Commercial Antenna Design Tools

Qing Huo Liu*
Department of Electrical and Computer Engineering, Duke University, Durham, NC, USA

Abstract

Antenna design traditionally relies on physical understanding of electromagnetic radiation, intuition, and experience, as well as trial-and-error experimentations. With the advent of computers and increasingly sophisticated numerical methods, however, computer-aided design tools play a central role in today's antenna design and optimization process. This chapter presents a summary of commonly used commercial antenna design simulation tools and their underlying computational electromagnetics methods.

Keywords

Antenna design; Computational electromagnetics; Finite element method; Finite difference time domain method; Method of moments; Computer-aided design

Introduction

Antenna design is an art that dates back to the early work of Hertz in 1886–1889 when he first experimentally verified the existence of electromagnetic waves, using his electric dipole antenna transmitter and ring receiver. Since then, traditional antenna design relies heavily on physical intuition and trial-and-error experimentation.

During the last few decades, computer technologies and computational science and engineering have revolutionized the design and optimization of antennas. Today, one can easily use commercially available antenna design tools to study how the antenna structure interacts with electromagnetic waves so that the structure and materials can be optimized to achieve the design goals.

Antenna design and optimization rely on solutions of Maxwell's equations. Unfortunately, only problems with canonical geometries (such as spheres, infinitely long circular cylinders, and planar layers) admit analytical solutions. Almost all antenna design problems require numerical solutions of Maxwell's equations, either exactly with full-wave solution methods or approximate methods such as high-frequency asymptotic techniques.

Computational electromagnetics is an important area that develops effective numerical methods for Maxwell's equations for applications in antenna design and optimization, in addition to many other application areas.

The goal of this chapter is to give an outline of the numerical methods commonly used in antenna design tools. First, several commercial antenna design tools are listed, followed by the basic electromagnetic theory. Then three numerical techniques widely used in these tools, i.e., the method of moments for surface integral equation solvers, finite element method, and finite difference time domain method, are discussed in more detail.

Table 1 Commonly used commercial antenna design tools

Abbreviation	Primary method	Additional methods	Company
COMSOL	FEM	FETD, DDM	COMSOL, Inc.
HFSS	FEM		ANSYS
EMCoS	MOM	FEM, FDTD, PO, GO, UTD	EMCoS
FEKO	MOM/MLFMM	High-frequency methods	Altair
newFASANT	MOM		FASANT
Microwave Studio	FIT	FEM, MOM, MLFMM	CST
SEMCAD	FDTD	Sub-gridding	SPEAG
XFDTD	FDTD	GTD, UTD	Remcom
Wavenology	DGTD/FDTD	SETD, FETD, SPICE	WCT

Commonly Used Commercial Antenna Tools

The commonly used commercial antenna design tools are listed in Table 1. Note that this may be a non-exhaustive list as there are certainly other software packages capable of doing antenna design simulations. Also note that open-source but noncommercial tools, such as the very well-known antenna design tool NEC (www.nec2.org) (NEC 2015) based on the method of moments (MOM), have not been included in the table.

Although most software packages use multiple numerical techniques, according to their primary methods involved, methods used by these commercial tools can be categorized into four classes: (a) frequency domain finite element method (FEM), (b) frequency domain method of moments, (c) finite difference time domain (FDTD) method, and (d) multiscale discontinuous Galerkin time domain (DGTD) method. Complementary methods including high-frequency asymptotic techniques have also been used to simulate electrically very large structures where the full-wave solutions are difficult to apply because of the sheer size of the problem.

General Flow of an Antenna Simulation Tool

A typical antenna simulation tool consists of following parts:

- **Graphic User Interface (GUI):** GUI is the central part of the software that the user interacts with. In general, the GUI provides the following functions:
  - **Problem definition:** The GUI allows the user to enter easily geometries, materials, sources, observers, boundary conditions, required results, and other simulation parameters.
  - **Problem modification:** The GUI also enables the user to modify the problem settings easily. This may include modifications to any parameters, including editing the geometries in the solid modeling.
  - **Preprocessing:** The GUI in general will enable the necessary preprocessing of the problem to validate the model and to prepare for the actual computation.
  - **Results and post-processing:** Finally, GUI allows the user to view results and to perform various post-processing.
  - **Design optimization and parameter sweeping:** Through GUI, the user can further perform design optimization of the antenna by optimizing certain parameters either through an optimization algorithm or by sweeping certain antenna parameters to search for the best configuration.
- **Preprocessing:** Typical preprocessing includes validation of the configuration, mesh generation, and other pre-computations including the source excitations.
- **Computational Engine:** This is the core of the numerical solver that gives the solutions to Maxwell's equations for the problem prescribed by the GUI. These methods will be further discussed in sections

DOI 10.1007/978-981-4560-75-7_5-1

"Method of Moments for Surface Integral Equations," "Finite Element Method," and "Finite Difference Time Domain Method."

- **Post-Processing:** The computational engine provides the basic near-field solutions, which can then be processed to arrive at the antenna performance characteristics including radiation pattern, gain, and efficiency. Near-to-far-field transformation is necessary to obtain the far fields from the computed near fields.

Numerical Methods for Antenna Simulation

Commonly used numerical methods can be divided into the frequency domain solvers and time domain solvers:

- **Frequency domain methods:** Antenna designers usually need to know the scattering parameters and other antenna performance characteristics over a frequency band. Thus, the antenna simulation is very often directly obtained in the frequency domain by assuming a time-harmonic excitation with a given frequency. By changing the input frequency, one can obtain the results over a frequency band. If the transient results are needed (especially for ultra-wideband antennas whose waveforms are often sought for), one can perform the inverse Fourier transform on the frequency domain results to arrive at time domain results. The frequency domain methods can be further divided into the following:
  - Partial differential equation solvers: They normally solve the 2nd-order vector Helmholtz equation that is derived from 1st-order Maxwell's equations (usually just Faraday's law and Ampere's law). Methods include finite element method (FEM), spectral element method, finite difference frequency domain method, and pseudospectral frequency domain method. As the FEM is the mostly commonly used frequency domain technique in commercial tools, it will be discussed in more detail in section "Finite Element Method."
  - Integral equation solvers: They solve the surface or volume integral equations derived from Maxwell's equations and Green's function for a background medium. Surface integral equation solvers based on the MOM are the mostly commonly used integral equation technique, so it will be discussed in more detail in section "Method of Moments for Surface Integral Equations."

- **Time domain methods:** If antenna characteristics are desired over a wide frequency range, it may be more advantageous to solve Maxwell's equations directly in time domain to arrive at the wideband waveforms. The frequency domain results such as scattering parameters often required by antenna designers can be obtained by Fourier transform of the transient results. Therefore, time domain methods often are preferred for wideband application as one can obtain all frequency domain results with a single simulation. On the other hand, if a narrow band result is needed, especially when the system has high resonances within this band, the frequency domain solvers are preferred. The time domain methods can be further divided into the following:
  - Partial differential equation solvers: Time domain PDE solvers work with either the 2nd-order vector wave equation or 1st-order Maxwell's equations. Methods include finite difference time domain (FDTD) method, finite element time method (FETD), spectral element time domain (SETD) method, pseudospectral time domain (PSTD) method, finite integration technique (FIT), and multi-resolution time domain (MRTD) method. As the FDTD is the mostly commonly used time domain technique in commercial tools (FIT may also be considered as a special FDTD method), it will be discussed in more detail in section "Finite Difference Time Domain Method."
  - Integral equation solvers: Time domain integral equation methods solve the surface or volume integral equations derived from Maxwell's equations and Green's function for the background medium in time domain. Unfortunately, despite vigorous research, time domain integral equation

DOI 10.1007/978-981-4560-75-7_5-1

solvers are relatively expensive in terms of computer memory and computation time and apparently have still yet to be incorporated into a commercial simulator. Thus, time domain integral equation methods will not be discussed in detail in this chapter.

Each method has its distinct advantages and disadvantages and no one single solver is perfect for all problems, so usually multiple numerical methods may be utilized in a commercial simulation tool to fully exploit the advantages of different methods.

Basics of Electromagnetics Theory

This section summarizes the fundamental concepts and equations in electromagnetics, including Maxwell's equations and boundary conditions. The materials below in this section are the condensed theory explained by Liu (2014).

Transient Electromagnetic Fields

Maxwell's equations describe the relation between electromagnetic sources and the fields. In electromagnetic simulations, one is interested in finding the following electric field intensity **E** and magnetic field intensity **H** from governing Maxwell's equations:

$$\nabla \times \mathbf{E} = -\mathbf{M}_i - \mathbf{M}_c - \frac{\partial \mathbf{B}}{\partial t} \tag{1}$$

$$\nabla \times \mathbf{H} = -\mathbf{J}_i - \mathbf{J}_c - \frac{\partial \mathbf{D}}{\partial t} \tag{2}$$

$$\nabla \cdot \mathbf{D} = \rho_{ei} + \rho_{ec} \tag{3}$$

$$\nabla \cdot \mathbf{B} = \rho_{mi} + \rho_{mc} \tag{4}$$

where the imposed electromagnetic sources include electric current density $\mathbf{J}_i$ and magnetic current density $\mathbf{M}_i$.

In addition, the continuity equations governing the conservation law of charges are

$$\nabla \cdot \mathbf{J}_{i,c} = -\frac{\partial \rho_{ei,c}}{\partial t} \tag{5}$$

$$\nabla \cdot \mathbf{M}_{i,c} = -\frac{\partial \rho_{mi,c}}{\partial t} \tag{6}$$

respectively, for the impressed sources and the conduction sources. Note that the total free electric and magnetic charge densities are

$$\rho_e = \rho_{ei} + \rho_{ec}, \quad \rho_m = \rho_{mi} + \rho_{mc} \tag{7}$$

where ρ_{ei} (ρ_{mi}) and ρ_{ec} (ρ_{mc}) are the electric (magnetic) charge densities due to the imposed and conduction electric (magnetic) current, respectively. Note that in this chapter, the magnetic sources are

DOI 10.1007/978-981-4560-75-7_5-1

included even though so far no isolated magnetic charges have been found. The reason for the introduction of these sources is for symmetry between electric and magnetic quantities and for the future possibility of finding magnetic monopoles. Moreover, it is often convenient to use equivalent magnetic current sources in solving antenna problem, for example, aperture antennas; under such circumstances, magnetic sources are typically more convenient in computation.

Additional equations are provided by constitutive relations. For anisotropic media, the relations between flux densities and field intensities are

$$\mathbf{D} = \overline{\overline{\epsilon}}\,\mathbf{E} = \epsilon_0 \overline{\overline{\epsilon}}_r\ \mathbf{E}, \tag{8}$$

$$\mathbf{B} = \overline{\overline{\mu}}\,\mathbf{H} = \mu_0 \overline{\overline{\mu}}_r\,\mathbf{H}. \tag{9}$$

where ϵ_0 and μ_0 are the permittivity and permeability of the vacuum, while $\overline{\overline{\epsilon}}$ and $\overline{\overline{\epsilon}}_r$ are the permittivity and relative permittivity tensors of the medium, and $\overline{\overline{\mu}}$ and $\overline{\overline{\mu}}_r$ are the permeability and relative permeability tensor of the medium, respectively. In general for a linear medium, the 3×3 permittivity and permeability tensors $\overline{\overline{\epsilon}}$ and $\overline{\overline{\mu}}$ are independent of the field strength. The conduction current densities are related to the field intensities by Ohm's law:

$$\mathbf{J}_c = \overline{\overline{\sigma}}_e \mathbf{E}, \tag{10}$$

$$\mathbf{M}_c = \overline{\overline{\sigma}}_m \mathbf{H}, \tag{11}$$

where σ_e (siemens/meter) and σ_m (ohms/m) are called the electric and magnetic conductivities, respectively. In general, electromagnetic media can be inhomogeneous, that is, all parameters $\overline{\overline{\epsilon}}, \overline{\overline{\mu}}, \overline{\overline{\sigma}}_e$, and $\overline{\overline{\sigma}}_m$ may be functions of position. Furthermore, some media can be dispersive, i.e., the parameters are functions of frequency.

Given the impressed electric and magnetic sources $\mathbf{J}_i\ \rho_{ei}$, $\mathbf{M}_i$, ρ_{mi}, the unknown quantities to be solved are $\mathbf{E}$, $\mathbf{H}$, $\mathbf{D}$, $\mathbf{B}$, $\mathbf{J}_c$, $\mathbf{M}_c$, ρ_{ec}, and ρ_{mc}. Equations 8, 9, 10, and 11 together with Eqs. 1, 2, 5, and 6 provide 20 scalar equations, from which all 20 unknowns can be solved. With the above constitutive relations, Maxwell's equation can now be written as

$$\nabla \times \mathbf{E} = -\mathbf{M}_i - \overline{\overline{\sigma}}_m \mathbf{H} - \overline{\overline{\mu}} \frac{\partial \mathbf{H}}{\partial t} \tag{12}$$

$$\nabla \times \mathbf{H} = \mathbf{J}_i + \overline{\overline{\sigma}}_e \mathbf{E} + \overline{\overline{\epsilon}} \frac{\partial \mathbf{E}}{\partial t} \tag{13}$$

$$\nabla \cdot \overline{\overline{\epsilon}}\mathbf{E} = \rho_{ei} + \rho_{ec} \tag{14}$$

$$\nabla \cdot \overline{\overline{\mu}}\mathbf{H} = \rho_{mi} + \rho_{mc} \tag{15}$$

In most cases only the isotropic media will be treated in this chapter, where $\overline{\overline{\epsilon}} = \epsilon \overline{\overline{I}}$, $\overline{\overline{\mu}} = \mu \overline{\overline{I}}$, $\overline{\overline{\sigma}}_e = \sigma_e \overline{\overline{I}}$, $\overline{\overline{\sigma}}_m = \sigma_m \overline{\overline{I}}$ where ϵ and μ are the scalar permittivity and permeability and $\overline{\overline{I}}$ is the identity tensor.

Time-Harmonic Electromagnetic Fields

Time-harmonic EM fields are those with a sinusoidal variation in time, for example,

DOI 10.1007/978-981-4560-75-7_5-1

$$\mathbf{E}(\mathbf{r},t) = \hat{x}E_x(\mathbf{r})\cos\left[\omega t + \phi_x(\mathbf{r})\right] + \hat{y}E_y(\mathbf{r})\cos\left[\omega t + \phi_y(\mathbf{r})\right] + \hat{z}E_z(\mathbf{r})\cos\left[\omega t + \phi_z(\mathbf{r})\right] \tag{16}$$

where the constant ω is the angular frequency. To simplify the treatment of time-harmonic fields, one can introduce the phasor notation $\tilde{\mathbf{E}}(\mathbf{r})$ of the corresponding instantaneous field $\mathbf{E}(\mathbf{r}, t)$. The relation between the instantaneous and phasor expressions is

$$\mathbf{E}(\mathbf{r},t) = \Re e\left[\tilde{\mathbf{E}}(\mathbf{r})e^{j\omega t}\right] \tag{17}$$

In general, the phasor expression

$$\tilde{\mathbf{E}}(\mathbf{r}) = \hat{x}\tilde{E}_x(\mathbf{r})\exp[j\phi_x(\mathbf{r})] + \hat{y}\tilde{E}_y(\mathbf{r})\exp\left[j\phi_y(\mathbf{r})\right] + \hat{z}\tilde{E}_z(\mathbf{r})\exp[j\phi_z(\mathbf{r})]$$

is complex, even though the instantaneous expression $\mathbf{E}(\mathbf{r}, t)$ is always real.

With this relation between the instantaneous and phasor expressions of the field, the time derivative $\frac{\partial}{\partial t}$ on the instantaneous field corresponds to $j\omega$ times the phasor expression of the field. Therefore, one can derive Maxwell's equations for the phasor form of electromagnetic fields as

$$\nabla \times \tilde{\mathbf{E}} = -\tilde{\mathbf{M}}_i - \overline{\overline{\sigma}}_m\tilde{\mathbf{H}} - j\omega\overline{\overline{\mu}}\tilde{\mathbf{H}} \tag{18}$$

$$\nabla \times \tilde{\mathbf{H}} = \tilde{\mathbf{J}}_i + \overline{\overline{\sigma}}_e\tilde{\mathbf{E}} + j\omega\overline{\overline{\epsilon}}\tilde{\mathbf{E}} \tag{19}$$

$$\nabla \cdot \epsilon\tilde{\mathbf{E}} = \widetilde{\rho}_{ei} + \widetilde{\rho}_{ec} \tag{20}$$

$$\nabla \cdot \mu\tilde{\mathbf{H}} = \widetilde{\rho}_{mi} + \widetilde{\rho}_{mc} \tag{21}$$

The continuity equations are

$$\nabla \cdot \sigma_e\tilde{\mathbf{E}} = -j\omega\widetilde{\rho}_{ec}, \tag{22}$$

$$\nabla \cdot \sigma_m\tilde{\mathbf{H}} = -j\omega\widetilde{\rho}_{mc}. \tag{23}$$

By introducing complex permittivity and permittivity,

$$\widetilde{\overline{\overline{\epsilon}}} = \overline{\overline{\epsilon}} - \frac{j\overline{\overline{\sigma}}_e}{\omega} \tag{24}$$

$$\widetilde{\overline{\overline{\mu}}} = \overline{\overline{\mu}} - \frac{j\overline{\overline{\sigma}}_m}{\omega} \tag{25}$$

Equations 18, 19, 20, 21, 22, and 23 can be rewritten compactly as

$$\nabla \times \tilde{\mathbf{E}} = -j\omega\widetilde{\overline{\overline{\mu}}}\tilde{\mathbf{H}} - \tilde{\mathbf{M}}_i \tag{26}$$

DOI 10.1007/978-981-4560-75-7_5-1

$$\nabla \times \tilde{\mathbf{H}} = j\omega\tilde{\bar{\bar{\epsilon}}}\tilde{\mathbf{E}} + \tilde{\mathbf{J}}_i \tag{27}$$

$$\nabla \cdot \tilde{\bar{\bar{\epsilon}}}\tilde{\mathbf{E}} = \tilde{\rho}_{ei} \tag{28}$$

$$\nabla \cdot \tilde{\bar{\bar{\mu}}}\tilde{\mathbf{H}} = \tilde{\rho}_{mi} \tag{29}$$

For simplicity, in the following discussions, the tilde on phasor quantities and the complex permittivity and permeability will be dropped, keeping in mind that all these quantities are in general complex.

Electric and Magnetic Vector Potentials

In the linear regime, material properties of an isotropic medium μ_r, ϵ_r, σ_e, and σ_m are independent of the field strength, and then Maxwell's equations constitute a linear system. Then the principle of linear superposition applies, i.e., electromagnetic fields can be written as the superposition of the fields ($\mathbf{E}_A$, $\mathbf{H}_A$) generated by $\mathbf{J}_i$ and ($\mathbf{E}_F$, $\mathbf{H}_F$) generated by $\mathbf{M}_i$:

$$\mathbf{E} = \mathbf{E}_A + \mathbf{E}_F, \quad \mathbf{H} = \mathbf{H}_A + \mathbf{H}_F \tag{30}$$

Because of the principle of superposition, one can solve ($\mathbf{E}_A$, $\mathbf{H}_A$) and ($\mathbf{E}_F$, $\mathbf{H}_F$) separately and then sum them up to obtain the total fields.

In particular, ($\mathbf{E}_A$, $\mathbf{H}_A$) due to $\mathbf{J}_i$ can be determined from the vector potential $\mathbf{A}$. In a homogeneous medium, $\mathbf{A}$ is governed by the vector Helmholtz equation

$$\nabla^2\mathbf{A} + \omega^2\mu\epsilon\mathbf{A} = -\mu\mathbf{J}_i \tag{31}$$

subject to a gauge condition because the divergence of $\mathbf{A}$ needs to specified to be unique. One may choose the so-called Lorenz condition (gauge)

$$\nabla \cdot \mathbf{A} = j\omega\mu\epsilon\phi_e = 0 \tag{32}$$

as the condition for its divergence, where ϕ_e is the electric scalar potential. Alternatively, Coulomb's gauge ($\nabla \cdot \mathbf{A} = 0$) can be chosen for the divergence.

Similarly, ($\mathbf{E}_F$, $\mathbf{H}_F$) generated by $\mathbf{M}_i$ can be obtained by the electric vector potential $\mathbf{F}$. This vector potential satisfies the vector Helmholtz equation

$$\nabla^2\mathbf{F} + k^2\mathbf{F} = -\epsilon\mathbf{M}_i \tag{33}$$

subject to the Lorenz condition

$$\nabla \cdot \mathbf{F} + j\omega\mu\epsilon\phi_m = 0 \tag{34}$$

where ϕ_m is the magnetic scalar potential.

Because of the principle of superposition, the total fields due to both electric and magnetic sources are

DOI 10.1007/978-981-4560-75-7_5-1

$$\begin{aligned}\mathbf{E} &= \mathbf{E}_A + \mathbf{E}_F = -j\omega\left[\mathbf{A} + \frac{1}{k^2}\nabla(\nabla\cdot\mathbf{A})\right] - \frac{1}{\epsilon}\nabla\times\mathbf{F} \\ \mathbf{H} &= \mathbf{H}_A + \mathbf{H}_F = -j\omega\left[\mathbf{F} + \frac{1}{k^2}\nabla(\nabla\cdot\mathbf{F})\right] + \frac{1}{\mu}\nabla\times\mathbf{A}\end{aligned} \tag{35}$$

where $k^2 = \omega^2\mu\epsilon$.

By the principle of superposition, if the electric current density is $\mathbf{J}_i(\mathbf{r})$ in a homogeneous medium, the magnetic vector potential is

$$\mathbf{A}(\mathbf{r}) = \mu\int_V \mathbf{J}(\mathbf{r}')g(\mathbf{r},\mathbf{r}')d\mathbf{r}' = \mu\mathbf{J}\bigotimes g \tag{36}$$

where

$$g(\mathbf{r},\mathbf{r}') = \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \tag{37}$$

is called scalar Green's function for the homogeneous medium and $\bigotimes$ denotes the three-dimensional spatial convolution. Similarly, the electric vector potential due to an arbitrary volume magnetic current source $\mathbf{M}(\mathbf{r})$ is given by

$$\mathbf{F}(\mathbf{r}) = \epsilon\int_V \mathbf{M}(\mathbf{r}')g(\mathbf{r},\mathbf{r}')d\mathbf{r}' = \epsilon\mathbf{M}\bigotimes g \tag{38}$$

which is the solution to Eq. 33.

Lumped Ports and Wave Ports

In antenna simulation, one needs to apply the signal to the antenna, usually through either a lumped port (also known as a discrete port) or a wave port.

A **lumped port** consists of a voltage (or current) source and an internal impedance and is connected to the computational mesh (or grid) as a lumped element. Usually the internal impedance is chosen as the standard characteristic impedance of the transmission line (such as a coaxial cable) connected to the antenna, for example, 50 Ω. Through the field-circuit coupling, one can solve for the current (or voltage) at the lumped port as well as the electromagnetic field excited in the whole computation domain. Then the input impedance and scattering parameters can be calculated.

A **wave port** is usually a more realistic representation of the antenna source when it is connected to a transmission line or a waveguide. Its input signal is represented as one (usually the fundamental) waveguide mode of the transmission line or waveguide. The waveguide mode pattern and its corresponding propagation constant as a function of frequency are obtained by solving an eigenvalue problem of the corresponding infinitely long waveguide, over the desired frequency band. When one of these incident waveguide modes (usually the fundamental mode) encounters the antenna structure, it will be partially scattered back to the waveguide and partially transmitted out through the antenna. The normalized scattered field versus the incident field gives the scattering parameter S_{11}.

DOI 10.1007/978-981-4560-75-7_5-1

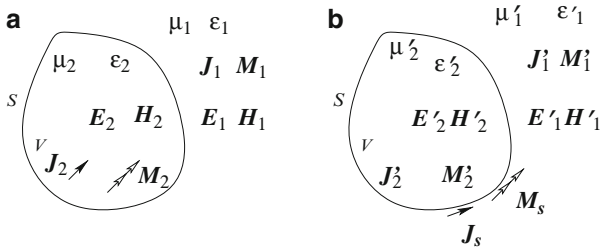

Fig. 1 Surface equivalence theorem. (**a**) The original problem. (**b**) The equivalent problem with surface sources

Near-Field and Far-Field Computation and Radiation Parameters

The lumped port or wave port inputs signal with excite electromagnetic waves in the antenna structure and gives rise to radiation of electromagnetic fields. The fields on the antenna outer surface or on a virtual box enclosing the antenna are known as the near fields. They can be obtained by solving Maxwell's equations discussed in sections.

Once the near fields are obtained, the electromagnetic fields at any location outside the antenna can be calculated by using background Green's functions. In particular, antenna engineers need to know the fields in the far zone to obtain the radiation pattern, gain, and antenna efficiency.

In order to obtain the near fields, Maxwell's equations are solved by various numerical methods in commercial antenna design tools. Described below are three commonly used methods, namely, method of moments (MOM), finite element method (FEM), and finite difference time domain (FDTD) method, as described in more detail by Liu (2015).

Method of Moments for Surface Integral Equations

Surface Equivalence Principle

The surface equivalence theorem is based on the uniqueness theorem: The field in a lossy region V is uniquely determined by the sources inside V plus the tangential electric field components specified over the surface S enclosing V (or the tangential magnetic field components or a combination of tangential **E** and **H**).

In Fig. 1, (a) is equivalent to (b) **outside** volume V if the surface sources are chosen as

$$\mathbf{J}_s = \hat{n} \times \left(\mathbf{H}_1' - \mathbf{H}_2'\right), \quad \mathbf{M}_s = -\hat{n} \times \left(\mathbf{E}_1' - \mathbf{E}_2'\right) \tag{39}$$

Note that inside and outside V, both the medium properties (μ_1', ϵ_1'), (μ_2', ϵ_2') and the fields $\left(\mathbf{E}_1' - \mathbf{H}_1'\right)$, $\left(\mathbf{E}_2' - \mathbf{H}_2'\right)$ can be chosen arbitrarily as long as (a) they satisfy Maxwell's equations in the respective new media by the new sources $\left(\mathbf{J}_1' - \mathbf{M}_1'\right)$ and $\left(\mathbf{J}_2' - \mathbf{M}_2'\right)$ and (b) they satisfy the boundary conditions on the surface S. In practice, obviously, one should make choices such that some fields are relevant to that in the original problem (otherwise, the solution to the equivalent problem will be useless).

By this surface equivalence principle, if the interested fields are $\left(\mathbf{E}_1' - \mathbf{H}_1'\right)$ outside V, the original problem can be solved if one can solve the equivalent problem (b). Here are several possible choices of the medium and fields inside V that can simplify the solution of (b).

If one chooses $\mu_1' = \mu_2' = \mu_1$, $\epsilon_1' = \epsilon_2' = \epsilon_1$, $\mathbf{E}_2' = 0$, $\mathbf{H}_2' = 0$, $\mathbf{J}_1' = \mathbf{J}_1$, $\mathbf{J}_2' = 0$, $\mathbf{M}_1' = \mathbf{M}_1$, and $\mathbf{M}_2' = 0$, then the equivalent currents become

$$\mathbf{J}_s = \hat{n} \times \mathbf{H}_1, \quad \mathbf{M}_s = -\hat{n} \times \mathbf{E}_1 \tag{40}$$

DOI 10.1007/978-981-4560-75-7_5-1

which radiate in the homogeneous medium (μ_1, ϵ_1). Therefore, the vector potentials due to these sources can be found through Green's function:

$$\mathbf{A}^{\text{sct}}(\mathbf{r}) = \mu_1 \int_S \mathbf{J}_s(\mathbf{r}') g_1(k_1 R) ds' \tag{41}$$

$$\mathbf{F}^{\text{sct}}(\mathbf{r}) = \epsilon_1 \int_S \mathbf{M}_s(\mathbf{r}') g_1(k_1 R) ds' \tag{42}$$

where $R = |\mathrm{r} - \mathrm{r}'|$ and $g_1(k_1 R) = \frac{e^{-jk_1 R}}{4\pi R}$ is Green's function in medium 1. However, again the sources in (Eq. 40) are unknown to be solved by integral equations or by some approximations. Here these surface currents will be solved using the surface integral equations described below.

Surface Integral Equations

To find the equivalent surface currents, one needs to form surface integral equations. This can be done with the above surface equivalence principle applied to the **exterior problem** and the **interior problem**, as detailed below.

The Exterior Problem: Using the above equivalence principle to the exterior problem, one has ($\mathbf{J}_{s1}$, $\mathbf{M}_{s1}$) on the surface S radiating in a homogeneous medium 1 to produce the scattered fields outside the object, where

$$\mathbf{J}_{s1} = \hat{n} \times \mathbf{H}_1 = \hat{n} \times \mathbf{H}_1^{\text{inc}} + \hat{n} \times \mathbf{H}_1^{\text{sct}} \tag{43}$$

$$\mathbf{M}_{s1} = -\hat{n} \times \mathbf{E}_1 = -\hat{n} \times \mathbf{E}_1^{\text{inc}} - \hat{n} \times \mathbf{E}_1^{\text{sct}} \tag{44}$$

where $\mathbf{E}_1^{\text{s}}$ and $\mathbf{H}_1^{\text{s}}$ represent the scattered electric and magnetic fields in the homogeneous medium 1.

The Interior Problem: Similarly, using the above surface equivalence principle to the interior problem, one has ($\mathbf{J}_{s2}$, $\mathbf{M}_{s2}$) on the surface S radiating in a homogeneous medium 2 to produce the scattered fields inside the object, where

$$-\mathbf{J}_{s2} = \hat{n} \times \mathbf{H}_2 = \hat{n} \times \left[\mathbf{H}_2^{\text{inc}} + \mathbf{H}_2^{\text{sct}}\right] \tag{45}$$

$$-\mathbf{M}_{s2} = -\hat{n} \times \mathbf{E}_2 = -\hat{n} \times \left[\mathbf{E}_2^{\text{inc}} + \mathbf{E}_2^{\text{sct}}\right] \tag{46}$$

where $\mathbf{E}_2^{\text{sct}}$ and $\mathbf{H}_2^{\text{sct}}$ represent the scattered electric and magnetic fields in the homogeneous medium 2.

If the object is dielectric, the tangential components of the electric and magnetic fields must be continuous across the interface S, or

$$\mathbf{J}_{s1} = -\mathbf{J}_{s2} \equiv \mathbf{J}_s, \quad \mathbf{M}_{s1} = -\mathbf{M}_{s2} \equiv \mathbf{M}_s \tag{47}$$

Hence, using the formulas for the scattered fields, one arrives at the surface EFIE

$$\hat{n} \times \mathbf{E}_1^{\text{inc}} = -\mathbf{M}_s - \hat{n} \times \left\{-j\omega\mu_1 \left[\mathbf{J}_s \bigotimes g_1 + \tfrac{\nabla}{k_1^2}(\nabla_s \cdot \mathbf{J}_s \bigotimes g_1)\right] - \nabla \times [\mathbf{M}_s \bigotimes g_1]\right\}_{S_+}$$
$$\hat{n} \times \mathbf{E}_2^{\text{inc}} = -\mathbf{M}_s - \hat{n} \times \left\{\left[-j\omega\mu_2 \left[\mathbf{J}_s \bigotimes g_2 + \tfrac{\nabla}{k_2^2}(\nabla_s \cdot \mathbf{J}_s \bigotimes g_2)\right] - \nabla \times [\mathbf{M}_s \bigotimes g_2]\right\}_{S_-}$$

and the surface MFIE

$$\hat{n} \times \mathbf{H}_1^{\text{inc}} = \mathbf{J}_s - \hat{n} \times \left\{ \left[-j\omega\epsilon_1 \left[\mathbf{M}_s \otimes g_1 + \frac{\nabla}{k_1^2} (\nabla_s \cdot \mathbf{M}_s \otimes g_1) \right] + \nabla \times [\mathbf{J}_s \otimes g_1] \right\}_{S_+}$$

$$-\hat{n} \times \mathbf{H}_2^{\text{inc}} = -\mathbf{J}_s - \hat{n} \times \left\{ \left[-j\omega\epsilon_2 \left[\mathbf{M}_s \otimes g_2 + \frac{\nabla}{k_2^2} (\nabla_s \cdot \mathbf{M}_s \otimes g_2) \right] - \nabla \times [\mathbf{J}_s \otimes g_2] \right\}_{S_-}$$

Note that $\mathbf{E}_2^{\text{inc}}$ and $\mathbf{H}_2^{\text{inc}}$ are the incident fields from medium 2 when there is a source inside. Therefore, unlike the incident fields in medium 1, this can be only due to a finite source but cannot be a plane wave.

The above equations only consider the observation point at $S_{\pm}$, i.e., infinitely close to the object surface. If the observation point is placed exactly on the surface, however, the terms involving the gradient of Green's function will have singularity; furthermore, the contributions of the surface convolution integral need to consider the local solid angle. Taking these into consideration, when the observation point is exactly on the object surface S, the EFIEs and MFIEs can be modified as

$$\begin{bmatrix} \mu_{r1}\mathcal{L}_1 & \mathcal{K}_1 + \mathcal{I}_1 \\ \mu_{r2}\mathcal{L}_2 & \mathcal{K}_2 + \mathcal{I}_2 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{J}}_s \\ \mathbf{M}_s \end{bmatrix} = -\begin{bmatrix} \hat{n}_1 \times \mathbf{E}_1^{\text{inc}} \\ \hat{n}_2 \times \mathbf{E}_2^{\text{inc}} \end{bmatrix} \tag{48}$$

$$\begin{bmatrix} -(\mathcal{I}_1 + \mathcal{K}_1) & \epsilon_{r1}\mathcal{L}_1 \\ -(\mathcal{I}_2 + \mathcal{K}_2) & \epsilon_{r2}\mathcal{L}_2 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{J}}_s \\ \mathbf{M}_s \end{bmatrix} = -\begin{bmatrix} \hat{n}_1 \times \tilde{\mathbf{H}}_1^{\text{inc}} \\ \hat{n}_2 \times \tilde{\mathbf{H}}_2^{\text{inc}} \end{bmatrix} \tag{49}$$

where $\hat{n}_1$ and $\hat{n}_2 = \hat{n}$ are the outward unit normal directions for medium 1 and medium 2, respectively, and the normalized $\tilde{\mathbf{J}}_s = \eta_0 \mathbf{J}_s$ and $\tilde{\mathbf{H}}^{\text{inc}} = \eta_0 \mathbf{H}^{\text{inc}}$ are used here. For $i = 1, 2$, one has

$$\mathcal{I}_i[\mathbf{f}] = (\hat{n}_i \cdot \hat{n}) \frac{\Omega_i}{4\pi} [\mathbf{f}] \tag{50}$$

$$\mathcal{L}_i[\mathbf{f}] = jk_0 \hat{n} \times \left[\int_S g_i(\mathbf{r}, \mathbf{r}') \mathbf{f}(\mathbf{r}') ds' + \frac{\nabla}{k_i^2} \int_S g_i(\mathbf{r}, \mathbf{r}') \nabla_s' \cdot \mathbf{f}(\mathbf{r}') ds' \right] \tag{51}$$

$$\mathcal{K}_i[\mathbf{f}] = \hat{n} \times \fint_s \nabla g_i(\mathbf{r}, \mathbf{r}') \times \mathbf{f}(\mathbf{r}') ds' \tag{52}$$

where $\mathrm{f} = \tilde{\mathbf{J}}_s$, M_s, $\hat{n} = \hat{n}_2 = -\hat{n}_1$ is the object's unit outward normal, $\fint$ represents the Cauchy principal integral, and Ω_i is the internal solid angle in region i; note that $\Omega_2 = \Omega$. Note that a Cauchy principal integral is one that does not include the contribution of the singular point at $\mathbf{r} = \mathbf{r}'$ in the above equations, which avoids the singularity of the derivative of Green's function.

For an electric impedance boundary, since $\mathbf{M} = -\hat{n} \times \widetilde{\eta}_e \tilde{\mathbf{J}}_s$ on the surface S, only the first equations above are needed. Thus, the EFIE for an electric impedance boundary is

$$[\mu_{ri}\mathcal{L}_i + (\mathcal{I}_i + \mathcal{K}_i)\hat{n} \times \widetilde{\eta}_e] \left[\tilde{\mathbf{J}}_s \right] = -\hat{n}_i \times \mathbf{E}^{\text{inc}} \tag{53}$$

and the MFIE for an impedance object is

$$[(\mathcal{I}_i + \mathcal{K}_i) - \epsilon_{ri}\mathcal{L}_i\hat{n} \times \hat{\eta}_e]\left[\tilde{\mathbf{J}}_s\right] = \hat{n}_i \times \eta_0 \mathbf{H}_i^{\text{inc}} \tag{54}$$

When $\widetilde{\eta}_e = 0$, the object becomes a PEC. Note that while the EFIE is applicable to both closed PEC objects and PEC shells, the MFIE only applies to closed PEC objects. This is because for a PEC shell, the electric current density on the shell is no longer given by $\mathbf{J}_s = \hat{n} \times \mathbf{H}$, but by $\mathbf{J}_s = \hat{n} \times (\mathbf{H}_2 - \mathbf{H}_1)$ where $\mathbf{H}_1$ and $\mathbf{H}_2$ are the magnetic fields on both sides of the shell.

Once the unknown current densities are obtained, the vector potentials $\mathbf{A}$ and $\mathbf{F}$ can be obtained through appropriate Green's functions

$$\mathbf{A}_i^{\text{sct}} = \mu_i \int_S ds' \tilde{\mathbf{J}}_s(\mathbf{r}') g_i(\mathbf{r} - \mathbf{r}'), \qquad \mathbf{F}_i^{\text{sct}} = \epsilon_i \int_S ds' \mathbf{M}_s(\mathbf{r}') g_i(\mathbf{r} - \mathbf{r}') \tag{55}$$

where $g_{1,\ 2}(\mathbf{r})$ are scalar Green's functions for the homogeneous media in the outer ($i = 1$) and inner ($i = 2$) regions, respectively.

Alternatively, the field everywhere in the ith region ($i = 1, 2$) can be found by

$$\begin{aligned} \frac{\Omega_i}{4\pi}\mathbf{E}(\mathbf{r}) &= \mathbf{E}_i^{\text{inc}}(\mathbf{r}) + \int_S \nabla_{gi}(\mathbf{r}, \mathbf{r}') \times \mathbf{M}_i(\mathbf{r}') ds' \\ &+ jk_0\eta_0\mu_{ri}\int_S \left[g_i(\mathbf{r}, \mathbf{r}')\mathbf{J}_i(\mathbf{r}') + \frac{1}{k_i^2}\nabla g_i(\mathbf{r}, \mathbf{r}')\nabla_s' \cdot \mathbf{J}_i(\mathbf{r}') \right] ds' \end{aligned} \tag{56}$$

$$\begin{aligned} \frac{\Omega_i}{4\pi}\mathbf{H}(\mathbf{r}) &= \mathbf{H}_i^{\text{inc}}(\mathbf{r}) + \int_S \nabla_{gi}(\mathbf{r}, \mathbf{r}') \times \mathbf{J}_i(\mathbf{r}') ds' \\ &+ jk_0\eta_0\epsilon_{ri}\int_S \left[g_i(\mathbf{r}, \mathbf{r}')\mathbf{M}_i(\mathbf{r}') + \frac{1}{k_i^2}\nabla g_i(\mathbf{r}, \mathbf{r}')\nabla_s' \cdot \mathbf{M}_i(\mathbf{r}') \right] ds' \end{aligned} \tag{57}$$

where $\mathbf{J}_i = -(\hat{n}_i \cdot \hat{n})\tilde{\mathbf{J}}_s$ and $\mathbf{M}_i = -(\hat{n}_i \cdot \hat{n})\mathbf{M}_s$ because of the normal directions being opposite for inner and outer regions. Note that in the above, if the observation point is away from the surface of the object, $\Omega_i = 4\pi$; when the observation point is on the surface S, only for the tangential components of the field, one uses Ω_i for the left-hand sides, but 4π for Ω_i for the normal components of $\mathbf{E}$ and $\mathbf{H}$.

Combined Field Integral Equations

Combined integral equations are used to overcome the internal resonance problem: when the operating frequency is near the object's internal resonance frequencies, the tangential electric and/or magnetic field on the object surface is not unique, as one may add any linear combination of the eigenmodes to the solution and the integral equation would still be satisfied. This is because the current due to an eigenmode of the cavity does not radiate.

The combined field integral equations can be obtained from Eqs. 48 and 49 by taking a linear combination of the two equations as

DOI 10.1007/978-981-4560-75-7_5-1

$$\begin{bmatrix} \alpha\mu_{r1}\mathcal{L}_1 - (1-\alpha)(\mathcal{I}_1 + \mathcal{K}_1) & \alpha(\mathcal{I}_1 + \mathcal{K}_1) + (1-\alpha)\epsilon_{r1}\mathcal{L}_1 \\ \alpha\mu_{r2}\mathcal{L}_2 - (1-\alpha)(\mathcal{I}_2 + \mathcal{K}_2) & \alpha(\mathcal{I}_2 + \mathcal{K}_2) + (1-\alpha)\epsilon_{r2}\mathcal{L}_2 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{J}}_s \\ \mathbf{M}_s \end{bmatrix} = -\begin{bmatrix} \hat{n}_1 \times \left[\alpha\mathbf{E}_1^{\text{inc}} + (1-\alpha)\tilde{\mathbf{H}}_1^{\text{inc}}\right] \\ \hat{n}_2 \times \left[\alpha\mathbf{E}_2^{\text{inc}} + (1-\alpha)\tilde{\mathbf{H}}_2^{\text{inc}}\right] \end{bmatrix} \tag{58}$$

where $0 \leq \alpha \leq 1$ is the factor of the EFIE.

Alternatively, one can add the two equations in Eq. 48 to form one EFIE, and the equations in Eq. 49 to form one MFIE to yield the following CFIE:

$$\begin{bmatrix} \mu_{r1}\mathcal{L}_1 + \mu_{r2}\mathcal{L}_2 & \mathcal{I}_1 + \mathcal{I}_2 + \mathcal{K}_1 + \mathcal{K}_2 \\ \mathcal{I}_1 + \mathcal{I}_2 + \mathcal{K}_1 + \mathcal{K}_2 & -\epsilon_{r1}\mathcal{L}_1 - \epsilon_{r2}\mathcal{L}_2 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{J}}_s \\ \mathbf{M}_s \end{bmatrix} = -\begin{bmatrix} \hat{n} \times \left(\mathbf{E}_1^{\text{inc}} - \mathbf{E}_2^{\text{inc}}\right) \\ \hat{n}_2 \times \left(\tilde{\mathbf{H}}_2^{\text{inc}} - \tilde{\mathbf{H}}_1^{\text{inc}}\right) \end{bmatrix} \tag{59}$$

Note that in the special case where the surface is smooth, one has $\mathcal{I}_1 - \mathcal{I}_2 = -\frac{\Omega}{4\pi}$ in the above equations. The integral equation in Eq. 59 is also known as the PMCHWT (Poggio-Miller-Chang-Harrington-Wu-Tsai) formulation based on the works by Poggio and Miller (1973), Chang and Harrington (1977), and Wu and Tsai (1977).

Method of Moments (MOM)

The surface integral equations in Eqs. 48 and 49 are referred as the SIEs in strong form. Denote $\tilde{\mathbf{J}}_s = \eta_0 \mathbf{J}_s$. Expand $\tilde{\mathbf{J}}_s$ and $\mathbf{M}_s$ in terms of divergence-conforming basis functions $\mathbf{f}_n^J$ and $\mathbf{f}_n^M$:

$$\tilde{\mathbf{J}}_s = \sum_{n=1}^{N^J} J_n \mathbf{f}_n^J(\mathbf{r}), \quad \mathbf{M}_s = \sum_{n=1}^{N^M} M_n \mathbf{f}_n^M(\mathbf{r}) \tag{60}$$

and substitute them into Eqs. 48 and 49. Let the testing functions for $\tilde{\mathbf{J}}_s$ and $\mathbf{M}_s$ be $\mathbf{w}_m^J$ and $\mathbf{w}_m^M$, respectively. By testing Eq. 48 with the testing functions $\hat{n} \times \mathbf{w}_m^J$ and $\hat{n} \times \mathbf{w}_m^M$

$$\int_S ds \begin{bmatrix} \hat{n} \times \mathbf{w}_m^J & 0 \\ 0 & \hat{n} \times \mathbf{w}_m^J \end{bmatrix} \cdot \begin{bmatrix} \mu_{r1}\mathcal{L}_1 & \mathcal{I}_1 + \mathcal{K}_1 \\ \mu_{r2}\mathcal{L}_2 & \mathcal{I}_2 + \mathcal{K}_2 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{J}}_s \\ \mathbf{M}_s \end{bmatrix} = \int_S ds \begin{bmatrix} \hat{n} \times \mathbf{w}_m^J & 0 \\ 0 & \hat{n} \times \mathbf{w}_m^J \end{bmatrix} \cdot \begin{bmatrix} \hat{n} \times \mathbf{E}_1^{\text{inc}} \\ -\hat{n} \times \mathbf{E}_2^{\text{inc}} \end{bmatrix}$$

one has

$$\begin{bmatrix} \mathbf{Z}_1^J & \mathbf{Z}_1^M \\ \mathbf{Z}_2^J & \mathbf{Z}_2^M \end{bmatrix} \begin{bmatrix} \mathbf{J} \\ \mathbf{M} \end{bmatrix} = \begin{bmatrix} \mathbf{V}_1^E \\ \mathbf{V}_2^E \end{bmatrix} \tag{61}$$

where $\mathbf{J}$ and $\mathbf{M}$ are vectors containing the unknown expansion coefficients in Eq. 60 for $i = 1, 2$,

DOI 10.1007/978-981-4560-75-7_5-1

$$\begin{aligned}\mathbf{Z}_i^J &\equiv \int_S ds\left(\hat{n}\times\mathbf{w}_m^J\right)\cdot\mu_{ri}\mathcal{L}_i\left[\mathbf{f}_n^J\right]\\ &= jk_0\mu_{ri}\int_S ds\int_S g_i(\mathbf{r},\mathbf{r}')\mathbf{w}_m^J(\mathbf{r})\cdot\mathbf{f}_n^J(\mathbf{r}')ds'\\ &-\frac{jk_0\mu_{ri}}{k_i^2}\int_S ds\int_S g_i(\mathbf{r},\mathbf{r}')\nabla_s\cdot\mathbf{w}_m^J(\mathbf{r})\nabla_s'\cdot\mathbf{f}_n^J(\mathbf{r}')ds'\end{aligned} \tag{62}$$

$$\begin{aligned}\mathbf{Z}_i^M &\equiv \int_S ds\left(\hat{n}\times\mathbf{w}_m^J\right)\cdot\left[\mathcal{K}_i+\mathcal{I}_i\right]\left[\mathbf{f}_n^M\right]\\ &= (-1)^i\int_S ds\frac{\Omega_i(\mathbf{r})}{4\pi}\left[\hat{n}\times\mathbf{w}_m^J(\mathbf{r})\right]\cdot\mathbf{f}_n^M(\mathbf{r})\\ &+\int_S ds\fint\mathbf{w}_m^J(\mathbf{r})\cdot\left[\nabla g_i(\mathbf{r},\mathbf{r}')\times\mathbf{f}_n^M(\mathbf{r}')\right]ds'\end{aligned} \tag{63}$$

Note that integration by parts is used in the second terms of $\mathbf{Z}_1^J$ and $\mathbf{Z}_2^J$. Similarly, the excitation vectors are given by

$$\begin{aligned}\mathbf{V}_i^E &= -\int_S ds\left(\hat{n}\times\mathbf{w}_m^J\right)\cdot\left(\hat{n}_i\times\mathbf{E}_i^{\text{inc}}\right)\\ &(-1)^{i+1}\int_S ds\mathbf{w}_m^J(\mathbf{r})\cdot\mathbf{E}_i^{\text{inc}}(\mathbf{r})\end{aligned} \tag{64}$$

Note that in the above, the identity $(\hat{n}\times\mathbf{w})\cdot(\hat{n}\times\mathbf{a}) = \mathbf{a}\cdot\mathbf{w}$ if $\hat{n}\cdot\mathbf{w} = 0$ is used. Equation 61 is the MOM matrix equation for the surface integral equation for the general case.

By the same token, the MFIEs in Eq. 49 can be written in a matrix form using the MOM

$$\begin{bmatrix}\mathbf{Z}_1^J & \mathbf{Z}_1^M\\ \mathbf{Z}_2^J & \mathbf{Z}_1^M\end{bmatrix}\begin{bmatrix}\mathbf{J}\\ \mathbf{M}\end{bmatrix} = \begin{bmatrix}\mathbf{V}_1^H\\ \mathbf{V}_2^H\end{bmatrix} \tag{65}$$

where for $i = 1, 2$,

$$\begin{aligned}\mathbf{Z}_i^M &\equiv \int_S ds\left(\hat{n}\times\mathbf{w}_m^M\right)\cdot\epsilon_{ri}\mathcal{L}_i\left[\mathbf{f}_n^M\right]\\ &= jk_0\epsilon_{ri}\int_S ds\int_S g_i(\mathbf{r},\mathbf{r}')\mathbf{w}_m^M(\mathbf{r})\cdot\mathbf{f}_n^M(\mathbf{r}')ds'\\ &-\frac{jk_0\epsilon_{ri}}{k_i^2}\int_S ds\int_S g_i(\mathbf{r},\mathbf{r}')\nabla_s\cdot\mathbf{w}_m^M(\mathbf{r})\nabla_s'\cdot\mathbf{f}_n^M(\mathbf{r}')ds'\end{aligned} \tag{66}$$

DOI 10.1007/978-981-4560-75-7_5-1

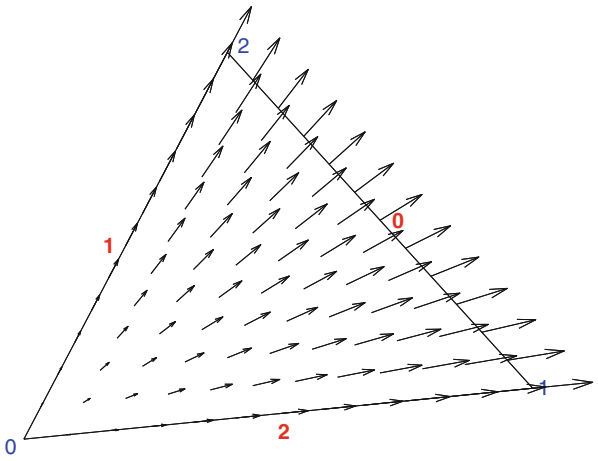

Fig. 2 Divergence-conforming basis function $\mathbf{B}_0$ associated with edge 0 (from node 1 to node 2) on a triangle. This is also known as the constant-normal/linear tangential (*CN/LT*) basis function. In computational electromagnetics, this is also better known as the Rao-Wilton-Glisson (*RWG*) function. The other two basis functions on this triangle, $\mathbf{B}_1$ and $\mathbf{B}_2$, are similar and thus not shown here

$$\begin{aligned}\mathbf{Z}_i^J \equiv & -\int_S ds\left(\hat{n}\times\mathbf{w}_m^J\right)\cdot\left[\mathcal{I}_i+\mathcal{K}_i\right]\left[\mathbf{f}_n^J\right] \\ = & (-1)^{i+1}\int_S ds\frac{\Omega_i(\mathbf{r})}{4\pi}\left[\hat{n}\times\mathbf{w}_m^M(\mathbf{r})\right]\cdot\mathbf{f}_n^J(\mathbf{r}) \\ & -\int_S ds\,{-\!\!\!\!\!\!\int}_S\mathbf{w}_m^M(\mathbf{r})\cdot\left[\nabla g_i(\mathbf{r},\mathbf{r}')\times\mathbf{f}_n^J(\mathbf{r}')\right]ds'\end{aligned} \tag{67}$$

Note that the integration by parts has been used in the second terms of $\mathbf{Z}_1^M$ and $\mathbf{Z}_2^M$. Similarly, the excitation vectors are given by

$$\begin{aligned}\mathbf{V}_i^H &= -\int_S ds\left(\hat{n}\times\mathbf{w}_m^M\right)\cdot\left(\hat{n}_i\times\tilde{\mathbf{H}}_i^{\text{inc}}\right) \\ &= (-1)^{i+1}\int_S ds\mathbf{w}_m^M(\mathbf{r})\cdot\tilde{\mathbf{H}}_i^{\text{inc}}(\mathbf{r})\end{aligned} \tag{68}$$

Divergence-Conforming Basis Functions

A Straight Triangle Element

When solving for $\mathbf{J}_s$ and $\mathbf{M}_s$ in the surface integral equations, the normal component should be continuous between adjacent elements. Vector basis functions satisfying this condition are known as divergence-conforming basis functions.

For a straight triangle element, there are three mixed-order divergence conformation basis functions. These are the so-called CN/LT basis functions, because their normal component is constant along an edge, while the tangential component with respect to an edge changes linearly within an element. These CN/LT functions are also known as the triangular rooftop or Rao-Wilton-Glisson (RWG) functions. The *i*th divergence-conforming basis corresponding to the *i*th edge of a triangle on the *xy* plane can be written as

DOI 10.1007/978-981-4560-75-7_5-1

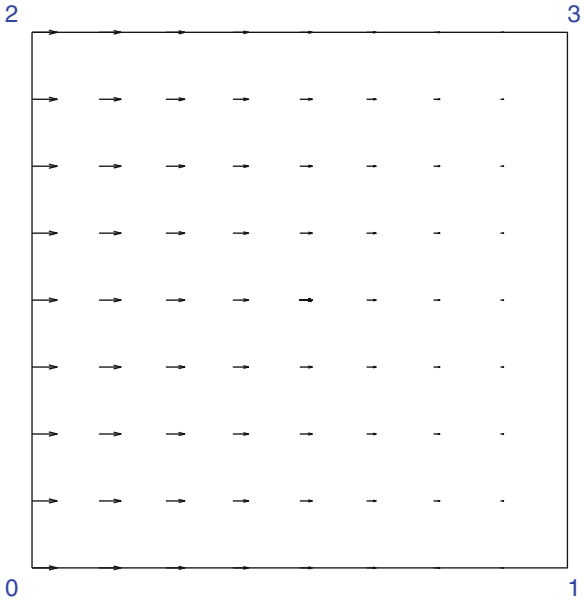

Fig. 3 Divergence-conforming basis function (CN/LT element) $\mathbf{B}_{02}^{(\xi,1)}$ in a reference square element, where subscript 02 indicates that the face is formed by vertices 0 and 2. The other three basis functions associated with the four faces, $\mathbf{B}_{01}$, $\mathbf{B}_{23}$, and $\mathbf{B}_{13}$, are similar except they are associated with the other three faces

$$\mathbf{B}_i = \omega_i \hat{z} \times (s_{i+2}\nabla s_{i+1} - s_{i+2}\nabla s_{i+2}), \quad i = 0, 1, 2 \tag{69}$$

where s_i (i = 0,1,2) are the simplex coordinates of the three vertices of the triangle. The divergence-conforming basis function $\mathbf{B}_0$ for a triangle is shown in Fig. 2.

A Reference Square Element

A curved quadrilateral element can be mapped into a reference square element by curvilinear mapping. On square reference element, the Mth order divergence-conforming basis functions are

$$\begin{aligned} \mathbf{B}^{(\xi,M)} &= \hat{\xi}\phi_i^{(M)}(\xi)\phi_j^{(M-1)}(\eta), \quad i = 0, \cdots, M; \qquad j = 1, \cdots, M-1 \\ \mathbf{B}^{(\eta,M)} &= \hat{\eta}\phi_i^{(M-1)}(\xi)\phi_j^{(M)}(\eta), \quad i = 0, \cdots, M-1; \quad j = 0, \cdots, M \end{aligned} \tag{70}$$

where $\phi_i^{(M)}(\xi)$ is the Mth mixed-order scalar basis function. For example, the 1st mixed-order rooftop functions are

$$\begin{aligned} \mathbf{B}^{(\xi,1)} &= \hat{\xi}p(\eta)t(\xi) \\ \mathbf{B}^{(\eta,1)} &= \hat{\eta}t(\eta)p(\xi) \end{aligned} \tag{71}$$

where $p(\xi)$ is a pulse basis function and $t(\xi)$ is a triangular basis function. One such 1st mixed-order rooftop function, $\mathbf{B}^{(\xi,\,1)}$, is shown in Fig. 3.

Coordinate Transformation for Divergence-Conforming Basis Functions

The above divergence-conforming basis functions have been given on a straight triangle and a square element. These can be referred to as the reference elements. In practice, however, one requires the elements to be able to conform with the problem geometry; thus, curved triangle and quadrilateral

DOI 10.1007/978-981-4560-75-7_5-1

elements are needed. The basis functions in such elements can be derived from those in the reference elements.

Contravariant Transformation: For vector integral equations, the unknowns are the electric and magnetic current densities ($\mathbf{J}_s$ and $\mathbf{M}_s$). Since these vectors have normal component continuity across adjacent elements, one needs to use the contravariant transformation

$$\mathbf{B} = \frac{1}{\det(\mathbf{J})}\mathbf{J}^T\hat{\mathbf{B}} \tag{72}$$

where $\hat{\mathbf{B}}$ is its representation in the reference element where it has normal continuity (contravariant components), or equivalently

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \frac{1}{\det(\mathbf{J})}\mathbf{J}^T \begin{bmatrix} \hat{B}_{\xi'} \\ \hat{B}_{\eta'} \\ \hat{B}_{\zeta'} \end{bmatrix} \tag{73}$$

Here the vector $\hat{\mathbf{B}}$ in the reference domain has been written in its contravariant components

$$\hat{\mathbf{B}} = \left(\hat{\mathbf{B}}\cdot\hat{\xi}'\right)\hat{\xi} + \left(\hat{\mathbf{B}}\cdot\hat{\eta}'\right)\hat{\eta} + \left(\hat{\mathbf{B}}\cdot\hat{\zeta}'\right)\hat{\zeta} = \hat{B}_{\xi'}\hat{\xi} + \hat{B}_{\eta'}\hat{\eta} + \hat{B}_{\zeta'}\hat{\zeta} \tag{74}$$

Examples of such field vectors are electric flux density **D** and magnetic flux density **B**. The divergence of such a vector can be written as

$$\nabla\cdot\mathbf{B} = \frac{1}{\det(\mathbf{J})}\hat{\nabla}\cdot\hat{\mathbf{B}} \tag{75}$$

where $\hat{\nabla}\cdot\hat{\mathbf{B}}$ represents the divergence in the reference element.

The surface integral equations are often applied to curved surfaces. Thus, one needs to map a curved element in three dimensions into a flat surface in two dimensions where the reference 2-D elements (e.g., triangle or square) are located. If the 2-D reference coordinates are (ξ, n), the mapping is

$$\begin{bmatrix} \dfrac{\partial}{\partial\xi} \\ \dfrac{\partial}{\partial\eta} \end{bmatrix} = \mathbf{J}\begin{bmatrix} \dfrac{\partial}{\partial x} \\ \dfrac{\partial}{\partial y} \\ \dfrac{\partial}{\partial z} \end{bmatrix}, \quad \mathbf{J} = \begin{bmatrix} \dfrac{\partial x}{\partial\xi} & \dfrac{\partial y}{\partial\xi} & \dfrac{\partial z}{\partial\xi} \\ \dfrac{\partial x}{\partial\eta} & \dfrac{\partial y}{\partial\eta} & \dfrac{\partial z}{\partial\eta} \end{bmatrix} \tag{76}$$

where the Jacobian matrix **J** is a 2 × 3 matrix and can be obtained easily by Lagrange interpolation functions (scalar basis functions) $\{\phi_n(\xi, \eta)\}$:

DOI 10.1007/978-981-4560-75-7_5-1

$$\begin{aligned} x &= \sum_n x_n \phi_n(\xi, \eta) \\ y &= \sum_n y_n \phi_n(\xi, \eta) \\ z &= \sum_n z_n \phi_n(\xi, \eta) \end{aligned} \tag{77}$$

where (x_n, y_n, z_n) are the locations of the control points. Under this transformation, the differential surface is

$$ds = |\mathbf{J}| d\xi d\eta \tag{78}$$

where $|\mathbf{J}|$ is not exactly the determinant of the Jacobian matrix as this Jacobian matrix is not square; instead, it is given by

$$|\mathbf{J}| = \sqrt{\left(\frac{\partial y}{\partial \xi}\frac{\partial z}{\partial \eta} - \frac{\partial z}{\partial \xi}\frac{\partial y}{\partial \eta}\right)^2 + \left(\frac{\partial z}{\partial \xi}\frac{\partial x}{\partial \eta} - \frac{\partial x}{\partial \xi}\frac{\partial z}{\partial \eta}\right)^2 + \left(\frac{\partial x}{\partial \xi}\frac{\partial y}{\partial \eta} - \frac{\partial y}{\partial \xi}\frac{\partial x}{\partial \eta}\right)^2} \tag{79}$$

The contravariant transformation for the divergence-conforming vector is

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \frac{1}{|\mathbf{J}|}\mathbf{J}^T \begin{bmatrix} \hat{B}_{\xi'} \\ \hat{B}_{\eta'} \end{bmatrix}, \quad \text{or } \mathbf{B} = \frac{1}{|\mathbf{J}|}\mathbf{J}^T \hat{\mathbf{B}} \tag{80}$$

The divergence of this vector is

$$\nabla_s \cdot \mathbf{B} = \frac{1}{|\mathbf{J}|}\hat{\nabla} \cdot \hat{\mathbf{B}} = \frac{1}{|\mathbf{J}|}\left(\frac{\partial \hat{B}_{\xi'}}{\partial \xi} + \frac{\partial \hat{B}_{\eta'}}{\partial \eta}\right) \tag{81}$$

The above expressions can be substituted into Eqs. 66 and 67 to obtain the impedance matrix in the MOM.

MOM Solution and MLFMA Acceleration

In the traditional MOM, matrix Eqs. 61 and 65 can be rewritten as

$$\mathbf{ZI} = \mathbf{V} \tag{82}$$

where $\mathbf{Z}$ is called the impedance matrix and $\mathbf{I}$ contains all the unknown expansion coefficients.

Traditionally, in the MOM the matrix Eq. 82 is solved either directly by methods such as Gauss elimination or LU decomposition or iteratively by Krylov subspace methods (Harrington 1968). However, as these impedance matrices are dense and complex, solving these matrix equations is very expensive. If the total number of unknowns in the system is N, a direct method costs (N^2) in memory and $O(N^3)$ in CPU time, which are prohibitive for large-scale problems.

The most remarkable breakthrough in integral equation solvers is the development of the fast multipole method (Rokhlin 1983; Coifman et al. 1993) and multilevel fast multipole algorithm (MLFMA, also called MLFMM) (Song and Chew 1995). It has been developed to reduce the CPU and memory requirements for the iterative solver from $O(N^2)$ to $O(N \log N)$, where N is the total number of unknowns. For more details of the MLFMA, the reader is referred to Chew et al. (2001). The MLFMA has been utilized in design tools such as FEKO.

Finite Element Method

The three-dimensional antenna design problem can be solved by the frequency domain finite element method (FEM) through the weak form formulation. The FEM has the excellent capability of modeling arbitrary structures with its unstructured mesh and can also treat material anisotropy and dispersion easily (Jin 1993; Volakis et al. 1998). Here the goal for the FEM is to solve Maxwell's equations in a 3-D anisotropic medium. The vector Helmholtz equation can be derived from Maxwell's curl equations (Faraday's law and Ampere's law) as

$$-\nabla \times \left(\overline{\overline{\mu}}_r^{-1} \nabla \times \mathbf{E}\right) + k_0^2 \overline{\overline{\epsilon}}_r \mathbf{E} = \mathbf{S}_e \tag{83}$$

where the source terms are

$$\mathbf{S}_e = j\omega\mu_0 \mathbf{J} + \nabla \times \left(\overline{\overline{\mu}}_r^{-1} \mathbf{M}\right)$$

and the anisotropic and potentially lossy medium is characterized by the complex relative permittivity and permeability tensors $\overline{\overline{\epsilon}}_r$ and $\overline{\overline{\mu}}_r$, respectively.

Weak Form Equation

One can derive the weak form of Maxwell's equations for anisotropic media by testing Eq. 83 with a vector testing function $\mathbf{w}_m$:

$$\begin{aligned} &\int_V \left[-(\nabla \times \mathbf{w}_m) \cdot \overline{\overline{\mu}}_r^{-1} (\nabla \times \mathbf{E}) + k_0^2 \mathbf{w}_m \cdot \overline{\overline{\epsilon}}_r \mathbf{E}\right] dv \\ &= \int_S \mathbf{w}_m \cdot \hat{n} \times \overline{\overline{\mu}}_r^{-1} (\nabla \times \mathbf{E}) ds + \int_V \mathbf{w}_m \cdot \mathbf{S}_e dv = -j\omega\mu_0 \int_S \mathbf{w}_m \cdot (\hat{n} \times \mathbf{H}) ds + \int_V \mathbf{w}_m \cdot \mathbf{S}_e dv \end{aligned} \tag{84}$$

These equations must be solved in conjunction with the outer boundary conditions.

Note that for both PEC and PMC outer boundary conditions, the surface integral terms in the above two equations are equal to zero.

For an unbounded problem, exact or approximate boundary conditions can be used at the outer boundary to mimic a radiation boundary condition. In recent years, the perfectly matched layer (PML) has become a powerful absorbing boundary condition. If PML is used an outer absorbing medium (Teixeira and Chew 1998), the permittivity and permeability tensors must be modified as

$$\overline{\overline{\epsilon}}_r' = [\det(\mathbf{S})]^{-1} \mathbf{S} \overline{\overline{\epsilon}}_r \mathbf{S}, \quad \overline{\overline{\mu}}_r' = [\det(\mathbf{S})]^{-1} \mathbf{S} \overline{\overline{\mu}}_r \mathbf{S} \tag{85}$$

where

$$\mathbf{S} = \text{diag}\left[\frac{1}{e_x}, \frac{1}{e_y}, \frac{1}{e_z}\right] \tag{86}$$

and $e_\eta = a_\eta - j\omega_\eta/\omega$ is the complex stretching factor in η direction ($\eta = x, y, z$) and a_η is the scaling factor, while ω is the attenuation factor. For the special case of the PML for an isotropic medium, one has

DOI 10.1007/978-981-4560-75-7_5-1

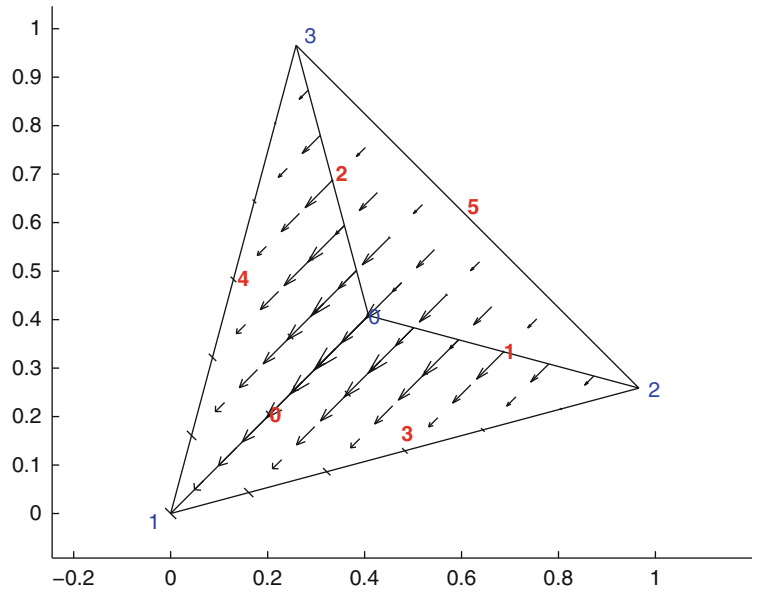

Fig. 4 CT/LN edge elements $\mathbf{B}_{ij}$ in a tetrahedron

$$\overline{\overline{\epsilon}}_r' = \epsilon_r \Lambda, \overline{\overline{\mu}}_r' = \mu_r \Lambda, \Lambda = \text{Diag}\left(\frac{e_y e_z}{e_x}, \frac{e_x e_z}{e_y}, \frac{e_x e_y}{e_z}\right) \tag{87}$$

The PML can be backed at the outer boundary by a perfect electric conductor or by a perfect magnetic conductor, making boundary integral term disappear in the weak form equation.

Curl-Conforming Vector Basis Functions

Edge Elements for Straight Tetrahedrons

For the vector electromagnetic problem, if scalar basis functions are used to expand the unknown field **E** above, they will produce spurious modes. Curl-conforming vector basis functions must be used. The most commonly used basis functions in 3-D electromagnetic problems in FEM are the mixed-order curl-conforming vector basis functions developed by Nedelec in 1980. These basis functions are commonly known as edge elements because they are based on the edges of the element, and the tangential components of these basis functions are one order lower than the normal component.

CT/LN (constant tangential/linear normal) edge elements are the lowest mixed-order edge elements for a tetrahedron in 3-D (Peterson et al. 1997). There are six such basis functions, each corresponding to one edge of the tetrahedron. The basis function for the edge *ij* (from node *i* to node *j*) is

$$\mathbf{B}_{ij} = w_{ij}\left(s_i \nabla s_j - s_j \nabla s_i\right) \tag{88}$$

where w_{ij} is the edge length between nodes *i* and *j* and s_{i} and s_{j} are the simplex coordinates of these nodes in the tetrahedron. The curl of this basis is $\nabla \times \mathbf{B}_{ij} =$ constant within the element; the divergence of this basis $\nabla \cdot \mathbf{B}_{ij} = 0$ within the element, but it is nonzero at the edges because of the discontinuity of its normal component at the edges.

The CT/LN edge elements for a tetrahedron are shown in Fig. 4.

The LT/QN (linear tangential/quadratic normal) edge elements are the next higher mixed-order basis functions for a tetrahedron. They have linear tangential component and quadratic normal component

DOI 10.1007/978-981-4560-75-7_5-1

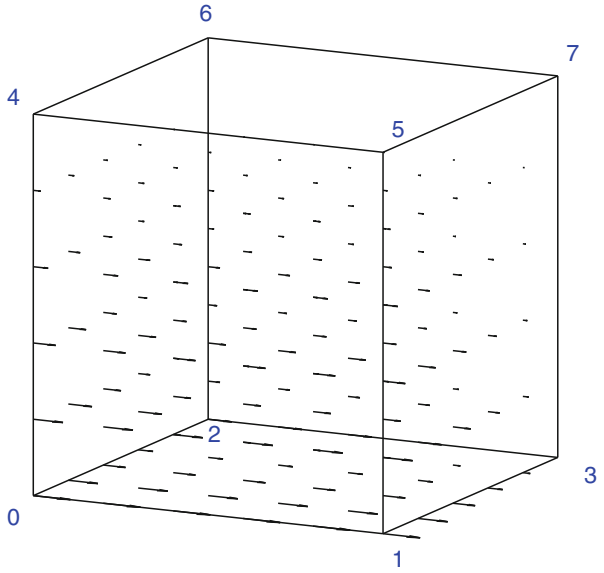

Fig. 5 CT/LN edge element $\mathbf{B}_{\xi,\,000}$ in a reference cube, where $\hat{\xi}$ is along the direction of edge 01

within an element. There are 20 such edge elements for one tetrahedron. If the four nodes of the tetrahedron are labeled as nodes 1, 2, 3, and 4, then these 20 LT/QN edge elements contain:

- 12 linear tangential functions (two per edge)

$$\mathbf{B}_{ij}^{(1)} = s_i \nabla s_j, \quad i \neq j \tag{89}$$

  where $ij = 12, 21, 13, 31, 14, 41, 23, 32, 24, 42, 34, 43$ and
- 8 quadratic normal functions (two per face)

$$\mathbf{B}_{ijk}^{(2)} = s_i s_j \nabla s_k - s_i s_k \nabla s_j, \quad i \neq j \neq k \tag{90}$$

  where $(i, j, k) = (1, 2, 3)$ and $(2, 3, 1)$ for face 123; $(1, 2, 4)$ and $(2, 4, 1)$ for face 124; $(2, 3, 4)$ and $(3, 4, 2)$ for face 234; and $(1, 3, 4)$ and $(3, 4, 1)$ for face 134. Note that these are unnormalized basis functions, i.e., their tangential components are not equal to 1 at the locations corresponding to edges.

Edge Elements for a Cube

The Mth mixed-order curl-conforming basis functions in a reference cubic element are

$$\begin{aligned}
\mathbf{B}_{\xi,\,ijk}^{(M)} &= \hat{\xi}\phi_i^{(M-1)}(\xi)\phi_j^{(M)}(\eta)\phi_k^{(M)}(\zeta), \\
&\quad i = 0, \cdots, M-1; (j,k) = 0, \cdots, M \\
\mathbf{B}_{\eta,\,ijk}^{(M)} &= \hat{\eta}\phi_i^{(M)}(\xi)\phi_j^{(M-1)}(\eta)\phi_k^{(M)}(\zeta), \\
&\quad j = 0, \cdots, M-1; (i,k) = 0, \cdots, M \\
\mathbf{B}_{\zeta,\,ijk}^{(M)} &= \hat{\zeta}\phi_i^{(M)}(\xi)\phi_j^{(M)}(\eta)\phi_k^{(M-1)}(\zeta), \\
&\quad k = 0, \cdots, M-1; (i,j) = 0, \cdots, M
\end{aligned} \tag{91}$$

The edge elements for a hexahedron are shown in Fig. 5.

DOI 10.1007/978-981-4560-75-7_5-1

Mapping Curl-Conforming Basis Functions to Nonstandard Elements

The edge elements shown above are for standard straight tetrahedron and cube elements. In practice, one would need to be able to apply these elements to nonstandard elements such as curved tetrahedron elements and straight and curved hexahedron elements. One needs to ensure that not only the geometry is properly mapped but also the basis functions satisfy the continuity of tangential components.

If the coordinate mapping from (x, y, z) coordinates to (ξ, η, ζ) coordinates is defined by

$$\begin{bmatrix} \frac{\partial}{\partial \xi} \\ \frac{\partial}{\partial \eta} \\ \frac{\partial}{\partial \zeta} \end{bmatrix} = \mathbf{J} \begin{bmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} \end{bmatrix}, \quad \mathbf{J} = \begin{bmatrix} \frac{\partial x}{\partial \xi} & \frac{\partial y}{\partial \xi} & \frac{\partial z}{\partial \xi} \\ \frac{\partial x}{\partial \eta} & \frac{\partial y}{\partial \eta} & \frac{\partial z}{\partial \eta} \\ \frac{\partial x}{\partial \zeta} & \frac{\partial y}{\partial \zeta} & \frac{\partial z}{\partial \zeta} \end{bmatrix} \tag{92}$$

where $\mathbf{J}$ is the Jacobian matrix, one can define the base vectors in the (ξ, η, ζ) coordinates as

$$\begin{bmatrix} \hat{\xi} \\ \hat{\eta} \\ \hat{\zeta} \end{bmatrix} = \mathbf{J} \begin{bmatrix} \hat{x} \\ \hat{y} \\ \hat{z} \end{bmatrix} \tag{93}$$

In addition, one can define the reciprocal base vectors as

$$\begin{bmatrix} \hat{\xi}' \\ \hat{\eta}' \\ \hat{\zeta}' \end{bmatrix} = \begin{bmatrix} \nabla\xi \\ \nabla\eta \\ \nabla\zeta \end{bmatrix} = \begin{bmatrix} \frac{\partial \xi}{\partial x} & \frac{\partial \xi}{\partial y} & \frac{\partial \xi}{\partial z} \\ \frac{\partial \eta}{\partial x} & \frac{\partial \eta}{\partial y} & \frac{\partial \eta}{\partial z} \\ \frac{\partial \zeta}{\partial x} & \frac{\partial \zeta}{\partial y} & \frac{\partial \zeta}{\partial z} \end{bmatrix} \begin{bmatrix} \hat{x} \\ \hat{y} \\ \hat{z} \end{bmatrix} = \frac{1}{\det(\mathbf{J})} \begin{bmatrix} \hat{\eta} \times \hat{\zeta} \\ \hat{\zeta} \times \hat{\xi} \\ \hat{\xi} \times \hat{\eta} \end{bmatrix} \tag{94}$$

Similarly, it can be shown that

$$\begin{bmatrix} \hat{\xi} \\ \hat{\eta} \\ \hat{\zeta} \end{bmatrix} = \det(\mathbf{J}) \begin{bmatrix} \hat{\eta}' \times \hat{\zeta}' \\ \hat{\zeta}' \times \hat{\xi}' \\ \hat{\xi}' \times \hat{\eta} \end{bmatrix} \tag{95}$$

The base vectors and reciprocal base vectors satisfy the orthogonality

$$\hat{\xi} \cdot \hat{\xi}' = \hat{\eta} \cdot \hat{\eta}' = \hat{\zeta} \cdot \hat{\zeta}' = 1 \tag{96}$$

$$\hat{\xi} \cdot \hat{\eta}' = \hat{\xi} \cdot \hat{\zeta}' = \hat{\eta} \cdot \hat{\zeta}' = 0 \tag{97}$$

Obviously,

$$\hat{\xi} \cdot \left(\hat{\eta} \times \hat{\zeta} \right) = \frac{1}{\hat{\xi}' \cdot \left(\hat{\eta} \times \hat{\zeta}' \right)} = \det(\mathbf{J}) \tag{98}$$

DOI 10.1007/978-981-4560-75-7_5-1

Under the above coordinate transformation, a vector **V** may be represented by its covariant components

$$\mathbf{V} = \left(\mathbf{V}\cdot\hat{\xi}\right)\hat{\xi}' + (\mathbf{V}\cdot\hat{\eta})\hat{\eta}' + \left(\mathbf{V}\cdot\hat{\zeta}\right)\hat{\zeta}' = \mathbf{V}_{\xi}\hat{\xi}' + \mathbf{V}_{\eta}\hat{\eta}' + \mathbf{V}_{\zeta}\hat{\zeta}' \tag{99}$$

or by its contravariant components

$$\mathbf{V} = \left(\mathbf{V}\cdot\hat{\xi}'\right)\hat{\xi} + (\mathbf{V}\cdot\hat{\eta}')\hat{\eta} + \left(\mathbf{V}\cdot\hat{\zeta}'\right)\hat{\zeta} = \mathbf{V}_{\xi'}\hat{\xi} + \mathbf{V}_{\eta'}\hat{\eta} + \mathbf{V}_{\zeta'}\hat{\zeta} \tag{100}$$

Covariant Mapping: To preserve the tangential continuity of a vector **E** after coordinate mapping, one should use the covariant mapping as

$$\mathbf{E} = \mathrm{J}^{-1}\hat{\mathbf{E}} \tag{101}$$

where $\hat{\mathbf{E}}$ is its representation in the reference element where it has tangential continuity. This equation can be written more explicitly as

$$\begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} = \mathbf{J}^{-1}\begin{bmatrix} E_\xi \\ E_\eta \\ E_\zeta \end{bmatrix} \tag{102}$$

Examples of such field vectors are electric field **E** and magnetic field **H**.

Contravariant Mapping: On the other hand, for a field vector **B** that satisfies normal component continuity, one should use the contravariant mapping

$$\mathbf{B} = \frac{1}{\det(\mathbf{J})}\mathbf{J}^T\hat{\mathbf{B}} \tag{103}$$

where $\hat{\mathbf{B}}$ is its representation in the reference element where it has normal continuity (contravariant components), or equivalently

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \frac{1}{\det(\mathbf{J})}\mathbf{J}^T\begin{bmatrix} B_{\xi'} \\ B_{\eta'} \\ B_{\zeta'} \end{bmatrix} \tag{104}$$

Examples of such field vectors are electric flux density **D** and magnetic flux density **B**.

The curl of a covariant vector is a contravariant vector. Therefore, the transformation of the curl operation of a covariant vector is

$$\nabla\times\mathbf{E} = \frac{1}{\det(\mathbf{J})}\mathbf{J}^T\hat{\nabla}\times\hat{\mathbf{E}} \tag{105}$$

where $\hat{\nabla}\times\hat{\mathbf{E}}$ is the curl in the reference (ξ, η, ζ) domain. All these transformations can be used in the weak form Helmholtz equation to obtain the system matrix equation, as described below.

DOI 10.1007/978-981-4560-75-7_5-1

Solution of FEM Matrix Equation

Now consider a simple case where the outer boundary is PEC or PMC, or an unbounded problem truncated by PML backed by PEC or PMC. In this case, the surface integral term in Eq. 84 vanishes. Thus, the weak form Eq. 84 becomes

$$-\int_V (\nabla \times \mathbf{w}_m)\overline{\overline{\mu}}_r^{-1} \cdot (\nabla \times \mathbf{E})dv + k_0^2 \int_V \mathbf{w}_m \overline{\overline{\epsilon}}_r \cdot \mathbf{E}dv = \int_V \mathbf{w}_m \cdot \mathbf{S}_e dv \tag{106}$$

The unknown electric field is expanded as

$$\mathbf{E}(\mathbf{r}) \approx \sum_{n=1}^{N} e_n \mathbf{f}_n(x, y, z) \tag{107}$$

where $\mathbf{f}_n$ is the curl-conforming basis functions. Furthermore, one chooses $\mathbf{w}_m = \mathbf{f}_m$ under the Galerkin method. Then the weak form Eq. 106 is converted into a matrix equation

$$\mathbf{ZI} = \mathbf{V} \tag{108}$$

where

$$Z_{mn} = -\int_V \nabla \times \mathbf{f}_m \cdot \overline{\overline{\mu}}_r^{-1} \nabla \times \mathbf{f}_n dv + k_0^2 \int_V \mathbf{f}_m \cdot \overline{\overline{\epsilon}}_r \mathbf{f}_n dv \tag{109}$$

and $\mathbf{V}$ is the excitation vector, while $\mathbf{I}$ contains all the unknown expansion coefficients for $\mathbf{E}$.

The FEM system equation in Eq. 108 is a sparse matrix because low-order basis functions only have interactions with their adjacent elements. For a smaller system, this equation can be solved by a direct matrix inversion method such as Gaussian elimination of LU decomposition. However, if the number of degrees of freedom N is too large for a direct solver, a preconditioned iterative solution is usually performed. Recently, domain decomposition methods have gained much attention (Vouvakis et al. 2006; Zhao et al. 2007). The domain decomposition method has also started to be utilized by commercial tools such as HFSS.

Finite Difference Time Domain Method

For wideband simulations, a time domain solution is often preferred because one can obtain all results within that bandwidth with just one single simulation. The goal for a time domain method is to solve for the transient electromagnetic fields $\mathbf{E}(\mathbf{r}, t)$ and $\mathbf{H}(\mathbf{r}, t)$ as functions of space and time.

In this section, the finite difference time domain (FDTD) method (Yee 1966; Taflove and Hagness 2005) is present as it is arguably the most commonly used time domain methods in computational electromagnetics. The key in the FDTD method is the use of a staggered grid in both time domain and spatial domain, so that the central differencing scheme can be applied to both spatial and temporal derivatives.

Time domain Maxwell's curl equations, i.e., Faraday's law and Ampere's law,

DOI 10.1007/978-981-4560-75-7_5-1

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} - \sigma_m \mathbf{H} - \mathbf{M} \tag{110}$$

$$\nabla \times \mathbf{H} = \epsilon \frac{\partial \mathbf{E}}{\partial t} + \sigma_e \mathbf{E} + \mathbf{J} \tag{111}$$

are solved in the FDTD method.

Time Domain PML Equations

For electromagnetic wave propagation and scattering in an unbounded medium, however, one needs to apply the radiation boundary condition to the above equations. Recently, the most popular radiation boundary condition is achieved by the perfectly matched layer (PML) originally proposed by Berenger (Berenger 1994; Chew and Weedon 1994). However, that PML formulation is based on the split-field components and is shown to be only weakly well posed. Here the strongly well-posed PML formulation by Fan and Liu (2003) is used.

In the strongly well-posed PML, Faraday's law and Ampere's law are modified in the PML in a compact form:

$$\nabla \times \tilde{\mathbf{E}} = -\mu \frac{\partial \tilde{\mathbf{H}}}{\partial t} - (\sigma_m + \mu \mathbf{\Lambda}_1)\tilde{\mathbf{H}} - \mathrm{M} - (\sigma_m \mathbf{\Lambda}_1 + \mu \mathbf{\Lambda}_2)\mathbf{H}^{(1)} - \sigma_m \mathbf{\Lambda}_3 \mathbf{H}^{(2)} \tag{112}$$

$$\nabla \times \tilde{\mathbf{H}} = \epsilon \frac{\partial \tilde{\mathbf{E}}}{\partial t} + (\sigma_e + \epsilon \mathbf{\Lambda}_1)\tilde{\mathbf{E}} + \mathbf{J} + (\sigma_e \mathbf{\Lambda}_1 + \epsilon \mathbf{\Lambda}_2)\mathbf{E}^{(1)} + \sigma_e \mathbf{\Lambda}_3 \mathbf{E}^{(2)} \tag{113}$$

where $\tilde{\mathbf{E}}$ and $\tilde{\mathbf{H}}$ are the modified electric field and magnetic field inside the PML, while the field variables with superscripts (1) and (2) denote the first and second time integration of the corresponding fields. In the physical (non-PML) domain, $\tilde{\mathbf{E}}$ and $\tilde{\mathbf{H}}$ reduce to $\mathbf{E}$ and $\mathbf{H}$, respectively, and no auxiliary fields are needed. Moreover, it is assumed that the sources $\mathbf{J}$ and $\mathbf{M}$ only exist in the physical domain. The PML auxiliary time-integrated fields are governed by ordinary partial differential equations:

$$\frac{\partial \mathbf{E}^{(1)}}{\partial t} = \tilde{\mathbf{E}} - \mathbf{\Lambda}_0 \mathbf{E}^{(1)} \tag{114}$$

$$\frac{\partial \mathbf{E}^{(2)}}{\partial t} = \mathbf{E}^{(1)} \tag{115}$$

$$\frac{\partial \mathbf{H}^{(1)}}{\partial t} = \tilde{\mathbf{H}} - \mathbf{\Lambda}_0 \mathbf{H}^{(1)} \tag{116}$$

$$\frac{\partial \mathbf{H}^{(2)}}{\partial t} = \mathbf{H}^{(1)} \tag{117}$$

In the above,

$$\mathbf{\Lambda}_0 = \mathrm{Diag}\left[\omega_x, \omega_y, \omega_z\right] \tag{118}$$

DOI 10.1007/978-981-4560-75-7_5-1

$$\mathbf{\Lambda}_1 = \mathrm{Diag}\left[\omega_y + \omega_z - \omega_x, \omega_x + \omega_z - \omega_y, \omega_x + \omega_y - \omega_z\right] \tag{119}$$

$$\mathbf{\Lambda}_2 = \mathrm{Diag}\left[\left(\omega_x - \omega_y\right)\left(\omega_x - \omega_z\right), \left(\omega_y - \omega_x\right)\left(\omega_y - \omega_z\right), \ \left(\omega_z - \omega_x\right)\ \left(\omega_z - \omega_y\right)\right] \tag{120}$$

$$\mathbf{\Lambda}_3 = \mathrm{Diag}\left[\omega_y\omega_z, \omega_z\omega_x, \omega_x\omega_y\right] \tag{121}$$

Equations 112, 113, 114, 115, 116, and 117 constitute the unsplit-field, strongly well-posed PML equations, with some auxiliary ordinary differential equations for $\mathbf{E}^{(1)}$, $\mathbf{E}^{(2)}$, $\mathbf{H}^{(1)}$, and $\mathbf{H}^{(2)}$. Note that except for the lower-order terms, Eqs. 112, and 113 are identical to original 3-D Maxwell's equations; furthermore, the lower-order terms require little additional computational cost since they are obtained by the ordinary differential equations.

In the above, ω_x, ω_y, and ω_z are the PML attenuation coefficients along the x, y, and z directions and are usually chosen to have a quadratic profile, increasing from the inner PML boundary to the outer boundary (Liu 1997, 1999).

Finite Difference Temporal Discretization

The 3-D FDTD method discretizes the fields with staggered grids in both temporal and spatial dimensions. In the temporal dimension, for example, the electric field and magnetic current density are defined at the integer time steps

$$\tilde{\mathbf{E}}^n = \mathbf{E}(\mathbf{r}, t = n\Delta t), \quad \mathrm{M}^n = \mathrm{M}(\mathbf{r}, t = n\Delta t), \tag{122}$$

while the magnetic field and electric current density are defined at the half-integer time steps

$$\mathbf{H}^{n+1/2} = \mathbf{H}(\mathbf{r}, t = (n + 1/2)\Delta t), \quad \mathbf{J}^{n+1/2} = \mathbf{J}(\mathbf{r}, t = (n + 1/2)\Delta t) \tag{123}$$

The central finite difference approximation in time gives

$$\frac{\partial f(\mathbf{r}, t)}{\partial t} = \frac{f(\mathbf{r}, t + \Delta t/2) - f(\mathbf{r}, t - \Delta t/2)}{\Delta t} + O\left(\Delta t^2\right) \tag{124}$$

where $O(\Delta t^2)$ indicates that the error term is of second order with Δt, as can be proved by using Taylor expansion. Similarly, if one uses the forward or backward finite differencing schemes, the error will be only first order. Using Eq. 124 in Eqs. 111 and 110, at $t = (n + 1/2)\Delta t$, one has

$$\epsilon(\mathbf{r})\frac{\mathbf{E}^{n+1} - \mathbf{E}^n}{\Delta t} + \sigma_e(\mathbf{r})\frac{\mathbf{E}^{n+1} - \mathbf{E}^n}{2} \approx \left(\nabla \times \mathbf{H}^{n+1/2} - \mathbf{J}^{n+1/2}\right) \tag{125}$$

Similarly, at $t = n\Delta t$, one has

$$\mu(\mathbf{r})\frac{\mathbf{H}^{n+1/2} - \mathbf{H}^{n-1/2}}{\Delta t} + \sigma_m(\mathbf{r})\frac{\mathbf{H}^{n+1/2} - \mathbf{H}^{n-1/2}}{2} \approx \left(\nabla \times \mathbf{E}^n - \mathbf{M}^n\right) \tag{126}$$

Hence,

DOI 10.1007/978-981-4560-75-7_5-1

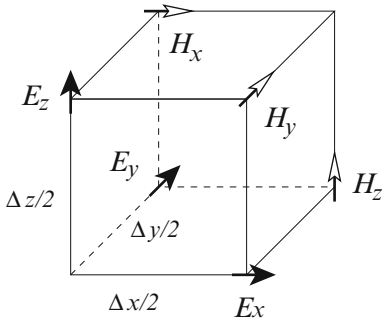

Fig. 6 The relative locations of field components in a 1/8 cell of the Yee staggered grid

$$\mathbf{H}^{n+\frac{1}{2}} = \frac{\mu - \Delta t\sigma_m/2}{\epsilon + \Delta t\sigma_m/2}\mathbf{H}^{n-\frac{1}{2}} - \frac{\Delta t}{\mu + \Delta t\sigma_m/2}\left[\nabla \times \mathbf{E}^n + \mathbf{M}^n\right] \tag{127}$$

$$\mathbf{E}^{n+1} = \frac{\epsilon - \Delta t\sigma_e/2}{\epsilon + \Delta t\sigma_e/2}\mathbf{E}^n + \frac{\Delta t}{\epsilon + \Delta t\sigma_e/2}\left[\nabla \times \mathbf{H}^{n+1/2} + \mathbf{J}^{n+1/2}\right] \tag{128}$$

This is a leap-frog system:

$$\left(\mathbf{H}^{-12}, \mathbf{E}^0\right) \rightarrow \mathbf{H}^{1/2} \rightarrow \mathbf{E}^1 \rightarrow \mathbf{H}^{3/2} \rightarrow \mathbf{E}^2 \rightarrow \mathbf{H}^{5/2} \cdots \tag{129}$$

Through the time stepping, $\mathbf{H}^{n\ +\ 1/2}$ and $\mathbf{E}^{n+1}$ can be found for all time steps provided that $\nabla \times \mathbf{E}$ and $\nabla \times \mathbf{H}$ can be obtained for the earlier time steps. The curl operations in the above are obtained by the spatial central differencing scheme below.

Finite Difference Spatial Discretization

Similar to the above staggered temporal grid where **E** and **H** are staggered by half a time step, one adopts the Yee grid for the spatial discretization so that the central differencing scheme can be applied. The computational domain of dimensions $L_x \times L_y \times L_z (x \in [x_{\min}, x_{\max} = x_{\min} + L_x]), y \in \left[y_{\min}, y_{max} = y_{\min} + L_y\right]$, $z \in \left[z_{\min}, z_{\max} = z_{\min} + L_z\right]\big)$ is discretized uniformly by $N_x \times N_y \times N_z$ cells, each with dimensions $\Delta x \times \Delta y \times \Delta z$, where $\Delta x = L_x/N_x$, $\Delta y = L_y/N_y$, and $\Delta z = L_z/N_z$ are the cell size along the x, y, and z directions, respectively. The integer grid point locations are

$$\begin{aligned} x_i &= x_{\min} + (i-1)\Delta x, \quad i = 1, \cdots, N_x + 1 \\ y_i &= y_{\min} + (j-1)\Delta y, \quad j = 1, \cdots, N_y + 1 \\ z_k &= z_{\min} + (k-1)\Delta z, \quad k = 1, \cdots, N_z + 1 \end{aligned} \tag{130}$$

while the half-integer grid points are at

$$\begin{aligned} x_{i+\frac{1}{2}} &= x_{\min} + \left(i - \frac{1}{2}\right)\Delta x, \quad i = 1, \cdots, N_x \\ y_{j+\frac{1}{2}} &= y_{\min} + \left(j - \frac{1}{2}\right)\Delta y, \quad j = 1, \cdots, N_y \\ z_{k+\frac{1}{2}} &= z_{\min} + \left(k - \frac{1}{2}\right)\Delta z, \quad k = 1, \cdots, N_z \end{aligned} \tag{131}$$

Furthermore, the temporal grid is also staggered, with the integer temporal grid points at

$$t_n = n\Delta t, \quad n = 1, \cdots, Nt \tag{132}$$

while the half-integer temporal grid points are at

$$t_{n+\frac{1}{2}} = \left(n + \frac{1}{2}\right)\Delta t, \quad n = -1, \cdots, Nt \tag{133}$$

Different components of the electromagnetic fields are located at different locations in this Yee grid, as shown in Fig. 6.

Specifically, one sets the tangential electric field components at the edge centers of a unit cell,

$$\begin{aligned} E^n_{x,\,i+1/2,j,k} &= E_x\left(x_{i+\frac{1}{2}}, y_j, z_k; t_n\right) \\ E^n_{y,\,i,j+1/2,k} &= E_y\left(x_i, y_{j+\frac{1}{2}}, z_k; t_n\right) \\ E^n_{z,\,i,j,\,k+1/2} &= E_z\left(x_i, y_j, z_{k+\frac{1}{2}}; t_n\right) \end{aligned} \tag{134}$$

and the same locations for **J**:

$$\begin{aligned} J^{n+\frac{1}{2}}_{x,\,i+1/2,j,k} &= J_x\left(x_{i+\frac{1}{2}}, y_j, z_k; t_{n+\frac{1}{2}}\right) \\ J^{n+\frac{1}{2}}_{y,\,i,j+1/2,k} &= J_y\left(x_i, y_{j+\frac{1}{2}}, z_k; t_{n+\frac{1}{2}}\right) \\ J^{n+\frac{1}{2}}_{z,\,i,j,\,k+1/2} &= J_z\left(x_i, y_j, z_{k+\frac{1}{2}}; t_{n+\frac{1}{2}}\right) \end{aligned} \tag{135}$$

The normal magnetic field components are set at the face centers of the unit cell,

$$\begin{aligned} H^{n+\frac{1}{2}}_{x,\,i,j+\frac{1}{2},k+\frac{1}{2}} &= H_x\left(x_i, y_{j+\frac{1}{2}}, z_{k+\frac{1}{2}}; t_{n+\frac{1}{2}}\right) \\ H^{n+\frac{1}{2}}_{y,\,i+\frac{1}{2},j,k+\frac{1}{2}} &= H_y\left(x_{i+\frac{1}{2}}, y_j, z_{k+\frac{1}{2}}; t_{n+\frac{1}{2}}\right) \\ H^{n+\frac{1}{2}}_{z,\,i+\frac{1}{2},j+\frac{1}{2},k} &= H_z\left(x_{i+\frac{1}{2}}, y_{j+\frac{1}{2}}, z_k; t_{n+\frac{1}{2}}\right) \end{aligned} \tag{136}$$

and the same locations for **M**:

$$\begin{aligned} M^n_{x,\,i,j+\frac{1}{2},k+\frac{1}{2}} &= M_x\left(x_i, y_{j+\frac{1}{2}}, z_{k+\frac{1}{2}}; t_n\right) \\ M^n_{y,\,i+\frac{1}{2},j,k+\frac{1}{2}} &= M_y\left(x_{i+\frac{1}{2}}, y_j, z_{k+\frac{1}{2}}; t_n\right) \\ M^n_{z,\,i+\frac{1}{2},j+\frac{1}{2},k} &= M_z\left(x_{i+\frac{1}{2}}, y_{j+\frac{1}{2}}, z_k; t_n\right) \end{aligned} \tag{137}$$

Note that in the above, the superscripts have been used to denote the temporal locations according to the central differencing scheme in temporal derivatives.

Then using the central differencing scheme (124) yields, for example,

DOI 10.1007/978-981-4560-75-7_5-1

$$\left.\frac{\partial H_z^{n+\frac{1}{2}}}{\partial y}\right|_{i+\frac{1}{2},j,k} \approx \frac{1}{\Delta y}\left[H_z^{n+\frac{1}{2}}\left(i+\frac{1}{2},j+\frac{1}{2},k\right) - H_z^{n+\frac{1}{2}}\left(i+\frac{1}{2},j-\frac{1}{2},k\right)\right] \equiv \frac{1}{\Delta y} Dy\left[H_z^{n+\frac{1}{2}}\right]\left(i+\frac{1}{2},j,k\right) \tag{138}$$

where the difference operator D_ξ ($\xi = x, y, z$) operating on a function $f_\eta^d(\eta = x, y, z;\ \ d = n \text{ or } n+\frac{1}{2})$ at spatial temporal grid point d is defined at the spatial grid point (a, b, c) as

$$D_\xi\left[f_\eta^d\right]_{a,b,c} = f^d_{\eta,(a,b,c)+\hat{\eta}\frac{1}{2}} - f^d_{\eta,(a,b,c)-\hat{\eta}\frac{1}{2}}, \quad \xi,\eta = x,y,z \tag{139}$$

Note that in the above expression, d, a, b, c are integers or half-integers depending of the field components.

Outer Boundary Conditions

Note that in the above updating equations, boundary conditions are needed. If a computational domain of $L_x \times L_y \times L_z$ is uniformly divided into $N_x \times N_y \times N_z$ cells, with $\Delta x = L_x/N_x$, $\Delta y = L_y/N_y$, and $\Delta z = L_z/N_z$, the number of field components in the whole domain is

$$\begin{aligned} E_x:&\quad N_x\left(N_y+1\right)\left(N_z+1\right)\\ E_y:&\quad \left(N_x+1\right)N_y\left(N_z+1\right)\\ E_z:&\quad \left(N_x+1\right)\left(N_y+1\right)N_z\\ H_x:&\quad \left(N_x+1\right)N_yN_z\\ H_y:&\quad N_x\left(N_y+1\right)N_z\\ H_z:&\quad N_xN_y\left(N_z+1\right)\end{aligned}$$

where it is assumed that the outer boundaries have the tangential **E** and normal **H** components. These boundary field components cannot be obtained by the time-stepping equations above, so they need to be determined by boundary conditions.

PEC Boundary Conditions

When the PEC boundary condition are required on the outer boundaries, it is convenient to make the tangential components of the electric field to be located at the outer boundaries, as discussed above where the tangential electric field components are located at the edge centers of a unit cell.

For example, PEC at $x = x_{min}$ and $x = x_{max}$ planes can be simply applied by setting

$$\begin{gathered} E_{y,1,j,k} = E_{y,N_x+1,j,k} = E_{z,1,j,k} = E_{z,N_x+1,j,k} = 0\\ H_{x,1,j,k} = H_{x,N_x+1,j,k} = 0\end{gathered} \tag{140}$$

In this case, one does not need to update these field components if they have been set zero at the beginning of the program.

Another boundary condition is the impedance boundary condition at one or all outer boundaries.

PMC Boundary Conditions

For PMC boundary conditions, it is more convenient to set the tangential components of the magnetic field at the outer boundary. This will require to shift the cell half a cell or, equivalently, exchange **E** and **H** in the above field locations. Then, one can apply the boundary conditions easily by setting

DOI 10.1007/978-981-4560-75-7_5-1

$$H_{y,1,j,k} = H_{y,N_x+1,j,k} = H_{z,1,j,k} = H_{z,N_x+1,j,k} = 0$$
$$E_{x,1,j,k} = E_{x,N_x+1,j,k} = 0 \tag{141}$$

Radiation Boundary Conditions

For unbounded media, one has to use a radiation condition to simulate the outgoing scattered fields so that there is negligible reflection from the truncated boundary at the computational edge. Several approximate radiation boundary conditions are possible:

- **Transmitting boundary condition:** Field extrapolation by using various transmitting boundary conditions, for example, Liao's, Lindman's, and Mur's absorbing boundary conditions.
- **Sponge boundary condition:** Tapered absorber outside the computational domain. This consists of a layer of lossy material of finite thickness outside the interested domain; the outer boundary conditions of this absorber are usually the PEC or PMC boundary conditions. This boundary condition is also known as the sponge boundary condition.
- **PML absorber:** In this case, the perfectly matched layer is used as a special absorber that provides highly effective attenuation to outgoing waves without giving rise to noticeable reflections.

In the following subsection, the PML absorbing boundary condition will be presented in the updating equations in the FDTD method.

The PML Updating Equations

The strongly well-posed PML for 3-D lossy media formulated by Fan and Liu (2003) is used here as presented in Eqs. 112, 113, 114, 115, 116, and 117. The discretization of these equations is similar to the regular Maxwell's equations, with the only difference being the additional ordinary differential equations in Eqs. 114, 115, 116, and 117. With the staggered grid discretization in temporal and spatial derivatives, one can obtain the field updating equations for the magnetic field:

$$\begin{aligned}\tilde{H}^{n+\frac{1}{2}}_{x,i,j+\frac{1}{2},k+\frac{1}{2}} &= B_{x1}\tilde{H}^{n-\frac{1}{2}}_{x,i,j+\frac{1}{2},k+\frac{1}{2}} - B_{x2}D_y\left[\tilde{E}^n_z\right]_{i,j+\frac{1}{2},k+\frac{1}{2}} \\ &\quad + B_{x3}D_z\left[\tilde{E}^n_y\right]_{i,j+\frac{1}{2},k+\frac{1}{2}} - B_{x4}H^{(1),n}_{x,i,j+\frac{1}{2},k+\frac{1}{2}} \\ &\quad - B_{x5}H^{(2),n}_{x,i,j+\frac{1}{2},k+\frac{1}{2}} - B_{x0}M^n_{x,i,j+\frac{1}{2},k+\frac{1}{2}}\end{aligned} \tag{142}$$

$$\begin{aligned}\tilde{H}^{n+\frac{1}{2}}_{y,i+\frac{1}{2},j,k+\frac{1}{2}} &= B_{y1}\tilde{H}^{n-\frac{1}{2}}_{y,i+\frac{1}{2},j,k+\frac{1}{2}} - B_{y2}D_z\left[\tilde{E}^n_x\right]_{i+\frac{1}{2},j,k+\frac{1}{2}} \\ &\quad + B_{y3}D_x\left[\tilde{E}^n_z\right]_{i+\frac{1}{2},j,k+\frac{1}{2}} - B_{y4}H^{(1),n}_{y,i+\frac{1}{2},j,k+\frac{1}{2}} \\ &\quad - B_{y5}H^{(2),n}_{y,i+\frac{1}{2},j,k+\frac{1}{2}} - B_{y0}M^n_{y,i+\frac{1}{2},j,k+\frac{1}{2}}\end{aligned} \tag{143}$$

$$\begin{aligned}\tilde{H}^{n+\frac{1}{2}}_{z,i+\frac{1}{2},j+\frac{1}{2},k} &= B_{z1}\tilde{H}^{n-\frac{1}{2}}_{z,i+\frac{1}{2},j+\frac{1}{2},k} - B_{z2}D_x\left[\tilde{E}^n_y\right]_{i+\frac{1}{2},j+\frac{1}{2},k} \\ &\quad + B_{z3}D_y\left[\tilde{E}^n_x\right]_{i+\frac{1}{2},j+\frac{1}{2},k} - B_{z4}H^{(1),n}_{z,i+\frac{1}{2},j+\frac{1}{2},k} \\ &\quad - B_{z5}H^{(2),n}_{z,i+\frac{1}{2},j+\frac{1}{2},k} - B_{z0}M^n_{z,i+\frac{1}{2},j+\frac{1}{2},k}\end{aligned} \tag{144}$$

where the finite difference coefficients are

DOI 10.1007/978-981-4560-75-7_5-1

$$B_{x0} = \left.\frac{2\Delta t}{2\mu + \Delta t\left(\sigma_m + \omega_{yzx}\mu\right)}\right|_{i,j+\frac{1}{2},k+\frac{1}{2}} \tag{145}$$

$$B_{x1} = \left.\frac{2\mu - \Delta t\left(\sigma_m + \omega_{yxz}\mu\right)}{2\mu + \Delta t\left(\sigma_m + \omega_{yzx}\mu\right)}\right|_{i,j+\frac{1}{2},k+\frac{1}{2}} \tag{146}$$

$$E_z^{(1),n+\frac{1}{2}} = \frac{2-\omega_z\Delta t}{2+\omega_z\Delta t}E_z^{(1),n-\frac{1}{2}} + \frac{2\Delta t}{2+\omega_z\Delta t}\tilde{E}_z^n \tag{183}$$

where the second-order time-integrated fields are updated first because this avoids storing two steps of the first-order time-integrated fields.

Similarly, for the time-integrated magnetic field components, one has

$$H_x^{(2),n} = H_x^{(2),n-1} + \Delta t H_x^{(1),n-\frac{1}{2}} = H_x^{(2),n-1} + \frac{\Delta t}{2}\left[H_x^{(1),n} + H_x^{(1),n-1}\right] = H_x^{(2),n-1} + \Delta t\left[\frac{2}{2+\omega_x\Delta t}H_x^{(1),n-1} + \frac{\Delta t}{2+\omega_x\Delta t}\tilde{H}_x^{n-\frac{1}{2}}\right] \tag{184}$$

$$H_y^{(2),n} = H_y^{(2),n-1} + \Delta t H_y^{(1),n-\frac{1}{2}} = H_y^{(2),n-1} + \frac{\Delta t}{2}\left[H_y^{(1),n} + H_y^{(1),n-1}\right] = H_y^{(2),n-1} + \Delta t\left[\frac{2}{2+\omega_y\Delta t}H_y^{(1),n-1} + \frac{\Delta t}{2+\omega_y\Delta t}\tilde{H}_y^{n-\frac{1}{2}}\right] \tag{185}$$

$$H_z^{(2),n} = H_z^{(2),n-1} + \Delta t H_z^{(1),n-\frac{1}{2}} = H_z^{(2),n-1} + \frac{\Delta t}{2}\left[H_z^{(1),n} + H_z^{(1),n-1}\right] = H_z^{(2),n-1} + \Delta t\left[\frac{2}{2+\omega_z\Delta t}H_z^{(1),n-1} + \frac{\Delta t}{2+\omega_z\Delta t}\tilde{H}_z^{n-\frac{1}{2}}\right] \tag{186}$$

DOI 10.1007/978-981-4560-75-7_5-1

$$H_x^{(1),n} = \frac{2-\omega_x\Delta t}{2+\omega_x\Delta t} H_x^{(1),n-1} + \frac{2\Delta t}{2+\omega_x\Delta t}\tilde{H}_x^{n-\frac{1}{2}} \tag{187}$$

$$H_y^{(1),n} = \frac{2-\omega_y\Delta t}{2+\omega_y\Delta t} H_y^{(1),n-1} + \frac{2\Delta t}{2+\omega_y\Delta t}\tilde{H}_y^{n-\frac{1}{2}} \tag{188}$$

$$H_z^{(1),n} = \frac{2-\omega_z\Delta t}{2+\omega_z\Delta t} H_z^{(1),n-1} + \frac{2\Delta t}{2+\omega_z\Delta t}\tilde{H}_z^{n-\frac{1}{2}} \tag{189}$$

The above equations give all field components for all time steps if the outer boundary conditions are known (usually it is the PEC boundary condition outside the PML). The procedure for the 3-D FDTD method is as follows:

Step 0: For time step $n = 0$, initialize all field components so that they satisfy the initial conditions for $\tilde{\mathbf{H}}^{-\frac{1}{2}}$, $\tilde{E}^0$, $\mathbf{H}^{(2),-1}$, $\mathbf{H}^{(1),-1}$, $\mathbf{E}^{(2),-\frac{1}{2}}$, and $\mathbf{E}^{(1),-\frac{1}{2}}$. For non-PML regions (i.e., the physical domain), the time-integrated fields are not needed. (Most of the time these are zero before $t = 0$.) For a required time window t_{max}, find $N_t = ceil(t_{max}/\Delta t)$, where Δt should be smaller than the maximum time step allowed by the CFL stability condition.

Step 1: Update the time-integrated magnetic fields $\mathbf{H}^{(2),n}$ and then $\mathbf{H}^{(1),n}$ inside the PML.

Step 2: Update the magnetic field components $\tilde{\mathbf{H}}^{n+\frac{1}{2}}$ inside PML and $\tilde{\mathbf{H}}^{n+\frac{1}{2}}$ in the physical domain besides the outer boundary (these can use the same array). Apply boundary conditions for the magnetic field components on the outer boundary; for PML backed by a PEC outer boundary, this is not needed explicitly because the zero normal magnetic field on PEC is already set in the initial condition.

Step 3: Update the time-integrated electric field $\mathbf{E}^{(2),n+\frac{1}{2}}$ and then $\mathbf{E}^{(1),n+\frac{1}{2}}$ inside the PML.

Step 4: Update the electric field component $\mathbf{E}^{n+1}$ everywhere except for the outer boundary. Apply boundary conditions for the electric field components on the outer boundary; for PML backed by a PEC outer boundary, this is not needed explicitly because the zero tangential electric field is already set in the initial condition.

Step 5: Increase the time step index n by 1. If $n > N_t$, then exit; otherwise, go back to Step 1 above.

Note that in the non-PML (physical) region, there is no need to include the time-integrated field components.

Accuracy and Stability Conditions

As discussed above, the FDTD method uses a regular (structured) grid where the grid lines are parallel to the coordinate axes. For objects having curved surfaces, therefore, there will be a so-called staircasing error due to the staircased approximation. As a result, the FDTD has lower accuracy than the finite element method in terms of geometrical representation. Typically, one can use the following guideline to choose the discretization step:

$$\Delta x \le \frac{\lambda_{\min}}{N_{PPW}} \tag{190}$$

where $\lambda_{\min}$ is the minimum wavelength in the whole domain at the highest frequency of interest and N_{PPW} denotes the sampling density in terms of the number of points per minimum wavelength. Typically, one

needs to choose $N_{PPW} = 10$ to 20 to ensure good accuracy. However, this is only a rough guideline, as the numerical dispersion error increases linearly with the number of time steps.

Given a fixed spatial discretization, the maximum time step increment has to satisfy the following condition:

$$\Delta t \leq \frac{\Delta x}{\sqrt{D} c_{\max}} \tag{191}$$

in order for the FDTD method to be stable, where c_{max} is the maximum speed of light $c_{\max} = c/\sqrt{\min(\mu_r \epsilon_r)}$ and D is the dimensionality; for example, $D = 3$ for 3-D problems.

Techniques to Improve the FDTD Method

In a homogeneous medium or a smooth medium where the material properties change continuously with space, all field components are continuous. Therefore, the central finite difference scheme used in the FDTD method will give the second-order accuracy.

On the other hand, if the material is discontinuous inside the computational domain, the FDTD method will only have the first-order accuracy. Furthermore, for curve geometries, the FDTD method will introduce the staircasing approximation error, further decreasing the accuracy.

Despite the simplicity and robustness of the FDTD method, its lower accuracy greatly limits its applications. Over the years, many techniques have been proposed to improve the FDTD method, especially to remove the first-order accuracy and the staircasing approximation. Below only the enlarged cell technique to improve the FDTD method will be discussed.

The Enlarged Cell Technique (ECT)

A conformal finite difference time domain (CFDTD) method has been put forward by Dey and Mittra (Dey and Mittra 1997; Yu and Mittra 2000) to accurately model curved perfectly conducting objects. The method deforms the grid locally to accommodate the curvature of the PEC surface and, therefore, avoids the significant staircase error of the conventional FDTD method in approximating boundaries.

In the CFDTD method, however, the deformed grid may lead to a numerical instability due to the existence of some small-area cells. To overcome this problem, previous methods either remove the problematic small cells by assuming them totally inside the conducting bodies or reduce the time step (Dey and Mittra 1997) to obtain a stable solution. These will either decrease the accuracy or increase the run time.

The ECT was developed by Xiao and Liu (2004, 2008) to preserve the accuracy of the CFDTD method without affecting its efficiency from the FDTD method. The most important step in the ECT is to enlarge the unstable small cells into the adjacent cells so that the scheme remains stable, yet without affecting the local accuracy because it makes the electromotive force conservative.

An obvious advantage of the ECT is that it is more efficient than the conventional CFDTD method because it can obtain a stable solution without time step increment reduction. Another advantage is found by recalling that the FDTD algorithm usually has a smaller dispersion error for a larger time step. So the ECT is even more accurate than the conventional CFDTD method by allowing a larger time step. Such an ECT method has been utilized in commercial tool Wavenology.

Toward the Multiscale DGTD Method

The predominant time domain commercial tools utilize FDTD (or FIT) methods, which are limited to single-scale problems. In order to solve multiscale problems with both electrically coarse but large regions as well as electrically fine details, it is desirable to use different techniques for different regions.

DOI 10.1007/978-981-4560-75-7_5-1

The discontinuous Galerkin time domain (DGTD) method provides such a possibility. It uses the discontinuous Galerkin method; thus, different regions can have different and non-conformal meshes (or grids), thereby allowing different schemes to be used to their advantages. The finite element time domain (FETD), finite difference time domain (FDTD), and spectral element time domain (SETD) methods have been combined in the DGTD framework to solve multiscale problems (Chen and Liu 2013). Furthermore, a nonlinear circuit solver based on SPICE has been combined into this DGTD method to allow true circuit-field interactions in some commercial tools (e.g., Wavenology).

Conclusion

Commercial antenna design tools have seen rapid development over the last two decades. Although most tools use the traditional finite element method, method of moments, and finite difference time domain method, there is a noticeable trend toward solving multiscale problems by developing new technologies that can allow multi-solver integration. This is expected to greatly impact the antenna design optimization and the integration of antennas with sensor networks.

Abstract

The principal computational electromagnetics techniques for solving antenna problems are reviewed. An introduction is given on a historical review of how antenna problems were solved in the past. The call for precise solutions calls for the use of numerical methods as found in computational electromagnetics. A brief introduction on differential equation solutions and integral solutions is given. The Green's function concept is introduced to facilitate the formulation of integral equations. Numerical methods and fast algorithms to solve these equations are discussed.

Then an overview of how electromagnetic theory relates to circuit theory is presented. Then the concept of partial element equivalence circuit is introduced to facilitate solutions to more complex problems. In antenna technology, one invariably has to have a good combined understanding of the wave theory and circuit theory.

Next, the discussion on the computation of electromagnetic solutions in the "twilight zone" where circuit theory meets wave theory was presented. Solutions valid for the wave physics regime often become unstable facing low-frequency catastrophe when the frequency is low.

Due to advances in nanofabrication technology, antennas can be made in the optical frequency regime. But their full understanding requires the full solutions of Maxwell's equations. Also, many models, such as perfect electric conductors, which are valid at microwave frequency, are not valid at optical frequency. Hence, many antenna concepts need rethinking in the optical regime.

Next, an emerging area of the use of eigenanalysis methods for antenna design is discussed. This can be the characteristic mode analysis or the natural mode analysis. These analysis methods offer new physical insight not possible by conventional numerical methods.

Then the discussion on the use of the domain decomposition method to solve highly complex and multi-scale antenna structures is given. Antennas, due to the need to interface with the circuit theory, often have structures ranging from a fraction of a wavelength to a tiny fraction of a wavelength. This poses a new computational challenge that can be overcome by the domain decomposition method.

Many antenna designs in the high-frequency regime or the ray optics regime are guided by ray physics and the adjoining mathematics. These mathematical techniques are often highly complex due to the rich physics that come with ray optics. The discussion on the use of these new mathematical techniques to reduce computational workload and offering new physical insight is given.

A conclusion section is given to summarize this chapter and allude to future directions.

Introduction

Maxwell's equations, completed by James Clerk Maxwell in 1864, have been guiding electromagnetic theory for over 150 years now (Maxwell 1865). Solutions to Maxwell's equations have offered physical insight and guidance for myriads of electromagnetics technologies including antenna design. In the beginning, it was the use of analytic solutions. For instance, the solution of a radiating Hertzian dipole offers insight on the physics of its radiation. It provides physical insight on its radiation pattern, the near field and far field of the dipole, its radiation resistance, its directivity, and its gain. These are all figures of merit for an antenna designer.

Due to the complex shapes of antennas, closed-form solutions are quickly exhausted. Then approximate solutions are sought, and they have been used to gain physical insight into the antenna design. For instance, the half-wave dipole has no closed-form solution, but physical intuition tells that the current distribution is close to being sinusoidal. Hence, many figures of merit of a half-wave dipole can be calculated based on approximate models.

Another area of antenna design where approximation methods reign superior is in high-frequency antennas or reflector antennas. Due to the large radius of curvature of the antennas, quasi-optical techniques such as the physical optics approximation can be used to ascertain the radiation field of the antenna. Ray optics can be used to gain physical insight. Edge diffraction from the edge of the parabolic reflector can be estimated by using the canonical solution of the Sommerfeld half-plane (Sommerfeld 1896). Uniform asymptotic theory and uniform theory of diffraction are both used to refine the solutions (Keller 1962; Kouyoumjian and Pathak 1974; Lee and Deschamps 1976; Hansen 1981). The idea of approximate methods to gain physical insight prevails up to the late 1970s and early 1980s even for microstrip antenna designs (Lo et al. 1979; Chew and Kong 1981).

Even though modeling and simulation are important, physical insight is equally important. The most famous of this is the design of the Yagi-Uda antenna, proposed by Professor Yagi and his student, Uda, in 1926 (Yagi and Uda 2014). They had the insight that an array of dipoles can act like a waveguide. The simple dipole, made of a length of straight wire, is also called a linear antenna. When this linear antenna is slightly less than a half wavelength, it is capacitive, and an array of them can act like a waveguide. Hence, the dipole array, put in front of a half-wave dipole, can help guide the energy of the radiation field in the forward direction, enhancing its radiation in that direction and, hence, its directivity. When the linear antenna is slightly larger than a half wavelength, it becomes inductive and ceases to be a waveguide. Such a linear antenna is used as a reflector in the Yagi-Uda array.

When numerical methods became popular, integral equation methods were designed to solve linear antennas more accurately. Examples of such integral equation are the Hallén integral equation and Pocklington integral equation (Balanis 2012b). Approximate numerical method together with semi-analytic methods was used to solve these integral equations. Semi-analytic methods were popular because of the slowness of computers back then (King 1956).

DOI 10.1007/978-981-4560-75-7_6-2

Computers became powerful very quickly with the advancement of the electronic computers. Differential equation solvers as well as integral equation solvers were developed to solve Maxwell's equations. In differential equation solvers, the unknowns are the field. Hence, the unknown counts are spread over volumetric space and, therefore, scale as the volume of the space of L^3 where L is the typical length of the simulation region. Moreover, in order to simulate an infinite region, absorbing boundary conditions are needed at the boundary of the simulation domain.

In integral equation solvers, the unknowns are the sources or the currents on the antenna. In many cases, these unknowns reside on the surface of the antenna structure, and thus, they live in a 2D manifold. In the cases of antennas that can be modeled by wire structures, the unknowns reside on a 1D manifold. Consequently, integral equation solvers became popular because the unknown count can be smaller. Very soon, integral equations were solved with the method of moments and applied to linear antennas. Linear antennas were popular because the unknowns were functions of a one-dimensional variable, and henceforth, they live in a one-dimensional space. Usually, many practical problems can be solved with a small number of unknowns and therefore needing the solution of small matrix systems.

As the antenna structure becomes more complex, more unknowns are needed. Early complex antenna structures were modeled with wire structures as in the numerical electromagnetic code (NEC). Very soon, surface patch models were developed and popularized (Burke and Poggio 1981; Rao et al. 1982).

A drawback of the integral equation solver is the memory usage. The matrix system is often dense and hence consumes $O(N^2)$ memory usage. For antennas that can be modeled as surface patches, $N \sim O((kL)^2)$ where L is the typical dimension of the antenna. Henceforth, memory usage scales as $(kL)^4$ for them. When used to solve linear antennas, $N \sim O(kL)$ and therefore the memory usage scales as $(kL)^2$.

On the other hand, differential equation solvers are easier to implement even though unknown counts are larger. Moreover, the innate matrix system that is related to a differential equation is inherently sparse. Therefore, when combined with iterative solvers, the matrix system can be efficiently stored with $O(N)$ memory where N is the dimension of the matrix and, hence, the number of unknowns. Furthermore, each matrix-vector product can be effected in $O(N)$ operations. Consequently, the iterative solver can be effected with $O(N)$ operations per iteration. Typically, the memory usage and CPU time usage scale as $(kL)^3$ when grid dispersion error is ignored. Hence, it could be more efficient than integral equation solvers.

A powerful differential equation solver is the finite-difference time-domain method invented by Yee (1966) and popularized by Taflove (1995). In this method, the construction of the matrix system is not needed, and a matrix-vector product is effected by some rather simple operations. Since only the unknown fields at different time steps need to be stored, the memory and CPU time usage are both $O(N)$. Even though FDTD is solved with time stepping, it is equivalent to iteration in iterative solvers. Iterative solvers are generally applied to frequency-domain solutions.

Due to advancements of differential equation solvers, their efficiency, and their simplicity, they have become rather popular. They can be used to solve problems with tens of thousands of unknowns easily and, hence, many practical real-world problems.

In recent years, however, fast integral equation solvers have been developed (Rokhlin 1990; Coifman et al. 1993; Chew et al. 2001). In these solvers, iterative methods are used to solve integral equations without the need to construct the matrix system. Thus, the matrix is never stored and only the action of the matrix on a vector needs to be stored. Henceforth, memory requirements of the fast integral equation solvers are reduced to $O(N \log N)$ for dynamic problems while to $O(N)$ to static or low-frequency problems. Moreover, the matrix-vector product can be effected in $O(N \log N)$ operations. So, the memory usage for an antenna that can be modeled by surface currents scales as $(kL)^2$ and the operations per iteration scale as $(kL)^2 \log kL$, greatly reducing the memory and CPU usage compared to differential equation solvers.

Differential Equations-Maxwell's Equations

Maxwell's equations establish that the theory of electricity and magnetism and theory of optics are actually one and the same theory. Both of them have waves propagating at the velocity of light. The velocity of light, and astronomical number, was established by Roemer via astronomical observation long ago (in year 1676).

Maxwell's equations in the time domain are completely described by the four equations:

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \tag{1}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{2}$$

$$\nabla \cdot \mathbf{D} = \varrho \tag{3}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{4}$$

When Maxwell's equations were first derived by Maxwell, they were not as elegant and succinct as the above. It was the work of Oliver Heaviside who casts them into the above form (Heaviside 1888).

For time-varying problems, the third and the fourth equations are derivable from the first two by taking their divergence. Hence, only the first two equations can be considered as independent, and only them need to be solved for time-varying problems.

Since there are four unknowns **E**, **H**, **D**, and **B** with two independent equations, the constitutive relations are the addition equations in order to obtain four equations and four unknowns, viz., for isotropic media,

$$\mathbf{D} = \epsilon \mathbf{E} \tag{5}$$

$$\mathbf{B} = \mu \mathbf{H} \tag{6}$$

The above constitutive relations are sufficient to describe most materials at microwave frequencies. For some materials such as ferrites, the above will have to be replaced with the constitutive relations for anisotropic media.

The Yee algorithm will solve the first two of the above first-order partial differential equations directly. But many algorithms will first convert the above into one second-order partial differential equation. By assuming $\exp(-i\omega t)$ dependence, $\partial/\partial t$ can be replaced by $-i\omega$ in the above equations. Then by dividing the first equation by ϵ, taking its curl, and then replacing the resultant right-hand side with the second Maxwell's equations, one arrives at

$$\nabla \times \epsilon^{-1} \nabla \times \mathbf{H} - \omega^2 \mu \mathbf{H} = \nabla \times \epsilon^{-1} \mathbf{J} \tag{7}$$

Similarly, one has

$$\nabla \times \mu^{-1} \nabla \times \mathbf{E} - \omega^2 \epsilon \mathbf{E} = i\omega \mathbf{J} \tag{8}$$

DOI 10.1007/978-981-4560-75-7_6-2

One needs only solve one of the two equations above since they are derivable from each other. When the above equation is solved by a numerical method, the field **H** or **E** is treated as the unknown, and the source is assumed known.

Scalar and Dyadic Green's Function

The Green's function is useful because it expresses the field in terms of the source of a system. It is the point source response of the partial differential equation or the field generated due to a point source. When a medium is homogeneous, such a response or Green's function can be found easily. It is well known that when the Helmholtz equation is driven by a point source, the response is the scalar Green's function, namely,

$$\nabla^2 g(\mathbf{r}, \mathbf{r}') + k^2 g(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \tag{9}$$

and $g(\mathbf{r}, \mathbf{r}') = \exp(ik|\mathbf{r} - \mathbf{r}'|)/(4\pi|\mathbf{r} - \mathbf{r}'|)$ and $k = \omega\sqrt{\mu\epsilon} = \omega/c$. Hence, when the medium is homogeneous, the above vector wave equation can be written as

$$\nabla\nabla \cdot \mathbf{E} - \nabla \cdot \nabla\mathbf{E} - k^2\mathbf{E} = i\omega\mu\mathbf{J} \tag{10}$$

where the identity has been used that $\nabla \times \nabla \times \mathbf{E} = \nabla\nabla \cdot \mathbf{E} - \nabla \cdot \nabla\mathbf{E}$. Furthermore, by noting that $\nabla \cdot \mathbf{E} = \varrho/\epsilon$, the above becomes

$$\nabla^2\mathbf{E} + k^2\mathbf{E} = -i\omega\mu\mathbf{J} + \nabla\varrho/\epsilon \tag{11}$$

By using the principle of linear superposition and the solution to Eq. 9, the solution to the above can be written as

$$\mathbf{E}(\mathbf{r}) = i\omega\mu\int_V d\mathbf{r}' g(\mathbf{r}, \mathbf{r}')\mathbf{J}(\mathbf{r}') - \int_V d\mathbf{r}' g(\mathbf{r}, \mathbf{r}')\nabla'\varrho(\mathbf{r}')/\epsilon \tag{12}$$

$$= i\omega\mu\int_V d\mathbf{r}' g(\mathbf{r}, \mathbf{r}')\mathbf{J}(\mathbf{r}') - \frac{1}{i\omega\epsilon}\nabla\int_V d\mathbf{r}' g(\mathbf{r}, \mathbf{r}')\nabla' \cdot \mathbf{J}(\mathbf{r}') \tag{13}$$

The above is reminiscent of that

$$\mathbf{E} = i\omega\mathbf{A} - \nabla\phi \tag{14}$$

One can also symbolically write that

$$\mathbf{E}(\mathbf{r}) = i\omega\mu\int_V d\mathbf{r}'\overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') \tag{15}$$

where the action of the dyadic Green's function on the current **J** plus the integral is to effect the integral in Eq. 12 above.

Integral Equation of Excitation

An antenna is usually made of metal and excited by a source. The source generates an incident field on the antenna. At microwave frequencies, metallic structures can be approximated by a perfect electric

DOI 10.1007/978-981-4560-75-7_6-2

conductor (PEC) where the tangential component of the electric field is zero. Otherwise, there would be infinite surface current flowing on the surface of the PEC structure.

As a result, a surface current is induced on the antenna so as to produce a field that cancels the incident field on the surface of the antenna structure. This physical concept can be represented by the following integral equation:

$$-\hat{t} \cdot \mathbf{E}_{inc}(\mathbf{r}) = i\omega\mu\hat{t} \cdot \int_S dS' \overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}'), \quad \mathbf{r} \in S \tag{16}$$

Source Excitation Methods

Reflector antennas are usually driven by a feed which is usually a horn antenna. The modeling of the feed can be done by the equivalence principle. For smaller antennas at lower frequencies, oftentimes, an antenna is driven by a current source or voltage source at its terminal. The equivalence principle can be used to obtain the equivalence problem that needs to be solved before approximations are made.

Equivalence Principle

The equivalence principle can be derived mathematically by invoking Green's theorem for scalar waves or vector Green's theorem for electromagnetic waves. But it can be argued physically or by the Gedankenexperiment. Imaging a set of sources generates **E** and **H** fields in free space. One defines a surface S on which one will impress the surface electric current $\mathbf{J}_s = \hat{n} \times \mathbf{H}$ and surface magnetic current $\mathbf{M}_s = \mathbf{E} \times \hat{n}$. One assumes that the fields $\mathbf{E} = \mathbf{H} = 0$ inside S and that the original fields are unchanged outside S. These fields definitely satisfy the jump conditions induced by $\mathbf{J}_s$ and $\mathbf{M}_s$ at the interface. Furthermore, the fields outside satisfy the boundary conditions (including the radiation condition at infinity) on the surface S, and hence, by the uniqueness theorem, they are the only solution (Figs. 1, 2, 3, 4, and 5).

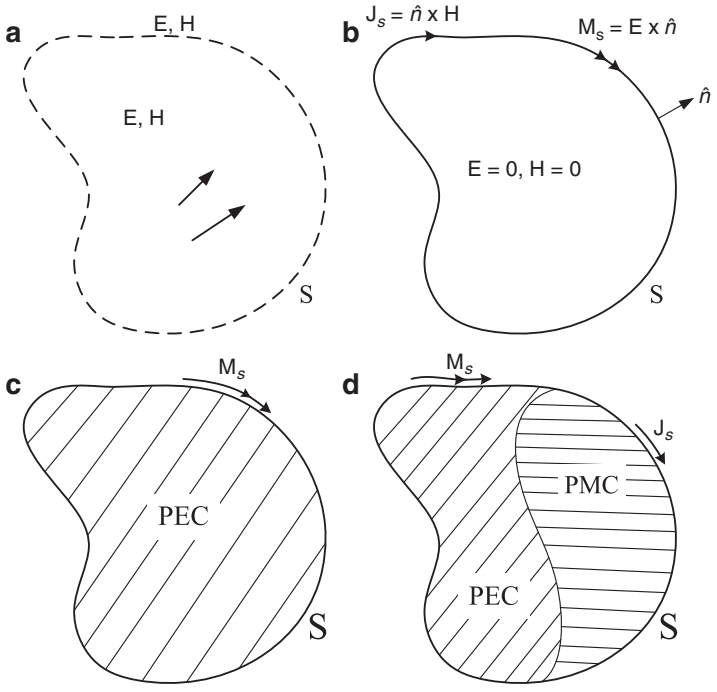

Fig. 1 By the equivalence principle, the four cases (**a**–**c**) and (**d**) generate equivalent fields outside the surface S

DOI 10.1007/978-981-4560-75-7_6-2

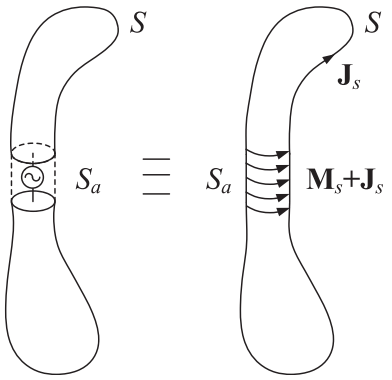

Fig. 2 For a voltage source driving an antenna at the gap, the equivalence principle can be invoked to make the case on the right to be equivalent to the case on the *left*. When the gap is filled with PEC, the electric current can be removed, with only the magnetic current impressed on it. When the gap is filled with PMC, the magnetic current can be removed with the electric current impressed on the PMC surface

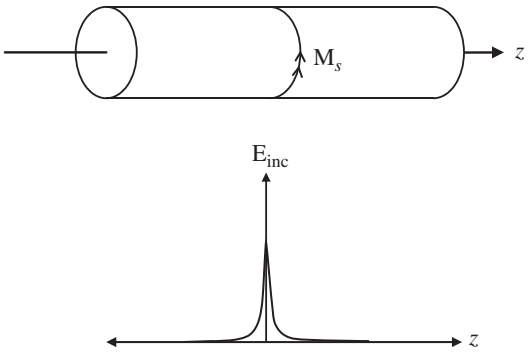

Fig. 3 An antenna driven by a very thin magnetic current ribbon. The incident field generated by the magnetic current ribbon can be approximated by a delta function

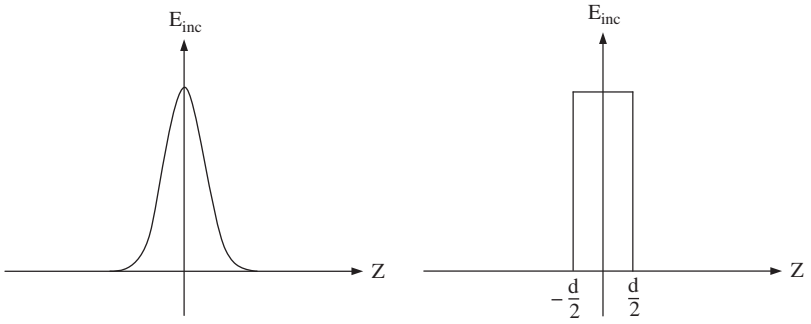

Fig. 4 The plot of the incident field generated by a finite-width magnetic ribbon. The incident field generated by the finite-width magnetic current ribbon can be approximated by a pulse function

Since the fields are zero inside S, one can insert a PEC inside S without affecting the fields outside. When the PEC fills the whole of the volume inside S, then the surface current $\mathbf{J}_s$ cannot radiate, as it will induce an image current that is negative of itself. Consequently, the magnetic current $\mathbf{M}_s$ alone, when impressed on the PEC surface, will radiate the same fields outside. A similar argument can be made when the volume is filled with PMC or a mixture thereof.

DOI 10.1007/978-981-4560-75-7_6-2

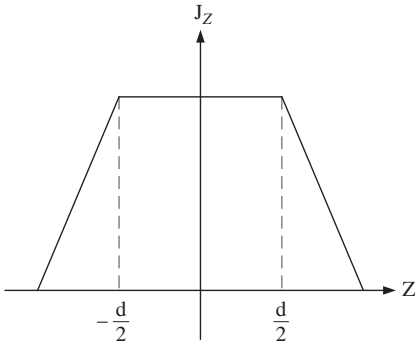

Fig. 5 The antenna can also be excited by a current source. The current source can be represented by one basis function with known and fixed amplitude

With the above equivalence principle established, one can use that to derive an equivalence model for an antenna driven by a source at its gap. First, by wrapping a surface S on the antenna snugly, one can represent the fields outside the antenna with impressed currents $\mathbf{J}_s$ and $\mathbf{M}_s$ per the above discussion. On the PEC surface of the antenna, $\mathbf{M}_s = 0$ since $\hat{n} \times \mathbf{E} = 0$. The only nonzero surface currents are $\mathbf{J}_s$ and $\mathbf{M}_s$ at the gap region. Now, one can fill the gap with PEC, and again, $\mathbf{J}_s$ does not radiate. Hence, only $\mathbf{M}_s$ impressed on the surface associated with the gap region is needed to produce the equivalent fields outside the antenna.

The impressed magnetic current can be modeled by a magnetic ribbon current. This magnetic current can be used to generate the incident field on the antenna, which will in turn induce a current on it. What is to be noted is that the magnitude of the magnetic current is related to the voltage across the gap. When the magnetic current ribbon is very thin, it produces a field that is sharply peaked at the location just beneath the ribbon. This sharply peaked function can be approximated by a delta function. Therefore, one can approximate the incident field just as a delta function. This is the well-known delta-gap model.

When the magnetic ribbon has a finite width, the incident field it generates will have a Gaussian-like pulse shape. This can be used as the incident field on the antenna. This Gaussian pulse will induce a voltage across the gap. But for simplicity, one can approximate the Gaussian pulse incident field with a square pulse with the same area. It will induce the same voltage drop across the gap (Lo et al. 2013).

To realize a magnetic ribbon source in the real world, one can use a small toroid as shown in Fig. 6. As is well known, a small loop antenna is like a magnetic dipole, and the toroid can be thought of as a string of magnetic dipoles forming a circle emulating a magnetic current loop. The current induced on the antenna wire is a transformer action, and the antenna wire is the secondary winding of the transformer. Such toroidal antennas have been used in well-logging exploration tools (Clark 1985).

Alternatively, one can fill the gap region with a perfect magnetic conductor (PMC) and impress only the electric current $\mathbf{J}_s$ as the equivalent current on the gap surface. One can solve this excitation problem to obtain $\hat{n} \times \mathbf{E}$ on the surface of the PMC gap and hence the voltage. With this voltage, one can calculate the input impedance of the antenna.

But a gap filled with a PMC material is an idealization of an open circuit where no current can flow. As an approximation, one can replace the gap with one filled with free space again and drive the antenna with a current source at the gap. The resultant voltage at the gap can then be calculated to obtain the input impedance. This is the current source driven antenna excitation model.

Subspace Projection Method

Integral equations and differential equations previously derived represent linear operator equations. One can describe a general linear problem with a linear operator equation as

DOI 10.1007/978-981-4560-75-7_6-2

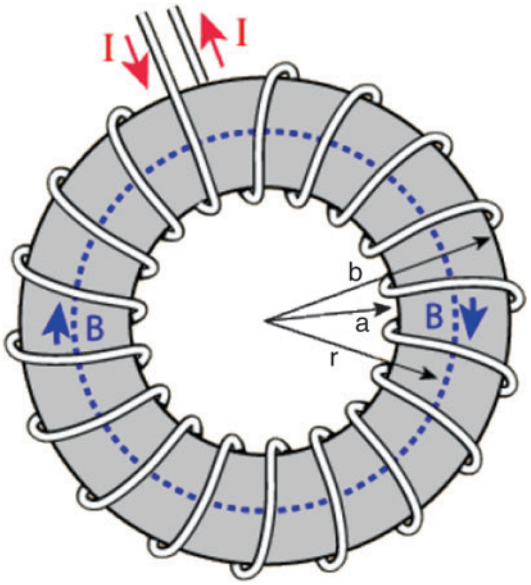

Fig. 6 A magnetic ribbon source can be approximated by a small toroid. The figure is from hyperphysics.phy-astr.gsu.edu/hbase/magnetic/toroid.html

$$\mathcal{L}f = h \tag{17}$$

where $\mathcal{L}$ represents a linear operator. This linear operator represents a differential operator in the case of differential equations, while it represents an integral operator for integral equations. In mathematical notation, one often writes $\mathcal{L} : V \rightarrow W$, meaning that it is a linear operator that maps elements of the vector space V to the elements of the vector space W, where V is known as the domain space and W the range space of the operator $\mathcal{L}$.

One illustrates the subspace projection method with scalar equations as the mathematical concept does not differ greatly when vector equations are used. For the differential operator, an explicit form may be

$$\left(\nabla^2 + k^2\right) f(\mathbf{r}) = h(\mathbf{r}) \tag{18}$$

which is the Helmholtz wave equation or the frequency-domain version of the wave equation. A boundary condition together with the radiation condition or a loss condition has to be stipulated in order to make the solution to the above equation unique (Chew 1990).

For the integral equation, one can consider a scalar integral equation and an explicit form is given:

$$\int d\mathbf{r}' g(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') = h(\mathbf{r}) \tag{19}$$

where $g(\mathbf{r}, \mathbf{r}') = \exp(ik|\mathbf{r} - \mathbf{r}'|)/(4\pi|\mathbf{r} - \mathbf{r}'|)$ is the Green's function which is also called the kernel.

These equations are not amenable to computation. They are equations in the infinite-dimensional Hilbert space with uncountably infinite indices. To make them computable, one can find a subspace in which an approximate solution of the above equations can be found and then project the solution into this subspace. This process can be methodically described as follows.

One chooses a basis set with N basis functions f_n, $n = 1, \ldots, N$ that spans the subspace that can approximate the domain space of the operator. One expands the unknown f in terms of the basis functions in this subspace, namely,

DOI 10.1007/978-981-4560-75-7_6-2

$$f(\mathbf{r}) \doteq \sum_{n=1}^{N} a_n f_n(\mathbf{r}) \tag{20}$$

The linear operator equation can then be written as

$$\sum_{n=1}^{N} a_n \mathcal{L} f_n \doteq h \tag{21}$$

The above equation can only be approximately satisfied since one has picked a finite number of basis functions. Moreover, the solution to Eq. 21 is still untenable. To make it more easily solvable, one converts Eq. 21 into a matrix equation by weighting or testing the equation with $w_m(\mathbf{r})$, $m = 1, \ldots, N$. Consequently, one has

$$\sum_{n=1}^{N} a_n \langle w_m, \mathcal{L} f_n \rangle = \langle w_m, h \rangle, \quad m = 1, \cdots, N \tag{22}$$

where the inner product is defined as

$$\langle u, v \rangle = \int u(\mathbf{r}) v(\mathbf{r}) d\mathbf{r} \tag{23}$$

The integral is over the support of the functions u and v. When they are defined over a volume (surface), one has a volume (surface) integral.

The above Eq. 22 implies that it can be exactly satisfied if one projects the Eq. 21 onto a subspace spanned by $w_m(\mathbf{r})$, $m = 1, \ldots, N$.

Recent research has shown that if the testing functions w_m are chosen from the dual space of the range space, the above can be a good approximation or matrix representation of the original operator equation (Cools et al. 2009). The dual space can be larger or smaller than the range space.

Equation 22 now constitutes a matrix equation:

$$\overline{\mathbf{L}} \cdot \mathbf{a} = \mathbf{h} \tag{24}$$

$$\left(\overline{\mathbf{L}}\right)_{mn} = \langle w_m, \mathcal{L} f_n \rangle \tag{25}$$

$$(\mathbf{a})_n = a_n \tag{26}$$

$$(\mathbf{h})_m = \langle w_m, h \rangle \tag{27}$$

$$(\mathbf{a}) = \left(\overline{\mathbf{L}}\right)^{-1} \cdot \mathbf{h} \tag{28}$$

The matrix equation can be solved by various means. In the above, the choice of the testing function is determined by the auxiliary equation (Chew 1990). The testing function should be chosen so that the auxiliary equation is solved accurately, whereas the choice of the expansion or basis function is to solve the primary equation accurately. The auxiliary equation is the adjoint or the transpose of the original equation where the range space and the domain space are swapped. It can be shown that the left domain

DOI 10.1007/978-981-4560-75-7_6-2

space of an operator is the dual space of the range space. Hence, if the testing functions solve the auxiliary equation well, they approximate the left domain space of the original operator, which is the dual space of the range space of the original equation, well. This is in agreement with the aforementioned recent findings.

The above procedure of converting the operator equation into a matrix equation is the underpinning method behind the finite-element method or the method of moments. They are variously known as Galerkin's method, Petrov–Galerkin's method, method of weighted residuals, collocation method, and point matching method (Chew 1990, Chap. 5). But they all can be regarded as subspace projection methods.

When $\mathcal{L}$ is a differential operator, the matrix $\overline{\mathbf{L}}$ is sparse because a differential operator is a local operator. However, when $\mathcal{L}$ is an integral operator, the matrix $\overline{\mathbf{L}}$ is dense. In differential equations, the unknown is the field that permeates all of space. Hence, the unknown count is usually large in differential equation solvers. But they come with sparse matrix systems that are cheaper to solve and store.

For integral equations, the unknown is the induced current on the antenna structure. Hence, the unknown count is smaller since the current resides only on or in a structure with finite support. But the ensuing matrix system is dense and is hard to store. Moreover, the matrix assembly of forming the matrix elements

$$\langle w_m, \mathcal{L} f_n \rangle \tag{29}$$

is tedious since the operator involves singularity that has to be evaluated with care (Graglia 1993).

Iterative Methods

When the unknown count is large, the matrix $\overline{\mathbf{L}}$ is never generated. Instead, iterative, matrix-free methods in numerical linear algebra are used to solve the matrix equation instead. Iterative methods can be made matrix-free because one needs only to write a code to produce the result

$$\overline{\mathbf{L}} \cdot \mathbf{a} \tag{30}$$

namely, the result of the action of a matrix on a vector, but not the matrix itself. For sparse matrices, this action can be effected with $O(N)$ operations. For dense matrices, it costs $O(N^2)$ to effect this action. However, various fast solvers have been developed that allow this action to be effected in $O(N)$ or $O(N \log N)$ operations (Chew et al. 2001, ref. therein).

When it comes to solving a matrix equation iteratively, numerical linear algebra plays an important role (Trefethen et al. 1997; Chew et al. 2009). The condition number and the distribution of the eigenvalues of the matrix system determine the convergence rate of iterative methods. The Krylov subspace method is a popular way to understand the convergence rate of iterative methods. In this method, one finds the solution to the matrix equation by finding the best-fit solution in a subspace called the Krylov subspace

$$\mathcal{K}^K\left(\overline{\mathbf{L}}, \mathbf{r}_0\right) = \left\{\mathbf{r}_0, \overline{\mathbf{A}} \cdot \mathbf{r}_0, \overline{\mathbf{A}}^2 \cdot \mathbf{r}_0, \cdots, \overline{\mathbf{A}}^{K-1} \cdot \mathbf{r}_0\right\} \tag{31}$$

where $\mathbf{r}_0 = \mathrm{h} - \overline{\mathbf{L}} \cdot \mathrm{a}_0$ where a_0 is the initial guess to the solution. The above Krylov subspace can be generated by performing $K-1$ matrix-vector product with the matrix $\overline{\mathbf{L}}$ on the vector $\mathbf{r}_0$. The method finds the optimal solution at the K-th iteration, $\mathbf{a}_K$, by letting it be $\mathbf{a}_K = \mathbf{a}_0 + \mathbf{z}_K$, such that $\mathbf{z}_K \in \mathcal{K}^K\left(\overline{\mathbf{L}}, \mathbf{r}_0\right)$. By so doing, the residual at the K-th iteration is

DOI 10.1007/978-981-4560-75-7_6-2

$$\begin{aligned}\mathbf{r}_K &= \mathbf{h} - \overline{\mathbf{L}} \cdot \mathbf{a}_K \\ &= \mathbf{r}_0 - \overline{\mathbf{L}} \cdot \mathbf{z}_K \in \left\{\mathbf{r}_0, \overline{\mathbf{L}} \cdot \mathbf{r}_0, \overline{\mathbf{L}}^2 \cdot \mathbf{r}_0, \cdots, \overline{\mathbf{L}}^K \cdot \mathbf{r}_0\right\} \\ &\in \mathcal{K}^{K+1}\left(\overline{\mathbf{L}}, \mathbf{r}_0\right)\end{aligned} \tag{32}$$

In other words, the residual error that is to be minimized can be written as

$$\begin{aligned}\mathbf{r}_K &= \mathbf{r}_0 + \alpha_1 \overline{\mathbf{L}} \cdot \mathbf{r}_0 + \alpha_2 \overline{\mathbf{L}}^2 \cdot \mathbf{r}_0 + \cdots + \alpha_K \overline{\mathbf{L}}^K \cdot \mathbf{r}_0 \\ &= \sum_{k=0}^{K} \alpha_k \overline{\mathbf{L}}^k \cdot \mathbf{r}_0 = P_K^o\left(\overline{\mathbf{L}}\right) \cdot \mathbf{r}_0\end{aligned} \tag{33}$$

where

$$P_K^o(x) = 1 + \alpha_1 x + \alpha_2 x^2 + \cdots + \alpha_K x^K$$

is an optimal polynomial with $\alpha_0 = 1$ and the coefficients $\alpha_1, \ldots, \alpha_K$ are chosen to minimize $\mathbf{r}_K$.

To understand the convergence of the above matrix polynomial, one expands r_0 in terms of the left and right eigenvectors of $\overline{\mathbf{L}}$ or (Chew et al. 2009, ref. therein)

$$\mathbf{r}_0 = \sum_{n=1}^{N} \mathbf{v}_n \left(\mathbf{w}_n^t \cdot \mathbf{r}_0\right) \tag{34}$$

where $\mathbf{v}_n$ is the right eigenvector, while $\mathbf{w}_n$ is the left eigenvector. They can be shown to share the same set of eigenvalues and are mutually orthogonal. That is, $\mathbf{w}_n \cdot \mathbf{v}_{n'} = \delta_{nn'}$. Therefore,

$$\overline{\mathbf{L}} \cdot \mathbf{v}_n = \lambda_n \mathbf{v}_n \tag{35}$$

$$\mathbf{w}_n^t \cdot \overline{\mathbf{L}} = \lambda_n \mathbf{w}_n^t \tag{36}$$

where the eigenvalue λ_n can be complex. One can easily show that

$$\overline{\mathbf{L}}^k \cdot \mathbf{r}_0 = \sum_{n=1}^{N} \lambda_n^k \mathbf{v}_n \left(\mathbf{w}_n^t \cdot \mathbf{r}_0\right) \tag{37}$$

By substituting the above into Eq. 33, one has

$$\mathbf{r}_K = \sum_{n=1}^{N} \sum_{k=0}^{K} \alpha_k \lambda_n^k \mathbf{v}_n \left(\mathbf{w}_n^t \cdot \mathbf{r}_0\right) = \sum_{n=1}^{N} P_K^o(\lambda_n) \mathbf{v}_n \left(\mathbf{w}_n^t \cdot \mathbf{r}_0\right) \tag{38}$$

$$\mathbf{r}_K = \sum_{k=0}^{K} \overline{\mathbf{L}}^k \cdot \mathbf{r}_0 = \sum_{n=1}^{N} P_K^o(\lambda_n) \mathbf{v}_n \left(\mathbf{w}_n^t \cdot \mathbf{r}_0\right) \tag{39}$$

$$\mathbf{r}_0 = g - \overline{\mathbf{L}} \cdot \mathbf{a}_0 \tag{40}$$

$$\mathbf{r}_1 = \mathbf{r}_0 + \alpha_1' \overline{\mathbf{L}} \cdot \mathbf{r}_0 \tag{41}$$

DOI 10.1007/978-981-4560-75-7_6-2

It is seen that the residual error in the K-th iteration is proportional to the value of the optimal polynomial $P_K^o(\lambda_n)$ at the N eigenvalues λ_n. If $K = N$, a polynomial can be found such that $P_K^o(\lambda_n)$ is exactly zero at all these eigenvalues, meaning that the residual error is zero. When K is less than N, if the eigenvalues are clustered together on the complex plane, the residual error can still be made small. Since the polynomial has value such that $P_K^o(0) = 1$, if there are many eigenvalues near to the origin, it is difficult to fit the polynomial so that it is small close to the origin. Hence, having eigenvalues close to the origin is bad for convergence, since it is hard to find the fitting polynomial. By the same token, if the eigenvalues are spread widely over the complex plane, it is hard to find a fitting polynomial as well. All these cases give rise to a bad condition number of the matrix system which is defined as $|\lambda_{max}|/|\lambda_{min}|$, the ratio of the largest eigenvalue to the smallest eigenvalue. Therefore, an ill-conditioned matrix has bad convergence when solved with iterative solvers.

Fast Algorithm for Integral Equations

Due to the increased workload of numerical methods when the antenna structure becomes electrically large (large compared to wavelength), there has been much interest in fast methods to solve the ensuing matrix equations derived from Maxwell's equations.

Differential equation solvers naturally give rise to sparse matrices. The solution process can be made matrix-free easily. The downside is the existence of the grid dispersion error whose deleterious effect increases with the size of the problem (Lee and Cangellaris 1992). In this case, the effort has been in reducing the unknown counts as the unknowns are fields that permeate all of space pervasively. Also, accuracy improvement is necessary to mitigate grid dispersion errors. A higher-order method is used to reduce unknown counts but with the peril of reducing the sparsity of the matrix. Also, the unknown count in differential equation solvers grows with the volume of the simulation region and, hence, suffers from the cruelty of dimensionality.

Methods to invert the finite-element matrix directly have been studied extensively. Because of the sparsity of the FEM matrix for differential equations, it can be directly inverted in $N^{1.5}$ in 2D and N^2 in 3D by the nested dissection ordering method (Axelsson and Barker 1984). Moreover, for domains where the shape is oblong, the frontal method proves popular in inverting the finite-element matrix.

Another hot area of research in differential equation solvers is the design of absorbing boundary conditions (ABCs) (Chew 1990, Chap. 4). Berenger's perfectly matched layers (PMLs) (Berenger 1994) and coordinate-stretching PML (Chew and Weedon 1994) have become highly popular among numericists in this area. Coordinate-stretching PML draws inspirations from the area of matched asymptotics where coordinate stretching is used to emphasize a certain physics of the problem. Furthermore, an anisotropic-medium PML has been developed (Sacks et al. 1995). This topic has spurred the interest of many researchers.

Most ABCs are not perfect; a rigorous, perfect ABC is actually a boundary integral equation truncation of a differential equation solution domain solved by FEM or FDM (Jin 2002; Volakis et al. 1998; Zhu and Cangellaris 2006). This has been avoided in the past because boundary integral equations give rise to dense matrix systems that are expensive to solve and store. But the advent of fast algorithms has changed the landscape (Chew et al. 2001; Peng et al. 2011). Boundary integral equations accelerated by fast algorithms have been used to reduce the domain size of finite-element methods since they act as rigorous absorbing boundary conditions.

Cruelty of Computational Complexity

Integral equations were difficult and expensive to solve in the past. They usually give rise to a dense matrix system requiring $O(N^3)$ computer time to solve and $O(N^2)$ memory requirements. These computational complexities are just too unwieldy for large problems. But advances in fast methods have

DOI 10.1007/978-981-4560-75-7_6-2

eliminated this bottleneck by reducing the size of α in the exponent in N^{α} in these computational complexity scalings.

For iterative solvers, a sleuth of method can reduce the computational time complexity to $O(N \log N)$. Moreover, many of these methods can be made matrix-free so that only the unknown vector and the diagonal part of the matrix corresponding to near-neighbor interactions need to be stored. Hence, the memory requirements can be reduced to $O(N)$. There are essentially three popular methods to speed up the solutions of integral equations:

- Fast Fourier transform-based techniques: In this technique, the integral operator is cast into a form that resembles a convolutional integral as much as possible. Then FFT is used to expedite the convolution, enabling its evaluation of matrix-vector products in $O(N \log N)$ operations. For surface structures or sparsely packed structures where a lot of zero padding in the FFT is needed, the complexity is worse and is not optimal (Borup and Gandhi 1984).
- Matrix compression-based techniques: The MOM matrix that follows from solving integral equations is low rank. The reasons for low rank are two: over-discretization of mesh density and far interactions between currents on the object. The Nyquist sampling theorem necessitates the discretization of at least two points per wavelength in order to capture the oscillatory nature of the currents on an object. But oftentimes, discretization far above the Nyquist sampling rate is used. In this case, redundancies are created in the unknown counts, and the rank of the ensuing matrix system is lower rank than the unknown counts. Such matrix systems can be easily compressed using matrix compression techniques, such as wavelets (Wagner et al. 1993, ref. therein), adaptive cross approximations, simple fast multipole, etc. (Zhao et al. 2004, ref. therein). Interaction matrices with low ranks due to far interactions are harder to compress. They cannot be compressed beyond the Nyquist barrier (Wagner et al. 1993), even though ray physics-based methods have been used to compress them further beyond the Nyquist barrier. When wave physics is involved, the only viable way to compress the matrices for far interaction efficiently is the multipole-based methods (Chew et al. 2001).
- Multipole-based methods: The simple fast multipole method can expedite the solution involving circuit physics or Laplace's solutions very easily. Extension of such an algorithm for wave physics cases has been proposed, but its verbatim use for wave physics cases does not work. The only viable method of expediting the wave physics case is the multilevel fast multipole algorithm (Chew et al. 2001), where anterpolation and interpolation between levels are added. The algorithm is a tree-based algorithm. The matrices for far interactions are analytically diagonalized on paper rather than by algebraic or numerical means. The number of diagonal elements needed is proportional to the rank of the matrices. The reason is that the ranks of the matrices increase with the group size compared to wavelength. Near the upper levels of the inverted tree, the ranks of the matrices are higher, while near the lower levels, their ranks are lower.

To be of the varying ranks of these matrices, their dimensions are different for different levels even if they are diagonalized. Hence, anterpolation and interpolation are needed between levels due to their different ranks, very much in the spirit of the multilevel multigrid schemes. With this augmentation, the multilevel fast multipole algorithm provides optimal complexity of performing a matrix-vector product with $O(N \log N)$ complexity. It is with this algorithm that wave physics problems with tens of millions to hundreds of millions and over three billion unknowns have been solved (Michiels et al. 2014).

The key to the multilevel fast multipole algorithm is the factorization of the matrix element L_{ij} when elements i and j are far apart. Then one can express (Chew et al. 2001).

$$L_{ij} = \tilde{\mathbf{V}}^{t}_{f,i,i_1} \cdot \bar{\mathbf{I}}^{t}_{1} \cdot \bar{\bar{\beta}}_{i_1,i_2} \cdot \bar{\mathbf{I}}^{t}_{2} \cdot \cdots \bar{\bar{\beta}}_{i_N,L} \cdot \bar{\bar{\alpha}}_{LL'} \cdot \bar{\bar{\beta}}_{L',j_N} \cdots \bar{\mathbf{I}}_{2} \cdot \bar{\bar{\beta}}_{j_2,j_1} \cdot \bar{\mathbf{I}}_{1} \cdot \tilde{\mathbf{V}}_{s,j_1,j} \tag{42}$$

DOI 10.1007/978-981-4560-75-7_6-2

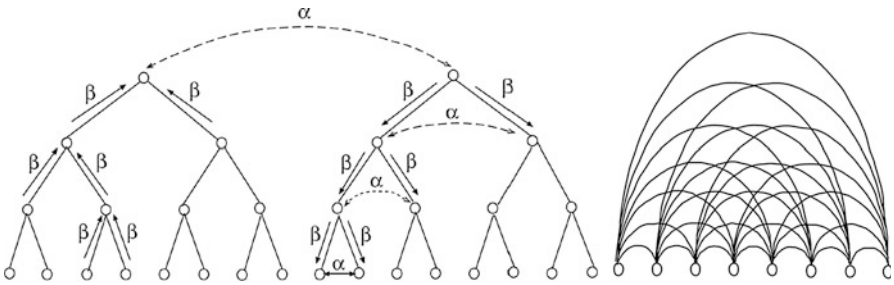

Fig. 7 The factorization of the matrix L_{ij} in Eq. 42 allows the matrix-vector product to emulate a telephone network connection (*left*) (Chew et al. 2001). The direct line connections between telephones (*right*) requires a large number of lines

The factorization allows a matrix-vector product to emulate a multilevel telephone network connection as shown in Fig. 7, where the number of telephone lines can be greatly reduced compared to a direct telephone connection. In the above, the $\widetilde{\overline{\alpha}}$ and $\widetilde{\overline{\beta}}$ matrices are diagonal, while the $\bar{\mathbf{I}}$ matrices are quasi-diagonal interpolation and anterpolation matrices that are not square. Hence, the storage requirements of the factorized matrices are small, and they can be reused in a tree algorithm. There are log N levels in this multilevel algorithm. Each level requires $O(N)$ in workload as well as memory requirements. Hence, the CPU and memory complexity are both $O(N \log N)$. Other factorizations do not lead to $O(N \log N)$ complexity.

The Circuit Models of Electromagnetic Structures

When electromagnetic waves are guided between electronic components through interconnects such as coaxial lines, strip lines, or other type of waveguides, a circuit is formed (Pozar 2011; Celik et al. 2002). The electronic circuit system is the static or quasi-static approximation of electrodynamics. Both fundamental circuit principles, Kirchhoff's current law (KCL) and Kirchhoff's voltage law (KVL), can be derived from Maxwell's equations (Pillegi et al. 1995; Balanis 2012a). Antennas can be considered as terminating devices in the circuit system for matching the impedance of the circuit to that of the propagation channel within a certain frequency band. However, unlike most quasi-static or static circuit components, the antenna's working principle has to depend on the dynamic field. Due to the displacement current, the electric field and the magnetic field couple to each other, which enables wave propagation (Chew 1990). It means that the reliable antenna modeling methods have to be based on the full-wave analysis. However, the circuit model of radiating structures can help to integrate their designs with other circuit subsystems to characterize and optimize the system performance. Hence, parameters such as the input impedance and return loss are popularly used. In practice, because a lot of antennas behave as the low Q resonating tank, many of their designs also rely on circuit interpretations for the performance optimization. Hence, circuit modeling methodologies for distributive electromagnetic structures will be the focus in this part.

Basic Circuit Laws from Maxwell's Equations

Resistance

For a current filament in a segment of the metallic wire with the finite conductivity σ, if the internal electric field $\mathbf{E}$ is uniform, the conducted current due to $\mathbf{E}$ is

$$\mathbf{J} = \sigma \mathbf{E} \tag{43}$$

DOI 10.1007/978-981-4560-75-7_6-2

Both current density and field are vectors in the same direction for isotropic media. For the current component flowing along the x direction in the Cartesian coordinate system, it is only related to the x component of **E**

$$J_x = \sigma E_x \tag{44}$$

For the static field, the electric field is equal to the negative gradient of the potential. If the conductor cross-section area that is orthogonal to the x direction is ΔS and J_x is assumed to be constant over a very small length ΔL_x, one can derive the current through the conductor along the x direction from Eq. 44

$$I_x = \frac{\Delta V_x}{R_x} \tag{45}$$

where ΔV_x is the potential (voltage) drop along the **x** direction and R_x is

$$R_x = \frac{\Delta L_x}{\sigma \Delta S} = \frac{\rho \Delta L_x}{\Delta S} \tag{46}$$

where ρ is the conventional resistivity. Hence, under the static approximation, Eq. 44 is the circuit Ohm's law in the **x** direction while Eq. 43 is the circuit Ohm's law in all directions. For electrodynamics, the electric field is not a simple gradient of the scalar potential. The current distribution could change rapidly as a function of space. Hence, Ohm's circuit law can only be applied for electrically small parts. For electrically large circuit systems, the full circuit model truly based on electrodynamics will be very complicated.

Inductance

Inductance characterizes the ability of a conductor in creating a voltage in either itself or other conductors through the current flowing through it. Based on Faraday's law, this definition is usually connected with looped conductors (Pozar 2011; Balanis 2012a). However, with the help from auxiliary potentials, one can define the partial inductance that is also consistent with the regular inductance definition. The relationship between the induced voltage v, current i, and inductance L is defined as

$$v = L \frac{\partial i}{\partial t} \tag{47}$$

If the time-dependent voltage v is measured on the current loop itself, L is called the self-inductance. If it is measured on another loop, L is called the mutual inductance.

It is also convenient to define the inductance through the magnetic flux when the dimension of the circuit system is electrically small. If ψ is the total magnetic flux through the loop generated by a current i, one has

$$\psi = Li \tag{48}$$

Assume that a loop is made of the perfect electric conductor and its cross section is zero. If the operating frequency is so low that the loop is electrically small, then the current on the loop has almost zero phase change. However, for the high-frequency case, the current changes rapidly. The conventional loop-based inductance will become improper for the physical interpretation and modeling.

DOI 10.1007/978-981-4560-75-7_6-2

Capacitance

The capacitance is the measure of the charge capacity of a conductor. It usually needs to be relative to a certain reference voltage or potential. If it is relative to infinity, it is the self-capacitance. If it is relative to another conductor, it is the mutual capacitance with that conductor. A classic definition of the capacitance is

$$C = \frac{Q}{V} \tag{49}$$

where Q is the net charge on the conductor while V is the bias DC voltage on the conductor relative to its reference (the potential of its reference is usually considered as 0). This definition is in a dual relationship with Eq. 48. Similar to Eq. 47, another definition can be written as (Balanis 2012a)

$$i = C\frac{\partial v}{\partial t} \tag{50}$$

Hence, the capacitance causes the branch currents between the conductor and its reference. Under the dynamic situation, the voltage variation at different locations of the conductor could be highly different and the potential itself is a limited term in describing the dynamic field. Hence, the practical capacitance definition for the full-wave case is more complicated than the static case.

Generally, the capacitance is less sensitive to frequencies since most conductors being used are of high conductivities. Hence, the static capacitance approximation based on Eq. 49 works very well in many practical modeling methods.

