 100% material recovery; bedridden terminally ill adult males with inoperable brain tumors; tissue distributions estimated from autopsy specimens. Case 6, iv injection of $\text{UO}_2(\text{NO}_3)_2$ enriched with $^{234,235}\text{UO}_2^{2+}$, age 60 years, body weight 57 kg. Case 8, iv injection of UCl_4 enriched with $^{234,235}\text{U}^{4+}$ in 0.2 M acetate buffer, pH 4.7, age 56 years, body weight 63 kg; most of the U detected in 'other tissues' was in the spleen (6.7%).

shifts from favoring liver to favoring bone with the decrease in ionic radius (r) that accompanies the addition of f-shell electrons (Durbin, 1962, 1973). Within each series, that is also the trend of increasing stability of complexes.

Within the lanthanide and actinide series, the stabilities of complexes with the same ligand increase with decreasing ionic radius (Cotton and Wilkinson, 1980), as illustrated for the actinide oxalate and citrate complexes in Table 31.8. It is reasonable to expect that the stabilities of their complexes with other biologically important ligands such as phosphate, for which stability constants are unavailable, will exhibit a similar trend. For the same ligand, complexes of the trivalent actinides tend to be more stable than those of their lanthanide analogs with the same ionic radii. For example, the EDTA complexes of the trivalent actinides are, on average, one to two orders of magnitude greater than those of the EDTA complexes with lanthanides of the same ionic radii (Sillen and Martell, 1964; Ahrland, 1986; Hulet, 1986).

For the purposes of this discussion, initial skeletal deposition is expressed as the skeletal fraction of the initial body burden ($\text{BB}_{0,\%}$ of injected amount), where $\text{BB}_0 = \text{skeleton} + \text{soft tissue} + \text{liver}_{\text{max}} = 100\% - \Sigma$ (urine). Skeleton, soft tissue, and urine are the measured amounts of actinide in those specimens (Table 31.1), and $\text{liver}_{\text{max}}$ is the sum of the measured amounts of actinide in the liver, GI tract plus contents, and passed feces. Biliary excretion of liver actinide into the GI tract and feces will be discussed in the context of actinides in

Table 31.8 Ionic radii and stabilities of complexes of some actinides with the low molecular weight ligands in mammalian plasma and tissues.

the liver. The initial skeletal fraction, skeleton/BB₀, normalizes the data by accounting for the somewhat variable early urinary excretion. Initial skeletal fractions of the trivalent lanthanides and actinides in rats are plotted vs ionic radius in Fig. 31.1. The straight-line segments were fitted by linear regression analysis to serve as eye guides. The initial skeletal fraction of Pu³⁺ lies so far

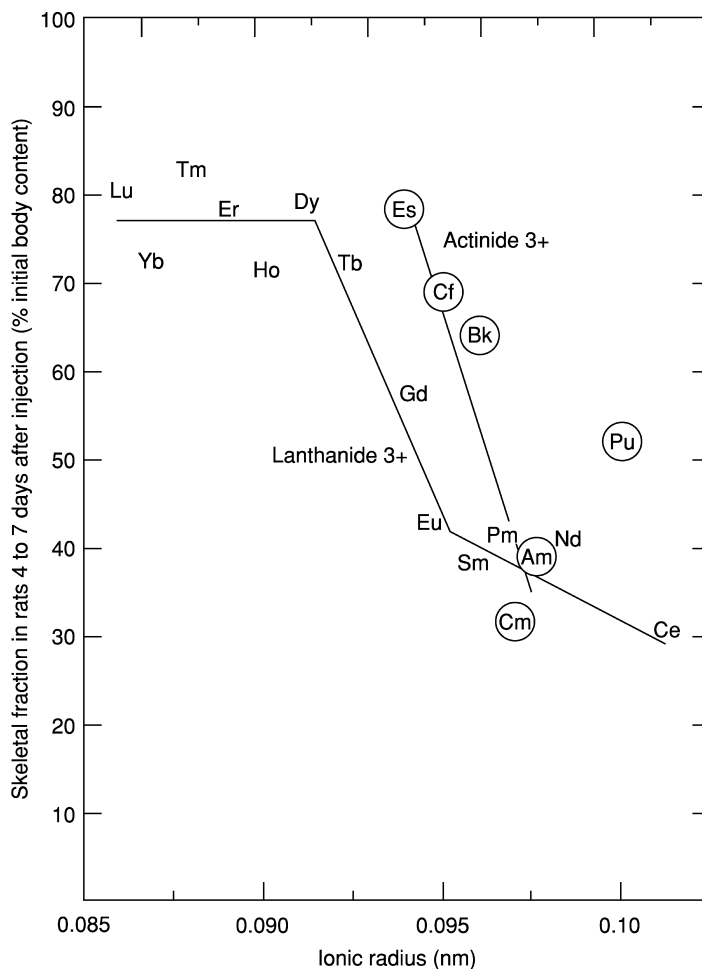

Fig. 31.1 Deposition of trivalent actinides and lanthanides in the skeleton of rats at 4 to 7 days after injection, expressed as percent of initial body content (% BB_0), and shown as functions of their six-coordinate ionic radii. Lanthanide data from Durbin (1973); actinide data from Table 31.1; ionic radii from Shannon (1976) and Katz et al. (1986).

from the trend line for the other trivalent actinides that it was not included in determining the regression line for the trivalent actinides. The aberrant behavior of Pu^{3+} supports the view that Pu^{3+} will be oxidized to Pu^{4+} *in vivo* (Carritt et al., 1947; Scott et al., 1948b).

The plot of initial skeletal fraction vs ionic radius for the trivalent actinides and lanthanides in rats (Fig. 31.1) is discontinuous. Six-coordinate ionic radii are those reported by Shannon (1976). Fig. 31.1 exhibits three distinct regions,

as follows: For the lanthanides, there is a plateau from Lu^{3+} to Tb^{3+} ($r < 0.0925$ nm), followed by a steeply declining region from Tb^{3+} to Eu^{3+} ($r = 0.0925$ – 0.095 nm), and a less steeply declining segment from Eu^{3+} to Ce^{3+} ($r \geq 0.095$ nm). For the trivalent actinides, Es^{3+} to Am^{3+} ($r = 0.094$ – 0.0975 nm), only the steeply declining central region was observed.

The initial skeletal fractions of Am^{3+} and Cm^{3+} in rats lie in the region defined by the larger lighter lanthanides; they resemble Pm^{3+} , which has about the same ionic radius, but two less f-shell electrons. The initial skeletal fraction of Es^{3+} lies within the region defined by the smaller heavier lanthanides; the initial skeletal fractions of Bk^{3+} , Cf^{3+} , and Es^{3+} most closely resemble the lanthanides, Gd^{3+} , Tb^{3+} , and Dy^{3+} , respectively, which have ionic radii 0.0025 nm smaller, on average, and one less f-shell electron.

If the increase in initial skeletal fraction with decreasing ionic radius found for the lanthanides and trivalent actinides depended only on their affinities for bone surface ligands (bone mineral and/or protein), a more gradual trend would be expected. The discontinuous pattern observed resembles the relationship between the size of a multivalent cation and its ability to occupy both of the similar but unequal metal-binding sites of transferrin (Tf), the iron-transport protein of mammalian blood plasma (Pecoraro *et al.*, 1981). The combined data for the skeletal deposition of the trivalent actinides and lanthanides in rats and metal binding to Tf suggest that the stabilities of their Tf complexes strongly influence the skeletal deposition of these trivalent metal ions.

Studies in several animal species show that a number of soft tissues other than liver accumulate radiologically significant concentrations of trivalent actinides (Lloyd *et al.*, 1970, 1974, 1975, 1976; Atherton and Lloyd, 1972; Durbin, 1973; Guilmette *et al.*, 1980). Autoradiographs of soft tissues of rats, dogs, monkeys, and baboons show that the initial actinide deposits are located extracellularly in the connective tissue components (Taylor *et al.*, 1969a,b, 1972a; Lloyd *et al.*, 1970; Durbin, 1973; Guilmette *et al.*, 1980). The connective tissue at most, but not all, of the sites of actinide deposition was shown histochemically to contain substances that react positively to the periodic-acid Schiff (PAS) stain for mucins, glycogen, and glycoproteins (Pearse, 1961; Taylor *et al.*, 1972a). The trivalent actinides were found deposited in the intertubular connective tissue of the kidneys of all of the species, and in the dogs, also in the capillary tufts and in or on the basement membrane of the glomerular capsule.

The most widely distributed deposition site identified in all of the tissues examined from all of the animals studied is the medial layer of the small arterioles, where the nuclides appeared to be localized in the connective tissue and not the smooth muscle layers. There was also some selective localization in specialized connective tissue components of the aorta, coronary arteries, and heart valves. Skeletal muscle and pelt contribute 43 and 14%, respectively, of the body weight of the study animals (Tables 31.1–31.6). Although the concentrations of the trivalent actinides in those tissues are low (0.5–2.5% per kg), most of the actinide in the body, apart from liver and skeleton, is associated with those

large tissue masses. Actinides in the walls of their abundant blood vessels can account for much of the early actinide content of these tissue masses.

All of the investigated trivalent actinides concentrated in the interfollicular connective tissue of the thyroid glands of the dogs, but not the primates. The stability of that binding was demonstrated by prolonged retention of $^{241}\text{Am}^{3+}$ (Lloyd *et al.*, 1970) and $^{249}\text{Cf}^{3+}$ - $^{249}\text{Bk}^{3+}$ (Taylor *et al.*, 1972a) and by the recovery with the insoluble connective tissue fraction of 95% of ^{241}Am in a homogenate of the thyroid of a $^{241}\text{Am}^{3+}$ injected dog (Stevens *et al.*, 1969). Combined, all of these observations suggest that the trivalent actinides bind to glycoprotein in the connective tissue ground substance, a hypothesis supported by the affinity of purified bone glycoprotein for $^{241}\text{Am}^{3+}$ *in vitro* (Chipperfield and Taylor, 1968, 1972).

31.2.2 Tetravalent and pentavalent actinides

Thorium, protactinium, and plutonium were injected in animals as Th^{4+} , Pa^{5+} , and Pu^{4+} , respectively, their most stable states in biological systems (dilute saline solution, mild redox conditions, nearly neutral pH). The biological data indicate that Np^{4+} and U^{4+} tend to be unstable *in vivo* (Tables 31.2 and 31.7).

(a) Th^{4+}

Tracers of citrate complexes of two shorter-lived Th isotopes were injected im in rats ($^{227}\text{Th}^{4+}$, Table 31.2) and iv in dogs ($^{228}\text{Th}^{4+}$, Table 31.4). Absorption of Th^{4+} from the im injection site in the rats was nearly complete in 8 days. There was no evidence of intravascular colloid formation in the iv-injected dogs. The initial distributions of Th^{4+} in the rats and dogs agreed well. Bone is the predominant deposition site of Th^{4+} . Liver deposition is low, but soon after injection, kidneys and other soft tissues account for a substantial fraction of the body content (13 to 18% at 1 to 23 days). About 10% of the injected Th^{4+} is excreted in the urine, mainly in the first 24 h. Fecal excretion is low for the rats and negligible for the dogs.

Autoradiographs were prepared from the soft tissues of a dog that died 10 days after sc injection of a lethal dose of $^{228}\text{Th}^{4+}$ ($10 \mu\text{Ci kg}^{-1}$ of $^{228}\text{ThCl}_4$, pH 4–5) (Erleksova, 1960). The published autoradiographs are overexposed, and the distribution of the $^{228}\text{Th}^{4+}$ is obscured by tracks from the ingrown $^{224}\text{Ra}^{2+}$ and ^{220}Rn daughters. There is phagocytized radiation-damaged cell debris in many of the tissues. However, the general pattern of Th^{4+} distribution in the soft tissues can be discerned, and it is nearly the same as that described above for Am^{3+} and Cf^{3+} in dogs (Taylor *et al.*, 1969b, 1972a; Lloyd *et al.*, 1970). Some Th^{4+} in the liver was contained within hepatic cells. In the kidneys, Th^{4+} was associated with the tubular epithelium and with cell debris in collecting tubules. Combined, these observations were taken as evidence for the intratubular dissociation of an ultrafilterable low molecular weight Th^{4+} complex present

in the plasma. The $^{228}\text{Th}^{4+}$ alpha tracks appeared mainly, if not entirely, to be located in the connective tissue components of the organs examined, including thyroid, testis, and adrenal glands, and in the medial layers of arterioles. In the lungs, the Th^{4+} was accumulated in the bronchiolar cartilages. Slow release of $^{228}\text{Th}^{4+}$ from the soft tissues of the dogs (Stover *et al.*, 1960) and the great affinity of bone glycoproteins for Th^{4+} *in vitro* (Chipperfield and Taylor, 1972) suggest that Th^{4+} can bind stably to PAS-positive proteins in connective tissue.

(b) U^{4+}

The initial distribution of U after iv injection of U^{4+} has been reported for rats (Neuman, 1949) and an adult man (Bernard and Struxness, 1957). The details of the human study are given in Table 31.7. The rats (63 days old males and 112 days old females, 200 g body weight) were injected iv with natural UCl_4 in 0.2 M acetate buffer, pH 4.6, at doses ranging from 1.5 to 3 mg U per kg. Excreta and all tissues were analyzed for U by a fluorometric method (Flagg, 1949). In the female rats killed at 5 days, the injected U was distributed as follows [original data of Neuman (1949) normalized to 100% material recovery]: liver and spleen 59%, kidneys 4%, skeleton 7%, urine 21%, feces 6%.

The initial distributions of U injected iv as U^{4+} in the rats and the man can be compared with those of soluble Pu^{4+} and UO_2^{2+} (Tables 31.2 and 31.7). The initial urinary excretion of the U was much greater than for Pu^{4+} , but much less than for UO_2^{2+} . Deposition of the U in bone was much less than for Pu^{4+} and about the same as for UO_2^{2+} . Deposition of the U in the kidneys was much less than would be expected for UO_2^{2+} . The U retained in the liver and spleen of the man was less than for Pu^{4+} , but much greater than for UO_2^{2+} ; in the rats, retention of the U in liver and spleen was much greater than would be expected for either soluble Pu^{4+} or UO_2^{2+} .

Several U compounds, including UCl_4 , are unstable *in vivo*, and are slowly oxidized to UO_2^{2+} in 0.025 M HCO_3^- pH 7.4 (Dounce, 1949). If, similarly to Th^{4+} and Pu^{4+} , U^{4+} circulated as a nonfilterable plasma protein complex that was cleared slowly from the plasma, only a small amount would be excreted by the kidneys. However, an important fraction of the U injected as U^{4+} was excreted in the urine during the first day (14 and 24% by the rats and the man, respectively). The presence of filterable U in the circulation is evidence that some of the U^{4+} was oxidized to UO_2^{2+} within minutes after the injection. The rats excreted an additional 7% of the U in the urine in days 2 to 5 (Neuman, 1949), and the man excreted an additional 44% in the interval 2 to 21 days, (Table 31.7), providing evidence of slow continuous oxidation to UO_2^{2+} of U^{4+} initially sequestered in the tissues. Parenterally injected UCl_4 is only about one-tenth as toxic to the kidneys of rats as $\text{UO}_2(\text{NO}_3)_2$; the LD_{50} s at 14 to 21 days are 25 and 2.5 mg U per kg body weight, respectively (Yuile, 1973). *In vivo* oxidation of U^{4+} and release of UO_2^{2+} into the circulation apparently proceed sufficiently slowly that the kidneys are not exposed to a toxic level of UO_2^{2+} .

(c) Np⁴⁺

Tetravalent ²³⁹Np⁴⁺ and ²³⁷Np⁴⁺ have been studied in rats (Table 31.2; Moskalev *et al.*, 1979; Paquet *et al.*, 1996; Ramounet *et al.*, 1998). The biological behavior of Np⁴⁺ would be expected to resemble Pu⁴⁺, based on similar chemical properties. Deposition of Np⁴⁺ in the skeleton is about the same as that of Pu⁴⁺ and within the range of values reported for initial skeletal Pu⁴⁺ content of rats (ICRP, 1972). However, the Np⁴⁺ content of the liver was well below that expected based on similarity to Pu⁴⁺. Urinary excretion of Np⁴⁺ was 24% in 4 days, more than 10 times that found for Pu⁴⁺, but less than the early urinary excretion of NpO₂⁺ (36% in 3 days, Table 31.2). Uptake of iv-injected ²³⁷Np⁴⁺ citrate in the skeleton was significantly faster than for ²³⁸Pu⁴⁺, but significantly slower than for ²³⁷NpO₂⁺ (Ramounet *et al.*, 1998).

(d) Pu⁴⁺

Most of the biological studies of Pu have been performed with ²³⁹Pu⁴⁺, however, other Pu isotopes have been used to take advantage of their special physical properties – the photon emissions of ²³⁷Pu⁴⁺, the greater specific radioactivity of ²³⁸Pu⁴⁺, and the beta particle emissions of ²⁴¹Pu. In addition to the numerous studies of injected Pu⁴⁺, various chemical forms of Pu⁴⁺ have been administered to animals by inhalation to measure absorption into the body and assess the local radiotoxicity of the Pu alpha particles in the tissues of the respiratory tract, and by mouth to measure absorption from the GI tract. Chemical forms of Pu that have been investigated in those studies range from soluble complexes to insoluble PuO₂ particles. In addition to the animal species represented in Tables 31.1–31.7, distribution, retention, and toxicity of injected Pu⁴⁺ have also been studied in rabbits, chinchillas, swine, and sheep (Buldakov *et al.*, 1969; Taylor, 1969; ICRP, 1972, 1986; Bair *et al.*, 1973; Vaughan *et al.*, 1973).

Overall, the initial distributions of injected Pu⁴⁺ in rats, mice, dogs, monkeys, and human adults are similar (Tables 31.1–31.5 and 31.7). On average, skeleton plus liver accounts for 85% of the injected Pu⁴⁺, and soft tissues other than liver and early urinary and fecal excretion, for 7, 4, and 5%, respectively. The initial Pu⁴⁺ distributions in the rats and dogs are nearly the same as those of the heavier trivalent actinides, Bk³⁺, Cf³⁺, and Es³⁺, whereas the Pu⁴⁺ distributions in the mice, monkeys, and human adults closely resemble Am³⁺. The combined data for the initial Pu⁴⁺ distributions in the five species may be compared to those for the trivalent actinide(s) they resemble most closely. The Pu⁴⁺ contents of the soft tissues other than liver, as well as the early fecal Pu⁴⁺ excretion are nearly the same as the best matched trivalent actinide(s). About 10% more of the injected Pu⁴⁺ is deposited in the skeleton plus liver (85%) than is found for the matched trivalent actinide(s) (75%), and that difference is accounted for by the smaller amount of early Pu⁴⁺ excretion in urine (4%, on average) compared with an average early excretion of 15% for the matched trivalent actinides.

Although the initial Pu^{4+} content of skeleton plus liver is nearly the same for all five species, the partitioning of the Pu^{4+} between those two tissues favors skeletal deposition in the rats and dogs, and liver in the mice, monkeys, and human adults. That species difference may be attributed in part to the less mature and/or more reactive skeletons of the rats and dogs at the time of Pu^{4+} injection (Durbin, 1975). The male rat skeleton grows slowly until late in life (Simpson *et al.*, 1950). In dogs, the degree of skeletal maturity (age at the time of Pu^{4+} injection) alters the proportions of Pu in the skeleton and liver in a reciprocal manner, favoring deposition in bone of juvenile dogs (3 months old) and young adult dogs (18 months old) and in the liver in older dogs (5 years old) (Bruenger *et al.*, 1983).

Autoradiographs of soft tissues of several species show that initially, soluble Pu^{4+} is prominently deposited in hepatic cells and to a lesser degree in the renal papillae, on nonskeletal mineralized structures both physiological (calcifying tracheal cartilages) and ectopic (calcified renal stones and scar tissue), and occasionally in involuting ovarian follicles and corpora lutea. Low concentrations are seen in the medial layer of arteries and arterioles and in the connective tissue of all tissues and organs examined, including bronchiolar cartilages, heart, testis, and thyroid gland (Painter *et al.*, 1946; Bloom, 1948; Erleksova, 1960; Cochran *et al.*, 1962; Jee and Arnold, 1962; Durbin, 1975; Green *et al.*, 1977; Miller *et al.*, 1980; Durbin *et al.*, 1985). Concentrations of Pu^{4+} in connective tissue are much less than those found for the heavier trivalent actinides. Those observations suggest that Pu^{4+} complexes with connective tissue glycoproteins are not as stable as the circulating Pu^{4+} complexes with plasma proteins, particularly Tf, or the complexes that Pu^{4+} forms at binding sites on the surfaces of hepatic cells and bone.

Carritt *et al.* (1947) studied groups of rats injected iv with $^{239}\text{Pu}^{4+}$ citrate at doses ranging from 0.14 to 231 $\mu\text{g kg}^{-1}$ (data for the 0.14 and 67 $\mu\text{g kg}^{-1}$ groups are included in Table 31.2), and Talbot *et al.* (1990) injected rats iv with 0.04 $\mu\text{g kg}^{-1}$ of $^{237,238}\text{Pu}^{4+}$ citrate. The results are essentially the same over the entire range of iv-injected Pu^{4+} doses indicating that, although limited in quantity, a sufficient number of Tf-binding sites were available to accommodate the largest amount of $^{239}\text{Pu}^{4+}$ (0.97 $\mu\text{mol kg}^{-1}$) injected.

(e) Pa^{5+}

The stable state of this poorly studied actinide appears to be Pa^{5+} *in vivo*. The eight-coordinate ionic radius of Pa^{5+} , 0.091 nm (Shannon, 1976), is smaller and the charge/radius ratio is larger than those of its quadrivalent neighbors, and it is more acidic and hydrolyzes at a lower pH (Smith and Martell, 1976; Katz *et al.*, 1986). Stability constants are not available for Pa^{5+} complexes with the low molecular weight ligands shown in Table 31.8, but complexes with those ligands and with Tf and tissue and bone glycoproteins should be as stable, if not more stable, than those formed by Pu^{4+} . Complete distribution and excretion

studies of Pa^{5+} have been conducted only in rats (Table 31.2). Distribution of the absorbed fraction of im-injected $^{233}\text{Pa}^{5+}$ in the tissue of rats – predominant deposition in the skeleton and low uptake in liver – closely resembles that of Th^{4+} . These results in rats are similar to those reported by others for im-injected $^{233}\text{PaCl}_5$ (Lanz *et al.*, 1946) or iv-injected, ultra filtered $^{233}\text{Pa}^{5+}$ citrate (Schuppler *et al.*, 1988).

There are incomplete data for the tissue distribution in baboons of iv-injected $^{233}\text{Pa}^{5+}$ ($10^{-6}\mu\text{g kg}^{-1}$) in 0.08 M citrate buffer, pH 3.2 (Ralston *et al.*, 1986). Initial excretion in urine was low (6% in 24 h). At 24 h, the Pa^{5+} content of the skeleton is estimated to be about 50% of the amount injected. Because plasma clearance of the Pa^{5+} is slow (Cohen and Ralston, 1983), much of the Pa^{5+} associated with soft tissue at early times can be accounted for by contained blood. By 21 days, when the plasma Pa^{5+} has been reduced to about 2% of the amount injected, measurements of excreta and *in vivo* γ -ray counting of the whole body indicate the following distribution of Pa^{5+} in this large animal: cumulative urine and feces 15 and 3%, respectively, skeleton 65%, all soft tissue 13%.

Ralston *et al.* (1986) reported that they also prepared an injection solution similar to the $^{233}\text{Pa}^{5+}$ described above, in which Pa was in the 6+ oxidation state. There is no evidence for the existence of a stable state of Pa higher than Pa^{5+} (Kirby, 1986b; Katz *et al.*, 1986), so it is reasonable to conclude that the procedures used to prepare the second solution made no change, and the oxidation state was Pa^{5+} in both injection media. Furthermore, the plasma clearances and whole-body retentions of the two preparations were identical, indicating that the oxidation state was the same, Pa^{5+} , in both cases.

31.2.3 The dioxo ions

(a) UO_2^{2+}

Hexavalent uranium, UO_2^{2+} , is the most stable state of U in the animal body. Many U compounds with broad ranges of composition and solubility have been fed to or inhaled by animals, and U metal fragments have been implanted in wounds. The fractions of the U that dissolve and are absorbed to blood are distributed in the tissues (skeleton and kidneys) and excreted in the urine similarly to injected $\text{UO}_2(\text{NO}_3)_2$ (Hodge, 1949; Maynard and Hodge, 1949; Stokinger *et al.*, 1949; Stradling *et al.*, 1985a,b, 1987, 1988; Hahn *et al.*, 2002).

Kidney is the only organ in which histopathological changes are seen consistently in U-poisoned animals. The nature and location of the renal injury (predominantly in the last third of the proximal tubules) are diagnostic of intake of UO_2^{2+} to blood (Voegtlin and Hodge, 1949, 1953; Hodge, 1949; Yuile, 1973). All of the U compounds studied that have any degree of dose-dependent toxicity exhibit the renal injury typical of UO_2^{2+} . The similarities to UO_2^{2+} (tissue distribution, urinary excretion, and kind and site of renal pathology) led to

the conclusion that the absorbed fractions of U compounds are converted to UO_2^{2+} under physiological conditions (Hodge, 1949; Dounce and Flagg, 1949).

The initial tissue distributions of U injected as UO_2^{2+} in the six mammalian species shown in Tables 31.2–31.7 agree well with one another, even though the sampling (postinjection) time ranged from 1 to 7 days and the UO_2^{2+} dose ranged from $2 \times 10^{-6} \mu\text{g kg}^{-1}$ of $^{237}\text{UO}_2^{2+}$ (baboon) to $300 \mu\text{g kg}^{-1}$ of $^{233}\text{UO}_2^{2+}$ (dog). Skeleton and kidneys are the main sites of UO_2^{2+} deposition. They each contain about 12% at 4 days, on average, 3.5% is present in all other soft tissues; about 73% has been excreted, almost entirely in the urine. Linear regression analysis indicates weak correlations of tissue deposition and urinary excretion with UO_2^{2+} dosage; weakly positive for U deposition in skeleton and kidneys and weakly negative for urinary excretion. Linear regression analysis of tissue deposition and urinary excretion with time after injection predicts that at 24 h after a UO_2^{2+} injection, the U will be distributed, as follows: skeleton 15%, kidneys 18%, other tissues 5%, and urine 63%. That predicted distribution is in essential agreement with the parameters of the biokinetic model for U most recently adopted by the ICRP (1995).

The U initially deposited in the kidneys passes into the urine with a half-time of about 7 days (ICRP, 1995), until nearly all of the original U deposit has been eliminated. Nearly all of the long-retained U in the body is in the skeleton (Neuman, 1949; Yuile, 1973; Stevens *et al.*, 1980; Wrenn *et al.*, 1985).

In young rapidly growing rats, UO_2^{2+} is less toxic to the kidneys than in adults, and it is less toxic in adult male rats than in females of the same age (Haven and Hodge, 1949). Neuman (1949) observed that growing rats stored more U administered as UO_2^{2+} in their skeletons than adults and that the incomplete skeletons of adult male rats took up more U than adult females. The relative proportion of the U dose deposited in the kidneys varied inversely with U storage in bone; the kidneys of the growing rats and adult male rats were spared by diversion of larger fractions of the injected U to the skeleton.

(b) NpO_2^+ , NpO_2^{2+}

The initial distributions in the tissues of im- or iv-injected $^{237}\text{NpO}_2^+$ in rats, mice, and monkeys agree well with one another (Tables 31.2, 31.3, and 31.5). Skeleton is the main site of Np deposition. Filtration into urine is the main excretory pathway, but little Np is deposited in the kidneys. At 1 to 4 days after injection, on average, 41% of the Np is in the skeleton, and the remainder is distributed as follows: liver 10%, kidneys 2%, other soft tissues 5%, urine 39%, and feces 2%. The initial distribution of circulating NpO_2^+ in the animals appears to be the result of competition between skeletal uptake and urinary excretion.

The initial distribution of Np in the tissues of a baboon-injected iv with $^{239}\text{NpO}_2^{2+}$ in 0.01 M NaHCO_3 was reported by Ralston *et al.* (1986), and those data are included in Table 31.6. The initial distributions of tracer quantities of $^{239}\text{NpO}_2^{2+}$ and $^{237}\text{UO}_2^{2+}$ in the baboon can be compared directly; the early

urinary excretion of the Np is much less, the skeletal deposition of Np is much greater, and Np deposition in the kidneys is much less than UO_2^{2+} . Distributions in the tissues and early urinary excretion of the dioxo Np ions are nearly the same regardless of the animal (rat, mouse, monkey, baboon), the reported valence state of the Np (NpO_2^+ , NpO_2^{2+}), the injected dose of Np (range, $4 \times 10^{-7} \mu\text{g kg}^{-1}$ of $^{239}\text{NpO}_2^{2+}$ or $^{239}\text{NpO}_2^+$ in baboons to $360 \mu\text{g kg}^{-1}$ of $^{237}\text{NpO}_2^+$ in rats), or the chemical composition of the injection medium (dilute nitric acid, isotonic saline, or citrate or bicarbonate buffer). Combined, these observations indicate that NpO_2^{2+} is unstable *in vivo* with respect to reduction to NpO_2^+ .

Under the conditions of poorly oxygenated, slowly flowing tissue fluid at an im wound site in rats, $200 \mu\text{g kg}^{-1}$ of $^{233}\text{UO}_2^{2+}$ was rapidly and quantitatively absorbed (Table 31.2). In contrast, absorption of $360 \mu\text{g kg}^{-1}$ of $^{237}\text{NpO}_2^+$ injected im was slow (22% at 1 day and 62% at 30 days, Morin *et al.*, 1973). Those results suggest some reduction to Np^{4+} at the wound site.

(c) PuO_2^{2+}

In several early studies of Pu distribution in animal tissues, mice, rats, rabbits, and dogs were injected iv or im with $^{239}\text{PuO}_2^{2+}$ (Finkle *et al.*, 1946; Painter *et al.*, 1946; Van Middlesworth, 1947; Carritt *et al.*, 1947; Kisieleski and Woodruff, 1948, Scott *et al.*, 1948b). Complete data sets are available only for rats, and those shown in Table 31.2 are representative for rats injected im with $^{238}\text{PuO}_2^{2+}$ citrate or iv with $^{239}\text{PuO}_2(\text{NO}_3)_2$. The deposition pattern of PuO_2^{2+} in rats (Table 31.2) can be compared with data for both Pu^{4+} and UO_2^{2+} in several animal species (Tables 31.2–31.7). The initial tissue distribution of Pu given as PuO_2^{2+} does not resemble that of its analog UO_2^{2+} , but is nearly the same as that of Pu^{4+} .

The early association of about 5% of iv-injected PuO_2^{2+} with red blood cells (Painter *et al.*, 1946) resembles UO_2^{2+} (Lipsztein, 1981), but not Pu^{4+} (Stover *et al.*, 1959). Urinary excretion of PuO_2^{2+} in the first 24 h was much less than for PuO_2^{2+} and only somewhat greater than for Pu^{4+} . Retention of Pu in the kidneys after injection of PuO_2^{2+} was much less than for UO_2^{2+} and about the same as that of Pu^{4+} . Absorption of Pu after im injection of $^{239}\text{PuO}_2\text{Cl}_2$ was slower and much less efficient than for UO_2^{2+} , but faster than for the same mass of im-injected $^{239}\text{PuCl}_4$ (Scott *et al.*, 1948b). Combined, these results indicate that PuO_2^{2+} is unstable *in vivo* with respect to reduction to Pu^{4+} .

31.3 ACTINIDE TRANSPORT IN BODY FLUIDS

31.3.1 Composition of mammalian plasma and tissue fluid

The concentrations of the major electrolytes in normal human blood plasma listed in Table 31.9 include cations that compete with actinide ions for circulating bioligands and low molecular weight anions with the potential for actinide

Table 31.9 Concentrations of low molecular weight electrolytes in human plasma and urine, and estimated concentrations in fluid entering last third of proximal renal tubules.

Electrolyte	Concentration (mM)		
	Plasma and tissue fluid	Late proximal tubule fluid ^a	Bladder urine ^b
Na ⁺	140 ^b	140	130
K ⁺	5 ^b	5	44
Ca ²⁺	1.5 ^c	2	4
Cl ⁻	110 ^b	110	140
HCO ₃ ⁻	25 ^b	8.8	1.6
HPO ₄ ^{2--d}	1 ^d	0.5	20
Citrate	0.1 ^d	0.1 ^e	4
pH	7.4	6.5 ^e	6.0

^e Estimated.

complexation. The concentrations of the major electrolytes in the plasma of the laboratory animals used in the studies of tissue distribution (Tables 31.1–31.7) differ little from each other or from those in human plasma (Altman and Dittmer, 1971; Loeb and Quimby, 1999).

Table 31.10 lists the fluid volumes (plasma, interstitial fluid) and the concentrations of proteins and iron in the plasma of the laboratory animals and human adults. Even though there is a 2000-fold range of body weight from mouse to man, their fractional plasma and tissue fluid volumes are similar. The mean fractional plasma and tissue fluid volumes of the animals are 43 ± 8 and 210 ± 39 mL kg⁻¹ body weight, respectively, similar to those of human adults. The concentrations of albumin, globulins, and Tf, the iron-transport protein of mammalian plasma, do not vary greatly among the animals and man. However, the concentration of plasma iron and the numbers of Tf-binding sites normally occupied by iron (saturation) differ among the species. Tf Fe-saturation, which ranges from 33 to 44% for the larger animals (beagle, nonhuman primates, man) and from 59 to 74% for the small rodents, is inversely correlated with body weight (Table 31.10) and directly correlated with metabolic rate (Brody, 1945).

31.3.2 Circulation of extracellular fluid

Foreign ions taken into the mammalian body are transported in the circulating extracellular fluid (ECF), which is actually two communicating compartments. The plasma is the fluid phase of the blood, and it is confined within the blood

Table 31.10 Fluid volumes and protein and iron concentrations in plasma of mature laboratory animals and human adults.

	<i>Mouse</i>	<i>Rat</i>	<i>Beagle dog</i>	<i>Macaque monkey</i>	<i>Human adult</i>

vessels. The interstitial (tissue) fluid is outside the vascular system, and it bathes the body cells and their supporting connective tissue.

Mammalian plasma is a steadily flowing, well-mixed, nearly neutral (pH 7.4), dilute saline solution containing numerous solutes (electrolytes and proteins) at closely regulated concentrations. The plasma water and filterable (low molecular weight, nonprotein constituents) are in steady-state exchange with the tissue fluid by outward diffusion through the arterial ends of the capillaries and inward diffusion at the venous ends, at a rate in human adults of about one plasma volume per min. The capillary walls are not completely impermeable, and between 50 and 100% of plasma proteins escape through the capillaries and reenter the blood via the lymphatic circulation daily (Cronkite, 1973). The composition of the tissue fluid approximates an ultrafiltrate of the plasma. It contains small molecules and electrolytes at about the same concentrations as the plasma, but the protein concentration is less than 20% of that in the plasma. The tissue fluid is the medium that transports the filterable dissolved solutes of the plasma to the body cells, and it transports cell products and wastes back into the plasma.

More tissue fluid is produced at the arterial ends of the capillaries than is withdrawn by diffusion back into the venous capillaries. That excess fluid and

the escaped protein are drained away and returned to the plasma by collocated lymph capillaries. The concentration of protein in lymph is somewhat greater than that in the tissue fluid.

31.3.3 Loose connective tissue

Tissue fluid does not flow freely; it penetrates and is confined within the loose connective tissue that fills the spaces between the capillaries and the cells of most tissues and organs. Loose connective tissue is composed of fine collagen and elastin fibers embedded in a colloidal gel hydrated by the tissue fluid. The solids of the gel are hydrated high molecular weight mucopolysaccharides (hyaluronic and chondroitin sulfuric acids) and glycoprotein. Both the structural proteins and the components of the connective tissue gel contain potential metal-binding sites – the carboxyl groups of the mucopolysaccharides, the carboxyl (aspartic and glutamic acid) and hydroxyl (tyrosine) side chains of the proteins, and the sialic acid side chains of the glycoproteins (Dounce and Lan, 1949; Passow *et al.*, 1961; Rothstein, 1961; Taylor, 1973a,b; Ham, 1974; Luckey and Venugopal, 1977; Pecoraro *et al.*, 1981).