KVL

Based on the integral form of Faraday's law, the overall voltage drop along a closed loop can be written as

$$\sum_c v_c = \oint_C d1 \cdot \mathbf{E} = -\frac{\partial \psi}{\partial t} \tag{51}$$

where the total magnetic flux is $\psi = \int_S ds \cdot \mathbf{B}$, the subscript c could be R, L, or C, v_R means the voltage drop due to resistors in the loop, v_L means the voltage drop due to inductors in the loop, and v_C means the voltage drop due to capacitors in the loop. Using Eq. 48, one has

$$\sum_c v_c = -L_s \frac{\partial_i}{\partial t} \tag{52}$$

or

$$\sum_c v_c + L_s \frac{\partial_i}{\partial t} = 0 \tag{53}$$

Here, L_s is the parasitic loop self-inductance when all lumped components are shorted. Sometimes it is also called the strayed inductance (Balanis 2012a). When the circuit dimension is electrically small, L_s is a very small value. For example, a circular loop with a 1 cm radius and 1 mm wire cross-section radius has a

DOI 10.1007/978-981-4560-75-7_6-2

self-inductance of 2.99×10^{-8}H. And it is already a very big circuit loop. Hence, if one ignores the parasitic voltage introduced by L_s under the low-frequency assumption, Eq. 53 becomes the standard Kirchhoff's voltage law (KVL):

$$\sum_c v_c = 0 \tag{54}$$

But if the frequency is very high, the voltage introduced by the self-inductance cannot be ignored. Conventional KVL will not be accurate anymore. Equation 53 has to be used to consider the effect of L_s.

KCL

Based on the continuity equation, a circuit node enclosed by a small closed volume V satisfies

$$\oint_S d\mathbf{S} \cdot \mathbf{J} + \frac{\partial}{\partial t} \int_V dr\rho = 0 \tag{55}$$

where ρ is the volumetric charge density while $\mathbf{J}$ is the current density. Under the low-frequency approximation, currents only flow through metal wires. The closed surface integral of the current density becomes the summation of branch currents. Further, by Eqs. 49 and 50, one has

$$\sum_b I_b + C_n \frac{\partial v_n}{\partial t} = 0 \tag{56}$$

This equation is also for low frequencies (Balanis 2012a). The subscript b refers to all branches. Here, v_n is the node voltage while C_n is the total parasitic self-capacitance of all branches connected to the node relative to the zero potential ground at infinity. It can be computed by excluding all lumped components inside $V$and computing the total self-capacitance of all conductors. At low frequencies, C_n is so small that it could be approximated as zero. Then the standard Kirchhoff's current law (KCL) is achieved:

$$\sum_b I_b = 0 \tag{57}$$

At high frequencies, the parasitic current introduced by the self-capacitance cannot be ignored. The conventional KCL based on the pure circuit theory will not be accurate anymore.

Partial Element Equivalent Circuit Method

The partial element equivalent circuit (PEEC) method was developed by Albert Ruehli to solve parasitic coupling problems by building the equivalence circuit based on the integral equation (Ruehli 1972, 1974; Ruehli and Brennan 1973). It was initiated for static or quasi-static applications with no retardation (delay) considered. Later it was extended to the full-wave case where the retardation is included. PEEC is a very convenient bridging method between electromagnetics and circuit theories. It is broadly used by many electronic design automation (EDA) softwares. It also greatly helps the modeling of resonating structures such as antennas. Even though the PEEC method solves the problem in the circuit solver, its formulation actually starts from the integral equation (Chew 1990). The modified nodal analysis (MNA)-based circuit solvers (Ho et al. 1975) basically consider the electric field and magnetic field decoupling effect happening at the low-frequency regime. Hence, it involves both KCL and KVL in the formulation. Some low-frequency full-wave integral equation simulation methods have also been developed based on

DOI 10.1007/978-981-4560-75-7_6-2

the same physical insight, such as the augmented electric field integral equation method (A-EFIE) (Qian and Chew 2009).

Partial Inductance

Assume that there are two loops i and j with currents I_i and I_j (Ruehli 1972). For low frequencies, both I_i and I_j are approximated to be constant over each loop. Then the mutual inductance L_{ij} between two loops is

$$L_{ij} = \frac{\psi_{ij}}{I_j}, \tag{58}$$

where ψ_{ij} is the magnetic flux through loop i due to the current in loop j. It can be further written as

$$\psi_{ij} = \int_{S_i} d\mathbf{S}_i \cdot \mathbf{B}_{ij} = \frac{1}{a_i} \int_{a_i} da_i \oint_i d\mathbf{l}_i \cdot \mathbf{A}_{ij}, \tag{59}$$

where S_i is the loop surface of loop i, $\mathbf{B}_{ij}$ is the magnetic flux density, $\mathbf{A}_{ij}$ is the magnetic vector potential at loop i due to the current in loop j, and a_i is the cross-section area of the loop i wire. The vector potential $\mathbf{A}_{ij}$ is formulated through an integral using the homogeneous medium Green's function as its kernel:

$$\mathbf{A}_{ij} = \oint_{\text{loop}_j} d\mathbf{r}' \frac{e^{-jk|\mathbf{r}_i - \mathbf{r}'|}}{4\pi|\mathbf{r}_i - \mathbf{r}'|} \mu \mathbf{J}_j(\mathbf{r}'). \tag{60}$$

Assuming that the working frequency is low and cross sections of wires are always small, then the current is almost uniform along the loop and at the cross section. Hence, one has

$$\mathbf{A}_{ij} = \frac{\mu}{4\pi} \frac{I_j}{a_j} \int_{a_j} da_j \oint_j d\mathbf{l}_j \left[\frac{1}{r_{ij}}\right], \tag{61}$$

where I_j is the loop j's current from the common circuit point of view. Using Eqs. 58 and 59, one has

$$L_{ij} = \frac{1}{a_i a_j} \frac{\mu}{4\pi} \oint_i \oint_j \int_{a_i} \int_{a_j} \left[d\mathbf{l}_i \cdot d\mathbf{l}_j da_i da_j \frac{1}{r_{ij}} \right]. \tag{62}$$

If a_i and a_j are small (current filaments), it can be further simplified to be independent from the cross section

$$L_{ij} = \frac{\mu}{4\pi} \oint_i \oint_j \left[d\mathbf{l}_i \cdot d\mathbf{l}_j \frac{1}{r_{ij}} \right]. \tag{63}$$

If the wire cross section is not small, the wire has to be split along the longitudinal direction into many current filaments. Each current filament is assumed to have a constant current at its cross section. Then Eq. 63 depicts the result of a group of inductors connected in a parallel fashion.

With the thin- and short-wire assumption, if one divides each loop into small segments, the mutual inductance is the summation of partial inductive contributions. For example, if loop i is partitioned into K pieces while loop j is divided into M pieces, then

DOI 10.1007/978-981-4560-75-7_6-2

$$L_{ij} = \sum_{k=1}^{K} \sum_{m=1}^{M} \frac{\mu}{4\pi} \frac{1}{a_{ik} a_{jm}} \int_{l_{ik}} \int_{a_{ik}} \int_{l_{jm}} \int_{a_{jm}} da_{ik} da_{jm} \frac{d\mathbf{l}_{ik} \cdot d\mathbf{l}_{jm}}{r_{km}}, \tag{64}$$

where subscript *ik* means the *k*-th current filament on loop *i*, *jm* means the *m*-th current filament on loop *j*, and *p* means *partial*. Here, a_{ik} is the cross-section area of the *k*-th current filament on loop *i* and l_{ik} is the *k*-th current filament of loop *i*. Other symbols are defined in a similar way. If one defines the kernel of the double summations in Eq. 64 to be the partial inductance $L_{p_{ij}}^{km}$, one has

$$L_{p_{ij}}^{km} = \frac{\mu}{4\pi} \frac{1}{a_{ik} a_{jm}} \int_{l_{ik}} \int_{a_{ik}} \int_{l_{jm}} \int_{a_{jm}} da_{ik} da_{jm} \frac{\left| d\mathbf{l}_{ik} \cdot d\mathbf{l}_{jm} \right|}{r_{km}}. \tag{65}$$

Then the total inductance is the summation of partial inductances

$$L_{ij} = \sum_{k} \sum_{m} S_{ij}^{km} L_{p_{ij}}^{km}, \tag{66}$$

where S_{ij}^{km} is the sign of the dot project of $d\mathbf{l}_{ik} \cdot d\mathbf{l}_{jm}$. Hence, it is either +1 or −1. If one ignores the integration over cross sections, the partial inductance is simplified to

$$L_{p_{ij}}^{km} = \frac{\mu}{4\pi} \int_{l_{ik}} \int_{l_{jm}} \frac{\left| d\mathbf{l}_{ik} \cdot d\mathbf{l}_{jm} \right|}{r_{km}} \tag{67}$$

The physical meaning of $L_{p_{ij}}^{km}$ is very intriguing. If one places both current filaments l_{ik} and l_{jm} on the same plane, as shown in Fig. 8, the projection lines from ending points of current *ik* to *jm* will form an

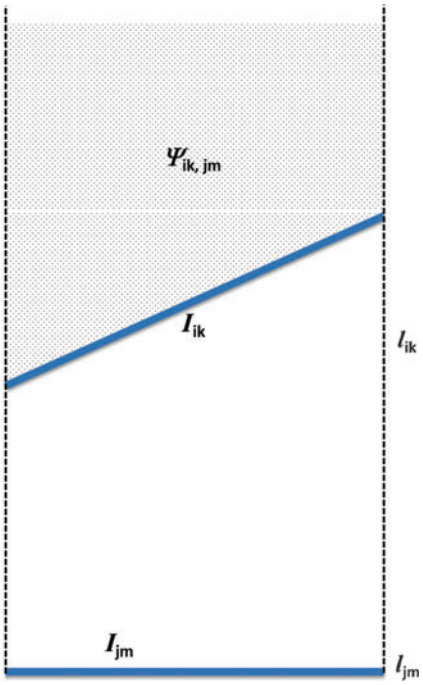

Fig. 8 The magnetic flux loop for the partial inductance

DOI 10.1007/978-981-4560-75-7_6-2

infinite loop with current *ik* and the infinity. Since the integration kernel (static Green's function) is zero at infinity, l_{jm} is orthogonal to both projection lines, and $\int_{l_{ik}}$ can be written as a loop integral in the partial inductance definition (Eq. 62) (if one ignores the absolute value operation $|\cdot|$ in the kernel). Hence,

$$L_{p_{ij}}^{km} = \frac{\mu}{4\pi}\oint_{l_{ik}} d\mathbf{l}_{ik} \cdot \int_{l_{jm}} \frac{d\mathbf{l}_{jm}}{r_{km}} = \oint_{l_{ik}} d\mathbf{l}_{ik} \cdot \frac{\mathbf{A}_{i,km}}{I_{jm}} = \frac{1}{I_{jm}} \int_{S_{ik}} d\mathbf{S}.\mathbf{B}_{i,km}. \tag{68}$$

where $\mathbf{A}_{i,km}$ is the magnetic vector potential defined in Eq. 60 generated inside the infinite loop by the current filament l_{jm}. Hence, even though the formulation of the partial inductance does not have a complete loop, it actually uses the loop formed with infinity through current project lines,

$$L_{p_{ij}}^{km} = \frac{\psi_{ik,jm}}{I_{jm}}. \tag{69}$$

The above definitions and properties are also applicable to cases when $i = j$ and $k = m$. It means that they are valid for self-inductances too. Using the mutual partial inductance as the reference, it can be understood that the self-partial inductance corresponds to the magnetic flux through a loop formed by the infinity, two orthogonal projection lines, and the current filament itself.

If two current filaments are both on the same rectangular loop and parallel to each other, they will have opposite current flow directions, as shown in Fig. 9. Then in Eq. 66 $S_{ii}^{km} = -1$ is for the mutual partial inductance $L_{p_{ii}}^{km}$ and $S_{ii}^{mm} = +1$ is for the self-partial inductance $L_{p_{ii}}^{km}$. Hence, the magnetic flux area from l_{ik} to infinity is completely canceled from the area from l_{im}. Hence, only the flux area in between the two current filaments is kept. When this area is closed by another pair of vertical current filaments, it forms a complete loop and the loop area will directly determine the total inductance, which is consistent with the conventional circuit concept.

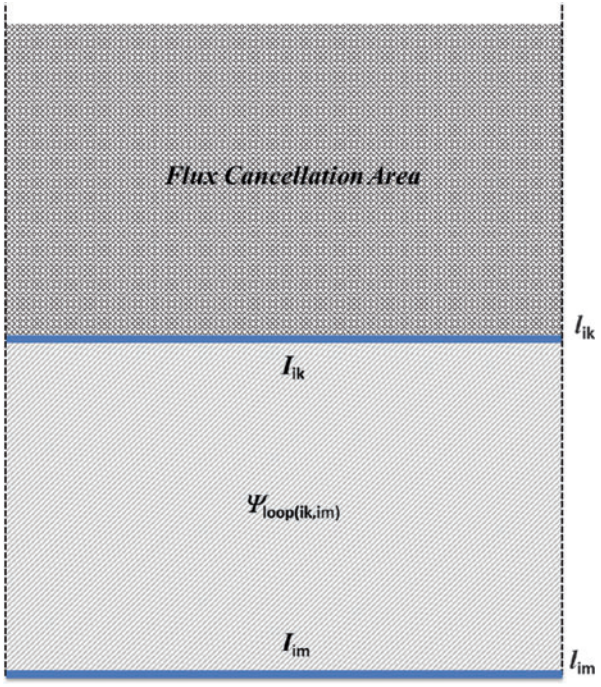

Fig. 9 The magnetic flux loop for the loop based on partial inductances

DOI 10.1007/978-981-4560-75-7_6-2

PEEC Formulation

Assume that circuit conducting interconnects are partitioned into N_l current filaments (Ruehli et al. 2003, 2013; Rong and Cangellaris 2001). If the conductivity is finite, its time-domain electric field for one wire segment is

$$\mathbf{E}(\mathbf{r},t) = \frac{\mathbf{J}(\mathbf{r},t)}{\sigma} + \frac{\partial \mathbf{A}(\mathbf{r},t)}{\partial t} + \nabla\phi(\mathbf{r},t) \tag{70}$$

The vector potential **A** is contributed from all current filaments including itself. Hence, it can be written as

$$\mathbf{A}(\mathbf{r},t) = \sum_{n_l=1}^{N_L} \frac{\mu}{4\pi} \int_{V_{n_l}} dr' G(\mathbf{r},\mathbf{r}') \mathbf{J}_{n_l}(\mathbf{r}',t') \tag{71}$$

where $\mathbf{J}_{nl}$ is the current density vector on the n_l-th current filament and $G(\mathbf{r}, \mathbf{r}')$ is the Green's function

$$G(\mathbf{r},\mathbf{r}') = \frac{1}{|\mathbf{r}-\mathbf{r}'|}. \tag{72}$$

t' is the source time with the retardation

$$t' = t - \frac{|\mathbf{r}-\mathbf{r}'|}{c/\sqrt{\mu_r \epsilon_r}}. \tag{73}$$

The scalar potential ϕ is contributed from the charge distribution. Since good conductors are usually used in the design, there is almost no charge inside the conductor. Hence, all charges are on the conductor surface. Assuming that all surfaces are partitioned into N_C nonoverlapping patches and the charge density on each patch is generally defined as ρ, the scalar potential is written as

$$\phi(\mathbf{r},t) = \sum_{n_c=1}^{N_C} \frac{1}{4\pi\epsilon} \int_{S_{n_c}} d\mathbf{r}' G(\mathbf{r},\mathbf{r}') \rho_{n_c}(\mathbf{r}',t') \tag{74}$$

Hence, Eq. 70 can be written as

$$\begin{aligned} \mathbf{E}(\mathbf{r},t) \quad &= \frac{\mathbf{J}(\mathbf{r},t)}{\sigma} + \sum_{n_l=1}^{N_L} \frac{\mu}{4\pi} \int_{V_{n_l}} d\mathbf{r}' G(\mathbf{r},\mathbf{r}') \frac{\partial \mathbf{J}_{n_l}(\mathbf{r}',t')}{\partial t} \\ &+ \sum_{n_c=1}^{N_C} \frac{1}{4\pi\epsilon} \nabla \int_{S_{n_c}} dS' G(\mathbf{r},\mathbf{r}') \rho_{n_c}(\mathbf{r}',t') \end{aligned} \tag{75}$$

For the m-th current filament, it is either inside or on the surface of the conductor. Hence, the electric field along its filament direction is always zero if one does Galerkin's testing along the current filament. Hence, one can have

DOI 10.1007/978-981-4560-75-7_6-2

$$\begin{aligned}&\frac{1}{\sigma}\int_{V_m} d\mathbf{r}_m J_m(\mathbf{r},t)\\&+\sum_{n_l=1}^{N_L}\frac{\mu}{4\pi}\int_{V_m}\int_{Vn_l} d\mathbf{r}_m d\mathbf{r}'_{n_l} G(\mathbf{r},\mathbf{r}')\frac{\partial J_{n_l}(t'_m)}{\partial t}S_{m,n_l}\\&+\sum_{n_c=1}^{N_C}\frac{1}{4\pi\epsilon}\int_{V_m} d\mathbf{r}_m\mathbf{u}_m\cdot\nabla\int_{S_{n_c}} ds'_{n_c} G(\mathbf{r},\mathbf{r}')\rho_{n_c}(\mathbf{r}',t')=0.\end{aligned} \tag{76}$$

Its first term corresponds to the resistive voltage drop

$$V_{R_m}=\frac{1}{\sigma}\int_{V_m} d\mathbf{r}_m J_m(\mathbf{r},t)=\frac{I_m}{\sigma}\int_{l_m} dl_m=\frac{l_m}{\sigma}I_m=R_m I_m. \tag{77}$$

where l_m is the longitudinal length of the m-th current filament. Hence, the first term shows the ohmic voltage drop due to the lossy conductor.

The second term corresponds to the inductance effect. Here, $S_{m,\,nl}$ is the vector dot between the testing current direction and the source current direction. If one assumes all filaments are along the Cartesian coordinate axes, $S_{m,n_l}=+1,-1$, or 0 depending on their relative directions. Using the partial inductance concept introduced in the previous subsection, one has

$$V_{L_m}=\sum_{n_l=1}^{N_L}\frac{\mu}{4\pi}\frac{1}{a_m a_{n_l}}\int_{V_m}\int_{V_{n_l}} d\mathbf{r}_m d\mathbf{r}'_{n_l} G(\mathbf{r},\mathbf{r}')\frac{\partial J_{n_l}(t'_m)}{\partial t}S_{m,n_l} \tag{78}$$

$$=\sum_{n_l=1}^{N_L} L_p^{mn_l}\frac{d}{dt}I_{n_l}(t'_m). \tag{79}$$

Hence, the second term is the voltage drop due to partial inductances. It shall be noted that there are two types of inductances contributed to V_{Lm}: one is the self-partial inductance and another one is the mutual partial inductance. Because there are many current filaments in reality, mutual partial inductances are much more complicated than the self-partial inductance.

The third term corresponds to the capacitive coupling. It could be represented by potentials or capacitances. It uses the central difference to approximate the gradient where $\mathbf{u}_m$ is the unit vector direction of the mth current flow. Assume that u_m represents x, y or z direction, then

$$\begin{aligned}V_{C_m}&=\sum_{n_c=1}^{N_C}\frac{a_m}{4\pi\epsilon}\left[\int_{S_{n_c}} dS' G(\mathbf{r}_{m+},\mathbf{r}')\rho_{n_c}(\mathbf{r}',t')-\int_{S_{n_c}} dS' G(\mathbf{r}_{m-},\mathbf{r}')\rho_{n_c}(\mathbf{r}',t')\right]\\&=\sum_{n_c=1}^{N_C}\frac{1}{4\pi\epsilon}\rho_{n_c}\cdot\left[\int_{S_{n_c}} dS' G(\mathbf{r}_{m+},\mathbf{r}')-\int_{S_{n_c}} dS' G(\mathbf{r}_{m-},\mathbf{r}')\right]\\&=\sum_{n_c=1}^{N_C} Q_{n_c}\left[pp^{+}_{i(m,n_c)}-pp^{-}_{i(m,n_c)}\right].\end{aligned} \tag{80}$$

DOI 10.1007/978-981-4560-75-7_6-2

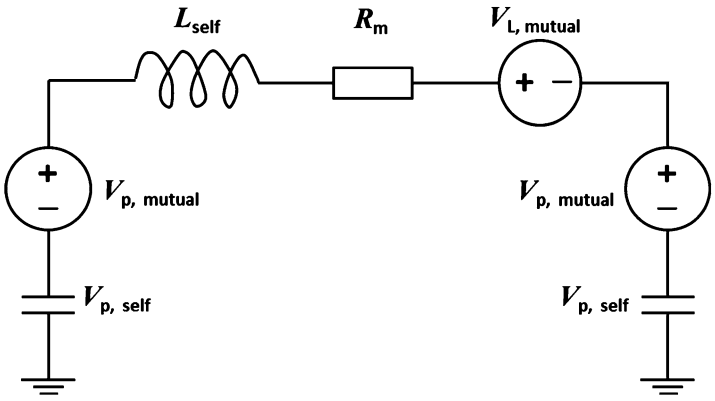

Fig. 10 The equivalent circuit of the PEEC model

where

$$pp^{\pm}_{i(m,n_c)} = \frac{1}{4\pi\epsilon}\frac{1}{a_{n_c}}\int_{S_{nc}} dS' G(\mathbf{r}_{m\pm}, \mathbf{r}'). \tag{81}$$

Here, the position $\mathbf{r}_{m+}$ and $\mathbf{r}_{m-}$ are the two end points of the m-th current filament. The current filaments' terminating nodes are located at the centers of piecewise constant charge density patches. This is very similar to the cell structure in the FDTD algorithm (Chew 1990). The third term therefore is interpreted as the charge-controlled voltage source (CCVC) in the equivalent circuit. By considering all three terms and their relationships with other parts of the system, an equivalent circuit can be easily built, as shown in Fig. 10.

The L_{self} is the self-partial inductance, R_m is the ohmic loss due to the finite conductivity, and $V_{i,\text{mutual}}$ is the voltage generated by other currents from other places through partial mutual inductances. Here, $V_{p,\text{mutual}}$ is the voltage generated by other branch currents from other places through partial mutual potentials, and $V_{p,\text{self}}$ is the voltage generated by the self-capacitive coupling or the self-partial potential coefficient.

Through this approach, the distributive structure can be modeled using a circuit. Since each electrically small piece could contribute to the mutual partial inductance and capacitively coupled potentials, the resultant circuit is a densely coupled one. If this circuit is solved by the circuit solver SPICE (Nagel and Pederson 1973; Warwick 2009), it results in a dense numerical matrix. Its solving process will be very expensive. Many methods could be employed to further solve this problem. It shall be noted that conventional SPICE solvers do not handle retardation. It means that the true full-wave circuit models cannot be solved by SPICE directly. Hence, certain modifications to SPICE solvers are necessary for handling circuit models based on the PEEC method.

Low-Frequency Computational Electromagnetics

An electromagnetic field can be obtained by solving the wave equations with enforced boundary condition. Because of the linearity of problems, the solution can be obtained in the frequency domain by Fourier transforming the equations in time, which theoretically covers the frequency range from static to optical regime. Generally speaking, the problems in solving the wave equations in the frequency domain can be classified into three regimes, which are defined as low-frequency regime, mid-frequency regime, and high-frequency regime (Chew et al. 2008). For low frequency, the typical electrical size (L) is much less than wavelength (λ), i.e., $L \ll \lambda$. At low frequency, the electromagnetic field physics is close to

DOI 10.1007/978-981-4560-75-7_6-2

that of the static field, where the magnetic field and the electric field are decoupled from each other. Hence, the electromagnetic wave equations reduce to the equation of electrostatics and the equation of magnetostatics that are completely decoupled from each other (Zhao and Chew 2000). Furthermore, the electrostatics equation or Poisson's equation governs the capacitive circuit physics, while the magnetostatics equation or Laplace's equation governs the inductive circuit physics. In the mid-frequency regime, the wavelength is comparable with the object size, $L \approx \lambda$. In this regime, the electric and magnetic fields are tightly coupled together. Thus, the electromagnetic fields become waves and are oscillatory as is typical of wave physics. In the high-frequency regime, the wavelength is much less than the object size, $L \gg \lambda$. The plane waves of the ray physics thus become dominant. In this section, our discussion will be focused on the low-frequency computation electromagnetics, which becomes more and more important in recent interdisciplinary research.

Understanding of Low-Frequency Region

Low-frequency computational electromagnetics has been studied for many years (Chew et al. 2008; Zhao and Chew 2000). Theoretically, the current or charge at static limit does not radiate but generates the field which is inversely proportional to the square of the distance from the source. For the on-chip-level antenna design, the typical size of the interconnects and devices is usually so much smaller than the wavelength (nanometer to micrometer levels in the standard CMOS process).

It implies that the surrounding field is primarily quasi-static; that is why circuit designers can utilize the lumped-circuit model instead of using the distributed-circuit model for the passive components, such as the interconnects, the inductors, and the capacitors. Hence, in order to capture the circuit physics with a universal solver, the well-developed full-wave solvers have to be revisited and corrected at low-frequency limit.

When $\omega \rightarrow 0$, the four Maxwell equations can be reduced into two parts: the magnetostatic part:

$$\nabla \times \mathbf{H} = \mathbf{J} \tag{82}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{83}$$

and the electrostatic part:

$$\nabla \times \mathbf{E} = 0 \tag{84}$$

$$\nabla \cdot \mathbf{D} = \rho = \lim \frac{\nabla \cdot \mathbf{J}}{i\omega} \tag{85}$$

Note that the current $\mathbf{J}$ in the electrostatic part must be of the order of ω in order to keep the right-hand side bounded. According to the Helmholtz decomposition (Collins 1966), the total current $\mathbf{J}$ naturally decomposes into a solenoidal (divergence-free) part and an irrotational (curl-free) part as

$$\mathbf{J} = \mathbf{J}_{sol} + \mathbf{J}_{irr} \tag{86}$$

where the solenoidal part $\mathbf{J}_{sol}$ represents eddy currents that produce primarily the magnetic field and the irrotational part $\mathbf{J}_{irr}$ represents charge currents that produce primarily the electric field at low frequencies. Both of them are equally important in capturing the inductive and capacitive circuit physics. When $\omega \rightarrow 0$, $\mathbf{J}_{irr}$ becomes much smaller than $\mathbf{J}_{sol}$; hence, the former usually cannot be captured correctly in the numerical calculation, due to the limit of computer precision. This is also known as the low-frequency inaccuracy problem (Chew et al. 2008). The problem in the electric field integral equation (EFIE) and its

DOI 10.1007/978-981-4560-75-7_6-2

solutions will be discussed in the following sections. On the other hand, the similar low-frequency problem also happened in the time-domain EFIE (TD-EFIE) (Andriulli et al. 2009), while the low-frequency inaccuracy problem happened in the magnetic field integral equation (MFIE) (Zhang et al. 2003).

Low-Frequency Problems in EFIE Formulation

Due to the decoupling between the electric field and magnetic field, there is a low-frequency breakdown problem in the EFIE formulation. The reasons for this breakdown can be classified into two catalogs: the frequency breakdown and the mesh density breakdown. The frequency breakdown occurs because the contribution of the vector potential is swamped by that of the scalar potential at low frequencies. Moreover, it will evoke the null space of the divergence operator in the scalar potential term and make the MoM matrix become extremely ill conditioned. Basically, the traditional EFIE operator can be written in its mixed potential form as

$$\mathcal{T}(\boldsymbol{J}) = \mathcal{T}_s(\boldsymbol{J}) + \mathcal{T}_h(\boldsymbol{J}) \tag{87}$$

in which the smoothing $(\mathcal{T}_s)$ and hypersingular $(\mathcal{T}_h)$ terms are defined as

$$\mathcal{T}_s(\boldsymbol{J}) = i\omega\mu\hat{\boldsymbol{n}}_r \times \int_{S'} dS' g(\boldsymbol{r}, \boldsymbol{r}')\boldsymbol{J} \tag{88}$$

$$\mathcal{T}_h(\boldsymbol{J}) = -\frac{1}{i\omega\varepsilon}\hat{\boldsymbol{n}}_r \times \nabla \int_{S'} dS' g(\boldsymbol{r}, \boldsymbol{r}')\nabla' \cdot \boldsymbol{J} \tag{89}$$

where

$$g(\boldsymbol{r}, \boldsymbol{r}') = \frac{e^{ik_0|r-r'|}}{4\pi|\boldsymbol{r} - \boldsymbol{r}'|} \tag{90}$$

is the free-space Green's function, k_0 is the wave number in the free space, ε and μ are the relative permeability and permittivity, and $\boldsymbol{J}$ is the surface current on an arbitrarily shaped PEC surface S' whose outward pointing unit normal at $\boldsymbol{r}$ is denoted by $\hat{n}_r$. The domain of both $\mathcal{T}_s$ and $\mathcal{T}_h$ is the surface S'. Here, $\mathcal{T}_s$ is referred to as a smoothing operator because the range space of the operator is smoothed by one order relative to its domain, while the hypersingular operator $\mathcal{T}_h$ lowers the smoothness of the domain space.

When $\omega \to 0$, the hypersingular term $\mathcal{T}_h$ which is $O(\omega^{-1})$ dominates over the smoothing term $\mathcal{T}_s$ which is $O(\omega^1)$. As mentioned above, because of the existence of the divergence operator in Eq. 89 and $\nabla' \cdot \boldsymbol{J}_{sol} = 0$, $\mathcal{T}_h$ has a null space. Thus, the ill-conditioned $\mathcal{T}$ behaves like a first-kind operator between the solenoidal and irrotational subspaces (Adams 2004). This makes the impedance matrix nearly singular and unsolvable at low frequencies (Zhao and Chew 2000). This is the so-called low-frequency breakdown problem for the EFIE operator.

Low-Frequency Remedies

In past decades, many research efforts have been carried out to avoid the imbalance inherent in the traditional EFIE operator. The most popular one is the loop-tree or loop-star decomposition, which separates the electrostatic and magnetostatic physics at low frequencies (Zhao and Chew 2000; Vecchi 1999; Lee et al. 2003). By introducing the charge in the unknown list and enforcing the current continuity constraint, the augmented version of EFIE was proposed, which is known as A-EFIE (Qian and Chew

DOI 10.1007/978-981-4560-75-7_6-2

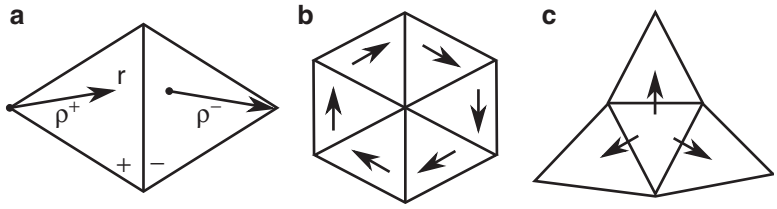

Fig. 11 Representations of (**a**) RWG, (**b**) loop, and (**c**) star basis functions

2008). The frequency scaling can be normalized in a balanced manner, thus remedying the low-frequency breakdown problem. In addition, the success of the developed Calderón multiplicative preconditioned EFIE (CMP-EFIE) method (Hsiao and Kleinman 1997; Adams 2004) has also made the original EFIE into a second-kind Fredholm integral equation operator, which is the so-called self-regularizing property of the $\mathcal{T}$ operator and immune to mesh density breakdown. Unfortunately, although stable at low frequencies, A-EFIE and CMP-EFIE all suffer from the low-frequency inaccuracy problem for the solved currents. As a remedy, the perturbation method has been applied to capture the accurate currents at different frequency orders (Qian and Chew 2010; Sun et al. 2013b).

Loop-Tree Decomposition

Instead of using the popular Rao–Wilton–Glisson (RWG) basis function, one can decompose the RWG basis function into the loop basis function whose members have zero divergence and the tree basis (or star basis) function whose members have nonzero divergence, as shown in Fig. 11. Here, $\rho^{\pm}(\mathbf{r})$ is the vector from the point $\mathbf{r}$ to the apex of the respective triangles, and $\pm$ is the support of the respective triangles. This is known as the loop-tree or loop-star decomposition, which is a quasi-Helmholtz decomposition because the tree or the star expansion functions are not curl-free. In some work based on the finite-element method, this is also known as the tree-cotree decomposition (Manges and Cendes 1995). Here, one shall call the space spanned by the RWG basis function as the RWG space, the subspace spanned by the tree (or star) basis function as the tree (or star) space, and that spanned by the loop basis function as the loop space. Therefore, the total surface current can be expanded as

$$\mathbf{J}(r') = \sum_{n=1}^{N_L} I_{Ln}\mathbf{J}_{Ln}(r') + \sum_{n=1}^{N_C} I_{Cn}\mathbf{J}_{Cn}(r') \tag{91}$$

where $\mathbf{J}_{Ln}(\mathbf{r}')$ is the divergence-free loop basis function such that $\nabla \cdot \mathbf{J}_{Ln}(\mathbf{r}') = 0$ and $\mathbf{J}_{Cn}(\mathbf{r}')$ is the nondivergence-free tree (or a star) basis function such that $\nabla \cdot \mathbf{J}_{Cn}(\mathbf{r}') \neq 0$, and it is used to model the charge in the system. The above can be written in the matrix form as

$$\mathbf{J}(r') = \mathbf{J}_L^t(r') \cdot \mathbf{I}_L + \mathbf{J}_C^t(r') \cdot \mathbf{I}_C \tag{92}$$

where the four column vectors in the right-hand side contain the expansion and coefficient elements in Eq. 91. By substituting the above into the EFIE and testing the result with the same set of the functions as in Galerkin's method, one has a matrix equation as

$$\begin{bmatrix} \overline{\mathbf{Z}}_{LL} & \overline{\mathbf{Z}}_{LC} \\ \overline{\mathbf{Z}}_{CL} & \overline{\mathbf{Z}}_{CC} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{I}_L \\ \mathbf{I}_C \end{bmatrix} = \begin{bmatrix} \mathbf{V}_L \\ \mathbf{V}_C \end{bmatrix} \tag{93}$$

where

DOI 10.1007/978-981-4560-75-7_6-2

$$\mathbf{V}_L = -\left\langle \mathbf{J}_L(r), \mathbf{E}^{inc}(r) \right\rangle \tag{94}$$

$$\mathbf{V}_C = -\left\langle \mathbf{J}_C(r), \mathbf{E}^{inc}(r) \right\rangle \tag{95}$$

$$\overline{\mathbf{Z}}_{LL} = i\omega\mu \left\langle \mathbf{J}_L(r), g(r,r'), \mathbf{J}_L^t(r') \right\rangle \tag{96}$$

$$\overline{\mathbf{Z}}_{LC} = i\omega\mu \left\langle \mathbf{J}_L(r), g(r,r'), \mathbf{J}_C^t(r') \right\rangle \tag{97}$$

$$\overline{\mathbf{Z}}_{CL} = i\omega\mu \left\langle \mathbf{J}_C(r), g(r,r'), \mathbf{J}_L^t(r') \right\rangle = \overline{\mathbf{Z}}^t{}_{LC} \tag{98}$$

$$\begin{aligned} \overline{\mathbf{Z}}_{CC} &= i\omega\mu \left\langle \mathbf{J}_C(r), g(r,r'), \mathbf{J}_C^t(r') \right\rangle \\ &- \frac{i}{\omega\varepsilon} \left\langle \nabla . \mathbf{J}_C(r), g(r.r'), \nabla' \cdot \mathbf{J}_C^t(r') \right\rangle \end{aligned} \tag{99}$$

In order to solve the system equation when $\omega \to 0$, the frequency normalization should be implemented as detailed in (Zhao and Chew 2000). It implies that even after the loop-tree decomposition, the matrix system is still ill conditioned because of the imbalance of the matrix elements, which is the so-called frequency-scaling behavior. Recently, the application of the loop-star/tree decomposition with the magnetic field and the Calderón preconditioned electric field integral operators is also studied (Andriulli 2012).

A-EFIE

Another remedy to the low-frequency breakdown problem is the A-EFIE, which avoids the imbalance inherent in the conventional EFIE by introducing the charge as the additional unknown. The same notations as those used in (Qian and Chew 2008) are used here. By introducing the current continuity condition, one can obtain the A-EFIE system as

$$\begin{bmatrix} \overline{\mathbf{V}} & \overline{\mathbf{D}}^T \cdot \overline{\mathbf{P}} \\ \overline{\mathbf{D}} & k_0^2 \overline{\mathbf{I}} \end{bmatrix} \cdot \begin{bmatrix} ik_0 \boldsymbol{j} \\ c_0 \rho \end{bmatrix} = \begin{bmatrix} \eta_0^{-1} \mathbf{b} \\ 0 \end{bmatrix} \tag{100}$$

where $\overline{\mathbf{V}}$ and $\overline{\mathbf{P}}$ are the vector potential and scalar charge matrices, respectively, $\overline{\mathbf{I}} \in \mathbf{R}^{p \times e}$ is an identity matrix, $\boldsymbol{j} \in \mathbf{C}^{e \times 1}$ represents the vector of current coefficient, $\rho \in \mathbf{C}^{p \times 1}$ represents the vector of charge coefficient, and $b \in \mathbf{C}^{e \times 1}$ denotes the excitation. The superscripts p and e indicate the number of patches and edges, respectively. Mathematically, it has a generalized saddle point form and can be reduced to a standard saddle point form in the low-frequency regime. Physically, this new equation system can also be understood as a complete Kirchhoff circuit law, which is solvable and stable with low-frequency circuit physics. It means that the first equation in Eq. 100 represents the Kirchhoff voltage law, while the second equation represents the Kirchhoff current law.

At very low frequencies, charge neutrality still causes rank deficiency of the A-EFIE system in Eq. 100. A simple method has been proposed to remedy this issue by dropping one charge unknown for each spanning tree, which results the A-EFIE system as

$$\begin{bmatrix} \overline{\mathbf{V}} & \overline{\mathbf{D}}^T \cdot \overline{\mathbf{P}} \cdot \overline{\mathbf{B}} \\ \overline{\mathbf{F}} \cdot \overline{\mathbf{D}} & k_0^2 \overline{\mathbf{I}}_r \end{bmatrix} \cdot \begin{bmatrix} ik_0 \boldsymbol{j} \\ c_0 \rho_r \end{bmatrix} = \begin{bmatrix} \mathbf{b} \\ 0 \end{bmatrix} \tag{101}$$

DOI 10.1007/978-981-4560-75-7_6-2

where the backward matrix $\overline{\mathbf{B}}$ and forward matrix $\overline{\mathbf{F}}$ are defined to map the charge unknowns back and forth, respectively, and ρ_r denotes the charge of unknown vectors. Then, one has

$$\rho_r = \overline{\mathbf{F}} \cdot \rho, \quad \rho = \overline{\mathbf{B}} \cdot \rho_r \tag{102}$$

However, the saddle point problems always suffer from the poor spectral property due to the zero diagonal block. Hence, the constraint preconditioner is usually required in order to regularize the saddle point matrix for easier solution. Since this preconditioning matrix should be inverted first, a highly sparse matrix is preferred and is given by

$$\overline{M} = \begin{bmatrix} \overline{\mathbf{V}}_d & \overline{\mathbf{D}}_r{}^T \cdot \overline{\mathbf{P}}_{rd} \\ \overline{\mathbf{D}}_r & k_0^2 \overline{\mathbf{I}}_r \end{bmatrix} \tag{103}$$

which can be solved by a fast direct solver like the multifrontal method. It implies that it will incur more computational cost in addition to the more unknowns in comparison with the traditional EFIE system. More details about this constraint preconditioning technique can be found in Benzi et al. (2005). Alternatively, the Calderón multiplicative preconditioner can be further implemented on A-EFIE, which does not need inverse preconditioning and avoids the saddle point problems as well (Sun et al. 2013a).

Calderon Preconditioning

Another popular remedy is to utilize the Calderón identity, which can be expressed as (Adams 2004).

$$\mathcal{T}^2(\boldsymbol{J}) = -\frac{\boldsymbol{J}}{4} + \mathcal{K}^2(\boldsymbol{J}) \tag{104}$$

It can be used to conduct a new operator by projecting the operator $\mathcal{T}$ of Eq. (87) into itself. In the above, $\mathcal{K}$ is the magnetic field integral equation (MFIE) operator (Chew et al. 2008)

$$\mathcal{K}(\boldsymbol{J}) = \hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \nabla \times \int_{S'} dS' g(\boldsymbol{r}, \boldsymbol{r}') \boldsymbol{J}. \tag{105}$$

It is important to notice from Eq. 104 that the composite operator $\mathcal{T}^2$ is actually a second-kind integral operator with its spectrum accumulating at -0.25. In other words, the $\mathcal{T}$ operator can be utilized to precondition itself, the so-called "self-regularizing property".

A multiplicative form of the Calderón multiplicative preconditioner (CMP) (Andriulli et al. 2008) was developed based on the div- and quasi-curl-conforming basis function, called the Buffa–Christiansen (BC) basis function (Buffa and Christiansen 2007). This preconditioning is straightforward to implement and easily integrated into existing MoM codes based on RWG basis functions. For the discretization of composite operator $\mathcal{T}^2$, the inner $\mathcal{T}$ operator is discretized by using div-conforming RWG basis function (source) and $\hat{n}_r \times$ RWG basis function, while the outer $\mathcal{T}$ operator is discretized by using div- and quasi-curl-conforming BC basis function (source) and $\hat{n}_r \times$ BC basis function. Therefore, the resulting Gram matrix is a mixed curl- and quasi-curl-conforming matrix, which is highly sparse and invertible. Subsequently, the CMP is applied on the combined field integral equation (CFIE) formulation for PEC objects (Bağci et al. 2009) and also for the single-source integral equations (Valdés et al. 2011).

It should also be noted that the BC basis function represents a subset of the functions proposed by Chen and Wilton in 1990 (Chen and Wilton 1990), which was named the dual basis. In other words, the idea of

DOI 10.1007/978-981-4560-75-7_6-2

these two basis functions is identical. Both of these two basis functions are a linear combination of RWG basis functions on the barycentrically refined triangles within a polygon pair and have the same dual basis property, i.e., approximately orthogonal to the original RWG basis function (Tong et al. 2009). The reason why the BC basis function has received more attention in the electromagnetics community is because of its success in the CMP (Andriulli et al. 2008), where the well-conditioned nature of the Gram matrices linking the BC basis functions to $\hat{n}_r \times$ RWG basis functions is ensured. Hence, one should rightfully call them the Chen–Wilton–Buffa–Christiansen (CWBC) basis function.

According to the decomposition in Eq. 87, the composite operator $\mathcal{T}^2$ can be further expanded as

$$\mathcal{T}^2 = \mathcal{T}_s^2 + \mathcal{T}_s\mathcal{T}_h + \mathcal{T}_h\mathcal{T}_s + \mathcal{T}_h^2 \tag{106}$$

where

$$\mathcal{T}_s^2(\boldsymbol{J}) = -\omega^2\mu^2\hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \int_{S'} dS' g(\boldsymbol{r},\boldsymbol{r}') \left[\hat{\boldsymbol{n}}'_{\boldsymbol{r}} \times \int_{S''} dS'' g(\boldsymbol{r}',\boldsymbol{r}'')\boldsymbol{J}\right] \tag{107}$$

$$\mathcal{T}_s\mathcal{T}_h(\boldsymbol{J}) = -\hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \int_{S'} dS' g(\boldsymbol{r},\boldsymbol{r}') \left[\hat{\boldsymbol{n}}'_{\boldsymbol{r}} \times \nabla' \int_{S''} dS'' g(\boldsymbol{r}',\boldsymbol{r}'')\nabla''\cdot\boldsymbol{J}\right] \tag{108}$$

$$\mathcal{T}_h\mathcal{T}_s(\boldsymbol{J}) = -\hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \nabla \int_{S'} dS' g(\boldsymbol{r},\boldsymbol{r}')\nabla'\cdot \left[\hat{\boldsymbol{n}}'_{\boldsymbol{r}} \times \int_{S''} dS'' g(\boldsymbol{r}',\boldsymbol{r}'')\boldsymbol{J}\right] \tag{109}$$

$$\mathcal{T}_h^2(\boldsymbol{J}) = -\frac{1}{\omega^2\varepsilon^2}\hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \nabla \int_{S'} dS' g(\boldsymbol{r},\boldsymbol{r}')\nabla'\cdot \left[\hat{\boldsymbol{n}}'_{\boldsymbol{r}} \times \nabla' \int_{S''} dS'' g(\boldsymbol{r}',\boldsymbol{r}'')\nabla''\cdot\boldsymbol{J}\right]. \tag{110}$$

Recalling the surface Helmholtz decomposition of the surface current $\boldsymbol{J}$ (Hsiao and Kleinman 1997),

$$\boldsymbol{J} = \nabla_S\phi + \hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \nabla_S\psi \tag{111}$$

where ϕ and ψ are scalar functions defined on S. The first term of Eq. 111 is purely irrotational (curl-free) while the second term is purely solenoidal (divergence-free). It is easy to show that (Adams 2004)

$$\nabla_S \cdot (\mathcal{T}_h(\boldsymbol{J})) = \nabla_S \cdot (\hat{\boldsymbol{n}}_{\boldsymbol{r}} \times \nabla\Phi) = 0. \tag{112}$$

where $\nabla_S\cdot$ is the surface divergence operator. As a result, the square of the hypersingular term $\left(\mathcal{T}_h^2\right)$ in Eq. 110 is identically zero. Consequently, the decomposed operator $\mathcal{T}^2$ in Eq. 106 can be rewritten as

$$\mathcal{T}^2 = \mathcal{T}_s^2 + \mathcal{T}_h\mathcal{T}_s + \mathcal{T}_s\mathcal{T}_h. \tag{113}$$

Notice that from Eqs. 107 to 109, the $\mathcal{T}_s^2 \sim O(\omega^2)$, while the $\mathcal{T}_s\mathcal{T}_h + \mathcal{T}_h\mathcal{T}_s \sim O(\omega^0)$, when $\omega \to 0$. In other words, the $\mathcal{T}_s\mathcal{T}_h$ and $\mathcal{T}_h\mathcal{T}_s$ are frequency invariant, so that these two terms behave like the identity operator. Meanwhile, $\mathcal{T}_s^2$ behaves like a compact operator and approaches zero when $\omega \to 0$. Therefore, the total operator $\mathcal{T}^2$ can be considered as an identity operator plus a compact operator, making it a well-conditioned second-kind Fredholm integral operator immune to low-frequency breakdown. Meanwhile, $\mathcal{T}_h^2 \sim O(\omega^{-2})$ implies that the square of the hypersingular term has to be set to zero; otherwise it will

DOI 10.1007/978-981-4560-75-7_6-2

swamp the contributions from the other three terms at low frequencies. However, if $\boldsymbol{J}$ is of the order smaller than ω^0 and the higher-order current is also important for certain problems, the decomposed $\mathcal{T}^2$ (without $\mathcal{T}_h^2$) still decreases with frequency. It does not cause the breakdown of the MoM but causes the inaccuracy of the electric current at low frequencies.

Perturbation Method

The low-frequency inaccuracy problem happens in many formulations such as EFIE, MFIE, and CMP-EFIE. As detailed in (Zhang et al. 2003; Qian and Chew 2010), although the formulations are stable at extreme low frequencies, the current unknowns cannot be computed accurately. To remedy this inaccuracy problem, a perturbation method introduced in this section will be discussed based on the expanded CMP-EFIE formulation in Eq. 113 (Sun et al. 2013b).

By expanding the Green's function with Taylor series as

$$g(\boldsymbol{r},\boldsymbol{r}') \approx \frac{1}{4\pi R}\left[1 + ik_0R + \frac{1}{2}(ik_0R)^2\right] \tag{114}$$

the sub-matrices can be expanded with respect to a small parameter $\delta = ik_0$. Then, one has

$$\left[\overline{\boldsymbol{Z}}_p^q\right] = \left[\overline{\boldsymbol{Z}}_p^{q(0)}\right] + \delta\left[\overline{\boldsymbol{Z}}_p^{q(1)}\right] + \delta^2\left[\overline{\boldsymbol{Z}}_p^{q(2)}\right] + O\left(\delta^3\right) \tag{115}$$

where the impedance matrices for the smoothing term are given by

$$\left[\overline{\boldsymbol{Z}}_p^{s(0)}\right]_{mn} = \frac{\mu}{4\pi}\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'\frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|}\boldsymbol{f}_{pn}(\boldsymbol{r}') \tag{116}$$

$$\left[\overline{\boldsymbol{Z}}_p^{s(1)}\right]_{mn} = \frac{\mu}{4\pi}\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'\boldsymbol{f}_{pn}(\boldsymbol{r}') \tag{117}$$

$$\left[\overline{\boldsymbol{Z}}_p^{s(2)}\right]_{mn} = \frac{\mu}{8\pi}\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'|\boldsymbol{r}-\boldsymbol{r}'|\boldsymbol{f}_{pn}(\boldsymbol{r}') \tag{118}$$

and the impedance matrices for the hypersingular term are given by

$$\left[\overline{\boldsymbol{Z}}_p^{h(0)}\right]_{mn} = \frac{1}{4\pi\varepsilon}\nabla\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'\frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|}\nabla'\boldsymbol{f}_{pn}(\boldsymbol{r}') \tag{119}$$

$$\left[\overline{\boldsymbol{Z}}_p^{h(1)}\right]_{mn} = \frac{1}{4\pi\varepsilon}\nabla\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'\nabla'\cdot\boldsymbol{f}_{pn}(\boldsymbol{r}') \tag{120}$$

$$\left[\overline{\boldsymbol{Z}}_p^{h(2)}\right]_{mn} = \frac{1}{8\pi\varepsilon}\nabla\int_{S_m} dS\boldsymbol{f}_{pm}(\boldsymbol{r})\cdot\int_{S_n} dS'|\boldsymbol{r}-\boldsymbol{r}'|\nabla'\cdot\boldsymbol{f}_{pn}(\boldsymbol{r}'). \tag{121}$$

At low frequencies, $\overline{Z}_p^q \approx \overline{Z}_p^{q(0)}$, because the zeroth-order of the Green's function in Eq. 114 is equal to its original form of Eq. 90.

DOI 10.1007/978-981-4560-75-7_6-2

For the current and excitation vectors, the same notations as those in Qian and Chew (2010) are used as

$$ik_0\boldsymbol{j} = \boldsymbol{j}^{(0)} + \delta\boldsymbol{j}^{(1)} + \delta^2\boldsymbol{j}^{(2)} + O\left(\delta^3\right) \tag{122}$$

$$\boldsymbol{b} = \boldsymbol{b}^{(0)} + \delta\boldsymbol{b}^{(1)} + \delta^2\boldsymbol{b}^{(2)} + O\left(\delta^3\right) \tag{123}$$

where

$$\left[\boldsymbol{b}^{(0)}\right]_m = -\eta^{-1}\int_{S_m} dS\boldsymbol{f}_{RWGm}(r)\cdot\boldsymbol{E}_0 \tag{124}$$

$$\left[\boldsymbol{b}^{(1)}\right]_m = -\eta^{-1}\int_{S_m} dS\boldsymbol{f}_{RWGm}(r)\cdot\boldsymbol{E}_0\left(\hat{k}_{inc}\cdot\tilde{\boldsymbol{r}}\right) \tag{125}$$

$$\left[\boldsymbol{b}^{(2)}\right]_m = -\frac{1}{2}\eta^{-1}\int_{S_m} dS\boldsymbol{f}_{RWGm}(r)\cdot\boldsymbol{E}_0\left(\hat{k}_{inc}\cdot\tilde{\boldsymbol{r}}\right)^2 \tag{126}$$

and $\hat{k}_{inc}$ is the unit vector of the incident direction and the tilde above $\boldsymbol{r}$ indicates the normalization by l, where l is a typical length scale.

Substituting them into Eq. 113 and matching the coefficients of like powers of δ, a recurrent system of equations for the current functions $\boldsymbol{j}$ is obtained. Firstly, matching the zeroth order of δ gives the lowest-order equation as

$$\left[\overline{\boldsymbol{Z}}^{s(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{h(0)}_{RW\,G} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{s(0)}_{RW\,G}\right]\cdot\boldsymbol{j}^{(0)} = \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(0)} \tag{127}$$

It can be noticed that the impedance matrix is equal to the three-term CMP-EFIE without $\mathcal{T}_h^2$ in Eq. 113 in static regime, where the contributions from the $\mathcal{T}_h^2$ of $O(\omega^2)$ disappear. That means the resultant matrix is similar to the form of an identity operator as the aforementioned analysis. Hence, it has a good spectral property at low frequencies and its iterative solution converges well. For the inductive circuit problem like an inductor, the loop current is inversely proportional to frequency, so that the leading term of current is ω^{-1}. According to Eq. 122, the inductive current $ik_0\boldsymbol{j}$ would be of this zeroth-order solution.

For the plane-wave scattering problem, the leading term of the current $\boldsymbol{j}$ is of the order of ω^0. Hence, $\boldsymbol{j}^{(0)} = 0$ and one can obtain the first- and second-order equations by matching the first and second order of δ as

$$\left[\overline{\boldsymbol{Z}}^{s(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{h(0)}_{RW\,G} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{s(0)}_{RW\,G}\right]\cdot\boldsymbol{j}^{(1)} = \overline{\boldsymbol{Z}}^{h(1)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(0)} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(1)} \tag{128}$$

and

$$\begin{aligned}\left[\overline{\boldsymbol{Z}}^{s(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{h(0)}_{RW\,G} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{s(0)}_{RW\,G}\right]\cdot\boldsymbol{j}^{(2)} &= \overline{\boldsymbol{Z}}^{s(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(0)} + \overline{\boldsymbol{Z}}^{h(1)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(1)} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(2)} \\ &\quad - \left[\overline{\boldsymbol{Z}}^{s(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{h(1)}_{RW\,G} + \overline{\boldsymbol{Z}}^{h(0)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{s(1)}_{RWG}\right]\cdot\boldsymbol{j}^{(1)} \\ &\quad - \left[\overline{\boldsymbol{Z}}^{s(1)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{h(0)}_{RW\,G} + \overline{\boldsymbol{Z}}^{h(1)}_{CW\,BC}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}^{s(0)}_{RW\,G}\right]\cdot\boldsymbol{j}^{(1)}\end{aligned} \tag{129}$$

DOI 10.1007/978-981-4560-75-7_6-2

Once the currents in the first three orders are obtained by solving (127, 128, and 129), the far-field results at very low frequencies can be obtained accurately.

It is important to notice that the impedance matrices on the left-hand side of Eqs. 127, 128, and 129 have both contributions from the smoothing and hypersingular terms, thus avoiding the null-space problem and breakdown at low frequencies. Similar to the augmented EFIE formulations, the decomposed CMP-EFIE operator is balanced at low frequencies after setting $\mathcal{T}_h^2 = 0$.

In particular, it can be observed that the leading term of the current $\boldsymbol{j}$ is of the order of ω^1 for the capacitive or differential circuit problems. It implies that the leading term of $ik_0\boldsymbol{j}$ is of the order of ω^2. Hence, the zeroth-order current $\boldsymbol{j}^{(0)}$ in Eq. 122, which is of the order of ω^0, and the first-order current $\boldsymbol{j}^{(1)}$ should be zero. For the delta-gap voltage source excitation, there is only the zeroth order $\boldsymbol{b}^{(0)}$ left in the right-hand side of the system. By utilizing this natural characteristic, the solution complexity of the matrix systems in Eqs. 127, 128, and 129 can be reduced significantly as

$$\left[\overline{\boldsymbol{Z}}_{CW\,BC}^{s(0)}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}_{RW\,G}^{h(0)} + \overline{\boldsymbol{Z}}_{CW\,BC}^{h(0)}\overline{\boldsymbol{G}}_m^{-1}\overline{\boldsymbol{Z}}_{RW\,G}^{s(0)}\right]\cdot\boldsymbol{j}^{(2)} = \overline{\boldsymbol{Z}}_{CW\,BC}^{s(0)}\overline{\boldsymbol{G}}_m^{-1}\boldsymbol{b}^{(0)} \tag{130}$$

where the second term in the left-hand side is usually much smaller than the first term, thus leading to a simpler formulation for the capacitive problems (Liu et al. 2014).

Optical Nanoantennas

A microwave or radiowave antenna is an electrical device which converts electric power into radiowaves, and vice versa. As analogues of microwave and radiowave antennas, optical nanoantennas (see Fig. 12) convert freely propagating optical radiation into localized electromagnetic energy, and vice versa (Novotny and Hulst 2011). They are indispensable building blocks for manipulating and controlling light–matter interaction at subwavelength scales. Nanoantennas have broad applications (see Fig. 13) in photodetection, solar energy, light emission, sensing, microscopy, and (surface-enhanced Raman) spectroscopy (Bharadwaj et al. 2009; Giannini et al. 2011; Biagioni et al. 2012; Krasnok et al. 2013). Currently, the tools of nanoscience and nanotechnology, such as focused ion beam milling (Muhlschlegel et al. 2005), electron-beam lithography (Kinkhabwala et al. 2009), and self-assembly schemes (Kalkbrenner et al. 2005), enable fabrication of nanoantennas down to nanoscales.

Theoretical Model

Computational electromagnetics (Chew et al. 2000; Jin 2014; Taflove and Hagness 2005), which is used for modeling the interaction of electromagnetic fields with physical objects and surrounding environment, plays an important role in characterizing and optimizing the optical design of nanoantennas. A rigorous, fast, and efficient solution to Maxwell's equations facilitates understanding underlying working principles, reducing experimental costs, and accelerating research and development periods. With the aid of state-of-the-art methods, critical physical parameters in the design of nanoantennas can be illustrated for observation and analyzed for optimization. It is highly desirable to know the strengths and weaknesses of various theoretical methods in modeling nanoantennas. Different from classical antennas, rigorous full-wave simulation of nanoantennas faces the following new challenges: (1) accurate near-field calculation; (2) computing numerical dyadic Green's functions in inhomogeneous electromagnetic environment; (3) complex multilayered, periodic, random, or composite structures; (4) highly dispersive and lossy materials (not perfect electric conductors); (5) strong evanescent wave couplings and mode hybridizations; and (6) multi-scale, nonlinear, and multiphysics effects.

Time-Domain Methods Versus Frequency-Domain Methods

Most optical materials are dispersive; therefore, a recursive convolution method (Luebbers et al. 1990) or a piecewise linear recursive convolution method (Kelley and Luebbers 1996) must be adopted for time-

DOI 10.1007/978-981-4560-75-7_6-2

domain methods. For noble metals with plasmonic effects in the visible light range, such as silver and gold, the complex refractive index has to be described by a large number of summation terms in the Lorentz–Drude model leading to a long calculation time. However, for frequency-domain methods, an experimentally tabulated refractive index of the dispersive material is incorporated directly. Another difficulty in time-domain methods is the treatment of periodic boundary conditions particularly for the oblique incidence caused by the anticausal property of the Floquet theorem. Hence, the ability of frequency-domain methods to handle the case of oblique incidence is clearly an important advantage over time-domain methods (Veysoglu et al. 1993). Moreover, time-domain methods suffer from numerical dispersion and stability problems in contrast to frequency-domain methods. This drawback becomes serious if a three-dimensional large-scale nanoantenna structure is investigated. A significant merit associated with a time-domain method is a broadband simulation at the frequencies of interest. The frequency-domain method can employ parallel computing technique to circumvent the problem. Compared to frequency-domain methods, time-domain methods cannot obtain accurate eigenvalue solutions but save considerable computer resources. Additionally, time-domain methods are easier and more convenient to model nonlinear and multiphysics effects in nanoantennas.

Integral Equation Methods Versus Differential Equation Methods

Differential equation methods involving finite-difference and finite-element algorithms (Jin 2014; Taflove and Hagness 2005) can treat a variety of inhomogeneous boundary conditions conveniently. The methods have a powerful ability to model a complex nanoantenna structure. The resultant matrix by differential equation methods is sparse due to the "local" nature of differential operators of Maxwell's equations or wave equations. The method consumes the memory cost of $O(N)$ and complexity of $O(N)$ per matrix-vector multiplication in the Krylov subspace iteration algorithm (Vandervorst 1992). Moreover, multifrontal or multigrid methods (Davis and Duff 1997) can speed up the solution process of the differential equations. To simulate the interaction between light and nanoantennas, an efficient absorption boundary condition (Berenger 1994; Chew and Weedon 1994) and additional volume grids enclosing the nanoantenna have to be adopted.

In comparison with differential equation methods, integral equation methods (Chew 1999, 2008) connect field components to equivalent currents by using "global" integral operators represented with dyadic Green's functions. As a result, integral equation methods always guarantee higher accuracy but lead to full dense matrix. Fortunately, matrix-free fast algorithms (Chew et al. 2000), such as fast Fourier transform (Catedra et al. 1989) and fast multipole methods (Greengard and Rokhlin 1987; Song et al. 1997), can significantly reduce computer resources required by solving the dense matrix. Thanks to the Green's tensor, the integral equation methods automatically satisfy the radiation boundary condition but need singularity treatments. In particular, the surface integral equation method having a unique feature of surface triangulation produces much smaller unknowns. However, the method can only be employed to analyze a homogeneous or piecewise-homogeneous structure. For an arbitrary inhomogeneity or complex environment encountered in nanoantennas, the near-field calculation by the surface integral equation method is hard to implement.

Mode-Matching Methods

The mode-matching method (Chew 1999; Bienstman and Baets 2001) is a commonly used technique for the formulation of optical problems, especially for structures consisting of two or more separated regions. It is based on expanding the fields and matching them at the boundaries of different regions and thus lends itself naturally to the analysis of some nanoantenna structures. The most representative of mode-matching methods involves rigorous coupled-wave analysis (Moharam et al. 1995), scattering matrix method (Yonekura et al. 1999), plane-wave expansion method (Johnson and Joannopoulos 2001), and T-matrix

DOI 10.1007/978-981-4560-75-7_6-2

method (Mishchenko et al. 2010). Using cheap computer resources, these methods are particularly useful in characterizing the optical response of periodic or multilayered nanoantennas, Yagi-Uda nanoantennas, and nanoantenna array. Absorption and radiation (scattering) characteristics of nanoantennas can be obtained with a program. However, mode-matching methods are not well suited for characterizing plasmonic effects because a large quantity of modes are required to describe the plasmon coupling and hybridization.

Optical Nanoantennas Versus Classical Antennas

This section introduces the basic principles and physical parameters that govern the operation of nanoantennas. The differences between classical antennas and optical nanoantennas are summarized.

Source and Receiver

Classical antennas use current (voltage) and electrical load as a source and receiver, respectively. However, the source and receiver of nanoantennas become quantum objects such as molecules, atoms, ions, or quantum dots. At this length scale, the light–matter interaction becomes quantized (Novotny and Hulst 2011).

Resonant Transducer

The design of classical antennas relates to the wavelength λ of incident or radiative electromagnetic waves (Novotny and Hulst 2011). For example, a half-wave antenna has a length L of λ/2, and a Yagi-Uda antenna has fixed separations between elements at fractions of λ. At microwave and radiowave regimes, metals can be regarded as perfect electric conductors (PECs). Thus, the scaling law was adopted to design antennas from one frequency to another. However, the scaling breaks down at optical frequencies, where metals (gold, silver, etc.) are highly lossy and dispersive materials and the skin depth of metals becomes comparable to the nanoantenna size. The permittivity of metals at optical regime can be expressed by a superposition of the Lorentz–Drude model (Maier 2007). Although an effective wavelength (Novotny and Hulst 2011) or a low-frequency circuit theory has been utilized (Alu and Engheta 2008) to simplify the nanoantenna design, a rigorous solution to Maxwell's equations is essential to capture the wave interaction between nanoantennas and sources/receivers. Particularly, the size of a resonant nanoantenna is much smaller than the wavelength of radiation, which breaks the half-wavelength limit.

Absorption, Scattering, and Extinction Cross Sections

The far-field radiation pattern adopted in classical antennas is still very useful to describe the angular response of nanoantenna radiation or scattering. However, the total absorption and scattering properties of a nanoantenna are easier to measure and calculate for optimized designs.

Given a plane-wave excitation (laser excitation can be well approximated as a plane-wave excitation in nanoantenna experiments), the scattering cross section, which estimates the total scattering strength of a nanoantenna as a function of frequency, is defined as (Tsang et al. 2000)

$$\sigma_s = \frac{\int_S \Re e\left[\frac{1}{2}\mathbf{E}_{sca} \times \mathbf{H}^*_{sca}\right] \cdot d\mathbf{S}}{|\mathbf{S}_{inc}|} \tag{131}$$

where * denotes the complex conjugation, S is an arbitrary surface enclosing the nanoantenna, $\mathbf{S}_{inc} = \frac{1}{2}\left[\mathbf{E}_{inc} \times \left(\mathbf{H}^*_{inc}\right)\right]$ is the incident energy flux, and $\mathbf{E}_{sca}$ and $\mathbf{H}_{sca}$ are the scattered electric and

DOI 10.1007/978-981-4560-75-7_6-2

magnetic fields, respectively. Considering the total power absorbed by a nanoantenna, absorption cross section is of the form (Tsang et al. 2000)

$$\sigma_a = -\frac{\int_S \frac{1}{2}\Re e[\mathbf{E}\times\mathbf{H}^*]\cdot d\mathbf{S}}{|\mathbf{S}_{inc}|} = \frac{\int_V k_0\epsilon_r''(\mathbf{r})|\mathbf{E}(\mathbf{r})|^2 dV}{|\mathbf{E}_{inc}|^2} \tag{132}$$

where ϵ_r'' is the imaginary part of relative permittivity and k_0 is the wave number of free space (background medium). The extinction cross section describes the intrinsic losses of a nanoantenna system including both absorption loss and scattering (or leaky) loss. Hence, the sum of the scattering and absorption cross sections is the extinction cross-section σ_e

$$\sigma_e = \sigma_a + \sigma_s \tag{133}$$

Moreover, another mathematical expression for the extinction cross section is to employ the optical theorem at the far-field limit (Tsang et al. 2000)

$$\sigma_e = \frac{4\pi}{k_0}\Im m\left[\mathbf{e}_{inc}\cdot\overline{\mathbf{F}}\cdot\mathbf{e}_{inc}\right] \tag{134}$$

and

$$\mathbf{E}_{sca} = \frac{\exp(ik_0 r)}{r}\overline{\mathbf{F}}\cdot\mathbf{E}_{inc}, \quad r\to\infty \tag{135}$$

where i is the imaginary unit and $\mathbf{e}_{inc}$ is the polarization unit vector of the incident electric field $\mathbf{E}_{inc}$. The absorption, scattering, and extinction cross sections can be obtained by a postprocessing procedure after rigorously solving Maxwell's equations (He et al. 2012).

Directivity, Gain, and Reciprocity

Nanoantenna gain is a product of radiation efficiency η_r and directivity D, i.e., $G = \eta_r D$, which is the same as classical antennas. The radiation efficiency is defined as the ratio of the far-field power P_r radiated by the emitter with a nanoantenna to the total delivered power, i.e., $\eta_r = P_r/(P_r + P_l)$, where P_l is the total ohmic loss by nanoantenna absorption. This is also identical to classical antennas. However, considering internal losses of the emitter itself, an internal efficiency is defined as (Krasnok et al. 2013)

$$\eta_{in} = \frac{P_0}{P_0 + P_{0l}} \tag{136}$$

where P_{0l} and P_0 are the internal losses and the power radiated by the emitter in the absence of the nanoantenna, respectively. Finally, the radiation efficiency is expressed as

$$\eta_r = \frac{P_r}{P_r + P_l + P_0(1-\eta_{in})/\eta_{in}} \tag{137}$$

From the above equations, the introduction of nanoantennas could significantly improve the radiation efficiency of a poor emitter ($\eta_{in} \ll 1$). Because of a resonant enhancement, the radiated power P_r with the

DOI 10.1007/978-981-4560-75-7_6-2

nanoantenna is much larger than the radiated power P_0 without the nanoantenna. Similar to classical antennas, reciprocity holds true for nanoantennas if the medium is the reciprocal medium $\left(\overline{\epsilon}_r = \overline{\epsilon}_r^t, \overline{\mu}_r = \overline{\mu}_r^t\right)$. Considering two nanoantenna systems with different sources $\mathbf{J}_1$ and $\mathbf{J}_2$, which respectively produce the fields $\mathbf{E}_1$ and $\mathbf{E}_2$, then $\int_V \mathbf{E}_1 \cdot \mathbf{J}_2 dV = \int_V \mathbf{E}_2 \cdot \mathbf{J}_1 dV$.

Input Impedance Versus Local Density of States

For classical antennas, guided structures (transmission line, coplanar waveguide, microstrip line, etc.) are utilized to control the amplitude and phase of feeding source. The input impedance of antennas should be matched with the characteristic impedance of guided structures to minimize the reflection. However, the guided structure is not needed for nanoantennas if the source is a quantum emitter or their clusters, which are located around the feeding gap (element) of nanoantennas. In this situation, the impedance matching concept is not applicable to the nanoantenna design. Typically, a focused laser beam is used to excite or feed nanoantennas. The excitation field to quantum emitters is enhanced by the nanoantenna. Meanwhile, radiation field from quantum emitters is again enhanced by the nanoantenna. For surface-enhanced Raman scattering (SERS), the enhancement factor is written as (Giannini et al. 2011)

$$G_{SERS} = \frac{\left|\mathbf{E}^p(\mathbf{r}_0, \omega_i)\right|^2}{\left|\mathbf{E}^p_{inc}(\mathbf{r}_0, \omega_i)\right|^2} \cdot \frac{\left|\mathbf{E}^d(\mathbf{r}_0, \omega_r)\right|^2}{\left|\mathbf{E}^d_{inc}(\mathbf{r}_0, \omega_r)\right|^2} \tag{138}$$

where $\mathbf{r}_0$ is the emitter point and $|\mathbf{E}|^2/|\mathbf{E}_{inc}|^2$ are due to local field enhancements. ω_i and ω_r are the angular frequencies respectively for the incident (pump) laser beam and Raman-shifted radiation field. The enhancement factor can be easily obtained by a near-field simulation of nanoantennas. It should be noted that $\mathbf{E}^p_{inc}(\mathbf{r}_0, \omega_i)$ is the incident E-field from the laser beam (that can be regarded as a plane wave) while $\mathbf{E}^d_{inc}(\mathbf{r}_0, \omega_r)$ is the incident E-field from the emitter (that can be regarded as a Hertzian dipole).

To let quantum emitters efficiently radiate electromagnetic waves, photon local density of states (LDOS) at the emitter point or spontaneous emission (decay) rate of the emitter should be enhanced. The spontaneous emission rate counts the number of spontaneously emitted photons per unit time. The LDOS counts the number of electromagnetic modes at the emitter point. Each electromagnetic mode can be taken as a decay channel. The more decay channels there are, the easier it is for an excited atom to emit photons via returning to its ground state (Novotny and Hulst 2011). Therefore, more decay channels mean a larger spontaneous emission rate. Nanoantennas could significantly boost spontaneous emissions (named Purcell effect) due to the highly localized near-field enhancement induced by plasmonic effects. For example, the gap plasmonic mode supported at metallic bow-tie antennas enhances the single-molecule fluorescence (Kinkhabwala et al. 2009).

The LDOS in reciprocal, lossless, inhomogeneous, and anisotropic medium can be connected to dyadic Green's functions or Green's tensor

$$\rho(\mathbf{r}_0, \omega_0) = \frac{k_0^2}{\pi\omega_0} \mathrm{Tr}\left\{\overline{\epsilon}_r^{1/2} \cdot \Im m\left[\overline{\mathbf{G}}^e(\mathbf{r}_0, \mathbf{r}_0; \omega_0)\right] \cdot \overline{\epsilon}_r^{1/2} + \overline{\mu}_r^{1/2} \cdot \Im m\left[\overline{\mathbf{G}}^m(\mathbf{r}_0, \mathbf{r}_0; \omega_0)\right] . \overline{\mu}_r^{1/2}\right\} \tag{139}$$

where $\overline{\mathbf{G}}^e$ and $\overline{\mathbf{G}}^m$ are the electric and magnetic dyadic Green's functions in inhomogeneous medium. $\overline{\epsilon}_r$ and $\overline{\mu}_r$ are the relative permittivity and relative permeability tensors. For lossless, isotropic, inhomogeneous, and nonmagnetic medium, the above can be simplified to (Novotny and Hecht 2006)

DOI 10.1007/978-981-4560-75-7_6-2

$$\begin{aligned}\rho(\mathbf{r}_0,\omega_0) &= \sum_{\mathrm{k}} |\mathrm{u}_{\mathrm{k}}(\mathbf{r}_0)|^2 \delta(\omega_{\mathrm{k}}-\omega_0) \\ &= \frac{2\omega_0}{\pi c^2}\mathrm{Tr}\left\{\Im\mathrm{m}\left[\overline{\mathbf{G}}^{\mathrm{e}}(\mathbf{r}_0,\mathbf{r}_0;\omega_0)\right]\right\}\end{aligned} \tag{140}$$

where $c = 1/\sqrt{\mu\epsilon}$ is the speed of light in the medium. Here, $\mathbf{u_k}$ are the eigenmodes of E-field in inhomogeneous medium satisfying an orthogonal relation $\int_v \mathbf{u}_{\mathrm{k}'}^{\dagger}(\mathbf{r})\epsilon_r(\mathbf{r})\mathbf{u}_{\mathrm{k}}(\mathbf{r})d\mathbf{r} = \delta_{k',k}$. The LDOS can be separated into radiative and non-radiative parts, which are connected to radiation efficiency in Eq. 137. According to Fermi's golden rule (Novotny and Hecht 2006), the spontaneous emission rate γ_{se} is proportional to the LDOS

$$\gamma_{se} = \frac{\pi\omega_0}{3\hbar\epsilon_0}|\mathbf{p}|^2\rho(\mathbf{r}_0,\omega_0) \tag{141}$$

where $\mathbf{p}$ is the electric dipole moment of the atomic (molecular) transition.

Computational electromagnetics plays an important role in obtaining the Green's tensor in arbitrary inhomogeneous environment. The Green's tensor in inhomogeneous medium can be found by solving the following vector wave equations:

$$\nabla\times\overline{\mu}^{-1}\cdot\nabla\times\overline{\mathbf{G}}^{\mathrm{e}} - \omega_0^2\overline{\epsilon}\cdot\overline{\mathbf{G}}^{\mathrm{e}} = \overline{\mathbf{I}}\delta(\mathbf{r}-\mathbf{r}') \tag{142}$$

$$\nabla\times\overline{\epsilon}^{-1}\cdot\nabla\times\overline{\mathbf{G}}^{m} - \omega_0^2\overline{\mu}\cdot\overline{\mathbf{G}}^{m} = \nabla\times\left[\overline{\epsilon}^{-1}\cdot\overline{\mathbf{I}}\delta(\mathbf{r}-\mathbf{r}')\right] \tag{143}$$

A finite-difference method has been developed to discretize the delta function (monopole source) and derivative of delta function (dipole source) (Qiao et al. 2011). Taking a 2D line source as an example, one gets

$$\delta\left(x-m'\Delta_x, y-n'\Delta_y\right)|_{x=m'\Delta_x, y=n'\Delta_y} \approx \frac{1}{\Delta_x\Delta_y} \tag{144}$$

$$\begin{aligned}\frac{\partial\delta\left(x-m'\Delta_x, y-n'\Delta_y\right)}{\partial y} &\approx -\frac{\delta\left(x-m'\Delta_x, y-(n'+0.5)\Delta_y\right)}{\Delta_y} \\ &\quad + \frac{\delta\left(x-m'\Delta_x, y-(n'+0.5)\Delta_y\right)}{\Delta_y}\end{aligned} \tag{145}$$

where Δ_x and Δ_y are the spatial steps along the x and y directions and (m', n') is the grid index corresponding to the line source point. Using the above techniques and the finite-difference implementation, the numerical dyadic Green's functions can be found accordingly. Recently, using multilayered Green's functions and integral equation approach, the numerical Green's tensor around an arbitrarily shaped metallic nanostructure deposited on a multilayered structure has been calculated (Chen et al. 2012b).

Weak Coupling and Strong Coupling Regimes

Consider a nanoantenna operating at a single resonant mode $\mathbf{u_k}$, such as a metallic dipole antenna. In this situation, spontaneous emission rate in Eq. 141 can be rewritten as (Andreani et al. 1999)

DOI 10.1007/978-981-4560-75-7_6-2

$$\gamma_{se} = \frac{2}{3\hbar\epsilon_0}|\mathbf{p}|^2\frac{Q}{V} \tag{146}$$

where Q is the quality factor of the resonant antenna and $V = 1/|\mathbf{u_k}(\mathbf{r}_0)|^2$ is the mode volume. According to Jaynes–Cummings model, strong and weak coupling regimes can be distinguished by using the atom-field coupling constant (Andreani et al. 1999)

$$\kappa = \sqrt{\frac{|\mathbf{p}|^2\omega}{2\hbar\epsilon_0 V}} \tag{147}$$

Weak coupling obeys the condition $\kappa \ll \gamma_{se}$. In this irreversible regime, the effect of vacuum fluctuation fields on the emitter can be treated as a perturbation. Due to large radiation and absorption losses, spontaneously emitted photons cannot react back upon the emitter. Strong coupling obeys the condition $\kappa \gg \gamma_{se}$. In this reversible regime, photons remain in the cavity for a long time and are absorbed and re-emitted many times, which is called vacuum Rabi oscillation. Strong coupling allows the electron and photon entangled to be a polariton, which is a quasiparticle. The strong coupling regime is quite important to cavity quantum electrodynamics and quantum computing. In Eqs. 146 and 147, the important characteristic parameters Q and V can be rigorously calculated by an eigenvalue analysis. Calculation of the mode volume V is trivial if the eigenmode $\mathbf{u_k}$ around the (resonant) working frequency ω of the nanoantenna has been obtained. The quality factor can be extracted from corresponding complex eigenfrequency via the equation $Q = \Re e(\omega_k)/[2\Im m(\omega_k)]$. Several fast and universal eigenvalue solvers have been developed for an arbitrary electromagnetic system (Dai et al. 2012, 2013, 2014; Sha et al. 2014).

Design Rules for Optical Nanoantennas

Broadband Nanoantennas

A broadband nanoantenna can be an absorber for light harvesting or be a (near-field) concentrator for light enhancement (Atwater and Polman 2010). It also can be a far-field reflector for light trapping (Yu et al. 2010). Tapered nonresonant structures (Maksymov et al. 2011) support propagating (not standing) waves and thus a broadband response. Alternatively, the multisized nanoantenna (Cui et al. 2011) is another way to obtain a broadband absorption or scattering. The mode coupling (hybridization) between individual resonators induces a spectral overlap between eigenmodes (Ye and He 2010). Meanwhile, high-order modes could be excited via a strong mode coupling or symmetry breaking (Giannini et al. 2011). According to the coupled-mode theory, a single-mode resonator will be operated at the critical coupling regime if the radiation loss is balanced with the absorption loss (Yu et al. 2010), which is similar to a maximum power transfer condition in electrical engineering. Under this condition, a maximum absorption can be achieved but with a narrow bandwidth. Additionally, a broadband reflector can be realized by resonators operated at the over-coupling regime (Yu et al. 2010), where the radiation loss is much larger than the absorption (ohmic) loss.

Wavelength-Selective Nanoantennas

Wavelength selectivity by nanoantennas is required to resolve and match vibrational modes of a target molecule. Radiation and ohmic losses can be reduced to construct a narrow-band resonator with a high-quality factor. A defect in a periodic structure can induce the wavelength selectivity as well (Joannopoulos

DOI 10.1007/978-981-4560-75-7_6-2

et al. 2008). The wavelength selectivity has been realized by a single dielectric sphere, where the constructive and destructive interferences between the broad dipole eigenmode (first term of the spherical harmonics in Mie series) and the narrow quadrupole eigenmode (second term of the spherical harmonics in Mie series) induce an extraordinary Fano resonance with an asymmetric and narrow spectral line (Liu et al. 2012). The Fano spectral line is fundamentally different from the Lorentz spectral line achieved by a single-mode resonator.

Directional Nanoantennas

Directional nanoantennas are useful for far-field detection and sensing. A high directivity can be obtained by the following rules: (1) far-field interference by using an antenna array (Liu et al. 2011); (2) near-field interference by using the reflector, such as Yagi-Uda antennas (Taminiau et al. 2008); (3) using optical couplers, such as gratings, Fabry–Perot directive antenna, etc. (Martin-Moreno et al. 2003); and (4) using high-order modes and mode interference, such as a single sphere antenna, whispering gallery antenna, etc. (Gerard et al. 2009; Liu et al. 2012; Staude et al. 2013).

Metallic Nanoantennas Versus Dielectric Nanoantennas

Metallic nanoantennas have an unprecedented ability to concentrate and confine electromagnetic fields at a deep subwavelength scale. Dielectric nanoantennas (Pellegrini et al. 2009) have a larger geometric size but with a lower ohmic loss. Dielectric nanoantennas could easily excite high-order eigenmodes or exhibit both electric and magnetic resonances (Gerard et al. 2009; Staude et al. 2013) and thus show a strong scattering capability. Also, they can be semiconducting materials themselves and are more compatible to optoelectronic devices (Chen et al. 2012a). Dielectric nanoantennas can be integrated with metallic ones to achieve better performances (Devilez et al. 2010).

Nonlinear Optical Nanoantennas

Metals at optical regime have nonlinear susceptibility. Strong electromagnetic fields in plasmonic nanoantennas significantly enhance nonlinear processes including second harmonic generation, Kerr effect, four-wave mixing, etc. (Kauranen and Zayats 2012). Far-field detection of high-order harmonic generation depends on (1) pump field intensity at the frequency of fundamental mode, (2) spatial overlap between fundamental eigenmode and high-order harmonic eigenmode, and (3) outcoupling (far-field radiation) strength of high-order harmonic eigenmode. There are many designs in literatures to enhance the nonlinear effects of nanoantennas (Kauranen and Zayats 2012). The nonlinear response of nanoantennas can be rigorously modeled with the self-consistent solution to coupled Maxwell's equations and hydrodynamic equation (Corvi and Schaich 1986). Using a surface susceptibility tensor, a surface integral equation approach has been proposed to model the second harmonic generation from symmetric metallic objects, where the surface contribution is much larger than the bulk one (Makitalo et al. 2011; Xiong et al. 2014). It is worthy of mentioning that symmetry breaking is an efficient way to enhance the second harmonic generation from plasmonic nanoantennas (Pu et al. 2010).

Control of Light Angular Momentum by Nanoantennas

Similar to an electron, a photon has spin and orbital angular momenta, which are respectively defined as (Bliokh et al. 2013)

$$\mathbf{P}_s = \frac{1}{8\omega}\nabla \times \Im m\left[\frac{\epsilon_0}{\mu_r}(\mathbf{E}^* \times \mathbf{E}) + \frac{\mu_0}{\epsilon_r}(\mathbf{H}^* \times \mathbf{H})\right] \tag{148}$$

DOI 10.1007/978-981-4560-75-7_6-2

$$\mathbf{P}_o = \frac{1}{4\omega}\Im m\left[\frac{\epsilon_0}{\mu_r}(\mathbf{E}^* \cdot \nabla \mathbf{E}) + \frac{\mu_0}{\epsilon_r}(\mathbf{H}^* \cdot \nabla \mathbf{H})\right] \tag{149}$$

The summation of the spin and orbital angular momenta is equal to the electromagnetic momentum density

$$\mathbf{P} = \mathbf{P}_s + \mathbf{P}_0 = \frac{\mathrm{Re}(\mathbf{E}^* \times \mathbf{H})}{2c^2} \tag{150}$$

Moreover, the time-averaged helicity density, which characterizes the difference between the number of right-hand and left-hand circularly polarized photons, is defined as (Bliokh et al. 2013)

$$h = \frac{-1}{2\omega c_0}\Im m\,(\mathbf{E}^* \cdot \mathbf{H}) \tag{151}$$

From Eqs. 148 and 151, linear polarized light has zero spin angular momentum and zero helicity. The left-handed and right-handed circular polarizations have different spin angular momentum and helicity. From Eq. 149, the orbital angular momentum of a light beam depends on the field spatial distribution (not on the polarization). It can be split into an internal and an external orbital angular momenta. The internal orbital angular momentum is an origin-independent angular momentum of a light beam that can be associated with a helical or twisted wavefront. The external orbital angular momentum is the origin-dependent (center of the beam-dependent) angular momentum. The total angular momentum is conserved if light goes through a rotationally symmetric nanostructure. To rotate circularly polarized light, chiral metamaterials as building blocks have been constructed via mirror symmetry breaking (Kwon et al. 2008; Ye and He 2010; Ye et al. 2010). Consequently, if a rotationally symmetric nanoantenna constructed by chiral metamaterials converts the right-hand circularly polarized light to the left-hand circularly polarized light, both spin and orbital angular momenta of light will be changed based on the total angular momenta conservation. Additionally, all the above physical quantities including spin and orbital angular momenta and helicity density can be computed by classical computational electromagnetics.

Tunable Active Nanoantennas

Optical responses of nanoantennas involving resonance frequency, bandwidth, radiation pattern, near-field distribution, etc., can be dynamically tunable and switchable by using optical, electrical, and mechanical ways. Plasmonic effects could induce a strong optical force to reconfigure the geometry of nanoantennas (Bonakdar et al. 2012) or enhance nonlinear (Kerr) effects to modify refractive indices of antennas or loads (Chen and Alu 2010). Permittivity of liquid crystals (Berthelot et al. 2009) and graphene (Yao et al. 2013; Ren et al. 2013) can be tunable with electrostatic fields. Hence, they have been introduced to electrostatically tune optical responses of nanoantennas. Nanomechanical control of an optical antenna was also reported in literatures (Merlein et al. 2008).

Modal Analysis for Antenna Design

Modal analysis, as the preoccupation of many researchers, has been successfully adopted in the investigation of conducting enclosures such as waveguides and resonators at different frequency bands (Collin

1991; Van Bladel 1985). Recently, characteristic mode analysis gains popularity among antenna engineers as it provides a systematic approach for antenna design which is no longer experience or intuition based. Initiated by Garbacz and refined by Harrington and Mautz (Garbacz and Turpin 1971; Harrington and Mautz 1971), characteristic mode theory was popularized by the work of Cabedo-Fabres within the last decade (Cabedo-Fabres et al. 2007). On the other hand, the well-documented literature on natural mode analysis mainly focuses on bounded or semi-bounded systems (even dielectric resonator antennas are normally enclosed by impenetrable boundaries when their modal shapes are sought for). Recent effort addresses bounded and unbounded problems using a general framework based on natural mode expansion, which offers useful physical insight into antenna operation, as well as an alternative of CMA for modal design and engineering (Dai et al. 2012, 2014).

Characteristic Mode Analysis

Considering the electric field integral equation (EFIE) for a perfect electric conductor (PEC) object, the characteristic mode analysis (CMA), formulated on top of the method of moments (MoM), aims to obtain the characteristic current modes $\mathbf{J}_n$ supported on the PEC surface S by solving the generalized eigenvalue equation

$$\overline{\mathbf{Z}} \cdot \mathbf{J}_n = v_n \overline{\mathbf{R}} \cdot \mathbf{J}_n \tag{152}$$

or

$$\overline{\mathbf{X}} \cdot \mathbf{J}_n = \lambda_n \overline{\mathbf{R}} \cdot \mathbf{J}_n, \tag{153}$$

where $\overline{\mathbf{Z}} = \overline{\mathbf{R}} + i\overline{\mathbf{X}}$, and $v_n = 1 + i\lambda_n$. Meanwhile, $\overline{\mathbf{Z}}$ is the impedance matrix for a given frequency, whose entries are calculated as

$$\begin{aligned} \left(\overline{\mathbf{Z}}\right)_{mn} &= i\omega\mu \left\langle \mathbf{f}_m, \overline{\mathbf{G}}, \mathbf{f}_n \right\rangle_S \\ &= i\omega\mu \int_s \mathrm{d}\mathbf{r}\, \mathbf{f}_m(\mathbf{r}) \cdot \int_s \overline{\mathbf{G}}, (\mathbf{r}, \mathbf{r}') \cdot \mathbf{f}_n(\mathbf{r}') \mathrm{d}\mathbf{r}', \end{aligned} \tag{154}$$

where $\overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}')$ is the dyadic Green's function and $\mathbf{f}_n(\mathbf{r})$ are RWG basis functions.

Since $\overline{\mathbf{R}}$ and $\overline{\mathbf{X}}$ are dense matrices, the use of fast algorithms for full matrix-vector product is indispensable to solve for λ_n and $\mathbf{J}_n$ iteratively. Otherwise, CMA can only be used to analyze small objects. The characteristic value (eigenvalue) λ_n is important as its magnitude is proportional to the object's reactive power. When $\lambda_n = 0$, the correspondent characteristic mode $\mathbf{J}_n$ is at resonance which is efficient in receiving or radiating energy. When $\lambda_n > 0$ ($\lambda_n < 0$), mode $\mathbf{J}_n$ is storing electric (magnetic) energy. The characteristic angle can be calculated as $\phi_n = 180^\circ - \arctan(\lambda_n)$. Hence, mode $\mathbf{J}_n$ is at resonance when $\phi_n = 180^\circ$ and stores energy only when $\phi_n = 90^\circ$ or 270°.

When an incident field $\mathbf{E}_{inc}$ exists, the induced current on the PEC object can be calculated by solving

$$\overline{\mathbf{Z}} \cdot \mathbf{I}_{ind} = \mathbf{V} \tag{155}$$

where

$$(\mathbf{V})_n = -\langle \mathbf{f}_n, \mathbf{E}_{inc} \rangle_S. \tag{156}$$

DOI 10.1007/978-981-4560-75-7_6-2

Since the orthogonal property of characteristic modes holds for $\lambda_m \neq \lambda_n$

$$\mathbf{J}_m^T \cdot \overline{\mathbf{R}} \cdot \mathbf{J}_n = 0, \tag{157}$$

one can easily expand $\mathbf{I}_{ind}$ in terms of $\mathbf{J}_n$ as

$$\mathbf{I}_{ind} = \sum_n \alpha_n \mathbf{J}_n \tag{158}$$

where the modal expansion coefficients are

$$\alpha_n = \frac{1}{1 + i\lambda_n} \frac{\mathbf{J}_n^T \cdot \mathbf{V}}{\mathbf{J}_n^T \cdot \overline{\mathbf{R}} \cdot \mathbf{J}_n} \tag{159}$$

Natural Mode Expansion

Natural mode analysis, when formulated in terms of integral equations, differs from CMA in that it is closely related to the problem of seeking for $\mathbf{J}$ such that $\overline{\mathbf{Z}} \cdot \mathbf{J} = 0$. This requires one to find natural resonances of an open system or, equivalently, roots of $\det\left[\overline{\mathbf{Z}}(\omega_n)\right] = 0$ on the complex plane. On the other hand, CMA should always yield real λ_n as a function of given frequencies along the real axis, while the correspondent $\mathbf{J}_n$ can never satisfy $\overline{\mathbf{Z}} \cdot \mathbf{J}_n = 0$.

It is quite challenging to find natural modes with integral equation solvers as the complexity of calculating $\det\left[\overline{\mathbf{Z}}\right]$ is $O(N^3)$ where N is the number of unknowns. In the singularity expansion-based studies, natural modes are extracted from the measured data rather than being directly calculated (Baum et al. 1991). However, natural mode analysis can be easily carried out if it is formulated in terms of differential equations.

Bounded Case

Consider an arbitrary inhomogeneity (where $\overline{\epsilon}$ and $\overline{\mu}$ are tensors) bounded in domain V by impenetrable boundaries at surface S. The electric field $\mathbf{E}_n$ and magnetic field $\mathbf{H}_n$ of a natural mode are governed by the linear eigenvalue equations

$$\nabla \times \overline{\mu}^{-1} \cdot \nabla \times \mathbf{E}_n = \omega_n^2 \overline{\epsilon} \cdot \mathbf{E}_n \tag{160}$$

and

$$\nabla \times \overline{\epsilon}^{-1} \cdot \nabla \times \mathbf{H}_n = \omega_n^2 \overline{\mu} \cdot \mathbf{H}_n, \tag{161}$$

respectively. On the surface S, the field satisfies $\hat{n} \times \mathbf{E}_n = 0$ or $\hat{n} \times \mathbf{H}_n = 0$ for PEC or PMC boundary, respectively, where $\hat{n}$ is the unit normal vector of S.

Taking the case of $\mathbf{E}_n$ as an example, similar analysis applies to the case of $\mathbf{H}_n$. When the medium is lossless, namely, $\overline{\epsilon} = \overline{\epsilon}^\dagger$ and $\overline{\mu} = \overline{\mu}^\dagger$, or reciprocal, namely, $\overline{\epsilon} = \overline{\epsilon}^T$ and $\overline{\mu} = \overline{\mu}^T$, one can show that for $\omega_m^2 \neq \omega_n^2$,

$$\left\langle \mathbf{E}_m^\gamma, \overline{\epsilon} \cdot \mathbf{E}_n \right\rangle_V = \int_V \mathbf{E}_m^\gamma(\mathbf{r}) \cdot \overline{\epsilon} \cdot \mathbf{E}_n(\mathbf{r})\, d\mathbf{r} = 0, \tag{162}$$

DOI 10.1007/978-981-4560-75-7_6-2

where $\gamma = *$ for the lossless case and omitted for the reciprocal case. Nontrivial degenerate modes satisfying $\omega_m^2 = \omega_n^2 \neq 0$ can be orthogonalized by applying the Gram–Schmidt process.

The operator $\left(\nabla \times \overline{\mu}^{-1} \cdot \nabla \times\right)$ has a null space spanned by countably infinite irrotational eigenmodes $\mathbf{E}_q$ associated with zero eigenvalues. They are orthogonal to nontrivial modes $\mathbf{E}_n$ and are expressible as $\mathbf{E}_q = \nabla \psi_q$, where ψ_q are solutions of eigenvalue equation

$$\nabla \cdot \overline{\epsilon} \cdot \nabla \psi_q(\mathbf{r}) = k_q^2 \psi_q(\mathbf{r}) \tag{163}$$

associated with eigenvalues k_q^2. Under prescribed boundary conditions (Dirichlet or Neumann) of a bounded V, for $k_p^2 \neq k_q^2$, the orthogonality property $\left\langle \psi_p^{\gamma}, \psi_p \right\rangle_V = 0$ or $\left\langle \mathbf{E}_p^{\gamma}, \overline{\epsilon} \cdot \mathbf{E}_q \right\rangle_V = 0$ holds, where γ is defined for the lossless case and reciprocal case, accordingly.

By using the eigenbasis $\mathbf{E}_n$ including $\mathbf{E}_q$, the solution of Eq. 8 in V can be expanded as

$$\mathbf{E}(\mathbf{r}) = \sum_n^{\infty} \alpha_n \mathbf{E}_n(\mathbf{r}) \tag{164}$$

where modal expansion coefficients α_n can be obtained using the modal orthogonality as

$$\alpha_n = \frac{1}{\omega_n^2 - \omega^2} \frac{\left\langle \mathbf{E}_n^{\gamma}, i\omega \mathbf{J} \right\rangle_V}{\left\langle \mathbf{E}_n^{\gamma}, \overline{\epsilon} \cdot \mathbf{E}_n \right\rangle_V} \tag{165}$$

In low-frequency applications, $\mathbf{E}_q$ are crucial in expanding the field. If the source $\mathbf{J}$ is not divergence-free, $\mathbf{E}_q$ may need to be included in the modal expansion solution.

When the inhomogeneity is lossy, namely, $\overline{\epsilon} \neq \overline{\epsilon}^{\dagger}$ or $\overline{\mu} \neq \overline{\mu}^{\dagger}$, or nonreciprocal, namely, $\overline{\epsilon} \neq \overline{\epsilon}^{T}$ or $\overline{\mu} \neq \overline{\mu}^{T}$, Eq. 162 is no longer valid. An approach for constructing orthogonal eigenmodes is to introduce an auxiliary system to the original one as follows (Chen and Lien 1980):

$$\Delta \times \left[\overline{\mu}^{-1}\right]^{\nu} \cdot \nabla \times \mathbf{E}_n^a = \left(\omega_n^2\right)^{\gamma} \overline{\epsilon}^{\nu} \cdot \mathbf{E}_n^a \tag{166}$$

where $\nu = \dagger$ and $\nu = T$ for lossy and nonreciprocal cases, respectively, and γ is defined the same as before. Equation 166 should be constructed in the same domain V as in Eq. 160, and the auxiliary fields $\mathbf{E}_n^a$ should satisfy the same boundary conditions as in Eq. 160 but with different material media. Therefore, one can obtain the nondegenerate orthogonality property as

$$\left\langle \mathbf{E}_m^{a\gamma}, \overline{\epsilon} \cdot \mathbf{E}_n \right\rangle_V = 0. \tag{167}$$

Similar to the original problem, degenerate curl-free modes of the auxiliary system satisfy $\mathbf{E}_q^a = \nabla \psi_q^a$ where ψ_q^a are eigensolutions of

$$\nabla \cdot \overline{\epsilon} \cdot \nabla \psi_q^a(\mathbf{r}) = \left(k_q^2\right)^{\gamma} \psi_q^a(\mathbf{r}) \tag{168}$$

Again, for $k_p^2 \neq k_q^2$, one has $\left\langle \mathbf{E}_p^{a\gamma}, \overline{\epsilon} \cdot \mathbf{E}_q \right\rangle_V = 0$. Therefore, the field excited by any current $\mathbf{J}$ can be expanded in terms of the complete set (assumed to be) of eigenbasis $\mathbf{E}_n$ where α_n are in a simple form of

DOI 10.1007/978-981-4560-75-7_6-2

$$\alpha_n = \frac{1}{\omega_n^2 - \omega^2} \frac{\left\langle \mathbf{E}_n^{a\gamma}, i\omega\mathbf{J} \right\rangle_V}{\left\langle \mathbf{E}_n^{a\gamma}, \overline{\epsilon} \cdot \mathbf{E}_n \right\rangle_V}. \tag{169}$$

Unbounded Case

A straightforward extension of natural mode expansion (NME) to unbounded problems is to let S tend to infinity. A small loss has to be introduced to the medium in V, which is equivalent to requiring the wave to be outgoing at infinity. The small loss also guarantees the uniqueness of the field solution due to a given source (Chew 1990).

Based on the modal behavior, natural modes can be approximately classified into trapped modes and exterior modes. The former resonate due to the inhomogeneity with most energy confined, while the latter resonate between the inhomogeneity and the far boundaries. Note that the energy confinement for a trapped mode in 3D problems is never perfect, unless the inhomogeneity is a perfectly enclosed cavity or a dielectric with an infinitely high refractive index. In certain geometries, some trapped modes are coupled to external radiation, which are also regarded as leaky modes.

As S approaches infinity, the spectra of trapped modes slightly broaden while the modal shapes remain almost unchanged. On the other hand, exterior modes are not "immune" to external variations. When the boundaries expand, the distribution of exterior modes on the complex ω plane becomes increasingly dense, which eventually yields a continuum. Thus, one may intuitively write the modal expansion solution of unbounded fields in the form of

$$\mathbf{E}(\mathbf{r}) = \sum_{n=1}^{N} \alpha_n \mathbf{E}_n(\mathbf{r}) + \int \mathrm{d}\omega' \alpha(\omega') \mathbf{E}(\omega'\mathbf{r}). \tag{170}$$

The discrete summation in Eq. 170 corresponds to trapped modes, while the integral corresponds to continuous exterior modes where $\alpha(\omega')$ should include the density of states.

In numerical studies, one can replace PEC/PMC boundaries with PMLs (Berenger 1994; Chew and Weedon 1994) to emulate unbounded media. When PMLs are implemented, the eigenspectra become discrete from which trapped modes can be easily distinguished from exterior ones since the quality factors

$$Q = \left| \frac{\Re e[\omega_n]}{2\Im m[\omega_n]} \right| \tag{171}$$

of the former are obviously larger. Moreover, exterior modes in this case include resonances inside PMLs which have large $\Im m[\omega_n]$. Using PMLs enables one to correctly capture the physics of trapped modes which are important in characterizing the field behavior of an excited system. Therefore, the model order can be greatly reduced through NME using only a few important modes.

The governing Eqs. 160 and 161 can be discretized with conventional differential equation solvers, such as FDM and FEM. The resultant generalized eigenvalue equations only have sparse matrices and therefore can be easily solved with iterative eigensolvers, such as Lanczos and Arnoldi methods (Lehoucq and Sorensen 1996). Shift-invert techniques can be used to calculate interior spectrum of the system, from which one may extract trapped modes that are physically important. For example, the −1st-, 0th-, and +1st-order modes of a composite right-/left-handed (CRLH) waveguide slot are found as shown in Fig. 14a–c. Consider an open-ended CRLH waveguide slot antenna (Fig. 15a) (Dong and Itoh 2010), where the substrate has a thickness of $h = 1.27$ mm and a relative permittivity of Eq. 44. Parameters in Fig. 15a are set as $\omega_1 = 0.3$ mm, $\omega_2 = 0.45$ mm, $\omega_3 = 9.6$ mm, and $\omega_s = 3.9$ mm. Figure 15b shows 50 natural frequencies searched around 11 GHz. One can easily identify five trapped modes as they have

DOI 10.1007/978-981-4560-75-7_6-2

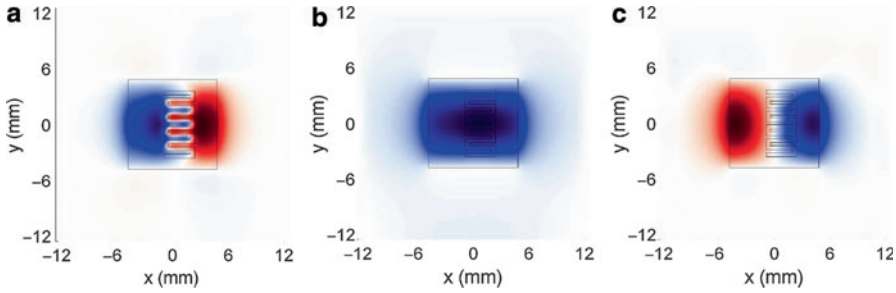

Fig. 14 Simulated modal shapes $\Re e[E_z]$ on an xy plane for several trapped modes: (**a**) −1st-order mode. (**b**) 0th-order mode. (**c**) +1st-order mode

small $\Im m[f_n]$, among which I, II, and III are −1st-, 0th-, and +1st-order resonances, respectively. The rest with large $\Im m[f_n]$ are exterior modes, which are well separated from trapped ones due to the existence of PMLs.

When the antenna is excited by a z-polarized current sheet operating at 5.9 GHz, the excited field $\Im m[E_z^{\mathrm{dir}}]$ can be approximately expanded using five trapped modes as good agreement is observed between Fig. 16a, b. More quantitatively, comparisons of the directly calculated field and the expanded fields with different numbers of trapped modes along $y = 0.36$ mm are given in Fig. 16c. The relative error is shown in Fig. 16d with respect to the number of modes used to expand the field. The small error near the source (Fig. 16c) may be reduced by taking the irrotational modes into account as the source is not divergence-free. A reduced modal approximation of the excited field in a properly operating antenna is achieved since only a few trapped modes dominate the expanded solution. Provided that trapped modes can be solved for by the shift-invert technique in a preprocessing stage, NME is well suited for a fast wideband field

DOI 10.1007/978-981-4560-75-7_6-2

approximation and for problems with different source configurations since the field reconstruction with a few modes consumes negligible CPU time.

Incorporation of PMLs in natural mode analysis leads to linear eigenvalue problems since PMLs behave as a wideband absorber for electromagnetic waves, whose working frequency can always be predetermined. This greatly simplifies the calculation of natural modes and renders NME a much simpler expression than that in Baum et al. (1991). Besides indicating modal radiation ability by modal quality factors, natural mode analysis also provides guidance on source placement for the excitation of desired modes. Furthermore, NME offers more flexibility in modeling complicated antennas than CMA where dielectric parts are included.

Equivalence Principle Algorithm for Antennas

The lack of analytical methods in terms of closed-form formulas or approximate asymptotic expressions has been a real motivation for antenna engineers to invoke computational electromagnetic methods to analyze and design antennas. Although the currently available numerical methods can address many problems in antenna structures modeling, there are other issues mostly related to multi-scale problems which cannot be properly addressed by these methods (Li and Chew 2007).

Multi-scale Problems

In general, traditional modeling techniques mainly focus on one scale (e.g., macroscopic or microscopic scales) and the physics change significantly over these scales. For example, when the macroscopic scale (or macroscale) is used, only the effect of the larger scales (sizes) is of interest and the effect of the smaller scales is modeled by some constitutive relations (Weinan 2012). It is known that macroscopic scale is efficient and microscopic scale is accurate. Hence, simultaneous incorporation of models at different scales helps to exploit the advantages offered by all of those scales. This so-called multi-scale concept for the electromagnetic modeling has been the research focus in the past two decades. A typical multi-scale

DOI 10.1007/978-981-4560-75-7_6-2

electromagnetic problem can be raised because of the nature of the electromagnetic fields. In fact, electromagnetic physics can be divided into: circuit physics, wave physics, and ray physics. From a numerical point of view, to model a multi-scale problem where both low-frequency circuit physics and high-frequency wave physics coexist, disparate meshing is not avoidable. This leads to a large number of unknowns reducing the convergence rate of the iterative solvers. As an example, consider a small patch antenna mounted on roof of a car. The antenna dimensions are in centimeters while the dimensions of the car are in meters. These are examples of multi-scale problems. To address these problems, a few ideas have been suggested where the domain decomposition method (DDM), the most popular one, will be discussed next.

Domain Decomposition Method

The main idea of domain decomposition method relies on dividing a larger solution domain into smaller nonoverlapping subdomains. Each of these individual subdomains can be solved independently while the interaction between adjacent subdomains is included through interface boundary conditions to guarantee the unique solution. In fact, the solutions of each subdomain are stitched together using some transmission condition (e.g., Robin-type transmission condition) and iterative algorithm to derive the solution of the large problem (Lu et al. 2008). In this manner, the solution of each subdomain is independent of the other subdomains. Hence, the meshing strategy can be optimally selected for each subdomain. The freedom to select the mesh strategy helps to facilitate the parallelization of the solution and its reuse and also to improve the condition number of the matrix system. These advantages have encouraged the combination of DDM with other electromagnetic solvers such as finite-element method and finite-difference frequency-domain method. Then, the domain decomposition method was used for solving three-dimensional large finite periodic problems such as photonic or electromagnetic bandgap structures and frequency-selective surfaces. In addition, relatively large dielectric aperture array, patch antenna array, and slotted waveguide array were successfully analyzed using DDM. To extend the application of DDM for integral equation-based solvers, the equivalence principle algorithm (EPA) was introduced by Chew (Chew and Lu 1993; Lu and Chew 1995).

Equivalence Principle Algorithm

Based on EPA, the entire solution domain is decomposed into many subdomains by defining appropriate closed surfaces which are called equivalence surfaces. The subdomains are enclosed by the equivalence surfaces and communicate mutually only through the closed surfaces. Consider a simple scenario where there are only two objects, namely, Object1 and Object2, and they are enclosed by two separate surfaces, namely, S_1 and S_2, respectively (Fig. 17). The entire EPA procedure for this case can be cast into four steps:

1. Outside-in propagation
   Initially, the collective effect of every other exterior sources is modeled by equivalent magnetic and/or electric currents on the equivalence surface S_1. These equivalent sources generate the original fields inside the S_1 and zero field outside. These equivalent currents, called incident currents are denoted as $\mathbf{J}_1^{inc}$ and $\mathbf{M}_1^{inc}$.
2. Solving for the induced current on enclosed object
   Having the incident field on Object1 produced by the equivalence currents and by invoking a solution method (e.g., MoM) the induced currents on Object1 denoted as $\mathbf{J}_1$ and $\mathbf{M}_1$, can be found.
3. Inside-out propagation
   Having found the currents on Object1, the scattered field distribution can be readily calculated anywhere inside or on the surface of S_1. Then, the equivalence principle can be used to calculate the

DOI 10.1007/978-981-4560-75-7_6-2

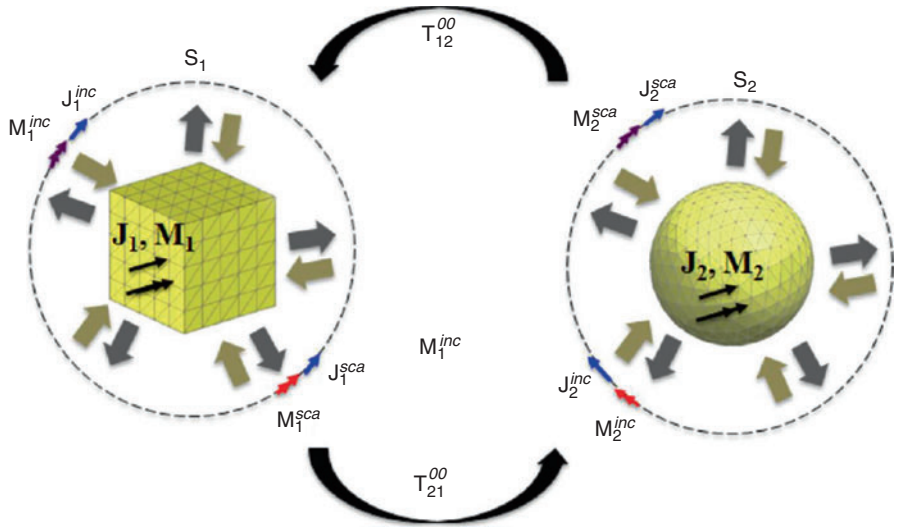

Fig. 17 A simple two-object scenario to explain the equivalence principle algorithm

equivalent currents on the surface (by defining the region of interest to be outside of S_1). These equivalent currents, called scattered currents are denoted as $\mathbf{J}_1^{sca}$ and $\mathbf{M}_1^{sca}$.

A similar procedure is applied to the other defined equivalence surfaces and the enclosed objects in a parallel manner. However, the procedure will not capture the whole physics until the interaction between the surfaces is also considered.

4. Interaction between equivalence surfaces

The interaction between S_1 and other equivalence surfaces (i.e., S_2 in this case) is modeled by introduction of an operator called the translation operator. Its main function is to transfer the effect of the equivalent currents from one equivalence surface to another equivalence surface. In contrast with domain decomposition methods for differential equation-based solvers, the subdomains do not have to touch each other (i.e., white space between the subdomains is allowed).

The entire EPA procedure for the two-object two-equivalence surface scenario can be described through the following equations:

$$\begin{bmatrix} \mathbf{J}_m^{sca} \\ \mathbf{M}_m^{sca} \end{bmatrix} = \begin{bmatrix} -\hat{n} \times \mathcal{K}_H^s \\ -\hat{n} \times \mathcal{L}_E^s \end{bmatrix} \cdot \left[\mathcal{L}_{\text{solver}}^{-1}\right] \cdot \begin{bmatrix} -\mathcal{L}_E^s & -\mathcal{K}_H^s \end{bmatrix} \cdot \begin{bmatrix} \mathbf{J}_m^{inc} \\ \mathbf{M}_m^{inc} \end{bmatrix} = S_{mm} \cdot \begin{bmatrix} \mathbf{J}_m^{inc} \\ \mathbf{M}_m^{inc} \end{bmatrix} \tag{172}$$

$$\begin{bmatrix} \mathbf{J}_m^{sca} \\ \mathbf{M}_m^{sca} \end{bmatrix} = \begin{bmatrix} -\hat{n} \times \mathcal{K}_H^s & -\hat{n} \times \mathcal{L}_H^s \\ -\hat{n} \times \mathcal{L}_E^s & -\hat{n} \times \mathcal{K}_E^s \end{bmatrix} \cdot \begin{bmatrix} \mathbf{J}_n^{sca} \\ \mathbf{M}_n^{sca} \end{bmatrix} = T_{mn}^{oo} \cdot \begin{bmatrix} \mathbf{J}_n^{sca} \\ \mathbf{M}_n^{sca} \end{bmatrix} \tag{173}$$

where $\mathcal{L}_E$, $\mathcal{K}_E$, $\mathcal{L}_H$, and $\mathcal{K}_H$ are integral operators and they are well defined in the literature (Li and Chew 2007). Also $\mathcal{L}_{\text{solver}}^{-1}$ represents the current solver part. Moreover, S_{mm} represents scattering operator for equivalence surface S_m and T_{mn}^{oo} shows the translation operator between surface m and n where $m, n = \{1, 2\}$. Combination of these two equations results in a system of equations as

$$\begin{bmatrix} \mathbf{J}_1^{sca} \\ \mathbf{M}_1^{sca} \end{bmatrix} - S_{11} \cdot T_{12}^{oo} \cdot \begin{bmatrix} \mathbf{J}_2^{sca} \\ \mathbf{M}_2^{sca} \end{bmatrix} = S_{11} \cdot \begin{bmatrix} \mathbf{J}_1^{inc} \\ \mathbf{M}_1^{inc} \end{bmatrix} \tag{174}$$

DOI 10.1007/978-981-4560-75-7_6-2

$$-S_{22}\cdot T_{21}^{oo}\cdot\begin{bmatrix}\mathbf{J}_1^{sca}\\ \mathbf{M}_1^{sca}\end{bmatrix}+\begin{bmatrix}\mathbf{J}_2^{sca}\\ \mathbf{M}_2^{sca}\end{bmatrix}=S_{22}\cdot\begin{bmatrix}\mathbf{J}_2^{inc}\\ \mathbf{M}_2^{inc}\end{bmatrix} \tag{175}$$

By solving this system of equations, the unknown scattered equivalent currents on equivalence surfaces will be calculated. Similar equations can be derived for more objects with more equivalence surfaces.

EPA for Connected Regions

The EPA procedure works well for objects which are not intercepted by the equivalence surface. However, in the antenna applications and many other electromagnetic problems, unconnected (isolated) region models are seldom used and one region may be connected with some other regions through wires, lumped elements, switches, and ground plane. In this case, the original continuous currents will be cut by the equivalence surface which leads into electric charge accumulation on both sides at the connection. This charge accumulation and current discontinuity result in a singular field generation which will induce a singular equivalence current on the intercepting equivalence surfaces and affects the accuracy of the results. Moreover, having objects very close to the equivalence surface requires computationally costly singularity subtraction and near-field treatments. In the literature, three methods, namely, singularity matching approach, fictitious junction basis method, and the tap basis scheme have been suggested to retain the current continuity and avoid the singularity. Tap basis scheme has been shown to model the continuous current accurately and no singular integral will be involved (Li and Chew 2007, 2008).

Tap Basis Scheme

For scenarios where the enclosed objects by an equivalence surface are connected to other objects enclosed by other equivalence surfaces, a tap basis scheme has been introduced in (Li and Chew 2007, 2008) to keep the current flowing smoothly in and out of the equivalence surfaces. Assume a metallic strip which is divided into two sections by defining two-equivalence surfaces (Fig. 18a). The strip is then divided into three regions by defining a transition region or tap basis region (Fig. 18b). To account for the tap basis, Eqs. 174 and 175 should be modified as

$$\begin{bmatrix}\mathbf{J}_1^{sca}\\ \mathbf{M}_1^{sca}\\ \mathbf{t}_{t1}\end{bmatrix}-S_{11}\cdot\begin{bmatrix}T_{12}^{oo}\cdot\begin{bmatrix}\mathbf{J}_2^{sca}\\ \mathbf{M}_2^{sca}\end{bmatrix}\\ -\mathcal{L}_{tt}^{-1}\cdot(\mathbf{t}_{t1}+\mathbf{t}_{t2})\end{bmatrix}=S_{11}\cdot\begin{bmatrix}\mathbf{J}_1^{inc}\\ \mathbf{M}_1^{inc}\\ -\mathcal{L}_{tt}\cdot\mathbf{E}_t^{i}\end{bmatrix} \tag{176}$$

$$\begin{bmatrix}\mathbf{J}_2^{sca}\\ \mathbf{M}_2^{sca}\\ \mathbf{t}_{t2}\end{bmatrix}-S_{22}\cdot\begin{bmatrix}T_{21}^{oo}\cdot\begin{bmatrix}\mathbf{J}_1^{sca}\\ \mathbf{M}_1^{sca}\end{bmatrix}\\ -\mathcal{L}_{tt}^{-1}\cdot(\mathbf{t}_{t1}+\mathbf{t}_{t2})\end{bmatrix}=S_{22}\cdot\begin{bmatrix}\mathbf{J}_2^{inc}\\ \mathbf{M}_2^{inc}\\ -\mathcal{L}_{tt}\cdot\mathbf{E}_t^{i}\end{bmatrix} \tag{177}$$

where $\mathcal{L}_{tt}^{-1}$ and $\mathbf{E}_t^i$ are the current solver operator and the incident field on the tap basis part, respectively. Moreover, $\mathbf{t}_{ti}=\mathcal{L}_{ti}\cdot\mathbf{J}_i$ represents the induced field by current on $i-th$ metallic object (i.e., $\mathbf{J}_i$) on the tap region. Expressions Eqs. 176 and 177 constitute six equations for six sets of unknowns [$\mathbf{J}_1^{sca}$, $\mathbf{M}_1^{sca}$, $\mathbf{t}_{t1}$, $\mathbf{J}_2^{sca}$, $\mathbf{M}_2^{sca}$, $\mathbf{t}_{t2}$]. The equations can be set up for the N object case. If no tap basis is involved with the object, the bottom rows of the equations disappear, and one reverts back to the ordinary EPA (Eqs. 174 and 175).

Antenna Modeling Using EPA in Literature

In the past two decades, the equivalence principle algorithm has been successfully used to solve multi-scale electromagnetic problems including antenna problems. Some of the reported works in the literature

DOI 10.1007/978-981-4560-75-7_6-2

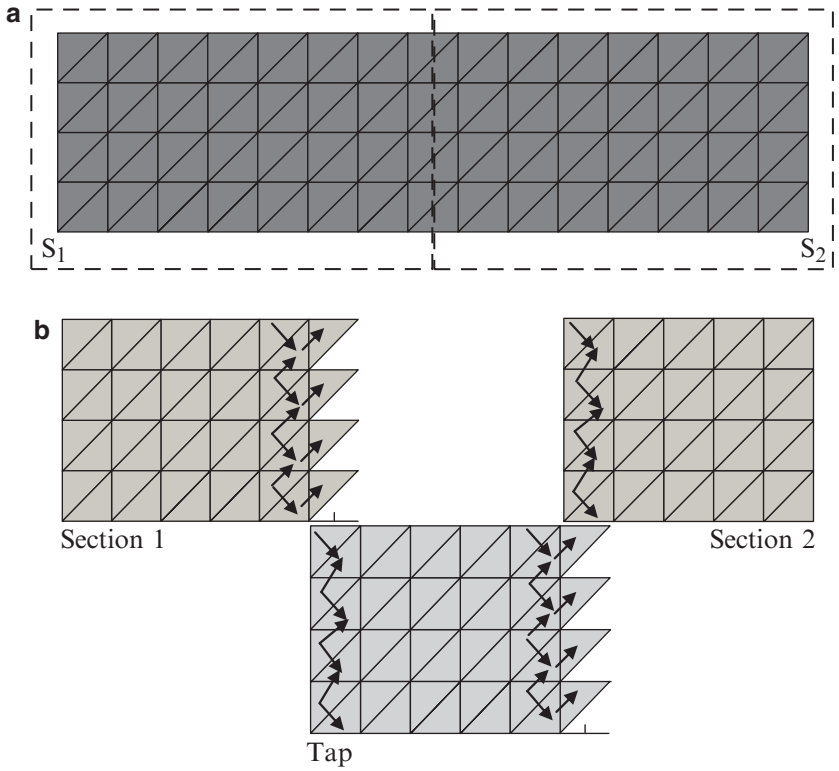

Fig. 18 Metallic strip. (**a**) Divided into two sections by two-equivalence surfaces, (**b**) introduction of tap basis to keep the current continuity

for analyzing antennas using EPA are summarized in Tables 1 and 2. The applications of EPA to analyze array antennas are listed in Table 1. Array of monopoles, U-shaped slot microstrips, and Yagi antennas have been successfully modeled and solved using EPA. In Table 2, applications of EPA for some other special cases are listed where EPA has been applied for analyzing an antenna mounted on the roof of a car, reconfigurable pixelled antennas, and a bow-tie antenna. Overall, the application of EPA helped significantly reduce the computational burden and accelerate the calculations.

Recently, several ideas have been suggested to improve the accuracy and convergence rate of EPA. Most of these works try to address problems associated with the equivalence surfaces. Application of multilevel fast multipole algorithm to calculate the interactions between the equivalence surfaces significantly accelerated the whole EPA procedure. Also, in Shao et al. (2014), utilization of grid-robust higher-order vector basis (GRHOVB) instead of curvilinear RWG function for the equivalence surfaces has been proposed to improve the accuracy of EAP. In Shao et al. (2012), instead of solving for both electric and magnetic currents on the equivalence surfaces, the concept of generalized impedance boundary condition (GIBC) has been utilized to define a relationship between these currents and reduce the number of unknowns. Despite all of these endeavors, EPA is still an open area for further research. The goal of the future works is to improve the accuracy and the speed of convergence as well as modifying EPA for newly emerging applications such as solar cells, implantable devices, and nanoscale structures.

High-Frequency Techniques for Antennas

For antennas with a reflector or a platform that is large compared to the wavelength, high-frequency techniques can be used to simulate electromagnetic scattered fields very efficiently. They are important in

DOI 10.1007/978-981-4560-75-7_6-2

Table 1 Application of EPA to model array antennas (Li and Chew 2007; Shao et al. 2011, 2012, 2013)

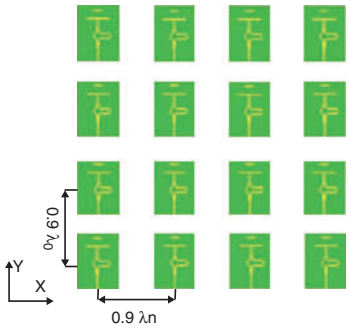
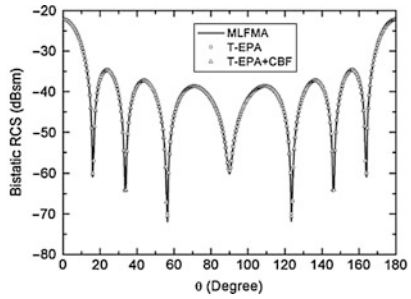
	Array of Yagi antennas	Bistatic RCS
	




three aspects (Samii and Israel 1980; Yaghjian 1984; Chou et al. 2005). First, high-frequency methods are much faster than full-wave methods on calculating electromagnetic scattered fields from electrically large antennas. Second, high-frequency methods could provide physical insights for the understanding of the radiation mechanisms of antennas. Typical high-frequency insights lead to wave physical critical points: the shadow and reflection boundaries, the caustics from surfaces of antennas, etc. Third, for complicated antenna structures, high-frequency methods have potential to be combined with the full-wave method well to solve radiation problems. Specifically, wave fields in electrically large parts exhibit the high-frequency ray physics phenomenon. While in electrically small and moderate parts, wave fields have circuit and wave physics behaviors, respectively. Thus, once the hybrid solvers in terms of high-frequency methods and full-wave solvers are developed, the efficiency of the electromagnetic wave simulation could be greatly enhanced.

DOI 10.1007/978-981-4560-75-7_6-2

Table 2 Application of EPA to solve antenna problems (Li and Chew 2008; Fallahpour et al. 2014; Shao et al. 2014)

Antenna type	Desired output
Antenna mounted on roof of a car	Radiation pattern
Reconfigurable pixelled antenna	RCS
Bow tie antenna on PEC plate	Radiation pattern

When the product of the wave frequency k and the diameter of the antenna a becomes tens to thousands, the electromagnetic waves assume the high-frequency localization phenomenon. In this sense, the high-frequency scattered fields have the high-frequency wave physics phenomenon and ray physics. Thus, high-frequency wave fields propagate like rays. With the aid of the high-frequency ray physics theory, various high-frequency methods were developed in the last century. For instance, for calculating the reflected and transmitted wave fields, the high-frequency methods contain the geometric optics (GO) method (Ling et al. 1989) and the physical optics (PO) method (Macdonald 1913). While for computing the diffracted wave fields in Fig. 19a, these methods correspond to the geometry theory of

DOI 10.1007/978-981-4560-75-7_6-2

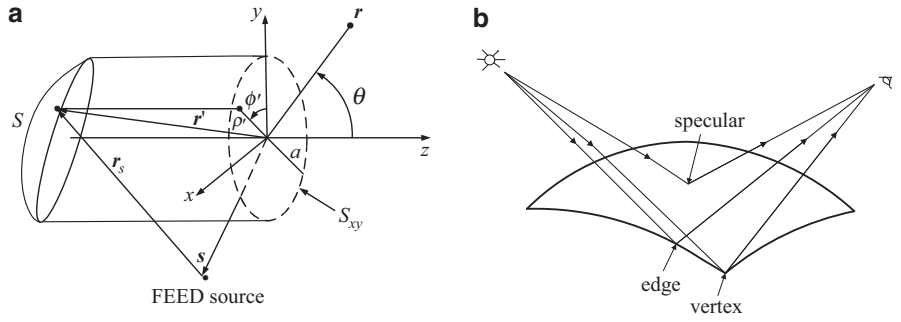


Fig. 19 (**a**) A shaped reflector antenna system. (**b**) High-frequency ray fields from the scatterer, including the reflected fields from the specular points and the diffracted fields from the edge and vertex

diffraction (GTD) (Keller 1962; Hansen 1981), uniform theory of diffraction (UTD) (Kouyoumjian and Pathak 1974), uniform asymptotic diffraction (UAT) (Lee and Deschamps 1976), physical theory of diffraction (PTD) (Ufimtsev 2005), and incremental length diffraction coefficients (ILDC) (Yaghjian et al. 1996). In the following, these high-frequency methods are introduced in an elegant way. Furthermore, fast solvers for the high-frequency scattered fields are addressed, including the high-frequency asymptotic method (HFA) (Conde et al. 2001; Carluccio et al. 2010) and the numerical steepest descent path method (NSDP) (Wu et al. 2012a, b, 2013a, b, c, 2014).

Radiation from Antennas

For the reflector antenna system with a location of the feed as shown in Fig. 19a, the electric scattered far fields could be expressed as

$$\mathbf{E}^{(s)}(\mathbf{r}) \approx \frac{ike^{ikr}}{4\pi r}\sqrt{\frac{\mu}{\epsilon}}\left(\bar{\mathbf{I}} - \hat{r}\hat{r}\right) \cdot \int_S dr' e^{-ik\hat{r}\cdot\mathbf{r}'}\mathbf{J}(\mathbf{r}') \tag{178}$$

Here, $\mathbf{J}(\mathbf{r}')$ is the induced electric current on the surface of the antenna, S, and $\mathbf{r}$ and $\mathbf{r}'$ denote the observation and integration source points. The projection aperture of S in the xy plane is the circular region, S_{xy}, with radius a as shown in Fig. 19a. Then, the radiation integrals $\mathbf{F}(\mathbf{r})$ could be obtained from Eq. 178, with the formulation

$$\mathbf{F}(\mathbf{r}) = \int_S d\mathbf{r}' e^{-ik\hat{r}\cdot\mathbf{r}'}\mathbf{J}(\mathbf{r}') = \int_0^a \int_0^{2\pi} e^{-ik\hat{r}\cdot\mathbf{r}'}\mathbf{J}(\mathbf{r}')\rho' T(\rho', \phi')d\rho' d\phi' \tag{179}$$

Here, $T(\rho', \phi')$ is the Jacobian transformation function for the antenna surface between (x, y, z) and (ρ, ϕ, z) coordinate systems.

The vector surface integrals $\mathbf{F}(\mathbf{r})$ in Eq. 179 are called the radiation integrals. Furthermore, the surface integral contains the phase information of the dyadic Green's function in the far-field region, the induced electric current, and the integration of the curvature from S.

High-Frequency Techniques

Geometric Optics Method

The ray path between any two points $\mathbf{p}_1$ and $\mathbf{p}_2$ in three-dimensional space follows Fermat's principle, that is,

DOI 10.1007/978-981-4560-75-7_6-2

$$\delta \int_{\mathbf{p}_1}^{\mathbf{p}_2} n(s)\, ds = 0 \tag{180}$$

Here, $n(s)$ is the refraction index of the medium and δ is the variation operator in variational calculus. Equation 180 expresses that the ray follows the path that minimizes the optical distances between $\mathbf{p}_1$ and $\mathbf{p}_2$. On invoking Fermat's principle in Eq. 180, the reflected rays could be determined from the incident field. This method is called the geometrical optics (GO) method. Furthermore, based on the ray tube theory and conservation of energy flux for light intensity, the reflected field $\mathbf{E}^{(r)}(\mathbf{r})$ at the distance s from the reflection point $\mathbf{p}_r$ of the scatterer could be expressed as

$$\mathbf{E}^{(r)}(\mathbf{r}) = \mathbf{E}^{(i)}(\mathbf{p}_r) \cdot \overline{\mathbf{R}} \sqrt{\frac{\rho_1(\mathbf{p}_r)\rho_2(\mathbf{p}_r)}{(\rho_1(\mathbf{p}_r)+s)\ (\rho_2(\mathbf{p}_r)+s)}} e^{iks} \tag{181}$$

Here, $\overline{\mathbf{R}}$ is the dyadic reflection coefficient, $\rho_1(\mathbf{p}_r)$ and $\rho_2(\mathbf{p}_r)$ are the principle radii of S at the point $\mathbf{p}_r$ of reflection, and s is the distance from $\mathbf{p}_r$ to $\mathbf{r}$ along the direction of reflected field. For the antenna with penetrable material, the transmitted wave fields also exist. The typical GO method for calculating the wave fields from the complicated cavity structure is the shooting and bouncing ray method (SBR) (Ling et al. 1989). Actually, by adopting the SBR method, multiple scattering wave fields are captured and calculated efficiently.

The GO method for calculating the scattered field has close connection with the scattered field in Eq. 178. On invoking the high-frequency asymptotic method for Eq. 178 in section "Basic Circuit Laws from Maxwell's Equations" in the following, one can obtain that the leading term in Eq. 178 corresponds to the GO ray field at the specular reflection point.

Geometric Theory of Diffraction

When the rays come to the wedges, the diffracted wave fields and the reflection and shadow boundaries come out. In this situation, for the case that the observation point lies in the transition and deep shadow regions, the GO method fails to capture the scattered wave fields very well. To remedy this aforementioned failure, Sommerfeld addressed the early high-frequency scattering problem from the perfect conducting half-plane (Sommerfeld 1896). The scattered field was expressed in terms of the Fresnel integral. By performing the asymptotic expansion of the Fresnel integral, the scattered far field could be easily evaluated. In the high-frequency diffracted wave current like the fringe current, the shadow and reflection boundaries were clearly demonstrated. Moreover, the regions for the observation point lying around the reflection and shadow boundaries are called transition regions.

The calculation of the diffracted ray field from the perfectly conducting curved wedge was developed by Keller (1962). This method was called the geometry theory of diffraction (GTD). The diffracted wave fields from the point $\mathbf{p}_d$ along the curved wedge has the similar formulation as (Eq. 181):

$$\mathbf{E}^{(d)}(\mathbf{r}) = \mathbf{E}^{(i)}(\mathbf{p}_d) \cdot \overline{\mathbf{D}} \sqrt{\frac{\rho_d(\mathbf{p}_d)}{s(\rho_d(\mathbf{p}_d)+s)}} e^{iks} \tag{182}$$

Here, $\overline{\mathbf{D}}$ is the dyadic diffraction coefficient in (Keller 1962), $\rho_d(\mathbf{p}_d)$ is the principle radius of the curved wedge at the point $\mathbf{p}_d$ of reflection, and s is the distance from $\mathbf{p}_d$ to $\mathbf{r}$ along the direction of the reflected field.

DOI 10.1007/978-981-4560-75-7_6-2

Furthermore, the diffraction coefficients $\overline{\mathbf{D}}$ could be obtained from the asymptotic expansion of the radiation integrals of the Sommerfeld half-plane diffraction problems. Thus, the fields from the GTD method contain both reflected and transmitted wave fields from GO method and the diffracted wave fields. Therefore, compared to the GO method, the GTD method provides a relatively mature way for calculating the high-frequency wave fields.

Again, on invoking the high-frequency asymptotic method in section "Basic Circuit Laws from Maxwell's Equations" for Eq. 178, the higher-order terms correspond to the diffracted ray fields. Moreover, these obtained diffracted ray fields agree well with the results generated from the GTD method. However, at the transition regions, these GTD diffraction coefficients become infinite; thus, the GTD diffracted wave fields become singular. Therefore, when the observation point lies around the transition regions, the GTD method breaks down.

Uniform Theory of Diffraction

To remedy the failure of the GTD method at the transition region, people developed the efficient uniform theory of diffraction (UTD) (Kouyoumjian and Pathak 1974) and uniform asymptotic diffraction (UAT) methods (Lee and Deschamps 1976). With the high-frequency wave physics aspect, on invoking the asymptotic technique, the radiation integrals for the diffracted wave fields from the wedge could be expressed as the superposition of contributions from high-frequency critical points. This superposition of critical-point contributions could also be regarded as the diffracted rays with the ray physics aspect. However, when the observation points lie in transition regions, these critical points will coalesce. In this situation, the asymptotic approximation of the radiation integrals fails to approximate these integrals well.

To account for the coupling of high-frequency critical points, the uniform asymptotic approximation of radiation integral could be adopted to remedy the breakdown of the GTD method at transitions. This method was called the UTD method, which provides the UTD diffraction coefficients in terms of the UTD transition function. The UTD transition function with the Fresnel function involved is used to compensate the GTD breakdown and makes the wave fields continuous around the transition regions. Meanwhile, with the observation point far away from the transition regions, the wave field results from the UTD and GTD methods could agree well with each other. Once Eq. 178 is derived in the uniform asymptotic way, higher accuracy for the diffracted wave fields will result in near-transition regions. The UTD method follows the asymptotic of the radiation integral. Thus, the breakdown problem of the GTD method around the transition regions could be well solved by the UTD method.

Physical Optics Method

The physical optics (PO) approximation serves as an efficient approach for analyzing the scattered electromagnetic fields. Early in 1913, Macdonald introduced the PO approximation concept by approximating the induced current on the surface of the consider scatterer (Macdonald 1913). The surface PO-induced current is approximated by doing the local tangent plane approximation, that is, the integration small surface patch along the electrically large object is assumed to be locally flat and smooth under the external high-frequency condition (Ufimtsev 2008). In this sense, for the incident high-frequency electromagnetic waves on the electrically large real-world objects, the PO approximation has revealed itself as an efficient way to calculate the scattered field (Lee and Mittra 1983). However, the PO current is not correct around the shadow boundary (Ufimtsev 2005), which leads to the fact that the physical optics method does not satisfy the reciprocity theorem.

With *ka* going from tens to thousands, by making use of the local tangential plane approximation for Eq. 179, the induced current in the lit region of considered scatterer could be approximated as

DOI 10.1007/978-981-4560-75-7_6-2

$$\mathbf{J}_{PO}(\mathbf{r}) = 2\hat{n}(\mathbf{r}) \times \mathbf{H}^{(i)}(\mathbf{r}) \tag{183}$$

Equation 183 is known as the PO current. Here, $\hat{n}(\mathbf{r})$ is the outward unit normal to the surface and $\mathbf{H}^{(i)}(\mathbf{r})$ is the incident field on the reflector antenna from the feed source. Here, $\mathbf{H}^{(i)}(\mathbf{r})$ in Eq. 183 is directly incident field generated by the feed to location $\mathbf{r}$ with the formulation

$$\mathbf{H}^{(i)}(\mathbf{r}) \simeq C\frac{e^{ikr_s}}{r_s}\mathbf{g}(\theta, \varphi) \tag{184}$$

with C as a known complex constant and $\mathbf{g}(\theta, \varphi)$ as the vector radiation function from the feed source, and it is assumed to be known.

After substituting $\mathbf{J}_{PO}$ in Eq. 183 into $\mathbf{J}$ in Eq. 178, one can obtain the PO scattered field from the reflector antenna. It could be represented by three radiation surface integrals. More specifically, the phase function in Eq. 178 contains the information from the dyadic Green's function, the shape function for the surface of the reflector antenna, and the incident magnetic field from the feed source. Owing to the highly oscillatory nature of the radiation integrand in Eq. 179, the direct numerical scheme for evaluating the integral makes the computational workload increase vastly when ka is large. The problem is more serious when there are many the observation points. Therefore, one needs to seek the efficient techniques to evaluate these PO integrals (Burkholder and Lee 2005).

Physical Theory of Diffraction

To remedy the limitation of the PO current, Ufimtsev introduced the edge wave current to correct the PO current, known as the physical theory of diffraction (PTD) method (Ufimtsev 2005). The PTD current, denoted as $\mathbf{J}_{PTD}$, takes the expression

$$\mathbf{J}_{PTD}(\mathbf{r}) = \mathbf{J}_{PO}(\mathbf{r}) + \mathbf{J}_{U}(\mathbf{r}) \tag{185}$$

Here, $\mathbf{J}_U(\mathbf{r})$ is the edge wave current which is used to correct the limited accuracy of $\mathbf{J}_{PO}(\mathbf{r})$ around the shadow boundary and in the shadow regions. Actually, $\mathbf{J}_U(\mathbf{r})$ could be obtained from the scattered wave solution of the canonical perfect conducting wedge scatterer (Ufimtsev 2005). After substituting $\mathbf{J}_{PTD}(\mathbf{r})$ in Eq. 185 into Eq. 178, one can obtain the scattered fields from the PTD method. The resultant scattered fields contain the PO scattered fields and the edge diffracted wave fields, which could also be regarded as the radiation integrals with highly oscillatory integrands. Compared to the GTD and the UTD method, the PTD method gives more accurate results than the GTD and the UTD methods via the integral formulations. Meanwhile, it is time consuming to adopt the PTD method by the direct adaptive numerical scheme for these radiation integrals.

Incremental Length Diffraction Coefficient Technique

The incremental length diffraction technique introduced by Shore and Yaghjian (Hansen and Shore 1998; Yaghjian et al. 1996) provides an efficient way to calculate the high-frequency diffracted wave fields from the perfect conducting scatterer. The nonuniform (NU) diffracted wave field could be obtained by the integration of the product of the Green's function with the NU current around the surface of the scatterer, S. Furthermore, the NU-diffracted wave field could be captured by simplifying the integration domain S into $C(\mathbf{r}_s, s)$ and dl (Hansen and Shore 1998), with dl as the shadow boundary of the scatterer. In the high-frequency regime, $C(\mathbf{r}_s, s)$ conforms locally to the shape of the scatterer around the shadow boundary point $\mathbf{r}_s$. This technique for the determination of the NU-diffracted wave field is called the incremental length diffraction coefficient (ILDC) technique (Hansen and Shore 1998; Yaghjian et al. 1996).

DOI 10.1007/978-981-4560-75-7_6-2

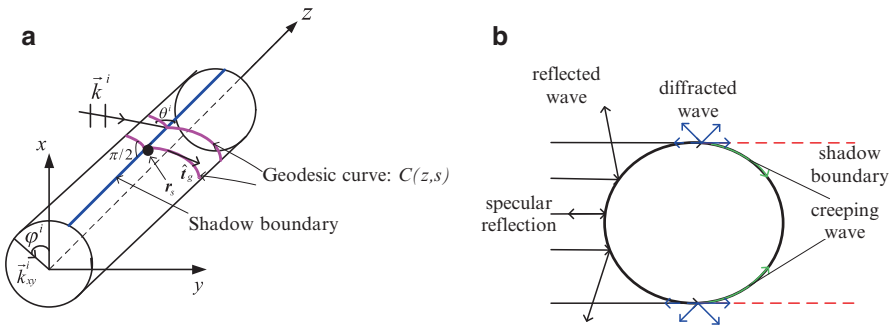

Fig. 20 (**a**) The obliquely incident plane wave impinges on the convex cylinder with finite length and the shadow boundary is shown by the *blue line* on the cylinder. The NU-Fock current in the shadow region follows the direction of the geodesic curve $C(z, s)$ by the *magenta color*. (**b**) PO current in the illuminated region and NU-Fock current around the shadow boundary and in the deep shadow region for the NU-diffracted and creeping waves

In particular, for the scatterer with convex shadow boundary, the NU-diffracted wave current is called the NU-Fock current (Fock 1946). The NU-diffracted wave field could be obtained from the integration of the product of the free-space Green's function and the NU-Fock current on S. Then, the resultant electric scattered field has the expression

$$\mathbf{E}^{(q)}(\mathbf{r}) = i\omega\mu\left(\bar{\mathbf{I}} + \frac{1}{k^2}\nabla\nabla\right) \cdot \int_S d\mathbf{r}' \frac{\mathbf{J}^{(q)}(\mathbf{r}')e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \tag{186}$$

The index q stands for the TE and TM cases (horizontal and vertical polarizations), and $\mathbf{J}^{(q)}(\mathbf{r}')$ is the NU-Fock current. In the far-field zone, Eq. 186 could be reformulated as

$$\mathbf{E}^{(q)}(\mathbf{r}) \approx \frac{ike^{ikr}}{4\pi r}\sqrt{\frac{\mu}{\epsilon}}\left(\bar{\mathbf{I}} - \hat{r}\hat{r}\right) \cdot \int_S d\mathbf{r}' e^{-ik\hat{r}\cdot\mathbf{r}'}\mathbf{J}^{(q)}(\mathbf{r}') \tag{187}$$

One can suppose that the integration surface S in Fig. 20 is given by $C(z, s) \times [z_0, z_1]$. Here, $C(z, s)$ is the integration curve and $[z_0, z_1]$ is the integration domain along the z direction. Then, with the strip of thickness dz as consideration, the far scattered field could be formulated as

$$d\mathbf{E}^{(q)}(\mathbf{r}) \approx dz\frac{ike^{ikr}}{4\pi r}\sqrt{\frac{\mu}{\epsilon}}\left(\bar{\mathbf{I}} - \hat{r}\hat{r}\right) \cdot \int_{C(z,s)} dsC'(z,s)e^{-ik\hat{r}\cdot C(z,s)}\mathbf{J}^{(q)}(C(z,s)) \tag{188}$$

In the illuminated region, the above $C(z, s)$ is normal to the shadow boundary. That is, $C(z, s)$ is the line along the $\mathbf{k}^i$ direction. In the shadow region, $C(z, s)$ is the geodesic curve which forms the constant angle with the z axis as θ^i. The above Eq. 188 is known as the ILDC formulation (Hansen and Shore 1998).

Fast Solvers for High-Frequency Scattered Fields

High-Frequency Asymptotic Method

To present the high-frequency asymptotic (HFA) method in an elegant way, one can study contour integrals of the type

$$I(k) = \int_C f(z)e^{ikg(z)}dz \tag{189}$$

DOI 10.1007/978-981-4560-75-7_6-2

Here, $\mathcal{C}$ is an integration domain in the real axis or a contour on the complex plane. Moreover, Eq. 189 could be treated as the simplification of the surface radiation integral Eq. 179 after some mathematical manipulations.

Due to the localization nature of the high-frequency wave field with the wave frequency k or the angular frequency ω approaching infinity, one can obtain an asymptotic approximation of the radiation integral in Eq. 189. This could be done by the "method of stationary phase" (or the "saddle point method"). That is, the major contribution of $I(k)$ comes from the neighborhood of the saddle point z_s satisfying $g'(z_s) = 0$. Here, one can assume that there is one saddle point z_s inside $\mathcal{C}$. Then, the leading term for the asymptotic expansion of Eq. 189 could be obtained by the expansion of $g(z)$ with the Taylor series and terminating at the second-order term, with the expression

$$I(k) \simeq f(z_s) e^{ikg(z_s)} \left(\frac{2\pi i}{kg''(z_s)} \right)^{1/2} \tag{190}$$

Furthermore, if $g''(z_s) = 0$, the above expansion Eq. 190 shall be modified with the Taylor series expansion of $g(z)$ to the third term. As is seen from Eq. 190, $I(k)$ is of $O\left(k^{-\frac{1}{2}}\right)$ and becomes increasingly accurate when k goes to infinity. The saddle point in two dimensions is called the "stationary phase point." Detailed discussion could be found in Conde et al. (2001) and Carluccio et al. (2010). By the same token, the integrand of the radiation integral in Eq. 189 is approximated by several leading terms. With the high-frequency wave physics aspect, the leading term in Eq. 190 corresponds to the GO ray fields at the specular reflection point, as shown in Fig. 19a. From Eq. 190, it is easy to see that the traditional HFA approach could provide the calculation of the radiation integral with frequency-independent workload.

Numerical Steepest Descent Path Method

Owing to the asymptotic process of the HFA method for radiation integrals in Eq. 179, the generated high-frequency scattered field results usually lose accuracy, in particular, when the parameter ka is not extremely large but lies in the high-frequency regime.

In the following, the application of the NSDP method for the PO scattered fields is considered. Since the PO scattered fields contain phase terms that have rapid variations in space, the resultant PO integrands are highly oscillatory in nature. To efficiently evaluate these surface PO integrals, the numerical steepest descent path (NSDP) method was proposed (Vico-Bondia et al. 2010; Zhang et al. 2014; (Wu et al. 2012a, b, 2013a, b, c). On invoking the NSDP method, the original PO real integration domain is deformed into the complex NSDPs on complex plane. In this manner, the PO integrands decay exponentially on these complex NSDPs, and they can be integrated with workload independent of frequency. In contrast to the HFA method, the only approximation in the NSDP method is the numerical integration of the exponential decay PO integrand. Hence, the proposed NSDP method improves the PO scattered field accuracy.

The definition of the NSDP follows that, for the given integration domain $[L_1, L_2]$ with the integrand $e^{ikg(x)}$, one can define the path functions $x = x_{L_m}(p)$, $m = 1, 2$, $p \in [0, \infty)$, satisfying three conditions (Chew 1990):

(a) $x_{L_m}(0) = L_m$, that is, the paths start at L_m.
(b) $\Re e(g(x_{L_m}(p))) = \Re e(g(x_{L_m}(0))) \equiv C$, where C is a constant.
(c) $\Im m(g(x_{L_m}(p))) = p$.

DOI 10.1007/978-981-4560-75-7_6-2

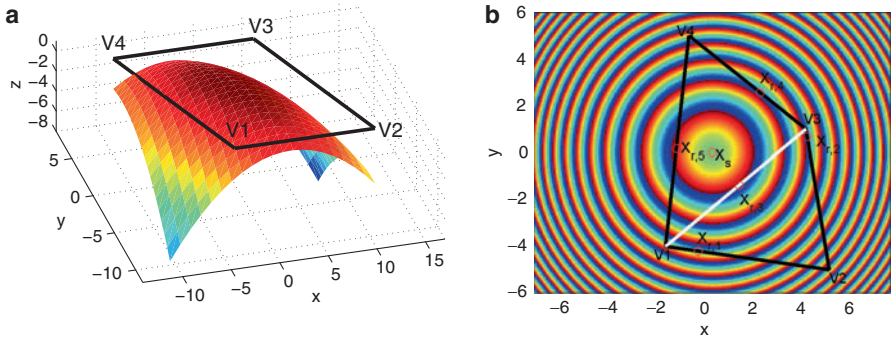

Fig. 21 (**a**) A parabolic PEC patch. (**b**) The projected $x-y$ quadrilateral domain $\mathbf{V}_1\mathbf{V}_2\mathbf{V}_3\mathbf{V}_4$ of the parabolic PEC patch

Then, after substituting $x = x_{L_m}(p)$ into the phase function $g(x)$, one sees that $e^{ikg(x_{L_m}(p))} = e^{ikg(L_m)-kp}$ decreases exponentially as $O(e^{-kp})$ when kp goes large. Hence, the path functions $x = x_{L_m}(p)$ are called the NSDPs. Through (a), (b), and (c), the NSDPs $x_{L_m}(p)$ for the end points L_m could be obtained (Chew 1990; Wu et al. 2012a, 2013a, b).

However, the phase behavior of $g(x)$ around the stationary phase point x_s is different from that around the end points. The corresponding NSDP shall also change. One notice that $g(x) - g(x_s)$ is a quadratic function around x_s after the Taylor expansion of the phase function at x_s (Chew 1990). Therefore, one can change the above condition (c) with $\Im m(g(x_{L_m}(p))) = p^2$ and define the corresponding NSDP, $x = x_0(p)$, $p \in (-\infty, \infty)$.

In the following, the application of the NSDP method for the PO scattered fields from the quadratic parabolic PEC patches as shown in Fig. 21 is considered. The projected xy quadrilateral domain is S_{xy}, denoted as $\mathbf{V}_1\mathbf{V}_2\mathbf{V}_3\mathbf{V}_4$. The edges are governed by $y = a_m x + b_m$, $m = 1, 2, 4, 5$. To capture the high-frequency critical-point phenomenon for PO scattered fields, one can consider that the PO integrand has the quadratic variation for the phase functions on the quadrilateral patches. After substituting $\mathbf{J}_{PO}$ into Eq. 178, the three PO surface integrals could be obtained. For simplicity, one can denote them as $\tilde{I}$. In the process for the reduction of the PO surface integral to several line integrals $I_2^{(a_m, b_m)}$, the complementary error function comes out in the integrand (Wu et al. 2012a, b). On invoking Stokes' phenomenon of the complementary error function, the phase functions on the edges are $g^{(m)}(x) = x^2 + (a_m x + b_m)^2$, and Stokes' lines are $y = -x - \frac{b_m}{a_m}$. Then, the NSDPs on the edges of the quadrilateral domain are (Chew 1990)

$$x_{L_m}(p) = \frac{\mathrm{sgn}(L'_m)}{\sqrt{1+a_m^2}}\sqrt{L_m'^2 + ip} + x_s, p \in [0, \infty) \tag{191}$$

$$x_{0,m}(p) = \frac{e^{\left(i\frac{\pi}{4}\right)}p}{\sqrt{1+a_m^2}} + x_s, p \in (-\infty, \infty) \tag{192}$$

where $x_s = -\frac{a_m b_m}{1+a_m^2}$ is the stationary phase point of phase function $g^{(m)}(x)$ defined on edges and $L'_m = \sqrt{1+a_m^2}(L_m - x_s)$. These NSDPs are demonstrated in Fig. 22. After changing the original PO integration path to the NSDPs and on invoking the Cauchy's integral theorem, the PO integral $\tilde{I}$ can be represented in terms of the NSDPs as

DOI 10.1007/978-981-4560-75-7_6-2

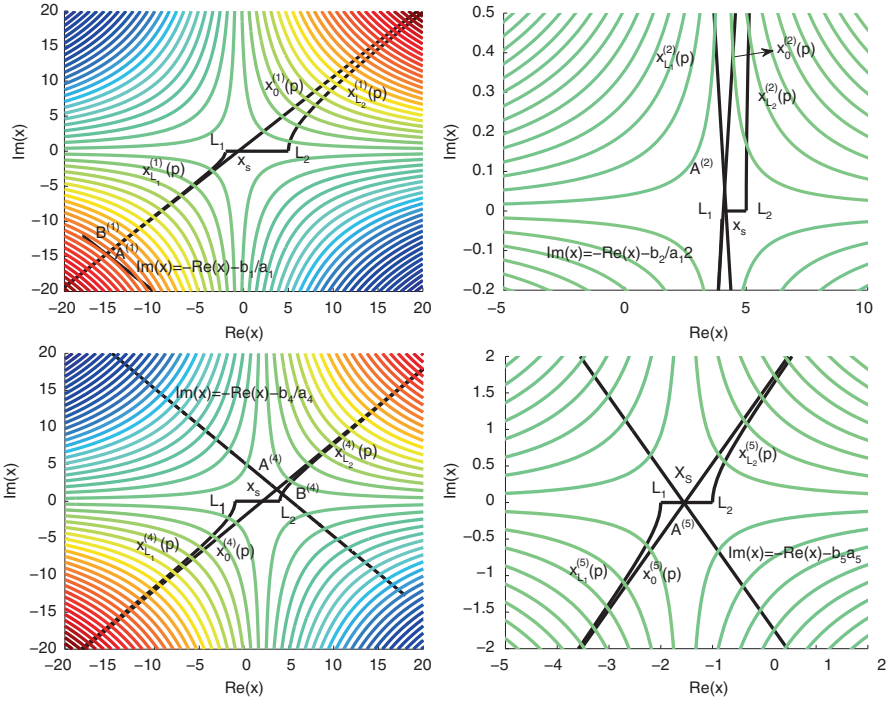

Fig. 22 The four sub-figures correspond to the NSDPs for the integrand of $I_2^{(a_m,b_m)}$, m = 1, 2, 4, 5, defined on the four edges of the quadrilateral domain $\mathbf{V}_1\mathbf{V}_2\mathbf{V}_3\mathbf{V}_4$ in Fig. 21

$$\tilde{I} = -I_2^{(a_1,b_1)} + I_2^{(a_2,b_2)} + I_2^{(a_4,b_4)} + I_2^{(a_5,b_5)} \tag{193}$$

where

$$\begin{aligned} I_2^{(a_1,b_1)} &= I_{L_1}^{(a_1,b_1)} - I_{L_2}^{(a_1,b_1)} + I_{x_s}^{(a_1,b_1)} \\ &+ K((\mathbf{V}_2(1),0)) - K((\mathbf{V}_1(1),0)) - K\left(\mathbf{B}^{(1)}\right) + K\left(\mathbf{A}^{(1)}\right) \end{aligned} \tag{194}$$

$$I_2^{(a_2,b_2)} = I_{L_1}^{(a_2,b_2)} + I_{x_s}^{(a_2,b_2)} - I_{L_2}^{(a_2,b_2)} + K((\mathbf{V}_2(1),(0)) - K\left(\mathbf{A}^{(2)}\right) \tag{195}$$

$$I_2^{(a_4,b_4)} = I_{L_1}^{(a_4,b_4)} + I_{x_s}^{(a_4,b_4)} - I_{L_2}^{(a_4,b_4)} + K\left(\mathbf{B}^{(4)}\right) - K\left(\mathbf{A}^{(4)}\right) \tag{196}$$

$$I_2^{(a_5,b_5)} = I_{L_1}^{(a_5,b_5)} + I_{x_s}^{(a_5,b_5)} - I_{L_2}^{(a_5,b_5)} + K\left(\mathbf{A}^{(5)}\right) - K((\mathbf{V}_1(1),0)) \tag{197}$$

Originally, $I_2^{(a_m,b_m)}$, m = 1, 2, 4, 5, are the highly oscillatory PO line integrals $I_2^{(a,b)}$ defined on the four edges $\overrightarrow{\mathbf{V}_1\mathbf{V}_2}$, $\overrightarrow{\mathbf{V}_2\mathbf{V}_3}$, $\overrightarrow{\mathbf{V}_3\mathbf{V}_4}$, and $\overrightarrow{\mathbf{V}_1\mathbf{V}_4}$ in Fig. 21, and in Eqs. 195, 196, and 197, $K(x)$ comes from Stokes' phenomenon of erfc(z)'s different asymptotic behaviors on different domains, which has a closed-form formula. At this point, PO integral is expressed in terms of NSDPs with an exponentially decay integrand, which could be evaluated in a frequency-independent workload.

Compared to the HFA method, one can see the advantage of the NSDP method after studying the high-frequency critical-point contributions from both methods. With the ray physics aspect, the high-frequency critical-point contributions from the stationary phase point, resonance point, and vertex point correspond

DOI 10.1007/978-981-4560-75-7_6-2

to the ray fields from the specular reflection point, the boundary specular reflection point, and the vertex point, respectively. The leading terms of the HFA approach for the high-frequency critical-point contributions including the stationary phase point, resonance point, and vertex point (Carluccio et al. 2010) are of $O\left(k^{-1}\right), O\left(k^{-\frac{3}{2}}\right), O\left(k^{-2}\right)$, respectively. On the other hand, these critical-point contributions could also be rigorously expressed via the PO integrand defined on the NSDPs. Since the process for evaluating the PO integral by the NSDP method uses less approximation, these PO integral results gain high accuracy from those produced by the HFA method. Meanwhile, the frequency-independent computation effort is achieved (Wu et al. 2012a, b, 2013a, b, c).

Conclusions

In this chapter, an overview of different computational electromagnetics (CEM) methods is given that are used to solve antenna problems. As computers become more powerful, these methods are more prevalent for antenna designs. Many software tools have been developed to enable better antenna designs. Hence, it is important for antenna designers and engineers to understand the working principles of different CEM methods or future methods that will be incorporated into these software tools. With better understanding, better antennas can be designed.

As antenna engineering often involves circuit design, it is also important that antenna designers understand how electromagnetic theory morphs into circuit theory when the feature sizes are much smaller than the wavelength. Antenna structures are designed to be of the order of wavelength or larger in order to receive the signals that are transmitted as waves. However, as these signals are received by the antennas, they invariably have to be routed through different systems using a combination of circuit and waveguide theories. It is instrumental that antenna engineers understand both the electromagnetic and circuit theory well.

As the signal is received, the signal is routed through a system where wave physics becomes circuit physics. Hence, it is also important that computation be done correctly in the "twilight" zone between the circuit theory and electromagnetic full wave theory.

Due to the advanced made in nanofabrication technology, it is now possible to make nanoantennas that are subwavelength even in the optical regime. These nanoantennas find applications in optical links in computer systems as front-end communication bus. They can provide the high data rate needed. They also can be used to enhance the optical emissions given by atoms and molecules or couple light energy to materials to enhance the generation of photoelectricity.

Many antenna designers use software to gain physical insight into the working of the antennas. It will be increasingly important that this software provides output parameters that offer a deeper insight into the workings of an antenna. This can be seen in the increasing use of characteristic mode analysis for antenna design. The future can be the use of natural mode analysis for better understanding and design of antennas.

Also, as systems become highly complex, it is prudent to decompose a larger system as a sum of smaller systems for ease of finding the solution. So the domain decomposition method comes in useful. The equivalence principle algorithm (EPA) is useful to achieve this decomposition, even though much research work is still needed.

As a final note, high-frequency scattering has always been important in design of reflector antennas. The improvement of the accuracy and speed of existing high-frequency techniques is an area that warrants further research.

General research directions are new numerical analysis tools for better antenna design and engineering. Fast CEM algorithms, robust and valid over a broad frequency range, are future goals. These future tools should handle multi-scale structures efficiently and robustly, with the least use of memory and computer

DOI 10.1007/978-981-4560-75-7_6-2

resource. Moreover, coupling to multiphysics simulation will become increasingly important as antennas are integrated into complex environments. New metrics for antenna design and performance need to be formulated as the complexity becomes higher.

Localized Waves: Theory, Techniques and Applications

Mohamed A. Salem* and Christophe Caloz
Polytechnique Montreal, Montreal, QC, Canada

Abstract

In the first part of the chapter, an introduction to localized waves (LWs) is presented as polychromatic superposition of propagation-invariant beams (PIBs) with specific spatiotemporally coupled spectra. In the second part of the chapter, the focus is shifted towards some of the peculiar characteristics of electromagnetic LWs that distinguish them from other types of electromagnetic waves. In the last part, a presentation of the state-of-the-art techniques and experiments to generate electromagnetic PIBs is illustrated. Since PIBs are near-field phenomena, the electromagnetic structures that generate them differ significantly from conventional radiating antennas.

Keywords

Localized waves; X-waves; Propagation-invariant beams; Bessel beams; Mathieu beams; Weber beams; Modal synthesis; Antenna arrays; Metasurfaces

Introduction

Dispersion is the phenomenon where the group velocity of the wave depends on its frequency (Hecht 1998). In three dimensions, the group velocity is defined as the gradient of the angular frequency ω with respect to the wave vector $\mathbf{k}$, $\mathbf{v}_g = \nabla_{\mathbf{k}}\omega$. It is also equivalently valid to define dispersion as the dependence of phase velocity on frequency, yet such dependence may not be immediately obvious from the expression of the phase velocity, especially in monochromatic (single angular frequency) waves. Dispersion affects the propagation of waves in space and time and often introduces distortions that limit the applicability range where the wave characteristics need to be maintained. Wave dispersion is essentially an intrinsic propagation characteristic of the wave and is present independent of the propagation medium. Dispersive media and guiding structures introduce additional dispersion to waves propagating in them and thus further limit the propagation distance where wave distortion is within application tolerance.

Spatial wave dispersion is the dependence of the wave propagation direction on its wave vector components. This effect is always present even in monochromatic waves, with the exception of ideal plane waves. Spatial dispersion gradually changes the transverse profile of the wave along its propagation direction, which limits the propagation range in applications where the transverse profile of the wave needs to be maintained, such as free-space communication, imaging, remote sensing, lithography, etc.

Temporal wave dispersion affects polychromatic waves (pulses) and is the dependence of the velocity of each spectral component on the wavelength. Temporal dispersion gradually changes the extent of the wave (longitudinal profile) in time, which limits the propagation range in applications where the longitudinal profile needs to be maintained, such as optical and wideband communication, chromatic imaging, etc.

Localized waves (LWs), therefore, emerge as a special class of waves that ideally propagate in homogeneous media free from intrinsic spatial and temporal dispersion. In practice, ideal LWs cannot be generated for reasons that will be shortly explained; nevertheless, it is possible to mold nonideal LWs with dispersion-resistant characteristics for arbitrary propagation distances. Currently, LWs are well established theoretically, verified experimentally, and have plethora of engineering applications.

Historical Overview

The existence of waves that propagate without dispersion was predicted in the works of Bateman (1915) and Courant and Hilbert (1966), yet waves that propagate rigidly (without distortion) attracted considerable attention in 1983 after the publication of the work of Brittingham (1983). In his seminal work, Brittingham set forth a free-space solution to Maxwell's equations that is packet-like in nature and propagates luminally (at the speed of light). This solution, named focus wave mode (FWM), possessed infinite energy and thus was deemed physically impossible.

In 1985, Sezginer (1985) demonstrated that finite-energy luminal pulses can be constructed to propagate nearly without distortion for a certain "large" depth of field, much larger than ordinary pulses, such as Gaussian ones. In a series of subsequent papers, Ziolkowski et al. (Ziolkowski 1989; Besiries et al. 1989; Shaarawi et al. 1990; Ziolkowski 1991; Ziolkowski et al. 1993; Donnelly and Ziolkowski 1993) developed a framework for constructing and launching finite-energy FWM variants.

About the same time, Lu and Greenleaf (1992a, b) mathematically constructed and experimentally verified a new class of waves that can propagate without distortion. These solutions had a characteristic X-shaped pulse profile (see Fig. 1) and hence were given the name X-waves. In three-dimensional space, X-waves look like two cones joined at the tip and propagate along the axis of the cones. X-waves also possessed the peculiar property that their pulse peak (often referred to as the centroid) propagates with superluminal velocity, i.e., propagates faster than the speed of light. Lu et al. initially studied acoustic X-waves and their experimental work showed that the centroid propagates with supersonic velocity. The centroid of electromagnetic X-waves propagates with superluminal velocities, and since the main interest is in electromagnetic waves here, the term superluminal is used and the reader should understand that it generally refers to velocities larger than the phase velocity in a homogeneous medium. Since the centroid velocity was considered equivalent to the group velocity of the pulse, the nature of the superluminal propagation of X-waves generated controversy to whether it contradicts the special theory of relativity or not. The superluminal propagation of X-waves was experimentally demonstrated in the optical regime by Saari and Reivelt in 1997 (Saari and Reivelt 1997) and in the microwave regime by Mugnai et al. in 2000 (Mugnai et al. 2000). It is now well understood that X-waves do not violate the special theory of relativity

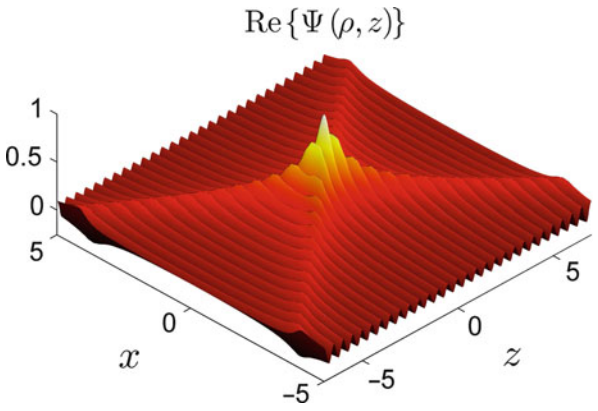

Fig. 1 Plot of the real part of the scalar X-wave introduced in Lu and Greenleaf (1992b) showing its characteristic X-shaped arms

DOI 10.1007/978-981-4560-75-7_8-1

since their superluminal centroids do not carry information. A detailed description of this phenomenon is given in section "Spectral Structure," but for now, the reader can think of this paradox as an analogy to the "superluminal scissors paradox," with the centroid analogous to the vertex and the advanced cone analogous to the blades.

The forementioned historical overview is by no means comprehensive and is meant to familiarize the reader with this topic. A comprehensive account on the historical development of LWs can be found in the introductory chapters of Hernández-Figueroa et al. (2008, 2013).

On the Name "Localized Waves": In his work, Brittingham described the localized wave solutions he found as "focus wave modes" (Brittingham 1983) pertaining to their self-reconstructing nature. Brittingham described these solutions as modes because they were propagating without distortion similar to guided wave modes. The term "localized wave" first appeared in the title of Ziolkowski's work on localized transmission of energy (Ziolkowski 1989). Ziolkowski went on and emphasized this name in his subsequent work. Later on, several terms describing LW solutions showed up in the literature and were mostly related to the Strategic Defense Initiative applications, such as electromagnetic missiles (Wu 1985; Wu and Lehmann 1985), electromagnetic bullets (Moses and Prosser 1986, 1990), and directed energy pulse trains (Ziolkowski 1989, 1991). When Lu and Greenleaf introduced the term "X-waves," it was regarded a separate class of waves as the common fundamental spectral structure of both wave families was not established yet. Recently, the term "nondiffracting waves" has been used to described the same waves (Hernández-Figueroa et al. 2013), probably pertaining to the work of Durnin on Bessel beams (Durnin 1987; Durnin et al. 1987). The term "nondiffracting" may be misleading in the sense that LWs are initially conceived as propagating solutions in a homogeneous media, whereas diffraction is conventionally associated with parts of the field scattered by an obstacle. Moreover, diffraction phenomena are also equivalently described as interference phenomena (bending of waves due to the interference of the spherical waves emitted by all unobstructed points on the wavefront). According to this description, LWs are in fact diffractive waves, since their undistorted propagation essentially depends on the interference between their different spectral components as will be shown in section "Spectral Structure." Hence, in what follows, the term "nondiffracting waves" will not be used, and the term "localized waves" (as a proper noun) will be used instead, to describe the unique spatiotemporally coupled solutions to the wave equation.

Applications

Localized waves are potentially superior to conventional waves and pulses in various applications. Areas of interest are not limited to acoustics, microwaves, and optics, but also extend to mechanics, geophysics, and even gravitational waves and elementary particle physics. The applications of LWs are numerous and span a broad range of scientific and industrial interests, such as communication, wireless energy, nondestructive testing, remote sensing, imaging, and biomedical radiography. For example, since their inception in acoustics, X-waves have been successfully employed in high-resolution ultrasound scanning of moving organs in the human body (Lu et al. 1994; Lu 1997; Cheng and Lu 2006). In electromagnetism, PIBs are extensively used in electromagnetic tweezers (Arlt et al. 2001; MacDonald et al. 2002, 2003), optical scalpels, particle manipulation and transportation (Arlt et al. 2000; Fan et al. 2000; Rhodes et al. 2002), optical lithography (Erdélyi et al. 1997; Garcés-Chávez et al. 2002; Yu et al. 2009), imaging (Herman and Wiggins 1991; Palma et al. 1996; Zhang et al. 2014), and free-space communication (Ziolkowski 1989, 1991; Salem and Bağci 2012a).

Applications and application areas where LWs can have an impact are plentiful. Past works have only revealed a small part of what LWs can offer in different areas. This limited exploitation of LWs was mainly due to two factors, the first being the incomplete understanding of the physical nature of LWs and how they interact and the second being the difficulty of generating them. In the following two sections, the

DOI 10.1007/978-981-4560-75-7_8-1

physical nature of LWs will be explored, in particular their spectral structure, and then some of the state-of-the-art approaches to generate them will be introduced.

Spectral Structure

In this section, the fundamental physics of LWs are explored in terms of their spectral structure. The strategy adopted here is to first explore the spectral structure of PIBs, then generalize from PIBs to LWs. It will be demonstrated that all the physical properties of LWs follow directly from the corresponding properties of their PIB constituents under a specific spatiotemporal coupling condition. In section "Historical Overview," PIB solutions of the source-free scalar wave equation are derived and their unique and characteristic spectral structure is determined. In section "Spatio-Temporal Coupling in Localized Wave Spectra," the spatiotemporal coupling condition that is necessary to form LWs from PIBs is established. In section "Electromagnetic Bessel-Type Localized Waves," vectorial electromagnetic LW expressions are derived from the scalar solutions, thus completing the spectral structure description of LWs.

It is interesting to note that the analysis of LW characteristics did not historically follow from PIBs as described here, but directly from Bateman constraint (Bateman 1915; Brittingham 1983; Ziolkowski 1989). Formulation in terms of polychromatic superposition of PIBs, specifically Bessel beams, appeared in the literature much later based on the work of Lu and Greenleaf (1992a, b).

Propagation-Invariant Beam Families

Propagation-invariant beams are defined through four essential characteristics: the first characteristic is being monochromatic waves, the second is that PIBs propagate along an axis, the third is that they propagate without distortion in their transverse profiles and with harmonic phase variation along their propagation axis, and the fourth is that their energy is concentrated in the transverse plane, i.e., they have a beam "spot." Propagation-invariant beams are thus similar to guided modes in waveguiding structures, except that, since they are propagating in a homogeneous medium, their spectra are not discretized. They may thus be considered as eigensolutions of the source-free scalar wave equation in homogeneous media.

Analyzing PIBs starts by writing the source-free wave equation in free space as

$$\left[\nabla^2 - \frac{\partial^2}{c^2 \partial t^2}\right] \Psi(\mathbf{r}, t) = 0, \tag{1}$$

where ∇^2 is the Laplacian, Ψ is the wave function, $\mathbf{r}$ is the position vector, and c is the speed of light in free space. To find the eigensolutions, which are of interest, the separation of variables is used to find solutions to Eq. 1, $\Psi(\mathbf{r}, t) = R(\mathbf{r})T(t)$. From the first characteristic of PIBs, only monochromatic waves are of interest; thus, the temporal dependence is fixed as $T(t) = \exp(j\omega t)$, where ω is the angular frequency of the beam. Alternatively, for the $\exp(-i\omega t)$ time dependence, replace j by $-i$ throughout. Substituting $R(\mathbf{r})\exp(j\omega t)$ into Eq. 1 yields Helmholtz equation

$$\left[\nabla^2 + k^2\right] R(\mathbf{r}) = 0, \tag{2}$$

where $k = \omega/c$ is the wave number. Equation 2 is not written in any specific coordinate system. However, to proceed, the set of coordinate systems need to be specified, where PIB solutions can be obtained. The second and third PIB characteristics suggest the need to use separation of variables again for the spatial dependence. From Morse and Feshbach (1953, pp. 509–510), it is known that there are only eleven

DOI 10.1007/978-981-4560-75-7_8-1

coordinate systems where Helmholtz equation is separable. From these coordinate systems, those that have at least one coordinate that spans $-\infty$ to $+\infty$ are chosen. This particular coordinate will correspond to the propagation axis of the PIB. This choice reduces the number of matching coordinate systems to four, namely, the Cartesian, the circular cylindrical, the parabolic cylindrical, and the elliptic cylindrical coordinate systems. In the case of the Cartesian coordinate system, all coordinates span $-\infty$ to $+\infty$, whereas in the other three cylindrical coordinate systems, only the z coordinate spans the same range. The last PIB characteristic, which requires them to have a "spot" in the transverse plane, further eliminates the Cartesian coordinates, since the eigensolutions in the Cartesian coordinates are plane waves with uniform transverse profiles.

The Laplacian in Eq. 2 is separated in a transverse term and a longitudinal term as $\nabla^2 = \nabla_\perp^2 + \partial_z^2$. Accordingly, the PIB spatial function can be also separated in transverse and longitudinal functions as $R(\mathbf{r}) = R_\perp(\rho)\exp(-j\beta z)$, where ρ is the transverse position vector and β is the wave vector component along the propagation axis, z. Substituting into Eq. 2 yields

$$\left[\nabla_\perp^2 + \chi^2\right] R_\perp(\rho) = 0, \tag{3}$$

with $\chi^2 = k^2 - \beta^2$. The transverse Laplacian $\nabla_\perp^2$ depends on the choice of the coordinate system. Table 1 summarizes the description of the three coordinate systems of interest and gives expressions of the transverse Laplacian in each system.

Eigensolutions of Eq. 2 in the circular, parabolic, and elliptic cylindrical coordinate systems are, respectively, known as Bessel (Durnin 1987), Weber (or parabolic) (Bandres et al. 2004), and Mathieu (or elliptic) beams (Gutiérrez-Vega et al. 2000). Any PIB is thus either one of these eigensolutions or a superposition thereof.

A pictorial representation of the PIB spectral structure is shown in Fig. 2. In the figure, k_x and k_y are the Cartesian transverse components of the wave vector. Waves with their spectrum confined within the red dashed circle at $k_x^2 + k_y^2 = \chi^2 = k^2$ are propagating waves. Waves with spectral components outside this circle are evanescent since their longitudinal wave vector component is imaginary according to $\beta^2 = k^2 - \chi^2$ and $\chi^2 > k^2$. Any single point within the circle represents a propagating plane wave in the direction defined by the direction cosines (k_x/k, k_y/k, β/k), e.g., the black star at $k_x = k_y = 0$ represents the spectrum of a plane wave propagating in the z-direction. The blue solid circle with radius χ/k is the locus of any propagating PIB. A PIB is thus understood as a continuum of an infinite number of plane waves propagating along a conical surface with a conical angle given by arcsin (χ/k). The distribution of the

Table 1 Transverse Laplacian in the coordinate systems supporting PIB eigensolutions Morse and Feshbach (1953, chapter 6)

Coordinate system	Relation to Cartesian	Transverse Laplacian

DOI 10.1007/978-981-4560-75-7_8-1

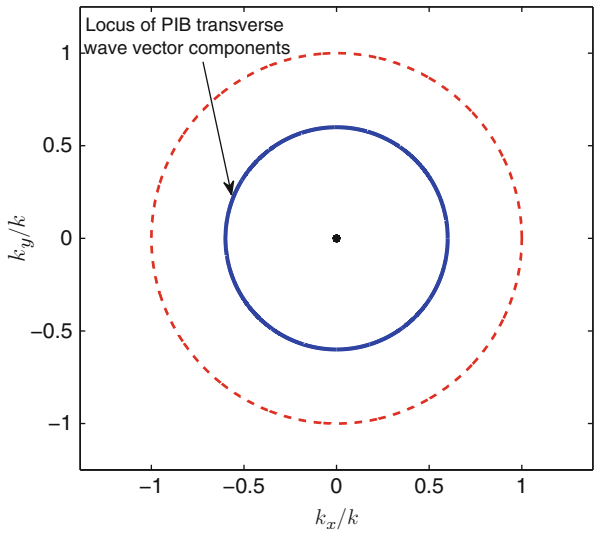

Fig. 2 Pictorial representation of the spectral structure of PIBs. Any point in the plane $k_x - k_y$ represents a plane wave of the form $\exp\left(-j\left[k_x x + k_y x + \sqrt{k^2 - k_x^2 - k_y^2}z\right]\right)$. All plane waves within the *red dashed* circle are propagating waves, while those outside the circle are evanescent. A PIB is a superposition of an infinite number of propagating plane waves having the same transverse wave number $\chi^2 = k_x^2 + k_y^2$. The distribution of the plane-wave magnitudes along the locus χ/k determines the family of the PIB, while the distribution of the phases of the plane waves determines the order of the PIB

magnitudes of these plane waves along the circle is what determines the family of the beam, and the distribution of the phases is what determines the order of the beam, e.g., all the plane waves in a Bessel beam have the same magnitude, while Weber beams are characterized by an increased relative magnitude in the vicinity of the two opposite points.

Spatiotemporal Coupling in Localized Wave Spectra

In this section, LW solutions will be constructed based on Bessel PIBs, noting from the discussion in the previous section that this process can be generalized to any type of PIBs. The choice of Bessel PIBs is due to their familiarity and the availability of mathematical framework to manipulate them.

Using separation of variables, the transverse function is expressed as $R_\perp = P(\rho)\,\Phi(\phi)$, where $P(\rho)$ is the radial dependence function and $\Phi(\phi)$ is the azimuthal dependence function. Substituting into Eq. 2,

$$P''(\rho)\Phi(\phi) + \frac{1}{\rho}P'(\rho)\Phi(\phi) + \frac{1}{\rho^2}P(\rho)\Phi''(\phi) + \chi^2 P(\rho)\Phi(\phi) = 0, \tag{4}$$

where the dash designates derivation with respect to the argument. Dividing by $P(\rho)\Phi(\phi)/\rho^2$ and rearranging the terms yields

$$\frac{\rho^2 P''(\rho)}{P(\rho)} + \frac{\rho P'(\rho)}{P(\rho)} + \chi^2\rho^2 = -\frac{\Phi''(\phi)}{\Phi(\phi)}, \tag{5}$$

where the left-hand side of (5) is only a function in ρ and the right-hand side is only a function in ϕ. The equation is now separated, and since solutions that are azimuthally periodic are sought after, the separation constant must be negative.

The azimuthal equation is written as

DOI 10.1007/978-981-4560-75-7_8-1

$$\Phi''(\phi) + m^2\Phi(\phi) = 0, \tag{6}$$

with $-m^2$ the separation constant. Equation 6 has the solution

$$\Phi(\phi) = Ce^{jm\phi} + De^{-jm\phi}, \tag{7}$$

where C and D are constants. Note that Eq. 7 may be alternatively written as $\Phi(\phi) = C\cos(m\phi) + D\sin(m\phi)$.

The radial equation is multiplied by ρ^2 and rearranged to read

$$P''(\rho) + \frac{1}{\rho}P'(\rho) + \left(\chi^2 + \frac{m^2}{\rho^2}\right)P(\rho) = 0. \tag{8}$$

Equation 8 is a modified version of Bessel differential equation and has the solution

$$P(\rho) = AJ_m(\chi\rho) + BY_m(\chi\rho), \tag{9}$$

where A and B are constants, $J_m(z)$ and $Y_m(z)$ are, respectively, the ordinary Bessel functions of first and second kind, and order m.

From Eqs. 7 and 9, the expression of the monochromatic Bessel beam of order m is written as

$$\psi(\rho, \phi, z, t; \chi, m, \beta, \omega) = J_m(\chi\rho)e^{jm\phi}e^{-j\beta z}e^{j\omega t}. \tag{10}$$

Note that $B = 0$ is set in the Bessel beam expression, since $Y_m(z) \to -\infty$ as $z \to 0$ and is thus unphysical. Also $\exp(-jm\phi)$ is omitted from the expression, since it is directly recovered from $\exp(jm\phi)$ by changing the sign of m.

Since Bessel beams are eigensolutions in the circular cylindrical coordinate system and thus form a complete and orthogonal set, they may be used as an expansion set for any arbitrary wave. The expansion is called the Fourier-Bessel expansion and takes the form

$$\Psi(\rho, \phi, z, t) = \sum_{m=-\infty}^{\infty}\int_0^{\infty} d\chi \int_{-\infty}^{\infty} d\beta \int_{-\infty}^{\infty} d\omega \chi \tilde{\Psi}_m(\chi, \beta, \omega) J_m(\chi\rho)e^{-j\beta z}e^{j\omega t}e^{jm\phi}, \tag{11}$$

where $\tilde{\Psi}_m(\chi, \beta, \omega) = \tilde{\Psi}_m(\beta, \omega)\delta\left(\chi^2 - \left[(\omega/c)^2 - \beta^2\right]\right)$ is the spectrum of $\Psi(\rho, \phi, z, t)$ and the Dirac delta is the spectral representation of Eq. 1.

If Ψ is an ideal LW, one may expect it to maintain its form along its axis, with the exception local variations, as it propagates. This propagation property is expressed as (Zamboni-Rached et al. 2002)

$$\Psi(\rho, \phi, z, t) = \Psi\left(\rho, \phi, z + \Delta z_0, t + \frac{\Delta z_0}{V}\right), \tag{12}$$

where Δz_0 is an arbitrary distance and V is the centroid speed.

Using Eq. 11, the translated wave in Eq. 12 is expressed as

DOI 10.1007/978-981-4560-75-7_8-1

$$\Psi\left(\rho,\phi,z+\Delta z_0,t+\frac{\Delta z_0}{V}\right)= \sum_{m=-\infty}^{\infty}\int_0^{\infty}d\chi\int_{-\infty}^{\infty}d\beta\int_{-\infty}^{\infty}d\omega\chi\widetilde{\Psi}_m(\chi,\beta,\omega)J_m(\chi\rho)e^{-j\beta[z+\Delta z_0]}e^{j\omega[t+(\Delta z_0/v)]}e^{jm\phi}. \tag{13}$$

One can immediately recognize that Eq. 12 is satisfied when $\exp(-j\beta[z+\Delta z_0])\exp(j\omega[t+(\Delta z_0/V)]) = \exp(-j\beta z)\exp(j\omega t)$, which yields the periodic reconstruction constraint

$$\omega = V\beta + \alpha, \tag{14}$$

where $\alpha = 2n\pi\frac{V}{\Delta z_0}$ and n an integer. This constraint does not contradict the spectral representation of the wave, which is taken into account by means of the Dirac delta in $\widetilde{\Psi}$ and the fact that the spectrum of the wave is indeed a function of β and ω as observed in $\hat{\Psi}$. Spectra of an LW solution may thus be written as

$$\tilde{\Psi}_m(\chi,\beta,\omega) = \tilde{\Psi}_m(\omega)\delta\left(\chi^2-\left[\left(\frac{\omega}{c}\right)^2-\beta^2\right]\right)\delta\left(\beta-\left[\frac{\omega-\alpha}{V}\right]\right). \tag{15}$$

This spectral representation effectively reduces the free spectral parameters to a single parameter, ω in this case. Note that the LW spectrum may be equally formulated for any of the other spectral components, except for m. The reduction in the degrees of freedom is the characteristic spatiotemporal coupling property of LWs, which essentially dictates the nature of the spatial spectrum upon choosing the temporal one and vice versa.

Electromagnetic Bessel-Type Localized Waves

So far, only the scalar LW solutions are discussed, and it was shown that they are naturally represented by superposition of PIBs with a specific spatiotemporal coupling constraint. In this section, the electromagnetic vectorial LWs are derived from the scalar solutions.

The strategy here is to make use of the Hertz vector potentials to derive the electromagnetic PIB fields from scalar PIB solutions and then construct LW superpositions from the electromagnetic PIBs under the spatiotemporal coupling constraint Eq. 14. The electric and magnetic fields are derived from the Hertz vector potentials as (Stratton 1941)

$$\mathbf{E} = \nabla(\nabla\cdot\Pi_e) - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\Pi_e - \mu_0\nabla\times\left(\frac{\partial}{\partial t}\Pi_h\right), \tag{16}$$

$$\mathbf{H} = \varepsilon_0\nabla\times\left(\frac{\partial}{\partial t}\Pi_e\right) + \nabla(\nabla\cdot\Pi_h) - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\Pi_h, \tag{17}$$

where ε_0 and μ_0 are the free-space permittivity and permeability, respectively, and Π_e and Π_h are the electric and magnetic Hertz vector potentials, which satisfy the source-free vector wave equation

$$\nabla\times\nabla\times\Pi(\mathbf{r},t) - \varepsilon_0\mu_0\frac{\partial^2}{\partial t^2}\Pi(\mathbf{r},t) = 0. \tag{18}$$

Assuming the same harmonic time dependence $\exp(j\omega t)$, Eq. 18 reduces to the vector Helmholtz equation

DOI 10.1007/978-981-4560-75-7_8-1

$$\nabla \times \nabla \times \Pi(\mathbf{r}, \omega) + k^2 \Pi(\mathbf{r}, \omega) = 0, \tag{19}$$

where $\varepsilon_0 \mu_0 = 1/c^2$.

Equation 19 is separable in transverse electric (TE) and transverse magnetic (TM) fields in six coordinate systems, among them the three cylindrical coordinate systems (Morse and Feshbach 1953, pp. 494–523) where PIBs are eigensolutions. Moreover, TE and TM separation in these three coordinate systems requires that the Hertz vector potentials have a single component, namely, in the z-direction. This reduces Eqs. 19 to 2, for which PIB solutions are already established. In such case, Π_e yields the TE field while Π_h yields the TM field. Hence, the Hertz vector potentials is written as

$$\Pi_{e/h}(\mathbf{r}, t) = A_{e/h} \Psi(\mathbf{r}, t) \hat{\mathbf{z}}, \tag{20}$$

where Ψ is scalar PIB function, $A_{e/h}$ is an arbitrary amplitude for the electric/magnetic Hertz vector potential component, and $\hat{\mathbf{z}}$ is the unit vector in the z-direction.

Without loss of generality, the TE and TM fields are derived in the circular cylindrical coordinate system from scalar Bessel PIBs. Substituting Eqs. 10 into 20 and then into Eqs. 16 and 17 yields the TE PIB electric and magnetic fields as

$$\begin{aligned} E_\rho(\rho, \phi, z, t) &= -A_e \frac{m\mu_0 k}{\chi^2 \rho} e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \\ E_\phi(\rho, \phi, z, t) &= A_e \frac{j\mu_0 k}{\chi^2} e^{jm\phi} e^{-j[\beta z - \omega t]} \frac{\partial}{\partial \rho} J_m(\chi\rho), \\ E_z(\rho, \phi, z, t) &= 0, \end{aligned} \tag{21}$$

$$\begin{aligned} H_\rho(\rho, \phi, z, t) &= -A_e \frac{j\beta}{\chi^2} e^{jm\phi} e^{-j[\beta z - \omega t]} \frac{\partial}{\partial \rho} J_m(\chi\rho), \\ H_\phi(\rho, \phi, z, t) &= -A_e \frac{m\beta}{\chi^2 \rho} e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \\ H_z(\rho, \phi, z, t) &= A_e e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \end{aligned} \tag{22}$$

and the TM PIB electric and magnetic fields as

$$\begin{aligned} E_\rho(\rho, \phi, z, t) &= -A_h \frac{j\beta}{\chi^2} e^{jm\phi} e^{-j[\beta z - \omega t]} \frac{\partial}{\partial \rho} J_m(\chi\rho), \\ E_\phi(\rho, \phi, z, t) &= -A_h \frac{m\beta}{\chi^2 \rho} e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \\ E_z(\rho, \phi, z, t) &= A_h e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \end{aligned} \tag{23}$$

$$\begin{aligned} H_\rho(\rho, \phi, z, t) &= -A_h \frac{m\varepsilon_0 k}{\chi^2 \rho} e^{jm\phi} e^{-j[\beta z - \omega t]} J_m(\chi\rho), \\ H_\phi(\rho, \phi, z, t) &= -A_h \frac{j\varepsilon_0 k}{\chi^2} e^{jm\phi} e^{-j[\beta z - \omega t]} \frac{\partial}{\partial \rho} J_m(\chi\rho), \\ H_z(\rho, \phi, z, t) &= 0. \end{aligned} \tag{24}$$

One notes here that in the case of zeroth-order ($m = 0$) PIBs, the TE field is purely azimuthally polarized, while the TM field is radially polarized. The polarization of higher-order PIBs is a combination of radial and azimuthal polarizations, while linear and elliptic polarizations cannot be achieved for these PIBs.

DOI 10.1007/978-981-4560-75-7_8-1

One also notes that no transverse electromagnetic (TEM) PIB solutions exist. This could be directly shown from the spectral structure of the beams, since they are superpositions of plane waves propagating oblique to the beam axis.

Electromagnetic LW solutions are obtained by superposition of electromagnetic PIBs under the constraint Eq. 14. This is carried out by replacing $A_{e/h}$ with the LW spectrum Eq. 15 and performing the Fourier-Bessel transform.

Moreover, the superposition of TE and TM LW fields with the same spectral function but different amplitudes can lead to new interesting wave phenomena. Some of these interesting phenomena resulting from this superposition were explored in the literature, such as truncated propagation (Salem and Bağci 2010), reflection and transmission at dielectric interfaces and slabs (Salem and Bağci 2012b), and reverse power flow (Salem and Bağci 2011).

Generation Techniques

In the previous section, the unique coupling between the spatial and temporal frequency components of LWs is explored. In this section, some techniques to generate PIBs are explored as the primary step to launch LWs. The first reported experimental generation of a Bessel beam was by Durnin et al. in 1987 (Durnin et al. 1987) for scalar optical beams using an annular slit at the focal plane of a collimating lens. A series of experiments followed, where scalar optical Bessel beams are generated using various techniques, such as axicons (Indebetouw 1989), computer generated holograms (CGHs) (Vasara et al. 1989), a combination of an annulus and a Fabry-Pérot resonator (Cox and Dibble 1992), spatial light modulators (SLMs) (Chattrapiban et al. 2003), and Mach-Zehnder interferometers (López-Mariscal et al. 2004). Generating vectorial electromagnetic Bessel beams has not been extensively reported in the literature. The lack of vectorial Bessel beam experiments is due to two main difficulties associated with generating and observing vectorial Bessel beams. The first difficulty is related to the polarization nature of the beam. As was shown in the previous section, Bessel beams posses a combination of radial and azimuthal polarizations, which require a new paradigm in designing the launching structures or antennas, since conventional structures are generally designed for linear or elliptic polarizations. The second difficulty is related to near-field nature of the beam. Since Bessel beams are near-field interferometric phenomena, their propagation distance is limited by the effective aperture of the launching structure, which effectively prevents any observation of Bessel beams in the far zone.

In this section, three different techniques to launch vectorial electromagnetic Bessel beams are detailed. The first approach is based on waveguide modal synthesis, where the propagating modes inside a waveguide section are superimposed to form a Bessel beam at the launching open end of the waveguide section. The second approach utilizes an antenna array with subsampled distribution to form an effective Bessel beam aperture. The third approach employs a metasurface, which is effectively thin metamaterial sheet, to transform an incident electromagnetic field into a Bessel beam field.

Waveguide Modal Synthesis

A truncated Bessel beam is set to be the aperture field at the open end of a flanged metallic circular waveguide section as shown in Fig. 3. As this aperture field would propagate outside the waveguide, it is taken as the transmitted field. Reflection from the aperture is ignored due to the presence of the metallic flange. The coefficients of the propagating modes inside the waveguide section are determined from the expansion of the aperture field in terms of the modes using the modes completeness and orthogonality properties. This further allows the matching of the tangential fields at the open end of the waveguide section. In order to excite the modes inside the waveguide with the required coefficients, a set of loop

DOI 10.1007/978-981-4560-75-7_8-1

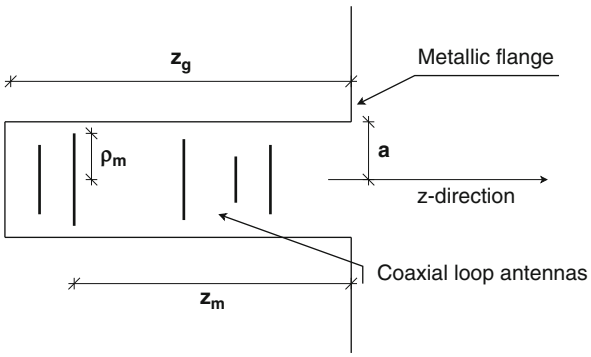

Fig. 3 Schematic showing the Bessel beam launcher setup (Reprinted from Salem et al. (2011) with permission)

antennas are placed coaxially inside the waveguide section. For power efficiency, a finite length waveguide section in the *z*-direction terminated by a perfect electric conductor is considered. The antennas are placed well away from each other to avoid cross-coupling. For simplicity, only the TE field is considered. This does not limit the applicability of the method, but simplifies the analysis and elucidates the steps of the scheme. Hence, from the axial symmetry of this configuration, only uniform currents are required to drive the antennas and excite TE modes. A relation between the current on any antenna and the excitation coefficient of each TE mode is thus established. A system of linear equations in the unknown antenna currents is constructed by choosing a number of antennas equal to the number of excited TE modes. Solving the linear system determines the antenna currents, and hence, the forward problem is solved to reconstruct the Bessel beam at the aperture. Finally, the generated beam is propagated away from the aperture and compared against the ideal truncated beam.

This approach to Bessel beam generation offers a lot of flexibility. As the generated beam is controlled directly by the antenna currents, it could be relatively easy to manipulate the beam intensity, spot size, and modulation, by controlling the excitation currents. Moreover, it allows for superposition of several Bessel beams by exciting the loop antennas with pulsed currents to launch LWs using the same setup.

Axisymmetric Transverse Electric Bessel Beams

Equation 10 gives the scalar Bessel beam solution of order *m*. The axisymmetric Bessel beam is the zero-order solution, which has no azimuthal variation. This Bessel beam has the form

$$\Psi(\rho, z, t) = AJ_0(\chi\rho)e^{j[\omega t - \beta z]}. \tag{25}$$

The time-average intensity of the beam $I(\rho, z)$ is independent of z, as

$$I(\rho, z) \propto |\langle \Psi(\rho, z)\rangle|^2 = |A|^2 J_0^2(\chi\rho), \tag{26}$$

where $\langle \Psi(\rho, z)\rangle$is the time-average function of $\Psi(\rho, z, t)$.

One also notes that the energy contained in each annular section (i.e., the area between two successive zeros of the Bessel function) is approximately equal to the energy contained in the central spot. Bessel and Gaussian beams have comparable power transport efficiencies in the Fraunhofer limit, yet the depth of field of a Bessel beam can be made arbitrary larger than that of a Gaussian beam with the same spot size, at the expense of higher power (Durnin et al. 1987).

While an ideal Bessel beam cannot be practically realized due to its infinite transverse extension and consequently infinite energy content, a truncated version could be realized. However, using an aperture of a finite radius in the transverse plane to limit the radial extension of the beam introduces edge diffraction

DOI 10.1007/978-981-4560-75-7_8-1

effects. Such effects cause the beam to spread as it propagates, hence limiting the invariant propagation range of the beam. It was shown in Durnin (1987) that the maximum propagation range $z_{\max}$ of a truncated version of the $J_0(\chi\rho)$ Bessel is

$$z_{\max} = a\sqrt{\left(\frac{k}{\chi}\right)^2 - 1}, \tag{27}$$

where a is the radius of the aperture.

The electromagnetic axisymmetric TE Bessel electric field is derived from Eqs. 25 and 21 as

$$\begin{aligned} E_\rho(\rho) &= 0, \\ E_\phi(\rho) &= AJ_1(\chi\rho), \\ E_z(\rho) &= 0, \end{aligned} \tag{28}$$

and the magnetic field is derived from Eqs. 25 and 22 as

$$\begin{aligned} H_\rho(\rho) &= -A\frac{\beta}{\omega\mu}J_1(\chi\rho), \\ H_\phi(\rho) &= 0, \\ H_z(\rho) &= -jA\frac{\chi}{\omega\mu}J_0(\chi\rho), \end{aligned} \tag{29}$$

where a (z, t) dependence of exp(j[$\omega t - \beta z$]) is assumed and omitted.

Field Modal Expansion

The TE Bessel beam field expressions Eqs. 28 and 29 can be expanded in terms of the propagating TE modes of a circular waveguide. Due to the axisymmetric nature of the Bessel beam, only axisymmetric TE modes, designated as TE_{0n} modes, would yield nonzero expansion coefficients. For a circular waveguide with radius a, the field components of the set of TE_{0n} (Collin 1990) read

$$\begin{aligned} e_\rho(\rho,z) &= 0, \\ e_\phi(\rho,z) &= jA_n\frac{\omega\mu}{\chi_{cn}}J_1(\chi_{cn}\rho)e^{\mp j\beta_n z}, \\ e_z(\rho,z) &= 0, \end{aligned} \tag{30}$$

and

$$\begin{aligned} h_\rho(\rho,z) &= \pm\frac{\beta_n}{\omega\mu}e_\phi(\rho,z), \\ h_\phi(\rho,z) &= 0, \\ h_z(\rho,z) &= A_n J_0(\chi_{cn}\rho)e^{\mp j\beta_n z}, \end{aligned} \tag{31}$$

where χ_{cn} satisfies $J_1(\chi_{cn}a) = 0$, $\chi_{cn}^2 = k^2 - \beta_n^2$, β_n is the propagation constant of the nth mode, A_n is a constant amplitude to be determined by the excitation, and the $\mp$; sign designates forward and backward propagation, respectively.

If the beam's transverse wave number χ is chosen such that $\chi = \chi_{cn}$, the Bessel beam is represented by a single TE mode. The excitation coefficient for that mode is thus $A_n = -j\chi/(\omega\mu)$. Other choices for the

DOI 10.1007/978-981-4560-75-7_8-1

beam's transverse wave number will yield some errors in the modal representation as all TE modes have to terminate at $\rho = a$. If the choice of χ results in a beam with transverse profile that has nonzero values at $\rho = a$, the modal representation will not be able to exactly replicate such profile.

The modal expansion of the beam in terms of the TE_{0n} modes utilizes the power orthogonality relation of modes (Collin 1990) such as

$$E_{\phi}^{\mathrm{BB}} = \sum_{n} c_n^{(e)} e_{\phi n}, \tag{32}$$

where E_{ϕ}^{BB} is the Bessel beam electric field component and $c_n^{(e)}$ are the expansion coefficients of the electric field, which are given by

$$c_n^{(e)} = \frac{1}{P_n} \int_0^{2\pi} \int_0^a E_{\phi}^{\mathrm{BB}} e_{\phi n}^* \rho d\rho d\phi, \tag{33}$$

where the symbol * stands for the complex conjugate and P_n is the normalization integral given by

$$P_n = \int_0^{2\pi} \int_0^a \left| e_{\phi n} \right|^2 \rho d\rho d\phi. \tag{34}$$

The calculated coefficients in Eq. 33 represent the expansion of the TE Bessel beam at $z = 0$, the open-end face of the waveguide. To avoid dealing with the diffraction effects at the edge of the waveguide, a metallic flange is introduced around the waveguide aperture (see Fig. 3) to force the electric field to be zero in the radial direction where $\rho > a$ at $z = 0^+$. The numerical results of calculating the magnetic field across the discontinuity show that such maneuver is an acceptable approximation as the value of the magnetic field along the discontinuity surface is several orders of magnitude less than its value on the aperture. Thus, the computed expansion coefficients in Eq. 33 are also the transmission coefficients of the field.

Excitation

The field inside the waveguide is excited by means of a series of loop antennas placed coaxially inside the waveguide (see Fig. 3 for a schematic). As previously stated, the field components are derived from the longitudinal magnetic field, which is now the solution to the inhomogeneous Helmholtz equation

$$\left(\nabla^2 + k^2\right) h_z(\rho) = -\sum_{m} I_m \delta(z - z_m) \frac{\delta(\rho - \rho_m)}{\rho}, \tag{35}$$

where I_m is the excitation current density on the mth antenna, z_m is the position of the mth antenna inside the guide, and ρ_m is its radius. The loop antennas are thin; thus, two Dirac delta functions $\delta(x)$ are sufficient to fully describe the geometry and position of each one. The antennas are assumed to be far enough from each other to avoid cross-coupling. The antennas are also placed adequately far enough from the ends of the waveguide to prevent interaction between the edges and the evanescent fields generated in the vicinity of each antenna.

Equation 35 is tackled by first solving the corresponding Green's function equation

$$\left(\frac{d^2}{dz^2} + \beta_n^2\right) g_n(z) = -I_m J_0(\chi_{cn} \rho_m) \delta(z - z_m), \tag{36}$$

DOI 10.1007/978-981-4560-75-7_8-1

subject to the boundary condition $g_n(z) = 0$ at $z = z_g$, where z_g is the length of the waveguide section. Here it is assumed that no field is reflected back from the open end of the waveguide section at $z = 0$. The solution of Eq. 36 is (Felsen and Marcuvitz 1994)

$$g_n(z) = \begin{cases} \tau_n e^{-j\beta_n z}, & z > z_m \\ \gamma_n \sin\left(\beta_n \left[z_g - z\right]\right), & z < z_m \end{cases} \tag{37}$$

where τ_n and γ_n are unknown coefficients and $\mathrm{Im}\{\beta_n\} > 0$.

The unknown coefficients are determined by applying the source condition which implies that at $z = z_m$, $g_n(z)$ is continuous, and its first derivative with respect to z is discontinuous by $-I_m J_0(\chi_{cn}\rho_m)$. Hence, for the field emerging at $z > z_m$

$$\tau_n = -\frac{j}{2\beta_n} I_m J_0(\chi_{cn}\rho_m) e^{j\beta_n z_m} \xi_{nm}, \tag{38}$$

where $\xi_{nm} = 1 - \exp(-2j\beta_n[z_g - z_m])$. The magnetic field is readily available as

$$h_z(\rho, z) = \frac{\sqrt{2}}{a} \sum_n \sum_m \tau_n \frac{J_0(\chi_{cn}\rho)}{J_0(\chi_{cn}a)} e^{-j\beta_n z} \xi_{nm}. \tag{39}$$

Using Maxwell's equations to determine the electric field

$$e_{\phi n}(\rho, z) = \frac{J\omega\mu\beta_n}{\chi_{cn}^2} \frac{\partial}{\partial\rho} h_{zn}(\rho, z), \tag{40}$$

and hence, the expansion coefficients in the azimuthal direction, c_n, are

$$c_n = \frac{1}{\sqrt{2}\chi_{cn}a} \sum_m I_m \frac{J_0(\chi_{cn}\rho_m)}{J_0(\chi_{cn}a)} e^{j\beta_n z_m} \xi_{nm}. \tag{41}$$

The set of coefficients c_n relate the current density on the mth antenna to the excitation coefficient of the nth mode. Thus, by choosing a number of antennas m equal to the number of modes n, one can construct a linear system that can be inverted to compute the unknown excitation currents from the known excitation coefficients. The linear system is given by

$$\mathbf{LJ} = \mathbf{C}, \tag{42}$$

where $\mathbf{J}$ is the vector of unknown current densities I_m, $\mathbf{C}$ is the vector of expansion coefficients $c_n^{(e)}$, and the elements of the matrix $\mathbf{L}$ are

$$L_{nm} = \frac{1}{\sqrt{2}\chi_{cn}a} \frac{J_0(\chi_{cn}\rho_m)}{J_0(\chi_{cn}a)} e^{j\beta_n z_m} \xi_{nm}. \tag{43}$$

The excitation currents are obtained by multiplying Eq. 42 by the inverse if the matrix $\mathbf{L}$.

In the case of $\chi = \chi_{cp}$, where the truncated Bessel beam could be fully represented by the mode number p, one should still use $m = n > 1$ number of antennas and modes, with the expansion coefficients $c_n = 0$ for $n \neq p$. This is essential to obtain a good approximation of the ideal truncated Bessel beam.

Numerical Example

To illustrate the technique, a numerical example is given, where a Bessel beam is generated inside the waveguide then propagated in free space. A beam with $\chi = \chi_{c4} = 13.3237/a$ and a propagation constant $\beta_4 = \sqrt{k^2 - \chi^2} \approx 5.5418/\lambda$ are chosen, which has four distinctive annular sections in the waveguide cross section. The launcher structure is a truncated circular waveguide section of length $z_g = 30\lambda$, where λ is the wavelength of the beam. The walls of the waveguide are perfect electric conductors and the waveguide has a radius $a = 4.5\lambda$. The choice of this value for the radius ensures that all TE_{0n} modes below TE_{09} are above cutoff.

Eight loop antennas are chosen to excite the beam. Here, the antennas are chosen to have uniformly decreasing radii as they are placed farther away from the open end of the waveguide starting with the largest radius of $\rho_m = 4.25\lambda$ and decreasing by half wavelength in each successive loop. The antennas are separated by 3λ from each other, and the first antenna is placed 4.5λ away from the open end of the waveguide.

The generation technique is demonstrated using two configurations: in the first configuration C_1, eight loop antennas are used for the analysis to match all propagating TE_{0n} in this waveguide section, while in the second configuration C_2, only the first four antennas are used, and consequently only the first four modes excitation coefficients are matched to the beam's coefficients. In both configurations, all expansion coefficients are identically zero except for $c_4^{(e)} = -j\chi/\omega\mu$.

The matrix elements relating the expansion coefficients to the excitation current densities are constructed using Eq. 43. The condition numbers of the resulting matrices $\mathbf{L}$ in ℓ^2 norm are 29.6325 and 8.2867 for C_1 and C_2, respectively, which indicate that the matrices are not ill-conditioned. The excitation current densities obtained after inverting $\mathbf{L}$ and multiplying with $\mathbf{C}$ are given in Table 2.

The relative error in the mode excitation coefficients obtained by solving the forward excitation problem is calculated as $\Delta_n = \left|\tilde{c}_n^{(e)} - c_n^{(e)}\right|$, where $\tilde{c}_n^{(e)}$ are the reconstruction coefficients. Results show that in C_1 and C_2, the generated matched modes have relative errors in the order of the machine precision, while in C_2 the unmatched modes have relative errors in the order of $\mathcal{O}(-14)$. The effect of launching the unwanted modes is apparent in Fig. 4, where the transverse intensity profiles of the ideal truncated and the reconstructed beams of C_1 and C_2 are plotted. The figure shows an excellent matching between the ideal truncated beam and that generated in C_1, while the beam generated in C_2 suffers from deformations due to the interference effects with the launched higher-order modes.

To further investigate the behavior of the generated beams, a finite-difference frequency-domain (FDFD) scheme is employed to simulate the propagation of the beam in free space. The developed FDFD scheme uses a 2D staggered grid in the $\rho - z$ plane following the body of revolution cell grid scheme in Taflove and Hagness (2005). The cell dimensions are $\Delta z = \Delta\rho = \lambda/20$ and the computation domain is 20λ in the z-direction and 15λ in the ρ-direction. An absorbing boundary of thickness 5λ is

DOI 10.1007/978-981-4560-75-7_8-1

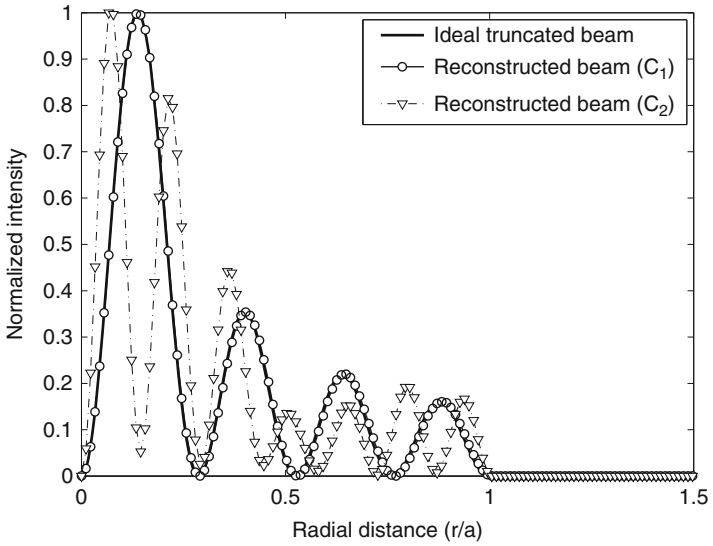

Fig. 4 Normalized intensity plot of the ideal truncated and the reconstructed Bessel beams at the open end of the circular waveguide section (Reprinted from Salem et al. (2011) with permission)

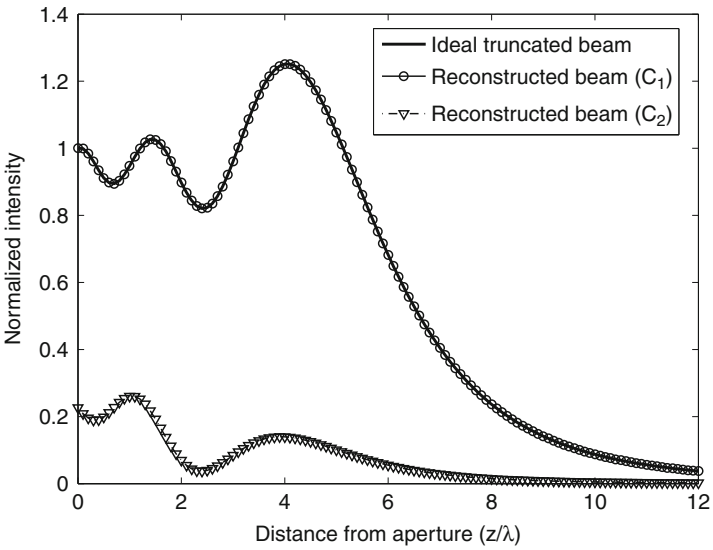

Fig. 5 Comparison between the intensities of the ideal truncated and the reconstructed Bessel beams along the propagation direction (Reprinted from Salem et al. (2011) with permission)

added before and after the computation domain in the z-direction, and an absorbing boundary of thickness 10λ is added after the computation domain in the ρ-direction. The absorbing layer is implemented by adding $i\varepsilon|x - x_{CD}|^{\delta}$ to the permittivity, where ε and δ are constants x and x_{CD} are cell number and the boundary cell number of the computation domain, respectively. For the z-direction, $\varepsilon_z = 0.075\Delta z$ and $\delta_z = 2.65$; and for the ρ-direction, $\varepsilon_\rho = 0.025\Delta\rho$ and $\delta_\rho = 0.65$. The FDFD scheme is tested with a unit strength impressed magnetic line source excitation at $\rho = 0$ and is verified to produce the magnetic field $H_z(\rho) = -k^2/(4\omega\mu_0)H_0^{(1)}(k\rho)$, with $H_0^{(1)}(k\rho)$ the Hankel function of first kind and zero order.

Figure 5 shows the normalized intensity plot of the reconstructed beams in comparison to an ideal truncated beam along the z-direction. The normalized intensity plot along the z-axis (at $\rho_a = 1.8412/\chi$, the maximum of the first annular section) in Fig. 5 shows that for the ideal beam and in the C_1

DOI 10.1007/978-981-4560-75-7_8-1

configuration, the beam intensity oscillates before it exhibits some focusing then sharply drops off. The simulation shows that the beam intensity drops below half of its initial value after propagating for a distance $z_{\max} \approx 6.8\lambda$, which is in the order of the geometrical optics approximation Eq. 27. For the beam in C_2, the intensity oscillates but does not exhibit the same focusing before decaying. The intensity drops below half of its initial value at $z_{\max} \approx 4.9\lambda$, which is less than the expected distance.

Figure 6 depicts the intensity of the generated Bessel beams in C_1 and C_2, respectively, in the transverse and propagation directions. The figure shows that the generated beams maintain their distinctive dark spot (due to the annulation of the intensity) at its center, while the beam reconstructed in C_1 maintains its shape in the transverse plane for longer propagation distance compared to that in C_2. The faster spread in the C_2 beam is due to the presence of higher-order modes with larger χ values.

Summary of the Technique

In summary, this Bessel beam generation technique takes advantage of completeness and orthogonality of the circular waveguide's modes. The transverse profile of the beam is decomposed in a finite number of

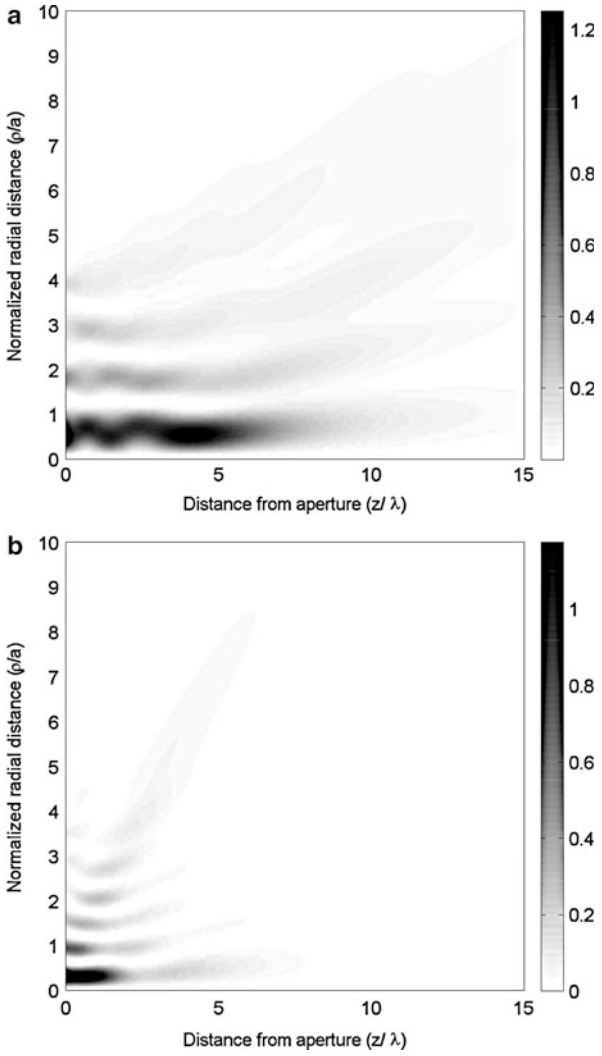

Fig. 6 Intensity plots of the reconstructed Bessel beams in the transverse plane and along the propagation direction for configurations (**a**) C_1 and (**b**) C_2 (Reprinted from Salem et al. (2011) with permission)

DOI 10.1007/978-981-4560-75-7_8-1

propagating TE_{0n} modes. Except for the case where the beam's transverse wave number χ matches one of the mode's cutoff wave numbers χ_{cn}, then the beam could be fully represented by a single mode.

Thin circular loop antennas are used to excite the modes. The antennas are placed coaxially inside the waveguide with proper separations from each other and the waveguide's ends. A relation between the antenna currents and the excitation coefficients of the modes is established. Using this relation, a system of linear equations is constructed with the antenna currents as the unknowns. It was shown that even in the case where the beam is fully represented by a single mode, it is recommended to include all propagating modes in the linear system for better matching. Solving the system yields the necessary antennas' currents. The obtained currents are used in the reverse process, and the generated beam is constructed at the open end of the waveguide. To simplify the calculations, a metallic flange is placed around the open end of the waveguide; thus, the reconstructed beam was taken as the aperture field and propagated in free space using an FDFD algorithm. Obtained numerical results for the propagation agree with the expected behavior of TE Bessel beams.

While the given numerical example serves the purpose of demonstrating the proposed scheme, several additional optimizations could be incorporated into it. An example could be optimizing the locations and radii of the antennas in order to minimize the effect of launched unwanted modes, in the case of using a number of antennas less than the total number of propagating modes. Another example of optimization is to solve for more than one parameter (antennas current) at the same time. Such optimizations could be achieved using numeric multi-objective optimization techniques, where the numeric technique simultaneously searches for the optimal parameter values that fulfill certain design constraints, such as error in excitation coefficients, antennas' current range, desired separation between antennas, or range of permissible antenna radii values.

Antenna Arrays

In this technique, the proposed concept is using a two-dimensional antenna array with a subsampled distribution for launching a zero-order pseudo-Bessel beam as an alternative and practical solution to the lack of simple, stable, and compact PIB sources. The antenna array is subsampled because, otherwise, the number of antennas in the array would be so large that the subsequent complexity would render any practical realization difficult. The term subsampled here refers to a spatial sampling of the Bessel distribution that does not meet the Nyquist criterion. It is shown that the generated beam may be engineered to propagate to several hundreds of wavelengths while maintaining its transverse localization.

The concept of an array to generate localized waves was initially proposed for launching acoustic LWs by Ziolkowski in 1992 (Ziolkowski 1992). The proposed array consists of patch or dipole antennas arranged within a circle of radius R_{array}. The most natural distribution in the case of circular symmetry is the hexagonal lattice, but a square lattice or a polar lattice could also be adequate, as shown in the Fig. 7. An almost paraxial approximation is assumed, where $\beta/\chi \gg 1$, and thus, the polarization of each array element is linear in a first approach. It is important to note that the use of the array (and thus its design) is quite different from classical arrays employed in radar, sensor, or communication applications. Ideally, the beam produced is intended to be used at distances ranging from a few tens to several hundreds of wavelengths from the launcher. To reach such distances using a pseudo-Bessel beam with a main lobe diameter of a few wavelengths only, the diameter of the launcher (D) is in the order of 50 to 100 wavelengths. From the classical far-zone limit, $2D^2/\lambda$ (Balanis 2005), it is found that a pseudo-Bessel beam extending to distances in the order of a few hundreds of wavelengths is in the near zone of the array. This means that classical array synthesis techniques and the concept of far-field radiation patterns are not pertinent to the proposed antenna array. Conversely, each antenna element has the dimension D of $\lambda/2$, so a distance of 10λ or more can be considered to be in its far field. Classical formulas for the far-field

DOI 10.1007/978-981-4560-75-7_8-1

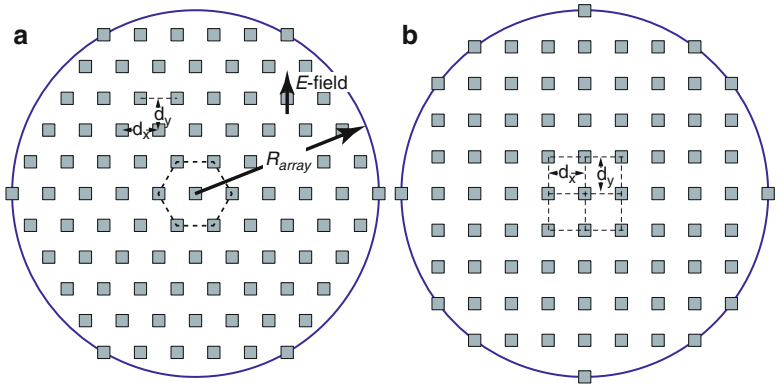

Fig. 7 Schematic representation of the pseudo-Bessel beam array antenna launcher using patch antenna elements. (2013) with permission)

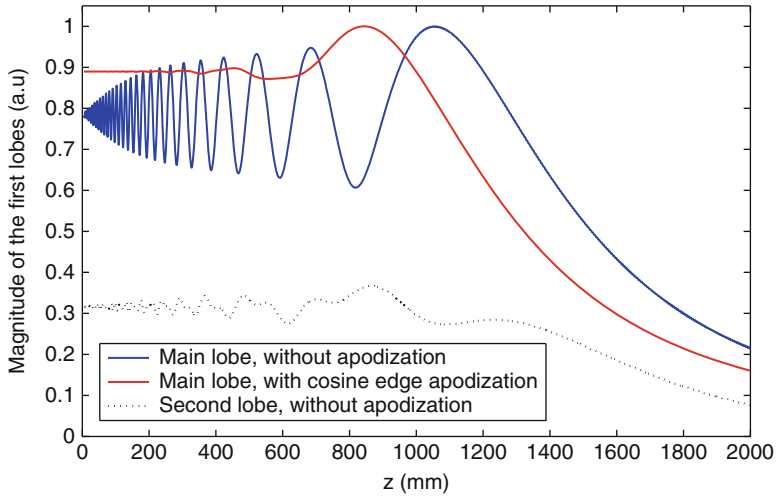

Fig. 8 Magnitude of the first two lobes along z for tapered and non-tapered truncated Bessel excitations (Reprinted from Lemaître-Auger et al. (2013) with permission)

radiation of dipoles or patch antennas can thus be used in the region of existence of the pseudo-Bessel beam (Balanis 2005).

The most intuitive excitation approach would be to sample the Bessel source function with a spacing that is less than the wavelength both to meet the Nyquist criterion and to avoid grating lobes, with each sampling point being the center of an antenna. However, this would lead to a prohibitively large number of required antenna elements, implying a complexity that would make any realization unpractical.

To relax this constraint, the possibility of subsampling the excitation function is investigated, i.e., using a spacing between antennas which is greater than the wavelength following an empirical perspective.

With an array of finite size, the tapering required to flatten the oscillations of the beam (see Fig. 8) forces the excitation function to depart from the Bessel function. Furthermore, by employing subsampling, one can expect that the excitation function will depart even more, up to a point where it becomes completely different from the Bessel function. The different excitation functions that lead to a Bessel or pseudo-Bessel beam are listed in Table 3.

The challenge is thus to find the optimal excitation function that would ideally produce a non-oscillating pseudo-Bessel beam of high quality.

Subsampling Synthesis

Least Mean Square Synthesis Technique: A numerical method was used for the synthesis of the antenna element excitations. The method was first proposed by Hernandez et al. (1992) for the synthesis of acoustic arrays launching LWs. The original method was intended for the generation of short pulsed signals, but it is easily adaptable to monochromatic beams. It works for scalar fields and is based on the minimization of the mean square error between the desired beam's transverse distribution, ψ, and the real field, $\hat{\psi}$. The error is computed at several points i contained inside a comparison region. Because the Bessel beam is a natural solution to the wave equation, it is assumed that if the beam is properly formed at a single transverse plane in a homogeneous medium, then it will also exist before and after that plane. In the present case, the comparison region is a circle of radius R_0 located at a transverse plane at a distance z_0 from the antenna array at an arbitrary position inside the Bessel beam region, the observation synthesis plane (OSP). This is illustrated in Fig. 9.

A second assumption is that in the region of existence of the Bessel beam, the distance between a point of interest and the antenna elements is large enough so that the fields produced by the latter are spherical. Therefore, all the antenna elements can be considered as point sources.

The scalar field at a point i of the OSP is

$$\hat{\psi}_i(x,y,z) = \sum_{l=1}^{L} \frac{e^{-jkr_{li}}}{r_{li}} f_l, \tag{44}$$

DOI 10.1007/978-981-4560-75-7_8-1

where L is the number of point sources, f_l is the complex amplitude excitation of the source l, and r_{li} is the distance between the source l and the observation point i. The mean square error (MSE) is

$$\mathrm{MSE} = \frac{1}{M}\sum_{i=1}^{M}\left(\hat{\psi}_i - \psi_i\right)^2, \tag{45}$$

where M is the total number of observation points. The minimization of the MSE with respect to each complex amplitude f_l results in the following linear system:

$$\sum_{i=1}^{M} h_{pi} g_i = \sum_{i=1}^{M} h_{pi} \sum_{l=1}^{L} h_{li} f_l, \tag{46}$$

where the terms h_{pi} are defined as follows:

$$h_{pi} = \frac{e^{-jkr_{pi}}}{r_{pi}}. \tag{47}$$

Equation 46 can take the matrix form

$$\mathbf{H}\psi = \mathbf{H}\mathbf{H}^{\mathrm{T}}\mathbf{f}, \tag{48}$$

where the elements of the matrix $\mathbf{H}$ are h_{li} and $\mathbf{f}$ is a vector with elements f_i. If the matrix $\mathbf{A} = \mathbf{H}\mathbf{H}^{\mathrm{T}}$ can be inverted, then the solution to Eq. 46 is immediately given as

$$\mathbf{f} = \mathbf{A}^{-1}\psi. \tag{49}$$

In practice, $\mathbf{A}$ is ill-conditioned and classical techniques like Gauss or LU method cannot be used. For example, for an array having 367 antennas, $\mathbf{A}$ is 367×367 and its condition number is 3.13×10^{17}.

Nevertheless, it was found that for the present problem, it is still possible to solve it directly without the use of any iterative numerical minimization techniques, contrarily as in Hernandez et al. (1992). The numerical technique is based on the singular value decomposition (SVD) of and on the neutralization effect of ill-conditioning by replacing all the small terms of the $\mathbf{A}$ matrix by infinity (Press et al. 2007).

Parametric Study: Four parameters have to be chosen in the numerical synthesis method, namely:

1. Sampling lattice of the array
2. Position of the OSP (z_0)
3. Radius of the OSP (R_0)
4. Sampling lattice of OSP

Confusion should be avoided between the sampling lattice of the array, which corresponds to the locations of the physical antenna elements of the array launcher, and the sampling lattice of the OSP, which corresponds to the points in the observation plane where the difference between the cross section of the ideal beam and that of the synthesized beam is realized according to Eq. 44.

DOI 10.1007/978-981-4560-75-7_8-1

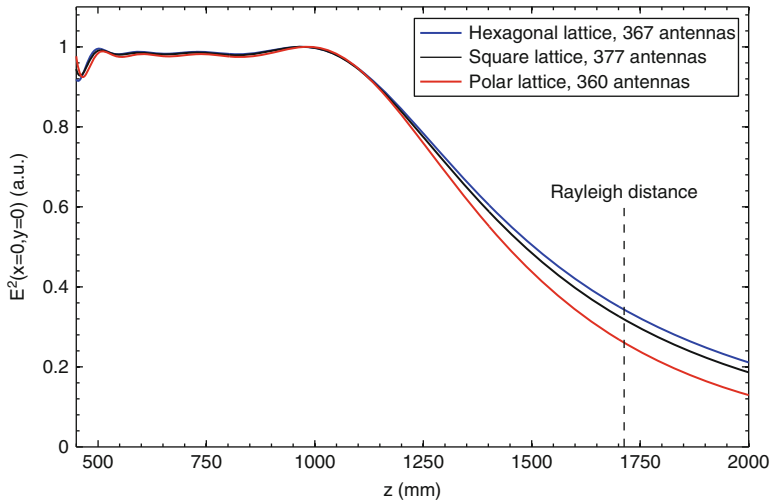

Fig. 10 Axial intensity for three different lattices having a comparable number of antennas. Array diameter is 360 mm, $\beta/\chi = 9.5, f = 50$ GHz, $R_0 = 90$ mm, and $z_0 = 650$ mm (Reprinted from Lemaître-Auger et al. (2013) with permission)

It was found that as long as the spatial sampling rate of the OSP satisfies the Nyquist criterion, its influence on the synthesized beam is almost unnoticeable. OSP sampling with a hexagonal and a square lattice are thus both possible choices.

1. *Sampling lattice of the array*: Three different lattices were tested: hexagonal, square, and polar. Using Eqs. 44 and 49, the complex amplitudes of the point source antennas were obtained.

It was found that, for a comparable number of antennas under the subsampling condition, the nature of the lattice has a minor impact on the pseudo-Bessel beam quality and on its maximum propagation length, as seen in Fig. 10. These results and all subsequent results are computed at a frequency of 50 GHz, chosen as an acceptable compromise between the size of a realizable proof-of-concept prototype and adequate propagation lengths that can be measured in a lab environment. The value of β/χ was chosen arbitrarily. The amplitudes of the obtained beams exhibit almost no oscillation and are similar up to a distance of 1,200 mm (200λ) from the array. Beyond that point, the beam obtained with the hexagonal lattice exhibits the slowest decrease in amplitude while the beam obtained with the polar grid exhibits the highest one. Before the distance of 500 mm($\sim 80\lambda$), the beam is not yet formed and the field distribution is different from the Bessel function, as it is shown in Fig. 11. Naturally, the transition is smooth and the limit of 500 mm is arbitrary. This is an effect of the array subsampling. However, for $z > 500$ mm, the Bessel beam is clearly formed and behaves as expected. An example of the field obtained for the hexagonal lattice is shown in Fig. 12, which almost exhibits no oscillation and thus no deformation along the propagation direction.

2. *Position of the observation synthesis plane (z_0)*: Of the four synthesis parameters, the distance of the OSP from the array has the greatest impact on the synthesized beam. If the OSP is too close to the array, the beam will rapidly form but it will not propagate over great distances. For larger values of z_0, the beam will propagate over greater distances, but will also be formed at a greater distance from the array. Example of simulation results is shown in Fig. 13 for a hexagonal lattice, while examples of beam evolution are shown in Fig. 14. It is a representative of similar behavior using other lattices.

Figure 13 may however be misleading because, whatever the OSP position is, after the Rayleigh distance (approximated by Eq. 27) is reached, the main lobe starts to spread. The zone where the pseudo-Bessel beam exists is thus limited. Other figures of merit are thus helpful as guidelines for the synthesis: first, the maximum distance from the array reached by the main lobe before the intensity spot size is doubled; second, the useful propagation length, i.e., the difference between parameter one and the starting position of the pseudo-Bessel beam; and third, the fraction of the total power that reaches an orthogonal target of diameter equals half of the smallest diameter of the intensity spot size. The three figures of merit are shown in Fig. 15. The first parameter is increasing with the increase of the OSP position, and it is the most pertinent one for applications like industrial surface inspections or secure high-speed point-to-point communication. The second parameter varies much less except for close OSP positions. Nevertheless, this physical parameter could be important to consider for quasi-optical millimeter-wave laboratory experimental benches, high-resolution hyperthermia, and confined-beam THz spectroscopy. Finally, the

last parameter is pertinent to all applications. It globally decreases with increasing OSP position. A trade-off must be made between the power delivered by the main lobe and either the distance at which power can be delivered or on the delivery range.

3. *Radius of the observation synthesis plane (R_0)*: The last parameter to consider is the radius of the OSP. Once again, there is an optimal value. As can be seen in Fig. 16, if R_0 is too small, the beam will have a maximum propagation length shorter than the Rayleigh distance, but will present very low oscillations. This is easily explained by the fact that the total width is so small that the beam has less secondary lobes which prevents the main beam's diffraction.

For R_0 values close to the optimal choice, the beam's propagation length is the longest possible while displaying very low amplitude oscillations. For increasingly larger values of R_0, the beam suffers from increasingly larger amplitude oscillations. This can be explained by the fact that R_0 is larger than what the

synthesis method for an array of fixed radius can naturally produce. This results in point sources close to the array edge having more power than the ones used in an array with optimal R_0 radii values. The efficiency of the natural tapering produced by the synthesis method thus decreases. The optimal value of R0 is smaller than the one indicated by geometrical optics, R_0', which is easily found from Eq. 27 as $R_0' = R_{\text{array}} - z_0\chi/\beta$.

In the present case, $R_0' = 112$ mm, while the optimal value found is close to 90 mm. The axial intensity of the beams obtained with these two values of R_0 is shown in Fig. 16.

Array Implementation

Synthesis Function: As previously mentioned, the excitation function is expected to greatly depart from the Bessel function using a subsampled distribution of the radiation aperture. This was confirmed for all the tested configurations. An illustration of this is presented in Fig. 17 for the hexagonal and polar lattices. To simplify the graphs, only the excitation values along the x-axis are presented. The Bessel function is

DOI 10.1007/978-981-4560-75-7_8-1

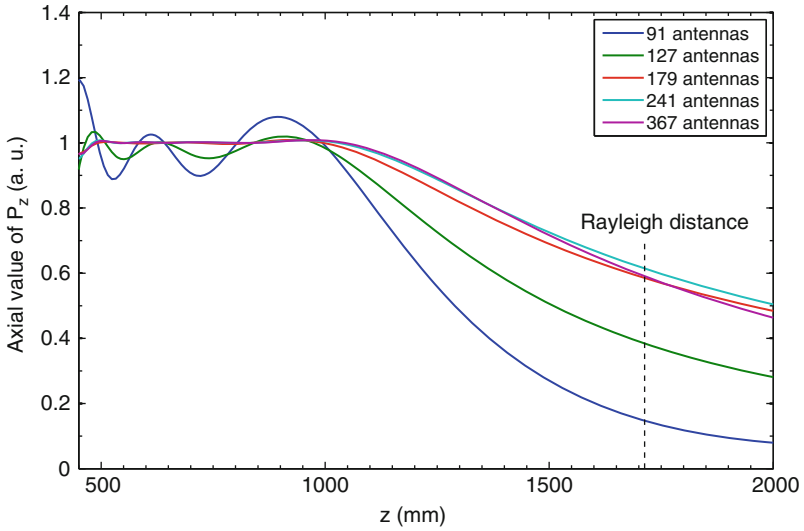

Fig. 18 Evolution of the axial *z*-component of the Poynting vector for hexagonal patch antenna arrays having different number of antennas (Reprinted from Lemaître-Auger et al. (2013) with permission)

also plotted for comparison. The differences between the excitation functions obtained with a hexagonal lattice and a polar one (see Fig. 19b) are only in the magnitude, the phase variations being almost identical for both lattices. This fact is intuitively explained by the antenna densities over the aperture surface which greatly differs between the two lattices. For the hexagonal lattice, the antenna density is uniform and the excitation amplitude has a main lobe in the center and decreases with some oscillations from the center to the outside. For the polar lattice, the antenna density decreases with increasing radius (see Fig. 19b). To compensate for this effect, the excitation amplitude first increases (still with oscillations though) and reaches its maximum at approximately 2/3 of the radius before decreasing. In both cases, the outer amplitude decrease is due to the natural tapering effect of the synthesis method.

As also noted, the magnitude and phase distributions for the two lattices are dramatically different from the Bessel function. Because the differences are seen all along the *x*-axis and not only at the edges, the underlying conclusion is that the subsampling distribution is the main cause of these differences.

Effect of Antenna Reduction in the Antenna Array: The antenna arrays discussed up to now all have 360 antennas or more. Such a large number of antennas render practical implementation very challenging. Therefore, the possibility of diminishing the number of antennas while conserving high-quality beams is investigated now. An example of results is shown in Fig. 18 for the hexagonal lattice. It is seen that a reduction of antennas from 367 to 179 antennas has almost no impact on the evolution of the axial intensity along the propagation distance. A greater decrease, however, has impact on the maximum propagation length and on the oscillation level. A good choice is thus 179 antennas. Other lattices present a similar behavior.

The drawback of decreasing the number of antennas in the array is the decrease of the power contained in the main beam with respect to the overall power emitted by the array. For example, with an 823-antenna array, 14 % of the power is contained inside the pseudo-Bessel beam. This power decreases to 8 % for a 179-antenna array and to 4 % for a 127-antenna array.

The relatively small fraction of useful power in the main beam is explained by the presence of secondary beams radiated by the array. This is a direct and unavoidable consequence of subsampling. A uniform array designed to radiate at broadside having an antenna spacing greater than λ radiates secondary beams, which are the near-field counterparts of the grating lobes in the far field. The only

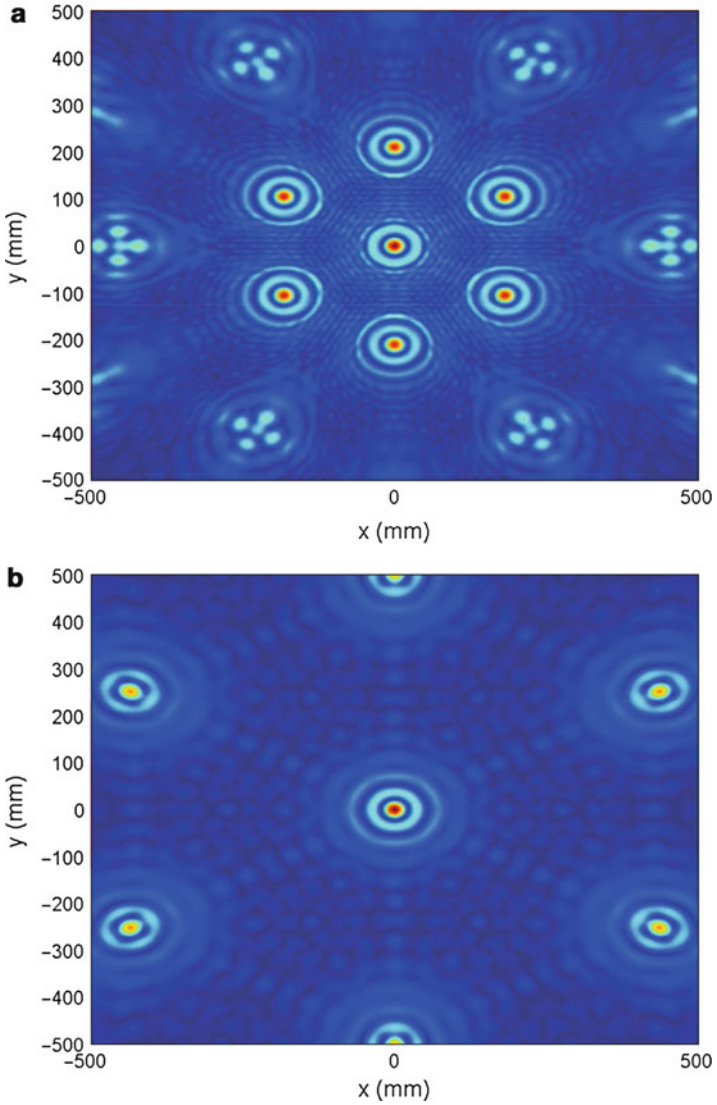

Fig. 19 Magnitude of the electric field in transverse planes located at (**a**) $z = 500$ mm; (**b**) $z = 1200$ mm (Reprinted from Lemaître-Auger et al. (2013) with permission)

difference is that the secondary lobes are also Bessel-like beams. They propagate with the same collimated behavior along directions diverging away of the z-axis. These "grating beams" are shown in Fig. 19.

Validation with Full-Wave Electromagnetic Simulations: Theoretical results for the hexagonal and polar lattice arrays were compared with electromagnetic full-wave simulations using the commercial software Ansoft Designer based on method-of-moments (MoM). The hexagonal and polar lattice arrays, shown in Fig. 20, employ 179 and 112 resonant patch antennas, respectively, operating at $f = 50$ GHz ($\lambda = 6$ mm) placed on a low-loss substrate ($\varepsilon_r = 2.2$, $h = 0.254$ mm, $\tan\delta = 0.0009$). To simplify the validation, the patch antennas were directly excited by a complex distribution (similar to Fig. 17) using excitation ports at the end of the feeding transmission line. The MoM results are from the near field of the antenna array.

Comparisons between the theoretical and MoM results for both lattices are presented in Fig. 21 which show good agreement. The small discrepancies between the results always appear in the vicinity of the maximum field, as it can be seen in Fig. 22. For all other transverse positions, the agreement is very good.

Figure 22 shows a comparison of the transverse value at different z-position of the z-directed Poynting vector along the x-axis. Good agreement is also observed between the theoretical and MoM results.

Summary of the Technique

Using a two-dimensional antenna array launcher for pseudo-Bessel beam generation with a minimal number of required antennas is discussed for practical implementation through the use of a subsampled distribution. It was shown that the subsampling distribution has a direct impact on the excitation function of the array greatly departing from a Bessel function. In order to obtain this excitation function, an analytical method was used based on the minimization of the least mean square of error between the desired field in a transverse plane and the real one. It was found that imposing the Bessel-like shape to the

desired field in a single plane is sufficient to obtain a pseudo-Bessel beam that propagates over several hundreds of wavelength. The synthesis method also naturally does the tapering of the excitation function to obtain very low oscillations. Full-wave simulation results are in good agreement with the theoretical predictions.

Variations to this technique, where leaky radiation is the main launching technique, were reported in Ettorre et al. (2012) and Ettorre and Grbic (2012), and another variation, where radially slotted-line antennas (RLSAs) are used, was reported by Mazzinghi et al. (2014).

Metasurfaces

Metasurfaces (Kuester et al. 2003; Holloway et al. 2009, 2012) may be considered as dimensional reductions of volumetric metamaterials (Caloz and Itoh 2005; Engheta and Ziolkowski 2006; Capolino 2009) and functional extensions of frequency selective surfaces (FSSs) (Munk 2000). They are composed of two-dimensional arrays of sub-wavelength scattering elements engineered to transform incident waves into desired reflected and transmitted waves. Compared to volumetric metamaterials, metasurfaces offer the advantage of being lighter in weight, easier to fabricate, and less lossy due to their reduced dimensionality, while compared to FSSs, they provide greater flexibility in design and much diversified functionalities.

A myriad of metasurfaces have been reported in the literature. Such metasurfaces are reported to perform electromagnetic transformation that was conventionally not possible using planar surfaces or FSSs, such as providing tunable reflection and transmission coefficients (Holloway et al. 2005), reflectionless plane-wave refraction (Pfeiffer and Grbic 2013), single-layer perfect absorption (Ra'di et al. 2013), polarization twisting (Shi et al. 2014), and vortex wave generation (Yu et al. 2011).

Due to their recent inception, metasurface synthesis techniques are in their developing stage. So far, only two universal approaches to synthesize metasurfaces have been introduced: one technique, based on transforming the wave momenta, the spatial spectral components of the wave and is suitable for scalar and paraxial wave transformation (Salem and Caloz 2014) and the second is based on the susceptibilities of the surface and is suitable for vectorial wave transformation (Achouri et al. 2014).

The technique discussed here is based on the surface susceptibility method as introduced in Achouri et al. (2014), which allows for closed-form solutions, and is hence extremely fast to compute. The technique describes the metasurface in terms of surface susceptibility tensors, where the susceptibility tensors are related through generalized sheet transition conditions (GSTCs) (Kuester et al. 2003) to the incident, reflected, and transmitted fields in the vicinity of the surface.

First, the metasurface synthesis problem is described and its general solution is provided, and then this synthesis technique is employed to transform a plane-wave incident on the metasurface into a transmitted Bessel beam.

Metasurface Synthesis Problem

A metasurface is an electromagnetic structure with sub-wavelength thickness ($\delta \ll \lambda$). The metasurface may be finite, with dimensions $L_x \times L_y$, or theoretically infinite. It is typically composed of a nonuniform arrangement of planar scattering elements that transforms incident waves into specified reflected and transmitted waves.

Figure 23 shows the sketch of the synthesis problem to solve, where it is required to find the metasurface composition that transforms an arbitrary specified incident wave, $\psi^{\mathrm{i}}(r)$, into an arbitrary specified reflected wave, $\psi^{\mathrm{r}}(r)$, and an arbitrary specified transmitted wave, $\psi^{\mathrm{t}}(r)$, assuming monochromatic waves. The solution to this synthesis problem will be expressed in terms of the surface transverse susceptibility tensor functions of $\rho = x\hat{x} + y\hat{y}$, $\overline{\overline{\chi}}_{\mathrm{ee}}(\rho), \overline{\overline{\chi}}_{\mathrm{mm}}(\rho), \overline{\overline{\chi}}_{\mathrm{em}}(\rho)$ and $\overline{\overline{\chi}}_{\mathrm{me}}(\rho)$, which represent the

DOI 10.1007/978-981-4560-75-7_8-1

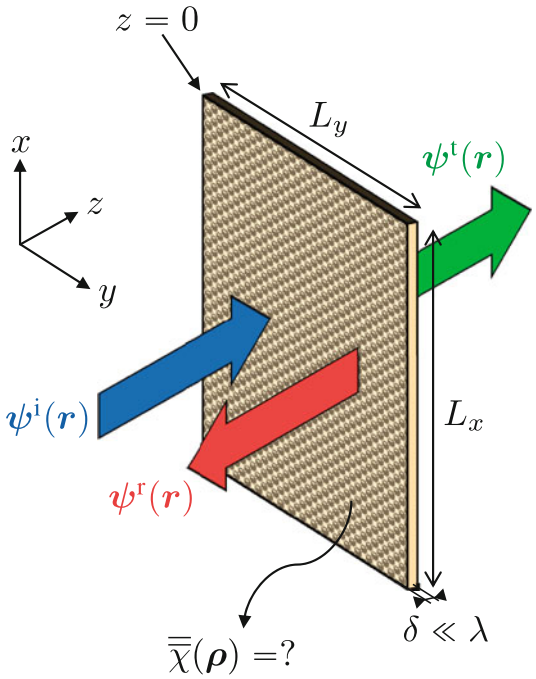

Fig. 23 Metasurface synthesis (inverse) problem to solve. A metasurface, generally defined as an electromagnetic two-dimensional nonuniform structure of extent $L_x \times L_y$ with sub-wavelength thickness ($\delta \ll \lambda$), is placed at $z = 0$. Determine the surface susceptibility tensors $\chi(\rho)$ of the metasurface transforming an arbitrary specified incident wave $\psi^{\mathrm{i}}(r)$ into an arbitrary specified reflected wave $\psi^{\mathrm{r}}(r)$ and an arbitrary specified transmitted wave $\psi^{\mathrm{t}}(r)$ (Reprinted from Achouri et al. (2014) with permission)

electric/magnetic transverse polarization responses (first subscript) to transverse electric/magnetic field excitations (second subscript).

The synthesis procedure will always yield $\overline{\overline{\chi}}_{\mathrm{ee}}(\rho), \overline{\overline{\chi}}_{\mathrm{mm}}(\rho), \overline{\overline{\chi}}_{\mathrm{em}}(\rho)$ and $\overline{\overline{\chi}}_{\mathrm{me}}(\rho)$ results, but will not guarantee that these results can be practically implemented using planar scattering elements. For instance, if the susceptibilities exhibit multiple spatial variations per wavelength, it may be difficult or impossible to realize. In such cases, one has to determine whether some features may be neglected or one may have to relax the design constraints (e.g., allow higher reflection or increase the metasurface dimensions).

The complete synthesis of a metasurface typically requires the additional step of determining the geometry of the scattering elements. This step is usually done using full-wave parametric analysis of judiciously selected scattering elements (Yu et al. 2011) or, under certain special conditions such as normal plane-wave incidence, using scattering elements with well-known electric and magnetic dipolar responses (Niemi et al. 2013). Since this second step involves scattering parameters, transformation formulas between susceptibilities and scattering parameters are provided to enable the complete synthesis of the metasurface.

Metasurface Boundary Conditions in Terms of Surface Susceptibility Tensors

A metasurface may be considered as an electromagnetic discontinuity in space. Conventional textbook electromagnetic boundary conditions do not apply to such a discontinuity, as was pointed out by Schelkunoff (1972), although they yield satisfactory results away from the discontinuities. Assuming an interface at $z = 0$, the conventional boundary conditions relate the fields at $z = 0^{\pm}$, but fail to describe the field behavior at the discontinuity itself ($z = 0$). This discrepancy is due to the fact that Stokes and Gauss theorems used to derive them assume field continuity in all the regions they apply to, including the

interface, whereas the fields may be discontinuous. For example, consider the conventional boundary condition for the normal component of the displacement vector D in the presence of surface charges ρ_s,

$$\hat{z} \cdot D|_{z=0^-}^{0^+} = \rho_s. \tag{50}$$

This relation is derived by applying Gauss theorem, $\int\int\int_V \nabla \cdot \mathbf{D} dV = \oiint_S \mathbf{D} \cdot \hat{\mathbf{n}} dS$, to a volume V enclosed by the surface S including the interface discontinuity with $\hat{\mathbf{n}}$ the normal unit vector to S. This theorem rigorously applies only if $\mathbf{D}$ is continuous inside the entire volume V, whereas in the case of a discontinuous $\mathbf{D}$, its projection onto S is not defined at the interface, and application of this theorem is not rigorously correct. Thus, since a metasurface may be modeled by Huygens sources (Pfeiffer and Grbic 2013), the correct field behavior on the metasurface cannot be determined using the conventional boundary conditions and rigorous boundary conditions, namely, GSTCs, must be applied. It should be noted that, from a physical perspective, a metasurface structure is not a single interface but rather a thin inhomogeneous slab and may be naturally treated as such. However, it is much simpler to treat the metasurface as a single interface using rigorous GSTCs, which is allowed by the fact that it is electromagnetically thin.

Rigorous GSTCs, treating discontinuities in the sense of distributions, were derived by Idemen (2011). The corresponding relations pertaining to this work were first applied by Kuester et al. to metasurfaces (Kuester et al. 2003). A detailed derivation is found in the appendix of Achouri et al. (2014), but the final form of the GSTC is expressed as

$$\hat{z} \times \Delta H = j\omega P_{\parallel} - \hat{z} \times \nabla_{\parallel} M_z, \tag{51a}$$

$$\Delta E \times \hat{z} = j\omega\mu M_{\parallel} - \nabla_{\parallel} \left(\frac{P_z}{\varepsilon} \right) \times \hat{z}, \tag{51b}$$

$$\hat{z} \cdot \Delta D = -\nabla \cdot P_{\parallel}, \tag{51c}$$

$$\hat{z} \cdot \Delta B = -\mu \nabla \cdot M_{\parallel}. \tag{51d}$$

In these relations, the terms in the left-hand sides represent the differences between the fields on the two sides of the metasurface, whose Cartesian components are defined as

$$\Delta \Psi_u = \hat{u} \cdot \Delta \Psi(\rho)|_{z=0^-}^{0^+} = \Psi_u^{\mathrm{t}} - \left(\Psi_u^{\mathrm{i}} + \Psi_u^{\mathrm{r}} \right),\ u = x, y, z, \tag{52}$$

where $\Psi(\rho)$ represents any of the fields H, E, D, or B; where the superscripts i, r, and t denote incident, reflected, and transmitted fields; and where P and M are the electric and magnetic surface polarization densities, respectively. In the most general case of a bi-anisotropic medium, these densities are related to the acting (or local) fields, E_{act} and H_{act}, by (Kong 1986; Lindell 1994)

$$P = \varepsilon N \langle \overline{\overline{\alpha}}_{\mathrm{ee}} \rangle E_{\mathrm{act}} + \varepsilon N \eta \langle \overline{\overline{\alpha}}_{\mathrm{em}} \rangle H_{\mathrm{act}}, \tag{53a}$$

$$M = N \langle \overline{\overline{\alpha}}_{\mathrm{mm}} \rangle H_{\mathrm{act}} + \frac{N}{\eta} \langle \overline{\overline{\alpha}}_{\mathrm{mm}} \rangle E_{\mathrm{act}}, \tag{53b}$$

DOI 10.1007/978-981-4560-75-7_8-1

where the $\langle \overline{\overline{\alpha}}_{ab} \rangle$ terms represent the averaged polarizabilities of a given scattering element, N is the number of scattering elements per unit area, and $\eta = \sqrt{\mu/\varepsilon}$. The acting fields are, by definition, the average fields on both sides of the surface taking into account the contributions of all the scattering elements (coupling effects) except that of the element being considered. The contribution of this element may be modeled by replacing it with a disk of radius R encompassing its electric and magnetic current dipoles. Kuester et al. express the fields of this disk as functions of the polarization densities P and M (Kuester et al. 2003), from which relations Eq. 53 can be rewritten as functions of the average fields. Their relations, with averaged polarizabilities replaced by surface susceptibilities for macroscopic description, read

$$P = \varepsilon \overline{\overline{\chi}}_{ee} \langle E \rangle + \varepsilon \overline{\overline{\chi}}_{em} \eta \langle H \rangle, \tag{54a}$$

$$M = \overline{\overline{\chi}}_{mm} \langle H \rangle \frac{+\overline{\overline{\chi}}_{me}}{\eta} \langle E \rangle, \tag{54b}$$

where the average fields are defined as

$$\langle \Psi_u \rangle = \hat{u} \cdot \langle \Psi \rangle(\rho) = \frac{\Psi_u^t + \left(\Psi_u^i + \Psi_u^r\right)}{2}, \; u = x, y, z, \tag{55}$$

where $\Psi(\rho)$ represents either H or E. The utilization of surface susceptibilities, which represent the actual macroscopic quantities of interest, allows for an easier description of the metasurface than element averaged polarizabilities and densities in Eq. 53.

The surface may be infinite or finite with dimensions $L_x \times L_y$. The two problems are automatically solved by specifying the fields Ψ_u^i, Ψ_u^r and Ψ_u^t in Eqs. 52 and 55 to be of infinite or finite $L_x \times L_y$ extent in the former and latter cases, respectively. In the finite case, truncation practically corresponds to placing a sheet of absorbing material around the metasurface. This operation neglects diffraction at the edges of the metasurface, as is safely allowed by the fact that a metasurface is generally electrically very large, but properly accounts for the finiteness of the aperture via the GSTCs (Eqs. 51a and 51b).

Synthesis Method

The proposed synthesis method solves the inverse problem depicted in Fig. 23, where the electromagnetic fields are specified everywhere (for all ρ) in the $z = 0$ plane on both sides of the metasurface and the properties of the metasurface are the unknowns to be determined. It is required to specifically find the surface susceptibilities that transform specified incident waves into specified transmitted and reflected waves. The method essentially consists in solving Eq. 51 for the components of the susceptibility tensors in Eq. 54.

The last terms in Eqs. 51a and in 51b involve the transverse derivatives of the normal components of the polarization densities, namely, $\nabla_{||} M_z$ and $\nabla_{||} P_z$. Solving the inverse problem for nonzero M_z and/or P_z would be quite involved since this would require solving the set of coupled non-homogenous partial differential equations formed by Eqs. 51a and 51b with nonzero $\nabla_{||} M_z$ and $\nabla_{||} P_z$. Although such a problem could be generally addressed by means of numerical analysis, the condition $P_z = M_z = 0$ is enforced, which will lead to convenient closed-form solutions for the susceptibilities. This restriction may limit the physical realizability of the metasurface in some cases, in the sense that the corresponding synthesized susceptibilities might be excessively difficult to realize with practical scattering elements. In such cases, the restriction might be removed without changing the main spirit of the method but at the cost of losing the closed-form nature of the solution. As shall be seen next, this restriction still allows the metasurface to

DOI 10.1007/978-981-4560-75-7_8-1

realize a large number of operations, given the large number of degrees of freedom provided by combinations of its bi-anisotropic susceptibility tensor components.

The method needs considering only Eqs. 51a and 51b as these two equations involve all the transverse field components, which is sufficient to completely describe the fields at each side of the metasurface according to the uniqueness theorem. These two equations, with $P_z = M_z = 0$, represent a set a four linear equations relating the transverse electric and magnetic fields to the effective surface susceptibilities. Thus, the solution of the inverse problem will consist in determining four transverse effective susceptibility tensors in Eq. 54.

Using the notation in Eqs. 52, 55, 51b, and 51a are rearranged to read

$$\begin{pmatrix} -\Delta H_y \\ \Delta H_x \end{pmatrix} = j\omega\varepsilon \begin{pmatrix} \chi_{\mathrm{ee}}^{xx} & \chi_{\mathrm{ee}}^{xy} \\ \chi_{\mathrm{ee}}^{yx} & \chi_{\mathrm{ee}}^{yy} \end{pmatrix} \begin{pmatrix} \langle E_{\mathrm{x}} \rangle \\ \langle E_{\mathrm{y}} \rangle \end{pmatrix} + j\omega\varepsilon\eta \begin{pmatrix} \chi_{\mathrm{em}}^{xx} & \chi_{\mathrm{em}}^{xy} \\ \chi_{\mathrm{em}}^{yx} & \chi_{\mathrm{em}}^{yy} \end{pmatrix} \begin{pmatrix} \langle H_{\mathrm{x}} \rangle \\ \langle H_{\mathrm{y}} \rangle \end{pmatrix}, \tag{56a}$$

$$\begin{pmatrix} \Delta E_y \\ -\Delta E_x \end{pmatrix} = j\omega\mu \begin{pmatrix} \chi_{\mathrm{mm}}^{xx} & \chi_{\mathrm{mm}}^{xy} \\ \chi_{\mathrm{mm}}^{yx} & \chi_{\mathrm{mm}}^{yy} \end{pmatrix} \begin{pmatrix} \langle H_x \rangle \\ \langle H_y \rangle \end{pmatrix} + \frac{j\omega\mu}{\eta} \begin{pmatrix} \chi_{\mathrm{me}}^{xx} & \chi_{\mathrm{me}}^{xy} \\ \chi_{\mathrm{me}}^{yx} & \chi_{\mathrm{me}}^{yy} \end{pmatrix} \begin{pmatrix} \langle E_x \rangle \\ \langle E_y \rangle \end{pmatrix}. \tag{56b}$$

Assuming single incident, reflected, and transmitted waves (only one wave of each of the three types), the system (Eq. 56) contains four equations for a total number of sixteen unknown susceptibility components. It is thus underdetermined as such, and it can be solved only by restricting the number of independent susceptibilities to four. This single-transformation underdetermination of Eq. 56 reveals two important facts: the first is that there exist many different combinations of susceptibilities that produce the same fields and second that a single metasurface has the fundamental capability to simultaneously manipulate several linearly independent incident, reflected, and transmitted waves. Specifically, a metasurface, as defined by Eq. 56b, can in principle manipulate up to four sets of incident, reflected, and transmitted waves (Achouri et al. 2014).

Two approaches may be considered to reduce the number of independent unknown susceptibilities. A first approach could consist in using more than four susceptibilities but enforcing relationships between some of them to ensure a maximum of four independent unknowns. For example, the conditions of reciprocity and losslessness would be a possible way to link some susceptibilities together, if this is compatible with design specifications. According to Kong (1986) and Lindell (1994), the conditions for reciprocity are

$$\overline{\overline{\chi}}_{\mathrm{ee}}^{\mathrm{T}} = \overline{\overline{\chi}}_{\mathrm{ee}}, \overline{\overline{\chi}}_{\mathrm{mm}}^{\mathrm{T}} = \overline{\overline{\chi}}_{\mathrm{mm}}, \overline{\overline{\chi}}_{\mathrm{me}}^{\mathrm{T}} = -\overline{\overline{\chi}}_{\mathrm{em}}, \tag{57}$$

and the conditions for losslessness are

$$\overline{\overline{\chi}}_{\mathrm{ee}}^{\mathrm{T}} = \overline{\overline{\chi}}_{\mathrm{ee}}^{*}, \overline{\overline{\chi}}_{\mathrm{mm}}^{\mathrm{T}} = \overline{\overline{\chi}}_{\mathrm{mm}}^{*}, \overline{\overline{\chi}}_{\mathrm{me}}^{\mathrm{T}} = \overline{\overline{\chi}}_{\mathrm{em}}^{*}, \tag{58}$$

where the superscripts T and * denote the matrix transpose and complex conjugate operations, respectively. Enforcing conditions between susceptibilities also enforces conditions on the fields on both sides of the metasurface. Therefore, this approach restricts the diversity of electromagnetic transformations achievable with the metasurface.

A second approach provides a more general synthesis method for quasi-arbitrary electromagnetic transformations. This approach consists in selecting only one susceptibility tensor component in each of the four equations included in Eq. 56. The number of possible combinations is huge; thus, the analysis here is limited to solutions for a single transformation by eliminating a number of susceptibility components from Eq. 56.

DOI 10.1007/978-981-4560-75-7_8-1

Single-Transformation Metasurface

The problem of single transformation with only one specified wave triplet is considered: (Ψ^{i}, Ψ^{r}, Ψ^{t}) for a mono-anisotropic $\left(\overline{\overline{\chi}}_{\mathrm{em}} \equiv \overline{\overline{\chi}}_{\mathrm{me}} = 0\right)$ and uniaxial $\left(\chi_{\mathrm{ee}}^{xy} \equiv \chi_{\mathrm{ee}}^{yx} \equiv \chi_{\mathrm{mm}}^{xy} \equiv \chi_{\mathrm{mm}}^{yx} = 0\right)$ and, hence, non-gyrotropic and reciprocal, metasurface. Solving Eq. 56 under these conditions yields the following simple relations for the remaining four susceptibilities:

$$\begin{aligned}
\chi_{\mathrm{ee}}^{xx} &= \frac{-\Delta H_y}{j\omega\varepsilon\langle E_x\rangle}, \\
\chi_{\mathrm{ee}}^{yy} &= \frac{\Delta H_x}{j\omega\varepsilon\langle E_y\rangle}, \\
\chi_{\mathrm{mm}}^{xx} &= \frac{\Delta E_y}{j\omega\mu\langle H_x\rangle}, \\
\chi_{\mathrm{mm}}^{yy} &= \frac{-\Delta E_x}{j\omega\mu\langle H_y\rangle},
\end{aligned} \tag{59}$$

where, according to Eqs. 52 and 55, $\Delta H_y = H_y^t - \left(H_y^i + H_y^{\mathrm{r}}\right)$, $\langle E_x\rangle = \frac{E_x^{\mathrm{t}} + \left(E_x^{\mathrm{i}} + E_x^{\mathrm{r}}\right)}{2}$ and so on.

By synthesis, a metasurface with the susceptibilities given by Eq. 59 will produce exactly the specified reflected and transmitted transverse components of the fields when the metasurface is illuminated by the specified incident field. Since the longitudinal fields are completely determined from the transverse components, according to the uniqueness theorem, the complete specified electromagnetic fields are exactly generated by the metasurface.

Consistency with Maxwell equations can be easily verified. Consider, for instance, Eq. 51c along with the relation $D = \varepsilon E + P$,

$$\begin{aligned}
D_z\big|_{z=0^-}^{0^+} &= \varepsilon E_z\big|_{z=0^-}^{0^+} + P_z = \varepsilon\Delta E_z + P_z \\
&= -\nabla\cdot P_\perp .
\end{aligned} \tag{60}$$

Substituting in this relation the relations Eq. 54 for $P_\perp$ and remembering the assumption that $P_z = 0$,

$$\Delta E_z = -\frac{\partial}{\partial x}\left(\chi_{\mathrm{ee}}^{xx}\langle E_x\rangle\right) - \frac{\partial}{\partial y}\left(\chi_{\mathrm{ee}}^{yy}\langle E_y\rangle\right), \tag{61}$$

which upon substitution of Eq. 59 reads

$$\begin{aligned}
\Delta E_z &= E_z^{\mathrm{t}} - E_z^{\mathrm{i}} - E_z^{\mathrm{r}} \\
&= \frac{j}{\omega\varepsilon}\left[\frac{\partial}{\partial y}\left(H_x^{\mathrm{t}} - H_x^{\mathrm{i}} - H_x^{\mathrm{r}}\right) - \frac{\partial}{\partial x}\left(H_y^{\mathrm{t}} - H_y^{\mathrm{i}} - H_y^{\mathrm{r}}\right)\right].
\end{aligned} \tag{62}$$

This equation represents a relation between linear combinations of the longitudinal electric fields and derivatives of the transverse magnetic fields of the incident (k = i), reflected (k = r), and transmitted (k = t) waves. From linearity, and subsequent superposition, these equations may be decomposed as

$$E_z^{\mathrm{k}} = \frac{j}{\omega\varepsilon}\left(\frac{\partial H_x^{\mathrm{k}}}{\partial y} - \frac{\partial H_y^{\mathrm{k}}}{\partial x}\right) = \frac{j}{\omega\varepsilon}\left(\nabla_t \times H^{\mathrm{k}}\right)_z, \tag{63}$$

which is nothing but the projection of Maxwell-Ampère equation upon the z-direction. This shows that the longitudinal fields are well defined with the relations Eq. 59 in accordance with the uniqueness theorem.

To establish the relationship linking the transmitted field to the incident field and the susceptibilities, the case of a reflectionless metasurface is considered. Inserting Eqs. 52 and 55 with $\Psi_u^{\mathrm{r}} = 0$ ($u = x, y$) into Eq. 59 and solving for the transmitted components of the fields yields

$$E_x^{\mathrm{t}} = -E_x^{\mathrm{i}} + \frac{8E_x^{\mathrm{i}} - j4\chi_{\mathrm{mm}}^{yy}\mu\omega H_y^{\mathrm{i}}}{4 + \chi_{\mathrm{ee}}^{xx}\chi_{\mathrm{mm}}^{yy}\varepsilon\mu\omega^2}, \tag{64a}$$

$$E_y^{\mathrm{t}} = -E_y^{\mathrm{i}} + \frac{8E_y^{\mathrm{i}} - j4\chi_{\mathrm{mm}}^{xx}\mu\omega H_x^{\mathrm{i}}}{4 + \chi_{\mathrm{mm}}^{xx}\chi_{\mathrm{ee}}^{yy}\varepsilon\mu\omega^2}, \tag{64b}$$

$$H_x^{\mathrm{t}} = -H_x^{\mathrm{i}} + \frac{8H_x^{\mathrm{i}} + j4\chi_{\mathrm{ee}}^{yy}\varepsilon\omega E_y^{\mathrm{i}}}{4 + \chi_{\mathrm{mm}}^{xx}\chi_{\mathrm{ee}}^{yy}\varepsilon\mu\omega^2}, \tag{64c}$$

$$H_y^{\mathrm{t}} = -H_y^{\mathrm{i}} + \frac{8H_y^{\mathrm{i}} - j4\chi_{\mathrm{ee}}^{yy}\varepsilon\omega E_x^{\mathrm{i}}}{4 + \chi_{\mathrm{ee}}^{xx}\chi_{\mathrm{mm}}^{yy}\varepsilon\mu\omega^2}. \tag{64d}$$

These relations show how each of the transmitted field components depends on their incident field counterparts and orthogonal duals, e.g., $E_x^{\mathrm{t}} = E_x^{\mathrm{t}}\left(E_x^{\mathrm{i}}, H_y^{\mathrm{i}}\right)$, etc. They have to be considered after the susceptibilities Eq. 59 have been synthesized for given specifications to determine whether they may be realized by a passive metasurface ($|E^{\mathrm{t}}| \leq |E^{\mathrm{i}}|$ and $|H^{\mathrm{t}}| \leq |H^{\mathrm{i}}|$) or require active elements.

The susceptibilities in Eq. 59 represent the synthesis (inverse problem) results of the proposed method, while Eq. 64 expresses the transmitted field components in terms of these susceptibilities (direct problem). Next, the relationships existing between the susceptibilities and the scattering parameters are established in order to enable the second step of the synthesis.

In the plane-wave approximation, which is naturally valid when the source of the incident wave is far enough from the metasurface, the response of each scattering element may be expressed in terms of its reflection and transmission coefficients (Pfeiffer and Grbic 2013; Asadchy and Fanyaev 2011; Asadchy et al. 2014). Since according to Eq. 64, the pairs (E_x^{t}, H_y^{t}) and (E_y^{t}, H_x^{t}) are proportional to their incident counterparts and orthogonal duals only, the problem splits into an x-polarized incident plane-wave problem and a y-polarized incident plane-wave problem, whose fields at normal incidence are, respectively, given by

$$E^{\mathrm{i}} = \hat{x}, \quad E^{\mathrm{r}} = R_x\hat{x}, \quad E^{\mathrm{t}} = T_x\hat{x}, \tag{65a}$$

$$H^{\mathrm{i}} = \frac{1}{\eta}\hat{y}, \quad H^{\mathrm{r}} = -\frac{R_x}{\eta}\hat{y}, \quad H^{\mathrm{t}} = \frac{T_x}{\eta}\hat{y}, \tag{65b}$$

and

$$E^{\mathrm{i}} = \hat{y}, \quad E^{\mathrm{r}} = R_y\hat{y}, \quad E^{\mathrm{t}} = T_y\hat{y}, \tag{66a}$$

DOI 10.1007/978-981-4560-75-7_8-1

$$H^{\mathrm{i}} = -\frac{1}{\eta}\hat{x}, \quad H^{\mathrm{r}} = \frac{R_y}{\eta}\hat{x}, \quad H^{\mathrm{t}} = \frac{T_y}{\eta}\hat{x}, \tag{66b}$$

where R_u and $T_u (u = x, y)$ represent reflection and transmission coefficients, respectively. The waves in Eqs. 65 and 66 are defined as rectilinear (i.e., they do not change direction at the metasurface) for consistency with periodic boundary conditions to be used in full-wave simulations for the second step of the synthesis. Inserting Eqs. 65 and 66 into Eq. 56 with the four nonzero susceptibilities given in Eq. 59 yields the transmission and reflection coefficients

$$T_x = \frac{4 + \chi_{\mathrm{ee}}^{xx}\chi_{\mathrm{mm}}^{yy}k^2}{\left(2 + jk\chi_{\mathrm{ee}}^{xx}\right)\left(2 + jk\chi_{\mathrm{mm}}^{yy}\right)}, \tag{67a}$$

$$R_x = \frac{2jk\left(\chi_{\mathrm{mm}}^{yy} - \chi_{\mathrm{ee}}^{xx}\right)}{\left(2 + jk\chi_{\mathrm{ee}}^{xx}\right)\left(2 + jk\chi_{\mathrm{mm}}^{yy}\right)} \tag{67b}$$

and

$$T_y = \frac{4 + \chi_{\mathrm{ee}}^{yy}\chi_{\mathrm{mm}}^{xx}k^2}{\left(2 + jk\chi_{\mathrm{ee}}^{yy}\right)\left(2 + jk\chi_{\mathrm{mm}}^{xx}\right)}, \tag{68a}$$

$$R_y = \frac{2jk\left(\chi_{\mathrm{mm}}^{xx} - \chi_{\mathrm{ee}}^{yy}\right)}{\left(2 + jk\chi_{\mathrm{ee}}^{yy}\right)\left(2 + jk\chi_{\mathrm{mm}}^{xx}\right)}, \tag{68b}$$

These relations may be used in the second step of the synthesis to determine the scattering parameters corresponding to the synthesized susceptibilities. Solving Eqs. 67 and 68 for the susceptibilities yields

$$\chi_{\mathrm{ee}}^{xx} = \frac{2j(T_x + R_x - 1)}{k(T_x + R_x + 1)}, \tag{69a}$$

$$\chi_{\mathrm{ee}}^{yy} = \frac{2j\left(T_y + R_y - 1\right)}{k\left(T_y + R_y + 1\right)}, \tag{69b}$$

$$\chi_{\mathrm{mm}}^{xx} = \frac{2j\left(T_y - R_y - 1\right)}{k\left(T_y - R_y + 1\right)}, \tag{69c}$$

$$\chi_{\mathrm{mm}}^{yy} = \frac{2j(T_x - R_x - 1)}{k(T_x - R_x + 1)}. \tag{69d}$$

In Eq. 68 and 69, the reflection and transmission coefficients are associated with scattering parameters S_{pq} with $p, q = 1, \ldots, 4$ accounting for the two ports (incident and transmitted waves) and two polarization (x and y). Specifically, assigning ports 1, 2, 3, and 4 to x-polarized input, y-polarized input, x-polarized output, and y-polarized output, respectively, one has $R_x = S_{11}$, $T_x = S_{31}$, $R_y = S_{22}$, and $T_y = S_{42}$, while the other 12 scattering parameters are not required since the chosen tensors are uniaxial so that the metasurface is not gyrotropic (i.e., does not involve transformations between x-polarized and y-polarized waves).

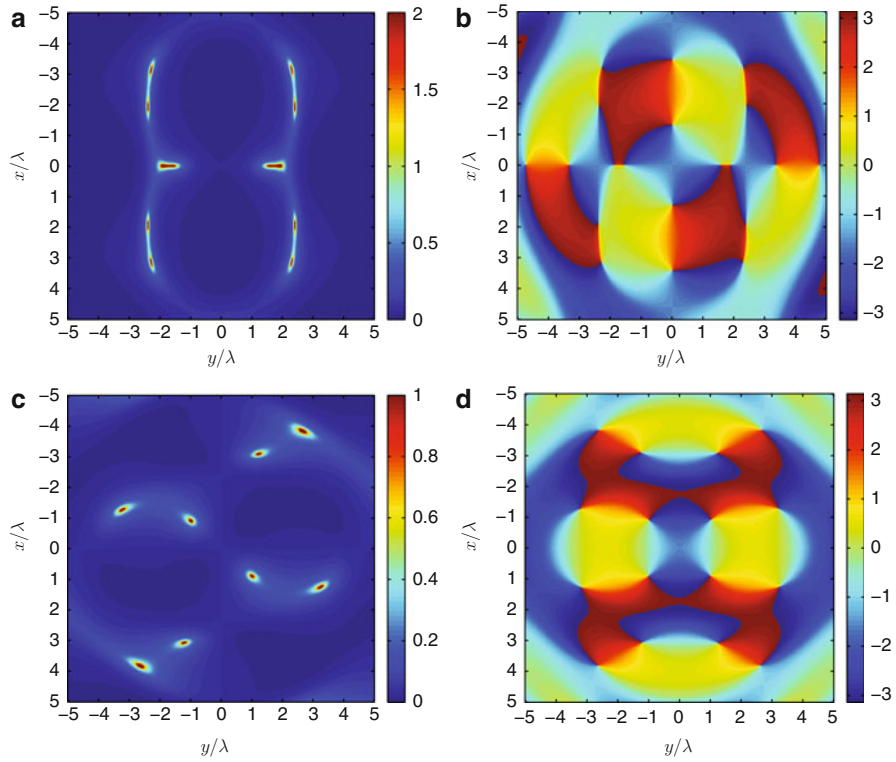

Fig. 24 Plot of the (**a**) magnitude and (**b**) phase of χ_{ee}^{xx} and (**c**) magnitude and (**d**) phase of χ_{ee}^{yy} for transformation of a normally incident plane wave into a normally transmitted Bessel of order $m = 3$ (Reprinted from Achouri et al. (2014) with permission)

Bessel Beam Transformation

The fundamental metasurface transformation relations are established, and one may thus use this synthesis technique to transform a normally incident plane wave into a normally transmitted Bessel beam. For diversity purpose, it is required to transmit a Bessel beam of order $m = 3$; such higher-order beams carry orbital angular momentum and may thus be used for various application, such as communication and particle manipulation.

Assuming the metasurface is located at $z = 0$, the incident plane-wave field reads

$$\begin{aligned} E^{\mathrm{i}}(x,y) &= (\hat{x}+\hat{y})\frac{\sqrt{2}}{2}, \\ H^{\mathrm{i}}(x,y) &= (\hat{y}-\hat{x})\frac{\sqrt{2}}{2\eta}, \end{aligned} \tag{70}$$

and the transmitted Bessel beam is assumed to be TE and is directly found from Eqs. 21 to 22 with $m = 3$. The amplitude of the Bessel beam is chosen such that the Poynting vectors $\left(S = \frac{1}{2}\mathrm{Re}\{E \times H^{*}\}\right)$ of the incident and transmitted fields are equal over the area of the metasurface (here, the surface is assumed to be $10\lambda \times 10\lambda$ in size), namely, $\int\int_S \mathrm{Re}\{E^{\mathrm{i}} \times H^{\mathrm{i}*}\}dS = \int\int_S \mathrm{Re}\{E^{\mathrm{t}} \times H^{\mathrm{t}*}\}dS$. This ensures that the power is conserved at the interface and, hence, that the metasurface is passive. The susceptibilities are found in a straightforward fashion by substituting the expressions of the incident and transmitted fields into Eq. 59 and χ_{ee}^{xx} and χ_{ee}^{yy} are plotted in Fig. 24. One notes here that the x- and y-components of the Bessel beam electromagnetic field are nonzero. Therefore, the incident fields must have electric and magnetic

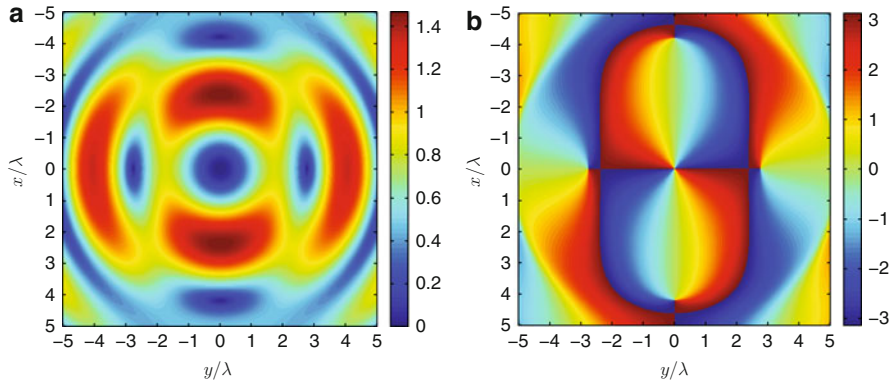

Fig. 25 Plot of the (**a**) magnitude and (**b**) phase of T_x for the Bessel beam transformation synthesis as depicted in Fig. 24 (Reprinted from Achouri et al. (2014) with permission)

components along both the x- and y-directions, as chosen in Eq. 70. In other words, the incident field must be properly polarized with respect to the prescribed transmitted wave.

Figure 25 plots the x-components of the transmission parameter. The y-components (not shown) are similar to the x-components and rotated by 90° with respect to them.

Summary of the Technique

A metasurface synthesis method based on transverse susceptibility tensors has been employed to transform an incident plane wave into a Bessel beam. The technique provides closed-form expressions for selected electric and magnetic susceptibility components required for the transformation. This synthesis method is essentially theoretical at this stage, and the physical scattering elements that would correspond to the synthesized ideal susceptibilities might be, in some cases, practically difficult or even impossible to realize. However, even in relatively extreme cases, typically corresponding to fast susceptibility variations in comparison with the wavelength, the proposed synthesis might be used as an initial and insightful step of the complete synthesis. Further discussion on this synthesis method is found in Achouri et al. (2014).

Conclusion

The early work of Brittingham on "focus wave modes" has stimulated much interest since it was first published in 1983. The possibility of generating beams and pulses with unprecedented properties and propagation characteristics has inspired many fundamental and applied researches and resulted in a deeper understanding on the mathematical, physical, and engineering aspects of LWs.

In this chapter, light has been shed on part of the historical development of LWs. A unified framework has been established to understand the physics of LWs via the spectral structure of PIBs. Finally, some of the state-of-the-art engineering techniques that could be applied to generate LWs have been unveiled.

Since the fundamental properties of LWs are now well understood, research has moved from the mathematical concepts into real applications, especially in the areas where LWs have an advantage over other waveforms, such as communication, manipulation of microparticles, remote sensing, and biophotonics. The future use of such wave fields seems very promising though more research is needed to establish innovative and practical techniques to generate and manipulate them.

Maxwell's Original Presentation of Electromagnetic Theory and Its Evolution

Tapan K. Sarkar[a]* and Magdalena Salazar-Palma[b]
[a]Department of Electrical Engineering and Computer Science, Syracuse University, Syracuse, NY, USA
[b]Department of Signal Theory & Communications, Universidad Carlos III de Madrid, Leganés, Madrid, Spain

Abstract

One of the objectives of this presentation is to illustrate how Maxwell came to his mathematical constructs of the work done before him by Oersted, Ampère, Faraday, Gauss, and so on, into a concise and precise mathematical form. In addition, the chapter addresses two specific topics which are fundamental in engineering electromagnetic education: how did Maxwell reached the conclusion that light was electromagnetic in nature and thereby revolutionized the last-century physics and the concept of displacement current? Maxwell first published his famous equations 20 in number in the early 1860s, and yet they were not accepted by the scientific community and were not put in the proper form till the early 1880s. The question is why it took over 20 years for the scientific community to grasp Maxwell's ideas. One of the reasons why Maxwell's theory was so difficult to follow was due to the development of Maxwell's thought process through different times. This made Maxwell not to identify his physical pictures with reality. Maxwell felt free to discard one picture and adopt another as often as expediency or convenience demanded. Maxwell's theory over the years evolved in two different steps. That is the other subject matter of this chapter.

Maxwell never believed that light could be generated electromagnetically. In fact, he was always silent about electromagnetic waves and their generation and detection. It took almost 25 years before Hertz discovered electromagnetic waves, and his ingenious experiments confirmed Maxwell's theory. Maxwell's ideas and equations were expanded, modified, and made understandable by the efforts of Hertz, FitzGerald, Lodge, and Heaviside. The last three are being referred to as the "Maxwellians." The early history of electromagnetic waves, up to the death of Hertz in 1894, is briefly discussed. The work of Hertz and the Maxwellians is briefly reviewed in the context of electromagnetic waves. It is found that historical facts do not support the views proposed by some, in the past, that Hertz's epoch-making findings and contributions were "significantly influenced by the Maxwellians." Finally, Maxwell's macroscopic theory was transformed to the microscopic theory based on electrons as its discovery came 18 years after Maxwell's death.

Introduction

The name of James Clerk Maxwell is synonymous with electromagnetics and electromagnetic waves. In this chapter, an attempt is made to describe what actually Maxwell did to come to the conclusion that light was electromagnetic in nature which revolutionized last-century physics. The bottom line is how Maxwell did actually make the connection between electricity and optics and magnetics and optics, as the connection between electricity and magnetism was already known at that time due to the works of Michael Faraday. However, it is also imperative to point out that what Maxwell presented as his theory in the 1800s and what is presented today are totally different even though some of the equations have remained the same over this long period. Maxwell did not reach the conclusion that light was electromagnetic in nature from the four equations that is presented in the various books today. To start with, Maxwell did not even write the four equations that bear his name in current time, but rather 20 in number starting with the potentials and not from the sources of currents and charges that are used today. It is important to remember the discovery of electron was made much later. Secondly, Maxwell's conclusion that revolutionized modern physics that light was electromagnetic in nature was based primarily on dimensional analysis, and he arrived to that conclusion long before he wrote his 20 equations. In addition, Maxwell could not have solved those 20 equations as he did not have the proper boundary conditions. Also, even though Maxwell introduced the concept of displacement current, he gave it up as quickly and yet in modern days textbooks have retained that terminology even after 150 years! Hence, it is difficult to present the historical development in a way that flows smoothly and easy to understand. Another factor that makes this presentation on this historical aspect difficult to present is that the genius of Maxwell was that he would start on a subject, work for a few years, give a gap of few years, and then restart it from a different viewpoint than when he left off as his thinking in the meantime has progressed along a different line of thought and he had reached a different conclusion than what he had started with. He would take the development of the subject to a new height in that new phase restarting after a gap in time with the old theory. He did that thrice with electromagnetic theory, and at each phase his way of thinking was quite different. This makes it difficult to follow what Maxwell had in his mind unless the context and the time are specified. It is to be recognized that there was a difference of about 20 years between Maxwell first writing the 20 equations and their modifications by Heinrich Hertz and Oliver Heaviside, reducing them to the scalar and vector versions, respectively, of the four equations that we use today. Since Maxwell never identified his physical pictures with reality, his theory was very difficult and sometimes even impossible to follow. This is because Maxwell left himself free to discard one picture and adopt another as often as expediency or convenience demanded. He described his method in the following words as written in the preface of his *Treatise* (Maxwell 1881):

> In the application of mathematics to the calculation of electrical quantities, I shall endeavour in the first place to deduce the most general conclusions from the data at our disposal, and in the next place to apply the results to the simplest cases that can be chosen. I shall avoid, as much as I can, those questions which, though they have elicited the skill of mathematicians, have not enlarged our knowledge of science. If we adopt a physical hypothesis, we see the phenomenon only through a medium, and are liable to that blindness to facts and rashness in assumption which a partial explanation encourages. We must therefore discover some method of investigation which allows the mind at every step to lay hold of a clear physical conception, without being committed to any theory founded on physical science for which that conception is borrowed.

Hence, unless the discussion of a particular topic is linked with Maxwell's thought process in that particular phase of the development of his theory, it is difficult to comprehend and even follow Maxwell's line of thinking (Sarkar et al. 2006, 2009; Sengupta and Sarkar 2003). So, with this introduction, an effort is made to recall the history.

Prologue

As the English physicist and mathematician Sir James Hopwood Jeans (1877–1946) Glazebrook (1896) pointed out:

> In his hands electricity first became a mathematically exact science and the same might be said of other larger parts of Physics. In whatever area he worked, he brought new innovation.

For example, as Sir John Ambrose Fleming wrote (Commemorative Volume 1931, p. 118):

> In electricity course, he gave us a new and powerful method of dealing with problems in networks and linear conductors. Kirchhoff's corollaries of Ohm's Law had provided a means only applicable in the case of simple problems in which one could foresee the direction of flow of current in each conductor. But that was not possible in complicated networks. Maxwell initiated a new method by considering the actual current in each wire to be the difference of two imaginary currents circulating in the same direction round each mesh of the network. In this way, the difficulty of foreseeing the direction of the real current was eliminated. The solution of the problem was then reduced to the solution of a set of linear equations and the current in any wire could be expressed as the quotient of two determinants. After Maxwell's death, in 1885 I communicated a paper to the Physical Society of London in which the method was extended so as to give an expression for the electrical resistance of any network between any two points.

One would immediately recognize this as a method for writing the loop equations that is currently available in all undergraduate electrical engineering textbooks dealing with electrical circuits, and yet no mention is made of Maxwell, the inventor of this technique! The point here is that Kirchhoff no doubt wrote the theorems on the loop and the node equations but did not provide a methodology on how to solve for them in an arbitrary circuit. That job was completed by Maxwell.

In 1871, Maxwell showed how a circuit containing both capacitance and inductance would respond when connected to generators containing alternating currents of different frequencies. Maxwell thus developed the phenomenon of electrical resonance in parallel to acoustic resonance first presented by Sir John William Strutt, Lord Rayleigh, and Maxwell also suggested naming Rayleigh's book on acoustics *The Theory of Sound*. Maxwell developed the electrical analog for the phenomenon of resonance when reviewing Rayleigh's paper *On Progressive Waves* (Harman 2002c, pp. 547–549) and wrote about it to Rayleigh (Harman 2002b, pp. 598–608). Maxwell provided a simpler mathematical expression for the wave velocity and group velocity than what was described by Rayleigh.

Maxwell developed a coherent set of units of measurement of electricity and magnetism in 1863. They were later adopted almost unchanged as the first internationally accepted system of units, which became known misleadingly as the Gaussian system, which is a combination of the electrostatic units and the electromagnetic units. Maxwell also introduced the M, L, and T notation in dimensional analysis in physics which is used currently, and yet nobody wonders who first thought about it. He also produced the first standard of electrical resistance in 1868. When creating his standard for electrical resistance, he wanted to design a governor to keep a coil spinning at a constant rate. He made the system stable by using the idea of negative feedback. He worked out the conditions of stability under various feedback arrangements in terms of the poles and zeros of the system. This was the first mathematical analysis of control systems (Maxwell 1881). This work did not get any attention till 1940, when gun control radars were in demand during the Second World War. After the war, the American mathematician Norbert Wiener (1894–1964) took things further and developed the science of cybernetics, based on his paper *On Governors* in 1868 (Sarkar et al. 2006, 2009).

With this background, it is now possible to discuss Maxwell's work on electromagnetic theory and outline his innovations at each phase of his work.

First Phase of Maxwell's Work on Electromagnetics

During the first phase of his work on electromagnetic theory, Maxwell thought about the following framework while he was in between jobs and before accepting a position at King's College. During this initial phase, Maxwell wrote down the following aspects of his development of electromagnetic theory. He tried to translate the experiments carried out by Faraday to suitable mathematical forms. As Maxwell wrote (Maxwell 1881):

> Before I began the study of electricity I resolved to read no mathematics on the subject till I had first read through Faraday's Experimental Researches on Electricity. I was aware that there was supposed to be a difference between Faraday's way of conceiving phenomena and that of the mathematicians, so that neither he nor they were satisfied with each other's language. I had also the conviction that this discrepancy did not arise from either party being wrong. As I proceeded with the study of Faraday, I perceived that his method of conceiving the phenomena was also a mathematical one, though not exhibited in the conventional form of mathematical symbols. I also found that these methods were capable of being expressed in the ordinary mathematical forms, and thus compared with those of the professed mathematicians. For instance, Faraday, in his mind's eye, saw lines of force traversing all space where the mathematicians saw centres of force attracting at a distance; Faraday saw a medium where they saw nothing but distance. Faraday sought the seat of the phenomena in real actions going on in the medium, they were satisfied that they had found it in a power of action at a distance impressed on the electric fluids. When I had translated what I considered to be Faraday's ideas into a mathematical form, I found that in general the results of the two methods coincided, so that the same phenomena were accounted for, and the same laws of action deduced by both methods, but that Faraday's methods resembled those in which we begin with the whole and arrive at the parts by analysis, while the ordinary mathematical methods were founded on the principle of beginning with the parts and building up the whole by synthesis. I also found that several of the most fertile methods of research discovered by the mathematicians could be expressed much better in terms of ideas derived from Faraday than in their original form. The whole theory, for instance, of the potential, considered as a quantity which satisfies a certain partial differential equation, belongs essentially to the method which I have called that of Faraday. According to the other method, the potential, if it is to be considered at all, must be regarded as the result of a summation of the electrified particles divided each by its distance from a given point. Hence many of the mathematical discoveries of Laplace, Poisson, Green and Gauss find their proper place in this treatise, and their appropriate expression in terms of conceptions mainly derived from Faraday.
>
> I shall endeavour to place in as clear a light as I can the relations between the mathematical form of this theory and that of the fundamental science of Dynamics, in order that we may be in some degree prepared to determine the kind of dynamical phenomena among which we are to look for illustrations or explanations of the electromagnetic phenomena. There is also a considerable mass of mathematical memoirs which are of great importance in electrical science, but they lie concealed in the bulky Transactions of learned societies; they do not form a connected system; they are of very unequal merit, and they are for the most part beyond the comprehension of any but professed mathematicians. I have therefore thought that a treatise would be useful which should have for its principal object to take up the whole subject in a methodical manner, and which should also indicate how each part of the subject is brought within the reach of methods of verification by actual measurement.

At this point, it is interesting to note that neither Michael Faraday nor Oliver Heaviside went to college for a formal education! This implies that the major contributions in the development of various concepts in electromagnetics were rather intuitive and were not carried out by an individual engrained in the contemporary mathematical sciences, and perhaps that is why new revolutionary developments were possible by Maxwell as he tried to put all these intuitive concepts into a consistent mathematical framework.

In 1855, Maxwell published the first part of his paper *On Faraday's Lines of Force* (Harman 2002a, pp. 337–375, Niven 1890a, pp. 155–229), where he used fluid flow as an analogy for lines of force shaped in his exposition based on physical geometry. His objective was to find a physical analogy which would help the mind to grasp the results of previous investigations without being committed to any theory founded on the physical science from which that conception is borrowed so that it is neither drawn aside from the subject in the pursuit of analytical subtleties nor carried beyond the truth by a favorite hypothesis.

DOI 10.1007/978-981-4560-75-7_12-1

The laws of electricity were compared with the properties of an incompressible fluid, the motion of which was retarded by a force proportional to the velocity, and the fluid was supposed to possess no inertia. The geometrical relations between lines and surfaces were crucial elements in Maxwell's field theory of electricity and magnetism, where the use of vectors, integral theorems, and topology became central to his mathematical method (Harman 2002a, pp. 14). Here, Maxwell introduced the concept of image theory for efficient calculation of the fields. Maxwell provided the mathematical basis of the theory of electric images which was earlier developed by Sir William Thomson (better known as Lord Kelvin) to illustrate that equivalent fields can be obtained from them (Maxwell 1881, pp. 226–227). He applied his analogy to the theory of electrostatics, dielectrics, paramagnetism, and diamagnetism, to Michael Faraday's ideas of magnetic properties of crystalline materials, and to electric currents. The second part of his paper proposed a theory based on his distinction between electric and magnetic quantities (acting through surfaces) and intensities acting along lines (Harman 2002a, pp. 15 & 371). Maxwell, thus, proceeded to consider the phenomenon of electromagnetism and showed how the laws discovered by André-Marie Ampère lead to conclusions identical to those of Faraday.

In 1861 Maxwell published the first two parts (Niven 1890a, pp. 451–488) of his paper *On Physical Lines of Force* and parts 3 and 4 (Niven 1890b, pp. 489–513) the following year. In the first part, he addressed that in all phenomena involving attractions or repulsions, or forces depending on the relative position of the bodies, he determined the magnitude and direction of the force which would act on a given body, if placed in a given position. The second part dealt with the question: Is there any mechanical hypothesis as to the condition of the medium indicated by lines of force, by which the observed resultant forces may be accounted for? What is the mechanical cause of this difference of pressures produced by the lines of force?

In the third part of the paper, Maxwell himself says:

> I showed how the forces acting between magnets, electric currents, and matter capable of magnetic induction may be accounted for on the hypothesis of the magnetic field being occupied with innumerable vortices of revolving matter, their areas coinciding with the direction of the magnetic force at every point of the field. The centrifugal force of these vortices produces pressures distributed in such a way that the final effect is a force identical in direction and magnitude with that which we observe. In addition he described the mechanism by which these rotations may be made to coexist, and to be distributed according to the known laws of magnetic lines of force.
>
> I conceived the rotating matter to be substance of certain cells, divided from each other by cell-wells composed of particles which are very small compared with the cells, and that it is by the motions of these particles, and their tangential action on the substance in the cells, that the rotation is communicated from one cell to another. [This is illustrated in Fig. 1] I have not attempted to explain this tangential action, but it is necessary to suppose in order to account for the transmission of rotation from the exterior to the interior parts of each cell, that the substances in the cells possess electricity of figure, similar in kind, though different in degree, that observed in solid bodies. The undulatory theory of light requires us to admit this kind of electricity in a luminiferous medium in order to account for transverse vibrations. We need not then be surprised if the magneto-electric medium possess the same property.

In addition, he introduced

> the concept of displacement current in dielectrics force acting between two electric field bodies and the rate of propagation of transverse vibrations through the elastic medium of which the cells are composed, on the supposition that its elasticity is due entirely to forces acting between pairs of particles.

Maxwell extends his model by providing the medium with elastic properties. Because the vortices' rotation is no longer of interest, Maxwell speaks of "elastic cells" surrounded by the layer of particles which play the role of electricity. This is illustrated in Fig. 1 as drawn by Maxwell. When these particles are displaced from their equilibrium positions, they distort the cells and call into play a force arising from their elasticity, equal and opposite to that which urges the particles away from their equilibrium position. This is illustrated in Fig. 2. The state of the medium, in which the particles are displaced (and the cells

DOI 10.1007/978-981-4560-75-7_12-1

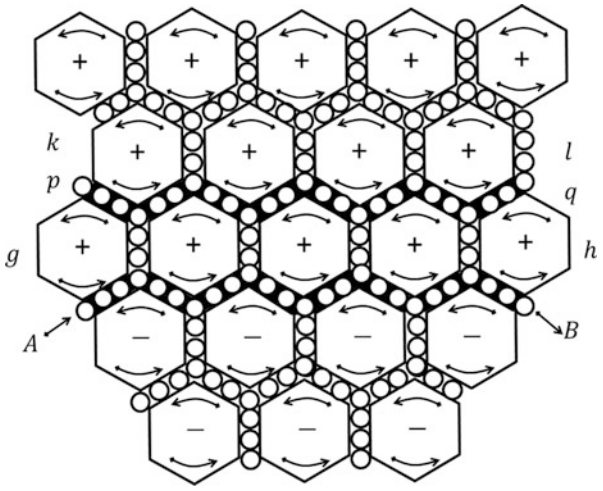

Fig. 1 Maxwell's drawing depicting his mechanical model of electromagnetic fields. Direction of rotation of the vortex tubes with hexagonal cross section is shown by *arrows*. The line of ball *A–B* moving to the right represents an electric current. Because of the rigidity of the structure, the motion of all vortices is synchronous

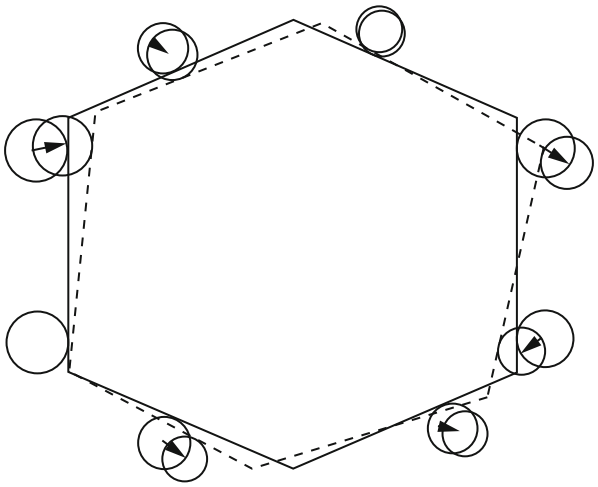

Fig. 2 Assuming vortex tubes elastic so that fixed balls could be displaced by electric force made Maxwell's model elastic and capable of carrying mechanical waves. Displacement of electricity corresponds to current creating a magnetic field

distorted) from their equilibrium position, is assumed to represent an electrostatic field. To Maxwell, this displacement current is like the real current as the vortices of Fig. 1 get distorted/displaced due to an externally applied field as shown in Fig. 2. Maxwell called the additional current generated due to the displacement of the fixed balls. But what happens *during* the displacement, the distortion of the magnetic vortices due to an applied field? In the light of his model, the answer is apparently obvious, and Maxwell makes a statement which will be of paramount relevance:

> This displacement does not amount to a current because when it has attained a certain value it remains constant, but it is a commencement of a current, and its variations constitute currents, in the positive or negative direction, according as the displacement is increasing or diminishing. The amount of the displacement depends on the nature of the body, and on the electromotive force.

Part 3 of his classic paper closes with the derivation of the relationship between the index of refraction of a substance and its relative electric and magnetic constants, $n^2 = \varepsilon_r \mu_r$ which helped him link light to

DOI 10.1007/978-981-4560-75-7_12-1

electricity. He made use of a bee's wax as a dielectric and measured its permittivity in a capacitor configuration. He then measured the refractive index by making a slab and light rays diffract through them. Thus, he established this equality both from a theoretical and experimental point of view. He mentioned in a letter to Faraday that the relationship between the refractive index and the dielectric constant could obviously provide a further check of the close connection between optical and electromagnetic phenomena.

In the fourth and last part of his classic paper (*The Theory of Molecular Vortices Applied to the Action of Magnetism on Polarized Light*), Maxwell applies his model to the analysis of the Faraday effect, and he succeeds in determining a quantitative law for the rotation of the polarization plane, which was in agreement with all known experimental results. The law involves also the mean radius of the molecular vortices, which motivates the abovementioned efforts to detect their existence in an independent, nonoptical way.

As Sir James Jeans points out:

> Maxwell pictured electromagnetic theory of light in terms of a medium whose properties could be specified completely in terms of a single mathematical constant. He saw that if the value of this constant could once be discovered, it ought to become possible to predict all phenomena of optical theory with complete mathematical precision. Maxwell showed that the constant in question ought to be merely the ratio of electromagnetic and electrostatic units of electricity and his first calculations suggested that this was in actual fact equal to the constant of the medium which measured the velocity of light.

The first mention of the great discovery comes in a letter, which he wrote to Michael Faraday on 19th October 1861:

> I suppose the elasticity of a sphere to react on the electrical matter surrounding it, and press it downwards. From the determination by Kohlrausch and Weber of the numerical relation between static and the magnetic effects of electricity, I have determined the elasticity of the medium in air, and assuming that it is the same with the luminiferous aether, I have determined the velocity of propagation of transverse vibrations. The result is 193,088 miles per second. Fizeau has determined the velocity of light as 193,118 miles per second by direct experiment.

Maxwell obtains the velocity for the wave propagation as 310,740,000 m/s. Furthermore, he states that:

> The velocity of transverse undulation in our hypothetical medium, calculated from the electromagnetic experiments of M. M. Kohlrausch and Weber, agrees so exactly with the velocity of light calculated from the optical instruments of M. Fizeau that we can scarcely avoid the inference that light consist in the transverse undulation of the same medium which is the cause of electric and magnetic phenomenon.

Even though the two numbers quoted above agreed to within 30 miles per second, oddly enough both are in error by more than 6,000 miles a second. When Maxwell came to publish his paper, *A Dynamical Theory of the Electromagnetic Field*, probably the most far-reaching paper he ever wrote, he gave the two velocities in terms of kilometers per second, Kohlrausch and Weber (310,740,000 m/s) and Fizeau (314,858,000 m/s), and nowhere near each other. Happily he seems to have realized that the velocity of light was not at all accurately known, and so he did not allow himself to be deterred, as Newton had been, by a substantial numerical disagreement in his law of universal gravitation.

Since the beginning, Maxwell was fully persuaded of the correctness of his hypothesis on the nature of light. This is clearly shown by the above reported letters, as well as by his interest in a precise determination of the "electromagnetic" value of the light velocity, as witnessed in the written letters to Henry Charles Fleeming Jenkin (27 August 1863) and Thomson (27 September and 15 October 1864), as well as the four parts of his classic paper published from September 1864 to February 1865.

Also in 1861, in setting up the standard for electrical resistance, he established the electrostatic units and the electromagnetic units to set up a coherent system of units and presented a thorough dimensional analysis of the electrical quantities. Thus, he put dimensional analysis on a scientific footing which was

Electric displacement / Surface-density	$\mathfrak{D}$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1}]$	$[L^{-\frac{3}{2}} M^{\frac{1}{2}}]$.
Electromotive force at a point	$\mathfrak{E}$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1}]$	$[L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-2}]$.
Magnetic induction	$\mathfrak{B}$	$[L^{-\frac{3}{2}} M^{\frac{1}{2}}]$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1}]$.
Magnetic force	$\mathfrak{H}$	$[L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-2}]$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-1}]$.
Strength of current at a point	$\mathfrak{C}$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}} T^{-2}]$	$[L^{-\frac{3}{2}} M^{\frac{1}{2}} T^{-1}]$.
Vector potential	$\mathfrak{A}$	$[L^{-\frac{1}{2}} M^{\frac{1}{2}}]$	$[L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-1}]$.

Fig. 3 List of dimensions for the various electrical quantities in both *ESU* and the *EMU* units. They all differ by the quantity LT^{-1}

discovered much earlier by Jean-Baptiste Fourier and others. The ESU and the EMU systems [Mahon 2003; Tolstoy 1981] of units were later mislabeled as the Gaussian system of units. In an 1863 memorandum, he introduced the dimensional notation which was to become the standard of using the powers of mass, length, and time. He also showed that the relation between the two electromagnetic units, ESU and EMU, has a dimension LT^{-1}, which has a value very close to that of the velocity of light (Harman 2002b, pp. 8). This is seen in Fig. 3. Later on, he also made an experiment to evaluate this number (Maxwell 1881) using purely electromagnetic principles.

This dimensional analysis prompted him to write the paper *A Dynamical Theory of the Electromagnetic Field* (Niven 1890a, pp. 526–597) in 1864 where he set out

> to establish the theory of the electromagnetic field because it has to do with the space in the neighborhood of the electric and magnetic bodies, and it may be called a Dynamical Theory, because it assumes that in that space there is matter in motion by which the electromagnetic phenomena are produced. In order to bring these results within the power of symbolical calculation, I then express them in the form of general equations of the electromagnetic fields (Maxwell 1881). The equations express –

A. The relation between the electric displacement, true conduction and the total current compounded of both. This equation expresses the total current. The variation of the electrical displacement must be added to the currents p, q, r to get the total motion of electricity which we may call p', q', r' to yield $p' = p + \frac{df}{dt}$; $q' = q + \frac{dg}{dt}$ and $r' = r + \frac{dh}{dt}$ where f, g, h denote the electric displacement along x, y, z.
B. The relation between the lines of magnetic force and the inductive coefficients of a circuit, as already deduced from the laws of induction. This equation represents the equation of magnetic force and is given by: $\mu\alpha = \frac{dH}{dy} - \frac{dG}{dz}$; $\mu\beta = \frac{dF}{dz} - \frac{dH}{dx}$; $\mu\gamma = \frac{dG}{dx} - \frac{dF}{dy}$; where α, β, γ are the magnetic force acting on a unit magnetic pole and F, G, H are the electromagnetic momentum.
C. The relation between the strength of a current and its magnetic effects, according to the electromagnetic system of measurements. This provides an equation for electric currents and expressed by $\frac{d\gamma}{dy} - \frac{d\beta}{dz} = 4\pi p'$; $\frac{d\alpha}{dz} - \frac{d\gamma}{dx} = 4\pi q'$; $\frac{d\beta}{dx} - \frac{d\alpha}{dy} = 4\pi r'$.

DOI 10.1007/978-981-4560-75-7_12-1

Table 1 Twenty variables originally introduced by Maxwell

Variable name used by Maxwell (*equivalent modern name*)	Symbol used by Maxwell	Modern equivalent Vector/scalar
Electromagnetic momentum (*magnetic vector potential*)	*F, G, H*	$\boldsymbol{A}$
Magnetic force (*magnetic field intensity*)	α, β, γ	$\boldsymbol{H}$
Electromotive force (*Electric field intensity*)	*P, Q, R*	$\boldsymbol{E}$
Current due to true conduction (*conduction current density*)	*p, q, r*	$\boldsymbol{J}$
Electric displacement (*electric flux density*)	*f, g, h*	$\boldsymbol{D}$
Total current (p^1, q^1, r^1) including variation of displacement (*conduction plus displacement current density*)	$\left\{ \begin{array}{l} p^1 = p + \frac{\mathrm{d}f}{\mathrm{dt}} \\ q^1 = q + \frac{\mathrm{d}g}{\mathrm{dt}} \\ r^1 = r + \frac{\mathrm{d}h}{\mathrm{dt}} \end{array} \right\}$	$\boldsymbol{J}_T$
Quantity of free electricity (*volume density of electric charge*)	*e*	ρ
Electric potential (*electric scalar potential*)	ψ	ψ

D. The value of the electromotive force in a body, as arising from the motion of the body in the field, the alteration of the field itself, and the variation of electric potential from one part of the field to another. This results in the equation of the electromotive force given by *P, Q, R* on a moving conductor as: $P = \mu\left(\gamma\frac{dy}{dt} - \beta\frac{dz}{dt}\right) - \frac{dF}{dt} - \frac{d\psi}{dx}$; $Q = \mu\left(\alpha\frac{dz}{dt} - \gamma\frac{dx}{dt}\right) - \frac{dG}{dt} - \frac{d\psi}{dy}$; $R = \mu\left(\beta\frac{dx}{dt} - \alpha\frac{dy}{dt}\right) - \frac{dH}{dt} - \frac{d\psi}{dz}$.

E. The relation between electric displacement, and the electromotive force which produces it. So when an electromotive force acts on a dielectric, it puts every part of the dielectric in a polarized condition, in which its opposite sides are oppositely electrified. If k is the ratio of the electromotive force to the electric displacement, then the equation for electric elasticity is given by $P = kf$; $Q = kg$; $R = kh$.

F. The relation between an electric current, and the electromotive force which produces it. In isotropic substances if ρ is the specific resistance referred to unit of volume, then the equation for electric resistance is given by $P = -\rho p$; $Q = -\rho q$; $R = -\rho\gamma$.

G. The relation between the amount of free electricity at any point, and the electric displacements in the neighborhood. If e is the quantity of free positive electricity contained in unit of volume at any point of the field, then the equation for free electricity is given by $e + \frac{df}{dx} + \frac{dg}{dy} + \frac{dh}{dz} = 0$.

H. The relation between the increase or diminution of free electricity and the electric currents in the neighborhood. This gives rise to the equation of continuity $\frac{de}{dt} + \frac{dp}{dx} + \frac{dq}{dy} + \frac{dr}{dz} = 0$.

Hence, there are 20 equations in all, involving 20 variable quantities summarized in Table 1 including the symbols used by Maxwell and the modern-day notations.

Maxwell also derived the coefficients of induction between two circuits in this paper. As he stated in the abstract of his paper:

> The proposed theory seeks for the origin of electromagnetic effects in the medium surrounding the electric or magnetic bodies, and assumes that they act on each other not immediately at a distance, but through the intervention of a medium which is progressive in nature.

It is also important to note that Maxwell believed in the ether theory as he states the following [Niven 1890a, b]:

DOI 10.1007/978-981-4560-75-7_12-1

The existence of the medium is assumed as probable, since the investigations of Optics have led philosophers to believe that in such a medium the propagation of light takes place.

He stated that the following quantities:

Electric currents by conduction, electric displacements, and Total currents; Magnetic forces, Electromotive forces, and Electromagnetic Momenta are involved in the mathematical expression for the electromagnetic fields.
Each of these quantities being directed quantity has three components; and beside these we have two others, the Free electricity and the Electric potential, making twenty quantity in all. There are twenty equations between these quantities, namely Equations of Total Currents, of Magnetic Force, of Electric Currents, of Electromotive Force, of Electric Elasticity, and of Electric Resistance, making six sets of three equations, together with one equation of Free Electricity, and another of Electric Continuity. The equations show that the transverse disturbances, and transverse disturbances only, will be propagated through the field, and that the number which expresses the number of electrostatic units of electricity in one electromagnetic unit, the standards of space and time being the same. The first of these results agrees with the undulatory theory of light as deduced from optical experiments. The second may be judged of by a comparison of the electromagnetical experiments of Wilhelm Eduard Weber and Rudolf Hermann Arndt Kohlrausch with the velocity of light as determined by astronomers in heavenly spaces, and by M. Foucault in the air of his laboratory.

Electrostatic units in an Electromagnetic Unit: 310,740,000 m/s
Velocity of light as found by Armand Hippolyte Louis Fizeau : 314,858,000 m/s
Velocity of light as found by Jean Bernard Leon Foucault : 298,000,000 m/s
Velocity of light deduced from aberration : 308,000,000 m/s

At the outset of the paper, the dynamical theory of the electromagnetic field borrowed from the undulatory theory of light the use of its luminiferous medium. It now restores the medium, after having tested its powers of transmitting undulations, and the character of those undulations, and certifies that the vibrations are transverse, and that the velocity is that of light. With regard to normal vibrations, the electromagnetic theory does not allow of their transmission. What then is light according to electromagnetic theory? It consists of alternate and opposite rapidly recurring transverse magnetic disturbances, accompanied with electric displacements, the direction of the electric displacement being at right angles to the magnetic disturbance, and both at right angles to the direction of the ray. The theory does not attempt to give a mechanical explanation of the nature of magnetic disturbance or of electric displacement, it only asserts the identity of these phenomena. . ... It discloses a relation between the inductive capacity of a dielectric and its index of refraction. .. The propagation of vibrations in a conducting medium is then considered and it is shown that the light is absorbed at a rate depending on the conducting power of the medium.

To answer now the specific question in more detail as to how did Maxwell reach the definite conclusion that light was electromagnetic in nature and at which point did it cease to be speculated, it is necessary to look at his letters. The first mention of the great discovery comes in a letter which he wrote to Faraday on the date 19 October 1861 [7, pp. 683–688, 5, p. 102]. For this part, it is relevant to refer to his book which was first published in 1873 and in a revised form in the second edition after his death in 1881 (Maxwell 1881). In (Maxwell 1881), Maxwell first presents the 20 equations as mentioned earlier. Even though he talks about the usage of the quaternion convention, the final expressions are in scalar form (Maxwell 1881, Ch. IX). In chapter X, he introduces the two systems of units, ESU and EMU, and illustrates that if the units of length, mass, and time are the same in the two systems, the number of electrostatic units of electricity contained in one electromagnetic unit is numerically equal to a certain velocity, the absolute value of which does not depend on the magnitude of the fundamental units employed [Maxwell 1881, Part II, p. 245]. In chapter XX, he shows that the disturbances in a media are propagated through a transverse electromagnetic wave which propagates at a velocity close to that of light. He furthermore compares the velocity of light measured by Fizeau (314,000,000 m/s) that measured through aberrations and the sun's parallax (308,000,000 m/s) and by Foucault (298,360,000 m/s) and that measured by Weber and Kohlrausch from the ratio between the ESU and the EMU units (310,740,000 m/s) and by Maxwell (288,000,000 m/s) and Lord Kelvin (282,000,000 m/s). From this comparison, Maxwell asserts that the velocity of light and the ratio of the two units are quantities of the same order of magnitude as also demonstrated from the previous quote.

DOI 10.1007/978-981-4560-75-7_12-1

Next, Maxwell observes in his theory that the refractive index of the media is related to the square root of the dielectric constant of a transparent media. He considers melted paraffin. The dielectric constant of paraffin had been measured by J. C. Gibson and T. Barclay to be 1.975 (Maxwell 1881, p. 398), and the refractive index of the same material had also been measured by Dr. J. H. Gladstone to be 1.43 [Maxwell 1881, p. 398]. But Maxwell confirms this by making a capacitor with a bee's wax as the dielectric to measure its dielectric constant and also fabricates a lens to measure the refractive index. In this way, he relates the electrical properties of a medium to that of optical properties of the medium. Finally, in chapter XXII, he explains the properties of ferromagnetism and diamagnetism by molecular currents and tries to explain the *Faraday effect* of the rotation of the polarization of the light passing through a magnetic medium, thus relating the magnetic properties to the optical properties. His Treatise (Maxwell 1881) thus illustrates that light is electromagnetic in nature, even though he lacked the information about the boundary conditions to solve the wave equation completely!

In 1868, he published the paper *On a Method of Making a Direct Comparison of Electrostatic with Electromagnetic Force; with a Note on the Electromagnetic Theory of Light* (Niven 1890b, pp. 125–143), where he described how he measured the speed of light by using 2,600 batteries to produce 3,000 V (Mahon 2003; Tolstoy 1981). The goal was to balance the electrostatic attraction between two charged metal plates against the magnetic repulsion between two current-carrying coils and build a balance arm to do this. He got a result of 288,000 km/s as compared to the current accepted value of 299,792.5 km/s.

He liked to use the quaternion convention. However, he wrote the final equations in the scalar form even though he used the terms "curl," "convergence," and "gradient." Nowadays, convergence is replaced by its negative, which is called divergence, and the other two are still in the standard mathematical literature. These are available in his paper *On the Mathematical Classification of Physical Quantities* (Niven 1890b, pp. 257–266). Maxwell identified light with electromagnetic waves and introduced the concept of ether as the basic medium of the electromagnetic field to retain the possibility of a mechanical interpretation. He presented his first paper on the new theory before the Royal Society in 1864 and published the comprehensive *A Treatise on Electricity and Magnetism* in 1873.

Maxwell considered magnetism as a phenomenon of rotation and electric currents as a phenomenon of translation. So in any magnetic field the medium is in rotation about the lines of magnetic force. Maxwell's theory sought unity through a highly plastic set of field equations coupled to Hamilton's principle, named after the Irish mathematician William Rowan Hamilton. In current bearing linear circuits, Maxwell thought that the currents were linked by rigid constraints to an intervening medium called the ether. Thus, the most difficult concepts for the modern reader to grasp in the original Maxwell's theory are the concepts of "charge" and "current." In modern theory, charge is the source of the electric field, and current is the source of the magnetic field. In his theory, charge is produced by the electric field; current, in the usual sense, is the rate of change of charge over time and is only indirectly related to the magnetic field. Therefore, in the Maxwellian theory, charge is a discontinuity of the displacement $\boldsymbol{D}$ and not in $\boldsymbol{E}$. Maxwell's goal was to create a theory of electromagnetism which made no use whatsoever of the microstructure of the matter. To Maxwell, the conduction current was effectively a continuous series of charging and discharging. The conduction current then is the process and growth of displacement. Maxwell proposed all currents are closed. In this fashion, he introduced the displacement current. Maxwell quite explicitly limited electric polarization to the boundary conditions on the flux characteristics of electric displacement and magnetic induction. Maxwell did not apply boundary conditions to explain the phenomenon of reflection and refraction. This was achieved by Hertz and Heaviside.

Maxwell introduced the term displacement current as he visualized that when an external field is applied to these molecular vortices, they are deformed or displaced and that also produces a current which he termed as the displacement current. To Maxwell, displacement current was the same as the real current and also flowed in the same direction (but in the modern theory used today, one uses either a conduction

DOI 10.1007/978-981-4560-75-7_12-1

current or a displacement current, and the flow of the displacement current is opposite to that of the conduction current).

In summary, in the first phase, Maxwell reached the conclusion that light was electromagnetic in nature from dimensional analysis and even constructed an experiment to measure the velocity of light by establishing how many ESU units are there in one EMU unit (Maxwell 1881).

Second Phase of Maxwell's Work on Electromagnetics

At this point, he resigned from King's College and went back to his home in the countryside. While he was there and before he accepted the Cavendish chair at Cambridge University, his thought process for the second phase began as during this stage he started writing his two-volume treatise covering about 1000 pages (Maxwell 1881). It is important to observe that Maxwell's thought process has radically changed during this phase when he started to write his treatise on electromagnetics. In this phase, Maxwell has abandoned his mechanical model of electromagnetic theory and starts the subject from an abstract point of view mainly using his equations. As he describes it:

> **I have confined myself almost entirely to the mathematical treatment of the subject, but I would recommend the student, after he has learned, experimentally if possible, what are the phenomena to be observed, to read carefully Faraday's Experimental Researches in Electricity**. He will there find a strictly contemporary historical account of some of the greatest electrical discoveries and investigations, carried on in an order and succession which could hardly have been improved if the results had been known from the first, and expressed in the language of a man who devoted much of his attention to the methods of accurately describing scientific operations and their results. It is of great advantage to the student of any subject to read the original memoirs on that subject, for science is always most completely assimilated when it is in the nascent state, and in the case of Faraday's Researches this is comparatively easy, as they are published in a separate form, and may be read consecutively. If by anything I have here written I may assist any student in understanding Faraday's modes of thought and expression, I shall regard it as the accomplishment of one of my principal aims to communicate to others the same delight which I have found myself in reading Faraday's Researches.

It is therefore quite relevant to point out that Maxwell by this time has discarded the mechanical model, along with it he also discarded the concept of displacement of current. In his thousand-page treatise, he never once mentions the term *displacement current*, whereas he confines himself to terms like currents in the dielectric. Perhaps it is high time that in the current textbooks the same thought process of Maxwell is followed with the concept of displacement current as it is not a current in a true sense as it does not produce a magnetic field.

In his treatise, Maxwell was able to show (Maxwell 1881, Art. 783 & 784; Equations 8 and 9) that in free space $\left(d^2\boldsymbol{J}\right)/(d\,t^2) + \left\{d\left(\nabla^2\Psi\right)\right\}/(d\,t) = 0$, where ψ is the scalar electric potential. He then made an important assertion, for which he provided no real justification: "$\nabla^2\Psi$," he said, *which is proportional to the volume density of the free electricity, is independent of t*, i.e., he claimed that the electric potential is determined solely by the spatial distribution of charge which in a nonconductor does not change. This is the assumption usually made in electrostatics, and Maxwell simply extended it to general electromagnetic theory without alteration or explanation. Time independence implied that the electric potential adjusted instantaneously across all space to any changes in the positions or magnitudes of the charges. It also implied $(d^2\boldsymbol{J})/(d\,t^2) = 0$, so that as Maxwell wrote:

> $\boldsymbol{J}$ must be a linear function of t, or a constant, or zero and we may therefore leave $\boldsymbol{J}$ and ψ out of account in considering wave disturbances.

In practice, Maxwell generally took $\boldsymbol{J} = 0$ and so worked out what we now call the *Coulomb gauge*, a gauge well suited to electrostatic problems but with the serious drawback in treating changing fields that it

DOI 10.1007/978-981-4560-75-7_12-1

requires the electric potential to be propagated instantaneously (Maxwell 1881). FitzGerald differed from Maxwell on this point, and instead of assuming the two potentials to be independent as Maxwell did, FitzGerald put $\boldsymbol{J} = -(d\Psi)/(dt)$ or equivalently $\nabla \bullet \boldsymbol{A} + (d\Psi)/(dt) = 0$. This *Lorenz gauge*, as it was later called, is much better suited to treating propagation phenomenon than was Maxwell's *Coulomb gauge* with $\boldsymbol{J} = 0$. This new gauge thus eliminated the question of the instantaneous propagation of the electric potential. However, FitzGerald found that Heaviside had independently done it already (Mahon 2003; Tolstoy 1981; Hunt 1991; Buchwald 1985)! As FitzGerald and Rowland put it in 1888, *That ψ should be murdered from treating propagation problems* (Heaviside 1893). Soon after, the same fate happened to $\boldsymbol{A}$, as Heaviside puts it:

> not merely the murder of Maxwell's ψ, but of that wonderful three legged monster with a scalar parasite on its back, the so called electrokinetic momentum at a point – that is the vector potential itself. (Heaviside 1893)

That is the first complete modification of Maxwell's theory done by Heaviside (1893) and Hertz [1962] to get rid of the potentials and to start the problem with the sources, i.e., currents and charges.

Even though the final results of the original Maxwell's theory are valid even today, the intermediary steps used to arrive at the conclusion were in question (Mahon 2003; Buchwald 1985). The first problem was associated with the definition of the charge.

Third Phase of Maxwell's Work on Electromagnetics

Maxwell, along with the English biologist Thomas Henry Huxley, was the joint scientific editor of the ninth edition of *Encyclopedia Britannica* (1879). There he provided an account of the motion of earth through ether. He had done experiments in 1860 which failed to detect any effect; however, he strongly believed in the existence of ether. At that time, his paper was rejected by Lord Kelvin, who was the reviewer, and so Maxwell put it in the *Encyclopedia Britannica*! Maxwell suggested that ether could perhaps be detected by measuring the velocity of light when light was propagated in opposite directions. He had further discussions in a letter to David Peck Todd, an astronomer at Yale. Maxwell's suggestion of a double-tracked arrangement led A. A. Mickelson, when he was working under Helmholtz as a student, to read Maxwell's work and then later to undertake his famous experiments on ether drag in the 1880s, and the rest is history.

The Evolution of the Original Maxwell's Theory to the Modern Times

After Maxwell's books on the Treatise were published in the European Continent, Helmholtz had been trying to understand Maxwell's theory of electromagnetism and to compare it with a theory based mostly on Newtonian mechanics (Bryant 1988). In 1879 Helmholtz called for an experimental validation of Maxwell's theory and had it published as a prize problem of the Prussian Academy of Science, often referred to as the *Berlin Prize*. For the 1882 prize, the problem stated (Hertz 1962; Bryant 1988):

> The theory of electrodynamics which was brought forth by Faraday and was mathematically executed by Mr. Cl. Maxwell presupposed that the formation and disappearance of the dielectric polarization in insulating media – as well as in space – is a process that has the same electrodynamic effects as an electrical current and that this process, just like a current, can be excited by electrodynamically induced forces. According to that theory, the intensity of the mentioned currents would have to be assumed equal to the intensity of the current that charges the contact surfaces of the conductor. The Academy demands that decisive experimental proof be supplied either
>
> for or against the existence of electrodynamic effects of forming or disappearing dielectric polarization in the intensity as assumed by Maxwell or

for or against the excitation of dielectric polarization in insulating media by magnetically or electrodynamically induced electromotive forces.

Answers to these questions had to be submitted by 1 March 1882, and the prize of 955 marks will be awarded. At that time, Hertz was working with Helmholtz at the Physical Institute in Berlin. Helmholtz thought that one of his students, Heinrich Hertz, would be most likely to succeed in this experimentation. He suggested to Hertz that, should he address this problem, the resources of the institute will be available to him. However, at that time, Hertz gave up the idea because he thought a solution was not possible, as he found no adequate sources for generation of high frequencies. However, he continued thinking about this problem. Hertz did an analytical thesis on the induced currents in a rotating metal sphere in a magnetic field (Bryant 1988; Hunt 1991). After graduating in 1880, he stayed on as an assistant to Helmholtz and then went to the University of Kiel as an instructor of theoretical physics. At Kiel, Hertz had no laboratory and was very impatient working only in theoretical physics. In 1884 at Kiel, he published the paper *On the relation between Maxwell's fundamental electromagnetic equations and the fundamental equations of the opposing electromagnetics* (Hertz 1884). He concluded that if he had to make a choice, he would choose Maxwell's theory. This work convinced him to carry out experimental work to verify this theory. In his book, he himself addresses the question as to what exactly is Maxwell's theory. In his words (Hertz 1962; Buchwald 1985, p.191):

Maxwell left us as the result of his mature thought a great treatise on Electricity and Magnetism; it might therefore be said that Maxwell's theory is the one propounded in that work. But such an answer will scarcely be regarded as satisfactory by all scientific men who have considered the question closely. Many a man has thrown himself with zeal into the study of Maxwell's work, and even when he has not stumbled upon unwanted mathematical difficulties, has never the less been compelled to abandon the hope of forming for himself an altogether consistent view of Maxwell's ideas. I have fared no better myself. Notwithstanding the greatest admiration for Maxwell's mathematical conceptions, I have not always felt quite certain of having grasped the physical significance of the statements. Hence, it was not possible for me to be guided directly by Maxwell's book. I have rather been guided by Helmholtz's work, as indeed may plainly be seen from the manner in which the experiments are set forth. But unfortunately, in the special limiting case of Helmholtz's theory which lead to Maxwell's equations, and to which the experiments pointed, the physical basis of Helmholtz's theory disappears, and indeed it does, as soon as action-at-a-distance is disregarded. **I therefore endeavored to form for myself in a consistent manner the necessary physical conceptions, starting from Maxwell's equations, but otherwise simplifying Maxwell's theory as far as possible by eliminating or simply leaving out of consideration those portions which could be dispensed within as much as they could not affect any possible phenomena**... To the question, "What is Maxwell's Theory?" I know of no shorter or more definite answer than the following: – Maxwell's theory is Maxwell's system of equations. Every theory which leads to the same system of equations, and therefore comprises the same possible phenomena, I would consider as being a form or special case of Maxwell's theory; every theory which leads to different equations, and therefore to different possible phenomena, is a different theory. Hence, in this sense, and in this sense only, may the two theoretical dissertations in the present volume be regarded as representations of Maxwell's theory? **In no sense can they claim to be precise rendering of Maxwell's ideas. On the contrary, it is doubtful whether Maxwell, were he alive, would acknowledge them as representing his own views in all respects**.

The 1884 paper (Hertz 1884), in which Hertz developed the coordinate form of Maxwell's equations discarding the potentials and getting the four equations that is used today in scalar form, 12 in number, helped Hertz to get his next appointment at the Technical High School at Karlsruhe in 1885, where he started his experimental work. There, he discovered how to generate and detect electromagnetic energy, in trying to address the problem of spurious electromagnetic radiation from high-power transformers during closing and opening of circuits (Tai and Bryant 1994; D'Agostino 1975). Finally, in 1887, he provided experimental results for the Berlin Prize, and it was published in his 1888 paper. It is not known whether Hertz collected the Berlin Prize money since the due date was over! He also made experiments to determine the velocity of electromagnetic wave propagation using a wire over a ground plane. With the transmission line open-ended at one end, he moved a detector along the lines and observed the distance between nulls is one half-wavelength and had a value of 2.8 m (Bryant 1988; Tai and Bryant 1994;

DOI 10.1007/978-981-4560-75-7_12-1

D'Agostino 1975). Hertz calculated the frequency of the source from the estimate of the capacitance and the inductance of the dipole resonator. For the velocity, the product of *wavelength* × *frequency*, he arrived at a value of 2×10^8 m/s not knowing of a computational error of $1/\sqrt{2}$ for the frequency. Without this error, his result would have been 2.8×10^8 m/s. After he published his results, this error was pointed out to him in a letter from H. Poincaré in 1890 (Bryant 1988; Tai and Bryant 1994; D'Agostino 1975).

However, what Hertz missed was the core idea of the discontinuity in the displacement (Buchwald 1985, p.193). The quandary of Hertz forced him into an uneasy compromise with the traditional Helmholtzian view on charge. Hertz distinguished the free electricity from which one calculates forces, and which is alterable by nonconducting means, from the true electricity, which is alterable only by conduction. So, though Hertz referred the measure of true charge to the divergence of the displacement, he preserved Helmholtzian wording because he had not seen how to avoid it. Whereas a Maxwellian would write apparent charge as $\nabla \bullet \boldsymbol{E}$, Hertz wrote of free charge and felt it necessary to retain the idea of bound charge to grant free charge physical significance, though he refused to consider why such a thing as bound charge exists. The significance of Hertz's famed rejection of the Maxwellian distinction between electric intensity and displacement in the free ether is now examined. Without this distinction, it is impossible, in Maxwellian theory, to understand the existence of a charged surface in vacuum because charge is due to the discontinuity in the displacement. The fact that in free ether $\boldsymbol{D}$ reduces to $\boldsymbol{E}$ is merely a mathematical artifact. This is due to the definition of capacity of the ether being unity. The conceptual and physical distinction between displacement and intensity is still essential. Not knowing or understanding this distinction goes to the heart of Maxwell's theory. Hertz felt free to ignore it where it seemed mathematically to make no difference. In addition, Hertz started from the sources of the fields which were charges in electrostatics and currents in magnetostatics and not treat the potentials as fundamental quantities in analogy to a mechanical model as Maxwell did. Hertz showed that at a dielectric boundary the tangential components of the electric fields are continuous and the normal component is discontinuous. He obtained similar boundary conditions for a magnetic media.

In short (Buchwald 1985), Hertz defined the electric and magnetic constants as unity in free space, thus eliminating displacement as a primary quantity. While this somewhat simplified the mathematical structure of Maxwell's theory, it was fatal to its dynamical basis. Heaviside raised this point with Hertz in 1890 after reading his first paper:

> On the Fundamental Equations of Electrodynamics. He asked, Can you conceive of a medium for electromagnetic disturbances which has not at least two physical constants, analogous to density and elasticity? If not, is it not well to explicitly symbolize them, leaving to the future their true interpretation?

Heaviside was calling on Hertz not to sacrifice for the sake of a small and perhaps illusory mathematical simplification, the dynamical ether, filled with stresses, strains, and stored energy on which Maxwell had built his theory. The British Maxwellians took this dynamical ether much more seriously than did their Continental counterparts, insisting that even on those points where Maxwell's theory required clarification and correction, this could and should be done without reducing the theory to a mere set of equations. The important modifications Heaviside had made to Maxwell's theory, including his abandonment of the potentials in favor of his four equations in the vector form that is termed Maxwell's equations today, he said, meant as sustentative changes or new departures, but were directed solely at bringing out the leading points of the theory more clearly than had Maxwell himself. Both Heaviside and FitzGerald drew a careful distinction between *Maxwell's treatise* and *Maxwell's theory* and said that Maxwell's book gave only an imperfect account of the real nature of the theory (Buchwald 1985).

In 1886, Hertz observed while examining some of the apparatus used in lecture demonstrations that the oscillatory discharge of a Leyden jar or induction coil through a wire loop caused sparks to jump a gap in a similar loop a short distance away. He recognized this as a resonance phenomenon and saw that such

DOI 10.1007/978-981-4560-75-7_12-1

sparking loops could serve as very sensitive detectors of oscillating currents and, thus, of electromagnetic waves. This provided him with the proper experimental tool which had eluded Lodge, FitzGerald, and others. His two papers:

> On the finite velocity of propagation of electromagnetic actions and The forces of electric oscillations, treated according to Maxwell's theory

both published in 1888 vindicated Maxwell's theory, and from then on it was accepted by the electromagnetic community (Tai and Bryant 1994; D'Agostino 1975).

Heaviside, on the other hand, differentiated between the absolute and the relative permeability and permittivity, defining the relative quantities as the ratio of the absolute value for a medium and that for free space. Heaviside rewrote Maxwell's equations in the vector form that is used today using the above modifications. There are conductors and nonconductors or insulators, and since the finite speed of propagation in the nonconducting space outside conductors was unknown, attention was almost entirely concentrated upon the conductors and an assumed field which was supposed to reside upon or in them and to move about, upon, or through them. And the influence on distant conductors was attributed to instantaneous action at a distance, ignoring an intermediate agent. Maxwell explained these actions of the intermediate agent of an intervening medium being transmitted at finite speed. In Heaviside's words (1893):

> What is Maxwell's Theory or what should we agree to understand by Maxwell's theory? The first approximation to the answer is to say there is Maxwell's book as he wrote it; there is his text and there are his equations, together they make his theory. But when we come to examine it closely, we find that this answer is unsatisfactory. To begin with, it is sufficient to refer to papers by physicists, written say during the twelve years following the first publication of Maxwell's Treatise, to see that there may be much difference of opinion as what his theory is. It may be, and has been, differently interpreted by different men, which is a sign that it is not set forth in a perfectly clear and unmistakable form. There are many obscurities and inconsistencies. Speaking for myself, it was only by changing its form of presentation that I was able to see it clearly, and so as to avoid inconsistencies. **It is therefore impossible to adhere strictly to Maxwell's theory as he gave it to the world, if only on account of its inconvenient form**. . . **But it is clearly not admissible to make arbitrary changes in it and still call it his. He might have repudiated them utterly. But if we have good reason to believe that the theory as stated in his treatise does require modification to make it self-consistent and to believe that he would have admitted the necessity of the change when pointed out to him, then I think the resulting modified theory may well be called Maxwell's**.

To understand the problem, one must introduce the Maxwellian concept of a current. It was apparently not possible to incorporate conductivity into the dynamical structure of the Maxwellian theory (Buchwald 1985). Maxwell did not himself incorporate conductivity directly into the dynamical structure of the theory. Rather, he treated Ohm's law as an empirical, independent fact and subtracted the electromagnetic intensity it requires from the induced intensity.