31.3.4 Distribution of actinides in plasma

Trace quantities of multivalent cations circulate in the body fluids as complexes (Taylor, 1972, 1998; Luckey and Venugopal, 1977). Any complexing species such as citrate ion injected with a foreign cation is rapidly diluted and removed from the circulation, and the cation must form new complexes with the filterable low molecular weight plasma constituents (Table 31.9) or with nonfilterable plasma proteins (Table 31.10) or both.

Distribution of actinide ions among the constituents of mammalian blood plasma has been studied in plasma and serum (plasma minus fibrinogen and clotting factors) of rats and dogs injected iv with soluble actinides (*in vivo*) and in whole blood, plasma or serum of rats, dogs, and human adults and purified plasma constituents incubated with actinide solutions (*in vitro*).

The analytical techniques have included: ultrafiltration, electrophoresis, electro dialysis, size exclusion and ion-exchange chromatography, immunochromatography, immunoprecipitation, protein precipitation, and spectroscopy. The information provided by those studies is mainly semiquantitative, because each procedure tends to disturb the natural speciation of the system (reviewed by Taylor, 1998). Furthermore, in the living animal competition for injected actinide ions among the plasma constituents and between the plasma constituents and the tissue ligands continually shifts the chemical speciation in the plasma compartment in favor of the most stable complex(es) (Dounce, 1949; Stevens *et al.*, 1968; Turner and Taylor, 1968a,b; Durbin *et al.*, 1972; Durbin, 1973; Ramounet *et al.*, 1998).

(a) Filterable low molecular weight ligands

The stabilities of actinide complexes with a given ligand, including the OH of water, increase in the order: $\text{MO}_2^+ < \text{MO}_2^{2+} \sim \text{M}^{3+} < \text{M}^{4+}$. For actinides of the same electric charge, e^- , the stabilities of complexes with the same ligand generally increase with decreasing ionic radius, r . The net effect is increased stabilities of complexes with the increasing ratio of electric charge to ionic radius, e/r . The most stable complexes formed by the 'hard' actinide ions are those with ligands that contain oxygen as the electron donor group. In general, the stabilities of the actinide complexes with such groups are in the order: $\text{SO}_4^{2-} < \text{CO}_2^- < \text{CO}_3^{2-} \sim \text{PO}_4^{3-}$ (Ahrland, 1986).

Most of the actinide ions introduced into mammalian plasma *in vivo* or *in vitro* tend to associate predominantly with plasma proteins, but in all cases an ultrafilterable low molecular weight fraction has been identified, ranging from small (<10%) for the trivalent, tetravalent, and pentavalent actinides (Stevens *et al.*, 1968; Popplewell and Boocock, 1968; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1971a) to large ($\geq 50\%$) for UO_2^{2+} and NpO_2^+ (Dounce, 1949; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980; Guilmette *et al.*, 1982).

Stability constants ($\log K_1$) of one-to-one complexes with several of the low molecular weight ligands present in mammalian plasma are shown in Table 31.8 for the actinides that have been studied in animals and humans (Tables 31.1–31.7). Table 31.8 also includes the ionic radii of those actinide species (Shannon, 1976), assigning coordination number 6 (CN 6) for the trivalent actinides and the dioxo actinide cations, MO_2^+ and MO_2^{2+} , and CN 8 for the tetravalent and pentavalent actinides. The ionic radii are included to emphasize the relationships among ionic charge and ionic radius (charge–radius ratio, e/r) and the tendencies of the metal ions to hydrolyze and form stable complexes. The first hydrolysis constants for the actinides are shown for comparison with the other ligands, because at the nearly neutral pH of mammalian plasma, in the absence of stable complexing ligands, all of the actinides that have been administered to animals, with the possible exception of NpO_2^+ , would be expected to hydrolyze and form colloidal hydroxides intravascularly.

(i) Citric and other alpha-hydroxy dicarboxylic acids

Citrate ion is the only low molecular weight ligand in mammalian plasma that is competitive with OH^- for all of the actinides studied (Table 31.9), and it is the only competitive ligand for the trivalent actinides. Dicarboxylic acids and phosphate may also compete with OH^- for the tetravalent actinides, and carbonate is competitive for the MO_2^{2+} dioxo actinide ions.

In addition to citrate, other alpha-hydroxy 3- and 4-carbon dicarboxylic acids (malic, oxaloacetic, tartaric) stably bind UO_2^+ . These tridentate ligands bind

metal ions through the alpha OH group as well as the two carboxylate groups, forming stable five- and six-membered chelate rings. Those ligands form UO_2^{2+} complexes that are stable enough to prevent and to reverse the inhibitory binding of UO_2^{2+} to protein enzymes (Singer *et al.*, 1951). Low concentrations of three alpha-hydroxy dicarboxylic acids (malic, oxaloacetic, isocitric) are present in human plasma (Table 31.9), and their combined concentration is about the same as that of citrate ion. Those organic acids may also participate in actinide complexation in the plasma.

A small fraction of the filterable plasma Ca^{2+} circulates as a citrate complex (concentration about 7×10^{-5} M, Neuman and Neuman, 1958). The concentration of plasma citrate is about 10^{-4} M (Table 31.9), so nearly 70% of the circulating citrate ion is bound to Ca^{2+} . The stabilities of the citrate complexes with trivalent and tetravalent actinides (Table 31.8) are several orders of magnitude greater than that of Ca-citrate ($\log K_f = 3.2$, Martell and Smith, 1977), and they can be expected to compete with Ca^{2+} for citrate *in vivo*.

When citrate complexes of the tri- and tetravalent actinides are injected iv, the subsequent behavior of the metal ion demonstrates that the injected complexes are transient and less stable than the complexes that the metal ions can form with plasma protein(s) and tissue ligands. In rats and dogs within 2 h after iv injection of the Pu-citrate complex, 90% of the Pu^{4+} in the plasma was found by gel chromatography to be bound to nonfilterable protein(s); by 24 h after the injection less than 5% of the circulating Pu^{4+} was associated with filterable low molecular weight species. Concurrently, excretion of Pu^{4+} in the urine, which is a modified, concentrated ultrafiltrate of plasma, declined rapidly demonstrating the disappearance of the originally ultrafilterable citrate complex from the plasma (Stevens *et al.*, 1968; Turner and Taylor, 1968a; Durbin *et al.*, 1972).

The presence of low concentrations of ultrafilterable citrate complexes of Pu^{4+} , Am^{3+} , and Cm^{3+} in plasma was shown indirectly through identification of their citrate complexes as the major, if not the only, species of those actinides in urine (Poplewell *et al.*, 1975; Stradling *et al.*, 1976). It is reasonable to assume that small amounts of other actinides and foreign metal ions circulate as citrate complexes that can be ultrafiltered by the kidneys and excreted in the urine.

Citrate ion, injected locally soon after Pu^{4+} is deposited in an im wound, is capable of complexing and hastening Pu^{4+} absorption (Volf, 1975).

(ii) Carbonate and bicarbonate

Most carbonates are sparingly soluble, but the actinide dioxo ions form stable carbonate complexes at physiological pH (Smith and Martell, 1976; Ahrland, 1986). The special cases of *in vivo* transport of UO_2^{2+} and NpO_2^{2+} as carbonate complexes are discussed below.

3.4.2 Nonfilterable plasma proteins

(a) Albumin and the globulins

Serum albumin and globulin are globular proteins that are soluble in dilute saline. In normal human plasma, albumin transports about 26% of Ca^{2+} and globulins transport about 7%. Ca^{2+} has low affinity for amino groups and monocarboxylic acids like acetate, but it is strongly chelated by polycarboxylic and hydroxycarboxylic acids like citrate (Neuman and Neuman, 1958). The serum proteins contain abundant amino acids with $-\text{COOH}$ side chains (aspartic acid, glutamic acid, cystine), $-\text{OH}$ side chains (serine, threonine, hydroxyproline), and phenolic side chains (tyrosine) (Hawk *et al.*, 1947). However, only carboxylate or hydroxyl side chains of the amino acids in close proximity to one another in the protein structure are able to bind Ca^{2+} and other multivalent cations.

The affinities of the serum proteins for cations depend on both their amino acid composition and the spatial arrangement of those amino acids and the binding units of their residues. The globular structures of the serum proteins are determined and maintained by the continuous coiling, bending, and folding of the polypeptide chains, which provide close approach of amino acid side chains that are widely separated in the primary (elongated) structure. That folded lattice-like three-dimensional structure provides numerous carboxyl and hydroxyl groups positioned suitably for metal binding (Schwartz and Fien, 1973). Nonspecific binding to serum proteins has been described for UO_2^{2+} , the trivalent lanthanides, and other multivalent metal ions (Painter *et al.*, 1946; Dounce and Lan, 1949; Gurd and Wilcox, 1956; Clarkson, 1961; Passow *et al.*, 1961; Rothstein, 1961; Kyker, 1962; Stevens *et al.*, 1965, 1968; Popplewell and Boocock, 1968; Stover *et al.*, 1968a; Bruenger *et al.*, 1969b, 1971b; Taylor, 1973a,b; Ham, 1974; Luckey and Venugopal, 1977).

The total concentrations of Ca^{2+} and Mg^{2+} in normal human plasma are about 2.5 and 1.0 mM, respectively. Assuming that Ca^{2+} and Mg^{2+} are distributed similarly among the constituents of plasma and that the strengths of their binding to the plasma proteins are similar, the fractions of the metal-binding sites of the plasma proteins normally occupied by the alkaline earth elements can be estimated. In human plasma, about 0.65 mM of Ca^{2+} is bound to albumin and about 0.17 mM is bound to the globulins; 0.26 and 0.07 mM of plasma Mg^{2+} are assumed to be associated with albumin and the globulins, respectively. The maximum Ca^{2+} and Mg^{2+} binding capacities of the plasma albumin and globulins are, on average, 11 and 6 moles of metal per 10^5 g of protein, respectively (Neuman and Neuman, 1958). The concentrations of albumin and the globulins in plasma are 6.5×10^{-4} and 21.0×10^{-4} M, respectively (Table 31.8). The mean molecular weights of serum albumin and the globulins are about 67 000 and 160 000, respectively (Hawk *et al.*, 1947). Calculations suggest that about 22% of the potential metal-binding sites of the plasma

proteins are normally occupied. Thus, binding sites are available for occupancy by foreign cations without need to displace their normal loads of Ca^{2+} and Mg^{2+} .

Nonspecific binding of the actinides by the plasma proteins is likely to be stronger than that of the alkaline earths, but weaker than specific binding to Tf (see below). The abundances of the plasma proteins and their potential binding sites may favor nonspecific actinide binding strong enough to withstand renal filtration, but too weak to compete with the ligands in liver, bone, and connective tissue.

(b) Transferrin

(i) Structure

Iron is transported in the plasma of mammals as Fe^{3+} bound to Tf, a specialized glycoprotein of molecular weight 79.6 kDa that migrates electrophoretically with the β -globulins. The amino acid sequence of transferrin has been defined. Each end of the Tf molecule has a globular sialoprotein moiety at which one Fe^{3+} atom may be bound in association with one bicarbonate molecule. The two iron-binding sites of Tf differ slightly. The C-terminal site is larger and binds Fe^{3+} more tightly than the smaller N-terminal site. At pH 7.4, the C-terminal site has an affinity for Fe^{3+} about five times greater than that of the N-terminal site. However, the weaker N-terminal site is preferentially occupied by Fe^{3+} , so kinetic and/or access factors may be more important than thermodynamic effects. Iron binding by Tf is pH-dependent, and Fe^{3+} is released at $\text{pH} < 7.4$.

(ii) Function

Tf is a true carrier molecule in that it is conserved for many cycles of Fe^{3+} delivery to the erythroblasts and reticulocytes (early and late stages of developing red cells) in the red bone marrow. Iron-bearing Tf, preferentially diferric Tf, binds to cell surface Tf receptors, forming clusters in surface pits, and these are internalized by endocytosis. Inside the developing red cells, the Fe–Tf receptor complex is contained in coated vesicles, which fuse with endosomes. Within the endosomes, the low pH (~ 5) releases one Fe^{3+} presumably from the N-terminal site. Release of a second Fe^{3+} may be mediated by other molecules and may involve reduction of Fe^{3+} to Fe^{2+} . Neither the Tf nor the Tf-receptor is degraded in the process. The Tf–Tf-receptor complex minus one or two Fe^{3+} atoms is returned to the cell membrane where, at pH 7.4, apotransferrin (iron-free Tf, apoTf) and/or monoferric Tf are released to the interstitial fluid and ultimately reenter the plasma to take up more Fe^{3+} . In addition to the developing red blood cells, hepatic cells and to a lesser degree most other cells possess surface Tf receptors and are able to endocytose Tf. When Tf is fully saturated with iron,

the iron absorbed from the GI tract is deposited in the liver (Katz, 1970; Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995).

Tf is synthesized mainly in the parenchymal cells of the liver. At any time about 50% of the exchangeable Tf is located extravascularly in interstitial fluid, and it is returned to the plasma compartment with a half-time of about 17 h. As is the case with the other serum proteins, Tf is destroyed at a first-order rate. Its survival half-time of about 9 days is significantly shorter than that of serum albumin. The sites of Tf destruction are believed to be liver and kidneys (Katz, 1970).

(iii) *Binding of foreign metal ions*

Tf binds Fe^{3+} ($r = 0.0645 \text{ nm}$, $elr = 46.5 \text{ e nm}^{-1}$) in preference to other biologically essential metal ions. Iron binding at both sites involves deprotonation of two tyrosine moieties and the association of one bicarbonate molecule. If a foreign multivalent cation is to occupy either binding site, it must be small enough to fit into the Fe-binding cavity, and have sufficient charge density (elr) to deprotonate both of the two tyrosine phenols required for stable binding (Luk, 1971; Harris *et al.*, 1981).

Metal coordination with apoTf was investigated by spectrophotometric titration of the Tf complexes of metal ions with a broad range of electric charge and ionic radius. Two tyrosines were coordinated at both binding sites by the small transition metal ions and the smaller lanthanides; each Tf molecule bound two metal ions and released four tyrosine protons (Fig. 31.2, Pecoraro *et al.*, 1981). The larger lanthanide ions were able to fit only into one Fe-binding site, presumably the larger C-terminal site, and the number of coordinated tyrosines per Tf molecule decreased from four to two. Because of the size difference in the two sites, the larger Th^{4+} ion is bound stably at one site and weakly at the other, whereas the smaller Zr^{4+} and Pu^{4+} ions are expected to be bound stably at both sites. Europium appears to be an indicator of the maximum size (0.095 nm) of a multivalent cation that can fit into and bind stably at both Tf-binding sites, whereas the larger La^{3+} , Am^{3+} , and Cm^{3+} ions are expected to bind only at the larger C-terminal site.

(c) **Actinide binding by transferrin**

Under appropriate experimental conditions all of the actinides investigated, except NpO_2^+ form variably stable complexes with plasma Tf (Poppellwell and Boocock, 1968; Stevens *et al.*, 1968; Stover *et al.*, 1968a; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1969b, 1971b; Taylor, 1970, 1998; Stevens and Bruenger, 1972; Durbin *et al.*, 1976; Cooper and Gowing, 1981; Peter and Lehmann, 1981; Guilmette *et al.*, 1982; Wirth *et al.*, 1985; Taylor and Farrow, 1987; Paquet *et al.*, 1996). The apparent stabilities of those actinide Tf

Fig. 31.2 Number of tyrosine moieties engaged in binding metal ions as related to their six-coordinate radii (Shannon, 1976). Data of Harris *et al.* (1981) and Pecoraro *et al.* (1981). Not measured but noted by their elemental abbreviations are Zr^{4+} and Pu^{4+} , which are small enough to fit into both Fe-binding sites and displace four tyrosine protons, and La^{3+} , Am^{3+} , and Cm^{3+} , which are too large to occupy the smaller N-terminal site and would be expected to displace only two tyrosine protons per transferrin molecule.

complexes is in the order expected based on their tendencies to form stable complexes:

Each Tf molecule possesses only two Fe-binding sites, and the concentrations of Tf in mammalian plasma are low (Table 31.10). Thus, the capacity of circulating Tf for transporting actinide ions is limited by both the total number of binding sites and the number of sites not already occupied by Fe^{3+} , that is, the degree of Fe saturation of the Tf. Stover *et al.* (1968a,b) showed that Tf binding of Pu^{4+} in plasma varied inversely with Fe–Tf saturation, and that relationship has also been demonstrated for Th^{4+} and Np^{4+} (Peter and Lehmann, 1981; Wirth *et al.*, 1985).

The actinide Tf complexes, with the possible exception of Pa^{5+} –Tf, are less stable than Fe–Tf, and the actinides are readily displaced from Tf by adding Fe^{3+} to the reaction medium (Poplewell and Boocock, 1968; Stover *et al.*, 1968a; Peter and Lehmann, 1981; Wirth *et al.*, 1985). Similarly to Fe–Tf, the Pu^{4+} , Th^{4+} , and UO_2^{2+} Tf complexes are pH-dependent and they begin to dissociate at $pH < 7$ (Bruenger *et al.*, 1971b). Presumably, the stabilities of the

Tf complexes with the other actinides are similarly pH-dependent (Popplewell and Boocock, 1968; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980).

(d) Association of actinides with erythrocytes

The trivalent and tetravalent actinides form variably stable complexes with the Fe-transport protein, Tf, and the iron storage protein, ferritin, but they are not incorporated into hemoglobin or associated with the stroma of erythrocytes (red blood cells).

The primary function of Tf is delivery of iron to the developing erythroblasts in the red bone marrow for synthesis of hemoglobin. Iron-bearing Tf binds to specific Tf-receptors on the erythroblast surfaces, and the complete complex, Fe-Tf-Tf-receptor, is internalized by endocytosis. Within the erythroblasts, the complex is taken up by lysosomes, where the reduced pH (5 to 5.5) causes dissociation of the complex and release of Fe³⁺. The released Tf is extruded from the cells for reuse (Aisen and Listowsky, 1980).

The simplest explanation for the absence from the interior of the erythroblasts of actinides and other multivalent cations that bind to Tf is that the foreign metal ions bound to Tf induce a conformational change in the protein structure that is not recognized by the erythroblast Tf-receptor. It is possible, but less likely, that foreign metal ions like Pu⁴⁺, freed from their pH-dependent Tf complexes at the low lysosomal pH, are rapidly shuttled out of the erythroblasts, bound to new Tf molecules, extruded at the cell surface, and recirculated. However, because the latter mechanism probably would be imperfect, small amounts of residual foreign metal ions could be left in the red cells, perhaps bound to the stroma, and that is not observed.

There is evidence that some actinides can bind transiently to the red cell membrane. Actinides in the 3+, 4+, 5+, MO₂⁺, and MO₂²⁺ oxidation states were equilibrated with aliquots of whole blood *in vitro*. Except for ²³⁹Pu³⁺ and UO₂²⁺, the actinide concentrations in the washed red cells were ≤10% of those in the plasma (Chevari and Likhner, 1968; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980).

Small fractions (≤4%) of iv-injected UO₂²⁺ and PuO₂²⁺ are transiently associated with the red cell membrane (Painter *et al.*, 1946; Lipsztein, 1981; Durbin *et al.*, 1997a). Clearance of UO₂²⁺ from the plasma volume is much faster than the rate of release of UO₂²⁺ from the red cell membrane. Consequently, most of the U in samples of whole human blood from individuals in equilibrium with their normal daily intakes of U in drinking water and foods is associated with the red cells (Hursh and Spoor, 1973; Wrenn *et al.*, 1985).

Evaluation of the clearance of iv-injected ²²⁸Th⁴⁺ citrate from the blood of beagles included measurements of the Th⁴⁺ bound to centrifugally separated red cells (Lloyd *et al.*, 1984a). The association of the Th⁴⁺ with red cells is

greater and somewhat more persistent than, but otherwise similar to, that of UO_2^{2+} . The red cell associated Th^{4+} rose rapidly from zero at the time of the injection to about 8% at 1 min and 30% at 6 h; at that time the blood Th^{4+} was about equally divided between plasma and cells. From 6 to 48 h, red cells accounted for as much as two-thirds of the Th^{4+} in whole blood, and the red cell fraction was being cleared with a half-time of about 14 h, one-half of the plasma clearance rate. By 30 days, the Th^{4+} associated with red cells was nearly 100 times that of the plasma. Between 2 and 30 days, a small fraction of the Th^{4+} was released from the red cells (3.5%) with a half-time of about 15 days. In the special case of Th^{4+} , binding to the red cell membrane is competitive with complexation by plasma Tf. Binding to the membrane is the most likely mechanism for the association of actinides with red cells. If, for example, Th^{4+} had entered the red cell interior, a much larger fraction of the 6 h maximum amount of the Th^{4+} associated with red cells would be expected to remain with the circulating red cells for a longer time (the life span of mammalian red cells is about 90 days (Cronkite, 1973)).

31.4 CLEARANCE OF ACTINIDES FROM THE CIRCULATION

Data for plasma clearances and early urinary excretion of the actinides in laboratory animals and man can be combined with the information developed for their reactions with the plasma constituents to assess their status in the circulation.

Plasma clearances of nine actinides injected iv in soluble form have been investigated in at least one mammalian species (data are not available for Ac^{3+} or Bk^{3+}). Industrially important UO_2^{2+} , Pu^{4+} , and Am^{3+} have been studied in several species. Plasma clearance data are available for two valence states of U (U^{4+} , UO_2^{2+}), two of Pu (Pu^{4+} , PuO_2^{2+}), and three of Np (Np^{4+} , NpO_2^+ , NpO_2^{2+}). Plasma clearance curves of the actinides are shown in Figs. 31.3–31.7, in rats, mice, beagles, nonhuman primates, and human adults, respectively. The plasma clearances of iv-injected Pu^{4+} , Am^{3+} , and UO_2^{2+} in the laboratory animals and human adults are compared in Figs. 31.8, 31.9, and 31.10, respectively.

The rates of clearance of the several actinides from mammalian plasma are determined largely by their chemical properties, in particular by their tendencies to form stable complex(es) with plasma Tf. The actinides that form the most stable Tf complexes are cleared slowly, whereas those that form only weak Tf complexes are cleared at much faster rates. The order of disappearance of the actinides introduced into mammalian plasma is independent of the animal used for study (Figs. 31.3–31.7). Combining the data for all of the animals, and based

Fig. 31.3 Clearance of iv-injected actinides from plasma volume of rats: $^{239}\text{Pu}^{4+}$ (Durbin et al., 1972); $^{241}\text{Am}^{3+}$ and $^{244}\text{Cm}^{3+}$ (Turner and Taylor, 1968a); $^{237}\text{Np}^{4+}$ and $^{237}\text{NpO}_2^+$ (Ramounet et al., 1998).

on the time (min) required to clear 90% of the iv-injected actinide from the plasma volume, plasma clearance rates are in the order:

Note that the 90% plasma clearance measure does not differentiate among the rapidly clearing lighter trivalent actinides and the actinide dioxo ions, which are all cleared at about the same rate, but by different mechanisms.

Fig. 31.4 Clearance of iv-injected actinides from plasma volume of mice: $^{238}\text{Pu}^{4+}$ citrate (Durbin et al., 1997b); $^{237}\text{NpO}_2^+$ (Durbin et al., 1998b); $^{232,234,235}\text{UO}_2^{2+}$ (Durbin et al., 1997a); $^{241}\text{Am}^{3+}$ and $^{238}\text{Pu}^{4+}$ + plasma (P. W. Durbin and B. Kullgren, unpublished data).

Plasma clearance of the actinides is modulated by the physiology of the animals used for study. Plasma retention of Pu^{4+} , Am^{3+} , and UO_2^{2+} in the different animals, as illustrated in Figs. 31.8–31.10, is in the order:

adult man > dog > baboon \geq monkey > rat > mouse.

Plasma actinide retention among the different animals is directly related to body size and inversely related to metabolic rate, renal filtration rate, and the degree of Fe saturation of the plasma Tf (Brody, 1945; Durbin et al., 1997b; Table 31.10).

Fig. 31.5 Clearance of *iv*-injected actinides from plasma volume of beagles: $^{239}\text{Pu}^{4+}$, $^{228}\text{Th}^{4+}$, $^{241}\text{Am}^{3+}$, $^{249}\text{Cf}^{3+}$, and $^{252}\text{Cf}^{3+}$ (Stevens and Bruenger, 1972); $^{244}\text{Cm}^{3+}$ (Atherton et al., 1973); $^{253}\text{Es}^{3+}$ (Atherton et al., 1974); $^{233}\text{UO}_2^{2+}$ (Stevens et al., 1980); $^{239}\text{PuO}_2^{2+}$ (Painter et al., 1946).

31.4.1 Trivalent actinides

(a) Ac^{3+}

Timed plasma data for Ac^{3+} injected *iv* in rats are insufficient to define a clearance curve, however, the pattern of disappearance of $^{227}\text{Ac}^{3+}$ from the plasma is similar to Am^{3+} and Cm^{3+} in the same animals (Fig. 31.3). Clearance was 90% complete in about 50 min and 99% complete in about 400 min. Also

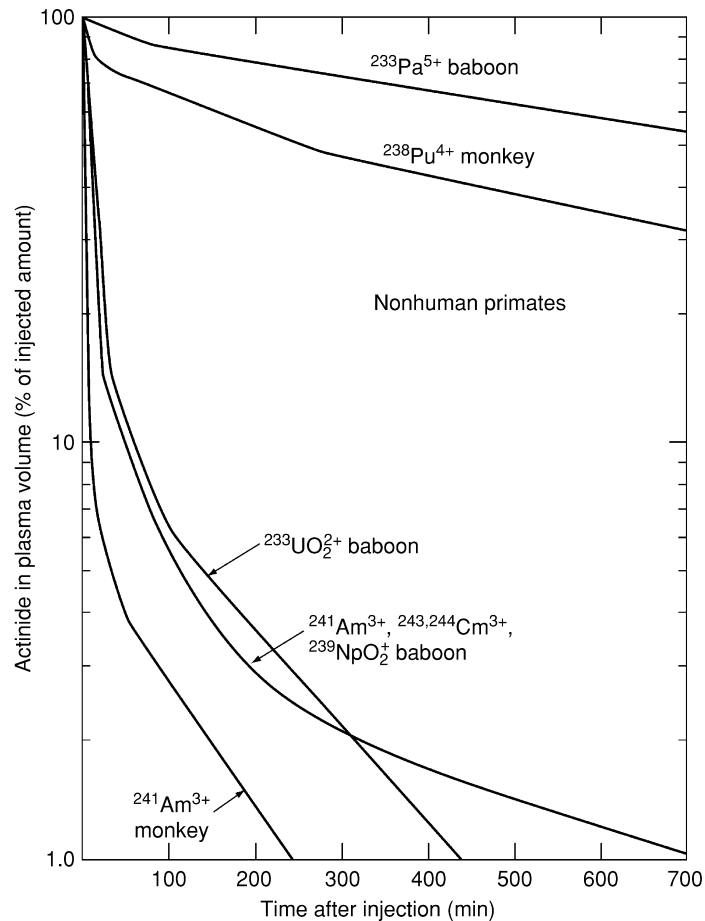

Fig. 31.6 Clearance of iv-injected actinides from plasma volume of nonhuman primates: monkey – $^{238}\text{Pu}^{4+}$ (Durbin et al., 1985), $^{241}\text{Am}^{3+}$ (Durbin, 1973); baboon – $^{241}\text{Am}^{3+}$ (Guilmette et al., 1980), $^{243,244}\text{Cm}^{3+}$ (Lo Sasso et al., 1981), $^{233}\text{UO}_2^{2+}$ (Lipsztein, 1981), $^{239}\text{NpO}_2^+$ and $^{233}\text{Pa}^{5+}$ (Ralston et al., 1986). (Note: The curves for $^{241}\text{Am}^{3+}$, $^{243,244}\text{Cm}^{3+}$, and $^{239}\text{NpO}_2^+$ in the baboons coincide, and a single curve is shown for all three nuclides.)

similarly to Am^{3+} and Cm^{3+} , tissue uptake was fast, and early urinary excretion was negligible (Taylor, 1970).

(b) Am^{3+} , Cm^{3+} , Cf^{3+} , Es^{3+}

Plasma clearances of iv-injected $^{241}\text{Am}^{3+}$ citrate or nitrate have been studied in five laboratory animals (Figs. 31.3–31.6, 31.9), and $^{243}\text{Cm}^{3+}$ or $^{244}\text{Cm}^{3+}$ citrate have been studied in three (Figs. 31.3, 31.5, and 31.6). Separate plasma curves

Fig. 31.7 Clearance of iv-injected actinides from blood volume of adult human males: $^{237}\text{Pu}^{4+}$ (Talbot et al., 1993); $^{234,235,238}\text{U}^{4+}$ and $^{234,235,238}\text{UO}_2^{2+}$ (Bernard and Struxness, 1957).

are not shown for Cm^{3+} in the rats (Fig. 31.3) or the baboons (Fig. 31.6), because they are indistinguishable from those for Am^{3+} in those animals. Clearances of Am^{3+} and Cm^{3+} from the plasma are fast: in all of the animals studied, they were 90% complete in 60 min and 99% complete in ≤ 600 min. Tissue uptake of both trivalent actinides is fast, and only small amounts are excreted in urine in the first 24 h (Taylor, 1962; Turner and Taylor, 1968a; Belyayev, 1969; Durbin, 1973).

Clearances of $^{249,252}\text{Cf}^{3+}$ and $^{253}\text{Es}^{3+}$ from the plasma of beagles was 90% complete in about 100 min, compared with 60 min for the two lighter larger

Fig. 31.8 Clearance of iv-injected Pu^{4+} from plasma volume of animals and man: $^{239}Pu^{4+}$, rat (Durbin et al., 1972); $^{238}Pu^{4+}$, mouse (Durbin et al., 1997b); $^{239}Pu^{4+}$, beagle (Stevens and Bruenger, 1972); $^{238}Pu^{4+}$, monkey (Durbin et al., 1985); $^{237}Pu^{4+}$, adult human male (Talbot et al., 1993); $^{238}Pu^{4+}$ + plasma, mouse (P. W. Durbin and B. Kullgren, unpublished data).

trivalent actinides, and the time required for 99% clearance of Cf^{3+} and Es^{3+} was about 200 min longer (Fig. 31.5). The slower plasma clearances of Cf^{3+} and Es^{3+} , compared with Am^{3+} and Cm^{3+} , confirmed the expectation that the two heavier smaller trivalent actinides would form more stable plasma protein complexes (Stevens and Bruenger, 1972; Atherton *et al.*, 1974).

Immediately after iv injection, the plasma contains rapidly declining fractions of the trivalent actinides in the form of the filterable low molecular weight complex injected (Turner and Taylor, 1968a). The major fraction apparently

Fig. 31.9 Clearance of iv-injected $^{241}\text{Am}^{3+}$ from the plasma volume of animals: rat (Turner and Taylor, 1968a); mouse (P. W. Durbin and B. Kullgren, unpublished data); beagle (Stevens and Bruenger, 1972); monkey (Durbin, 1973); baboon (Guilmette et al., 1980).

forms weak nonfilterable complex(es) with Tf and other plasma proteins, which prevent renal filtration into urine, but are much less stable than the complexes that the trivalent actinides can form with ligands on hepatic cell and bone surfaces and in connective tissue.

In rats injected iv with Am^{3+} or Cm^{3+} citrate, about 50% was protein bound at 1 min and 95% was bound at 60 min (Turner and Taylor, 1968a). *In vivo* and *in vitro* studies of the associations of Ac^{3+} , Am^{3+} , Cm^{3+} , and Cf^{3+} with plasma proteins show that Tf is a major carrier of the trivalent actinides in mammalian plasma, however, those complexes are weak, and they do not survive the more

Fig. 31.10 Clearance of iv-injected UO_2^{2+} from the plasma volume of animals and man: $^{232}UO_2^{2+}$ mouse (Durbin et al., 1997a); $^{233}UO_2^{2+}$ beagle (Stevens et al., 1980); $^{233}UO_2^{2+}$ baboon (Lipsztein, 1981); $^{234,235,238}UO_2^{2+}$ adult human male (Bernard and Struxness, 1957).

rigorous analytical procedures (Poppellwell and Boocock, 1968; Turner and Taylor, 1968a; Bruenger *et al.*, 1969b, 1971b; Taylor, 1970; Stevens and Bruenger, 1972; Cooper and Gowing, 1981). Provisional formation constants ($\log K_1$) have been calculated, 5.3 and 6.5 for Am^{3+} and Cm^{3+} , respectively (Taylor, 1998), and these are similar to the value of the apparent stability constant for binding of Gd^{3+} to the C-terminal site of human Tf (Zak and Aisen, 1988).

Binding of Am^{3+} by Tf is reduced when Fe^{3+} saturation of Tf is high and eliminated altogether by addition of Fe^{3+} in excess of the Tf iron-binding

capacity (Popplewell and Boocock, 1968; Bruenger *et al.*, 1969b). The trivalent actinides also bind to plasma proteins other than Tf. Depending on the experimental conditions and the analytical methods, variable fractions of the trivalent actinides in plasma associate with the heaviest proteins and with albumin (Turner and Taylor, 1968a; Bruenger *et al.*, 1969b, 1971b; Stevens and Bruenger, 1972).

31.4.2 Tetraivalent and pentavalent actinides

(a) Th⁴⁺

Clearance of iv-injected ²²⁸Th⁴⁺, studied only in beagles, is somewhat faster than, but comparable to that of ²³⁹Pu⁴⁺ in the same animal (Fig. 31.5). Reduction to 10% occurred in 0.5 day, and 99% of the injected Th⁴⁺ had disappeared from the plasma in 1.5 days. A larger fraction of the Th⁴⁺ was excreted in 21 days than was found for Pu⁴⁺ (Table 31.4).

Transferrin is the main protein carrier of Th⁴⁺ in the plasma. The larger Th⁴⁺ ion forms a Tf complex that appears to be less stable than the Pu⁴⁺-Tf complex. Similarly to Pu⁴⁺, the Th⁴⁺-Tf complex is destabilized by excess Fe³⁺. Binding of Th⁴⁺ to Tf is suppressed in Fe³⁺-saturated plasma, permitting formation of less stable complexes with the heavier plasma proteins and small filterable ligands (Bruenger *et al.*, 1971a; Peter and Lehmann, 1981; Pecoraro *et al.*, 1981).

(b) U⁴⁺

Clearance from the blood of iv-injected ^{234,235,238}U⁴⁺ was studied in rats (data not shown, Neuman, 1949) and an adult man (Table 31.7, Fig. 31.7; Bernard and Struxness, 1957). Based on their similar properties, the disposition of U⁴⁺ *in vivo* would be expected to resemble Th⁴⁺ and Pu⁴⁺, with stable binding to plasma protein and delayed blood clearance (Tables 31.4, 31.7; Figs. 31.5, 31.7). However, disappearance from the blood of both the rats and man of U injected iv as U⁴⁺ was fast. In humans, it was 90% complete in 200 min and 99% complete in 24 h. During the first hour after injection, clearance from the blood of U injected as U⁴⁺ was nearly the same as that of UO₂²⁺ (Fig. 31.7). Thereafter, U in the blood declined at nearly the same rate as UO₂²⁺, but the U concentration in the blood was about 1.7 times greater than that of UO₂²⁺. Overall, the clearance of U⁴⁺ from human blood closely resembled that of UO₂²⁺ and differed markedly from the plasma clearances of Th⁴⁺ and Pu⁴⁺ in the dogs and Pu⁴⁺ in adult men.

By analogy to Th⁴⁺ and Pu⁴⁺, binding of U⁴⁺ by circulating Tf would be expected, but there is little evidence for such stable binding *in vivo*. The absence from the U⁴⁺ blood curve of a major rapidly forming and slowly clearing component argues against formation of a stable U⁴⁺-Tf complex *in vivo*.