It is important to point out that Heaviside's duplex equations, as he called them, can be found in Maxwell's own writing in 1868, *Note on the Electromagnetic Theory of Light*. Maxwell gave a clear statement of the second circuital law relating the magnetic current to the curl of the electric force, crediting it to Faraday and asserting that it afforded "the simplest and most comprehensive" expression of the facts. But despite the advantages of this simple equation, particularly in treating electromagnetic waves, Maxwell did not use it at all in his *Treatise* in 1873, and it remained unknown even to his close students till 1890 when Maxwell's scientific papers (Niven 1890a, b) were published. It is rather amusing to note that even Lodge (one of the Maxwellians) actually credited this equation to Heaviside in his Presidential Address to the Physical Society in February 1899, when the Irish physicist and mathematician Sir Joseph Larmor pointed out to him that it was in the writing of Maxwell himself (Mahon 2003; Tolstoy 1981; Tai and Bryant 1994; D'Agostino 1975)!

DOI 10.1007/978-981-4560-75-7_12-1

In summary, why Maxwell's theory was not accepted for a long time by contemporary physicists was that there were some fundamental problems with his theory. Also, it is difficult to explain using modern terminology as to what those problems were. As stated in Buchwald (1985):

> Maxwellian theory cannot be translated into familiar to the modern understanding because the very act of translation necessarily deprives it of its deepest significance, and it was this significance which guided British research. It assumed that field and matter can always be treated as a single dynamical system, subject to modification according to the circumstances.

In modern days, we reject this very basis of the Maxwellian theory! Maxwell's paper in 1862 *On Physical Lines of Force* described an elaborate mechanism for ether. He was deeply attached to the mechanism despite certain problems with it and remained throughout his life till 1879 strongly committed to the principle to model building. Yet, in 1864, his paper on *A Dynamical Theory of the Electromagnetic Field* avoided specifying the structure of the ether, but, nevertheless, presumed the field to be governed by what he called dynamical laws. This was done by treating $\boldsymbol{H}$ as a velocity and $\boldsymbol{D}$ as the curl of the corresponding mechanical displacement. Through such assumption, it does not mean that the true structure of the ether is fully understood. Maxwell's theory was based on the assumption that all electromagnetic phenomena, including boundary conditions, can be obtained by applying Hamilton's principle to suitably chosen field energy densities which contain the appropriate electrical parameters like permittivity and permeability for the material medium. Modern theory implies that this can at best work on certain occasions as the macroscopic fields ($\boldsymbol{D}$, $\boldsymbol{H}$) are not a simple dynamical system but a construct obtained by averaging over the true state and the combined field vectors ($\boldsymbol{E}$, $\boldsymbol{B}$) with material vectors ($\boldsymbol{P}$, $\boldsymbol{M}$). Hence, where modern theory introduces the electron, the Maxwellian theory invented new forms of energy. This was possible because the Maxwellians were quite willing to invent modifications to the basic equations governing the electromagnetic field – as long as the results held up experimentally. Modern theory seeks unified explanations in an unmodifiable set of field equations coupled through the electron motions to intricate microphysical models. Maxwellian theory sought unity through a set of field equations coupled to Hamilton's principle. In Maxwell's theory, the goal was to create a theory of electromagnetism which made no use whatsoever of the microstructure of matter. Hence, the basic problem in understanding Maxwell's theory by a modern reader is to decipher what exactly did Maxwell mean by the words *charge* and *current*! Some of this confusion depends on Maxwell's having altered at least once his choice for the sign for the charge density in the equation which links it to the divergence of the electric flux $\boldsymbol{D}$. The conduction current in Maxwell's theory cannot be simply explained! The details of these subtleties may be found in Buchwald (1985). Finally, as pointed out by Bruce J. Hunt (1991):

> When the 1880s began, Maxwell's theory was virtually a trackless jungle. By the second half of the decade, guided by the principle of energy flow, Poynting, FitzGerald and above all Heaviside have succeeded in taming and pruning that jungle and in rendering it almost civilized.

In modern electrodynamics, we do not regard the field itself as a material structure, so we do not consider the stresses that may act upon it. Electromagnetic radiation, for example, transports energy and momentum, but stresses arise only when the radiation impinges on material structures. The Maxwellians did not think in this way. For them energy inhomogeneity, whether matter is present or not, implies stress. Indeed after the discovery of Poynting's theorem, they realized that the free ether must be stressed when transmitting radiation and so must move. In Maxwellian theory, the electromagnetic field transmits stress and is itself acted upon by stress. In modern theory, the field only acts; it is not acted upon (Buchwald 1985). There is an alternate point of view to this, however (Sarkar et al. 2006). For example, one side of Poynting's theorem has $[\boldsymbol{J} \bullet \boldsymbol{E}]$, while the other side has only fields. So one can say that the fields act on $\boldsymbol{J}$ or that the fields act on themselves, especially in cases like perfect electric conductors where no total work is done on the current and yet energy ends up in the fields.

DOI 10.1007/978-981-4560-75-7_12-1

In summary, the great difficulty with Maxwellian theory is that one cannot set up correspondences between mechanical and field variables which lead to consistent results unless one ignores conductivity, as illustrated by Heaviside. Heaviside's demonstration of this fact was based on Green's potential function. He suggested using $\boldsymbol{E}$ as the velocity instead of $\boldsymbol{H}$ in the mechanical model, and this requires a complete reconstruction of Maxwellian theory, as Maxwell did it the other way around (Buchwald 1985).

The mathematical formulation of *macroscopic* electromagnetic phenomena was accomplished by Maxwell (Larmor 1937). According to Maxwell's theory, electromagnetic radiation is produced by the oscillation of electric charges, the charges that produce light were unknown. Since it was generally believed that an electric current was made up of charged particles, Hendrik Antoon Lorentz in 1892 theorized that the atoms of matter might also consist of charged particles and suggested that the oscillations of these charged particles (electrons) inside the atom were the source of light. It should be noted that this occurred prior to the experimental clarification of the basic properties of the electron; those were not measured until 1897 and 1898 when Joseph John Thomson succeeded in a determination of the charge to mass ratio and in a first measurement of the elementary charge for an isolated electron. Lorentz thus constructed a *microscopic* theory by using Maxwell's equations and adding to it an expression for the force which a charged particle experiences in the presence of electric and magnetic fields. This microscopic theory is a description of matter in terms of its charged atomic fragments, ions, and electrons. The success of this microscopic theory lay in the proof first provided by Lorentz that the macroscopic Maxwell theory can be deduced from this microscopic theory by a suitable averaging process over the motion of the individual ions and electrons. The Maxwellian and Continental ideas were so profound that only Lorentz was able to retain the substantial character of charge while incorporating certain Maxwellian elements that did not violate basic preconceptions. Lorentz's theory computes interparticle actions directly by using retarded forces, and it employs careful microphysical averaging. It is interesting to note that the Lorentz force equation is very similar to Maxwell's equation (D) as described in section First Phase of Maxwell's Work on Electromagnetics. However, Lorentz's theory very much obscures the difference between ionic motions and the basic field equations (Buchwald 1985).

From 1894 to 1897, the British electromagnetic theory abandoned the basic principles of Maxwellian theory, and the entire subject was reconstructed on a new foundation – the electron, developed by Joseph Larmor in consultation with George FitzGerald (Buchwald 1985). Larmor thus effected a second revolution in the Maxwellian theory, one in which the electron had become the fundamental for generation of the field. Heaviside felt that Larmor's idea of the electron was not sufficiently fundamental. The major impact of Larmor's theory was the destruction of the idea that continuum theory can serve as a sufficient basis for electromagnetism. Maxwell's theory with its fundamental assumption that the electromagnetic field can be subjected to precisely the same type of analysis as the material continuum was an artifact after 1898. This was the second conceptual modification of Maxwell's theory after the first modifications carried out by Hertz and Heaviside, even though the basic equations still remained the same. Larmor's student, John Gaston Leathem, connected mathematically displacement with polarization by writing $\boldsymbol{D} = \boldsymbol{E} + \boldsymbol{P}$ and thus effectively destroying the Maxwell-FitzGerald theory of using Hamilton's principle as a starting point based on a continuous energy function (Buchwald 1985).

From this time onward, future work on electromagnetism, in Britain and in the Continent, depended directly on microphysics based on the electron rather on the macrophysics. Hence, there was a complete divorce between the matter and the field (Buchwald 1985). Thus, the nature of conduction, the stumbling block in Maxwell's theory, led to the final modification by Larmor and Lorentz by incorporating the microscopic view of matter through the introduction of the electron as the source of charge, the flow of which results in a current. These sources now produce the fields.

DOI 10.1007/978-981-4560-75-7_12-1

In short, the current perception of Maxwell's theory consists of Maxwell's system of equations supplemented by his initial radical concept of displacement current. A relevant question here is: Is this displacement current a physical reality? If so, then how is it that it produces radiation similar to that by conduction current? Currently accepted forms of Maxwell's equations as obtained through the work of Hertz, Heaviside, Lodge, FitzGerald, Lorentz, and Larmor are given as follows by these equations which are available in any modern textbook on electromagnetic theory: $\boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t} = \nabla \times \boldsymbol{H}$, $-\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times \boldsymbol{E}$, $\nabla \bullet \boldsymbol{D} = q_v$, $\nabla \bullet \boldsymbol{B} = 0$, and $\nabla \bullet \boldsymbol{J} = \frac{-\partial q_v}{\partial t}$, along with $\boldsymbol{B} = \mu \boldsymbol{H}$ and $\boldsymbol{D} = \varepsilon \boldsymbol{E}$. Equation of continuity here is included for completeness.

Epilogue

Finally, it would be interesting to draw the curtain on James Clerk Maxwell. In his hands electricity became an exact science and this can be said of many other branches of physics. In fact, it is not well appreciated that Maxwell can be called the greatest scientist of the last century even if he did nothing on electromagnetics. His contributions are everywhere and often few researchers in electromagnetics are aware of them. For completeness, Maxwell's contribution to electrical engineering is listed numerically in this section.

1. It is true that G. R. Kirchhoff wrote the laws related to the voltages and currents in a circuit, but as Sir Ambrose Fleming pointed out, the method to solve for the loop (and the node) equations for a general circuit by assuming flow of current in each wire to be the difference between two imaginary currents circulating in opposite directions in the network and then writing the solution as a ratio of two determinants was invented by him.
2. Maxwell showed how a circuit containing both capacitance and inductance would respond when connected to AC generators of different frequencies. He developed the phenomenon of electrical resonance in parallel to acoustic resonance developed by Lord Rayleigh. Maxwell developed the electrical analog when reviewing Rayleigh's paper and wrote about it to Rayleigh. He introduced a simpler concept for the group and the phase velocities.
3. Maxwell developed a coherent set of units of measurement of electricity and magnetism. They were later adopted almost unchanged as the first internationally accepted system of units, which became known misleadingly as the Gaussian system, which is a combination of the electrostatic units and the electromagnetic units. He introduced the *M*, *L*, and *T* notation in dimensional analysis.
4. He developed an experiment to measure the velocity of light from purely electrical means. He measured the speed of light by using 2,600 batteries to produce 3,000 V. The goal was to balance the electrostatic attraction between two charged metal plates against the magnetic repulsion between two current-carrying coils and build a balance arm to do this. He got a result of 288,000 km/s as compared to the current accepted value of 299,792.5 km/s. This was a direct application of his dimensional analysis, namely, to find how many *ESU* units are there in one *EMU* unit.
5. He wrote on the various ways to assess the color of the macula which in the eye is responsible for the quality of the vision. Nowadays when an ophthalmologist is checking the quality of the macula in a person's eyes, he/she is performing what is known as *Maxwell's yellow spot test*.
6. He developed the fish-eye lens to look into the retina of the eye.
7. A normal eye has three sorts of receptors for color. Maxwell demonstrated that in color-blind people their eyes are sensitive to only two rather than to three.

DOI 10.1007/978-981-4560-75-7_12-1

8. Maxwell chose the three primary colors to generate white light as red, green, and blue. Today, color television works on this principle, but Maxwell's name is rarely mentioned. However, other choices for the primary colors are equally viable. Maxwell demonstrated that other colors can be generated by using the barycentric coordinate system by placing the three primary colors red, green, and blue at the apex of a triangle, while white is achieved at the centroid when using light. If instead of light one uses color paints, then the centroid will be black instead of white.
9. He took the first color photograph using the same principles as it is done today, by superposing the three images taken in different colors!
10. He also showed that radiation pressure from the sun exists, which has a force of 4 pounds per square mile, which was later used to explain why the tails of the comets move away from the sun as they approach it.
11. He introduced and first applied a statistical law to a physical process. His discovery opened up an entirely new approach to physics, which led to statistical mechanics and to the use of probability distributions in quantum mechanics.
12. He introduced the concept of ensemble averaging. This enabled people to explain the properties of matter in terms of the behavior, en masse, of its molecules. Thus, using the method of ensemble averaging, the whole system is much easier to analyze, rather than dealing with individual components. He thus introduced the Maxwellian distribution.
13. He first asserted that the second law of thermodynamics is a statistical law. So if one throws a bucket of water into the sea, one cannot get the same bucket of water out again as the law applies to molecules in masses and not to individuals.
14. He developed the thought process related to Maxwell's demon which could violate the second law of thermodynamics and in this way create a perpetual motion. Through the application of Maxwell's demon, Leo Szilard developed the concept of quantization of information in terms of entropy which was later used in the development of information theory and was redeveloped by Claude Shannon.
15. He was the first to analyze the motion of Saturn's rings using mathematical analysis.
16. He illustrated how to generate objects having multiple foci using graphical means. Today, the same principles are used to generate optical lenses with multiple foci.
17. He developed a platometer on how to measure area of a planar arbitrary shaped object.
18. He produced a standard for electrical resistance.
19. When creating his standard for electrical resistance, he designed a governor to keep a coil spinning at a constant rate. He made the system stable by using the idea of negative feedback. He worked out the conditions of stability under various feedback arrangements. This was the first mathematical analysis of control systems. This work did not get any attention till 1940, when gun control radars were in demand during the Second World War. After the war, the American mathematician Norbert Wiener took things further and developed the science of cybernetics.
20. He introduced the idea of relaxation time into physics, engineering, and glaciology, by drawing on a suggestion of the Scottish physicist J. D. Forbes that a glacier behaves as a solid at times shorter than the relaxation time but like a liquid at longer times. This is related to the collision between gas molecules and replacing the concept of mean free path between collisions as a function of temperature.
21. In the 1870s during two discussions, he first emphasized what is now called the *butterfly effect – the fact that tiny differences in initial conditions can produce huge final effects* – the starting point of chaos theory.
22. Maxwell also wrote a paper on the "Protection of Building from Lightning." In that paper, he pointed out that most of the published writing dealt with were on the necessity of obtaining what telegraph engineers call a good earth connection. The telegraphist uses the earth to complete his circuit;

DOI 10.1007/978-981-4560-75-7_12-1

therefore, it is of great importance to him; but the protection of buildings from electric discharges has a different aim and a different method.

23. He also extended the work of the English mathematician A. Cayley published in 1859. The surface of the earth has high areas or hills and low areas with a bottom point. There are also ridges, valleys or dales, and passes. He thought that the numbers of each of these features must be somehow related by mathematical rules. His original ideas about the earth's surface have now evolved into a branch of topology called global analysis.
24. Maxwell introduced Hamilton's word *RELATIVITY*, in the way that physicists now understand it, in his small book *Matter and Motion* of 1876 (Maxwell 1876). He had noticed that the interpretation of electromagnetic induction was different depending on whether one considers a magnet approaching a wire loop or a loop approaching a magnet. The French mathematician, physicist, and engineer J. H. Poincaré read the work; A. Einstein learned of it from Poincaré; and the rest is history.
25. Last but not the least, he developed the fundamental principles of electromagnetic theory including the assertion that light is electromagnetic in nature.

Conclusion

This chapter has provided an introduction of the developments made up to the time of Maxwell in the creation of the theory of electromagnetism based on merging the different theories related to magnetism, electricity, and light. This is a unique theory where the fundamental equations did not change even though the philosophy went through two complete modifications: the first one by Hertz and Heaviside and the second by Larmor by introducing the microscopic structure of the matter into the macroscopic equations developed by Maxwell. The four of his equations that are used today were simultaneously developed by Hertz who wrote in the scalar form before he carried out his experiments, and what is available in modern textbooks under the heading of Maxwell's equations was written by Oliver Heaviside who first put them in the vector form. Also, a brief outline of Maxwell's other works is provided, as his name is not only synonymous with electromagnetic waves, but also Maxwell single-handedly laid the basic foundations of electrical engineering. In his hands electricity first became an exact science. The bottom line is that Maxwell can be called the greatest scientist of the last century even if he did absolutely nothing on electromagnetics as illustrated by the list of his accomplishments provided in the last section.

Finally, it is important to also note that the first patent on wireless was filed by an American dentist by the name of Mahlon Loomis, exactly the same year in 1864 when Maxwell first wrote his equations (Sarkar et al. 2006). This illustrates that important discoveries in the area of electromagnetics and wireless were done by researchers who had little or no formal education like Faraday and Heaviside or even education in physics like Loomis. Also Maxwell, who was a mathematician by training, wrote that he did not want to employ any mathematical principles until he went through all of Faraday's experiments in order to understand first the physical phenomena involved. Thus, one other conclusion of this presentation could be that in our teaching of electromagnetics, we should first provide the context and highlight the physical phenomena before going through all the mathematical details. Perhaps it is time for a change on how we teach electromagnetics to the students!

Concept and Applications of Receiving Mutual Impedance

Hon Tat Hui
University of Macau, Macau, China

Abstract

The concept of receiving mutual impedance is introduced through derivation from a method of moments (MoM) analysis. The theoretical and experimental methods for the determination of the receiving mutual impedance are given and illustrated with typical examples of dipole and monopole antenna arrays. The fundamental difference, namely, the truly isolated state between the receiving mutual impedance and the conventional mutual impedance, is explained. Typical examples for the application of the receiving mutual impedance are given to demonstrate the validity and accuracy of using this concept. These examples include applications in direction of arrival (DOA) estimation, in interferences suppression, in magnetic resonance imaging (MRI) phased-array design, and in multiple-input and multiple-output (MIMO) communication systems.

Keywords

Receiving mutual impedance; Mutual coupling; Mutual impedance; Antenna arrays; Phased arrays; Method of moments; DOA estimation; Interference suppression; Magnetic resonance imaging; MIMO antenna arrays

Introduction

Mutual coupling is a common problem in the application of antenna arrays. It significantly affects the operation of all types of antenna arrays. The study of mutual coupling problem started several decades ago and attracted the attention of not just antenna engineers and researchers but also many researchers from other disciplines such as communications and biomedical imaging where antenna arrays are frequently used. Compared to a single antenna, an antenna array is able to provide the spatial information of a signal distribution. However, this function critically relies on the independence or distinctiveness of the signals received or transmitted from different antenna elements in the array. In reality, this is simply impossible because antenna elements interact with each other, i.e., they mutually couple with each other. In order to restore the independent signals received or transmitted from the antenna elements, the mutual coupling effect has to be removed or mitigated. Hence, it is very important to find ways to decouple the array signals received or transmitted from antenna arrays. In Gupta and Ksienski (1983), the effect of mutual coupling on the performance of adaptive arrays was studied by deriving the open-circuit voltages from the measured voltages across the antenna terminal loads. This method was later used in Yeh et al. (1989) to compensate for the mutual coupling effect of a dipole array used in direction findings. In Pasala and Friel (1994) and Yuan et al. (1998), the mutual coupling effect was investigated by solving the entire electromagnetic boundary value problem of the antenna array, but this requires the knowledge of the current distributions on the antenna elements which are not available in real situations. In Adve and Sarkar

Hon Tat Hui: deceased.

DOI 10.1007/978-981-4560-75-7_13-2

(2000), the principle to remove the mutual coupling effect is basically the same as in Pasala and Friel (1994), but a known incoming elevation angle of the signal and the interferences was assumed. This enables the reduction of the number of equations to the number of antenna elements in the array. This assumption makes it possible to eliminate the mutual coupling effect in an exact manner rather than approximately as by the method in Gupta and Ksienski (1983).

Notwithstanding these previous efforts, what makes this mutual coupling problem more complicated was that some recent findings (Hui 2003, 2004a, b; Lui et al. 2009; see also Wu and Nie 2008; Daniel 1974) pointed out that it is inappropriate to characterize the mutual coupling effect in transmitting and receiving antenna arrays in the same way. More specifically, they pointed out that a different characterization method from those used for transmitting antenna arrays is needed for receiving antenna arrays. They showed that the conventional mutual impedance concept is only suitable for characterizing the mutual coupling effect in transmitting antenna arrays and that a new concept, called the "receiving mutual impedance", has to be used for characterizing the mutual coupling effect in receiving antenna arrays. As receiving antenna arrays have applications in many different areas such as radar detection, remote sensing, interference cancellation, MIMO communications, magnetic resonance imaging (MRI), etc., it becomes very necessary to explore this concept in a greater depth and to explain the salient differences in using this concept from the conventional one.

The Development of the Concept of Receiving Mutual Impedance from the Method of Moments (MoM)

This section will introduce the development of the concept of receiving mutual impedance from the method of moments (Balanis 2005). Consider a linear dipole antenna array with n dipole antennas as shown in Fig. 1. The dipole antenna elements are assumed to be thin wires of equal length $\ell = 0.5\lambda$ and equal thickness with a radius $a << \lambda$, where λ is the operation wavelength. The dipole elements are placed along the x-axis with an equal separation $d = 0.5\lambda$ between them. The dipole axes are parallel to the z-axis. All the dipole elements are connected at their feeding points to a terminal load Z_L.

Assume that the dipole array is to receive an incoming signal which is a plane wave of electromagnetic field propagating in a three-dimensional space. By using the standard moment method analysis (Harrington 1993) and discretizing each antenna into m segments, a system of $m \times n$ linear equations can be obtained in the following matrix form:

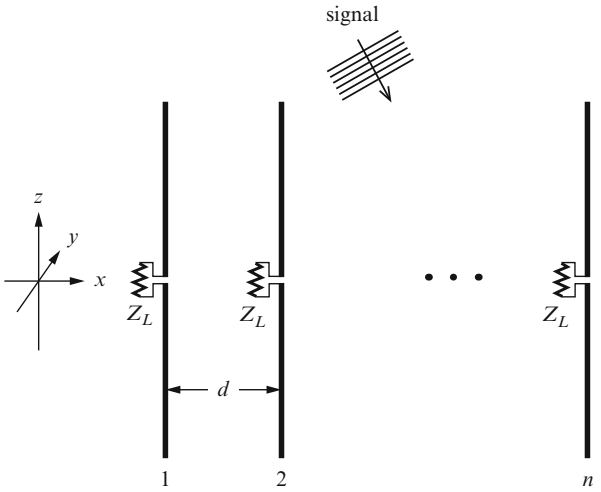

Fig. 1 The linear dipole antenna array for receiving a signal

DOI 10.1007/978-981-4560-75-7_13-2

$$\begin{bmatrix} [Z^{11}] & [Z^{12}] & \cdots & [Z^{1n}] \\ [Z^{21}] & [Z^{22}] & \cdots & [Z^{2n}] \\ \vdots & \vdots & \ddots & \vdots \\ [Z^{n1}] & [Z^{n2}] & \cdots & [Z^{nn}] \end{bmatrix} \begin{bmatrix} [I^1] \\ [I^2] \\ \vdots \\ [I^n] \end{bmatrix} = \begin{bmatrix} [V^1] \\ [V^2] \\ \vdots \\ [V^n] \end{bmatrix} \tag{1}$$

where the matrix blocks are respectively

$$[Z^{\alpha\beta}] = \begin{bmatrix} z_{11}^{\alpha\beta} - Z_L & z_{12}^{\alpha\beta} & \cdots & z_{1m}^{\alpha\beta} \\ z_{21}^{\alpha\beta} & z_{22}^{\alpha\beta} & \cdots & z_{2m}^{\alpha\beta} \\ \vdots & \vdots & \ddots & \vdots \\ z_{m1}^{\alpha\beta} & z_{m2}^{\alpha\beta} & \cdots & z_{mm}^{\alpha\beta} \end{bmatrix} \tag{2}$$

$$[I^{\alpha}] = [\, I_1^{\alpha} \quad I_2^{\alpha} \quad \cdots \quad I_m^{\alpha} \,]^T \tag{3}$$

$$[V^{\alpha}] = [\, V_1^{\alpha} \quad V_2^{\alpha} \quad \cdots \quad V_m^{\alpha} \,]^T. \tag{4}$$

For the matrix in Eq. 2, the element $z_{\mu\nu}^{\alpha\beta}$ (with $\alpha, \beta = 1, 2, \cdots, n$ and $\mu, \nu = 1, 2, \cdots, m$) denotes the impedance between the μth segment of the αth antenna element and the νth segment of the βth antenna element. The first segment is assumed to be connected to the terminal load Z_L. The vectors in Eqs. 3 and 4 are, respectively, the current distributions and the voltage distributions on the αth dipole element. The superscript "T" in Eqs. 3 and 4 denotes the matrix transpose operation. The voltage vector in Eq. 4 represents the excitation for the array due to the incoming signal. For the matrix elements $z_{\mu\nu}^{\alpha\beta}$ in Eq. 2, they can be expressed explicitly in terms of the dyadic Green's functions as follows:

$$z_{\mu\nu}^{\alpha\beta} = -j\omega\mu_0 \int_{\ell} I_{\mu}^{\alpha}(z) G_{zz}(z, z') I_{\nu}^{\beta}(z') dz' dz \tag{5}$$

where

$$G_{zz}(z, z') = \left[3 + j3k_0R - (k_0R)^2\right] \frac{(z - z')^2}{R^2} + \left[-1 - jk_0R + (k_0R)^2\right] \tag{6}$$

and

$$R = \left| \vec{R} - \vec{R} \right| = \sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2}. \tag{7}$$

From Eq. 1, it can be seen that the existence of the mutual coupling effect is due to the off-diagonal matrix blocks, i.e., $[Z^{\alpha\beta}]$ with $\alpha \neq \beta$. If the current distributions on the dipole elements, $[I^{\alpha}]\, \alpha = 1, 2, \cdots, n$, are exactly known, the mutual coupling effect can be exactly quantified. For example, if the mutual coupling effect due to all other antenna elements on the pth antenna element is to be eliminated, then the pth row of Eq. 1 can be first rewritten as

$$[Z^{pp}][I^p] = -\left[Z^{p1}\right]\left[I^1\right] - \cdots - \left[Z^{p(p-1)}\right]\left[I^{p-1}\right] - \left[Z^{p(p+1)}\right]\left[I^{p+1}\right] - \cdots - [Z^{pn}][I^n] + [V^p]. \tag{8}$$

DOI 10.1007/978-981-4560-75-7_13-2

It is seen that the left-hand side of Eq. 8 is exactly the system of equations resulted from the moment method analysis for the pth antenna element as if it were standing alone without the presence of all other antenna elements. However, the right-hand side of Eq. 8 has two excitation sources now:

(i) The excitation voltage induced by the current distributions on the other antenna elements =

$$-\left[Z^{p1}\right]\left[I^{1}\right]-\cdots-\left[Z^{p(p-1)}\right]\left[I^{p-1}\right]-\left[Z^{p(p+1)}\right]\left[I^{p+1}\right]-\cdots-\left[Z^{pn}\right]\left[I^{n}\right] \tag{9}$$

(ii) The excitation voltage due to the incoming signal on the pth antenna element =

$$\left[V^{p}\right] \tag{10}$$

By the principle of superposition, the effects on the pth antenna element due to these two excitation sources are independent, meaning that the field generated by any one of these two excitation sources satisfies the boundary conditions on the pth antenna alone and hence can exist independent of the field generated by the other source. Thus, if the current distributions on the antenna elements are completely and exactly known, the quantity $-\left[Z^{p1}\right]\left[I^{1}\right]-\cdots-\left[Z^{p(p-1)}\right]\left[I^{p-1}\right]-\left[Z^{p(p+1)}\right]\left[I^{p+1}\right]-\cdots-\left[Z^{pn}\right]\left[I^{n}\right]$ can be readily calculated, and the exact mutual coupling voltages from all other antenna elements can be determined.

The problem now is that only the voltages or currents on the antenna terminal loads can be measured (known). The knowledge of the *distributions* of the currents or voltages on every point of the antenna elements is not available. That is, at most only one point (the feeding point) of the current or voltage distribution in Eq. 3 or Eq. 4 can be measured. To solve this problem, a "single-mode" approximation can be made. That is, the current distribution on each antenna element in the array is treated as consisting of a single-mode current. Furthermore, the terminal currents and voltages on the antenna elements are used to describe the antenna array as an n-port network. By doing so, Eq. 8 is reduced to

$$\left(Z_t'^{pp}-Z_L\right)I_t'^{p}=-Z_t'^{p1}I_t'^{1}-\cdots-Z_t'^{p(p-1)}I_t'^{p-1}-Z_t'^{p(p+1)}I_t'^{p+1}-\cdots-Z_t'^{pn}I_t'^{n}+V_t'^{p} \tag{11}$$

in which a subscript "t" is added to signify that these variable/quantities are referred to the antenna *terminals*. Note also that the variables in Eq. 3 have been added with a prime to indicate that they are obtained under the single-mode assumption. The measurable quantities in Eq. 3 are the terminal currents $I_t'^{1},\ I_t'^{2},\ \cdots, I_t'^{p}, \cdots,\ I_t'^{n}$. On the left-hand side of Eq. 3, the term $\left(Z_t'^{pp}-Z_L\right)I_t'^{p}$ is the sum of the voltage dropped across the self-impedance of the pth antenna, $Z_t'^{pp}I_t'^{p}$, and the voltage dropped across the terminal load of the pth antenna, $-Z_L I_t'^{p}$. The voltage dropped across the self-impedance of the pth antenna $Z_t'^{pp}I_t'^{p}$ is not practically measurable. So this can further be removed from the left-hand side of Eq. 3 so that only the voltage dropped across the terminal load Z_L of the pth dipole element remains on the left-hand side of Eq. 3. However, to do so, it is also required to remove correspondingly that part of coupled voltages and that part of the incident voltage from the right-hand side of Eq. 3 which excite the voltage drop across the self-impedance. Finally, after the removal of these voltages from both sides of Eq. 3, the following new equation is obtained

$$-Z_L I_t^{p}=V_p=-Z_t^{p1}I_t^{1}-\cdots-Z_t^{p(p-1)}I_t^{p-1}-Z_t^{p(p+1)}I_t^{p+1}-\cdots-Z_t^{pn}I_t^{n}+U_t^{p} \tag{12}$$

DOI 10.1007/978-981-4560-75-7_13-2

where $-Z_t^{p1}I_t^1 - \cdots - Z_t^{p(p-1)}I_t^{p-1} - Z_t^{p(p+1)}I_t^{p+1} - \cdots - Z_t^{pn}I_t^n$ is the total coupled voltage dropped across the terminal load Z_L of the pth antenna due to the current distributions (single mode) on the other antenna elements in the array, U_t^p is the excitation voltage across the terminal load Z_L of the pth antenna due to the incoming signal alone, and V_p is the voltage across the terminal load Z_L of the pth antenna. Note that the prime notation on the term $I_t'^p$ on the left-hand side of Eq. 4 has been dropped to simplify the expression.

Thus from Eq. 4, it can be seen that the total terminal voltages V_p across the terminal load of the pth antenna can be expressed as a sum of products, each of which (e.g., $-Z_t^{pk}I_t^k$) is a multiplication of the terminal current (I_t^k) on an antenna element (other than the pth antenna) with a quantity known as the "modified mutual impedance" Z_t^{pk}. It is called "modified" because the meaning of this mutual impedance (Z_t^{pk}) is different from the conventional mutual impedance (Balanis 2005; Jordan 1968) (commonly denoted by Z_{pk}) in that this modified mutual impedance Z_t^{pk} measures only the *coupled voltage* across the terminal load of the pth antenna while the conventional mutual impedance Z_{pk} measures the *open-circuit voltage* on the pth antenna. The open-circuit voltage is the voltage dropped across the total impedance (i.e., the terminal load plus the self-impedance) of the pth antenna. Another difference is that the modified mutual impedance Z_t^{pk} refers to the situation where both antenna elements (the pth and kth) are in the passive mode (receiving mode) so that the current I_t^k is induced by an external signal whereas the conventional mutual impedance Z_{pk} refers to the situation where the pth antenna is in the passive mode while the kth antenna is in an active transmitting mode. Although this latter difference is not of a fundamental one, it does result in two different current distributions on the kth antenna under these two different situations. The two different current distributions on the kth antenna, in turn, induce different coupled voltages on the pth antenna. Thus, the modified mutual impedance Z_t^{pk} is different from the conventional mutual impedance Z_{pk}, and so a new name is given for this modified mutual impedance – the receiving mutual impedance. **Its definition is the ratio of the coupled voltage dropped across the terminal load of the *p*th antenna (due to the reradiation of the current distribution on the *k*th antenna) to the terminal current on the *k*th antenna, while the antenna array is in the passive receiving mode and excited by an external electromagnetic plane wave.** As the definition of the receiving mutual impedance requires an external plane wave source (which is to simulate the signal the antenna array is to receive), the result is that the value of the receiving mutual impedance is in general dependent on the direction (incident angle) of the plane wave. The difference between the receiving mutual impedance Z_t^{pk} and the conventional mutual impedance Z_{pk} will be demonstrated in the next section.

Another observation from Eq. 4 can be obtained by rewriting it as

$$\begin{aligned} V_p &= -Z_L I_t^p = -Z_L\left(I_c^p + I_s^p\right) \\ &= W + U_t^p \\ &= -Z_t^{p1}I_t^1 - \cdots - Z_t^{p(p-1)}I_t^{p-1} - Z_t^{p(p+1)}I_t^{p+1} - \cdots - Z_t^{pn}I_t^n + U_t^p \end{aligned} \tag{13}$$

where I_t^p has been split into two parts: I_c^p and I_s^p so that I_c^p is that part of the current on the pth antenna that is induced by the scattered fields from the other antenna elements and I_s^p is that part of the current on the pth antenna that is induced by the incoming signal U_t^p along. I_c^p can be termed as the *coupled current*, and I_s^p can be termed as the *isolated current* on the pth antenna. In Eq. 5, W is used to denote the total coupled voltage, i.e.,

$$W = -Z_t^{p1}I_t^1 - \cdots - Z_t^{p(p-1)}I_t^{p-1} - Z_t^{p(p+1)}I_t^{p+1} - \cdots - Z_t^{pn}I_t^n \tag{14}$$

DOI 10.1007/978-981-4560-75-7_13-2

and hence

$$\begin{cases} W = -Z_L I_c^p = \text{total coupled voltage} \\ U_t^p = -Z_L I_s^p = \text{signal voltage} \end{cases}. \tag{15}$$

From Eqs. 5 and 7, it can be seen that if all the receiving mutual impedances Z_t^{pk} and the terminal currents $I_t^k \ (k = 1, 2, \cdots, (p-1), (p+1), \cdots, n)$ on the antenna elements are known, it is able to quantify and remove the total coupled voltage W from the terminal voltage across the terminal load of the pth antenna, leaving behind the isolated signal voltage U_t^p. Note that this result cannot be obtained by using the conventional mutual impedances Z_{pk} (Balanis 2005; Jordan 1968; Gupta and Ksienski 1983). The set of isolated signal voltages $U_t^p \ (p = 1, 2, \cdots, n)$ is known as the ideal array manifold and is one of the important fundamental concepts in array signal processing.

Theoretical and Experimental Methods for the Determination of the Receiving Mutual Impedance

As explained in the last section, for characterizing the mutual coupling effect in a receiving antenna array, it is more accurate to use the receiving mutual impedance. The next question is how to determine it. As the receiving mutual impedance is different from the conventional mutual impedance, different methods are needed. In this section, theoretical and measurement methods will be introduced to determine the receiving mutual impedance.

Theoretical Methods for the Determination of the Receiving Mutual Impedance

Theoretical Method Based on the Calculation of Current Distributions

This section will introduce the development of the concept of receiving mutual impedance from the method of moments (Hui 2004a). Consider a two-antenna array as shown in Fig. 2. For an antenna array with more than two elements, it can be considered as consisted of different pairs of two-element arrays with different separations. By the definition of receiving mutual impedance, it is the ratio of the coupled voltage dropped across the terminal load of the first antenna to the source terminal current on the second antenna, whereas both antennas are in the passive receiving mode and excited by an external electromagnetic plane wave. Hence the simplest theoretical method for determining the receiving mutual impedance is to excite the two antennas by a plane wave and obtain the current distribution on antenna 2 (denote its

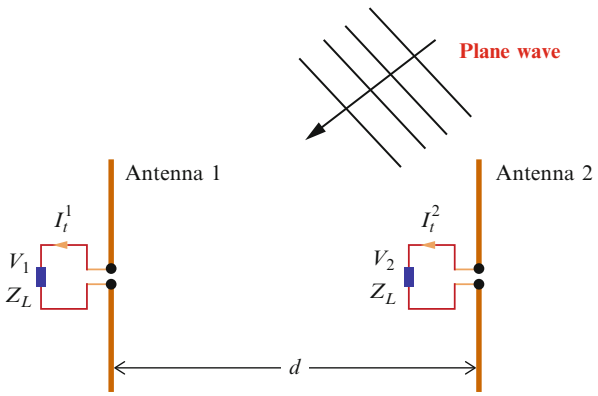

Fig. 2 The scenario for the theoretical calculation of the receiving mutual impedance

DOI 10.1007/978-981-4560-75-7_13-2

value at the terminal load as I_t^2). Then remove the plane wave source and excite antenna 1 by the current distribution on antenna 2 (reradiation). Calculate the voltage dropped across the terminal load of antenna 1 (denote it as W_1). Then the receiving mutual impedance Z_t^{12} can be determined by (see Eq. 21)

$$Z_t^{12} = -\frac{W_1}{I_t^2}. \tag{16}$$

The receiving mutual impedance Z_t^{21} can also be determined similarly. By this method, it is required to first calculate the current distribution on antenna 1 or antenna 2, which later served as the reradiation source. Some software may not be able to assign and use a current distribution as the excitation source. In this case, an alternative method as introduced below can be used.

Theoretical Method Based on the Calculation of Antenna Terminal Voltages

This section will introduce the development of the concept of receiving mutual impedance from the method of moments (Hui 2003). For the two receiving antennas shown in Fig. 2, V_1 and V_2 are the total received voltages across the terminal loads of antennas 1 and 2, respectively, when the array is excited by a plane wave. The corresponding terminal currents on the two antennas are I_t^1 and I_t^2. Using these terminal quantities (which can be directly measured), the receiving mutual impedance Z_t^{12} can be calculated as follows:

$$\begin{aligned} Z_t^{12} &= \frac{\text{Coupled voltage across antenna 1}'\text{s terminal load}}{\text{Received current on antenna 2}'\text{s terminal load}} \\ &= -\frac{V_1 - U_t^1}{I_2} \end{aligned} \tag{17}$$

where U_t^1 is the received voltage across the terminal load of antenna 1 when antenna 1 is excited by the plane wave alone (with antenna 2 removed from the array). U_t^1 can be termed as the isolated voltage on antenna 1, and it can be calculated as shown in Fig. 3. Using this method, there is no need to calculate the current distribution on the antennas. Because of this advantage, this method is also suitable for experimental determination of the receiving mutual impedance, as will be shown later. In a similar way, Z_t^{21} can also be determined.

A typical calculation of the receiving mutual impedance is shown in Fig. 4. This is the receiving mutual impedance Z_t^{12} between two monopole antennas at a frequency of 2.4 GHz and is shown against the separation between the two antennas. The dimensions of the monopole antennas are length = 3 cm (0.24λ at 2.4 GHz) and radius = 0.3 mm. Each monopole antenna is connected to a terminal load of $Z_L = 50\Omega$. The plane wave used to excite the array comes from the horizontal direction with $\theta = 90°$ and

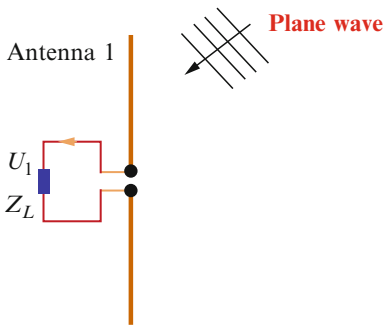

Fig. 3 The situation for the calculation of the isolated voltage U_t^1

DOI 10.1007/978-981-4560-75-7_13-2

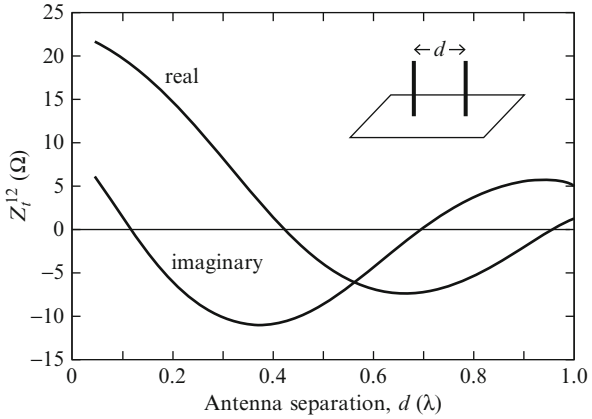

Fig. 4 The receiving mutual impedance Z_t^{12} between two monopole antennas with their separation at a frequency of 2.4 GHz

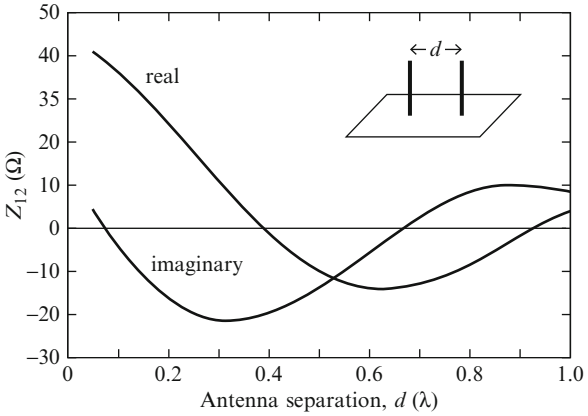

Fig. 5 The corresponding conventional mutual impedance Z_{12} between the two monopole antennas as shown in Fig. 4

from an azimuth angle $\phi = 0$. Note that due to the circular symmetry of the monopole antennas, the received currents on the two monopoles are independent of ϕ, and hence the value of ϕ can be arbitrary. For comparison, the corresponding conventional mutual impedance Z_{12} between these two monopole antennas is shown in Fig. 5.

Experimental Methods for the Determination of the Receiving Mutual Impedance

Experimental Method Considering Two Antenna Elements at a Time

This subsection will describe the experimental method considering two antenna elements at a time (Hui 2004b). To determine the receiving mutual impedance experimentally, a vector network analyzer (VNA) is required to take measurements inside an anechoic chamber, as shown in Fig. 6. The same two monopoles as in Fig. 4 are considered again here for the experimental measurement. The operating frequency is 2.4 GHz, and the two monopoles are kept at a fixed separation of 6.25 cm (half wavelength at 2.4 GHz). The monopoles are labeled as monopole 1 and monopole 2. By using the toggle switch as shown in Fig. 6, the scattering parameters (S_{12} or S_{21}) of the two monopoles are measured in turn. The measured scattering parameter, for example, S_{21}, is converted into a voltage according to Pozar (1990)

$$S_{21} = \frac{\beta}{\alpha} \tag{18}$$

DOI 10.1007/978-981-4560-75-7_13-2

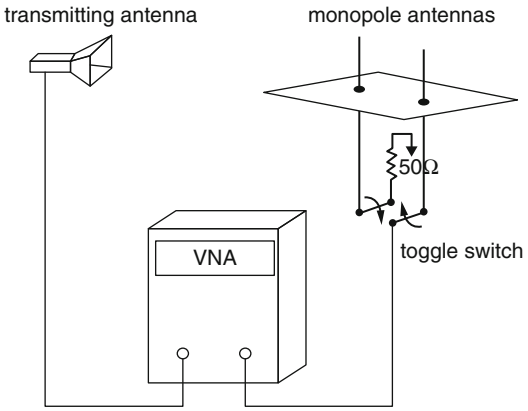

Fig. 6 The measurement of the receiving mutual impedances inside an anechoic chamber using a vector network analyzer

where α is the square root of the power emitted by the transmitting horn inside the anechoic chamber and $\beta = V/\sqrt{Z_0}$ is the square root of the power received by a monopole element with V being the terminal voltage of the monopole element and Z_0 being the system impedance (50Ω). Both α and β are complex values with magnitudes and phases. The detailed measurement procedures are as follows (Hui 2004b):

1. Measure S_{21} at monopole 1's terminal with monopole 2's terminal connected to a load Z_0. Denote it as S_{21_1}.
2. Measure S_{21} at monopole 2's terminal with monopole 1's terminal connected to a load Z_0. Denote it as S_{21_2}.
3. Measure S_{21} at monopole 1's terminal with monopole 2 removed (taken away from the array). Denote it as S'_{21_1}.
4. Measure S_{21} at monopole 2's terminal with monopole 1 removed (taken away from the array). Denote it as S'_{21_2}.

Throughout the whole measurement process, the positions of the two monopoles must be kept fixed since any change in their positions will alter the phase and magnitude of S_{21}. This is especially true when one of the antennas is being taken away from or put back into its original position. Now convert the measured scattering parameters S_{21} into its respective terminal voltages using Eq. 10. That is,

$$V_t^1 = S_{21\_1}\alpha\sqrt{Z_0} \tag{19}$$

$$V_t^2 = S_{21\_2}\alpha\sqrt{Z_0} \tag{20}$$

$$V_t'^1 = S'_{21\_1}\alpha\sqrt{Z_0} \tag{21}$$

$$V_t'^2 = S'_{21\_2}\alpha\sqrt{Z_0} \tag{22}$$

where

V_t^1 is the measured voltage at monopole 1's terminal with monopole 2's terminal connected to a load Z_0.
V_t^2 is the measured voltage at monopole 2's terminal with monopole 1's terminal connected to a load Z_0.
$V_t'^1$ is the measured voltage at monopole 1's terminal with monopole 2 removed.
$V_t'^2$ is the measured voltage at monopole 2's terminal with monopole 1 removed.

DOI 10.1007/978-981-4560-75-7_13-2

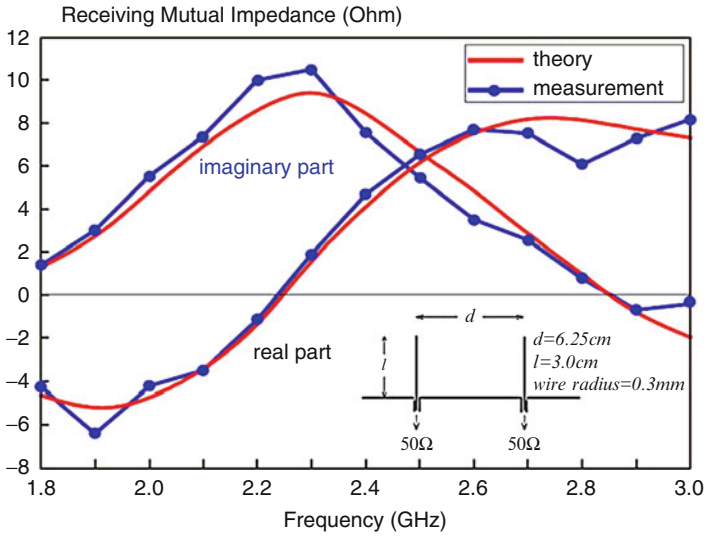

Fig. 7 The receiving mutual impedance Z_t^{12} between two monopole antennas with frequency at a fixed separation of 6.25 cm (0.5λ at 2.4 GHz). The two antennas are the same as those in Fig. 4

Then from Eq. 9,

$$V_t^1 = U_t^1 - Z_t^{12} I_t^2, \quad V_t^2 = U_t^2 - Z_t^{21} I_t^1 \tag{23}$$

$$V'^1_t = U_t^1, \quad V'^2_t = U_t^2 \tag{24}$$

$$I_t^1 = -\frac{V_t^1}{Z_0}, \quad I_t^2 = -\frac{V_t^2}{Z_0}, \quad I'^1_t = -\frac{V'^1_t}{Z_0}, \quad I'^2_t = -\frac{V'^2_t}{Z_0}. \tag{25}$$

From Eqs. 15 and 16, the following two relations can be obtained:

$$-\left(V_t^1 - V'^1_t\right) = Z_t^{12} I_t^2, \quad -\left(V_t^2 - V'^2_t\right) = Z_t^{21} I_t^1. \tag{26}$$

Finally, using Eq. 17, the measured values of Z_t^{12} and Z_t^{21} can be determined as

$$\begin{aligned} Z_t^{12} &= \frac{\left(V_t^1 - V'^1_t\right)}{V_t^2} Z_0 & Z_t^{21} &= \frac{\left(V_t^2 - V'^2_t\right)}{V_t^1} Z_0 \\ &= \frac{\left(S_{21\_1} - S'_{21\_1}\right)}{S_{21\_2}} Z_0, & &= \frac{\left(S_{21\_2} - S'_{21\_2}\right)}{S_{21\_1}} Z_0. \end{aligned} \tag{27}$$

Thus, the receiving mutual impedances can be obtained in terms of the measured scattering parameters. An example measurement result of Z_t^{12} with frequency is shown in Fig. 7 for two monopole antennas (same as the two antennas in Fig. 4) at a fixed separation of 6.25 cm. The result is compared with the theoretically calculated one.

DOI 10.1007/978-981-4560-75-7_13-2

Experimental Method Considering All Antenna Elements Together

Strictly speaking, the previous experimental method is an approximation method only this section will introduce the development of the concept of receiving mutual impedance from the method of moments (Lui and Hui 2010a, b, c). This is because it only considers two antenna elements at a time. But doing this would ignore the scattering effect from other antenna elements in the array, if the array has more than two antenna elements. This shortcoming can be overcome in some types of antenna arrays. Two typical such antenna arrays are the monopole and dipole arrays because the element pattern of a monopole or a dipole is omnidirectional in the azimuth plane. For this type of antenna arrays, the receiving mutual impedances of all the antenna elements can be determined simultaneously (not two at a time) and accurately by measurement or calculation.

Consider an n-element dipole antenna array as shown in Fig. 1. When an incoming plane wave signal is incident on the array from a horizontal direction ϕ (with $\theta = 90$), the terminal voltage on the antenna elements can be represented as (see Eq. 19)

$$\begin{cases} V_1 = -Z_L I_t^1 = -Z_t^{12} I_t^2 - \cdots - Z_t^{1n} I_t^n + U_t^1 \\ V_2 = -Z_L I_t^2 = -Z_t^{21} I_t^1 - \cdots - Z_t^{2n} I_t^n + U_t^2 \\ \vdots \\ V_p = -Z_L I_t^p = -Z_t^{p1} I_t^1 - \cdots - Z_t^{p(p-1)} I_t^{p-1} - Z_t^{p(p+1)} I_t^{p+1} - \cdots - Z_t^{pn} I_t^n + U_t^p \\ \vdots \\ V_n = -Z_L I_t^n = -Z_t^{n1} I_t^1 - \cdots - Z_t^{n(n-1)} I_t^{n-1} + U_t^n \end{cases}. \tag{28}$$

The terminal currents I_t^p can be expressed using the terminal voltages V_p as

$$I_t^1 = -\frac{V_1}{Z_L},\ I_t^2 = -\frac{V_2}{Z_L},\ \cdots,\ I_t^n = -\frac{V_n}{Z_L}. \tag{29}$$

Putting Eq. 21 into Eq. 20, the following matrix equation can be obtained:

$$\begin{bmatrix} 1 & -\frac{Z_t^{12}}{Z_L} & \cdots & -\frac{Z_t^{1(n-1)}}{Z_L} & -\frac{Z_t^{1n}}{Z_L} \\ -\frac{Z_t^{21}}{Z_L} & 1 & \cdots & -\frac{Z_t^{2(n-1)}}{Z_L} & -\frac{Z_t^{2n}}{Z_L} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ -\frac{Z_t^{(n-1)1}}{Z_L} & -\frac{Z_t^{(n-1)2}}{Z_L} & \cdots & 1 & -\frac{Z_t^{(n-1)n}}{Z_L} \\ -\frac{Z_t^{n1}}{Z_L} & -\frac{Z_t^{n2}}{Z_L} & \cdots & -\frac{Z_t^{n(n-1)}}{Z_L} & 1 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_{n-1} \\ V_n \end{bmatrix} = \begin{bmatrix} U_t^1 \\ U_t^2 \\ \vdots \\ U_t^{n-1} \\ U_t^n \end{bmatrix}. \tag{30}$$

Consider the first row of Eq. 22. It is written below:

$$V_1 - Z_t^{12}\frac{V_2}{Z_L} - \cdots - Z_t^{1k}\frac{V_k}{Z_L} \cdots - Z_t^{1n}\frac{V_n}{Z_L} = U_t^1. \tag{31}$$

The terminal voltages in Eq. 23, $V_1, V_2, \cdots, V_n$, and U_t^1 are measured when the incoming signal comes from an azimuth angle ϕ (with $\theta = 90$). It is not difficult to understand that due to the different positions

DOI 10.1007/978-981-4560-75-7_13-2

of the antenna elements and the unequal mutual coupling effect, these terminal voltages (especially their phases) are dependent on the incoming direction ϕ of the signal. But on the other hand, the receiving mutual impedances in Eq. 23 are independent of the incoming direction of the signal due to the circular symmetry and the omnidirectional radiation patterns of the antenna elements. These receiving mutual impedances depend only on the relative position of the antenna elements. Because of these two observations, the measurement of the terminal voltages can be carried out at different azimuth angles (but same θ). If this measurement is repeated $(n-1)$ times at $(n-1)$ different azimuth angles, the following system of equations can be obtained:

$$\begin{cases} V_1^{\phi_1} - Z_t^{12}\dfrac{V_2^{\phi_1}}{Z_L} - \cdots - Z_t^{1k}\dfrac{V_k^{\phi_1}}{Z_L}\cdots - Z_t^{1n}\dfrac{V_n^{\phi_1}}{Z_L} = U_t^{1,\phi_1} \\ V_1^{\phi_2} - Z_t^{12}\dfrac{V_2^{\phi_2}}{Z_L} - \cdots - Z_t^{1k}\dfrac{V_k^{\phi_2}}{Z_L}\cdots - Z_t^{1n}\dfrac{V_n^{\phi_2}}{Z_L} = U_t^{1,\phi_2} \\ \vdots \\ V_1^{\phi_{n-1}} - Z_t^{12}\dfrac{V_2^{\phi_{n-1}}}{Z_L} - \cdots - Z_t^{1k}\dfrac{V_k^{\phi_{n-1}}}{Z_L}\cdots - Z_t^{1n}\dfrac{V_n^{\phi_{n-1}}}{Z_L} = U_t^{1,\phi_{n-1}} \end{cases} . \tag{32}$$

The system in Eq. 24 contains $(n-1)$ unknowns, i.e., the receiving mutual impedances $Z_t^{12}, Z_t^{13}, \cdots, Z_t^{1n}$. But there are also $(n-1)$ equations in this system. Hence Eq. 24 can be uniquely solved, and the $(n-1)$ receiving mutual impedances can be determined accurately. The $(n-1)$ azimuth angles, $\phi_1, \phi_2, \cdots, \phi_{n-1}$, for the incoming signal directions can be chosen to be equally divided in the angular range $0 \sim \pi$. When the second row of Eq. 22 is considered and the above procedure is repeated, the receiving mutual impedances, $Z_t^{21}, Z_t^{23}, \cdots, Z_t^{2n}$, can be determined in the same way. This procedure can be repeated $(n-1)$ times, and all the receiving mutual impedances in Eq. 22 can then be determined. Obviously, this method can also be used to theoretically calculate the receiving mutual impedances of an antenna array. As this method accounts for the scattering effect from all the antenna elements in the array, it is accurate, especially when the element separation is very small. A typical determination of the receiving mutual impedances of an eight-element dipole array by using this method and the method described in section "Experimental Method Considering Two Antenna Elements at a Time" is shown in Table 1 (Lui

Table 1 Comparison of receiving mutual impedances determined using the two measurement methods in sections "Experimental Method Considering Two Antenna Elements at a Time" and "Experimental Method Considering All Antenna Elements Together." The antenna array is an eight-element uniform linear array with dipole antenna elements. The length of the monopoles is 0.48λ and diameter of the dipoles is 0.6 mm. The operation frequency is 2.4 GHz. The element separation is denoted by d

and Hui 2010a). It can be seen that the differences between these two methods are significant only when the element separation is very small, i.e., $d = 0.15\lambda$.

Comparison of the Receiving Mutual Impedance and the Conventional Mutual Impedance

In order to compare the receiving mutual impedance and the conventional mutual impedance, a brief revision of the conventional mutual impedance is required. Consider a two-element transmitting dipole antenna array with the dipole elements parallel to the z-axis as shown in Fig. 8. When the dipole antennas are excited by excitation sources V_{s1} and V_{s2} at their feeding terminals, the tangential electric field $E_1(z)$ on the surface of the antenna 1 can be written as follows (Ishimaru 1991):

$$E_1(z) = E_{11}(z) + E_{12}(z) \tag{33}$$

where $E_{11}(z)$ and $E_{12}(z)$ are the tangential electric fields on the surface of antenna 1 caused by currents on antenna 1 and antenna 2, respectively. The conventional mutual impedances Z_{12} can be derived through the following procedure. Multiply Eq. 25 with the current on antenna 1, $I_1(z)$, on both sides and integrate throughout the length of antenna 1, the following expression is obtained:

$$-I_t^1\left(V_{s1} - V_{g1}\right) = -I_t^1 V_1 = \int_\ell I_1(z)E_{11}(z)d\ell + \int_\ell I_1(z)E_{12}(z)d\ell \tag{34}$$

where I_t^1 is the terminal current on antenna 1 ($I_1(z)$ is the current distribution on antenna 1), V_{g1} is the voltage dropped across the source impedance, and $V_1 = V_{s1} - V_{g1}$ is the voltage across the terminal of antenna 1. From Eq. 26, the following expression can be obtained:

$$\begin{aligned} V_1 &= I_t^1\left[\frac{-1}{\left(I_t^1\right)^2}\int_\ell I_1(z)E_{11}(z)d\ell\right] + I_t^2\left[\frac{-1}{I_t^1 I_t^2}\int_\ell I_1(z)E_{12}(z)d\ell\right] \\ &= I_t^1 Z_{11} + I_t^2 Z_{12} \end{aligned} \tag{35}$$

where Z_{11} is the self-impedance of antenna 1, I_t^2 is terminal current on antenna 2, and

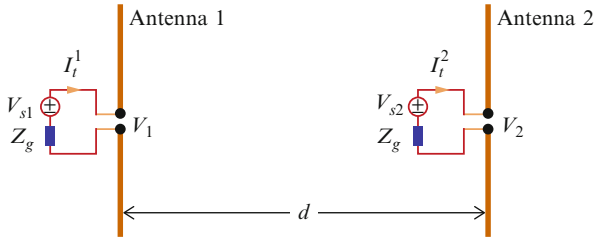

Fig. 8 A two-element transmitting dipole antenna array

DOI 10.1007/978-981-4560-75-7_13-2

$$Z_{12} = \left[\frac{-1}{I_t^1 I_t^2}\int_{\ell} I_1(z)E_{12}(z)d\ell\right] = \text{Conventional mutual impedance.} \tag{36}$$

Equations 28 and 27 show that the conventional mutual impedance Z_{12} measures the "*open-circuit voltage*" dropped across the terminal of antenna 1 due to the *scattered* field $E_{12}(z)$ produced by the current on antenna 2. On the other hand, the receiving mutual impedance Z_t^{12} defined in section "Theoretical and Experimental Methods for the Determination of the Receiving Mutual Impedance" for two receiving antennas measures the voltage dropped across the *terminal load* of antenna 1 due to the *total* field produced by the current on antenna 2. Thus, the terminal voltage across the terminal load of antenna 1 can be written as

$$V_1 = Z_t^{12} I_t^2 + U_t^1. \tag{37}$$

Except this difference, another more fundamental difference can be seen from Eqs. 27 and 29. For the receiving mutual impedance in Eq. 29, the coupled voltage term $Z_t^{12} I_t^2$ truly characterizes the *complete* mutual coupling effect on antenna 1 due to the current on antenna 2. Hence when this coupled voltage $Z_t^{12} I_t^2$ is taken away from the terminal voltage V_1, the remaining voltage U_t^1 is the truly isolated voltage across the terminal load of antenna 1. That is, U_t^1 is the voltage on antenna 1 when antenna 2 is taken away (completely absent) from the array. On the other hand, this is not the case with the conventional mutual impedance in Eq. 27 for the transmitting dipole antenna array. The coupled voltage term $I_t^2 Z_{12}$ in Eq. 27 is *not* the *complete* mutual coupling effect on antenna 1 due to the current on antenna 2. This is because this term only accounts for the coupled voltage on antenna 1 due to the scattered field from antenna 2, $E_{12}(z)$. The total coupled voltage should also include the additional coupled voltage on antenna 1 produced by the additional current on antenna 1 (on top of the original isolated current on antenna 1 when it stands alone) that is induced by the current on antenna 2. Because of this, when the coupled voltage $I_t^2 Z_{12}$ in Eq. 27 is taken away from the total terminal voltage V_1, the remaining voltage $I_t^1 Z_{11}$ does not represent the truly isolated voltage across the terminal of antenna 1 as it were alone. That means the uncoupled voltage $I_t^1 Z_{11}$ is different from the voltage on antenna 1 when antenna 2 is taken away from the array. This difference is not trivial as in many antenna array applications, it is required to have the ideal undistorted array signals (ideal array manifold), i.e., the isolated voltages, $U_t^1, U_t^2, \cdots, U_t^n$, and these can only be obtained by using the receiving mutual impedances. This difference is a fundamental one.

The Application of the Receiving Mutual Impedance in the Direction-of-Arrival (DOA) Estimation

The application of the concept of receiving mutual impedance in the direction-of-arrival (DOA) estimation using an antenna array is to be demonstrated in this section. Typical DOA estimation algorithms, such as MUSIC (Schmidt 1986; Schmidt and Franks 1986) and ESPRIT (Roy and Kailath 1989), are known to be highly sensitive to the errors in the array manifold. In practical antenna arrays, one common error in the array manifold is the mutual coupling effect among the antenna elements. When there is mutual coupling, compensation methods are usually required in order to restore the correct array manifold. There have been many compensation methods proposed before (e.g., Hui 2003; Gupta and Ksienski 1983; Dandekar et al. 2002; Lau et al. 2004; Yang and Nie 2005; Goossens and Rogier 2007; Ye and Liu 2008; Wu and Nie 2009; Hui 2007; Yu et al. 2011; Yu and Hui 2011; Niow and Hui 2012; Yeh et al. 1989). Among these

compensation methods, the one proposed originally in Gupta and Ksienski (1983) which uses the conventional mutual impedances to characterize the mutual coupling effect is probably the most popular one and can be termed as the conventional mutual impedance method (CMIM). However, CMIM uses the conventional mutual impedances to characterize the mutual coupling effect in receiving antenna arrays (direction finding arrays) and hence suffers from the drawback of inaccuracy as it fails to recover the isolated voltages (the ideal array manifold) on the antenna elements as explained in section "Comparison of the Receiving Mutual Impedance and the Conventional Mutual Impedance." In this section, the use of receiving mutual impedances to improve the accuracy of DOA estimation is illustrated through several examples.

In the Presence of Uncorrelated Array Noise

As shown in Fig. 9, a seven-monopole array is constructed to operate at 2.4 GHz to detect two coherent signals. The dimensions of the individual monopole antennas are optimized to be 30 mm (0.24λ), and the

DOI 10.1007/978-981-4560-75-7_13-2

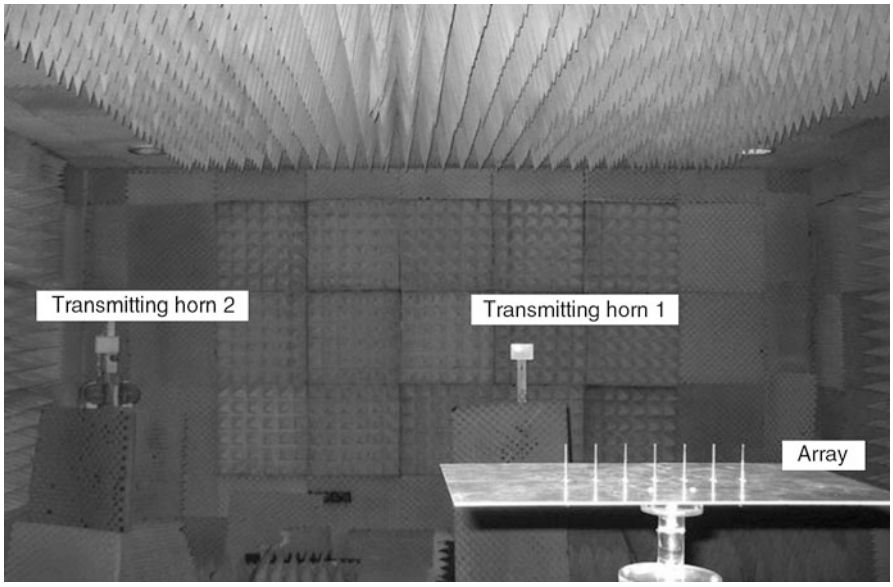

Fig. 11 The experimental setup for the two-source DOA estimation inside an anechoic chamber

diameter of the monopoles is 1 mm. The separation between adjacent monopole elements is 25 mm (0.2λ at 2.4 GHz). An isolated monopole antenna with these dimensions has a return loss of about 16 dB at 2.4 GHz. The measured receiving mutual impedances Z_t^{12} (the receiving mutual impedance between the first and the second elements) are shown in Fig. 10. The corresponding measured conventional mutual impedances are also shown for comparison. The conventional mutual impedances are obtained from the measurement of the two-port S parameters of the pair of antenna elements. The experimental setup is shown in Fig. 11. Two coherent sources are simulated by two transmitting horn antennas inside the anechoic chamber. The two horn antennas are fed from a VNA (vector network analyzer) output port through a power divider such that the powers' output to the two horn antennas is equal. The measured S_{21} parameter, which indicates the relative power received by the monopoles, is converted into voltages (see Eq. 27). In this way, all the received voltages V_i $(i = 1,\ 2, \cdots, 7)$ on the antenna elements can be measured one by one. The angular separation between the two horn signals is varied from about 50–30°. Using Yeh's method (Yeh et al. 1989) for DOA estimation with the MUSIC algorithm, a covariance matrix $\mathbf{R}$ can be formed as follows:

$$\mathbf{R} = E\{\mathbf{v}(t)\mathbf{v}^T(t)\} = \frac{1}{2}\mathbf{V}\mathbf{V}^H \tag{38}$$

where $E\{\}$ is the expectation operator, $\mathbf{v}(t)$ is the time-domain vector of the antenna terminal voltages (including noise), $\mathbf{V}$ is the corresponding phasor representation of $\mathbf{v}(t)$, and "^{H}" is the conjugate transpose operator.

Note that in Eq. 30, the time-domain expectation values of the covariance matrix ($E\{\mathbf{v}(t)\mathbf{v}^T(t)\}$) elements are replaced by their equivalent phasor-domain values (the elements of $\mathbf{V}\mathbf{V}^H$) which are exactly the output from the VNA machine. The equivalence between the time-domain expectation operation and the multiplication operation in the phasor-domain can be obtained from many textbooks, for example, Cheng's book (Cheng 1983). Once $\mathbf{R}$ is obtained, a transformed covariance matrix $\mathbf{R}'$ is formed according to Yeh's method (Yeh et al. 1989):

DOI 10.1007/978-981-4560-75-7_13-2

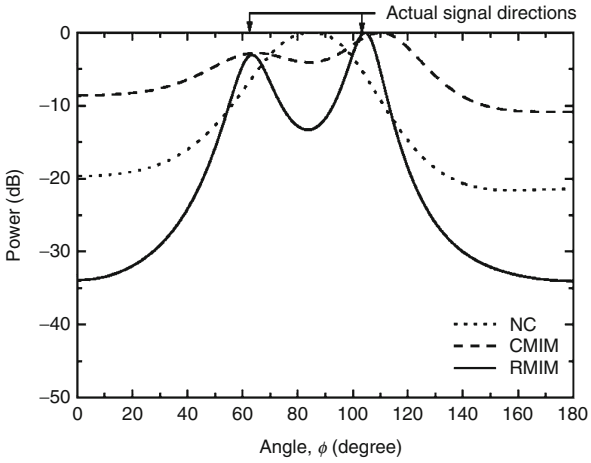

Fig. 12 The MUSIC spectra for the estimation of two sources at $\phi_1 = 62.4°$ and $\phi_2 = 103.2°$ with an angular separation of 40.8°. The spectra were obtained with the mutual coupling effect being compensated by different methods: (i) with no compensation (NC), (ii) using the conventional mutual impedance method (CMIM), and (iii) using the receiving mutual impedance method (RMIM). The averaged SNR of the received voltages is 34.6 dB (Taken from (Yu et al. 2011)

$$\mathbf{R}' = \mathbf{ZRZ}^H = \frac{1}{2}\mathbf{ZVV}^H\mathbf{Z}^H = \frac{1}{2}\mathbf{UU}^T + \frac{1}{2}\sigma^2\mathbf{ZZ}^T \tag{39}$$

where $\mathbf{U}$ is the vector for the compensated signal voltages, σ^2 is the noise power received at the antenna terminals, and $\mathbf{Z}$ is the mutual impedance matrix on the left-hand side of Eq. 22, with $n = 7$. That is,

$$\mathbf{Z} = \begin{bmatrix} 1 & -\frac{Z_t^{12}}{Z_L} & \cdots & -\frac{Z_t^{16}}{Z_L} & -\frac{Z_t^{17}}{Z_L} \\ -\frac{Z_t^{21}}{Z_L} & 1 & \cdots & -\frac{Z_t^{26}}{Z_L} & -\frac{Z_t^{17}}{Z_L} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ -\frac{Z_t^{61}}{Z_L} & -\frac{Z_t^{62}}{Z_L} & \cdots & 1 & -\frac{Z_t^{67}}{Z_L} \\ -\frac{Z_t^{71}}{Z_L} & -\frac{Z_t^{72}}{Z_L} & \cdots & -\frac{Z_t^{76}}{Z_L} & 1 \end{bmatrix}. \tag{40}$$

The reason to form the transformed covariance matrix $\mathbf{R}'$ is that it can be used in the spatial smoothing method for detecting two coherent sources. Note that the noise associated with $\mathbf{R}'$ in Eq. 31 is correlated now ($\sigma^2\mathbf{ZZ}^T$) although the noise itself is assumed to be uncorrelated among the antenna elements. The correlation in noise is due to antenna mutual coupling, and this will affect the MUSIC operation to some extent. (In the next section, the case with spatial correlated noise will be investigated, i.e., the case in which the array noise is itself correlated even before received by the array.) With the transformed covariance matrix $\mathbf{R}'$, a generalized eigenvalue decomposition was performed to enable the construction of a MUSIC spatial spectrum function (Yeh et al. 1989).

Figure 12 shows the MUSIC estimation results when the two sources are coming from angles of $\phi_1 = 62.4°$ and $\phi_2 = 103.2°$ with an angular separation of 40.8°. It can be seen that even at this relatively large angular separation, both the NC (no compensation) and CMIM cases fail to correctly detect the two source directions. On the other hand, when the RMIM (receiving mutual impedance method) was used, the MUSIC spectrum correctly indicates the source directions with relatively small errors. The results in

DOI 10.1007/978-981-4560-75-7_13-2

Fig. 12 are obtained at an SNR of 39.1 dB and averaged over the antenna elements with a standard deviation of 7.0 dB. More details can be obtained from Yu's paper (Yu et al. 2011).

In the Presence of Correlated Array Noise: An Intensive Treatment of Array Noise

Recent studies (Torrieri and Bakhru 1997; Zhao and Zhang 2000; Craeye et al. 2004; Kisliansky et al. 2007) have shown that under practical situations, array noise tends to be correlated, even at a moderate antenna element separation such as half wavelength. Because of this, many modified DOA estimation methods have been proposed to tackle the problem of correlated noise (e.g., Zhao and Zhang 2000; Prasad et al. 1988; Rajagopal and Rao 1991; Qi et al. 2005; Werner and Jansson 2005; Qi et al. 2007). In Prasad et al. (1988) and Zhao and Zhang (2000), a covariance differencing method was developed to remove the correlated noise covariance matrix which was characterized as a symmetric Toeplitz matrix. In Qi et al. (2005) and Qi et al. (2007), the spatial difference smoothing (SDS) method was developed, relying similarly on the Toeplitz nature of the correlated noise covariance matrix to handle the correlated noise. Most of the previous correlated noise handling methods did not consider the effect of antenna mutual coupling.

In the following, a new method is introduced to tackle correlated noise in DOA estimations in the presence of antenna mutual coupling. Unlike the previous methods in Craeye et al. (2004) and Kisliansky et al. (2007) which considered noise as an internal and an external parts, in this method, the array noise is divided into a coupled and an uncoupled components whose origins can be traced back into the array environment and the internal circuitry of the antenna elements. Through this division of noise, the coupled and uncoupled noise components can be handled separately. More importantly, it is shown that antenna mutual coupling in the coupled noise component can be compensated in the same way as the signals, leading to a simple but very effective MUSIC DOA estimation algorithm.

Coupled Array Noise Modeling Using Receiving Mutual Impedances

Consider an antenna array with n elements employed in DOA estimation in the presence of both external and internal noise. The external noise is the noise that comes from the environment of the array, while the internal noise is the noise generated inside the antenna elements. The received array signal vector $\mathbf{x}(t)$ at time t is given by

$$\mathbf{x}(t) = \mathbf{v}(t) + \mathbf{n}_c(t) + \mathbf{n}_u(t) \tag{41}$$

where $\mathbf{v}(t)$ is an $n \times 1$ column vector for the signal voltages due to the incoming signals, $\mathbf{n}_c(t)$ is an $n \times 1$ column vector for the coupled noise voltages, and $\mathbf{n}_u(t)$ is an $n \times 1$ column vector for the uncoupled noise voltages. $\mathbf{v}(t)$, $\mathbf{n}_c(t)$, and $\mathbf{n}_u(t)$ are assumed to be mutually uncorrelated. Note that all the signals and noise are expressed in their analytic forms unless stated otherwise. Here the division of noise into the coupled and uncoupled components has an advantage for the MUSIC DOA estimation algorithm, especially when compensation for antenna mutual coupling effect is required. This will be explained in the next section (section "MUSIC DOA Estimation Algorithm with Coupled Array Noise").

For an antenna array, noise mainly comes from two physical sources: external environment and the internal circuitries (Craeye et al. 2004). The external environmental noise source induces coupled noise currents on the antenna elements and generates the coupled noise voltages $\mathbf{n}_c(t)$ in Eq. 33. The internal circuit noise sources (mainly the input stages of the low-noise amplifiers (LNAs) or the resistive terminal loads of the antennas) produce noise currents on the antenna elements which consist of two parts: the uncoupled noise current and the coupled noise current. For example, in the kth antenna, its internal circuit noise source excites an uncoupled noise current $i_{u,kk}(t)$ on itself as when it is in the isolated mode. The fields from this current in turn induce coupled noise currents $i_{c,pk}(t)$ ($p \neq k,$ and $p = 1, 2, \cdots, n$) on all the

DOI 10.1007/978-981-4560-75-7_13-2

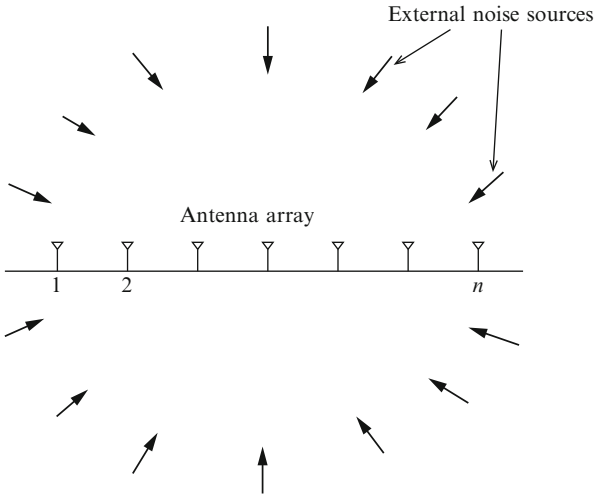

Fig. 13 The scattering field model for the generation of coupled noise with s plane EM waves coming from random directions to an antenna array

other antenna elements. It is assumed that the coupled and uncoupled currents excited by the internal noise source of a particular antenna are weakly correlated as they appear on different antennas. Furthermore, the internal noise currents of different antennas are uncorrelated. When all the internal circuit noise sources of the antenna array are considered in this way, the uncoupled noise currents $i_{u,kk}(t)$ $(k = 1, 2, \cdots, n)$ give rise to the uncoupled noise voltages $\mathbf{n}_u(t)$ in Eq. 33, while the coupled noise currents $i_{c,pk}(t)$ give rise to coupled noise which is modeled in the same way as (see below) and as part of the environmental noise and contribute to total coupled noise voltages $\mathbf{n}_c(t)$ in Eq. 33.

To model the coupled noise coming from the outside environment of the antenna elements, a scattering field model as shown in Fig. 13 can be used. The coupled noise voltages $\mathbf{n}_c(t)$ are considered to be produced by a large number of external random noise sources in the form of scattered electromagnetic (EM) plane waves with random amplitudes and phases. These random EM plane waves give rise to $\mathbf{n}_c(t)$ through the antenna mutual impedance matrix $\mathbf{Z}$ as,

$$\mathbf{n}_c(t) = \mathbf{Z}^{-1}\mathbf{e}(t) \tag{42}$$

where $\mathbf{e}(t)$ is an $n \times 1$ column vector of the random noise voltages at the antenna elements when the antenna mutual coupling is not considered. The reason to express the coupled noise voltages in the form of Eq. 34 is that both $\mathbf{Z}$ and $\mathbf{e}(t)$ can be calculated or measured directly. As the antenna array is in the receiving mode, the elements of the antenna mutual impedance matrix $\mathbf{Z}$ in Eq. 34 are the receiving mutual impedances of the array which can be obtained by calculation or measurement (Hui 2004b). The form of $\mathbf{Z}$ is given by Eq. 32 for an n element case. In Eq. 34, the noise voltage vector $\mathbf{e}(t)$ without mutual coupling can be calculated using a standard numerical method such as MoM (Harrington 1993). Based on the couple noise model in Fig. 13, consider s narrow-band EM plane waves impinging on the n-element antenna array from directions ϕ_k $(k = 1, 2, \ldots s)$ at time t_i $(i = 1, 2, \ldots)$. The amplitudes and phases of these plane waves are random Gaussian variables, which are both independently generated for each direction and each time instance (Kisliansky et al. 2007). Assuming each antenna (considering dipole antennas here for ease of illustration) is divided into m segments in the MoM procedure, then the element $e_j(t_i)$ of the noise voltage vector $\mathbf{e}(t_i)$ at time instant $t = t_i$ can be calculated as follows:

DOI 10.1007/978-981-4560-75-7_13-2

$$\begin{bmatrix} z_{j,11} & z_{j,12} & \cdots & z_{j,1m} \\ z_{j,21} & z_{j,22} & \cdots & z_{j,2m} \\ \vdots & \vdots & \ddots & \vdots \\ z_{j,m1} & z_{j,m2} & \cdots & z_{j,mm} \end{bmatrix} \begin{bmatrix} I_{j,1}(t_i) \\ I_{j,2}(t_i) \\ \vdots \\ I_{j,k}(t_i) \\ \vdots \\ I_{j,m}(t_i) \end{bmatrix} = \begin{bmatrix} n_{j,11}(t_i) + n_{j,12}(t_i) + \cdots + n_{j,1s}(t_i) \\ n_{j,21}(t_i) + n_{j,22}(t_i) + \cdots + n_{j,2s}(t_i) \\ \vdots \\ n_{j,m1}(t_i) + n_{j,m2}(t_i) + \cdots + n_{j,ms}(t_i) \end{bmatrix} \tag{43}$$

$$e_j(t_i) = I_{j,1}(t_i) Z_L \tag{44}$$

where the first matrix on the left-hand side of Eq. 35 is the MoM impedance matrix for the *j*th antenna and the second column vector on the left-hand side of Eq. 35 is the current distribution for the *j*th antenna. The column vector on the right-hand side of Eq. 35 is the voltage vector due to the *s* noise source plane waves impinging on each segment of the *j*th antenna. Equation 36 simply calculates the noise voltage of the *j*th antenna by multiplying the current on the terminal segment (first segment) with the antenna terminal load Z_L. The noise voltages of all other antenna elements can be calculated in the same way. Once $\mathbf{e}(t_i)$ is known, the covariance matrix $\mathbf{N}_c$ of the coupled noise voltage vector can be expressed as

$$\mathbf{N}_c = E\{\mathbf{n}_c(t)\mathbf{n}_c^H(t)\} = \mathbf{Z}^{-1} E\{\mathbf{e}(t)\mathbf{e}^H(t)\}\mathbf{Z}^{-H} \tag{45}$$

where the noise correlation matrix $E\{\mathbf{e}(t)\mathbf{e}^H(t)\}$ represents only the spatial correlation and its elements are known for many typical wave distributions, such as the Bessel function for a uniform incident wave distribution (Clarke 1968) received by a uniform linear array (ULA).

To model the uncoupled noise voltages $\mathbf{n}_u(t)$, the equivalent circuit of a receiving antenna element as shown in Fig. 14 is considered. In this equivalent circuit, Z_{ant} is the input impedance of the antenna, and Z_{in} is the impedance looking into the input terminal of the LNA, which is connected to the antenna terminal (Craeye et al. 2004). The two sources, V_n and I_n, are the equivalent noise voltage and current generated by the noise resistance of the LNA. The uncoupled noise voltage generated by V_n and I_n is the noise voltage dropped across the input impedance Z_{in} of the LNA when this antenna element is receiving in an isolated mode. For example, for the *p*th antenna element, uncoupled noise voltage is

$$n_{u,p} = \frac{V_n Z_{in}}{Z_{ant} + Z_{in}} + \frac{I_n Z_{ant} Z_{in}}{Z_{ant} + Z_{in}}. \tag{46}$$

Since $n_{u,p}$ represents the *uncoupled* noise components, the covariance matrix of $\mathbf{n}_u(t)$ is a diagonal matrix

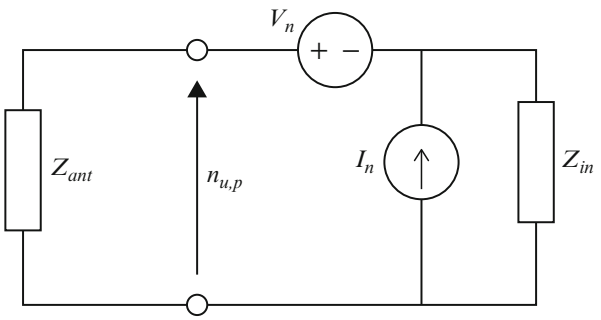

Fig. 14 The circuit noise model for the *p*th antenna element connected to an LNA with an input impedance of Z_{in} and noise sources V_n and I_n

whose diagonal elements are all the same and can be calculated from the following equation (cf. eq. (19) in Craeye et al. 2004):

$$\begin{aligned}\mathbf{N}_u &= E\{\mathbf{n}_u(t)\mathbf{n}_u^H(t)\} \\ &= \frac{4k_BT_0B|Z_{in}|^2}{|Z_{ant}+Z_{in}|^2}\left(R_n + |Z_{ant}|^2G_n + 2\mathrm{Re}\left\{Z_{ant}^*Y_\gamma^*\right\}R_n\right)\mathbf{I}_{n\times n}\end{aligned} \tag{47}$$

where k_B is the Boltzmann's constant, T_0 is the 290 K standard noise temperature, B is the instantaneous bandwidth of observation, and $\mathbf{I}_{n\times n}$ is the $n \times n$ identity matrix. The other symbols R_n, G_n, and Y_γ in Eq. 39 are the noise resistance, conductance, and admittance, respectively, of the LNA whose values can be obtained from the data sheet of the LNA. The uncoupled noise power σ_u^2 dissipated in the respective LNAs can be calculated by dividing the magnitude squares of the diagonal elements of Eq. 39 by Z_{in}^* and taking the real part. The advantage of formulating the uncoupled noise covariance matrix in Eq. 39 is that it can be determined beforehand by calculation using known parameters in Eq. 39 or by a direct measurement on an LNA. This is an important observation which enables us to subtract the uncoupled noise covariance matrix $\mathbf{N}_u$ from the received signal-plus-noise covariance matrix, as shown in the next section.

MUSIC DOA Estimation Algorithm with Coupled Array Noise

Using the noise covariance matrices in Eqs. 37 and 39, the covariance matrix of the received signal with noise is

$$\mathbf{R} = E\{\mathbf{x}(t)\mathbf{x}^H(t)\} = E\{\mathbf{v}(t)\mathbf{v}^H(t)\} + \mathbf{N}_c + \mathbf{N}_u. \tag{48}$$

As explained in the last section, the uncoupled noise covariance matrix $\mathbf{N}_u$ can be determined beforehand. Hence after the signal-plus-noise covariance matrix is obtained, the following difference covariance matrix can be calculated immediately:

$$\begin{aligned}\mathbf{R}_d = \mathbf{R} - \mathbf{N}_u &= E\{\mathbf{v}(t)\mathbf{v}^H(t)\} + \mathbf{N}_c \\ &= E\{\mathbf{v}(t)\mathbf{v}^H(t)\} + \mathbf{Z}^{-1}E\{\mathbf{e}(t)\mathbf{e}^H(t)\}\mathbf{Z}^{-H}\end{aligned} \tag{49}$$

Now the noise covariance matrix in Eq. 41 contains only the coupled noise. This is a great advantage as the signal covariance matrix and noise covariance matrix can be decoupled at the same time. Furthermore, as the signals $\mathbf{v}(t)$ are subjected to the same coupling process as the coupled noise $\mathbf{n}_c(t)$, the coupled signal voltage vector can also be expressed in terms of the mutual impedance matrix $\mathbf{Z}$ as (cf. Eq. 34)

$$\mathbf{v}(t) = \mathbf{Z}^{-1}\mathbf{u}(t) \tag{50}$$

where $\mathbf{u}(t)$ is the uncoupled signal voltage vector (cf. Eq. 22). By applying Eq. 42 into Eq. 41 and multiplying Eq. 41 on the left and right-hand sides with $\mathbf{Z}$ and $\mathbf{Z}^H$, respectively, the following decoupled signal-plus-noise covariance matrix is obtained:

$$\begin{aligned}\mathbf{R}_d' &= \mathbf{Z}\mathbf{R}_d\mathbf{Z}^H \\ &= E\{\mathbf{u}(t)\mathbf{u}^H(t)\} + \left(\sigma_c^2/\mathrm{Re}\{1/Z_{in}\}\right)E\{\mathbf{s}(t)\mathbf{s}^H(t)\}\end{aligned} \tag{51}$$

where

DOI 10.1007/978-981-4560-75-7_13-2

$$\mathbf{s}(t)\mathbf{s}^H(t) = \mathbf{e}(t)\mathbf{e}^H(t)/\left(\sigma_c^2/\mathrm{Re}\{1/Z_{in}\}\right) \tag{52}$$

is the normalized spatial noise correlation matrix and σ_c^2 is the power of the coupled noise at each element when there is no spatial correlation. Note that Eq. 43 is an important new result in array signal theory for DOA estimation. In Eq. 43, the correct uncoupled array manifold has been restored in $\mathbf{u}(t)$. The decoupled noise covariance matrix $E\{\mathbf{e}(t_i)\mathbf{e}^H(t_i)\}$ is not uncorrelated as previous studies assumed. Instead, noise is still spatially correlated though the antenna mutual coupling effect has been removed. This is due to the random distribution of the incoming noise directions. The exact noise correlation structure of $E\{\mathbf{e}(t_i)\mathbf{e}^H(t_i)\}$ depends on the signal environment. Furthermore, for the MUSIC DOA estimation algorithm, the method used in Yeh et al. (1989; see eq. (13) in Yeh et al. 1989) can still be directly used for either noncoherent or coherent signals by the following changes:

$$\begin{aligned} SAS^+ &\rightarrow E\{\mathbf{u}(t)\mathbf{u}^H(t)\}, \\ \sigma^2 &\rightarrow \frac{\sigma_c^2}{\mathrm{Re}\{1/Z_{in}^H\}}, \\ \mathbf{Z}_0\mathbf{Z}_o^+ &\rightarrow E\{\mathbf{s}(t)\mathbf{s}^H(t)\}. \end{aligned} \tag{53}$$

In the next section, it will demonstrate the improved performance of using Eq. 43 in MUSIC DOA estimation.

Simulation Examples

Coupled Array Noise To investigate the correlation of the coupled noise, the magnitudes of the noise current correlation coefficients (Kisliansky et al. 2007) between two center-fed half-wavelength dipole antennas at different antenna separations, d, are recalculated using a numerical method. The dipole wire radius is $\lambda/500$ (where λ is the wavelength in free space), and the two dipoles are shorted through their terminals, i.e., $Z_L = 0$. In the numerical method, an MoM computer simulation tool, FEKO (http://www.feko.info/), is used. Each dipole is discretized into 63 segments, each of which has a length of $\lambda/125$. To simulate the coupled noise, 50 plane waves are used to excite the array. These plane waves have random amplitudes and phases and are vertically polarized. They come uniformly from the horizontal directions along the plane $\theta = \pi/2$. This number of plane waves is obtained after several convergence tests. The results are shown in Fig. 15 and compared with the results obtained in Kisliansky et al. (2007). It can be seen that these results are almost the same as those in Kisliansky et al. (2007).

For the normalized spatial noise correlation matrix in Eq. 44, it is well known that its elements follow the variation of the Bessel function $J_0(kd)$ across the array if the noise comes uniformly on the horizontal plane. This result can be demonstrated using a modeling method (as mentioned below). Shown in Fig. 16 is the calculated spatial correlation coefficients of the coupled noise for different elements with respect to the first element in a ten-element dipole antenna array with an element separation d equal to 0.5λ. The variation of the Bessel function is also shown for comparison. The dipole antennas are same as the two dipole antennas in Fig. 15, but now all of them are connected to a 50Ω terminal load. The same numerical scheme is used and the coupled noise is generated in the same way as in Fig. 15. After the noise voltages are obtained, they are decoupled as in Eq. 43 using the receiving mutual impedance matrices $\mathbf{Z}$ and $\mathbf{Z}^H$. From the result in Fig. 16, it can be seen that the noise spatial correlation of the antenna elements follows almost exactly as the Bessel function.

To illustrate the variation of the noise power across the elements of an antenna array due to antenna mutual coupling, the noise powers of a seven-element dipole array with different element separations are

DOI 10.1007/978-981-4560-75-7_13-2

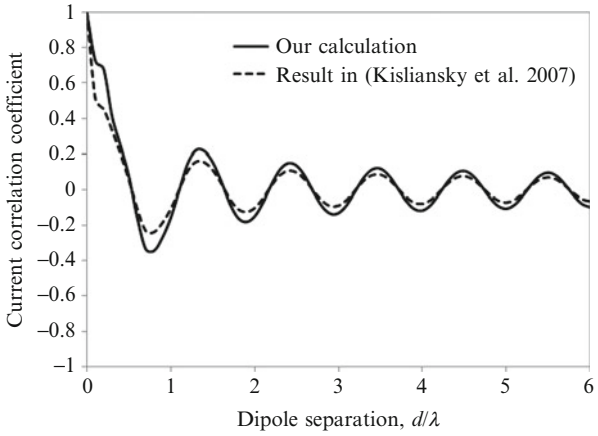

Fig. 15 The magnitude of the noise current correlation coefficient between two dipole antennas at different antenna separations

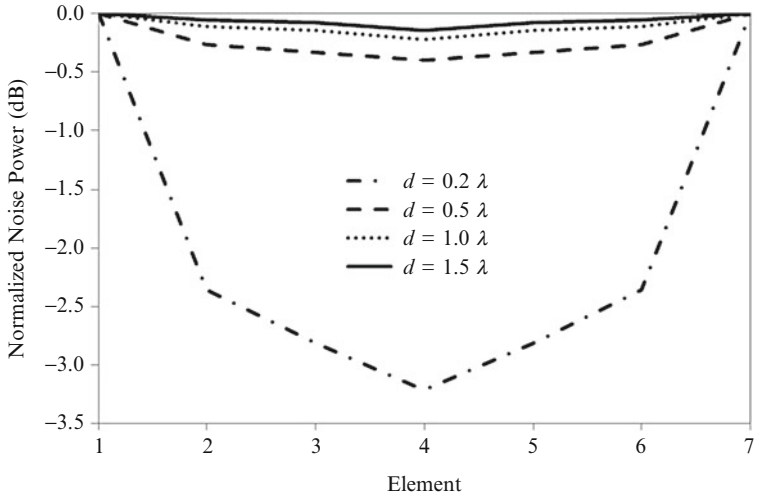

Fig. 17 The normalized noise power for a seven-element dipole array at different element separation

DOI 10.1007/978-981-4560-75-7_13-2

calculated. The dipoles are the same as the dipoles in Fig. 15 and the coupled noise is generated in the same way. The results are shown in Fig. 17 with the noise powers being normalized to those of the edge elements. It can be seen that when the element separation is decreased, the element noise powers differ significantly. At an element separation of $d = 0.2\lambda$, the power difference between the central element and the edge elements is more than 3 dB. On the other hand, when the element separation is increased, the element noise powers tend to be equalized. The results in this figure indicate the importance of the antenna mutual coupling on the distribution of the noise power across an antenna array.

DOA Estimation Experiments In the first DOA estimation experiment, the seven-element array studied in Fig. 17 is used to detect two coherent signals in the presence of coupled and uncoupled noise. The terminal voltages of the dipoles are calculated by FEKO and processed by the MUSIC DOA algorithm. In the literature, Yeh et al. (1989) have provided a DOA study on such a dipole array before. But they considered only the uncoupled noise. In the simulation of the signal environment, the coupled noise is generated as described above. To determine the uncoupled noise, the parameters in Eq. 39 are $Z_{in} = Z_L = 50\Omega$, $Z_{ant} = 70.05 - j8.73\Omega$, $T_0 = 290$ K, $R_n = 50\Omega$, $G_n = 0$, and $Y_\gamma = 0$. That is, the antenna terminal loads, Z_L, are treated as a one-port network. With these noise parameters, the uncoupled noise power dissipated at each antenna terminal load Z_{in} is calculated to be $\sigma_u^2 = 2.76 \times 10^{-21}$ W/Hz, which is equivalent to an effective noise temperature of 200 K. For illustration purpose, it is also assumed that the coupled noise power (when there is no antenna mutual coupling) has the value of $\sigma_c^2 = 2.76 \times 10^{-21}$ W/Hz at a 1 Hz bandwidth. Table 2 shows the coupled and uncoupled noise powers in each element at different element separations under this situation. The coupled noise powers in the third and the fourth columns of Table 2 are the diagonal elements of the matrix $\mathbf{N}_c$ in Eq. 37. The detection results are shown in Fig. 18a and b for element separations of $d = 0.5\lambda$ and $d = 0.2\lambda$, respectively. The MUSIC spectra in these two figures are produced with two cases of noise: (i) coupled noise (with the uncoupled noise removed as in Eq. 41) and (ii) uncoupled noise only (the conventional case). In these two cases, the average noise powers are made equal for the sake of comparison, and the SNR is specified at 3 dB with respect to the average coupled noise power σ_c^2. The two signals are coming from the directions of $\phi = 0°$ and 15°, and both are on the horizontal plane ($\theta = 90°$). In Fig. 18a, the result obtained in Yeh et al. (1989) is also shown. It can be seen that in both Fig. 18a and b, the results using the coupled noise (see Eq. 43) are more accurate and have much higher peaks than the results using only the uncoupled noise. Furthermore, in Fig. 18a, both the coupled and the uncoupled cases produce results more accurately than the result in Yeh et al. (1989). The reason is that they both use the receiving mutual impedances in the mutual coupling compensation, whereas the results in Yeh et al. (1989) were obtained using the conventional mutual impedances for the mutual coupling compensation.

Table 2 Noise powers in each element of the seven-element dipole antenna array

Element	Uncoupled noise power σ_u^2 (W/Hz)	Coupled noise power at $d = 0.2\lambda$ (W/Hz)	Coupled noise power at $d = 0.5\lambda$ (W/Hz)
1	2.76×10^{-21}	1.99×10^{-21}	2.41×10^{-21}
2	2.76×10^{-21}	1.16×10^{-21}	2.26×10^{-21}
3	2.76×10^{-21}	1.05×10^{-21}	2.23×10^{-21}
4	2.76×10^{-21}	9.58×10^{-22}	2.23×10^{-21}
5	2.76×10^{-21}	1.05×10^{-21}	2.23×10^{-21}
6	2.76×10^{-21}	1.16×10^{-21}	2.26×10^{-21}
7	2.76×10^{-21}	1.99×10^{-21}	2.41×10^{-21}

DOI 10.1007/978-981-4560-75-7_13-2

In the second experiment, the sensitivity of the MUSIC DOA estimation algorithm to the error in the subtraction of the uncoupled noise in Eq. 41 is investigated. As explained earlier, the current method relies on the removal of the uncoupled noise covariance matrix $\mathbf{N}_u$ from the covariance matrix $\mathbf{R}$. Whereas $\mathbf{N}_u$ can be either calculated or measured beforehand, its accurate value may be subjected to errors, leading to the uncoupled noise power being over- or underestimated. The effect of this is shown in Fig. 19a, b, where Fig. 19a is for the case when the uncoupled noise power is overestimated and Fig. 19b is for the case when the uncoupled noise is underestimated. The dipole array and the signal environment are the same as those in the first DOA estimation experiment, and the element separation is 0.5λ. From Fig. 19a, it can be seen that if the uncoupled noise is overestimated, it will have a rather significant effect on the detection results. There are a number of secondary peaks in the MUSIC spectra which indicate wrong signal directions. The heights of these secondary peaks decrease with the increase in the uncoupled noise power overestimation (represented by an increasing percentage of the uncoupled noise power being subtracted from the coupled noise power). From Fig. 19b, it can be seen that an underestimation of the uncoupled noise power has the same significant effect as for the overestimation case. But the secondary peaks tend to move away from the two signal peaks. From these two figures, it can be inferred that an accurate determination of the uncoupled noise power is very important in the proposed method.

The Application of the Receiving Mutual Impedance in Interference Suppression

In adaptive nulling, it has been shown (Adve and Sarkar 2000) that antenna mutual coupling will significantly affect the depths and the accuracy of positioning the nulls of the radiation pattern toward the interferences. In this section, it is to investigate by using computer simulations the performance of a linear dipole array with seven antenna elements employed for adaptive nulling by using the concept of receiving mutual impedance to characterize and compensate for the mutual coupling effect. The performance will be compared with that using the conventional mutual impedances. The dipole array is the one shown in Fig. 1. The dimensions of the array are $n = 7$, $d = 0.5\lambda$, $\ell = 0.5\lambda$, $a = \lambda/200$, and $Z_L = 50\ \Omega$. The adaptive nulling algorithm used in the following examples is the direct data domain (DDD) adaptive

DOI 10.1007/978-981-4560-75-7_13-2

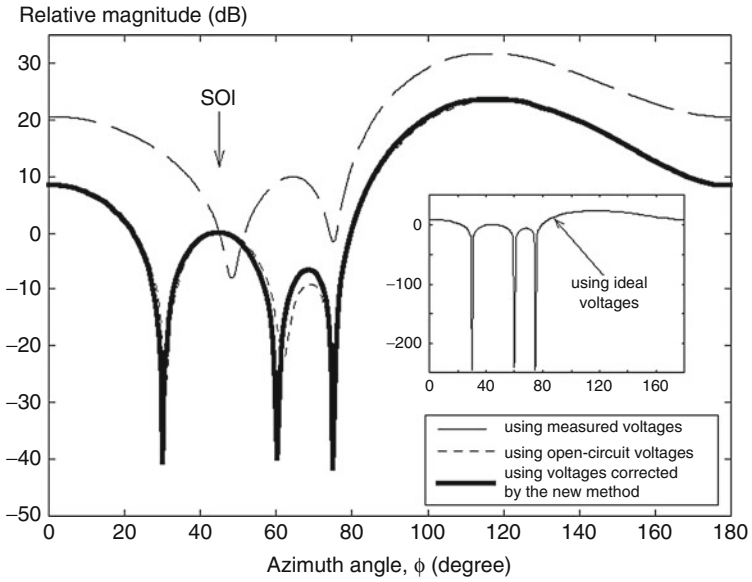

Fig. 20 The adaptive radiation patterns obtained by using the measured voltages, the open-circuit voltages, the voltages corrected by the new method (using receiving mutual impedances), and the ideal voltages. The signal environment is shown in Table 3

	Amplitude (V/m)	Azimuth ϕ (degree)	Elevation θ (degree)
Signal of interest (SOI)	1.0 $\hat{z}$	45	90
Interference #1	1.0 $\hat{z}$	75	90
Interference #2	1.5 $\hat{z}$	60	90
Interference #3	2.0 $\hat{z}$	30	90

algorithm (Sarkar et al. 1996), which is simple and easy to implement. A detailed description of this algorithm can be found in Sarkar et al. (1996, 2000). The required inputs to the DDD adaptive algorithm are the voltages on the antenna terminal loads and the knowledge of the direction of arrival (DOA) of the signal of interest (SOI). The received voltages on the antenna terminal loads are first compensated for the mutual coupling effect and then passed to the adaptive algorithm. The signal environment is shown in Table 3. The SOI and interferences are plane waves linearly polarized in the z direction. This example has been studied before in Adve and Sarkar (2000). The result is shown in Fig. 20. Adaptive radiation patterns obtained by using four types of antenna terminal voltages are shown in Fig. 20. The dash-line radiation pattern is the result obtained by using the measured (or received) voltages across the antenna terminal loads which have not been compensated for the mutual coupling effect. The dotted-line radiation pattern is the result obtained by using the open-circuit voltages derived by using the conventional mutual impedances to compensate for the mutual coupling effect (Gupta and Ksienski 1983). The solid-line radiation pattern is the result obtained by using the receiving mutual impedances to compensate for the mutual coupling effect. The small graph inside Fig. 20 shows the radiation pattern obtained by using ideal voltages across the terminal loads which are completely free from any mutual coupling effect. Both the ideal voltages and the measured voltages are calculated by the moment method (Harrington 1993) with the current distribution on each antenna being expanded by 20 sinusoidal basis functions, and the Galerkin method is used in the matching procedure. From Fig. 20, it can be seen that the (*uncompensated*)

DOI 10.1007/978-981-4560-75-7_13-2

measured voltages give a wrong result and therefore can hardly be used to suppress the interferences. The open-circuit voltages can be used to locate the three interferences but the dips are not deep enough. On the other hand, when the compensated (corrected) voltages are obtained by using the receiving mutual impedances (new method), the dips are both more accurate and substantially deeper. For the ideal case, the dips are much deeper than all the other cases because it is a theoretically ideal situation in which the antenna elements are completely isolated from each other.

The above method has also been used to study other signal situations such as different signal elevation angles and different interference strengths. The details can be found in Hui (2004a).

The Application of the Receiving Mutual Impedance in Magnetic Resonance Imaging (MRI)

Phased arrays can be used in magnetic resonance imaging (MRI) to reduce the low signal-to-noise ratio (SNR) problem and the long scanning time problem (Hyde et al. 1986; Sodickson and Manning 1997; Roemer et al. 1990). However, many previous studies have revealed that mutual coupling effect makes it difficult to obtain independent undistorted signals from the MRI phased-array antenna elements. Obviously this problem is inherently more serious in MRI phased arrays than traditional arrays employed for receiving signals in the far-field region. This is because MRI phased arrays are virtually receiving in the near-field region with the element spacing in the order of ~0.1 wavelength, compared with that of the traditional arrays in the order of half wavelength. This is due to the low operation frequencies used in MRI. Thus, some traditional decoupling or compensation methods for the mutual coupling effect may not work effectively for MRI phased arrays. In view of this, some special compensation methods have been designed for MRI phased arrays, especially for coil arrays. Two such popular compensation methods are the overlapping of adjacent coils and the use of low input impedance preamplifiers (Roemer et al. 1990). However, constraints on the use of these two methods have been pointed out by some researchers (Ohliger et al. 2004). Moreover, overlapping of adjacent coils reduces the imaging area, and the use of low input impedance preamplifiers sacrifices the condition of maximum power transfer. Lumped-element decoupling networks have recently been suggested (Zhang and Webb 2004) to tackle this problem, but the decoupling power is still limited.

In this section, the concept of receiving mutual impedance is employed to solve the mutual coupling problem in the design of phased arrays for MRI. For mutual coupling analysis, it is sufficient to consider a two-coil phased array for MRI as shown in Fig. 21. The two coils are square in shape and made of a metallic strip with a side length of L and strip width s. The distance between the centers of the two coils is denoted by d, which can be changed to vary the amount of mutual coupling. The coils are aligned along the y axis on the y-z plane and are equidistant from the origin. The two coils are not exactly at the same plane but offset by a small separation dx in the x direction so that they can overlap with each other. There are four fixed capacitors C_1, C_2, C_3, and C_4 and one tuning capacitor C_t placed along the coils for smoothing the current distributions and making the coils to resonate at the desired frequency f_0, as shown in Fig. 21b. When the coils are placed alone, each of them resonates at the frequency f_0 with a very small self-resistance r. An external matching circuit is thus required to match the small resistance r to the system impedance of 50Ω, as shown in Fig. 21b. The imaged sample is assumed to be a rectangular slice (to simulate the active slice inside an imaged person) and placed in the region with negative x coordinates and close to the phased array as shown in Fig. 22. Its dimensions along the x, y, and z directions are denoted, respectively, by a, b, and c. The relative position of the active slice from the phased array is indicated by the distances of the active slice from the origin which are denoted by px, py, and pz,

DOI 10.1007/978-981-4560-75-7_13-2

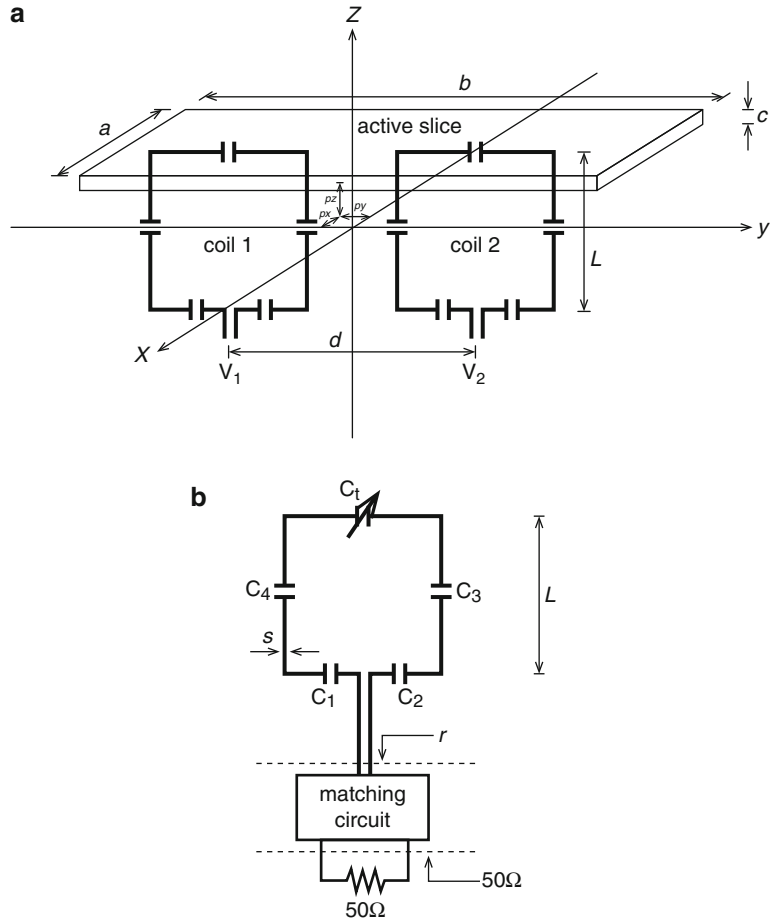

Fig. 21 (**a**) The two-coil phased array for MRI and the active slice, (**b**) the coil configuration and the matching capacitors

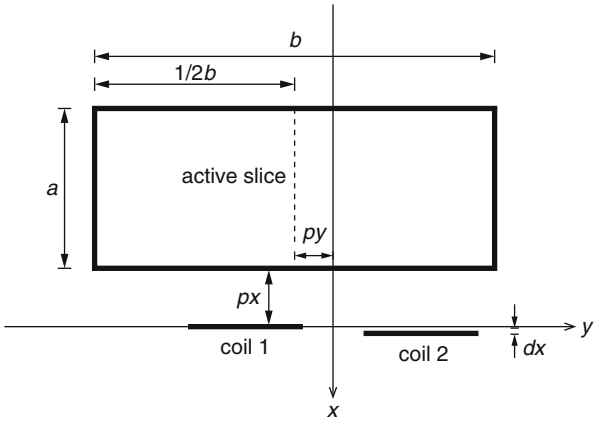

Fig. 22 Top view of the active slice and its relative position to the phased array

respectively, as shown in Figs. 21a and 22. In MRI, the active slice is the signal source whose spatial position can be accurately controlled by the gradient magnetic fields (Jin 1999).

Now assume the received terminal voltages (across the terminal load, $Z_L = r$) are V_1 and V_2, which can be measured or calculated. To simplify the following analysis, the terminal voltages are assumed to be taken before the matching circuit as shown in Fig. 21a. The actual terminal voltages across the 50Ω

DOI 10.1007/978-981-4560-75-7_13-2

resistors differ from V_1 and V_2 by just a multiplicative constant. V_1 and V_2 are corrupted with mutual coupling. If mutual coupling is removed from V_1 and V_2, the uncoupled voltages U_1 and U_2 can be obtained. The relation of V_1 and V_2 to U_1 and U_2 is through the receiving mutual impedances, as explained before in Eq. 22, i.e.,

$$\begin{bmatrix} U_t^1 \\ U_t^2 \end{bmatrix} = \begin{bmatrix} 1 & -\dfrac{Z_t^{12}}{Z_L} \\ -\dfrac{Z_t^{21}}{Z_L} & 1 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \tag{54}$$

where Z_t^{12} and Z_t^{21} are receiving mutual impedances between the two coils. For an example of illustration, the dimensions of the two coils are taken to be $L = 12$ cm, $s = 1$ cm, and $dx = 0.15$ cm. The capacitor values and the resonant frequencies are calculated for four cases of the dc magnetic field, $B_0 = 0.5$ T, 1.0 T, 1.5 T, and 2.0 T. They are shown in Table 4. The dimensions of the active slice are $a = 20$ cm, $b = 40$ cm, and $c = 0.25$ cm, which is approximately the case in spinal cord imaging. In the computer simulations, the active slice is used both as the external source for the calculation of the receiving mutual impedances, and the signal source for the calculation of the signal voltages received by the coils. The method of moments (Harrington 1993) is used in the numerical calculations. The calculated receiving mutual impedances with coil separation d are shown in Table 5. The coil separation is expressed in terms of the side length of the coils, L. The relative position of active slice is at $px = -1$ cm, $py = 0$, and $pz = 0$. It can be seen that at $d = 0.9$ L, both Z_t^{12} and Z_t^{21} reach very low values (real and imaginary parts). This indicates that mutual coupling is small at this separation due to the cancellation of some part of the flux linkage through the overlapping area. This separation corresponds to an ~2 % overlapping area between the two coils. This justifies the use of overlapping method as a means for decoupling adjacent coils in a phased array (Roemer et al. 1990). However, overlapping alone is hardly enough as will be shown later. From Table 5, it can also be seen that the receiving mutual impedances increase rapidly at $d = 1.0\,L$, especially Z_t^{12}. This indicates strong coupling between the two coils as there is no cancellation of flux linkage at this separation.

For the calculation of terminal voltages, three types of terminal voltages are investigated. The first type is the measured (or received) terminal voltages which include all the mutual coupling effect, i.e., V_1 and V_2 in Eq. 46. These voltages can be measured directly. The second type is the compensated terminal voltages U_t^1 and U_t^2 calculated by using Eq. 46. They are calculated from the knowledge of the new mutual impedances (receiving mutual impedances) Z_t^{12} and Z_t^{21}. The last type is the ideal uncoupled terminal voltages, denoted by U'^1_t and U'^2_t, which are calculated when the coils are isolated from each other. U'^1_t and U'^2_t are used as an ideal reference for comparison. To measure U'^1_t and U'^2_t, one coil has to be removed from the array before the measurement of voltage on the other coil and vice versa.

Table 4 The capacitors, self-impedances, and resonant frequencies of the two coils for use at different DC magnetic field strengths. The dimensions of the two coils are $L = 12$ cm and $s = 1$ cm

To characterize the performance of the receiving mutual impedance compensation method, two criteria are employed to indicate the accuracy of this method and to compare it with previous ones. The first is the percentage errors of the compensated terminal voltages and is defined by

$$\%\text{ error in compensated terminal voltage } U_t^i = \frac{\left\|U_t^i - U'^i_t\right\|}{\left\|U'^i_t\right\|} \times 100\%, \quad i = 1,\ 2 \tag{55}$$

where $\|z\|$ represents the norm of the complex number z. It measures the % deviation of the compensated voltages from the ideal uncoupled ones. The second criterion is the isolation between the two coils and is defined by

$$\alpha_{ij} = \left| 20\log\left(\frac{\left\|U_t^i - U'^i_t\right\|}{\left\|U'^{ij}_t\right\|} \right) \right|, \quad i, j = 1,\ 2. \tag{56}$$

It measures the relative amount of signal that couples from one coil to the other after using the receiving mutual impedance compensation method. The larger this value, the smaller is the coupled signal. A similar isolation criterion as this one Eq. 48 was used before in Zhang and Webb (2004) although its meaning may not be exactly the same as Eq. 48.

DOI 10.1007/978-981-4560-75-7_13-2

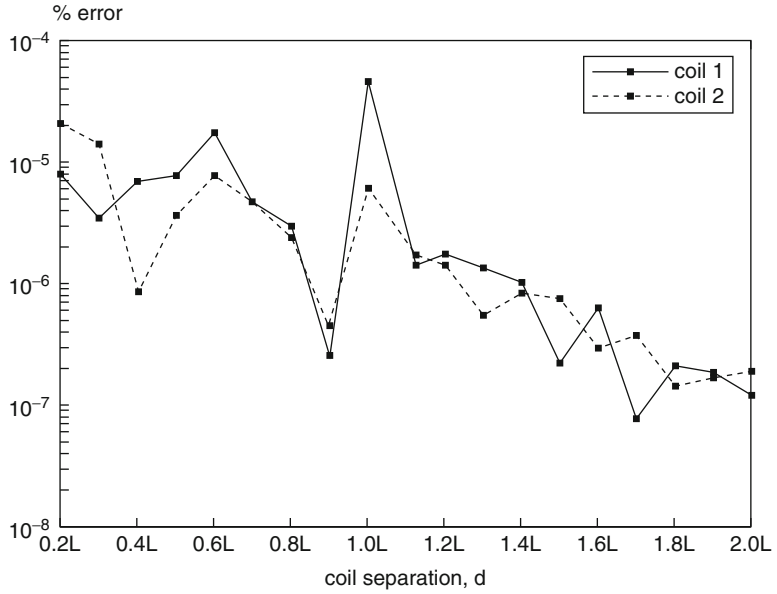

Fig. 23 Percentage errors in the compensated terminal voltages with coil separation for $f_0 = 63.9$ MHz and $px = -1$ cm, $py = 0, pz = 0$

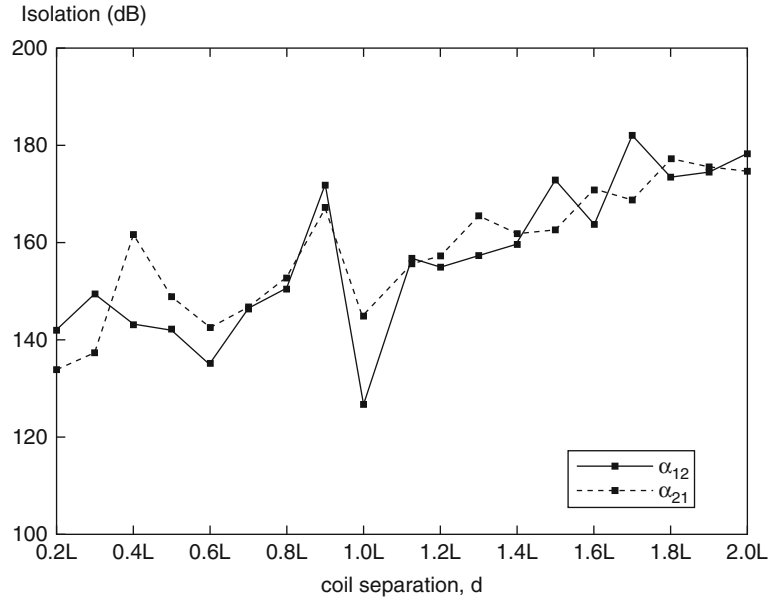

Fig. 24 Isolations of the compensated terminal voltages with coil separation for $f_0 = 63.9$ MHz and px $= -1$ cm, py $= 0$, pz $= 0$

The variation of % errors in the compensated terminal voltages with coil separation is shown in Fig. 23 with $f_0 = 63.9$ MHz ($B_0 = 1.5$ T) and $px = -1$ cm, $py = 0, pz = 0$. It can be seen that the % errors are extremely small, smaller than 10^{-4} % even for $d = 0.2\,L$, i.e., the two coils almost completely overlapped with each other. This indicates that the coupled voltages are almost completely removed. A very low % error (both for coil 1 and coil 2) can be seen at $d = 0.9\,L$, corresponding to the small mutual impedances as shown in Table 5. Figure 24 shows the isolations of the compensated terminal voltages with coil separation. It can be seen that they show a similar trend as the % errors (but turned upside down) and are

DOI 10.1007/978-981-4560-75-7_13-2

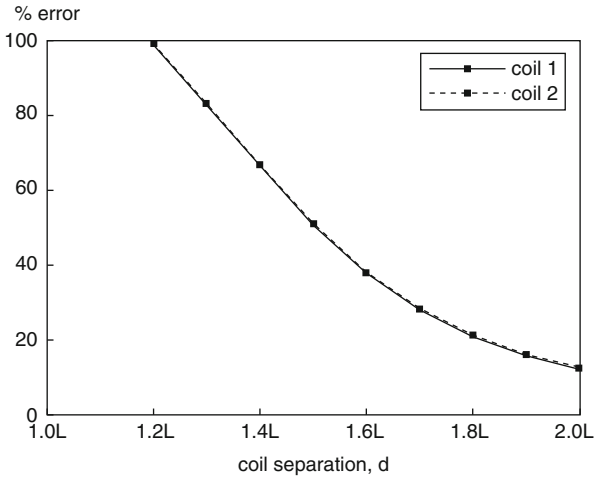

Fig. 25 Percentage errors in the compensated terminal voltages with coil separation using the conventional open-circuit voltage method (Gupta and Ksienski 1983)

generally greater than 120 dB. The corresponding % errors in the compensated terminal voltages using the open-circuit voltage method (Gupta and Ksienski 1983) are shown in Fig. 25. It can be seen that even at a separation of $d = 1.2\ L$, the % errors are as large as about 100 %. In a recent study (Zhang and Webb 2004), it was reported that a capacitive decoupling network can achieve an isolation between two phased-array coils of 20 dB ~ 40 dB. This is much smaller than the isolation that can be achieved by the current compensation method. However, this comparison is based on the assumption that isolation in both cases is taken to be a measure of the relative amount of signal coupled from one coil to other.

As mentioned above, the calculation of the receiving mutual impedances relies on the accurate knowledge of the position of the active slice. In a real situation of MRI, the position of the imaged area (i.e., the active slice) may be under a constant change during the imaging process, whereas the receiving mutual impedances are calculated based only on one position of the active slice. The effect resulted from the change of the active slice position from that used in the calculation of the receiving mutual impedance is important, one that needs to be determined. Figures 26, 27, and 28 show the relations between the % errors and the changes of the position of the active slice along the three axes, indicated by px, py, and pz, respectively. The results are obtained at 63.9 MHz ($B_0 = 1.5$ T) and $d = 1.125\ L$. The receiving mutual impedances used in the calculation are obtained with the slice at $px = -1$ cm, $py = 0$, and $pz = 0$. It can be seen that even when *px*, *py*, or *pz* varies over a substantial distance range, the % errors are still very small. For the change of px and py, the % errors are smaller than 1 %, and for the change of *pz*, the % errors are smaller than 4 %. The isolation between the two coils for the worst case is found to be still greater than 30 dB. That means that even in a practical case when the active slice position is changed to a different position from that used for the calculation of the receiving mutual impedances, the resulting error is still very small. On the other hand, if the change of the active slice position is too large, one may need to reposition the array so that the errors resulting from the change of slice position are still kept within small values as shown above.

More studies on using the receiving mutual impedance concept in the design of phased arrays can be found from the studies in Li et al. (2008), Hui et al. (2006), and Liang et al. (2012, 2013a, b), especially those more recent ones in Liang et al. (2012, 2013a, b).

The Application of the Receiving Mutual Impedance in Signal Correlation Analysis for MIMO Systems

Theory of the Characterization of the Antenna Mutual Coupling Effect in MIMO Systems

Multiple-input and multiple-output (MIMO) systems are well known for achieving a greater system capacity (Foschini and Gans 1998) than the conventional ones employing only single antennas at the two

DOI 10.1007/978-981-4560-75-7_13-2

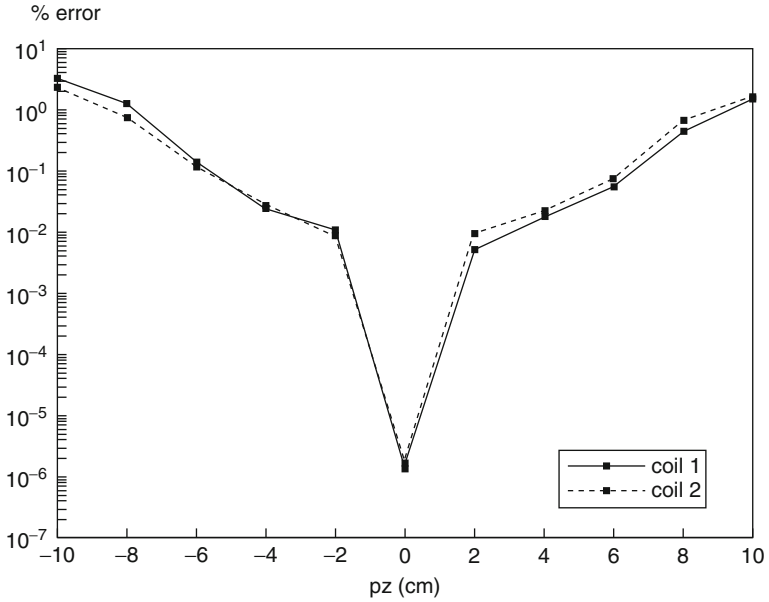

Fig. 28 Percentage error in the compensated terminal voltages with the active slice deviation pz by using the receiving mutual impedance compensation method

sides of a communication link. For MIMO systems, except that spatial correlation due to the multipath scattering effect will contribute to the channel correlation, antenna mutual coupling will also contribute (Svantesson 2002; Jungnickel et al. 2003). Consider the MIMO system shown in Fig. 1 with N transmitting antennas and M receiving antennas. In the transmitter antenna array, antenna mutual coupling causes the input signals to couple to neighboring antennas. This effect can be represented by a mutual coupling impedance matrix as

$$\mathbf{v}_T = \mathbf{Z}_t^{-1}\mathbf{v}_s \tag{57}$$

where $\mathbf{v}_s = [V_{s1}, V_{s2}, \cdots, V_{sN}]^T$ is the excitation voltage vector with mutual coupling not taken into account, $\mathbf{v}_T = [V_{T1}, V_{T2}, \cdots, V_{TN}]^T$ is the excitation voltage vector when mutual coupling is taken into account, and

$$\mathbf{Z}_t = \begin{bmatrix} 1 & \frac{Z_{12}}{Z_{g2}+Z_{22}} & \cdots & \frac{Z_{1N}}{Z_{gN}+Z_{NN}} \\ \frac{Z_{21}}{Z_{g1}+Z_{11}} & 1 & \cdots & \frac{Z_{2N}}{Z_{gN}+Z_{NN}} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{Z_{N1}}{Z_{g1}+Z_{11}} & \frac{Z_{N2}}{Z_{g2}+Z_{22}} & \cdots & 1 \end{bmatrix}. \tag{58}$$

In Eq. 50, Z_{ij}, $(i,j = 1, 2, \cdots, N)$ are the conventional mutual impedances used to characterize the mutual coupling effect in transmitting antennas (Gupta and Ksienski 1983), Z_{ij} are the self-impedances of the antennas, and Z_{gi} are the source impedances of the excitation sources driving the antennas. The equivalent circuits for the case of two transmitting antennas for mutual coupling analysis are shown in Fig. 30.

DOI 10.1007/978-981-4560-75-7_13-2

Similarly, for the output signals, they are also modified by the antenna mutual coupling effect in the receiving antenna array. The actual output coupled voltage vector $\mathbf{v}_c$ is related to the uncoupled output voltage vector $\mathbf{v}_u$ as

$$\mathbf{v}_c = \mathbf{Z}_r^{-1}\mathbf{v}_u \tag{59}$$

where $\mathbf{Z}_r$ is the mutual impedance matrix containing the receiving mutual impedances

$$\mathbf{Z}_r = \begin{bmatrix} 1 & -\frac{Z_t^{12}}{Z_L} & \cdots & -\frac{Z_t^{1M}}{Z_L} \\ -\frac{Z_t^{21}}{Z_L} & 1 & \cdots & -\frac{Z_t^{2M}}{Z_L} \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{Z_t^{M1}}{Z_L} & -\frac{Z_t^{M2}}{Z_L} & \cdots & 1 \end{bmatrix}. \tag{60}$$

In Eq. 51, $\mathbf{v}_c$ and $\mathbf{v}_u$ are the voltage vectors across the antenna terminal loads. If the total uncoupled output voltages (the open-circuit voltages $\mathbf{v}_{oc}$) are required, then $\mathbf{v}_u$ is related to the open-circuit voltage vector $\mathbf{v}_{oc}$ as

$$\mathbf{v}_u = \frac{Z_L}{Z_{in} + Z_L}\mathbf{v}_{oc}. \tag{61}$$

In Eq. 53, it is assumed that all the antenna elements have the same internal impedance Z_{in} and terminal impedance Z_L. Equation 51 then becomes

$$\mathbf{v}_c = \frac{Z_L}{Z_{in} + Z_L}\mathbf{Z}_r^{-1}\mathbf{v}_{oc}. \tag{62}$$

But for comparison with the performance of the uncoupled system whose output is expressed using the open-circuit voltages, it is required to change the terminal coupled voltage vector $\mathbf{v}_c$ to the open-circuit coupled voltage vector $\mathbf{v}'_{oc}$. That is,

$$\mathbf{v}'_{oc} = \frac{Z_{in} + Z_L}{Z_L}\mathbf{v}_c. \tag{63}$$

Combining Eqs. 49, 54, and 55, the signal model for an MIMO system under both spatial correlation and antenna mutual coupling, as well as channel noise, can be obtained as follows:

$$\mathbf{v}'_{oc} = \mathbf{Z}_r^{-1}\mathbf{H}\mathbf{Z}_t^{-1}\mathbf{v}_s + \mathbf{v}_n \tag{64}$$

where $\mathbf{v}_n$ is the vector of noise voltages which are assumed to be not affected by antenna mutual coupling. Note that spatial correlation is included inside the channel matrix $\mathbf{H}$, while antenna mutual coupling is included inside the matrices $\mathbf{Z}_t$ and $\mathbf{Z}_r$.

Numerical Example

Consider the MIMO system shown in Fig. 29 with three transmitting antennas and three receiving antennas (M=N=3), as well as their equivalent circuits as shown in Fig. 30. The transmitting and receiving

DOI 10.1007/978-981-4560-75-7_13-2

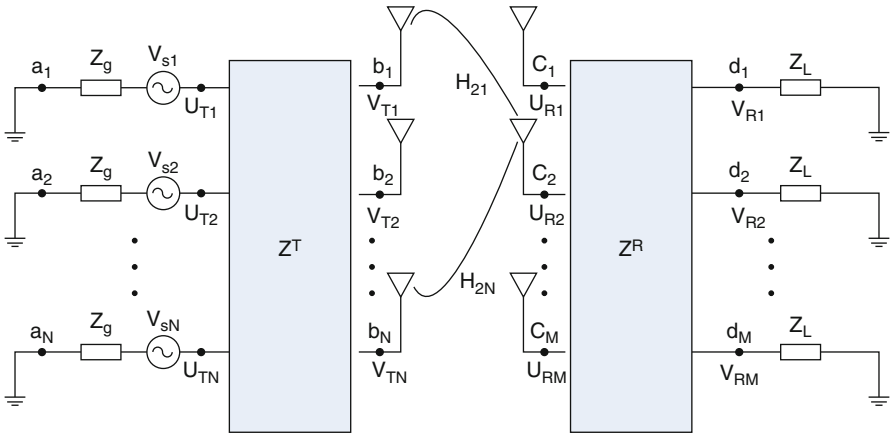

Fig. 29 An MIMO system with antenna mutual coupling effect

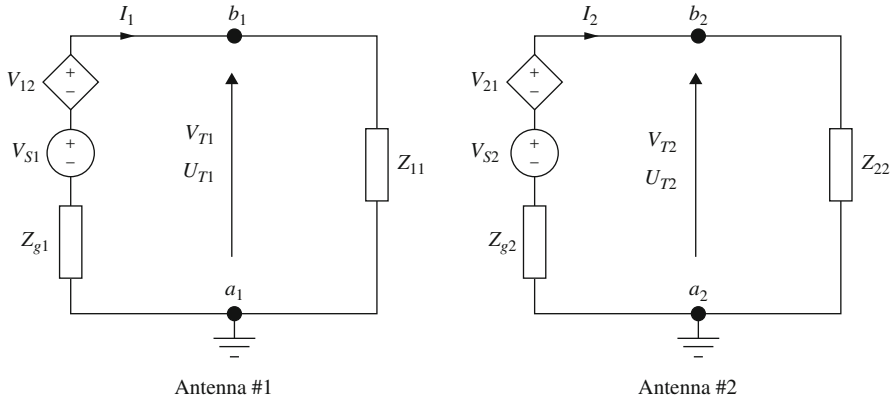

Fig. 30 The equivalent circuits of two transmitting antennas for mutual coupling analysis

antennas are all dipole antennas and that both the transmitting and receiving antennas are aligned to form two uniform linear arrays (ULAs). The antenna separations at the transmitter and receiver are 0.2λ and 0.15λ, respectively. The angle of departure (AOD) at the transmitter and the angle of arrival (AOA) at the receiver of the multipath signals are all 360°. This leads to the spatial correlation coefficients for the antenna elements varying in the form of the Bessel function (Clarke 1968). Assume that the channels are Gaussian random channels with a unit variance and a zero mean. For the transmitting antenna array, the mutual impedances between two transmitting antennas are

$$d_t = 0.2\lambda, Z_{12} = 25.91 - j15.34\Omega, Z_{21} = 25.28 - j15.78\Omega$$

$$d_t = 0.4\lambda, Z_{13} = -0.90 - j20.30\Omega, Z_{31} = -1.42 - j20.11\Omega.$$

For the receiving antenna array, the receiving mutual impedances between two receiving antennas are

$$d_r = 0.15\lambda, Z_t^{12} = -17.73 + j2.75\Omega, Z_t^{21} = -17.48 + j2.94\Omega$$

$$d_r = 0.30\lambda, Z_t^{13} = -8.29 + j10.44\Omega, Z_t^{31} = -7.96 + j10.51\Omega.$$

DOI 10.1007/978-981-4560-75-7_13-2

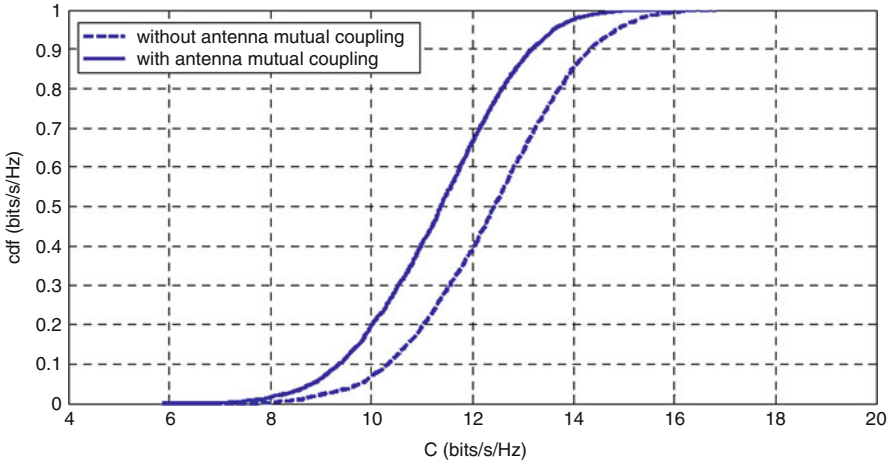

Fig. 31 The channel capacity of an MIMO system with and without antenna mutual coupling

The internal impedance of the dipole antennas is

$$Z_{in} = 39.00 + j7.17\Omega = Z_{11} = Z_{22} = Z_{33}.$$

The terminal load impedance of the dipole antennas is

$$Z_L = 50\Omega.$$

The channel capacity of this MIMO system can be obtained by Monte Carol simulations. The results are shown in Fig. 31 at an SNR = 20d. It can be seen that antenna mutual coupling has reduced the channel capacity substantially.

Summary

In this chapter, the concept of receiving mutual impedance is introduced through derivation from a typical MoM analysis. The theoretical and experimental methods for the determination of the receiving mutual impedance are laid down. The measured and theoretical receiving mutual impedances for typical dipole and monopole antenna arrays are given as examples. The fundamental difference, namely, the truly isolated state between the receiving mutual impedance and the conventional mutual impedance, is explained. Typical examples for the application of the conception of receiving mutual impedance are provided. These include applications in DOA estimation, in interferences suppression, in MRI phased-array design, and in MIMO communication systems.

Metamaterials and Antennas

Richard W. Ziolkowski*
Department of Electrical and Computer Engineering, The University of Arizona, Tucson, AZ, USA

Abstract

A variety of antennas have been engineered with metamaterials and metamaterial-inspired constructs to improve their performance characteristics. Interesting examples include electrically small, near-field resonant parasitic (NFRP) antennas that require no matching network and have high radiation efficiencies. Experimental verification of their predicted behaviors has been obtained. This NFRP electrically small paradigm has led to a wide variety of multiband and multifunctional antenna systems. The introduction of active metamaterial constructs further augments the antenna designer's toolbox and leads to systems with many interesting and useful properties.

Introduction

There has been a paradigm shift in recent years in the research on the physical properties of electromagnetic materials. This trend can be traced primarily to the development of metamaterials (MTMs) and their exotic physics properties and unusual engineering applications (Engheta and Ziolkowski 2006; Eleftheriades and Balmain 2005; Caloz and Itoh 2005). Metamaterials are artificial media whose basic unit cells are engineered in order that the overall composite possesses predesigned macroscopic physical properties which can be tailored for specific applications. By engineering the unit cell to a scale that is much smaller than the operating wavelength, the MTM exhibits homogenized material properties. MTMs are typically created by designing those inclusions to have resonant properties near a particular wavelength λ of interest, through either planar or volumetric loadings of space. They have provided extremely interesting flexibility in the engineering design processes for a variety of electromagnetic, acoustic, elastic, and thermal wave applications. Several electromagnetic prototypes have been developed for radiating and scattering applications operating from UHF to optical frequencies.

A generally accepted MTM classification scheme in terms of the effective permittivity and permeability of the MTM is shown in Fig. 1 (Engheta and Ziolkowski 2006). Materials normally occurring in nature are usually double positive (DPS). MTM interest in DPS characteristics is commonly connected with desires to achieve permittivity or permeability values that are either large or less than one for either or both parameters. The double negative (DNG) metamaterials (MTMs), which are immediately associated with negative refraction effects, were proposed over 40 years ago (Veselago 1968). They were experimentally demonstrated at the turn of this century. Since then, a large variety of artificial material constructs have

*Email: ziolkowski@ece.arizona.edu

DOI 10.1007/978-981-4560-75-7_14-1

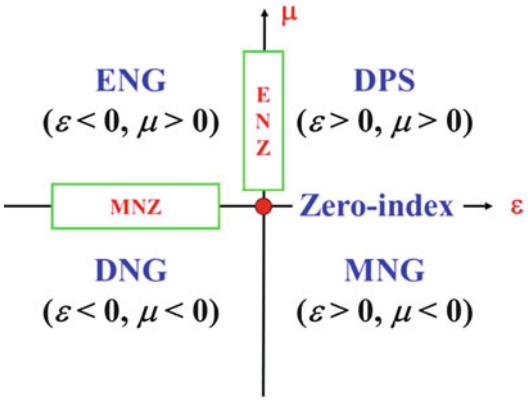

Fig. 1 Metamaterial classifications

been designed, fabricated, and tested, confirming many of the exotic MTM properties (Smith et al. 2000; Ziolkowski 2003; Erentok and Ziolkowski 2007a; Engheta and Ziolkowski 2005).

The epsilon negative (ENG) and mu negative (MNG) MTMs are termed single negative (SNG), in direct contrast to the DNG cases. While the DPS and DNG MTMs allow propagating waves, all waves in SNG MTMs are evanescent. Extreme MTMs exhibit an extreme material or electromagnetic wave parameter. For instance, MTMs that have epsilon-near-zero (ENZ) or mu-near-zero (MNZ) characteristics also have a near-infinite or near-zero wave impedance. Zero-index MTMs have simultaneously zero permittivity and permeability and, thus, a zero index of refraction. Consequently, they exhibit spatially static (dynamic in time), infinite wavelength behaviors (Ziolkowski 2004).

The adaptation of a variety of epsilon-negative (ENG), mu-negative (MNG), and DNG metamaterials or simply metamaterial unit cells to achieve enhanced performance characteristics of antenna systems has since received considerable research attention. This includes studies, for instance, of small antennas (Ziolkowski and Kipple 2003, 2005; Qureshi et al. 2005; Stuart and Tran 2005, 2007; Stuart and Pidwerbetsky 2006; Ziolkowski and Erentok 2006, 2007; Erentok and Ziolkowski 2007a, b, c, 2008; Alici and Ozbay 2007; Arslanagić et al. 2007; Ziolkowski 2008a, b; Antoniades and Eleftheriades 2008; Lee et al. 2008; Greegor et al. 2009; Kim and Breinbjerg 2009; Ziolkowski et al. 2009a, b; Mumcu et al. 2009; Jin and Ziolkowski 2009, 2010a; Lin et al. 2010); multi-functional antennas (Sáenz et al. 2008; Herraiz-Martnez et al. 2009; Antoniades and Eleftheriades 2009; Jin and Ziolkowski 2010b, c, 2011; Lin et al. 2011; Zhu et al. 2010); infinite-wavelength antennas (Sanada et al. 2004; Lai et al. 2007; Park et al. 2007); patch antennas (Buell et al. 2006; Ikonen et al. 2007; Alú et al. 2007; Bilotti et al. 2008); leaky-wave antenna arrays (Eleftheriades and Balmain 2005; Caloz and Itoh 2005; Eleftheriades et al. 2007; Caloz et al. 2008); higher-directivity antennas (Enoch et al. 2002; Wu et al. 2005; Martinez et al. 2006; Franson and Ziolkowski 2009); low-profile antennas achieved with a variety of modified ground planes (Erentok et al. 2005; Erentok et al. 2007d; Yang and Rahmat-Samii 2009), e.g., artificial magnetic conductors (AMCs); and dispersion engineering of time-domain antennas (Caloz et al. 2008; Ziolkowski and Jin 2008). The proliferation of wireless devices for communication and sensor applications has restimulated interest in many different types of antennas. The often conflicting requirements of, for instance, efficiency, bandwidth, directivity, weight, and cost have made the design tasks onerous for antenna engineers with traditional schemes. The metamaterial-inspired engineering of antennas and their performance characteristics has provided an alternative approach to addressing these pressing issues.

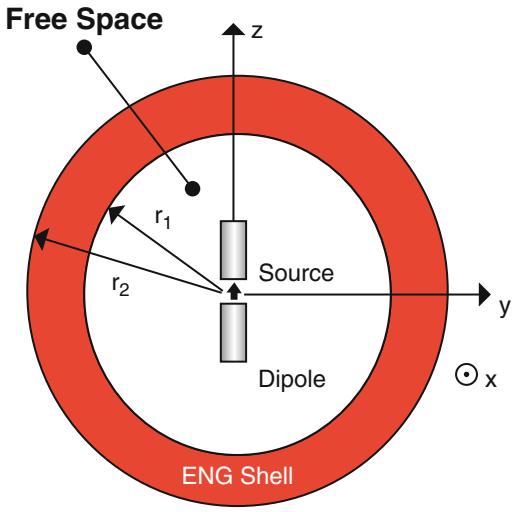

Fig. 2 Original metamaterial-based, efficient electrically small antenna consisting of a center-fed dipole antenna surrounded by an ENG shell

Metamaterial-Based Antennas

The idea of using a resonant metamaterial object in the near field of an electrically small radiator to significantly enhance its performance was introduced in (Ziolkowski and Kipple, 2003; Ziolkowski and Kipple 2005; Ziolkowski and Erentok 2006; Erentok and Ziolkowski 2008) and reviewed in (Ziolkowski et al. 2011). The theoretical models began with enclosing a radiating dipole with double negative or single negative spherical metamaterial shells. For instance, nearly complete matching to a 50Ω source was achieved for a coax-fed dipole (loop) antenna within an ENG (MNG) or DNG shell without any external matching circuit, and high radiation efficiencies were realized giving overall (realized) efficiencies near 100 %. One of the original designs is shown in Fig. 2.

The physical explanation for this configuration is illustrated in Fig. 3. When an electrically small DPS sphere is illuminated by an electromagnetic wave, it responds as an electrically small dipole radiator, which is known to be a highly capacitive element. An electrically small shell also responds in this manner. However, if it is filled with an ENG material, its permittivity is negative, and, hence, its capacitance is negative. This means the shell acts as an inductive element. The combination of the lossy capacitive and inductive elements, i.e., the juxtaposition of the positive and negative material regions, yields a lossy (RLC) resonator.

The driven element, the electrically small dipole antenna, has a large negative reactance, i.e., it too is a capacitive element. Because the lossy resonator is in the extreme near field of the driven element, the fields involved and the subsequent responses are large. It was found that the reactance of this near-field resonant parasitic (NFRP) element, the resonant core-shell structure, can be conjugate matched to the dipole reactance by adjusting their sizes and material properties to achieve an antenna resonance at

$$f_{res} = \frac{1}{2\pi} \frac{1}{\sqrt{L_{eff} C_{eff}}} \tag{1}$$

where L_{eff} and C_{eff} are, respectively, the effective inductance and capacitance of the system, in order to have the total reactance equal to zero (It is noted that in the dual case, a loop antenna and an MNG shell,

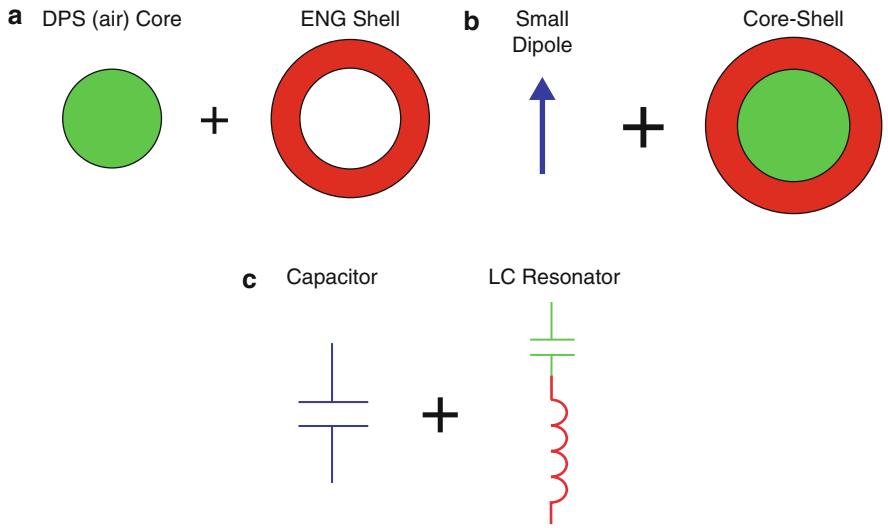

Fig. 3 The physics underlying the electrically small core shell configuration. (**a**) When excited, the DPS core acts as a small dipole element and, hence, is a capacitive element. The ENG shell responds as an electrically small dipole. However, because $\varepsilon < 0$ in the shell, it acts as an inductive element (**b**) Combining the core and shell, he resulting core-shell element acts like an LC resonator that can be matched to a driven electrically small dipole antenna, and (**c**) the circuit elements equivalent to the radiators in (**b**)

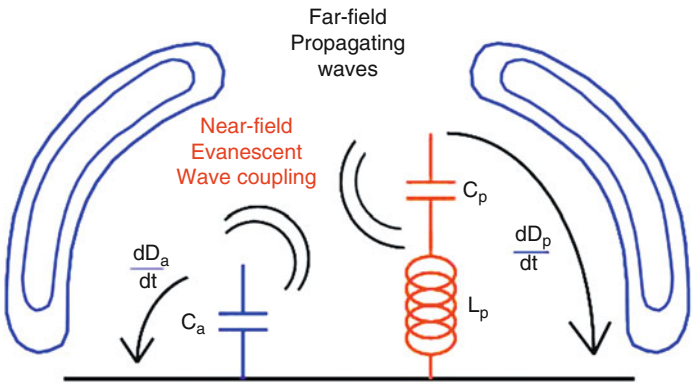

Fig. 4 The basic physics governing the behavior of an electrically small, near-field resonant (NFRP) antenna

the first antenna resonance is generally an antiresonance). Moreover, by tuning the effective capacitances and inductances of both the driven and parasitic elements, the entire antenna can be nearly completely matched to the source. Consequently, it can be said that the NFRP element acts as an impedance transformer.

Furthermore, by arranging the NFRP element so that the currents on it dominate the radiation process, high radiation efficiency and, consequently, very high overall efficiency, i.e., the ratio of the total radiated power to the total input power, can be realized. This basic physics of a NFRP element-based electrically small antenna is depicted in Fig. 4. On the other hand, the bandwidth remains commensurate with the electrical size of the antenna. It was demonstrated (Ziolkowski and Erentok 2007) that with an active ENG shell, the bandwidth could be increased considerably beyond the well-known Chu (1948) and Thal (2006) limits. The introduction of non-Foster elements, which will be discussed later in this chapter, achieves this theoretical construct.

DOI 10.1007/978-981-4560-75-7_14-1

For example, the 300 MHz version of the dipole-ENG shell antenna shown in Fig. 2 was predicted to have an overall efficiency greater than 97 % when $ka = 0.12$ (Ziolkowski and Erentok 2006). It is noted, however, that because the antenna is electrically small, one would expect its directivity to be near that of a small dipole element, i.e., 1.76 dB. Furthermore, the bandwidth will be small. In particular, if a is the radius of the smallest sphere enclosing the entire antenna, $k = 2\pi/\lambda_{res} = 2\pi f_{res}/c$ is the free-space wavenumber at the resonance frequency, and RE is the radiation efficiency of the antenna, then the antenna is electrically small if $ka \leq 0.5$ (1.0) if a (no) ground plane is involved. The Chu lower bound on the quality factor of an electrically small antenna is (Best 2005)

$$Q_{lb} = RE \times \left[\frac{1}{(ka)^3} + \frac{1}{ka}\right] \tag{2}$$

giving $FBW_{ub} \approx 2/Q_{lb}$ as the upper bound of the half-power VSWR fractional bandwidth.

An important practical difficulty with the metamaterial-shell concept is the need to have extremely small unit cell sizes. For instance, if a $ka = 0.10$ antenna is desired, the thickness of the unit cell would be on the order of $\lambda_{res}/100$, thus requiring unit cells at least $\lambda_{res}/300$ in size to have three unit cells across the shell thickness and, consequently, something like a bulk metamaterial. Some of the smallest unit cells fabricated to date are $\lambda/75$ at 400 MHz (Erentok et al. 2007b). Furthermore, when there are losses associated with each unit cell, having many of them can lead to a large cumulative loss value. This behavior has been verified (Greegor et al. 2009) with a dual version of the system shown in Fig. 1. An antenna consisting of an electrically small driven magnetic loop and a mu-negative sphere was designed and fabricated. The measured results demonstrated that the MNG sphere did provide matching of the antenna to the source. However, because of the losses associated with each unit cell and because there were many cells involved in the overall design, it also did not achieve the expected high radiation efficiency.

There have been numerous other metamaterial-based antenna designs considered at RF frequencies. Electrically small antenna designs have been realized with small sets of unit cells and have been shown to have many potential applications (Dong and Itoh 2012). Moreover, the MTM-based NFRP paradigm has been extended to visible wavelengths, leading to active ENZ optical metamaterials (Gordon and Ziolkowski 2008), as well as passive and active nanoantenna (Arslanagić et al. 2007; Geng et al. 2011, 2012, 2013), nanolaser (Gordon and Ziolkowski 2007; Liberal et al. 2014), highly directive nanoantenna (Liberal et al. 2014; Arslanagić and Ziolkowski 2012), nanoamplifier (Arslanagić and Ziolkowski 2010; Arslanagić and Ziolkowski 2014), and quantum jammer (Arslanagić and Ziolkowski 2010, 2013, 2014) designs. The basic configuration is shown in Fig. 5. It results from the fact (Arslanagić et al. 2007) that the driven dipole antenna does not have to be internal to the resonant core-shell element to produce the enhanced total radiated power. As long as the dipole couples strongly with the resonator, the desired enhanced response occurs.

Metamaterial-Inspired Antennas

It was found (Erentok and Ziolkowski 2008) that a NFRP element constructed from a single MTM unit cell is sufficient to achieve the desired matching and high radiation efficiency properties. The resulting radiating systems were termed *metamaterial-inspired* antennas rather than metamaterial-based antennas because only a single MTM unit cell was used and not a bulk medium. One does not need a large resonator around the entire radiating element but rather only a single unit cell – an electrically small resonator – in

the near field of the driven radiator to achieve nearly complete matching to the source without any matching circuit and nearly 100 % overall efficiency. The initial designs made use of the analytical results that matched the type of driven element with the appropriate type of MTM. Both electric and magnetic coupling mechanisms between the driven and NFRP elements have since been explored. These metamaterial-inspired NFRP elements have led to a variety of interesting electrically small antenna systems. Several of these metamaterial-inspired NFRP designs have been fabricated and tested; the measured results are in good agreement with their simulated values.

Electric NFRP, Electric Coupling

The first NFRP antenna that was tested for its overall efficiency performance was the electric 2D EZ antenna shown in Fig. 6. The term *EZ* was chosen to reflect the fact that these original NFRP antennas were "easy" to design and fabricate. It was a Rogers Duroid^{TM} 5880 design. A monopole was printed on

one side of the Duroid sheet and was coaxially fed through a copper ground plane. The NFRP element was a small meander line connected to the ground plane on the other side of the Duroid sheet. It has been demonstrated (Imhof et al. 2006; Imhof 2006) that this is a unit cell of an ENG MTM. It was demonstrated experimentally (Erentok and Ziolkowski 2008) that a 2D electric EZ antenna with $f_{res} = 1.37$ GHz and $ka \sim 0.49$ was nearly completely matched to the 50Ω source and had an overall efficiency ~94 %, with a 4.1 % fractional bandwidth. The NFRP element is electrically coupled to the driven monopole. The fields generated by the currents on the horizontal lines are nearly cancelled out by their images through the ground plane. The vertical elements radiate coherently and provide the high radiation efficiency.

With an interest to achieve an adjustable and potentially tunable version of this NFRP antenna, the Z antenna, whose 570 MHz, 31 mil, 2 oz Duroid 5880 realization is shown in Figs. 7a and b, was designed, fabricated by Boeing Research and Technology in Seattle, WA, and tested in the reverberation chambers at the National Institute of Science and Technology (NIST) in Boulder, CO (Ziolkowski et al. 2009b). The meander line was reduced to two simple J-elements connected with a lumped element inductor. The bottom J-element is connected to the ground plane. The monopole is coaxially fed through the ground plane. It was a 30 mm × 30 mm design incorporating a CoilCraft 47nH inductor. Measurements were taken with both the small ground plane version (120.6 mm diameter copper disk) shown in Fig. 7 and a larger ground plane version (the small ground plane version was inserted into an 18 in × 18 in = 457.2 mm × 457.2 mm copper ground plane). A physical comparison of the Z antenna and the reference ETS LINGREN 3106 double-ridged waveguide horn, which is about 94 % efficient in its

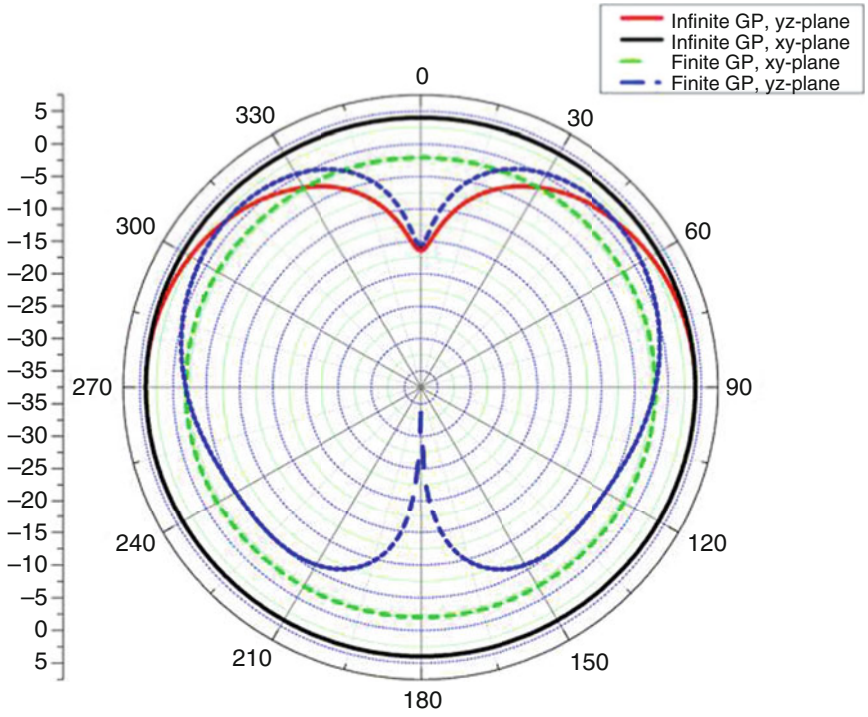

Fig. 9 HFSS-predicted patterns for the Z antenna at f_{res} have the expected electric monopole with a finite ground plane shapes

200 MHz-2GHz frequency band, is shown in Fig. 8. An overall efficiency equal to 80 % was measured at the resonance frequency $f_{res} = 566.2$ MHz ($ka = 0.398$) with a half-power fractional bandwidth $FBW = 3.0$ %, giving $Q = 4.03\ Q_{lb}$. There was little difference between the small ground plane and larger ground plane results. The predicted gain patterns in the small and large ground plane configurations are shown in Fig. 9, confirming that the Z antenna acts like a small vertical monopole with a finite ground plane. A second Z antenna, a 40 mm × 40 mm design incorporating a CoilCraft 169nH maxi inductor, had a 46 % measured overall efficiency at $f_{res} = 294.06$ MHz ($ka = 0.276$). Both sets of experimental results demonstrated, as predicted, the ability to obtain a lower resonance frequency with a simple redesign using a larger lumped element value. These experiments not only confirmed the predicted controllability of the resonance frequency but also provided information on how to treat the lumped element inductor in the electromagnetic simulations. Based on these results, an updated Z antenna was designed with an overall efficiency of OE = 82.3 % ($|S_{11}| = -25.44$ dB) at $f_{res} = 285.6$ MHz ($ka = 0.428$) (Ziolkowski et al. 2009b).

As it was recognized that the NFRP elements were the key to these electrically small designs, several variations have been designed to allow for other functionalities, which will be described below. For instance, the NFRP element associated with the Z antenna can be simplified considerably (Ziolkowski 2008a, b; Jin and Ziolkowski 2009; Jin and Ziolkowski 2011). The version shown in Fig. 10a consists of a split vertical segment connected by a lumped element inductor. The size of the upper horizontal metal rectangle is adjustable to tune the input reactance. HFSS simulations of the currents at the resonance frequency confirm that they are mainly on the vertical segments, which means this antenna radiates as a monopole over the ground plane and that the overall efficiency is above 90 % (Jin and Ziolkowski 2009). The second version in Fig. 10b utilizes a distributed NFRP element. The vertical strip couples directly to the driven monopole, the metal arc provides the inductance, and the horizontal strips provide additional capacitance. In resonance, HFSS simulations predict that the overall efficiency is above 90 % and confirm that the currents, as shown in Fig. 10b, are mainly on the vertical segment of the NFRP element, which again indicates why this antenna radiates as a monopole over the ground plane (Ziolkowski et al. 2011).

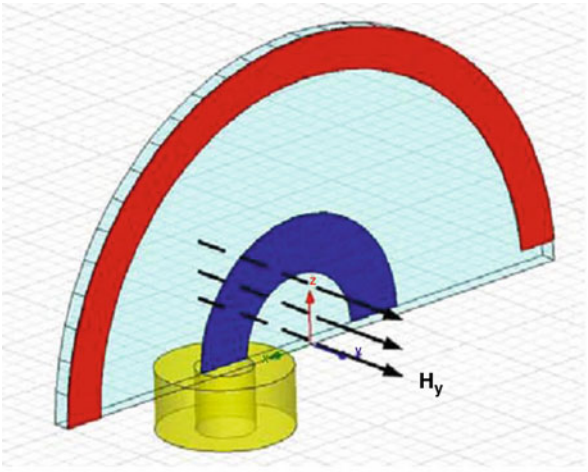

Fig. 11 The magnetic flux of the printed semi-loop antenna coaxially fed through a finite ground plane drives the CLL NFRP element in this variation of the 2D magnetic EZ antenna

Magnetic NFRP, Magnetic Coupling

In a similar fashion, the NFRP element can be driven with the magnetic field of the driven element. In conjunction with the analytical solutions, a driven magnetic semiloop antenna coaxially fed through a finite ground plane was first considered. This led to the magnetic 2D and 3D EZ antennas (Erentok and Ziolkowski 2007a, b; Ziolkowski et al. 2009b; Lin et al. 2010). This feed-coupling scheme is graphically illustrated in Fig. 11, which illustrates a variation of the 2D magnetic EZ antenna. The parasitic element is a capacitively loaded loop (CLL), which was originally used successfully to achieve an artificial magnetic conductor metamaterial (without any ground plane) (Erentok et al. 2005). Both distributed and lumped element versions have been fabricated and tested successfully (Erentok and Ziolkowski 2008).

The 3D magnetic EZ antenna is composed of an electrically small loop antenna that is coaxially fed through a finite ground plane and that is integrated with an extruded CLL element. This 3D CLL structure is designed to be the NFRP element. The measured results (Ziolkowski et al. 2009b) for the 3D magnetic EZ antenna demonstrated that for an electrical size, $ka \sim 0.43$, at 300.96 MHz, nearly complete matching to a 50 Ω source, and a high overall efficiency (>94 %) was achieved. These results and those in Erentok and Ziolkowski (2007b, c) established that the CLL-based elements can work in many frequency bands, e.g., from the ultrahigh-frequency (UHF) band to the X band. While negative permeability cannot be ascribed to either the 2D or 3D CLL elements themselves, a metamaterial constructed with them as its unit cell inclusion would exhibit MNG properties. Nonetheless, as with the electric source–electric coupling

DOI 10.1007/978-981-4560-75-7_14-1

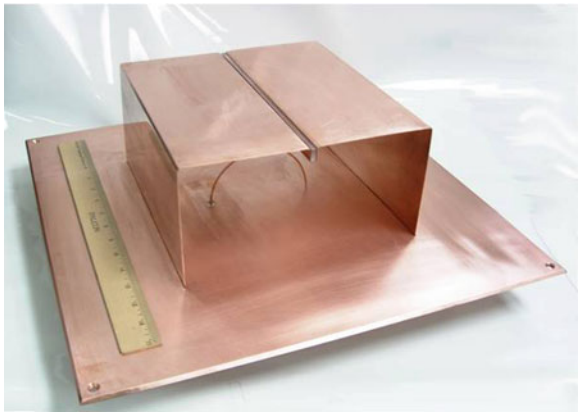

Fig. 12 The fabricated 100 MHz 3D magnetic EZ antenna in its small ground plane configuration

cases, it is the electrically small, magnetic-based NFRP CLL structure that provides the ability to match the electrically small loop antenna to the source. This can be visualized with the configuration dual to that shown in Fig. 4. The NFRP element again enhances the radiation process to achieve high radiation efficiencies. In particular, the CLL element can be engineered to control the strong magnetic flux generated by the small driven loop antenna and convert it into the appropriate currents flowing on the CLL element. Furthermore, this magnetic coupling process between the driven loop and the NFRP CLL element can be adjusted to tune the resonance of the entire antenna system according to Eq. 1 (Erentok and Ziolkowski 2008; Kim and Breinbjerg 2009). These metamaterial-engineered NFRP antennas again help overcome the loss issues associated with an actual metamaterial-based antenna design (Greegor et al. 2009). The wire versions of the CLL NFRP antennas have also been designed and show similar performance characteristics (Lin et al. 2011).

A similar low-profile (height ~ $\lambda_{res}/25$) 3D magnetic EZ antenna was designed for operation at 100 MHz. The fabricated antenna is shown in Fig. 12. The measured and simulated results were in very good agreement. This $ka = 0.46$ antenna was measured to have OE ~ 95 % and a half-power VSWR fractional bandwidth of 1.52 % ($Q = 11.06\ Q_{lb}$) at $f_{res} = 105.2$ MHz. This design utilized a quartz spacer ($\varepsilon_r = 3.78$) to help lower the resonance frequency and to provide mechanical stability during shipping and operation. Similar antennas have been designed for operation at 20 MHz using simply a $\varepsilon_r = 100$ spacer (Lin et al. 2010).

The corresponding HFSS-predicted gain patterns are shown in Fig. 13; the maximum gain value is 5.94 dB. Because the gain patterns are symmetric, it can be immediately inferred that the surface currents induced on the electrically small CLL element by the flux of the driven semiloop antenna are uniform and symmetric. This behavior is verified with the HFSS-predicted vector surface current distributions. This current distribution also demonstrates that this electrically small antenna system is radiating as a magnetic dipole over a finite ground plane (Lin et al. 2010).

Magnetic NFRP, Electric Coupling

Several important features distinguish the electric-based and the magnetic-based cases. The electric-based cases generally exhibit about half the Q values of the magnetic-based cases. Simply, the variation of the input impedance with frequency associated with a resonance is smaller than that associated with an antiresonance (Yaghjian and Best 2005). The electric-based cases radiate a vertical electric monopole type pattern; the magnetic-based cases radiate a horizontal magnetic dipole type pattern. The rate of decrease in the radiation efficiency as *ka* decreases is slower for the electric-based cases than for the magnetic-based ones. Because for many applications one would like broadside radiators and high radiation efficiencies for

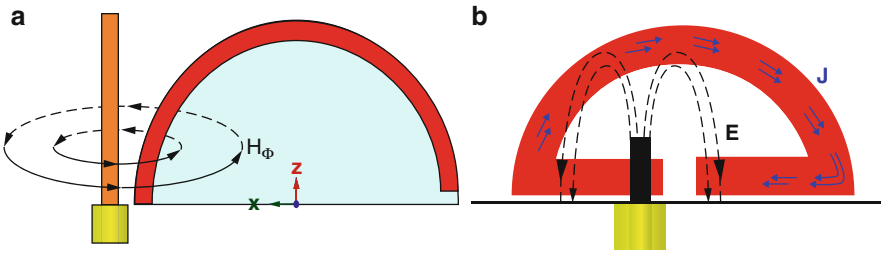

Fig. 14 Antenna composed of a driven electric source that is (**a**) magnetically coupled and (**b**) electrically coupled to a (magnetic) CLL-based NFRP element

yet smaller *ka* values, antennas with a driven electric source have been investigated that are either magnetically or electrically coupled to a magnetic NFRP element. At first, because it deviated from the MTM-based analytical solution paradigm, this cross-design was not expected to yield a successful antenna. Fortunately it was, and it was found that it provides some interesting flexibilities for the multifunctional designs to be discussed below.

The driven electric source, magnetically coupled design is illustrated in Fig. 14a. The magnetic field flux generated by the driven monopole is directly coupled to the CLL element. A realization of this design has been reported (Alici and Ozbay 2007). While it does produce a pattern with its maximum in the direction orthogonal to the plane, this magnetically coupled design is more sensitive and requires larger ka values to achieve nearly complete matching to the source than the corresponding electrically coupled design shown in Fig. 11b. The protractor antenna (Jin and Ziolkowski 2011) illustrated in Fig. 14b has a thin gap between the horizontal legs of the CLL-based NFRP element and the ground plane. Because this NFRP element is in the extreme near field of the driven element, the electric fields across this gap are very large. Note that if the monopole were centered on the CLL element, the magnetic flux contributions would

DOI 10.1007/978-981-4560-75-7_14-1

completely cancel because of symmetry; and the radiation process would be very weak from the electric field-generated currents along either side of the NFRP protractor element because a majority of them would be canceled by their images in the ground plane. However, by offsetting the monopole, the electric driven currents can form the desired loop mode around the CLL element. This loop mode radiates the desired magnetic dipole over a ground plane pattern. The coupling is strong, and consequently, the radiation efficiency can be large. Over 85 % overall efficiencies have been demonstrated for several protractor antennas (Jin and Ziolkowski 2010b; Jin and Ziolkowski 2011).

Multifunctional Electrically Small Antennas

Because of the known need for more functionality in a given antenna, the single antenna designs have been extended to multiantenna ones while trying to maintain the same footprint (overall size). By properly combining and phasing their effective electric and magnetic dipoles electrically small multiband, circular polarized (CP), elemental Huygens source and broader bandwidth antennas were obtained that are nearly completely matched to a 50Ω source and have high radiation efficiencies. These various designs are reviewed below.

Multiband Antennas

Several multiband antenna systems which consist of multiple NFRP elements in the very near field of the driven element, each being resonant at a specified, unique frequency, have been developed (Jin and Ziolkowski 2010c; Lin and Ziolkowski 2010). At each antenna resonance, only one or majorly one parasitic element efficiently radiates. It is worth pointing out that the directly driven monopole remains essentially nonradiating at all of the resonant frequencies. Impedance matching to the source at all multiband frequencies is achieved by adjusting the dimensions of each parasitic element and its distance from (and, hence, coupling to) the driven monopole. When there are multiple parasitic elements, the couplings among the parasitics also impact the radiation and matching processes. Efficient multiband operation results from properly understanding the effects of these multiple resonances and how to minimize their couplings. This NFRP approach is a distinct difference from the directly driven multiband dipole antennas proposed in Herraiz-Martnez et al. (2009) and related works that use parasitic split resonant rings to achieve the multiband capability. At each resonant frequency, the directly driven dipole plays a significant part in the radiation process, and the SRRs act as different loads at different resonant frequencies. Using the simplified NFRP element shown in Fig. 10a, the dual-band GPS L1 (1575.4 MHz) and L2 (1227.6 MHz) antenna shown in Fig. 15 was designed (Jin and Ziolkowski 2010c). In the same manner, a quad-band 430.0 MHz and GPS L1 (1575.42 MHz), L2 (1227.60 MHz), and L5 (1176.45 MHz) antenna was also designed (Jin and Ziolkowski 2010c).

The dual-band, asymmetric split EZ antenna system shown in Fig. 16 was designed to achieve a low-frequency dual-band system for low-earth-orbit satellite (LEOS) communications: 137.475 MHz uplink and 149.15 MHz downlink bands (Lin and Ziolkowski 2010). Note that these frequencies are separated by only 11 MHz. The radiation efficiencies for those resonant frequencies are 96.4 % and 71.5 %, respectively.

The reason why the higher resonant frequency has lower radiation efficiency is due to the currents being in opposition in these two CLL elements, i.e., they are out of phase. At the lower frequency, they are in phase. These EZ design results have provided us with the insight into the need for careful recognition of the relative current flows on the set of NFRP elements to achieve the highest possible radiation efficiencies. By controlling the relative phases of the currents, a related dual-band 429.8 MHz (SATCOM) and 1575.6 MHz (GPS L1) design, in which the two 3D CLL NFRP elements are nested

and the semiloop antenna is diagonally oriented to excite each element, has radiation efficiencies of 83.8 % and 97.5 %, respectively (Lin and Ziolkowski 2010).

Another dual-band application is the desire to have both satellite positioning (GPS) and communications. Highly compact, multifunctional antennas that can communicate with satellites to accommodate both voice and data exchanges, while providing GPS functionality, are of great interest for portable

communication device applications. For this reason, a dual-band GPS L1 (1575.42 MHz) and Global Star (GS, 1610–1621 MHz) electrically small, planar NFRP antenna shown in Fig. 17 was designed (Jin et al. 2012). This antenna has, by choice (Jin et al. 2012), a square footprint of 1.0×1.0 in^2. It was designed to be fabricated with the Rogers Duroid 4350 board material, which has a relative permittivity equal to 3.66, a loss tangent equal to 0.004, a 0.762-mm substrate thickness, and a 0.017-mm (0.5 oz) copper thickness.

To achieve the desired dual-band performance, two NFRP elements were incorporated with a single driven element. The two NFRP elements lie on one side of the Duroid sheet; the driven element, which is coaxially fed, lies on the other side. The NFRP elements are both top-loaded meander-line dipoles, which are rectangular variations of the circular Egyptian-axe dipole NFRP elements introduced in Jin and Ziolkowski (2010b). Both dipoles are the same except for the gaps between the capacitive loads, i.e., the capacitances formed by the gaps between the ends of the arrows. Because of the differences in the resulting capacitances, two independent resonant frequencies were obtained. However, to avoid any unnecessary structural overlaps and to keep the NFRP elements in a one-layer layout, the meander lines were introduced on their legs to increase the overall inductance while allowing a decrease in the requisite capacitances provided by their gaps and still maintaining the desired operating frequency. Furthermore, the NFRP elements are oriented orthogonal to each other. This necessitates the overlapping of these elements at the center of the square. It also required the introduction of the driven bowtie antenna (orange), which facilitates electric coupling to each NFRP element. Because the two dipoles are perpendicularly

DOI 10.1007/978-981-4560-75-7_14-1

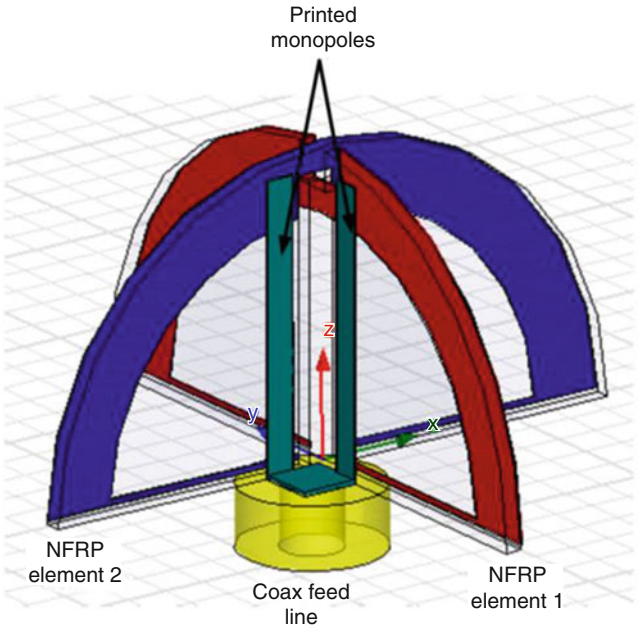

Fig. 18 CP protractor antenna. The CP behavior is achieved at a frequency between two closely spaced resonances through a 90° phase shift obtained between their input reactances

oriented, they operate essentially independently even though they are connected. The red (horizontal) dipole in Fig. 17a has a larger gap (G1) and is thus resonant at the GS band. The blue (vertical) dipole has a smaller gap (G2) and thus operates at the GPS L1 band.

CP Antennas

Another functionality that has been added to the NFRP antenna paradigm is circular polarization (CP). In all of the cases noted above, the antennas are linearly polarized (LP). To achieve a CP system with a single feed in an electrically small package, one needs two orthogonal dipole radiators with an effective 90° phase shift between them. This behavior was realized with the protractor antenna system shown in Fig. 18. It is a GPS L1 CP design (Jin and Ziolkowski, 2011) with $a = 15$ mm; $f_{res} = 1575.4$ MHz giving $ka = 0.495$; a 89.2 % overall efficiency; a 29.3 MHz (−10 dB) bandwidth; a 7.2 MHz CP bandwidth; and an axial ratio equal to 0.26. Each protractor element produces a magnetic dipole parallel to the ground plane. One is tuned to be resonant below the desired operating frequency and thus creates an inductive reactance at it. The other is tuned to be resonant above the desired operating frequency and thus creates a capacitive reactance at it. Because these protractor NFRP elements are orthogonal to each other, their resonances can be tuned independently to generate the 90° phase shift between them necessary for the CP behavior.

Similarly, the planar (no ground plane) GPS L1 design shown in Fig. 19 was obtained (Jin and Ziolkowski 2010b). It has $ka = 0.539$ at 1575.4 MHz, an overall efficiency of 85 %, a 31.4 MHz (−10 dB) bandwidth, a 7.2 MHz CP bandwidth, and an axial ratio of 0.66. It makes use of the same phase shift paradigm but with two of the Egyptian axe NFRP elements shown in Fig. 14b and a driven printed dipole antenna. On the other hand, an electrically small wire, GPS L1 CP antenna, shown in Fig. 16, has been obtained (Lin et al. 2011) using two CLL-based wire NFRP elements driven by a coaxially fed semiloop antenna. It has $a = 15$ mm giving ka = 0.495 at $f_{res} = 1575.4$ MHz, a 96.9 % overall efficiency, a 30.7 MHz (−10 dB) bandwidth, a 7.9 MHz CP bandwidth, and an axial ratio of 0.6. The requisite phase shift is obtained by tuning the angle between the semiloop antenna and the NFRP elements (Fig. 20).

DOI 10.1007/978-981-4560-75-7_14-1

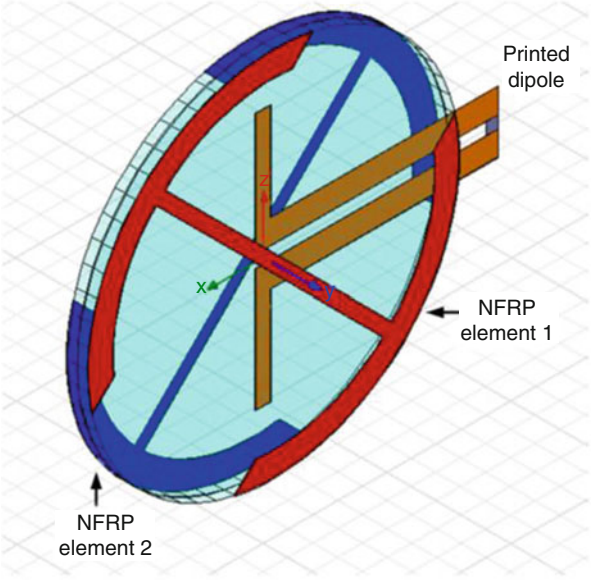

Fig. 19 A GPS L1 CP antenna consisting of two dipole NFRP elements and a driven printed dipole antenna. The CP behavior is achieved at a frequency between two closely spaced resonances through a 90° phase shift obtained between their input reactances. This Rogers Duroid™ 5880 design consists of three metal and two dielectric layers. The NFRP elements are on the outside faces of the dielectric layers; the printed dipole lies between those dielectric layers

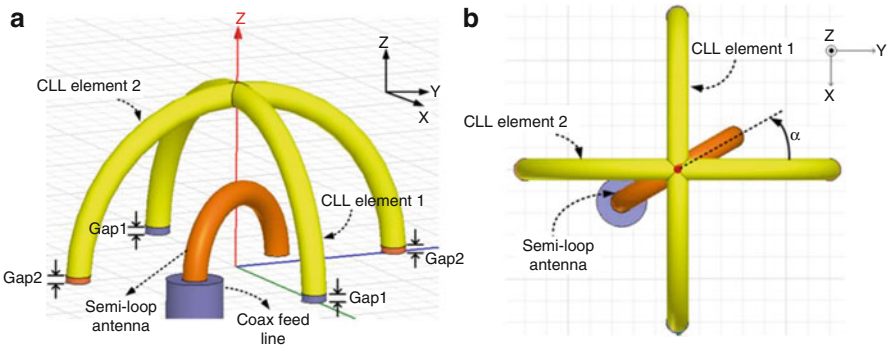

Fig. 20 Geometry of a GPS L1, CLL-based NFRP CP wire antenna whose coax-fed semi-loop is rotated α° with respect to the ZY-plane. The two CLL NFRP elements have two closely spaced resonances; the requisite 90° phase shift between their input reactances is obtained by tuning the angle α between the driven semi-loop antenna and the NFRP elements

In the same manner, the GS/GPS antenna shown in Fig. 17 was modified to achieve the CP GPS-L1 version shown in Fig. 21, i.e., by simply tuning the resonances of each NFRP element to the requisite values. The axial ratio is minimum at 1.580 GHz with a value AR = 0.84. The overall efficiency at this frequency was 73.41 %. The corresponding peak directivity was (1.88 dB).

Multifunctional Designs

The multiband and CP aspects have been combined together (Jin and Ziolkowski 2011) into the dual-band GPS L1/L2 protractor antenna whose design is shown in Fig. 22a and whose fabricated prototype is shown in Fig. 22b. It was found possible to interleave two pairs of protractor NFRP elements with the appropriate phasing between the resonances to produce CP at both the GPS L1 and L2 frequencies with a single feed structure. As depicted in Fig. 22a, one can see in Fig. 22b the two pairs of protractor elements

DOI 10.1007/978-981-4560-75-7_14-1

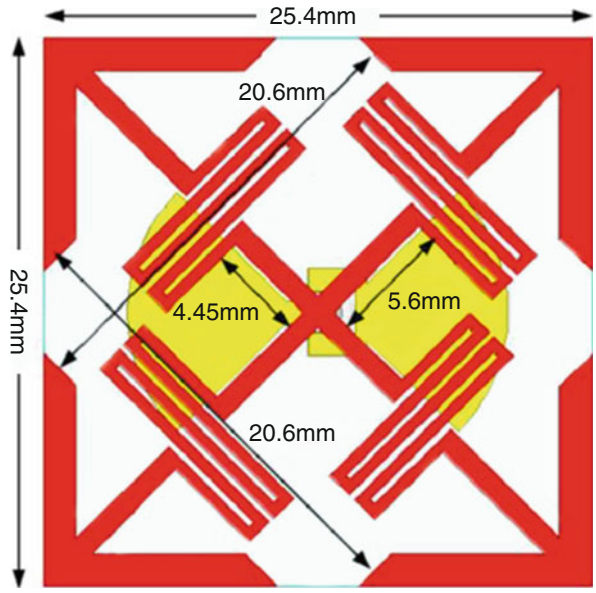

Fig. 21 Planar GPS L1 CP NFRP antenna

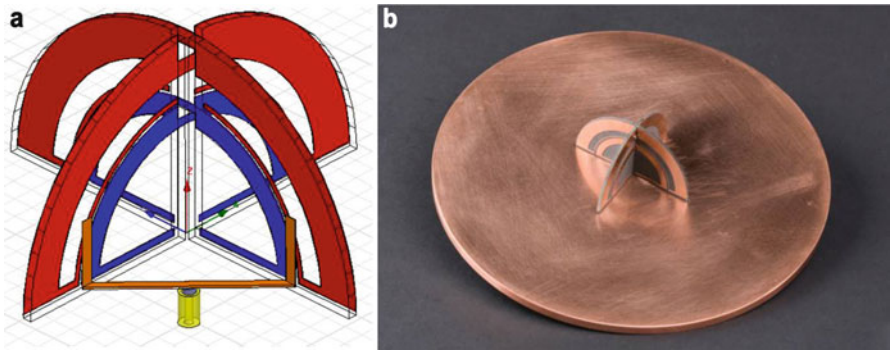

Fig. 22 Dual-band CP GPS L1/L2 NFRP antenna. (**a**) HFSS design (the L1 and L2 bands are associated, respectively, with the blue inside and red outside NFRP elements), (**b**) fabricated prototype

lying on two pieces of Rogers Duroid^{TM} 5880, which are oriented orthogonal to each other and to the finite copper ground plane. The initial experiments have demonstrated the basic operating principles, including the high overall efficiencies and the CP behavior (Jin and Ziolkowski 2011).

Planar multiband, CP GPS antennas have been obtained (Ta et al. 2012, 2013a, b, c) as variations of the designs shown in Figs. 17 and 21. The version shown in Fig. 23 covers the GPS L1–L5 bands. The primary radiating elements are two crossed printed dipoles, which incorporate a 90 phase delay line realized with a vacant-quarter printed ring to produce the CP radiation and broadband impedance matching. To achieve multiple resonances, each dipole arm is divided into four branches with different lengths, and a printed inductor with a barbed end is inserted in each branch to reduce the radiator size. An inverted, pyramidal, cavity-backed reflector is incorporated with the crossed dipoles to produce a unidirectional radiation pattern with a wide 3-dB axial ratio (AR) beamwidth and a high front-to-back ratio. This multiband CP antenna has broad impedance matching and 3-dB AR bandwidths covering the GPS L1–L5 bands.

DOI 10.1007/978-981-4560-75-7_14-1

Elemental Huygens Sources

Using the same NFRP element principles, an electrically small, elemental Huygens source can be obtained (Jin and Ziolkowski 2010b). It requires the combination of an electric and a magnetic dipole. A GPS L1 planar design that combines the Egyptian axe NFRP element for the electric dipole and two NFRP protractor elements to achieve a similar amplitude magnetic dipole is shown in Fig. 24a. It is a Rogers Duroid^{TM} 5880 design consisting of three metal and two dielectric layers. The NFRP elements lie on the outside faces of the dielectric layers; the driven printed dipole antenna lies between those dielectric layers. It has $ka = 0.46$ at $f_{res} = 1475$ MHz, a 85.9 % overall efficiency, and a 23.2 MHz (−10 dB)

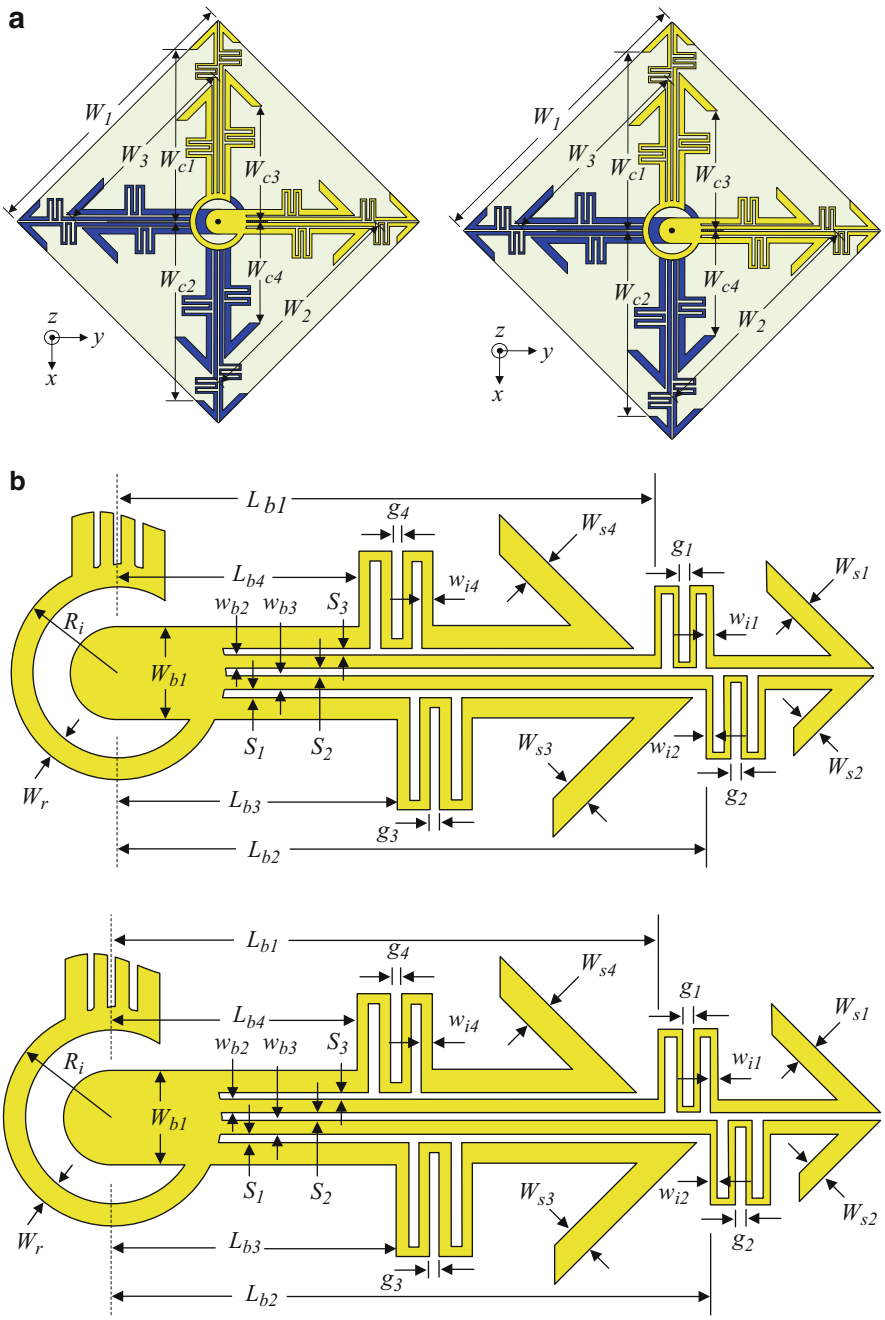

Fig. 23 (continued)

DOI 10.1007/978-981-4560-75-7_14-1

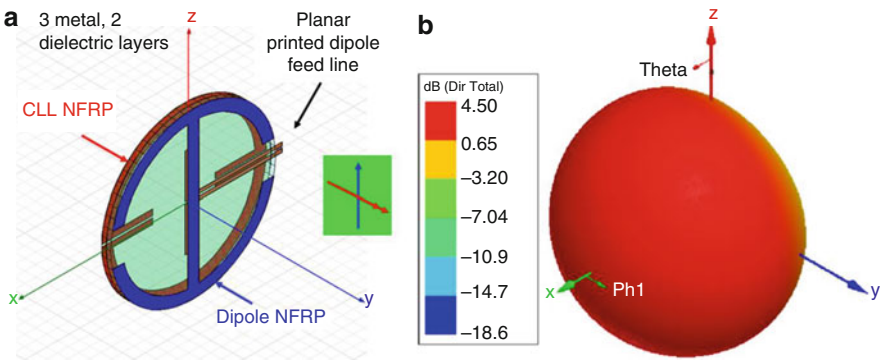

Fig. 24 An electrically small Huygens source that combines equal amplitude electric and magnetic dipoles and nearly achieves the maximum possible directivity. (**a**) HFSS design (the effective electric and magnetic dipoles are depicted in the insert), and (**b**) HFSS-predicted 3D directivity pattern

bandwidth. The HFSS-predicted 3D directivity pattern at this resonance frequency is shown in Fig. 18b. It has a maximum directivity of 4.5 dB and a 17.1 dB front-to-back ratio. The ideal maximum is 4.77 dB (i.e., a directivity of 3).

Using these concepts, a Huygens source nanoparticle laser has been designed (Liberal et al. 2014). The design is a three-layer, 120 nm outer-radius, nanoparticle consisting of a gain impregnated silicon core, a silver (ENG) shell surrounding it, and a gain impregnated silicon outer coating. At visible wavelengths, the high permittivity of silicon allows the appearance of a magnetic dipole mode in addition to the electric one. The former is associated with the outer shell; the latter with the core. By tuning the radius and gain constants, a proper balance of the electric and magnetic dipole modes is obtained. Lasing with a directivity of 3 in the forward scattering direction with respect to the exciting field occurs at 673.1 nm.

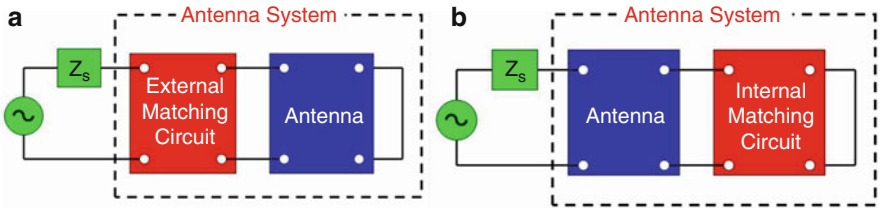

Fig. 25 Introducing active elements into an antenna system allows one to overcome the passive bounds on its bandwidth. (**a**) External active matching circuit, and (**b**) internal active matching element

Non-Foster Electrically Small Antennas

As noted previously, there is an upper bound on the bandwidth of a passive electrically small antenna. As noted, recent efforts (Gustafsson et al. 2009; Yaghjian and Stewart 2010) have led to improved versions of the original Chu limit. Nevertheless, as Eq. 2 indicates, the fractional bandwidth basically decreases as $(ka)^3$ when ka becomes smaller. Moreover, it also indicates that one can obtain more bandwidth simply by reducing the radiation efficiency, i.e., by introducing more loss into the antenna. Another more complicated approach is to combine together multiple radiating elements with slightly different but overlapping resonance frequencies. It was found that some care must be exercised in this strategy. If the NFRP elements are too tightly coupled, the resonances tend to merge together and produce an even narrower bandwidth response. Moreover, it is usually difficult physically to squeeze several elements into an electrically small footprint. A variety of metamaterial-inspired electrically small antennas have been designed with Q factors that reach the fundamental bound (Best 2004, 2005, 2009; Kim et al. 2010; Kim 2010). Note, however, that even if an antenna reaches the upper bound, that bound is extremely small and the bandwidth cannot surpass it.

A method to overcome the passive bound is to introduce active elements into the antenna system. As shown in Fig. 25a, the standard approach (Aberle and Loepsinger-Romak 2007; Sussman-Fort and Rudish 2009) is to introduce an active matching circuit that produces the necessary resistance and reactance variations to maintain matching of the antenna to the source over a large bandwidth. Because of the sensitivity of active circuits, this becomes both a rather difficult design task and realization issue. In contrast, a metamaterial-inspired paradigm is to introduce the active element internally, integrating it with the NFRP element. This internal matching circuit approach, illustrated in Fig. 25b, has led to several successful designs (Jin and Ziolkowski 2010a; Zhu and Ziolkowski 2011, 2012a, b, 2013; White et al. 2012; Mirzaei and Eleftheriades 2013).

Consider the NFRP antenna shown in Fig. 26. This canopy antenna was designed (Jin and Ziolkowski 2010a) to approach the Chu-Thal limit. The legs of the canopy are lumped element inductors; the canopy is a copper spherical shell cap. With passive inductors, $ka = 0.047$ designs with $Q = 1.75\ Q_{Chu} = 1.17\ Q_{Thal}$ have been obtained with high overall efficiencies.

It was demonstrated further, as with the Z antennas, that the antenna resonances can be tuned over a frequency band with the same physical structure by varying only the value of the inductors. It was found that with this frequency-agile behavior, the inductor value decreases with an increasing resonance frequency, i.e., to achieve a larger instantaneous bandwidth, the inductor would have to be an active non-Foster element. Such an active inductor was designed with a Linvill-based negative impedance convertor (NIC) (Linvill 1953). HFSS simulations demonstrated a 10 % fractional bandwidth at 300 MHz was possible when $ka = 0.047$, nearly a thousandfold improvement over the passive design. This active design provides a different paradigm from the traditional non-Foster approaches. In principle, it requires only non-Foster reactive matching without any resistive matching. This simplifies the requirements on the active element considerably. This design is analogous to the original active analytical solution that

DOI 10.1007/978-981-4560-75-7_14-1

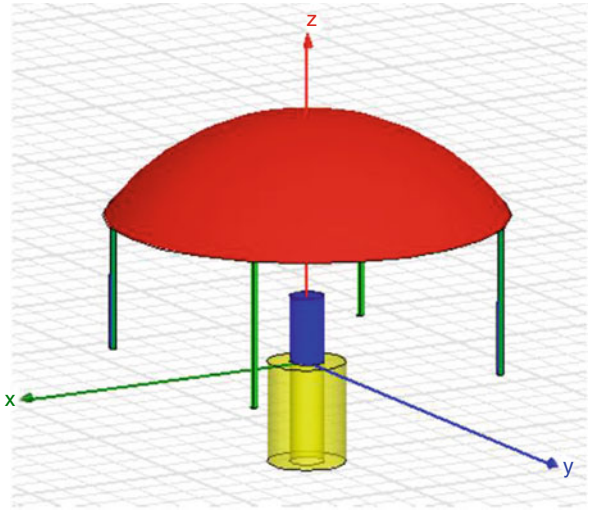

Fig. 26 Canopy antenna design. The NFRP element consists of four vertical legs (*green*), each being a lumped element inductor, and a copper spherical cap (*red*). The driven element is a monopole (*blue*) coaxially fed (*yellow*) through the ground (xy) plane. Efficient designs with $ka = 0.047$ at 300 MHz when the inductor is passive have bandwidths that approach the Chu-Thal limits and exhibit over 10 % bandwidth when an active inductor is used

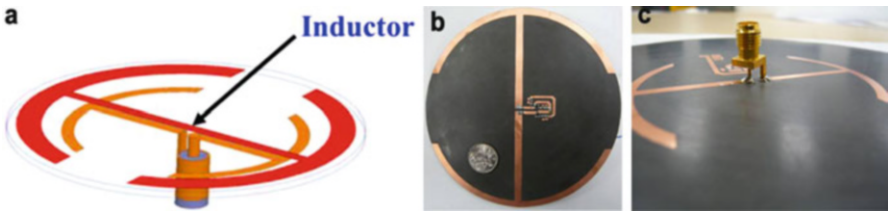

Fig. 27 Non-Foster-augmented Egyptian axe dipole (EAD) antenna to realize an efficient, electrically small antenna with large instantaneous impedance bandwidth. (**a**) Isometric view of the HFSS model, and (**b**) top and (**c**) bottom views of the fabricated and measured prototype

produced a large fractional bandwidth for the idealized metamaterial-based, gain impregnated core-shell NFRP element, dipole-driven antenna system (Ziolkowski and Erentok 2007).

To test these non-Foster-augmented, metamaterial-inspired antenna concepts, the Egyptian axe dipole antenna shown in Fig. 27a was designed, fabricated, and tested. A lumped element inductor, which is placed across the gap centered in the NFRP element, is treated as a tunable element. The $ka = 0.444$ EAD design for 300 MHz was obtained initially. Its frequency-agile behavior was then determined by varying the inductor value. The resulting non-Foster reactance was matched with a two-BJT Linvill NIC circuit. This circuit was then incorporated into the NFRP element as shown in Figs. 27b and c. The measured instantaneous impedance bandwidth was improved by a factor of 6.2 and was about a factor of 4 greater than the passive upper bound (Zhu and Ziolkowski 2012b, 2013). Similar performance improvements were obtained for a non-Foster-augmented protractor antenna (Zhu and Ziolkowski 2012a).

As with any active element, the stability of a non-Foster element is a significant practical issue. Component and fabrication tolerances can adversely affect the system enough that it will become unstable. It has been demonstrated that a key test of stability is to consider the time-domain response of the entire system – the non-Foster circuit and the antenna system augmented with it. Growth in time of any frequency component is an indicator of an instability. The stability of the NIC circuits and their integration

with the EAD's radiating elements was confirmed in this manner before it was verified by experiment (Zhu and Ziolkowski 2013).

The internal non-Foster design paradigm has been extended to enhance not only the impedance bandwidth but also the directivity bandwidth (Tang et al. 2013). This was accomplished by introducing yet another NFRP element, augmenting it with a non-Foster element, and tuning it to act like an AMC surface. This approach also provided a solution to the holy grail of electrically small antennas: a design that exhibits simultaneously high efficiency, high directivity, impedance matching, and large front-to-back ratio (FTBR) over a broad instantaneous bandwidth. This antenna configuration is shown in Fig. 28 (Ziolkowski et al. 2013). The EAD antenna is augmented with an inductor-based NIC; it is integrated with a slot-modified parasitic disk that is augmented with a capacitor-based NIC.

The HFSS-simulated performance characteristics of this electrically small, $ka = 0.94$, system include a radiation efficiency > 81.63 %, directivity > 6.25 dB, FTBR > 26.71 dB over a 10.0 % fractional bandwidth. This yields a directivity-to-quality factor ratio which is greater than 10 times the fundamental upper bound: $(D/Q) > 10 \times (D/Q)_{\text{bare EAD}}$. These results are illustrated in Fig. 29. The directivity patterns in Fig. 29a have the characteristic cardioid pattern. This behavior persists over the bandwidth of the system. Consequently, it confirms that the parasitic disk acts as a broad-bandwidth AMC element. The other performance characteristics in Fig. 29b demonstrate a rather uniform behavior of the various performance characteristics over the entire bandwidth of the system.

Summary

As more has been learned about metamaterials and their electromagnetic properties, a variety of metamaterial-based and metamaterial-inspired antenna systems have been developed from RF to optical frequencies. Their metamaterial constructs have led to enhanced performance characteristics. An electrically small antenna paradigm, the metamaterial-inspired near-field resonant parasitic (NFRP) antenna, is an example. It has provided realizations of a variety of interesting multifrequency, multifunctional designs whose input impedance can be nearly completely matched to the source and that exhibit high radiation efficiencies. The different coupling mechanisms between the driven and NFRP elements provide extra degrees of freedom to tailor the currents that produce the radiated fields. Both planar and volumetric loadings of space are possible with the NFRP elements, leading to more flexibility in antenna designs. The introduction of internal non-Foster elements provides a means to overcome the physical constraints associated with passive systems, e.g., a path to large instantaneous bandwidths. Moreover, the recognition that non-Foster-based elements can also be used to modify other antenna properties provides yet more design degrees of freedom. In particular, it allows one to design an electrically small antenna with simultaneous high efficiency, high directivity, large front-to-back ratio, and nearly complete impedance

DOI 10.1007/978-981-4560-75-7_14-1

matching over a large instantaneous bandwidth, i.e., active metamaterial constructs have provided the means to overcome the usually assumed performance characteristic trade-off approach to small antenna design.

At the heart of any wireless system is an antenna. Metamaterials, whether explicitly introduced into an antenna system as physical constructs or implicitly introduced using their often exotic properties to guide specifics of a design, have provided exciting new opportunities to antenna engineers to meet the needs of a continually increasing demand for wireless products. Given slightly more than a decade of experience with the engineering applications of metamaterials, there is a great hope that they may be able to provide additional degrees of freedom for the design of many different forms of electromagnetic systems from DC to light.

Optimization Methods in Antenna Engineering

Douglas Werner*, Micah Gregory, Zhi Hao Jiang and Donovan E. Brocker
The Pennsylvania State University, University Park, PA, USA

Abstract

Optimization strategies have been heavily used in the antenna design community for many years. Oftentimes, the details of the strategies and optimization configurations are left out of the designs in open literature. The goal of this chapter is to inform the reader of many of the algorithms currently being used in the antenna design community, give a detailed operation of four of the most commonly used algorithms, and compare their performance on test functions and an example antenna design problem. Additionally, several recent examples of complex antenna designs which made use of these algorithms will be examined.

Keywords

Optimization; Evolutionary strategy; Antennas; Covariance matrix adaptation; Particle swarm; Differential evolution; Genetic algorithm; Function minimization

Introduction

Due to the complex and ever-changing requirements for antenna capabilities, global optimization strategies have seen extensive and increasing use in the field of antenna design. Antennas and systems which require ultra-wideband, multiband, and multifrequency operation are prime candidates for making use of optimization to find a suitable set of geometric and material properties which fulfill the requisite performance criteria. These strategies are often invaluable tools for the design of antenna structures which have no closed-form solutions to determine their impedance and gain characteristics. Oftentimes, an antenna must be designed in a constrained fashion due to the profile of the supporting device as well as other practical considerations. This can present a particularly challenging problem to the antenna engineer, one well suited for global optimization.

Optimization strategies are iterative algorithms that aim to minimize a user-determined cost function given a set of parameters and settings. The optimizable parameters are a set of binary or real-coded values that are passed to the cost function which is constructed such that low-cost values represent designs that are more desirable than those with higher values. For antenna design, the cost function evaluation process often includes some form of simulation or computation that determines the performance characteristics of the device generated using the associated set of input parameters. The cost function can return one or more values for single-objective or multi-objective optimization, respectively. Since these simulations or computations are usually very time-consuming processes, it is highly desirable to use an optimization strategy which requires the fewest cost function calls to achieve the desired cost function goal.

There exists many different types of optimization strategies, and it is not unusual that some are better suited for certain classes of antenna design than others. In this chapter, an overview of the operation,

DOI 10.1007/978-981-4560-75-7_15-1

functionality, and usage of several algorithms commonly used in antenna design will be provided. Then, some performance comparisons involving test functions and concept antenna designs will be presented. Lastly, several detailed examples of interesting antenna designs that have been produced with the aid of global optimization strategies will be covered.

Introduction to the Algorithms

Four algorithms are chosen here in this chapter for close examination of their performance on an assortment of test functions and antenna design problems. They are the genetic algorithm (GA), particle swarm optimization (PSO), differential evolution (DE), and the covariance matrix adaptation evolutionary strategy (CMA-ES). The GA is most commonly implemented in a binary scheme; however, the binary strings can also be used to represent discretized real values according to the number of bits chosen to represent each value. The remaining three algorithms are naturally real coded and lend themselves to optimizations with continuously variable parameters.

The GA has had a significant impact on the field of antenna design since it was conceived in the early 1970s (Holland 1973). It is an iterative, population-based algorithm with operation based on the theory of natural selection and survival of the fittest. The population members have their chromosomes (binary strings that form the set of input parameters to the cost function) blended and mutated in a way that lends itself to constantly forming better-performing (lower cost) future population members, while still effectively exploring the given search region. The binary operation makes it well suited for decision- or on/off-based optimization, but it has been applied effectively to many real-valued problems as well by representing real parameters with a finite number of chromosome bits. It has seen extensive application in antenna design as well as many other electromagnetic problems due to its ease of use, simple implementation, and global search abilities (Haupt and Werner 1995, 2007; Rahmat-Samii and Michielssen 1999; Weile and Michielssen 1997; Johnson and Rahmat-Samii 1997). For example, it has been used in the design of wire antennas (Altshuler 2002; Boag et al. 1996; Altshuler and Linden 1997; Werner et al. 2008), array synthesis (Bray et al. 2002; Gregory and Werner 2009; Gregory and Werner 2010; Gregory et al. 2010a; Petko and Werner 2008; Spence and Werner 2008; Boeringer and Werner 2004, 2005; Haupt 1994; Ares-Pena et al. 1999; Weile and Michielssen 1996), planar and patch antenna design (Kerkhoff and Ling 2007; Johnson and Rahmat-Samii 1999; Villegas et al. 2004), and many others (Jones and Joines 1997; Mosallaei and Rahmat-Samii 2001; Villegas et al. 2004; Santarelli et al. 2006; Akhoondzadeh-Asl et al. 2007; Godi et al. 2007; Werner et al. 2001).

PSO was introduced in the mid-1990s as an algorithm based on the swarm behavior of insects such as bees as they search for food (Eberhart and Kennedy 1995; Kennedy and Eberhart 1995, 2001). Like the GA, PSO is a population-based iterative algorithm; however, it tends to operate more cooperatively than competitively. Each population member moves around the search space based on recorded memory of its personal best-found location and the best-found location (lowest cost function value) of all of the population members (global best). Rather than binary strings that form chromosomes, each population member is comprised of two vectors of real-valued parameters, one forming its position and the other its velocity. Particle swarm has been a very popular algorithm in the antenna design community due to its ease of use, easy implementation, and reasonably good optimization performance (Robinson and Rahmat-Samii 2004; Gies 2004; Jin and Rahmat-Samii 2007, 2008). It has been successfully applied to a wide variety of antenna design problems such as multiband and wideband antennas (Jin and Rahmat-Samii 2005; Lizzi et al. 2007, 2008) as well as phased array design (Boeringer and Werner 2004; Boeringer et al. 2005) and many others.

DE appeared in the late 1990s as a new powerful global optimization algorithm (Storn and Price 1997). Being a real-valued strategy like PSO, it is well suited to many of the same design problems (Rocca et al. 2011; Goudos et al. 2011). It is an iterative, population-based algorithm that operates by generating

DOI 10.1007/978-981-4560-75-7_15-1

mutant vectors (candidate solution sets) based on current population members, testing to see if they perform better and replacing members if they do. Some examples of where DE has been applied include low-RCS antennas (Wang et al. 2010), circularly polarized microstrip antennas (Deb et al. 2014), monopulse antennas (Massa et al. 2006), slot antennas (Li et al. 2014), Yagi-Uda design (Goudos et al. 2010), and array synthesis (Chen and Wang 2012; Zhang et al. 2013; Lin et al. 2010; Panduro et al. 2009; Kurup et al. 2003).

The last algorithm to be considered is the covariance matrix adaptation evolutionary strategy (CMA-ES), introduced in the early 2000s by Hansen and Ostermeier (2001; Hansen et al. 2003). It has seen increasing interest coupled with a growing number of applications in the electromagnetic and antenna design community (Gregory et al. 2010b, 2011; Gregory and Werner 2011) due to its ease of use and fast, robust optimization characteristics. Like PSO and DE, it is also a global population-based, real-valued iterative algorithm. It operates by intelligently moving a Gaussian search distribution of varying shape and size throughout the search space. The population is formed by sampling from the search distribution at each iteration; the population size is simply the number of samples taken from this distribution. It has been successfully applied to many different electromagnetic and antenna design problems including planar antennas (Gregory et al. 2011; Gregory and Werner 2013), dielectric resonator antennas (Fang et al. 2011; Fang and Leung 2012; Leung et al. 2013; Pan et al. 2014), phased arrays (Gregory et al. 2011, 2013; Zhang et al. 2012), and electromagnetic band-gap materials (Martin et al. 2014).

These algorithms are all excellent choices for antenna designers seeking enhanced performance characteristics from their design criteria. In the following section, they will be discussed and analyzed on various problems, giving the reader a better understanding of how they operate, and which algorithms might be a better choice for a particular design problem.

Alternative Algorithms

Although not discussed in detail or applied in this chapter, there are many other algorithms that have been used in the design of electromagnetic structures such as antennas. Some are stochastic, and others are based on natural phenomena similar to the GA or PSO. Some examples include simulated annealing (Kirkpatrick et al. 1983; Murino et al. 1996; Coleman et al. 2004; Martínez-Fernández et al. 2007), ant colony optimization (Rajo-Iglesias and Quevedo-Teruel 2007; Rocca et al. 2008; Lewis et al. 2009; Dorigo et al. 2006), evolutionary programming (Hoorfar 2007; Jamnejad and Hoorfar 2004; Hoorfar and Chellapilla 1998), invasive weed optimization (Karimkashi and Kishk 2010), wind-driven optimization (WDO) (Bayraktar et al. 2011, 2013), clonal selection algorithm (CLONALG) (Castro and Von Zuben 2002; Campelo et al. 2005; Bayraktar et al. 2010, 2012), and many others. In addition to these, there are often variations of the aforementioned algorithms (including the GA, PSO, DE, and CMA-ES) to include additional features such as multi-objective optimization, additional or different operators (such as mutation, selection, etc.), mixed-parameter optimization (i.e., real-valued and/or binary parameters), and so on. In general, most algorithms are very flexible and customizable and can be modified as needed to better suit certain types of design problems.

The Genetic Algorithm

The genetic algorithm (GA), primarily due to its binary nature, has been extensively used in electromagnetics for a variety of reasons including ease of implementation, easy modification for additional or different features, robust global optimization, and suitability to many different types of design problems, including most notably to antennas. In this chapter, the basic single-objective GA will be discussed and utilized in the proposed test function and antenna design problems.

Fig. 2 Binary chromosome examples (randomly configured) which combine decisions with discretized real values

GA Operation

The GA is an iterative, population-based algorithm with basic operation outlined in Fig. 1 that aims to refine a set of parameters such that the lowest possible cost function value is obtained (Holland 1973). It is initialized by randomly configuring the chromosomes of a user-determined number of population members. Prior to this, the chromosome must usually be configured according to the optimization task at hand. On occasion, all of the design parameters are natively binary and hence the chromosome configuration is straightforward. The GA can be configured to include discretized, real-valued parameters by defining them by a simple binary representation or Gray code. It is up to the user to determine the number of bits to include to define each parameter, with fewer bits making the optimization task easier at the cost of reduced parameter resolution. Typically, the design problem will lend some insight into the desired resolution (i.e., antenna fabrication tolerance, etc.). To describe the operation of the GA, an example problem will be considered here that has 15 decisions (binary 0 s and 1 s) and two 5-bit parameters for a total chromosome length of 20 bits as shown in Fig. 2. In this case, the 5-bit parameters have 2^5 possible values, and the binary sequences must be mapped to the available parameter ranges before being passed to the cost function. Usually, most freely available GA tools will automatically make these mappings.

After the chromosomes are initialized, the algorithm continues by evaluating each population member based on the user-defined cost function. Once the cost values for each population member are computed, the process that generates new population members can begin. The first step is selection, where parent population members are chosen for reproduction based on their cost. There are several different types of GA selection methods such as roulette wheel, rank-based, and tournament, with the most commonly used being the tournament variety. In this case, small tournaments (usually two or three members) are held between population members that are drawn at random; their cost values are compared and the lowest cost member is passed on for crossover. This is done until a pool of better-performing members are obtained

DOI 10.1007/978-981-4560-75-7_15-1

Crossover Point	1																2							
Parent 1	0	1	1	1	0	0	1	0	1	1	0	0	1	1	0	0	0	1	1	1	1	0	1	0	0

Fig. 4 Example of the uniform crossover being applied to the sample population members

that is of sufficient size for the number of children desired from each crossover pair. In the example GA to be considered, one child is obtained per set of parents, therefore a crossover pool of $PopSize \times 2$ is required.

In crossover, traits from two (and sometimes more) parents are combined to (hopefully) form an offspring with lower cost. In the binary GA, this is done by blending the chromosomes, which can be accomplished in different fashions such as a single-point or uniform crossover as shown in Figs. 3 and 4, respectively. The GA can be configured to yield one or two children per set of parents; in the case of one child, the second offspring is simply not generated. The uniform crossover is employed here as it is generally recommended for best optimization performance. A user-determined crossover probability (p_{cross}) determines the likelihood of crossover for the single-point type, or the ratio of one parent's genes to another for the uniform type. For the single-point type, if the crossover is to occur (i.e., $U_{\text{rand}}[0,1] < p_{\text{cross}}$), then the crossover location is determined at random. For uniform crossover, $p_{\text{cross}} = 0.5$ is generally recommended to evenly combine the genes of both parents. A $p_{\text{cross}} \neq 0.5$ causes the offspring to favor the characteristics of one parent or another. Each mask bit is determined by generating a random number in [0,1] and choosing the first parent if it is less than p_{cross} and the second if greater than p_{cross}.

Once enough offspring are generated to refill the population, they are then mutated to create new genetic traits and explore new portions of the search space. There are several ways to implement mutation, the two most common being creep mutation and jump mutation. Jump mutation is where single bits are inverted based on a mutation probability p_{mutate}. Creep mutation is where parameter values are incremented or decremented by a small amount (usually ± 1 LSB). For example, a positive creep mutation of parameter 1 in member 1 would change from 00111 to 01000. Although many bits are changed here, the parameter value itself has only been changed by one least-significant-bit. On occasion, both forms of mutation may be used simultaneously. In the example GA employed in this chapter, only jump mutations are implemented.

After mutation, the iterative cycle repeats with cost function evaluation of the new population members. The algorithm can be terminated if a maximum number of iterations or cost function evaluations are exceeded, time is expired, or the cost function goal is met. For problems where there is no defined goal, indefinite minimization is commonly performed where convergence criteria are monitored (i.e., the best cost value has not been exceeded for a certain number of iterations) or the algorithm is simply terminated after a certain number of iterations.

DOI 10.1007/978-981-4560-75-7_15-1

Comments on Usage of the GA

Typically, the GA will require a large population compared to the other algorithms, especially if discretized parameters are used with a large number of bits. Tradeoffs invariably occur in terms of optimization performance versus number of bits used to define parameters. If time and computational resources are available, it is sometimes advantageous to perform multiple optimizations on the problem with various, increasing population sizes. If the best achieved cost function values are not significantly different upon convergence, then the population size is likely adequate for the problem and algorithm configuration at hand. If this is undesirable, it is usually advisable to choose a large population to ensure that an adequate solution is found. Population sizes on the order of chromosome length are generally sufficient for most problems. Jump mutation rates are typically $1/n_{\text{chrome}}$, where n_{chrome} is the number of bits in the encoded chromosomes. This leads to a high probability that single bit in the chromosome will be flipped per population member during the mutation process.

Unlike the remaining PSO, DE, and CMA-ES algorithms, the GA natively includes parameter boundaries due to the nature of its binary chromosome. Therefore, no boundary handling needs to be implemented, except where creep mutations cause an overflow or underflow of bits (e.g., positive creep with 1111 or negative creep with 0000), which can be easily prevented in the code. Generally, the GA is most suited to and has been successfully applied to many electromagnetic design problems where decision-based parameters are primarily implemented. One popular and compelling example is a thinned linear array on a periodic lattice as demonstrated in Haupt (1994), where each GA chromosome bit controls the amplitude or presence of an associated element (i.e., on or off). In Thors et al. (2005) and Gregory and Werner (2009), the GA was used to configure the pixellized metal that comprises the radiating portion of planar antenna elements. A 0 or 1 in the GA chromosome directly controls the absence or presence of a metal "pixel," while other discretized GA parameters determine the remaining properties such as dielectric constants and thicknesses of a substrate/superstrate material.

Particle Swarm Optimization

The first of the real-coded optimization strategies covered here is PSO, a very popular algorithm in the electromagnetic and antenna design community. This is due to its simple operation, making implementation straightforward, along with very capable optimization performance. Many antenna optimization problems naturally lend themselves to real-valued design parameters, making strategies such as PSO an excellent choice for these tasks.

PSO Operation

As previously mentioned, PSO is a cooperative swarm-based optimization strategy that is based on natural phenomena such as bees searching for food. Each particle moves about the search space in an effort to find function values of lower cost. It uses knowledge of its personal best-found location (set of parameter values that are the inputs to the cost function) and the global best location to determine the direction to travel in future iterations. Social and nostalgia constants, as well as particle inertia, determine the specific velocity and direction of the particles as they move about. A flowchart of the operation of PSO is shown in Fig. 5. The algorithm is initialized with the particles randomly distributed in the desired search region and velocities randomly configured such that $v_{ij}^{(g=0)} = U_{\text{rand}}\left(\text{range}_j^{\min}, \text{range}_j^{\max}\right)$, where j is the parameter index and i is the population member index.

DOI 10.1007/978-981-4560-75-7_15-1

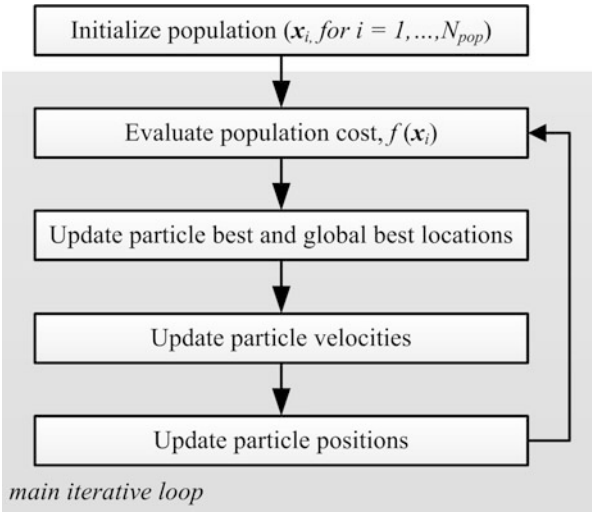

Fig. 5 Operation of particle swarm optimization

The particles are first evaluated for cost, and then the cost values are recorded; the particle with the lowest cost has its position recorded as the global best location, and the cost values of each particle are recorded as their current best location. Particle velocities are then updated according to

$$\boldsymbol{v}_i^{(g+1)} = \omega(g) \cdot \boldsymbol{v}_i^{(g)} + c_1 \cdot U_{\text{rand}}(0,1) \cdot \left(\boldsymbol{x}_i^{\text{best}} - \boldsymbol{x}_i^{(g)}\right) + c_2 \cdot U_{\text{rand}}(0,1) \cdot \left(\boldsymbol{x}_{\text{global}}^{\text{best}} - \boldsymbol{x}_i^{(g)}\right), \quad (1)$$

where g is the iteration number, $\boldsymbol{x}_i$ is the current particle position, $\omega(g)$ is the particle inertia at iteration g, c_1 is the cognitive constant, c_2 is the social constant, $\boldsymbol{x}_i^{\text{best}}$ is the best location found by particle i, $\boldsymbol{x}_{\text{global}}^{\text{best}}$ is the lowest cost location found in the optimization thus far, and $U_{\text{rand}}(0,\ 1)$ is a random number uniformly distributed between 0 and 1. At this point, the velocities are examined for limiting purposes in order to prevent particles from crossing over an excessive portion of the search space during a single iteration. This is accomplished though a conditional statement

$$\text{if } \|\boldsymbol{v}_i\| > v_{\max} \text{ then } \boldsymbol{v}_i = v_{\max} \cdot \boldsymbol{v}_i, \quad (2)$$

where $\|\boldsymbol{v}_i\|$ is the parameter-normalized velocity (i.e., lies between 0 and 1) and $v_{\max}$ is a user-determined maximum velocity constant. Once new velocities are computed, the particles' new positions can then be updated using

$$\boldsymbol{x}_i^{(g+1)} = \boldsymbol{x}_i^{(g)} + \boldsymbol{v}_i^{(g+1)}. \quad (3)$$

The particle inertia $\omega(g)$ is a term that varies throughout the optimization, initially starting at $\omega_{\max}$ for iteration 1 and then tapering linearly to $\omega_{\min}$ at iteration g^{exp} and then holding constant thereafter. This is done to encourage a more global search at the beginning of the optimization and gradually move to a more local search near the end. One potential issue with this is the need to predict how many iterations that the optimization will require to find a suitable cost value, as using different values of g^{exp} can have a significant impact on the convergence of the algorithm.

In order to constrain the particles to a desired search space, boundary conditions must be applied at each iteration in order to limit particle positions in such a way that does not significantly disturb the effectiveness of the optimization. This can become especially important when regions of low cost lie

DOI 10.1007/978-981-4560-75-7_15-1

on the boundaries of parameter spaces, a situation that can frequently occur in many design problems. There are several different types of boundary conditions in use. Incorporated here is the absorbing boundary condition, where if a particle strikes a boundary, the associated parameter is set to that boundary value, and the velocity of a particle in that direction is set to zero.

Comments on Usage of PSO

There are several strategy parameters to configure with PSO; however, there are commonly available suggested values that tend to give good performance on a wide range of problems. The suggested values are usually $c_1 = c_2 = 2.0$ and $v_{\max} = 0.5$. Typically, the inertial parameters $\omega_{\max}$ and $\omega_{\min}$ are set to 0.9 and 0.4, respectively. The expected number of iterations $g^{\exp}$ is highly problem dependent. Using too small of a value will lead to early convergence, potentially resulting in a poor cost value. Using too large of a value will lead to slow convergence and cause the algorithm to take more iterations than may normally be required. To illustrate the potential performance differences, a ten-dimensional Ackley test function is selected as a test case for PSO with four different choices of $g^{\exp}$. Twenty seeds are run for each case with a population size of 20 members to obtain a statistical performance comparison. It can be seen that there is not a significant difference between the results with $g^{\exp} = 20$ and $g^{\exp} = 100$, except that one of the seeds converged before reaching the desired function value of 10^{-10}. With a larger $g^{\exp}$, however, the optimization times grow without any significant benefit. Another issue is that for the same problem, a good choice of $g^{\exp}$ can vary with population size (Fig. 6).

It is easy to see how choosing parameters such as $g^{\exp}$ is very important to achieving an efficient and effective optimization. Unlike test functions, in most realistic optimization scenarios, the user does not know the global cost function minimum or how many iterations are needed to obtain a good solution (if one is even possible). A poor choice of $g^{\exp}$ can lead to either a bad solution or an optimization that takes much longer than needed, often without the designer being aware. Becoming familiar with the design problem and operation of the algorithm is then a key factor in obtaining fruitful, worthwhile optimizations.

Differential Evolution

DE is another popular real-valued global optimization algorithm that has found use in solving many challenging electromagnetic design problems. It does not have a strong foundation in nature such as PSO; however, it has several attractive properties from a functional standpoint. One is that unlike traditional

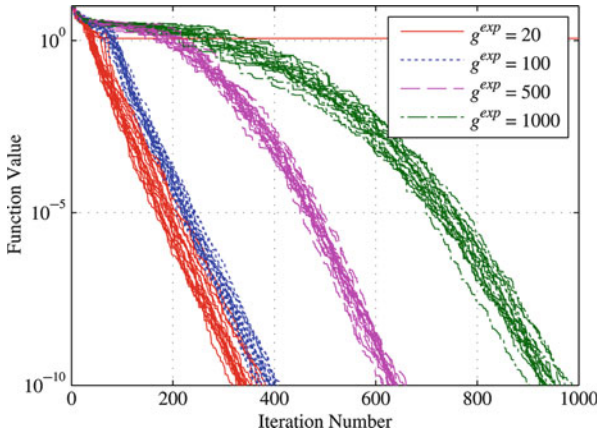

Fig. 6 Comparison of PSO on the ten-dimensional Ackley test function for different values of $g^{\exp}$

DOI 10.1007/978-981-4560-75-7_15-1

gradient-based methods, only cost function comparisons are used instead of cost derivatives. Another is that information is shared among individuals in the population in an effort to create future members with lower cost. Differential evolution can be a powerful tool when properly applied to challenging design problems.

Operation of Differential Evolution

The iterative operation of DE is shown in Fig. 7. It is initialized in the same way as many other real-valued optimization strategies such as PSO, where a population is distributed randomly inside the search domain. The population is then evaluated to obtain cost values for each member. The iterative process then begins, starting by choosing the first population member and three other distinct population members (with index p, q, r). A test vector ($\boldsymbol{y}$) is generated using these three members and two evolutionary parameters, along

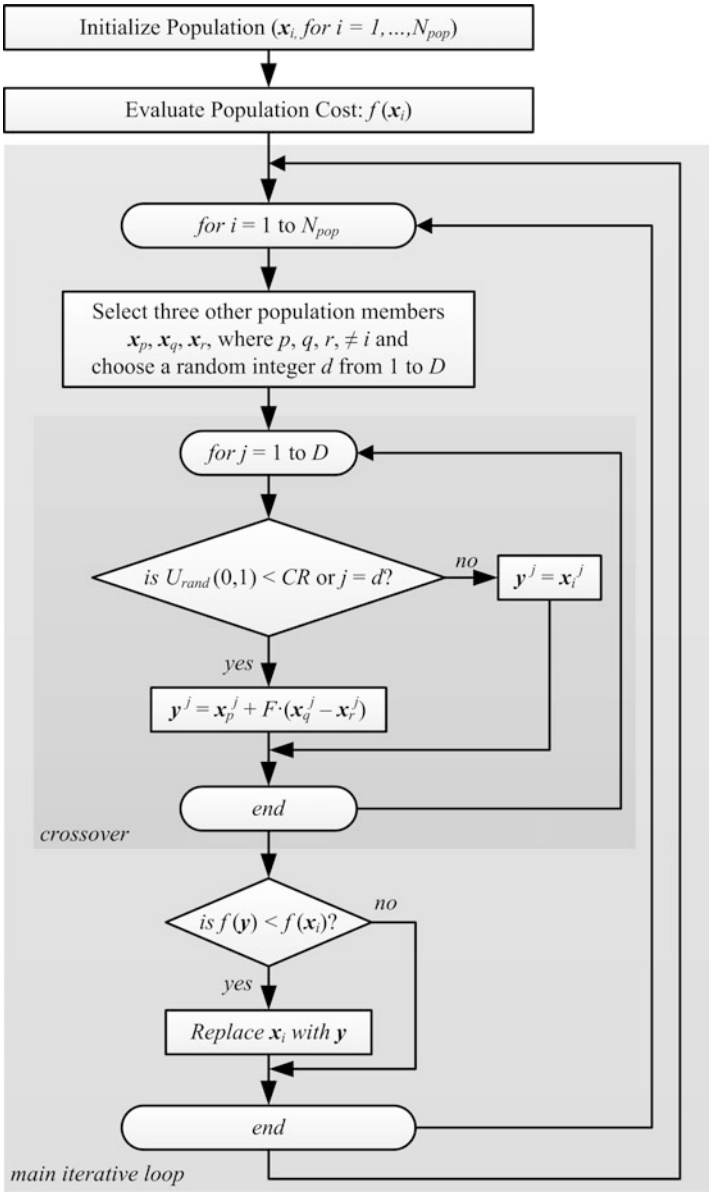

Fig. 7 Operation of DE on a D-dimensional problem. The superscript j represents the parameter index of the given population vector

DOI 10.1007/978-981-4560-75-7_15-1

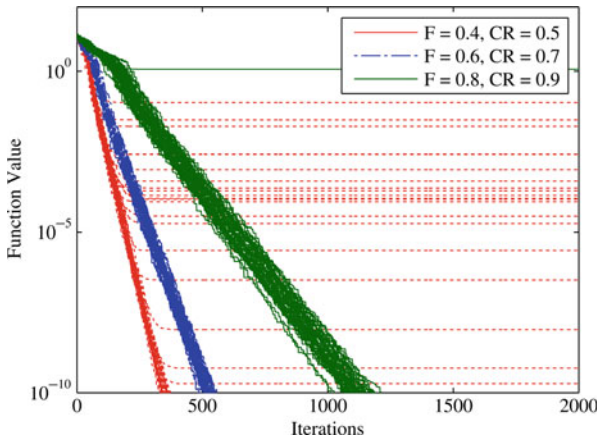

Fig. 8 Operation of DE on the ten-dimensional Ackley test function with various settings of *CR* and *F* and a population size of 20. Fifty seeds are used for each pair of algorithm settings

with several random variables as shown in Fig. 7. The test vector is a blend of the properties of the three vectors and the original vector, with proportions determined by the crossover process. Much like the GA, the crossover rate determines the proportions; at least one parameter in the test vector is used in order to provide a unique individual and avoid wasting a cost function evaluation (i.e., when $j = d$). The test vector is then evaluated for cost and if it is better than the population member initially considered, it replaces that member.

This process repeats for each population member. Ideally, the test vectors provide a continuous improvement to the population. At any time in the process, the algorithm can terminate if the cost function goal is achieved, the maximum number of function evaluations or iterations are achieved, or time is expired.

The two evolutionary parameters can play an important role on the performance of the optimization. The crossover rate (*CR*) determines the rate at which new test parameters are injected into the trial vector. A large crossover rate will lead to test vectors that are very different from the initial population member, creating a very exploratory search. The weighting constant (*F*) determines the proportion of distance between the second and third test vectors that is added to the first. An example of how these parameters can affect the performance of DE is shown in Fig. 8, where the algorithm is applied with various selections of *CR* and *F*. The limits of ($F = 0.4$, $CR = 0.5$) to ($F = 0.8$, $CR = 0.9$) are those generally recommended for common usage. Cost function variable dependence, noise, and other properties determine which set of evolutionary parameters are most effective for the problem at hand. It can be seen that with ($F = 0.4$, $CR = 0.5$), DE performs fast, but with limited success as evidenced by the large number of seeds that converge before reaching the cost function goal of 10^{-10}. With ($F = 0.6$, $CR = 0.7$), DE is both reasonably fast and reliable. With ($F = 0.8$, $CR = 0.9$), DE is reliable yet tends to be slower than needed, taking almost twice as long on average to reach the cost function goal.

Comments on Usage of DE

Like PSO, boundary conditions must be applied to prevent population members from exiting the desired or feasible search space. In this case, when any parameter in a trial vector is location out of the boundaries, it is snapped to the corresponding boundary. This method is fairly effective and requires little in terms of computational resources.

Because of its operation, it is easily observed that DE requires at least a population size of four members to function. In general, population sizes must be sufficiently large to ensure robust optimization, while not being so large that optimization time is excessive. Like the other algorithms, this behavior is highly

DOI 10.1007/978-981-4560-75-7_15-1

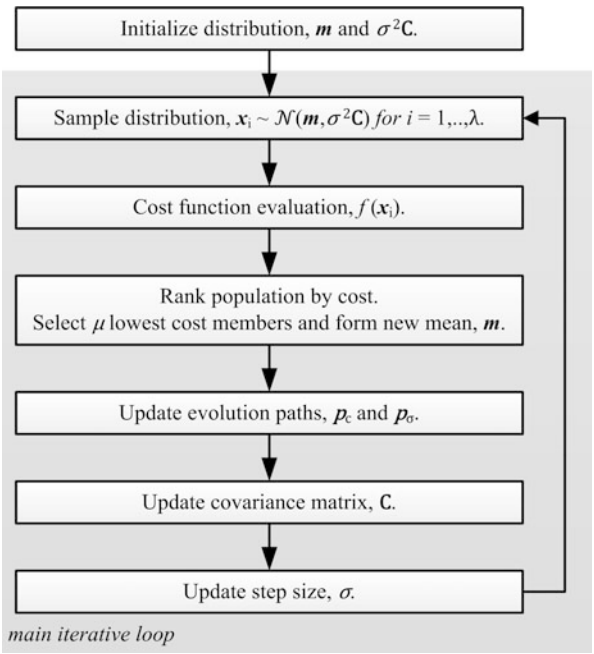

Fig. 9 Operational diagram of CMA-ES

problem dependent. It has been suggested to choose a population size of between five and ten times the number of optimizable parameters if unsure of the problem difficulty; however, it will be shown that smaller populations can be successful on easier problems (Storn and Price 1997). For difficult problems, further optimizations with larger populations can be carried out if poor results are initially achieved.

In practical use, the effectiveness of DE can be somewhat sensitive to the choice of the crossover rate and weighting constant, as is shown in Fig. 8. The parameters used for the test function in Fig. 8 will not always have the same relative outcomes for all problems (i.e., $F = 0.8$, $CR = 0.9$ may prove to be more effective than $F = 0.4$, $CR = 0.5$ in some cases). Because of this, two set of parameters for DE will be used for the analysis presented in this chapter. It is up to the user to determine the parameter values that are most appropriate for the problem at hand, although some insight is given in Storn and Price (1997).

The Covariance Matrix Adaptation Evolutionary Strategy

The covariance matrix adaptation evolutionary strategy (CMA-ES) is a relative newcomer to the field of evolutionary computation as well as electromagnetic design. Like PSO and DE, it is a real-valued population-based optimization algorithm that operates on an iterative foundation. Internally, the algorithm is much more complex than either PSO or DE; however, it is self-adaptive and only requires the user to choose a population size before beginning an optimization rather than population size plus several other evolutionary parameters.

Operation of CMA-ES

A functional diagram of CMA-ES can be found in Fig. 9. The internal operating constants, vectors, and arrays are given in Tables 1 and 2. Superscripts with parenthesis indicate the parameter value at the indicated iteration (i.e., iteration g or $g + 1$). Since CMA-ES is a distribution-based algorithm, it differs slightly in its population initialization than the other algorithms. Rather than typical uniform distribution of the population in the search domain, the initial distribution position is chosen randomly, and its size is

$\mathbf{B} \in \mathbb{R}^{N \times N}$	Eigenvectors of the covariance matrix
$\mathbf{D} \in \mathbb{R}^{N \times N}$	Eigenvalues of the covariance matrix
$\boldsymbol{p}_c \in \mathbb{R}^N$	Evolution path
$\boldsymbol{p}_\sigma \in \mathbb{R}^N$	Conjugate evolution path

Table 2 Additional scalars used internally by CMA-ES and their definitions

$w_i = \frac{\log_2(\mu+0.5)-\log_2(i)}{\sum_{j=1}^{\mu}(\log_2(\mu+0.5)-\log_2(j))}$	Selection weights
$\mu_{\text{eff}} = \left(\sum_{i=1}^{\mu} w_i^2\right)^{-1}$	Variance effective selection mass
$c_\sigma = \frac{\mu_{\text{eff}}+2}{N+\mu_{\text{eff}}+5}$	Learning rate for step size control
$c_1 = \frac{2}{(N+1.3)^2+\mu_{\text{eff}}}$	Learning rate for rank-one update of covariance matrix
$c_\mu = \min\left(1 - c_1, \frac{2\mu_{\text{eff}}-4+2/\mu_{\text{eff}}}{(N+2)^2+\mu_{\text{eff}}}\right)$	Learning rate for rank-μ update of covariance matrix
$c_c = \frac{4+\mu_{\text{eff}}/N}{N+4+2\mu_{\text{eff}}/N}$	Learning rate for cumulation for the rank-one update of covariance matrix
$d_\sigma = 1 + c_\sigma + 2 \cdot \max\left(0, \sqrt{\frac{\mu_{\text{eff}}-1}{N+1}} - 1\right)$	Damping for step size control

configured such that the standard deviation of the distribution is (typically) one third of the parameter range for each parameter. Like the other algorithms, if there is some insight on where to search initially, it can be used to alter the initial distribution to improve optimization performance.

After the initial distribution is configured, the population is created by drawing samples according to

$$\boldsymbol{z}_k \sim \mathcal{N}(\mathbf{0}, \mathbf{I}), \tag{4}$$

where 0 is a vector of length N and the identity matrix, $\mathbf{I}$ is of size $N \times N$. This is done since most computer systems will natively generate random values from the standard normal distribution (rather than one that is skewed and with covariances). The samples are then transformed to the desired mean location and distribution shape through

$$\boldsymbol{x}_k^{(g)} = \boldsymbol{m}^{(g)} + \sigma \boldsymbol{y}_k^{(g)}, \tag{5}$$

where

DOI 10.1007/978-981-4560-75-7_15-1

$$\boldsymbol{y}_k^{(g)} = \mathbf{B}\mathbf{D}\boldsymbol{z}_k. \tag{6}$$

Note that $\mathbf{B}$ and $\mathbf{D}$ are generated using principle component analysis (eigen-decomposition), where $\mathbf{C} = \mathbf{B}(\mathbf{D})^2\mathbf{B}^T$. The first round of cost function evaluations are now carried out using $\boldsymbol{x}_k^{(g)}$. Afterwards, the population members are sorted according to cost, indicated by $\boldsymbol{y}_{i:\lambda}^{(g)}$ and $\boldsymbol{x}_{i:\lambda}^{(g)}$, where the lowest cost members are the first entries. Then, a weighted average of the positions of the best performing μ members (typically $\lfloor \lambda/2 \rfloor$) is used to reposition the new distribution mean according to

$$\langle \boldsymbol{y} \rangle_w = \sum_{i=1}^{\mu} w_i \boldsymbol{y}_{i:\lambda}^{(g)} \tag{7}$$

and

$$\boldsymbol{m}^{(g+1)} = \boldsymbol{m}^{(b)} + \sigma^{(g)} \boldsymbol{y}_w. \tag{8}$$

Next, the evolution paths are updated according to

$$\boldsymbol{p}_\sigma^{(g+1)} = (1 - c_\sigma)\, \boldsymbol{p}_\sigma^{(g)} + \sqrt{c_\sigma(2 - c_\sigma)\mu_{\text{eff}}} \left(\mathbf{C}^{(g)}\right)^{-1/2} \frac{\boldsymbol{m}^{(g+1)} - \boldsymbol{m}^{(g)}}{\sigma^{(g)}} \tag{9}$$

and

$$\boldsymbol{p}_c^{(g+1)} = (1 - c_c)\, \boldsymbol{p}_c^{(g)} + \sqrt{c_c(2 - c_c)\mu_{\text{eff}}}\, \frac{\boldsymbol{m}^{(g+1)} - \boldsymbol{m}^{(g)}}{\sigma^{(g)}}, \tag{10}$$

where $\mathbf{C}^{-1/2} = \mathbf{B}\mathbf{D}^{-1}\mathbf{B}^T$ and, since $\mathbf{D}$ is diagonal only, results in a simple matrix inversion. These evolution paths serve to keep track of the movement of the distribution and are used to give the algorithm its self-adaptive properties.

The covariance matrix is then updated, where three separate contributions are employed which are termed the rank-μ update (with portion c_μ), rank-one update (with portion c_1), and the cumulative update (with portion $1 - c_1 - c_\mu$). The cumulative update is simply the amount of the historical portion of the previous covariance matrix to use. The rank-one update is formed using the evolution path, which serves to elongate the covariance matrix in the direction of the movement of the mean, where lower cost regions of the search space are likely to be found. The rank-μ update is formed from a scaled estimation of distribution between the surviving population members and the previous distribution mean. The complete covariance update is given by

$$\mathbf{C}^{(g+1)} = \left(1 - c_1 - c_\mu\right)\mathbf{C}^{(g)} + c_1 \left(\boldsymbol{p}_c^{(g+1)}\right)\left(\boldsymbol{p}_c^{(g+1)}\right)^T + c_\mu \sum_{i=1}^{\mu} w_i \left(\boldsymbol{y}_{i:\lambda}^{(g+1)}\right)\left(\boldsymbol{y}_{i:\lambda}^{(g+1)}\right)^T, \tag{11}$$

where

$$\boldsymbol{y}_{i:\lambda}^{(g+1)} = \frac{\left(\boldsymbol{x}_{i:\lambda}^{(g+1)} - \boldsymbol{m}^{(g)}\right)}{\sigma^{(g)}}. \tag{12}$$

DOI 10.1007/978-981-4560-75-7_15-1

With small populations, cumulation allows the algorithm to operate efficiently by smoothing out the reshaping of the covariance matrix over several iterations, avoiding sporadic movement and reshaping that could be caused by small sample sizes. The final part of the iterative process is the step size update, where the conjugate evolution path is compared with the expected value of a normal distribution, and the size of the distribution is appropriately scaled via

$$\sigma^{(g+1)} = \sigma^{(g)} e^{\frac{c_\sigma}{d_\sigma}\left(\frac{\|\boldsymbol{p}_\sigma^{(g+1)}\|}{\mathrm{E}\|\mathcal{N}(\mathbf{0},\mathbf{I})\|}-1\right)}. \tag{13}$$

This allows the algorithm to increase speed (enlarge the distribution) or slow down (shrink the distribution) as needed throughout the course of the optimization. Large steps seen in the conjugate evolution path lead to an increase in the step size, ideally reducing the number of iterations needed to move to the cost function goal. Small steps lead to a reduction in the step size, allowing for a more focused local search and convergence on an optimum.

To illustrate the operation of CMA-ES, a plot of the movement and reshaping of the distribution, along with population sampling and selection is given in Fig. 10. Here, a relatively large population is used on a two-dimensional rotated hyperellipse test function to more clearly illustrate the behavior of CMA-ES across several iterations. In Fig. 10a, the selection process is illustrated at the first iteration. The μ members that have the lowest cost (those closest to the focal point of the test function contour lines) are filled in and used to generate the new mean location through a weighted average. The empty circles are members that were in the sample but discarded from the selection pool. In Fig. 10b, the movement of the mean is shown by the arrows connecting the centers of the distributions. The use of covariance matrix (rather than a vector of variances) allows the distribution to elongate in different dimensions diagonally, a particularly powerful feature for problems with inseparable relationships between variables in the cost function. That is, problems which cannot be adequately minimized by optimizing each variable independently. The long dashed lines represent the single standard deviation likelihood of selection of the distribution, while the short dashed lines represent the covariance matrix principle axes.

Comments on Usage of CMA-ES

Given that CMA-ES is much more internally complex than any of the other aforementioned algorithms, it must possess some other benefits that make it an attractive choice for engineers and designers. Indeed, the self-adaptive properties make the algorithm easy to use and an efficient choice for most kinds of design problems as no evolutionary parameters other than population size need to be chosen. In general, difficult problems require larger population sizes to obtain satisfactory optimization results; the usual drawback to using larger populations is an increased number of cost function evaluations. In cases where a population size that is much more than sufficient is used on a problem, the optimization can take significantly longer than needed; however, this potential drawback must be balanced with the possibility of using too small a population size and not achieving a good end result. In many cases, the amount of cost function evaluations required to achieve a certain cost function goal does not grow significantly for larger-than-needed population sizes with CMA-ES, especially for difficult problems (Hansen and Ostermeier 2001). That is, there is not a significant time penalty for choosing a population size that is large, as will be shown for several of the example problems in the following sections.

In general, the only evolutionary parameter that must be chosen for CMA-ES is the population size. Hansen recommends a population size of

$$\lambda = 4 + \lfloor 3 \cdot \ln(N) \rfloor. \tag{14}$$

DOI 10.1007/978-981-4560-75-7_15-1

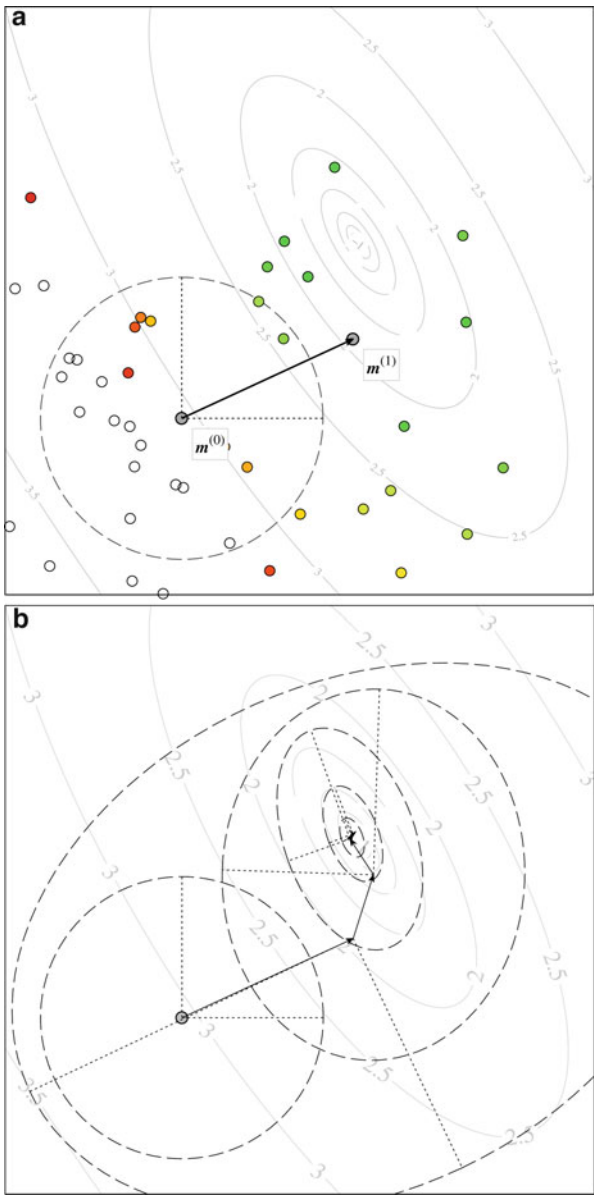

Fig. 10 Illustration of the population sampling and selection process with generation of the new mean (**a**) and movement and reshaping of the search distribution of CMA-ES across several iterations (**b**) using a population size of 50 members on a two-dimensional rotated hyperellipse test function

More difficult problems such as those with noisy, discontinuous, or multimodal cost landscapes may require larger population sizes. As with the other optimization algorithms, if unsatisfactory results are obtained with small population sizes, optimizations can be restarted with larger populations (Auger and Hansen 2005).

Due to the collapsing distribution size as CMA-ES begins to converge on a low-cost region, it is fairly easy to determine when CMA-ES has converged and is no longer producing improved cost values. If the average cost value of the population is very close to the lowest cost value, this is generally a good indicator that the algorithm is sufficiently converged. In some cases, this can be used to automate algorithm termination and minimize wasted CPU time.

Boundary conditions must be handled differently than the other algorithms covered in this chapter. Since the algorithm operates with assumptions made about the sampling distribution, samples that are out

DOI 10.1007/978-981-4560-75-7_15-1

of boundaries cannot simply be snapped to the appropriate bounds with no consequences. In the case of Hansen's CMA-ES publicly available code (Hansen 2014), a method is used that applies an internal fitness penalty to members that leave the feasible range, with progressively increasing penalties if the mean continues to move away from the associated boundary. Sampled values are always truncated to the search domain before being passed to the cost function, however, in order to prevent non-feasible solutions.

Algorithm Performance Comparisons

In this section, the four algorithms that have been covered thus far will be applied to several test functions and antenna design task. Test functions are a fast, commonly used method for determining the relative performance of algorithms on problems of various dimensions. They are particularly convenient since the function minimum values and their associated parameter sets are known a priori for any number of dimensions. Single-objective test functions are often classified into unimodal or multimodal types, with unimodal having only one global and local optimum and multimodal functions having more than one local optima but still typically only one global minimum. They will be used here to gain further understanding of the algorithms and how well they perform on different types of problems.

Test Function Comparisons

Four different test functions will be utilized here as a basis for comparison of the algorithms. One is a unimodal and real valued; two are multimodal, real valued; and one is a binary decision-based test function. The functions, their minimum values, and the set of parameters that yield these values are given in Table 3. For the GA to use the real-valued test functions, the binary chromosomes must be configured to translate to real-valued numbers that span the range of the allowed input parameters ($\boldsymbol{x}$). Because of this, the allowable ranges $x_i \in [x_{\min}, x_{\max}]$ are shifted from their traditional ranges such that the discrete values translated from the GA result in sets that contain $\boldsymbol{x}^{\text{best}}$. For example, a 4-bit chromosome can realize 16 values. For the Ackley test function, this results in $b_i \in \{-28, -24, \ldots, -4, 0, 4, \ldots, 28, 32\}$, a set which contains a zero, allowing the algorithm to reach the desired function value of 10^{-10}. The same is done for the other two real-valued test functions and these same ranges will work for the 8 bits per parameter trials as well. In actual realistic optimization scenarios, the global best ($\boldsymbol{x}^{\text{best}}$) is not known a priori, and the user must choose bit lengths sufficiently large for the problem, but not so large such that it hinders GA performance. The number of bits that define each parameter can be different and are often determined based on knowledge of the problem.

In the case of the real-valued test functions, ten dimensions are used ($N = 10$). For the binary test function, 40 dimensions are used to allow for a beneficial comparison between the GA 4 bits per parameter case. Here, the GA will still use a 40-bit chromosome, but the real-valued algorithms will require 40 parameters. Since the real values are rounded in the function to binary values, this creates a discontinuous cost landscape which can be challenging for the algorithms but nevertheless appears in some realistic optimization problems. For particle swarm optimization, the expected number of iterations must be chosen before each optimization; values are given in Table 4. Values are adjusted and usually decreased as population size increases. If the algorithm is generally unsuccessful on a particular function, then the values are not decreased as drastically or at all. For all of the algorithms, population sizes start at ten members and are increased on a 1-2-5 basis until either a reasonable success rate is achieved, a maximum population size of 500 is reached, or the optimization times become excessive (which can sometimes occur even with smaller population sizes). Trials are typically run until convergence. For differential evolution, two sets of evolutionary parameters are used, indicated by DE1 ($F = 0.8$,

500	–	–	–	750

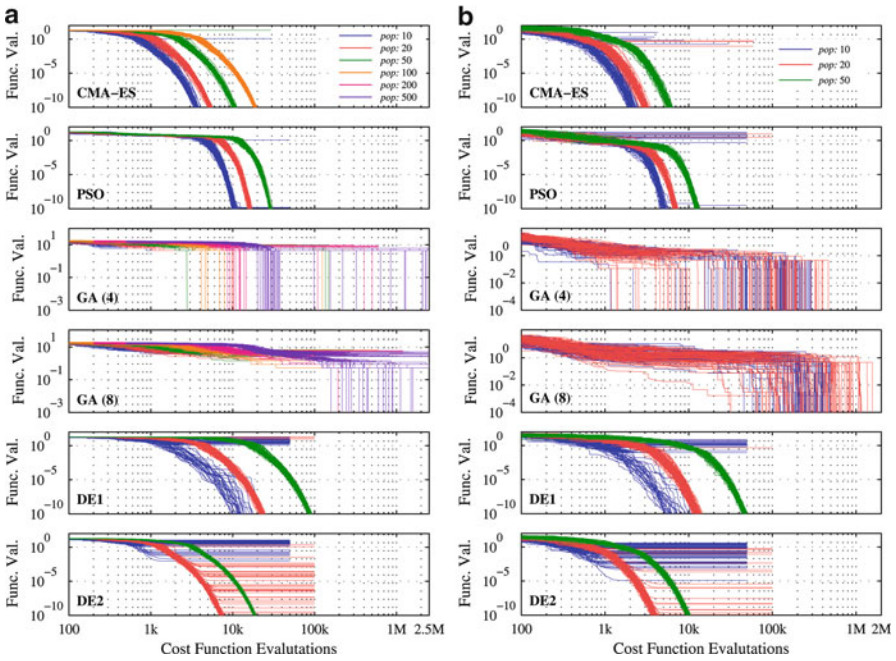

Fig. 11 Optimization results for the Ackley (**a**) and Levy (**b**) test functions. Each line represents the best function value obtained for the optimization seed at the given number of function evaluations

$CR = 0.9$) and DE2 ($F = 0.4$, $CR = 0.5$). The maximum number of iterations for all algorithm and test function combinations is chosen such that the optimizations are well converged before termination, or an excessive number of function evaluations is reached. Lastly, 100 trials are run for each population size, algorithm, and function case in order to obtain some statistical significance to the data.

The results of the optimizations for each of the test functions are given in Figs. 11 through 14. Data is arranged such that the number of function evaluations is maintained on the bottom axes rather than iteration counts to give a better comparison between algorithms and population sizes. Note that the vertical axes for the GA cases are different since the very small function values (i.e., between 0 and 10^{-6}) do not exist due to the parameter discretization (i.e., the closest function value to the minimum is 10^{-3} for the Levy function, realized by the GA chromosome being one bit off). In this case, the ranges are adjusted to show more details of the progress of the optimizations. A summary of the success and average number of function evaluations (NFE) of the algorithms for each of the test functions is given in Table 5. For the Pattern test function, 40 bits were used such that the GA (4) case resulted in the same length chromosome as for the real-valued test functions. Although not comparable to the other results, 80 bits were used for the GA (8) case.

DOI 10.1007/978-981-4560-75-7_15-1

Table 5 Summary of results for the four algorithms applied to test functions. Success rates and mean number of function evaluations required are listed for the seeds that were successful. Asterisks for the Pattern test function indicate that the number of parameters (bits) was 80 instead of 40 for the other cases

For the Ackley test function, CMA-ES, PSO, and DE1 performed fairly well with small population sizes. With slightly larger population sizes, DE2 was also relatively reliable. The GA had difficulty with this test function for both parameter bit lengths, achieving only reasonable success with the 4-bit parameters and a population size of 50, albeit with large NFE requirements. For the Levy function, all of the algorithms were able to competently reach the function goal, especially with population sizes of 20 and 50. The GA did require on average more than an order of magnitude more function evaluations than the real-coded algorithms, however. The Rosenbrock test function presented a particularly difficult problem for the optimization strategies. Optimizations were truncated at 3×10^7 NFE due to the extreme time requirements. For PSO, some additional seeds may have reached the function goal value; however, the NFE requirement for these seeds would not be very practical when compared to the performance of the other algorithms. CMA-ES fared the best here, with reliable optimization achieved at a population size of 50 and with a relatively small NFE requirement. DE1 and GA (4) performed reasonably well with population sizes above 20; however, the 4-bit discretization of the input parameters for the GA may have significantly reduced the difficulty of the test function by eliminating some of the deceptive features of its landscape that the other real-coded algorithms must contend with. For the 8-bit GA case, these features reappear, and the difficulty of the problem is restored, leading to a much more significant challenge. Population sizes larger than 200 were not used due to the already very large NFE requirements of the smaller population sizes. The Pattern test function presented an interesting problem for the real-valued optimization strategies. As expected for the GA cases, the function was relatively easy and required very few function evaluations to achieve success. Reliability was also excellent, even for the 80-bit pattern

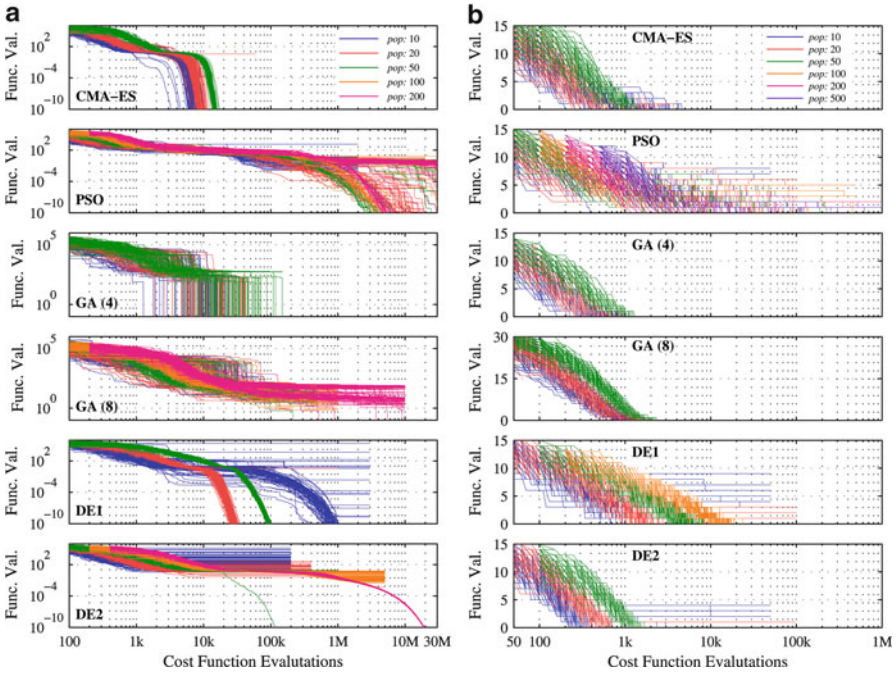

Fig. 12 Optimization results for the Rosenbrock (**a**) and Pattern (**b**) test functions. Each line represents the best function value obtained for the optimization seed at the given number of function evaluations. For the GA (8) case, 80 bits in the pattern function are used instead of 40 bits as with the GA (4) and real-coded algorithms

length used in the GA (8) case. Of the real-valued strategies, CMA-ES and differential evolution were effective at finding the function minimums. CMA-ES and DE2 are surprisingly competitive to the GA for population sizes of 20 and 50, indicating that they fare well for problems where rounding of the input parameters is performed or decisions are required (Fig. 12).

The four test functions that have been used with the algorithms here illustrate some of their strengths and weaknesses that the user must keep in mind when an optimization is to be performed. In addition, it is shown how the algorithms behave with differing population sizes. For example, it is common for many of the algorithms to optimize at a fast pace for small population sizes; however, it can be seen that the drawback is potential unreliability. For realistic design problems, a best guess is usually made as to the difficulty of the problem, and the user must decide on a population size that will likely give good results with a reasonable optimization time.

Antenna Design Task

In this section, the algorithms will be applied to a simple antenna design task to compare their performance on a realistic problem that may be encountered. The antenna is a simple planar slotted patch with eight optimizable parameters. The design is based on the antenna considered in Maci et al. (1995), where a standard patch antenna has two symmetrical rectangular cutouts. A drawing and details for the patch design are given in Fig. 13 with parameter ranges provided in Table 6. To avoid unrealizable designs (e.g., the probe feed in the middle of a slot), some parameters (lengths) are based on fractions of other parameters. The patch antenna is optimized for S_{11} and gain at two target frequencies of 900 MHz and 1.6 GHz, well within the ratio prescribed by Maci et al. (1995) for this type of antenna design. For this design task, population sizes of 15 members will be used for all of the algorithms. The optimizations are truncated at 400 iterations (6,000 cost function evaluations), with 100 iterations expected for the PSO algorithm ($g^{\exp}$). The cost function corresponding to the design is given by

DOI 10.1007/978-981-4560-75-7_15-1

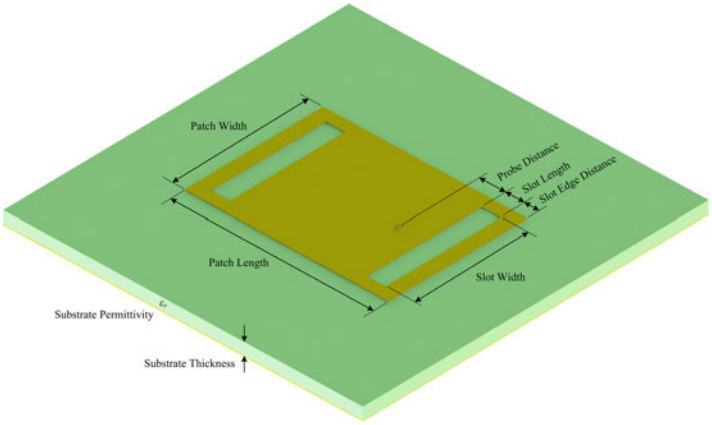

Fig. 13 Slotted patch antenna design with the dimensions and optimizable parameters indicated

Table 6 Optimizable parameters and ranges for the slotted patch antenna design problem

Parameter	Range
Patch length	5–14 cm
Patch width	(0.6–1.1) × patch length
Slot width	(0.6–0.95) × patch width
Slot length	(0.04–0.1) × patch length
Slot edge distance	(0.02–0.1) × patch length
Probe distance	(0.05–0.3) × patch length
Substrate thickness	0.81–3.18 mm
Substrate permittivity	(2.0–4.5) × ε_0

$$F_{\mathrm{COST}}(\boldsymbol{x}) = \sum_{n=1,2} \max\left(0, S_{11}(\boldsymbol{x}, f_n) - S_{11}^{\mathrm{goal}}\right)^2 + \max\left(0, G^{\mathrm{goal}} - G(\boldsymbol{x}, f_n)\right)^2, \tag{15}$$

where scattering coefficients and gain values are expressed in dB and given by $S_{11}^{\mathrm{goal}} = -10\mathrm{dB}$ and $G^{\mathrm{goal}} = 5\mathrm{dBi}$. Squared terms are used here to balance performance across the multiple objectives and frequency points.

The method-of-moments simulation tool FEKO is employed to efficiently evaluate the candidate antenna designs to determine their scattering coefficients and gain. Approximately 20 s are required per cost function evaluation (on eight cores of an Intel Xeon 2.6 GHz processor); however, this can vary based on the geometry of the design (i.e., larger patches require more triangles and longer simulation times). Since this is many orders of magnitude longer than what is required for test functions, it is of considerable interest to be able to find suitable antenna designs in the fewest number of cost function evaluations. Ten seeds are used for each of the four algorithms as a basis for comparison.

The results of the antenna design analysis are shown in Fig. 14 and Table 7. An example of the performance that can be expected from an optimized seed (taken from the pool of CMA-ES results) is shown in Fig. 15. The optimized design clearly meets the specified S_{11} and gain requirements, and the radiation patterns at the two frequencies of interest possess no irregularities, indicating that the optimization is producing designs as intended. Since the cost function contains square terms, the values are

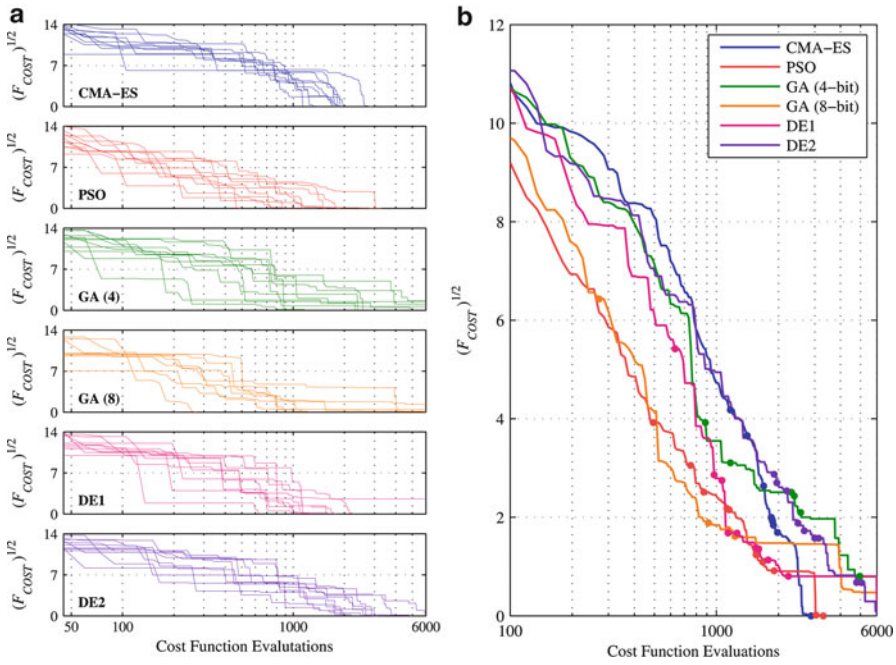

Fig. 14 Results of the slotted patch antenna design comparison. In (**a**), each optimization seed is given by an individual line that signifies the best result of that optimization at the given number of cost function evaluations. In (**b**), each line is the average of the 10 seeds' best cost value achieved at the given iteration. Each circle represents the occurrence of a seed reaching the cost goal ($F_{\mathrm{COST}} = 0$) for the associated algorithm

Table 7 Summary of results for the slotted patch antenna design problem

Algorithm	Successful seeds	Mean NFE of successful seeds	Mean cost value of unsuccessful seed(s)
CMA-ES	10	1,830	–
PSO	10	1,589	–
GA (4)	6	2,380	1.595
GA (8)	5	765	0.447
DE1	9	1,362	6.475
DE2	9	3,022	0.086

plotted as the square root of cost to make them more clearly visible. Circles are placed along the mean cost lines where seeds achieved success. As may be expected since this is a real-valued optimization problem, the real-valued algorithms fared the best. CMA-ES and PSO achieved a 100 % success rate with low NFE requirements. Differential evolution was also fairly competitive at 90 % success rates for both parameter settings. The first parameter setting, however, yielded on average much faster optimization times. The genetic algorithm was somewhat effective on this problem for both cases. Given that six seeds reached the cost function goal, it is clearly evident that the parameters had sufficient resolution with 4 bits per parameter; however, it is interesting to note that the case with 8 bits per parameter fared better. It is possible that the higher-resolution case offered more possible solutions that satisfied the cost requirement and performance goals, allowing the algorithm to more effectively reach the cost goal. Given that the mean cost value of the unsuccessful seeds is much lower than the 4-bit scenario, this may indeed be the

DOI 10.1007/978-981-4560-75-7_15-1

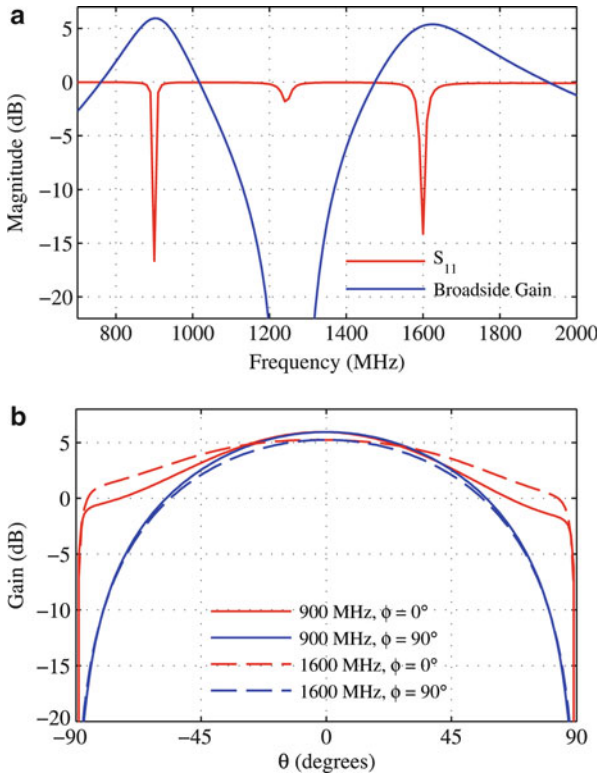

Fig. 15 Scattering coefficient and broadside gain for one of the seeds optimized with CMA-ES

case. In all situations, however, useful designs will likely have been produced for the antenna designer, even if the ideal cost value of 0 has not been achieved. This is indeed a great benefit of these global optimization strategies, where suitable antenna designs can be produced autonomously with minimal user interaction and overhead.

Practical Design Examples

In addition to the test functions and designs that have been shown in the previous section, some detailed examples of where these algorithms have been recently applied in the antenna design community are given here. The first example is a more complex version of the slotted patch antenna discussed in the previous section. The second is a simple monopole antenna with enhanced performance through the addition of a two-layer cylindrical anisotropic high-index metamaterial coating. The last is a low-profile substrate-integrated waveguide antenna with significantly enhanced directivity achieved through the application of an anisotropic low-index metamaterial coating.

Folded, Shorted Meander-Slot Patch Antenna

Miniaturization has been a popular field in antenna design due in large part to the desire for portability in mobile and wireless communications devices (Volakis et al. 2010; Fujimoto and James 2001). Microstrip patch antennas are particularly attractive due to their low profile and ease of fabrication; however, a conventional patch antenna has a length of ~λ/2 making it too large for many wireless applications. As a result, several design methodologies have been developed to reduce the size of the patch antenna. Typically, these techniques utilize some combination of meandered conductors, notches, and shorting (Li et al. 2004; Kan and Waterhouse 1999; Wang and Yang 1998). Generally speaking, the main

DOI 10.1007/978-981-4560-75-7_15-1

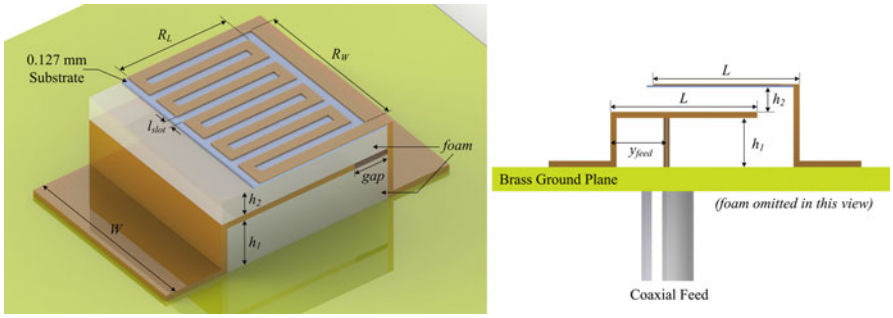

Fig. 16 Parameterized antenna geometry used for optimization: side view (*left*) and *top view* (*right*)

drawbacks of employing these size-reducing techniques are reduced gain, increased cross-polarization, and reduced bandwidth. In addition to size reduction, many wireless systems also require multiband operation. Several techniques to achieve dual- or multiband operation with patch antennas have been reported; two common methods include a stacked patch configuration (Long and Walton 1979) or placing slots on the patch surface (Maci et al. 1995; Lee et al. 1997). Employing a combination of the aforementioned techniques creates the possibility of developing reduced size multiband patch antennas (Chen et al. 2003; Ollikainen et al. 1999; Guo et al. 2000; Brocker et al. 2014), which will be explored here.

In Maci et al. (1995), the authors demonstrated that dual-frequency operation with a frequency ratio of less than 2 could be achieved by placing thin slots near the radiating edges of a conventional patch antenna. As outlined in Guo et al. (2000), the two operational modes of the slotted patch antenna are TM_{10} and TM_{30}, which have minimum potential at the center plane of the patch. Hence, a short can be implemented in this plane at the cost of maximum broadside gain. As a result, the length of the slotted patch can be reduced by a factor of about 2. In addition to reduced gain, it is noted that the shorted slotted patch (SSP) antenna will exhibit increased cross-polarization, specifically in the H-plane. In Maci et al. (1995), the authors showed that the dual-band frequency ratio is a characteristic of the slot lengths. Therefore, even after the short is applied (subsequently reducing the patch length), the width of the patch and slot is fixed by the targeted frequencies, presenting a challenge for further patch size reduction. To overcome this limitation, the straight slot can be replaced with a meandered slot, creating a longer path for slot perimeter currents while at the same time allowing for a reduced patch width. The footprint of the antenna element is further reduced by employing the techniques presented in Li et al. (2004), where the authors demonstrated that the shorted-patch antenna can be folded while still maintaining suitable radiation and input properties. The proposed design here is folded once, reducing the footprint of the antenna by half, with the resulting geometry shown in Fig. 16. To demonstrate the effectiveness of the design procedure, the Wi-Fi bands of 2.4 and 5.0 GHz were targeted for optimization and fabrication.

The composition and construction of the antenna element shown in Fig. 16 were based on ease of fabrication. For example, the metal patch sections are fairly easy to bend and form without substrates. As a result, foam was inserted between patch layers for structural support. The meander pattern was created by chemically etching a 0.127-mm-thick Rodgers RT/duroid® 5880 copper-plated substrate. A 1.57-mm-thick brass square ground plane was used that was 0.3 λ at 2.4 GHz (~3.75 cm) on an edge. The lower patch layer of the antenna element was fed by a 12.7-cm-long semirigid RG402 coaxial cable. This relatively long feed was not considered during optimization since it would dramatically increase the size of the simulation domain and associated simulation time. Instead, the coax waveguide considered during optimization was only 3 mm long. When coupled with the small ground plane, different lengths of coaxial feed line did not significantly affect the input impedance of the antenna element; however, radiation patterns were affected. Therefore, the longer coax was integrated into the simulation after the

DOI 10.1007/978-981-4560-75-7_15-1

optimization, allowing for better agreement between simulated and measured radiation patterns. If a larger ground plane were utilized, however, the effect of the coax length on the radiation characteristics would be reduced.

The antenna element was optimized using CMA-ES for better than (or equal to) −12-dB reflection coefficient and better than (or equal to) 6 dBi of broadside gain at each frequency, requiring a relatively simple cost function given by

$$F_{\mathrm{SSPA}} = \sum_{i=1}^{n} \left(12 + \max\left\{S_{11}^{\mathrm{dB}}(f_i),\ -12\right\}\right)^2 + \sum_{i=1}^{n} \left(6 - \min\left\{\mathrm{Gain}^{\mathrm{dB}}(f_i), 6\right\}\right)^2. \tag{16}$$

In this case, the $n = 2$ frequencies are 2.4 and 5.0 GHz. The squaring operations help to evolve designs with balanced performance for all goals and frequencies. Throughout the optimization procedure, the cost value of each candidate design was evaluated using Ansoft HFSS.

The optimization configuration and parameters are listed in Table 8. A crucial step in any optimization is the initial parameterization; that is, specifying the optimization variables and their respective ranges. In general, a large enough search space (i.e., parameter ranges) should be specified such that a design with a suitable cost value can be generated; however, if the search space is too vast, the optimization algorithm can be overwhelmed and may fail due to pre-convergence on a local minimum that does not meet the cost goal. In addition, for designs which must be physically realized, geometries and components (i.e., capacitor values) must be specified such that only feasible solutions are generated in the cost function. Alternatively, optimized designs can have their geometric or component values rounded to the nearest feasible solution after the optimization, and then fine tuning can be applied if the performance is significantly degraded.

Antenna geometric parameters and ranges are determined here such that resulting designs can be feasibly constructed with the available fabrication technologies. For example, if the patch width is limited to 0.1 λ at 2.4 GHz (12.5 mm) and the meander is composed of five back-and-forth segments with traces approximately as wide as their spacing, the feature sizes would be approximately 0.6 mm, a reasonable value for a photolithography fabrication setup. Hence, l_{slot} was permitted to vary from 0.4 to 0.6 mm with the described configuration. Next, the substrate thicknesses h_1 and h_2 were restricted to discrete multiples of the available foam sheet thicknesses. Specifically, the thicknesses were only permitted to take one of two values, indicated by the *minimum* and *maximum* in Table 8. Because CMA-ES uses continuous variables, binary selection was achieved through rounding as in the previous section using the Pattern test function. The ranges for variable R_w were chosen based on findings from Maci et al. (1995) where it was shown that the slot must stretch the width of the path in order to achieve a radiation maximum at

Table 8 Optimized antenna geometry parameters

Parameter	Minimum value	Maximum value	Optimized value	Fabricated value
L	8.00 mm	9.50 mm	9.50 mm	9.50 mm
W	11.50 mm	12.50 mm	12.48 mm	**12.70** mm
gap	2.50 mm	3.00 mm	2.73 mm	**2.31** mm
R_L	0.70*L	0.80*L	0.80*L	0.80*L
R_W	0.80*W	0.90*W	0.87*W	0.87*W
h_1 (discrete)	1.59 mm	3.18 mm	3.18 mm	**3.22** mm
h_2 (discrete)	1.59 mm	3.18 mm	1.59 mm	**1.65** mm
l_{slot}	0.40 mm	0.60 mm	0.60 mm	0.60 mm
y_{feed}	0.20*L	0.80*L	0.34*L	0.34*L

DOI 10.1007/978-981-4560-75-7_15-1

broadside. Note that R_w, as well as R_L, was specified in terms of fractions of W and L, respectively. The *gap* parameter should be small in order to keep the overall antenna size to a minimum, however, during fabrication *gap* is set when the support tabs shown in Fig. 16 are soldered to the ground plane. Since this is expected to be a large source of fabrication error, *gap* was configured to be at least 2–3 mm to avoid any detrimental effects due to manufacturing imperfections.

CMA-ES was utilized to carry out the antenna optimization of the nine variables listed in Table 8. A population size of 16 was used and converged to the optimized values by the 24th iteration. The optimized antenna element achieved a cost function value of $F_{\mathrm{SSPA}} = 9.58$. In terms of antenna performance, this cost equated to better than −12 dB reflection coefficients at both frequencies and 2.9 and 5.9 dBi broadside gain at 2.4 and 5.0 GHz, respectively. Once the 12.7-cm-long coax feed was included in the optimized antenna design, the calculated broadside gains changed to 3.4 and 5.5 dBi at 2.4 and 5.0 GHz, respectively. The antenna impedance was not significantly affected by including the longer coax feed model.

The design was fabricated and measured in order to validate the simulated results of the optimized design. The fabricated prototype is shown in the inset of Fig. 17, where a comparison of the simulated and measured reflection coefficients is given. Although the fabricated design agreed well with the simulated results of the optimized design, further improvement in agreement was achieved by measuring the dimensions of the fabricated antenna element and modifying the simulation model accordingly. The parameters that required adjustment in the simulation are given in bold in the last column of Table 8. Figure 18 compares the radiation pattern of the simulation model and the fabricated antenna element, where excellent agreement was again found.

It has been shown here that optimization strategies such as CMA-ES are a powerful tool for antenna design. It was used in this case to optimize the parameters of a folded, shorted-patch antenna with a meander slot in order to achieve significant size reduction and multiband operation. An antenna with this amount of complexity generally does not lend itself to closed-form solutions such as with standard patch or folded-patch structures, hence a simulation tool was required that allowed the antenna parameters to be accurately determined. Because the design had a significant number of geometric parameters that needed to be optimized, a parametric optimization or simple hand tuning would be impractical; however, CMA-ES proved to be a capable strategy for finding a suitable set of parameters that met the performance criteria. The proposed antenna design methodology and optimization yielded a miniaturized dual-band patch antenna with dimensions all smaller than 0.1 λ (at 2.4 GHz). The resulting design achieved −10-dB

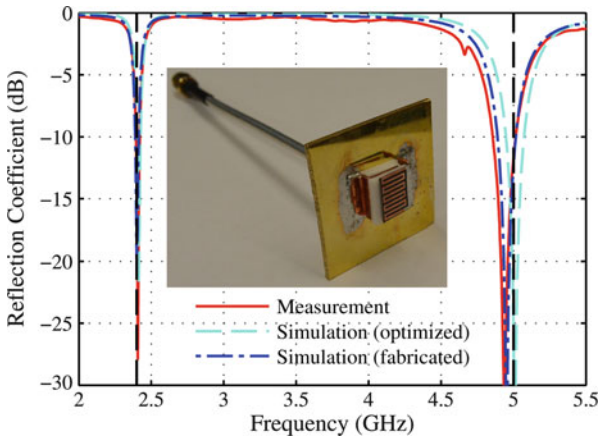

Fig. 17 Simulated and measured reflection coefficient of optimized antenna element using a $0.3\lambda_{2.4\mathrm{GHz}}$ (≈3.75 cm) square ground plane along with the fabricated structure (*inset*). Vertical *dashed lines* indicate the targeted frequencies of the optimization

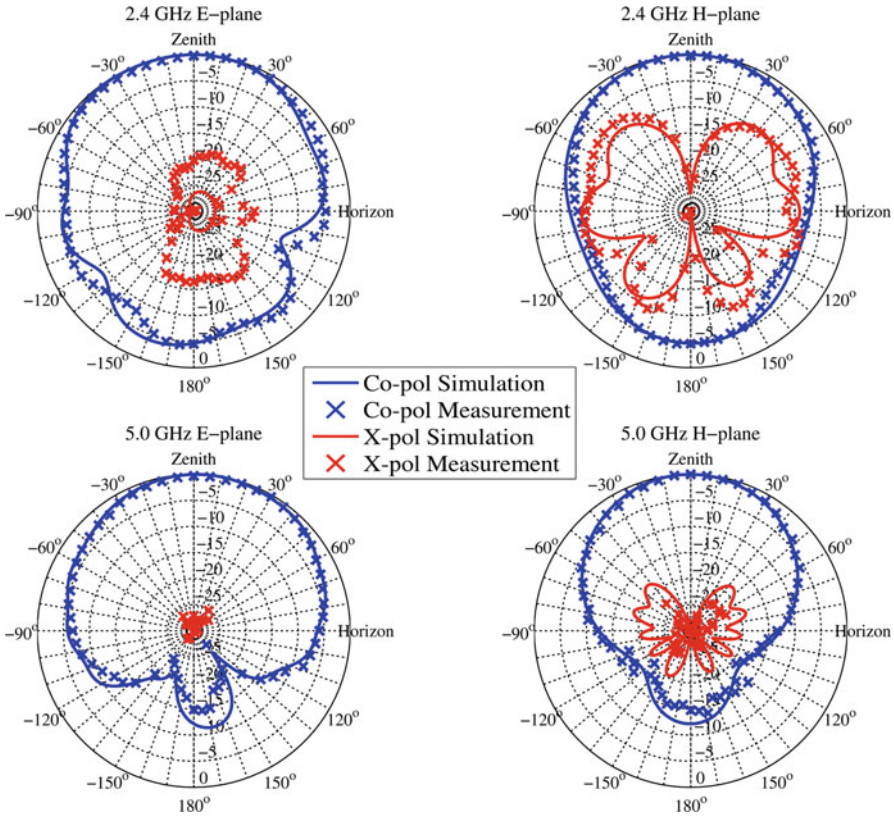

Fig. 18 Radiation pattern of optimized antenna element using a 0.3 λ (~3.75 cm) square ground plane. *Solid lines* represent simulated radiation patterns and ×'s represent measured radiation patterns. Broadside gains were simulated and calculated to be 3.4 dBi and 5.5 dBi at 2.4 GHz and 5.0 GHz, respectively

impedance matching bandwidths of 1.0 % and 2.5 % at 2.4 and 5.0 GHz, respectively. The broadside gains of the optimized antenna element were 3.4 and 5.5 dBi at 2.4 and 5.0 GHz, respectively. Furthermore, the small antenna size was leveraged to include a ground plane size of only 0.3 λ (at 2.4 GHz), an exceedingly small figure compared to typical antenna ground plane requirements.

Broadband Monopole Antenna Enabled by a Metamaterial Coating

Broadband antennas have been widely used in various wireless communication systems for high data transfer rates and in radar systems for achieving shorter pulse durations. Several techniques have been proposed since the early 1970s to broaden the impedance bandwidth of wire and planar antennas while maintaining their vertical polarization. Conventional approaches include placing conducting sleeves around the main radiator to provide a second resonance at a higher frequency (Volakis 2007; King and Wong 1972) or inserting lumped series resistor-inductor circuits into an electrically long wire monopole (Volakis 2007; Lo and Lee 1988). The planar version of the sleeve monopole has been realized by using planar sleeves on both sides of an end-loaded microstrip monopole on the same printed circuit substrate (Spence and Werner 2006). In addition to using conducting sleeves to produce a second resonance, bulk dielectric resonators of various shapes have also been utilized to enhance the impedance bandwidth of wire antennas (Chang and Kiang 2007; Guha et al. 2009). Other techniques involving reshaping the periphery of the planar monopole to achieve functionality similar to a traveling wave antenna have also been reported (Liang et al. 2005; Chen et al. 2007). The gradually tapered slot between the edge of the planar monopole and the ground plane enables impedance matching over a broad bandwidth. More recently, artificial electromagnetic metamaterials have been shown to extend the bandwidth of planar

DOI 10.1007/978-981-4560-75-7_15-1

monopoles and microstrip antennas by properly loading split ring resonators or negative refractive index transmission lines (Palandoken et al. 2009; Antoniades and Eleftheriades 2009).

Presented in this section are the design optimization and experimental validation of an octave bandwidth quarter-wave wire-type monopole antenna surrounded by an ultrathin flexible anisotropic metamaterial coating. In contrast to previously reported broadband vertical polarized planar monopoles which typically develop multiple lobes in their radiation patterns as frequency increases (Liang et al. 2005; Chen et al. 2007), the new octave bandwidth metamaterial-enabled monopole has stable vertically polarized radiation patterns over the entire frequency band of operation. Moreover, compared to broadband open-sleeve dipoles and monopoles (King and Wong 1972) as well as broadband dielectric resonator antennas fed by monopoles (Chang and Kiang 2007; Guha et al. 2009), the proposed metamaterial-coated monopole antenna is more compact and extremely lightweight, suggesting possible applications ranging from broadband arrays to portable wireless devices.

Unit Cell Design

The unit cell of the metamaterial coating is comprised of two identical I-shaped copper patterns printed on both sides of a Rogers ULTRALAM® 3850 substrate (see Fig. 19a). The thicknesses of the substrate (d_s) and the copper (d_c) are 51 and 17 μm, respectively. Using this thin flexible substrate, the nominally planar metamaterial structure can be easily formed into a cylindrical configuration. The effective medium

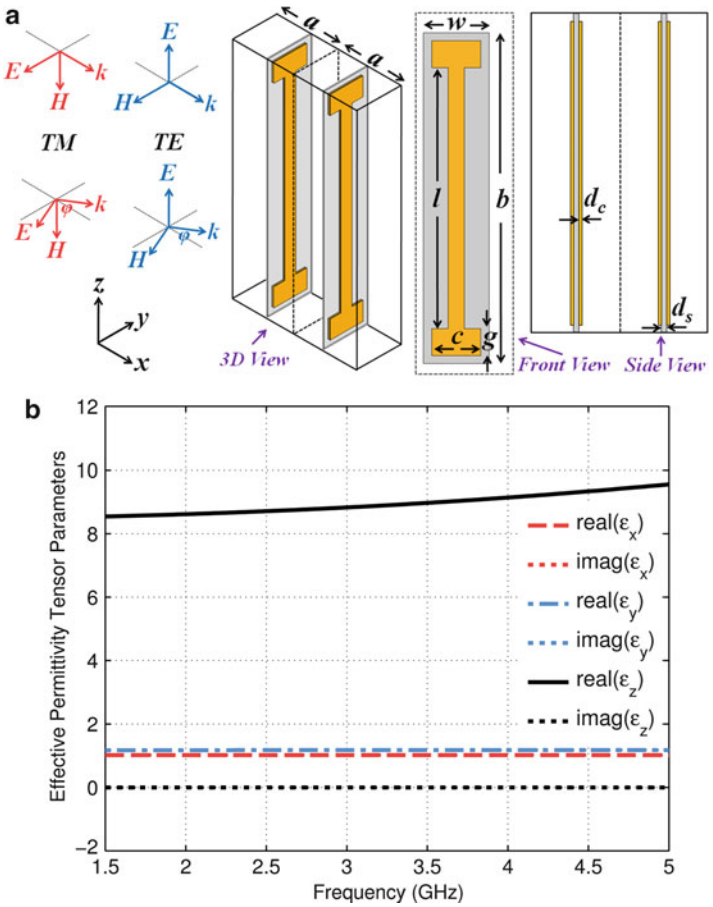

Fig. 19 (**a**) Geometry and dimensions of the unit cells of the anisotropic metamaterial coating. All dimensions are in millimeters: $a = 2.5$, $d_s = 0.051$, $d_c = 0.017$, $w = 2$, $b = 10$, $c = 1.5$, $g = 0.8$, and $l = 8$. (**b**) Real and imaginary parts of the retrieved effective anisotropic permittivity tensor parameters (ε_x, ε_y, ε_z)

DOI 10.1007/978-981-4560-75-7_15-1

properties of the metamaterial are obtained according to the diagram shown in Fig. 19a, where periodic boundary conditions are assigned to the walls in the *y*- and *z*-directions. A TE/TM polarized plane wave, with the *E*-field/*H*-field oriented along the *z*-direction, is incident from the left half-space at an angle of φ ($0^\circ \leq \varphi \leq 90^\circ$) with respect to the *x*-axis. An anisotropic inversion technique (Jiang et al. 2011a) was employed to extract all six effective permittivity and permeability tensor quantities from the scattering parameters calculated at different angles of incidence using HFSS™.

The retrieved effective permittivity tensor parameters are shown in Fig. 19b. It can be seen that none of the parameters exhibit a resonant response in the band of interest as a result of the subwavelength I-shaped elements, which corroborates previously reported results on I-shaped unit cells utilized for broadband microwave metamaterial devices (Liu et al. 2009; Jiang et al. 2011b). The retrieved ε_x and ε_y parameters have nondispersive values near unity, whereas ε_z exhibits a large value that can be attributed to the inductance provided by the central microstrip in the I-shaped elements and capacitance associated with the gaps between the stubs of adjacent unit cells in the *z*-direction. Controlling the series inductance and capacitance enables manipulation of the value of ε_z across the band, which will be optimized during the design process. The three effective permeability tensor parameters (not shown here) have nondispersive values equal to unity with very low loss, indicating that the metamaterial does not have any effect on the radiated magnetic field.

Optimization of the Monopole Antenna Coated with Metamaterial

The configuration of the monopole antenna with and without the metamaterial coating is shown in Fig. 20. The monopole is 28.5 mm long and resonates at 2.5 GHz. The cylindrical metamaterial coating is composed of two concentric layers of printed metamaterial cells as illustrated in Fig. 20b. The inner and outer layers contain 8 and 16 unit cells along their circumference, respectively, in order to approximate a circular outer periphery to minimize its impact on the monopole's omnidirectional radiation patterns in the *H*-plane. A genetic algorithm (GA) (Haupt and Werner 2007) was employed during the design process to optimize the dimensions of the I-shaped metamaterial unit cell and the periodicities of the metamaterial in both the *z*- and φ-directions, which determine the height and radius of the coating, respectively. In this case, the GA that is included with the MATLAB optimization toolbox was employed with 8 bits per parameter. Single-point crossover was used with a random mutation probability of 0.02 applied only at even generations. The optimization used a cost function given by

$$F_{\text{MONOPOLE}} = \sum_{i=1}^{n} \max\{VSWR(f_i) - 2, 0\} + \sum_{i=1}^{n} \max\{0.95 - \text{Efficiency}(f_i), 0\}, \tag{17}$$

with $n = 12$ frequency points evenly distributed from 2.2 to 4.4 GHz (0.2 GHz increments). The six parameters to be optimized are the monopole length (h_a), the radius of the inner functional layer (d_i), the height of each unit cell (b), the length of the central bar of the I-shaped cell (l), the length of the end bars of the I-shaped cell (c), and the width of the end bars of the I-shaped cell (g). A population size of 32 was used, with the GA requiring 30 generations before obtaining the desired cost goal of 0.01, yielding an approximate performance of VSWR $\leq$ 2 over the specified frequency range. The resulting metamaterial coating shown in Fig. 20 has an outer radius of 5 mm (about $\lambda/24$ at 2.5 GHz), ensuring a compact footprint in the radial direction. The resulting optimized monopole performance is given in Fig. 21, along with the VSWR of the uncoated monopole and that of a monopole coated with a perfect homogenous anisotropic material with identical material tensors.

The monopole alone yields a VSWR $\leq$ 2 bandwidth of 0.4 GHz (2.3~2.7 GHz) with a single resonance at 2.5 GHz, whereas with the GA-optimized metamaterial coating present, the VSWR $\leq$ 2 bandwidth is remarkably broadened to 2.3 GHz (2.1~4.4 GHz). The main resonance shifts down slightly to 2.35 GHz,

and a new resonance is enabled at 3.85 GHz. To further examine the efficacy of the anisotropic effective medium model, a homogeneous anisotropic effective medium coating was also simulated, showing a VSWR with a behavior similar to that of the actual optimized metamaterial coating. The VSWR ≤ 2 bandwidth is 2.2 GHz (2.1~4.3 GHz) with the first and the second resonance located at 2.32 and 3.65 GHz, respectively, indicating that the assumed homogeneous anisotropic effective medium model is a valid approximation for the actual curved metamaterial. This is primarily because a sufficient number

of small unit cells are used to form the cylindrical coating such that the metamaterial still possesses a reasonably good local flatness.

Experimental Verification

The metamaterial coating was fabricated and assembled with the monopole as shown in Fig. 22a. VSWR measurements were carried out using an Agilent E8364B network analyzer. Figure 22b compares the simulated and measured VSWRs of the monopole with and without the metamaterial coating on a 32×32 cm ground plane. The measured VSWR of the monopole alone is almost identical to the simulated results with VSWR ≤ 2 from 2.3 to 2.7 GHz. With the metamaterial present, a 2.14:1 ratio bandwidth (2.15~4.6 GHz) of VSWR ≤ 2 is obtained. Frequency shifts of 0.05 and 0.2 GHz were found in the lower and higher ends of the band, respectively, the likely result of a slight tilt between the monopole and the coating, as well as fabrication imperfections.

DOI 10.1007/978-981-4560-75-7_15-1

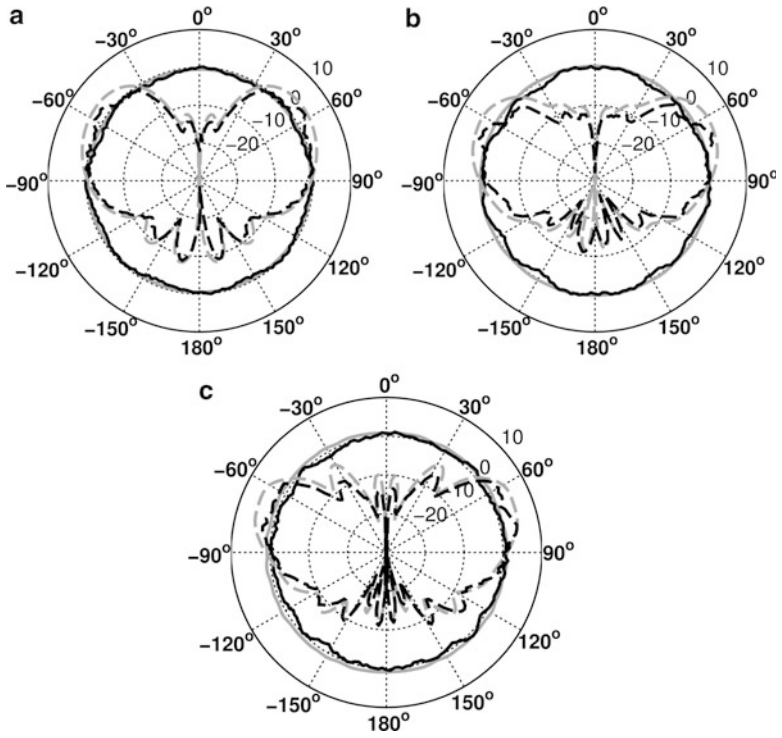

Fig. 23 Simulated and measured *H*-plane (*x*-*y* plane) and *E*-plane (*y*-*z* plane) radiation patterns of the metamaterial-coated monopole at (**a**) 2.2 GHz, (**b**) 3.3 GHz, and (**c**) 4.4 GHz. *Gray lines*: simulated *H*-plane patterns. *Black lines*: measured *H*-plane patterns. *Dashed gray lines*: simulated *E*-plane patterns. *Dashed black lines*: measured *E*-plane patterns

The radiation patterns of the metamaterial-coated monopole were also measured in an anechoic chamber. Figure 23 presents the simulated and measured *E*-plane and *H*-plane patterns at 2.2, 3.3, and 4.4 GHz. The *H*-plane patterns exhibit stable omnidirectional radiation characteristics throughout the entire band. The gain variations are around 0.5 and 1.2 dB for simulation and measurement, respectively. The increased measured gain variation as a function of the azimuthal angle is primarily caused by the imperfection of assembly and noise as well as the antenna rotation platform. In the *E*-plane, characteristic rabbit-ear-shaped patterns can be observed which are very similar to the patterns for the monopole without the metamaterial coating, indicating that the added coating has negligible impact on the spatial distribution of the radiated energy of the monopole. The maximum gain of the metamaterial-coated monopole varies from 3.75 to 5.46 dBi in the VSWR ≤ 2 band with the direction of maximum gain moving from 32° to 26° off horizon due to the finite-sized ground plane used in both simulation and measurement. The measured gain is 0.3–0.8 dB smaller than the simulated values. The overall very good agreement between simulation and measurement confirms the expected performance of the proposed metamaterial antenna coating.

Comparison to Sleeve Monopole Antenna

In order to prove the utility of the anisotropic metamaterial coating and demonstrate that the additional complexity is worthwhile, simulations for monopole antennas surrounded with simple parasitic conducting sleeves are carried out as shown in Fig. 24a. When the parasitic conducting sleeves are employed, a monopole-like resonance mode can be excited on the sleeves, thereby extending the impedance bandwidth of the original antenna. As a fair comparison, the footprint of the sleeve monopole is fixed to be the same as that of the optimized metamaterial-coated monopole, and the design is optimized for the largest possible bandwidth. It can be seen from Fig. 24b that the sleeve monopole achieves a

DOI 10.1007/978-981-4560-75-7_15-1

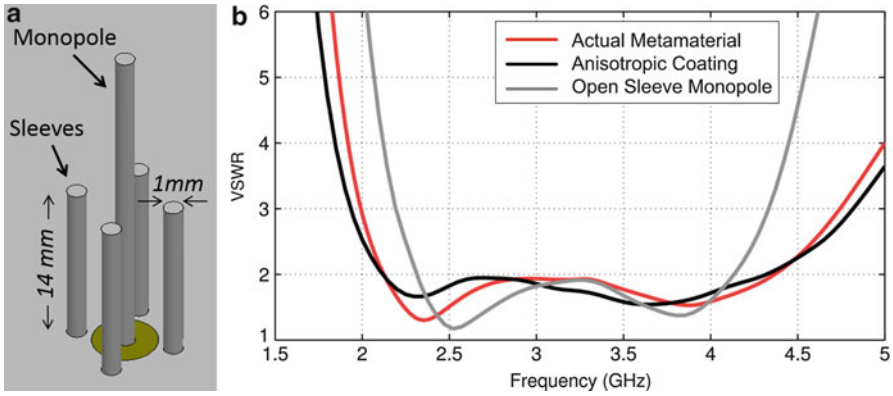

Fig. 24 (**a**) Configuration of sleeve monopole with the same horizontal footprint. (**b**) Simulated VSWR of the sleeve monopole, monopole with actual metamaterial coating, and monopole with homogeneous anisotropic effective medium coating

VSWR ≤ 2 bandwidth from 2.3 to 4.15 GHz, which is about 21 % narrower than that of the metamaterial-coated monopole.

Low-Profile SIW-Fed Slot Antenna with High-Gain Enabled by a Metamaterial Coating

It is of particular interest to capably generate unidirectional radiation with high-gain at broadside in a single compact antenna for applications such as point-to-point communications, wireless power transfer, radar systems, and various other wireless systems (Balanis 2008; Chen and Luk 2009). Conventional approaches have utilized methods such as high-Q Fabry-Pérot (FP) cavities (Guérin et al. 2006; Volakis 2007) to obtain narrowband high directivity with a profile of a half of the operating wavelength. Recent advanced FP cavity designs employing metamaterial surfaces allow the total device thickness to be reduced to around $\lambda/9$ (Feresidis et al. 2005; Sun et al. 2012). However, most of these FP cavity antennas exhibit an enhanced directivity and matched input impedance over very narrow bandwidths, which considerably limits their utility. Apart from the FP cavity-related techniques, another metamaterial approach for increasing directivity has recently been theoretically proposed and experimentally demonstrated by embedding the electromagnetic source within a volumetric isotropic and anisotropic zero-index material/low-index material (ZIM/LIM) lens (Enoch et al. 2002; Ziolkowski 2004; Turpin et al. 2010; Jiang et al. 2012a; Cheng and Cui 2011). However, these ZIM or anisotropic ZIM (AZIM) lenses are usually electrically large in all three dimensions, unavoidably resulting in increased net size and weight of the device.

Recently, it has been proposed that thin single- and bilayer-grounded metamaterial slabs with either isotropic negative or zero index of refraction can give rise to novel electromagnetic properties such as surface wave guidance (Baccarelli et al. 2005a) and suppression (Baccarelli et al. 2003) as well as frequency-dependent directive radiation (Lovat et al. 2006; Baccarelli et al. 2005b; Alu et al. 2007; Shahvarpour et al. 2011). The structures considered thus far are generally infinite or finite but electrically long and support leaky waves with phase velocities slightly higher than that in free space. As a result, the direction of peak radiation drifts away from broadside and varies as a function of frequency, rendering them unsuitable for maintaining broadband high-gain unidirectional radiation at broadside (Liu et al. 2002; Caloz and Itoh 2005; Lovat et al. 2006; Baccarelli et al. 2005a; Alu et al. 2007; Shahvarpour et al. 2011). In this section, a low-profile, high-gain, and compact-footprint antenna that is

DOI 10.1007/978-981-4560-75-7_15-1

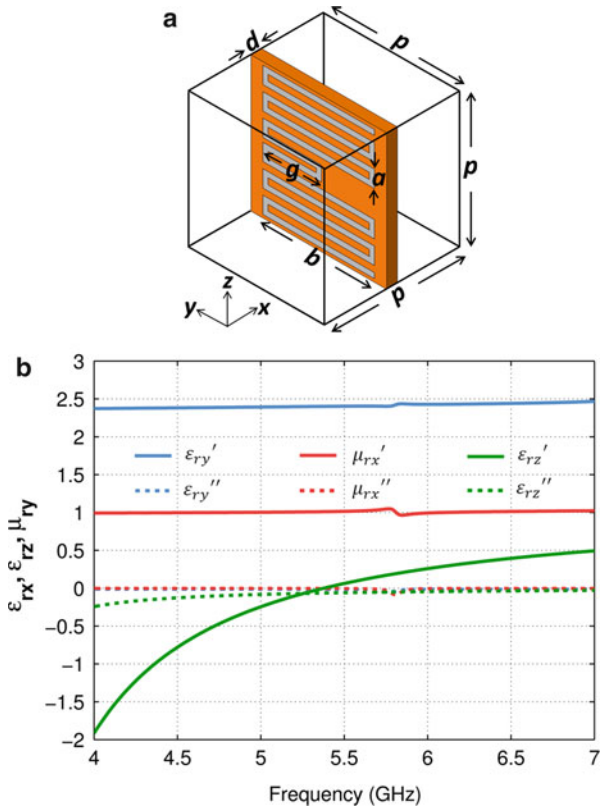

Fig. 25 (**a**) Geometry of the end-loaded dipole unit cell for constructing an anisotropic ZIM. The dimensions are $p = 6.5$ *mm*, $b = 5.35$ mm, $a = 0.7$ mm, $d = 0.508$ mm, and $g = 2.8$ mm. The substrate material is Rogers RT/duroid 5880 with a dielectric constant of 2.2 and a loss tangent of 0.009. (**b**) The retrieved effective medium parameters μ_{rx}, ε_{ry}, and ε_{rz}

composed of a subwavelength thick AZIM coating and a substrate-integrated waveguide (SIW) (Deslandes and Wu 2003) fed slot antenna is proposed and experimentally realized.

Metamaterial Unit Cell Design

To realize materials with anisotropic zero-/low-index properties, periodic end-loaded dipole resonators (ELDRs) are employed (Jiang et al. 2012b). The self-inductance of the wire and the capacitance provided by the gaps between the meandered end-loaded arm traces give rise to an electric resonance. The unit cell geometry and dimensions are shown in Fig. 25a. To retrieve the effective medium parameters (ε_{ry}, ε_{rz}, and μ_{rx}), an infinite doubly periodic array of ELDRs was simulated in HFSS, with periodic boundary conditions and Floquet ports properly assigned to the boundaries of the simulation domain. Scattering results are then used with an anisotropic parameter inversion algorithm (Jiang et al. 2011a). The retrieved ε_{ry}, ε_{rz}, and μ_{rx} are shown in Fig. 25b, with ε_{ry} and μ_{rx} being virtually nondispersive with values around 2.4 and 1, respectively. ε_{rz} exhibits a Lorentz-shaped electric resonance with an effective plasma frequency of 5.38 GHz. Furthermore, because the resonance tail is weakly dispersive, the value of ε_{rz} remains positive and below 0.15 within the broad frequency range of 5.4–6.1 GHz. In this frequency band, the practical dispersive metamaterial has β_y^{TM} that varies from a near-zero value to 0.35. This geometry yields a broader low-index bandwidth compared to that of the commonly used subwavelength electric LC resonator (Schurig et al. 2006) due to the lower quality factor provided by the large capacitance inherent in the meandered arms.

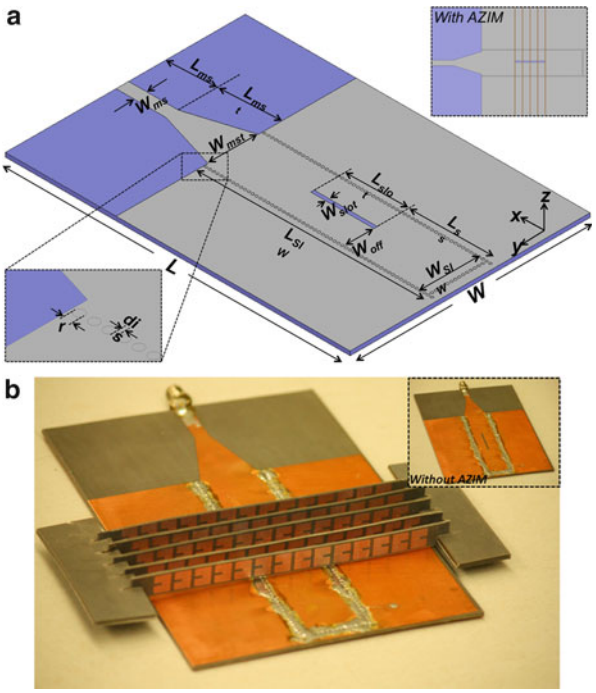

Fig. 26 (**a**) Schematic view of the SIW-fed slot antenna. The dimensions are $L = 133$, $W = 92.5$ mm, $W_{ms} = 4.83$ mm, $L_{ms} = 19$ mm, $W_{mst} = 19.3$ mm, $L_{mst} = 23.5$ mm, $r = 1$ mm, $dis = 0.5$ mm, $L_{SIW} = 86.75$ mm, $W_{SIW} = 22.5$ mm, $W_{\text{slot}} = 1.33$ mm, $L_{\text{slot}} = 24.4$ mm, $L_{ss} = 32.55$ mm, and $W_{\text{off}} = 11.24$ mm. The substrate material is Rogers RT/duroid 5880 with a dielectric constant of 2.2 and a loss tangent of 0.009. The substrate thickness is 1.575 mm. The *inset* in the *top right* corner shows the SIW-fed slot antenna symmetrically covered by the AZIM coating with five rows in the *y*-direction each containing 14 unit cells. (**b**) Photograph of the fabricated SIW-fed slot antenna covered by the AZIM coating. The inset shows the SIW-fed slot antenna alone

Slot Antenna Integrated with AZIM Coating

A half-wave slot fed by an SIW is adopted here due to its low profile compared to cavity backed or conventional waveguide fed slots. The SIW is another emerging technology that has been widely applied in microwave and millimeter wave components (Hao et al. 2005; Liu et al. 2007) and antennas (Zhang et al. 2011; Wu et al. 2012) due to its planar topology which can be readily connected to other planar guided-wave transmission lines. A schematic view of the SIW-fed slot antenna is shown in Fig. 26a. It is comprised of a 50 Ω microstrip and a shorted SIW with a longitudinal slot cut on its broad wall. The SIW is equivalent to a conventional rectangular waveguide filled with dielectric that only supports TE_{n0} modes due to its subwavelength height. A tapered microstrip is used for impedance matching between the 50 Ω feed line and the SIW. In order to achieve a magnetic dipole mode in the slot for efficient radiation, the length of the slot is chosen to be about $\lambda/2$ at 5.8 GHz. The distance between the center of the slot and the shorted wall of the SIW in the *x*-direction is set to be about $3\lambda/4$ at 5.8 GHz, which allows the standing wave peak to be located at the center of the slot. The slot also has a slight offset from the central axis of the SIW in the *y*-direction, following design considerations for the slot antenna fed by a conventional rectangular waveguide. The AZIM coating is then placed directly on top of the SIW-fed slot antenna. The single-layer metamaterial coating consists of five strips in the *x*-direction, each having 14 unit cells in the *y*-direction. The 14 cells are oriented symmetrically in the *y*-direction to maintain a mirror symmetry, which helps to reduce beam squinting of the AZIM-coated slot.

The geometrical properties of the AZIM-coated SIW antenna were optimized using CMA-ES (Gregory et al. 2011) for suitable impedance matching and radiation properties. The ten parameters to be optimized are the SIW length (L_{SIW}) and width (W_{SIW}), the slot length (L_{slot}), the width of the slot (W_{slot}), the

DOI 10.1007/978-981-4560-75-7_15-1

distance between the slot and the sidewall of the SIW (W_{offset}), the distance between the slot and the end of the SIW (L_{ss}), the width (W_{mst}) and length (L_{mst}) of the tapered microstrip, the length of the ELDRs (b), and the length of the central line of the ELDRs (g). The cost function includes contributions from the input and radiation properties via

$$F_{\text{SIW-AZIM}} = \sum_{i=1}^{n} \max\left\{S_{11}^{dB}(f_i) + 10, 0\right\} + \sum_{i=1}^{n} \max\left\{10 - \text{Gain}^{dB}(f_i), 0\right\}, \tag{18}$$

with a goal of 0.01. The $n = 5$ frequency samples include 5.6, 5.7, 5.8, 5.9, and 6.0 GHz. The cost function targets S_{11} of less than −10 dB and broadside gain higher than 10 dBi in the band of interest. For the optimization, a population of 25 was used, and 30 generations were required to obtain a design with suitable properties. Again, Ansoft HFSS was employed to simulate the structure to gather the requisite electromagnetic properties. The resulting thickness of the optimized AZIM coating is only 6.5 mm (~0.12 λ at 5.8 GHz), much thinner than conventional FP cavities (Guérin et al. 2006; Feresidis et al. 2005), or recently proposed bulky ZIM lenses (Enoch et al. 2002; Ziolkowski 2004; Turpin et al. 2010; Jiang et al. 2012a; Cheng and Cui 2011).

The simulated S_{11} of the SIW-fed slot antenna is shown in Fig. 27a. The S_{11} is below −10 dB from 5.58 to 6.03 GHz. The normalized E-plane (y-z plane) and H-plane (x-z plane) radiation patterns at 5.6, 5.8, and 6.0 GHz are presented in the top portions of Fig. 28a through f. As a comparison, the normalized radiation patterns for the same antenna on a ground plane infinite in the y-direction are also plotted. It can be seen that, for the infinite ground plane case, omnidirectional radiation exists in the E-plane, while the beam

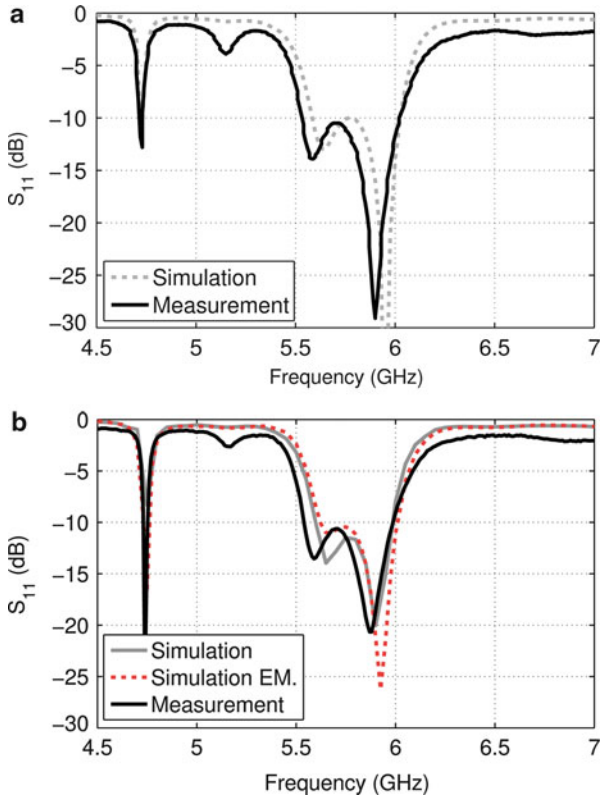

Fig. 27 (**a**) Simulated and measured S_{11} of the SIW-fed slot antenna without the AZIM coating. (**b**) Simulated and measured S_{11} of the SIW-fed slot antenna with the AZIM coating, including the dispersive homogeneous effective medium AZIM coating

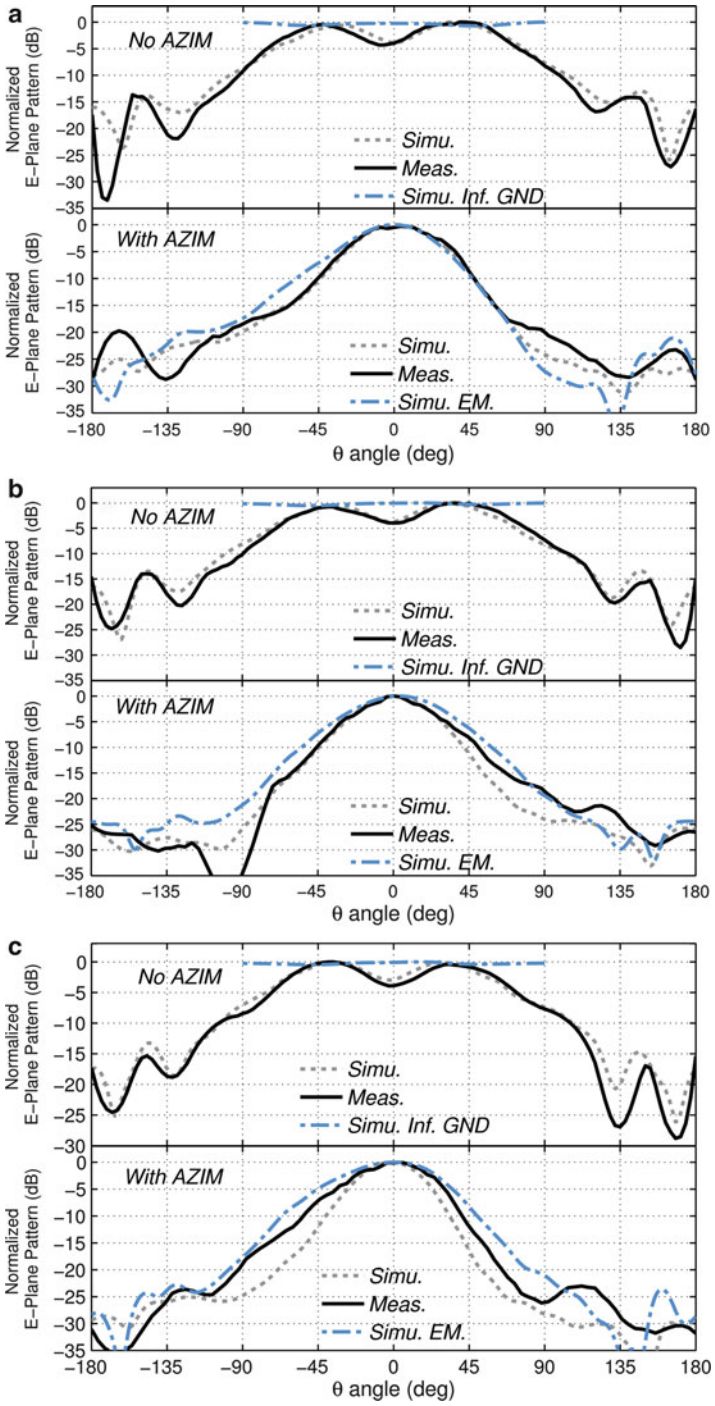
DOI 10.1007/978-981-4560-75-7_15-1

maximum is directed at broadside in the *H*-plane. However, for a finite ground plane with a size of 1.7λ in the *y*-direction, significant edge diffraction can be observed in the *E*-plane, showing two peaks located at around 40–45° off broadside. The double-peak radiation in the *E*-plane caused by the finite ground plane is undesirable for unidirectional radiation due to the gain drop at broadside. The *H*-plane patterns are similar for the two cases since the ground plane size in the *x*-direction is identical. The simulated broadside gain of the antenna on the finite and infinite (in the *y*-direction) ground planes are shown in Fig. 29a. For the infinite ground plane case, the broadside gain is maintained at around 5 dBi, while for the finite ground plane case, the gain varies from 3 to 3.8 dBi.



DOI 10.1007/978-981-4560-75-7_15-1

Simulated and measured normalized radiation patterns of the SIW-fed slot antenna with and without the AZIM coating in the *H*-plane (*x*-*z* plane) at (**d**) 5.6 GHz, (**e**) 5.8 GHz, and (**f**) 6.0 GHz. The simulated *E*- and *H*-plane patterns for the SIW-fed slot antenna without the AZIM coating on a ground plane infinite in the *y*-direction and the simulated *E*- and *H*-plane patterns for the SIW-fed slot antenna with the homogeneous dispersive effective medium AZIM coating are also shown for comparison

DOI 10.1007/978-981-4560-75-7_15-1

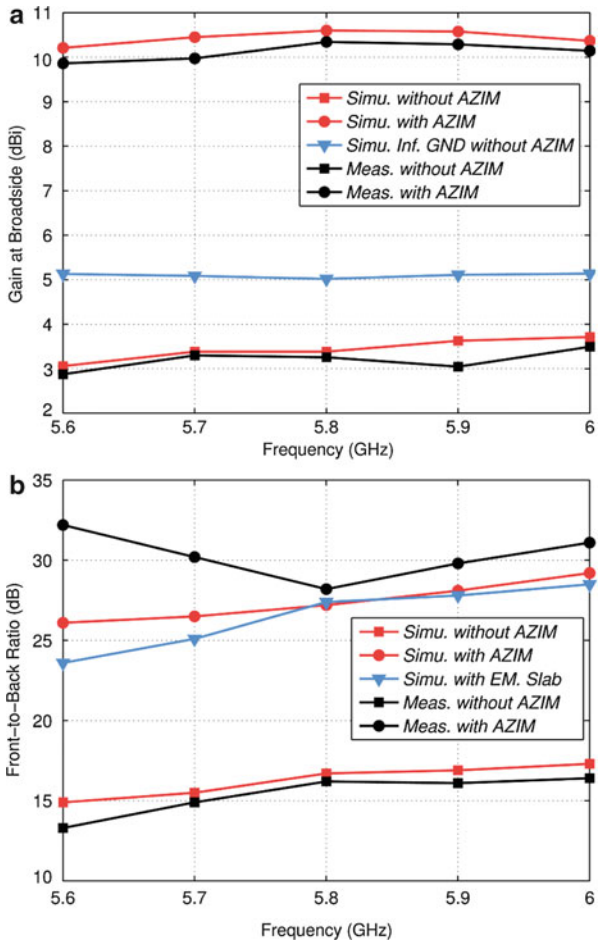


Fig. 29 (**a**) Simulated and measured gain at broadside ($\theta = 0°$) for the SIW-fed slot antenna with and without the AZIM coating. (**b**) Simulated and measured front-to-back ratio for the SIW-fed slot antenna with and without the AZIM coating (*EM*: an effective medium with properties equivalent to the AZIM coating)

As shown in Fig. 27b, the simulated S_{11} of the integrated antenna is below −10 dB from 5.6 to 6 GHz which is very similar to that of the slot alone. This robust input impedance behavior ensures that the AZIM coating can be readily added onto or taken away from the slot to achieve different radiation properties without any additional modification to the slot antenna itself. The normalized *E*-plane (*y*-*z* plane) and *H*-plane (*x*-*z* plane) radiation patterns at 5.6, 5.8, and 6.0 GHz are presented in Fig. 28a through f (bottom sections). In this case, the combined system produces a well-defined single beam at broadside observed in the *E*-plane with a beam squint less than 2° off broadside and a 3 dB beamwidth of about 35–40°. In contrast to the radiation properties in the *E*-plane, the *H*-plane patterns have beamwidths similar to the slot without the AZIM coating. Most notable is that the broadside gain is significantly increased to 10.2–10.6 dBi with the coating, an improvement of about 7 dB over the slot alone. It should also be noted that the front-to-back ratio is greatly reduced by about 10 dB throughout the entire frequency range, which is shown in Fig. 29b. Both the broadside gain increase and the front-to-back ratio drop are primarily attributed to the reduction of fields at the edges of the ground plane, a result of the presence of the AZIM coating. As an alternative perspective, the ultrathin AZIM coating can be considered a highly efficient radiating aperture comprised of an array of subwavelength radiators fed by the slot. The simulated aperture efficiency is greater than 87 % throughout the band.

DOI 10.1007/978-981-4560-75-7_15-1

As a comparison, the actual metamaterial coating structure is replaced by a homogeneous slab with the dispersive effective anisotropic material parameters. It can be observed that the S_{11} and the front-to-back ratio of the slot covered with the effective medium slab correspond well to those of the slot covered with the actual discrete metamaterial. The radiation patterns in both the *E*-plane and *H*-plane also show good agreement, especially in the main beam; the greatest disagreement can be found in the angular range near the back lobes. The strong correlation here justifies the effective medium approximation that was employed, which is assumed to be valid due to the subwavelength size of the unit cells.

Experimental Verification

The SIW-fed slot antenna and the AZIM coating structure were fabricated and assembled as shown in Fig. 26b. An Agilent E8364B network analyzer was used to characterize the S_{11} of the slot with and without the AZIM coating. As shown in Fig. 27a, b, good agreement can be found between simulations and measurements not only in terms of the −10-dB bandwidth but also the resonance positions. The measured S_{11} of the slot with and without the AZIM coating has a −10-dB band from 5.52 to 6.03 GHz and from 5.54 to 6.01 GHz, respectively. They are both slightly broader than the simulations predict due to minor resonant frequency shift at 5.6 GHz and the lower quality factors of both resonances within the −10-dB bandwidth.

The radiation patterns and the gain of the slot antenna with and without the AZIM coating, shown in Fig. 28a through f, were characterized in an anechoic chamber using an automated antenna movement platform. The measured radiation patterns in both the *E*-plane and *H*-plane agree well with the simulated results. Specifically, patterns exhibiting a double peak can be seen for the slot alone, while a single sharp beam pointing at broadside can be observed for the slot with the AZIM coating. The measured 3-dB beamwidth in the *E*-plane is about 40–50°, slightly broader than the simulated beamwidth, especially in the high-frequency band. This is mainly attributed to fabrication and assembly imperfections, which result in a nonideal symmetry in the actual metamaterial structure. The measured broadside gain for the slot with and without the AZIM coating is in the range of 9.8–10.4 dBi and 2.9–3.5 dBi, respectively, indicating an improvement of about 6.9 dBi. The measured front-to-back ratio is displayed in Fig. 29b, showing more than a 10-dB reduction throughout the band which is in good agreement with simulation.

Conclusion

In addition to these three examples, optimization strategies have been successfully applied on countless occasions to other antenna design problems not only in the open literature but in the manufacturing sector as well. These algorithms are extremely useful and powerful if properly applied to the design task at hand. A detailed overview of the usage and operation of several popular optimization algorithms that are well suited for antenna design has been given here. Through comparisons with test functions and an example antenna design task, a good understanding of how the parameterization (coding of the values that require optimization), choice of evolutionary parameters (such as the weighting constant and crossover rate of differential evolution), and even the choice of algorithm itself has been conveyed. For more information, the reader is encouraged to access the websites of the algorithm creators as well as other freely available online materials not only for further reading but to obtain code samples and application examples in order to facilitate their own antenna designs.

Physical Bounds of Antennas

Mats Gustafsson*, Doruk Tayli and Marius Cismasu
Department of Electrical and Information Technology, Lund University, Lund, Sweden

Abstract

Design of small antennas is challenging because fundamental physics limits the antennas performance. Physical bounds provide basic restrictions on the antenna performance solely expressed in the available antenna design space. These bounds offer antenna designers a priori information about the feasibility of antenna designs and a figure of merit for different antenna designs. Here, an overview of physical bounds on antennas and the development from circumscribing spheres to arbitrary shaped regions and embedded antennas are presented. The underlying assumptions for the methods based on circuit models, mode expansions, forward scattering, and current optimization are illustrated and their pros and cons are discussed. The physical bounds are compared with numerical data for several antennas.

Keywords

Physical bounds; Limitations; Stored energy; Q-factor; Small antennas; Circuit models; Mode expansions; Forward scattering; Sum rules; Convex optimization

Introduction

Physical bounds provide information about the maximum achievable performance of antennas (Hansen 1981, 2006; Hansen and Collin 2011; Volakis et al. 2010; Skrivervik and Gustafsson 2012). Bounds are derived, in general, independently of antenna material and type. This makes the physical bounds a powerful tool for developing and analyzing all types of antennas. The bounds are expressed in parameters that describe the geometry and electromagnetic properties of the antennas. Moreover, the bounds themselves and their underlying theory provide insight to antenna design and antenna theory. The bounds offer a priori information of the feasibility of a specific antenna, they give a measure for the figure of merit of an antenna, and they can be used as stopping criteria in heuristic optimization algorithms and for the optimization of the antenna position in wireless terminals.

Antenna performance deteriorates with decreasing electrical size, i.e., physical size measured in wavelengths (Skrivervik et al. 2001; Best and Hanna 2010). The bounds are therefore particularly important for the design of electrically small antennas. There are several definitions of the electrical size of antennas. The classical definition is the radius, measured in wavelengths, of the smallest sphere circumscribing the antenna (Chu 1948; Hansen 1981, 2006; Hansen and Collin 2011; Volakis et al. 2010; Skrivervik and Gustafsson 2012); see also Fig. 1. This is most suitable for antennas with a spherical shape (Best 2004). A generalized measure of electrical size is used for antennas of arbitrary shape and antennas embedded in devices, e.g., mobile phones, tablets, and laptops; see Fig. 1. It should be pointed out that for antennas embedded in devices, the devices may be electrically large, whereas the antennas are electrically small.

DOI 10.1007/978-981-4560-75-7_18-1

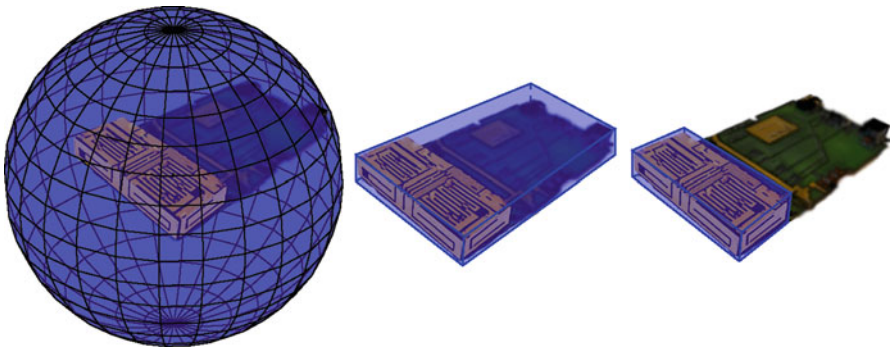

Fig. 1 Illustration of circumscribing geometries used for physical bounds. (*Left*) Circumscribing sphere introduced by Wheeler (1947) and Chu (1948) and used for spherical mode expansions. (*Middle*) Box circumscribing the antenna structure used in the forward scattering approach (Gustafsson et al. 2007a, 2009b, 2010). (*Right*) Box circumscribing the antenna region used in antenna current optimization (Gustafsson and Nordebo 2013)

In small antenna theory, matching bandwidth and efficiency are two performance parameters often considered for analysis (e.g., Wheeler 1947; Chu 1948; Harrington 1961; Collin and Rothschild 1964; Fante 1969; McLean 1996; Foltz and McLean 1999; Sten et al. 2001; Geyi 2003a; Karlsson 2004; Yaghjian and Best 2005; Gustafsson and Nordebo 2006; Thal 2006; Pozar 2009; Nyberg et al. 2010; Glazunov et al. 2011; Hansen et al. 2012). The radiation pattern and the polarization parameters are also of importance in some studies (Gustafsson et al. 2007a, 2009b; Gustafsson and Nordebo 2013). The bandwidth of an antenna depends on the threshold level of the reflection coefficient (or equivalently the standing wave ratio) (Pozar 1998; Volakis et al. 2010; Hansen and Collin 2011) and it is customarily expressed in terms of the corresponding Q-factor (or antenna Q). This latter parameter is defined as the ratio of the energy stored in the fields created by an antenna, to the energy dissipated by radiation and ohmic heating (Pozar 1998; Volakis et al. 2010). The Q-factor is inversely proportional to the fractional bandwidth (Yaghjian and Best 2005; Gustafsson and Nordebo 2006).

The concept of physical bounds for electrically small antennas was introduced by Wheeler (1947) and Chu (1948) at the end of the 1940s. Wheeler used two-lumped-element circuit models to estimate antenna bandwidth and practical efficiency of small antennas. The classical results by Chu (1948) express the lower bound on the Q-factor of antennas in terms of the antenna radius and wave number; see Fig. 1. Although these results are useful and provide a first step in analyzing small antennas, they underestimate the lower bound on the Q-factor of non-spherical antennas. More recently, the forward scattering sum rule presented in Gustafsson et al. (2007a, 2009b, 2010) expresses antenna performance and bounds in terms of the polarizability of the antenna structure or any circumscribing shape; see Fig. 1. These bounds are more realistic than those derived for spherical geometries and are beneficial for analyzing many small antennas that utilize the circumscribing geometry efficiently. On the other hand, the forward scattering sum-rule bounds are less useful for antennas that are embedded in or placed in the proximity of larger structures. Instead, these situations can be studied using antenna current optimization (Gustafsson and Nordebo 2013; Gustafsson et al. 2014b). In this technique the structure is decomposed, into an antenna region with controllable currents and a surrounding structure with induced currents.

The remainder of this paper is organized as follows. Section "Background and Overview" presents an overview of physical bounds. Section "Antenna Quantities for Physical Bounds" reviews the antenna quantities used in the physical bounds. Physical bounds for small antennas based on circuit models and mode expansions are discussed in section "Circuit Models and Mode Expansions," forward scattering in section "Forward Scattering Sum Rule," and current optimization in section "Antenna Current

DOI 10.1007/978-981-4560-75-7_18-1

Fig. 2 Physical bounds on antennas answer the *fundamental question: how good can an antenna be*? Bounds can be determined using circuit models (1947), mode expansions (1948), sum rules (2007), and current optimization (2012). Antenna current optimization is the most flexible method (yet) to obtain physical bounds appropriate for many practical antenna design situations

Optimization." Bandwidth bounds for array antennas are discussed in section "Periodic Array Antennas." The paper is concluded in section "Conclusions."

Background and Overview

Physical bounds on antennas have been analyzed in different ways since the work of Wheeler (1947) and Chu (1948), and some of them have been mentioned previously. An attempt to categorize the physical bound approaches and methods is made in Fig. 2, even though not all can be described and characterized. Four main techniques have been classified to derive the physical bounds. These are circuit models, mode expansions, forward scattering, and antenna current optimization.

Circuit models consisting of an inductor or capacitor and a radiation resistance were used by Wheeler (1947) to approximate the input impedance of antennas. Based on these circuits, he estimated the radiation power factor (related to the inverse of the Q-factor) and bandwidth of antennas. The results obtained by Wheeler, even though approximate, provide physical insight into the dependence of performance on the shape and material loading of antennas. Chu (1948) used circuit models of spherical modes to compute the stored energy and Q-factor for spherical geometries. The results obtained from circuit models have been generalized to mixed modes and nonmagnetic sources by Thal (2006, 2009).

Physical bounds on antennas can be obtained by expanding the fields in spherical modes, also referred to as spherical vector waves, outside a circumscribing sphere of the antenna structure. Chu (1948) used

DOI 10.1007/978-981-4560-75-7_18-1

this mode expansion together with circuit models to compute the minimum stored energy and to derive the Q and D/Q bounds for single spherical modes, where D is the directivity. He showed that the dipole modes have the lowest Q-factor and that the Q-factor of antennas can be reduced by letting the antenna excite a combination of electric (transverse magnetic TM) and magnetic (transverse electric TE) modes. Mode expansions have dominated the research on physical bounds since Chu's work (see e.g., Harrington 1961; Collin and Rothschild 1964; Fante 1969; McLean 1996; Foltz and McLean 1999; Sten et al. 2001; Geyi 2003a; Karlsson 2004; Kwon 2005; Yaghjian and Best 2005; Gustafsson and Nordebo 2006; Thal 2006; Pozar 2009; Nyberg et al. 2010; Glazunov et al. 2011; Davis et al. 2011; Hansen et al. 2012) and the historical expose in Volakis et al. (2010). The mode expansion approach to physical limitations provides simple analytic formulas for the lower bound on the Q-factor for single modes (Collin and Rothschild 1964; McLean 1996). In addition, this approach provides insight into the physics of combinations of different modes (e.g., TE + TM). Thal extended the mode expansions by restricting the electromagnetic fields to originate from electric current densities (Thal 2006).