When $^{233}\text{U}^{4+}$ citrate was added to plasma *in vitro* and chromatographed on G-25 Sephadex, <10% of the U eluted with the plasma proteins (Bruenger *et al.*, 1971b).

(c) Np^{4+}

Plasma clearance of Np^{4+} was studied in rats injected iv with about $310 \mu\text{g kg}^{-1}$ ($0.4 \mu\text{mol per rat}$) of $^{237}\text{Np}^{4+}$ citrate, and plasma was sampled at 1, 2, 6, and 24 h (Fig. 31.3, Ramounet *et al.*, 1998). Paquet *et al.* (1996) injected rats iv with a tracer of $^{239}\text{Np}^{4+}$ citrate (17 pg kg^{-1}) or 1.2 mg kg^{-1} ($1.1 \mu\text{mol per rat}$) of $^{237}\text{Np}^{4+}$ citrate. Blood was sampled only at 24 h, at which time the plasma volumes of both groups contained 4 to 5% of the injected Np, in good agreement with the data of Fig. 31.3. Because no blood samples were taken sooner than 60 min after injection, the earliest phases of the plasma clearance curve for Np^{4+} are poorly defined. Renal excretion of Np at 24 h was about 20% of the amount injected regardless of the mass of Np^{4+} injected.

Based on their similar chemical properties, plasma clearances of Np^{4+} and Pu^{4+} would be expected to be similar, that is, slow clearance accompanied by slow tissue uptake and little early urinary excretion (Table 31.2). In the rats, plasma clearances of Np^{4+} and Pu^{4+} were 90% complete in 500 and 1150 min, respectively. After 2 h, their clearance rates were similar, and 99% of both actinides disappeared from the blood in 2 days. Extrapolation of the terminal slope of the Np^{4+} plasma curve (Fig. 31.3) to $t = 0$ suggests that about 16% of the injected Np^{4+} circulated bound to nonfilterable protein, compared with stable protein binding of $\geq 50\%$ of the Pu^{4+} .

Sephacryl S-300 and DEAE-cellulose chromatography were used to investigate protein binding of Np in the plasma taken from rats 30 min after iv injection of $10 \mu\text{Ci}$ of $^{239}\text{NpO}_2^+$ nitrate. At 30 min after injection, based on the plasma clearances of NpO_2^+ in other animals (Figs. 31.3, 31.4, and 31.6), it may be estimated that about 5% of the injected Np would still be in the plasma, most likely bound to protein. Both chromatographic techniques showed that $\geq 95\%$ of the Np applied to the columns collocated with the Fe-Tf peak. Results were essentially the same when $^{239}\text{NpO}_2^+$ was incubated with rat serum *in vitro*, except that the fraction of Np applied to the columns eluting with the Tf peak was reduced to about 70%. Specific Np binding to Tf was confirmed by manipulation of the Fe saturation of the Tf; the association of the Np with the Tf peak decreased as the iron saturation of the Tf was increased. In highly Fe^{3+} -saturated preparations, larger fractions of the Np tended to be associated with both the heavier plasma proteins and with the low molecular weight solutes (Wirth *et al.*, 1985). These studies demonstrated binding of Np to Tf, but as Wirth *et al.* (1985) and Taylor (1998) suggest, it is likely to be complexation of Np^{4+} rather than of the weakly complexing NpO_2^+ . These results also imply that some of the $^{239}\text{NpO}_2^+$ injected in the rats or added to rat serum *in vitro* was reduced to Np^{4+} .

(d) Pu⁴⁺

Plasma clearances of iv-injected Pu⁴⁺ citrate are shown in Figs. 31.3–31.7 for rats, mice, beagles, monkeys, and human adults, respectively, and Fig. 31.8 compares the clearances of Pu⁴⁺ in all of these animals. Clearance of Pu⁴⁺ from the plasma is slow in all of the mammals studied. It was 90% complete in 0.2 to 0.75 day in mice and rats and 1.5 to 5 days in monkeys, beagles, and human adults. Reduction of plasma Pu⁴⁺ to 1% of its initial value required from 0.7 to 1 day in the rodents and 2.5 to 21 days in the larger animals and man.

Delayed clearance from the plasma of rats and dogs of iv-injected ²³⁹Pu⁴⁺ or ²³⁹PuO₂²⁺ and minimal amounts of urinary Pu excretion in the first 24 h were indications that Pu introduced into mammalian plasma was rapidly and almost quantitatively bound to nonfilterable plasma protein (Finkle *et al.*, 1946; Painter *et al.*, 1946; Muntz and Guzman-Barron, 1947; Stevens *et al.*, 1968). Slow plasma clearance of Pu⁴⁺ along with minimal renal excretion is evidence for rapid formation of a stable Pu⁴⁺ complex with plasma protein and for the slow kinetics of the exchanges of Pu⁴⁺ between Tf and the tissue ligands.

Transferrin is the main, if not the only, protein carrier of Pu⁴⁺ in normal mammalian plasma (Popplewell and Boocock, 1968; Stevens *et al.*, 1968, 1975; Stover *et al.*, 1968a; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1971a; Durbin *et al.*, 1976; Lehmann *et al.*, 1983; Taylor, 1998). A provisional stability constant derived for Pu⁴⁺–Tf (log *K*₁=21.8, Taylor, 1998) is close to but less than that derived for Fe³⁺–Tf (log *K*₁=24; Raymond *et al.*, 1980). Pu–Tf is destabilized by reduction of the pH, by addition of excess Fe³⁺, and by increasing the concentration of citrate ion to ten times that of normal plasma. The latter two reactions may contribute to the release of Pu⁴⁺ from Tf to competing tissue ligands.

A small fraction (≤5%) of circulating Pu⁴⁺ is associated with low molecular weight plasma ligands, suggesting that an equilibrium exists between those ligands and the Tf-bound fraction of circulating Pu⁴⁺. In highly Fe³⁺-saturated plasma, Pu⁴⁺ can bind to the heavier proteins, and a larger than usual fraction associates with the low molecular weight ligands (Popplewell and Boocock, 1968; Stover *et al.*, 1968a).

(e) Pa⁵⁺

Baboons were injected iv with 10⁻⁶ μg kg⁻¹ of ²³³Pa⁵⁺ in 0.08 M Na citrate pH 3.2, and blood was sampled frequently for 21 days (Fig. 31.5, Cohen and Ralston, 1983; Ralston *et al.*, 1986). Clearance of the Pa⁵⁺ from the plasma was slower than that of ²³⁹Pu⁴⁺ citrate in beagles (Figs. 31.5 and 31.8), and comparable to that of ²³⁷Pu⁴⁺ in adult men (Figs. 31.7 and 31.8). Plasma clearance was 90% complete in 6 days and 99% complete in 21 days. It was as slow as the plasma clearances of Pu⁴⁺ and Th⁴⁺ in the beagles, and along with low early urinary excretion, a good indication of the formation of a stable Pa⁵⁺ plasma protein complex.

Pa^{5+} , incubated with normal human plasma *in vitro*, was associated with the Tf peak, indicating that the stable complex was Pa^{5+} -Tf (Bruenger *et al.*, 1971b). Taylor and Farrow (1987) prepared a solution for animal injection by diluting a stock solution of $^{233}\text{Pa}^{5+}$ in 8 M HCl with normal saline and adjusting to pH 7 with NaHCO_3 . The distribution of the Pa^{5+} in the serum from rats killed and bled at 5 and 50 min after injection was investigated by gel and ion-exchange chromatography and electrophoresis. In all procedures, the $^{233}\text{Pa}^{5+}$ was associated only with the Tf fraction of the serum proteins.

In normal mammalian plasma, Tf binds Th^{4+} , Np^{4+} , and Pu^{4+} (Peter and Lehmann, 1981; Lehmann *et al.*, 1983; Wirth *et al.*, 1985). Binding of those tetravalent actinides by Tf is reduced in Fe-saturated serum, and they are all released from their Tf complexes by treatment with excess Fe^{3+} . These findings are regarded as evidence that Fe^{3+} -Tf is more stable than the actinide $^{4+}$ -Tf complexes. In contrast, Tf binding of Pa^{5+} was not prevented by presaturation of Tf with Fe^{3+} , nor was it reversed by addition *in vitro* of excess iron to rat serum containing Pa^{5+} (Taylor and Farrow, 1987). Those findings suggest that the Pa^{5+} -Tf complex is more stable than the Tf complexes of the tetravalent actinides and also more stable than Fe^{3+} -Tf.

(f) Summary

The charge/radius ratios of ferric iron and the tetra- and pentavalent actinides are, in units of $e \text{ nm}^{-1}$, as follows: Pa^{5+} , 54.9; Fe^{3+} , 46.2; Pu^{4+} , 41.7; Np^{4+} , 40.8; Th^{4+} , 38.1 (eight-coordination is assumed for the actinides, six-coordination is assumed for Fe^{3+} , Table 31.8) (Shannon, 1976). Based on the positive correlation of the stabilities of actinide complexes and their charge/radius ratios, the stabilities of their Tf complexes would be predicted to be in the above order. The apparent stabilities of their Tf complexes in normal mammalian plasma relative to one another and to Fe^{3+} are in that expected order.

31.4.3 The dioxo ions

(a) UO_2^{2+}

Plasma clearance of iv-injected UO_2^{2+} has been studied in mice, beagles, baboons, and human adults (Figs. 31.4–31.7, 31.10). It was fast in all of the species studied; clearance was 90% complete in 10 to 80 min, and 99% was cleared in 60 to 700 min. Urinary excretion and uptake of UO_2^{2+} in the tissues are fast, as illustrated by measurements in mice (Durbin *et al.*, 1997a). Both processes begin immediately after the UO_2^{2+} is introduced into the blood and continue until the plasma is cleared (about 100 min). Diffusion of filterable low molecular weight complexes between the plasma and tissue fluid and weak binding to plasma protein briefly delay, but do not otherwise interfere with renal filtration of UO_2^{2+} or its deposition in the skeleton.

During the first few days after intake to blood about 85% of absorbed UO_2^{2+} is filtered through the kidneys, about 85% of the filtered fraction is eliminated in passed urine, but about 12% of the injected UO_2^{2+} is deposited in the kidneys (Tables 31.2–31.7). The UO_2^{2+} retained in the kidneys is bound mainly to the brush border of the luminal surfaces of the cells that line the proximal tubules, the site of the renal injury (Tannenbaum, 1951a,b). Binding of UO_2^{2+} to cell membranes is the presumed cause of the cell damage, but the mechanism – conformational changes, blockage of ion channels that interfere with the cell's absorptive functions, and/or inhibition of membrane enzymes required for cell respiration – is not certain (Dounce, 1949; Kirschbaum and Oken, 1979; Kirschbaum 1982; Leggett, 1989).

The large fraction of circulating UO_2^{2+} that is rapidly excreted in urine is indicative of formation of ultrafilterable UO_2^{2+} complexes with low molecular weight ligands in the plasma. Uranyl ion is rapidly and quantitatively absorbed from an im or sc injection site (Tables 31.2 and 31.5), even though formation of *in situ* poorly transportable hydrolysis products is expected at physiological pH, indicating that sufficient concentrations of ligands for UO_2^{2+} are also present in tissue fluid. Bicarbonate was presumed to be the dominant ligand for UO_2^{2+} in the body fluids; UO_2^{2+} complexes with phosphate and organic acids were considered to be of lesser importance (Dounce and Flagg, 1949; Muntz and Guzman-Barron, 1951).

The evidence for bicarbonate as the principal low molecular weight ligand for UO_2^{2+} in body fluids was indirect. Addition of HCO_3^- greatly increased the ultrafilterability of UO_2^{2+} added to blood serum. Protein precipitated with UO_2^{2+} redissolved, and enzymes inhibited with UO_2^{2+} were reactivated by addition of HCO_3^- . The urinary pH of cats and rabbits was lowered or raised by manipulation of their diets: acidification of the urine reduced UO_2^{2+} excretion and increased UO_2^{2+} deposition in the kidneys. Conversely, alkalinization increased urinary UO_2^{2+} excretion and reduced UO_2^{2+} deposition in the kidneys. Infusion of excess HCO_3^- in rabbits injected iv with UO_2^{2+} resulted in more and more rapid urinary UO_2^{2+} excretion and even less UO_2^{2+} retention in the kidneys than increasing urinary pH alone. The stability of the filtered UO_2^{2+} complex was more dependent on the concentration of HCO_3^- in the filtrate than on the pH (Dounce, 1949; Dounce and Flagg, 1949; Wills, 1949; Muntz and Guzman-Barron, 1951).

The abundance of HCO_3^- in both plasma and tissue fluid greatly exceeds those of the other low molecular weight ligands (phosphate, organic acids, Table 31.9). Uranyl carbonate complexes are more stable than those with phosphate and citric acid (Table 31.8; Grenthe *et al.*, 1992). The circulating filterable UO_2^{2+} complex is pH-dependent, whereas UO_2 citrate is stable over the physiological pH range (Dounce and Flagg, 1949).

About 40% of circulating UO_2^{2+} is bound to nonfilterable plasma protein. Based on estimated molecular weight and electrophoretic properties, the protein that bound UO_2^{2+} was originally thought to be serum albumin (Dounce, 1949;

Dounce and Flagg, 1949; Muntz and Gurman-Barron, 1951). Stevens *et al.* (1980) demonstrated that the protein that binds UO_2^{2+} in plasma is Tf. The UO_2^{2+} -Tf complex is demonstrably weaker than the complexes that UO_2^{2+} forms with carbonate. As the plasma UO_2^{2+} is depleted by glomerular filtration of the low molecular weight complexes, the equilibrium between the filterable and nonfilterable complexes is continuously reestablished by dissociation of the nonfilterable protein complex and shift to the filterable complex until UO_2^{2+} has been cleared from the plasma by renal filtration and binding to bone.

As the plasma ultrafiltrate formed by the renal glomeruli is converted to bladder urine >99% of the water and electrolytes are reabsorbed, mainly in the proximal tubules, and the pH is reduced. Bicarbonate and phosphate are preferentially reabsorbed as the fluid passes through the proximal tubule, and by the time the tubular fluid enters the last third of the proximal tubule (the site of UO_2^{2+} deposition and renal injury), their concentrations are 0.35 and 0.50, respectively, of those in the plasma (Wong *et al.*, 1986). Under these conditions UO_2^{2+} carbonate complexes formed in the plasma will become less stable.

The concentration of HCO_3^- in bladder urine is usually <1% of that in plasma, and the pH is about 6, whereas the concentrations of phosphate and citrate are slightly greater than in the plasma (Table 31.9). The UO_2^{2+} carbonate complexes formed in the plasma cannot survive the transit through the entire renal tubule system to the bladder, and the chemical form of UO_2^{2+} in urine is not likely to be the same as in the circulating fluids.

Speciation calculations can be used to identify and provide estimates of the relative concentrations of the UO_2^{2+} complexes that are likely to form in biological fluids. Concentrations of the important constituents of human plasma and bladder urine are shown in Table 31.9. The concentrations of these constituents in the fluid entering the last third of the proximal renal tubules (site of UO_2^{2+} deposition and renal injury) were estimated from the renal micropuncture data of Wong *et al.* (1986) (Table 31.9). Consensus values are available for the formation constants of the UO_2^{2+} complexes with the ligands in biological fluids at $T = 25^\circ\text{C}$ and ionic strength $I = 0.1 \text{ M}$, the closest match to the conditions in biological fluids. A very stable soluble neutral dicalcium uranyl triscarbonate complex, $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$, was shown to influence the speciation of UO_2^{2+} in the region pH 6 to 10 of calcite-rich U mining waters (Bernhard *et al.*, 2001). That complex was included in the present calculations, because the chemical conditions in the mine waters resemble those in blood plasma and renal tubular fluid, both of which are nearly neutral and contain significant concentrations of Ca^{2+} and HCO_3^- .

(i) *Complexes in plasma*

The conditions for the plasma calculations were, as follows: Data for the human UO_2^{2+} injection case (Table 31.7) were combined with human data for fluid volumes and Tf concentrations (Table 31.10) to calculate an initial UO_2^{2+}

concentration in plasma of 10^{-5} M and a concentration of available Tf-binding sites of 3.6×10^{-5} M. The partitioning of UO_2^{2+} in the plasma was set at 60% associated with ultrafilterable ligands and 40% bound to nonfilterable Tf (Stevens *et al.*, 1980). No correction was made for the small fraction of newly injected UO_2^{2+} ($\leq 4\%$) that is transiently associated with red blood cells (Dounce, 1949; Stevens *et al.*, 1980; Lipsztein, 1981; Durbin *et al.*, 1997a).

The set of equations for the competing reactions was solved simultaneously. The predominant filterable UO_2^{2+} complex in the plasma, identified as $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$, can account for 86% of the filterable UO_2^{2+} , with 13% in the form of the triscarbonate complex, and about 1% as the biscarbonate (Table 31.11). The selected concentration of Tf-binding sites and fraction of UO_2^{2+} bound to Tf yielded a value for the formation constant of UO_2^{2+} -Tf, $\log K_f = 14.5$, which agrees reasonably well with a reported value of $\log K_f = 16$ determined in a solution much more dilute than 0.1 M NaCl (Ansoborlo *et al.*, 2003).

(ii) *Complexes in proximal renal tubular fluid*

Only a crude estimate can be made of the speciation of the UO_2^{2+} complexes that exist in the chemical milieu of the fluid flowing through the late proximal renal tubules, because the fluid in the last third of the proximal tubules is not accessible to micropuncture sampling. The composition of the tubular fluid shown in

Table 31.11 UO_2^{2+} complexes with the low molecular weight ligands of biological fluids as identified by speciation calculations.^{a,b}

<i>Distribution of UO_2^{2+} complex species (% of total)</i>				
UO_2^{2+} complex	$\log K_f$	<i>Plasma ultrafiltrate</i>	<i>Late proximal tubule fluid^c</i>	<i>Bladder urine</i>
$\text{UO}_2(\text{CO}_3)_2^{2-}$	16.2 ^c	0.6	7.0	0.2
$\text{UO}_2(\text{CO}_3)_3^{4-}$	21.6 ^c	13	6.3	<0.1
$\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{Aq})$	28.1 ^d	86	73	0.4
UO_2HPO_4	7.2 ^e	<0.1	0.3	77
UO_2 citrate	7.4 ^e	<0.1	0.5	22
'Tubule protein' ^f	–	–	13	–

^a Values for formation constants at $T=25^\circ\text{C}$ and ionic strength $I=0.1$ used as best match to 0.14 M NaCl in biological fluids.

^b The ionization constant for HCO_3^- given in Grenthe *et al.* (1992) was recalculated to $\log K_i = -9.9$ at ionic strength $I=0.1$ M.

^c NEA (1992). Calculated from composition of fluid entering last third of proximal tubules.

^d Bernhard *et al.* (2001).

^e Martell and Smith (1977).

^f Membrane of proximal tubule microvilli.

Table 31.9 is the set of measurements made closest to the beginning of the last third of the proximal tubules (Wong *et al.*, 1986). The concentration of HCO_3^- and the tubular fluid pH continue to be reduced during the traverse of the last portion of the proximal tubule, but by how much before the fluid enters the more distal nephron cannot be estimated, because Wong *et al.* (1986) did not report measurements of the concentration of HCO_3^- in the distal tubules.

Specification of chemical conditions for the tubular fluid calculations introduces additional uncertainty. During its transit through the last third of the proximal tubules, about 13% of the injected UO_2^{2+} is lost from the fluid phase and is deposited on the membrane of the brush border microvilli. To take account of that loss to protein binding, it was assumed that the contact between the tubular fluid and the membrane of the microvilli was so intimate that the membrane protein could be considered to be 'virtually' in solution. The concentration of membrane protein-binding sites was set at 10^{-4} M, assuming that the binding sites for UO_2^{2+} were three times more abundant than those of Tf. The concentrations of the UO_2^{2+} complexes calculated for the plasma ultrafiltrate were used as starting conditions for the UO_2^{2+} content of the tubular fluid.

The dominant complex is still $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$ (Table 31.11), which can account for 73% of the UO_2^{2+} entering the system, 13% is bound to kidney protein (fixed by starting conditions), the bicarbonate (7%) is more important than in the plasma, whereas the triscarbonate (6.3%) is less important than in plasma. In addition, about 1% of the UO_2^{2+} in this system is predicted to be associated with phosphate and citrate. The selected concentration and fractional binding of UO_2^{2+} to tubule membrane protein yielded a value for a 'formation constant' of UO_2^{2+} -membrane protein, $\log K_f = 9.6$. The fixed protein 'concentration' and $\log K_f$ are coupled, and both are uncertain.

(iii) Complexes in bladder urine

The conditions for the urine calculations were as follows: The human UO_2^{2+} injection case (Table 31.7) excreted 59% of the injected UO_2^{2+} (14 μmol) in 1.4 L of urine in the first 24 h (Hursh and Spoor, 1973), and the concentration of UO_2^{2+} in urine was 10^{-5} M. The concentrations of the constituents of urine of humans consuming an ordinary diet are those given in Table 31.9. The speciation calculations indicate that only 1% of the excreted UO_2^{2+} would still be a carbonate complex, and 99% would be present as phosphate and citrate complexes (Table 31.11). Diets that raise the pH and/or increase HCO_3^- in urine and HCO_3^- infusion, which increases both the HCO_3^- concentration and the pH of the urine, would allow survival of greater fractions of the carbonate complexes filtered from plasma and their excretion in the urine.

Two questions that have received little attention are the near absence at low UO_2^{2+} intakes to blood of significant UO_2^{2+} deposition in portions of the renal tubular system distal to the proximal tubules and the spreading out of the renal injury at toxic UO_2^{2+} doses. The degree and extent of renal injury

caused by UO_2^{2+} are dose-dependent. At low to moderately toxic intakes to blood, cell damage is limited to the later portion of the proximal tubules, seen in microscopic sections as occupying the region near the cortico-medullary junction. With increasing doses of UO_2^{2+} , the cellular injury becomes progressively more widespread, extending proximally to the earlier portions of the proximal tubules and the distal tubules in the cortical region and distally to the loops of Henle in the medulla (Barnett and Metcalf, 1949). Autoradiographs of the kidneys of rodents given low doses of $^{232}\text{UO}_2^{2+}$ or $^{233}\text{UO}_2^{2+}$ verified that deposition of the UO_2^{2+} coincided with the zone of low-dose cellular injury. When the shorter-lived U isotopes were given augmented with toxic amounts of $^{238}\text{UO}_2^{2+}$, autoradiographs showed more U deeper in the cortex (earlier portions of the proximal tubules and distal tubules) and deeper into the medulla (loops of Henle) than were seen with the lower doses of UO_2^{2+} .

In chemical terms, when high concentrations of UO_2^{2+} (10^{-3} M) were circulating, the carbonate complexes filtered from the plasma apparently begin to destabilize at the conditions of the earlier portions of the proximal tubules (Table 31.9), and the concentrations of phosphate and citrate are insufficient to prevent UO_2^{2+} binding to the presumably lower affinity proteins of the membrane of the later segments of the renal tubule system.

The microvilli of the proximal tubule brush border are specialized for absorption, and the brush border presents a surface area many orders of magnitude greater than the luminal surface of the more distal portions of the renal tubule system (Berliner, 1973). Combined, the lower concentrations of potential UO_2^{2+} binding sites and lower affinities for UO_2^{2+} of these sites (less than those of phosphate and citrate) could account for the apparent lack of binding of low doses of UO_2^{2+} in the more distal tubule segments.

(b) NpO_2^+

Plasma clearance of iv-injected $^{237}\text{NpO}_2^+$ was studied in rats and mice (Figs. 31.3 and 31.4). Clearance of NpO_2^+ from mouse plasma was fast, with 90% clearance in 10 min and 99% clearance in 60 min. At 100 min, skeletal uptake and urinary excretion accounted for 80% of the injected Np (Table 31.3). Plasma clearance of Np was also investigated in baboons injected iv with 1 ng kg^{-1} of ^{239}Np or $100 \mu\text{g kg}^{-1}$ of ^{237}Np reported as NpO_2^+ or NpO_2^{2+} in solutions of Na citrate, NaHCO_3 , or NaNO_3 (Ralston *et al.*, 1986). No differences were found in the plasma clearances, urinary excretion rates, or whole-body retentions of the differing masses of Np or Np oxidation states or chemical compositions of the injection media. Those findings indicate that either NpO_2^{2+} had not been formed or that it was promptly reduced to NpO_2^+ *in vivo*. Plasma clearance of NpO_2^+ was fast in the baboons; it was 90% complete in about 45 min and 99% complete in about 300 min (Fig. 31.6).

The plasma clearance of iv-injected $^{237}\text{NpO}_2^+$ nitrate in the rats differs somewhat from those of the other animals (Figs. 31.3, 31.4, and 31.6). About 80% of

the injected Np was cleared from the plasma as rapidly as in the mice and baboons (in about 20 min, Figs. 31.4 and 31.6), but clearance of the remaining 20% was slow and resembled that of Np^{4+} in the same animal models. Overall clearance was slow; it was 90% complete in 160 min and 99% complete only after 1.7 days. In the three animals, a small fraction of the iv-injected NpO_2^+ was cleared from the plasma as slowly as Pu^{4+} (0.5% in the mice, 2% in the baboons, and 5.5% in the rats). The complexes of NpO_2^+ are weak (Table 31.8), and it is reasonable to consider that these small slowly clearing fractions of the injected Np had been reduced to Np^{4+} *in vivo* and were circulating complexed with serum proteins.

Human plasma was incubated with ^{237}Np as Np^{4+} , NpO_2^+ , or NpO_2^{2+} in 0.08 M Na citrate buffer pH 3.2. Chromatography on G-25 Sephadex indicated that about 20% of the Np in all these preparations was associated with serum proteins. Chromatography on G-100–200 Sephadex indicated that the ^{237}Np , applied as NpO_2^+ , was distributed among the heavy proteins (22%), the albumin-Tf peak (33%), and low molecular weight species (44%). Re-chromatography of the albumin-Tf peak on DEAE-Sephadex showed only a moderate tendency of the Np to be associated with the Tf peak (Bruenger *et al.*, 1971b).

Protein precipitation, dialysis, ultrafiltration, and gel chromatography (150-Sephadex) were used to study protein binding of $^{239}\text{NpO}_2^+$ incubated with dog serum. All of those procedures indicated that about 50% of the Np was associated with protein, but no specific protein(s) could be identified. Protein binding was weak, and gel chromatography showed that about 20% of the applied Np was associated with the heaviest proteins and 80% eluted with the low molecular weight species in the same fraction as NpO_2NO_3 (Guilmette *et al.*, 1982).

Intravenously injected NpO_2^+ is rapidly cleared from the plasma of mice, rats, and baboons, mainly to urinary excretion and uptake in bone (Tables 31.2, 31.3, 31.5, and 31.6; Figs. 31.3, 31.4, and 31.6). There is little evidence for protein binding of NpO_2^+ in the plasma. Combined, these observations are good indicators that, in accord with its tendency to form only weak complexes, NpO_2^+ does not form stable complexes with plasma protein (Bruenger *et al.*, 1971b; Guilmette *et al.*, 1982). Stable binding of Np to Tf apparently requires that the injected NpO_2^+ be reduced *in vivo* to Np^{4+} , which forms complexes as stable as those of Pu^{4+} . *In vivo* reduction of NpO_2^+ to Np^{4+} is likely to be slow, because it involves the breaking of M–O bonds, but as Durbin *et al.* (1998b) and Taylor (1998) point out, at pH 7.4 in the presence of ligands with great affinity for Pu^{4+} and Np^{4+} but little affinity for NpO_2^+ and an average eH in mammalian plasma of about 270 mV (Van Rossum and Schamhart, 1991), such reduction is theoretically possible.

The low molecular weight NpO_2^+ species transported in the plasma, filtered by the kidneys into the urine, and rapidly deposited in bone (Tables 31.2, 31.3, and 31.5) have not been identified. Hydrolysis of NpO_2^+ is not expected at physiological pH. Some of the NpO_2^+ , which behaves like a large monovalent

cation, may exist as a hydrated ion, and carbonate is known to stabilize NpO_2^+ (Ahrlund, 1986). Both an aqueous ion and a NpO_2^+ carbonate complex should be ultrafilterable and excreted by the kidneys into the urine.

The identities of the NpO_2^+ species that may be expected in mammalian plasma can be calculated for the specific set of conditions in the plasma volume of a 6.2 kg monkey immediately after iv injection of $42 \mu\text{g kg}^{-1}$ of $^{237}\text{NpO}_2^+$ (Table 31.5); the concentration of the NpO_2^+ would be $4.5 \times 10^{-6} \text{ M}$ in 0.025 M HCO_3^- at pH 7.4 (Tables 31.8 and 31.9). The stability constants of the NpO_2^+ carbonate, phosphate, and citrate complexes are as shown in Table 31.8.

The speciation calculations predict that in mammalian plasma hydrolysis of NpO_2^+ is negligible, and about 20% of the injected NpO_2^+ circulates as a hydrated ion, $\text{NpO}_2^+(\text{aq})$, 50% as $\text{NpO}_2\text{CO}_3^-$, 20% as $\text{NpO}_2\text{HPO}_4^-$, and 10% as a NpO_2^+ citrate complex. The concentration of HCO_3^- and the pH are too low to allow formation of a bicarbonate.

The $\text{NpO}_2\text{CO}_3^-$ complex is unstable at the reduced HCO_3^- and pH in the renal tubules (Table 31.9). In the urine, NpO_2^+ is likely to be about equally divided between its HPO_4^{2-} and citrate complexes.

The fraction of iv-injected NpO_2^+ that deposits in the kidneys is $\leq 3\%$ (Tables 31.2, 31.3, and 31.6), the tendency of NpO_2^+ to bind to kidney tissue protein is apparently much less than that of UO_2^{2+} . However, if the amount of Np injected (oxidation state not certain) is in the toxic range ($\geq 6 \text{ mg kg}^{-1}$), even that small fractional kidney deposit will result in renal tubular injury of the same nature at the same anatomical location that is typically seen with much smaller doses of UO_2^{2+} (Maynard and Hodge, 1949; Ballou *et al.*, 1962; Mahlum and Clarke, 1966).

(c) PuO_2^{2+}

A dog was injected iv with $0.84 \mu\text{g Pu}$ per kg of $^{239}\text{PuO}_2^{2+}$ in a solution containing $0.01 \text{ M Na citrate}$ and 0.14 M NaCl , pH 7 (Painter *et al.*, 1946). About 35% of the injected Pu was cleared from the plasma in the first 20 min, but in contrast to its analog, UO_2^{2+} , clearance of about 65% of the injected PuO_2^{2+} from the plasma was as slow as that of Pu^{4+} in beagles (Fig. 31.5). Comparisons of the plasma clearance pattern and early urinary excretion in the dog and the tissue distributions in rats of Pu injected as PuO_2^{2+} with those of Pu^{4+} and UO_2^{2+} in the same animals (Tables 31.2 and 31.4) show that the disposition of PuO_2^{2+} does not resemble that of UO_2^{2+} , but is similar to that of Pu^{4+} . Combined, these observations indicate reduction of PuO_2^{2+} to Pu^{4+} *in vivo*. Where in the body that reduction occurs is not known, but because it is rapid, it is likely to take place in the circulating fluids.

The stabilities of the bicarbonate complexes of UO_2^{2+} and PuO_2^{2+} are similar (Table 31.8). However, after iv injection of $^{239}\text{PuO}_2^{2+}$ in rats little Pu was excreted in the urine, and the distribution of the Pu was nearly the same as that of iv-injected $^{239}\text{Pu}^{4+}$ citrate (Table 31.2; Carritt *et al.*, 1947). These results

also suggest that PuO_2^{2+} is rapidly reduced to Pu^{4+} in the circulation (Table 31.2). However, when $^{239}\text{PuO}_2\text{Cl}_2$ was injected im in rats, Pu absorption was greater and faster than when the same mass of Pu was injected im as $^{239}\text{PuCl}_4$ or $^{239}\text{PuCl}_3$, suggesting that some PuO_2^{2+} was mobilized from the wound site in a transportable form before it could be reduced to Pu^{4+} and hydrolyzed *in situ* (Scott *et al.*, 1948b).

31.5 TISSUE DEPOSITION KINETICS

The kinetics of the tissue uptake of some actinides and lanthanides have been studied to relate differences in their biological behavior to their chemical properties, to aid in developing procedures for the therapeutic removal of actinides from the body, to identify the biological processes underlying the several components of the plasma clearance curves, and to determine whether the target tissues take up actinide bound to plasma protein or complexed by low molecular weight plasma ligands or both. The experimental design of the kinetic studies, which as a practical matter have been conducted only in rats and mice, involves killing groups of animals at intervals from 1 min to 24 h after iv injection of an actinide and measuring the nuclide content of the blood, and/or plasma, tissues, and excreta.

31.5.1 Tissue deposition kinetics in rats

Tissue uptake data have been reported for iv-injected $^{241}\text{Am}^{3+}$ by Belyayev (1969), for $^{239}\text{Pu}^{4+}$ by Schubert *et al.* (1950) and Rosenthal and Schubert (1957), and for four representative lanthanides (Durbin *et al.*, 1955). Taylor (1962) reported that the pattern of uptake of iv-injected $^{241}\text{Am}(\text{NO}_3)_3$ or $^{241}\text{Am}^{3+}$ citrate in the bones of growing rats more closely resembled that of Ca^{2+} than Pu^{4+} . The data from those studies were recalculated to account for nuclide in the contained plasma of the tissues (Durbin *et al.*, 1972; Durbin, 1973). Within the first 5 min after iv injection of Ca^{2+} , Ce^{3+} , Eu^{3+} , Am^{3+} , or Pu^{4+} in rats, as much as 50% of the injected nuclide disappeared from the plasma, but could not be accounted for by excretion or uptake in bones and liver. Material balance studies with Ca^{2+} and four lanthanides demonstrated that at that time 75 to 90% of the missing nuclide was present transiently in the bulk soft tissue, indicating association with interstitial water (ISW) rather than with cellular components. The light lanthanides, Ce^{3+} and Eu^{3+} , Ca^{2+} , and Am^{3+} bind weakly to plasma proteins, and 50 to 60% of the injected amounts of those nuclides had diffused into ISW (Durbin, 1973). Plasma Tf binds stably to Pu^{4+} , and only 20 to 40% of iv-injected Pu^{4+} diffused into ISW, depending on whether the Pu^{4+} was administered as the nitrate or complexed with citrate (Durbin *et al.*, 1972).

The fraction of iv-injected nuclide diffusing into ISW depends on the stability of its protein complex(es). The less stable the protein binding, the more slowly the complex forms, and the larger is the fraction that promptly leaves the plasma by diffusion into ISW or immediate uptake by bone and/or liver or urinary excretion.

These kinetic studies of Am^{3+} and lanthanides demonstrated that the initial fast decline in the plasma clearance curves (first exponential component) was the combined result of rapid early deposition in the target tissues and urinary excretion and diffusion of filterable nuclide from the plasma to ISW, most of which is associated with the bulk soft tissues. Delayed return to the plasma compartment from ISW contributes to the second and third components of the plasma clearance curves and supports continued, but slower, uptake in the tissues. The multiexponential equations that describe the uptake of Am^{3+} in the bone and liver of rats have rate terms in common with each other and with the equations of clearance from the plasma and the soft tissues (ISW). Common terms in the transport equations are expected for two communicating fluid compartments (Durbin *et al.*, 1997b). The common rate terms in the liver and skeleton uptake equations indicated that Am^{3+} was being accumulated in both tissues from common pools – initially, from complexes with low molecular weight plasma ligands, and later from the weak plasma protein complexes (Durbin, 1973).

The recalculated data for Pu^{4+} clearance from the plasma and the uptake kinetics of Pu^{4+} in rat skeleton and liver (Schubert *et al.*, 1950; Rosenthal and Schubert, 1957) were combined with data for protein binding of Pu^{4+} in rat and dog plasma measured at times from a few minutes to 24 h after injection of Pu^{4+} citrate (Stevens *et al.*, 1968; Turner and Taylor, 1968a). These data were used to solve a biokinetic compartment model of circulatory transport and tissue uptake (Durbin *et al.*, 1972). The Pu^{4+} complexed with Tf and the Pu^{4+} complexed with filterable low molecular weight plasma ligands were designated as bound or free, respectively. The model structure consisted of four interconnecting transport compartments – plasma-bound, plasma-free, ISW-bound, and ISW-free. The plasma-bound and plasma-free compartments communicated with four effectively nonreturning sinks – liver, skeleton, soft tissue, and excreta. The numerical solutions of the model implied the following: Pu^{4+} -free binds to protein, mainly to Tf, in the ISW as well as in the plasma; little, if any Pu^{4+} -bound is excreted or deposited in the liver; which suggests that Tf binding is not a necessary precondition for liver uptake of Pu^{4+} ; both Pu^{4+} -bound and Pu^{4+} -free are taken up by bone.

31.5.2 Tissue deposition kinetics in mice

Detailed studies of tissue uptake kinetics were conducted in mice injected iv with $^{232,235}\text{UO}_2\text{Cl}_2$ (Fig. 31.11, Durbin *et al.*, 1997a), $^{237}\text{NpO}_2\text{Cl}$ (Fig. 31.12, Durbin *et al.*, 1998b), $^{241}\text{Am}^{3+}$ citrate (Fig. 31.13, P. W. Durbin and B. Kullgren,

Fig. 31.11 Clearance from extracellular fluid (ECF) of mice, uptake in EFC-free skeleton and ECF-free kidneys, and cumulated urinary excretion of iv-injected $^{232,234,235}\text{UO}_2\text{Cl}_2$ ($100 \mu\text{g kg}^{-1}$ of U). Data of Durbin et al. (1997a).

unpublished data) , or $^{238}\text{Pu}^{4+}$ citrate (Fig. 31.14, Durbin *et al.*, 1997b, P. W. Durbin and B. Kullgren unpublished data) . These studies provide useful comparisons of the deposition kinetics of actinides in their four biologically important oxidation states that form complexes with plasma constituents ranging in stability from very weak to strong. In all of these studies, female mice of the same strain and age were used. Nuclides were injected iv, and data were taken from groups of five mice killed at 16 timed intervals from 1 min to 24 h. Actinide content of plasma and all tissues of each mouse (including its entire skeleton) and pooled excreta of each five-mouse group were determined by

Fig. 31.12 Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected $^{237}\text{NpO}_2\text{Cl}$ ($200 \mu\text{g kg}^{-1}$ of Np). Data of Durbin *et al.* (1998b).

scintillation counting. On average, 95% of the injected actinide was recovered in these material balance studies.

The fractional volumes of plasma and ECF in the tissues and whole body had been measured in similar mice (Durbin *et al.*, 1992). Those fluid distributions were used to calculate and apportion among its tissues the actinide removed in the plasma sample of each mouse, approximately recreating the total in-life actinide content of each tissue. The amounts of actinide deposited in the target tissues at each time (t), ECF-free tissue (t), was estimated by subtracting the amount of actinide calculated to be in their contained plasma $[P(t)]$ and

Fig. 31.13 Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected $^{241}\text{Am}^{3+}$ citrate ($0.23 \mu\text{g kg}^{-1} \text{Am}$). Unpublished data of P. W. Durbin and B. Kullgren.

ISW $[I(t)]$ from their measured values that had been corrected for blood loss; skeleton $[\text{Sk}(t)]$, liver $[\text{L}(t)]$, and kidneys $[\text{K}(t)]$ (Durbin *et al.*, 1992, 1997a,b, 1998b),

$$\text{ECF-free skeleton} = [\text{Sk}(t) - \text{P}_{\text{Sk}}(t) - \text{I}_{\text{Sk}}(t)]$$

$$\text{ECF-free liver} = [\text{L}(t) - \text{P}_{\text{L}}(t) - \text{I}_{\text{L}}(t)]$$

$$\text{ECF-free kidneys} = [\text{K}(t) - \text{P}_{\text{K}}(t) - \text{I}_{\text{K}}(t)].$$

The tissue uptake data (deposited fractions), expressed as percent of injected actinide in ECF-free tissues, are plotted vs time to 120 min after injection in Figs. 31.11–31.14. Those curves and the parameters of their multiexponential

Fig. 31.14 Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected $^{238}\text{Pu}^{4+}$ citrate ($0.09 \mu\text{g kg}^{-1} \text{Pu}$). Data of Durbin et al. (1997b) and unpublished data of P. W. Durbin and B. Kullgren.

equations were obtained by log-linear regression analysis. The curves were plotted for clearance of actinides from the plasma (Fig. 31.4) and ECF (Figs. 31.11–31.14) of mice, and their equations were calculated to 120 min after injection for UO_2^{2+} , NpO_2^{2+} , and Am^{3+} and to 480 min for Pu^{4+} . Each has three exponential components,

Plasma (t) or $\text{ECF}(t) = \sum A_i e^{-\lambda_i t}$ (% of amount injected), t is min after injection.

Maximum actinide accumulations in the ECF-free tissues and urinary excretion were estimated from the tabular data. Equations were derived to describe

the actinide uptake in the target tissues and cumulated urinary excretion using published methods (Comar, 1955; Durbin, 1973). The exponential tissue uptake equations were calculated to 120 min for UO_2^{2+} , NpO_2^+ , and Am^{3+} and to 480 min for Pu^{4+} . Nearly all of the tissue uptake equations also have three negative exponential terms,

Tissue(t) or cum. urine(t) = $\sum A_i(1 - e^{-\lambda_i t})$ (% of injected amount), t is min after injection.

The parameters, coefficients (A_i , %), and rate constants (λ_i , min^{-1}) of the plasma and ISW clearance equations and the equations describing actinide uptake in the ECF-free tissues and cumulated urinary excretion are collected in Table 31.12. Table 31.12 also includes the maximum values of the ECF-free tissue deposits and total urinary excretion and the approximate postinjection times of maximum accumulation. This table also includes, for comparison, the parameters of the two-component plasma clearance curves determined in similar mice for the organic tracers, CaNa_3 - ^{14}C -DTPA and ^3H -inulin, which are freely diffusible, do not accumulate in any tissue, and are quantitatively filtered into the urine (Durbin *et al.*, 1997b). The deposition kinetics studies of Am^{3+} and Pu^{4+} in the mouse confirmed the findings for those actinides in rats, and deposition kinetic studies were extended to include UO_2^{2+} and NpO_2^+ .

In the mice, the first two exponential terms of the plasma clearance equations of Am^{3+} , UO_2^{2+} , and NpO_2^+ are similar to those of the diffusible tracers, CaNa_3 - ^{14}C -DTPA and ^3H -inulin (Table 31.12). Within 5 min, about 85% of those injected actinides and the organic molecules have diffused into ISW, been filtered by the kidneys, and, for the actinides, been taken up by the skeleton and liver.

Immediate diffusion of large fractions of these three injected actinides into ISW and some early urinary excretion show that upon introduction into the plasma they exist mainly as 'free' filterable complexes with small ligands (either plasma constituents or, in the case of Am^{3+} with the injected excess citrate). Initially, large fractions of these actinides are taken up in the liver or kidneys and skeleton at very fast rates. The coefficients of the first components of their uptake equations (A_1) account for accumulation of 40–80% of the maximum deposits in the skeleton and about 30% of the maximum liver deposits. The rate constants (λ_1) imply uptake half-times of 0.3 to 0.8 min in bone and 1 to 1.4 min in liver (Table 31.12). Tissue uptake and urinary excretion persist, but more slowly at times longer than 5 min postinjection as is shown by the rate constants of the second and third components of their uptake equations (λ_2 and λ_3).

The deposition kinetics of Pu^{4+} differ quantitatively from those of the other three actinides of differing oxidation state, mainly because Pu^{4+} forms a stable complex with plasma Tf, while the complexes that NpO_2^+ , UO_2^{2+} , and Am^{3+} form with Tf and other plasma proteins are very weak. In the mice, about 75% of Fe-binding sites of plasma Tf are occupied by Fe^{3+} (Table 31.10). During the first few minutes after iv injection of Pu^{4+} citrate, about one-half of the Pu^{4+} appeared to be 'free' and circulating as a filterable low molecular weight species.

^{*} % of injected nuclide and minutes (min) is time after injection.

^a Data sources are as follows: ^{232,234,235}UO₂Cl₂, Durbin *et al.* (1997a); ²³⁷NpO₂Cl, Durbin *et al.* (1998b); ²⁴¹Am³⁺ citrate, P. W. Durbin and B. Kullgren (unpublished data); ²³⁸Pu⁴⁺ citrate, Durbin *et al.* (1997b) and P. W. Durbin and B. Kullgren (unpublished data).

^b Equations for plasma and ISW clearance were fitted from $t(0)$ to $t(120 \text{ min})$, and those for tissue accumulation and cumulated urinary excretion were fitted from $t(0)$ to $t(\text{maximum})$. Maximum tissue accumulation and cumulated urinary excretion values and the postinjection times at which those maxima were attained were estimated from Figs. 31.11–31.14.

^c Clearance equations are of the form, $\text{plasma}(t)$ or $\text{ISW}(t) = \sum A_i e^{-\lambda_i t}$, and those for accumulation in the tissues and cumulated urinary excretion are of the form, $\text{tissue}(t)$ or $\text{cum. urine}(t) = \sum A_i (1 - e^{-\lambda_i t})$, where $\text{plasma}(t)$, $\text{ISW}(t)$, $\text{tissue}(t)$, and $\text{cum. urine}(t)$ are expressed as % of injected actinide and t is min. after injection.

^d Actinide calculated to have diffused into interstitial water (ISW).

^e ECF-free kidneys (t) are combined with cum. urine (t) to account for all actinide filtered by the kidneys.

^f Durbin *et al.* (1997b).

Only about 25% of the injected Pu^{4+} diffused into ISW, and skeleton and liver uptakes were about 30% of their maximum accumulated amounts (Table 31.12). The initial rates of Pu^{4+} deposition in liver and skeleton were about the same as those for the other study actinides (half-times 0.4 and 1.7 min, respectively, for skeleton and liver).

Subsequently, return of Pu^{4+} from ISW was slower than for the other actinides. Plasma Pu^{4+} retention was prolonged, renal excretion was negligible, and uptake in the target tissues proceeded at rates 1/3 to 1/10 as fast as those observed for the other actinides. Skeletal uptake persisted for about 24 h or until nearly all of the Pu^{4+} had been cleared from the plasma, during which time nearly all of the Pu^{4+} in the plasma was likely to be bound to Tf (components 2 and 3). Renal filtration, although small, also persists, indicating the continuous presence of a small fraction of 'free' Pu^{4+} . Net uptake in liver essentially stops when the 'free' Pu^{4+} has been reduced to a low level.

31.5.3 Summary

Bone and liver cell surfaces have great affinities for actinides (except that liver does not accumulate UO_2^{2+}), and those tissues take up (bind) actinides rapidly during the first few minutes after iv injection, when substantial fractions of the actinides are likely to be circulating as weak complexes with small filterable ligands. The reduced rates of tissue uptake and renal filtration that emerged in the mice at postinjection times longer than 5 min were not likely to be caused by sudden changes in the tissue affinities for actinides or the saturation of metal-binding sites. Alteration of the renal filtration rate is scarcely possible, because that rate is a species-specific constant (Smith, 1951; Durbin and Schmidt, 1989; Durbin *et al.*, 1997b). The reductions in tissue uptake and renal excretion rates and their related plasma clearance rates appear to be due to changes taking place in the transport system. Rapid diffusion of actinides from plasma to ISW and slow return reduce the rate at which the actinides are presented to the tissues. Protein binding, most importantly for Pu^{4+} , decreases the differences between the stabilities of the actinide complexes with the tissue ligands and those with the plasma ligands, effectively reducing the competitiveness of the tissue ligands and delaying or preventing the transfer of actinide from plasma ligands to tissue ligands.

31.6 ACTINIDES IN THE LIVER

Large fractions of injected soluble trivalent and tetravalent actinides are taken up by the liver, and their retention in liver has been studied because of its importance for tumor induction and radiation dosimetry (Tables 31.1–31.7; Finkle *et al.*, 1946; Painter *et al.*, 1946; Hamilton, 1947b, 1948c; ICRP, 1959,

1972, 1986; Durbin 1960, 1962, 1973; Cochran *et al.*, 1962; Stover *et al.*, 1968b, 1971; Taylor and Bensted, 1969; Mewhinney *et al.*, 1972; McKay *et al.*, 1972; Lloyd *et al.*, 1972b, 1984b; Taylor *et al.*, 1972b; Guilmette *et al.*, 1980; Lo Sasso *et al.*, 1981; Durbin *et al.*, 1985; NCRP, 2001).

Autoradiographic studies show that the actinides initially are distributed nearly uniformly in liver cells. With the passage of time after injection, actinide retained in the liver of rats, dogs, and monkeys tends to be located mainly in the Kupffer cells as aggregates associated with hemosiderin (Cochran *et al.*, 1962; Durbin, 1973, 1975; Durbin *et al.*, 1985).

31.6.1 Liver microanatomy

The initial binding sites in the liver for soluble blood-borne metal ions including the tri- and tetravalent actinides are the two sinusoidal membrane surfaces of the one-cell thick sheets of hepatocytes. The membranes facing the sinusoidal blood spaces possess numerous microvilli that project into the fluid-filled space. The microvilli are rich in receptors, enzymes, and transport proteins, and they provide an enormous surface area for absorption of blood-borne substances. Bile is secreted at the canalicular hepatic surfaces between the cells into minute ducts that ultimately coalesce and empty into the common bile duct (Ham, 1974; Ballatori, 1991).

31.6.2 Liver blood supply

The liver has an abundant blood supply; it receives about 20% of the cardiac output (Detweiler, 1973). Two-thirds of liver blood is delivered by the portal vein, which transports blood from the GI tract. The hepatic artery supplies the remainder. The two sets of blood vessels branch into capillaries that end in blood-filled spaces (sinusoids), where the venous and arterial blood mix. The thin flat lining cells that separate the sinusoidal hepatic cell surfaces from the sinusoidal blood are porous (pore size about 0.1 μm in diameter), thereby excluding red blood cells and larger particles while allowing access of the whole plasma to the hepatocyte microvilli. The sinusoidal lining contains fixed phagocytes (Kupffer cells) that recognize and ingest colloidal particles (Ham, 1974; Ballatori, 1991).

31.6.3 Transport of metals into liver cells

Entry of metal ions into hepatic cells may be via facilitated diffusion and/or by liquid phase, adsorptive, and receptor-mediated endocytosis, followed by temporary residence in the cytosol as complexes formed with binding proteins or in the lysosomes. In endocytosis, a vesicle of membrane invaginates into a sac, which sinks into the cytoplasm matrix. These vesicles fuse with each other or with other vesicles or with lysosomes. It has recently been shown that the liver

cell internalizes more than 20% of its volume and between 5 and 50% of its surface area each hour by a process termed membrane recycling. Rapid membrane recycling is likely to be a major contributor to the hepatic intake of metals that have high affinities for membrane-binding sites (Ballatori, 1991).

Iron is transported into hepatocytes by at least two independent pathways. The dominant mechanism is receptor-mediated endocytosis in which Fe-Tf binds to specialized Tf-receptors on the hepatocyte surface. Membrane binding is followed similarly to the delivery of Fe-Tf to developing erythrocytes, by endocytosis, and internalization of the Fe-Tf-Tf-receptor complex, fusion of the endocytotic vesicle with other vesicles, release of the Fe within the acidic vesicles, and extrusion of the iron-depleted Tf (Ballatori, 1991). Hepatic uptake of the normally very small fraction of Fe³⁺ circulating as a low molecular weight complex has been shown to occur by direct binding to integral membrane protein. Membrane binding is probably followed by internalization in the energy-dependent membrane recycling process (Planas-Bohne *et al.*, 1985, 1989; Planas-Bohne and Duffield, 1988; Planas-Bohne and Rau, 1990).

31.6.4 Iron storage

(a) Ferritin

Ferritin serves as a source of stored iron that can be mobilized for red cell production. It is a large water-soluble complex of protein (apoferritin, molecular weight about 450 kDa) and ferric oxyhydroxide. At the usual level of iron saturation (18%), the weight of the complex is about 620 kDa. The protein forms a shell within which crystals of iron hydroxide and phosphate are dispersed in a lattice-like relationship. Apoferritin is synthesized in response to intracellular iron by the ribosomes of nearly all mammalian cells, but liver, spleen, and bone marrow are especially rich in stored ferritin. At low iron levels, new iron is incorporated into existing apoferritin molecules, particularly those with a partially iron-filled core. Elevated iron stimulates production of apoferritin, which rapidly takes up excess iron. The residence time of ferritin in the cell cytosol is brief, and it tends to accumulate within lysosomes.

Iron is incorporated into and stored in ferritin as Fe³⁺, but to break the coordination bonds and be released from the ferritin complex, the iron must be reduced to Fe²⁺. It is then reoxidized in the cytosol and bound by intracellular Tf (Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995).

(b) Hemosiderin

The other iron storage compound, hemosiderin, is found mainly in the macrophages of the bone marrow, the Kupffer cells of the liver, and phagocytic cells in the spleen. It is not water-soluble. It is composed of ferritin partially stripped of the protein component and contains 25 to 35% iron by weight. Much

hemosiderin appears to consist of ferric hydroxide core crystals (Fairbanks and Beutler, 1995).

31.6.5 Actinide association with stored iron

Investigations of actinide retention in the whole liver were extended to include identification of the constituents of hepatic cells that bind and store them (Taylor, 1972; Duffield and Taylor, 1986). Preliminary analysis of clear, particle-free homogenates of the livers of dogs injected iv with $^{239}\text{Pu}^{4+}$ citrate indicated that the Pu^{4+} was associated with ferritin (Bruenger *et al.*, 1969a). Competitive binding studies showed that the ferritin complexes of Pu^{4+} and Am^{3+} are more stable than their Tf complexes (Bruenger *et al.*, 1969a; Stover *et al.*, 1970).

The subcellular distributions of soluble iv-injected actinides in the livers of several animal species have been investigated using a variety of techniques. The actinides ($^{227}\text{Ac}^{3+}$, $^{233}\text{Pa}^{5+}$, $^{238}\text{Pu}^{4+}$, $^{239}\text{Pu}^{4+}$, $^{241}\text{Am}^{3+}$, $^{244}\text{Cm}^{3+}$, $^{249}\text{Cf}^{3+}$, $^{237}\text{NpO}_2^+$, and $^{239}\text{NpO}_2^+$) were studied in rats, mice, dogs, rabbits, baboons, and/or hamsters. Homogenates were prepared from the livers, and the subcellular organelles were separated from each other and from the filterable cytosol by means of differential centrifugation and centrifugation through sucrose or salt density gradients into nuclei plus cell debris, mitochondria, lysosomes, microsomes, and cytosol. Marker enzymes were used to identify mitochondria and lysosomes, and ^{59}Fe was used to identify ferritin. The nature of the actinide-binding protein(s) in the cytosol was investigated using gel chromatography and electrophoresis (Taylor, 1969, 1970, 1972; Taylor *et al.*, 1969a,b; Boocock *et al.*, 1970; Stover *et al.*, 1970; Bruenger *et al.*, 1971a, 1972, 1976; Grube *et al.*, 1978; Schuppler *et al.*, 1988; Paquet *et al.*, 1995, 1996, 1998). These methods did not provide clear separation of 'iron-rich' heavy lysosomes from the mitochondria.

In more recent studies, actinide-injected animals were pretreated with Triton WR 1339, which causes liver lysosomes to imbibe water and swell, thus reducing their density enough to allow clean separation from the mitochondria (Gruner *et al.*, 1981; Winter and Seidel, 1982; Sutterlin *et al.*, 1984). Carrier-free electrophoresis has also been used to obtain a clear separation of lysosomes from all other organelles (Seidel *et al.*, 1986). Most of those studies were conducted using liver material from rats injected with ultrafilterable $^{239}\text{Pu}^{4+}$ citrate, and the results agree with supporting studies of liver material from rats and other animals injected iv or im with other soluble actinides and $^{141}\text{Ce}^{3+}$.

Combined, all of the studies of subcellular distribution of actinides in the liver show that ferritin is the predominant actinide-binding protein within the hepatocytes, and the lysosomes are the main subcellular storage organelles. Actinides that have entered the hepatocytes are initially mainly associated with the soluble lighter 'apoferritin-rich' ferritin in the cytosol, and to a lesser degree, they are sequestered in lysosomes. With time, the actinide associated with the soluble ferritin in the cytosol declines and the lysosomal actinide fraction, which includes the heavier 'iron-rich' ferritin, increases (Boocock *et al.*, 1970; Bruenger

et al., 1971a; Grube *et al.*, 1978; Seidel *et al.*, 1986). That is the same time-dependent pattern followed by newly acquired hepatic iron – initial incorporation into freshly synthesized apoferritin in the cytosol followed by gradual accumulation in lysosomes of ferritin that has acquired more iron (Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995). At times longer than 70 days in dogs injected iv with $^{239}\text{Pu}^{4+}$ citrate, the concentration of the Pu^{4+} in the nuclei-cell debris fraction increased, and it was shown autoradiographically that the Pu^{4+} was contained in the Kupffer cells in association with hemosiderin (Cochran *et al.*, 1962; Taylor *et al.*, 1969a,b; Bruenger *et al.*, 1971a).

In addition to their presence in the cytosol and lysosomes in association with ferritin, and depending on the mass injected or used to incubate cultured hepatocytes, lower specific activity $^{237}\text{NpO}_2^+$, and $^{239}\text{Pu}^{4+}$ localized in the hepatic cell nuclei in association with an as yet unidentified nuclear matrix protein (Schuler and Taylor, 1987; Paquet *et al.*, 1995, 1996).

31.6.6 Actinide uptake by liver cells

The multivalent lanthanides and actinides, particularly Pu^{4+} , share some metabolic properties of iron. They form variably stable complexes with Tf in the plasma and are stored in the liver associated with ferritin. It was reasonable to postulate that, like iron, these metals would be bound to and be taken into hepatic cells by a Tf-mediated receptor mechanism. However, in a series of elegant experiments using cultured liver cells (primary rat hepatocytes and human hepatoma Hep-G2 cells) and isolated rat hepatocyte membrane, Planas-Bohne and coworkers demonstrated that the mechanism by which Pu^{4+} (and presumably other trivalent and tetravalent metals) are bound to and taken into liver cells is not only independent of, but is actually hampered by, Tf binding (Planas-Bohne *et al.*, 1985, 1989; Schuler and Taylor, 1987; Schuler *et al.*, 1987; Planas-Bohne and Duffield, 1988; Planas-Bohne and Rau, 1990).

Uptake of Pu^{4+} from a medium containing Pu^{4+} citrate into liver cells was not influenced substantially by the Pu^{4+} concentration or the molar ratio, citrate: Pu^{4+} , suggesting a nonspecific nonsaturatable mechanism. Cell uptake of Pu^{4+} was much reduced at 4°C, compared with 37°C, suggesting that transport into the cells was energy dependent. Cells incubated with $^{239}\text{Pu}^{4+}$ - ^{14}C -citrate did not bind or take in the ^{14}C -citrate suggesting ligand exchange between the Pu^{4+} citrate and the Pu^{4+} receptor complex(es). If the Pu^{4+} was prebound to Tf, uptake of Pu^{4+} into the cells and by isolated perfused rat liver was very low, only about 10% of the uptakes from Pu^{4+} citrate.

Liver cell intake of Pu^{4+} from its citrate complex requires a high activation energy and can be prevented by inhibition of oxidative phosphorylation; other processes seem not to be important. Uptake of Pu^{4+} by liver cells from the Pu^{4+} citrate complex can be prevented by chelators (EDTA, DFO) and by unsaturated Tf suggesting that the Pu^{4+} reacts directly with constituents of the liver cell

membrane. The stabilities of the Pu^{4+} receptor complex(es) appear to be greater than that of Pu^{4+} citrate but less than that of Pu^{4+} -Tf or Pu^{4+} -EDTA.

Fragments of purified rat hepatocyte membrane were incubated with Pu^{4+} citrate. Binding of Pu^{4+} to the membrane was pH-dependent (optimal at pH 7.4), saturatable, and independent of temperature, suggesting direct binding of Pu^{4+} at a limited number of sites. Binding of Pu^{4+} was prevented by the presence of unsaturated Tf, EDTA, or DFO, indicating that membrane binding of Pu^{4+} involved Pu^{4+} complexation with a spatially suitable arrangement of amino acid residues at the binding sites. The two kinds of binding sites found for Pu^{4+} were shown not to be phospholipids or glycoproteins, but large integral membrane proteins (molecular weight between 150 and 400 kDa), and they are different from the two kinds of binding sites identified with direct uptake of iron. When membrane was incubated with Pu^{4+} - ^{125}I -Tf and then solubilized and subjected to gel filtration, the Pu^{4+} eluted in fractions different from those containing ^{125}I -Tf bound to membrane protein receptors or unbound ^{125}I -Tf, indicating dissociation of the Pu^{4+} -Tf complex.

31.6.7 Summary

From the standpoint of actinide biology, the most important results are that Pu^{4+} can bind directly to a limited number of sites on the hepatic cell membrane and be internalized, that transport of the Pu^{4+} into hepatic cells is not mediated by Tf, and that complexation of Pu^{4+} by Tf suppresses Pu^{4+} binding to hepatic cell membrane. It is reasonable to assume that the elements of group III and subgroup IV and the lanthanides and other actinides can also bind directly, possibly at the same or similar hepatocyte-binding sites as Pu^{4+} . Direct metal binding in the liver and its suppression by competition with Tf suggest an explanation for the observed direct correlation between the fractional deposition of the lanthanides and actinides in the liver and the instabilities of their Tf complexes (for which increasing ionic radius and plasma clearance rates are crude proxies) (Tables 31.1–31.7; Figs. 31.3–31.7; Durbin, 1962, 1973). The hepatic cell metal-binding sites compete successfully with bone surfaces for multivalent cations like Ce^{3+} and Am^{3+} that circulate complexed with small plasma ligands like citrate or as weak complexes with Tf or other plasma proteins. However, competition for metals that form more stable Tf complexes, like Th^{4+} and Pu^{4+} , favors bone, and the source of the uptake in liver may be mainly the small fraction that circulates as low molecular weight complexes (Durbin *et al.*, 1972; Planas-Bohne *et al.*, 1989).

31.7 ACTINIDES IN BONE

The defining characteristic of the biological behavior of the actinides in mammals, and the chemically similar elements of group III, subgroup IV, and the lanthanides, is their intraskeletal distribution. As soon as suitable radioisotopes

became available, autoradiographs were prepared from undecalcified sections of the femora of rats injected with fission products ($^{91}\text{Y}^{3+}$, $^{95}\text{Nb}^{3+}$, $^{95}\text{Zr}^{4+}$, $^{144}\text{Ce}^{3+}$, $^{147}\text{Pm}^{3+}$, $^{152,154}\text{Eu}^{3+}$) and five actinides ($^{227}\text{Ac}^{3+}$, $^{234}\text{Th}^{4+}$, $^{239}\text{Pu}^{4+}$, $^{241}\text{Am}^{3+}$, $^{242}\text{Cm}^{3+}$) (Axelrod, 1947; Hamilton, 1947b). Autoradiographs of five representative radioelements were included in the original reports; the remainder was published later as a complete set (Durbin, 1962).

The deposition patterns of $^{45}\text{Ca}^{2+}$ and $^{89}\text{Sr}^{2+}$ in rat bones had already been studied autoradiographically, and it was shown that the alkaline earth elements penetrated into and were nearly uniformly distributed throughout the bone mineral volume (Hamilton, 1941; Pecher, 1942). The internal distribution of the multivalent cations was markedly different. None was initially incorporated into the bone volume. The tetravalent elements (Zr^{4+} , Th^{4+} , and Pu^{4+}) were deposited at endosteal surfaces, particularly on the trabeculae of the spongy bone and beneath the periosteum. The distribution patterns of the trivalent cations generally resembled the tetravalent elements, but there was also substantial spotty deposition in the compact bone, which was later shown to be on the mineralized walls of vascular channels.

The radioisotopes of all of the trivalent and tetravalent elements have been classified for the purposes of radiation dosimetry as 'bone surface seekers'. The methods used for calculating radiation doses to the bone cells and marrow surrounding the deposits of these nuclides in the skeleton have taken into account their nonuniform intraskeletal distribution (ICRP, 1959, 1967, 1979).

Actinide binding to the calcified bone surfaces is the net result of several biological and chemical processes: the nature of the bone mineral crystals and the organic bone matrix, the relative affinities of the individual actinides for the mineralized surface and the plasma ligands, the ability of the circulating actinide complexes to pass through or between the cells on resting surfaces and penetrate the osteoid and active osteoblasts on growing surfaces, and the richness of the blood supply and its proximity to the bone surfaces.

31.7.1 Bone surfaces

Detailed descriptions of the microanatomy of the skeleton and of bone growth and maintenance remodeling are available in specialized works (Bourne, 1956; Frost, 1963; Ham, 1974). The periosteal surface is beneath the outer tissue layer that envelops the whole bones. The endosteal surface is the inner aspect of whole bones plus the much larger surface of the three-dimensional interconnected network of the fine bony bars, rods, and plates of the spongy (trabecular) bone. The vascular (Haversian) surface is the cylindrical lining of the numerous vascular channels that penetrate and nourish the compact (cortical) bone. The large anatomical surface of the mammalian skeleton – about 12 m^2 in an adult human male – is about equally divided between the endosteal and Haversian surfaces (Spiers, 1968; Lloyd and Marshall, 1972; ICRP, 1979).

Three general bone surface types are recognizable histologically: actively growing, resting, and resorbing. Depending on age and stage of skeletal maturity, the abundances of the three surface types vary in individual bones and in the whole skeleton. New bone is laid down at the active surfaces, which are recognized by the presence of regular rows of tall columnar cells (active osteoblasts) located just above a variably thick layer of uncalcified or poorly calcified bone matrix (osteoid). A thin strongly PAS-positive margin marks the line of calcification. The cell and osteoid layers covering sites of active bone formation make these sites the least accessible to circulating metal ions. Resting surfaces are covered with a layer of thin flattened cells, which line the adjacent calcified surface. The bone beneath the resting cells is usually more calcified than that beneath the cells on the growing surfaces. The mineral-organic interface stains PAS-positive. Resting bone surface sites, which are predominant in human adults, are well mineralized, but their accessibility is somewhat hindered by the overlying cell layer. Resorbing surfaces are recognized by their irregular outline, their high degree of mineralization, the intense PAS-positive stain at the calcified margin, the absence of covering cells, and the presence of the large multinuclear osteoclasts that dissolve and digest bone. The resorbing sites are exposed directly to the circulating blood and/or tissue fluid, making them the most accessible.

The vascular channels of cortical bone (horizontal Volkmann's canals and longitudinal Haversian systems) are short cylindrical tunnels in the well-mineralized compact bone. They are lined with a layer of flattened endosteal cells, so their inner aspect resembles resting bone surface. The central space is filled with loose connective tissue and one large capillary or two small arterial and venous capillaries.

31.7.2 Bone blood supply

The blood supplies to the periosteum, the internal skeletal sites containing fatty marrow, and the vascular channels of cortical bone are closed capillary beds that effectively retain the red cells and nearly all of the plasma protein and allow only filterable low molecular weight plasma constituents and filterable metal complexes access to the bone surfaces. Erythropoietic marrow contains large vascular sinusoids with a discontinuous lining that permits whole plasma to pass into the extravascular space. The bony trabeculae embedded in the red marrow are exposed not only to metal ions complexed with the low molecular weight constituents of tissue fluid but also their nonfilterable complexes with plasma proteins (Ham, 1974; Wronski *et al.*, 1980; Miller *et al.*, 1982).

31.7.3 Intraskkeletal distribution of actinides

More refined and definitive autoradiographic techniques confirmed the early observations of the surface-limited deposition of actinides in bone. Sectioning and autoradiography of undecalcified bone are difficult, and later studies

focused on $^{233}\text{UO}_2^{2+}$, $^{239}\text{Pu}^{4+}$, $^{241}\text{Am}^{3+}$, and most recently ^{237}Np . In addition to revealing important details of the initial distribution of these actinides in bone, they have helped to define the mechanisms of release of actinides bound to bone and the kinds and extent of local radiation damage.

(a) $^{241}\text{Am}^{3+}$

The initial intraskeletal distribution of $^{241}\text{Am}^{3+}$ was investigated autoradiographically in rats (Taylor *et al.*, 1961; Durbin *et al.*, 1969; Durbin, 1973; Priest *et al.*, 1983), dogs (Herring *et al.*, 1962; Lloyd *et al.*, 1972b; Polig *et al.*, 1984), and monkeys (Durbin, 1973, 1975). $^{241}\text{Am}^{3+}$ is initially deposited nearly uniformly on all types of bone surfaces – endosteal, periosteal, and Haversian canals. Deposition is somewhat more intense on resorbing and resting surfaces than on actively growing surfaces. No $^{241}\text{Am}^{3+}$ was found initially as a diffuse distribution in the bone volume (Herring *et al.*, 1962; Priest *et al.*, 1983). Results for $^{249,252}\text{Cf}^{3+}$ in rats were essentially the same as for $^{241}\text{Am}^{3+}$ (Durbin, 1973).

(b) Pu^{4+}

Initial intraskeletal distribution of Pu^{4+} ($^{238}\text{Pu}^{4+}$ or $^{239}\text{Pu}^{4+}$) was studied autoradiographically in rats (Arnold and Jee, 1957; Taylor *et al.*, 1961; Priest and Giannola, 1980), dogs (Arnold and Jee, 1959, 1962; Herring *et al.*, 1962; Wronski *et al.*, 1980), and monkeys (Durbin, 1975). Soluble Pu^{4+} is initially deposited almost entirely on endosteal surfaces, in particular, the surfaces of the trabeculae of spongy bone closest to the sinusoidal circulation of the erythropoietic marrow that surrounds them. In the beagles, the initial surface concentrations of $^{239}\text{Pu}^{4+}$ on the fine trabeculae in vertebral bodies, pelvis, and proximal humerus (sites in spongy bone containing red marrow) were four to eight times greater than on the coarser trabeculae in the proximal ulna and distal humerus (sites containing fatty marrow) (Wronski *et al.*, 1980). Endosteal deposition is not uniform, and Pu^{4+} concentrations on endosteal surfaces decrease generally in the order: resorbing > resting > actively growing. Deposits of Pu^{4+} on periosteal surfaces are less intense, and those on Haversian canal surfaces are very low. There is no initial diffuse distribution of Pu^{4+} in the bone volume.

(c) UO_2^{2+}

The initial intraskeletal distribution of UO_2^{2+} ($^{232}\text{UO}_2^{2+}$ or $^{233}\text{UO}_2^{2+}$) was studied autoradiographically in rats (Priest *et al.*, 1982) and dogs (Rowland and Farnham, 1969; Stevens *et al.*, 1980). Uranyl ion is initially deposited on all bone surface types, but it is found preferentially on actively growing surfaces that are laying down new bone. Similarly to Ra^{2+} , UO_2^{2+} is deposited in the calcifying zones of skeletal cartilage. In the dogs, a detectable fraction diffused into the bone volume.

(d) $^{237}\text{NpO}_2^+$

The intraskeletal distribution of ^{237}Np , injected iv as $^{237}\text{NpO}_2\text{NO}_3$, was investigated autoradiographically in rats (Wirth and Volf, 1984; Sontag, 1993). The initial distribution appears to be nearly uniform on all endosteal and periosteal surfaces and the vascular canal surfaces of compact bone. There is no evidence for early diffusion of Np into the bone volume.