Physical bounds were generalized to arbitrary shapes using the forward scattering sum rule in Gustafsson et al. (2007a, 2009b, 2010). In this approach, antennas are analyzed in receive mode. It was shown that the interaction over all frequencies between an incident electromagnetic plane wave and an antenna is related to the polarizability of the radiating structure. The bounds derived with this approach are valid for arbitrarily shaped antennas made of reciprocal, linear, and time-translational materials. These bounds are formulated in terms of the quotient between the directivity and Q-factor D/Q, and of the product of the realized gain and bandwidth. The forward scattering sum-rule bounds have been verified for several antennas with electrical sizes up to $ka \approx 1.5$, where k is the wave number and a is the radius of the smallest sphere circumscribing the antenna. Yaghjian and Stuart derived similar bounds on the Q-factor in the limit of small antennas $ka \ll 1$ using a different technique (Yaghjian and Stuart 2010). These latter bounds were generalized to electric and magnetic sources in Yaghjian et al. (2013).

Antenna current optimization can be used to derive physical bounds on antennas from optimal current distributions on the radiating structure (Gustafsson et al. 2012a; Gustafsson and Nordebo 2013). This approach is widely applicable to practical antenna design situations and has the potential to include many different requirements on, e.g., performance, size, etc. One of the challenges of this method is to express the antenna quantities involved in defining the parameters of interest, in terms of the current density on the antenna. For example, here the energy expressions introduced by Vandenbosch (Vandenbosch 2010) for current densities in free space (see also Geyi 2003b; Gustafsson and Jonsson 2015b; Gustafsson et al. 2014a; Harrington 1972) are used to express the Q-factor of antennas. These energy expressions are further used in minimization of the stored energy to determine current densities optimum in the sense of maximum gain-Q ratio for a fixed radiated field. These and many other antenna design situations result in convex optimization problems (Gustafsson and Nordebo 2013), which are easily solvable by common numerical methods (Grant and Boyd 2011).

There are alternative approaches to analyze electrically small or large antennas. A few of these approaches are briefly discussed in the following. Thiele et al. (2003) propose an approach to physical limitations based on the concepts of superdirectivity and visible and invisible spatial regions of the fields created by an antenna (Taylor 1955). A method based on the capacity of the free space communication channel is described in Nordebo et al. (2006) and Gustafsson and Nordebo (2007). Considerations about directivity limitations of antennas are presented in Kildal and Best (2008). Bandwidth limitations for infinite array antennas are analyzed in Doane et al. (2013), Jonsson et al. (2013), and Doane et al. (2014) using the results in Rozanov (2000) and Gustafsson and Sjöberg (2011); see section "Periodic Array Antennas".

Antenna Quantities for Physical Bounds

Antenna Parameters

Antenna parameters commonly used in the study of small antennas include the bandwidth, Q-factor, input impedance, reflection coefficient, etc. The parameters used in this section are introduced in the following.

The reflection coefficient, Γ, of an antenna is determined from its input impedance, $Z_a = R_a + jX_a$, as

$$\Gamma = \frac{Z_a - Z_0}{Z_a + Z_0} = \frac{R_a - Z_0 + jX_a}{R_a + Z_0 + jX_a}, \tag{1}$$

where Z_0 is a normalization impedance, usually the characteristic impedance of the transmission line that feeds the antenna. The mismatch depends on the difference between the real part and the commonly real-valued normalization impedance, $R_a - Z_0$, and the reactance, X_a.

The *bandwidth* of an antenna is defined as "the range of frequencies within which the performance of the antenna, with respect to some characteristic, conforms to a specified standard" by the IEEE in (IEEE145-1993). Usual performance metrics are matching, efficiency, radiation pattern, polarization, etc. In this chapter, the focus is on the matching bandwidth defined as the frequency interval $[f_1, f_2]$ for which the amplitude of the reflection coefficient $|\Gamma|$ is smaller than a given threshold Γ_0; see Fig. 3. The bandwidth of narrowband antennas is usually expressed as fractional bandwidth, B, defined as the bandwidth normalized with the center frequency, $f_0 = (f_1 + f_2)/2$, i.e.,

$$B = \frac{f_2 - f_1}{f_0} = \frac{\omega_2 - \omega_1}{\omega_0}, \tag{2}$$

where the angular frequency is $\omega = 2\pi f$.

The Q-factor for an antenna is defined as the ratio between the maximum of the stored electric, W_e, and magnetic, W_m, energies and the dissipated power $P_r + P_\Omega$ (Yaghjian and Best 2005), i.e.,

$$Q = \max\{Q_e, Q_m\} = \frac{2\omega \max\{W_e, W_m\}}{P_r + P_\Omega} = \eta \frac{2\omega \max\{W_e, W_m\}}{P_r}, \tag{3}$$

where the electric and magnetic Q-factors are $Q_e = 2\omega W_e/(P_r + P_\Omega)$ and $Q_m = 2\omega W_m/(P_r + P_\Omega)$, respectively, and the efficiency $\eta = P_r/(P_r + P_\Omega)$, where P_r denotes the radiated power and P_Ω the

ohmic and dielectric power losses. The electric and magnetic Q-factors correspond to the stored energy in the capacitors and inductors, respectively, normalized with the dissipated power in the resistors for lumped circuit networks, see section "Antenna Tuning and Matching".

Antenna Tuning and Matching

Tuning is used to eliminate the reactance mismatch in Eq. 1. An antenna with input impedance $Z_a = R_a + jX_a$ is capacitive if $X_a < 0$ and inductive if $X_a > 0$. The simplest way to tune an antenna which is not self-resonant is by connecting a lumped element as in one of the situations depicted in Fig. 4. The tuning capacitance and inductance are chosen such that the tuned input impedance, Z_a, is purely resistive at the resonance frequency.

More complex matching networks can be used to increase the bandwidth of antennas, as illustrated in Fig. 5. The bandwidth potential is a concept that gives information about the bandwidth achievable with a two-lumped-element matching network (Rahola 2009). The upper bound on the fractional bandwidth for lossless matching networks is given by the Bode-Fano limit (Fano 1950; Hansen 2006; Gustafsson and Nordebo 2006)

$$B \leq \frac{27}{Q|\Gamma_{0,\,\mathrm{dB}}|}, \tag{4}$$

for an RLC antenna input impedance with the threshold level $\Gamma_{0,\mathrm{dB}} = 20 \log_{10} \Gamma_0$.

The bandwidth is inversely proportional to the Q-factor, i.e., a high Q-factor implies a narrow bandwidth. The precise proportionality is determined by the shape of the reflection coefficient, i.e., by its dependence on frequency, that is often quantified with the distribution of the resonances. The simplest case of a single resonance corresponds to series or parallel RLC circuits (see right inset of Fig. 6), where the fractional bandwidth for a single resonance is (Yaghjian and Best 2005)

$$B \approx \frac{2}{Q} \quad \frac{\Gamma_0}{\sqrt{1-\Gamma_0^2}} = \frac{2}{Q} \quad \text{for} \quad \Gamma_0 = 1/\sqrt{2}\,. \tag{5}$$

The reflection coefficients for single resonance RLC circuits with $Q = 5$, 10, and 40 are depicted in Fig. 6.

DOI 10.1007/978-981-4560-75-7_18-1

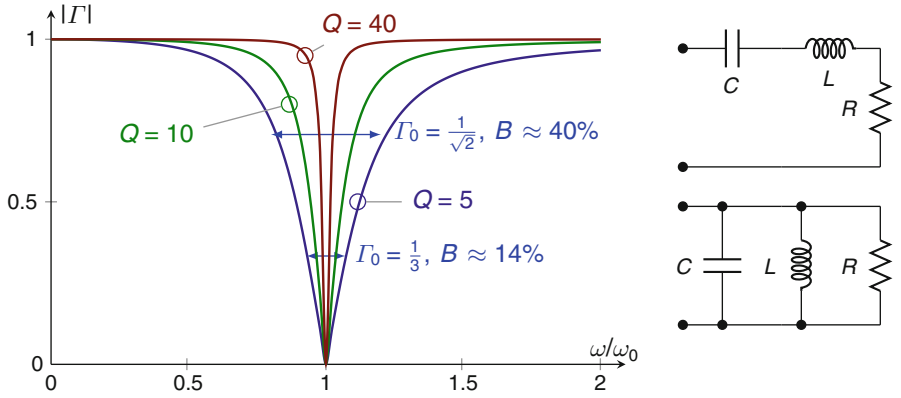

Fig. 6 Reflection coefficient, $|\Gamma|$, for RLC circuits (*inset right*) with $Q = \{5,\ 10,\ 40\}$. The corresponding fractional bandwidths for $\Gamma_0 = \{1/\sqrt{2}, 1/3\}$ are depicted

The estimate Eq. 5 is very accurate for $Q \gg 2$ for the RLC circuit. The special case of the half-power bandwidth $B \approx 2/Q$ predicts an infinite bandwidth for $Q = 1$. This suggests that the Q-factor is most useful for $Q \gg 1$. Reasonable accuracy in Eq. 5 is obtained for $Q > 5$ or $Q > 10$, in practice. The assumption of a single resonance is however essential for Eq. 5. The use of multiple resonances to increase the bandwidth (Hansen 2006) is described less accurately by this expression.

Differentiation of the input impedance offers an alternative method to estimate the Q-factor of antennas (Yaghjian and Best 2005; Gustafsson and Nordebo 2006; Kajfez and Wheless 1986):

$$Q_{z'} = \omega|\Gamma'| = \frac{\omega|Z'_{\mathrm{m}}|}{2R} = \frac{\omega|Z' + \mathrm{j}|X||}{2R} = \frac{\sqrt{(\omega R')^2 + (\omega X' + |X|)^2}}{2R}, \tag{6}$$

where Z_{m} denotes the input impedance tuned to resonance with a series capacitor or inductor, as in Fig. 4 (see also Gustafsson et al. 2014a). Equation 6 is exact for the RLC series circuit and often very accurate for antennas with $Q \gg 1$. However, this expression can underestimate the Q-factor for multiple resonances (Gustafsson and Nordebo 2006; Stuart et al. 2007; Gustafsson and Jonsson 2015a; Gustafsson et al. 2014a).

The $Q_{z'}$ estimate Eq. 6 can be interpreted as a local Padé approximation of the reflection coefficient (or input impedance) with a lumped-element circuit (Gustafsson and Nordebo 2006). This expression estimates the bandwidth Eq. 5 for $B \ll 1$ or similarly $\Gamma_0 \ll 1$. Accurate estimates of the fractional bandwidth Eq. 5 using $Q_{z'}$ require that the first-order derivative $|Z'_{\mathrm{m}}|$ (linear term) dominates over the second- and higher-order derivatives. This requirement is not always met and there are synthesized cases with $|Z'_{\mathrm{m}}| \approx 0$ where $Q_{z'}$ overestimates the fractional bandwidth using Eq. 5 (Gustafsson and Nordebo 2006; Gustafsson and Jonsson 2015a; Gustafsson et al. 2014a).

Stored Electric and Magnetic Energies

Physical bounds on antennas are often derived using the electromagnetic fields that surround the antenna (Harrington 1961; Collin and Rothschild 1964; Fante 1969; McLean 1996; Foltz and McLean 1999; Sten et al. 2001; Geyi 2003a; Karlsson 2004; Yaghjian and Best 2005; Thal 2006; Volakis et al. 2010). Consider an antenna confined to the region V as depicted in Fig. 7. The antenna current density is denoted $\boldsymbol{J}(\boldsymbol{r})$ and the radiated electric field is $\boldsymbol{E}(\boldsymbol{r})$ that simplifies to

$$\boldsymbol{E}(\boldsymbol{r}) = \frac{\mathrm{e}^{-\mathrm{j}kr}}{r}\boldsymbol{F}(\hat{\boldsymbol{r}}) \quad \text{as} \quad r \to \infty\,, \tag{7}$$

DOI 10.1007/978-981-4560-75-7_18-1

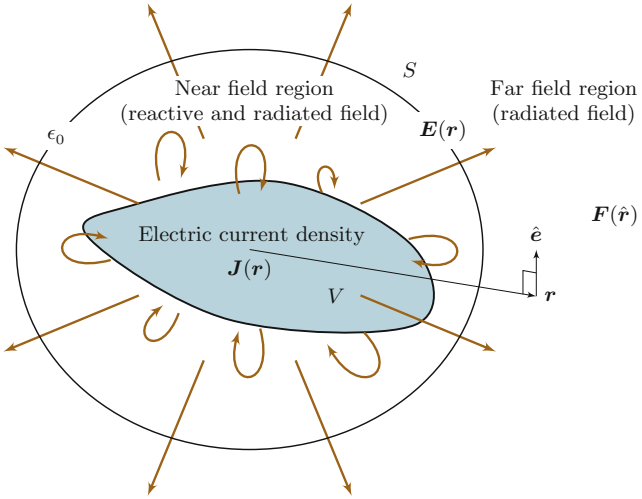

Fig. 7 Reactive and radiated fields from a current density $\boldsymbol{J}(\boldsymbol{r})$ in the volume V. Note that, in the far field, $\hat{\boldsymbol{e}}$ is perpendicular to $\boldsymbol{r}$

where $\boldsymbol{F}$ is the electric far field, $r = |\boldsymbol{r}|$, and $\hat{\boldsymbol{r}} = \boldsymbol{r}/r$. The time average electric and magnetic energy densities in free space are $w_\mathrm{e} = \epsilon_0|\boldsymbol{E}|^2/4$ and $w_\mathrm{m} = \mu_0|\boldsymbol{H}|^2/4$, respectively, where $\boldsymbol{H}(\boldsymbol{r})$ is the magnetic field. These energy densities resemble the time average energies stored in capacitors and inductors, $W_\mathrm{e} = C|V|^2/4$ and $W_\mathrm{m} = L|I|^2/4$, respectively. The energy in a region is obtained by integrating the energy density in that region. The $1/r$ decay of the field, see Eq. 7, implies that the total electromagnetic energy for antennas in free space is unbounded and hence dominated by the contributions from the radiated field far away from the antenna.

The stored electromagnetic energy is the part of the energy that is not radiated. This energy is confined to the near-field region around the antenna. The stored energy has been evaluated in the history of antenna technology by different methods. Chu (1948) and Thal (2006) used circuit models of the spherical vector waves to determine the stored energy for spherical regions. Synthesized lumped-circuit models give an alternative method to estimate the Q-factor from the input impedance of antennas (Gustafsson and Jonsson 2015a). Collin and Rothschild (1964) calculate the stored energy by subtraction of the energy density of the power flow giving

$$W_\mathrm{e}^{(\mathrm{P})} = \frac{\epsilon_0}{4}\int_{\mathbb{R}^3_\mathrm{r}} |\boldsymbol{E}(\boldsymbol{r})|^2 - \eta_0 \mathrm{Re}\{\boldsymbol{E}(\boldsymbol{r}) \times \boldsymbol{H}(\boldsymbol{r})^* \cdot \hat{\boldsymbol{r}}\}\ \mathrm{dV}, \tag{8}$$

for the electric stored energy, where the asterisk* denotes complex conjugation and $\mathbb{R}^3_\mathrm{r} = \{\boldsymbol{r} : \lim_{r0\to\infty}|\boldsymbol{r}| \le r_0\}$ denotes an infinitely large spherical volume (see also Fante 1969; McLean 1996; Geyi 2003a; Karlsson 2004; Yaghjian and Best 2005; Gustafsson and Jonsson 2015b). The magnetic energy is expressed in terms of a magnetic energy density analogous to Eq. 8. The integral expressions by Vandenbosch (2010) represent the stored energy as quadratic forms in terms of current densities. These expressions are particularly useful as radiated fields are generated by current densities on the antenna structure. Furthermore, these integral expressions are directly applicable to antenna current optimization (Gustafsson et al. 2012a; Gustafsson and Nordebo 2013). They are identical to subtraction of the energy density of the radiated field for many cases (Gustafsson and Jonsson 2015b) and reduce to the stored energy in Geyi (2003b) and Carpenter (1989) in the limit of small antennas. Here, the stored electric and magnetic energies given by the integral expressions (Vandenbosch 2010; Gustafsson and Jonsson 2015b)

DOI 10.1007/978-981-4560-75-7_18-1

$$W_{\mathrm{e}} = \frac{\eta_0}{4\omega} \int_V \int_V \nabla_1 \cdot \boldsymbol{J}(\boldsymbol{r}_1) \ \nabla_2 \cdot \boldsymbol{J}(\boldsymbol{r}_2)^* \frac{\cos\left(k|\boldsymbol{r}_1 - \boldsymbol{r}_2|\right)}{4\pi k|\boldsymbol{r}_1 - \boldsymbol{r}_2|} - \left(k^2 \boldsymbol{J}(\boldsymbol{r}_1) \cdot \boldsymbol{J}(\boldsymbol{r}_2)^* - \nabla_1 \cdot \boldsymbol{J}(\boldsymbol{r}_1) \ \nabla_2 \cdot \boldsymbol{J}(\boldsymbol{r}_2)^*\right) \frac{\sin\left(k|\boldsymbol{r}_1 - \boldsymbol{r}_2|\right)}{8\pi} \mathrm{dV}_1 \mathrm{dV}_2 \tag{9}$$

and

$$W_{\mathrm{m}} = \frac{\eta_0}{4\omega} \int_V \int_V k^2 \boldsymbol{J}(\boldsymbol{r}_1) \cdot \boldsymbol{J}(\boldsymbol{r}_2)^* \frac{\cos\left(k|\boldsymbol{r}_1 - \boldsymbol{r}_2|\right)}{4\pi k|\boldsymbol{r}_1 - \boldsymbol{r}_2|} - \left(k^2 \boldsymbol{J}(\boldsymbol{r}_1) \cdot \boldsymbol{J}(\boldsymbol{r}_2)^* - \nabla_1 \cdot \boldsymbol{J}(\boldsymbol{r}_1) \ \nabla_2 \cdot \boldsymbol{J}(\boldsymbol{r}_2)^*\right) \frac{\sin\left(k|\boldsymbol{r}_1 - \boldsymbol{r}_2|\right)}{8\pi} \mathrm{dV}_1 \mathrm{dV}_2, \tag{10}$$

respectively, are used, where it is noted that $\eta_0/\omega = \mu_0/k$. The corresponding radiated power is (Geyi 2011; Vandenbosch 2010; Gustafsson and Jonsson 2015b)

$$P_{\mathrm{r}} = \frac{\eta_0}{2} \int_V \int_V \left(k^2 \boldsymbol{J}(\boldsymbol{r}_1) \cdot \boldsymbol{J}(\boldsymbol{r}_2)^* - \nabla_1 \cdot \boldsymbol{J}(\boldsymbol{r}_1) \ \nabla_2 \cdot \boldsymbol{J}(\boldsymbol{r}_2)^*\right) \frac{\sin\left(k|\boldsymbol{r}_1 - \boldsymbol{r}_2|\right)}{4\pi k|\boldsymbol{r}_1 - \boldsymbol{r}_2|} \mathrm{dV}_1 \mathrm{dV}_2. \tag{11}$$

These energy expressions resemble the impedance matrices obtained from the electric field integral equation (EFIE) (Harrington 1972, 1975; Gustafsson et al. 2014a). The stored energies are also generalized to electric and magnetic currents (Jonsson and Gustafsson 2015) and lossy media (Gustafsson et al. 2014a).

Sum Rules

Sum rules have been used to derive physical bounds on electromagnetic systems such as: matching networks (Fano 1950), radar absorbers and array antennas (Rozanov 2000; Doane et al. 2013; Jonsson et al. 2013), antennas (Gustafsson et al. 2007a, 2009b; Gustafsson 2010c), scattering (Sohl et al. 2007; Gustafsson 2010b), high-impedance surfaces (Gustafsson and Sjöberg 2011), and metamaterials (Sohl et al. 2008; Gustafsson and Sjöberg 2010; Gustafsson et al. 2012b). The sum rules are integral identities that often relate the parameter of interest integrated over all frequencies with some low-frequency quantity.

The sum rules presented here are based on integral identities for Herglotz functions (Nussenzveig 1972; Bernland et al. 2011b) or similarly positive real (PR) functions (Zemanian 1987). Positive real functions (Zemanian 1987), $Z(s)$, are analytic and $\mathrm{Re}\{Z(s)\} \geq 0$ for $\mathrm{Re}\, s > 0$. They are often found in linear, passive, and causal systems (Bernland et al. 2011b; Zemanian 1987). The identities

$$\frac{1}{\pi} \int_{\mathbb{R}} \frac{\mathrm{Re}\, Z(\mathrm{j}\omega)}{\omega^2} \, \mathrm{d}\omega \stackrel{\mathrm{def}}{=\!=} \lim_{\varepsilon \to 0^+} \lim_{y \to 0^+} \frac{1}{\pi} \int_{-1/\varepsilon}^{1/\varepsilon} \frac{\mathrm{Re}\, Z(\mathrm{j}\omega + y)}{\omega^2} \mathrm{d}\omega = a_1 - b_1 \leq a_1 \tag{12}$$

are valid for all PR functions having the asymptotic expansions

$$Z(s) = a_1 s + \mathrm{o}(s) \quad \text{as} \quad s \hat{\to} 0 \quad \text{and} \quad Z(s) = b_1 s + \mathrm{o}(s) \quad \text{as} \quad s \hat{\to} \infty, \tag{13}$$

where $\hat{\to}$ means limits in some sector $0 < \alpha < |\arg s| < \pi/2 - \alpha$ and the principal value integral Eq. 12 is interpreted as a limit from the complex valued right half plane; see Bernland et al. (2011b) for details.

Circuit Models and Mode Expansions

Wheeler used circuit models to analyze small antennas (Wheeler 1947). The electric antenna consists of a lumped capacitance in parallel with a radiation resistance. The corresponding magnetic antenna is a lumped inductance in series with a radiation resistance. These results provide intuition and rules of thumb.

Chu (1948) determined the minimum stored energy around an antenna in three steps:

1. Circumscribe the antenna by a sphere with radius a; see Fig. 8.
2. Expand the radiated electromagnetic field outside the circumscribing sphere in spherical modes (Van Bladel 2007; Harrington 1961; Hansen 1988; Thal 1978); see Fig. 9.
3. Compute the stored energy outside the sphere from a lumped circuit representation of the spherical modes (Thal 1978).

The lumped-element circuit models of the electric ($TM_{m,1}$) and magnetic dipole ($TE_{m,1}$) modes (Chu 1948; Thal 1978; McLean 1996) are depicted in Fig. 10. The electric and magnetic cases having identical order (n-index) are dual such that the corresponding Q-factors are identical. The electric dipole has the stored electric and magnetic energies and radiated power

DOI 10.1007/978-981-4560-75-7_18-1

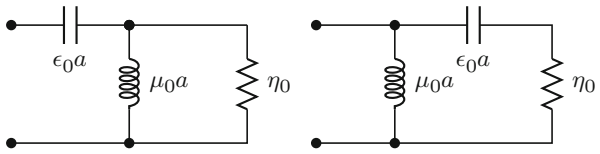

Fig. 10 Lumped-element circuit models of the electric ($TM_{m,1}$) and magnetic dipole ($TE_{m,1}$) modes (Chu 1948; Harrington 1961; Thal 1978)

$$W_{\mathrm{e}} = \frac{\eta_0 |I|^2}{4\omega} \frac{1}{ka}, \quad W_{\mathrm{m}} = \frac{\eta_0 |I|^2}{4\omega} \frac{ka}{1+k^2a^2}, \quad \text{and} \quad P_{\mathrm{r}} = \frac{\eta_0 |I|^2}{2} \frac{k^2a^2}{1+k^2a^2}, \tag{14}$$

respectively, for a current source I. The electric energy dominates over the magnetic energy, $W_{\mathrm{e}} > W_{\mathrm{m}}$, i.e., the electric dipole mode is capacitive. The stored energy and radiated power give the Chu bound for single mode antennas, stating that the Q-factor of a single mode lossless antenna circumscribed by a sphere with radius a satisfies

$$Q \geq Q_{\mathrm{Chu}} = \frac{2\omega \max\{W_{\mathrm{e}}, W_{\mathrm{m}}\}}{P_{\mathrm{r}}} = \frac{2\omega W_{\mathrm{e}}}{P_{\mathrm{r}}} = \frac{1}{(ka)^3} + \frac{1}{ka}. \tag{15}$$

The inequality $Q \geq Q_{\mathrm{Chu}}$ is interpreted as the contribution to the Q-factor from the stored energy within the spherical volume. This means that antenna designs reaching the Chu lower bound should have negligible electric field inside the sphere (Chu 1948).

Circuit models and closed-form expressions are convenient for dipole modes. However, these methods become increasingly complicated for higher-order modes; see also Fig. 9. The input impedance of the circuits modeling spherical modes offers an approximation of the Q-factor. Chu approximated the Q by differentiation of the reactance (Chu 1948) to show that $Q_n \sim (ka)^{-2n-1}$ as $ka \to 0$ for modes of order n (see also Gustafsson and Nordebo 2006) for the corresponding results from the differentiation of the input impedance (Eq. 6). Chu also discussed the case of mixed TM and TE modes, e.g., the Huygens source in Fig. 9, and showed that mixed modes can lower the bound on Q by a factor of two for $ka \ll 1$ (Chu 1948; Harrington 1961) by, e.g., using an inductive TE mode instead of a lumped inductor as the tuning element in Fig. 4. The resulting Q-factor is bounded as

$$Q \geq \frac{1}{2(ka)^3} + \frac{1}{ka} \tag{16}$$

for larger ka (McLean 1996; Pozar 2009).

Mode expansions have dominated the research on physical bounds since these expansions were introduced by Chu (see, e.g., Harrington 1961; Collin and Rothschild 1964; Fante 1969; McLean 1996; Foltz and McLean 1999; Sten et al. 2001; Geyi 2003a; Karlsson 2004; Thal 2006; Nyberg et al. 2010; Yaghjian and Best 2005; Gustafsson and Nordebo 2006; Pozar 2009 and the historical expose in Volakis et al. (2010)). In particular Collin and Rothschild (Collin and Rothschild 1964) used spherical mode expansions and analytic evaluation of Eq. 8 to derive closed-form expressions of the Q-factor for spherical modes of arbitrary order, e.g.,

$$Q_1 = \frac{1}{(ka)^3} + \frac{1}{ka}, \quad Q_2 = \frac{18}{(ka)^5} + \frac{6}{(ka)^3} + \frac{3}{ka}, \quad \text{and} \quad Q_n \sim \frac{1}{(ka)^{2n+1}}, \tag{17}$$

DOI 10.1007/978-981-4560-75-7_18-1

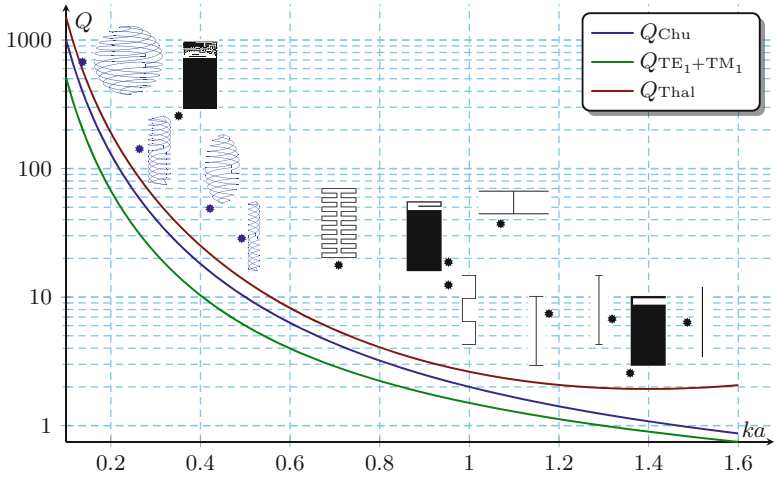

Fig. 11 The Chu Eq. 15, Thal Eq. 18, and mixed-mode bounds on Q compared with numerical estimates using $Q_{Z'_{\mathrm{in}}}$ in Eq. 6; see Tables 1 and 2 (Altair Development 2014). Wire antennas (*blue*) and planar antennas (*black*) are depicted. The different types of dipoles (*black*) are constructed with planar strips

where the rapid increase in the Q-factor for small antennas $ka \ll 1$ and higher-order modes $n > 1$ are noted.

Equivalent (surface) currents (Van Bladel 2007) offer a powerful interpretation of physical bounds. The Chu bound in Eq. 15 is derived under the assumption of negligible stored energy in the interior of a sphere. This requires electric, $\boldsymbol{J}$, and magnetic, $\boldsymbol{M}$, surface currents to exist on this sphere in free space; see Fig. 8. Antennas without magnetic currents (or magnetic material) have internal fields and hence an internal stored energy. Thal (2006) extended the Chu bound to the case of only electric surface currents by adding the energy stored in the interior of a sphere. The resulting bound for the electric dipole mode is

$$Q \geq \frac{3}{2(ka)^3} = \frac{3}{2} Q_{\mathrm{Chu}} \quad \text{for } ka \ll 1 \tag{18}$$

(see also Hansen and Collin 2009; Hansen et al. 2012). The closed-form expressions for arbitrary spherical modes are (Gustafsson and Jonsson 2015b)

$$Q^{(\mathrm{P})}_{\tau n,\mathrm{e}}(\kappa) = \kappa - \frac{\left(\kappa \mathrm{R}^{(1)}_{\tau n}(\kappa) \mathrm{R}^{(2)}_{\tau n}(\kappa)\right)'}{2\left(R^{(1)}_{\tau n}(\kappa)\right)^2} \quad \text{and} \quad Q^{(\mathrm{P})}_{\tau n,\mathrm{m}} = Q^{(\mathrm{P})}_{\tau n,\mathrm{e}}(\kappa) - \frac{\mathrm{R}^{(2)}_{\tau n}(\kappa)}{\mathrm{R}^{(1)}_{\tau n}(\kappa)} \tag{19}$$

for the electric and magnetic Q-factors, respectively, with $\kappa = ka$. Here the expressions for the TE ($\tau = 1$) and TM ($\tau = 2$) modes are written in identical forms by using radial functions (Hansen 1988); see Appendix A "Radial Functions."

The Chu (Eq. 15), Thal (Eq. 18), and mixed mode bounds are compared with several antennas in Fig. 11 (see also Sievenpiper et al. 2012). All antennas have Q-factors above the bounds, as expected. The folded spherical helix antenna fills the spherical surface and performs close to the Thal bound (Eq. 18), while the dipole and planar antennas do not utilize the spherical volume as efficiently as spherical helices. This implies that the former have Q-factors closer to the bounds than the latter. On the other hand, for the cylindrical structures, cylindrical helix and spheroidal helix, the antenna performance is between the performance of spherical and planar structures. It should be noted that increasing the thickness of the wire and strip antennas decreases their Q-factors. There are several suggestions for antennas with Q-factors

DOI 10.1007/978-981-4560-75-7_18-1

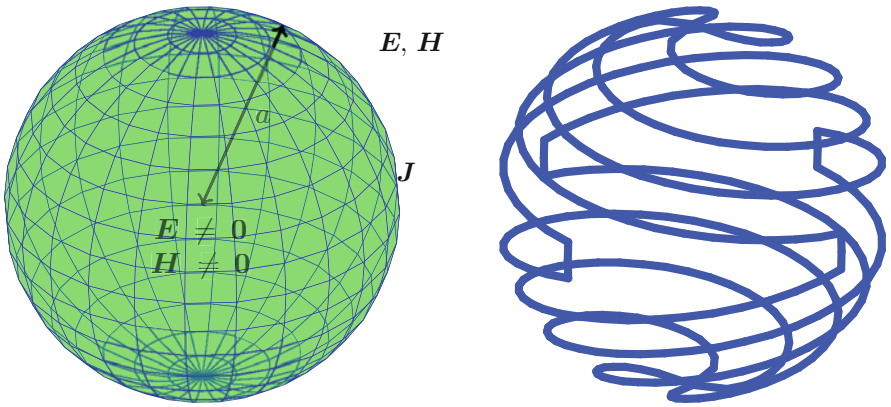

Fig. 12 (*Left*) The Thal model (Thal 2006) with an electromagnetic field in the interior of the sphere and electric surface currents $\boldsymbol{J}$. (*Right*) The folded spherical helix (Best 2004) with electric surface currents and Q-factor $Q \approx 1.5Q_{\text{Chu}}$

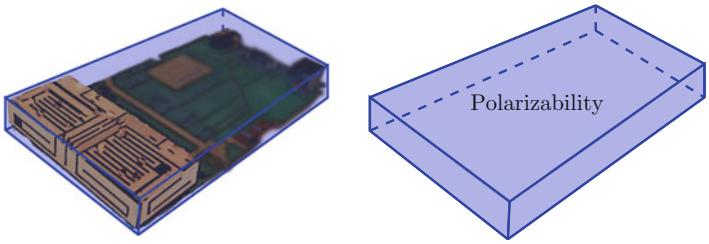

Fig. 13 (*Left*) Circumscribing box for an antenna. (*Right*) Polarizability of the circumscribing structure to determine the physical bounds Eq. 23

approaching the Chu lower bound or corresponding bounds for TE and mixed-mode cases. The folded spherical helix (see Fig. 11) investigated by Best (2004) has a Q-factor close to the Thal bound (see also Adams et al. 2011). Kim proposed a few designs reaching close to the physical bounds on Q (Kim 2012; Kim et al. 2010; Figs. 12 and 13).

Most antennas are not spherical and, as seen in Fig. 11, their Q-factors are far from the bound. This has encouraged researchers to extend the mode expansions to non-spherical regions. Collin and Rothschild (1964) used cylindrical waves to derive bounds for infinite cylinders and Foltz and McLean (1999) and Sten et al. (2001) used expansions in spheroidal coordinates to derive bounds for antennas confined to spheroidal volumes. However, it turns out to be difficult to extend the results from spherical regions using mode expansions. An alternative approach based on sum rules for spherical waves is investigated in Bernland et al. (2011a) and Bernland (2012), where the bandwidth is shown to be related to the polarizability. The case with spherical regions in the vicinity of a ground plane is analyzed in Sten et al. (2001). There are also extensions to antennas embedded in lossy media (Karlsson 2004).

Forward Scattering Sum Rule

The forward scattering bounds in Gustafsson et al. (2007a, 2009b) and Derneryd et al. (2009) are solely based on the assumptions of linearity, time-translational invariance, causality, and reciprocity. These are generally accepted assumptions in the antenna community and valid for a large class of antennas, e.g., antennas with metallic and dielectric components, antennas fed by a single transmission line, impedance matched with a matching network, etc. Some of the main advantages of these forward scattering bounds

DOI 10.1007/978-981-4560-75-7_18-1

are that they are simple to use, provide physical insight into small antennas given by expressions in terms of polarizability dyadics, hold for arbitrary enclosing geometries, and are formulated in terms of the realized gain (the parameter quantifying the system gain) and bandwidth or the directivity and Q-factor.

Physical bounds on arbitrarily shaped antennas were introduced in Gustafsson et al. (2007a) and further developed in Gustafsson et al. (2009b), Derneryd et al. (2009), Gustafsson et al. (2010), Sohl and Gustafsson (2008), Gustafsson and Sohl (2009), and Gustafsson (2011). These results are based on the forward scattering sum rule (Sohl et al. 2007; Gustafsson 2010b) that states that the all-spectrum interaction between objects and electromagnetic fields is proportional to the electro-, $\boldsymbol{\gamma}_{\mathrm{e}}$, and magneto-static, $\boldsymbol{\gamma}_{\mathrm{m}}$, polarizability dyadics, i.e.,

$$\frac{1}{\pi}\int_{\mathbb{R}} \frac{\sigma_{\mathrm{a}}(k)+\sigma_{\mathrm{s}}(k)}{k^2}\,\mathrm{d}k = \hat{\boldsymbol{e}}^{*}\cdot\boldsymbol{\gamma}_{\mathrm{e}}\cdot\hat{\boldsymbol{e}} + (\hat{\boldsymbol{r}}\times\hat{\boldsymbol{e}}^{*})\cdot\boldsymbol{\gamma}_{\mathrm{m}}\cdot(\hat{\boldsymbol{r}}\times\hat{\boldsymbol{e}}) \tag{20}$$

for all objects composed of linear, passive, and time-translational invariant media (Sohl et al. 2007; Gustafsson and Sohl 2009; Gustafsson 2010b). Here, σ_{a} and σ_{s} are the absorption and scattering cross sections, respectively. This identity was derived for dielectric spheroids in Purcell (1969) and generalized to arbitrary objects and polarizations in Sohl et al. (2007), Gustafsson and Sohl (2009), and Gustafsson (2010b), see also Eq. 12.

An antenna identity is obtained from the forward scattering sum rule by using reciprocity and the relation between the effective aperture (or absorption cross section) and partial directivity for lossless antennas:

$$\sigma_{\mathrm{a}}(k,\hat{\boldsymbol{r}},\hat{\boldsymbol{e}}) = \frac{\pi}{k^2}\Big(1-|\Gamma(k)|^2\Big)D(k,-\hat{\boldsymbol{r}},\hat{\boldsymbol{e}}). \tag{21}$$

Combining Eqs. 20 and 21 gives

$$\int_0^{\infty} \frac{\Big(1-|\Gamma(k)|^2\Big)D(k,\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})}{k^4}\,\mathrm{d}k = \frac{\eta}{2}(\hat{\boldsymbol{e}}\cdot\boldsymbol{\gamma}_{e}\cdot\hat{\boldsymbol{e}} + (\hat{\boldsymbol{r}}\times\hat{\boldsymbol{e}})\cdot\boldsymbol{\gamma}_{\mathrm{m}}\cdot(\hat{\boldsymbol{r}}\times\hat{\boldsymbol{e}})), \tag{22}$$

for the linear polarization $\hat{\boldsymbol{e}}$, where the generalized (or all spectrum) absorption efficiency η (Gustafsson et al. 2007a, 2009b; Gustafsson 2010b) is introduced. This is further transformed to a bound on the D/Q (directivity bandwidth product) expressed in terms of the high-contrast polarizability dyadic, $\boldsymbol{\gamma}_{\infty} \geq \boldsymbol{\gamma}_{\mathrm{e}}$ by assuming a resonance model (Gustafsson et al. 2007a, 2009b) and

$$\frac{D}{Q} \leq \frac{\eta k^3}{2\pi}\hat{\boldsymbol{e}}\cdot\boldsymbol{\gamma}_{\infty}\cdot\hat{\boldsymbol{e}} \leq \frac{\eta k^3}{2\pi}\max\operatorname{eig}\boldsymbol{\gamma}_{\infty} \tag{23}$$

for nonmagnetic media, $\boldsymbol{\gamma}_{\mathrm{m}} = \mathbf{0}$ (see Gustafsson et al. 2007a, 2009b for the case of electric and magnetic media). The lower bound on the Q-factor

$$Q \geq \frac{6\pi}{k^3 \max\operatorname{eig}\ \boldsymbol{\gamma}_{\infty}} \tag{24}$$

is based on the fact that small electric dipoles have directivity $D = 3/2$ and generalized absorption efficiency $\eta \leq 1/2$ (Gustafsson et al. 2010). Results similar to those introduced in this paragraph are

derived by Yaghjian and Stuart (2010) using antenna current optimization (Gustafsson et al. 2012a) (see also Vandenbosch 2011; Thal 2012; Yaghjian et al. 2013). This bound is identical to that derived by Thal (2006) for small spherical structures in Eq. 18 with electric currents radiating as an electric dipole, i.e.,

$$Q \geq \frac{3}{2k^3a^3} = \frac{3}{2}Q_{\text{Chu}} \quad \text{for} \quad ka \ll 1\,, \tag{25}$$

where the high-contrast polarizability dyadic $\boldsymbol{\gamma}_\infty = 4\pi a^3\mathbf{I}$ for a sphere with the radius a is used.

The computed bounds Eqs. 23 and 24 for spheroids (Gustafsson et al. 2007a), cylinders (Gustafsson et al. 2009b), planar rectangles (Gustafsson et al. 2009b), and planar ellipses (Gustafsson 2011) are depicted in Fig. 14. The Chu (Eq. 15) and Thal (Eq. 18) bounds for $ka \ll 1$ are also included for comparison. The results illustrate how the bound depends on the shape and polarization of the electric field. The spheroid simplifies to a sphere for $\ell_1 = \ell_2$ with the bound $D/(Qk^3a^3) = 1$ that is identical to the result in Eqs. 18 and 25 by Thal (2006) using the directivity $D = 3/2$. Several antennas are compared with the bound in Fig. 15 (see also Gustafsson et al. 2009b, 2010; Best 2009; Shahpari et al. 2014). The comparisons show that many antennas perform close to the bounds.

The forward scattering identity in Eq. 20 and bound in Eq. 23 show that the antenna performance is proportional to the polarizability of the antenna structure. Polarizability quantifies the charge-separation properties of a structure, i.e., the induced dipole moment is proportional to the polarizability, $\boldsymbol{p} = \epsilon_0\boldsymbol{\gamma}_{\text{e}} \cdot \boldsymbol{E}$. For example, large metallic regions at the extremities of an antenna increase the maximum achievable D/Q-performance of that antenna, for linear polarization in the direction of the antenna extremities. This is illustrated for a planar capped dipole structure in Fig. 16 (see also Gustafsson et al. 2009a). The polarizability for a planar square metallic rectangle in the xy-plane with side lengths ℓ is $\boldsymbol{\gamma}_\infty \approx 1.04\ell^3(\hat{\boldsymbol{x}}\hat{\boldsymbol{x}} + \hat{\boldsymbol{y}}\hat{\boldsymbol{y}})$. The polarizability for the capped dipole, $\boldsymbol{\gamma}_\infty \approx \ell^3(0.51\hat{\boldsymbol{x}}\hat{\boldsymbol{x}} + 0.93\hat{\boldsymbol{y}}\hat{\boldsymbol{y}})$, is lower as some metal is removed. The polarizability is higher in the $\hat{\boldsymbol{y}}$ -direction than in the $\hat{\boldsymbol{x}}$-direction as the metal strips at the edges allow a large charge separation in the $\hat{\boldsymbol{y}}$-direction. This is further illustrated in the right part of Fig. 16, where the polarizability for planar capped dipoles with area A is depicted. Note that the capped dipoles have zero volume and that the polarizability reduces with approximately a factor of 3, whereas the area decreases a factor of 10^4. The antenna performance for an electric dipole antenna is hence not simply related to the volume or area but to the structures' ability to separate charge.

Closed-form expressions are available for the polarizability dyadics of structures such as spheroids, planar ellipses, half spheres, etc. (Jones 1945; Sohl et al. 2007; Kleinman and Senior 1986; Sihvola et al. 2004). An illustrative example is given by the polarizability of a dielectric sphere with radius a (Jackson 1999; Van Bladel 2007; Cheng 1989; Griffiths 1999), i.e.,

$$\boldsymbol{\gamma}_{\text{e}} = 4\pi a^3\frac{\epsilon_{\text{r}} - 1}{\epsilon_{\text{r}} + 2}\mathbf{I} \leq 4\pi a^3\mathbf{I} = \boldsymbol{\gamma}_\infty. \tag{26}$$

This simple example illustrates two important properties of the polarizability dyadic with implications for antenna design, i.e., the polarizability is increasing in the relative permittivity ϵ_{r} and the size a (Jones 1985; Sjöberg 2009). For other structures the polarizability is calculated numerically using the method of moments (Gustafsson 2011; Helsing and Perfekt 2013; Shahpari et al. 2013) or the finite element method (Sohl et al. 2007). The polarizability and the associated bound on D/Q are approximated by rational functions for cylinders and planar rectangles in Gustafsson (2011); see also the MATLAB code (Gustafsson 2010a).

The forward scattering bounds are generalized to electric and magnetic media by inclusion of the magnetic polarizability $\boldsymbol{\gamma}_{\text{m}}$ in Eqs. 23 and 24 (see Gustafsson et al. 2007a, 2009b). The generalization to

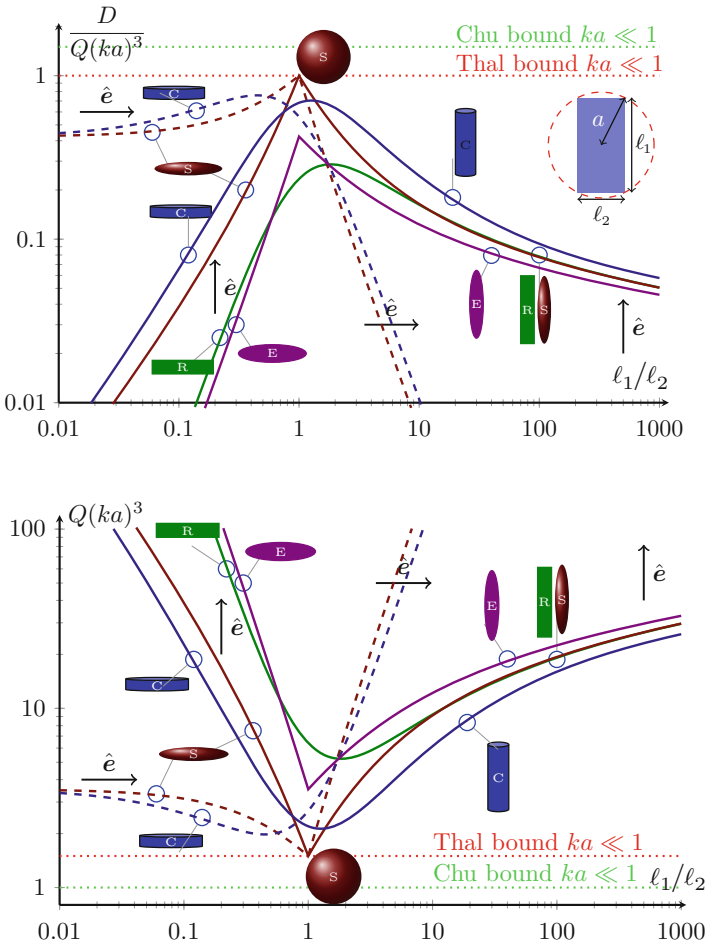

Fig. 14 Forward scattering bound on D/Q (*top*) and Q (*bottom*) normalized with $(ka)^3$ for nonmagnetic spheroids, cylinders, planar rectangles, and planar ellipses with height ℓ_1 and width ℓ_2 (Gustafsson 2011) using $\eta = 1/2$. Vertical polarization in *solid lines* and horizontal polarization in *dashed lines*

elliptic polarization is discussed in Gustafsson and Sohl (2009). Ultra-wideband and multiband antennas are analyzed in Sohl and Gustafsson (2008), and Derneryd et al. (2009). The main drawback with the forward scattering results in Gustafsson et al. (2007a, 2009b) is that they are only useful when the entire volume can be used for the antenna design. They are therefore not useful for antennas integrated (or embedded) into devices such as mobile phones and laptops.

Antenna Current Optimization

Optimization can be used to handle simultaneous requirements on the performance and size of complex radiating structures. Here, a typical wireless device structure composed of an antenna region and a ground plane (see Fig. 17, and Fig. 21) is considered. The entire structure occupies the volume denoted by V and consists of, e.g., screen, battery, electronics, RF circuitry, antenna(s), etc., for a mobile phone. The antenna, which is part of the structure, is restricted to the region occupying the volume V_A. The antenna designer is assumed to be allowed to specify the spatial distribution of metal and dielectrics in the region V_A. The electromagnetic properties of the remaining region $V_G = V - V_A$ is assumed to be fixed. The discussion is restricted to electric current densities and use of the stored energy expression Eqs. 9 and 10.

Physical bounds are determined for arbitrarily shaped antennas inside of a box in the presence of a fixed structure outside of the box. (*Right*) Current optimization with controllable current in the antenna region (the *box*) and induced current in the remaining structure (here the ground plane)

Magnetic current densities can in many cases lower the bounds on Q and can be analyzed using the stored energy expressions in Jonsson and Gustafsson (2015).

Many antenna design requirements can be formulated as optimization problems. These problems can be further reformulated as optimization problems in terms of antenna current distributions. An example is presented in the following.

Antenna design. From the antenna design perspective, the optimization problem is to design an antenna by proper shaping and choosing of the materials in the antenna region for optimal performance. The current and voltage in one or more feed points determine the matching properties of the antenna. The current distribution in the entire radiating structure determines the radiation properties.

Current distribution. In terms of current density, the antenna optimization problem is to determine the currents in the antenna region that yield optimal performance. These currents are determined without considering the feeding structures such that only radiation properties of the antenna are quantified in the performance of the antenna.

Maximization of G/Q

The partial gain Q-factor quotient is

$$\frac{G(\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})}{Q}=\frac{4\pi P(\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})}{2\omega\max\{W_{\mathrm{e}},W_{\mathrm{m}}\}}=\frac{\pi|\hat{\boldsymbol{e}}^{*}\cdot\boldsymbol{F}(\hat{\boldsymbol{r}})|^{2}}{\omega\eta_{0}\max\{W_{\mathrm{e}},W_{\mathrm{m}}\}}, \tag{27}$$

where $P(\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})$ is the partial radiation intensity for the polarization $\hat{\boldsymbol{e}}$ and direction $\hat{\boldsymbol{r}}$, $\boldsymbol{F}(\hat{\boldsymbol{r}})$ is the far field (Eq. 7), W_{e} is the stored electric energy (Eq. 9), and W_{m} is the stored magnetic energy (Eq. 10). The quantities in Eq. 27 are approximated using a method of moments approach and expanding the current density on the antenna in terms of local basis functions (Eq. 40), as

$$\begin{aligned}
&\hat{\boldsymbol{e}}^{*}\cdot\boldsymbol{F}\approx\mathbf{F}\mathbf{I} && \text{far field in direction } \hat{\boldsymbol{r}} \text{ and polarization } \hat{\boldsymbol{e}},\\
&W_{\mathrm{e}}\approx\frac{1}{4\omega}\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I} && \text{stored E-energy, } \mathbf{X}_{\mathrm{e}} \text{ electric reactance,}\\
&W_{\mathrm{m}}\approx\frac{1}{4\omega}\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I} && \text{stored M-energy, } \mathbf{X}_{\mathrm{m}} \text{ magnetic reactance.}
\end{aligned}$$

The partial gain Q-factor ratio (Eq. 27) becomes

$$\frac{G(\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})}{Q}\approx\frac{4\pi|\mathbf{F}\mathbf{I}|^{2}}{\eta_{0}\max\left\{\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I},\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I}\right\}}. \tag{28}$$

DOI 10.1007/978-981-4560-75-7_18-1

It is assumed that the MoM approximation is sufficiently accurate for the purpose of the analysis.

The optimization problem of maximizing the G/Q ratio in Eq. 28 can be formulated as the problem of minimizing the stored energy for a fixed partial radiation intensity

$$\begin{array}{ll} \text{minimize}_{\mathbf{I}} & \max\left\{\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I}, \mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I}\right\} \\ \text{subject to} & |\mathbf{F}\mathbf{I}|^2 = 1, \end{array} \tag{29}$$

where the normalization $|\mathbf{F}\mathbf{I}|^2 = 1$ or equivalently $|\mathbf{F}\mathbf{I}| = 1$ is used. The formulation in Eq. 29 is possible due to the scaling invariance of G/Q in terms of the current matrix $\mathbf{I}$, i.e., G/Q is invariant for the complex scaling $\mathbf{I} \rightarrow \alpha\mathbf{I}$. Moreover, this scaling invariance shows that an arbitrary phase $\mathbf{F}\mathbf{I} = 1$ that removes the absolute value operation (Gustafsson and Nordebo 2013) can be considered. The convex optimization problem of minimizing the stored energy for a fixed partial far field in one direction (Gustafsson and Nordebo 2013), i.e.,

$$\begin{array}{ll} \text{minimize}_{\mathbf{I}} & \max\left\{\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I}, \mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I}\right\} \\ \text{subject to} & \mathbf{F}\mathbf{I} = 1 \end{array} \tag{30}$$

is obtained. Let $\mathbf{I}_{\mathrm{o}}$ denote a current matrix that solves Eq. 30. The minimum value of the stored energy in Eq. 30 is unique although the current matrix $\mathbf{I}_{\mathrm{o}}$ is not necessarily unique. This optimum current gives an upper bound on G/Q for the considered direction $\hat{\boldsymbol{r}}$ and polarization $\hat{\boldsymbol{e}}$, i.e.,

$$\frac{G(\hat{\boldsymbol{r}}, \hat{\boldsymbol{e}})}{Q} \leq \left.\frac{G(\hat{\boldsymbol{r}}, \hat{\boldsymbol{e}})}{Q}\right|_{\mathrm{ub}} = \frac{4\pi|\mathbf{F}\mathbf{I}_{\mathrm{o}}|^2}{\eta_0 \max\left\{\mathbf{I}_{\mathrm{o}}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I}_{\mathrm{o}}, \mathbf{I}_{\mathrm{o}}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I}_{\mathrm{o}}\right\}}. \tag{31}$$

Alternative formulations are available for the convex optimization problem in Eq. 30 (Gustafsson and Nordebo 2013). These formulations can be solved with, e.g., CVX (Grant and Boyd 2011), a dual formulation (Gustafsson et al. 2014b), etc. (see Gustafsson and Nordebo 2013 and Gustafsson et al. 2015 for illustrations).

The optimization problem in Eq. 30 can be solved analytically in the limit of small antennas (Gustafsson et al. 2012a), giving

$$\frac{G(\hat{\boldsymbol{r}},\hat{\boldsymbol{e}})}{Q} \leq \frac{k^3}{4\pi}\hat{\boldsymbol{e}}^* \cdot \boldsymbol{\gamma}_\infty \cdot \hat{\boldsymbol{e}} \quad \text{as} \quad ka \rightarrow 0 \tag{32}$$

for the case of electric, $W_{\mathrm{e}} \geq W_{\mathrm{m}}$, antennas. This result confirms the forward scattering bounds in Eqs. 23 and 24, as also illustrated in Fig. 14. The general case with electric and magnetic current densities is analyzed in Yaghjian et al. (2013) and Jonsson and Gustafsson (2015) and shows that the electric polarizability dyadic in Eq. 32 is replaced with the sum of the electric and magnetic polarizability dyadics. The lower bound on the Q-factor for electric dipoles is (Yaghjian et al. 2013; Jonsson and Gustafsson 2015)

$$Q \geq \frac{6\pi}{k^3 \max \operatorname{eig}\left(\boldsymbol{\gamma}_{\mathrm{e}} + \boldsymbol{\gamma}_{\mathrm{m}}\right)} \quad \text{as} \quad ka \rightarrow 0 \tag{33}$$

(see Yaghjian et al. 2013; Jonsson and Gustafsson 2015 for additional cases and examples).

DOI 10.1007/978-981-4560-75-7_18-1

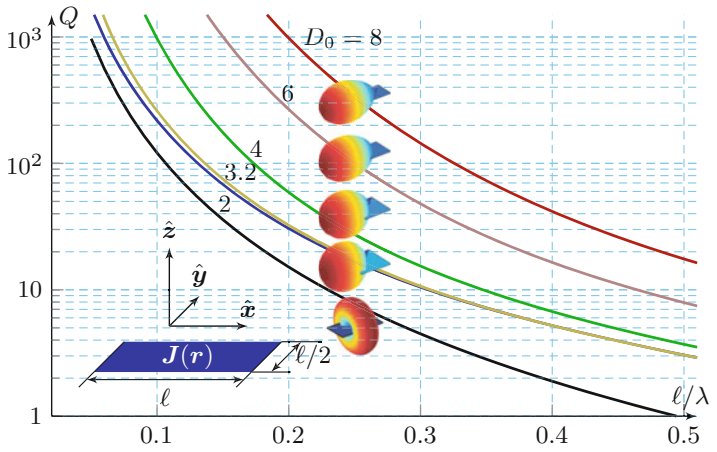

Fig. 18 Illustration of the physical bound on the Q-factor for antennas constrained to a planar rectangle with length ℓ and width $\ell/2$ that radiates with directivity $D(\hat{\boldsymbol{x}}) \geq D_0$ for $D_0 = \{2, 3.2, 4, 6, 8\}$ (see Gustafsson and Nordebo 2013)

Superdirectivity and Prescribed Radiation Patterns

Antennas with a higher directivity than typical antennas of the same size are often referred to as superdirective antennas (Best et al. 2008; Hansen 2006; Kim et al. 2012; Margetis et al. 1998). The increase of the Q-factor for small antennas with high directivity is analyzed by adding the constraint $D \geq D_0$ to Eq. 30. Written in the far field, the partial directivity is at least D_0 if

$$D_0 \leq D = \frac{4\pi|\hat{\boldsymbol{e}}^* \cdot \boldsymbol{F}(\hat{\boldsymbol{r}})|^2}{2\eta_0 P_{\mathrm{r}}} \Rightarrow P_r \leq \frac{2\pi|\hat{\boldsymbol{e}}^* \cdot \boldsymbol{F}(\hat{\boldsymbol{r}})|^2}{\eta_0 D_0}. \tag{34}$$

This is added as the convex constraint $\frac{1}{2}\mathbf{I}^{\mathrm{H}}\mathbf{R}\mathbf{I} \leq 2\pi/(\eta_0 D_0)$ to the optimization problem Eq. 30, giving

$$\begin{array}{ll} \text{minimize}_{\mathbf{I}} & \max\left\{\mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{e}}\mathbf{I}, \mathbf{I}^{\mathrm{H}}\mathbf{X}_{\mathrm{m}}\mathbf{I}\right\} \\ \text{subject to} & \mathbf{F}\mathbf{I} = 1 \\ & \mathbf{I}^{\mathrm{H}}\mathbf{R}\mathbf{I} \leq \dfrac{4\pi}{\eta_0 D_0}. \end{array} \tag{35}$$

This optimization problem is solved using CVX (Grant and Boyd 2011) for a planar rectangle with side lengths ℓ and $\ell/2$, and $D_0 = \{2, 3.2, 4, 6, 8\}$. The minimum Q-factor, for a radiated field with the partial directivity at least D_0 in the $\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}}$-direction for the polarization $\hat{\boldsymbol{e}} = \hat{\boldsymbol{y}}$, is depicted in Fig. 18. These Q-factors are compared to the Q-factor in Eq. 24 obtained from the forward scattering bound on D/Q in Eq. 23 for the same rectangle. In the forward scattering bound, it is assumed that the antennas radiate as electric dipoles. Under this assumption, the directivity is 1.5 in a direction normal to the plane of the structure (see Fig. 18), and the generalized absorption efficiency is $\eta = 1/2$ (Gustafsson et al. 2009b; Gustafsson 2010a). Note that the constraints $D \geq D_0 = \{4, 6, 8\}$ yield optimum current densities with directivities $D = D_0$. However, the constraint $D \geq 2$ results in an optimum current that contributes both an electric and a magnetic dipole such that the directivity is $D \geq 2.9$, for $\ell/\lambda \geq 0.05$; see the curves labeled 2 and 3.2 in Fig. 18.

Embedded Antennas

The antenna current optimization method can be generalized to derive bounds for antennas embedded in devices, e.g., as that depicted in Fig. 17. This generalization is based on decomposing the current density

DOI 10.1007/978-981-4560-75-7_18-1

into the controllable currents, $\boldsymbol{J}_{\mathrm{A}}$, and induced currents, $\boldsymbol{J}_{\mathrm{G}}$, (Gustafsson and Nordebo 2013; Cismasu and Gustafsson 2014a, b). A region of the considered device, V_{A} (see Fig. 21), is reserved for a structure that can be engineered by, e.g., optimization, manual or computer-aided design, etc. The currents in this region, $\boldsymbol{J}_{\mathrm{A}}$, are considered controllable. The remaining part of the device, V_{G} is considered fixed such that it supports the induced current density $\boldsymbol{J}_{\mathrm{G}}$. Due to the linearity of Maxwell's equations, $\boldsymbol{J}_{\mathrm{G}}$ depends linearly on $\boldsymbol{J}_{\mathrm{A}}$. This dependence can be written $\boldsymbol{J}_{\mathrm{G}} = \mathbf{C}\boldsymbol{J}_{\mathrm{A}}$, where $\mathbf{C}$ is determined from, e.g., the MoM impedance matrix (Peterson et al. 1998; Jin 2011; Johnson and Rahmat-Samii 1999). The bounds on the G/Q of a rectangular, infinitely thin, perfect electric conducting (PEC) device with the dimensions ℓ and $\ell/2$ in which the region with controllable currents may occupy 6 %, 10 %, and 25 % of the device at one end in the ℓ direction are depicted in Fig. 19. These bounds are compared to the bound of the entire structure obtained from the forward scattering sum rule described in section "Forward Scattering Sum Rule" (see also Gustafsson et al. 2007a, 2009b; Gustafsson 2010a). Other cases of embedded devices and details can be found in Gustafsson et al. (2014b), Cismasu and Gustafsson (2014a,b), and Cismasu et al. (2014).

Periodic Array Antennas

Sum rules are used to derive limitations on the bandwidth for array antennas in Doane et al. (2013) and Jonsson et al. (2013). The bandwidth of infinite periodic array antennas is limited by the thickness of the array. Consider a periodic array antenna with thickness d above a PEC ground plane; see Fig. 20. The antenna performance is analyzed in receiving mode by assuming a reciprocal lossless antenna with scattering reflection coefficient, ρ, of equal amplitude as the reflection coefficient in the feed Eq. 1, i.e., $|\Gamma| = |\rho|$. Here, the fundamental mode of the reflected wave is considered. This transforms the antenna to an absorber and the sum rule (Rozanov 2000; Doane et al. 2013; Jonsson et al. 2013)

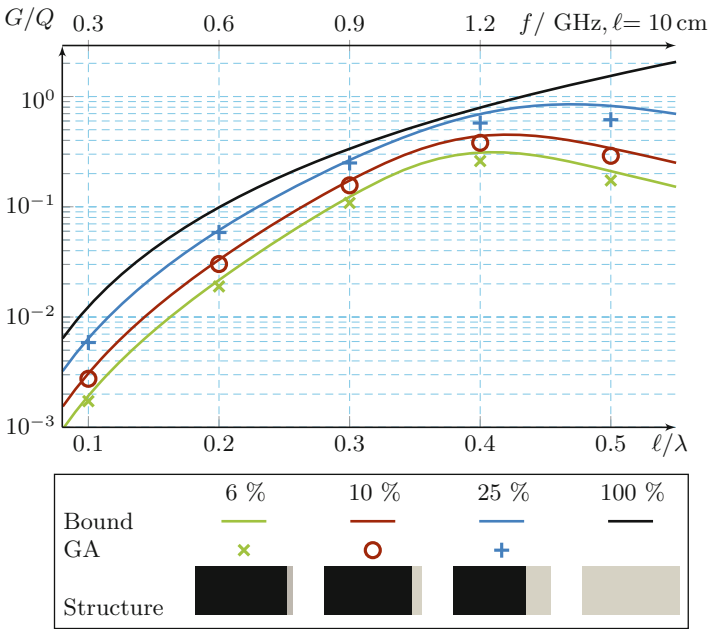

Fig. 19 GA-optimized antenna G/Q ratios (Eq. 28), *marks*, compared with physical bounds on G/Q obtained with a formulation equivalent to Eq. 30 for a rectangular wireless device model in which the antenna may occupy 6 %, 10 %, and 25 % of the device at one end; see Fig. 17. The physical bound on the G/Q ratio of a rectangular, infinitely thin, PEC sheet (Gustafsson et al. 2007a, 2009b; Gustafsson 2010a) is labeled "100 %." *Gray-shaded areas* have controllable currents

DOI 10.1007/978-981-4560-75-7_18-1

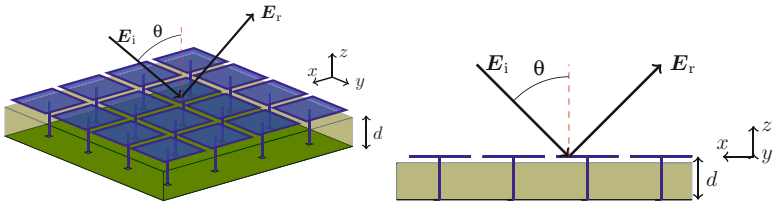

Fig. 20 Periodic array antenna above a PEC ground plane

$$\frac{1}{\pi}\int_{\mathbb{R}} \frac{1}{k^2}\ln\frac{1}{|\rho(k)|}\,\mathrm{d}k \le d\left(1+\frac{\gamma}{2dA}\right) \le d\ \max\{\mu_r\}\begin{cases}\cos\theta & \text{TE}\\ 1/\cos\theta & \text{TM}\end{cases} \tag{36}$$

first derived by Rozanov (2000) for layered structures with $\max\{\mu_r\}$, denoting the maximal static relative permeability of the structure. Here, the low-frequency expansion from Gustafsson and Sjöberg (2011) is used to extend the results to periodic structures.

The sum rule is transformed to the bandwidth bound (Rozanov 2000; Doane et al. 2013; Jonsson et al. 2013)

$$\lambda_2-\lambda_1 \le \frac{2\pi^2 d\max\{\mu_r\}}{\ln|\Gamma_0|^{-1}}\begin{cases}\cos\theta & \text{TE}\\ 1/\cos\theta & \text{TM}\end{cases} \tag{37}$$

for linearly polarized waves, where Γ_0 denotes the threshold level for the reflection coefficient over the wavelength interval $[\lambda_1, \lambda_2]$. Array antennas are analyzed and compared with antenna designs in Doane et al. (2013) and Jonsson et al. (2013). An array figure of merit is also introduced in Jonsson et al. (2013).

Conclusion

Physical bounds on antennas answer questions such as: *how good can an antenna be*? Antenna bounds have evolved from spherical regions (1948) to arbitrary-shape structures (2007) and embedded structures (2013). Here, an overview of methods based on circuit models, mode expansions, sum rules, and optimization and a discussion of some of their pros and cons are presented. This characterization is chosen to emphasize the key characteristics of the majority of the published methods for the study of physical bounds.

All presented bounds are based on assumptions. The forward scattering bounds are, e.g., based on the assumption of linear, reciprocal, time-translational invariant material parameters. These assumptions are valid for most antennas but switches and non-Foster matching can potentially be used to overcome the limitations (Ziolkowski et al. 2013). Moreover, bounds based on the stored energy, such as the Chu bound Eq. 15 and the antenna current optimization in section "Antenna Current Optimization," assume that the stored energy can be determined accurately using Eqs. 8, 9, and 10. There are initial investigations on the stored energy expressions (Hazdra et al. 2011; Gustafsson and Jonsson 2015a, b; Gustafsson et al. 2014a), but much work remains before the stored energy is fully understood.

The D/Q and Q-factor limits for small electric dipole antennas composed of nonmagnetic materials are well understood. There are several independent derivations that provide similar results (Gustafsson et al. 2007a, 2009b, 2010, 2012a; Gustafsson and Nordebo 2013; Yaghjian and Stuart 2010; Yaghjian et al. 2013; Vandenbosch 2011); see also Eqs. 23 and 32 for this case. In addition, many antenna designs are shown to perform close to the bounds (see Gustafsson et al. 2009b, 2010; Best 2009; Shahpari

DOI 10.1007/978-981-4560-75-7_18-1

et al. 2013; Fig. 15). Antennas embedded in finite PEC structures are investigated in Cismasu and Gustafsson (2014a, b) and are also shown to perform close to the bounds. The D/Q results for electric dipole antennas work well up to about half-a-wavelength-sized structures ($ka \approx 1.5$) (Gustafsson et al. 2009b, 2010). The corresponding lower bounds on the Q-factor for larger structures are not well understood, except for the case with prescribed radiation patterns, e.g., dipole patterns (Chu 1948; Thal 2006; Gustafsson and Nordebo 2013).

Although there has been a strong development on the physical bounds in recent years, there are still many open questions. The case with mixed electric and magnetic dipole patterns, magnetic materials, and superdirective antennas Eq. 35 are not as well understood in the sense of realized antenna designs although there are some suggested designs. Efficiency is the most important small antenna parameter besides bandwidth. There are only some initial investigations for lossy structures (Gustafsson 2013), so much work remains on fundamental limitations for efficiency.

A Radial Functions

The radial functions in Hansen (1988) are defined as

$$\mathrm{R}_{\tau n}^{(p)}(\kappa) = \begin{cases} z_n^{(p)}(\kappa) & \tau = 1 \\ \dfrac{1}{\kappa} \dfrac{\partial\left(\kappa z_n^{(p)}(\kappa)\right)}{\partial \kappa}, & \tau = 2, \end{cases} \tag{38}$$

where $z_n^{(1)} = \mathrm{j}_n$ are Bessel functions, $z_n^{(2)} = \mathrm{n}_n$ Neumann functions, $z_n^{(3)} = \mathrm{h}_n^{(1)}$ Hankel functions (Hansen 1988), and $\kappa = ka$. The derivatives of $\mathrm{R}_{\tau n}^{(p)}(\kappa)$ are easily expressed in spherical Bessel and Hankel functions as

DOI 10.1007/978-981-4560-75-7_18-1

$$\frac{\partial \mathrm{R}_{\tau n}^{(p)}}{\partial \kappa} = \begin{cases} \dfrac{\partial}{\partial \kappa} z_n^{(p)} & \tau = 1 \\ \dfrac{-\mathrm{R}_{\tau n}^{(p)}}{\kappa} + \dfrac{n(n+n) - \kappa^2}{\kappa^2} z_n^{(p)} & \tau = 2. \end{cases} \tag{39}$$

B High-Contrast Polarizability Dyadics

The high-contrast polarizability dyadic $\boldsymbol{\gamma}_\infty$ is determined from the induced normalized surface charge density, ρ, as

$$\hat{\boldsymbol{e}} \cdot \boldsymbol{\gamma}_\infty \cdot \hat{\boldsymbol{e}} = \frac{1}{E_0} \int_S \hat{\boldsymbol{e}} \cdot \boldsymbol{r} \rho(\boldsymbol{r}) \ \mathrm{dS},$$

where ρ satisfies the integral equation

$$\int_S \frac{\rho(\boldsymbol{r}_1)}{4\pi |\boldsymbol{r} - \boldsymbol{r}_1|} \ \mathrm{dS}_1 = E_0 \boldsymbol{r} \cdot \hat{\boldsymbol{e}} - V$$

with the constraint of zero total charge

$$\int_S \rho(\boldsymbol{r}) \ \mathrm{dS} = 0.$$

used to determine the voltage V.

C Expansion in Terms of Basis Functions

Consider a surface S with current density $\boldsymbol{J} = \boldsymbol{J}(\boldsymbol{r})$; see Fig. 7. Expand the current density in local basis functions

$$\boldsymbol{J}(\boldsymbol{r}) \approx \sum_{n=1}^{N} I_n \boldsymbol{\psi}_n(\boldsymbol{r}) \tag{40}$$

and introduce the $N \times 1$ matrix $\mathbf{I}$ with elements I_n to simplify the notation. The basis functions are assumed to be real valued, divergence conforming, and having vanishing normal components at the boundary (Peterson et al. 1998). For embedded antennas, it is assumed that the currents $\boldsymbol{J}_\mathrm{A}$ in the antenna volume V_A are controllable and induce the currents $\boldsymbol{J}_\mathrm{G}$ in the volume V_G; see Fig. 21.

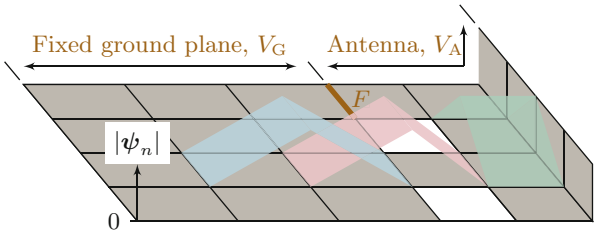

Fig. 21 Illustration of rectangular mesh element discretization and "rooftop" basis function amplitude for a three-dimensional radiating structure. Metal areas are depicted in gray shading. The amplitudes of three of the total $6 \times 3 + 5 \times 4 - 4 - 3$ basis functions are depicted in *blue*, *pink*, and *green shading*. The feeding edge is marked F

DOI 10.1007/978-981-4560-75-7_18-1

A standard MoM implementation of the EFIE using the Galerkin procedure computes the impedance matrix $\mathbf{Z} = \mathbf{R} + \mathrm{j}\mathbf{X}$ with the elements

$$\frac{Z_{mn}}{\eta_0} = \mathrm{j}\int_S\int_S \left(k^2\boldsymbol{\psi}_{m1}\cdot\boldsymbol{\psi}_{n2} - \nabla_1\cdot\boldsymbol{\psi}_{m1}\nabla_2\cdot\boldsymbol{\psi}_{n2}\right)\frac{e^{-\mathrm{j}kR_{12}}}{4\pi kR_{12}}\ \mathrm{dS}_1\,\mathrm{dS}_2,$$

where $\psi_{n1} = \psi_n(\boldsymbol{r}_1), \psi_{n2} = \psi_n(\boldsymbol{r}_2), n = 1,\ldots,N$, and $R_{12} = |\boldsymbol{r}_1 - \boldsymbol{r}_2|$. The differentiated MoM impedance matrix

$$\begin{aligned}\frac{k\partial Z_{mn}}{\eta_0\partial k} = \int_S\int_S &\mathrm{j}\left(k^2\boldsymbol{\psi}_{m1}\cdot\boldsymbol{\psi}_{n2} + \nabla_1\cdot\boldsymbol{\psi}_{m1}\nabla_2\cdot\boldsymbol{\psi}_{n2}\right)\frac{\mathrm{e}^{-\mathrm{j}kR_{12}}}{4\pi kR_{12}}\\ &+\left(k^2\boldsymbol{\psi}_{m1}\cdot\boldsymbol{\psi}_{n2} - \nabla_1\cdot\boldsymbol{\psi}_{m1}\nabla_2\cdot\boldsymbol{\psi}_{n2}\right)\frac{\mathrm{e}^{-\mathrm{j}kR_{12}}}{4\pi}\ \mathrm{dS}_1\mathrm{dS}_2\end{aligned}$$

is used to estimate the stored energy. The differentiated reactance matrix, $\mathbf{X}' = \mathrm{Im}\mathbf{Z}'$, gives the stored magnetic and electric energies

$$W_\mathrm{m} \approx \frac{1}{8}\mathbf{I}^\mathrm{H}\left(\frac{\partial\mathbf{X}}{\partial\omega} + \frac{\mathbf{X}}{\omega}\right)\mathbf{I} \quad \text{and} \quad W_\mathrm{e} \approx \frac{1}{8}\mathbf{I}^\mathrm{H}\left(\frac{\partial\mathbf{X}}{\partial\omega} - \frac{\mathbf{X}}{\omega}\right)\mathbf{I},$$

respectively. These expressions are identical to the stored energy expressions introduced by Vandenbosch (Vandenbosch 2010) using a MoM approximation (see also Harrington 1972; 1975). Introduce the electric $\mathbf{X}_\mathrm{e}$, and magnetic $\mathbf{X}_\mathrm{m}$, reactance matrices

$$\mathbf{X}_\mathrm{e} = \frac{1}{2}\left(\omega\frac{\partial\mathbf{X}}{\partial\omega} - \mathbf{X}\right) \quad \text{and} \quad \mathbf{X}_\mathrm{m} = \frac{1}{2}\left(\omega\frac{\partial\mathbf{X}}{\partial\omega} + \mathbf{X}\right).$$

The total radiated power is determined from $\mathbf{R} = \mathrm{Re}\{\mathbf{Z}\}$.

The far field Eq. 7 in the direction $\hat{\boldsymbol{r}}$ projected on $\hat{\boldsymbol{e}}$ is approximated by the $N \times 1$ matrix $\mathbf{FI} \approx \hat{\boldsymbol{e}}^* \cdot \boldsymbol{F}(\hat{\boldsymbol{r}})$ defined as

$$\mathbf{FI} \approx -\mathrm{j}k\eta_0\sum_{n=1}^{N} I_n\int_S \hat{\boldsymbol{e}}^*\cdot\boldsymbol{\psi}_n(\boldsymbol{r})\frac{\mathrm{e}^{\mathrm{j}k\hat{\boldsymbol{r}}\cdot\boldsymbol{r}}}{4\pi}\,\mathrm{dS}. \tag{41}$$

It is assumed that the numerical approximation is sufficiently accurate so the approximate equal to ($\approx$) above can be replaced with equalities.

D Numerical Results for the Presented Antennas

Numerical simulation data for the antennas presented in this chapter are collected in Table 1 for wire antennas and Table 2 for planar antennas.

Abstract

In this chapter, transmission-line-based metamaterials are presented, and their application to the design of passive and active antennas is outlined. Transmission-line metamaterials, also termed negative-refractive-index transmission-line (NRI-TL) metamaterials, are formed by periodically loading a transmission line with lumped-element series capacitors and shunt inductors, and it is shown that they can support both forward and backward waves, as well as standing waves with a zero propagation constant. These rich propagation characteristics form the underlying basis for their use in many antenna applications, including leaky-wave antennas, compact resonant antennas, and multiband antennas. The resonant characteristics of the NRI-TL metamaterial structures reveal how these structures can be designed to offer multiband responses whose resonant frequencies are not harmonically related while offering large degrees of miniaturization. Design equations for rapid prototyping are presented, enabling the simple design of metamaterial antennas to a given specification using standard microwave substrates and loading elements in either fully printed form or surface-mount chip components. A number of passive metamaterial antenna applications are presented, including examples of zeroth-order resonant antennas, negative-order resonant antennas, epsilon-negative antennas, mu-negative antennas, metamaterial dipole antennas, and metamaterial-inspired antennas. Active non-Foster matching networks for small antennas are also presented using negative impedance converters (NICs) and negative impedance inverters (NIIs), and it is demonstrated how these can be applied to metamaterial-inspired antennas. Finally, a new method of implementing reactive non-Foster elements using loss-compensated negative-group-delay (NGD) networks is presented that exhibits improved stability, dispersion, and achievable bandwidth.

Keywords

Negative-refractive-index transmission line (NRI-TL); Metamaterials; Electrically small antennas; Compact antennas; Resonant antennas; Planar antennas; Multiband antennas; Dispersion engineering; Composite right-/left-handed (CRLH) materials; Active antennas; Active non-Foster matching networks; Negative impedance converters; Negative impedance inverters

Introduction

The emergence of a new class of engineered electromagnetic materials, known as negative-refractive-index (NRI) metamaterials, realized using either split-ring resonators and wires or reactively loaded transmission lines, has generated great interest within the electromagnetics community, for their potential to create new devices that exhibit altogether new phenomena or improved performance characteristics compared to their conventional counterparts.

*Email: mantonia@ucy.ac.cy

DOI 10.1007/978-981-4560-75-7_21-1

The term NRI derives from the fact that these materials can have simultaneously negative material parameters (permittivity ϵ and permeability μ), and therefore a negative-refractive index, and as such they exhibit phenomena that are not readily encountered in nature, hence the prefix "meta." More generally, the material parameters can be engineered to have positive, negative, and zero values by what is known as "dispersion engineering." Furthermore, by controlling the material parameters as a function of space, this allows the electric and magnetic fields, and therefore the power flow, to be arbitrarily directed within a structure, which has opened up an entirely new field of "transformation optics" (Pendry et al. 2006). Some examples of unusual phenomena that have been obtained using metamaterials are the creation of a completely flat perfect lens (Pendry 2000), sub-wavelength resolution imaging beyond the diffraction limit (Grbic and Eleftheriades 2004), electromagnetic cloaking (Pendry et al. 2006; Zedler and Eleftheriades 2011), and backward-wave and broadside radiation from a planar leaky-wave structure (Grbic and Eleftheriades 2002; Iyer and Eleftheriades 2004).

The recent growth in metamaterial research has also resulted in an analogous increase in the amount of publications in this area. Notable among these are several books that have been published recently on metamaterials, each with a different focus (Eleftheriades and Balmain 2005; Engheta and Ziolkowski 2006; Caloz and Itoh 2006; Marques et al. 2007; Capolino 2009; Cui et al. 2010), and several antenna-related textbooks and handbooks that contain dedicated sections on metamaterials (Balanis 2008, 2012; Volakis 2007; Volakis et al. 2010). In general, metamaterials can be designed for either guided-wave applications (e.g., phase shifters, couplers, power dividers, resonators, etc.) or radiating applications (leaky-wave antennas, small resonant antennas, and active variants of these). The focus of this contribution is on *transmission-line*-based metamaterials, as these pertain to the design of passive and active resonant antennas.

The *transmission-line* approach to synthesizing NRI metamaterials relies on periodically loading conventional microwave transmission lines with lumped-element series capacitors and shunt inductors. This approach was introduced in Eleftheriades et al. (2002), Antoniades and Eleftheriades (2003), Caloz and Itoh (2003), and Sanada et al. (2004), and subsequently the materials were termed negative-refractive-index transmission-line (NRI-TL) metamaterials to reflect the fact that a negative-refractive index can be achieved by reactively loading a host transmission line. An example of such a two-dimensional NRI-TL metamaterial unit cell is shown in Fig. 1.

NRI-TL metamaterials have since proven to be very practical due to their planar nature and the large negative-index bandwidth and low transmission losses that can be achieved. Furthermore, as will be subsequently shown in this chapter, NRI-TL metamaterials exhibit propagation characteristics with

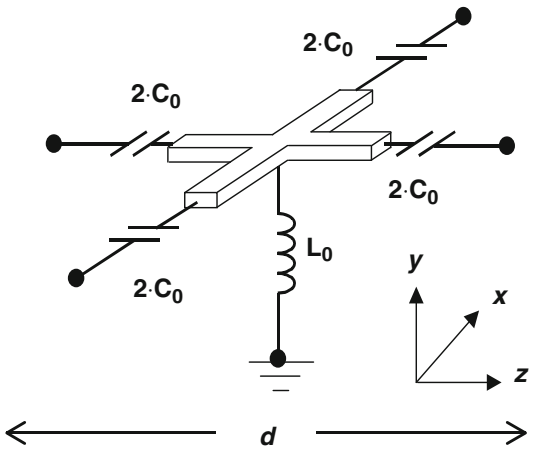

Fig. 1 Two-dimensional NRI-TL metamaterial unit cell (Iyer et al. 2003). © 2003 OSA

DOI 10.1007/978-981-4560-75-7_21-1

alternating stopbands and passbands, supporting backward waves in the left-handed band (NRI region), forward waves in the right-handed band (positive-refractive-index (PRI) region), and standing waves with a zero propagation constant between the left-handed and right-handed bands. These versatile propagation characteristics are a key element for the use of NRI-TL metamaterials in the design of multiband antennas, enabling the creation of tailored frequency responses. They also enable a large degree of miniaturization by exploiting the fact that the obtained zero propagation constant is independent of the length of the structure and the fact that in the backward-wave region, the propagation constant is inversely proportional to the frequency. The transmission-line approach to synthesizing NRI-TL metamaterials has also proven to be very useful for the integration of NRI-TL devices and antennas with other circuits on the same substrate, since they have a completely planar form factor.

Here, it should be noted that due to the relatively recent development of metamaterials, there are different terminologies that are used in the literature to denote these materials. Transmission-line based metamaterials have also been termed composite right-/left-handed (CRLH) materials (Lai et al. 2004), a terminology that reflects both their left-handed and right-handed propagation characteristics. Other designations for NRI media in which the effective permittivity and permeability are simultaneously negative include double-negative (DNG) media (Engheta and Ziolkowski 2006) and left-handed media (LHM) (Veselago 1968). Furthermore, single-negative (SNG) media denote media where one of the material parameters is negative and include two variants: epsilon-negative (ENG) media, where the permittivity ϵ is negative, and mu-negative (MNG) media where the permeability μ is negative. Finally, for epsilon-near-zero (ENZ) and epsilon-zero (EZR) media, the permittivity ϵ is near zero and zero, respectively, while for mu-near-zero (MNZ) and mu-zero (MZR) media, the permeability is near zero and zero, respectively.

Negative-Refractive-Index Transmission-Line Theory

NRI-TL Metamaterial Structure

In order to understand the operation of resonant antennas based on transmission-line metamaterials, the propagation and impedance properties of one-dimensional NRI-TL metamaterials will first be outlined. This allows the visualization of the different antenna modes that these metamaterials have to offer, while providing simple design equations for the design of single-band and multiband resonant antennas.

The one-dimensional NRI-TL metamaterial phase-shifting line shown in Fig. 2 has been constructed by periodically loading a host transmission line with a characteristic impedance of Z_0 with series capacitors C_0 and shunt inductors L_0. Here, $Z_0 = \sqrt{L/C}$, where L and C are the per unit length inductance and capacitance of the transmission line. It can be designed to occupy an arbitrary length and to provide an arbitrary phase shift, and has an inherent phase-compensating nature. This is because it incorporates both a transmission-line component with an equivalent low-pass topology that contributes a negative phase shift and a backward-wave component with a high-pass topology that contributes a positive phase shift.

The phase-shifting line consists of identical repeating symmetrical unit cells, where each of these unit cells can be considered to be a small NRI-TL metamaterial phase-compensating structure. Figure 3 shows two possible implementations of the elementary phase-compensating NRI-TL metamaterial unit cell; the T configuration was developed in Eleftheriades et al. (2002) and Antoniades and Eleftheriades (2003) and the Π configuration was subsequently developed in Elek and Eleftheriades (2005). It can be recognized that the T and Π unit cells are simply related by a shift of the reference planes defining each unit cell within the larger periodic structure shown in Fig. 2. As such, it is expected that their propagation characteristics will be identical, something which will be subsequently verified in the following section. The T unit cell has a host transmission line with characteristic impedance Z_0 and length d that is loaded with two series

DOI 10.1007/978-981-4560-75-7_21-1

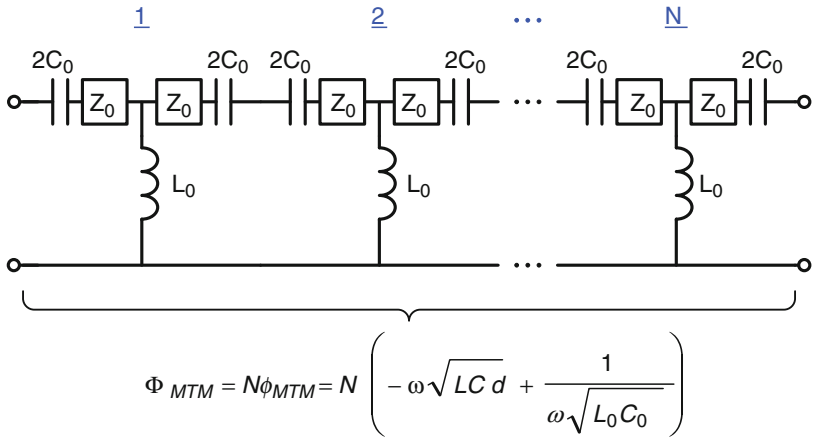

Fig. 2 *N*-stage NRI-TL metamaterial phase-shifting line

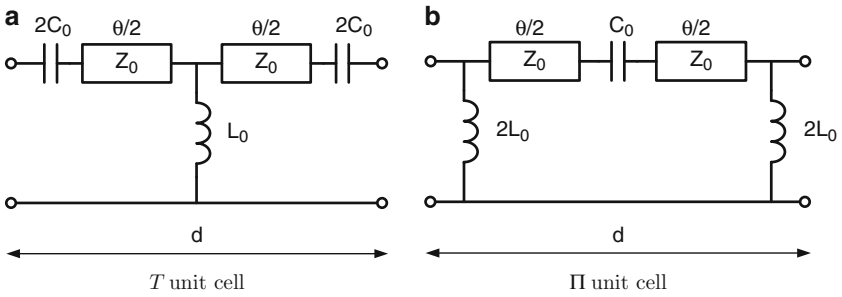

Fig. 3 NRI-TL metamaterial unit cells

capacitors $2C_0$ and a shunt inductor L_0, while the Π unit cell has a host transmission line also with characteristic impedance Z_0 and length d that is loaded with one series capacitor C_0 and two shunt inductors $2L_0$. The choice of which topology to use for a particular design mainly depends on the intended application and the technology in which the circuits are realized. Implementations of both unit cells will be shown in the section "Antenna Design Using TL-Metamaterials" for both microstrip and coplanar waveguide designs.

Propagation and Impedance Characteristics of the *T* Unit Cell

The propagation characteristics of a metamaterial line that consists of identical symmetric unit cells can be determined by conducting a periodic Bloch-Floquet analysis (Collin 1992) on each unit cell in Fig. 3. The details of the periodic analysis can be found in Antoniades (2004, 2009), and the key results are summarized here as these relate to the design of phase-shifting lines for antenna applications.

The dispersion relation for a periodic structure comprising an infinite number of metamaterial T unit cells as shown in Fig. 3a is

$$\cos(\beta_{BL}d) = \left(1 - \frac{1}{4\omega^2 L_0 C_0}\right)\cos(\theta) + \left(\frac{1}{2\omega C_0 Z_0} + \frac{Z_0}{2\omega L_0}\right)\sin(\theta) - \frac{1}{4\omega^2 L_0 C_0}. \quad (1)$$

Here, β_{BL} is the Bloch propagation constant for the periodic structure with periodicity d, as shown in Fig. 3. The Bloch propagation constant therefore provides a complete picture of the propagation characteristics of the periodic structure, which are typically displayed as a function of frequency on a dispersion diagram.

DOI 10.1007/978-981-4560-75-7_21-1

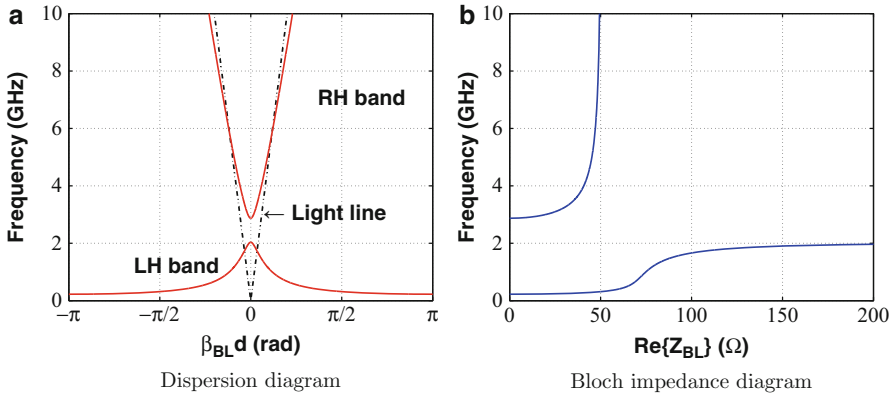

Fig. 4 Characteristics of a representative NRI-TL metamaterial T unit cell with parameters $C_0 = 5$ pF, $L_0 = 25$ nH, $Z_0 = 50\ \Omega$, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz. Note that in this case, $Z_{0,\mathrm{BW}} = \sqrt{L_0/C_0} > Z_0$

A representative dispersion diagram obtained using Eq. 1 is shown in Fig. 4a. It can be observed that the propagation characteristics of the structure exhibit alternating passbands and stopbands. The two passbands that are of interest are the lower left-handed (LH) band which supports backward waves and the upper right-handed (RH) band which supports forward waves. The light line is also shown in Fig. 4a, which demarcates the transition between slow-wave and fast-wave propagation. Therefore, the metamaterial structure supports backward and forward waves that can be either slow or fast. This indicates that the metamaterial can be used for either guided-wave applications in the slow-wave regions outside of the light cone (Islam and Eleftheriades 2007, 2012; Eleftheriades 2007; Lai et al. 2004) or leaky-wave antenna applications in the fast-wave region within the light cone (Antoniades and Eleftheriades 2008a; Mehdipour and Eleftheriades 2014; Hashemi and Itoh 2011). Furthermore, at the two frequency points where $\beta_{\mathrm{BL}} d = 0$, the metamaterial can also be used for resonant antenna applications. These, and additional resonant modes that can be excited on this structure, will be outlined in the section "Antenna Design Using TL-Metamaterials."

The characteristic impedance of the periodic structure, known as the Bloch impedance, is defined at the terminals of each unit cell and has positive and negative solutions, which correspond to the forward and reflected traveling waves, respectively. It should be noted that the Bloch impedance of a periodic structure is not unique and will depend on the location of the reference planes for each unit cell. Therefore it is expected that the two metamaterial unit cells of Fig. 3 will have different Bloch impedances. The Bloch impedance for the periodic structure comprising an infinite number of T metamaterial unit cells can be written as

$$Z_{\mathrm{BL,T}} = \pm \sqrt{\frac{\left(Z + \frac{Z^2 Y}{8} + \frac{Y Z_0^2}{2}\right)\cos(\theta) + \frac{j}{2}\left(\frac{Z^2 Y_0}{2} + Y Z Z_0 + 2Z_0\right)\sin(\theta) + \frac{Z^2 Y}{8} - \frac{Y Z_0^2}{2}}{\frac{Y}{2}\cos(\theta) + jY_0 \sin(\theta) + \frac{Y}{2}}}, \tag{2}$$

where

$$Z = \frac{1}{j\omega C_0} \quad \& \quad Y = \frac{1}{j\omega L_0}. \tag{3}$$

DOI 10.1007/978-981-4560-75-7_21-1

A representative Bloch impedance diagram for the metamaterial T unit cell obtained using Eq. 2 is shown in Fig. 4b. It can be observed that a real Bloch impedance exists only within the passbands of the periodic structure, while within the stopbands, the Bloch impedance is imaginary. It can also be observed that the Bloch impedance exhibits a large variation throughout the left-handed band and remains around 50 Ω for a very small frequency range. As such, the metamaterial structure will exhibit the undesirable feature of a very narrow impedance bandwidth when it is matched to a 50 Ω feed line, as is frequently done for antenna applications. On the contrary, in the right-handed band, the Bloch impedance converges to a constant value of 50 Ω as the frequency increases. This is a very desirable feature that enables broadband matching of the periodically loaded metamaterial line to a feed line or a terminating load.

In the design of the metamaterial unit cells, it is interesting to note that depending on the values of the elements loading the host transmission line, the Bloch impedance characteristics can be significantly different. In order to further understand the Bloch impedance behavior, the characteristic impedance of the host transmission line Z_0 must be compared with the characteristic impedance of the backward-wave line that loads the host TL, $Z_{0,\mathrm{BW}} = \sqrt{L_0/C_0}$. For the example shown in Fig. 4 with loading-element parameters of $C_0 = 5$ pF and $L_0 = 25$ nH, the characteristic impedance of the backward-wave line is $Z_{0,\mathrm{BW}} = 70.7$ Ω, which is greater than the characteristic impedance of the host transmission line, $Z_0 = 50$ Ω. Considering now the case where $Z_{0,\mathrm{BW}}$ is less than Z_0, the values of $C_0 = 15$ pF and $L_0 = 25$ nH are chosen, resulting in $Z_{0\ \mathrm{BW}} = 40.8$ Ω.

The dispersion and Bloch impedance diagrams for this second case are shown in Fig. 5. Here, it can be observed that even though the general dispersion characteristics are very similar to the ones shown in Fig. 4a, the Bloch impedance characteristics have changed significantly. Within the lower left-handed band, the Bloch impedance no longer passes through the 50 Ω point, but rather attains a maximum value of only 39 Ω, indicating that it is impossible to match the metamaterial line to 50 Ω within the lower left-handed band. This is an important consideration that should be taken into account when designing metamaterial lines using T unit cells with $Z_{0,\mathrm{BW}} < Z_0$. If, however, it is desired to match the line to 50 Ω within the upper right-handed band, then the T unit cell with $Z_{0,\mathrm{BW}} < Z_0$ is still an attractive option.

It can therefore be concluded that in order to obtain a Bloch impedance diagram of the form shown in Fig. 4b, where the metamaterial line consisting of T unit cells can be matched to a specific impedance (in this case $Z_0 = 50$ Ω) in both the lower left-handed and the upper right-handed bands, then the following condition must be satisfied:

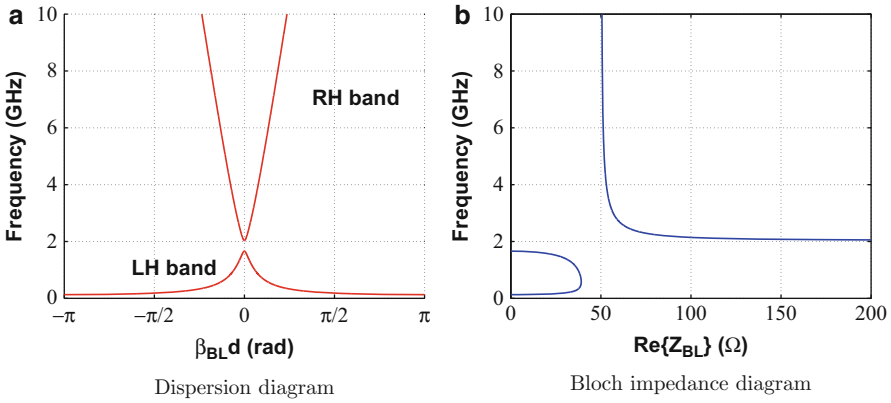

Fig. 5 Characteristics of a representative NRI-TL metamaterial T unit cell with parameters $C_0 = 15$ pF, $L_0 = 25$ nH, $Z_0 = 50$ Ω, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz. Note that in this case, $Z_{0,\mathrm{BW}} = \sqrt{L_0/C_0} < Z_0$

DOI 10.1007/978-981-4560-75-7_21-1

$$Z_{0,\mathrm{BW}} > Z_0 \quad \text{or} \quad \sqrt{\frac{L_0}{C_0}} > \sqrt{\frac{L}{C}}. \tag{4}$$

Relation to Compact Resonant Antennas

One might wonder how the analysis of an infinitely long periodic structure relates to the design of compact, resonant antennas that typically would consist of only a few unit cells. The answer lies in the fact that even though the above analysis was carried out assuming an infinitely long periodic structure, the propagation and impedance characteristics can be retained even for a finite structure, by simply terminating it on both ends in its Bloch impedance. This eliminates any reflections at the source and load and allows the propagating waves along the line to effectively see an infinite periodic medium. The periodic structure can therefore be made arbitrarily small, and in the extreme case it can consist of a single unit cell, without affecting its propagation and impedance characteristics, simply by ensuring that it is excited and terminated in its Bloch impedance. For compact antennas, which are inherently one-port devices, the terminating impedance condition can be achieved by designing the structures such that the radiation resistance is as close as possible to the Bloch impedance, which for typical antennas is chosen to be 50 Ω. As will be seen in the section "Antenna Applications of TL-Metamaterials," antenna designs based on transmission-line metamaterials enable a high radiation resistance close to 50 Ω to be achieved even for very-low-profile antennas, which also translates into the additional benefit of providing a high radiation efficiency.

Propagation Characteristics of the *Π* Unit Cell

A similar procedure can be carried out for the analysis of the metamaterial *Π* unit cell of Fig. 3b. It has been found that the dispersion characteristics of the *Π* unit cell are identical to those of the *T* unit cell and are also given by Eq. 1 (Antoniades 2009). The Bloch impedance of the metamaterial *Π* unit cell is given by

$$Z_{\mathrm{BL},\Pi} = \pm \sqrt{\frac{\frac{Z}{2}\cos(\theta) + jZ_0\sin(\theta) + \frac{Z}{2}}{\left(Y + \frac{ZY^2}{8} + \frac{ZY_0^2}{2}\right)\cos(\theta) + \frac{j}{2}\left(\frac{Y^2Z_0}{2} + YZY_0 + 2Y_0\right)\sin(\theta) + \frac{ZY^2}{8} - \frac{ZY_0^2}{2}}}, \tag{5}$$

with the same expressions for Z and Y from Eq. 3.

Representative dispersion and Bloch impedance diagrams for the metamaterial *Π* unit cell are shown in Fig. 6 for the case where $Z_{0,\mathrm{BW}} > Z_0$ and in Fig. 7 for the case where $Z_{0,\mathrm{BW}} < Z_0$. As expected, the dispersion characteristics of the *Π* unit cell for the case where $Z_{0,\mathrm{BW}} < Z_0$ shown in Fig. 7a are identical to the dispersion characteristics of the *T* unit cell shown in Fig. 5a. The Bloch impedance of the two unit cells also has very similar characteristics in the upper right-handed band, as can be verified from Figs. 5b and 7b. In the lower left-handed band, however, the Bloch impedance for *Π* unit cell with $Z_{0,\mathrm{BW}} < Z_0$ has the additional advantage that it passes through 50 Ω, thus also enabling the matching of the metamaterial line within this band. For the *Π* unit cell operating under the condition that $Z_{0,\mathrm{BW}} > Z_0$ shown in Fig. 6, the Bloch impedance does not pass through the 50 Ω point in the left-handed band; therefore, it is not possible to match the line to 50 Ω within this band. Thus, in order to match the line to 50 Ω in both the left-handed and right-handed bands, the following condition for the *Π* unit cells must be satisfied:

$$Z_{0,\mathrm{BW}} < Z_0 \quad \text{or} \quad \sqrt{\frac{L_0}{C_0}} < \sqrt{\frac{L}{C}}. \tag{6}$$

DOI 10.1007/978-981-4560-75-7_21-1

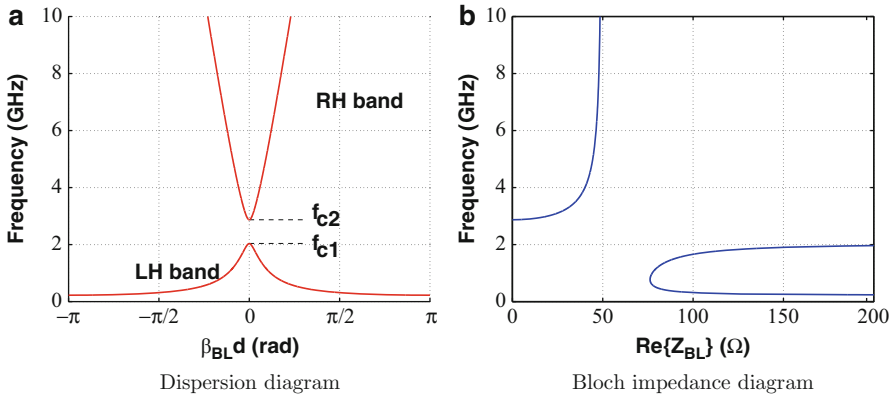

Fig. 6 Characteristics of a representative NRI-TL metamaterial Π unit cell with parameters $C_0 = 5$ pF, $L_0 = 25$ nH, $Z_0 = 50\ \Omega$, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz. Note that in this case, $Z_{0,\mathrm{BW}} = \sqrt{L_0/C_0} > Z_0$

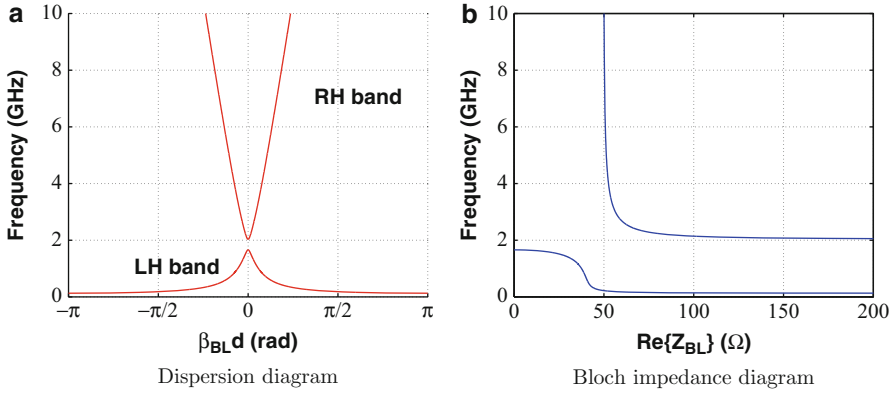

Fig. 7 Characteristics of a representative NRI-TL metamaterial Π unit cell with parameters $C_0 = 15$ pF, $L_0 = 25$ nH, $Z_0 = 50\ \Omega$, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz. Note that in this case, $Z_{0,\mathrm{BW}} = \sqrt{L_0/C_0} < Z_0$

Furthermore, the useful cases of the T unit cell with $Z_{0,\mathrm{BW}} > Z_0$ shown in Fig. 4 and the Π unit cell with $Z_{0,\mathrm{BW}} < Z_0$ shown in Fig. 7 can be compared. It can be observed that the dispersion characteristics of the Π unit cell are similar to the dispersion characteristics of the T unit cell; however, the Bloch impedances of the two unit cells exhibit complementary characteristics, as can be verified from Figs. 4b and 7b. These complementary characteristics can be attributed to the complementary forms of the Bloch impedances given by Eqs. 2 and 5.

By inspection of both Figs. 4b and 7b, it can also be observed that if the stopband were closed, then a metamaterial line that consists of either T or Π unit cells would not suffer from the rapid Bloch impedance changes around the vicinity of the stopband and would remain close to 50 Ω over a much wider bandwidth extending down to low frequencies. The method by which the stopband can be closed will be outlined in the following section, where it will be demonstrated that indeed when the stopband is closed, the Bloch impedance exhibits a significantly wider bandwidth.

Effective Medium Propagation Characteristics

The dispersion relation of Eq. 1 is sufficient to fully characterize the propagation characteristics of the NRI-TL metamaterial structure. For practical applications, it is useful to consider the case where the

DOI 10.1007/978-981-4560-75-7_21-1

periodically loaded metamaterial line can be considered an effective medium, thus providing further insight into its operation.

In order to consider a series of cascaded unit cells as an effective periodic medium, the physical length of the unit cell must be much smaller than a wavelength, translating into a small electrical length θ, i.e., $\theta \ll 1$. In addition, a small phase shift per unit cell is required in order to avoid the large phase shifts associated with the lower Bragg cutoff frequency, i.e., $\beta_{\mathrm{BL}} d \ll 1$. In order to reflect the effective nature of the periodic metamaterial medium, the Bloch propagation constant β_{BL} will be written as β_{MTM} henceforth. Thus, under the aforementioned assumptions that $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$ and considering a periodicity of d for each unit cell, the effective metamaterial propagation constant can be written as

$$\beta_{\mathrm{MTM}} = \pm\omega\sqrt{L_{\mathrm{eff}} C_{\mathrm{eff}}} = \pm\omega\sqrt{\left[L - \frac{1}{\omega^2 C_0 d}\right]\left[C - \frac{1}{\omega^2 L_0 d}\right]}. \tag{7}$$

Equation 7 demonstrates that the effective propagation constant of the metamaterial medium has a similar form to the propagation constant of a conventional transmission line but with effective inductance and capacitance terms, L_{eff} and C_{eff} given by the expressions in the square brackets of Eq. 7. Examining this equation, it can be observed how this medium can exhibit a positive, a negative, and a zero propagation constant, simply by changing the values of the loading parameters L_0 and C_0. When the loading reactance is negligible, the host transmission-line parameters L and C dominate and a forward wave is present on the structure. On the other hand, when the loading reactance is dominant and greater than the individual L and C values, L_{eff} and C_{eff} become negative, and thus the structure supports a backward wave. Finally, when the loading reactances are equal to the host transmission-line parameters L and C, then the effective propagation constant is zero, and there is no propagation along the structure. In this case, a standing wave is established along the structure that has a constant amplitude (i.e., no variation along the z-direction) that varies with time. The lumped-element equivalent circuit of the NRI-TL unit cell under the effective medium conditions $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$ is shown in Fig. 8, where L_{eff} can be considered the effective inductance of the series branch, while C_{eff} can be considered the effective capacitance of the shunt branch.

Setting each of the effective material parameters L_{eff} and C_{eff} equal to zero in Eq. 7 results in expressions for the cutoff frequencies of the lower and the upper edges of the stopband, f_{c1} and f_{c2}, respectively, as shown in Fig. 6a:

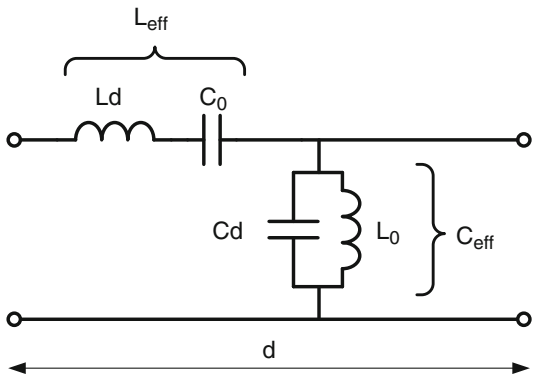

Fig. 8 Lumped-element equivalent circuit of the NRI-TL unit cell under the effective medium conditions $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$

DOI 10.1007/978-981-4560-75-7_21-1

$$f_{c1} = \min\left\{ \frac{1}{2\pi\sqrt{LC_0 d}}, \quad \frac{1}{2\pi\sqrt{L_0 Cd}} \right\} = f_{-0}, \tag{8}$$

$$f_{c2} = \max\left\{ \frac{1}{2\pi\sqrt{LC_0 d}}, \quad \frac{1}{2\pi\sqrt{L_0 Cd}} \right\} = f_{+0}. \tag{9}$$

Note that f_{c1} and f_{c2} also correspond to the zero-degree resonance frequencies f_{-0} and f_{+0}, respectively, discussed in the section "Resonant Characteristics of NRI-TL Metamaterials." Considering the scenario where $1/2\pi\sqrt{LC_0 d} < 1/2\pi\sqrt{L_0 Cd}$, the lower edge of the stopband, f_{c1}, is given by the series resonance between the total series inductance of the transmission line, Ld, and the loading capacitor C_0, while the upper edge of the stopband, f_{c2}, is given by the shunt resonance between the total shunt capacitance of the transmission-line section, Cd, and the loading inductance L_0.

By equating f_{c1} and f_{c2}, the stopband between the two cutoff frequencies can be closed, and a continuous band is formed between the lower left-handed and the upper right-handed bands. The impedance matching condition for closing the stopband in a NRI-TL metamaterial structure can therefore be written as (Eleftheriades et al. 2002)

$$Z_0 = \sqrt{\frac{L_0}{C_0}}. \tag{10}$$

The condition of Eq. 10 can also be written as

$$Z_{0,\mathrm{BW}} = Z_0 \quad \text{or} \quad \sqrt{\frac{L_0}{C_0}} = \sqrt{\frac{L}{C}}. \tag{11}$$

Thus, according to the above impedance matching condition, for a uniform transition between the left-handed band and the right-handed band, the characteristic impedance of the NRI backward-wave line components that load the line must be the same as the characteristic impedance of the PRI host transmission line.

Furthermore, under the effective medium conditions $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$, the Bloch impedances for both the T and the Π unit cells reduce to the characteristic impedance of the backward-wave line. Therefore, all three characteristic impedances are equal, resulting in a perfectly matched NRI-TL metamaterial structure:

$$Z_{\mathrm{BL}} = Z_{0,\mathrm{BW}} = Z_0. \tag{12}$$

Figure 9a shows a representative dispersion diagram obtained using Eq. 1 for either a T or a Π metamaterial unit cell when the impedance matching condition of Eq. 10 is imposed. It can be observed that compared to the open dispersion diagram of Fig. 6a, there is now a single passband comprising the lower left-handed band that smoothly transitions into the upper right-handed band at the design frequency of $f_0 = 2$ GHz. Thus, depending on the region of operation, Fig. 9a highlights the fact that the NRI-TL metamaterial structure can support forward and backward waves as well as the peculiar case of standing waves with a zero-degree phase shift ($\beta_{\mathrm{BL}} d = 0$) at the closed stopband point of $f_0 = 2$ GHz. Additionally, around the design frequency, the phase response is linear and broadband with frequency.

Figure 9b shows the Bloch impedance diagrams for both the T and π unit cells under the impedance matching condition of Eq. 10, which exhibit as expected complementary characteristics. From Fig. 9b, it

DOI 10.1007/978-981-4560-75-7_21-1

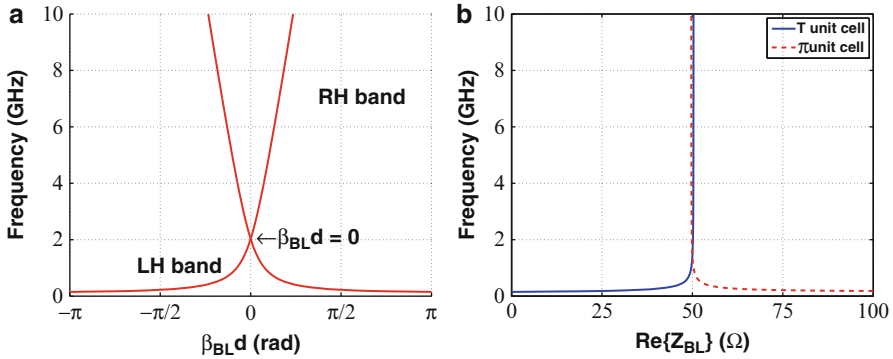

Fig. 9 Characteristics of representative NRI-TL metamaterial T and Π unit cells with parameters $C_0 = 10$ pF, $L_0 = 25$ nH, $Z_0 = 50\ \Omega$, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz. Note that in this case, the impedance matching condition of $Z_0 = \sqrt{L_0/C_0}$ is imposed, and the stopband is closed

can be observed that the Bloch impedance remains remarkably constant around 50 Ω for a much wider bandwidth compared to the open stopband cases of Figs. 4b and 7b, which suffer from rapid changes in the Bloch impedance around the vicinity of the stopbands.

The impedance matching condition of Eq. 10 can subsequently be used in Eq. 7 to derive an approximate expression for the effective propagation constant of the line, given as

$$\beta_{\text{MTM}} = \omega\sqrt{LC} + \frac{-1}{\omega\sqrt{L_0C_0}d} \tag{13}$$

$$\beta_{\text{MTM}} = \beta_{\text{H-TL}} + \beta_{\text{BW}}. \tag{14}$$

This expression can be interpreted as the sum of the propagation constants of the host transmission line, $\beta_{\text{H-TL}}$, and a uniform backward-wave line, β_{BW}, formed by the loading elements L_0 and C_0. The analogous effective phase shift per unit cell can be written as

$$\phi_{\text{MTM}} = -\beta_{\text{MTM}}d. \tag{15}$$

Inserting Eq. 13 into Eq. 15, the effective phase shift per NRI-TL metamaterial unit cell under the impedance matching condition of Eq. 10 can be written as (Antoniades and Eleftheriades 2003)

$$\phi_{\text{MTM}} = -\omega\sqrt{LC}d + \frac{1}{\omega\sqrt{L_0C_0}} \tag{16}$$

$$\phi_{\text{MTM}} = \phi_{\text{H-TL}} + \phi_{\text{BW}}. \tag{17}$$

Equation 16 can be recognized as the sum of the phases incurred by the host transmission line, $\phi_{\text{H-TL}}$, and the backward-wave line, ϕ_{BW}, which was described initially in Fig. 2. This equation succinctly describes the inherent phase-compensating nature of each NRI-TL metamaterial unit cell. By adjusting the values of the loading elements L_0 and C_0 while maintaining the impedance matching condition, the effective phase shift across each unit cell can be tailored to produce a net positive, negative, or even a 0° phase shift at a given frequency. It should be emphasized that the necessary conditions for the phase relationship presented in Eq. 16 to be valid are that the impedance matching condition of Eq. 10 must be

DOI 10.1007/978-981-4560-75-7_21-1

satisfied, the physical length of the unit cell must be small compared to the wavelength, i.e., $|\phi_{\text{H-TL}}| \ll 1$, and the phase shift per unit cell must also be small, i.e., $|\phi_{\text{MTM}}| \ll 1$.

Multistage NRI-TL Metamaterial Phase-Shifting Lines

The propagation characteristics of a single metamaterial unit cell presented in the sections "Propagation and Impedance Characteristics of the T Unit Cell" and "Propagation Characteristics of the Π Unit Cell" can be used to design multistage metamaterial lines, provided that the metamaterial line is terminated in its Bloch impedance. In this manner, each unit cell within the finite metamaterial line will effectively see an infinite periodic medium and will thus retain its propagation characteristics. Consequently, the phase expressions derived assuming an infinite periodic medium can be used in order to characterize the phase response of a finite metamaterial structure.

If the source and load terminations are equal to the characteristic impedance of the metamaterial line in the matched case (Eq. 12), then from Eq. 16, the total phase incurred by an N-stage metamaterial line as shown in Fig. 2 can be written as the sum of the phase incurred by each constituent unit cell:

$$\Phi_{\text{MTM}} = N\phi_{\text{MTM}} = N\left(-\omega\sqrt{LC}d + \frac{1}{\omega\sqrt{L_0C_0}}\right). \tag{18}$$

In order to verify the validity of the above arguments, the phase response of a representative four-stage metamaterial line was obtained using the effective medium phase shift of Eq. 18, periodic analysis of a cascade of four identical T unit cells, and the Agilent-ADS circuit simulator, and the results are shown in Fig. 10.

It can be observed that the phase responses obtained from the effective medium analysis, from the periodic analysis, and from Agilent-ADS are identical within the passband of the structure. As expected, the effective medium response of Eq. 18 does not exhibit a low-frequency cutoff. At low frequencies below 0.15 GHz, the structure has a stopband, and therefore the periodic analysis is not able to predict the phase. Nevertheless, these results confirm that the propagation characteristics derived for the infinitely periodic case can also be used to design finite-length metamaterial phase-shifting lines, provided that the lines are terminated in their Bloch impedance.

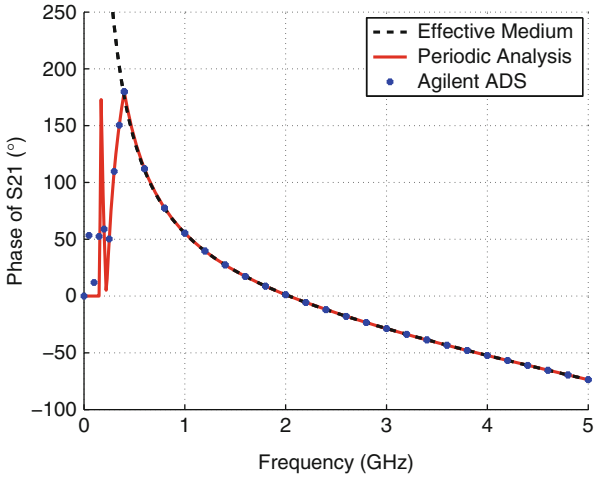

Fig. 10 Phase responses of a four-stage NRI-TL metamaterial line obtained using the effective medium phase shift of Eq. 18, periodic analysis, and the simulator Agilent-ADS. Parameters used: $Z_{\text{term}} = 50\ \Omega$, $C_0 = 10$ pF, $L_0 = 25$ nH, $Z_0 = 50\ \Omega$, $d = 3$ mm, and $\theta = 8.8°$ at 2 GHz

Antenna Design Using TL Metamaterials

Resonant Characteristics of NRI-TL Metamaterials

Multiband Operation

The rich dispersion characteristics of metamaterials form the underlying basis for their use in many antenna applications. In this section, the resonant characteristics of NRI-TL metamaterial structures are analyzed by considering their dispersion diagrams. These can be used to visualize how these structures can be designed to offer multiband responses whose resonant frequencies are not harmonically related while offering large degrees of miniaturization.

Figure 11 shows a representative dispersion diagram obtained using Eq. 1, where the propagation characteristics of the metamaterial can be observed. When investigating the resonant properties of this structure, of particular interest are the frequencies where the total electrical length is equal to zero and integer multiples of π (Eleftheriades 2009), i.e.,

$$\beta_{\mathrm{BL}}\ell_{\mathrm{TOT}} = n\pi \quad ; \quad n = \pm 0, \quad \pm 1, \quad \pm 2 \ldots \tag{19}$$

Thus, for resonant antenna applications, effective radiation can be achieved from the metamaterial structure when its total length ℓ_{TOT} is equal to integer multiples of half a wavelength (Schussler et al. 2004a; Caloz and Itoh 2006):

$$\ell_{\mathrm{TOT}} = n\frac{\lambda}{2} \quad ; \quad n = \pm 0, \quad \pm 1, \quad \pm 2 \ldots \tag{20}$$

In the general case where N unit cells are used in order to implement the metamaterial structure with a total length of $\ell_{\mathrm{TOT}} = Nd$, then the analogous electrical length per unit cell becomes

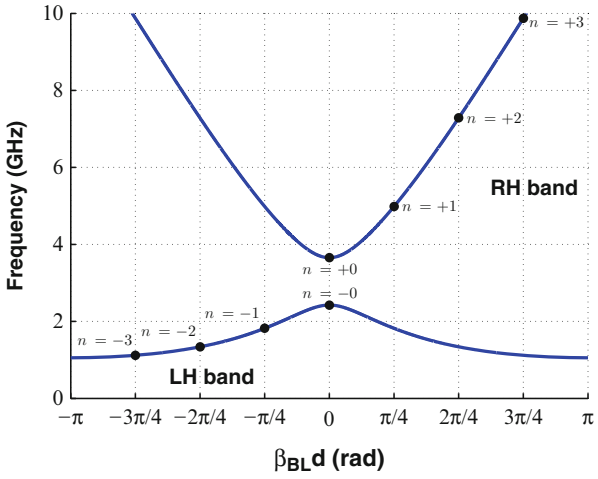

Fig. 11 Typical dispersion diagram for a NRI-TL metamaterial unit cell with parameters $C_0 = 0.14$ pF, $L_0 = 30$ nH, $Z_0 = 300\ \Omega$, $d = 12.5$ mm, and $\theta = 45°$ at 3 GHz. Superimposed are the locations of the nth order resonances for a metamaterial structure that consists of a cascade of $N = 4$ unit cells. Note the contraction of the resonant frequencies in the left-handed (LH) band compared to the right-handed (RH) band and the fact that the resonant frequencies are not harmonically related

DOI 10.1007/978-981-4560-75-7_21-1

$$\beta_{\mathrm{BL}} d = \frac{n\pi}{N} \quad ; \quad n = \pm 0, \quad \pm 1, \quad \pm 2 \ldots \pm (N-1) \tag{21}$$

An N-stage metamaterial structure can therefore support negative-order ($n < 0$) resonances in the left-handed band, zeroth-order ($n = 0$) resonances at the $\beta_{\mathrm{BL}} d = 0$ point, and positive-order ($n > 0$) resonances in the right-handed band. This is in contrast to conventional right-handed structures that can support only positive-order resonances within the right-handed region of their respective dispersion diagram.

The resonances that are achievable with a metamaterial structure are depicted graphically on the dispersion diagram of Fig. 11 for the representative case of $N = 4$ unit cells. Thus, within the irreducible Brillouin zone of $-\pi < \beta_{\mathrm{BL}} d < \pi$ on the dispersion diagram, there are potentially $2N$ resonances that can be excited. For every nth resonance that occurs at each of the $\beta_{\mathrm{BL}} d = \frac{n\pi}{N}$ points along the horizontal axis, there is an analogous resonance frequency, f_n, along the vertical axis. In general, the total number of resonances that are excited within a metamaterial structure will be less than $2N$ and will depend on the excitation mechanism and the terminal impedances. Since each nth resonance corresponds to a particular mode, i.e., a particular field distribution on the structure, the excitation mechanism will determine which modes are coupled to and therefore which modes appear in the resulting frequency response. In practical antenna applications, it is not in general possible to couple to all of the modes simultaneously using a single feed; therefore, the number of resonances that will typically appear will be less than $2N$. This can be observed in many of the examples subsequently shown in the section "Antenna Applications of TL-Metamaterials."

In order to keep the antenna size small, typically only the $n = \pm 0$ and $n = \pm 1$ resonances are employed in the design of metamaterial antennas, i.e., when $\beta_{\mathrm{BL}} \ell_{\mathrm{TOT}} = \pm 0$ and $\beta_{\mathrm{BL}} \ell_{\mathrm{TOT}} = \pm \pi$. At these frequencies, resonant standing waves are excited on the structure. Two conventional applications which employ a $+\pi$ resonance are a $\lambda/2$ dipole antenna whose current distribution has a phase shift of π along the length of the dipole and a $\lambda/2$ patch antenna which also establishes a π phase shift between its two radiating edges. As has been outlined above, structures that employ NRI-TL metamaterial loading also have the ability to excite the $+\pi$ resonance but have the additional benefit and flexibility of exciting the $\pm$zero and the $-\pi$ resonances at nonharmonic frequencies.

Compact Designs with a Small Number of Unit Cells, *N*

The $n = \pm 0$ zeroth-order resonances (ZOR) are independent of the total number of unit cells N in the structure (Antoniades and Eleftheriades 2003), since each constituent unit cell incurs in and of itself 0°. This can be seen by setting $n = 0$ in Eq. 21. Thus, any number of unit cells can be chosen in order to implement the $n = \pm 0$ resonances, including the limiting case of $N = 1$. The zeroth-order resonances are therefore well suited for antenna miniaturization purposes, as will be outlined in the subsequent section. For the general case of a dispersion relation with an open stopband, as shown in Fig. 11, the zero-degree resonance will occur at two resonant frequencies, f_{-0} and f_{+0}. Note that these two frequencies are the same as the cutoff frequencies f_{c1} and f_{c2} in Fig. 6a. Note also that in terms of nomenclature, the $n = \pm 0$ zeroth-order resonance (ZOR) frequencies are also known as zero-degree frequencies, zero-index frequencies, infinite-wavelength frequencies, epsilon-zero (EZR) frequencies, and mu-zero (MZR) frequencies.

The $\pm\pi$ resonances will depend on the total number of unit cells comprising the metamaterial structure. Thus, for a structure consisting of N unit cells, the $\pm\pi$ resonances will be excited when the electrical length per unit cell is equal to $\beta_{\mathrm{BL}} d = \pm \pi/\mathrm{N}$, from Eq. 21. It should be noted that the number of unit cells used to implement the metamaterial structure is in theory arbitrary; however, in practice it is limited by the space that is available to implement the host transmission line and the loading elements L_0 and C_0 for each metamaterial unit cell.

DOI 10.1007/978-981-4560-75-7_21-1

As will be shown in the section "Design Equations for Rapid Prototyping," a larger number of unit cells results in larger loading-element values L_0 and C_0 required in order to implement the desired phase shift per unit cell. From Eqs. 24 and 25, if N unit cells are used in order to implement the structure, then the values of the required loading elements will be N times larger than the implementation with a single unit cell. Thus, N should be kept small in order to facilitate the physical realization of the loading elements L_0 and C_0, especially if these are implemented in fully printed form. Additionally, if the loading elements L_0 and C_0 are implemented using off-the-shelf surface-mount chip components, then it is advantageous to keep their values low since these generally come in smaller packages and have higher self-resonant frequencies (see for example the Coilcraft Inc. chip inductor datasheet (Coilcraft Inc 2015)). Finally, a single unit cell realization of the $\pm\pi$ resonances should be avoided, since this corresponds to operation at the onset of the lower and upper stopband regions, which are associated with high insertion losses.

Antenna Miniaturization

Negative-Order Resonant Modes, $n < 0$

For the purpose of antenna miniaturization, the resonant frequencies that lie within the lower left-handed band on the dispersion diagram of Fig. 11 are of most interest. This is because these negative-order resonant modes with $n < 0$ are associated with large propagation constants at low frequencies and a contraction of the guided wavelength as the frequency decreases (Schussler et al. 2004a; Lee et al. 2006; Iizuka and Hall 2007; Eleftheriades 2009).

Within the lower left-handed band, the backward-wave propagation constant $\beta_{\mathrm{BW}} = -1/\omega\sqrt{L_0C_0}d$ is dominant (see Eq. 13), which is inversely proportional to the frequency. Therefore, the propagation constant increases as the frequency decreases, allowing large propagation constants to be achieved at low frequencies, facilitating the realization of the $-\pi$ resonance. Furthermore, the propagation constant is also inversely proportional to the loading-element values L_0 and C_0, therefore enabling large propagation constants to be achieved with small loading-element values. This enables the design of compact resonant antennas with loading elements that can be easily realized in printed form, while maintaining the overall antenna size much smaller than $\lambda/2$.

The above scenario is in contrast to conventional right-handed lines, where the propagation constant is directly proportional to the frequency, therefore necessitating antenna sizes that are on the order of $\lambda/2$ in order to create resonant antennas. The size of resonant right-handed antennas can be reduced by employing slow-wave low-pass loading; however, since the propagation constant is proportional to the loading-element values, the required loading-element values are significantly larger than the ones required for the metamaterial-loaded antennas with the same size reduction.

With reference to Fig. 11, note that in the left-handed band, the resonant frequencies are spaced much closer together compared to the resonances in the right-handed band, and they are *not* harmonically related. This can again be attributed to the fact that the dominant backward-wave propagation constant in this band is inversely proportional to the frequency. In the right-handed band, the propagation constant of the host transmission line $\beta_{\mathrm{H\text{-}TL}} = \omega\sqrt{LC}$ is dominant; therefore, the propagation constant is directly proportional to the frequency, and the resonant frequencies *are* harmonically related. Thus, the metamaterial structure exhibits a contraction of the resonant frequencies in the left-handed (LH) band compared to the right-handed (RH) band. Furthermore, the locations of the resonant frequencies can be directly controlled by adjusting the loading-element values L_0 and C_0, through a process called "dispersion engineering."

DOI 10.1007/978-981-4560-75-7_21-1

Zeroth-Order Resonant (ZOR) Modes, $\mathbf{n = \pm 0}$

Antenna miniaturization can also be achieved at the two points on the dispersion diagram where the propagation constant is zero, i.e., for the $n = \pm 0$ ZOR frequencies of f_{-0} and f_{+0}. In the closed stopband case shown in Fig. 9, these two frequencies merge into one ZOR frequency, $f_{\pm 0}$. Note that the two ZOR frequencies are not harmonically related and can be easily adjusted by changing the metamaterial structure's transmission line and loading parameters (see Eqs. 8 and 9). This provides great flexibility when designing ZOR antennas, since it allows the ZOR frequencies to be placed arbitrarily.

At the two ZOR frequencies, the phase shift that each metamaterial unit cell incurs is 0° and is independent of the unit cell's physical length. Therefore, any number of unit cells, N, can be cascaded together, and the resulting overall phase shift that the metamaterial structure incurs will still be 0°. Thus, in theory the zero-degree metamaterial structures can be made infinitesimally small, enabling large degrees of antenna miniaturization. In practice, the size of the zero-degree unit cells is limited by the available space required to implement the host transmission line and the loading elements L_0 and C_0, especially if these are realized in printed form. In order to achieve the equivalent -2π phase shift from a conventional transmission line, its length must be one guided wavelength, λ_g. Consequently, the physical size of the zero-degree metamaterial structures can be made significantly smaller than that of a λ_g transmission line and in the limiting case can be simply a single zero-degree metamaterial unit cell.

Note that for antenna applications, a single unit cell realization of the zero-degree resonances is not problematic, as was the case for the $\pm\pi$ resonances described in the section "Compact Designs with a Small Number of Unit Cells, N." This is because for the case of a closed stopband, the $\beta_{\mathrm{BL}}d = \pm 0$ point is not at the edge of a stopband region, and in the open stopband case, even though the two $\beta_{\mathrm{BL}}d = \pm 0$ points are at the edge of the central stopband, the impedance seen at the terminals of the antenna primarily consists of the radiation resistance of the structure. For the latter case, if the radiation resistance of a single unit cell is not high enough, this could necessitate the use of additional unit cells in order to increase the overall antenna radiation resistance.

Design Equations for Rapid Prototyping

When designing compact antennas, a designer will typically try to achieve a targeted performance within a specified antenna volume or the targeted performance could be sought while attempting to minimize the antenna volume. Alternatively, the maximum antenna performance could be sought for a specified volume. Performance metrics could include input impedance bandwidth, multiband operation, polarization, directive properties, and radiation efficiency.

For the design of compact antennas based on transmission-line metamaterials, once the mode of operation is chosen based on the analysis of the section "Resonant Characteristics of NRI-TL Metamaterials," e.g., $n = 0$ or $n = -1$, the primary concern is to obtain the loading-element values L_0 and C_0 required to realize the metamaterial. Thus, for a given antenna volume, the designer must choose the number of metamaterial unit cells N that will be used in the realization of the antenna, as well as the technology that the transmission lines will be implemented in (e.g., microstrip, coplanar waveguide, etc.). Typically, based on the volume constraints and the system impedance, the designer will also choose the parameters of the host transmission line, namely, the characteristic impedance Z_0 and the propagation constant $\beta_{\text{H-TL}}$, and the length of each unit cell d. This will in turn define the electrical length of each transmission-line section $\theta = \beta_{\text{H-TL}}d$ and the corresponding phase that each transmission-line section incurs $\phi_{\text{H-TL}} = -\theta = -\beta_{\text{H-TL}}d$. These parameters will subsequently allow the designer to calculate the loading-element values required to achieve a specific phase shift for each metamaterial unit cell. Below are outlined two methods for obtaining these loading-element values: the first method provides simple and intuitive approximate design equations derived from the effective medium case of the section "Effective Medium Propagation Characteristics," and the second method provides exact design equations derived

DOI 10.1007/978-981-4560-75-7_21-1

for the periodic medium case of the sections "Propagation and Impedance Characteristics of the T Unit Cell" and "Propagation Characteristics of the Π Unit Cell."

Approximate Expressions for NRI-TL Metamaterials

For the effective medium outlined in the section "Effective Medium Propagation Characteristics," closed-form expressions can be derived for the values of the loading elements L_0 and C_0 required to produce a desired phase shift per unit cell ϕ_{MTM} at a given frequency ω_0, given a section of host transmission line with parameters Z_0 and $\phi_{\text{H-TL}}$. Approximate expressions for the loading elements can be obtained by substituting the impedance matching condition of Eq. 10 into Eq. 16 and solving for L_0 and C_0

$$L_0 = \frac{Z_0}{\omega_0(\phi_{\text{MTM}} - \phi_{\text{H-TL}})}, \tag{22}$$

$$C_0 = \frac{1}{\omega_0 Z_0(\phi_{\text{MTM}} - \phi_{\text{H-TL}})}. \tag{23}$$

It should be noted that since the impedance matching condition of Eq. 10 was used in the derivation of Eqs. 22 and 23, these are only valid when the stopband is closed and in the effective medium limit of $|\phi_{\text{MTM}}| \ll 1$ and $|\phi_{\text{H-TL}}| \ll 1$. Nonetheless, these expressions are very simple and intuitive and clearly highlight the factors that affect the values of the loading elements.

The loading-element values can also be expressed in terms of the total phase shift that the metamaterial structure incurs. If the metamaterial structure consists of N unit cells, and the total phase shift that it incurs is $\Phi_{\text{MTM}} = N\phi_{\text{MTM}}$ given by Eq. 18, while the total phase shift that the host transmission line incurs is $\Phi_{\text{H-TL}} = N\phi_{\text{H-TL}}$, then from Eqs. 22 and 23 the loading-element values can be written as

$$L_0 = N\left(\frac{Z_0}{\omega_0(\Phi_{\text{MTM}} - \Phi_{\text{H-TL}})}\right), \tag{24}$$

$$C_0 = N\left(\frac{1}{\omega_0 Z_0(\Phi_{\text{MTM}} - \Phi_{\text{H-TL}})}\right). \tag{25}$$

These expressions reveal that from a design point of view, it is advantageous to keep N small, i.e., use a small number of unit cells, resulting in smaller values for the required loading-element values.

Exact Expressions for NRI-TL Metamaterials

For the periodic medium of the sections "Propagation and Impedance Characteristics of the T Unit Cell" and "Propagation Characteristics of the Π Unit Cell," the exact expressions for the loading elements can be obtained by employing the full dispersion relation of Eq. 1 for the general case where the stopband can be either open or closed. In both cases, it is desired to calculate the loading elements for a given phase shift per unit cell, $\phi_{\text{MTM}} = -\beta_{\text{BL}}d$, and Bloch impedance, Z_{BL}.

Closed Stopband

Considering first the case when the stopband is closed, recall from Fig. 9 that the Bloch impedance remains very close to the value of Z_0 over a large frequency range. Thus, a very good approximation for the Bloch impedance for a large range of frequencies is actually the value of Z_0. Therefore, the impedance matching condition of Eq. 10 is rearranged to obtain an expression of the loading inductance L_0 in terms of C_0 and Z_0:

DOI 10.1007/978-981-4560-75-7_21-1

$$L_0 = C_0 Z_0^2. \tag{26}$$

By substituting Eq. 26 into Eq. 1, a quadratic equation in terms of C_0 is obtained:

$$(\cos(\beta_{BL}d) - \cos(\theta))C_0^2 - \left(\frac{\sin(\theta)}{\omega_0 Z_0}\right)C_0 + \frac{1+\cos(\theta)}{4\omega_0^2 Z_0^2} = 0. \tag{27}$$

The solution to the above quadratic equation can be written as

$$C_0 = \frac{\left(\frac{\sin(\theta)}{\omega_0 Z_0}\right) \pm \sqrt{\left(\frac{\sin(\theta)}{\omega_0 Z_0}\right)^2 - 4(\cos(\beta_{BL}d) - \cos(\theta))\left(\frac{1+\cos(\theta)}{4\omega_0^2 Z_0^2}\right)}}{2(\cos(\beta_{BL}d) - \cos(\theta))}. \tag{28}$$

The positive solution of the quadratic equation is sought, therefore resulting in unique values for L_0 and Co from Eqs. 26 and 28. A particular case of Eq. 27 arises when $\beta_{BL}d$ is equal to θ (or equivalently $|\phi_{MTM}| = |\phi_{H\text{-}TL}|$). In this case, the first term of Eq. 27 is equal to zero, and the loading capacitance C_0 can be simply expressed as

$$C_0 = \frac{1+\cos(\theta)}{4\omega_0 Z_0 \sin(\theta)}. \tag{29}$$

Open Stopband

The open stopband case is the most general case and proceeds in a similar, yet slightly more complicated manner. The two design parameters in this case are the phase shift per unit cell, given by the dispersion relation of Eq. 1, and the Bloch impedance given by Eq. 2 or 5. Both the dispersion and Bloch impedance relations are functions of L_0 and C_0; however, an attempt to find a closed-form expression for these reveals that the expression quickly becomes very complicated. A simple way to overcome this problem is to solve for L_0 and C_0 graphically by expressing C_0 in terms of L_0 through the general form of the dispersion relation of Eq. 1, given in terms of Z and Y. Therefore, Eq. 1 can be written as

$$Z = \frac{\cos(\beta_{BL}d) - \cos(\theta) - j\frac{YZ_0}{2}\sin(\theta)}{\frac{Y}{4}\cos(\theta) + j\frac{Y_0}{2}\sin(\theta) + \frac{Y}{4}} = \frac{1}{j\omega C_0}. \tag{30}$$

Recall from Eq. 3 that $Z = 1/j\omega C_0$ and $Y = 1/j\omega L_0$. Substituting Eq. 30 into the Bloch impedance expressions of Eq. 2 or 5 and by sweeping the value of L_0, a range of values for the Bloch impedance is obtained. The final value of L_0 is obtained by selecting the value that corresponds to the desired Bloch impedance. The loading capacitance C_0 is subsequently found by substituting the value of L_0 into $Y = 1/j\omega L_0$ and then into Eq. 30.

In summary, NRI-TL metamaterial structures have the ability to support negative-order resonances, positive-order resonances, and zeroth-order resonances, meaning that they can incur a positive, negative, or zero phase shift depending on the values of the loading elements while maintaining a small physical size. In addition, only a few unit cells are required in order to achieve the resonant characteristics necessary to implement compact resonant antennas. Furthermore, antenna miniaturization can be achieved for structures that support negative-order resonances and/or zeroth-order resonances. With

DOI 10.1007/978-981-4560-75-7_21-1

these in mind, the following section focuses on various antenna applications that have exploited the beneficial properties of metamaterials to create multiband, compact, and efficient antennas.

Antenna Applications of TL Metamaterials

Zeroth-Order Resonant Antennas, $n = \pm 0$

A Zero-Index NRI-TL Metamaterial Folded-Monopole Antenna

The first antenna described herein that employs the $n = 0$ zeroth-order resonance of NRI-TL metamaterials is an electrically small folded-monopole antenna, as shown in Fig. 12 (Antoniades and Eleftheriades 2008b). This is also referred to as a zero-index metamaterial antenna, since at the $\beta_{\mathrm{BL}} d = 0$ point, the refractive index is equal to zero. This antenna was first presented in Eleftheriades et al. (2004) and subsequently in Eleftheriades et al. (2007) using fully printed loading elements, and variations using surface-mount lumped-element components were presented in Qureshi et al. (2005) and Eleftheriades (2007).

The metamaterial antenna consists of $N = 4$ microstrip NRI-TL metamaterial unit cells that are arranged in a 2×2 configuration over a ground plane. Each metamaterial unit cell was designed to excite the $n = 0$ zeroth-order resonant mode under a closed stopband condition at a design frequency of $f_0 = 3$ GHz. The antenna was designed based on the symmetric NRI-TL metamaterial Π unit cell shown in Fig. 3b. The Π topology was chosen because it reveals the natural monopole folding effect that the circuit provides, which is achieved by feeding the antenna from the base of one of the inductors.

In order to feed each of the vertical vias of the antenna in phase, it is required that each metamaterial unit cell incurs 0° at the design frequency, f_0. Therefore, for a chosen unit cell size, Eqs. 22 and 23 were used to design metamaterial unit cells that incurred a phase shift of $\phi_{\mathrm{MTM}} = 0°$ at 3 GHz, under the closed stopband condition of Eq. 10.

Even-Odd Mode Analysis

The proposed zero-index metamaterial antenna of Fig. 12 can be analyzed by decomposing the antenna current into a superposition of an even mode (I_e) and an odd mode (I_o). Since the antenna is symmetrical, analysis of a single unit cell that contains two vias will reveal the general characteristics of the entire antenna, namely, that the even-mode current is dominant on the structure. Even though the analysis of a single unit cell only models two folded arms (vias), nevertheless this provides a qualitative measure of the antenna performance. Furthermore, Goubau has analyzed the case of an N-element folded monopole where only one of the monopoles is excited and has demonstrated that the results can be generalized from the two-element case (Goubau 1976; Vaughan and Bach-Andersen 2003, pp. 515–518).

Beginning with the even-mode excitation, two equal voltages (V/2) are applied to each end of the metamaterial unit cell of Fig. 3b as shown in Fig. 13a. Due to the symmetry of the unit cell, this effectively places an open circuit (OC) at the center of the structure, thus producing two identical decoupled circuits. Note that in the circuit of Fig. 13a, the vertical vias connecting the inductors to ground have been explicitly included in order to highlight their importance as the main radiating elements in the structure.

Each via can then be replaced with its corresponding radiation resistance R_r and its associated inductance L_{via} can be added to the lumped inductor value L_0', resulting in a total inductance of L_0. By replacing the short transmission-line sections with their equivalent series inductance $L' = Ld$ and capacitance $C' = Cd$, the circuit of Fig. 13b is obtained. No current will pass through the series resonator formed by $L'/2$ and $2C_0$ because it is open circuited on one end; therefore, these components can be removed from the circuit. At resonance (when $\phi_{\mathrm{MTM}} = 0°$), the series resonator formed by $2L_0$ and $C'/2$

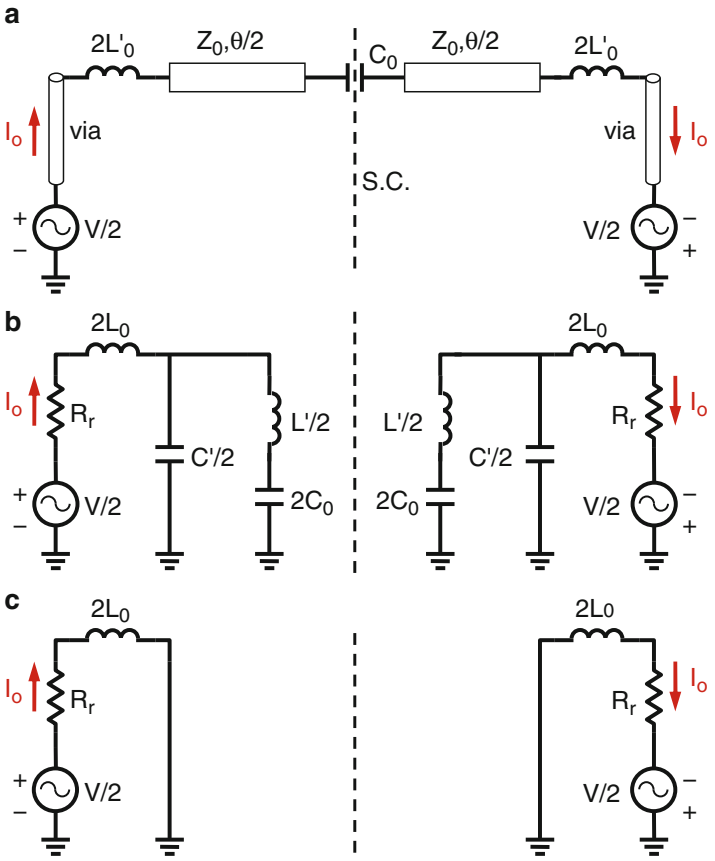

Fig. 14 Odd-mode equivalent circuits for a single unit cell of the zero-index metamaterial antenna: (**a**) TL-based metamaterial unit cell, (**b**) lumped-element equivalent circuit, and (**c**) simplified lumped-element circuit at resonance (Antoniades and Eleftheriades 2008b) © 2008 IEEE

will become a short circuit, therefore resulting in the final simplified circuit of Fig. 13c. Since no other impedances are present in the circuit other than R_r, maximum current will be delivered to the radiation resistance, given by $I_e = (V/2)/R_r$.

Considering now the odd-mode excitation, an equal and opposite voltage is applied to each end of the metamaterial unit cell as shown in Fig. 14a. Due to the symmetry of the unit cell, this effectively places a short circuit (SC) at the center of the structure, thus producing two identical decoupled circuits with equal and opposite excitations. If the vias are then replaced with their corresponding radiation resistance R_r and inductance L_{via} and the short transmission-line sections with their equivalent series inductance $L' = Ld$ and capacitance $C' = Cd$, the circuit of Fig. 14b is obtained. At resonance, the series resonator formed by $L'/2$ and $2C_0$ will become a short circuit, thus shorting out $C'/2$ and therefore resulting in the final simplified circuit of Fig. 14c. It can now be observed that the odd-mode current will be given by $I_o = (V/2)/(R_r + j\omega 2L_0)$. Therefore, the $2L_0$ inductor plays a pivotal role in adjusting the odd-mode current, and for any value of the loading inductor $2L_0$, I_e will always be greater than I_o.

Considering some representative values, a short monopole with a uniform current distribution will have a radiation resistance of (Schelkunoff and Friis 1952)

$$R_r = 160\pi^2 (h/\lambda)^2. \tag{31}$$

DOI 10.1007/978-981-4560-75-7_21-1

A close approximation to a uniform current distribution can be achieved by top loading the monopole with a metal plate, something that is inherently achieved in the microstrip design shown in Fig. 12. Therefore, for a monopole with $h/\lambda = 1/20$, the radiation resistance from Eq. 31 will be $R_r = 4\ \Omega$. Assuming that the excitation voltage is V = 1 volt, for a typical value of $L_0 = 20$ nH, at 3 GHz the magnitude of the odd-mode current is $|I_o| = 0.66$ mA. The corresponding even-mode current is $|I_e| = 127$ mA, which is approximately 190 times greater than $|I_o|$. Therefore, since the majority of the current flowing on the vertical vias lies in the even mode, this enables the metamaterial structure to act as a good radiator.

From the above discussion, it can be seen that a short monopole has a radiation resistance in the range of a few ohms, which makes it hard to match to 50 Ω. A simple way to increase the input impedance of a resonant antenna is to use a multiple folding technique (Best 2005), which relies on the fact that the currents in each arm of the antenna are in phase. As has been demonstrated with the even-odd mode analysis, this is naturally achieved with the NRI-TL metamaterial unit cell. For an antenna with N folded arms, the input impedance is given by (Best 2005)

$$R_{\text{in}} \approx N^2 R_r. \tag{32}$$

Thus, an antenna with $N = 4$ folded arms that are each $\lambda/20$ long and have $R_r = 4\ \Omega$ would have an input impedance of $R_{\text{in}} = 64\ \Omega$. This is sufficiently close to 50 Ω to provide a good match; therefore, the height of the antenna was chosen to be $h = \lambda/20 = 5$ mm.

Having established through the even-odd mode analysis that at the design frequency the zero-index metamaterial antenna maximizes the even-mode current, this enables it to be modeled as a folded monopole, thus exhibiting a substantial increase in the radiation resistance from Eq. 32. Consequently, all four vias of the antenna are excited with equal currents in terms of their magnitude and phase. Figure 15a, b shows the geometry and the simulated current distribution of the metamaterial antenna obtained using a full-wave simulator, where it can be observed that indeed all four vias are excited with equal currents. The four-unit-cell design was further extended to a design with eight unit cells as shown Fig. 15c, d, where it can again be observed that all eight vias are excited equally.

Figure 15e, f compares the input impedance of the two antennas, which verifies that indeed the radiation resistance increases according to N^2. For the four-via antenna of Fig. 15a, the full-wave simulated input resistance at resonance is $R_{\text{in}} = 70.6\ \Omega$, which is very close to the theoretical value of 64 Ω that was calculated above using Eq. 32. For the eight-via antenna of Fig. 15c, the full-wave simulated input resistance at resonance is as expected approximately four times that of the four-via antenna, i.e., $R_{\text{in}} \approx 8^2(70.6/4^2) = 282\ \Omega$. It can be noted that this result is different than the one presented in Best (2014), where the driven via is out of phase with the remaining vias. Here, all the vias are excited in phase and the folding effect of Eq. 32 is fully realized.

The final antenna of Fig. 12 has dimensions of $\lambda_0/10 \times \lambda_0/10 \times \lambda_0/20$ over a $0.45\lambda_0 \times 0.45\lambda_0$ ground plane, and it exhibits a 53 MHz −10 dB measured $|S_{11}|$ bandwidth around 3.1 GHz, as shown in Fig. 16a, and a relatively high radiation efficiency of 70 %. The radiation patterns shown in Fig. 16b, c verify that this antenna radiates a vertically polarized linear electric field vector, consistent with a vertically oriented folded-monopole geometry.

A Planar Dual-Mode NRI-TL Metamaterial-Loaded Monopole Antenna

In order to increase the bandwidth of the metamaterial antenna shown in the section "A Zero-Index NRI-TL Metamaterial Folded-Monopole Antenna," a natural extension is to create the aforementioned zero-index folded-monopole topology within the widely popular printed monopole structure. This suggests that the corresponding vertical monopole geometry of Fig. 12 is flattened into a single horizontal plane in line with the feed, which reduces significantly the height of the antenna. Figure 17 shows such a

DOI 10.1007/978-981-4560-75-7_21-1

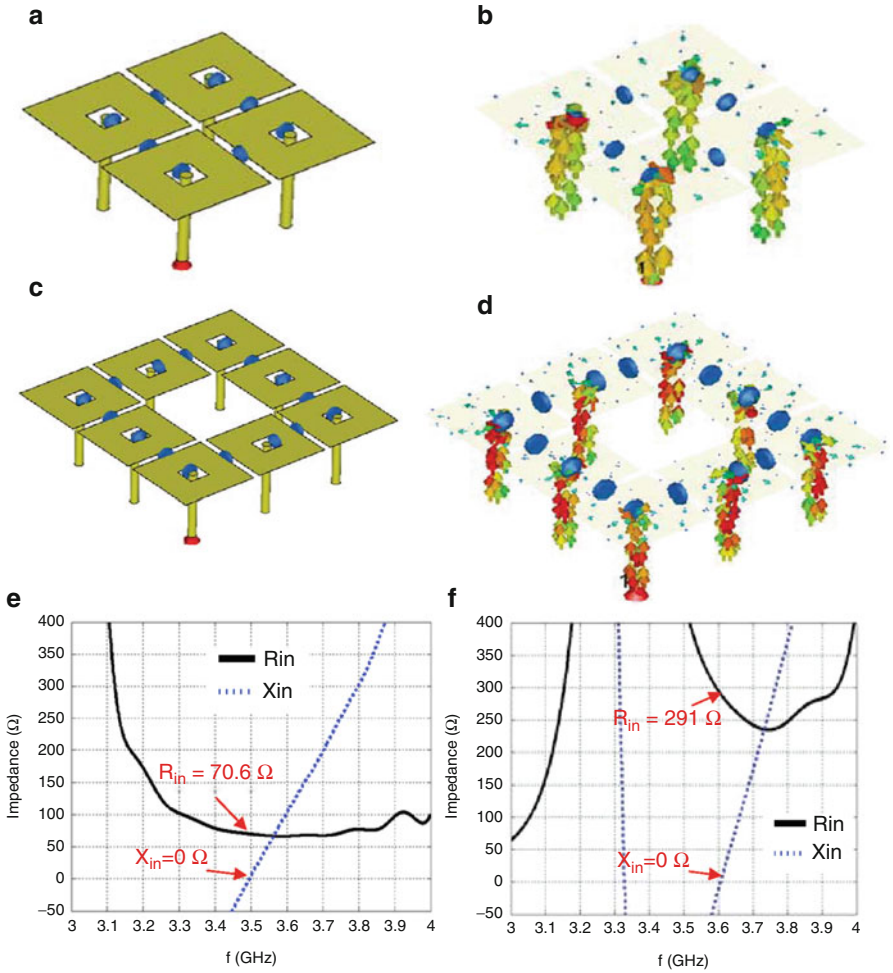

Fig. 15 (**a**) Zero-index metamaterial antenna geometry from Antoniades and Eleftheriades (2008b) with N = 4 unit cells, (**b**) current distribution at the resonant frequency of the antenna with N = 4 unit cells (all vias are in-phase), (**c**) antenna with N = 8 unit cells, (**d**) current distribution at the resonant frequency of the antenna with N = 8 unit cells (all vias are in-phase), (**e**) input impedance of the antenna with N = 4 unit cells, and (**f**) input impedance of the antenna with N = 8 unit cells. metamaterial-loaded antenna, where a single NRI-TL metamaterial unit cell has been integrated directly onto a printed monopole (Antoniades and Eleftheriades 2009).

The metamaterial unit cell was designed to operate at the $n = 0$ zeroth-order resonance under a closed stopband condition at a design frequency of $f_0 = 5.5$ GHz. Thus, at 5.5 GHz, the antenna acts as a folded monopole in the x-direction, while at 3.55 GHz, the metamaterial loading enables the top edge of the ground plane to act as a half-wavelength dipole in the orthogonal y-direction, effectively creating an additional $n = -1$ resonant mode. By virtue of the orthogonality between the two radiating modes, the metamaterial antenna exhibits an $|S_{11}|$ response with a dual resonance, as seen in Fig. 17b, and therefore a very wide measured −10 dB impedance bandwidth of 4.06 GHz.

The dual-mode operation of the antenna can be explained by considering the current distribution on the metamaterial-loaded antenna at each of the resonant frequencies, as shown in Figs. 18a and 19a. At 5.5 GHz, the metamaterial-loaded monopole was designed to achieve a zero phase shift, $\phi_{\text{MTM}} = 0°$; therefore, the currents along the monopole and along the bottom thin inductive strip were in phase. Thus, at this frequency, the metamaterial loading was used to create a two-arm folded monopole, similar to the four-arm folded monopole of the section "A Zero-Index NRI-TL Metamaterial Folded-Monopole

Antenna." As was outlined above, by adjusting the value of the loading inductance L_0, it is possible to effectively eliminate the odd-mode current on the monopole, enabling the even-mode current along the *x*-direction to radiate, as shown in Fig. 18a. Additionally, at 5.5 GHz, the currents on the two ground planes are out of phase and the balanced CPW mode is preserved; therefore, these currents do not contribute to any radiation.

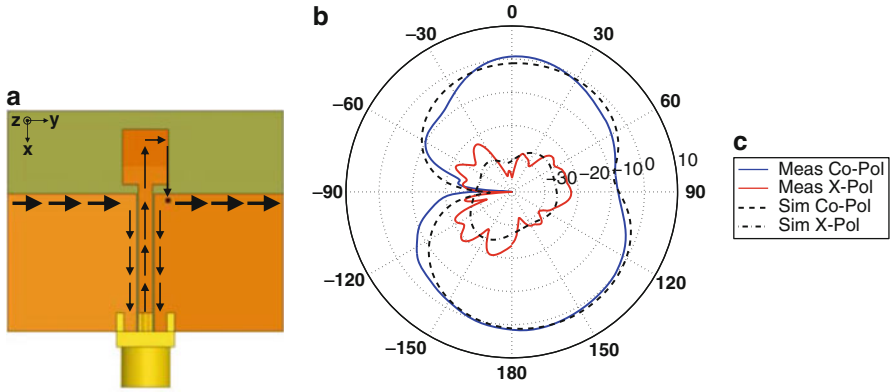

Fig. 19 (**a**) Simulated current distributions on the conductors of the metamaterial-loaded monopole antenna. (**b**) Radiation patterns in the *xy*-plane at 3.55 GHz. (**c**) Legend (Antoniades and Eleftheriades 2009), © 2009 IEEE

The radiation patterns in the *xy*-plane for the metamaterial-loaded antenna at 5.5 GHz are shown in Fig. 18b. Here, it can be observed that the antenna exhibits radiation patterns with a horizontal *x*-directed linear electric field polarization, consistent with *x*-directed currents along the monopole and the bottom thin inductive strip, shown in Fig. 18a. Thus, the radiation patterns verify that at 5.5 GHz the metamaterial loading of the monopole antenna enables it to operate as a short folded monopole.

At 3.55 GHz, the antenna no longer acts as a folded monopole along the *x*-axis, but rather as a dipole oriented along the *y*-axis. At this frequency, the metamaterial-loaded monopole acts as a balun for the ground plane currents, resulting in co-phased currents along the top edges of both the left and right ground plane sections, as shown in Fig. 19a. This renders the ground plane as the main radiating element at this frequency.

The radiation patterns in the *xy*-plane for the metamaterial-loaded antenna at 3.55 GHz are shown in Fig. 19b. At this frequency, the antenna exhibits radiation patterns with a horizontal *y*-directed linear electric field polarization, consistent with a *y*-directed current along the ground plane of the structure, as shown in Fig. 19a. Thus, the radiation patterns verify that at 3.55 GHz, the ground plane acts as the main radiating element for the antenna, providing an orthogonal polarization to the one observed at 5.5 GHz.

Thus, the metamaterial-loaded monopole antenna achieves a very-wide-band $|S_{11}|$ response by merging the resonances of the $n = 0$ zeroth-order resonant mode with the $n = -1$ resonant mode, which each provide orthogonal radiation patterns. The total size of the antenna is only $22 \times 30 \times 1.59$ mm, and the

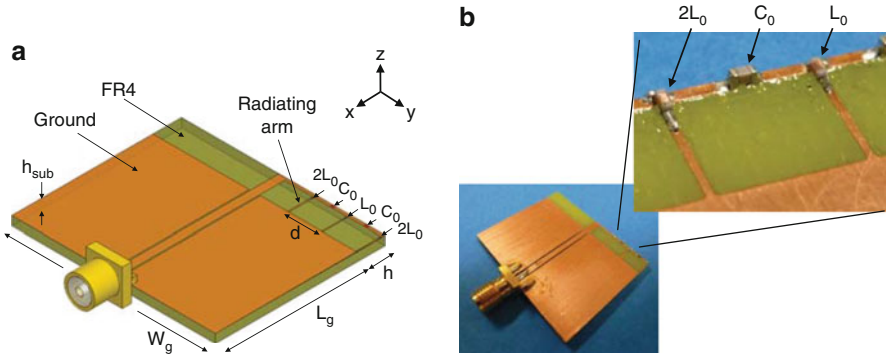

Fig. 20 Planar multi-mode NRI-TL metamaterial folded-monopole antenna. Dimensions (mm): $W_g = 36$, $L_g = 25$, $h = 5$, $d = 6$, $W_{cpw} = 1.55$, $S_{cpw} = 0.2$, $h_{sub} = 1.59$. Loading: $C_0 = 0.4$ pF, $L_0 = 12$ nH (Antoniades et al. 2013), © 2013 IEEE

measured radiation efficiency is on the order of 90 % at both 3.55 GHz and 5.5 GHz. Furthermore, its compact and low-profile design is fully printed and does not require the use of any chip lumped-element components or an external matching network.

A Planar Multi-mode NRI-TL Metamaterial Folded-Monopole Antenna

Another related antenna that is based on a fully planar topology, but which is designed to excite multiple modes, is the folded-monopole antenna shown in Fig. 20 (Antoniades et al. 2013). Here, a coplanar waveguide (CPW) transmission line has been used to feed two NRI-TL metamaterial Π unit cells that are placed asymmetrically at the top right-hand side of the structure and which are implemented using surface-mount chip components. The shunt connections to the CPW ground plane form the thin radiating arms when the antenna is excited at its zero-index folded-monopole frequency.

The metamaterial unit cells were designed to operate under an open stopband condition with a $n = 0$ zeroth-order resonance frequency around 4 GHz. At this frequency, the currents are in phase on the thin radiating arms of each unit cell, and this allows the antenna to be treated as a short multi-arm folded monopole, enabling it to be matched to 50 Ω, even though the height of each arm is only $\lambda_0/14$. Similar to the antenna presented in the section "A Planar Dual-Mode NRI-TL Metamaterial-Loaded Monopole Antenna," Fig. 21a (top) shows the current distribution at 4.18 GHz, where it can be observed that indeed at this zero-index frequency, the currents on all of the radiating arms of the metamaterial unit cells, as well as the CPW feed line, are in phase and are along the x-direction. Figure 21a (bottom) shows the current distribution at 1.92 GHz, where it can be observed that at this frequency an orthogonal dipolar mode is excited along the y-direction, equivalent to the $n = -1$ resonant mode. These two resonances can be observed in the $|S_{11}|$ response shown in Fig. 21b, in addition to another two resonances at 0.98 GHz and 1.43 GHz. The resonance at 1.43 GHz is equivalent to the $n = -2$ mode, while the resonance at 0.98 GHz is a mode created by the CPW ground plane.

The planar metamaterial folded-monopole antenna of Fig. 20 has a total size of $30 \times 36 \times 1.59$ mm^3, while the height of each radiating arm is only 5 mm. It exhibits three resonances that are matched below −10 dB, at 1.43 GHz, 1.95 GHz, and 3.81 GHz, with associated bandwidths of 25 MHz, 110 MHz, and 405 MHz, respectively, with measured radiation efficiencies in the range of 70–92 %.

Other Zeroth-Order Resonant Antennas

There are numerous other examples of antennas reported in the literature that have used the $n = 0$ zeroth-order resonance in their design to achieve beneficial characteristics such as size reduction, monopolar radiation, and multiband performance. Notable among these are the designs outlined below.