(e) $^{91}\text{Y}^{3+}$, $^{144}\text{Ce}^{3+}$, $^{170}\text{Tm}^{3+}$

The initial intraskeletal distribution of these three trivalent metal ions was studied autoradiographically in growing dogs (Jowsey *et al.*, 1958), and $^{91}\text{Y}^{3+}$ was also investigated in rachitic young dogs and weanling rabbits (Herring *et al.*, 1962). The distributions of these trivalent elements in bone were similar to $^{241}\text{Am}^{3+}$. They were located on all bone surfaces, with the greatest concentrations associated with highly mineralized surfaces of resorbing or resting bone. There was little or no deposition in areas of active bone formation, and no deposition in osteoid tissue. All three radioisotopes were deposited on the mineralized surfaces of the resting and resorbing Haversian systems in cortical bone, but at intensities less than on the endosteal surfaces.

(f) Summary

Within the skeleton, deposition of multivalent cations is initially limited to the anatomical surfaces in the order: endosteal > periosteal > cortical vascular channels, and among the bone surfaces in the order: resorbing > resting > actively growing.

The intensities of the local surface deposits are positively correlated with accessibility to the blood supply, the nature of the local blood supply, the degree of mineralization of the surface, and the instability of the complexes formed with Tf and other plasma proteins.

31.7.4 Retention – remodeling and redistribution

Prolonged skeletal retention is a distinguishing feature of the actinides (ICRP, 1959, 1972, 1979, 1993, 1995; Leggett, 1985, 1989, 1992a,b). The actinides (except UO_2^{2+}), once deposited on bone surfaces, appear to be released only when the bone containing them is physically destroyed (Arnold and Jee, 1957, 1959). There are long-term skeletal retention data for several actinides in beagles. The terminal slope of the skeletal retention function for UO_2^{2+} in the beagles has a half-time of about 3 years: UO_2^{2+} is lost from bone by chemical processes as well as by structural remodeling, and because it is efficiently excreted in the urine, little is redeposited in bone (Rowland and Farnham, 1969; Stevens *et al.*, 1980; Leggett, 1989). Retention of the trivalent and tetravalent actinides in the

beagle skeleton is much more prolonged. The half-times of the terminal slopes of the skeletal retention equations for $^{241}\text{Am}^{3+}$, $^{249}\text{Cf}^{3+}$, and $^{228}\text{Th}^{4+}$ are 15 to 18 years (Stover *et al.*, 1960; Lloyd *et al.*, 1972b, 1976, 1984a,b). About 56% of the initial skeletal deposit of $^{239}\text{Pu}^{4+}$ is cleared with a half-time of about 1.6 years; later measurements of $^{239}\text{Pu}^{4+}$ in the skeletons of individual dogs at postinjection times as long as 4400 days yielded a curve with a slope that could not be distinguished from zero (Stover *et al.*, 1962, 1972; Stover and Atherton, 1974).

The mature mammalian skeleton is not static, and it undergoes much internal structural change throughout the life span. During growth, structural remodeling (both resorption and accretion) is vigorous and extensive, and there is a net increase in bone mass. After skeletal growth is complete, remodeling and bone turnover involve only small fractions of the skeleton at any time, and there is little change in skeletal mass. During the last years of life of some mammals, resorption exceeds replacement leading to a slow decrease in skeletal mass (Bourne, 1956; Frost, 1963).

Bone resorption and accretion are surface-limited processes (Bourne, 1956; Ham, 1974). In the mature skeleton, turnover of bone (resorption and accretion) at the surfaces of the fine trabeculae of spongy bone is faster than at the surfaces of the larger trabeculae in the flat and membranous bones and in the distal ends of the long bones and the surfaces of the cortical bone vascular channels (about eight times faster in young adult beagles and four times faster in human adults) (Arnold and Jee, 1962; Arnold and Wei, 1972; ICRP, 1973; Wronski *et al.*, 1980).

Actinide-labeled bone surfaces may be resorbed by osteoclasts or be buried beneath new bone in the course of structural remodeling, or they may remain unaltered (Copp *et al.*, 1946; Arnold and Jee, 1962; Durbin *et al.*, 1969; Durbin, 1973; Wronski *et al.*, 1980; Sontag, 1993). The actinide content of the resorbed bone is eventually dissolved by the osteoclasts and/or marrow macrophages, released into the circulation, and redistributed among the target tissues (Arnold and Jee, 1962; Priest and Giannola, 1980; Priest *et al.*, 1983; Durbin and Schmidt, 1985; Durbin *et al.*, 1985). There is evidence indicating that solubilized actinide released from bone (or any other body site) is complexed and transported by the same plasma ligands (mainly Tf) and distributed among the same target tissues in the same proportions as the soluble form originally injected (Arnold and Jee, 1962; Durbin *et al.*, 1969; Jee, 1972a,b; Durbin, 1973; Priest and Giannola, 1980; Leggett, 1985, 1989, 1992a,b).

Redeposition in the skeleton can occur on both old (preinjection) surfaces augmenting their existing actinide concentrations and on new (postinjection) surfaces, which will acquire a lighter more diffuse label than those labeled immediately after the injection. With the passage of time, resorption of actinide-labeled bone surfaces (mainly trabeculae at red marrow sites) and redeposition of substantial fractions of the released and solubilized actinide will reduce the concentrations at the bone surfaces and increase the concentration in the

bone volume, tending to equalize the concentration in bones containing red marrow sites (vertebral bodies, ribs, sternum, pelvis, proximal ends of humerus and femur) and those that are mainly cortical bone (Durbin, 1973; Durbin *et al.*, 1985; Durbin and Schmidt, 1985; Sontag, 1993).

31.7.5 Summary

Prolonged retention of actinides deposited in the skeleton is the combined result of redeposition in bone of actinide released from soft tissues, removal from bone only by the relatively slow process of bone resorption, recirculation after release bound mainly to plasma proteins (which severely impedes excretion), and redeposition at new bone sites of large fractions of the actinide released from initially labeled bone sites.

31.8 ACTINIDE BINDING IN BONE

The specific nature of the initial chemical reactions underlying the fixation of actinides in living bone is incompletely understood.

31.8.1 Composition of bone

The compositions of mature mammalian cortical and trabecular bone are, on average, about 61, 26, and 13% by weight and 40, 35, and 27% by volume, mineral, organic matrix, and water, respectively (Gong *et al.*, 1964). The mineral phase [hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] exists as minute tablet-shaped crystals 2 to 2.5 μm wide, 3.5 μm long, and 0.25 to 0.5 μm thick, and these are aligned parallel to the longitudinal direction of the collagen fibers of the matrix (Neuman and Neuman, 1958). At the microscopic level, bone is not homogeneous, but it is reasonable to assume that the proportions of mineral and matrix on fully mineralized bone surfaces are about the same as the bulk volume composition, that is, that the exposed surface area is about equally divided between mineral crystals and organic matrix along with some bound water. By the same reasoning, bone that is not fully developed would be expected to have a smaller proportion of mineral exposed on the surface.

31.8.2 Actinide binding to bone *in vivo*

There is good, if inferential, evidence for *in vivo* actinide binding to bone mineral. In living mammals, the initial skeletal binding site of the actinides and their trivalent and tetravalent chemical analogs is at the mineral-organic interface. Actinide deposition is greatest on bare, fully mineralized resorbing surfaces and least on growing surfaces covered by a layer of bone matrix

(osteoid) (Jowsey *et al.*, 1958; Herring *et al.*, 1962). In rachitic animals, bone continues to grow but is very poorly mineralized: In such animals, Pu^{4+} passed through the nonmineralized osteoid and deposited on the first available mineralized structures (Jee and Arnold, 1962). Actinides also accumulate on calcified nonskeletal structures such as renal calculi, calcified scar tissue, and calcified tracheal and bronchial cartilage (Painter *et al.*, 1946; Jee and Arnold, 1962; Durbin, 1973; Durbin *et al.*, 1985).

31.8.3 Actinide binding to bone mineral *in vitro*

Neuman (1953) demonstrated that binding of UO_2^{2+} by bone mineral *in vitro* was a reversible ion-exchange process: One UO_2^{2+} displaced two Ca^{2+} ions and immobilized two PO_4^{3-} moieties. *In vivo*, UO_2^{2+} deposits at growth sites in the skeleton, and it accompanies hydroxyapatite crystal growth *in vitro*. However, the evidence indicates that UO_2^{2+} is limited to the crystal surfaces, presumably because it is too large and too polar to 'fit' into the crystal lattice (Neuman and Neuman, 1958).

Jowsey *et al.* (1958) prepared solutions of $^{91}\text{Y}^{3+}$, $^{144}\text{Ce}^{3+}$, and $^{170}\text{Tm}^{3+}$ in human plasma reconstituted with water or with 0.0034 M sodium citrate. Bovine cortical bone was used to prepare the following dry powders (particle size not specified): fat-free whole bone, ED-bone (bone powder heated in ethylenediamine to digest the organic matrix); bone ash (heated at 600°C to destroy the organic matrix); EDTA-bone (bone powder treated with EDTA to remove the mineral fraction). Calcium phosphate [$\text{Ca}_3(\text{PO}_4)_2$] was included as a bone mineral surrogate, and charcoal and glass wool were included as nonspecific particulate controls. The dry powders (250 mg each) were placed in small paper thimbles, a solution of lanthanide in plasma or in citrated plasma was percolated through the solids, and two rinses of isotope-free media were applied. On average, uptake of the lanthanides by ED-bone, whole bone, $\text{Ca}_3(\text{PO}_4)_2$, and bone ash was 42, 40, 33, and 19% respectively, of the amounts present in the plasma media. Uptakes were about 30% greater from citrated plasma. The powdered organic matrix, charcoal, and glass wool did not take up the lanthanides from plasma, with or without added citrate. Thin sections of bone embedded in methylmethacrylate were incubated in a solution containing $^{91}\text{Y}^{3+}$, and autoradiographs showed that all of the calcified surfaces took up the lanthanide.

Foreman (1962) prepared a solution of $^{239}\text{Pu}^{4+}$ in 0.05 M lactate buffer pH 7. Bovine cortical bone was used to prepare the following dry powders (particle size not specified in most cases): fat-free whole bone, bone ash (700°C, 100–200 mesh), coarse bone ash (>100 mesh); KOH-bone (bone powder heated in KOH and ethylene glycol to digest the organic matrix); EDTA-bone (decalcified organic matrix). Carborundum, alundum, and pumice were included as particulate controls. Samples of each powder were shaken for 24 h with 100 to 200 mL of the Pu^{4+} -lactate buffer solution, and the clear supernatant was sampled periodically after allowing the solids to settle. After 24 h, the four particulates

containing bone mineral had taken up $\geq 95\%$ of the Pu^{4+} in the medium. The initial uptake rates of the bone mineral samples were in the order: bone ash (fine) > bone ash (coarse) \gg KOH-bone \gg whole bone. At equilibrium, the EDTA-decalcified organic fraction took up $\leq 10\%$ of the available Pu^{4+} . The Pu^{4+} did not adhere to the three inert mineral powders. Addition of 0.2 M Ca^{2+} or 0.2 M Na^+ to the buffer medium did not change either the rates or 24 h uptakes of Pu^{4+} by the whole bone or bone ash powders.

Foreman (1962) also prepared whole rat femora, as follows: fresh bone cleaned of adhering soft tissue; bone ash (700°C furnace); KOH-bone; and EDTA-bone. Four replications of each femur preparation were sealed in cellophane bags and surgically implanted in the peritoneal cavities of 'host' rats. The 'host' rats were injected iv with $^{239}\text{Pu}^{4+}$ citrate 24 h later and killed 48 h after the Pu^{4+} injection. Uptake of the Pu^{4+} in the living femora of the 'host' rats was reproducible, on average, $164\,400 \pm 66\,000$ cpm per whole bone. Uptakes of Pu^{4+} in the implanted femora that had been heat or chemically ashed were nearly the same, about 40% of that in the living bone of their 'hosts', while Pu^{4+} uptakes in the implanted fresh bone and EDTA-decalcified bone were 15 and 6%, respectively. The chemically or heat ashed bone preparations that were essentially free of organic tissue barriers had the greatest affinities for the Pu^{4+} , while the affinity of the decalcified bone matrix was the least. An important outcome of this experiment was the demonstration of the passage of Pu^{4+} through the semipermeable cellophane membrane, implying the presence of a filterable Pu^{4+} complex in the interstitial fluid of the peritoneal cavity.

Chipperfield and Taylor (1972) prepared dilute solutions of $^{239}\text{Pu}^{4+}$, $^{241}\text{Am}^{3+}$, and $^{244}\text{Cm}^{3+}$ nitrates, each of these was mixed with 3 mL of solutions of tris buffer pH 7.2 containing chelators, including: 3.4×10^{-4} M sodium citrate, 3.2×10^{-4} M EDTA, 2.4×10^{-4} M DTPA, 3.4×10^{-6} M Tf, or 4×10^{-6} M bone sialoprotein or bone chondroitin sulfate-protein complex. Fine cortical bone ash powder (200–300 mesh) was added (10 mg) to each actinide-chelator solution and stirred vigorously for 1 h. Supernatant containing unbound actinide and solids containing bound actinide were separated by centrifugation. In the absence of a chelator, all three actinides were quantitatively associated with the bone mineral fraction. The fractions bound to the bone mineral (100% – reported solution content) for Pu^{4+} , Am^{3+} , and Cm^{3+} , respectively, were as follows: Tf (98, 99, 84); citrate (73, 100, 100); bone glycoproteins, on average (79, 92, 92); EDTA (91, 70, 61); DTPA (14, 0, 0). Effectiveness for preventing actinide binding to bone mineral, which can be viewed as the stabilities of their complexes with the chelators relative to those formed with the bone ash is in the order: Tf \leq citrate < bone glycoproteins < EDTA < DTPA. Binding of Am^{3+} and Cm^{3+} to bone mineral was the same in this test system and nearly quantitative in the presence of Tf, citrate, or the bone glycoproteins; it was partially prevented by EDTA and completely prevented

by DTPA. Binding of Pu^{4+} to bone mineral was nearly quantitative in the presence of Tf, partially prevented by EDTA, the bone glycoproteins, or citrate, and incompletely prevented by DTPA.

Guilmette *et al.* (1998, 2003) prepared solutions of $^{238}\text{Pu}^{4+}$, $^{239}\text{Pu}^{4+}$, and $^{241}\text{Am}^{3+}$ in 0.0034 to 0.005 M sodium citrate. Finely ground bovine bone ash and synthetic bone mineral (hydroxyapatite, HAP) were characterized by X-ray diffraction, and their measured specific surface areas were 10.7 and 65 $\text{m}^2 \text{g}^{-1}$, respectively. Each actinide was stirred for 24 h with 10 mg of a mineral powder in 0.1 M HEPES buffer pH 7.2. The solid and supernatant were separated by ultrafiltration. Under these conditions $\geq 99\%$ of the actinide was bound to the minerals. Varying masses of $^{238}\text{Pu}^{4+}$ and $^{239}\text{Pu}^{4+}$ (0.001–100 μg) and $^{241}\text{Am}^{3+}$ (0.001–1.0 μg) were added to 10 mg of bone ash or HAP to characterize the relationships between actinide binding and mineral surface area, that is, the binding capacity. For Pu^{4+} , masses $\leq 10 \mu\text{g}$, and for all $^{241}\text{Am}^{3+}$ masses studied, binding to both minerals was $\geq 99\%$ in 24 h. However, when the mass of $^{239}\text{Pu}^{4+}$ was 100 μg , more than 50% incubated with bone ash and 20% incubated with HAP remained unbound at 24 h. The data are consistent with the larger specific surface area of HAP presenting more binding sites, and they may also be interpreted as signifying that the mineral surfaces contain a saturatable number of potential metal-binding sites per unit area. The DTPA chelates of $^{238}\text{Pu}^{4+}$ and $^{241}\text{Am}^{3+}$ were incubated with 10 mg of HAP. There was no indication that the $^{241}\text{Am}^{3+}$ -DTPA complex dissociated in favor of mineral binding. In contrast, 50% of the $^{238}\text{Pu}^{4+}$ -DTPA complex dissociated in 24 h in favor of binding to the bone mineral. The stability of $^{241}\text{Am}^{3+}$ -DTPA is evidently greater, while that of $^{238}\text{Pu}^{4+}$ -DTPA is somewhat less, than the stabilities of their respective bone mineral complexes.

Guilmette *et al.* (2003) investigated removal of $^{238}\text{Pu}^{4+}$ and $^{241}\text{Am}^{3+}$ from bone mineral by 24 h incubation of those actinides prebound to HAP by chelators in solutions of 0.1 M HEPES buffer pH 7.2. Binding of $^{238}\text{Pu}^{4+}$ and $^{241}\text{Am}^{3+}$ by HAP is sufficiently stable that ZnNa_3 -DTPA removed only 1.4% of the Am^{3+} and $\leq 0.1\%$ of the Pu^{4+} sorbed to the mineral. Actinide removal from HAP was tested with a set of tetra-, hexa-, and octadentate ligands with linear or branched backbones containing bidentate catecholate (CAM) or hydroxypyridinonate (HOPO) metal-binding groups. Removal of Pu^{4+} (4–54%) was achieved only by the linear octadentate CAM and HOPO ligands. Removal of Am^{3+} (5–21%) was achieved with several linear or branched tetra-, hexa-, or octadentate ligands.

Bostick *et al.* (2000), Moore *et al.* (2003), and Thomson *et al.* (2003) conducted investigations in support of the management and remediation of actinide-contaminated groundwaters, sediments, and wastewaters. Batch sorption and column tests demonstrated the great affinities of UO_2^{2+} , NpO_2^+ , Pu^{4+} , Am^{3+} , and stable Ce^{3+} for natural and synthetic apatites, including hydroxyapatite, $\text{Ca}_3(\text{PO}_4)_2$, and bone ash.

31.8.4 Actinide binding by bone glycoproteins

A case can be made for the participation of some low abundance organic matrix constituents in the binding of actinides in living bone (reviewed by Duffield and Taylor, 1986). *In vitro* complexation of Th^{4+} and Pu^{4+} , and to a lesser degree, Am^{3+} and Cm^{3+} by isolated mucoprotein substituents of bone matrix has been demonstrated.

All of the multivalent lanthanides and actinides studied autoradiographically deposit most intensely on fully mineralized bone surfaces, anatomical sites that also stain positively with PAS for the presence of mucosubstances (Jowsey, 1956; Herring *et al.*, 1962; Williamson and Vaughan, 1964; Vaughan *et al.*, 1973). Paraphrasing Jowsey (1956) in response to a conference participant's question: In areas of bone resorption, the PAS staining is the result of the depolymerized state of the mucopolysaccharides in the ground substance (matrix). In such state there are presumably free side chains of the mucopolysaccharide molecules (containing potentially chelating 1,2-hydroxy groups), which are oxidized by the periodic acid to aldehydes and take up the Schiff stain.

Nearly 90% of the organic bone matrix is collagen, which contributes about 20% of the weight of native bone. Five distinct glycoprotein fractions were extracted from bovine cortical bone. Their designations and weight fractions of native bone (% by weight) are, as follows: bone sialoprotein, 0.25%; bone chondroitin sulfate-protein complex, 0.18%; three less well-characterized glycoprotein fractions – glycoprotein I and II, 1.57% combined; cetylpyridonium chloride (cpc) soluble glycoprotein, 0.1%. While not regarded as conclusive, supporting experiments indicate that the sialoprotein content (and perhaps also the other mucosubstances) of bone are formed and laid down in the matrix during bone formation. The functions of the mucosubstances of mature bone are not known (Herring, 1964). Bone sialoprotein contains large proportions of sialic, glutamic, and aspartic acids; 15, 20, and 15 moles of acids per mole of protein, respectively.

Chipperfield and Taylor (1968, 1970, 1972) used gel filtration (Sephadex G-25 and G-50) to investigate the bonding of ultrafiltered dilute solutions of $^{228}\text{Th}^{4+}$, $^{239}\text{Pu}^{4+}$, $^{241}\text{Am}^{3+}$, and $^{244}\text{Cm}^{3+}$ nitrates incubated with the isolated bone glycoproteins noted above. The proteins were dissolved in tris buffer pH 7.2, and the protein:metal molar ratios were 1:1 for Pu^{4+} and 10:1 for the higher specific activity radionuclides. The results of those studies are collected in Table 31.13. Those results, although variable and regarded by the authors as semiquantitative, indicate that at physiological pH the isolated glycoprotein fractions of bone matrix can form complexes with Th^{4+} and Pu^{4+} , and to a lesser degree, with Am^{3+} and Cm^{3+} . Under these experimental conditions, the affinities of the bone glycoprotein fractions for Th^{4+} and Pu^{4+} apparently exceed the affinities for these actinides of reconstituted human Tf or apo-Tf. Two of the bone glycoproteins, bone sialoprotein and bone chondroitin sulfate-protein

Table 31.13 Collected data for association of selected actinides with isolated bone glycoproteins, human transferrin, and poly-L-glutamic acid.^a

Protein	Percent of applied actinide eluted with protein

complex, were about as effective as EDTA in competing with bone ash for Pu⁴⁺, Am³⁺, and Cm³⁺.

Supporting studies demonstrated that actinide binding by the bone glycoproteins was pH dependent; maximum binding of Pu⁴⁺ by bone sialoprotein is at pH 6, and of Am³⁺ and Cm³⁺ at pH 8. These results were interpreted by the authors to mean that Pu⁴⁺ was bound by the abundant carboxyl groups of the protein's amino acid side chains, but that those carboxyl groups were less important for binding the trivalent actinides. Binding of Pu⁴⁺ by bone sialoprotein was reduced, but not abolished, by mild acid hydrolysis (removal) of the terminal sialic acid moieties, which suggests that the sialic acid groups may also participate in metal binding.

31.8.5 Summary

Actinide binding in bone is a surface phenomenon. However, except for UO₂²⁺, binding of the trivalent and tetravalent actinides and NpO₂⁺ to bone surfaces is so stable that those metals neither migrate into the bone volume via the canaliculi nor are released back into the circulation by ion exchange or complexation with the ligands of the constantly flowing plasma and tissue fluid.

At physiological pH, trivalent and tetravalent lanthanides and actinides, UO₂²⁺ and NpO₂⁺, bind stably to native and synthetic bone mineral *in vitro*. Actinide uptake by various bone mineral preparations was nearly quantitative

from buffered solutions (lactate, tris, HEPES, pH 7–7.4) even from those solutions that also contained 0.3 to 0.5 mM citrate, whole plasma, or human Tf. In general, actinide uptake by the crystalline bone mineral preparations (synthetic HAP, chemically ashed KOH-glycol bone, or ED-bone) was faster than for bone ash, $\text{Ca}_3(\text{PO}_4)_2$, or powdered defatted whole bone, in which about one-half of the exposed particle surface is organic matrix. Actinide uptake by bone mineral is positively correlated with the surface area of the particles and appears to be saturable, indicating a fixed number of binding sites per unit surface area.

Hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] presents an organized Ca^{2+} -poor negatively charged surface with unsatisfied negative charges on adjacent phosphates. If Ca^{2+} is replaced, as is the case for UO_2^{2+} , there is access to the oxygens of two and perhaps three phosphates. The complexes of Th^{4+} and Pu^{4+} with bone mineral are more stable than the complexes that these metal ions form with $\text{ZnNa}_3\text{-DTPA}$, indicating that the crystals themselves provide spatially suitable multidentate binding sites.

The PAS-positive staining at the organic–mineral interface of bone surfaces, which are the actinide deposition sites in the skeleton, suggested that bone glycoproteins may participate in actinide binding, even though powdered decalcified bone matrix does not bind actinides. Five isolated low abundance bone glycoproteins form variably stable actinide complexes. The binding units of these proteins are considered to be mainly free sialic acid, the monodentate carboxyl groups of glutamic acid, and the bidentate alpha-hydroxy-carboxyl groups of aspartic acid.

The mineral crystals of native bone are sandwiched between layers of matrix collagen fibers, and the exposed bone surfaces do not present as many metal-binding sites as isolated bone mineral crystals. The most stable complexes of the trivalent lanthanides and actinides are six-coordinate (six M–O bonds), and those of the tetravalent actinides are eight-coordinate (eight M–O bonds). It would seem that *in situ* the number and configuration of the exposed potential binding groups of the glycoproteins alone would be insufficient to provide enough suitably arranged binding groups for stable actinide complexation. However, in living bone, both the mineral crystals and the neighboring matrix constituents (glycoproteins) combined may furnish sufficient numbers of binding groups suitably arranged in three-dimensional space for rapid stable actinide complexation *in situ*.

31.9 *IN VIVO* CHELATION OF THE ACTINIDES

The potential hazards to human health of the radioactive fission products and new heavy elements created by nuclear fission were recognized early, stimulating the search for effective ways to remove internally deposited radioelements

from the body (Schubert, 1955; Voegtlin and Hodge, 1949, 1953; Stone, 1951). Chemical agents that form stable excretable actinide complexes were soon recognized as the only practical therapy for internal contamination (decorporation) (Voegtlin and Hodge, 1949, 1953; Schubert, 1955; Rosenthal, 1956; Catsch, 1964). Such agents should have greater affinity for actinides at physiological pH than the biological ligands, low affinities for essential divalent metals, and low toxicity at effective dose. Reviews and proceedings of conferences on the development of chelators suitable for removal of internally deposited actinides have dealt with the chemistry of metal chelates, animal studies to determine ligand effectiveness for reducing actinide burdens in the tissues and amelioration of actinide-induced chemical and radiation damage, ligand toxicity, and clinical applications (Rosenthal, 1956; Seven and Johnson, 1960; Kornberg and Norwood, 1968; Volf, 1978; NCRP, 1980; Raymond and Smith, 1981; Taylor, 1991; Bhattacharyya *et al.*, 1992; Durbin *et al.*, 1997a, 1998a,b; Stradling *et al.*, 2000a,b; Wood *et al.*, 2000; Gorden *et al.*, 2003).

31.9.1 Polyaminopolycarboxylic acids

The first chelating agent investigated was ethylenediaminetetraacetic acid (H_4 -EDTA). Its Ca^{2+} salt, $CaNa_2$ -EDTA, was introduced to avoid toxic depletion of serum Ca^{2+} . It enhanced excretion of $^{91}Y^{3+}$, $^{144}Ce^{3+}$, and $^{239}Pu^{4+}$ in rats (Foreman and Hamilton, 1951; Hamilton and Scott, 1953). But $CaNa_2$ -EDTA is a poor actinide decorporation agent: it is renally toxic at effective dose; it depletes essential Zn^{2+} and other divalent metals; its efficacy cannot be improved except by increasing the administered dose.

Pentacarboxyl diethylenetriaminopentaacetic acid (H_5 -DTPA) and its Ca^{2+} and Zn^{2+} salts ($CaNa_3$ -DTPA introduced in 1957 and $ZnNa_3$ -DTPA introduced in 1965) improved lanthanide and actinide decorporation compared with $CaNa_2$ -EDTA (Catsch and L e, 1957; Kroll *et al.*, 1957; Smith, 1958; Catsch and von Wedelstaedt, 1965). Those clinically approved DTPA salts are effective decorporation agents for the trivalent lanthanides and actinides, less effective for Pu^{4+} and Th^{4+} , and nearly ineffective for reducing the body content of UO_2^{2+} or NpO_2^+ . [See references cited in Volf, 1978; Durbin *et al.*, 1997a, 1998a,b; Gorden *et al.*, 2003]. Although nominally octadentate, $CaNa_3$ -DTPA appears not to coordinate fully with Pu^{4+} , and it does not remove Pu^{4+} bound to bone mineral *in vitro* (Raymond and Smith, 1981; Guilmette *et al.*, 2003).

Several variants and derivatives of DTPA have been prepared and tested in animals, including polyaminopolycarboxylic acids with longer central bridges or additional carboxyl groups (Catsch, 1964); a dihydroxamic acid derivative, $ZnNa$ -DTPA-DX (Durbin *et al.*, 1989b; Stradling *et al.*, 1991; Volf *et al.*, 1993); lipophilic derivatives containing long alkane side chains (Volf, 1978; Raymond and Smith, 1981; Miller *et al.*, 1993). None of those DTPA-based

ligands was substantially more effective for *in vivo* chelation of lanthanides or Pu⁴⁺ or less toxic than native CaNa₃-DTPA, and most have been abandoned.

31.9.2 Desferrioxamine

Desferrioxamine (DFO), a linear tris-hydroxamate ligand, is a member of a class of compounds (siderophores) elaborated by microorganisms to obtain iron from the environment (Raymond and Smith, 1981). *In vivo* Pu⁴⁺ chelation is hampered by the weak acidity of the hydroxamic groups, which are not ionized at pH < 8; they are deprotonated only slowly at pH 7.4 by Fe³⁺ and Pu⁴⁺ but not by trivalent actinides (Taylor, 1967; Durbin *et al.*, 1980, 1989b; Rodgers and Raymond, 1983).

31.9.3 Siderophores as model chelators

Investigations of the siderophores and their structures and coordination chemistry identified the powerful hexadentate iron-sequestering agent, enterobactin (EB). EB is produced by enteric bacteria (*E. coli*) to obtain Fe³⁺ from the nearly neutral contents of the mammalian intestine (see references in Raymond and Smith, 1981 and Gorden *et al.*, 2003). It contains three bidentate catecholate binding groups attached through amide linkages to a cyclic 1-serine backbone and is preorganized for binding. The properties and structure of EB and similarities in the coordination properties of Pu⁴⁺ and Fe³⁺ provided the basis for rational design of highly selective multidentate actinide chelators that would be effective at physiological pH.

(a) Catecholate ligands

Multidentate catecholate ligands based on the EB model (denticity 4–8) were prepared containing catechol (CAM), sulfocatechol [CAM(S)], carboxycatechol [CAM(C)], or catecholamide (TAM) metal-binding groups (Fig. 31.15) attached through amide linkage to linear (LI-), cyclic (CY-), aromatic (ME-), or branched (TREN-, H(2,2)-) backbones. Syntheses and structures of the CAM ligands are collected in Gorden *et al.* (2003). All of those ligands were evaluated for promotion of excretion of ²³⁸Pu⁴⁺ from mice (30 μmol kg⁻¹ ligand ip 1 h after iv injection of ²³⁸Pu⁴⁺ citrate, kill at 24 h). Catecholate ligands of denticity <8 and those containing only CAM groups were marginally effective for *in vivo* Pu⁴⁺ chelation. The water-soluble octadentate ligands with flexible linear backbones based on spermine were more effective than octadentate ligands with attached lipophilic side chains or those with cyclic backbones. Reduction of skeleton Pu⁴⁺ by 3,4,3-LICAM(S) and of liver Pu⁴⁺ by 3,4,3-LICAM(C) were greater than obtained with an equimolar amount of CaNa₃-DTPA (Durbin *et al.*, 1980, 1984, 1989a,b, 1996; Lloyd *et al.*, 1984c). Those

Fig. 31.15 Catechol and hydroxypyridonate metal-binding units incorporated into multidentate ligands for *in vivo* chelation of actinides. Catechol (CAM), 5-sulfocatechol (CAM(S)), 4-carboxycatechol (CAM(C)), methylterephthalamide (MeTAM), 1,2 hydroxypyridinone (1,2-HOPO), Me-3,2-hydroxypyridinone (Me-3,2-HOPO).

ligands were much more effective than $\text{CaNa}_3\text{-DTPA}$ at doses $\leq 30 \mu\text{mol kg}^{-1}$, and they were orally active.

Although some of the *in vivo* properties of the two octadentate catechol ligands are favorable, both are defective. *In vivo* chelation of Am^{3+} (and presumably other trivalent actinides and lanthanides) was significantly less than with $\text{CaNa}_3\text{-DTPA}$ (Lloyd *et al.*, 1984c; Stradling *et al.*, 1986, 1989;

Volf, 1986; Volf *et al.*, 1986). The specific electric charge (e/r) of Am^{3+} is not great enough to deprotonate more than three of the eight OH groups of the tetracatecholate ligands at pH 7.4 (Kappel *et al.*, 1985). Furthermore, both of these nominally octadentate ligands are only functionally hexadentate at $\text{pH} < 12$. As the pH is reduced below 7.4, binding of Pu^{4+} by the more lipophilic 3,4,3-LICAM(C) becomes progressively less stable, and at pH 6 to 6.5 (the ambient pH of the lungs and renal tubules), the tetradentate species of the Pu^{4+} -3,4,3-LICAM(C) complex dominates (Kappel *et al.*, 1985; Durbin *et al.*, 1989a). Chelation of inhaled Pu^{4+} deposited in the lungs is weak and less effective than with CaNa_3 -DTPA. The Pu^{4+} complex with 3,4,3-LICAM(C) that formed in the blood at pH 7.4 partially dissociates at the reduced pH of the kidneys depositing Pu^{4+} residues (Stradling *et al.*, 1986, 1989; Volf, 1986; Volf *et al.*, 1986; Durbin *et al.*, 1989a). 3,4,3-LICAM(S) was found to be renally toxic in dogs at the effective dose (Lloyd *et al.*, 1984c).

At pH 7.4, methylterephthalamide (MeTAM) forms a more stable ferric complex than any other catecholate-binding group (Durbin *et al.*, 1996). MeTAM was introduced into three octadentate ligands with differing backbones; the MeTAM group was attached to the N-terminal of DFO, and four MeTAM groups were incorporated into linear spermine (3,4,3-LIMeTAM) and branched PENTEN [H(2,2)-MeTAM]. Reductions of body Pu^{4+} by these octadentate ligands were similar to each other, somewhat greater than for 3,4,3-LICAM(C), and significantly greater than for CaNa_3 -DTPA. Their Pu^{4+} complexes are stable over the physiological pH range, and no Pu^{4+} residues were left in the kidneys. These lipophilic ligands are sparingly soluble at $\text{pH} < 8$, their solutions are rapidly air oxidized, and their reductions of body Pu^{4+} in mice, similar to that obtained with 3,4,3-LICAM(C), suggested that they were also functionally hexadentate at pH 7.4.

(b) Hydroxypyridinonate ligands

Bidentate metal-binding groups more acidic than derivatized catechol and were required to achieve full eight-coordination with Pu^{4+} and to stably bind trivalent actinides in dilute aqueous solution at physiological pH. Highly selective HOPO metal-binding units occur in a few siderophores. The 1,2-HOPO and Me-3,2-HOPO isomers (Fig. 31.15) are structural and electronic analogs of hydroxamic acid and catechol, respectively. Their Fe^{3+} complexes are exceptionally stable, and both isomers are deprotonated and ready for metal binding at physiological pH (Scarrow *et al.*, 1985).

The 1,2-HOPO and Me-3,2-HOPO binding units were derivatized by attaching a carboxyl group adjacent to the OH group on the pyridinone ring; the COOH group can then be attached to amines on the selected molecular backbones through amide linkages. An important feature of the 1,2-HOPO and Me-3,2-HOPO complexes is that, as is observed in the catecholamide complexes, strong hydrogen bonds between the amide proton and the adjacent oxygen

Fig. 31.16 Strong hydrogen bonds between the amide proton and the adjacent oxygen donor enhance the stabilities of the metal complexes of the catecholate and hydroxypyridonate ligands (Xu *et al.*, 2001).

donor increase the stabilities of their metal complexes (Fig. 31.16) (Xu *et al.*, 1995, 2001). Sets of multidentate 1,2-HOPO and Me-3,2-HOPO ligands were prepared, as follows: tetradentate with linear backbones (α - ω -alkanediamines – 3-LI-, 4-LI-, 5-LI- 6-LI- and 2-aminoethylether, 5-LIO-); hexadentate with a linear spermidine backbone (3,4-LI-) or with a tripodal branched backbone triethyleneamine (TREN-); octadentate with a linear spermine backbone (3,4,3-LI-), or through attachment of one HOPO group to the N-terminal of DFO (DFO-), (Fig. 31.17) (White *et al.*, 1988; Xu *et al.*, 1995; Xu and Raymond, 1999; Durbin *et al.*, 2000b).

Ligand efficacies were assessed for *in vivo* Pu⁴⁺ chelation by administering them to mice that had been injected iv with ²³⁸Pu⁴⁺ citrate, as follows: ligand injected ip (30 $\mu\text{mol kg}^{-1}$) at 1 h (prompt injection), variable ligand dose at 1 h (dose effectiveness), ligand ip at 24 h (delayed effectiveness), ligand given orally at 5 min (oral activity). The ferric complexes of some ligands were administered promptly by ip injection or orally to assess competition between the ferric and Pu⁴⁺ complexes. Mice were killed 24 h after the ligand administration, and all tissues and excreta were radioanalyzed for Pu⁴⁺ (White *et al.*, 1988; Xu *et al.*, 1995; Durbin *et al.*, 2000b; Gorden *et al.*, 2003). Selected ligands were also assessed for *in vivo* chelation of ²⁴¹Am³⁺, ²³²UO₂²⁺ or ²³³UO₂²⁺, and ²³⁷NpO₂⁺ (Durbin *et al.*, 1994, 1997a, 1998b, 2000a).

(c) Ligands for Pu⁴⁺

1,2-HOPO and Me-3,2-HOPO ligands (tetradentate with 4-LI-, 5-LI-, 5-LIO-backbones, hexadentate with a TREN- backbone, and octadentate with a 3,4,3-LI- or H(2,2)- backbone) given ip or orally after the Pu⁴⁺ iv injection at doses ranging from 0.1 to 100 $\mu\text{mol kg}^{-1}$ were significantly and markedly superior to equimolar amounts of CaNa₃-DTPA for promoting Pu⁴⁺ excretion. Promotion of Pu⁴⁺ excretion by ip injection of 30 $\mu\text{mol kg}^{-1}$ of the linear 1,2-HOPO ligands (injected ip 1 h after the Pu⁴⁺ injection) was positively correlated with

(a.) Spermine

(d.) Tripodal amine

(b.) Alkanediamine

(e.) Penten

(c.) Di(aminoethyl) ether

Fig. 31.17 Linear and branched molecular backbones used for multidentate actinide chelating agents: tetradentate (b, alkanediamines; c, di(aminoethyl)ether); hexadentate (d, tripodal amine); octadentate (a, spermine; e, penten).

ligand denticity, indicating formation of a complete eight-coordinate complex with octadentate 3,4,3-LI(1,2-HOPO) (White *et al.*, 1988; Gorden *et al.*, 2003).

At the standard 30 $\mu\text{mol kg}^{-1}$ dose given to mice ip at 1 h after the Pu^{4+} injection, the tetra-, hexa-, and octadentate Me-3,2-HOPO ligands all promoted nearly the same amount of Pu^{4+} excretion. Apparently, the stabilities of the Pu^{4+} complexes with the tetradentate and hexadentate Me-3,2-HOPO ligands and the ligand concentrations established in the blood at this dose level are large enough to allow those ligands to compete for Pu^{4+} with the bioligands. However, when the Me-3,2-HOPO ligands were given orally, at lower doses, or as ferric complexes, the octadentate ligands, which have 1:1 stoichiometry for binding Pu^{4+} , were clearly more effective for *in vivo* Pu^{4+} chelation than the ligands of lesser denticity (Durbin *et al.*, 1989b, 2000b; Xu *et al.*, 1995; Gorden *et al.*, 2003).

The efficacies of the structurally analogous pairs of 1,2-HOPO and Me-3,2-HOPO ligands were compared in several Pu^{4+} removal protocols in mice. Overall, the Me-3,2-HOPO ligands were more effective for *in vivo* Pu^{4+} chelation than their structural 1,2-HOPO analogs (Durbin *et al.*, 2000b). The greater affinity of Me-3,2-HOPO for Pu^{4+} *in vivo* agrees with the greater stabilities of

the Me-3,2-HOPO complexes with other 'hard' metal ions like Fe^{3+} and Th^{4+} (Scarrow *et al.*, 1985; Veeck *et al.*, 2004).

Both octadentate HOPO ligands with the branched H(2,2)-backbone were highly effective for *in vivo* Pu^{4+} chelation, but they were considered to be too toxic to warrant further investigation (Durbin *et al.*, 1997a, 2000b). Low-toxicity DFO-(1,2-HOPO) given by ip injection is about as effective as 3,4,3-LI(1,2,-HOPO) for *in vivo* Pu^{4+} chelation, and it is moderately effective when given orally or at low dose (White *et al.*, 1988; Durbin *et al.*, 1989b). However, the weak acidity of the three hydroxamate groups prevents that ligand from competing effectively for inhaled Pu^{4+} deposited in the lungs and from stably binding Am^{3+} (Stradling *et al.*, 1991; Volf *et al.*, 1993, 1996a). *In vivo* Pu^{4+} chelation by DFO-(Me-3,2-HOPO) was significantly poorer than was obtained with its analog, DFO-(1,2-HOPO), but better than with native DFO. The lower than expected efficacy of DFO-(Me-3,2-HOPO) may be attributed to its lower aqueous solubility and the instability of its Pu^{4+} complex at the lower end of the physiological pH range (Xu *et al.*, 1995).

Among the ligand sets, the most effective for *in vivo* Pu^{4+} chelation is linear octadentate 3,4,3-LI(1,2-HOPO). Although it contains the less stably binding 1,2-HOPO unit, it has good aqueous solubility, and the flexible linear spermine backbone apparently confers advantages for Pu^{4+} binding by allowing a more favorable spatial arrangement of the four binding groups around the Pu^{4+} center. The 3,4,3-LI(1,2-HOPO) ligand is markedly superior to $\text{CaNa}_3\text{-DTPA}$ for reducing Pu^{4+} in all tissues when given by injection, oral administration, or subcutaneous infusion after an iv or im injection or inhalation of Pu^{4+} nitrate or citrate in rats and mice (White *et al.*, 1988; Durbin *et al.*, 1989b, 2000b; Stradling *et al.*, 1992, 1993; Volf *et al.*, 1993, 1996a,b; Gray *et al.*, 1994). It is effective at doses as low as $0.03 \mu\text{mol kg}^{-1}$ in mice. When injected or infiltrated into an im wound site, it is more effective than $\text{CaNa}_3\text{-DTPA}$ for reducing the body and wound site content of Th^{4+} (Stradling *et al.*, 1995a).

It was considered that the effectiveness of the octadentate 3,4,3-LI(1,2-HOPO) ligand might be improved, if the thermodynamically more potent Me-3,2-HOPO were introduced. Concerns about toxicity, lipophilicity, and aqueous solubility of a tetra-Me-3,2-HOPO ligand led to the synthesis of the mixed ligand, 3,4,3-LI(1,2-Me-3,2-HOPO). Two 1,2-HOPO units occupy the central secondary amines and two Me-3,2-HOPO units are attached to the terminal primary amines of spermine. Substitution of the two Me-3,2-HOPO groups for 1,2-HOPO slightly increased the stability of the Pu^{4+} complex at pH 7.4 and the lipophilicity and oral activity of the ligand, while somewhat reducing acute toxicity at high dose (Xu *et al.*, 2002). However, the modest thermodynamic gain was offset by the reduction in hydrophilicity, which appears to be an important property of 3,4,3-LI(1,2-HOPO), most likely facilitating its access to Pu^{4+} in the skeleton (Durbin *et al.*, 2000b, 2003).

Crystals have been prepared from water of structurally analogous $\text{Ce}^{4+}[\text{5-LI}(\text{Me-3,2-HOPO})_2]$ and $\text{Pu}^{4+}[\text{5-LIO}(\text{Me-3,2-HOPO})_2]$ complexes (Fig. 31.18).

Fig. 31.18 Molecular structures (viewed from the side) of $Ce(IV)[5-LIO(Me-3,2-HOPO)]_2$ (left side, Xu *et al.*, 2000) and $Pu(IV)[5-LIO(Me-3,2-HOPO)]_2$ (right side, Gorden *et al.*, 2005).

In both cases the 2:1 structure is demonstrated. The overall ligand geometries resemble sandwich structures that are defined by the oxygen atoms coordinating to the Ce^{4+} and Pu^{4+} centers (Xu *et al.*, 2000; Gorden *et al.*, 2005). Solution thermodynamic studies of the Ce^{4+} complex system gave an overall formation constant of the complex ($\log \beta_2$) of 41.6, and the formation constant of the analogous Pu^{4+} complex is expected to be essentially the same.

(d) Ligands for Am^{3+}

The efficacies of ligands containing HOPO groups for *in vivo* chelation of Am^{3+} and for removing Am^{3+} from bone mineral are generally in the order: octadentate > hexadentate > tetradentate (Guilmette *et al.*, 2003). The octadentate ligands more than satisfy the requirement for six-coordination preferred by Am^{3+} , and if three of their bidentate metal-binding units can bind to Am^{3+} without steric hindrance, the extra binding group appears to enhance the stabilities of their Am^{3+} complexes. As noted above, *in vivo* chelation of Am^{3+} by the octadentate ligands containing carboxy- or sulfocatechol [CAM (C), CAM(S)] or by hydroxamate (as in the octadentate ligands with the DFO-backbone) is weak because too few of the hydroxyl groups of those ligands can be deprotonated by Am^{3+} (and presumably other trivalent actinides) to form stable complexes at physiological pH (Lloyd *et al.*, 1984c; Kappel *et al.*, 1985; Stradling *et al.*, 1986, 1989; Volf, 1986; Volf *et al.*, 1986; Zhu *et al.*, 1988).

Four HOPO ligands have been investigated in rats and mice for *in vivo* chelation of Am^{3+} : octadentate 3,4,3-LI(1,2-HOPO), hexadentate TREN-(Me-3,2-HOPO), tetradentate 5-LI(Me-3,2-HOPO), and 5-LIO(Me-3,2-HOPO). When given by injection or orally ($30 \mu\text{mol kg}^{-1}$) to rats or mice contaminated with $^{241}Am^{3+}$ by injection or infiltration into a wound, all four of those ligands were more effective than an equimolar amount of

CaNa₃-DTPA. Octadentate 3,4,3-LI(1,2-HOPO) was about as effective as CaNa₃-DTPA, while the other HOPO ligands of lesser denticity were less effective than CaNa₃-DTPA for reducing body and lung Am³⁺ when the Am³⁺ had been inhaled (Stradling *et al.*, 1992; 1993, 1995b; Volf *et al.*, 1993, 1996; Durbin *et al.*, 1994; Gray *et al.*, 1994; Volf, 1996; Gorden *et al.*, 2003).

(e) Ligands for UO₂²⁺

Soluble uranyl ion, UO₂²⁺, is nephrotoxic, and because bone is the major storage organ for UO₂²⁺, the high specific activity uranium isotopes also induce bone cancer (Voegtlin and Hodge, 1949, 1953; Finkel and Biskis, 1968; Hodge, 1973). Although sought since the 1940s, no multidentate ligand was identified that would efficiently bind UO₂²⁺ *in vivo*, promote its excretion, and reduce deposits in kidneys and bone (reviewed by Durbin *et al.*, 1997a). The modest reductions of acute UO₂²⁺ poisoning obtained with tiron, a bidentate sulfocatecholate, suggested that multidentate ligands containing similar binding groups would be effective *in vivo* UO₂²⁺ chelators.

Representative tetra-, hexa-, and octadentate ligands with linear or branched backbones containing CAM(S), CAM(C), MeTAM, 1,2-HOPO, or Me-3,2-HOPO groups (20 in all) were evaluated in mice for *in vivo* chelation of UO₂²⁺. Experimental conditions were: ²³² + ²³⁵UO₂Cl₂ or ²³³UO₂Cl₂ pH 4 injected iv, 30 μmol kg⁻¹ of ligand injected ip at 5 min (see Fig. 31.11), ligand: U molar ratio 75 to 91, kill at 24 h. All of the test chelators were screened for acute toxicity. Except for the two tetradentate 1,2-HOPO ligands and CaNa₃-DTPA, all of the injected test chelators significantly reduced UO₂²⁺ in the kidneys compared with controls, and ligands containing CAM(S), CAM(C), or MeTAM groups also significantly reduced UO₂²⁺ in the skeleton. Administered orally at molar ratios from 90 to 300, the linear tetradentate ligands containing Me-3,2-HOPO, CAM(S), or CAM(C) and 3,4,3-LI(1,2-HOPO) significantly reduced UO₂²⁺ binding in the kidneys, but not in the skeleton. The combined assessments of ligand efficacy and acute toxicity identified tetradentate 5-LIO(Me-3,2-HOPO) and 5-LICAM(S) as the most effective low toxicity agents for UO₂²⁺. They efficiently removed circulating UO₂²⁺ at molar ratios as low as 20, removed useful amounts of newly deposited UO₂²⁺ from kidneys and/or bone at molar ratios ≥100, and reduced kidney UO₂²⁺ significantly when given orally at molar ratios ≥100. 5-LIO(Me-3,2-HOPO) has greater affinity for UO₂²⁺ in the kidneys, 5-LICAM(S) has greater affinity for UO₂²⁺ in bone, and a 1:1 mixture of the two ligands (total ligand: U molar ratio 91) reduced kidney and bone UO₂²⁺ to 15 and 58% of control, respectively – more than an equimolar amounts of either ligand alone (Durbin *et al.*, 1989b; 1997a, 2000a; Gorden *et al.*, 2003).

Crystals of uranyl chelates with the set of linear tetradentate Me-3,2-HOPO ligands demonstrate a 1:1 structure and show that those ligands bind in a nearly planar ring perpendicular to the plane of the dioxo oxygens (Fig. 31.19) (Xu and Raymond, 1999).

Fig. 31.19 Molecular structure of $UO_2[5-LI(Me-3,2,-HOPO)]$ (Xu and Raymond, 1999).

(f) Ligands for NpO_2^+

As noted above in the sections dealing with tissue distribution, circulatory transport, and tissue uptake kinetics, the oxidation state of Np *in vivo* is uncertain and probably variable. Rapid plasma clearance and substantial urinary excretion of NpO_2^+ resemble the behavior of UO_2^{2+} , while the deposition in the skeleton of nearly one-half of Np taken into blood and its prolonged retention resemble Pu^{4+} . Redox conditions *in vivo* range from an oxidizing environment in the lungs to more reducing environments in the tissues. Depending on the oxidation state of the Np introduced into the blood (Np^{4+} , NpO_2^+ , NpO_2^{2+}), the local conditions in the blood and tissues, and the availability of stabilizing bioligands, both reduction of NpO_2^+ and oxidation of Np^{4+} may be expected (Duffield and Taylor, 1986; NCRP, 1988; Taylor, 1998). The complexes formed by NpO_2^+ are weak, while those of Np^{4+} are about as stable as those of Pu^{4+} with the same ligands (Table 31.8).

$CaNa_3$ -DTPA was injected ip at ligand:Np molar ratios ≥ 50 in rats that had been injected iv with ^{237}Np or ^{239}Np citrate solutions (oxidation states uncertain). Excretion of both Np isotopes was increased, the Np content of liver and kidneys was reduced, but there was little reduction in skeleton Np (Smith, 1972b). Effective reduction of ^{239}Np in the body of rats was achieved by ip injection of octadentate 3,4,3-LICAM(C), given at very large ligand:Np molar ratios 1 h after iv injection of $^{239}NpO_2NO_3$. But similarly to the experience with *in vivo* chelation of Pu^{4+} by that ligand, the Np complex formed in the blood partially dissociated leaving a residue of Np in the kidneys (Volf and Wirth, 1986). These observations were taken as an indication of the presence *in vivo* of chelatable Np^{4+} .

Based on that encouraging result, a systematic investigation was undertaken of the *in vivo* chelation of Np by a set of representative multidentate ligands. The ligands assessed for Np chelation were tetra-, hexa-, and octadentate with linear or branched backbones containing CAM(C), CAM(S), 1,2-HOPO, or Me-3,2-HOPO binding groups. Mice were injected ip with a ligand ($30 \mu\text{mol kg}^{-1}$,

ligand:Np molar ratio 22) 5 min after the iv injection of $^{237}\text{NpO}_2\text{Cl}$ (see Fig. 31.12) and killed at 24 h. All 10 test ligands, but not $\text{CaNa}_3\text{-DTPA}$, significantly reduced body Np, regardless of denticity or the identity of the binding group. Most ligands significantly reduced Np in the liver, and except for 3,4,3-LICAM (C), also in the kidneys. Significant reduction of Np in the skeleton was also achieved with tetradentate 5-LIO(Me-3,2-HOPO) and 5-LI(Me-3,2-HOPO), and octadentate H(2,2)-(1,2-HOPO), H(2,2)-(Me-3,2-HOPO), and 3,4,3-LICAM(C). Except for tetradentate 5-LI(Me-3,2-HOPO), which was orally active at lower dose, ligand:Np molar ratios ≥ 22 were required to obtain significant reductions in body Np, when the test ligands were given orally at 5 min (Durbin *et al.*, 1994, 1998a,b).

Experiments were undertaken to examine the efficacy of 3,4,3-LI(1,2-HOPO) for *in vivo* chelation of ^{237}Np in contaminated wounds in rats. Ligand:Np molar ratios ranged from 4.3 to 285. Early infiltration of the wound site with the ligand was effective, but delayed treatments were progressively less effective. 3,4,3-LI(1,2-HOPO) was able to complex the Np at the wound site before it was translocated to blood, but Np deposited in the tissues became progressively less accessible to the ligand (Paquet *et al.*, 1997, 2000).

Based on the combined considerations of ligand efficacy and acute ligand toxicity, the most promising ligands for *in vivo* chelation of Np are in order: tetradentate 5-LIO(Me-3,2-HOPO) and 5-LI(Me-3,2-HOPO), octadentate 3,4,3-LI(1,2-HOPO), and hexadentate TREN-(Me-3,2-HOPO).

ACKNOWLEDGMENTS

The author wishes to thank the following members of the Lawrence Berkeley National Laboratory, Chemical Sciences Division, for their essential contributions to the preparation of this manuscript: Dr. Wayne W. Lukens, Jr. for the speciation calculations for UO_2^{2+} and NpO_2^+ in blood plasma; Lindarae M. Aubert and Lynne A. Dory for manuscript preparation; and Dr. Norman M. Edelstein for his patience and assistance. Flavio Robles of the Creative Services Group and Dr. Jide Xu of the U. C. Department of Chemistry provided the illustrations.

APPENDIX: SOURCES OF MATERIALS ON ACTINIDE BIOLOGY

The pioneering biological studies with actinides conducted during World War II (1942–1946) encompassed the following: pharmacology and toxicology of injected, ingested, and inhaled uranium compounds (Tannenbaum, 1951a,b; Voegtlin and Hodge, 1949, 1953); biokinetics of injected and ingested fission products, plutonium, and actinide fission by-products (Lanz *et al.*, 1946; 1947a,b, 1948a,b, 1949b; Carritt *et al.*, 1947; Finkle *et al.*, 1946; Hamilton,

1947b, 1948c); acute toxicity of injected fission products and plutonium (Painter *et al.*, 1946; Bloom, 1948; Fink, 1950); biokinetics and acute toxicity of inhaled or intratracheally intubated fission products and plutonium (Abrams *et al.*, 1946a,b, 1947; Scott *et al.*, 1947b, 1949a). Stannard (1988) summarized the designs and major findings of those studies and provided the tables of contents for the otherwise unpublished Plutonium Project documents and reports.

Actinide biology summaries and reviews include: General reviews – (Durbin, 1960, 1962), Finkel and Biskis (1968), Stover and Jee (1972), Nenot and Stather (1979), ICRP (1972, 1986), Duffield and Taylor (1986), Stannard (1988), Thompson (1989); Element-specific reviews, uranium – Hursh and Spoor (1973), Yuile (1973), Durbin and Wrenn (1975); neptunium – Thompson (1982), NCRP (1988); plutonium – Bair *et al.* (1973), Vaughan *et al.* (1973), Bair (1974), Durbin (1975); transplutonium elements – Durbin (1973); conference proceedings – Rosenthal (1956), Dougherty *et al.*, 1962), Thompson (1962), Mays *et al.* (1969), Thompson and Bair (1972), Healy (1975), Wrenn (1975), Jee (1976), Wrenn (1981), Gerber *et al.* (1989), Stather and Karaoglou (1994), Métivier *et al.* (1998), Stather *et al.* (2003); databases compiled for radiation protection guidance – ICRP (1959, 1972, 1979, 1980, 1986).

The bibliographies of three reports dealing with the deposition and biological effects of plutonium and other selected radionuclides provide an introduction to the large research program on internally deposited radionuclides undertaken in the USSR (Buldakov *et al.*, 1969; Moskalev *et al.*, 1969; Moskalev, 1972).

APPENDIX I

NUCLEAR SPINS AND MOMENTS OF THE ACTINIDES

Nuclear spins and nuclear moments are used to test the single-particle models and nuclear quadrupole moments provide the deformation of the nucleus. In the following table, we present measured values of ground state spin in units of \hbar , magnetic dipole moment (μ) in units of nuclear magneton, and spectroscopic quadrupole moment (Q) in units of barns. The data have been taken from Raghavan (1989) and Firestone and Shirley (1996).

<i>Nuclide</i>	<i>Nuclear spin</i> (\hbar)	<i>Nuclear magnetic moment</i> (nuclear magneton)	<i>Electric quadrupole moment</i> (barns)
²¹⁷ Ac	9/2	+3.825(45)	
²²⁷ Ac	3/2	+1.1(1)	+1.7(2)
²²⁹ Th	5/2	+0.46(4)	+4.3(9)
²²⁸ Pa	3	+3.48(33)	
²³⁰ Pa	2	+2.00(29)	
²³¹ Pa	3/2	+2.01(2)	-1.72(5)
²³³ Pa	3/2	+3.39(70)	-3.0
²³³ U	5/2	0.59(5)	3.663(8)
²³⁵ U	7/2	-0.38(3)	4.936(6)
²³⁷ Np	5/2	+3.14(4)	+3.886(6)
²³⁸ Np	2		
²³⁹ Np	5/2		
²³⁹ Pu	1/2	+0.203(4)	
²⁴¹ Pu	5/2	-0.683(15)	+5.6(20)
²⁴¹ Am	5/2	+1.61(3)	+4.2(13)
²⁴² Am	1	+0.3879(15)	-2.4(7)
^{242m} Am	5	+1.00(5)	+6.5(20)
²⁴³ Am	5/2	+1.61(4)	+4.30(3)
²⁴³ Cm	5/2	0.41	
²⁴⁵ Cm	7/2	0.5 (1)	
²⁴⁷ Cm	9/2	0.37	
²⁴⁹ Bk	7/2	2.0(4)	+5.79

APPENDIX II

NUCLEAR PROPERTIES OF ACTINIDE AND TRANSACTINIDE NUCLIDES

Irshad Ahmad

DISCUSSION

In this appendix, an elementary discussion of the nuclear properties of heavy elements is presented. For a better understanding of the subject, the reader should refer to nuclear chemistry textbooks (Krane, 1988; Choppin *et al.*, 2002) and for the information on decay data, the *Table of Isotopes* (Firestone and Shirley, 1996) or the *Table of Radioactive Isotopes* (Browne and Firestone, 1986) or *Nuclear Data Sheets* (Tuli, 2004) should be consulted.

Isotopes of all elements with $Z \geq 89$ are radioactive. The most common mode of decay for these nuclei is by the emission of alpha particles (${}^4\text{He}$ ions). Alpha decay energies have been experimentally measured (Browne and Firestone, 1986; Firestone and Shirley, 1996) for most nuclides and these can also be calculated from atomic masses (Wapstra *et al.*, 2003). The α decay of a nucleus with atomic number Z and atomic mass A produces a daughter nucleus with atomic number $Z-2$ and atomic mass $A-4$. During the α decay, about 2% of the available decay energy is imparted to the recoiling daughter nucleus and the remaining energy is carried off by the fast moving α -particle. Several groups of α -particles are emitted by a sample of a nuclide, each with a definite energy. For the actinide nuclides, α -particle energies range from about 4 to 11 MeV. As a rule, α -particle energy increases with increasing Z , and for a given element, it decreases with increasing mass number.

The α -decay half-life decreases exponentially with increasing energy. As a guide, every 50 keV increase in the decay energy reduces the half-life by a factor of ~ 2 . The dependence of the α -decay half-life on the decay energy is given by the well-known Geiger–Nuttall law and more recently by Viola–Seaborg formula. A very useful quantity that facilitates the understanding of the mechanism of α -decay is the concept of hindrance factor. It is defined as the ratio of the experimental partial α -decay half-life to the theoretical half-life calculated on the assumption that the α -particle pre-exists in the nucleus and during its emission, it carries no angular momentum. An alpha transition in which the

ground state configuration of the parent nucleus remains unchanged is called 'favored transition'. All alpha transitions between the ground states of even-even nuclei are favored transitions and are assigned a hindrance factor of one.

Like elements of lower Z , each actinide element has one or more β -stable isotopes. Isotopes heavier than the β -stable isotope decay by the emission of β^- particles (electrons) and isotopes lighter than the β -stable isotopes decay by electron capture (EC). Electron capture decay is usually accompanied by the emission of K x-rays of the daughter nuclide. These x-rays provide a signature of the decaying nuclide. In heavy nuclei, β^+/EC ratio is very small and, as a consequence, positron (β^+) emission has been observed only in a few nuclei. The β -decay energy increases as the mass of the isotope gets further away from the line of β -stability. A quantity denoted by $\log ft$ is very useful in classifying the β transitions and estimating the β -decay half-lives of unknown nuclei. The ft value, also called the reduced β transition probability, is the energy-independent transition rate.

Spontaneous fission is a decay process in which a nucleus breaks up into two almost equal fragments. Each fission event is accompanied by the release of about 200 MeV energy and the emission of two to four neutrons. More than hundred nuclides are produced in fission of a nuclide sample and the mass yields and charge distributions have been measured for many fissioning systems (Wahl, 1989; Ahmad and Phillips, 1995). The fission half-life depends on the fissility parameter Z^2/A and is the major decay mode for many isotopes of element 100 and beyond. Nuclides with reasonable fission branch and available for experiments and industrial use are ^{248}Cm ($t_{1/2} = 3.40 \times 10^5$ years) and ^{252}Cf ($t_{1/2} = 2.64$ years). The isotope ^{252}Cf is widely used as a neutron source in industry and research.

Another rare mode of decay for heavy elements is the decay by the emission of intermediate mass fragments. These fragments are heavier than α particles but smaller than fission fragments. The branching ratio for this kind of radioactivity is extremely small ($\sim 10^{-10}$). Examples of such radioactivity are the ^{24}Ne emission by ^{231}Pa and ^{232}U (Price, 1989).

Alpha and β transitions usually populate excited states in addition to the ground states of the daughter nuclei. The excited states then decay to the ground state by emission of γ rays and conversion electrons. Typical half-lives of the excited states range from 10^{-9} to 10^{-14} s. However, in some cases, the decay of an excited state is forbidden for fast magnetic dipole ($M1$), electric dipole ($E1$), or electric quadrupole ($E2$) transitions because of the angular momentum selection rule. Such states have half-lives between nanoseconds and years. An excited state that has a half-life value greater than a nanosecond is called a 'metastable' state or 'isomer'. The isomeric state either de-excites to the ground state of the same nucleus by an internal transition (IT) or it decays by the usual mode of disintegration.

Most isomers occur because of the large difference between the spins of the excited state and the ground state. However, there are isomers which result not

by the difference in the spins of the states but by the difference in the shapes. These isomers decay by fission and are called 'fission isomers' or 'shape isomers' and have half-lives between 10^{-9} and 10^{-3} s. These isomers have deformations that are twice as large as the deformations of the ground states. More than 50 fission isomers have been discovered (Vandenbosch, 1977).

Very neutron-deficient nuclides decay predominantly by electron capture (EC). In some of these nuclei, the EC decay energy is quite large (> 4 MeV) and hence states at high excitation energy are populated in the daughter nucleus and a small fraction of these excited states decay by fission. Delayed fission of many nuclei has been observed (Hall and Hoffman, 1992).

Nuclear structure studies of actinide nuclides have been performed using a variety of techniques. These include high-resolution alpha, electron and gamma-ray spectroscopy, charged-particle transfer reaction spectroscopy, and Coulomb excitation studies. These investigations have provided significant information on the shape, size, and single-particle potential of actinide nuclei. The available data establish a spheroidal shape for nuclei with $A \geq 225$, with major to minor axes ratio of ~ 1.25 . The intrinsic quadrupole moments of actinide nuclei have been measured to be about 10^{-23} e cm² and the nuclear radii are about 10^{-12} cm.

Although most actinide nuclei have spheroidal shapes, there are indications that some neutron-deficient Ac and Pa nuclei have small octupole deformation in their ground states. These nuclei are pear-shaped and are axially symmetric but they are reflection asymmetric. Examples of such nuclei are ²²⁹Pa and ²²⁵Ac (Ahmad and Butler, 1993).

In nuclei, nucleons (neutrons and protons) move in orbits under the influence of the central nuclear potential. Nilsson (1955) and others (Chasman *et al.*, 1977) have calculated the eigenvalues and eigenfunctions of nucleons in a deformed potential as a function of the deformation β . Plots of the eigenvalues versus the deformation, commonly known as Nilsson diagrams, are extremely useful in understanding the single-particle properties of actinide nuclei. Each Nilsson state is characterized by a set of quantum numbers Ω , π , N , N_z , and Λ . The quantum number Ω is the projection of the single-particle angular momentum on the nuclear symmetry axis and π is the parity of the wavefunction. The asymptotic quantum numbers N , N_z and Λ denote the oscillator shell number, the number of the oscillator quanta along the symmetry axis, and the projection of the orbital angular momentum on the symmetry axis, respectively. In heavy nuclei, neutrons (protons) fill each orbital above the closed shell of 126 (82) pairwise and thus the ground state of an odd-mass nucleus is simply the orbital occupied by the last unpaired nucleon. All even-even nuclei have ground state spin-parity of 0^+ .

A spheroidal nucleus rotates about an axis perpendicular to the nuclear symmetry axis. The projection, K , of the total angular momentum, I , on the symmetry axis is the same as Ω . The rotation of a spheroidal nucleus generates a rotational band with spin sequence $K, K+1, K+2, \dots$. The

rotational energy E_I of a level with spin I is given by the expression

$$E_I = \frac{\hbar^2}{2\mathfrak{S}} I(I + 1),$$

where \hbar is Planck's constant and \mathfrak{S} is the nuclear moment of inertia. Typical values of $\hbar^2/2\mathfrak{S}$ are 7.0 keV for even–even actinide nuclei and 6.0 keV for odd-mass nuclei. The ground state band of an even–even nucleus has spin-parity sequence $0^+, 2^+, 4^+ \dots$; odd spin values are not allowed.

Qualitative and quantitative analysis of actinide samples can be performed by using a variety of techniques (Knoll, 2000). Gross counting with a 2π (50%) geometry gas proportional counter can be used to determine the α or β^- count rate in a sample. These counters have very low background for α particles but somewhat higher background for electrons. Background of ~ 0.1 α count per minute can be easily achieved for these counters.

Alpha pulse height analysis can be used to identify nuclides in a sample. Alpha spectra are measured either by Au–Si surface barrier detectors or passivated implanted planar silicon (PIPS) detectors. For best resolution (full width at half maximum), which can be as low as 9.0 keV, extremely thin sources are required. Precise energies and intensities of alpha groups have been tabulated by Ritz (1991).

Gamma-ray spectroscopy with high-resolution germanium spectrometers provides a powerful technique for qualitative and quantitative analysis of actinide samples. For high-energy γ rays in the range of 200 keV to 1.5 MeV, large volume Ge detectors provide the best sensitivity. Resolutions (FWHM) of less than 2.0 keV at the ^{60}Co 1332.5 keV line are easily achieved. In actinide nuclei, K x-ray energies lie in the 80–160 keV range and can be measured with high-resolution low-energy planar spectrometers (LEPS). K x-rays are produced when a vacancy in the K shell of an atom, created by electron capture or internal conversion, is filled by an electron from a higher shell. These K x-rays energies depend on the atomic number and there is sufficient separation between the energies of adjacent elements for them to be clearly identified. The Cm K x-ray spectrum produced in the alpha decay of ^{251}Cf and measured with a high-resolution LEPS is displayed in Fig. A.2.1. The resolution (FWHM) of the spectrometer is about 500 eV. Measurements of gamma ray spectrum and K x-ray spectrum are very useful in identifying and quantifying odd-mass nuclei.

L x-rays of actinide nuclei, which are produced when a vacancy in the L subshell of an atom is filled by an electron from a higher shell, have energies in the 10–30 keV range. Spectra of L x-rays can be measured with lithium-drifted silicon, Si(Li), detectors with resolutions (FWHM) of ~ 300 eV. A Np L x-ray spectrum from ^{241}Am alpha decay, measured with a Si(Li) spectrometer, is shown in Fig. A.2.2. These spectra are also characteristic of the element but are more complex. The definition of x-ray components is given in (Firestone and Shirley, 1996). Even–even nuclei decay to excited levels of daughter nuclei which de-excite by highly L converted transitions generating L x-rays. Thus even–even

Fig. A.2.1 K X-ray spectrum of Cm, produced in the alpha decay of ^{251}Cf , measured with a $2\text{ cm}^2 \times 1\text{ cm}$ LEPS spectrometer.

nuclei, which do not have any intense γ rays, can be analyzed by L X-ray spectroscopy.

Fissioning nuclides like ^{252}Cf can be assayed by measuring the gamma-ray spectrum with large-volume Ge detectors and using the intensities of gamma rays emitted in the decay of the abundant fission fragments (Ahmad *et al.*, 2003).

Some actinide nuclides have very long half-lives and hence they occur in nature. These include ^{232}Th , ^{235}U and ^{238}U which decay through a series of isotopes terminating at stable Pb isotopes. Isotopes of Ac, Th, and Pa are usually separated from the parent nuclides and used in the chemical and nuclear studies of these elements.

Transuranium isotopes are produced by long irradiations in nuclear reactors. In the US, there is a national program for the production and isolation of transuranium isotopes utilizing the High Flux Isotope Reactor (HFIR) at the Oak Ridge National Laboratory. The heaviest nuclide produced in this program is the 100 day ^{257}Fm . Neutron-deficient actinide isotopes are usually produced by nuclear reactions in charged particle accelerators.

All data in the tables of nuclear properties given in the preceding chapters and in this appendix have been taken from Browne and Firestone (1986), Firestone and Shirley (1996), Nuclear Data Sheets (Tuli, 2004) and from the

Fig. A.2.2 *L* X-ray spectrum of Np, produced in the alpha decay of ^{241}Am , measured with a 1 cm diameter and 5 mm thick Si(Li) detector.

web sites at the Isotope Project, Lawrence National Berkeley Laboratory (<http://www.lbl.gov>) and at the Nuclear Data Center, Brookhaven National Laboratory (<http://www.nndc.bnl.gov>). For the heaviest elements, data were taken from Armbruster (2000) and Hofmann and Münzenberg (2000). The cut-off date for literature survey was June 2004.

The notations for decay modes in the tables are: α for alpha decay, β^- for β^- decay, β^+ for positron decay, EC for electron capture decay, IT for isomeric transition, and SF for spontaneous fission. The letter m after a mass number represents an isomer. Isomers with half-lives of less than 1 s (except for the heaviest elements) and fission isomers are omitted from the tables. Energies and intensities are given for the most abundant α groups and most intense γ rays; for β^- particles, the maximum energy β_{max} is given. In the last column of Table A2.1, only the convenient methods of production are given; 'nature' denotes that the nuclide occurs in nature and 'multiple neutron capture' means that the nucleus is produced by multiple neutron capture in a high-flux reactor such as HFIR.

The specific activity S in disintegrations per minute per microgram was calculated using the expression

$$S = \frac{4.17449 \times 10^{17}}{t_{1/2}A},$$

where $t_{1/2}$ is half-life of the nuclide in minutes and A is the atomic mass in atomic mass units. The half-lives and atomic masses were taken from the references mentioned earlier in this text.

TABLES

In the following tables we reproduce the tables in each of the chapters 2 through 14 that contain the nuclear properties of the actinide and transactinide isotopes. We then give a table of specific activities of these isotopes.

Nuclear properties of actinium isotopes.

<i>Mass number</i>	<i>Half-life</i>	<i>Mode of decay</i>	<i>Main radiations (MeV)</i>	<i>Method of production</i>
206	33 ms	α	α 7.750	$^{175}\text{Lu}(^{40}\text{Ar},9\text{n})$

^a Decay modes are denoted by: α for alpha decay, β⁻ for beta decay, EC for electron capture, IT for isomeric transition, and SF for spontaneous fission. The decay mode given in this column represents either the major decay mode or the only observed decay mode.