DOI 10.1007/978-981-4560-75-7_21-1

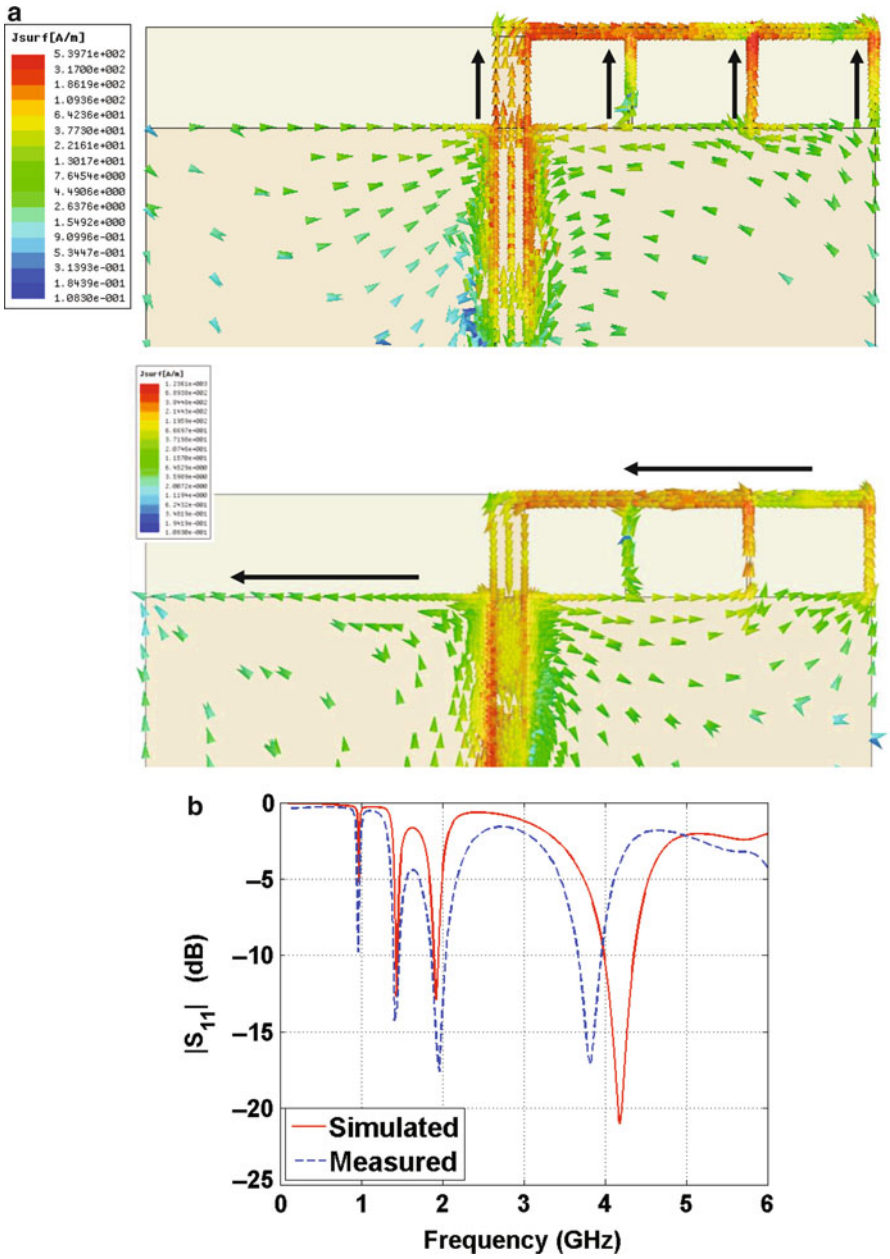

Fig. 21 (**a**) Simulated current distributions: (*top*) at 4.18 GHz, (*bottom*) at 1.92 GHz. (**b**) $|S_{11}|$ responses for the multi-mode folded-monopole antenna of Fig. 20 (Antoniades et al. 2013), © 2013 IEEE

Among the fully printed designs, a compact monopole antenna with single-cell metamaterial loading is described in Zhu et al. (2010), in which a planar monopole antenna is loaded with a via-less NRI-TL metamaterial unit cell, similar to the antenna described in the section "A Planar Dual-Mode NRI-TL Metamaterial-Loaded Monopole Antenna," and a defected ground plane is used in order to achieve a tri-band response with high radiation efficiencies. A zeroth-order resonant antenna is presented in Lee (2011) that comprises two fully printed metamaterial unit cells implemented in an asymmetric coplanar waveguide configuration. The antenna achieves in-phase horizontally directed currents on both of its shunt inductive strips at the ZOR frequency, which results in radiation patterns with a horizontal linear electric field polarization analogous to that of a short dipole directed along the axis of the inductive strips. A compact zeroth-order resonant antenna based on a fully printed dual-arm spiral configuration is

DOI 10.1007/978-981-4560-75-7_21-1

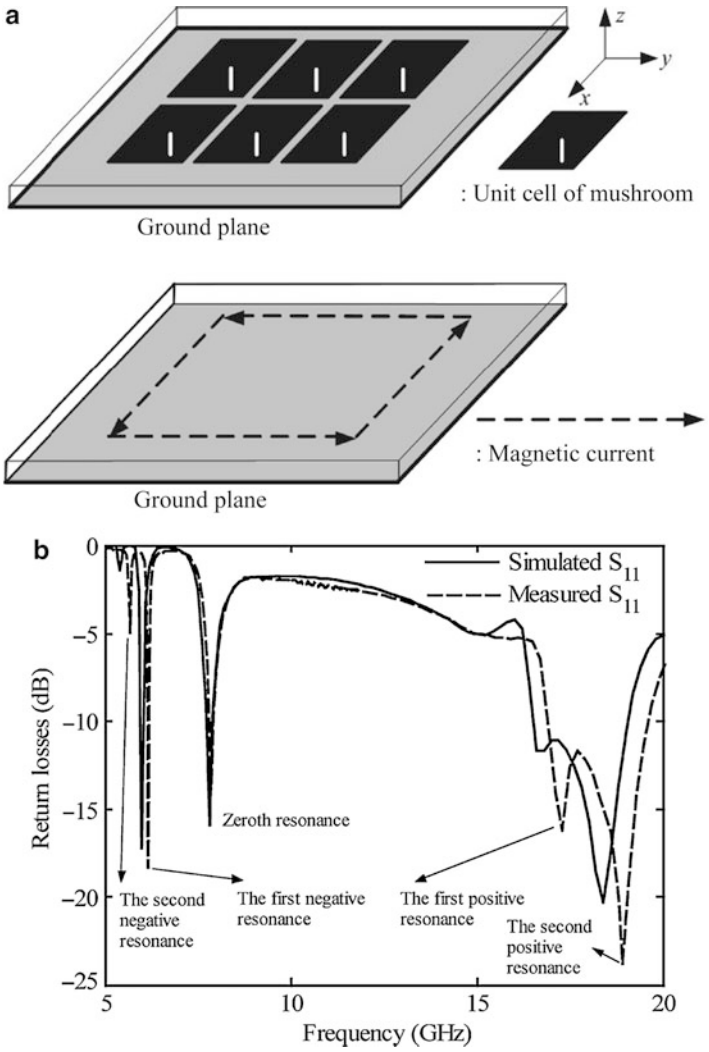

Fig. 22 (**a**) Proposed 3 × 2 mushroom ZOR antenna: (*top*) layout, (*bottom*) equivalent magnetic loop current. (**b**) $|S_{11}|$ responses (Lee and Lee 2007) © 2007 IEEE

presented in Liu et al. (2012), which is very compact and also exhibits dipole-like radiation patterns, albeit with a narrow bandwidth. In Bertin et al. (2012), three versions of fully printed metamaterial-loaded monopoles are presented, which exhibit monopolar radiation patterns and multiband responses that cover the DCS-1800, UMTS, Wi-Fi, and part of the LTE frequency bands.

Several designs have also been reported that are based on the Sievenpiper mushroom structure (Sievenpiper et al. 1999). In Lai et al. (2007), a microstrip mushroom structure is used to implement one-dimensional infinite-wavelength resonant antennas with monopolar radiation patterns, which exhibit resonances at both the $n = -1$ and $n = 0$ ZOR frequencies. The mushroom structure of Lai et al. (2007) was further miniaturized in Baek and Lim (2009) by etching a spiral slot in the ground plane, thus increasing the value of the shunt inductive loading at the expense of degraded radiation patterns. A two-dimensional version of the mushroom structure is presented in Lee and Lee (2007), seen in Fig. 22a, and it is shown that this structure emulates a horizontal magnetic loop current over a perfect electric conductor, thus producing monopolar radiation patterns at its ZOR frequency. The $|S_{11}|$ response of the antenna, shown in Fig. 22b, exhibits a $n = 0$ zeroth-order resonance at around 7.8 GHz, in addition to $n = -2$, $n = -1$, $n = 1$, and $n = 2$ resonances.

Negative-Order Resonant Antennas, $n < 0$

A Compact Metamaterial-Loaded Patch Antenna

As outlined in the section "Resonant Characteristics of NRI-TL Metamaterials," when operated in the left-handed band, i.e., with negative-order resonances, NRI-TL metamaterials can be used to miniaturize the size of conventional antennas that would normally require a resonant length of $\lambda/2$ to achieve a π phase shift across their length. Thus, the size of a conventional patch antenna that has a π phase shift between its two radiating edges can be significantly reduced by using NRI-TL metamaterials to achieve the equivalent $-\pi$ phase shift between its two radiating edges or equivalently the $n = -1$ resonant mode.

The first antenna described herein that employs the $n = -1$ resonant mode of NRI-TL metamaterials to shrink the physical size of a microstrip patch antenna is presented in Schussler et al. (2004a, b) and is shown in Fig. 23a. The fabricated prototype shown in Fig. 23a consists of two microstrip unit cells that are fed using a tapped-inductor feeding technique. Here, the shunt loading inductor L_0 has been realized using vertical wires and the series loading capacitor C_0 has been realized using a metal-insulator-metal (MIM) capacitor structure. The configuration of Fig. 23a can also be recognized as the one-dimensional version of the Sievenpiper mushroom structure, albeit with different loading compared to the $n = 0$ designs outlined in the section "Other Zeroth-Order Resonant Antennas."

The fabricated prototype of the metamaterial patch antenna has dimensions of $\lambda_0/40 \times \lambda_0/15 \times \lambda_0/40$ over a 0.6×0.6 mm^2 ground plane, and the $|S_{11}|$ response shown in Fig. 23b shows that the metamaterial patch antenna exhibits a simulated $n = -1$ resonance at 0.5 GHz with a -10 dB bandwidth of 1.5 %, while the measured resonance occurs at approximately 0.6 GHz. The measured radiation patterns in the E-plane (*xz*-plane) and the H-plane (*yz*-plane), also shown in Fig. 23b, indicate that the antenna radiates in the same manner as a conventional patch antenna, but with reduced efficiency and gain.

A Metamaterial-Based Low-Profile Broadband Mushroom Antenna

A two-dimensional antenna that uses a negative-order resonance in order to achieve a π phase shift between its radiating edges is presented in Liu et al. (2014). The antenna, shown in Fig. 24a, is a Sievenpiper mushroom structure that consists of a 4×4 array of unit cells over a ground plane that is fed by a microstrip line through a slot cut into the ground plane. The distinguishing feature of this antenna is that by placing the feeding slot directly beneath the center gap between the mushroom cells, both the

DOI 10.1007/978-981-4560-75-7_21-1

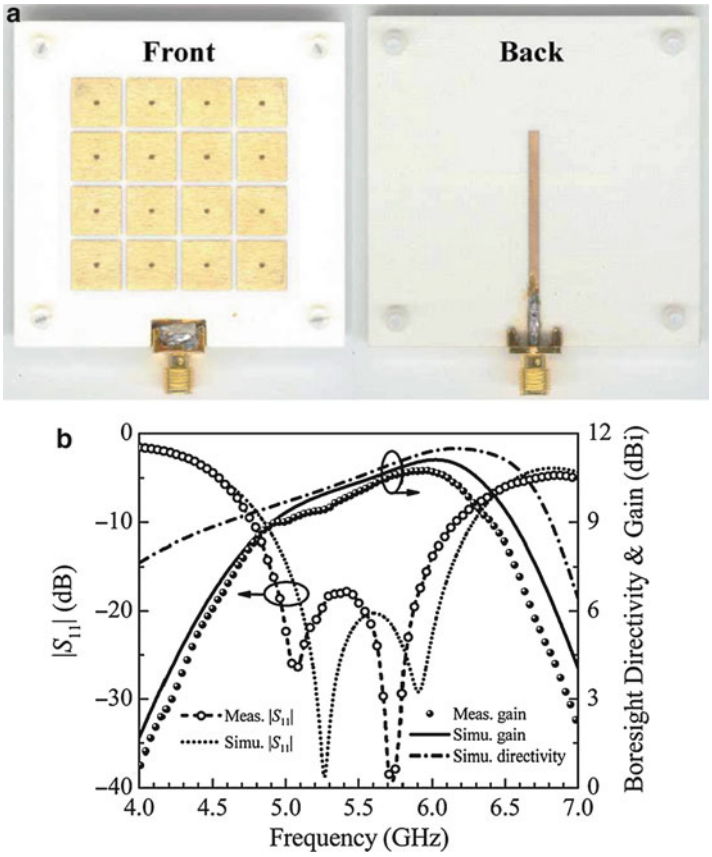

Fig. 24 (**a**) Photograph of the slot-fed metamaterial mushroom antenna. (**b**) $|S_{11}|$, directivity, and gain responses (Liu et al. 2014) © 2014 IEEE

TM_{10} and the TM_{20} modes can be excited simultaneously at nonharmonic adjacent frequencies, thus providing a broadband $|S_{11}|$ response, as shown in Fig. 24b, while maintaining radiation at broadside throughout the operating band.

Figure 25a shows the simulated electric field distribution for the mushroom antenna at 4.97 GHz, where it can be observed that the field distribution resembles the TM_{10} mode of a conventional patch antenna. A notable difference, however, is that the electric fields in the gaps between the mushroom cells and at the radiating edges at the two open ends of the antenna are in phase, therefore producing radiation. Thus, the quality factor of the mushroom antenna decreases compared to the conventional patch antenna, leading to a bandwidth enhancement.

Figure 25b shows the simulated electric field distribution for the mushroom antenna at 5.98 GHz, where it can be observed that the field distribution resembles the antiphase TM_{20} mode of a conventional patch antenna. The slot excitation on the ground plane beneath the central mushroom gap enforces opposite electric fields across the central slot region, thus exciting the antiphase TM_{20} mode with out-of-phase E_z components in the central region. This, in turn, results in co-phased electric fields in the gaps between the mushroom cells and at the radiating edges at the two open ends of the antenna, therefore also producing radiation.

The metamaterial mushroom antenna of Fig. 24a has an overall size of $60 \times 60 \times 4.1$ mm^3 and attains a measured −10 dB bandwidth of 25 %, from 4.77 to 6.16 GHz, with an average gain of 9.9 dBi. Across the bandwidth, the measured antenna efficiency is greater than 76 %, and the cross-polarization levels are less than 20 dB.

Metamaterial-Loaded Substrate Integrated Waveguide Slot Antennas

Another type of antenna that uses negative-order resonances in order to achieve size miniaturization is shown in Fig. 26a (Dong and Itoh 2010). The miniaturized waveguide slot antenna consists of a substrate integrated waveguide (SIW) that has a slot etched on its surface. The slot acts as a series loading capacitor C_0 and forms the main radiating element, while the shunt inductive posts of the SIW provide the shunt inductive loading L_0, thus enabling this type of antenna to exhibit NRI-TL metamaterial characteristics. By operating the antenna at its negative-order resonant frequencies, which are well below the initial waveguide cutoff frequency, this leads to a significant degree of miniaturization. Two different versions of

DOI 10.1007/978-981-4560-75-7_21-1

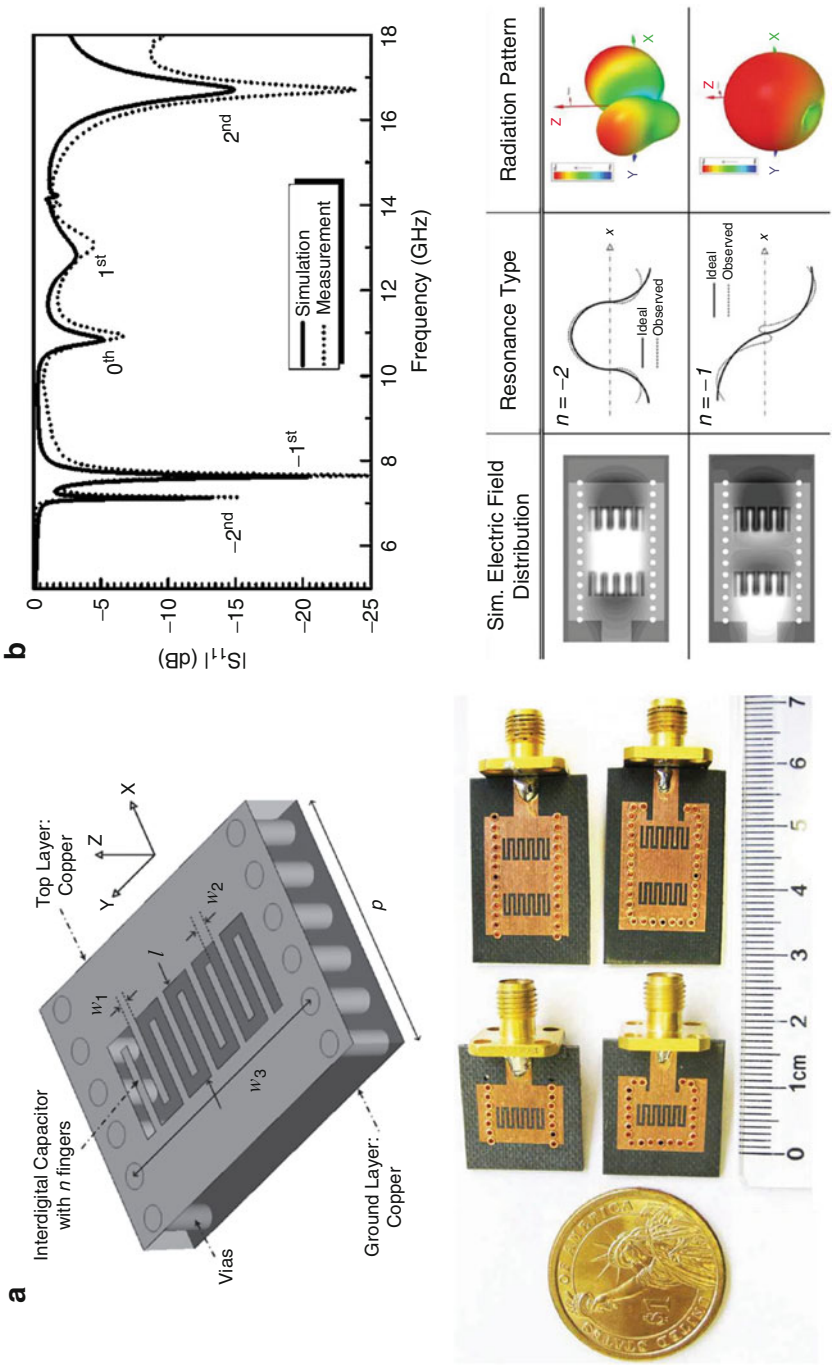

Fig. 26 (**a**) Metamaterial-loaded substrate integrated waveguide slot antennas, (**b**) $|S_{11}|$ responses, simulated electric field distributions, and radiation patterns at the $n = -2$ and $n = -1$ resonances (Dong and Itoh 2010) © 2010 IEEE

the antenna are presented, one which is open ended and one which is short ended, as shown in the prototypes on the bottom of Fig. 26a. The short-ended antenna, which represents a quasi-quarter-wavelength resonator, is essentially a cavity-backed slot antenna and therefore exhibits a high gain, while the open-ended antenna has a small size owing to its quasi-half-wavelength operation in the left-handed region.

The characteristics of a two-stage open-ended slot antenna are shown in Fig. 26b. From the $|S_{11}|$ responses, the multiband nature of the antenna can be observed, where the five resonances $n = -2$, $n = -1$, $n = 0$, $n = 1$, and $n = 2$ can be identified. The field distributions and radiation patterns for the $n = -2$ and $n = -1$ modes shown on the bottom of Fig. 26b indicate that the antenna can exhibit both dipolar and patch-type radiation characteristics at closely spaced resonant frequencies. The measured bandwidths of the antennas range from 1.5 % to 2.6 %, the measured gain from 3.2 to 6.8 dBi, and the measured efficiencies from 77 % to 91 %. The overall sizes of the antennas range from $0.265\lambda_0 \times 0.318\lambda_0 \times 0.03\lambda_0$ to $0.506\lambda_0 \times 0.343\lambda_0 \times 0.03\lambda_0$.

Other Negative-Order Resonant Patch Antennas

Various other metamaterial patch antennas have been reported in the literature that exploit the advantages of negative-order resonances that NRI-TL metamaterials have to offer (Lee et al. 2006; Tretyakov and Ermutlu 2005; Alu et al. 2007; Herraiz-Martinez et al. 2008a; Wang et al. 2010; Dong et al. 2011). One- and two-dimensional versions of metamaterial patch antenna designs that have used negative-order resonances to achieve size reduction and multiband responses have been shown in Lee et al. (2006). Additionally, in Tretyakov and Ermutlu (2005), a theoretical analysis has been presented on the benefits of using transmission-line-based metamaterials to create patch antennas with enhanced bandwidth characteristics and reduced size. Finally, in Alu et al. (2007), the possibility of designing sub-wavelength resonant patch antennas using metamaterials has been theoretically analyzed, and it is demonstrated that these designs may exhibit in principle an arbitrarily low resonant frequency for a fixed dimension, but they may not necessarily radiate efficiently when their size is electrically small. By employing a circular patch geometry, it has been shown that specific modes can be selected that enable the patch antenna to be compact, but yet exhibit comparable radiation performance to that of a conventional patch antenna of standard dimensions.

Epsilon-Negative (ENG) Antennas

Another transmission-line-based metamaterial structure that supports a zeroth-order resonant mode is the so-called epsilon-negative (ENG) structure shown in Fig. 27a in its distributed form and in Fig. 27b in its lumped-element form. It can be observed that this topology is simply an NRI-TL metamaterial unit cell

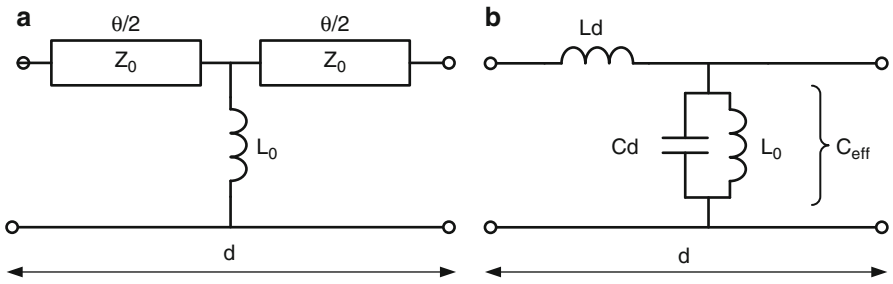

Fig. 27 Epsilon-negative (ENG) metamaterial unit cell: (**a**) symmetric distributed equivalent circuit, (**b**) lumped-element equivalent circuit

DOI 10.1007/978-981-4560-75-7_21-1

from Fig. 3 with the series loading capacitor C_0 removed, resulting in a shunt inductor-loaded transmission line.

Considering the dispersion diagram of Fig. 11, it has been outlined in the section "Resonant Characteristics of NRI-TL Metamaterials" that the NRI-TL metamaterial structure exhibits two $n = \pm 0$ zeroth-order resonant frequencies f_{-0} and f_{+0}, which can be adjusted by changing the values of the loading elements L_0 and C_0, according to Eqs. 8 and 9. Removing the series loading capacitor C_0 is equivalent to letting its value go to infinity, $C_0 = \infty$; therefore, the zeroth-order resonant frequencies become

$$f_{-0} = 0, \tag{33}$$

$$f_{+0} = \frac{1}{2\pi\sqrt{L_0(Cd)}}. \tag{34}$$

These results indicate that the ENG metamaterial structure has only one zeroth-order resonant frequency, which is determined by the values of the shunt elements in the unit cell of Fig. 27b. Therefore, for a fixed length of host transmission line, the zeroth-order resonant frequency f_{+0} can be easily tuned by simply adjusting the value of the loading inductance L_0. Additionally, like the NRI-TL metamaterial structure, the zeroth-order resonant frequency of the ENG structure is also independent of its physical length; however, since the loading capacitor C_0 has been eliminated, this allows larger degrees of antenna miniaturization to be achieved.

The dispersion relation for the ENG metamaterial structure of Fig. 27a can be obtained by setting $C_0 = \infty$ in the dispersion relation of the NRI-TL metamaterial structure given by Eq. 1 and can be written as

$$\cos(\beta_{\mathrm{BL}} d) = \cos(\theta) + \left(\frac{Z_0}{2\omega L_0}\right)\sin(\theta). \tag{35}$$

Under the effective medium conditions $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$, Eq. 35 becomes

$$\cos(\beta_{\mathrm{BL}} d) \approx 1 - \frac{1}{2}\left(\omega^2 LCd^2 - \frac{Ld}{L_0}\right). \tag{36}$$

Using Eq. 7, the effective propagation constant of the ENG metamaterial structure can be written as

$$\beta_{\mathrm{ENG}} = \omega\sqrt{L_{\mathrm{eff}} C_{\mathrm{eff}}} = \omega\sqrt{L\left[C - \frac{1}{\omega^2 L_0 d}\right]}, \tag{37}$$

$$\beta_{\mathrm{ENG}} = \sqrt{\omega^2 LC - \frac{L}{L_0 d}}. \tag{38}$$

Equation 37 demonstrates that with the appropriate value of the shunt inductor L_0, the effective shunt capacitance C_{eff} of the ENG structure (see Fig. 27b) can be made equal to zero, resulting in a zero propagation constant and therefore a zeroth-order resonance. Exactly at the zeroth-order resonance frequency f_{+0}, the effective permittivity of the structure is equal to zero and is therefore termed the epsilon-zero (EZR) point.

DOI 10.1007/978-981-4560-75-7_21-1

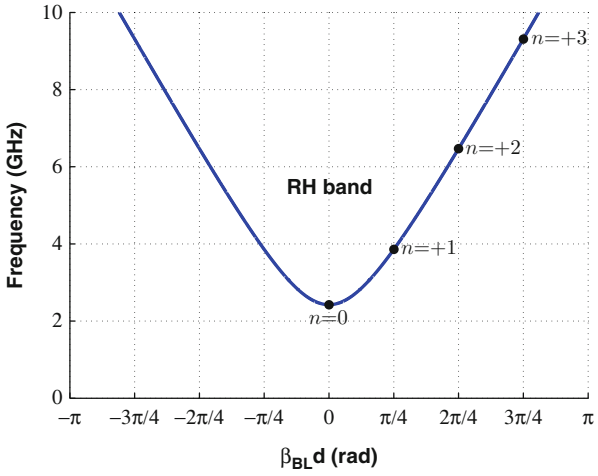

Fig. 28 Typical dispersion diagram for an ENG metamaterial unit cell with parameters $L_0 = 30$ nH, $Z_0 = 300\ \Omega$, $d = 12.5$ mm, and $\theta = 45°$ at 3 GHz. Superimposed are the locations of the nth order resonances for an ENG metamaterial structure that consists of a cascade of $N = 4$ unit cells

A representative ENG dispersion diagram is shown in Fig. 28, which was obtained using Eq. 35 and the same parameters as the NRI-TL metamaterial structure in Fig. 11. It can be observed that the ENG structure exhibits a lower stopband and a forward right-handed propagation band, and the backward left-handed band has been eliminated. Thus, unlike the NRI-TL structure which supports both forward and backward waves, the ENG structure supports only forward propagating waves, similar to a conventional transmission line. However, unlike a transmission line, propagation on the ENG structure begins above the zeroth-order resonance frequency of f_{+0} given approximately by Eq. 34; therefore, it exhibits a high-pass behavior with a DC offset.

In the general case where N unit cells are used in order to implement the ENG metamaterial structure with a total length of $\ell_{\text{TOT}} = Nd$, then the electrical length per unit cell, analogous to Eq. 21, becomes

$$\beta_{\text{ENG}} d = \frac{n\pi}{N} \quad ; \quad n = 0, 1, 2 \ldots (N-1) \tag{39}$$

An N-stage ENG metamaterial structure can therefore support a zeroth-order ($n = 0$) resonance at the $\beta_{\text{BL}} d = 0$ point, as well as positive-order ($n > 0$) resonances in the right-handed band, as shown in Fig. 28.

A Double-Resonant ENG Metamaterial Folded-Monopole Antenna

An example of an ENG metamaterial-based compact antenna is shown in Fig. 29 (Zhu and Eleftheriades 2009b). It uses the same folding technique and has a similar form to the NRI-TL metamaterial folded-monopole antenna described in the section "A Zero-Index NRI-TL Metamaterial Folded-Monopole Antenna"; however, it is implemented using ENG metamaterial unit cells. Recall that for the NRI-TL folded monopole, the shunt loading inductor L_0 was responsible for maximizing the even-mode current, and the series loading capacitor C_0 did not play a pivotal role in this process. Therefore, the elimination of the series loading capacitor C_0 in the ENG structure does not affect the ability of the antenna to act as a folded monopole, and the even-mode current is still maximized. Moreover, the ENG folded-monopole antenna of Fig. 29 employs a doubly resonant metamaterial structure in order to increase its bandwidth. The antenna consists of two ENG metamaterial arms, and each arm is designed to exhibit zeroth-order resonances at two closely spaced frequencies. Each arm comprises a microstrip transmission line loaded

DOI 10.1007/978-981-4560-75-7_21-1

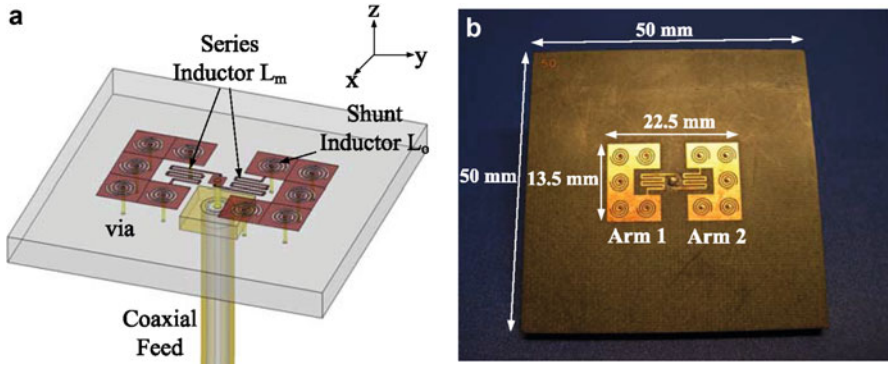

Fig. 29 Double-resonant ENG metamaterial folded-monopole antenna: (**a**) three-dimensional diagram, (**b**) photograph of the fabricated prototype (Zhu and Eleftheriades 2009b) © 2009 IEEE

with five shunt spiral inductors, whose zero-index frequency can be tuned by adjusting the value of the loading inductors. A wideband performance is achieved by merging the corresponding two resonances together into a single passband.

The antenna has dimensions of $\lambda_0/4 \times \lambda_0/7 \times \lambda_0/29$ over a $0.55\lambda_0 \times 0.55\lambda_0$ ground plane. A series meander-line inductor is employed at the feed point to compensate the capacitive input impedance, thus achieving a good impedance match to 50 Ω over a 100 MHz −10 dB measured $|S_{11}|$ bandwidth around 3.3 GHz, as shown in Fig. 30. The antenna also exhibits a vertical linear electric field polarization, similar to that of a short monopole over a small ground plane, a measured gain of 0.79 dBi, and a measured radiation efficiency of 66 %.

Other Epsilon-Negative (ENG) Antennas

Various other ENG metamaterial antennas have been reported in the literature (Lai et al. 2007; Park et al. 2007; Park and Lee 2011; Niu et al. 2013; Niu and Feng 2013; Kim et al. 2009). In Lai et al. (2007), an inductor-loaded transmission line, essentially a one-dimensional microstrip mushroom structure without the series gaps between each of the unit cells, is used to implement a one-dimensional infinite-wavelength resonant antenna with monopolar radiation patterns at the $n = 0$ ZOR frequency. This antenna was then extended to a two-dimensional version in order to increase the gain and to reduce asymmetries in the radiation patterns. In Park et al. (2007), also a one-dimensional mushroom structure

DOI 10.1007/978-981-4560-75-7_21-1

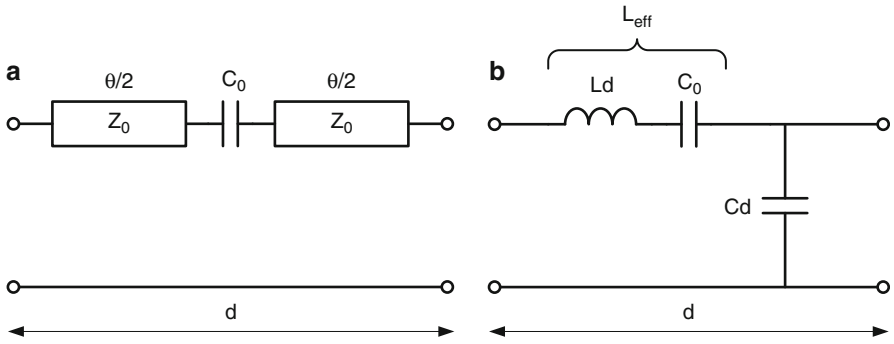

Fig. 31 Mu-negative (MNG) metamaterial unit cell: (**a**) symmetric distributed equivalent circuit, (**b**) lumped-element equivalent circuit

without the series gaps is investigated for different unit cell sizes with good gain performance. Finally, in Niu et al. (2013), a fully planar ENG antenna is presented that is implemented in asymmetric coplanar waveguide technology and which achieves dual-band and wideband performance by exciting both the $n = 0$ and the $n = 1$ resonant modes.

Mu-Negative (MNG) Antennas

Another transmission-line-based metamaterial structure that supports a zeroth-order resonant mode, which is also a variation of the NRI-TL metamaterial structure, is the so-called mu-negative (MNG) structure shown in Fig. 31a in its distributed form and in Fig. 31b in its lumped-element form. It can be observed that this topology is simply an NRI-TL metamaterial unit cell from Fig. 3 with the shunt loading inductor L_0 removed, resulting in a series capacitor-loaded transmission line.

Removing the shunt loading inductor L_0 from the NRI-TL metamaterial structure is equivalent to letting its value go to infinity, $L_0 = \infty$; therefore, from Eqs. 8 and 9, the zeroth-order resonant frequencies for the MNG metamaterial become

$$f_{-0} = 0, \tag{40}$$

$$f_{+0} = \frac{1}{2\pi\sqrt{(Ld)C_0}}. \tag{41}$$

These results indicate that the MNG metamaterial structure, like the ENG structure, has only one zeroth-order resonant frequency, which is determined by the values of the series elements in the unit cell of Fig. 31b. Therefore, for a fixed length of host transmission line, the zeroth-order resonant frequency f_{+0} can be easily tuned by simply adjusting the value of the loading capacitance C_0. Additionally, like the NRI-TL metamaterial structure, the $n = 0$ zeroth-order resonant frequency of the MNG structure is also independent of its physical length; however, since the loading inductor L_0 has been eliminated, this allows larger degrees of antenna miniaturization to be achieved.

The dispersion relation for the MNG metamaterial structure of Fig. 31a can be obtained by setting $L_0 = \infty$ in the dispersion relation of the NRI-TL metamaterial structure given by Eq. 1 and can be written as

$$\cos(\beta_{\mathrm{BL}} d) = \cos(\theta) + \left(\frac{1}{2\omega C_0 Z_0}\right)\sin(\theta). \tag{42}$$

DOI 10.1007/978-981-4560-75-7_21-1

Under the effective medium conditions $\theta \ll 1$ and $\beta_{\mathrm{BL}} d \ll 1$, Eq. 42 becomes

$$\cos\left(\beta_{\mathrm{BL}} d\right) \approx 1 - \frac{1}{2}\left(\omega^2 LCd^2 - \frac{Ld}{C_0}\right). \tag{43}$$

Using Eq. 7, the effective propagation constant of the MNG metamaterial structure can be written as

$$\beta_{\mathrm{MNG}} = \omega\sqrt{L_{\mathrm{eff}} C_{\mathrm{eff}}} = \omega\sqrt{\left[L - \frac{1}{\omega^2 C_0 d}\right] C}, \tag{44}$$

$$\beta_{\mathrm{MNG}} = \sqrt{\omega^2 LC - \frac{C}{C_0 d}}. \tag{45}$$

Equation 44 demonstrates that with the appropriate value of the series capacitor C_0, the effective series inductance L_{eff} of the MNG structure (see Fig. 31b) can be made equal to zero, resulting in a zero propagation constant and therefore a zeroth-order resonance. Exactly at the zeroth-order resonance frequency f_{+0}, the effective permeability of the structure is equal to zero and is therefore termed the mu-zero (MZR) point.

A representative MNG dispersion diagram is shown in Fig. 32, which was obtained using Eq. 42 and the same parameters as the NRI-TL metamaterial structure in Fig. 11. It can be observed that the MNG structure exhibits a very similar response to the ENG structure, with a lower stopband and a forward right-handed propagation band, and the backward left-handed band has been eliminated. Thus, unlike the NRI-TL structure which supports both forward and backward waves, and similar to the ENG structure, the MNG structure supports only forward propagating waves, similar to a conventional transmission line. However, unlike a transmission line, propagation on the MNG structure begins above the zeroth-order resonance frequency of f_{+0} given approximately by Eq. 41; therefore, it exhibits a high-pass behavior with a DC offset. Note also that by comparing the three dispersion diagrams shown in Figs. 11, 28, and 32, the location of the $n = -0$ resonance for the NRI-TL structure corresponds to the $n = 0$ resonance of the

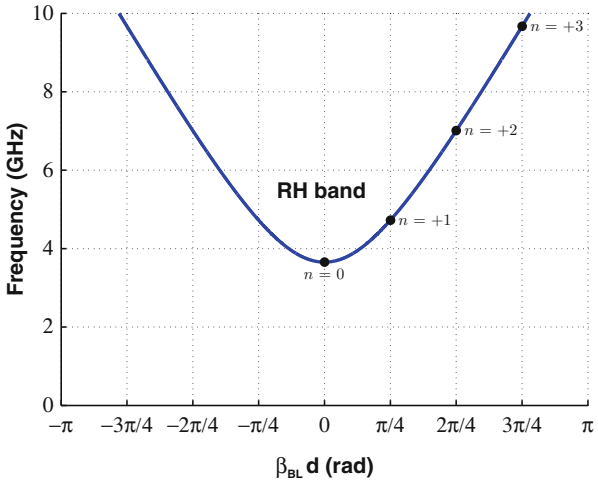

Fig. 32 Typical dispersion diagram for an MNG metamaterial unit cell with parameters $C_0 = 0.14$ pF, $Z_0 = 300\ \Omega$, $d = 12.5$ mm, and $\theta = 45°$ at 3 GHz. Superimposed are the locations of the nth order resonances for an MNG metamaterial structure that consists of a cascade of $N = 4$ unit cells

DOI 10.1007/978-981-4560-75-7_21-1

ENG structure, and the location of the $n = +0$ resonance for the NRI-TL structure corresponds to the $n = 0$ resonance of the MNG structure.

In the general case where N unit cells are used in order to implement the MNG metamaterial structure with a total length of $\ell_{TOT} = Nd$, then the electrical length per unit cell, analogous to Eq. 21, becomes

$$\beta_{MNG} d = \frac{n\pi}{N} \quad ; \quad n = 0, 1, 2, \ldots (N-1) \tag{46}$$

An N-stage MNG metamaterial structure can therefore support a zeroth-order ($n = 0$) resonance at the $\beta_{BL} d = 0$ point, as well as positive-order ($n > 0$) resonances in the right-handed band, as shown in Fig. 32.

A Dual-Band MNG Metamaterial Loop Antenna

An example of a dual-band MNG metamaterial loop antenna is shown in Fig. 33a (Park et al. 2010). It uses a microstrip transmission line that is loaded with series interdigital capacitors in order to implement the MNG metamaterial unit cells. Interdigital capacitors with different finger numbers were investigated, and it was found that ones with a higher number of fingers result, as expected, in a larger series loading capacitance, C_0, and therefore a lower zeroth-order resonance frequency. However, the trade-off of implementing a larger loading capacitance is a larger size.

It is noted that because the zeroth-order resonance for the MNG structure is obtained at the resonant frequency of the series branch of the MNG structure of Fig. 31b, short-circuit boundary conditions are necessary at the ends of an MNG resonant structure in order to support a resonance. This is in contrast to ENG resonant structures, which require open-circuit boundary conditions in order to support a zeroth-order resonance, which is due to the shunt branch of the ENG structure, as seen in Fig. 27b. The MNG antenna is therefore formed by short-circuiting a capacitively loaded microstrip transmission line at its

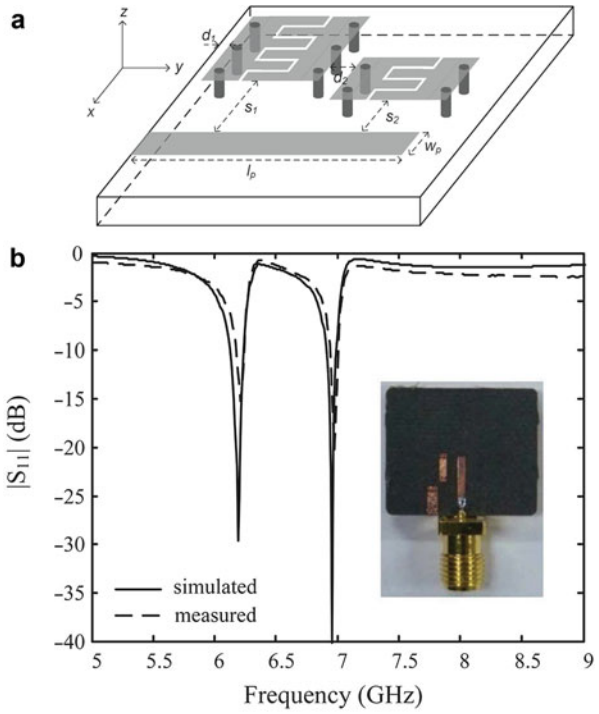

Fig. 33 (**a**) Dual-band MNG metamaterial loop antenna, (**b**) $|S_{11}|$ responses (Park et al. 2010) © 2010 IEEE

DOI 10.1007/978-981-4560-75-7_21-1

two ends with metallic vias, and it is fed using a microstrip line that magnetically couples into the resulting loop. The microstrip feed line is open ended and is designed to have a length equal to a quarter wavelength at the antenna's zeroth-order resonant frequency. The use of the microstrip feed line therefore limits the minimum achievable size for the MNG antenna to a quarter wavelength.

A dual-band antenna is created by adding a second MNG structure with a different size, and therefore a different zeroth-order resonance, to the same feed line, as shown in Fig. 33a. In this design, the first MNG structure consists of a single unit cell that has an interdigital capacitor with six fingers that resonate at a frequency of 6.2 GHz, and the second MNG structure also consists of a single unit cell that has an interdigital capacitor with four fingers that resonate at a frequency of 7 GHz. The distance between each of the MNG structures and the feed line was optimized in each case in order to maximize the coupling to each of the resonators.

The $|S_{11}|$ response of the antenna is shown in Fig. 33b, where the dual-band performance can be observed. The MNG antenna achieves 1.03 % and 0.95 % fractional bandwidths at 6.2 GHz and 7 GHz, respectively, with associated measured gains of 2.3 dBi and 3.3 dBi and efficiencies of 83 % and 84 %. The size of the antenna is $0.108\lambda_0 \times 0.175\lambda_0$ at 6.2 GHz and $0.121\lambda_0 \times 0.197\lambda_0$ at 7 GHz.

Other Mu-Negative (MNG) Antennas

Various other MNG metamaterial antennas have been reported in the literature (Bilotti et al. 2008; Wei et al. 2012a, b). In Bilotti et al. (2008), the size reduction of a circular patch antenna that is printed on a substrate that is partially with an MNG metamaterial is theoretically investigated. It is shown that a sub-wavelength metamaterial patch antenna can be achieved with satisfactory matching and radiating performance by employing split-ring resonators as the magnetic inclusions beneath the patch antenna. In Wei et al. (2012a, b), two versions of MNG loop antennas are presented, which consist of circular loop antennas that are periodically loaded with capacitors. This configuration enables uniform, in-phase current along the loop, therefore achieving a horizontally polarized omnidirectional radiation pattern, similar to a magnetic dipole antenna, even though the perimeter of the loop is comparable to the operating wavelength. Additionally, the capacitive loading enables a wide impedance bandwidth to be achieved.

NRI-TL Metamaterial Dipole Antennas

Most of the metamaterial antenna applications that have been described so far have been based on folded monopoles, printed monopoles, and patch antennas. Another type of antenna that can be designed based on metamaterial techniques, and which exhibits negative-order, zeroth-order, and positive-order resonances, is the differentially fed dipole antenna.

Some examples of metamaterial-loaded dipole antennas that have been reported in the literature are Ziolkowski and Erentok (2006), Jin and Ziolkowski (2010), Herraiz-Martinez et al. (2008b, 2011), Iizuka and Hall (2007), Liu et al. (2009), and Antoniades and Eleftheriades (2011a, b, 2012). In Ziolkowski and Erentok (2006), an electrically small electric dipole antenna was surrounded by a negative-permittivity shell, and it was demonstrated that the distributed inductance of the shell could be resonantly matched to the capacitive electrically small dipole. Thus, a resonant system was achieved which was matched to the source impedance, therefore leading to high overall efficiencies. Metamaterial-engineered planar dipole antennas have also been presented in Jin and Ziolkowski (2010), which have linear or circular polarizations. Another idea presented in Herraiz-Martinez et al. (2008b) demonstrated that a printed dipole antenna that is loaded with split-ring resonators can achieve a dual-band $|S_{11}|$ response.

The authors in Iizuka and Hall (2007) and Liu et al. (2009) have demonstrated that creating a dipole antenna from an asymmetrically loaded left-handed transmission line leads to a difference in the amplitudes of the out-of-phase currents on each of the transmission-line conductors. Therefore, the two currents do not completely cancel each other out in the far field, enabling the structure to radiate. Even

DOI 10.1007/978-981-4560-75-7_21-1

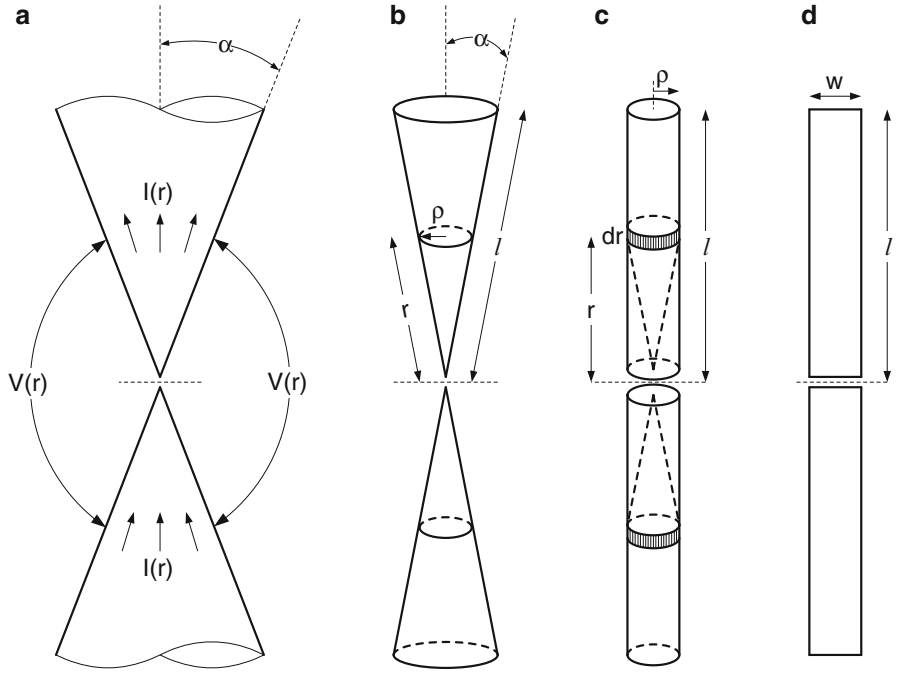

Fig. 34 The evolution of Schelkunoff's infinite biconical antenna into a planar dipole antenna. (**a**) Infinite biconical antenna, (**b**) finite biconical antenna, (**c**) cylindrical dipole antenna, and (**d**) planar dipole antenna (Antoniades and Eleftheriades 2012) © 2012 IEEE

though a multiband $|S_{11}|$ response is achieved, the reported efficiency and gain of the antennas in Iizuka and Hall (2007) are quite low, due to the partial cancelation of the current, combined with the presence of material losses in the printed components. In Liu et al. (2009), the authors have optimized the design of the left-handed dipoles in order to improve the efficiency of their antennas.

Herein, a technique is adopted for the design of a metamaterial-loaded dipole antenna that does not rely on an asymmetrically loaded transmission line in order to create an unbalanced radiating current. Instead, in an approach initially proposed by Schelkunoff, the two arms of a dipole antenna are modeled as the two conductors of a biconical transmission line. The biconical transmission line can subsequently be transformed into its equivalent dipole counterpart through the process shown in Fig. 34. This allows the dipole antenna to be treated as the host transmission line in a conventional NRI-TL metamaterial structure and provides a suitable medium for the placement of the loading elements. As such, the NRI-TL properties of the structure are maintained, while still creating an efficient radiator.

The proposed NRI-TL metamaterial-loaded dipole antenna is shown in Fig. 35 (Antoniades and Eleftheriades 2012). It consists of a planar dipole antenna on an FR4 substrate in the shape of a bow tie with a small flare angle, two series capacitive gaps forming the loading capacitance C_0, and two shunt inductive strips forming the loading inductance L_0, resulting a two-unit-cell metamaterial-loaded dipole antenna.

Referring to Fig. 35, the first NRI-TL unit cell is formed by the two central dipole conductors connected to the feed, which are joined at their ends through two vias to a thin inductive strip on the bottom of the substrate. Thus, the two central dipole conductors effectively form a transmission line with a characteristic impedance Z_{01} and length l_1 which is inductively loaded at its end with a thin inductive strip with an inductance L_{01}. Since the dipole arms have a finite length, Schelkunoff showed that this can be modeled as a terminal impedance, Z_{t1}, connected to the end of the transmission line. Therefore, this terminal impedance must be added in parallel to the impedance of the thin inductive strip. The transmission line

DOI 10.1007/978-981-4560-75-7_21-1

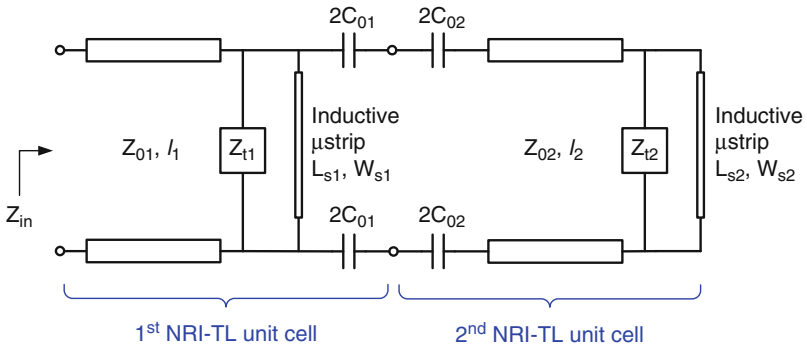

Fig. 36 Equivalent circuit of the NRI-TL dipole antenna of Fig. 35 (Antoniades and Eleftheriades 2012) © 2012 IEEE

is also connected to a series capacitance $2C_{01}$, formed in part due to the capacitive gaps in each of the dipole arms.

The second NRI-TL unit cell is formed by the two outer dipole conductors, which are also joined at their ends through two vias to a longer thin inductive strip, which was centered on the bottom of the board. Thus, the two outer dipole conductors effectively form another transmission line with a characteristic impedance Z_{02} and length l_2, which is inductively loaded at its end with a longer inductive strip with an inductance L_{02}. To the impedance of the thin inductive strip, the terminal impedance, Z_{t2}, of the finite dipole arms must be added as with the first unit cell. The transmission line is also connected at its input to a series capacitance $2C_{02}$, formed in part due to the capacitive gaps in each of the dipole arms.

In this manner, the equivalent circuit of the NRI-TL dipole antenna shown in Fig. 36 is formed, which consists of two cascaded asymmetric NRI-TL metamaterial unit cells. Figure 37a shows the $|S_{11}|$ responses obtained from the Agilent-ADS circuit simulator for the equivalent circuit of the dipole antenna of Fig. 36 for different values of the inductive strip length L_{s2}. Note that while L_{s2} was varied, the total length of the antenna was kept at $L_2 = 50$ mm, and all of the other geometrical parameters were also kept constant. Figure 37b shows the full-wave simulated $|S_{11}|$ responses obtained from Ansoft-HFSS for the NRI-TL dipole antenna of Fig. 35 for different values of the bottom inductive strip L_{s2}. It can be observed that the general performance of the antenna equivalent circuit matches well with the performance obtained from the full-wave HFSS results, thus validating the antenna equivalent circuit. It can also be observed that all of the antenna responses exhibit multiband characteristics, with four distinct resonances in the frequency range shown.

Parameters: $C_{01} = C_{02} = 0.2$ pF, $L_{s1} = 28$ mm, $W_{s1} = 0.1$ mm, $L_{s2} = 35 \rightarrow 50$ mm, $W_{s2} = 0.1$ mm, $Z_{01} = 312.6\ \Omega$, $Z_{02} = 355.2\ \Omega$, $l_1 = 13.6$ mm, $l_2 = 10.9$ mm, and $\beta l_1 = 49°$ and $\beta l_2 = 39.2°$ at 3 GHz. (**b**) HFSS simulated $|S_{11}|$ responses of the multiband NRI-TL metamaterial-loaded dipole antenna of Fig. 35 for different values of the bottom inductive strip length, $L_{s2} = 35 \rightarrow 50$ mm (Antoniades and Eleftheriades 2012) © 2012 IEEE

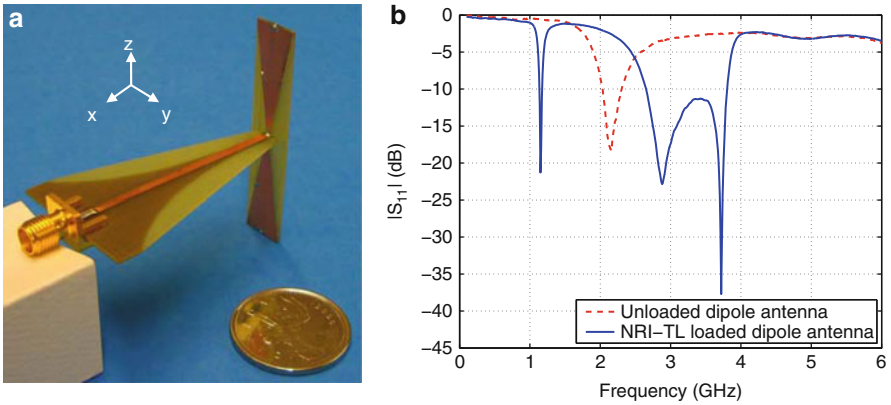

Fig. 38 Photograph of the NRI-TL metamaterial-loaded dipole antenna of Fig. 35 with $L_{s2} = 50$ mm, fed using a broadband transition. (**b**) Measured $|S_{11}|$ response of the antenna in (**a**), compared with the measured $|S_{11}|$ response of a reference unloaded dipole antenna fed using the same transition and with the same overall dimensions (Antoniades and Eleftheriades 2012) © 2012 IEEE

The fabricated prototype of the NRI-TL dipole antenna is shown in Fig. 38a. The measured $|S_{11}|$ response of the antenna is shown in Fig. 38b, compared to the measured $|S_{11}|$ response of a reference unloaded dipole antenna. It can be observed that the NRI-TL dipole antenna exhibits three distinct resonances corresponding to the $n = -1$, $n = -0$, and $n = +0$ resonances at 1.15 GHz, 2.88 GHz, and 3.72 GHz, with associated -10 dB bandwidths of 37 MHz and 1150 MHz, while the unloaded antenna exhibits only a single resonance at 2.15 GHz with a bandwidth of 275 MHz. Thus, the NRI-TL dipole antenna exhibits a 47 % reduction of the lowest resonant frequency compared to the reference unloaded dipole antenna. Furthermore, at 1.15 GHz, the length of the antenna, $L_2 = 50$ mm, is $0.19\lambda_0$, which represents a miniaturization factor of approximately two compared to the unloaded dipole antenna which has a length of $0.36\lambda_0$ at its resonant frequency of 2.15 GHz. Throughout the bands of operation, the antenna maintains a linear electric field polarization, and the measured gain and radiation efficiency vary from 0.11 dBi to 3.26 dBi and 49.5–95.6 %, respectively.

Metamaterial-Inspired Antennas

The numerous antenna designs that have been published on transmission-line-based metamaterials, as well as volumetric metamaterials based on split-ring resonators and wires, have also led to the creation of many antenna designs that are not metamaterial-based per se but that have been inspired by metamaterial concepts. Thus, metamaterials have provided a conceptual route for implementing many small resonant antennas (Zhu and Eleftheriades 2009a, 2010; He and Eleftheriades 2012; Ryan and Eleftheriades 2012).

A dual-band monopole antenna that employs metamaterial-inspired reactive loading is shown in Fig. 39a (Zhu and Eleftheriades 2009a). It comprises a two-arm fork-like CPW-fed monopole with a thin-strip inductor loaded on top of the monopole and an interdigital capacitor loaded on the right-side arm. Alternatively, it can be seen as a T-shaped slot cut out of the rectangular patch with a capacitor loaded on its right. This metamaterial-inspired loading enables the antenna to operate in two modes, covering the lower Wi-Fi band of 2.40–2.48 GHz and the upper Wi-Fi band of 5.15–5.80 GHz. The first mode is a monopole mode that operates at the upper Wi-Fi band, where the capacitor becomes a short circuit and the inductor becomes an open circuit. In addition to the monopole resonance at the upper Wi-Fi band, the metamaterial-inspired reactive loading introduces a second resonant mode the lower Wi-Fi band. At this frequency, the antenna no longer acts as a monopole along its axis, but rather as a slot along this axis.

Figure 39b shows the $|S_{11}|$ response of the metamaterial-inspired antenna, compared to the $|S_{11}|$ response of a reference unloaded antenna, where a dual-band performance of the metamaterial-inspired antenna can be clearly seen compared to the unloaded CPW-fed monopole antenna. The antenna exhibits a measured −10 dB bandwidth of 90 MHz at the lower Wi-Fi band from 2.42 to 2.51 GHz and a bandwidth of 3.2 GHz from 4.52 to 7.72 GHz for the upper Wi-Fi band, with measured efficiencies of 89.2 % at 5.50 GHz and 64.0 % at 2.46 GHz and measured gains of 1.53 at 5.50 GHz and 0.71 at 2.46 GHz. The measured radiation patterns confirm the operation of the antenna as a conventional printed monopole in the upper band and a slot in the lower band.

Active Non-Foster Matching Networks for Small Antennas

Having described numerous passive antenna applications of transmission-line metamaterials in the previous section, the focus of this section shifts to active devices and specifically how these can be used in the design of compact and broadband antennas.

Antenna matching for receivers improves the received signal-to-noise ratio (SNR) and, for transmitters, enhances the radiated power efficiency. However, for electrically small antennas, because of their high-quality factor (high-Q), matching becomes a challenging task. In fact, a fundamental limit on the quality factor of a linearly polarized antenna with a radiation efficiency of η and an electrical size of ka, due to Wheeler (1947), Chu (1948), and Harrington (1960), is given by

$$Q = \eta\left(\frac{1}{k^3a^3} + \frac{1}{ka}\right). \tag{47}$$

The Chu limit above inversely relates the minimum achievable Q of an antenna to its electrical size; therefore, a small antenna assumes a high-Q. In turn, to match a high-Q electrically small antenna with a lossless passive matching network, the achievable matching bandwidth is constrained by another fundamental limit – namely, the Bode-Fano limit (Bode 1947; Fano 1950). This limit inversely relates the matching bandwidth to the Q of the load to be matched (here the antenna). All previously discussed small metamaterial antennas in this chapter were passive and thus subject to these matching limitations. The employment of active components, including reactive non-Foster elements, in the antenna or in the matching network, is sought to overcome either of these fundamental limits, and this will be the subject of this section. But, what are reactive non-Foster elements?

Zobel and Foster established that passive, non-dissipative, two-terminal reactances exhibit a positive slope with frequency (Zobel 1923; Foster 1924) – that is, the reactance X and the susceptance B of such networks for all frequencies satisfy:

$$\frac{\partial X}{\partial \omega} > 0 \quad \text{and} \quad \frac{\partial B}{\partial \omega} > 0\,. \tag{48}$$

Nonetheless, one can think of reactive elements with an anomalous behavior which, in contrast to Eq. 48, exhibit a negative slope with frequency; hence, they are called non-Foster reactive elements. For the reactances X_{NF} and susceptances B_{NF} of such networks and at least in part of the frequency spectrum:

$$\frac{\partial X_{NF}}{\partial \omega} < 0 \quad \text{and} \quad \frac{\partial B_{NF}}{\partial \omega} < 0\,. \tag{49}$$

Simple representative examples of non-Foster elements include negative capacitors and negative inductors.

Implementation of Reactive Non-Foster Elements

The networks employed for synthesizing non-Foster reactive elements must inevitably lack the condition of Foster's reactance theorem in Eq. 48. Therefore, these elements need to be designed using lossy (Mirzaei and Eleftheriades 2013c) or non-passive – i.e., active – networks (Linvill 1953). Traditionally, non-Foster reactive elements are implemented by two groups of circuits called negative impedance converters (NICs) and negative impedance inverters (NIIs). The operation of these circuits is schematically shown in Fig. 40.

DOI 10.1007/978-981-4560-75-7_21-1

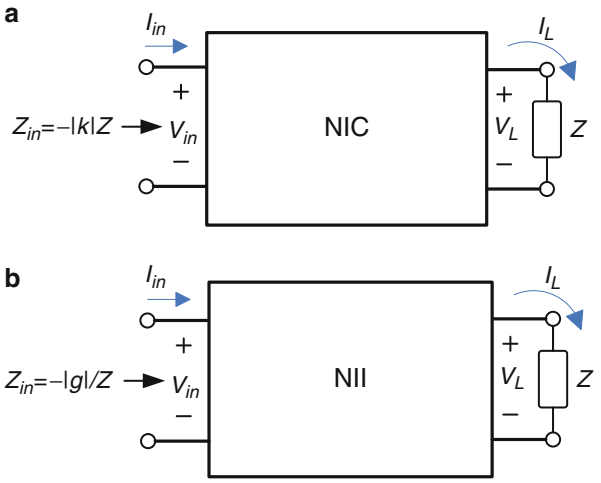

Fig. 40 The operation of (**a**) a negative impedance converter (NIC) and (**b**) a negative impedance inverters (NII) as two-port networks

According to Fig. 40a, NICs are two-port networks terminated at one port to an impedance, and looking into the other port, the negative of the termination impedance, with a scaling factor, is seen. For example, terminating such a network to a capacitor results in a negative capacitor. This property remains invariant by interchanging the input and output ports. Moreover, NICs change either the direction of the load current or invert the polarity of the load voltage, as seen from the input terminals. These two types are, respectively, named current-inversion NICs (INICs) and voltage-inversion NICs (VNICs). Furthermore, NIC circuits are usually open-circuit stable (OCS) at one port and short-circuit stable (SCS) at the other port (Brownlie 1966). A port is said to be OCS (SCS), if for any arbitrary passive impedance Z connected to the other port, the network obtained by open-circuiting (short-circuiting) the OSC (SCS) port remains stable. However, the knowledge of OCS and SCS ports does not provide enough information about the stability of a given NIC circuit terminated to arbitrary loads except for an open or short circuit (Stearns 2011).

On the other hand, according to Fig. 40b, for terminated NIIs, the driving-point impedance at the input port is the inverse of the termination impedance, with a negative scaling factor. The operation of NIIs is similar to gyrators, but with a difference that NIIs have a negative gyration resistance (or conductance). As such, terminating an NII to a capacitor results in a negative inductor, as seen from the input port.

An inventory of some of the NIC circuits has been gathered in Sussman-Fort (1998) and Stearns (2011). These circuits include Linvill's single-ended and balanced VNICs (Linvill 1953), Larky's INIC (Larky 1956, 1957), Yanagisawa's INIC (Yanagisawa 1957), Sandberg and Nagata's INIC (Sandberg 1960; Nagata 1965), Hakim's VNICs and INIC (Hakim 1965), and Myers' VNICs and INICs (Myers 1965). In addition to these NIC circuits, a popular NII realization that uses two FET devices can be found in Brucher et al. (1995) and Kolev et al. (2001).

It should be noted that different NIC and NII circuits perform differently in terms of stability margin, noise, nonlinear behavior, and sensitivity to the transistor parameters. More importantly, the stability issues of a selected NIC or NII need to be carefully treated for a successful implementation of non-Foster reactive elements. The difficulty of this treatment becomes more obvious by noticing that all numerical port-based stability tests, including Rollet's k factor and μ test, which work sufficiently well in many microwave amplifier design tasks, widely fail in predicting the stability of non-Foster circuits (Stearns 2011, 2012, 2013).

DOI 10.1007/978-981-4560-75-7_21-1

A complete assessment of the network poles, by calculating the zeros of the network determinant (or its normalized determinant), can be a comprehensive way of determining the stability of non-Foster circuits, where a stable circuit must have no right-hand plane (RHP) poles (Bode 1947). In this regard, by building up on the concept of the normalized determinant function (NDF) and a simple way of calculating the NDF using "return ratios" (Bode 1947), Struble and Platzker implemented a method to evaluate the NDF using CAD tools (Struble and Platzker 1993; Platzker and Struble 1994). These days, the NDF method can be found integrated into commercial microwave simulation tools. The NDF analysis takes into account the effects of all loops in the network and is a reliable method. Nevertheless, it requires access and control over the internal linear-dependent sources in the models of the active devices used in the design. Therefore, when having access only to the S-parameters or the compiled linear models with no control over the active dependent sources inside the model, this method cannot be employed. In these situations, the Nyquist test applied to an accurate estimation of the loop gain in the feedback network can be a compelling choice (Middlebrook 1975; Tian et al. 2001).

More recently, an alternative approach for implementing reactive non-Foster elements using loss-compensated negative-group-delay (NGD) networks has been presented (Mirzaei and Eleftheriades 2013c). This approach naturally leads to stable implementations. It is developed by observing that non-Foster reactive elements and loss-compensated NGD networks influence propagating waves in a similar fashion.

Antennas with External Non-Foster Matching Networks

A brief review of the early applications of non-Foster reactive elements in small antenna matching networks can be found in Sussman-Fort and Rudish (2009). In this regard, the early works of Harris et al. (Harris and Myers 1968) and Perry (Albert 1973), which are briefly explained below, remarkably stand out. Other related works have been reported in Albee (1976), Bahr (1977), Sussman-Fort and Rudish (2009), Stearns (2011, 2013), White et al. (2012) and Xu et al. (2012). These applications can be explained with the help of a representative equivalent-circuit model.

An electrically small dipole or monopole antenna can be modeled with a simple series-*RC* equivalent circuit, where the radiation resistance is proportional to the square of frequency – i.e., $R_r = R_0(f/f_0)^2$. In this relation, R_0 represents the radiation resistance at a given frequency f_0.

Assuming that one has access to non-Foster inductances and capacitances, the antenna can be perfectly matched to the characteristic impedance of the system Z_0 as shown in Fig. 41a, where a negative capacitor

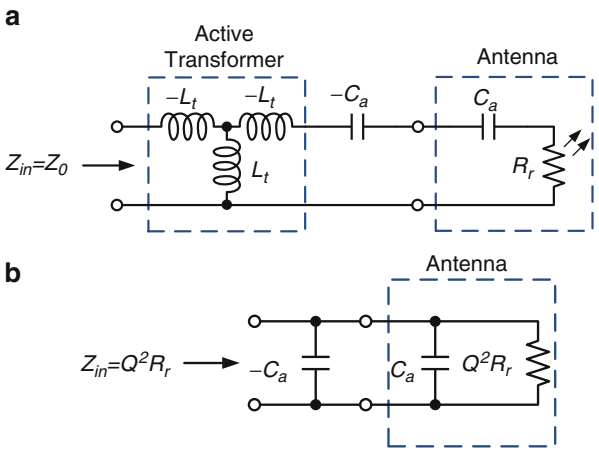

Fig. 41 (**a**) Perfect matching and (**b**) a more practical approach for matching an electrically small monopole using reactive non-Foster elements

DOI 10.1007/978-981-4560-75-7_21-1

tunes out the capacitance of the antenna and a step-up non-Foster T-transformer is used to cancel out the quadratic frequency dependence of R_r and match it to Z_0 (Skahill et al. 1998).

This scheme is too complicated, and considering all practical trade-offs, including difficulty of implementation, biasing, and noise, usually a much simpler approach involving only one series or parallel non-Foster capacitor at the terminals of the antenna is adopted. The scheme using a series floating negative capacitor is the same as the one in Fig. 41a without the non-Foster T-transformer. Using this approach, the antenna reactance is effectively eliminated, but the input resistance remains small and highly frequency dependent. Thereby, the antenna is not matched to the characteristic impedance of the system. Another scheme using one parallel capacitor, due to Harris et al. (Harris and Myers 1968), can be explained by converting the equivalent circuit of the small monopole antenna from a series *RC* to parallel *RC* as shown in Fig. 41b. This equivalent circuit is valid because of the large Q of an electrically small antenna. Then, by placing a single-negative capacitor parallel to the terminals of the antenna, the reactive part of the input admittance can be effectively eliminated over a broad frequency range, but the remaining resistive part is highly frequency dependent, assumes very large values, and is not matched to the characteristic impedance of the system. Nevertheless, overall improvements in gain (Harris and Myers 1968; Albert 1973) and SNR (Sussman-Fort and Rudish 2009) in a wide frequency range have been reported using such simple schemes involving one series or parallel non-Foster capacitor.

These ideas of matching have attracted strong interest over the past few decades; however, the actual implementations have remained challenging due to the difficulty of realizing high-Q reactive non-Foster elements – mainly due to the stability issues which were previously discussed. In addition, in a practical implementation, other relevant issues, including the total power consumption, nonlinearity, and noise, need to be addressed.

Antennas with Embedded Non-Foster Matching Networks

Small antennas internally augmented by non-Foster reactive elements can provide a wider matching bandwidth at the input terminals compared to their passive counterparts. In fact, augmentation with reactive non-Foster elements is an extension to the antenna loading with passive Foster reactive elements which is widely employed for controlling the antenna parameters. Non-Foster reactive elements can potentially replace these Foster elements, leading to broadband operation. In particular, for broadband matching applications, the starting point is an antenna whose resonant frequency can be configured with a passive reactive Foster element, and herein a procedure is presented for replacing it with reactive non-Foster elements to make it broadband at the antenna terminals.

To explain the idea, it is assumed that a certain frequency-reconfigurable antenna around the resonant frequency can be modeled with a simple resonant equivalent circuit – say, a *series-RLC* circuit – and the resonant frequency of the antenna can be tuned using a variable capacitor C_t, as shown in Fig. 42a. It is also assumed that the antenna has a large radiation resistance close to the characteristic impedance of the system. This implies that, if electrically small, the antenna provides a very narrow bandwidth due to its large Q.

Subsequently, by assuming access to ideal non-Foster reactive elements, C_t can be replaced with a parallel combination of $-C_a$ and $-L_a$ to cancel out the antenna reactances, as shown in Fig. 42b, and the antenna will be matched over the entire frequency range where the model is valid. Note that such a simple model cannot represent the general complicated model of most antennas over a broad bandwidth, but it simply and sufficiently motivates the idea. Besides, for the actual design, as explained next in this section, the antenna tuning data, rather than its exact model, is required.

DOI 10.1007/978-981-4560-75-7_21-1

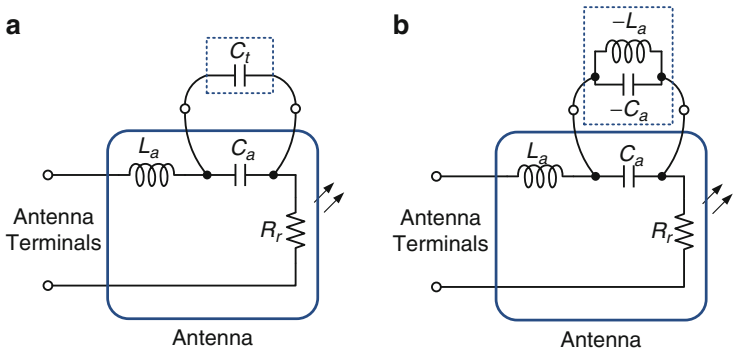

Fig. 42 (**a**) A simple series resonant model for an antenna for which the resonant frequency can be tuned using a tuning capacitor C_t. (**b**) C_t can ideally be replaced with a combination of non-Foster reactive elements to satisfy the resonance condition over a broad frequency range and to obtain a broadband matching at the antenna input terminals

Practical Design of Embedded Non-Foster Matching Networks

The design of an embedded non-Foster matching network can be performed totally based on the frequency reconfigurability of the underlying passive antenna. The design process leads to the synthesis of a two-terminal network which can replace the tuning capacitor or inductor, C_t or L_t, in the passive antenna to achieve a broadband operation. In this section, the design procedure is explained in three steps:

Step I: Selecting a Suitable Passive Antenna

Suitable antennas for the purpose of embedding non-Foster matching networks include frequency-reconfigurable (or frequency-agile) antennas for which the resonant frequency can be swept over a broad range using a variable capacitor C_t or an inductor L_t.

An example of such an antenna is shown in Fig. 43, which is a metamaterial-inspired monopole patch loaded with a varactor and fed by a coplanar waveguide (CPW), as shown in the section "Metamaterial-Inspired Antennas" (Mirzaei and Eleftheriades 2011b; Zhu and Eleftheriades 2009a). Other examples include a PIFA antenna (Di Nallo et al. 2007; Bit-Babik et al. 2007), as well as antennas presented in Zhu and Ziolkowski (2012a, b) and Ziolkowski et al. (2013). In fact, there is no limitation on the size of a suitable antenna as long as the non-Foster circuit can be fitted into the space provided. Therefore, this method can be attractive for matching electrically small antennas.

Step II: Obtaining the Frequency Reconfigurability and Tuning Behavior

The resonant frequency of the selected antenna can be tuned by the tuning element loading the antenna (C_t or L_t). The tuning behavior is a graph of $B_t = \omega C_t$ or $X_t = \omega L_t$ versus resonant frequencies ω, which can be measured or simulated over the desired bandwidth in some discrete frequencies for the passive antenna.

For example, a scaled version of the antenna from Fig. 43 and its tuning behavior are demonstrated in Fig. 44. This figure shows a large tuning bandwidth in the lower UHF band. The results in this graph are translated to a $B_t = \omega C_t$ versus ω graph in Fig. 44c, which exhibits a negative slope in accordance with the expected non-Foster behavior.

Step III: Fitting a Synthesizable Reactance Function to the Tuning Data and Calculating the Parameters of the Embedded Matching Network

In this step, an appropriate function has to be fitted to the graph representing the antenna tuning behavior. This function should represent a synthesizable reactance (susceptance function $B_t(\omega)$ or inductance function $X_t(\omega)$) using a combination of Foster and non-Foster elements. The idea here is to replace the

DOI 10.1007/978-981-4560-75-7_21-1

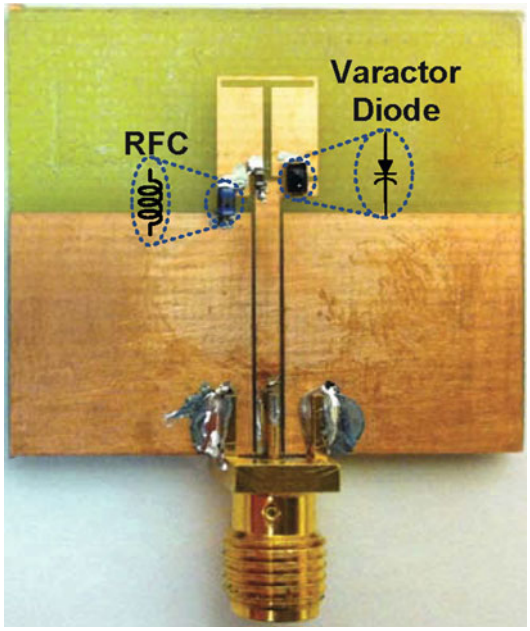

Fig. 43 Example of a metamaterial-inspired frequency-reconfigurable antenna, suited for embedding a non-Foster matching network (Mirzaei and Eleftheriades 2011b) © 2011 IEEE

tuning element C_t or L_t with a network that satisfies the resonance condition in a broad frequency range. As the sample graph in Fig. 44c illustrates, such a network synthesizes a non-Foster reactance at its terminals; hence, it can be implemented using a combination of non-Foster $-C$ and $-L$ and Foster C and L elements. The following criteria can be used to select the most appropriate non-Foster network among all possible combinations:

- Error function: that is, how closely the synthesized reactance follows the tuning data.
- Complexity: that is, how difficult the implementation of the network is. In particular, implementations with fewer non-Foster components are preferred.
- Component values: that is, very large or very small values for the capacitors and inductors are not desirable.
- The sensitivity of the fitted curve to the value of the network elements: that is, how the antenna response changes if there exist some variation, dispersion, and error in the implementation of the network elements. This variation is more pronounced for the non-Foster elements, because of the more difficult implementation and limited quality factor.

After finalizing the non-Foster network selection, such a network can be implemented using appropriate NIC or NII circuits. Two implementation examples are shown in Fig. 45, where the antenna in Fig. 45a is the non-Foster version of the passive antennas shown in Figs. 43 and 44a. For the implementations in Fig. 45a, b, a 10 dB fractional bandwidth equal to 8.1 % and 8.2 % for return losses, respectively, around the center frequencies of 465 MHz and 306.7 MHz, has been obtained. For these two antennas, ka is equal to 0.486 and 0.506 at these center frequencies, where k is the free-space wave number and a is the radius of the smallest sphere circumscribing the antennas. According to a widely accepted criterion, $ka \approx 0.5$ marks the value below which the antennas can be regarded as electrically small; therefore, these two implementations approximately satisfy the condition for being electrically small. The bandwidth of 8.1 % of the antenna in Fig. 45a should be compared to the original 2.9 % bandwidth of the passive antenna

DOI 10.1007/978-981-4560-75-7_21-1

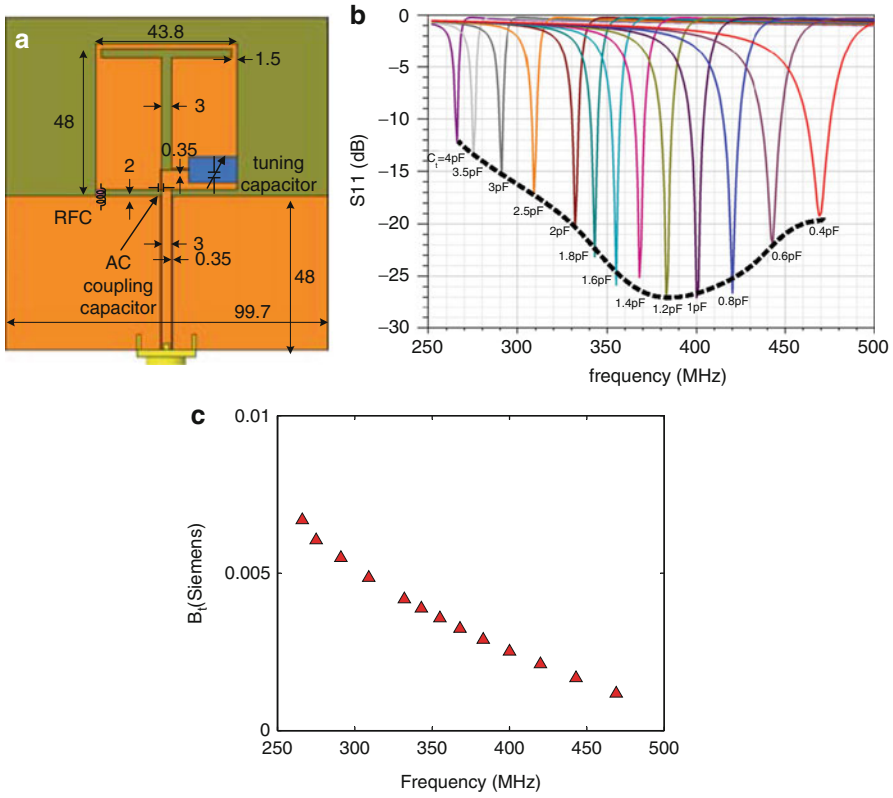

Fig. 44 (**a**) Dimensions of the frequency-reconfigurable antenna suitable for embedding a non-Foster matching network. (**b**) Simulation data using a finite-element field solver demonstrates that the resonant frequency of the antenna can be tuned by tuning the loading capacitor C_t. (**c**) Graph of the tuning susceptance $B_t = \omega C_t$ vs. frequency (Mirzaei and Eleftheriades 2013b) © 2013 IEEE

shown in Fig. 44b. However, it should be noted that due to practical limitations (discussed below), a very broad bandwidth, similar to the dashed-line graph in Fig. 44b, cannot be achieved. Nonetheless, the actual implementations, exemplified above, show a significant improvement in the antenna matching bandwidth (Mirzaei and Eleftheriades 2011a; Mirzaei and Eleftheriades 2013b; Zhu and Ziolkowski 2012a, b; Ziolkowski et al. 2013).

Promises and Challenges of Non-Foster Matching Networks for Antennas

The ideas of antennas with non-Foster matching networks have attracted strong interest over the past few decades; however, the actual implementations have remained challenging due to the difficulty of realizing high-Q reactive non-Foster elements – mainly due to the stability issues which were previously discussed. In practice, an unavoidable dispersion in the implementation of the reactive non-Foster elements, their limited quality factors, and sensitivity of the matching bandwidth to these variations tend to significantly limit the achievable bandwidth (Mirzaei and Eleftheriades 2013b). In addition, in a practical implementation, other relevant issues, including the total power consumption, nonlinearity, and noise, need to be addressed. For example, although a non-Foster matching network for a receiving antenna improves the received signal level by improving the matching bandwidth, it also increases the noise level. For such an application, the achievable signal-to-noise ratio at the antenna terminals, rather than the actual matching bandwidth, will utterly matter.

DOI 10.1007/978-981-4560-75-7_21-1

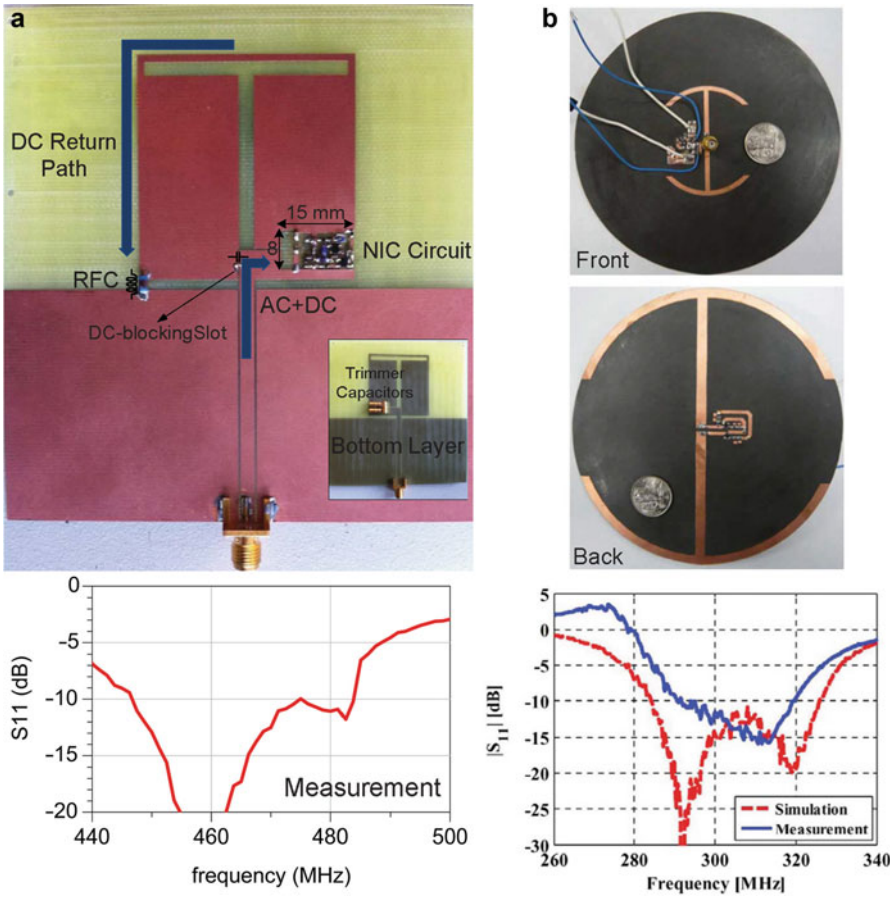

Fig. 45 (**a**) Metamaterial-inspired monopole antenna with an embedded non-Foster matching network (Mirzaei and Eleftheriades 2011a, 2013b), © 2011, 2013 IEEE. (**b**) Near-field resonant parasitic "Egyptian axe dipole" antenna with an embedded non-Foster matching network (Zhu and Ziolkowski 2012a) © 2012 IEEE

Some of these challenges, including the stability and dispersion issues, can be addressed by a recently proposed method for implementing reactive non-Foster elements using loss-compensated negative-group-delay (NGD) networks (Mirzaei and Eleftheriades 2013c). In this kind of non-Foster elements, the negative slope of the reactance is synthesized in a lossy NGD network, and the losses are compensated separately by amplification. This is in contrast to the traditional NIC and NII networks where the active and passive parts are intertwined in a circuit with positive feedback loops that tend to destabilize the circuit. The full application of this kind of non-Foster elements is due to further development of bilateral amplification blocks. Nevertheless, when using regular unilateral amplifiers, a special unilateral version of non-Foster reactances can be obtained which can prove useful for specific applications (Mirzaei and Eleftheriades 2013a, c, 2014). For example, a unilateral floating negative capacitor can be useful for matching applications, for which a −2.4 pF implementation is shown in Fig. 46 in the frequency range of 1–1.5 GHz. The experimental results show that a low-dispersion unilateral capacitor with a good quality factor has been obtained in this bandwidth.

Conclusion

In this chapter, the theory and operation of transmission-line-based metamaterials has been presented, and it has been shown how this can be used to design various types of passive and active antennas. The transmission-line-based metamaterial structure was formed by periodically loading a conventional microwave transmission line with lumped-element series capacitors and shunt inductors. The resulting structure was termed a negative-refractive-index transmission-line (NRI-TL) metamaterial, and it was shown through a dispersion analysis that it can support both backward waves in the left-handed NRI region and forward waves in the right-handed positive-refractive-index (PRI) region. Furthermore, it can support standing waves with a zero propagation constant at the transition point between the NRI and PRI regions.

The rich propagation characteristics of NRI-TL metamaterials form the underlying basis for their use in many antenna applications, including leaky-wave antennas, compact resonant antennas, and multiband antennas. The resonant characteristics of the NRI-TL metamaterial structures were analyzed with the aid of a dispersion diagram, enabling one to clearly visualize how these structures can be designed to offer multiband responses whose resonant frequencies are not harmonically related while offering large degrees of miniaturization.

Specifically, it was outlined how effective radiation can be achieved from a metamaterial structure when its total electrical length is equal to integer multiples of π, including zero and negative integer values, referred to as the zeroth-order and negative-order resonant modes, respectively. The individual resonant frequencies can be adjusted by changing the values of the reactive loading of the transmission line through a "dispersion engineering" process, therefore allowing the resonances to be placed at multiple nonharmonic frequencies. Subsequently, it was demonstrated how NRI-TL metamaterial antennas can be designed that are independent of their overall physical size, which is in contrast to conventional

DOI 10.1007/978-981-4560-75-7_21-1

resonant antennas whose size is on the order of $\lambda/2$. This useful property allows compact metamaterial antenna designs to be achieved at a fraction of the size of conventional antennas by employing the zeroth-order and negative-order modes of the NRI-TL metamaterials.

Design equations for rapid prototyping have been presented, allowing an antenna designer to easily determine the loading-element values required for a metamaterial antenna with certain volume and system impedance constraints. Guidelines have also been provided for the physical realization of the loading elements, either in fully printed form or using off-the-shelf surface-mount chip components.

In order to highlight the advantages that transmission-line metamaterials have to offer in the design of antennas, a number of passive metamaterial antenna applications have been presented. These include examples of zeroth-order resonant antennas, negative-order resonant antennas, epsilon-negative antennas, mu-negative antennas, metamaterial dipole antennas, and metamaterial-inspired antennas.

In the concluding section, active non-Foster matching networks for small antennas have been presented, and it has been demonstrated how these can be applied to metamaterial-inspired antennas. The implementation of reactive non-Foster elements was presented using two networks: negative impedance converters (NICs) and negative impedance inverters (NIIs). The limitations of antennas that employ external non-Foster matching networks were described, followed by the benefits of using antennas with embedded non-Foster matching networks. Subsequently, a practical design procedure for antennas with embedded non-Foster matching networks was presented, and it was shown how this can be applied to a specific metamaterial antenna design.

Finally, in order to overcome some of the limitations faced by conventional reactive non-Foster elements, including stability, dispersion, and achievable bandwidth, a new method of implementing reactive non-Foster elements using loss-compensated negative-group-delay (NGD) networks was presented. Using this method, it was demonstrated that a low-dispersion unilateral negative capacitor with a good quality factor can be achieved over a wide bandwidth.

Theory of Transformation Optics in Antenna Design

Di Bao and Tie Jun Cui*
State Key Laboratory of Millimeter Waves, Department of Radio Engineering, Southeast University, Nanjing, P. R. China

Abstract

Transformation optics provides a bridge between the electromagnetic functionality of the device and the material properties of the custom-engineered media. This chapter includes an overview of transformation optics theory and their application in antenna engineering. The basic theory of transformation optics is analyzed, including the general transformation and quasi-conformal mapping. Reviews are focused on the planar lens antenna, the multibeam antenna, the Luneburg lens antenna, and the metasurface Luneburg lens.

Keywords

Transformation optics; conformal mapping; quasi-conformal transformation optics; metamaterials; lens antenna; luneburg lens; metasurface

Introduction

Einstein's general theory of relativity (Crelinsten 2006) indicates that the matter-energy densities result in motion of matter and light propagating in a curved space-time domain (Wald 1984). In 1961, Dolin applied the idea of curved space to electromagnetic system with inhomogeneous fillings (Dolin 1961) for the first time. He proved that Maxwell's equations are form invariant under a space-deforming transformation and proposed an early form of invisibility cloak. In the 1990s, Pendry's group's insightful work reestablished the field of transformation optics (TO), or transformation electromagnetics (Ward and Pendry 1996, 1998). However, limited by naturally available materials to physically realize the design, the concept did not attract much attention.

Metamaterials have been a hot research field since the beginning of this century (Pendry et al. 1999; Shelby et al. 2001). In 2006, its impressive progress and capability to realize gradient index (GRIN) structure with spatially varying permittivity and permeability values inspired scientists that it is possible to implement the inhomogeneous and even anisotropic constitutive parameters of the TO structure with metamaterials (Pendry et al. 2006; Leonhardt 2006). TO has finally attracted intensive attentions, which leads to the development of many novel functional devices, such as the invisible free-space cloak (Pendry et al. 2006; Schurig et al. 2006), carpet cloak (Li and Pendry 2008; Liu et al. 2009; Ma et al. 2009), omnidirectional absorber (Narimanov and Kildishev 2009; Cheng et al. 2010), EM concentrator (Rahm et al. 2008; Yaghjian and Maci 2009), etc. (Mei and Cui 2012; Werner and Kwon 2014).

Transformation optics has also offered great flexibility to design novel antenna, such as a planar focusing antenna (Kong et al. 2007; Kwon and Werner 2009), highly directive multibeam antenna (Jiang et al. 2008b), small aperture antenna (Luo et al. 2009; Lu et al. 2009), layered lens antenna (Jiang et al. 2008a; Tichit et al. 2009), and transformed Luneburg lens (Demetriadou and Hao 2011). Most of

DOI 10.1007/978-981-4560-75-7_22-1

these early works contain inhomogeneous and anisotropic materials with both tensor ε and μ values, which are difficult to realize with only a few physical verification examples (Tichit et al. 2011; Jiang et al. 2011, 2012) and suffer from high loss and narrow bandwidth. In 2008, the quasi-conformal transformation optics (QCTO) was proposed, which is capable of designing all-dielectric transformation devices while still maintaining the performance. Following this theory, many kinds of transformation antenna have been reported (Mei et al. 2010; Tang et al. 2010; Yang et al. 2011a, b; Kwon 2012; Wu et al. 2013; Oliveri et al. 2014) and experimental demonstrations have been carried out in both 2D and 3D cases (kundtz and Smith 2010; Ma and Cui 2010; Mei et al. 2011; Liang and Hum 2014; Mateo-Segura et al. 2014) and surface wave (Wan et al. 2014).

In this chapter, the general transformation optics is introduced first, and its applications in multibeam antenna and layered lens antenna are reviewed. Then, the quasi-conformal mapping is presented along with its utilization in flattened Luneburg lens, surface flattened Luneburg lens, and planar lens design. In both parts, the first device is explained in detail to show how the transformation works.

General Transformation Optics

Theory of General Transformation Optics

Based on coordinate transformation, transformation optics can map a free space (virtual system) into a distorted space (physical system) and link the spatial distortions to changes in the distributions of the material's constitutive parameter tensors. The physical implementation of the materials in the transformed space is the designed transformation optics device, where the route of the wave is decided by how the space is distorted or, equivalently, how the material properties vary across the geometry (Pendry et al. 2006; Leonhardt 2006).

Considering a coordinate transformation which maps a virtual system (x_1, x_2, x_3) to a physical system (x_1', x_2', x_3'), the form invariance of Maxwell's equations can be employed to derive the constitutive parameters of the medium in the transformed space as (Pendry et al. 2006)

$$\overline{\varepsilon'} = \frac{\overline{\Lambda}\overline{\varepsilon}\overline{\Lambda}^T}{det\left(\overline{\Lambda}\right)}, \quad \overline{\mu'} = \frac{\overline{\Lambda}\overline{\mu}\overline{\Lambda}^T}{det\left(\overline{\Lambda}\right)} \tag{1}$$

where $\overline{\Lambda}$ is the Jacobian matrix and can be expressed as

$$\overline{\Lambda} = \begin{pmatrix} \frac{\partial x_1'}{\partial x_1} & \frac{\partial x_1'}{\partial x_2} & \frac{\partial x_1'}{\partial x_3} \\ \frac{\partial x_2'}{\partial x_1} & \frac{\partial x_2'}{\partial x_2} & \frac{\partial x_2'}{\partial x_3} \\ \frac{\partial x_3'}{\partial x_1} & \frac{\partial x_3'}{\partial x_2} & \frac{\partial x_3'}{\partial x_3} \end{pmatrix} \tag{2}$$

In the design of most transformation lens antenna, 2D cases with TE wave incidence are usually considered in the first step. 3D design can be obtained by rotating the 2D results, and TM mode can be calculated with the principle of duality.

DOI 10.1007/978-981-4560-75-7_22-1

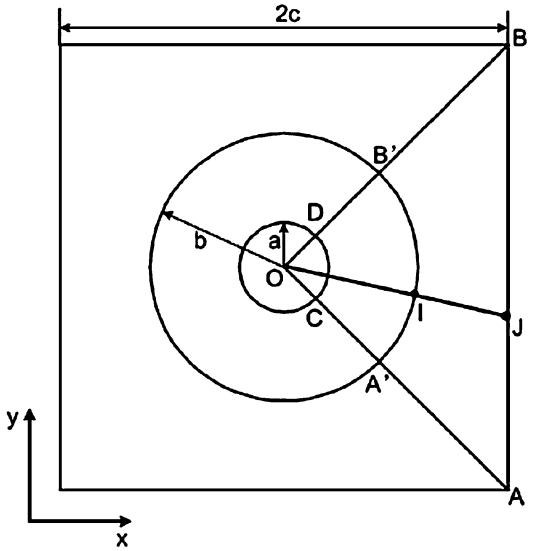

Fig. 1 Configuration of cylindrical-to-plane-wave conversion in the Cartesian coordinate (Jiang et al. 2008b)

In the Cartesian coordinate system, the TE wave consists of only H_x', H_y', and E_z' components; then only μ_{xx}', μ_{yy}', μ_{xy}', μ_{yx}', and ε_{zz}' contribute. So the Jacobian matrix $\overline{\Lambda}$ can be simplified as

$$\overline{\Lambda} = \begin{pmatrix} \dfrac{\partial x'}{\partial x} & \dfrac{\partial x'}{\partial y} & 0 \\ \dfrac{\partial y'}{\partial x} & \dfrac{\partial y'}{\partial y} & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{3}$$

Even in 2D cases, the permittivity and permeability values generated from Eq. 1 are generally anisotropic and inhomogeneous diagonal tensors with extremely high or lower than unity values. Metamaterials are capable of accessing these extreme medium properties in the design with the dispersive resonant unit cell, and the anisotropic properties can be implemented by rotating the directions of the metamaterial unit cell (Schurig et al. 2006; Jiang et al. 2011, 2012). Such resonant structure will inevitably increase the losses and reduce the bandwidth of operation.

Multibeam Antenna via Continuous Transformation Optics

Based on coordinate transformation, the conversion from cylindrical waves to plane waves in a short range has been proposed (Jiang et al. 2008b) with potential applications in a four-beam antenna or a compact range for near-field measurement of plane waves.

As shown in Fig. 1, the square domain is divided into four identical triangles, and one of the triangles, OAB, is discussed first for simplicity. If the fan-shaped area $\widehat{OCD}$ is transformed to a bigger space in sector $\widehat{OA'B'}$ and the arc $CA'B'D$ is transformed to a trapezia-like region $A'ABB'$, then cylindrical waves excited at the origin would propagate through the square $A'ABB'$ with the equiphase surface changing from circle to plane. The transformation in triangles OAB could be written as

DOI 10.1007/978-981-4560-75-7_22-1

$$r' = \begin{cases} br/a, & 0 \le r \le a, \\ \dfrac{cr - bx}{(b-a)x}(r-a) + b, & a \le r \le b, \end{cases} \tag{4}$$

where (x, y) is an arbitrary point in the virtual (original) space, (x', y') is the corresponding point in the physical (transformed) space, $r = \sqrt{x^2 + y^2}$, and $r' = \sqrt{x'^2 + y'^2}$.

The coordinate transformation can be mathematically described as

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{cases} \begin{pmatrix} bx/a \\ by/a \\ z \end{pmatrix}, & 0 \le r \le a, \\ \begin{pmatrix} \dfrac{(c - bx/r)\ (r-a)}{b-a} + \dfrac{bx}{r} \\ \dfrac{(c - bx/r)\ (r-a)y}{(b-a)x} + \dfrac{by}{r} \end{pmatrix}, & a \le r \le b. \end{cases} \tag{5}$$

With Eqs. 3 and 5, the Jacobian transformation can be obtained as

$$\overline{\Lambda} = \begin{cases} \begin{pmatrix} b/a & 0 & 0 \\ 0 & b/a & 0 \\ 0 & 0 & 1 \end{pmatrix}, & 0 \le r \le a, \\ \begin{pmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & 0 \\ 0 & 0 & 1 \end{pmatrix}, & a \le r \le b, \end{cases} \tag{6}$$

in which

$$\begin{aligned} a_{11} &= \frac{cr^2x - br^3 + b^2y^2}{(b-a)r^3}, \\ a_{12} &= \frac{\left(cr^2 - b^2x\right)y}{(b-a)r^3}, \\ a_{21} &= \frac{\left(acr^3 - b^2x^3 - cr^2y^2\right)y}{x^2(b-a)r^3}, \\ a_{22} &= \frac{b^2x^3 + cr^4 - acr^3 + cr^2y^2 - br^3x}{(b-a)r^3x}. \end{aligned}$$

The determinant of the above Jacobian matrix can be calculated as

$$\det \overline{\Lambda} = \begin{cases} b^2/a^2, & 0 \le r \le a \\ a_{11}a_{22} - a_{12}a_{21}, & a \le r \le b \end{cases}. \tag{7}$$

According to Eq. 1, the permittivity and permeability tensors of the medium in the physical space can be obtained as

DOI 10.1007/978-981-4560-75-7_22-1

$$\overline{\varepsilon_r'} = \overline{\mu_r'} = \begin{cases} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & a^2/b^2 \end{pmatrix} & 0 \le r' \le b, \\ \begin{pmatrix} \varepsilon_{xx} & \varepsilon_{xy} & 0 \\ \varepsilon_{yx} & \varepsilon_{yy} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{pmatrix} & b \le r', \quad x' \le c, \end{cases} \tag{8}$$

in which

$$\varepsilon_{xx} = \frac{a_{11}^2 + a_{12}^2}{\det(\overline{\Lambda})}, \tag{9a}$$

$$\varepsilon_{xy} = \frac{a_{11}a_{21} + a_{12}a_{22}}{\det(\overline{\Lambda})} = \varepsilon_{yx}, \tag{9b}$$

$$\varepsilon_{yy} = \frac{a_{21}^2 + a_{22}^2}{\det(\overline{\Lambda})}, \tag{9c}$$

$$\varepsilon_{zz} = \frac{1}{\det(\overline{\Lambda})}. \tag{9d}$$

The constitutive parameter tensors for the triangle *OAB* are now fully provided in Eq. 9 in the transformed coordinates (x', y'). Rotating these equations with angles of $\pi/2$, π, and $3\pi/2$ around the z-axis, the corresponding relative permittivity and permeability tensors could be obtained in the whole square domain. To verify the effectiveness of the design, full-wave simulations have been carried out based on finite-element method. The cylindrical waves are excited by a line-current source of infinite length oriented in the z direction in the origin of the coordinate system at 8 GHz. The electric field distribution inside and outside the conversion materials is shown in Fig. 2. It can be observed that when the cylindrical

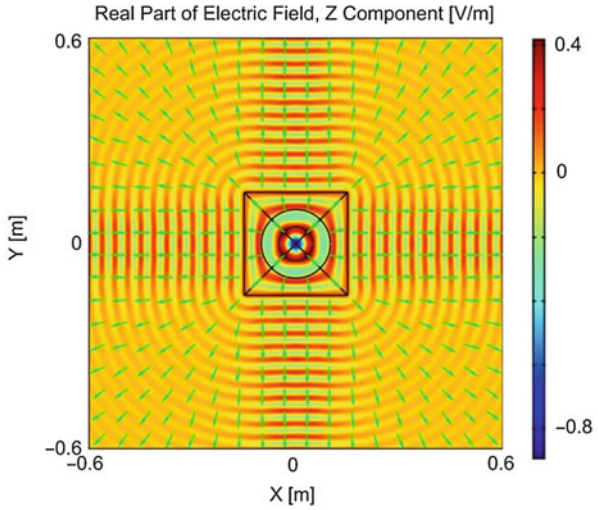

Fig. 2 The distributions of electric fields and power-flow lines for the conversion from cylindrical waves to plane waves via the layered optical transformation (Jiang et al. 2008b)

DOI 10.1007/978-981-4560-75-7_22-1

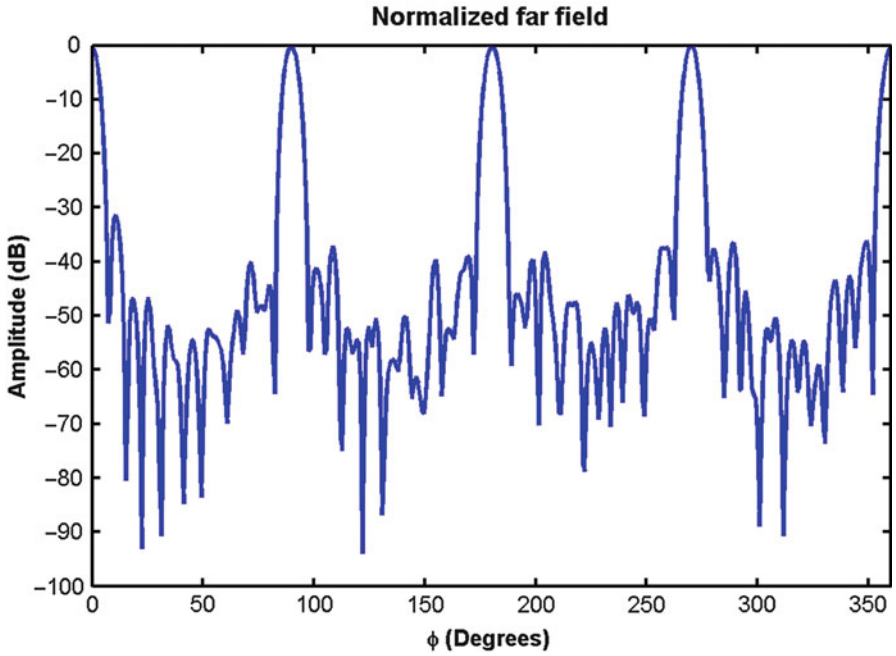

Fig. 3 The far-field radiation pattern of the multibeam antenna (Jiang et al. 2008b)

wave propagates through the short conversion metamaterial layer, four beams of plane waves can be clearly observed in the neighboring area. The far-field radiation pattern of the multibeam antenna is also calculated and plotted in Fig. 3, which exhibits little scattering effect at the four corners of the square and high-directivity radiation to the four directions with the antenna aperture as small as eight wavelengths in free space.

A similar highly directive four-beam antenna has then been designed and experimentally demonstrated by D. H. Werner's group in 2011 (Jiang et al. 2011) by mapping a long and narrow isosceles triangles into another isosceles triangles with big vertex angle. The lens is physically realized with split-ring resonators (SRRs) in the G-band with an embedded monopole antenna source. The anisotropic material parameters of the transformed medium are implemented by rotating the directions of the SRR unit cell. Experimental results indicate that the lens obtains a quadbeam radiation pattern over 20 % bandwidth with a gain enhancement of about 6.5 dB.

Lens Antennas Based on Layered Optical Transformation

The optical transformation has been applied to design a 2D layered homogeneous lens with uniaxially anisotropic material (Jiang et al. 2008a). As shown in Fig. 4, the virtual space is a rectangle $ABCD$, while the physical space is a trapezia $ABC'D'$. Both spaces are divided into n layers as the shaded region indicates. For the kth $(1 \leq k \leq n)$ layer, an elongating coordinate transformation is defined as

$$x' = x + \frac{(k - 0.5)\ (b - a)x}{na}, \quad (1 \leq k \leq n), \tag{10a}$$

$$y' = y, \tag{10b}$$

$$z' = z. \tag{10c}$$

DOI 10.1007/978-981-4560-75-7_22-1

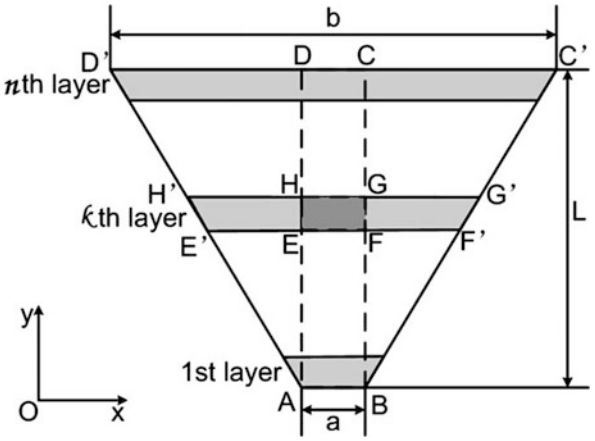

Fig. 4 The 2D layered lens in the Cartesian coordinate system (Jiang et al. 2008a)

If the incident signal is emitted from port *AB*, then the local properties of the EM fields in the small region *ABCD* will be mapped to a large region $ABC'D'$ while still maintaining the equiphase front at port $C'D'$ as port *CD*, which promises a high-gain performance for the lens.

The full expressions of the constitutive parameter tensors in each layer of the physical space can then be derived from Eq. 1 as

$$\varepsilon_{xx}^{k} = \mu_{xx}^{k} = \alpha_k, \tag{11a}$$

$$\varepsilon_{yy}^{k} = \mu_{yy}^{k} = 1/\alpha_k, \tag{11b}$$

$$\varepsilon_{zz}^{k} = \mu_{zz}^{k} = 1/\alpha_k. \tag{11c}$$

where all the off-diagonal parameters are zero and

$$\alpha_k = 1 + \frac{(k - 0.5)\ (b - a)}{na}. \tag{12}$$

Full expressions of the constitutive parameter tensors are provided in Eq. 11. In the practical case of TE wave illumination with E field polarized along the *z*-axis, only ε_{zz}^{k}, μ_{xx}^{k}, and μ_{yy}^{k} are required in Eq. 11. In these equations, the dispersion relations of the physical space can be kept unchanged if the products of $\mu_{xx}^{k}\varepsilon_{zz}^{k}$ and $\mu_{yy}^{k}\varepsilon_{zz}^{k}$ are identical as those in the above equations. One of the convenient sets for physical realization is

$$\mu_{xx}^{k} = 1, \quad \varepsilon_{zz}^{k} = 1, \quad \mu_{yy}^{k} = 1/\alpha_k^2, \quad 1 \le k \le n, \tag{13}$$

where only μ_{yy}^{k} has different value in each layer of the transformed lens antenna, so the lens is easy to realize physically with metamaterials. There would be no reflection for normal incidence because of the impedance matching.

For comparison, the lens antenna is also designed based on continuous optical transformation in (Jiang et al. 2008a), and full-wave simulations of these lens antennas placed inside a PEC horn antenna are performed at 6 GHz. The electric field distributions of the lens antenna composed of layered homogeneous material defined as Eq. 11 are first studied as shown in Fig. 5a. The lens in Fig. 5b is composed of

DOI 10.1007/978-981-4560-75-7_22-1

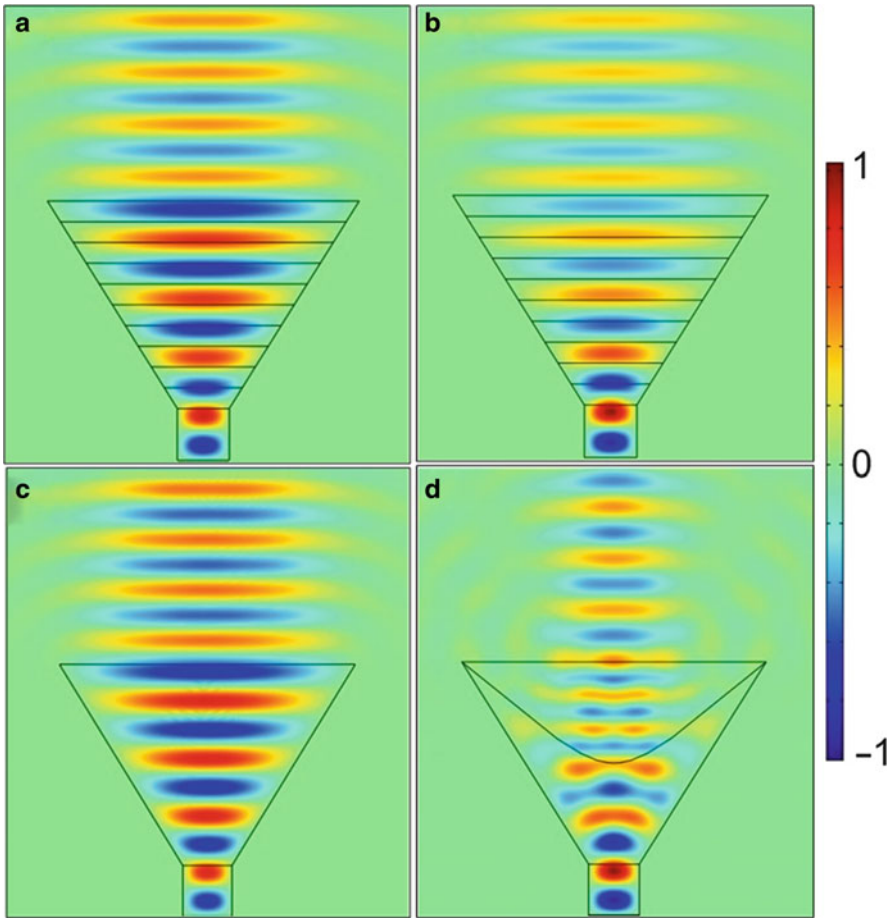

Fig. 5 The electric field distribution of the lens antennas located in the same PEC horn antenna excited with a line-current source. The lens is composed of (**a**) layered homogeneous medium following Eq. 11, (**b**) layered homogeneous medium following Eq. 13, (**c**) inhomogeneous and anisotropic materials defined by continuous transformation, and (**d**) regular dielectric (Jiang et al. 2008a)

layered homogeneous material defined according to the simplified parameters in Eq. 13. It can be observed that the reflections in Fig. 5b are less than those in Fig. 5a. Figure 5c demonstrates the field distribution of the lens designed by continuous optical transformation, and it reveals strong standing waves and reflection inside the lens.

As a comparison with the conventional lens, a horn antenna filled with collimating lens composed of regular dielectric in accordance with the method in (Liberti and Rappaport 1999) is shown in Fig. 5d. The dimension of the PEC horn is the same in all four subfigures, so it is obvious that the three OT lens antennas can concentrate almost all EM powers as beam of plane waves in front of the antennas and hence much better performance than the conventional lens. Such transformation can be applied to design multibeam antennas as well.

Quasi-Conformal Transformation Optics

Mathematically, there are infinite kinds of mapping from one virtual domain to one physical domain with different analytical or numerical methods (Chen et al. 2009; Chang et al. 2010). Researchers can optimize the transformation to minimize the anisotropy of the designed medium to quasi-isotropic material for

DOI 10.1007/978-981-4560-75-7_22-1

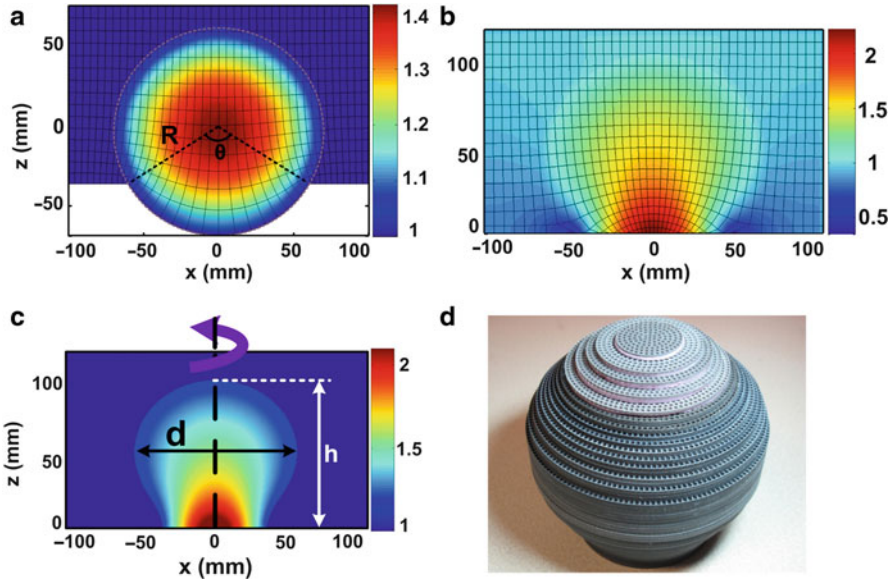

Fig. 6 (**a**) The refraction index distribution of 2D Luneburg lens embedded in the virtual space. (**b**) The refractive index distribution of 2D flattened Luneburg lens in the physical space. (**c**) The final refract index distribution in the *xoz* plane. (**d**) The photo of the fabricated 3D lens (Ma and Cui 2010)

engineering application (Li and Pendry 2008; Werner and Kwon 2014). The detailed theory and operating mechanism of QCTO are presented in the following subsection with the design examples.

Three-Dimensional Luneburg Lens Based on Quasi-Conformal Transformation Optics

A Luneburg lens is a spherically symmetric gradient index lens which could guide the incoming collimated rays from infinity to a focal point on the opposite surface of the lens without any aberrations. The application of Luneburg lens is restricted from the gradient index distribution of refractive index, which is difficult to implement, and the spherical surface, which leads to mismatch to the planar feeding source or detector array. In 2010, Kundtz and Smith proposed a solution by flattening the spherical surface into a planar surface with the QCTO carried out a 2D experimental demonstration with metamaterials (Kundtz and Smith 2010). A series of Luneburg lens has been designed in Yang's group (Demetriadou and Hao 2011; Quevedo-Teruel et al. 2012; Quevedo-Teruel and Hao 2013) with an all-dielectric ceramic flat lens fabricated (Mateo-Segura et al. 2014). Cui's group designed a 3D flattened Luneburg lens based on the QCTO and fabricated the lens with all-dielectric metamaterials in three dimensions (3D) at Ku-band (Ma and Cui 2010). The designed 3D lens is more advantageous than conventional lens with no aberration, a zero focal distance, a flattened focal surface, and the ability to construct radiation beams at extremely large angles.

For simplicity, the 2D case is considered first with TE wave incidence. The Luneburg-based lens and its background area as shown in Fig. 6a are mapped to a new lens in a rectangular area with a part of flat surface in Fig. 6b. The Luneburg surface in the virtual space with a radius R has the refractive index distribution in free space as

$$n = \sqrt{2 - \frac{r^2}{R^2}}. \tag{14}$$

DOI 10.1007/978-981-4560-75-7_22-1

In the virtual space, the very fine grid is generated with near-orthogonal cells such that

$$\frac{\partial x'}{\partial y} \simeq 0, \tag{15a}$$

$$\frac{\partial y'}{\partial x} \simeq 0. \tag{15b}$$

Since x' and y' are functions of both x and y, Eq. 15 can be also written according to the chain rule as

$$\frac{\partial x'}{\partial y} = \frac{\partial x'}{\partial x}\,\frac{\partial x}{\partial y} \simeq 0, \tag{16a}$$

$$\frac{\partial y'}{\partial x} = \frac{\partial y'}{\partial y}\,\frac{\partial y}{\partial x} \simeq 0. \tag{16b}$$

So the Jacobian matrix in Eq. 3 can be reduced to

$$\overline{\Lambda} = \begin{pmatrix} \dfrac{\partial x'}{\partial x} & 0 & 0 \\ 0 & \dfrac{\partial y'}{\partial y} & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{17}$$

The permittivity and permeability values can then be calculated by Eq. 1 as

$$\epsilon'_z = \frac{\epsilon_z}{det\Lambda} \simeq \epsilon_z \frac{\Delta x \Delta y}{\Delta x' \Delta y'}, \tag{18a}$$

$$\mu' = \mu_0 \begin{pmatrix} \dfrac{\left(\frac{\partial x'}{\partial x}\right)^2}{det\Lambda} & 0 \\ 0 & \dfrac{\left(\frac{\partial y'}{\partial y}\right)^2}{det\Lambda} \end{pmatrix} \tag{18b}$$

where Δx, Δy, $\Delta x'$, and $\Delta y'$ are the dimensions of each cell in the two coordinate systems in Fig. 6.

According to the theoretical study in (Li and Pendry 2008), the suitable coordinate transform has been chosen in the design so that the anisotropic factor can be dismissed with unit permeability value. The physical medium can then be described by Eq. 18a alone. The refractive index value in the transformed lens can be expressed as

$$n' \simeq n\sqrt{\frac{\Delta x \Delta y}{\Delta x' \Delta y'}}. \tag{19}$$

The refractive index distribution is drawn in Fig. 6b. The background cells with refractive index value close to unity are all set to be air, and the final 2D refractive index profile is plotted in Fig. 6c. The 3D refractive index distribution can now be generated by rotating the 2D surface along the z-axis in Fig. 6c.

DOI 10.1007/978-981-4560-75-7_22-1

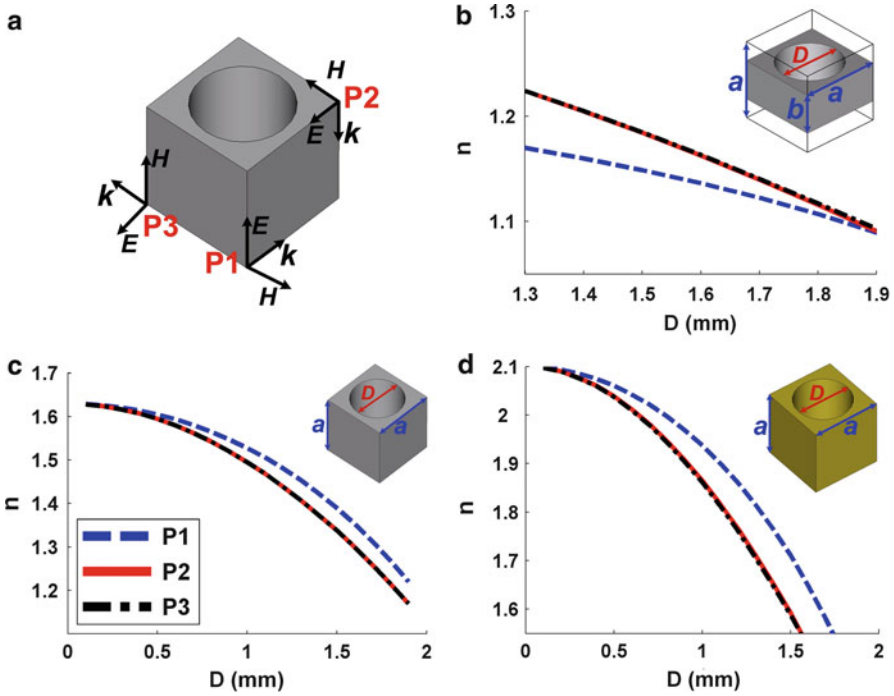

Fig. 7 The relations between the refractive index and the hole's diameter D at 15 GHz under different polarizations. (**a**) Three polarizations P1, P2, and P3 for a unit cell, (**b**) the 2 × 2 × 1 mm^3 F4B unit cell, (**c**) the 2 × 2 × 2 mm^3 F4B unit cell, (**d**) the 2 × 2 × 2 mm^3 R4B unit cell (Ma and Cui 2010)

The transformed 3D Luneburg lens is then fabricated with multilayered nonresonant metameterials, which is realized by drilling inhomogeneous holes in two kinds of dielectric plates, FR4 ($\varepsilon = 4.4$, $\delta = 0.025$) and F4B($\varepsilon = 2.65$, $\delta = 0.001$). Three kinds of unit cells have been studied to fulfill the designed refractive index distribution, and the effective refractive index values of these structures are calculated with the S-parameter retrieval method (Smith et al. 2002) and plotted in Fig. 7. All three orthogonal polarizations of incident waves are considered and quasi-isotropic properties have been observed.

Simulated and measured near electric fields of the lens have been carried out with excellent agreement, and the measured radiation pattern of the 3D lens in Ku-band is plotted in Fig. 8 (Ma and Cui 2010). A coax-to-waveguide device with the aperture size of 16 × 8 mm^2 was applied as the feeding source at three typical source positions on the flattened focal surface. As shown in Fig. 8, the patterns in the left column illustrate far-field radiation diagrams in E-plane (horizontally polarization) with different feeding locations at 12.5, 15, and 18 GHz, and those in the right column are the patterns in H-plane (vertically polarization). Highly directive beam is observed, and the radiation direction can be effectively controlled by the feeding position in a range of 50° with respect to the normal direction (*z*-axis).

Flattened Metasurface Luneburg Lens

Quasi-conformal mapping has also been successfully utilized in metasurface antenna design, such as the flattened metasurface Luneburg lens (Wan et al. 2014). The transformation of the metasurface lens is similar to the 2D part of the previous 3D Luneburg lens design, as shown in Fig. 6a–c. In the physical realization, the surface refractive indexes are related to the surface impedances, which can be readily obtained with U-shaped metallic unit cell as shown in Fig. 9a, and the surface refractive index values can be controlled by tuning the parameter *h*. The designed flattened Luneburg metasurface lens is fabricated as shown in Fig. 9b, with three antipodal Vivaldi antennas function as the planar source array to excite the

DOI 10.1007/978-981-4560-75-7_22-1

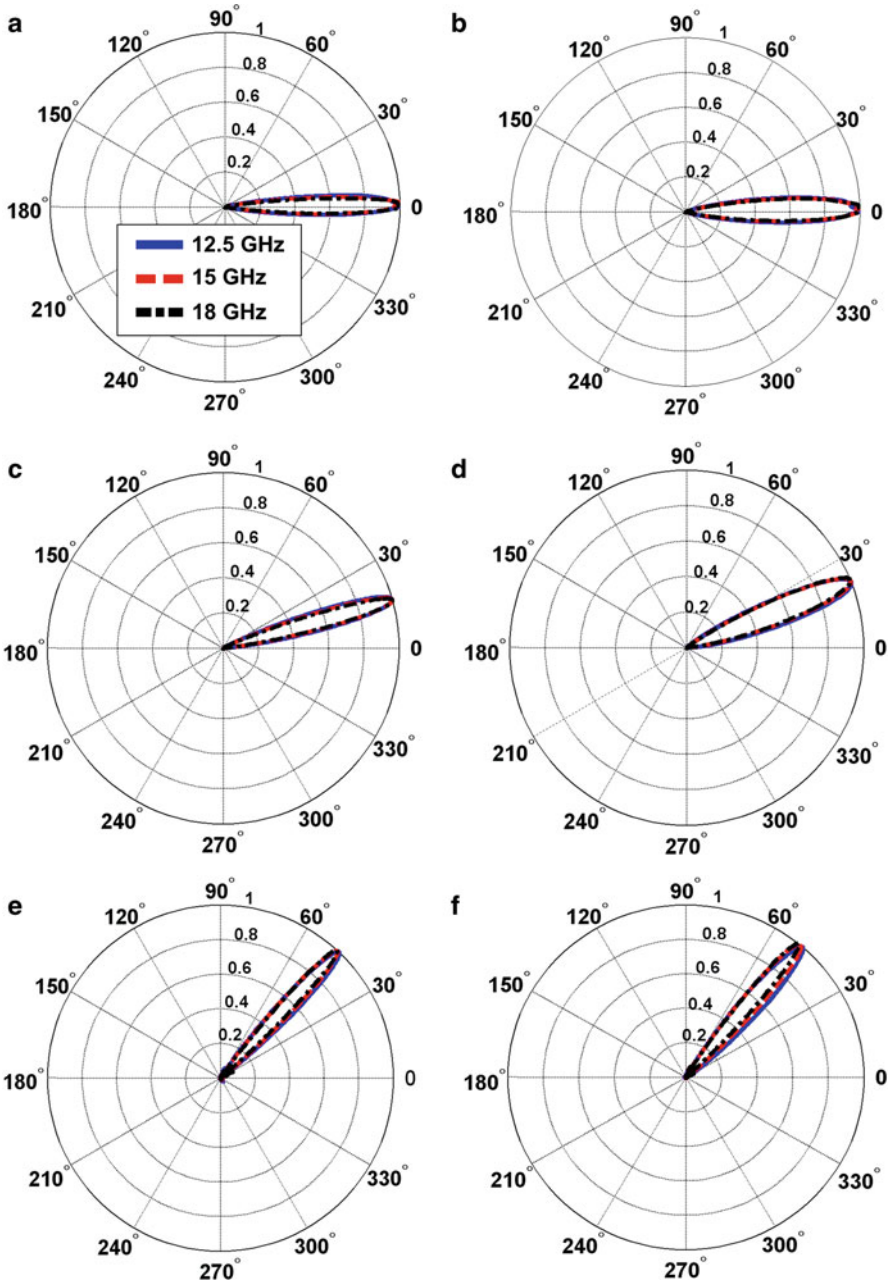

Fig. 8 The measured far-field pattern of the 3D lens in E-plane (**a**, **c**, **e**) and H-plane (**b**, **d**, **f**) at 12.5, 15, and 18 GHz. The location of the feeding source is (**a**, **b**): ($x = 0$ and $y = 0$), (**c**, **d**): ($x = -10mm$ and $y = 0$), and (**e**, **f**): ($x = -30mm$ and $y = 0$), respectively (Ma and Cui 2010)

TE-mode surface wave on the surface. The measured near-electric field distribution at 9 GHz is shown in Fig. 9c. It can be observed that the Vivaldi antennas at different locations can excite surface waves propagating along different directions from the Luneburg lens. More simulation and experimental results indicate that the lens is also working at 8 and 10 GHz (Wan et al. 2014).

Planar Focusing Reflector Lens Antenna

Parabolic antenna can produce the narrow beamwidths and high directivity, and it has been widely used in point-to-point communications, such as microwave relay links to carry telephone and television signals

DOI 10.1007/978-981-4560-75-7_22-1

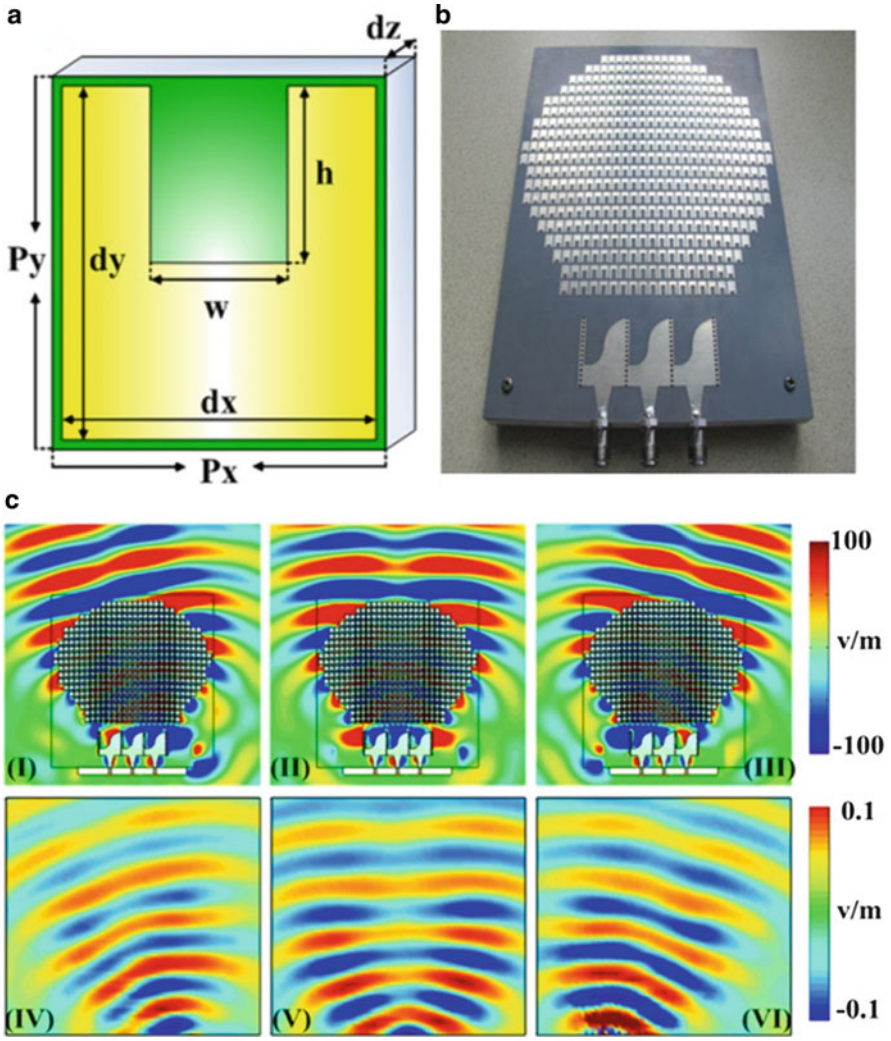

Fig. 9 (**a**) The U-shaped particle. (**b**) The photo of the designed flattened Luneburg lens. (**c**) The simulated (*top three subfigures*) and measured (*bottom three subfigures*) near-field distribution when exciting the right antenna (*I* and *IV*), the central antenna (*II* and *V*), and the left antenna (*III* and *VI*), respectively (Wan et al. 2014)

between neighboring cities, satellite and spacecraft communication antennas, radio telescopes, and so on. In 2007, J. A. Kong's group suggested the design of a low-profile planar focusing antenna based on the general transformation of a parabolic antenna (Kong et al. 2007) and verified the performance of the designed anisotropic and inhomogeneous antenna with simulation. Based on quasi-conformal mapping, the novel planar focusing antenna has been designed and verified through numerical simulation with commercial software (Mei et al. 2010) and the finite-difference time-domain method (Tang et al. 2010) independently in 2010 and was experimentally demonstrated in 2011 (Mei et al. 2011).

The virtual and physical spaces in the experimental verification work (Mei et al. 2011) are illustrated in Fig. 10a, b. The curved boundary at the bottom of the virtual space is a 2D parabolic reflector. Based on quasi-conformal mapping, the quasi-rectangular region in the virtual space as Fig. 10a is transformed into a standard rectangle in the physical space as Fig. 10b in TE mode. The refractive index distribution in the designed physical space is shown in Fig. 10c. The less than one material parameters are all set to one to avoid dispersive resonant structure in the physical implementation. The refractive index value in most part of region I is close to one, so it is excluded from the final design and the domain of the flat lens antenna is then reduced to region II.

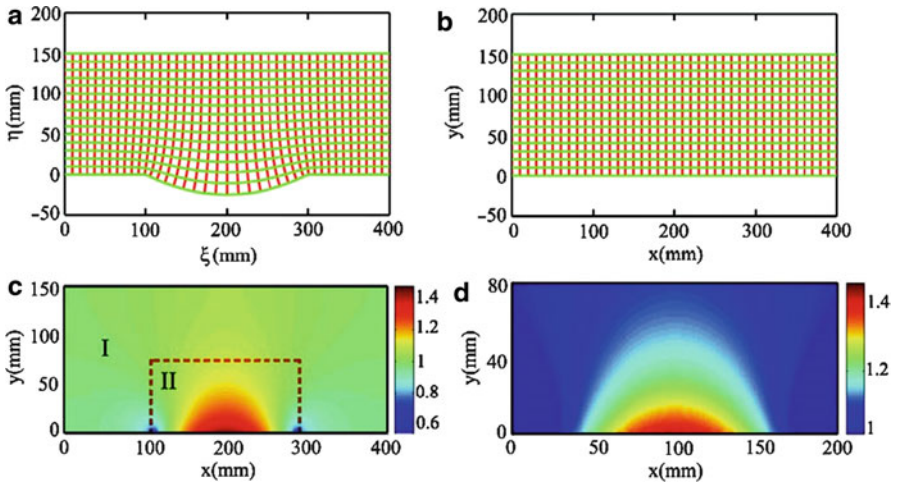

Fig. 10 (**a**) The virtual space of the parabolic reflector. (**b**) The physical space of the planar antenna with quasi-conformal mapping. (**c**) The refractive index distribution in (**b**). (**d**) The refractive index distribution of the final lens antenna with the n less than one set to one (Mei et al. 2011)

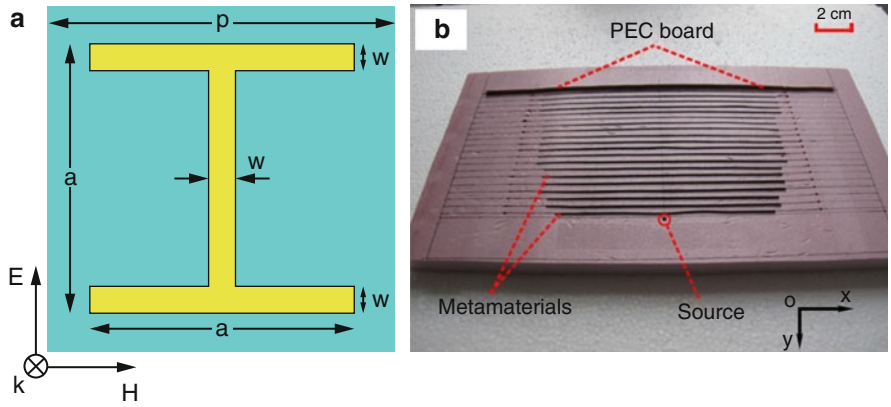

Fig. 11 (**a**) The geometry of the I-shaped unit cell. (**b**) The schematic of the fabricated planar antenna (Mei et al. 2011)

The planar antenna is designed in X-band with the broadband and low-loss I-shaped metamaterials as depicted in Fig. 11a. A different refractive index value in the transformed device can be obtained by changing the height of the I-shaped structure, *a*. PCB strips supported by refractive index value close to one foam structure are constructed to build the planar lens as illustrated in Fig. 11b. The measured near-field distributions of the parabolic reflector and planar lens antenna at 10 GHz agree well with each other as shown in Fig. 12. Further simulation and experimental results indicate that the planar antennas have a broadband performance from 8.5 to 11.5 GHz.

Conclusion

In this chapter, the transformation optics under two main types has been reviewed: the general transformation and the quasi-conformal mapping. Based on these theories, application examples including the multibeam antenna, layered lens antenna, 3D flattened Luneburg lens, flattened metasurface Luneburg lens, and planar reflector lens are introduced to demonstrate the flexibility of TO provided to manipulate EM wave and design novel antennas.

Abstract

Traditionally, frequency selective surfaces (FSSs) comprising structures with periodicity in two dimensions have important applications as spatial filters in microwave and optics. Due to the manufacturing process, they are usually in the form of printed patches on a dielectric substrate or apertures in a conducting screen. Multiple FSS screens and dielectric layers can be stacked together to meet desirable spectral filter responses. For these structures, a surface discretization of the unknown currents and/or electric fields is more convenient, and efficient integral equation solutions are sought thereafter. Recent developments in manufacturing processes, material properties, and new wave phenomena call for periodic structures with three-dimensional (3D) unit-cell elements. There are situations that a volumetric discretization of the unit cell is more appropriate, and differential equation solutions are preferred. The advent of powerful commercial simulation tools allows effective FSS designs with more flexibility. Compounded with the popularity of 3D printings, some previously unimaginable FSS structures can now be cost-effectively realized. Exploitation of transmission and reflection information obtained from FSS also paves the way for better antenna designs.

Planar frequency selective surface; Frequency selective surface with 3D unit cells; Lens antennas; Reflectarrays; 3D printing

Introduction

Frequency selective surfaces (FSSs) comprising structures with periodicity in two dimensions have important applications as filters in microwave and optics. One household application is the microwave oven door screen which allows us to observe the food cooking inside the oven but prevents the leakage of microwave radiation to ensure user safety. In the US patent, *Microwave Oven Door Screen* (US4, 051, 341 approved Sept. 27, 1977), it described that the door screen generally comprises a pair of transparent plates and a microwave shielding material made with punched holes on aluminum plate of thickness 0.1–0.35 mm. The aperture has a diameter of 1.2 mm or less, and the center-to-center spacing between two apertures is from 1.4 to 1.8 mm for effective microwave shielding. Figure 1a shows a typical modern microwave oven door whose design is not much different from what was described in the patent more than 37 years ago. On a larger scale, Fig. 1b shows a typical honeycomb panel used for RFI/EMI shielded enclosures which provides electromagnetic shielding and air ventilation.

FSSs with periodic apertures are inductive whose spectral response is typically a high-pass/band-pass filter. In contrast, FSSs with periodic array of patches are capacitive, behaving as a low-pass/band-stop filter. Various spectral responses can be achieved through a combination of the inductive and capacitive screens, dielectric loading, unit-cell geometry, and spacing between unit cells.

The scattering mechanism of periodic structures was reported by D. Rittenhouse in 1786 (Stroke 1967). He became interested in the diffraction effects observed through a silk handkerchief at a distant lamp. He constructed one-dimensional (1D) periodic structure in the form of equally spaced parallel hairs. J. von Fraunhofer independently invented the first ruled optical gratings in 1821. From then on, the investigations of FSSs were basically through experimental means and physical interpretations, including the Wood's anomaly observed experimentally with ruled diffraction gratings (Wood 1902).

Spectral response of FSSs was predicted by numerical modeling as early as 1960s. Scattering by a doubly periodic array of square apertures on a conducting plane was modeled with variational method by Kieburtz and Ishimaru (1961) in which the accuracy of the results strongly depends on the chosen trial functions. With the advent of electronic computing and numerical methods, more accurate characterizations of FSSs were reported, and point matching (Ott et al. 1967), waveguide modes (Chen 1970), and plane-wave expansion (Lee 1971) were employed for the analysis of rectangular patches or apertures.

The shape of the unit-cell element also plays a key role to spectral response of the FSS. For thin wire structure, Pelton and Munk (1979) approximated the induced currents on the cross dipole element by two cosinusoidal components. For currents in ring elements, Parker and Hamdy (1981) employed a series of cosine and sine functions which are periodic in the angular position. In the analysis of square loops, Hamdy and Parker (1982) treated the currents as a superposition of those on four coupled rectangular strips expanded with sinusoidal functions. Spectral-domain formulation for the analysis of FSSs with cross dipole and Jerusalem cross elements was introduced by Tsao and Mittra (1984) in which the convolution in the integral equation is conveniently replaced by a product in the spectral domain. A junction basis function was also introduced to correctly account for the current discontinuity at the junction of the cross. The same formulation was extended to analyze circular patch FSSs (Mittra et al. 1984). In the spectral domain formulation, basis functions are chosen such that they are analytically Fourier transformable. For the circular patch case, Chebyshev functions of the first and second kinds were employed. Their Fourier transforms are combinations of different orders of Bessel function of the first kind. In all these approaches, known functions representing the unknown currents are regarded as entire-domain basis functions, and a few of them are sufficient. Therefore, the unknown weighting coefficients can be obtained by a simple inversion of the obtained impedance matrix. In contrast, to provide modeling flexibility, a larger number of subdomain basis functions are employed instead.

Rubin and Bertoni (1983) employed subsectional basis functions to approximate current distributions on a periodically perforated plane. The impedance matrix elements involve double infinite summations that need to be judicially truncated. These double summations were rapidly summed using fast Fourier transforms (FFTs) by Cwik and Mittra (1987) by enforcing uniform, rectangular discretizations. However, the number of summation terms was limited to the size of the FFT. This problem was alleviated by Chan and Mittra (1990) by showing that due to the periodicity of the Floquet modes, terms with the same exponentials could be summed prior to the use of FFTs. The double summations converge rapidly, and it also demonstrates that the relative convergence phenomenon discussed in Lee (1971) does not exist if sufficient number of terms is included in the summation. This efficient method has also been employed to investigate FSS periodically loaded with nonlinear devices (Epp et al. 1992). A review paper summarizing the analysis methods for planar FSSs was published by Mittra et al. (1988), and the efficient approach presented in Chan and Mittra (1990) was validated in infrared (Schimert et al. 1990) and millimeter waves (Schimert et al. 1991).

DOI 10.1007/978-981-4560-75-7_23-1

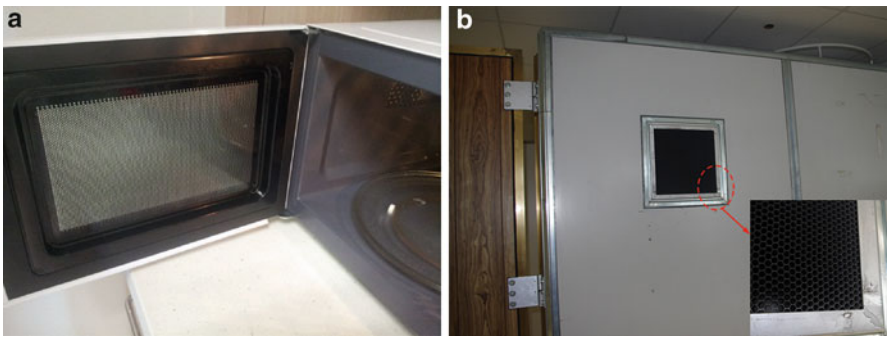

Fig. 1 (**a**) A typical microwave oven door and (**b**) honeycomb panel used for shield room

The use of uniform rectangular discretization, however, limits the flexibility in modeling the unit-cell geometry. A hybrid spectral/spatial approach for a free-standing FSS based on the Poisson summation formula was demonstrated by Jorgenson and Mittra (1990) in which no assumptions about the discretization of the unit cell were made. The spatial domain formulation converges rapidly when the Green's function between the source point and field point is subtracted by another Green's function with the field point slightly lifted off from the plane of the FSS. The subtracted contribution is compensated by the spectral domain formulation which also converges rapidly due to an exponential decay when evaluated off the FSS. This approach allows evaluation of the honeycomb-type panel shown in Fig. 1b (Jorgenson and Mittra 1991). For FSS embedded in layered dielectrics, Kipp and Chan (1994) adopted the same hybrid approach with the spatial domain Green's function evaluated by the complex image method (Chow et al. 1991). The spatial contribution is further accelerated by using Shank's transformation (Singh and Singh 1990). In the complex image method, the spatial Green's function is broken into three parts: the quasi-dynamic image, the complex image, and the surface wave terms. Double summation of the first two terms can be further accelerated by Ewald's method (Jordan et al. 1986) and the last term by the lattice-sum method (Chin et al. 1994). These techniques are then integrated into the hybrid method (Yu and Chan 2000).

When the FSS is not planar, numerical methods presented above would not be applicable and one has to resort to other techniques such as the finite-element method (FEM) and the finite-difference time-domain (FDTD) method in which volumetric discretization of the 3D unit cell is often adopted. A switchable, tunable grating was presented by Bushbeck and Chan (1993). The grating is in the form of a plastic slab with periodic channels filled with fluid. The surface of the slab bulges up periodically when pressure is applied to the fluid. Spectral response of this grating was analyzed with two-dimensional (2D) FE-M. In general, 3D FEM method allows for flexible modeling of doubly periodic structures (Eibert et al. 1999). Another partial-differential equation approach is the FDTD method. Veysoglu et al. (1993) proposed a Floquet field mapping to account for the periodic boundary conditions for the leading and trailing ends of the unit cell at oblique incidence. The performance of the method deteriorates with the increase of incidence angle. This problem can be alleviated with a combination of sine and cosine excitations (Harms et al. 1994). In addition to Floquet field mapping for the periodic FDTD equations, Roden et al. (1998) employed a split-field update method which led to a less stringent stability criterion and more accurate geometrical modeling with nonorthogonal FDTD grids. On the other hand, the advantage of obtaining a range of frequency response in a single time-domain simulation disappears due to the use of Floquet field mapping. 3D FSSs with double periodicity can also be solved using volumetric/surface integral equation approach with the periodic Green's function obtained by Ewald's transformation (Shi and Chan 2010).

Recent Development

In addition to a large volume of journal papers on FSSs and periodic structures, there are also many books published over the years, ranging from theory, analysis, optimization, and design (Wu 1995; Vardaxoglou 1977; Rahmat-Samii and Michelssen 1999; Munk 2000; Capolino 2009). Except for Capolino (2009) which focuses on new electromagnetic properties of metamaterials in the form of periodic 2D/3D structures, these books have been published for over a decade. Therefore, it is also beneficial to provide a brief review on some selected recent work on FSSs, and obviously many other works are left out here given the limited space.

Shen and his research group proposed 3D FSS structures that consist of a 2D periodic array of 3D unit cells formed by vertically placed microstrip structures (Rashid and Shen 2010, 2011; Rashid et al. 2012, 2014). The 3D FSSs offered arbitrarily pseudo-elliptical performance by exciting a suitable number of propagating modes and controlling their coupling with air. Compared to conventional 2D FSSs, 3D FSS structures provide more design flexibility although they require more physical assembly. The use of resonant metallic elements in FSSs could be problematic at very high power. J. H. Barton et al. (2012, 2014) investigated all-dielectric FSSs for high-power microwaves. Because of lack of metals, arcing at field concentration points and heating in the conductors were successfully avoided. This technology could find a variety of applications in high-power microwave systems, including radomes, beam shaping, and more.

Ohira et al. (2004, 2005) and Bossard et al. (2005, 2006) employed genetic algorithm (GA) to design FSSs with desired performances. This methodology was very direct and flexible but could be time consuming as there is no one-to-one correspondence between the filter response and the unit-cell geometry. Novel waveguide filters are designed using GA to determine which pixels of a bitmap are printed with conductor (Ohira et al. 2005) on each FSS screen and cascading three screens to form a waveguide band-pass filter with a steep roll-off. Switches are incorporated into the FSS in Bossard et al. (2005) which makes the surface reconfigurable for either single-, dual-, or tri-band operation. The surface can also be polarization dependent or independent, subject to different on and off patterns of the switches. Other active FSS structures were reported by Sanz-Izquierdo et al. (2010, 2011) and Sanz-Izquierdo and Parker (2014) on which active components were loaded to tune the filtering characteristics. The designs could be used for various applications including modification of the electromagnetic architecture of buildings and the control of electromagnetic wave propagation to improve the efficiency of radio spectrum use.

Practical applications of traditional FSSs are restricted in limited space, so it is difficult to arrange larger number of elements with large physical sizes to make a finite FSS with better performance. In addition, large element sizes and large periodicities lead to difficulties, especially in conforming to curved surfaces. In Liu et al. (2009), Yan et al. (2014), and Yu et al. (2014), miniaturized FSSs were investigated by respectively loading lumped reactive components and meandering wires. The proposed FSS structures exhibited superior miniaturization and provided favorable resonant stability at various incidence angles. Substrate integrated waveguide (SIW) technology was applied to design high-performance FSS structures by Luo et al. (2005, 2006, 2007). The high-Q property of SIW cavities greatly improved the frequency selectivity of the FSSs, which was significant for the applications in antenna radome, object stealth, etc. Resulting from the coupling between cavity mode and aperture mode, SIW FSSs have additional transmission zeros nearby the passbands, which improved the frequency selectivity.

Metallic wire grid can be viewed as a nonresonant inductive component, and metallic patches separated by thin air gaps can be viewed as a nonresonant capacitive component. Based on this theory, Sarabandi and Behdad (2007) proposed a variety of low-profile FSSs with sub-wavelength unit cells by cascading these nonresonant components. Further studies on low-profile FSSs designed by combining resonant and

DOI 10.1007/978-981-4560-75-7_23-1

nonresonant elements were presented by Bayatpur and Sarabandi (2008), Behdad et al. (2009), and Al-Joumayly and Behdad (2009). Actually, an FSS with any arbitrary multipole or non-commensurate multiband filtering response can be obtained using the approach described above. In addition, the proposed FSS structures have extremely small overall profiles and stable resonant frequency with respect to the incidence angle.

Recently, research on terahertz (THz) devices has been rapidly expanded due to a wide range of applications, including chemical and biological sensing, remote sensing, imaging, and submillimeter-wave applications. Some fabrication approaches with high manufacturing accuracy, such as wafer micro-fabrication technology and electron-beam evaporation technology, were used to fabricate THz FSS structures. Dickie et al. (2005, 2009, 2014) proposed a variety of FSSs for THz applications. Based on a precision micromachining technique, the fabricated metallic FSSs have low insertion loss due to lack of substrate loss. Active tuning of FSS at 0.86 THz was reported by Chang et al. (2013). Fish-net FSS was printed on polymer-dispersed liquid crystal, and the resonant frequency can be tuned by varying the voltage applied to the FSS.

FSSs can be applied to the design of antennas to reduce planar antenna radar cross section (RCS), enhance gain and directivity, and improve bandwidth. Many researchers have designed antennas based on FSS structures to obtain desired performances (Jazi and Denidni 2010, 2013; Foroozesh and Shafai 2010; Genovesi et al. 2012). Jazi and Denidni (2010, 2013) applied different active FSSs to design sweeping-beam radiation-pattern antenna and reconfigurable-agile radiation-pattern antenna. These antennas provided superior radiation performances in terms of bandwidth, radiation pattern, and gain. Additionally, there was more freedom to control the antenna radiation characteristics. Foroozesh and Shafai (2010) used a highly reflective patch-type FSS as the superstrate of a cavity resonant antenna to obtain high peak gains and offer wide input impedance and gain bandwidths. Genovesi et al. (2012) investigated how to reduce the RCS of a common patch array antenna at the out-of-band frequencies by using FSSs. Finally, replacing the solid ground plane of the array antenna with a hybrid FSS was proven to be an effective means, which reduced the RCS but also preserved the radiation performance of the antenna.

Due to the advent in both computer hardware and computational methods, the emphases of FSS research are shifted toward more complex unit-cell geometry to satisfy new design specifications and higher operating frequencies. Based on the review of more recent works, FSS design is first modeled with commercially available software such as HFSS (Ansoft HFSS, 3D EM Simulator, version 14.0.0). 3D unit-cell elements are used for providing more design flexibility. Conventional multilayered printed-circuit technologies may not be sufficient to meet new demands, and alternative fabrication processes are needed. Some of these issues will be addressed in this chapter.

Multilayered FSS Filter

FSSs have been widely used as spatial filters; however, most FSS designers only focus their efforts in getting the right passband and stopband, multiband response, or stability against different angles of incidence. In reality, design specifications of an FSS filter are not different from those of a filter in microwave circuitry. For example, an FSS band-pass filter should have a low insertion loss in the passband and a steep roll-off at the band skirts which are often overlooked (Chiu and Chang 2009; Sarabandi and Behdad 2007). The sharp roll-off can be achieved by high-order filters by stacking several FSS screens, but this may increase the insertion loss. One approach to improve stopband rejection is to introduce transmission zeros in the filter design (Ma et al. 2006; Chu and Wang 2008). Ma et al. (2006) presented how the electric coupling, magnetic coupling, and their combination between two resonators can affect the presence and locations of the transmission zero (TZ) using two separate coupling paths.

DOI 10.1007/978-981-4560-75-7_23-1

Similar approach will be adopted here to illustrate how FSS designers can improve the spectral responses of their designs.

Recently, because of the availability of unlicensed 60 GHz spectrum, researches on 60 GHz devices are being rapidly expanded, but little research work has been reported on the 60 GHz FSSs. In general, there are two approaches to obtain high filter selectivity, including increasing resonance orders and adding TZs. Higher-order structures would be complicated and large, so in this work TZs are added to improve frequency selectivity. Certainly, higher-order characteristics are also investigated in section "Stability and Higher-Order Characteristics." In Luo et al. (2007) and Rashid et al. (2012), cross coupling has been introduced to obtain multiple TZs around the passband. In Luo et al. (2008), two FSSs with one TZ each have been combined to realize an FSS structure with multiple TZs. However, these high-selectivity FSSs are difficult to design at 60 GHz or THz because of their 3D structures.

In this section, a dual-polarized FSS structure at 60 GHz based on aperture-coupled resonators is proposed. It provides multiple TZs resulting from the mixed electric and magnetic couplings, therefore achieving high-frequency selectivity. In addition, the FSS is easy to design and fabricate due to the simple and planar structure. In contrast, an SIW FSS structure in section "SIW FSS with Multiple TZs" will be presented, similarly providing two or three TZs. However, as mentioned above, this SIW structure is difficult to fabricate due to the presence of many small metallic vias.

Tightly Coupled FSS Structure and Analysis

The objective of this work is to design a 60 GHz FSS with high frequency selectivity. In Pous and Pozar (1991), a coupling FSS structure based on the aperture-coupled microstrip patch has been designed. However, there is no TZ around the passband; the same is true in the patch-aperture-patch or aperture-patch-aperture FSS (Chan et al. 1992). In this work, based on the coupling resonator theory, an FSS with mixed electric and magnetic couplings is designed, producing two TZs at finite frequencies.

Tightly Coupled FSS Structure

The 60 GHz FSS is designed using two cross resonators coupled by rectangular apertures. It consists of three metal layers separated by two substrates. In this work, Rogers Duroid 5880 is applied as the substrate to support the structure because of its stable dielectric constant of 2.2 and low loss tangent of 0.004 at

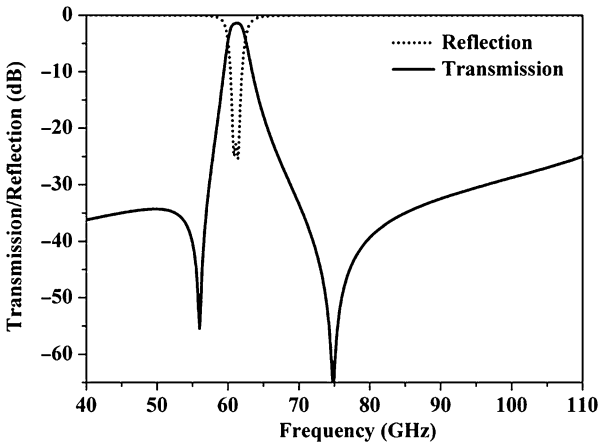

Fig. 3 Frequency responses of the proposed FSS

60 GHz (Li and Luk 2014). Figure 2a–c shows the configuration of the proposed FSS unit cell. In the unit cell, the cross resonators on the top and bottom layers are identical and viewed as two half-wavelength resonators. Four identical rectangular apertures etched on the middle ground are directly located between each end of the top and bottom crosses. The final FSS is realized by periodical arrangement of the unit cells.

The proposed FSS is modeled conveniently using the integral equation as described in Mittra et al. (1988). As the method has been experimentally verified at various frequencies (Schimert et al. 1990, 1991), only the numerical results are focused for this structure. Table 1 lists the dimensions of the proposed FSS. The simulated frequency responses of the proposed FSS for an x- or y-polarized normal incidence are plotted in Fig. 3. The FSS produces two transmission poles (TPs) in the passband. It has insertion and return losses of 1.4 and 23 dB at the operating frequency of 61 GHz, respectively. This second-order structure has symmetric response with a fractional 3-dB bandwidth of 4.1 % (2.5 GHz). The two produced TZs are located, respectively, at 56 and 75 GHz both with an attenuation level of around 60 dB, which are helpful to achieve superior frequency selectivity and suppress the lower and upper sidebands.

Analysis of the FSS

Figure 4 shows the coupling diagram for the proposed FSS in Fig. 2, in which the resonators on the top and bottom layers are represented by the squares. Through the coupling apertures on the middle layer, mixed electric and magnetic couplings exist between the two resonators. From the theory of coupling filter, the FSS structure obtains a narrow bandpass response with two TPs in the passband. One of TPs is due to the individual resonators, and the other one appears as a combined effect of the resonators plus the effect of the coupling apertures. Due to the mixed couplings, two TZs can be produced at real finite frequencies and their frequencies can be adjusted by the location and dimensions of the coupling apertures. As described in Ma et al. (2006), when the electric coupling is dominant, the two produced TZs would be located at lower and upper sides of the passband, respectively. While the magnetic coupling is dominant, two TZs would be produced and both located at upper side of the passband.

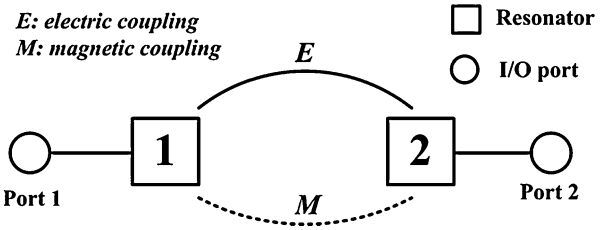

Fig. 4 Coupling diagram for the proposed FSS

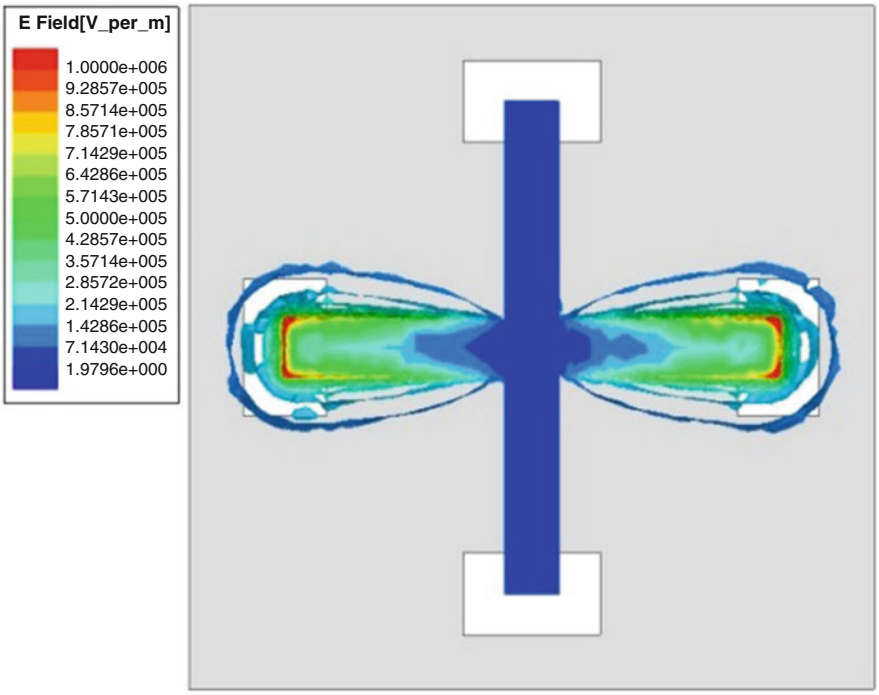

Fig. 5 E-field distributions of the FSS unit cell at the operating frequency for an x-polarized normal incidence

Figure 5 shows the electric field (E-field) distributions of the FSS unit cell at 61 GHz in the passband for an x-polarized normal incidence. As observed, the electric field is mainly concentrated around the ends of the cross resonators. This fact demonstrates that the coupling between the resonators is mainly electric coupling. Therefore, there are two TZs, respectively, located at the lower and upper sidebands, as shown in Fig. 4. Adjusting appropriately the locations of the coupling apertures can affect the strength of the electric and magnetic couplings and then change the frequencies of the TZs. Figure 6 shows the transmission responses with various locations of the coupling apertures. It is noted that all the coupling apertures are relocated symmetrically, as shown in the inset of Fig. 6. As found, one of the TPs changes slightly, while the other shifts to lower frequencies with relocation of the coupling apertures. Additionally, when the coupling apertures are located around the ends of the crosses ($l_m = 0.1$ mm), with dominant electric coupling, the produced TZs are separately located at lower and upper sidebands. When the coupling apertures are close to the centers of the crosses ($l_m = 0.2$ mm or 0.3 mm), with dominant magnetic coupling, all the produced TZs are located at upper sidebands. At last, as the apertures are moved to the centers of the crosses ($l_m = 0.4$ mm), there are the strongest magnetic coupling and the weakest electric coupling that no TZs appear at finite frequencies. Actually, the FSS structure investigated in Pous and Pozar (1991) is a special case of the design presented here.

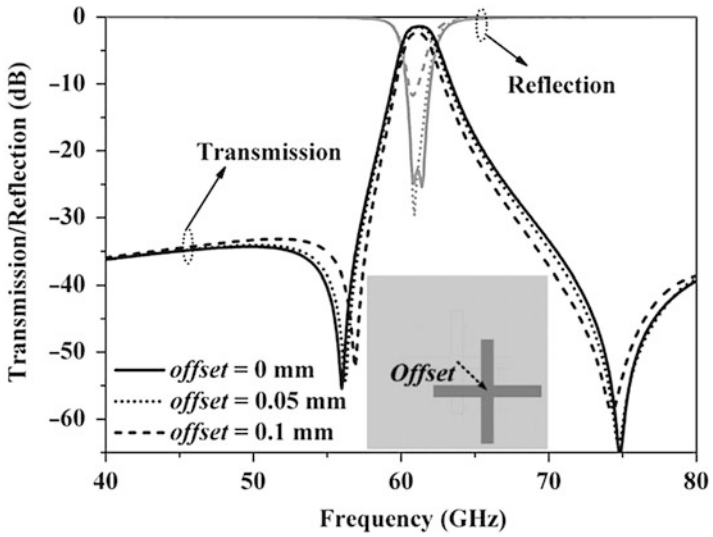

Fig. 7 Effects of the offset between resonators at different layers on frequency response of the FSS structure

Stability and Higher-Order Characteristics

Stability Analysis

As shown in Fig. 2, since the proposed FSS needs to be realized by stacking three metal layers supported by two substrates, there could be a misalignment between the top and bottom layers. Figure 7 shows effects of the offset between resonators at different layers on the frequency response of the FSS, in which the parameter offset is clearly defined and shown in the inset. It can be found that the structure is still stable until the offset goes up to 0.1 mm.

The simulated transmission coefficients of the FSS illuminated by plane waves with incident angles of 0° and 30° for both TE and TM polarizations are plotted in Fig. 8. In the figure, "theta" represents the angle between the propagation vector of the incident wave and the normal direction to the surface. As observed, the operating frequency and bandwidth are very stable in case of oblique incidence for the two

DOI 10.1007/978-981-4560-75-7_23-1

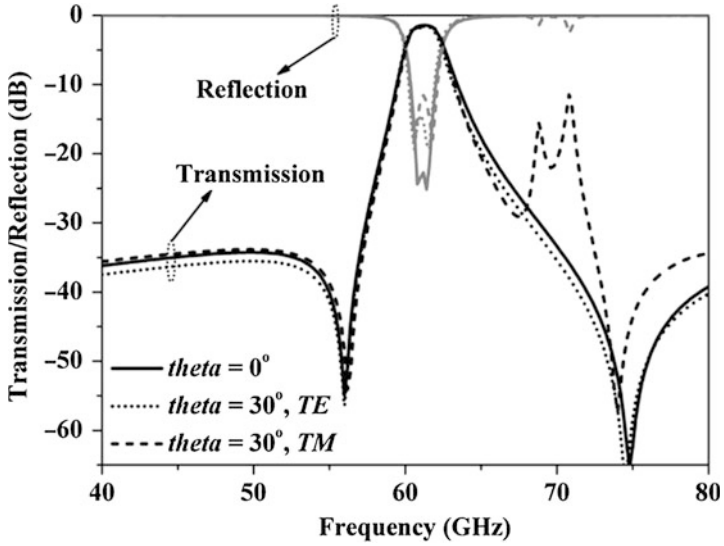

Fig. 8 Simulated transmission coefficients of the FSS with different incident angles and polarization states

polarization states. For an incident angle of 30°, some unwanted resonances emerge at around 70 GHz. Fortunately, the amplitudes are below −12 dB. The frequency response of the structure is relatively stable to variations of incident angle and polarization state.

Higher-Order Characteristics

In order to further improve the frequency selectivity, a higher-order FSS is realized by stacking two second-order FSS structures shown in Fig. 2 with an air spacing of 1.3 mm, as shown in Fig. 9a. The stacked FSSs, respectively, have dominant electric and magnetic couplings, causing that the higher-order FSS would produce multiple TZs nearby the passband simultaneously. Figure 9b shows the simulated frequency responses of the higher-order FSS. From the figure, one TZ at the lower sideband and two TZs at the upper sideband are found, which improve the frequency selectivity to a large extent. Furthermore, comparison of the simulated responses of the original second-order FSS and the higher-order FSS illustrates that stacking FSSs can greatly improve the filter response.

SIW FSS with Multiple TZs

Substrate integrated waveguide (SIW) technology has already been applied to design high-performance FSS structures (Luo et al. 2005, 2006, 2007). Resulting from multiple coupling paths, a transmission zero (TZ) nearby the passband can be obtained, therefore improving the upper or lower stopband of the frequency responses. In order to further enhance the frequency selectivity, two FSS structures individually with one TZ have been combined to obtain multiple TZs (Luo et al. 2008). However, this combined FSS suffers from a complicated structure that it is difficult to design and practically use.

In this section, substrate integrated waveguide (SIW) technology is similarly applied to design FSS structures. Due to the existing multiple coupling paths through multiple resonators, including slot resonator, cavity resonator, and Fabry-Perot resonator, multiple TZs can be obtained to suppress the lower and upper stopbands.