^b 1 year = 365.243 days.

^c Specific activity is given in units of disintegrations per minute per microgram and contains one more significant figure than the half-life in order to avoid rounding-off errors.

^d For commonly used isotopes, specific activities are also given in units of Curies per gram. 1 Ci = 2.22 × 10¹² disintegrations per minute = 3.7 × 10¹⁰ Bq.

use of, 2592–2593
- Actinide compounds
electronic structure of, 1893–1998
actinyl ions and oxo complexes, 1914–1933
actinyl complexes, 1920–1928
‘bare’ species and ions in solids, 1928–1932
high oxidation oxygen species, 1932–1933, 1932t
uranyl ion and related species, 1914–1920
halide complexes, 1933–1942
oxyhalides, 1939–1942
uranium hexafluoride and related complexes, 1933–1939
matrix-isolated, 1967–1991
binary carbonyls, 1984–1987
carbide oxides, 1976–1984
description of, 1968
developments of, 1969
dioxides, 1970–1976
nitride-oxides, 1989–1991
nitrides, 1987–1989
overview of, 1968–1970
organometallics, 1942–1967
actinocenes, 1943–1952
cyclopentadienyl complexes, 1952–1959
miscellaneous, 1965–1967
six- and seven-membered ring complexes, 1959–1962
uranium (III) complexes, 1962–1965
relativistic approaches, 1902–1914
double groups, 1910–1914
excited electronic states, 1909–1910
Hartree-Fock and density functional approaches, 1902–1904
RECPs, 1907–1909
relativistic effects, 1904–1907
speciated ions, 1991–1992
unsupported metal-metal bonds, 1993–1994
magnetic properties of, 2361–2362
thermodynamic properties of, 2113–2213
antimonides, 2197t, 2203–2204
arsenides, 2197t, 2203–2204
carbides, 2195–2198
chalcogenides, 2203t, 2204–2205
complex halides, 2179–2182
group IIA elements, 2205, 2206t–2207t
group IIIA elements, 2205–2206, 2206t–2207t, 2208f
group IVA elements, 2206–2208, 2206t–2207t
halides, 2157–2179
hydrides, 2187–2190
nitrides, 2200–2203
nitrohalides, 2182–2185
oxides, 2192–2195
oxides and complex oxides, 2135–2157
oxyhalides, 2182–2187
oxyhydroxides, 2193–2195
phosphides, 2197t, 2203–2204
pnictides, 2200–2204
selenides, 2203t, 2204–2205
sulfides, 2203t, 2204, 2204f

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- tellurides, 2203t, 2204–2205
transition elements, 2208–2211
trihydroxides, 2190–2192
transition metal characteristics of, 2333–2334
- Actinide concept
 history of, 3, 1754–1755
 periodic table and, 10–11
- Actinide-CU. *See* DIPEX resin
- Actinide elements, 1753–1830
 absorption cross section of, 2233
 atomic volumes of, 922–923, 923f
 biological behavior, 1813–1818
 bioremediation, 1817–1818
 in body fluids, 1814–1815
 bone uptake, 1817
 general considerations, 1813–1814
 liver uptake, 1815–1816
 in bone, 1817, 3400–3406
 americium (III), 3403
 binding of, 3406–3412
 blood supply of, 3402
 composition of, 3406
 as deposition site, 3344–3445
 neptunyl ion, 3404
 plutonium (IV), 3403
 retention of, 3404–3406
 surfaces of, 3401–3402
 uranyl ion, 3403
 cyclopentadienyl complexes of, 1952–1959
 3 ligands + X, 1956–1957
 4 ligands, 1953–1954
 ‘base-free’ 3 ligands, 1954–1956, 1955f
 metal-metal bonds, 1958–1959
 mixed ligands, 1957–1958
 overview of, 1952–1953, 1953f
 structure of, 1953, 1953f
 definition of, 18
 discovery of, 4, 5f–7f, 8–10
 divalent, 2525–2526
 electronic structures of, 2024, 2024t
 observed spectra of, 2077–2079
 electronic structures of, 1770–1773,
 1842t–1850t, 1851–1860, 1851f,
 1894–1897, 1896f–1897f, 1896t–1897t
 crystal-field interaction, 2036–2056
 determination of, 1858–1860, 1860f
 energies of, 1853–1858, 1854f, 1855t,
 1856f, 1859f
 free-ion interactions, 2020–2036
 general considerations, 1770
 periodic table position, 1773, 1774f
 redox potentials *v.*, 1859–1860, 1860f
 relative energies, 2016–2020
 relativistic approaches for, 1902–1914
 relativistic effects on, 1898–1900
 spectroscopic studies, 1770–1771
 structure, 1771–1773, 1772t, 1773f
 electrorecovery of, 2719–2721
 elution of, 1625f
 entropy of, 2539, 2542f, 2543t
 in environment, 3013–3014, 3015f
 analytical techniques for, 3018–3020,
 3019t
 anthropogenic, 3016
 dispersal of, 3016–3017
 mining, 3017
 natural occurrence, 3014–3016, 3015f
 separation of, 3021
 environmental aspects of, 1803–1813
 in hydrosphere, 1807–1810
 man-made, 1805–1807
 of natural origin, 1804–1805
 nuclear waste disposal, 1811–1813
 overview of, 1803
 sorption and mobility, 1810–1811
 experimental techniques, 1764–1769
 column partition chromatography, 1769
 hazards, 1764–1765
 ion-exchange chromatography,
 1767–1768, 1768f
 liquid-liquid extraction, 1768–1769
 long-lived nuclides, 1765–1766
 tracer techniques, 1766
 ultramicrochemical manipulation, 1767
 extraction of
 DIDPA, 1276
 HDEHP, 1275
 organophosphorus and
 carbamoylphosphonate reagents,
 1276–1278
 reductive, 2719
 stripping of, 1280–1281
 TRPO, 1274–1275
 f-d promotion energies of, 1560, 1561f,
 1586–1588, 1587f
 ground state configuration of, 1895, 1897t
 heptavalent, 2527
 hexavalent, 2527
 cyclopentadienyl complexes, 2847–2851
 energy levels, 2081–2082, 2083t, 2084f
 hydrolytic behavior of, 2553–2556,
 2554f–2555f, 2554t–2555t
 observed spectra of, 2079–2085, 2080t
 stability constants of, 2571–2572, 2573f
 ionization potentials of
 by laser spectroscopy, 1873–1875, 1874t
 by RIMS, 1875–1879, 1877t,
 1878f–1879f
 lanthanide elements *v.*, 2, 10–11
 atomic volume, 1578–1579, 1578f
 bonding in, 584–585
 extraction from, 1286–1289, 1407
 free-ion interaction and crystal-field
 strength, 2062–2064, 2063t
 ligand displacement series for, 2806
 phonon energy relaxation, 2096

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Actinide elements (*Contd.*)
 relativistic effects on, 1898, 1899f
 separation from, 2635, 2635f
 lanthanide separation from, 2669–2677, 2757–2760
 Cyanex 301, 2675–2676
 dithiophosphinic acids, 2676
 LIX–63, 2759–2760
 process applications, 2670–2671
 separation factors for, 2669–2670, 2670t
 soft-donor complexants for, 2670–2671, 2673
 sulfur donor extractants, 2676–2677, 2677t
 TALSPEAK, 2671–2673, 2672f, 2760
 TPTZ, 2673–2675, 2674t
 TRAMEX process, 2758–2759, 2759f
 laser spectroscopy of, 1873
 ionization potentials by, 1873–1875, 1874t
 super-deformed fission isomers of americium, 1880–1884, 1881f, 1883f–1884f, 1883t
 ligand bonding of, 1900–1901
 long-lived, 1763, 1764t
 lowest level of configurations of, 1841, 1842t–1850t
 magnetism in, 2354–2356
 in mammalian tissues, 3339–3424
 binding in bone, 3406–3412
 bone, 3400–3406
 liver, 3395–3400
 matrix-isolated, 1967–1991
 binary carbonyls, 1984–1987
 carbide oxides, 1976–1984
 description of, 1968
 developments of, 1969
 dioxides, 1970–1976
 nitride-oxides, 1989–1991
 nitrides, 1987–1989
 overview of, 1968–1970
 metallic state and 5f-electron phenomena of, 2307–2373
 basic properties, 2313–2328
 cohesion properties, 2368–2371
 general observations, 2328–2333
 magnetism, 2353–2368
 overview of, 2309–2313
 strong correlations, 2341–2350
 strongly hybridized, 2333–2339
 superconductivity, 2350–2353
 weak correlations, 2339–2341
 metallic state of, 1–2, 964, 1784–1790
 crystal structure, 1785–1787, 1786t
 electronic structures, 1788–1789, 1789f
 polymorphic transformation, 1787
 preparation, 1784–1785
 properties of, 1786t
 superconductivity, 1789–1790
 natural occurrence of, 1755–1756, 1804–1805, 3014–3016, 3273, 3274t–3275t, 3276
 new properties of, 1872–1873
 optical spectra and electronic structure of, 2013–2103
 crystal-field interaction, 2036–2056
 divalent, 2077–2079
 free-ion interactions, 2020–2036
 penta- and hexavalent, 2079–2085, 2080t
 tetravalent, 2064–2076
 trivalent, 2056–2064
 f orbital in, 1894–1895, 1896f, 1896t
 overview of, 1–2, 2f
 oxidation states, 1774–1784
 complex-ion formation, 1782–1784
 hydrolysis and polymerization, 1778–1782
 ion types, 1777–1778, 1777t, 1779f, 1780t
 ions in aqueous solution, 1774–1776, 1775t
 parameters of, 1864–1866
 least-squares fitted values, 1864–1865, 1864f
 radial integral comparisons, 1865, 1866
 pentavalent, 2526–2527
 circulation clearance of, 3376–3379
 cyclopentadienyl complexes, 2845–2847
 energy levels, 2081–2082, 2083t, 2084f
 hydrolytic behavior of, 2552–2553
 initial distribution in mammalian tissues, 3350–3354
 observed spectra of, 2079–2085, 2080t
 plutonium oxidation and reduction by ions of, 1133–1137, 1134t–1135t
 practical applications, 1825–1829
 medical and other, 1828–1829
 neutron sources, 1827–1828
 nuclear power, 1826–1827
 portable power sources, 1827
 production of, 2729–2736
 bismuth phosphate process, 2730
 BUTEX process, 2731

autoreduction of, 1331
complexes of, carbonate, 1341
compounds of
halides, 1315
sulfates, 1321
electrode potentials of, 1329, 1329t
extraction of, HDEHP, 1275
hydrolysis, 1340
preparation of, 1326–1327
reduction of
by hydrogen peroxide, 1335
by other reductants, 1335
TBP extraction of, 1272
- Americium (vii)
absorption spectra of, 1367–1368, 1368f
electrode potentials of, 1329, 1329t
preparation of, 1327
- Americium antimonide, 1318
Americium bismuthide, 1318
Americium carbide
entropy of, 2196, 2197t
formation enthalpy of, 2195–2196, 2197t
high-temperature properties of, 2198, 2198f, 2199t
- Americium (v) carbonate, in americium precipitation, 1271
Americium carbonates, structural chemistry of, 2426–2427, 2427t
Americium chalcogenides, structural chemistry of, 2409–2414, 2412t–2413t
Americium dibromide, structure of, 2415
Americium dichloride, 2179, 2180t
structure of, 2415
Americium diiodide
magnetic properties of, 2266
structure of, 2415
Americium dioxide, 1303, 1313
enthalpy of formation, 2136–2137, 2137t, 2138f
entropy of, 2137–2138
EPR of, 2292
heat capacity of, 2138–2141, 2139f, 2142t
magnetic properties of, 2291–2292
phase relations of, 2396
phase transformation of, 2292
Americium (iii) fluoride, stability constants of, 1354–1355
Americium hexafluoride, thermodynamic properties of, 2164t
Americium hydrides
entropy of, 2188, 2189t
formation enthalpy of, 2187–2188, 2187t, 2189t, 2190f
high-temperature properties of, 2188–2190, 2190t
structure of, 2404
Americium monoxide, structure of, 2395
Americium nitride, 1317–1319
Americium oxalate, in americium precipitation, 1270–1271
Americium oxides
phase relations of, 2395–2396
structure of, 2395–2396
Americium oxyhalides, structural chemistry of, 2421, 2422t, 2423, 2424t–2426t
Americium phosphates, structural chemistry of, 2430–2433, 2431t–2432t
Americium phosphide, 1318
Americium pnictides, structure of, 2409–2414, 2410t–2411t
Americium sesquioxide
formation enthalpy of, 2143–2146, 2144t, 2145f
high-temperature properties of, 2139f, 2146–2147
structure of, 2395, 2396t
Americium sesquisulfide, 1316–1317
Americium sulfates, structural chemistry of, 2433–2436, 2434t
Americium tetrahalides, structural chemistry of, 2416, 2418t
Americium (iii) thiocyanate, 1355
Americium trichloride,
thermodynamic properties of, 2170t, 2172, 2173t
Americium trihalides, structural chemistry of, 2416, 2417t
Americium tritelluride, 1317

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Diamide extractants
 actinide extraction with, 1285–1286, 1408
 overview of, 1285
- 1,2-Diaminocyclohexane tetraacetic acid (DCTA)
 fermium complexes with, 1629
 mendelevium complexes with, 1635
- Diamyl(aryl)phosphonate (DAAP)
 for THOREX process, 2736
 in U/TEVA•Spec, 3284
- 1,3-Diazidobenzene, cyclopentadienyl complex reaction with, 2809, 2810f
- 1,4-Diazidobenzene, cyclopentadienyl complex reaction with, 2809, 2810f
- DIBC, protactinium extraction with, 182, 188
- Dibenzoylmethane (DBM), actinide extraction with, 3287
- Dibenzyl sulfoxide, for protactinium extraction, 181–182
- DIBK, protactinium extraction with, 182
- Dibutyl butylphosphonate (DBBP), americium extraction with, 1274
- Dibutyl-*N,N*-diethylcarbamylphosphonate (DDCP), extraction with, 3282

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Dibutylphosphoric acid (HDBP), separation with, 2650
- Dicarbollide ligands, 2868–2869
cyclopentadienyl *v.*, 2868
generation of, 2868–2869
geometry of, 2868
- Dicarboxylic acids, in plasma, 3360–3361
- 5,7-Dichloro-8-hydroxyquinoline,
californium extraction with, 1513
- DIDPA. *See* Diisodecylphosphoric acid
- N,N*-Diethyl hydroxylamine (DEH),
neptunium (vi) reduction with, 761
- Diethylenetriamine pentaacetate (DTPA)
americium separation with, 2671–2672
in bone binding study, 3408–3409
as chelating agent, 3413–3114
curium separation with, 1409, 2672
extraction with, 3282
plutonium complex with, 1176–1177, 1178t,
1179–1181
for removal, 1823
for plutonium removal, with DFO, 1824
separation with, 2640–2641
- Differential pulse polarography (DPP), for
environmental actinides, 3049t, 3052,
3053f
- Differential pulse voltammetry (DPV), for
environmental actinides, 3049t, 3052,
3053f
- Diffusion rates
of einsteinium, 1606
of plutonium, 958–960, 959t
- Diglycolamides, for solvating extractant
system, 2659–2660
- Dihalides
structural chemistry of, 2415–2416
thermodynamic properties of, 2178–2179,
2180t–2181t, 2181f
gaseous, 2179
solid, 2178–2179
- Dihexyl-*N,N*-diethylcarbamoylmethyl
phosphonate (DHDECMP)
in actinide production, 2737–2738
americium extraction with, 1277–1278
extractant comparison with, 2763–2764,
2763t
in solvating extractant system, 2655, 2656t
- Di-isobutylketone (DIPK), protactinium
extraction with, 176, 178, 182, 188
- Diisodecylphosphoric acid (DIDPA)
actinide extraction with, 2753–2756
flow sheet for, 2755, 2755f
overview of, 2753–2755, 2755f
tests for, 2755–2756
americium extraction with, 1276
extractant comparison with, 2763–2764,
2763t
neptunium extraction with, 713
- Di-isopropylcarbinol (DIPC), protactinium
extraction with, 175
- β -Diketone
complexes
of actinide elements, 1783
of californium, 1554
of fermium, 1629
for oxidation state speciation, 2726
separation with, 2632, 2680
TTA *v.*, 2650
- Dimethyl oxalate, actinium precipitation
with, 38
- Dimethyl sulfoxide (DMSO), for
protactinium extraction, 181–182
- 1,1-Dimethylhydrazine (DMHz), neptunium
(vi) reduction with, 761
- N,N*-Dimethyl-*N',N'*-dibutyl-2-
hexoxyethylmalonamide, actinide
extraction with, 1769
- N,N*-Dimethyl-*N,N*-dibutyl-2-tetradecyl
malonamide (DMDBTDMA)
actinide extraction with, 1285–1286,
2658–2659, 2756
extractant comparison with, 2763–2764,
2763t
- N,N'*-Dimethyl-*N,N'*-dibutyldodecyloxyethyl
malonamide (DMDBDDEMA),
actinide extraction with, 2658
- N,N'*-Dimethyl-*N,N'*-dioctylhexyloxyethyl
malonamide (DMDOHEMA),
actinide extraction with, 2658
- Dimitrovgrad Dry Process (DDP)
applications, separation efficiency in,
2707–2708
dissolution for, 2705
minor actinide behavior in, 2706–2707,
2707f
for MOX fuel reprocessing, 2692–2693
uranium and plutonium recovery,
2705–2706
- Di-*n*-hexyl hexanamide (DHHA), for
THOREX process, 2736
- Dinonylnaphthalene sulfonic acid (HDNNS),
americium extraction with, 1286–1287,
2673–2675, 2674t
- Dioxide dichloride, of uranium, 567–570
- Dioxides
magnetic properties of, 2272–2294
americium, 2291–2292
curium, 2292–2293
neptunium, 2282–2288
plutonium, 2288–2290
uranium, 2272–2282
of plutonium, reactions of, 3219–3222
thermodynamic properties of, 2136–2143
enthalpy of formation, 2136–2137, 2137t,
2138f
entropy, 2137–2138

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Dioxides (*Contd.*)
 high-temperature properties, 2138–2141, 2139f, 2142t
 nonstoichiometry, 2141–2143
- Dioxouranium (v), aqua ions of, 594t, 595
- Dioxouranium (vi), aqua ions of, 594t, 596, 596f
- DIPC. *See* Di-isopropylcarbinol
- DIPEX resin
 for americium extraction, 1294
 for separation, 3284–3285
- Diphenyl sulfoxide, for protactinium extraction, 181–182
- Diphenyl-*N,N*-dibutylcarbonylmethylenephosphine oxide (D Φ DBuCMPO), in TRUEX process, 1283, 2739
- Diphonix resin
 for actinide extraction, 716
 for americium extraction, 1293–1294
 for ion exchange, 2642–2643, 2643f
- Dipicolinates, structural chemistry of, 2441t–2443t, 2446–2447, 2446f
- Dipivaloylmethanato complex, of californium, 1541
- DIPK. *See* Di-isobutylketone
- Dirac equation, for relativistic methods, 1904–1905
- Dirac-Coulomb-Breit (DCB) Hamiltonian, for relativistic treatments, 1670
- Dirac-Fock (DF)
 for electronic structure calculation, 1670, 1900
 element 113–184 ground state configurations, 1722, 1722t
 RECPs with, 1907–1908
- Dirac-Fock linear combination of atomic orbitals (DF-LCAO), for electronic structure calculation, 1670–1671
- Dirac-Hartree-Fock calculations, on uranyl, 1917–1918
- Dirac-HF methods, equations for, 1905
- Dirac-Kohn-Sham methods, equations for, 1905
- Dirac-Slater discrete-variational method (DS-DV method), for electronic structure calculation, 1671
- Dirac-Slater (DS) method, for electronic structure calculation, 1670
- Direct oxide reduction (DOR)
 MSE *v.*, 869
 for plutonium metal production, 866–869, 868f–869f
 furnace for, 868f
 process for, 866–868
 results of, 868–869, 869f
- in pyroprocessing, 2694
 pyroredox *v.*, 875
 use of, 2692

reprocessing of, 704
DMDBDMA, 2756
n-Octyl(phenyl)-*N,N*-diisobutylcarbamoyl methylphosphine oxide for, 1407–1408
Purex process for, 710–712, 710f, 1273–1276, 1285
TRPO for, 2753, 2754t
TRUEX process for, 1275, 2740–2745
uranium in, 270
- Highly enriched uranium (HEU)
description of, 1755
production and use of, 1755–1758
- High-performance liquid chromatography (HPLC)
ARCA with, 1665
berkelium separation with, 1449–1450, 1450f
curium separation with, 1433
einsteinium separation with, 1585
ICPMS and, 3068–3069, 3068f
for separation, 3281
- High-purity germanium detector (HPGe)
for gamma-spectroscopy, 3297–3299, 3299f
for uranium analysis, 635
- High-purity product refinement, of uranium ore, 314–317, 315f–316f, 317t
- High-temperature properties
of carbides, 2198, 2198f, 2199t
of dioxides, 2138–2141, 2139f, 2142t
of halides, 2162t–2163t
of hexahalides, 2162t–2163t
of hydrides, 2188–2190, 2190t
ions in condensed phase, 2116–2118, 2117t, 2119t–2120t, 2121f
of nitrides, 2199t, 2202
of oxides
with alkali metals, 2151–2153
with alkaline earth metals, 2157, 2158t
of oxyhalides, 2182, 2183t–2184t, 2186t–2187t
of pentahalides, 2162t–2163t
of sesquioxides, 2139f, 2146–2147
of tetrahalides, 2166t, 2167–2168
of transition metal compounds, 2207t, 2208f, 2211
of trihalides, 2162t–2163t, 2176–2177, 2177f
- Hill plot, for uranium compounds, 2331–2333, 2332f
- HLLW. *See* High-level liquid waste

 chemical properties of, 336–337, 337t
 crystal structures of, 329–330, 329t
 electrical resistivity, 333
 magnetic properties and bonding of, 333–336, 334f, 335t
 other compounds of, 337–339
 phase relations and dissociation pressures of, 330–332, 330f–331f
 preparative methods for, 329
 reactions of, 337, 337t
 thermodynamic properties, 332–333, 332t
 use of, 333
 Hydrobiotite, uranyl-loaded, 3156
 Hydrobromic acid, rutherfordium extraction with, 1697–1698
 Hydrocarbyls, of neptunium, 752
 Hydrochloric acid
 curium separation in, 1409
 dubnium separation in, 1705
 plutonium processing in, 836
 rutherfordium extraction with, 1696–1699
 uranates (v) and (iv) dissolution in, 381–382
 uranium
 compound dissolution in, 632
 metal reactions with, 328
 oxide reactions with, 370–371
 Hydrofluoric acid
 protactinium (iv) precipitation by, 222
 as protactinium solvent, 176, 178–179
 rutherfordium extraction with, 1699–1700
 Hydrofluorination, of uranium, 319, 320f
 Hydrogen
 plutonium
 corrosion by, 977–979
 hydrides reaction with, 3215–3216
 metal reaction with, 3223–3225, 3224f
 and water formation of, 3250
 radiolytic formation of, 3246–3247
 hazards of, 3248–3249
 uranium
 metal solubility of, 330f, 331–332
 reaction with, 3239–3242, 3240f, 3241t
 Hydrogen peroxide
 berkelium extraction with, 1448
 protactinium extraction with, 175, 179
 reduction by
 americium (v), 1335–1336
 americium (vi), 1335
 UO₂ dissolution in, 371
 Hydrolytic behavior
 of actinide cations, 2545–2556, 2545f
 hexavalent, 2553–2556, 2554f–2555f, 2554t–2555t
 pentavalent, 2552–2553
 tetravalent, 2547–2552, 2549t–2550t, 2551f–2552f
 trivalent, 2546, 2547f, 2547t–2548t
 of actinide complexes, ternary, 2592–2593
 of actinide elements, 1555, 1778–1782, 1810–1811
 of americium, 1339–1340
 of berkelium, 1475–1479, 1477t–1478t
 of californium, californium (iii), 1554
 in mammalian body, 3340
 of neptunium, 766–770
 neptunium (iii), 768
 neptunium (iv), 768–769
 neptunium (v), 727, 769–770
 neptunium (vi), 770
 neptunium (vii), 770
 tendency towards, 766, 767t
 of 5f orbital, 3100
 of plutonium
 characterization of, 1146–1147
 importance of, 1146
 ions, 1110–1111
 nitrides, 1019
 plutonium (iii), 1147–1149, 1148t
 plutonium (iv), 1148t, 1149–1150, 1781
 plutonium (v), 1154–1155
 plutonium (vi), 1155–1156
 plutonium (vii), 1156
 stability of, 1146–1156
 of protactinium, 170–171, 179
 protactinium (iv), 222, 1780
 protactinium (v), 209–212, 210f, 211t, 212f, 1782
 of rutherfordium, 1701
 of seaborgium, 1711
 sorption process v., 1810
 of thorium, 119–120, 121t, 122f
 of transactinide elements, 1686–1687, 1687t
 of uranium
 aqueous complexes, 597–600, 599t
 carbides, 403–405
 pentavalent and complex halides, 501
 uranium (iv), 585–586, 1780–1781
 Hydrometallurgy, 2727–2729
 long-lived actinides in HLW, 2729, 2729t
 problem for, 2728–2729
 SNF overview, 2727–2728

- Hydrosilylation, organometallic intermediates
in, 2916–2918, 2917f
- Hydrosphere, actinide elements in, 1807–1810

of uranium oxides, 1971
XRD and, 3065
XRF and RAMS with, 3069
- Ingestion, of actinide elements, 1818–1820
- Inhalation, of actinide elements,
1818–1820
- Inner sphere, complexation, 2563–2566,
2566f, 2567t
confusion over, 2564
conversion to, 2564–2565
stability constant, 2565, 2566f
thermodynamic data, 2566, 2567f

- In-situ* Volatilization and On-line detection apparatus (IVO), for hassium study, 1713, 1714f
- Instrumental neutron activation analysis (INAA)
 applications of, 3303–3305
 description of, 3303
 ICPMS v., 3329
 RNNAs v., 3305–3306
 sensitivity of, 3305
 for uranium, 636
- Integral fast reactor (IFR)
 electrorefining with, 2713
 reprocessing in, 2713–2714
- Intense Pulsed Neutron Source (IPNS)
 of curium dioxide, 2292–2293
 of plutonium dioxide, 2289, 2290f
- Intermediate coupling
 for free-ion interactions modeling, 2023–2026
 overview of, 2023
- Intermetallic compounds
 of americium, 1302, 1304t
 of berkelium, 1461
 magnetic studies of, 2238, 2356–2361
 heavy-fermion materials, 2360
 high uranium content, 2357
 itinerant ferromagnets, 2358–2359
 low uranium concentration, 2359
 lower uranium content, 2358
 other compounds, 2360–2361
 very low uranium concentration, 2359–2360
- of plutonium, 862–987
 applications of, 862
 crystal structure data for, 899, 900t–915t
 electronic structure, theory, and modeling, 921–935
 history of, 862
 mechanical properties, 968–973
 nature of, 863
 overview of, 898–899
 oxidation and corrosion, 973–979
 physical and thermodynamic properties of, 935–968
- of uranium, 325–326, 325t
 hydrides as, 338–339
 molybdenum, 326, 326f
 noble metals, 325–326
 transition-metal compounds, 325
 x-ray crystallography for, 325
- Iodates
 of actinide elements, 1796
 of neptunium, equilibrium constants for, 773t
 of plutonium, 1172–1173
 of protactinium, gravimetric methods with, 230
- Iodides
 of actinide elements, 1796
 of berkelium, 1469
 of californium, 1533
 of neptunium, 738
 equilibrium constants for, 773t
 triiodide, 738
- of plutonium, 1092–1100
 preparation of, 1092–1095
 properties of, 1087t, 1098–1100
 solid-state structures of, 1084t, 1096–1097, 1096f–1098f
- protactinium derivatives of, 197–199, 207–208
- of uranium
 complexes, 498–499
 oxide and nitride, 499–500
 uranium tetraiodide, 497–498
 uranium triiodide, 454–455
- Ion exchange chromatography
 for actinide and lanthanide separation, 2669–2670
 for actinide element study, 1767–1768, 1768f
 actinium purification by, 18, 30–32
 for americium purification, 1289–1293
 anion-exchange resin systems, 1291–1292
 cation-exchange resin systems, 1290–1291
 inorganic exchangers, 1292–1293
- ARCA for microscale, 1665
 for berkelium extraction, 1449
 for californium separation, 1508–1509, 1510f, 1512
 for curium separation, 1409–1410
 deployment of, 846
 for einsteinium separation, 1585
 flow sheet for, 849, 850f
 improvements of, 851
 for metal ion separation, 846
- methods for
 anion exchange, 2635–2637, 2635f, 2642
 in aqueous phase, 2638
 cation exchange, 2636–2641, 2637f
 citric acid for, 2638–2639, 2639t
 Diphonix, 2642–2643, 2643f
 EDTA and HDEHP for, 2639–2640, 2641t
 α -HIBA for, 2639–2641, 2640f, 2641t
 historical development of, 2634–2635
 lactic acid for, 2639, 2639t, 2641t
 NTA and DTPA for, 2640–2641
 trivalent actinides from lanthanides, 2635, 2635f
- for neptunium extraction, 714
 operation of, 850–851
 overview of, 845–846
 for plutonium concentration, 845–852
 after extraction, 846–847

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

synthesis of, 725
- Neptunium disulfide
preparation of, 739
properties of, 739–740
- Neptunium hexafluoride
chemical behavior of, 733
crystal structure of, 731t
energy level analysis of, 2083–2085, 2083t, 2085f
lattice parameters of, 731t, 732
magnetic susceptibility of, 2243
physical properties of, 733
preparation of, 732–734
structural chemistry of, 2419, 2421, 2421t
studies of, 1938
thermodynamic properties of, 2160–2161, 2160t, 2162t–2164t
- Neptunium hydrides
entropy of, 2188, 2189t
formation enthalpy of, 2187–2188, 2187t, 2189t, 2190f
high-temperature properties of, 2188–2190, 2190t
structure of, 2403–2404
- Neptunium monophosphide, 743
- Neptunium monoxide
dissociative energy of, 2149–2150, 2150f
in gas-phase, 2148–2149, 2148t
structure of, 2394
- Neptunium nitride, 742–743
preparation of, 742–743
properties of, 743
- Neptunium oxides
structure of, 2394
thermodynamic properties of, 2136, 2136t
- Neptunium oxyhalides, structural chemistry of, 2421, 2422t, 2423, 2424t–2426t
- Neptunium pentafluoride, structural chemistry of, 2416, 2419, 2420t
crystal structure of, 731t
preparation of, 731–732
- Neptunium pentahalides, structural chemistry of, 2416, 2419, 2420t
- Neptunium pentaoxide, synthesis of, 726
- Neptunium pentasulfide
preparation of, 740
properties of, 740
- Neptunium phosphates, structural chemistry of, 2430–2433, 2431t–2432t
- Neptunium pnictides, structure of, 2409–2414, 2410t–2411t
- Neptunium series ($4n + 1$), 24f
actinium–225 in, 20, 24f
in nature, 27
thorium–229 from, 53
- Neptunium sesquioxide, formation enthalpy of, 2143–2146, 2144t, 2145f
- Neptunium sulfates, structural chemistry of, 2433–2436, 2434t
- Neptunium tetrabromide, preparation of, 737
- Neptunium tetrachloride
identification of, 737
magnetic properties of, 2258t, 2260–2261
oxychloride preparation from, 738
preparation of, 736
properties of, 736–737
- Neptunium tetrafluoride
absorption spectra of, 2068, 2070f
crystal structure of, 731t
preparation of, 730–731
thermodynamic properties of, 2165–2169, 2166t
- Neptunium tetrahalides, structural chemistry of, 2416, 2418t
- Neptunium tribromide, preparation of, 737–738
- Neptunium trichloride
oxychloride preparation from, 738
preparation of, 737

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Neptunium trifluoride
 crystal structure of, 731t
 preparation of, 730
- Neptunium trihalides, structural chemistry of, 2416, 2417t
- Neptunium triiodide, preparation of, 738
- Neptunium trisulfide
 preparation of, 740
 properties of, 740
- Neptunium-235
 stability of, 702
 synthesis of, 702–703
- Neptunium-236
 stability of, 702
 synthesis of, 702–703
- Neptunium-237
 absorption cross section of, 2233
 from americium-241, 1828
 detection of
 AMS, 3062–3063
 γ S, 3302
 ICPMS, 3327–3328
 limits to, 3071t
 MBAS, 3043
 MBES, 3028
 NAA, 3055–3057, 3056t, 3058f
 NMR, 3033
 PCNAA, 3307
 α S, 3294–3295
 TIMS, 3314–3315
 determination of, 705, 706f, 783–785
 with ICPMS, 789, 790f
 DIDPA extraction of, 1276
 environmental hazards of, 1807
 half-life of, 700, 703
 mössbauer spectroscopy of, 793
 natural occurrence of, 704, 782–783, 1756
 from neutron irradiation, 1756–1757
 nuclear properties of, 3277t
 plutonium-236 and 238 from, 703, 817, 1758
 from plutonium-241, 705, 706f, 783–785
 protactinium-233 from, 171
 significance of, 700
 SIMS of, 788–789
 synthesis of, 701–703
 toxicity of, 1820
- Neptunium-238
 half-life of, 702
 nuclear properties of, 3277t
- Neptunium-239
 detection of, INAA, 3304–3305
 determination of, 784
 half-life of, 702
 natural occurrence of, 704, 1756
 nuclear properties of, 3277t
 SIMS of, 788–789
 synthesis of, 702
 from uranium-238, 702, 704
 from uranium-239, 255
- Neptunocene
 properties of, 1946–1948
 structure of, 2486, 2488t
- Neptunyl (v)
 disproportionation of, 759
 speciation of, 3111t–3112t, 3121–3122, 3133–3134
 stability constants of, 2571, 2572f
- Neptunyl (vi), speciation of, 3111t–3112t, 3122–3123
- Neptunyl ion
 aqueous solution absorption spectra of, 2080, 2081f
 charge-transfer transition of, 2089
 complexes of
 porphyrins and phthalocyanines, 2464t, 2465–2466, 2466f–2467f
 structure of, 2400–2402
 complexes with, 1923
 crown ether complex of, 2449t, 2450
 in DDP, 2706
 formates of, 2257
 hydration number of, 2531, 2533t
 hydrolytic behavior of, 2553
 ligands for, 3422–3423
 magnetic properties of, 2240–2247, 2255t
 in mammalian tissues
 bone, 3404
 circulation clearance of, 3368–3369, 3368f–3375f, 3377, 3384–3386
 initial distribution, 3342t–3344t, 3355–3356
 transferrin binding to, 3364
 reduction of, 2591
 stability constants of, 2576, 2576f
 study of, 1931, 1933
- Nernst analysis
 of berkelium (iv) and (iii), 3108
 of neptunium (iv) and (iii), 3108
- Nernst equation, for aqueous actinide elements, 3097–3098
- Nernst plot
 for aqueous actinide elements, 3099, 3099f
 of neptunium, 3099, 3099f, 3108
- Network structures, factors in, 579
- Neutralized cladding removal waste (NCRW), TRUEx process for, 2740
- Neutron activation analysis (NAA)
 for berkelium, 1484
 californium-252 for, 1828
 for environmental actinides, 3055–3057, 3056t, 3058f
 fundamentals of, 3302–3303
 INNA, 3303–3305
 for neptunium, 785–786, 789
 RNNA, 3305–3307

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Neutron activation analysis (NAA) (*Contd.*)
for trace analysis, 3302–3307
for uranium, 635–636
- Neutron capture
in actinide elements, 1828
berkelium, 1444
curium
curium–244, 1400
production of, 1400
einsteinium from, 1582
plutonium
isotope formation, 825–826, 825f
plutonium–239 formation with, 823–824
- Neutron crystallography, for electronic structure, 1770
- Neutron diffraction
for coordination geometry study, 602–603
description of, 2383
for hydration study, 2528
sources for, 2383
for structural chemistry, 2383–2384
types of, 2383–2384
X-ray diffraction *v.*, 2383
- Neutron emissions
from actinide elements, 1827–1828
actinium for, 43
californium–252 for, 1505–1507, 1506t
californium–254 for, 1505, 1506t
curium–248 for, 1505, 1506t
- Neutron irradiation
for actinide and transactinide element production, 1756–1761, 1761t
actinium from, 1756
of americium, 1268
of californium–252, 1507
neptunium from, 1757
in nuclear power, 1826–1827
of plutonium, 1757
protactinium from, 1756
for SNF transmutation, 1811–1812
of uranium, 3–4, 1756–1757
- Neutron scattering
for actinide element study, 14
advantages of, 2232–2233
disadvantages of, 2233–2234
history of, 2232
magnetic dipole moment and, 2232
of neptunium dioxide, 2284–2286, 2285f–2286f
RXS *v.*, sample size, 2237–2238
of uranium
dioxide, 2274, 2285–2286, 2286f
tetrachloride, 2248, 2250f
x-ray scattering *v.*, sample size, 2233–2234
- Neutron spectroscopy (NS), for environmental actinides, 3026t, 3029
- Neutrons
in actinide synthesis, 3–4, 8–9
thermonuclear device production of, 9
- NFL. *See* Non-Fermi liquid
- Nickel, plutonium melting point and, 897
- Ningyoite, uranium in, 259t–269t, 275
- Niobates, of uranium, uranium (iv), 277–280
- Niobium foil, berkelium adsorption on, 1451
- Niobium, protactinium purification from, 178–186
ion exchange, 180–181, 180f
precipitation and crystallization, 178–186
solvent extraction and extraction chromatography, 181–186, 183f
- NIR-VIS. *See* Near-infrared and visible spectroscopy

- Plutonium (III) (*Contd.*)
 preparation and stability of, 1125, 1131
 oxoplutonates of, alkaline earth metals, 1058
 precipitation with
 fluoride, 838
 oxalate, 836–837
 reduction potentials of, 2715, 2716f
 reduction to metal, 870–872, 873f
 speciation of, 3113t, 3117–3118
 structure of, 593
- Plutonium (IV)
 absorption spectrum of, 849
 adsorption of, *B. sphaericus*, 3182–3183
 anion-exchange chromatography for, 848–849, 848f
 in biological systems, 1819
 compounds of
 carbonate of, 1162–1163
 carboxylates, 1177–1180, 1178t
 hydroxide, 838
 iodates, 1172–1173
 nitrates of, 1167–1168
 oxalate, 837, 1174–1175
 peroxide, 837–838, 1175–1176
 perrhenates, 1068
 phosphates, 1171–1172
 sulfates of, 1169–1170
 vanadates, 1069
 coordination numbers of, 1112
 detection of, limits to, 3071t
 disproportionation of, 1119–1122
 distribution coefficients of, 842, 842t, 848, 848f
 extraction of, DHDECMP, 2737–2738
 free-ion parameters of, 2038–2039, 2038t
 hydrolytic behavior of, 1148t, 1149–1150
 ligands for, 3417–3420, 3420f
 magnetic properties of, 2261–2262
 magnetic susceptibilities, 2261–2262
 in mammalian tissues
 bone, 3403
 bone binding, 3407–3409
 circulation clearance of, 3368–3369, 3368f–3375f, 3378
 glycoproteins, 3410–3411, 3411t
 initial distribution, 3341t–3344t, 3346t, 3352–3353
 liver, 3398–3400
 transferrin binding to, 3364, 3365
 natural occurrence of
 in hydrosphere, 1807–1810
 sorption and mobility, 1810
 oligomerized, 3210–3211
 oxidation state
 equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
 preparation and stability of, 1131–1132
 oxoplutonates of
 alkali metals, 1056
 alkaline earth metals, 1058
 crystallographic data of, 1060t–1061t
 polymerization of, 1150–1154, 1151f, 1153f
 applications of, 1150
 characterization of, 1152–1153
 history of, 1151–1152
 precipitation with
 hydroxide, 838
 oxalate, 837
 peroxide, 837–838
 reduction of, 1139–1140
 rutherfordium extraction with, 1697–1698
 separation of
 HDEHP for, 2651, 2651f
 PUREX process, 2732
 from SNF, 2646
 solvating extractant system for, 2654–2655
 speciation of, 3108–3109, 3113t, 3136
- Plutonium (V)
 adsorption, *B. sphaericus*, 3182–3183
 compounds of
 carbonate of, 1163–1165
 carboxylates, 1178t, 1180–1181
 nitrates of, 1168
 oxalate, 1175
 peroxide, 1175–1176
 phosphates, 1172
 coordination numbers of, 1112
 disproportionation of, 1122–1123
 hydrolytic behavior of, 1154–1155
 in hydrosphere, 1807–1810
 magnetic properties of, 2257–2261
 oxidation state
 equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
 preparation and stability of, 1132
 oxoplutonates of
 alkali metals, 1056
 alkaline earth metals, 1058
 crystallographic data of, 1060t–1061t
 with pyrochemical processes, 2698–2699, 2699f
 reduction of, 1143
- Plutonium (VI)
 adsorption, *B. sphaericus*, 3182–3183
 compounds of
 carbonate of, 1165–1166
 carboxylates, 1178t, 1180–1181
 iodates, 1173
 nitrates of, 1167–1168
 peroxide, 1175–1176
 phosphates, 1172
 distribution coefficients of, 842, 842t
 hydrolytic behavior of, 1155–1156
 magnetic properties of, 2247–2257

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- manganite and hausmannite reactions with, 3176–3177
- oxidation state
equilibrium of, 1123–1125, 1124f–1125f, 1126t–1130t
preparation and stability of, 1132
- oxoplutonates of
alkali metals, 1057
alkaline earth metals, 1058–1059
crystallographic data of, 1060t–1061t
oxygen exchange with solvent water, 1133
with pyrochemical processes, 2698–2699, 2699f
- reduction of, 1138–1139, 1142–1143
alpha-induced, 1145–1146, 1146t
kinetics, 760–761
- separation of, PUREX process, 2732
- speciation of, 3113t, 3126
- Plutonium (vii)
coordination numbers of, 1112–1113
hydrolytic behavior of, 1156
magnetic properties of, 2240–2247
oxidation state, preparation and stability of, 1132–1133
- oxoplutonates of
alkali metals, 1057
alkaline earth metals, 1059
crystallographic data of, 1060t–1061t
speciation of, 3113t, 3126
- Plutonium carbide
entropy of, 2196, 2197t
formation enthalpy of, 2195–2196, 2197t
high-temperature properties of, 2198, 2198f, 2199t
- Plutonium carbonates, structural chemistry of, 2426–2427, 2427t, 2428f
- Plutonium chalcogenides, structural chemistry of, 2409–2414, 2412t–2413t
- Plutonium diboride, 999t, 1000, 1000f
- Plutonium dicarbide
chemical properties of, 1008
structure of, 1005t, 1006–1007, 1007f
- Plutonium dioxide
covalency in, 1196–1199, 1197f, 1200f
crystal structure of, 2289–2290
crystal-field splittings of, 2288–2289
electronic structure of, 1044, 1196–1199, 1197f, 1200f, 1976
gas pressure generation with, 3248–3251
in gas-phase, 2148t, 2149
handling of, 3201
hazards of, 3249
IPNS of, 2289, 2290f
JT effect of, 2290
magnetic properties of, 2288–2290
magnetic susceptibility of, 2290, 2291f
oxidation of plutonium metal, 973, 3229
physical properties of, 1032, 1032t
- plutonium metal production from, 866
preparation of, 1031–1034
pellets, 1032–1033
single crystals, 1033–1034
spheres, 1033
reactions of, 3219–3222
stability of, 3200
storage of, 3201
structure of, 1027t, 1037, 1038f, 1041–1044, 1042f–1043f, 2395
thermodynamic properties of, 1047t, 1048, 3250
enthalpy of formation, 2136–2137, 2137t, 2138f
entropy of, 2137–2138
heat capacity of, 2138–2141, 2139f, 2142t
XPS of, 861
- Plutonium disilicide, structure of, 1015, 1016f
- Plutonium dodecaboride, 999t, 1002, 1002f
- Plutonium finishing plant (PFP), TRUEX process at, 2740, 2741f
- Plutonium fluorides, 1077–1092
chemical properties of, 1092
precipitation with, 838
preparation of, 1077–1082
overview of, 1077–1078
plutonium hexafluoride, 1080–1082, 1081f
plutonium pentafluoride, 1079–1080
plutonium tetrafluoride, 1078–1079
plutonium trifluoride, 1078
properties of, 1083–1092
radiation decomposition of, 1090–1092
solid-state structures of, 1082–1083, 1084t, 1085f
plutonium hexafluoride, 1083, 1084t
plutonium tetrafluoride, 1083, 1084t, 1085f
plutonium trifluoride, 1082, 1084t
- Plutonium halides, 1077–1108
chlorides, bromides, and iodides, 1092–1100
preparation of, 1092–1095
properties of, 1098–1100
solid-state structures of, 1096–1097
- fluorides, 1077–1092
preparation of, 1077–1082
properties of, 1083–1092
solid-state structures of, 1082–1083
- oxyhalides of, 1100–1102
preparation and properties of, 1101–1102
solid-state structures of, 1102
stability of, 1077
- ternary halogenoplutonates, 1102–1108
phase diagram of, 1104, 1108f
preparation of, 1103–1104
- Plutonium heptaboride, 999t, 1002
- Plutonium hexaboride, 999t, 1001–1002, 1002f

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Plutonium hexafluoride
 absorption spectra of, 2084–2085.2086f
 chemical properties of, 1092
 covalency in, 1193–1196
 electronic structure of, 1194–1196, 1195f
 energy level analysis of, 2083–2085, 2083t, 2085f
 preparation of, 1080–1082, 1081f
 properties of, 1086–1090, 1087t
 radiation decomposition of, 1090–1092
 structure of, 1083, 1084t, 2419, 2421, 2421t
 studies of, 1938
 thermodynamic properties of, 2160–2161, 2160t, 2162t–2164t
- Plutonium hydrides
 air reaction with, 3218
 electrical properties of, 3205
 entropy of, 2188, 2189t
 formation enthalpy of, 2187–2188, 2187t, 2189t, 2190f
 high-temperature properties of, 2188–2190, 2190t
 hydrogen reaction with, 3215–3216
 nitrogen reaction with, 3217–3218
 oxygen reaction with, 3216–3217
 phase diagram of, 990, 991f–992f, 3204–3205, 3205f
 reaction rates of, 3215
 structure of, 2403–2404
 thermodynamic properties of, 3205, 3206t
 water reaction with, 3219, 3229
- Plutonium hydroxides, 3213
 precipitation with, 838
- Plutonium monocarbide
 chemical properties of, 1007–1008
 structure of, 1004–1006, 1005t
- Plutonium monophosphide, 1021–1022
- Plutonium monosilicide, structure of, 1014, 1015f
- Plutonium monoxide
 dissociative energy of, 2149–2150, 2150f
 in gas-phase, 2148t, 2149
 physical properties of, 1028
 preparation of, 1028–1029
 structure of, 2394–2395
- Plutonium nitride, 3212–3213
 enthalpy of formation of, 2197t, 2200–2201
 entropy of, 2197t, 2201–2202
 high-temperature properties of, 2199t, 2202
 reactions of, 3222–3223
- Plutonium oxalate, precipitation with, 837
- Plutonium oxides, 1023–1049, 3206–3212
 applications of, 1023–1025
 container material compatibility with, 1049
 dioxide, 1031–1034
 formation enthalpies of, 1971
 hazards of, 3257–3258, 3258t
 interface of, 976–977, 978f
 monoxide, 1028–1029
 phase diagram of, 1025, 1026f, 1039–1041, 1040f, 1071–1073, 1073f, 3206–3208, 3207f, 3211–3212, 3211f
 phase equilibria, 1025–1026, 1026f
 plutonium (VIII), 1932–1933
 preparation of, 1028–1036, 3206–3207
 higher oxides, 1034–1036
 plutonium dioxide, 1031–1034
 plutonium monoxide, 1028–1029
 plutonium sesquioxide, 1029–1031
 properties of
 chemical, 1048–1049
 melting behavior, 1045
 oxygen diffusion, 1044–1045
 thermodynamic properties, 1047–1048, 1047t
 vaporization behavior, 1045–1047, 1046f
 reaction rates of, 3219–3222
 safe storage, 3260–3262, 3261f
 sesquioxide, 1029–1031
 sesquioxide phase with, 3208
 solid-state structures of, 1027t, 1036–1044, 1038f–1040f, 1042f–1043f
 stability of, 3207
 structure of, 2394–2395
 ternary
 with actinides, 1070–1077
 with lanthanide oxides, 1069–1070
 thermal decomposition of, 3211
 thorium oxides with, 1070–1071
 uranium oxides with, 1070–1077
 applications of, 1070–1071
 phase diagram of, 1071–1073, 1073f
 preparation of, 1073–1074
 properties of, 1074–1077
- Plutonium oxyhalides, structural chemistry of, 2421, 2422t, 2423, 2424t–2426t
- Plutonium pentafluoride, preparation of, 1079–1080
- Plutonium peroxide, precipitation with, 837–838
- Plutonium phosphates, structural chemistry of, 2430–2433, 2431t–2432t
- Plutonium pnictides, structure of, 2409–2414, 2410t–2411t
- Plutonium sesquioxide
 formation enthalpy of, 2143–2146, 2144t, 2145f
 high-temperature properties of, 2139f, 2146–2147
 layer formation, 3208
 oxide phase with, 3208
 phase relationships of, 3207
 physical properties of, 1030
 preparation of, 1029–1031
 reactions of, 3219

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- structure of, 1027t, 1037–1038, 1038f–1039f, 2395
thermodynamic properties of, 1047–1048, 1047t
- Plutonium silicides, structural chemistry of, 2406t, 2408
- Plutonium sulfates, structural chemistry of, 2433–2436, 2434t
- Plutonium tetraboride, 999t, 1000–1001, 1001f
- Plutonium tetrachloride
preparation of, 1093–1094, 1094f
stabilization of, 1184
- Plutonium tetrafluoride
plutonium metal from, 866
from plutonium with americium–241, 1270
preparation of, 1078–1079
properties of, 1085–1086, 1087t
structure of, 1083, 1084t, 1085f
thermodynamic properties of, 2165–2169, 2166t
- Plutonium tetrahalides, structural chemistry of, 2416, 2418t
- Plutonium tribromide
organic-solvent soluble, 1182–1183
preparation of, 1095
properties of, 1087t, 1098–1100, 1099t
solid-state structure of, 1084t, 1096–1097, 1097f–1098f
structural chemistry of, 2416, 2417t
- Plutonium trichloride
magnetic properties of, 2262
organic-solvent soluble, 1182–1183
preparation of, 1092–1093
properties of, 1087t, 1098–1100, 1099t
solid-state structure of, 1084t, 1096, 1096f, 1098f
- Plutonium trifluoride
organic-solvent soluble, 1182–1183
preparation of, 1078
properties of, 1083–1085, 1087t
structure of, 1082, 1084t
thermodynamic properties of, 2169, 2170t–2171t
- Plutonium trihalides, structural chemistry of, 2416, 2417t
- Plutonium triiodide
organic-solvent soluble, 1182–1183
preparation of, 1095
solid-state structure of, 1084t, 1096–1097
- Plutonium tritelluride, structure of, 1053, 1053f
- Plutonium, Uranium, Reduction, Extraction process. *See* PUREX process
- Plutonium-231, discovery of, 815
- Plutonium-236
detection of, α S, 3295
from neptunium-237, 703
nuclear properties of, 3277t
ultrapure preparation of, 822
- Plutonium-237, ultrapure preparation of, 822
- Plutonium-238
applications of, 817–819
curium-242 and -244 v., 1400
detection of
limits to, 3071t
RIMS, 3321
 α S, 3295
discovery of, 814–815, 817
as energy production by-product, 1805
half-life of, 815, 817
as heat source, 703, 1758
Mössbauer spectroscopy of, 861
from neptunium–237, 703
from neptunium–238, 861
nuclear properties of, 3277t
for power generation, 1827–1828
uranium–234 from, 257
- Plutonium–239
absorption cross section of, 2233
americium–241 from, 1268, 1758
critical parameters of, 820–821, 821t
curium from, 1758–1759
detection of
AMS, 3062–3063, 3319
FTA, 3307
 γ S, 3302
ICPMS, 3327–3328
limits to, 3071t
RIMS, 3321
 α S, 3295
TIMS, 3314
discovery of, 815
environmental hazards of, 1807
half-life of, 820
heat capacity of, 945
importance of, 820
ionization potential of, 1875
IP of, 859
maximum allowed dose of, 1821
Mössbauer spectroscopy of, 861–862
natural occurrence of, 822–824, 823t, 1756
neutron capture formation of, 823–824
nuclear energy with, 815
nuclear properties of, 3277t
for nuclear weapons, 1805
production of
from neptunium–239, 861
in nuclear reactor, 1826
from uranium–239, 255, 1757
radioactivity of, 1765
security risk of, 1758
study with, 1765
toxicity of, 1820
transmutation products of, 984–985, 985f
- Plutonium–240
detection of
AMS, 3319

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Plutonium–240 (*Contd.*)

 as energy production by-product, 1805
 Fourier transform spectrum of, 858, 858f
 heat capacity of, 947, 947f
 nuclear properties of, 3277t
 study with, 1765
- Plutonium-243, as beta emitter, 825
- Plutonium-244
 detection of, AMS, 3062–3063
 Fourier transform spectrum of, 858, 858f
 natural occurrence of, 822, 824
 nuclear properties of, 3277t
 spontaneous fission of, 824
 study with, 1765
- Plutonocene
 electronic structure of, 1199–1203,
 1201f–1202f
 HOMO of, 1946
 properties of, 1946–1948
- Plutonyl (v)
 formation of, 3210
 speciation of, 3113t, 3123–3124
- Plutonyl (iv), hydrolytic behavior of,
 2551–2552, 2551f–2552f
- Plutonyl (vi), speciation of, 3113t, 3123–3124,
 3134
- Plutonyl ion
 aqueous solution absorption spectra of,
 2080, 2081f
 complexes of, 1922–1923
 cation-cation, 2594
 structure of, 2400–2402
 extraction of, REDOX process,
 2730–2731
 highest composition of, 3210
 hydrolytic behavior of, 2553
 in mammalian tissues
 circulation clearance of, 3378, 3386–3387
 erythrocytes association with, 3366–3367
 initial distribution, 3342t, 3356
 reduction of, 2591
 study of, 1931–1932
- PMBP. *See* 1-Phenyl-3-methyl-4-
 benzoylpyrazolone
- Pnictides
 of americium, 1305t–1312t, 1317–1319
 coordination of, 1358–1359
 of berkelium, 1464t–1465t, 1470
 preparation of, 1460
 of californium, 1530t–1531t, 1538–1539
 of curium, 1413t–1415t, 1421
 of neptunium, 742–744
 applications of, 742
 of plutonium, 1016–1023
 antimony system, 1022–1023
 arsenic system, 1022
 families of, 1016–1017
 nitrogen system, 1017–1021
 phosphorus system, 1021–1022
 valency and electronic structure, 1023
 of protactinium, 204–207
 structural chemistry of, 2409–2414,
 2410t–2411t
 thermodynamic properties of, 2200–2204
 gaseous nitrides, 2202–2203
 phosphides, arsenides, and antimonides,
 2203–2204
 solid nitrides, 2200–2202
 of thorium, 97–101, 98t, 99f
 antimony, 98t, 100
 arsenides, 98t, 100
 bismuth, 98t, 100
 nitrides, 97–99, 98t, 99f
 phosphides, 98t, 99–100
 of uranium, 407–412, 408t–409t
 nitride, 407–411, 408t–409t, 411f
 others, 411–412
 preparation of, 411–412
- Polarizability, of transactinide elements, 3,
 1675–1676
- Polarography
 for californium, 1548
 for neptunium, determination of, 791–792
 for protactinium, 220, 227
 for uranium, 3066
- Polonium, discovery of, 245
- Polonium–212, seaborgium study interference
 by, 1708

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Polyaminopolycarboxylic acids, as chelating agents, 3413–3414
- Polymerization
of actinide elements, 1778–1782
of plutonium (iv), 1150–1154, 1151f, 1153f, 1781, 1810
of protactinium (iv), 1780
of thorium (iv), 1778–1781
of uranium (iv), 1780–1781
- Polypnictide, complexes of, with cyclopentadienyl, 2836
- Porphyrin complexes, structural chemistry of, 2463–2467, 2464t, 2466f–2467f
- Potassium
chloride, in electrorefining, 2714–2715
permanganate, for uranium carbonate leaching, 307–308
with thorium molybdates, 112
with thorium sulfates, 105
- Potentiometric method
for neptunium, 781–782
determination of, 790–791
for protactinium, 227
- Powder diffraction techniques, for oxides, 2389
- Powder neutron scattering, overview of, 2383–2384
- Powder X-ray diffraction
of cyclopentadienyl complexes, tetravalent, 2814–2815
overview of, 2382–2383
- Power production. *See* Nuclear energy
- PPs. *See* Pseudopotentials
- Praseodymium, UO₂ solid solutions with, oxygen potentials of, 395t, 396
- Precipitation
of americium, 1270–1271
of berkelium, 1449
crystallization *v.*, 832–833

reduced phases, 274–280
sorption of, 257
neptunium–237 production from, 701
nuclear properties of, 255–257
of uranium isotopes, 259t–269t
occurrence in nature of, 162
ore processing and separation, 302–317
complexities of, 302–303
high-purity product refinement, 314–317, 315f–316f, 317t
methods of, 302
pre-concentration, 303–304
recovery from leach solutions, 309–317
roasting or calcination, 304
organometallic chemistry of, 630–631
oxidation of, self-sustained, 3245–3246
oxidation states of, 257, 276–277, 328, 1914–1915, 2526
in aqueous solution, 1774–1776, 1775t
ion types, 1777–1778, 1777t
plutonium and
δ-phase plutonium influence of, 985
oxidation and reduction, 1136–1137
from plutonium decay, 985, 985f
production of
REDOX process, 2730–2731
TLA process, 2731–2732
protactinium separation from, 180, 180f, 183
pyrochemical methods for
molten chlorides, 2695–2696, 2697f
molten fluorides, 2701
processing for, 2702
quadrupole moments of, 1884, 1884f
redox speciation for, 3100–3103, 3101t–3102t
reduction potentials of, 1778, 1779f, 2127–2131, 2130f–2131f, 2525, 2525f
in RTILs, 2687–2688, 2689f
solution chemistry of, 590–630
aqueous uranium complexes, 597–606
ligand substitution reaction mechanisms, 606–624
uranium aqua ions, 590–597
uranyl (vi) fluorescence properties and photochemistry, 624–630
structure and coordination chemistry of, 579–590
compounds of organic ligands, 589–590, 591f
overview of, 579
uranium (iii) compounds, 584–585, 585f
uranium (iv) compounds, 585–588, 586f–588f
uranyl (v) compounds, 588–589
uranyl (vi) compounds, 580–584, 580f–584f
sublimation enthalpy of, 2119t–2120t, 2122–2123, 2122f
superconductivity of, 1789
thermodynamic properties of
enthalpy of formation, 2123–2125, 2124f–2125f, 2539, 2541t
entropy of, 2539, 2542f, 2543t
thorium separation from, 2734–2735
uranium hydride reactions with, 3246
Uranium (iii)
absorption spectra of, 2091, 2092f
aqua ion of, 593, 594t
biochemistry of, 630
bromides of
bromo complexes, 454
uranium tribromide, 453
uranium tribromide hexahydrate, 453–454
chlorides of
anhydrous chloro complexes, 450–452
magnetic data, 2229–2230, 2230t
uranium trichloride, 446–448
uranium trichloride complexes with neutral donor ligands, 452
uranium trichloride hydrates and hydrated chloro complexes, 448–450
compounds of, 575–576
structures and coordination geometry of, 584–585, 585f
crystal-field splittings of, 2057–2058, 2057f
energy level structure, 2058, 2058f
fluorides of, 421–456
uranium trifluoride, 444–445

nitrogen-containing, 500
physical properties of, 456, 457t–481t
stability of, 456
structure of, 456, 482
hydration of, 2531
hydrolytic behavior of, 585–586, 2550–2551
iodides of, 497–499
iodo complexes, 498–499
oxide and nitride, 499–500
uranium tetraiodide, 497–498
in living organisms, 631
magnetic properties of, 2247–2257, 2255t
in mammalian tissues
circulation clearance of, 3376–3377
initial distribution, 3342t, 3346t, 3351
organometallic chemistry of, 630
phases of, 280–302
bonding, 280–281
polymerization of, 1780–1781
with pyrochemical processes, 2696, 2697f
reduction by, americium (V), 1337
separation of
SNF, 2646
solvating extractant system for, 2654–2655
speciation of, 3101t–3102t, 3105–3106, 3136
spectroscopic properties of, 2066–2067, 2066t
water exchange in complexes of, 611t–612t, 614
in wyartite, 290
Uranium (V)
bromides of, 526–528
oxides, 527–528
ternary and polynary, 526–527

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- ternary and polynary oxide and oxobromo, 528
- uranium pentabromide, 526
- chlorides of, 522–526
 - complex chloride compounds, 523–524
 - oxide, 524–525
 - oxochloride, 525–526
 - uranium pentachloride, 522–523
- fluorides of, 518–521
 - complex fluoro compounds, 520–521
 - oxide fluorides and complexes, 521
 - uranium pentafluoride, 518–520
- halides of, 501–529
 - absorption spectra, 501
 - bonding in, 576–577
 - complexes with, 601
 - physical properties of, 501, 502t–517t
 - stability of, 501
- magnetic properties of, 2240–2247, 2247t
- oxides, 372t–378t, 380–382
- in pyrochlore and zirconolite, 279
- in wyartite, 290
- Uranium (vi)
 - americium (v) interaction with, 1356
 - bacterial reduction of, 297
 - bromides of, 571–574
 - uranium oxobromo complexes, 572–574
 - uranyl bromide, 571–572
 - uranyl hydroxide bromide and bromide hydrates, 572
 - chlorides, 567
 - oxochloro complexes, 570
 - perchlorates and related compounds, 570–571
 - uranium dioxide dichloride, 567–569
 - uranium hexachloride, 567
 - uranyl chloride hydrates and hydroxide chlorides, 569–570
 - detection of
 - ISEs, 3029
 - limits to, 3071t
 - NMR, 3033
 - RAMS, 3035
 - RBS, 3063–3064, 3064f
 - distribution coefficients of, 842, 842t
 - extraction of, 3066
 - americium (iii) v., 1284
 - TBP, 3282
 - ferrihydrate adsorption of, 3166–3167
 - fluorides of, 557–564
 - complex fluorides, 563–564
 - hexavalent oxide fluoride complexes, 566–567
 - uranium hexafluoride, 557–563
 - uranium oxide difluoride, 565–566
 - uranium oxide tetrafluoride, 564–565
 - halides of, 529–575
 - absorption spectra of, 529, 557
 - applications of, 529
 - bonding in, 576–577
 - complexes with, 601
 - ground state of, 557
 - mixed halogeno-complexes, 574–575
 - iodides of, 574
 - magnetic properties of, 2239–2240
 - oxides, 371–380, 372t–378t
 - phosphates of, 297
 - polarography for, 791–792
 - with pyrochemical processes, 2696, 2697f
 - separation of
 - HDEHP for, 2651, 2651f
 - PUREX process, 2732
 - SFE for, 2682
 - sulfuric acid dissolution of, 305
- Uranium aqua ions, 590–597
 - applications of, 593
 - dioxouranium (v), 594t, 595
 - dioxouranium (vi), 594t, 596, 596f
 - oxidation states of, 590
 - oxygen atoms in, 592–593
 - redox behavior of, 590–591, 592f, 594t
 - tetrapositive uranium, 593–595
 - tripositive uranium, 593
- Uranium arsenide, magnetic properties of, 2234–2235, 2235f
- Uranium azide, 602, 603t
- Uranium bis-cycloheptatrienyl, ionic configuration of, 2246
- Uranium borides, structural chemistry of, 2406t, 2407
- Uranium borohydride
 - structure of, 2404–2405, 2405f
 - uranium (iv), 337

- ternary and polynary compounds, 495–497, 526–527
 - bonding in, 496–497
 - oxide and oxobromo compounds, 528
 - physical properties of, 496, 526–527
 - preparation of, 495–496, 526
- uranium dioxide monobromide, 527–528
 - preparation of, 527
 - properties of, 527–528
- uranium oxide tribromide, 527
- uranium oxobromo complexes, 572–574
 - physical properties of, 573
 - preparation of, 572
 - reactions of, 573–574
- uranium pentabromide, 526
- uranium tetrabromide, 494–495
 - absorption spectra of, 495

- Uranium bromides (*Contd.*)
 physical properties of, 495
 preparation of, 494–495
 uranium tribromide, 453
 preparation of, 453
 properties of, 453
 uranium tribromide hexahydrate, 453–454
 uranyl bromide, 571–572
 physical properties of, 571–572
 preparation of, 571
 uranyl hydroxide bromide and bromide
 hydrates, 572
- Uranium carbide
 entropy of, 2196, 2197t
 formation enthalpy of, 2195–2196, 2197t
 high-temperature properties of, 2198, 2198f,
 2199t
- Uranium carbide oxides
 binding energy of, 1980
 electronic structure of, 1977–1978, 1977t,
 1982, 1983f
 ground state configuration of, 1978–1979,
 1979f
 interesting compounds of, 1982–1984, 1984t
 isolation of, 1978
- Uranium carbonates, structural chemistry of,
 2426–2427, 2427t
- Uranium carbonyl, 1984–1985
- Uranium chalcogenides, structural chemistry
 of, 2409–2414, 2412t–2413t, 2414f
- Uranium chlorides
 anhydrous complexes, 450–452
 physical properties of, 451
 preparation of, 450–451
 sodium in, 451–452
 structure of, 451
 complexes, 492–493, 523–524
 isolation of, 523
 ligands of, 492–493
 magnetic properties of, 493
 oxochloro, 494, 570
 oxychloride, 494
 physical properties of, 492–493, 524
 preparation of, 492–493, 523–524
 nitride, 500
 oxide, 524–525
 oxochloride, 525–526
 absorption spectra of, 526
 preparation of, 525–526
 perchlorates and related compounds,
 570–571
 physical properties of, 571
 preparation of, 570–571
 uranium dioxide dichloride, 567–569
 hydrates, 569–570
 hydroxide chlorides, 569–570
 physical properties of, 568–569
 preparation of, 567–568
 reactions of, 568–569
 uranium hexachloride, 567
 properties of, 567
 synthesis of, 567
 uranium pentachloride, 522–523
 preparation of, 522
 properties of, 522–523
 uranium perchlorates, 494
 uranium tetrachloride, 490–492
 application of, 490–491
 magnetic properties of, 491–492
 physical properties of, 490–491
 preparation of, 490
 uranium trichloride, 446–448, 447f
 absorption spectra of, 447
 magnetic properties of, 448
 with neutral donor ligands, 452
 physical properties of, 446–447
 preparation of, 446
 structure of, 447, 447f
 uranium trichloride hydrates, 448–450
 absorption spectra of, 449–450
 structure of, 448–449
 synthesis of, 448–450
- Uranium complexes, aqueous, 597–606
 donor-acceptor interactions of, 597
 hydrolytic behavior of, 597–600, 599t
 inorganic ligand complexes, 601–602, 601t
 organic ligand complexes, 603–605, 604t
 structure of, 597
 ternary uranium complexes, 605–606
 uranium (iii), uranium (iv), uranyl (v), and
 uranyl (vi) complexes, 598, 601t, 604t
 between uranyl (v) and other cations, 606
- Uranium deposits
 classification of, 270–273
 groups of, 270
 locations of, 271
 exploration of, 3065
 at Koongarra deposit, 273
 at Oklo, Gabon, 271–272
 at Pena Blanca, Chichuhua District,
 Mexico, 272–273

 - thermodynamic properties of, 2160t, 2161, 2164–2165, 2164t
 - Uranium pentafluoride, 518–520
 - characterization of, 519–520
 - compounds of, 576–577
 - preparation of, 518
 - properties of, 518–519, 519f
 - reduction of, 518

Vol. 1: 1–698, Vol. 2: 699–1395, Vol. 3: 1397–2111, Vol. 4: 2113–2798, Vol. 5: 2799–3440

- Uranium pentafluoride (*Contd.*)
structural chemistry of, 2416, 2419, 2419f, 2420t
thermodynamic properties of, 2160t, 2161, 2164–2165, 2164t
- Uranium pentahalides, structural chemistry of, 2416, 2419, 2420t
- Uranium perchlorate, 570–571
physical properties of, 571
preparation of, 570–571
- Uranium phosphates, structural chemistry of, 2430–2433, 2431t–2432t, 2433f
- Uranium pnictides, structure of, 2409–2414, 2410t–2411t
- Uranium selenolate, from cyclopentadienyl complexes, 2807–2808
- Uranium sesquioxide, formation enthalpy of, 2143–2146, 2144t, 2145f
- Uranium silicides, structural chemistry of, 2406t, 2408
- Uranium sulfates
magnetic susceptibilities of, 2252
structural chemistry of, 2433–2436, 2434t, 2435f
- Uranium tetrabromide, 494–495
absorption spectra of, 495
physical properties of, 495
preparation of, 494–495
- Uranium tetrachloride, 490–492
application of, 490–491
magnetic properties of, 491–492
covalency of, 2249–2251
crystal-field splittings of, 2249
magnetic susceptibility, 2248, 2249f
physical properties of, 490–491
preparation of, 490
reduction of, 319
thermodynamic properties of, 2165–2169, 2166t
- Uranium tetrafluoride, 484–486
absorption spectra of, 2068, 2069f
applications of, 484
coordination chemistry of, 600
hydrates, 486–487
physical properties of, 486–487
preparation of, 486
physical properties of, 485–486
preparation of, 484–485
reduction of, 319
thermodynamic properties of, 2165–2169, 2166t
uranium hexafluoride preparation from, 485
- Uranium tetrahalides, structural chemistry of, 2416, 2418t
- Uranium tetraiodide, 497–498
physical properties of, 498, 498f
preparation of, 497–498
thermodynamic properties of, 2166t, 2168
- Uranium thiocyanate, 602, 603t
- Uranium thiolate, from cyclopentadienyl complexes, 2807–2808
- Uranium tribromide, 453–454
hexahydrate, 453–454
physical properties of, 453–454
preparation of, 453
magnetic susceptibility of, 2257–2258, 2258t
physical properties of, 453
preparation of, 453
- Uranium trichloride, 446–448
absorption spectra of, 447
hydrates and hydrated complexes, 448–450
absorption spectra of, 449–450
structure of, 448–449
synthesis of, 448–450
magnetic properties of, 448
magnetic susceptibility of, 2257–2258, 2258t
with neutral donor ligands, 452
physical properties of, 446–447
preparation of, 446
structural chemistry of, 447, 447f, 2416, 2417t
thermodynamic properties of, 2170t, 2173t, 2176–2178
- Uranium trifluoride
magnetic susceptibility of, 2257, 2258t
monohydrate, 445–446
preparation of, 445
physical properties of, 445
preparation of, 444–445
structure of, 445
thermodynamic properties of, 2169, 2170t–2171t, 2176–2178
- Uranium trihalides, structural chemistry of, 2416, 2417t
- Uranium trihydride
magnetic properties of, 2257, 2362
structure of, 2403
- Uranium triiodide, magnetic susceptibility of, 2257–2258, 2258t
- Uranium trioxide
in gas-phase, 2148, 2148t
structure of, 2393–2394, 2393f
- Uranium tris-cyclopentadienyl, magnetic susceptibility of, 2259, 2259t
- Uranium X₁ (UX₁). *See* Thorium–234