FSS Structure

Figure 10 shows the unit cell of the proposed SIW FSS with a square lattice. As seen in the unit cell, two identical square loop patches are located horizontally on the top and bottom layers, respectively. Metallic

DOI 10.1007/978-981-4560-75-7_23-1

vias forming vertical sidewalls are located next to outer edges of the square loop patches, in which a certain center-to-center spacing between adjacent vias (d_p as given in Table 2) needs to be reached, as described in Zhang et al. (2005). Such unit cells are arranged periodically to construct an SIW FSS. In this structure, a Fabry-Perot resonator exists in the substrate zone between adjacent sidewalls. The rectangular slots surrounded by the loop patches on the top and bottom layers can construct a slot resonator, and, in contrast, the metallic sidewalls provide a cavity resonator. Actually, it is not difficult to conclude that the Fabry-Perot resonator is mainly determined by the thickness of the used substrate and the gap between adjacent sidewalls (Lima and Parker 1996), and the slot resonator and cavity resonator are mainly determined by the edge lengths of the rectangular slots and inner edge lengths of the SIW cavity, respectively. Therefore, by adjusting the related geometrical parameters, one can achieve two different frequency responses, which are the second-order and third-order frequency characteristics.

Second-Order Response

When the size of the cavity constructed by the metallic via array is small so that the resonant frequency of this cavity resonator is far from the interested frequency range, the cavity can actually be viewed as a Faraday cage (Xu et al. 2008). The Faraday cage at this time can reduce the interferences between unit cells and provide a Fabry-Perot resonator located between adjacent Faraday cages in a doubly periodic

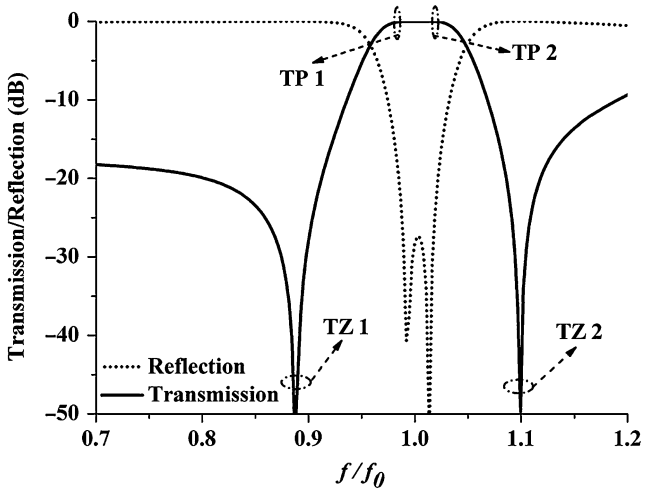

Fig. 11 Frequency responses of the second-order FSS

array, as described above. Therefore, in the frequency range of interest, there should be two transmission poles generated by the slot resonator and the Fabry-Perot resonator, respectively. The simulated frequency response curves are plotted in Fig. 11. In the following simulation models, the via array is replaced by a square solid wall with inner edge length $l_c = l_p - 2d$ and outer edge length l_p (where l_p and d are shown in Fig. 10), and the obtained results are all for an x- or y-polarized normal incidence and normalized. From Fig. 11, one can see that there are two TPs in the passband, which are labeled as TP 1 and TP 2. Two TZs at the lower and upper sidebands are also obtained, which are labeled as TZ 1 and TZ 2, respectively. TZ 1 is caused by the couplings between slot resonant mode and evanescent modes in free space, while TZ 2 is by the couplings between slot resonant mode and Fabry-Perot resonant mode. These produced TZs improve the frequency selectivity of the FSS structure to a great extent, and their generation mechanism will be analyzed in the next subsection in detail. However, the upper stopband is not successfully suppressed, especially at frequencies over the 1.2 f_0, in which f_0 is the central frequency. The reason causing the

DOI 10.1007/978-981-4560-75-7_23-1

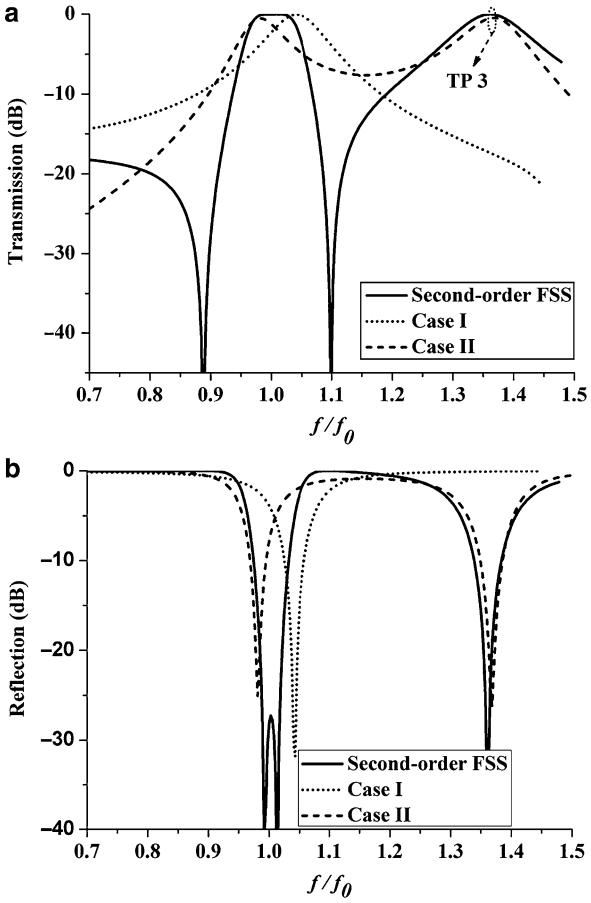

Fig. 12 Frequency responses of the second-order FSS and the structure in two cases: (**a**) transmission and (**b**) reflection

imperfect upper stopband can be found from the frequency responses over a wide frequency range. As shown in Fig. 12a, an additional TP labeled as TP 3 emerges at around 1.4 f_0, which is caused by the Faraday cage as a cavity resonator. This undesired TP worsens the frequency performance of the upper stopband, and one solution is to reduce the size of the Faraday cage and keep its resonant frequency far away from the frequency range of interest.

In order to clearly show the working mechanism of the produced TPs, including TP 1, TP 2, and TP 3, the different components of the FSS structure shown in Fig. 10 are investigated individually. Frequency performance analysis of the Fabry-Perot resonator alone can be realized by filling the rectangular slots of the original FSS structure with metal, called Case I here. Filling the gaps between adjacent sidewalls can help to independently analyze the slot resonator and the cavity resonator constructed by the via array, designated as Case II. From Fig. 12a, b, TP 1 and TP 3 of the original second-order FSS coincide with the ones of Case II, which are caused by the slot resonator and the cavity resonator. TP 2 coincides with that of Case I, which is caused by the Fabry-Perot resonator. The frequencies of all the three TPs of the original FSS structure accurately agree with the ones of the TPs of Cases I and II, validating the different components of the FSS structure which can be adjusted independently to obtain the desired frequency response.

Figure 13 shows the E-field distributions on the FSS structure at frequencies of the three transmission poles. As observed, the E-field distributions once again verify the conclusion that the three transmission poles TP 1, TP 2, and TP 3 are caused by the three resonators, i.e., the slot resonator, Fabry-Perot resonator, and cavity resonator, respectively. Based on this conclusion, one can change the frequencies of

DOI 10.1007/978-981-4560-75-7_23-1

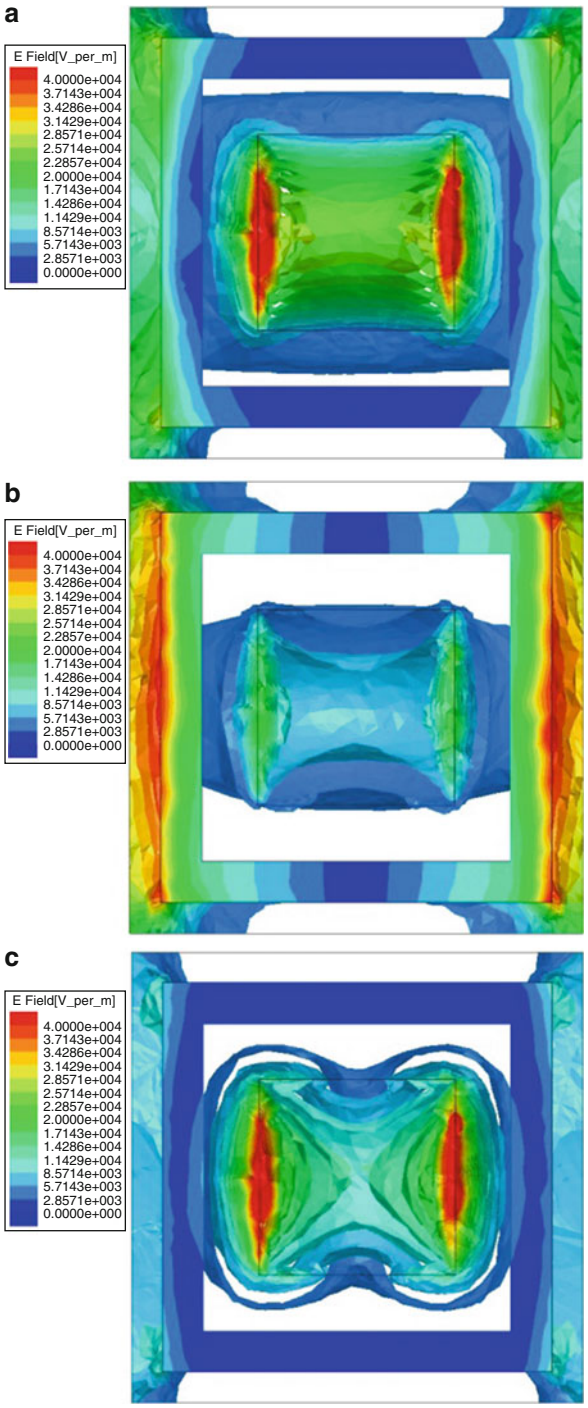

Fig. 13 E-field distributions of the second-order FSS structure at frequencies of three transmission poles: (**a**) TP 1, (**b**) TP 2, and (**c**) TP 3

the transmission poles in the passband by separately adjusting the geometrical parameters l_s and g. Meanwhile, in order to shift the undesired resonance of the TP 3 to a higher frequency, one can reduce the inner edge length of solid walls l_c labeled in the inset of Fig. 14c as much as possible. Figure 14 clearly shows the frequency responses of the FSS structure with various values of the related parameters l_s, g, and l_c, which can guide us to design an FSS with the desired responses. It should be reiterated that the metallic via array is replaced by solid metallic walls in the simulation models.

DOI 10.1007/978-981-4560-75-7_23-1

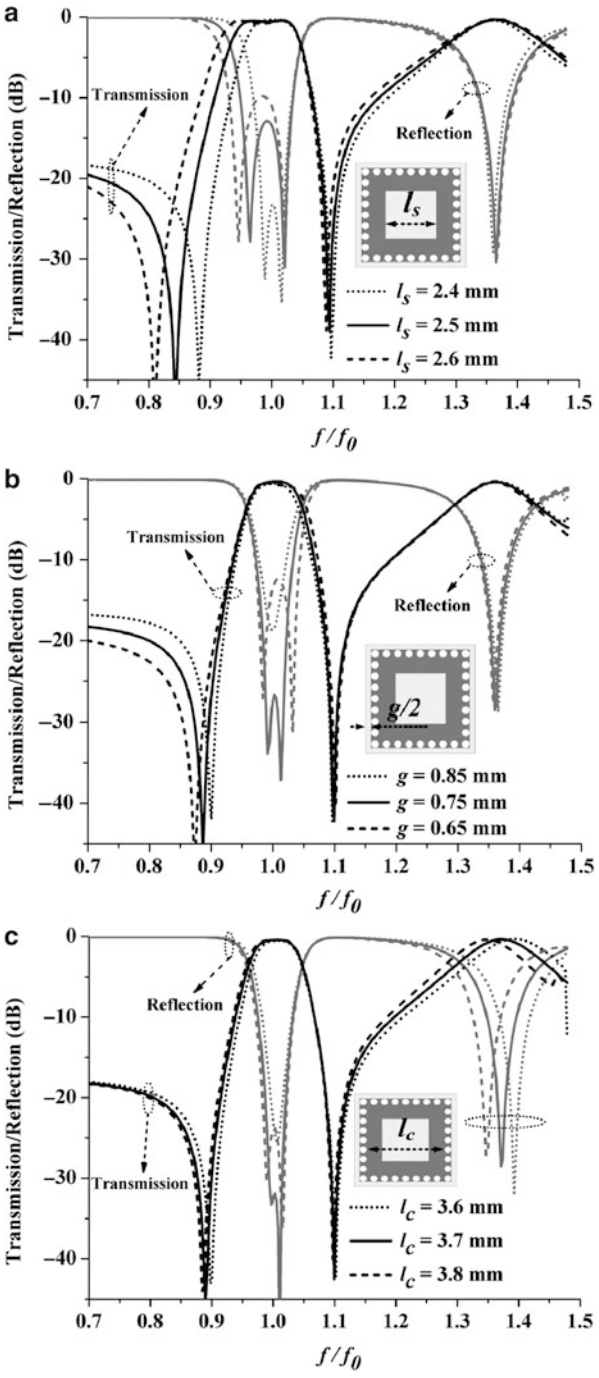

Fig. 14 Frequency responses of the FSS with different parameters: (**a**) l_s, (**b**) g, and (**c**) l_c

In order to validate the proposed design, the second-order FSS is designed in V band and its simulated frequency responses for an x- or y-polarized normal incidence are shown in Fig. 15. In the simulation model, metallic vias with a certain center-to-center spacing (d_p as given in Table 2) are used to construct the sidewalls, and Rogers Duroid 5880 is applied as the substrate to support the structure because of its stable dielectric constant of 2.2 and low loss tangent of 0.004 at 60 GHz (Li and Luk 2014). Table 2 lists values of the related parameters. From the figure, the central frequency of the FSS passband is 56.5 GHz. There are two TPs in the passband with a 3-dB bandwidth of 5.5 % (3.1 GHz) and two TZs located at

DOI 10.1007/978-981-4560-75-7_23-1

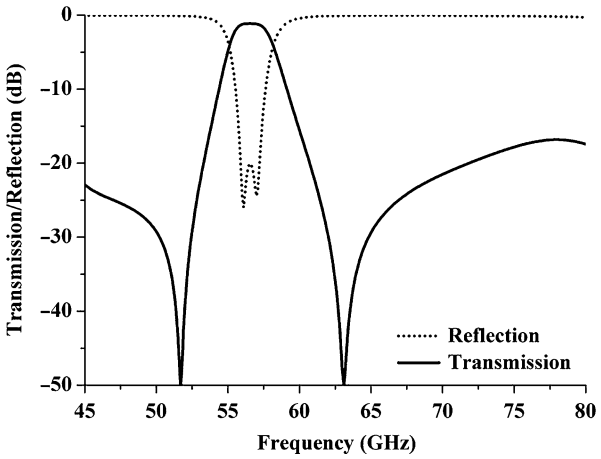

Fig. 15 Frequency responses of the second-order FSS in V band for normal incidence

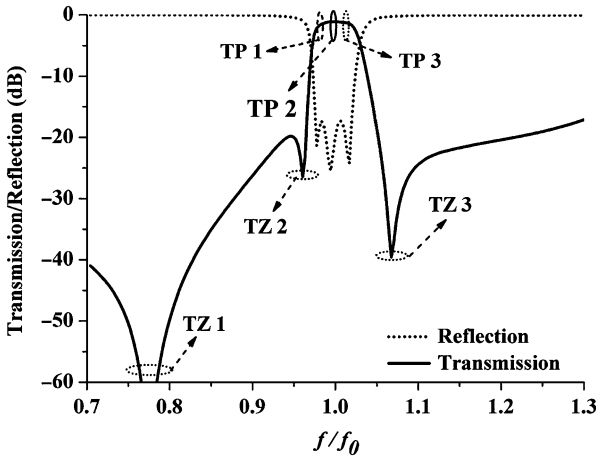

Fig. 16 Frequency responses of the third-order FSS

51.7 and 63 GHz, respectively. Over the frequency ranges from 45 to 53 GHz and from 61 to 80 GHz, the stopband suppression is better than 20 dB. In the passband, the insertion and return losses are about 1.4 and 20 dB, respectively. Actually, the negative impacts of the cavity on the upper stopband have already been lowered to a certain extent.

Third-Order Response

As described in Luo et al. (2007), the cavity resonator constructed by the via array would couple with the slot resonator to produce an additional TZ. In this part, the cavity is enlarged to realize a third-order response. Figure 16 depicts the normalized frequency curves of the third-order FSS. Three TPs in the passband, labeled as TP 1, TP 2, and TP 3, and three TZs around the passband, labeled as TZ 1, TZ 2, and TZ 3, can be found. TZ 1 and TZ 2 are located at the lower sideband, and TZ 3 is located at the upper sideband, thereby improving the frequency selectivity of the FSS structure. Similar to the second-order response, the three transmission poles, TP 1, TP 2, and TP 3, are generated by the Fabry-Perot resonator, slot resonator, and cavity resonator, respectively, which can be verified by the E-field distributions shown in Fig. 17.

DOI 10.1007/978-981-4560-75-7_23-1

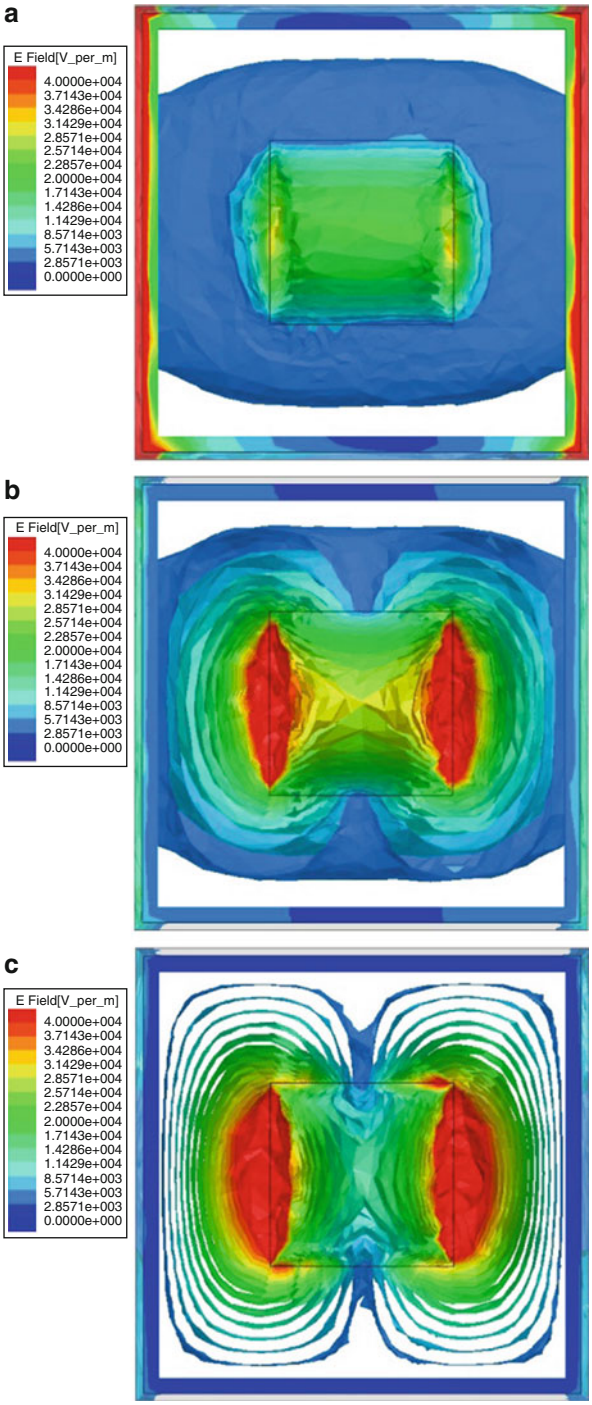

Fig. 17 E-field distributions of the third-order FSS at frequencies of three transmission poles: (**a**) TP 1, (**b**) TP 2, and (**c**) TP 3

The produced TPs have already been analyzed above; in this subsection, the generation mechanism of the three produced TZs is reiterated. The diagrams of couplings causing the three TZs are shown in Fig. 18. TZ 1 at the lower frequency is caused by the couplings between slot resonant mode and evanescent modes in free space (Rashid et al. 2012), while the TZ 2 and TZ 3 are caused by the couplings between slot resonant mode and Fabry-Perot resonant mode and the couplings between slot resonant mode and cavity resonance mode, respectively. Similarly, for a further demonstration, the different

DOI 10.1007/978-981-4560-75-7_23-1

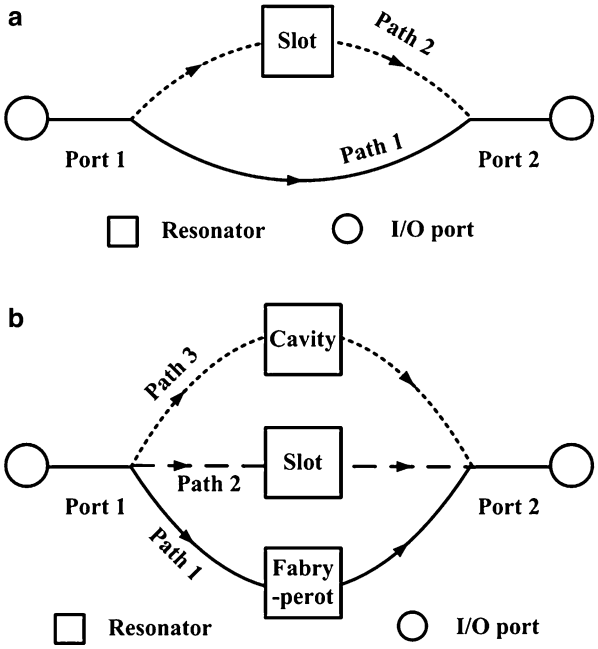

Fig. 18 Diagrams of couplings causing three TZs: (**a**) TZ 1, (**b**) TZ 2, and TZ 3

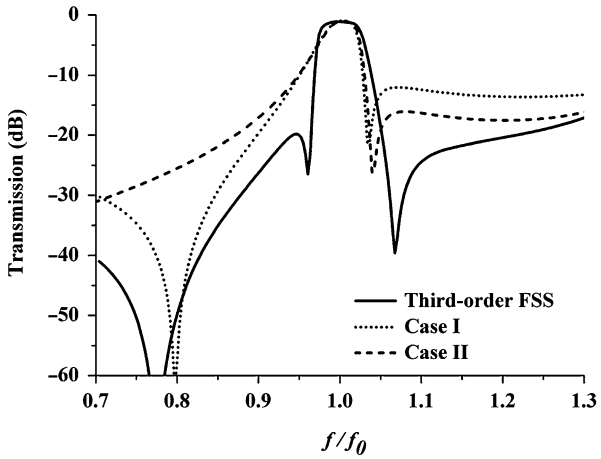

Fig. 19 Normalized transmission responses of the third-order FSS and the structure in two cases

components of the FSS structure shown in Fig. 10 are independently investigated. Replacing the substrate between adjacent sidewalls by air can remove the Fabry-Perot resonator, and this case is called Case I here. Filling the air gaps between adjacent sidewalls using metals can independently study the slot resonator and the cavity resonator, designated Case II. The simulated responses of the original third-order FSS and the structure in the two cases are plotted in Fig. 19. In Case I, there are two TZs at finite frequencies, i.e., TZ 1 and TZ 3. In Case II, there is only one TZ at the upper sideband, namely, TZ 3. Based on the comparison results shown in Fig. 19, it is quite easy to draw the conclusion described at the beginning of this paragraph. In comparison with the second-order response, these three TZs of the third-order response further improve the frequency selectivity, especially over the lower stopband.

In order to validate the third-order frequency characteristics, the third-order FSS is designed in V band and its simulated frequency responses for normal incidence are shown in Fig. 20. Similarly, in the

DOI 10.1007/978-981-4560-75-7_23-1

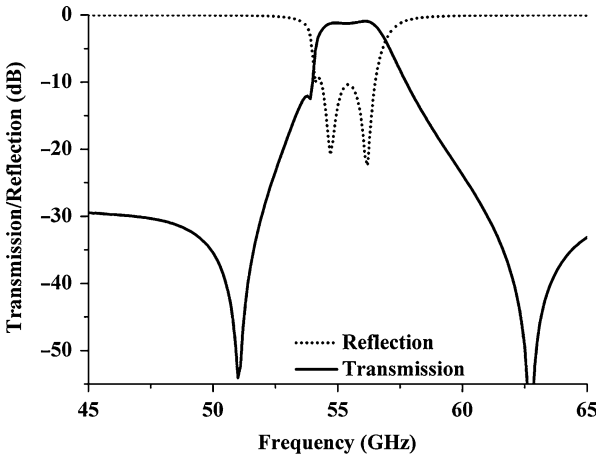

Fig. 20 Frequency responses of the third-order FSS in V band for normal incidence

simulation model, metallic vias and Rogers Duroid 5880 are used to construct the cavities and support the whole structure, respectively. Dimensions of the FSS are shown in Table 2. As shown in Fig. 20, the central frequency of the FSS is 55.5 GHz. There are three TPs in the passband with a 3-dB bandwidth of 4.9 % (2.7 GHz) and three TZs around the passband. In the passband, the insertion and return losses are about 0.9 and 10 dB, respectively.

Summary for SIW FSS

In section "SIW FSS with Multiple TZs," a kind of SIW FSSs has been presented and its second-order and third-order responses are investigated, respectively. Because of multiple coupling paths, the FSS provides multiple TZs, thus greatly improving the high frequency selectivity. The produced TPs have also been analyzed by showing the E-field distributions and comparing the frequency characteristics of the FSS in different cases. Two practical designs in V band have been provided, which verify the described second-order and third-order responses. The prototypes of the V-band FSSs could be fabricated by the standard printed-circuit-board (PCB) and plated through-hole technologies. However, due to so many small metallic vias, fabrication would become a big problem when the operating frequency continues going up, particularly into the THz regime.

FSS with 3D Unit-Cell Elements

3D FSS Introduction

In the previous section, FSSs are composed of periodic screens supported by planar dielectric layers. When the unit-cell element is 3D, they could be referred to as frequency selective volumes (FSVs) (Yang et al. 1997) or more fashionably as metamaterials (Engheta and Ziolkowski 2006). When the 3D unit cell does not have many fine details, typical FEM solver like HFSS would be sufficient. In contrast, when the number of unknowns is kept increasing, one needs to resort to other efficient algorithms, for example, the integral-equation-based multilevel Green's function interpolation method (MLGFIM) developed for the analysis of arbitrary 3D composite dielectric and conducting objects with double periodicity in which the periodic Green's function is calculated by applying Ewald's transformation (Shi and Chan 2010). The use of multilevel scheme substantially reduces the periodic Green's function points, and therefore, the matrix-fill time can also be reduced. The volume-surface integral equation for dielectric and conducting objects is formulated with conformal basis functions defined on curvilinear hexahedral and quadrilateral

DOI 10.1007/978-981-4560-75-7_23-1

elements which are used to discretize the 3D unit cell. Periodic boundary conditions are introduced to the unknowns on the opposite boundaries of the unit cell. The resulting matrix equation is solved iteratively using the MLGFIM. This approach scales linearly with the number of unknowns for both CPU time per iteration and the computer memory storage.

For the examples presented here, the 3D unit cells can be effectively modeled by HFSS, and readers are referred to its manual for detail construction of the unit-cell model. However, it should be mentioned that a rhombic box enclosing the unit cell can be chosen to account for the two axes of periodicity that are not necessarily orthogonal. One boundary surface of the box is designated as a master boundary, and the other boundary opposite to it is the slave. Fields at the master and slave boundaries satisfy the Floquet conditions. A Floquet port allows the flexible choices of polarization and angle of incidence.

The fabrication of FSVs or metamaterials with 3D unit cell is not as straightforward as the planar FSSs using PCB technology. The emergence of inexpensive 3D printing allows us to realize exotic unit-cell geometrical designs that are previously unimaginable. In this section, the effectiveness of commercial software like HFSS has been demonstrated for the analysis of periodic structures with 3D unit cells which can be conveniently fabricated by inexpensive 3D printing. The simulated spectral responses are validated by experiments.

Measurement Setup

Figure 21 shows the measurement setup, in which the two ports of the Agilent E8361A PNA network analyzer (10 MHz–67 GHz) are connected to a pair of transmitting and receiving horns, individually providing a 23.8-dBi gain. Alignment of the setup is made using a laser source. The FSS sample under test is mounted on a microwave absorbing panel with an opening window slightly smaller than the size of the sample. In the 60 GHz band, the measured transmission response through the microwave absorber has an insertion loss larger than 50 dB. The transmission response of the FSS is obtained by taking the difference of the measured $|S_{21}|$ with and without the sample.

3D FSSs Fabricated by 3D Printing

3D FSS samples can be fabricated using a Stratasys Objet30 Scholar 3D printer, which is convenient and inexpensive. Figures 22 and 23 show the 3D printer and some fabricated FSS samples, respectively. As shown, the 3D printer can easily fabricate various FSSs with previously unimaginable 3D structures

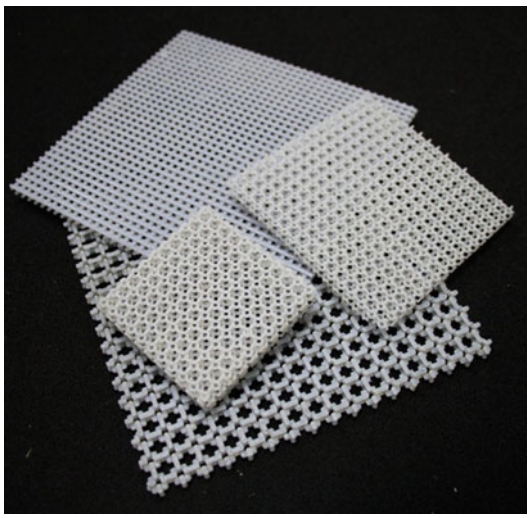

Fig. 23 Samples of FSSs with 3D unit cells fabricated by 3D printing

which cannot be realized by the standard PCB processing technology. As examples, two kinds of 3D FSSs, including woodpile FSS and torus FSS, will be introduced in detail in the following subsections.

Woodpile FSS

The first example of FSSs with 3D unit cells is a simple four-layer woodpile structure. Each layer has a thickness of 1.3 mm, and the size of the whole unit cell is 4.5 mm by 4.5 mm. The rods are 1.25 mm in width and height and the center-to-center separation is 4.5 mm, and the third layer is stacked with the rods shifted by 2.25 mm with respect to the first layer. Figure 24a–c shows the top view and side view of the FSS structure and its unit cell, respectively, and Fig. 24d shows the fabricated woodpile FSS. The woodpile was printed with polymer material which has an estimated dielectric constant of 2.95 and a loss tangent of 0.01. Slabs of different thickness with gloss and matt formats were first made, and time-domain spectroscopy measurement was conducted. Material electrical property was then extracted out from the measured data. After each layer of printing with 25 μm resolution, the surface is cured by ultraviolet light. During the printing process, air voids of the FSS were filled with water-soluble material which was washed off after the fabrication was completed.

Figure 25 shows the measured transmission response versus simulated results with different relative permittivities ranging from 2.5 to 3.5 with the same loss tangent of 0.01. In the measurement, the first and second resonances occur at 53.5 and 58.2 GHz, respectively. For the relative permittivity of 2.95, the

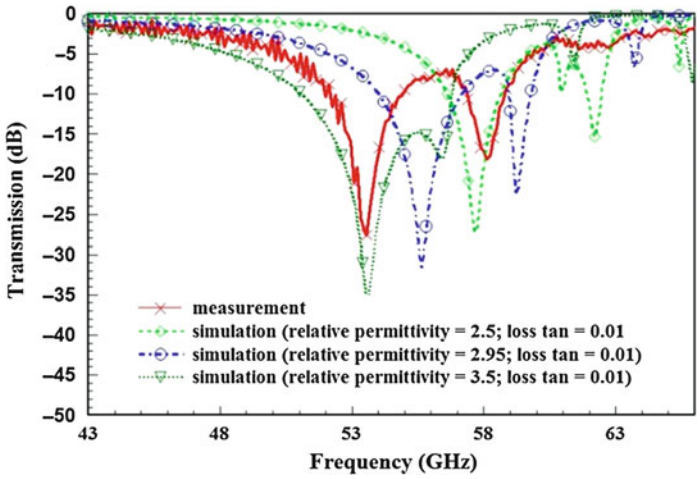

Fig. 25 Frequency responses of the four-layer woodpile FSS with different material properties

simulated first resonance occurs at 55.5 GHz and the second resonance occurs at 59.2 GHz, having a respective error of 3.8 % and 1.7 %. If one tunes the relative permittivity to 3.5, the first resonance matches that of the measured result, while the second resonance shifts to 56.4 GHz with an error of 3.1 %.

Torus FSS

In this subsection, a kind of FSS structure consisting of a torus array, called torus FSS, is investigated. It has more complex 3D unit cells compared to the woodpile FSS described above. Figure 26 shows the two-layer and four-layer torus FSS structures, in which Fig. 26a shows the top view of the two-layer torus FSS, and Fig. 26b shows the side view of the four-layer torus FSS. Figure 26c, d shows the unit cells of the two FSSs. At last, a four-layer torus FSS example is fabricated and its prototype is shown in Fig. 26e.

For the relative permittivity of 2.95 and loss tangent of 0.01 in the HFSS models, the measured results are compared with the simulated ones, as shown in Fig. 27. For the four-layer torus FSS, the resonance occurs at 45 GHz for both the measurement and simulation. For the two-layer torus FSS, however, the measured resonant frequency is shifted to 45.48 GHz while the simulated resonant frequency is 46.52 GHz. The predicted error is around 2.3 %. It should be noted that the simulated resonances are not as deep as the measured ones, and therefore, the loss tangent is increased from 0.01 to 0.035 and repeated the simulations while keeping the relative permittivity of 2.95 fixed. Figure 28 shows the comparison of the measured and simulated results. It is shown that the resonance location remains the same for both two-layer and four-layer torus FSSs, but the levels of transmission loss between the simulations and measurements have much better agreement when a loss tangent of 0.035 is used. As there is some degree of rotational symmetry of the torus FSS, it is expected that the resonant frequency would not be seriously affected by rotating the FSS screen with respect to the plane of the incident field. For verification, the fabricated two-layer FSS shown in Fig. 29a is measured for different rotation angles, and the measured results are depicted in Fig. 29b. As seen, the resonance location is slightly shifted by about 1 % for rotating the two-layer torus FSS by 45°.

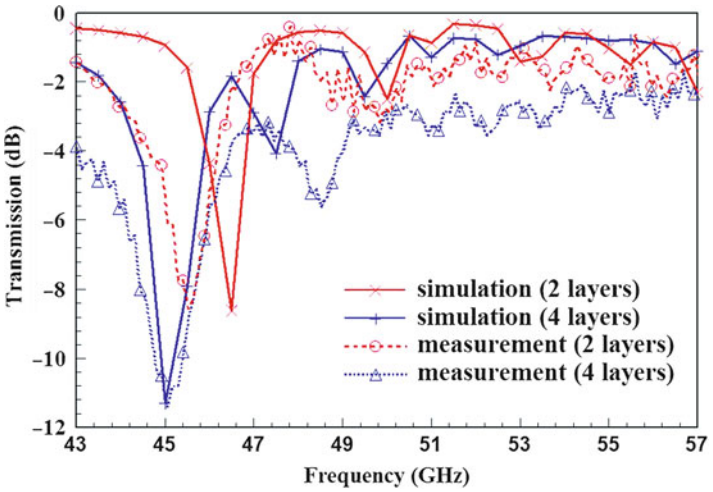

Fig. 28 Transmission responses of the torus FSSs when the loss tangent is changed to 0.035

Discussion on the FSSs Fabricated by 3D Printing

In this section, it has been demonstrated that commercial software like HFSS indeed yields accurate results in modeling FSS with complex 3D unit cells, which can be conveniently fabricated by 3D printing. It has also been demonstrated that the relative permittivity of the printing material needs to be reasonably characterized. For the woodpile and torus FSSs, the relative permittivity of the material is not high and the unit cells are partially filled with air, and therefore, the resonant frequency is not very sensitive to the slight changes of the relative permittivity. However, the level of transmission would mainly depend on the value of the loss tangent of the used material.

Design of Antennas Using Results from Periodic Structures

In sections "Multilayered FSS Filter" and "FSS with 3D Unit-Cell Elements," FSSs with planar and 3D unit cells in which the periodic elements are identical have been analyzed. In this section, the information calculated for the periodic case is used to design dielectric lens antennas and reflectarrays in which the

DOI 10.1007/978-981-4560-75-7_23-1

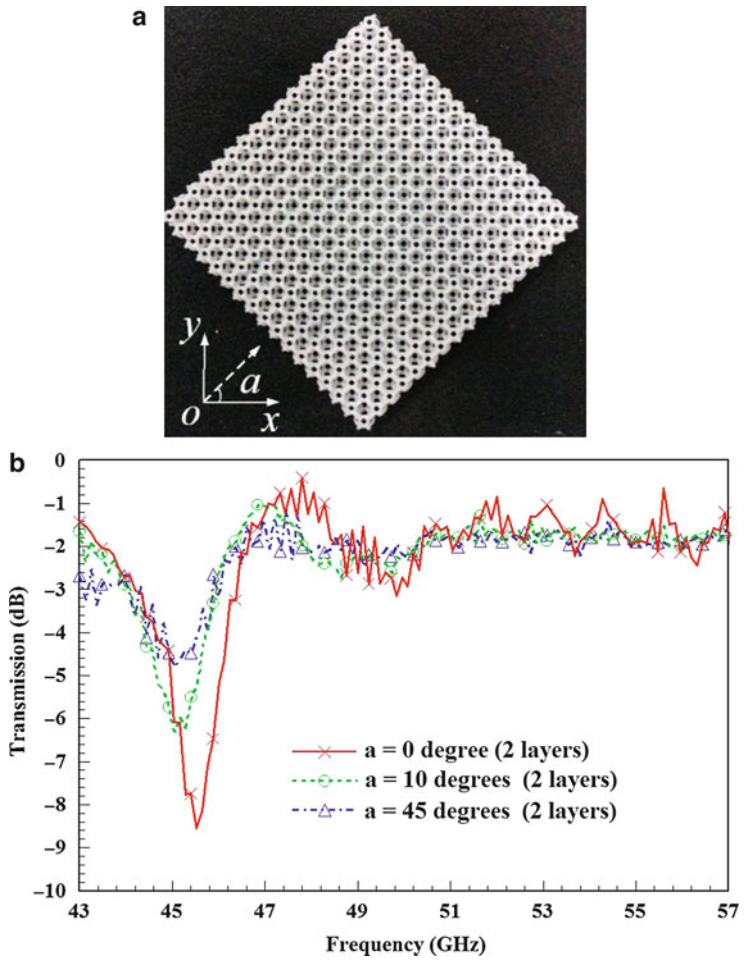

Fig. 29 Transmission responses of the two-layer torus FSS with different rotation angles (**a**) Fabricated FSS prototype (**b**) Measured results

array elements are different. Lens antennas and reflectarrays are suitable candidates for millimeter-wave applications as they have space-fed structures, leading to lower feeding loss when compared to patch antenna arrays. The antenna elements are carefully designed such that their total transmission or reflection phase can completely compensate for the phase difference due to different path lengths from the antenna feed to the position of the corresponding unit cell. For the dielectric lens antenna operating at 60 GHz, the low-cost 3D printing technology is used. In contrast, for the microstrip reflectarrays, conventional printed-circuit-board technology is employed for the construction of the wideband and dual-band antennas.

Lens Antennas

In making use of 3D printing technology for the lens antenna, it is assumed that the lens antenna is composed of a periodic array of square dielectric columns of variable column heights (Yi et al. 2014). The height of the column is determined such that the total electric length from the source to the bottom of the column, through the column, and from the top of the column to a common horizontal reference plane is constant.

Matching Layers

Knowing that reflection will occur at the interface of two different materials and, in this case, air and the 3D printing polymer material, two matching layers are added near the top and bottom surfaces of the

DOI 10.1007/978-981-4560-75-7_23-1

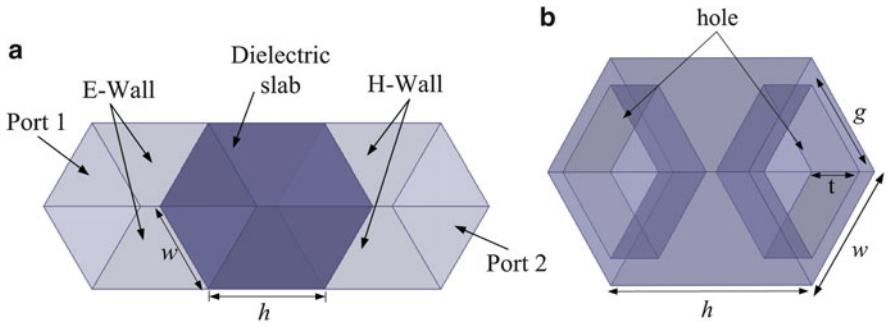

Fig. 30 (**a**) Simulation setup of the dielectric column without matching layers. (**b**) Dielectric column with two matching layers. $w = 2.5$ mm, $g = 1.9$ mm, and $t = 0.95$ mm

column to reduce the reflection. Figure 30a shows the simulation setup of the dielectric column without the matching layer. When incorporated with the matching layers, the dielectric column in Fig. 30a is replaced by the column with two matching layers in Fig. 30b. The matching layers are formed by introducing two square voids near the top and bottom surfaces of the dielectric column. All the dimensions of the column and voids are integral multiples of the printing resolution of the 3D printer at 25 μm. The relative dielectric constant and loss tangent at 60 GHz are $\varepsilon_r = 2.95$ and $\tan\delta = 0.01$, respectively. The dimensions of the matching layer are determined as a quarter-wave transformer to match the air region with the dielectric layer. The effective dielectric constant needed for the matching layer is given by $\varepsilon_e = \sqrt{\varepsilon_r \times 1}$ and the thickness $t = \frac{\lambda_e}{4} = \frac{\lambda}{4\sqrt{\varepsilon_e}}$, where λ is the wavelength in air and λ_e is the effective wavelength in the matching layer. The width of the square void is optimized such that the effective dielectric constant is equal to $\varepsilon_e = \sqrt{2.95} \approx 1.72$, and this results in $g = 1.9$ mm.

The columns with and without the matching layers are simulated using HFSS with the periodic boundary conditions at normal incidence. The simulated magnitudes of the reflection coefficient ($|S_{11}|$) and transmission coefficient ($|S_{21}|$) against the column height at 60 GHz are shown in Fig. 31a, b, respectively. With the matching layers, $|S_{11}|$ is below -30 dB for the whole range of column height from 2 to 10 mm. As a consequence, $|S_{21}|$, the total insertion loss due to reflection and material loss only slightly increases to about 0.7 dB at $h = 10$ mm. Nonetheless, the loss is not very significant.

Lens Antennas With and Without Matching Layers

Both the lens antennas with and without the matching layers are designed and simulated at 60 GHz. Both models have 19 × 19 square dielectric columns with various heights to provide the required phase compensation. The antenna is fed by a point source from the center of planar surface of the lens with a focus-to-diameter ratio (F/D) of 0.41. Figures 32 and 33 show the simulation models without and with the matching layers, respectively. When viewing from the top, the model without the matching layers resembles a grid of 19 × 19 squares (Fig. 32a) which are of different heights. When viewing from the bottom, it is flat plate as shown in Fig. 32b. The 3D view of the model is shown in Fig. 32c. On the other hand, the model with the matching layers when viewing from the top (Fig. 33a) and from the bottom (Fig. 33b) resembles an array of 19 × 19 square patches. Each patch is in fact a square void of size g by g with a depth of t. The 3D model is shown in Fig. 33c. Figure 34 shows the comparison of the simulated directivities of the two models. It shows that the directivity of the lens antenna with the matching layers is 0.7 dB higher than that of lens antenna without the matching layers throughout the whole frequency band from 50 to 70 GHz which demonstrates the effectiveness of the matching layers.

DOI 10.1007/978-981-4560-75-7_23-1

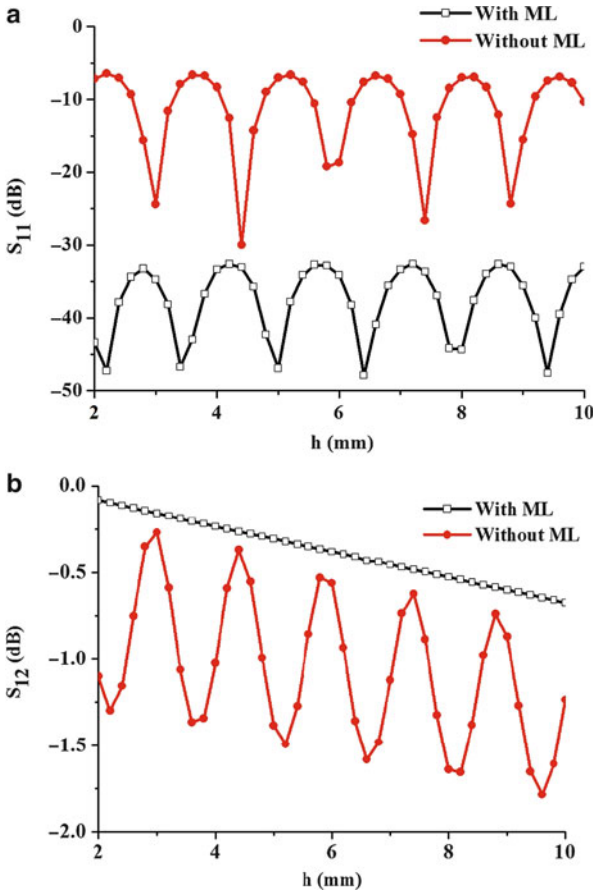

Fig. 31 Simulated $|S_{11}|$ and $|S_{21}|$ against column height with and without matching layers. (**a**) $|S_{11}|$ and (**b**) $|S_{21}|$

Lens Antenna Measurement

The lens antenna with matching layers was fabricated using the 3D printer, and the prototype is shown in Fig. 35a. The prototype was excited by a waveguide and mounted on an NSI near-field measurement system as shown in Fig. 35b for gain and pattern measurements. Figure 36 shows the comparison of the measured and simulated peak gains of the lens antenna. In general, there is about maximum 1 dB difference between the simulated and measured gains from 50 to 67 GHz covering the whole 60 GHz band. The measured peak gain is 23.5 dBi at 61 GHz. This is possibly due to the imprecise dielectric constant and loss tangent, but it could also be due to the measurement setup and alignment.

Figure 37 shows the comparisons of the measured and simulated radiation patterns of the lens antenna prototype at 60 GHz. The side-lobe levels are below −18 dB and −14 dB in H and E planes, respectively. Excellent agreement between the simulated and measured results is obtained.

In this subsection, it has been successfully demonstrated that design of a dielectric lens antenna is based on the transmission phase information computed for a doubly periodic structure with 3D unit-cell geometry. The antenna gain is enhanced by reducing the reflection loss due to material discontinuity at the lens and air interfaces using two matching layers. A low-cost fabricated prototype of the high-gain millimeter-wave antenna at 60 GHz using 3D printing technology has also been demonstrated.

Microstrip Reflectarray

In the previous subsection, the use of utilizing the transmission phase of 3D element of different column heights for a lens antenna design has been demonstrated. In this subsection, the reflection phase of a

periodic array of unit-cell element will be exploited for the design of reflectarrays by varying the geometrical parameters of the unit cell (Wu et al. 2014).

Working Principle of Reflectarray

Figure 38 shows the working principle of a typical reflectarray. The reflectarray can be single layered or multiple layered. A single-layered reflectarray is preferred for its lower fabrication cost and lower weight. The phase difference $\Delta\varnothing$ due to the path length difference of is $S_2 - S_1 = \Delta S$ compensated by the reflection phase of the reflecting element such that all the reflected fields are radiating in phase in a

DOI 10.1007/978-981-4560-75-7_23-1

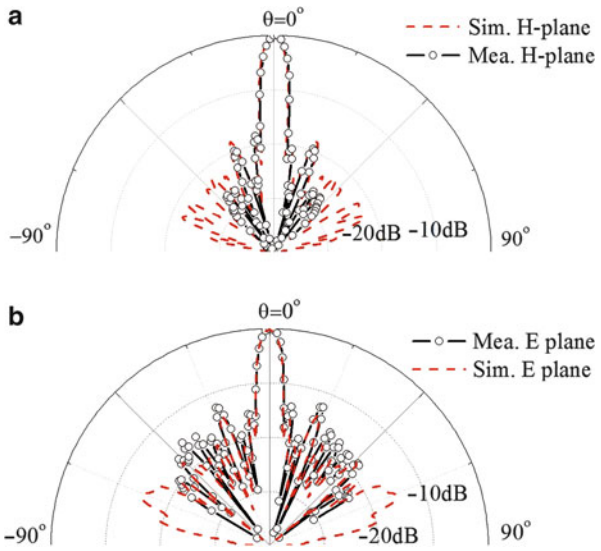

Fig. 37 Comparison of measured and simulated radiation pattern at 60 GHz. (**a**) H plane and (**b**) E plane

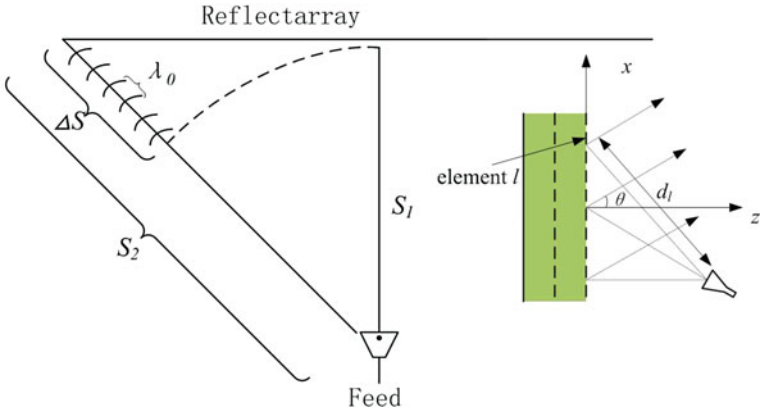

Fig. 38 Working principle of a reflectarray

designated direction. The maximum phase difference would be $\frac{\Delta S}{\lambda_o} 2\pi$, where λ_o is the free-space wavelength. Successful design of the reflectarray requires the reflected phase covering the whole range of the 360°, and the reflected phase variation with respect to the changing geometrical parameters should be as linear as possible (Huang and Encinar 2007). Conventional unit cells of square patches with different dimensions or square patches with fixed dimensions attached with a stub of different lengths cannot meet both of these requirements as shown in Fig. 39, resulting in lower antenna gain, distorted radiation pattern, and narrow antenna bandwidth.

Dual-Resonance Unit Cell

Unit-cell geometry with multiple resonances would allow us to generate a phase curve that varies smoothly with changing parameters. Figure 40 shows a square unit cell with a ring and an I-shaped dipole (Chen et al. 2013). Each side of the unit cell is L=10 mm and the outer radius of the ring is fixed at $R_o = 4.2$ mm. Four degrees of freedom are provided, namely, the gap width W_S between the circular ring and the I-shaped dipole, the inner radius of the ring R_i, and the ratios of $N = 0.5\frac{W_G}{(R_i - W_S)}$ and

DOI 10.1007/978-981-4560-75-7_23-1

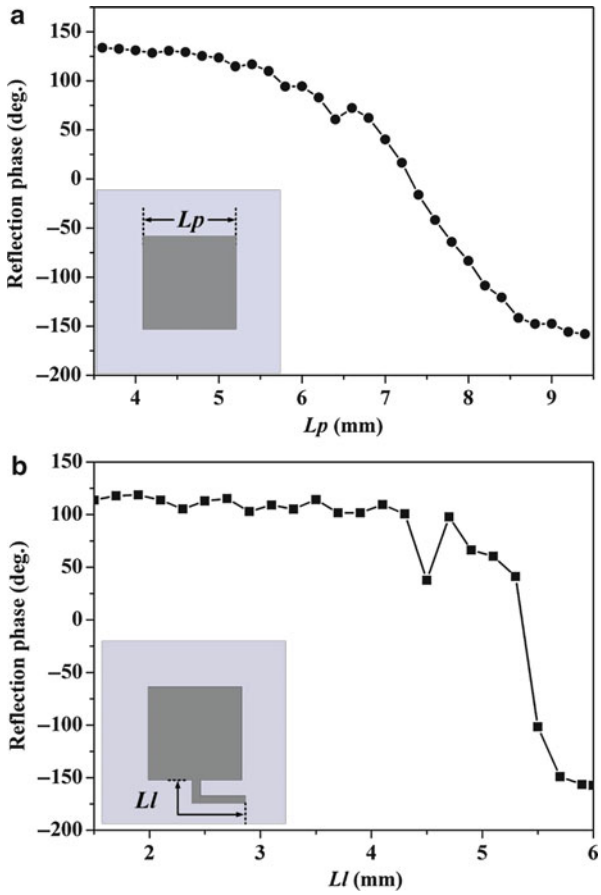

Fig. 39 Reflection phase of (**a**) square patch of various dimensions *Lp* and (**b**) square patch of fixed dimensions ($Lp = 5$ mm) with various stub lengths *Ll* (10.5 GHz, vertical polarization; substrate thickness $h = 1.5$ mm; dielectric constant $\varepsilon_r = 2.2$; side length of unit cell $L = 10$ mm)

$M = 0.5\frac{W_B}{(R_i - W_S)}$. Here W_G and W_B are the length and width of the center portion of the I-shaped dipole, respectively. The dielectric constant of the substrate is $\varepsilon_r = 2.2$, and its thickness is $h = 1.5$ mm. Also shown in Fig. 40 is the reflection phase comparison of the I-shaped dipole, the ring, and the combination of the two versus frequency. A uniform plane wave polarized to the x direction impinges on the periodic surface at normal incidence. While both the reflection phases of periodic surfaces composed of the ring and the I-shaped dipole alone change smoothly, they do not cover the entire 360°. In contrast, the double resonance provided by the combined structure covers the whole range of phase delay needed with slowly changing phase gradient. Similar phase behavior will be obtained if one varies the parameters at a fixed frequency.

Figure 41a shows the smooth changing phase of FSS with the ring and I-shaped dipole combined unit cell at 10.5 GHz. It covers over 400° phase change, obviously better than those obtained by conventional elements shown in Fig. 39. This is achieved by changing the inner radius of the ring from 1.5 to 3.5 mm while other parameters are optimal. Figure 41b on the other hand shows the reflection phase variations at different frequencies from 9.5 to 11.5 GHz. At each frequency, the whole 360° reflection phase is covered by changing the inner radius of the ring while keeping W_S, M, and N unchanged. The length and width of the central portion of the I-shaped dipole will proportionally change according to the varying R_i. The resulting phase-frequency curves are approximately linear from 9.5 to 11.5 GHz. Figure 42 shows the current distributions on the combined ring/I-shaped dipole FSS for $R_i = 2.7$ mm at 9.5, 10.5, and

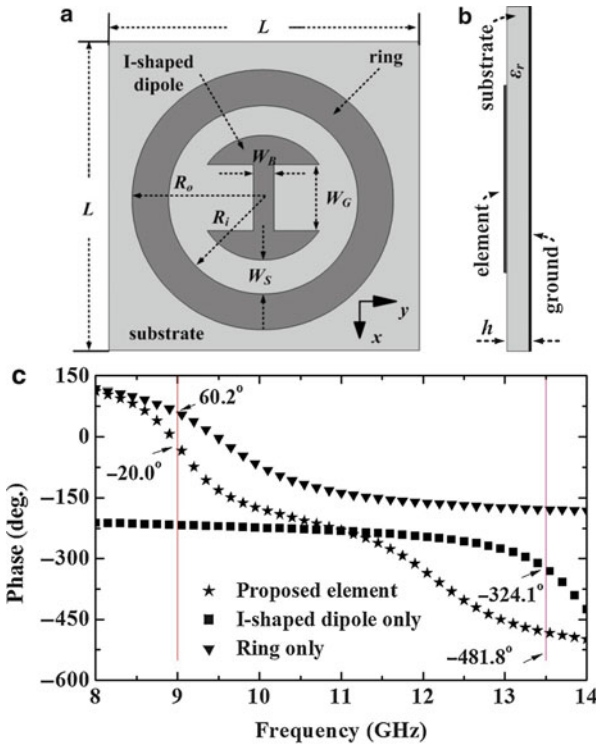

Fig. 40 Unit cell with double resonances. (**a**) Top view, (**b**) side view, and (**c**) phase delay comparison of the different elements ($M = 0.1$, $N = 0.8$, $W_s = 0.15$ mm, $R_i = 2.7$ mm)

11.5 GHz. By controlling the four parameters, one can effectively change the current distributions and resonant frequencies which in turn change the amplitude and gradient of the phase delay versus frequency. The resonant frequency of the ring by itself is around 9.2 GHz while that of the I-shaped dipole is around 22.3 GHz. The large separation of these two resonance frequencies allows us to have more linear phase variation by tuning different parameters.

In the conventional reflectarray design, the desired phase delay at a particular array element is compensated by tuning the element geometrical parameters at the center frequency. However, the reflection phases at the edge frequencies may be deviated from the desired phases significantly, therefore limiting the operating bandwidth of the reflectarray. Instead of compensating the phase delay at a single frequency, the almost linear phase curves as appear in Fig. 41b would allow us to compensate the phase delay for a band of frequencies if one can create a reflection phase database by tuning the four parameters of R_i, W_s, M, and N. The parametric sweeping was done in HFSS according to the tuning range of the four parameters: N from 0.4 to 0.6, M from 0.1 to 0.2, W_s from 0.15 to 0.35 mm, and R_i from 1.5 to 3.5 mm with an incremental step of 0.05. It should be noted that the value of the outer radius is kept at $R_o = 4.2$ mm so that the mutual coupling among the array elements is more or less the same.

Design of Wideband Reflectarray

By exploiting the linear phase-frequency response or this dual-resonance element depicted in Fig. 40, one can minimize the difference between the desired and realized phases at the lower and upper edges of the frequency band denoted by f_l and f_u, respectively. The desired phase Φ delays should fulfill

$$\Phi(f_l)(n) - \Phi(f_l)(n+1) = \Phi(f_u)(n) - \Phi(f_u)(n+1) \tag{1}$$

DOI 10.1007/978-981-4560-75-7_23-1

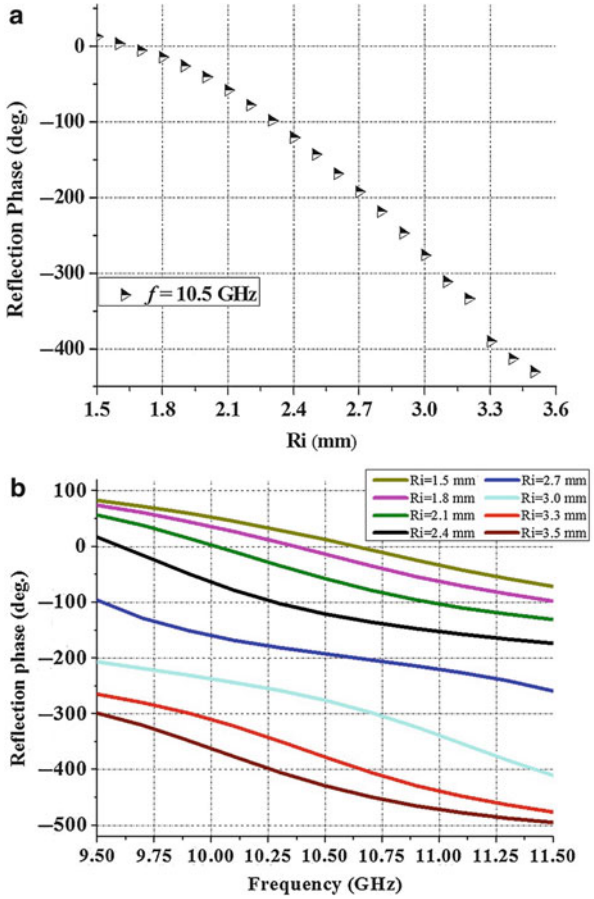

Fig. 41 Reflection phase (**a**) at a fixed frequency versus R_i and (**b**) versus frequency for different values of R_i ($M = 0.15$, $N = 0.5$, $W_s = 0.25$ mm, $R_o = 4.2$ mm)

where n is the nth element and n+1 is the (n+1)th element as shown in Fig. 43. The value of (1) is the desired phase delay difference between the nth and (n+1)th elements at center frequency. The optimal parameters of R_i, W_s, M, and N can be obtained such that the achieved phases are as close to the desired values as possible. Base on the generated database for the phase compensation, a 6 × 10 element reflectarray with a scattering angle of 30° for normal incidence of plane waves was designed and fabricated (Chen et al. 2013) and the model for simulation is shown in Fig. 44 in which symmetric boundary condition is assigned to the plane with a normal direction of –x axis. A simulated 3-dB directivity-drop bandwidth of 22.3 % is achieved when the reflectarray is centered at 10.5 GHz and the predetermined f_l and f_u are 10 and 11 GHz, respectively. The computed aperture efficiency at 10.5 GHz is 38.5 %. Comparison of the normalized simulated and measured radiation patterns is shown in Fig. 45, and a good agreement is obtained.

Unit Cell with Two Split Rings and an I-Shaped Dipole

Another unit cell that can provide a wideband linear phase delay was introduced by Chen et al. (2012) which is given in Fig. 46. The dimensions of the unit cell and the substrate are the same as in those Fig. 40. The outer ring of Fig. 40 is now split into two coupled open rings which generate three resonances. The two variable gaps of the two rings provide more flexibility in tuning the reflection phase. Again, the reflection phase of the FSS with each set of geometrical parameters is simulated by using HFSS under periodic boundary conditions with normal incidence and x-polarized electric fields. By varying two

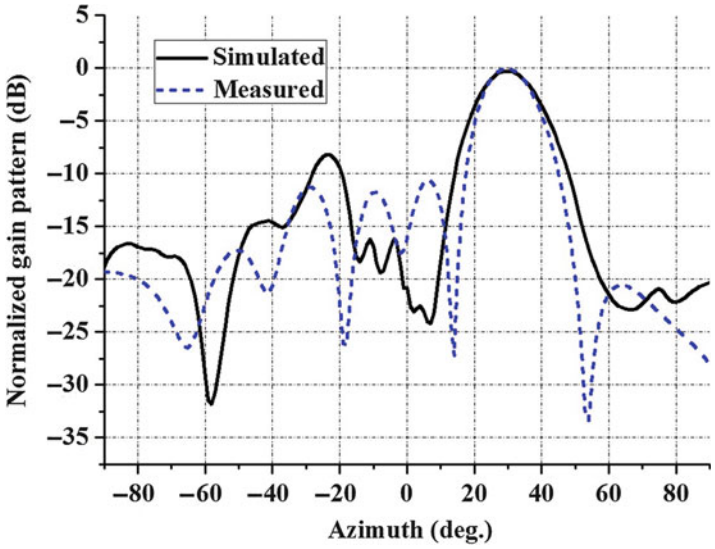

Fig. 45 Comparison of the simulated and measured radiation patterns at 10.5 GHz.

parameters, W_2 and M, while fixing the remaining parameters as given in Fig. 46, linear phase-frequency curves covering a large range of angles are obtained.

Two classes of elements with different geometrical parameters are employed to generate the phase curves in Fig. 47. In Class 1, W_2 varies from 2.0 to 2.0 mm when M is fixed at 0.5 mm. In contrast, for Class 2, W_2 is fixed at 4.0 mm when M varies from 0.4 to 4 mm. By combining these two classes, both range and linearity requirements for the phase delay can be satisfied from 12 to 14 GHz. Based on these reflection phase curves and design condition in (1), a 20 × 20 element reflectarray was designed (Chen et al. 2012) and the measurement setup is shown in Fig. 48. The heights of the feed horn and the reflectarray are $h_f = 100$ mm and $h_r = 100$ mm, respectively, and the elevation angle of the horn is $\alpha = 17°$. The distance from the feeder to the reflectarray is $d = 470$ mm.

The simulated and measured radiation patterns in the H plane are shown in Fig. 49, and they compare very well at 12, 13, and 14 GHz. Only the simulated E-plane patterns at 12, 13, and 14 GHz are shown in Fig. 50 as measurement could not be conducted due to the obstruction of the supporting structure. It is observed that the main beams at 12 and 14 GHz are slightly shifted from that of the center frequency.

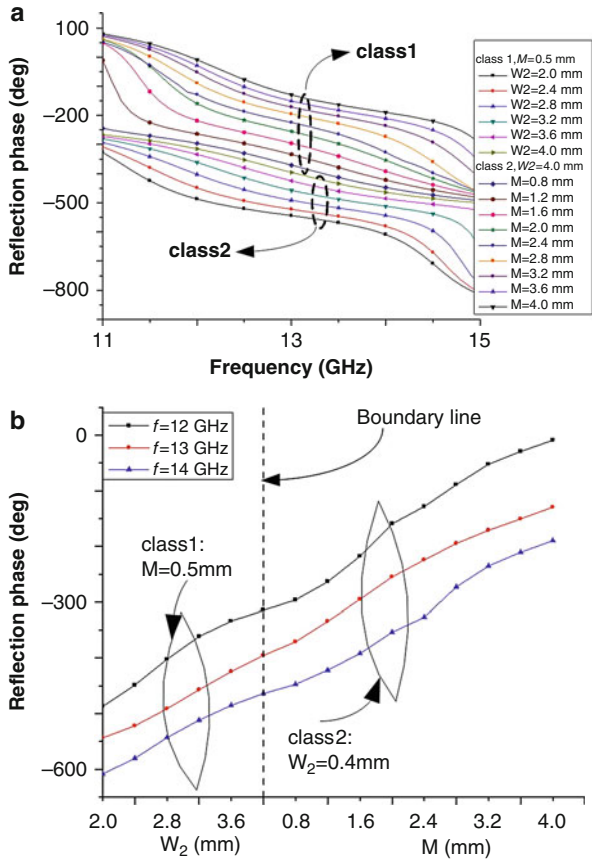

Fig. 47 Reflection phase versus (**a**) frequency and (**b**) dimensional parameters of two classes of elements

This is attributed to the parallel phase characteristic of the elements and the use of design condition (1). The simulated 3-dB directivity-drop bandwidth is 22.7 % from 11.75 to 14.75 GHz. The directivity at 13 GHz is 26.68 dBi which is equivalent to 50 % aperture efficiency.

Phase-Phase Distribution of Dual-Resonance Unit Cell for Dual-Band Reflectarray

The unit-cell elements in Figs. 40 and 46 allow us to design reflectarrays operating at 9–11 GHz and 12–14 GHz, respectively. It would be interesting to see how they can be combined to design a dual-band reflectarray that can operate at both 9 and 13.5 GHz. As discussed in Tsai and Bialkowski (2003), the achievable reflection phase range for a traditional reflectarray element is less than 360° for a single-layer substrate. This can be approximately calculated by $2\pi \times (1 - kh/\pi)$ for a small substrate thickness h, where k is the wave number in the substrate (Qu et al. 2014a). The combined ring/I-shaped dipole unit cell in Fig. 40 has two resonances, and some of the required phase compensation at both 9 and 13.5 GHz cannot be simultaneously satisfied, leading to design failure. Figure 51 shows the phase-phase distribution

DOI 10.1007/978-981-4560-75-7_23-1

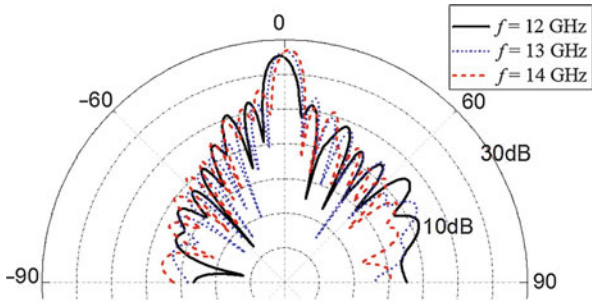

Fig. 50 Simulated E-plane patterns at 12, 13, and 14 GHz

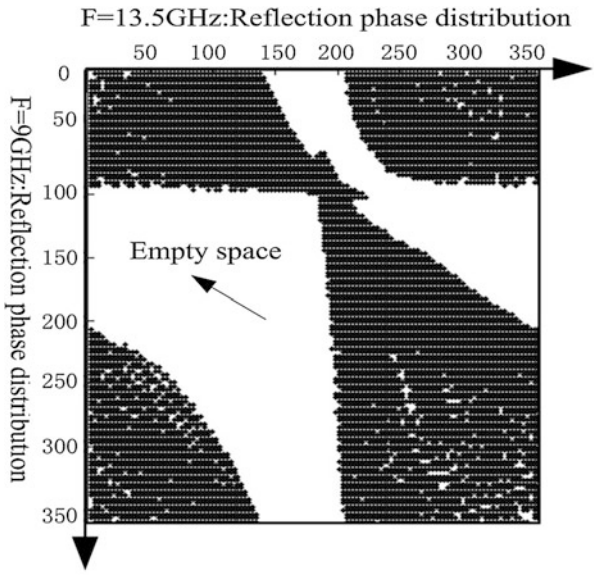

Fig. 51 Phase-phase distribution of the dual-resonance element at 9 and 13.5 GHz

of the dual-resonance element at 9 and 13.5 GHz. Each dot in the plot indicates that a combination for a phase compensation of p_1 degree at 9 GHz and p_2 degree at 13.5 GHz within an error of less than 3° is achievable by a set of parameters (R_i, W_s, M, N). However, both p_1 and p_2 can be any value within the range of 0–360° in general cases. The empty space in Fig. 51 indicates that within the range of parametric tuning, no specific unit cell can satisfy this ($p1$, $p2$) combination simultaneously. Therefore, another unit-cell element as shown in Fig. 52 was introduced in Qu et al. (2014a), in which four resonances are provided.

Four-Resonance Unit Cell

The element depicted in Fig. 52 is designed by combining the unit cells in Figs. 40 and 46 with a circular ring, two concentric open rings, and an I-shaped dipole. As shown in Fig. 46, the gap widths W_1 and W_2 are for tuning the phase delay at the upper frequencies. The circular ring is mainly for the tuning of the lower frequencies. The parameters W_1, W_2, M and are tuned to build the database for designing the reflectarray where $M = 0.5W_B/(R_i - 0.9mm)$. The outer radius of the ring is fixed at $R_o = 4.2$ mm. The widths of the two centric rings are 0.3 mm and the gap size g is 0.1 mm, and $N = \frac{0.5W_G}{(R_i - 0.9\ mm)}$ is fixed at 0.6. The tuning ranges of W_1, W_2, M, and R_1 are 3.5–4.0, 0.5–3.0, 0.4–3.0, and 0.05–0.5 mm and in step sizes of 0.5, 0.5, 0.2, and 0.05, respectively. Figure 53 shows the phase-phase distribution of the

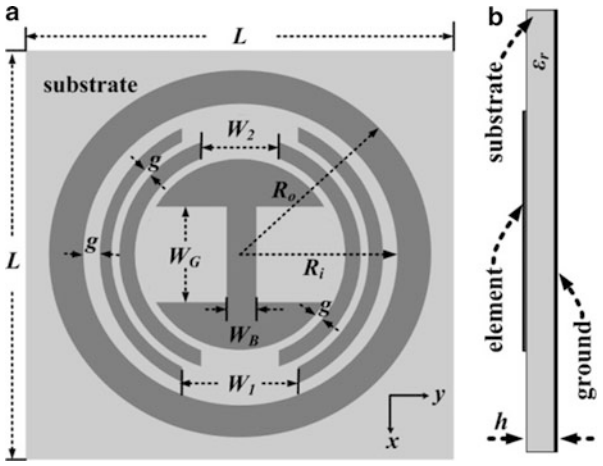

Fig. 52 Four-resonance unit cell. (**a**) Top view and (**b**) side view

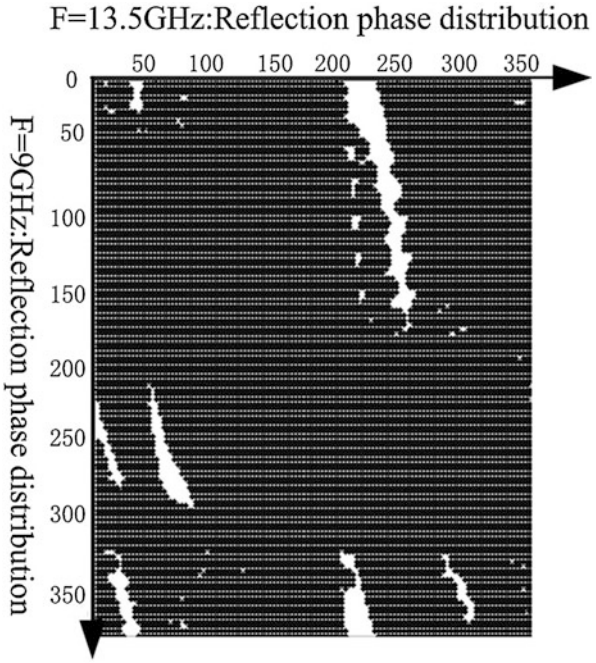

Fig. 53 Phase-phase distribution of the dual-resonance element at 9 and 13.5 GHz

four-resonance element at 9 and 13.5 GHz. The empty space in Fig. 53 is substantially smaller than that in Fig. 51. The unfilled areas in Fig. 53 are mainly attributed to the high sensitivity of the phase variation to the dimensions, meaning that the fabrication tolerance of the unit-cell element may affect the performance of the designed reflectarray. Therefore, the phase information of this element should be used to complement that of Fig. 51. That is, only when one cannot find a corresponding set of parameters in Fig. 51 using the element in Fig. 40, the phase information in Fig. 53 using the element in Fig. 52 should be used.

A 20 × 20 Dual-Band Reflectarray Using Hybrid Elements

Following the design procedure as discussed above, a 20 × 20 reflectarray with two types of elements in Figs. 50 and 52 has been designed, and the measurement setup is similar to that in Fig. 48 with the same values for the parameters $\propto, h_f, h_r$, and d. The focus-to-diameter (F/D) ratio of the reflectarray is about

DOI 10.1007/978-981-4560-75-7_23-1

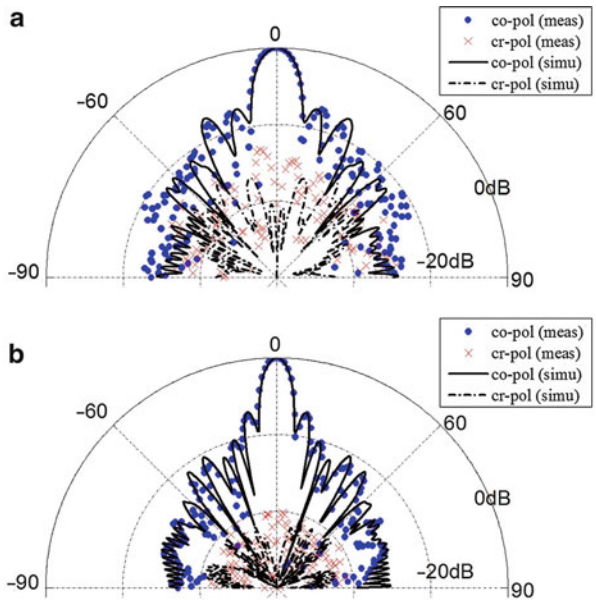

Fig. 54 Comparison of the simulated and measured radiation patterns in the H plane at (**a**) 9 GHz and (**b**) 13.5 GHz of the reflectarray with hybrid elements

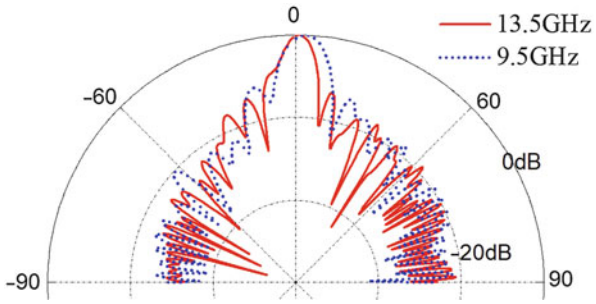

Fig. 55 Simulated radiation patterns in the E plane of the reflectarray with hybrid elements at 9 and 13.5 GHz

2.35. There are 278 dual-resonance elements and 122 four-resonance elements. Figure 54 shows the comparison of the simulated and measured radiation patterns in the H plane. Very good agreements are obtained for both 9 and 13.5 GHz. The measured side lobes are around −15 dB for both frequencies, and the measured cross-polarizations (cr-pols) are below −16 and −40 dB at 9 and 13.5 GHz, respectively. As mentioned earlier, due to the presence of the supporting structure, measurement in the E plane cannot be performed, and therefore, only simulated radiation patterns in the E plane are shown in Fig. 55. It is noted that there is a slight shift of the main beam from +z direction by about 2–1° at 9 and 13.5 GHz, respectively. The simulated cr-pols are below −40 dB for both frequencies. The comparison of the simulated and measured gains versus frequency is shown in Fig. 56. As the direction of the peak gain slightly shifted with frequency, the simulated and measured gains are compared at $\theta = 1°$. There is about 0.5-dBi difference between the simulated and measured results in both frequency bands. The measured gains are 18 and 24 dBi at 9 and 13.5 GHz, respectively.

The bandwidth of the reflectarray can be widened with the use of unit-cell elements that have multiple resonances as illustrated by the three examples discussed above. This design methodology can be extended to higher frequencies into the terahertz regime (Qu et al. 2014b). An operating bandwidth of over 36 % for the wideband design and over 40 % for the frequency-scanning design with beam scanning

DOI 10.1007/978-981-4560-75-7_23-1

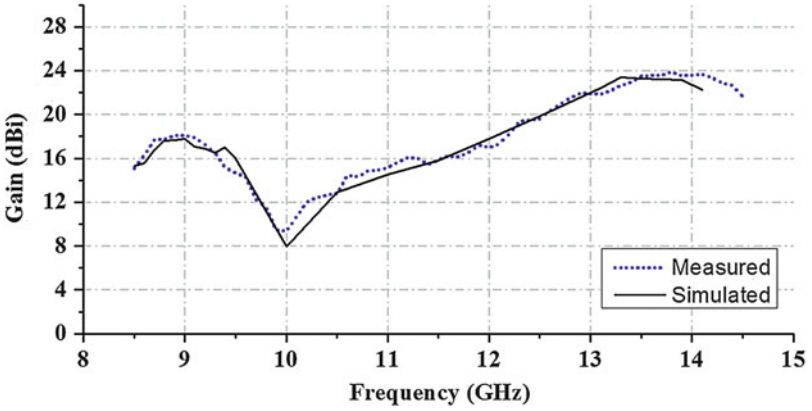

Fig. 56 Comparison of the simulated and measured gains versus frequency of the 20 × 20 reflectarray with hybrid elements

angle of −35° to −5° from 0.2 to 0.3 THz are achieved. It should be noted that for these multiple resonant structures with fine details, the simulation time would be substantially increased, whether integral equation method or finite-element solution is used. For HFSS simulation of the dual-resonance unit cell shown in Fig. 40, each simulation for a set of parameters at one frequency point costs 0.24 GB memory and 80 s on average on a computer with 4-GB memory and Intel Core i3 CPU@2.93. The memory and CPU time increase to 0.64 GB and 158 s for the four-resonance unit cell in Fig. 52..

Conclusion

This chapter began with brief descriptions of some of the earlier works on FSSs, mainly on the physical interpretations of the observed scattering phenomena associated with periodic structures. Numerical modeling of the FSS started 50 years ago first with the variation method and later with the method of moments. Unit-cell geometries of the FSS are limited as restricted by the choices of suitable basis functions.

With the modeling of flexibility of the subdomain basis functions, a variety of numerical techniques were developed in the 1980s and 1990s to speed up the convergence of the doubly infinite summation associated with the integral equation formulation of the FSS. The FSS structures were still mostly in the form of planar types in which FSS screens can be fabricated conveniently with PCB technologies.

With the advent of computer technology both in computational speed and larger memory storage, partial-differential equation-based solvers, e.g., HFSS, become popular tools in analyzing FSSs. The time-consuming computation of the periodic Green's function in the integral equation formulation can be effortlessly replaced by enforcing the periodic boundary conditions in the FEM formulation. The use of 3D unit-cell elements in FSS greatly enhances the design flexibility. The focus of FSS research gradually shifted from developing fast numerical methods to the applications of commercial solvers for new FSS structures.

The solutions to periodic structure can be exploited to design array antennas as well as switchable and tunable arrays when active devices are incorporated. With the convenience of commercial solvers, new unit-cell geometries can be designed to meet new challenges in array antennas. Some more recent research developments on FSS in the past decade have also been included.

A key function of the FSSs is used as a spatial filter. The design of FSS filter is not different from that of a filter in microwave circuits. A good filter needs to have small insertion loss and sharp roll-off at the band

skirts. In this book chapter, introduction of transmission zeros in the spectral response of the FSS to enhance the selectivity of the FSS filter has been presented. Higher-order filters are also discussed.

The increasing popularity of 3D printing allows us to fabricate FSS with 3D unit cells conveniently. The effective use of 3D printing has been demonstrated to construct 3D FSSs that cannot be easily realized otherwise. The spectral responses of the fabricated 3D FSSs compared favorably with simulated results even in the millimeter-wave frequency band. The uncertainty of the dielectric constant created some sight shift in the resonant frequency.

The transmission and reflection phases of the FSS can be exploited for array antenna designs. In this chapter, the transmission phase is used for a lens antenna design. There is only 1-dBi difference in the simulated and measured peak gains. The difference can be attributed to the fabrication tolerance or measurement alignment but also the accuracy in determining the dielectric constant and loss tangent of the 3D printing materials.

FSSs with double-resonance and four-resonance unit cells are discussed for which their reflection phase covers a wide range of angles and linear phase-frequency curves can be obtained. These phase curves have been successfully used to design wideband and dual-band reflectarrays. The beam tilt in the E plane due to frequency shift from the center frequency can be exploited to design frequency-scanning reflectarrays (Qu et al. 2014b).

The emerging fields of THz science and technology call for novel research activities and technological developments such as THz tunable sources, filters, antennas, and detectors, and it is envisaged that researches on FSS will continue to expand into THz regime.

Acknowledgement

The authors would like to express their gratitude to H. Yi of the University of Electronic Science and Technology of China and D. Q. Liu, P. Zhao, and K. B. Ng of the City University of Hong Kong for their contributions in the design, simulation, and measurement of some of the frequency selective surfaces, lens antennas, and reflectarrays illustrated in this chapter. This work was supported partly by a GRF grant from the Hong Kong Research Grants Council Project No. CityU 110713 and partly by the Natural Science Foundation of China (NSFC) Project No. 61371051.

Linear Wire Antennas

Kazuhiro Hirasawa*
Institute of Information Sciences and Electronics, University of Tsukuba, Tsukuba, Ibaraki, Japan

Abstract

This chapter shows the basic characteristics of a linear wire antenna in time-harmonic electromagnetic fields. The application of the method of moments is explained briefly to obtain the current distribution on the antenna. For a transmitting antenna, input impedances, current distributions, and radiation patterns are shown for four typical antenna lengths. For a receiving antenna, current distributions and reradiation patterns are shown when the complex conjugate of the input impedance is loaded at the receiving point. The received and reradiated power of the loaded receiving antenna is shown for three different plane-wave incident angles. Also the application of the Thevenin equivalent circuit is discussed for the calculation of the received power. Characteristics of a Yagi-Uda antenna are shown where the optimum gain of a reactance-loaded Yagi-Uda antenna is compared with that of an end-fire array.

Keywords

The method of moments; Linear wire antenna; Transmitting antenna; Receiving antenna; Thevenin equivalent circuit; Received power; Reradiated power; Scattered power; Reactance loading; Yagi-Uda antenna; End-fire array; Optimization; Biquadratic programming method

Introduction

In this chapter time-harmonic electromagnetic fields are only considered. In section "History," the brief history of a linear dipole antenna development and analysis is introduced. The application of the method of moments (MoM) to a linear wire antenna is explained in section "Analysis" where an electric-field boundary value problem is solved to obtain the current distribution on the transmitting antenna. In section "Transmitting Dipole Antenna," transmitting antenna characteristics such as input impedances, current distributions, and radiation patterns are shown for some antenna lengths. In section "Monopole Antenna," the equivalence between a monopole antenna on a large ground plane and a dipole antenna is explained. In section "Receiving Dipole Antenna," an MoM treatment of a receiving antenna with a plane-wave incidence is shown where the input power, received power, and reradiated power are derived from the incident voltage and the induced current on the antenna. Also the application of the MoM and the Thevenin equivalent circuit is discussed for a receiving dipole antenna. In section "Received Power and Reradiated Power," the received power and the reradiated power are shown for a receiving antenna when the complex conjugate of the input impedance is loaded. In section "Yagi-Uda Antenna," characteristics of a Yagi-Uda antenna are presented where the optimum gain of a reactance-loaded Yagi-Uda antenna is compared with that of an end-fire array.

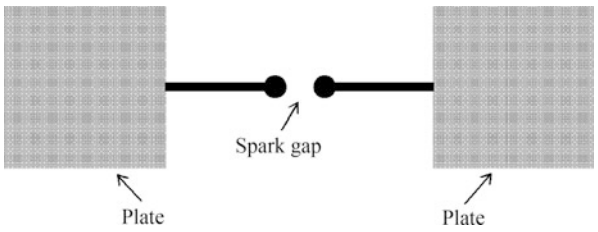

Fig. 1 A plate-loaded transmitting dipole antenna for Hertz's experiment

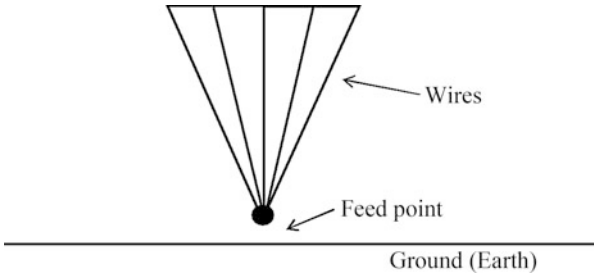

Fig. 2 A transmitting monopole antenna on the earth for Marconi's transatlantic wireless communication

History

In 1886 H. R. Hertz (Hertz 1962; Weeks 1968) used a plate-loaded dipole antenna (about 1.5 m long) shown in Fig. 1 to transmit sparked electromagnetic waves in his experiment and showed the existence of electromagnetic waves predicted in 1864 by J. C. Maxwell (1873). In 1901 G. Marconi built a fan-type monopole antenna (about 45 m high) on the earth shown in Fig. 2. It consists of 50 vertical wires to transmit the first transatlantic wireless signals from England to Canada (Weeks 1968). The wires are supported by a horizontal wire with two vertical masts.

In 1906 de Forest invented the first triode vacuum tube that can continuously amplify higher-frequency signals than those used by G. Marconi. Since then a half-wavelength dipole antenna has been used for wireless communications. A Yagi-Uda antenna consisting of wires of about a half-wavelength is invented by H. Yagi (1928) and S. Uda (1926).

E. Hallén, L. V. King, H. C. Pocklington, and R. W. P. King are early contributors to calculate the current distribution on a linear wire antenna (Pocklington 1897; King 1937, 1956; Hallén 1938). The most difficult part of the antenna analysis is to find the current distribution.

With the development of computers, frequency-domain numerical analysis methods such as the method of moments (MoM) (Harrington 1993) have been widely used for the analysis of various antennas (Hirasawa and Haneishi 1991; Balanis 2005; Stutzman and Thiele 2012; Kraus and Marhefka 2002).

Analysis

In this chapter time-harmonic electric and magnetic fields $\boldsymbol{E}$ and $\boldsymbol{H}$ are only considered and $e^{j\omega t}$ is assumed where $\omega = 2\pi f$ (f, operating frequency). A transmitting straight wire antenna of length h and radius a in free space (ε_0, μ_0) is considered as shown in Fig. 3. It is assumed that the antenna is lossless, $a = 0.001\lambda$ (λ is a free-space wavelength), and the feed gap is infinitesimal. Voltage V applied at the feed point produces the current on the antenna. Once the current is known, it is easy to calculate the antenna

DOI 10.1007/978-981-4560-75-7_25-1

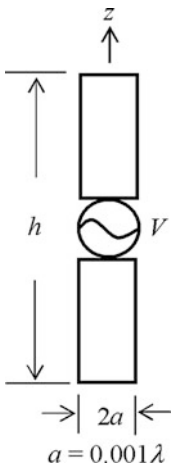

Fig. 3 A dipole antenna on the z-axis with length h, radius a, and feed voltage V

characteristics such as input impedance and gain. A FORTRAN program (Hirasawa and Haneishi 1991) may be used to obtain transmitting antenna characteristics shown in this chapter.

An equivalent theorem (Harrington 2001) is used to obtain the current distribution on a linear wire antenna. In Fig. 4, a closed surface C is assumed just outside the antenna and the equivalent problem is considered where $\boldsymbol{E}$ and $\boldsymbol{H}$ outside C are the same as the original problem and $\boldsymbol{E}$ and $\boldsymbol{H}$ inside C are forced to be zero. This situation is realized by using impressed electric field $\boldsymbol{E}^{imp}$ and equivalent electric current density $\boldsymbol{J}_s$

$$\boldsymbol{J}_s = \hat{n} \times \boldsymbol{H} \tag{1}$$

on C. The unit vector $\hat{\mathbf{n}}$ is normal and outward to C. In Eq. 1, $\boldsymbol{H}$ is a magnetic field on C and $\boldsymbol{E}^{imp}$ on C is to produce voltage V at the feed gap of the antenna. In the equivalent problem, the electric field inside C is forced to be zero and conductors such as antennas inside C can be deleted. Therefore, $\boldsymbol{J}_s$ can be in free space and the free-space Green's function can be used to solve the boundary value problem to obtain $\boldsymbol{J}_s$ with known $\boldsymbol{E}^{imp}$.

In the equivalent problem shown in Fig. 4, the electric field just inside C becomes

$$E_z(J_z) + E_z^{imp} = 0 \tag{2}$$

where it is assumed that J_z is an equivalent line current and E_z^{imp} is constant just inside and outside C. On the other hand, just outside C the boundary condition becomes

$$E_z^{imp} = \begin{cases} \dfrac{V}{d_0} \cdots \text{feed} \\ 0 \cdots \text{elsewhere} \end{cases} \tag{3}$$

In Eqs. 2 and 3, the boundary condition is only considered on the z-component of the electric fields due to the thin wire assumption ($a = 0.001\lambda$). Also the impressed electric field E_z^{imp} is nonzero just outside the feed point, V is a known feed voltage, and d_0 is the distance of an infinitesimal feed gap.

Next an antenna with one impedance load Z_L is considered as shown in Fig. 5. The total electric field $E_z + E_z^{imp}$ becomes zero inside C as Eq. 2, but at the infinitesimal loading point $E_z + E_z^{imp}$ is equal to E_z^L due to Z_L:

DOI 10.1007/978-981-4560-75-7_25-1

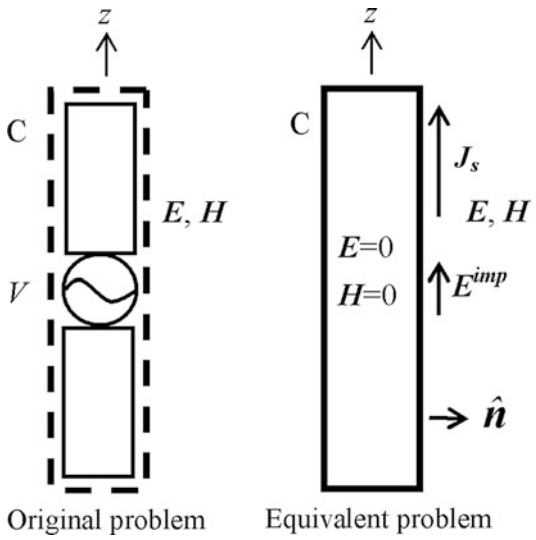

Fig. 4 An original and the equivalent problem: both have the same electromagnetic fields outside region *C*

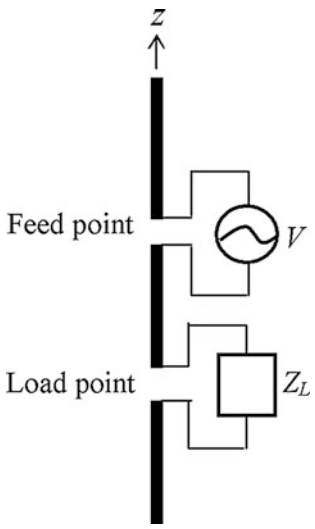

Fig. 5 A transmitting antenna with feed voltage *V* and load Z_L

$$E_z(J_z) + E_z^{imp} = \begin{cases} E_z^L \cdots \text{load} \\ 0 \cdots \text{elsewhere} \end{cases} \tag{4}$$

Before the MoM is applied to the boundary conditions (Eqs. 2, 3, and 4), line current J_z with unknown I_n is assumed as

$$J_z(z') = \sum_{n=1}^{N} I_n J_{zn}(z') \tag{5}$$

where N is the number of the expansion functions and the nth expansion function is

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_25-1

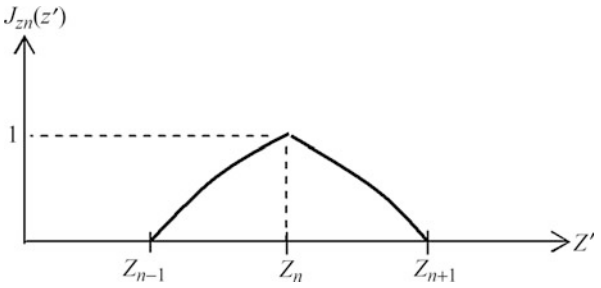

Fig. 6 An expansion function for the current on the wire

$$J_{zn}(z') = \begin{cases} \dfrac{\sin k(z' - z_{n-1})}{\sin k(z_n - z_{n-1})} \cdots z_{n-1} \le z' \le z_n \\ \dfrac{\sin k(z_{n+1} - z')}{\sin k(z_{n+1} - z_n)} \cdots z_n \le z' \le z_{n+1} \\ 0 \ldots\ldots\ldots\ldots\ldots \text{elsewhere} \end{cases} \tag{6}$$

and $\Delta z = h/(N+1), z_{n+1} - z_n = z_n - z_{n-1} = \Delta z, k = 2\pi/\lambda$ (Fig. 6) (Stutzman and Thiele 2012). Current coefficient I_n is a complex number and is determined to satisfy the boundary conditions in Eqs. 2, 3, and 4.

For current J_{zn}, vector potential $\boldsymbol{A_n}(x,y,z)$ has only a z-component and electric field E_{zn} is expressed as

$$E_{zn} = -j\omega\mu_0 A_{zn} + \frac{1}{j\omega\varepsilon_0} \cdot \frac{\partial^2 A_{zn}}{\partial z^2} \tag{7}$$

$$A_{zn}(x,y,z) = \int_{-\Delta z}^{\Delta z} \frac{J_{zn}(\boldsymbol{r}')e^{-jk|\boldsymbol{r}-\boldsymbol{r}'|}}{4\pi|\boldsymbol{r}-\boldsymbol{r}'|} dz' \tag{8}$$

Position vectors $\boldsymbol{r}(= x\hat{\boldsymbol{x}} + y\hat{\boldsymbol{y}} + z\hat{\boldsymbol{z}})$ and $\boldsymbol{r}' = (x'\hat{\boldsymbol{x}} + y'\hat{\boldsymbol{y}} + z'\hat{\boldsymbol{z}})$ with unit vectors $\hat{\boldsymbol{x}}$, $\hat{\boldsymbol{y}}$, and $\hat{\boldsymbol{z}}$ are from the origin to an observation point (x, y, z) on C and to a point (x', y', z') on the line current, respectively. Electric field $E_{zn}(z)$ on the surface of cylinder C with radius a is due to current J_{zn} on the z-axis and becomes

$$E_{zn}(z) = -\frac{j30}{\sin(k\Delta z)}\left[\frac{e^{-jkr_{n-1}}}{r_{n-1}} - \frac{2\cos(k\Delta z)e^{-jkr_n}}{r_n} + \frac{e^{-jkr_{n+1}}}{r_{n+1}}\right] \tag{9}$$

where r_{n-1}, r_n, and r_{n+1} are the distances from points z_{n-1}, z_n, and z_{n+1} on the z'-axis to a point z on the cylinder C with radius a (Fig. 7) (Jordan and Balmain 1968).

An inner product

$$\langle \boldsymbol{E}_n(z), \boldsymbol{J}_w(z) \rangle = \int_{-\Delta z}^{\Delta z} \boldsymbol{E}_n(z) \cdot \boldsymbol{J}_w(z) dz \tag{10}$$

is chosen where $\boldsymbol{E}_n(z)$ is an electric field on C produced by current $J_{zn}(z')$ in Eq. 6. $\boldsymbol{J}_w(z)$ is a weighting function on C.

DOI 10.1007/978-981-4560-75-7_25-1

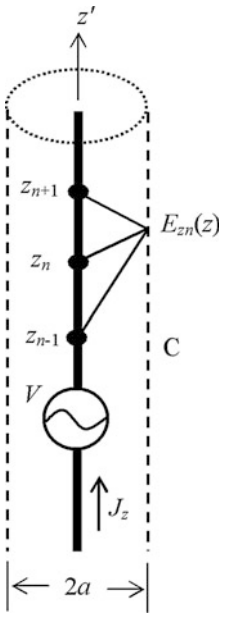

Fig. 7 Electric field $E_{zn}(z)$ on C (radius a) due to line current $J_{zn}(z')$

At first a transmitting antenna without impedance load Z_L in Fig. 3 is considered to obtain the current distribution on the antenna. A weighting function $\boldsymbol{J}_w(z)$ is chosen to be the same as the expansion function in Eq. 6, and the MoM is applied to the boundary condition in Eqs. 2 and 3 with the inner product of Eq. 9. Then, the simultaneous linear equations are derived as

$$\sum_{n=1}^{N} Z_{mn} I_n = V_m \ (m = 1, 2, \cdots, N) \tag{11}$$

where element Z_{mn} of matrix $[Z]$ is a mutual impedance between two small dipoles (section $z_{n-1} - z_{n+1}$ on the z'-axis and section $z_{m-1} - z_{m+1}$ on the surface C). The infinitesimal feed points are z_n and z_m. Mutual impedance Z_{mn} is obtained from Eq. 10 as

$$Z_{mn} = -\int_{z_{m-1}}^{z_m} \frac{\sin k(z - z_{m-1})}{\sin k(z_m - z_{m-1})} E_{zn}(z)dz - \int_{z_m}^{z_{m+1}} \frac{\sin k(z_{m+1} - z)}{\sin k(z_{m+1} - z_m)} E_{zn}(z)dz \tag{12}$$

Equation 12 can be calculated numerically by using a Gauss quadrature (Abramowitz and Stegun 1965), and Eq. 11 can be written in a matrix form as

$$[Z][I] = [V] \tag{13}$$

where impedance matrix $[Z]$ is $N \times N$ and current matrix $[I]$ and feed voltage matrix $[V]$ are $N \times 1$. Unknown current matrix $[I]$ is obtained by solving the simultaneous linear equations.

Matrix $[V]$ has only one nonzero element corresponding to a feed point. The feed point has to be chosen to coincide with the peak of an expansion function (Fig. 6). Then, input impedance Z_{in} becomes

$$Z_{in} = \frac{V}{I} \tag{14}$$

DOI 10.1007/978-981-4560-75-7_25-1

where V and I are the elements of $[V]$ and $[I]$ in Eq. 13 corresponding to the feed point.

For a transmitting antenna with impedance load Z_L shown in Fig. 5, the matrix equation is obtained from the boundary conditions (3) and (4) as

$$[Z][I] = [V] + \left[V^L\right] \tag{15}$$

where Z_L is loaded at the load point corresponding to the peak of an expansion function (Fig. 6). The mth element of load voltage matrix $[V^L](N \times 1)$ has

$$V_m^L = -\int_{z_{m-1}}^{z_{m+1}} E_z^L J_{zm}(z)dz \tag{16}$$

$$= -Z_L I_n (n = m) \tag{17}$$

where I_n is the nth element of the current matrix. From Eqs. 15 and 17, the matrix equation

$$\left[Z + Z^L\right][I] = [V] \tag{18}$$

is derived where load matrix $[Z^L]$ is $N \times N$ and the nth diagonal element Z_{nn}^L is only nonzero. In Eqs. 13 and 18, it is assumed that $[V]$ is known and unknown $[I]$ is obtained numerically.

Electric field E_θ is the only component of the far electric field for the linear dipole (length h) located in the z-axis direction and is obtained from Eq. 7 as

$$E_\theta = j\omega\mu_0 A_z \sin\theta \tag{19}$$

$$A_z = \frac{e^{-jkr}}{4\pi r} \int_{-\frac{h}{2}}^{\frac{h}{2}} J_z(z) e^{jkz\cos\theta} dz \tag{20}$$

Gain G is defined as

$$G = 4\pi r^2 \frac{|E_\theta|^2}{\eta_0 P} \tag{21}$$

In Eq. 21 $\eta_0 = \sqrt{\mu_0/\varepsilon_0}$, r is the distance from the antenna to the far electric field E_θ and input power P of an antenna is expressed by voltage V and current I at the feed point as

$$P = \mathrm{Re}(VI^*) \tag{22}$$

where Re and * denote "real part" and "complex conjugate," respectively. Since E_θ is proportional to $1/r$ as shown in Eq. 20, G is constant with respect to r in the far field. Then, higher G gives higher $|E_\theta|$ with constant P as shown in Eq. 21.

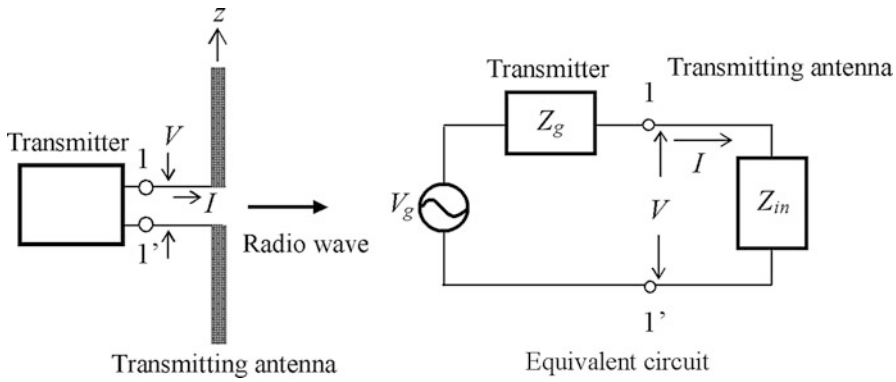

Fig. 8 An antenna with a transmitter and the equivalent circuit where current I is at the feed point

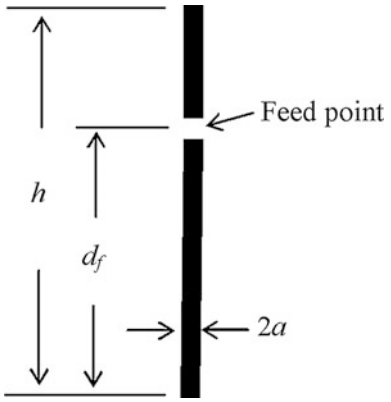

Fig. 9 A dipole antenna with an offset feed

Transmitting Dipole Antenna

Figure 8 shows a transmitting dipole antenna with a transmitter and the equivalent circuit. Equivalent circuits are often used to explain some antenna functions from the circuit point of view without using $\boldsymbol{E}$ and $\boldsymbol{H}$. The left-hand side of 1-1′ is the Thevenin equivalent circuit of the transmitter that can be used to obtain current I flowing terminal 1. Voltage V_g is the open-circuit voltage of the transmitter when output terminals 1-1′ are open circuited. Impedance Z_g is the input impedance of the transmitter when the source switch is off. Then, the complicated transmitter circuit is simply expressed by the voltage source and the impedance if only current I flowing on the antenna is desired without knowing the details of the transmitter. Impedance Z_{in} $(= R_{in} + jX_{in})$ is the input impedance of the antenna, and R_{in} is called the radiation resistance closely related to the radiated power of the antenna. Thus, a transmitting dipole antenna with feed voltage V is considered in this chapter as shown in Fig. 3 and the transmitter is omitted for simplicity. Also it is recognized that voltage V is equal to V_g when $Z_g = 0$.

An offset-feed dipole antenna ($a = 0.001\lambda$) is shown in Fig. 9 to investigate the effects of the position of the feed point. Length d_f is the distance to the feed from the bottom end of the dipole. The input impedance of a half-wavelength dipole antenna is shown in Fig. 10 where d_f is changed from 0 to 0.5λ. R_{in} is very large near the end of the dipole due to the small current and becomes a minimum in the center due to the current maximum. X_{in} becomes capacitive when the feed is near the end due to the large charge accumulation at the end and inductive or the least capacitive at the center due to the current maximum.

DOI 10.1007/978-981-4560-75-7_25-1

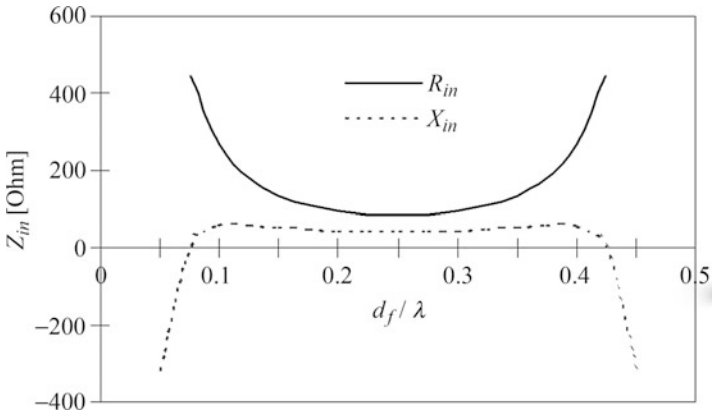

Fig. 10 Input impedance Z_{in} ($= R_{in} + jX_{in}$) of a half-wavelength dipole antenna with an offset feed

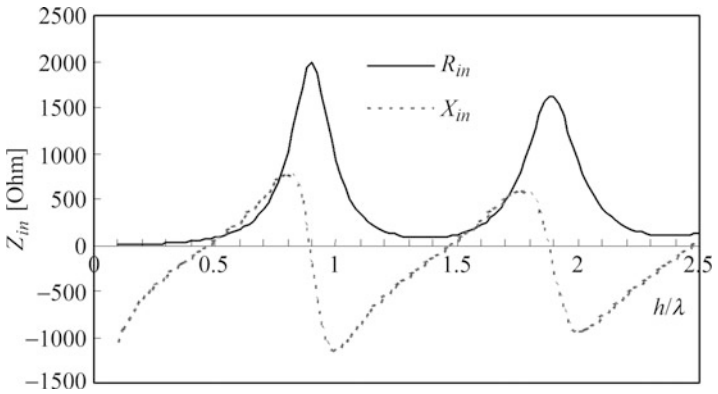

Fig. 11 Input impedances Z_{in} ($= R_{in} + jX_{in}$) of a center-fed dipole antenna of length h

From the impedance matching point of view, it is recognized that the best position of the feed point is near the center for the half-wavelength dipole, and this is one of the reasons why the center-fed half-wavelength dipole is widely used.

Figure 11 shows input impedance Z_{in} of a center-fed dipole antenna ($d_f = h/2$, $a = 0.001\lambda$) with respect to h/λ. The real part R_{in} is maximum around $h = 0.9\lambda$ and 1.9λ. The imaginary part X_{in} is capacitive when h is less than 0.5λ. X_{in} becomes zero around 0.5λ and 0.9λ, 1.5λ, 1.9λ, and 2.5λ. When X_{in} is zero, it is called that the antenna is resonant. There are two kinds of resonance: series resonance (0.5λ, 1.5λ, and 2.5λ) and parallel resonance (0.9λ and 1.9λ). For series resonance, R_{in} is not large, but R_{in} is very large for the parallel resonance, and the dipole antenna is usually used around the series resonance, especially around the first series resonance ($h = 0.5\lambda$). Input resistance R_{in} is 70–100 [Ohm] around $h = 0.5\lambda$ and good impedance matching can be obtained easily with the connected transmission line.

Figure 12 shows current distributions on dipoles ($d_f = h/2$) of $h = 0.5\lambda$, λ, 1.5λ, and 2λ where $V = 1$ [V]. The current amplitude has a peak every half-wavelength. When $h = 0.5\lambda$ and λ, the phase is almost constant except the feed point. When $h = 1.5\lambda$ and 2λ, the phase change is about 180° [deg.] except around the feed and the phase transition.

Figure 13 shows the normalized vertical radiation patterns $|E_\theta|$ corresponding to the currents in Fig. 12. The horizontal radiation patterns $|E_\theta|$ are omnidirectional and are not shown here. When the phase of the current is constant on a dipole antenna such as a half-wavelength or a one-wavelength dipole, there is only one radiation peak, but there are more than one radiation peak when the current phase changes on dipoles

DOI 10.1007/978-981-4560-75-7_25-1

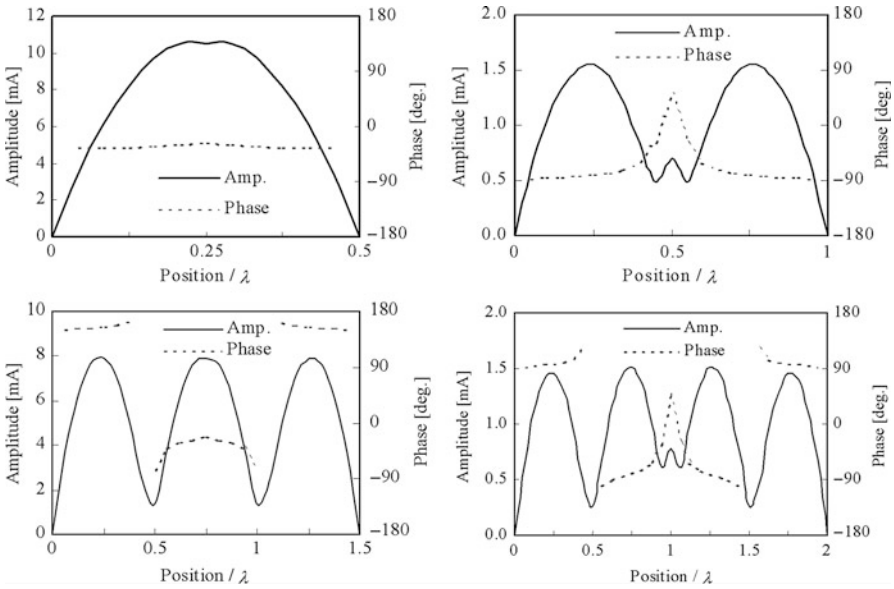

Fig. 12 Currents (amplitude and phase) on center-fed dipole antennas for $h = 0.5\lambda$, 1λ, 1.5λ, and 2λ ($V = 1$[V])

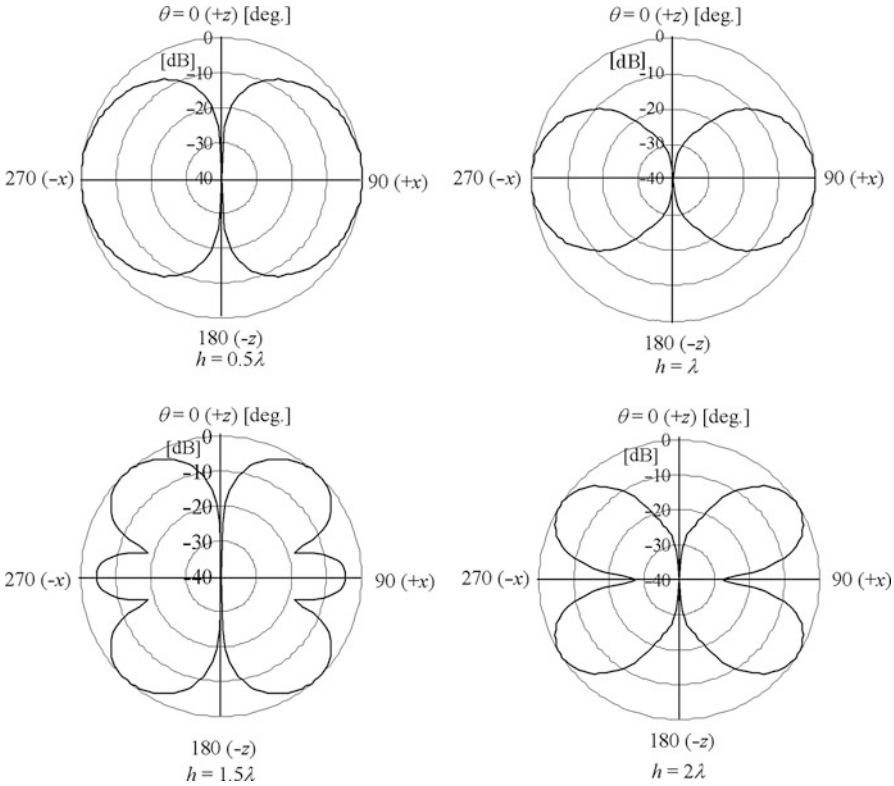

Fig. 13 Normalized vertical radiation patterns of the center-fed dipole antennas corresponding to the currents in Fig. 12

of $h = 1.5\lambda$ and 2λ. Then, the radiated energy is distributed into more than one vertical direction. This causes inefficient radiation in the desired direction and undesired radiation in the other directions. Therefore, a half-wavelength dipole antenna is used widely due to its unidirectional vertical radiation and easy impedance matching.

DOI 10.1007/978-981-4560-75-7_25-1

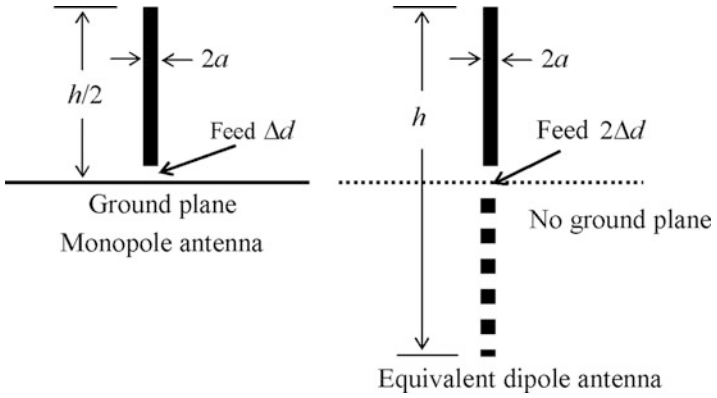

Fig. 14 A monopole antenna on an infinite ground plane and the equivalent dipole antenna

Monopole Antenna

A monopole antenna on a large ground plane such as the earth and building roofs can be used to make antennas smaller without sacrificing communication quality. For the first transatlantic wireless communication, G. Marconi built a monopole antenna (45 m) where the earth is used as a large ground plane (Fig. 2). The operating frequency of the transmitter is under 100 kHz and the antenna is still small in wavelength (Weeks 1968).

A monopole antenna on an infinite ground plane is equivalent to a dipole antenna shown in Fig. 14. The currents on the monopole and the electric field are the same as those of the dipole in the upper half-space. Since the infinitesimal feed distance of the monopole is Δd and that of the dipole is $2\Delta d$, voltage $V^m = E_z^{imp}\Delta d$ at the monopole feed becomes half of $V^d = E_z^{imp}(2\Delta d)$ at the dipole feed where E_z^{imp} is the impressed electric field shown in Fig. 4. Thus, their input impedances Z_{in}^m and Z_{in}^d have the following relation:

$$Z_{in}^m = \frac{2V^m}{2I^m} = \frac{V^d}{2I^d} = \frac{Z_{in}^d}{2} \tag{23}$$

Since $V^m = V^d/2$ and $I^m = I^d$, $P^m = P^d/2$ from Eq. 22. Then, from Eq. 21, the relation between monopole and dipole gain G^m and G^d is obtained as

$$G^m = 2G^d \tag{24}$$

Receiving Dipole Antenna

For a z-directed receiving antenna and the equivalent circuit shown in Fig. 15, it is assumed that a plane wave $\boldsymbol{E}^{imp}$ is incident and impedance Z_L is loaded at the receiving point on the antenna. Also Z_{in} and V_o are the input impedance and the open-circuit voltage of the receiving antenna, respectively. In Figs. 4 and 15, the position of $\boldsymbol{E}^{imp}$ is on the feed point for the transmitting antenna and is outside for the receiving antenna. Therefore, for the receiving antenna, the boundary condition is the same as Eq. 4 and the matrix equation to obtain the current distribution becomes Eq. 18. It is assumed that the receiving point is infinitesimal and corresponds to the peak of the expansion function (Fig. 6).

The incident plane wave is assumed as

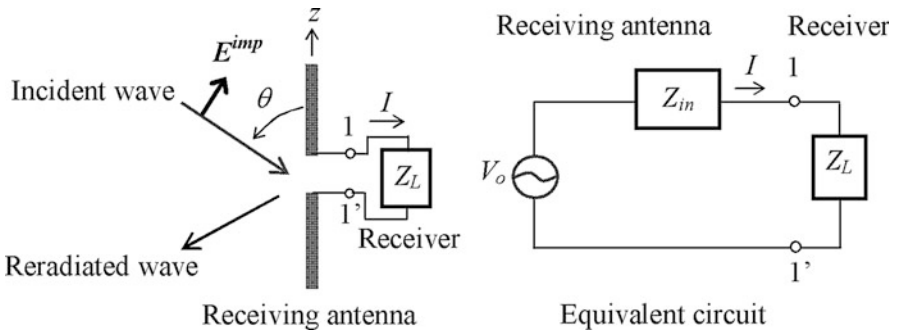

Fig. 15 A receiving antenna with a receiver and the equivalent circuit where current I is at the receiving point

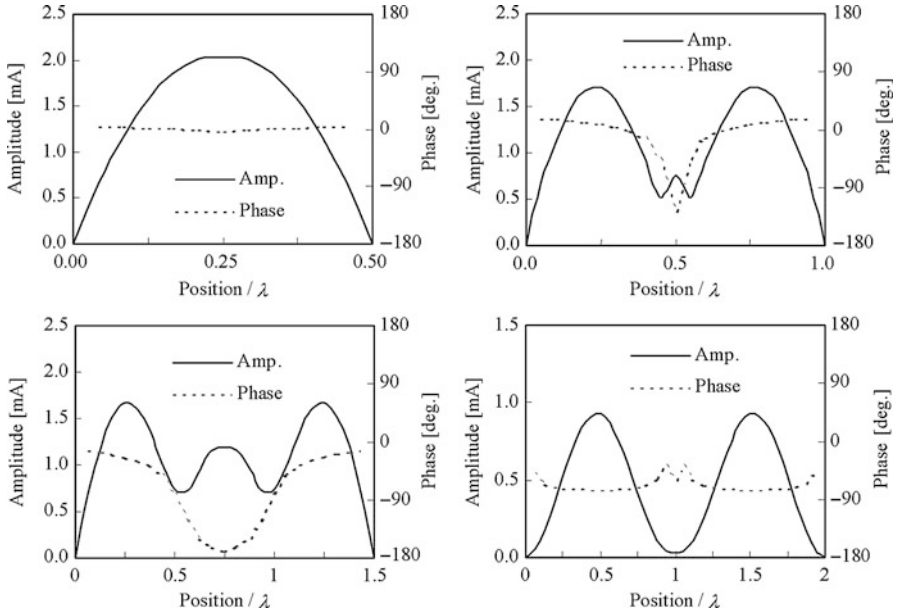

Fig. 16 Currents (amplitude and phase) on center-loaded receiving dipole antennas for $h = 0.5\lambda$, 1λ, 1.5λ, and $2\lambda \left(Z_L = Z_{in}^*, E_\theta{}^{imp} = -1[\mathrm{V/m}], \theta = 90^\circ\right)$

$$\boldsymbol{E}^{\boldsymbol{imp}}(z) = \hat{u}_{\boldsymbol{i}} \boldsymbol{e}^{-j\boldsymbol{k}_i \cdot \hat{z} z} \tag{25}$$

where unit vector $\hat{u}_{\boldsymbol{i}}$ specifies the polarization. Wave-number vector $\boldsymbol{k}_{\boldsymbol{i}}$ is in the direction of the incident wave and $|\boldsymbol{k}_{\boldsymbol{i}}| = 2\pi/\lambda$. Then, the element of incident voltage matrix $[V]$ becomes

$$V_m = \int_{z_{m-1}}^{z_{m+1}} J_{zm} \hat{z} \cdot \hat{u}_{\boldsymbol{i}} \boldsymbol{e}^{-j\boldsymbol{k}_i \cdot \hat{z} z} dz \tag{26}$$

Current distributions on center-loaded receiving dipoles of $h = 0.5\lambda$, λ, 1.5λ, and 2λ are shown in Fig. 16 where it is assumed that electric field $E_\theta{}^{imp}$ $(= -1$ [V/m]) is normally incident ($\theta = 90^\circ$) and load $Z_L = Z_{in}$* at the receiving point. Figure 16 can be compared to the current distributions of the transmitting antennas in Fig. 12. The amplitude peak appears every half-wavelength that is similar to that of the transmitting antenna for $h = 0.5\lambda$, λ, 1.5λ. When $h = 2\lambda$, there are only two amplitude peaks for the receiving case instead of the four peaks for the transmitting one. This is because the current distribution as well as the receiving characteristics is dependent on the incident wave and the load value at the receiving

DOI 10.1007/978-981-4560-75-7_25-1

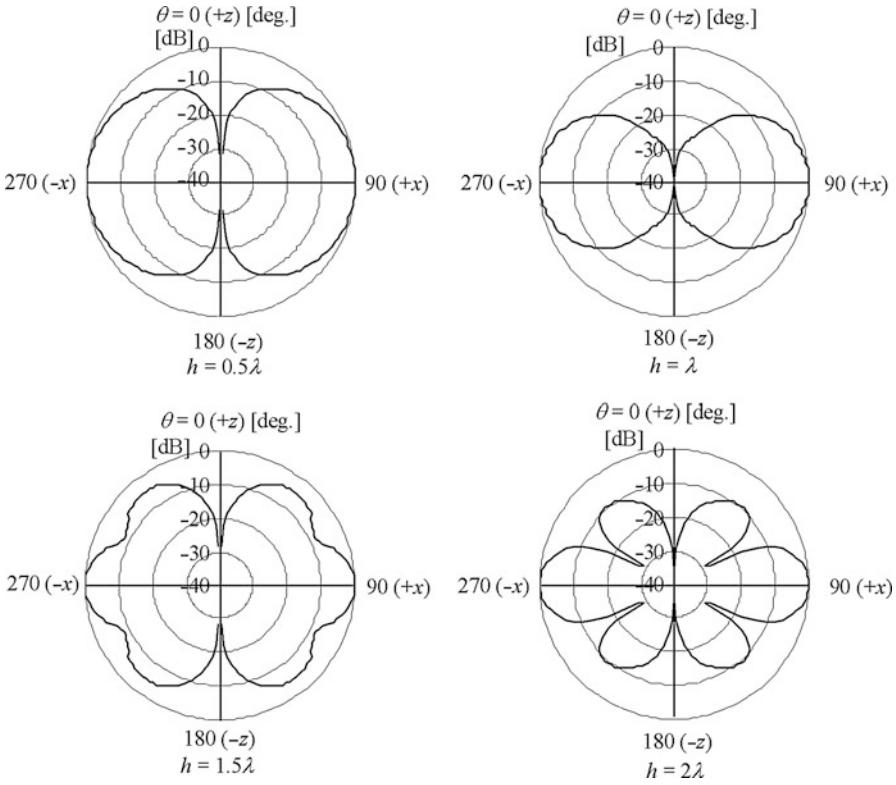

Fig. 17 Normalized vertical reradiation patterns of the center-loaded dipole antennas corresponding to the currents in Fig. 16

point (Hirasawa 1987). Figure 17 shows the normalized vertical reradiation pattern $|E_\theta|$ corresponding to the current in Fig. 16. If the reradiation and radiation patterns in Figs. 17 and 13 are compared, they are similar for $h = 0.5\lambda$ and λ where there is only one peak ($\theta = 90°$). When $h = 1.5\lambda$, the maximum is in the $\theta = 90°$ direction in Fig. 17 instead of $\theta = 45°$ in Fig. 13. Also there are no deep nulls in the reradiation pattern that are quite different from the radiation pattern. When $h = 2\lambda$, there is a peak in the $\theta = 90°$ direction instead of the null in the radiation pattern. The horizontal reradiation patterns $|E_\theta|$ are omnidirectional and are not shown here. Also the receiving and the radiation patterns are the same for an antenna due to the reciprocity theorem (Stutzman and Thiele 2012), and the receiving pattern is not discussed here.

Open-circuit voltage V_o in Fig. 15 can be obtained from short-circuit current I_s by the MoM. The element of $[I]$ corresponding to the receiving point in Eq. 18 becomes I_s when the element of $[Z_L]$ is set to zero:

$$V_o = Z_{in} I_s \tag{27}$$

The Thevenin equivalent circuit on the left-hand side of terminals 1-1′ in Fig. 15 is valid only for the calculation of the current and received power at Z_L (Silver 1949). Therefore, in general, the power consumed at Z_{in} does not show the correct reradiated power. Similarly it is recognized that the electromagnetic fields in Fig. 14 are the same only above the upper half-space for the monopole and the dipole problem. It is important to keep in mind the valid region of the equivalent problem.

The incident, received, and reradiated powers are respectively expressed as

DOI 10.1007/978-981-4560-75-7_25-1

$$P_{in} = \sum_{n=1}^{N} \mathrm{Re}\left(V_n I_n^*\right) \tag{28}$$

$$P_{re} = \mathrm{Re}(Z_L)|I|^2 \tag{29}$$

$$P_{ra} = P_{in} - P_{re} \tag{30}$$

Reradiated power P_{ra} can be also obtained by integrating power density ($|E_\theta|^2/\eta_0$) over a large sphere. In Eq. 29, I is the current at the receiving point where impedance Z_L is loaded. Powers in Eqs. 28–30 are all obtained by using the MoM. Also P_{re} can be obtained correctly by using the Thevenin equivalent circuit shown in Fig. 15 as discussed above.

Received Power and Reradiated Power

Received and reradiated (or scattered) powers on the receiving dipole antenna have been investigated with the relation to the MoM and the Thevenin equivalent circuit since 1994. The reradiated power and the received power of a center-loaded dipole antenna and a Yagi-Uda antenna of load $Z_L = Z_{in}{}^*$ are calculated by the MoM and the limitation of the Thevenin equivalent circuit is shown (Hirasawa et al. 1994, 1997). Since then various discussions have been reported for a receiving antenna on the Thevenin equivalent circuit and the reradiated power (Collin 2003; Onuki et al. 2007; Best and Kaanta 2009).

In this section, incident, received, and reradiated powers with respect to three incident angles $\theta = 90°$, 60°, and 30° are shown for a center-loaded receiving dipole antenna of load $Z_L = Z_{in}{}^*$. With this load impedance, the maximum power is received at the load. It is also assumed that incident electric field $\left|E_\theta{}^{imp}\right| = 1[\mathrm{V/m}]$. Figure 18 shows received power P_{re} with respect to dipole length h. Also received power P_{re} is obtained from the Thevenin equivalent circuit (Fig. 15) once the open-circuit voltage V_o is obtained from Eq. 27. Figure 19 shows reradiated power P_{ra} from Eq. 30 with respect to h. P_{ra} can be also obtained by integrating power density ($|E_\theta|^2/\eta_0$) over a large sphere. In general P_{ra} cannot be calculated from the Thevenin equivalent since the circuit on the left-hand side of terminals 1-1′ in Fig. 15 is equivalent to the original problem only for the calculation of current I and P_{re} (Silver 1949; Collin 2003). Figure 20 shows P_{re}/P_{ra}. The reradiated power becomes larger than the received power as

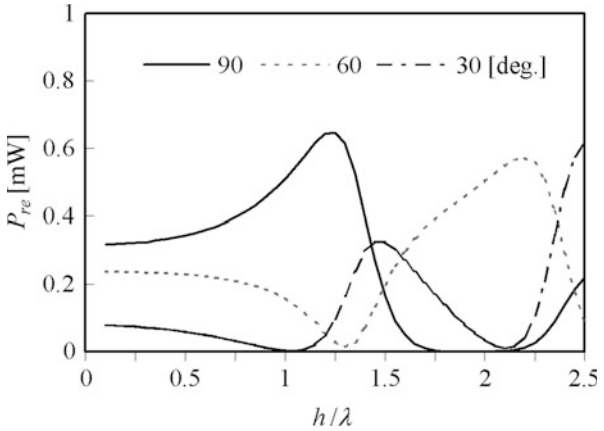

Fig. 18 Received power P_{re} with $\left|E_\theta{}^{imp}\right| = 1[\mathrm{V/m}]$ and $Z_L = Z_{in}{}^*$ for three incident angles $\theta = 90°$, 60°, and 30°

DOI 10.1007/978-981-4560-75-7_25-1

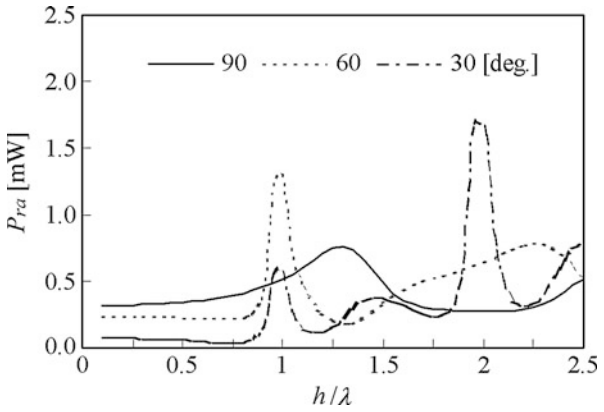

Fig. 19 Reradiated power P_{ra} with $\left|E_\theta^{imp}\right| = 1[\mathrm{V/m}]$ and $Z_L = Z_{in}$* for three incident angles $\theta = 90°$, 60°, and 30°

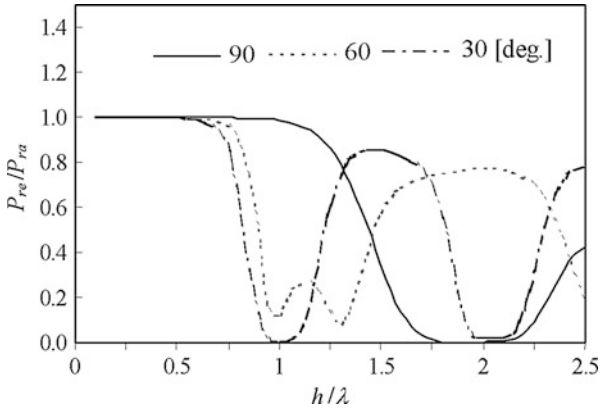

Fig. 20 P_{re}/P_{ra} with $\left|E_\theta^{imp}\right| = 1[\mathrm{V/m}]$ and $Z_L = Z_{in}$* for three incident angles $\theta = 90°$, 60°, and 30°

h becomes larger than 0.9λ, 0.6λ, and 0.55λ for incidence angles $\theta = 90°$, 60°, and 30°, respectively. Figure 21 shows the current distribution (amplitude) for $h = \lambda$ and the current amplitude becomes almost zero at the receiving point for $\theta = 30°$. Thus, the corresponding P_{re} and P_{re}/P_{ra} becomes very small.

Figures 18, 19, and 20 show that the receiving antenna can receive and reradiate 50 % of the incident power at best and receive less than 50 % of the incident power when h is larger than a certain length. Also this can be explained by separating the current distribution on the receiving dipole antenna into the coupling component and the non-coupling component. Then, the former contributes to the received power at the load but the latter only contributes to the reradiated power (Onuki et al. 2007).

Yagi-Uda Antenna

A typical Yagi-Uda antenna of six elements (Yagi 1928; Uda 1926) is shown in Fig. 22. It consists of one feed dipole, a reflector, and a director. The reflector is a wire located behind the feed dipole and is usually a little longer than the feed dipole. The director consists of a few wires in front of the feed dipole, and they are a little shorter than the feed dipole. The wire element spacing is 0.25λ–0.375λ where the mutual coupling is strong between the elements. The reflector and director guide electromagnetic fields efficiently in the x-axis direction. The antenna has a high gain in the x-axis direction with only one feed. The gain

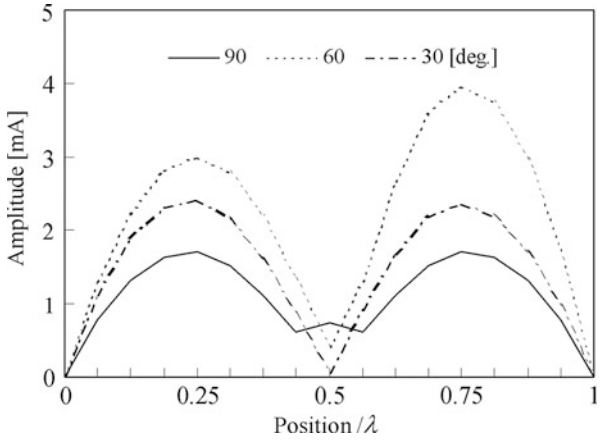

Fig. 21 Current amplitudes on the center-loaded receiving dipole antenna ($h = 1\lambda$) with $\left|E_\theta{}^{imp}\right| = 1[\mathrm{V/m}]$ and $Z_L = Z_{in}{}^*$ for three incident angles $\theta = 90°$, 60°, and 30°

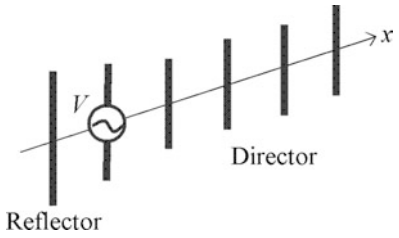

Fig. 22 A six-element Yagi-Uda antenna

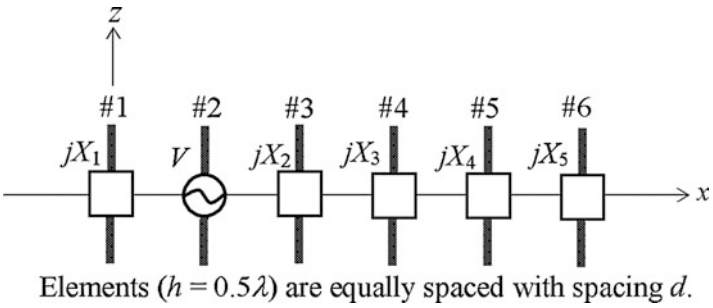

Fig. 23 An equally spaced Yagi-Uda antenna with six half-wavelength elements and five reactance loads

increases gradually with the increase of the number of director wires. Due to the simple structure, it is lightweight and easy to make. Thus, it is widely used as TV and FM receiving antennas in many countries.

Figure 23 shows a reactance-loaded Yagi-Uda antenna where the elements are equally spaced. Each element is a half-wavelength wire with $a = 0.001\lambda$. The reactance loads and the feed are located in the center of the element. The current distribution is changed by loading a reactance component on a wire except the feed wire. In Fig. 24 the optimum gain in the x-axis direction ($\theta = 90°$, $\phi = 0°$) is compared with that of the end-fire array shown in Fig. 25 where all elements are fed. The loaded reactance values for the optimum gain are obtained by using a biquadratic programming method (Hirasawa 1980, 1987, 1988). The difference between the optimum gains by reactance loads and feeds is 0.8 dB for element spacing $d = 0.35\lambda$ as shown in Fig. 24. Figure 26 shows the normalized horizontal radiation patterns ($\theta = 90°$)

DOI 10.1007/978-981-4560-75-7_25-1

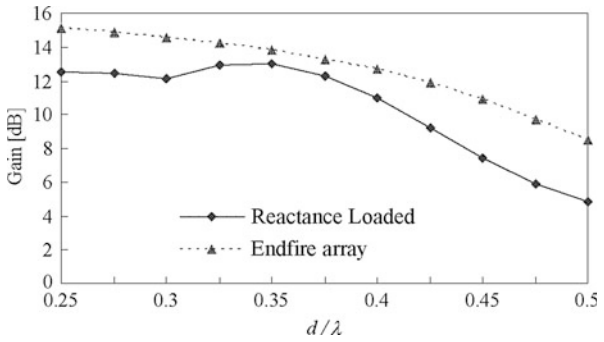

Fig. 24 Optimum gains of a six-element Yagi-Uda antenna with optimum loads compared with those of an end-fire array

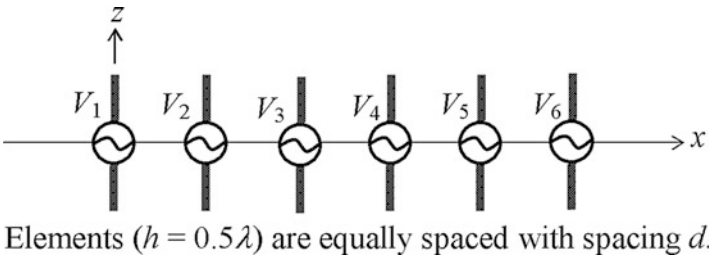

Fig. 25 An equally spaced end-fire array with half-wavelength elements

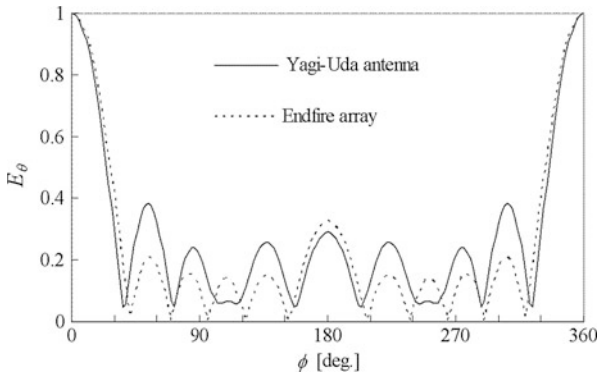

Fig. 26 Normalized horizontal radiation patterns of the optimum Yagi-Uda antenna and end-fire array when $d = 0.35\lambda$

for a reactance-loaded Yagi-Uda antenna and the end-fire array when $d = 0.35\lambda$. The sidelobes of the end-fire array are a little bit lower than those of the optimized Yagi-Uda antenna and the slightly higher gain is obtained by the end-fire array. Figures 27 and 28 show the input impedance and the loaded reactance values for the optimum gain. As d gets smaller, R_{in} becomes smaller. Therefore, $d = 0.3\lambda - 0.375\lambda$ may be good in the point of gain and impedance matching. The loaded reactance values for the optimum gain are all capacitive as shown in Fig. 28. It is quite difficult to realize the optimum gain by adjusting six feed voltages accurately, but it is much easier to realize the optimum gain of the Yagi-Uda antenna by using five capacitors.

Conclusion

A brief history is shown for a linear wire antenna development and its frequency-domain analysis methods. Then, the MoM is explained with the electric-field boundary conditions for a transmitting and receiving linear wire antenna. By using the MoM, transmitting linear wire antenna characteristics such as input impedances, current distributions, and radiation patterns are calculated. For receiving antennas, current distributions, reradiation patterns, received power, and reradiated power are shown when a plane wave is incident and the complex conjugate of the input impedance is loaded at the receiving point. Also the application of the Thevenin equivalent circuit is discussed for the receiving antenna. At the end the gain of a reactance-loaded Yagi-Uda antenna is shown and compared with that of an end-fire array.

Abstract

This chapter on loop antennas covers implementation aspects of both electrically small and electrically large loops which have a wide range of applications. On one side, they are still a part of the old broadcasting systems such as analog radios, and, on the other side, they are increasingly gaining attention for the contemporary high-definition video transmission and reception. The chapter begins with electrically small loops and coil antennas and covers its different aspects of radiation and losses, tuning, quality factor, and matching. Subsequently, resonant full-wave loops and their polarization are presented. A technique is shown on how loops can be placed in closed vicinity of a communicating device conducting surface without losing efficiency. In the final part, single-element beam steering loop antennas and their arrays for enabling devices to achieve high throughput and high-gain wide scanning range are discussed.

Keywords

Loop antennas; Circularly polarized antennas; Coil antennas; Electrically small antennas; Directive antennas; Ferrite antennas; Receiving antennas; Man-made noise; Multi-feed antennas; Resonant antennas; Rhombic antennas; Switched feeds; Reconfigurable loop antennas and their arrays; Wide scan high-gain adaptive arrays

Introduction

A loop antenna is an antenna where the radiating conductor forms a loop. Loop antennas have existed and have continuously evolved since the earliest days of radio. Consequently, "loop antennas" is now a subject area that is too large for all its features to be covered in just a chapter or even in any single book. Instead, three particular aspects are covered in this chapter:

1. Electrically small loop antennas and their close relations: electrically small multi-turn coils
2. Full-wave self-resonant loops and how they can be modified to cover different frequency bands and to radiate different polarizations and to radiate with high gain
3. Multi-feed loops where the radiation pattern is steered by switching between feeds

A common feature of all these aspects is that they are ways of saving physical space. Electrically small loop and coil antennas save space by being small. Full-wave loops can be used to save space by sharing that space with conducting structures already occupying the space. They can also be combined with other

*Email: peterma@hmgcc.gsi.gov.uk

DOI 10.1007/978-981-4560-75-7_26-1

loops to create compact directive radiators. And multi-feed loops save space by reusing the same radiating element (the loop) to generate several beams.

Electrically Small Loop and Coil Antennas

Introduction

What an electrically small loop or coil antenna consists of. An electrically small antenna is one that is much less than a wavelength across. In addition for the loops and coil antennas discussed below, it is assumed that the distance around the loop and along the length of the coil is short enough that the current can be approximated as near constant.

Because of the low conversion factor between currents on a small structure and radiation and because of the way the current contributions to radiation cancel out in loop and coil antennas (gone into in detail in subsection "Radiation and Losses"), electrically small antennas generally require tuning components to resonate, so that the amount of current carried, and hence the coupling to radiation, is maximized. For electrically small coil and loop antennas, this means tuning with one or more capacitors across the ends of the inductive coil or loop. In addition, they require some connection to their transceiver. There are many ways of achieving this, and some of them are discussed in subsection "Matching." However, other than ensuring that the antenna is impedance and/or noise matched to the transceiver circuitry, the method of matching usually has little effect upon the antenna performance, which is more dependent upon the antenna geometry and upon the environment surrounding the antenna.

Applications. The main application for electrically small loop and coil antennas has been as the antennas in medium- and long-wave broadcast radio receivers. The earlier antennas had the interior of the antenna filled with air. High-permeability soft ferrite was introduced in the 1950s, and coil antennas wrapped around a ferrite core have now become predominant as antennas for medium and long-wave reception. (Subsection "Receiving Antennas and Man-Made Electrical Noise" gives the reasons why they are widely used for this application.)

In the second half of the twentieth century, electrically small loop and coil antennas found another major application within radio pagers, operating at up to UHF (ultra high frequency band; 300MHz to 3GHz). The significant advantages over alternative antenna types are their relatively small size and their relative immunity to detuning due to the pager being carried on a user's body, e.g., mounted on a belt, clipped to a shirt, or placed in a pocket (subsection "Proximity Effects and Detuning" discusses proximity detuning).

Section overview. This section is arranged as follows. First, in subsection "Radiation and Losses," the radiation and losses are calculated, both for electrically small loops and coils and also for comparison for electrically small dipoles. These calculations reveal that electrically small loops and coils are less efficient radiators than dipoles of comparable size. Then, it is followed by subsections "Receiving Antennas and Man-Made Electrical Noise," "Near Field Noise," "Far Field Noise," "Tuning Components and Quality Factors," "Quality Factors," "Finding the Inductance of an Electrically Small Loop or Coil Antenna," and "Proximity Effects and Detuning," which are on the reasons why, despite their inefficiencies, loops and coils became popular for radio reception and for near-human body antennas. These subsections cover (a) the effects of man-made electrical noise on receiving antenna performance, (b) losses due to tuning components and how to find the component values, and (c) detuning from coupling to human bodies and other nearby objects. The last subsection, "Matching", discusses those matching issues that have not already been covered in earlier sections.

There is little discussion of an antenna's impedance bandwidth. This is because electrically small loops and coils tend to be used for narrowband communications. For electrically small loops and coils, the

DOI 10.1007/978-981-4560-75-7_26-1

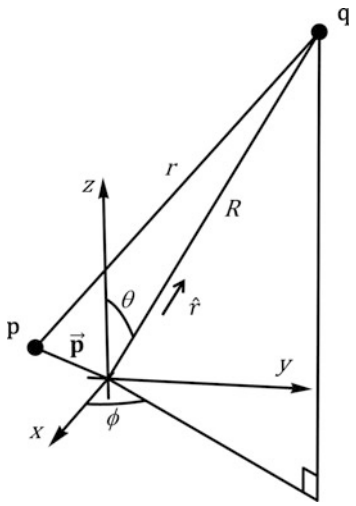

Fig. 1 Coordinates used in calculating radiation

antenna bandwidth tends to be primarily determined by the Ohmic losses of the antenna. For most designs the antenna bandwidth has a lower limit of around 1/2 % and is often around 1–2%, which is adequate for their applications.

Radiation and Losses

This subsection discusses radiation and losses by calculating them for a transmitting antenna. That the efficiency of the antenna when receiving is the same follows from the reciprocity theorem [e.g., see Collin (2001) for a discussion and derivation of the reciprocity theorem].

Radiation in terms of current. In order to calculate the radiation from a loop or coil antenna, one can use the Schelkunoff formula for the far field due to currents (Schelkunoff 1939) [see also Lee (1984)]. This formula comes from the formula for electric field in terms of magnetic vector potential **A** and electric scalar potential Φ. In general, with

$$\mathbf{A} = \frac{\mu}{4\pi}\iiint_v \mathbf{J}\frac{e^{-jkr}}{r}dv\,\Phi = \frac{1}{4\pi\varepsilon}\iiint_v \rho\frac{e^{-jkr}}{r}dv \tag{1}$$

where **J** is the current density, ρ is the charge density, r is the distance between current or charge source at point **p** and the point **q** at which **A** or Φ is being evaluated, and v denotes integration over volume (Fig. 1), then the electric field **E** is given by

$$\mathbf{E} = -j\omega\mathbf{A} - \nabla\Phi \tag{2}$$

See, for instance, Collin (2001), for a derivation of the above formulae.

Schelkunoff showed that when the electric field is due to the far field, the following simplifications apply:

$$\frac{e^{-jkr}}{r} \cong \frac{e^{-jkR}}{R}e^{jk\vec{\mathbf{p}}\cdot\hat{\boldsymbol{r}}} \tag{3}$$

where R is the distance between the antenna's center and **q**, $\hat{\boldsymbol{r}}$ is the direction vector pointing from the center of the antenna to **q** in the far field, and $\vec{\mathbf{p}}$ is the position vector of point **p**. Then, in an r, θ, ϕ

DOI 10.1007/978-981-4560-75-7_26-1

spherical coordinate system, the contribution of Φ to **E** is to cancel out with the radial component of **A**, and **E** becomes

$$\mathbf{E} = -j\omega\{0, A_\theta, A_\phi\} \tag{4}$$

where **A** simplifies to

$$\mathbf{A} \cong \mathbf{A}_{FF} = \frac{\mu}{4\pi}\frac{e^{-jkR}}{R}\iiint_v \mathbf{J} e^{jk\vec{\mathbf{p}}\cdot\hat{\mathbf{r}}}\, dv \tag{5}$$

Electrically small dipole. Before applying the above formula to calculating the radiation from a small loop or coil, it will be useful to apply it to the simpler case of a small dipole. Suppose the electrically small dipole is oriented along the *z*-axis with its terminals at the origin of the coordinate system. The current at the terminals is denoted I_0. The current's magnitude decays toward the open ends of the arms. The way it decays depends on the shape of the arms, but in practice for small antennas one can approximate the current distribution as linear, with it decaying to zero at the tip of the arms. Therefore, the current *I* can be modeled as

$$I(z) = I_0\left(1 - \frac{|z|}{\frac{l_0}{2}}\right) \quad \text{for } -\frac{l_0}{2} \le z \le \frac{l_0}{2} \tag{6}$$

where the dipole's overall length is l_0 and each of the dipole arms is $l_0/2$ long. In the above, the magnitude of *I* is taken as the root-mean-square (rms) value of the current, so as to avoid the need for factors of ½ in the formulae for radiated power and Ohmic losses. The peak magnitude is $\sqrt{2}$ times the rms value (Harrington 2001).

The exponential part of the formula for **A** can be expanded as

$$e^{jk\vec{\mathbf{p}}\cdot\hat{\mathbf{r}}} = 1 + s + \frac{s^2}{2!} + \frac{s^3}{3!} + \ldots \quad \text{where } s = jkz\cos\theta \tag{7}$$

For small distances where $kz \ll 1$, only the leading term is significant. Substituting this approximation and the formula for $I(z)$ into the equations for the far field gives

$$\mathbf{A} = \frac{\mu}{4\pi}\frac{e^{-jkR}}{R}\frac{I_0 l_0}{2}\hat{\boldsymbol{z}} \tag{8}$$

$$E_\theta = \frac{j\omega\mu}{4\pi}\frac{e^{-jkR}}{R}\frac{I_0 l_0 \sin\theta}{2} \qquad E_\phi = 0 \tag{9}$$

where $\hat{\boldsymbol{z}}$ is the unit direction vector in the *z*-direction. The radiated power density is given by

$$P_{\text{Rad dipole}} = \frac{|\mathbf{E}|^2}{Z_0} = \frac{\left(\frac{\omega\mu|I_0|l_0\sin\theta}{8\pi R}\right)^2}{Z_0} = Z_0\left(\frac{|I_0|l_0\sin\theta}{4\lambda R}\right)^2 \tag{10}$$

DOI 10.1007/978-981-4560-75-7_26-1

The total radiated power is the integration of the radiated power density over the sphere of radius R:

$$P_{\text{Rad}T\text{ dipole}} = 2\pi R^2 \int_0^{\pi} Z_0 \left(\frac{|I_0| l_0 \sin\theta}{4\lambda R} \right)^2 \sin\theta \, d\theta = \frac{Z_0 \pi}{6} \left(\frac{|I_0| l_0}{\lambda} \right)^2 \tag{11}$$

The directivity is given by

$$D_{\text{dipole}} = \frac{4\pi \, P_{\text{Rad dipole}}}{P_{\text{Rad}T\text{ dipole}}} = \frac{3 \sin^2\theta}{2} \tag{12}$$

It is useful to compare the radiated power with the power lost through resistive losses. Assuming that the dipole is made of a wire with resistivity ρ_w per meter, then the losses are given by

$$P_{\Omega\text{ dipole}} = 2\rho_w \int_0^{\frac{l_0}{2}} |I_0|^2 \left(1 - \frac{|z|}{\frac{l_0}{2}} \right)^2 dz = \frac{1}{3} \rho_w |I_0|^2 l_0 \tag{13}$$

The radiation efficiency *R.E.* is given by

$$R.E. = \frac{P_{\text{Rad}T}}{P_{\text{Rad}T} + P_{\Omega}} = \frac{P.F.}{P.F. + 1} \tag{14}$$

where the power factor *P.F.* is

$$P.F. = \frac{P_{\text{Rad}T}}{P_{\Omega}} \tag{15}$$

When $P.F. \ll 1$, then $R.E. \approx P.F.$

For the dipole,

$$P.F._{\cdot\text{dipole}} = \frac{Z_0 \pi l_0}{2\rho_w \lambda^2} \tag{16}$$

So the power factor, and therefore for small values the radiation efficiency, is proportional to the dipole length. For example, if the dipole is 1/20th wavelength long, $P.F._{\cdot\text{dipole}} \cong 0.079 Z_0/(\rho_w \lambda)$, and if the dipole is 1/100th wavelength long, $P.F._{\cdot\text{dipole}} \cong 0.016 Z_0/(\rho_w \lambda)$.

Electrically small wire loop. In order to compute radiation from the currents in a small loop, first the case of a small rectangular loop will be considered. Then the results will be extended to loops that are planar but otherwise of arbitrary shape.

Consider an electrically small rectangular loop whose sides are parallel to the x and y axes. For the moment, consider only the far electric field in the plane where $\phi = 0$. Then the direction vector to the far field has the form $\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}} \sin\theta + \hat{\boldsymbol{z}} \cos\theta$ where $\hat{\boldsymbol{x}}$, $\hat{\boldsymbol{y}}$, and $\hat{\boldsymbol{z}}$ are the unit length direction vectors in the x-, y-, and z-directions. Therefore, $\vec{\boldsymbol{p}} \cdot \hat{\boldsymbol{r}} = p_x \sin\theta + p_z \cos\theta$, and

$$e^{jk\,\vec{\mathbf{p}}\cdot\hat{\mathbf{r}}} = e^{jk(p_x \sin\theta + p_z \cos\theta)} = e^{jkp_x \sin\theta} e^{jkp_z \cos\theta} \tag{17}$$

DOI 10.1007/978-981-4560-75-7_26-1

Substituting this into the equation for $\mathbf{A}_{FF}$ gives

$$\begin{aligned}\mathbf{A}_{FF} &= \frac{\mu}{4\pi}\frac{e^{-jkR}e^{jkp_z\cos\theta}}{R}\iiint_v \mathbf{J}e^{jkp_x\sin\theta}\,dv \\ &= \frac{\mu}{4\pi}\frac{e^{-jkR}e^{jkp_z\cos\theta}}{R}\left(\int_{x_1}^{x_2} dx\left(\hat{\boldsymbol{x}}I_0e^{jkx\sin\theta} - \hat{\boldsymbol{x}}I_0e^{jkx\sin\theta}\right) + \int_{y_1}^{y_2} dy\left(\hat{\boldsymbol{y}}I_0e^{jkx_2\sin\theta} - \hat{\boldsymbol{y}}I_0e^{jkx_1\sin\theta}\right)\right)\end{aligned} \tag{18}$$

where the sides parallel to the x-axis run between x_1 and x_2 and the sides parallel to the y-axis run between y_1 and y_2, and as with the dipole derivation case, I_0's magnitude corresponds to the rms value.

The integration with respect to x is for the two arms parallel to the x-axis, and the contributions from these arms cancel with each other. This leaves the contribution from the two arms parallel to the y-direction. The exponent remaining within the integral can be evaluated using a Taylor expansion:

$$e^{jkp_x\sin\theta} = 1 + s_x + \frac{{s_x}^2}{2!} + \frac{{s_x}^3}{3!} + \ldots \qquad \text{where } s_x = jkp_x\sin\theta \tag{19}$$

The first term of the expansion cancels in the integrand. This leaves the second term as the most significant, and the integration reduces to

$$\int_{y_1}^{y_2} dy\left(I_0e^{jkx_2\sin\theta} - I_0e^{jkx_1\sin\theta}\right) \cong \int_{y_1}^{y_2} dyI_0jk(x_2 - x_1)\sin\theta = I_0jk\sin\theta(y_2 - y_1)(x_2 - x_1) \tag{20}$$

$(y_2 - y_1)(x_2 - x_1)$ is the product of the length and width of the rectangular loop and is equivalent to the loop's area $A_{\text{rectangular loop}}$. So $\mathbf{A}_{FF}$ simplifies to

$$\mathbf{A}_{FF} = \frac{jk\mu}{4\pi}\frac{e^{-jkR}e^{jkp_z\cos\theta}}{R}I_0\sin\theta A_{\text{rectangular loop}}\hat{\boldsymbol{y}} \tag{21}$$

Substituting this back into the equation for the electric far field gives

$$E_\theta = 0\; E_\phi = \frac{\omega\mu k}{4\pi}\frac{e^{-jkR}e^{jkp_z\cos\theta}}{R}I_0\sin\theta A_{\text{rectangular loop}} = c_{\text{rect}}I_0\sin\theta A_{\text{rectangular loop}} \tag{22}$$

where c_{rect} represents the factors that are independent of I_0, θ, and loop dimensions. It can be rearranged by expressing ω and k in terms of the speed of light c and wavelength λ and expressing $c\,\mu$ in terms of Z_0:

$$\frac{\omega\mu k}{4\pi} = \frac{4\pi^2 c\mu}{4\pi\lambda^2} = \frac{\pi Z_0}{\lambda^2} \tag{23}$$

$$c_{rect} = \frac{e^{-jkR}e^{jkp_z\cos\theta}}{R}\frac{\pi Z_0}{\lambda^2} \tag{24}$$

DOI 10.1007/978-981-4560-75-7_26-1

Now consider the far field at a point **q** in the *x-z* plane from a loop L_A of arbitrary outline in a plane parallel to the *x-y* plane with a current I_0 circulating around it in the anticlockwise direction. To calculate the far field, one can conduct a thought experiment where the area enclosed by the loop is filled with small rectangular loops all of which have I_0 circulating around them in the anticlockwise direction. On the boundaries between adjacent rectangular loops, the currents cancel, and so the net current within the interior of the tessellation of rectangular loops is 0, the same as for L_A. The only places where the current does not cancel out are at the exterior boundary of the tessellation, where here it is I_0, the same as on the arbitrary outlined loop. Therefore, the radiated field from the arbitrary outlined loop is the same as from the tessellation of rectangular loops. The radiation from the tessellation of rectangular loops is given by summing the fields of the individual loops, which for E_ϕ is the sum of $c_{rect}\sin\theta$ times their areas, or

$$E_\phi = c_{rect} I_0 A_{\mathrm{LA}} \sin\theta \tag{25}$$

where A_{LA} is the total area enclosed by the loop.

The above was calculated for far field points where $\phi = 0$. But one can argue that the result applies for any angle of ϕ by noting that as the shape of the loop in the x-y plane is arbitrary, one could rotate the coordinate system about the z-axis by $-\phi$ and arrive at the same result. So the above equation applies for all ϕ.

The radiated power density is given by

$$P_{\mathrm{Rad\ loop}} = \frac{|\mathbf{E}|^2}{Z_0} = \frac{|c_{rect}|^2 (|I_0| A_{\mathrm{LA}} \sin\theta)^2}{Z_0} = Z_0 \left(\frac{\pi |I_0| A_{\mathrm{LA}} \sin\theta}{\lambda^2 R} \right)^2 \tag{26}$$

The total power radiated is given by

$$P_{\mathrm{Rad}T\ \mathrm{loop}} = 2\pi R^2 \int_0^\pi Z_0 \left(\frac{\pi |I_0| A_{\mathrm{LA}} \sin\theta}{\lambda^2 R} \right)^2 \sin\theta \, d\theta = \frac{8 Z_0 \pi^3}{3} \left(\frac{|I_0| A_{\mathrm{LA}}}{\lambda^2} \right)^2 \tag{27}$$

The Ohmic losses are given by

$$P_{\Omega\mathrm{loop}} = \rho_w \oint dl \, |I_0|^2 = \rho_w p_{\mathrm{LA}} \, |I_0|^2 \tag{28}$$

where p_{LA} is the perimeter of the loop.

The power factor is given by

$$P.F._{\cdot \mathrm{wire\ loop}} = \frac{P_{\mathrm{Rad}T\ \mathrm{loop}}}{P_{\Omega\mathrm{loop}}} = \frac{8 Z_0 \pi^3}{3 \rho_w p_{\mathrm{LA}}} \left(\frac{A_{\mathrm{LA}}}{\lambda^2} \right)^2 \tag{29}$$

To compare with the result for a dipole, consider a square loop, with sides of length l_0. If $l_0 = \lambda/20$, then $P.F._{\mathrm{loop}} \cong 0.0026\, Z_0/(\rho_w \lambda)$, and if $l_0 = \lambda/100$, $P.F._{\cdot loop} \cong 2.1 \times 10^{-5}\, Z_0/(\rho_w \lambda)$. So for antennas made out of the same wire and a 20th of a wavelength across, the dipole's power factor is 30 times better than the loop's, and for antennas a hundredth of a wavelength across the dipole's power factor is 760 times larger than that of the loop.

DOI 10.1007/978-981-4560-75-7_26-1

For later comparison with the strip metal loop case, it is useful to consider when the wire diameter is much greater than the skin depth, and therefore the relation $\rho_w = \rho_s/(\pi d)$ applies, where ρ_s is the surface resistivity. Then

$$P.F._{\text{wire loop}} = \frac{8Z_0\pi^4 d}{3\rho_s p_{\text{LA}}}\left(\frac{A_{\text{LA}}}{\lambda^2}\right)^2 \tag{30}$$

Electrically small loop of strip metal. Some electrically small loop antennas are constructed from strips of metal rather than wires, in order to reduce the Ohmic losses of the loop. The computation of the radiated field can be thought of as a summation of the field from a collection of electrically small wire loops stacked along the z-axis. So the field calculation proceeds as for the calculation of a small wire loop above, except that there is an integration over the current density with z. That is, Eq. 25 is modified to

$$E_\phi = \int_{z_1}^{z_2} dz\, c_{rect}(z)\, I(z) A_{\text{LA}}(z) \sin\theta \tag{31}$$

The z dependant factor in c_{rect} is $e^{jkz\cos\theta}$, which can be expanded by Taylor expansion:

$$e^{jkz\cos\theta} = 1 + s_z + \frac{s_z^2}{2!} + \frac{s_z^3}{3!} + \ldots \qquad \text{where } s_z = jkz\cos\theta \tag{32}$$

and for small kz the leading constant term dominates and the other terms can be neglected. Also usually the loop has constant cross-sectional area A_{LA}. Then the right-hand side of Eq. 31 becomes the same as Eq. 25, and the formulae for the radiated power and total power radiated are as given in Eqs. 26 and 27.

The formula for the Ohmic losses is

$$P_{\Omega\ \text{strip loop}} = \oint dl \iint_S dS\rho\, |J|^2 = \rho\, p_{\text{LA}} \iint_S dS\rho\, |J|^2 \tag{33}$$

where ρ is the bulk resistivity, J is the current density, p_{LA} is the perimeter of the loop, and the double integral over S denotes integration across a cross section of the strip. The variation in current density depends on the loop geometry; because of induction, current tends to be pulled towards the inner side of the strip. It also depends upon z as the current concentrates near the corners of the strip. Therefore, the double integral is difficult to evaluate. However, for many applications, the thickness of the strip is significantly greater than the skin depth, and then the formula can be written as

$$P_{\Omega\ \text{strip loop}} = \rho_S\, p_{\text{LA}} \left(\int_{z_1}^{z_2} dz \left(|J_{S\ \text{inner}}|^2 + |J_{S\ \text{outer}}|^2 \right) + \int_{x_{\text{inner}}}^{x_{\text{outer}}} dx \left(|J_{S\ \text{top}}|^2 + |J_{S\ \text{bottom}}|^2 \right) \right) \tag{34}$$

where ρ_s is the surface resistivity in Ohms per square, J_s is the surface current density, "inner" and "outer" signify the surfaces to the inside $x = x_{\text{inner}}$ and outside $x = x_{\text{outer}}$ of the strip, and "top" and "bottom" signify the surfaces at the top $z = z_2$ and bottom $z = z_1$ of the strip. The above integrals are difficult to estimate analytically but, for a wide range of cases applicable to VHF (very high frequency band; 30 to

DOI 10.1007/978-981-4560-75-7_26-1

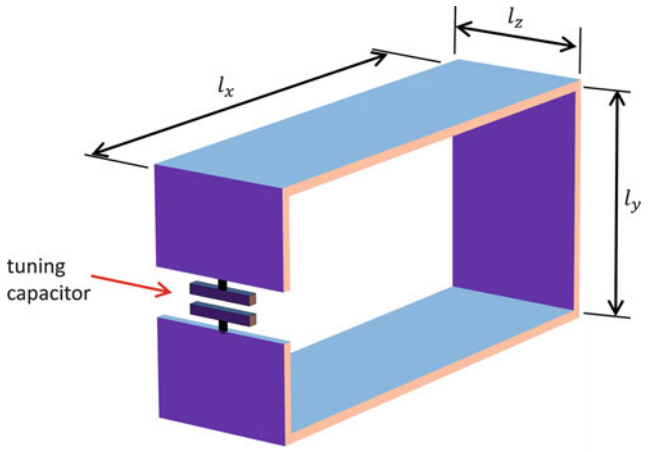

Fig. 2 Dimensions of a rectangular loop. While the tuning capacitor is shown in its often preferred position in one of the shorter sides (see subsection "Proximity Effects and Detuning"), its location is immaterial to the validity of Eq. 39

300MHz) and UHF body-borne loops (e.g., for radio pagers), have been examined numerically. These numerical studies have shown that the following approximation can be made:

$$P_{\Omega \text{ strip loop}} = \rho_S \, p_{\text{LA}} \, \beta \left(\int_{z_1}^{z_2} dz \, 2|J_S|^2 \right) = 2\rho_S \, p_{\text{LA}} \, \beta \, l_z |J_S|^2 = \rho_S \, p_{\text{LA}} \, \beta \frac{|I_0|^2}{2 \, l_z} \tag{35}$$

where $l_z = (z_2 - z_1)$ is the strip's width. In other words, one can approximate the power lost by calculating the Ohmic losses assuming that the current density is constant and along the inner and outer sides. The additional losses due to the current preferring the inner side and collecting at the edges of the strip and due to the current at the top and bottom surfaces are taken care of by introducing a factor β where $1 < \beta < \sim 1.6$. Combining this with Eq. 27 gives

$$P.F._{\text{strip loop}} = \frac{16 \, l_z Z_0 \pi^3 \left(\frac{A_{\text{LA}}}{\lambda^2} \right)^2}{3 \, \rho_S \, p_{\text{LA}} \, \beta} \tag{36}$$

The difference between this and Eq. 30 is

$$\frac{P.F._{\text{strip loop}}}{P.F._{\text{wire loop}}} = \frac{2 l_z}{d \pi \beta} \tag{37}$$

In radio pagers, there is often enough space available to use a 5 mm width strip metal, or one could use a relatively thick wire (e.g., 1 mm diameter) to save material costs. The power factor improvement from using a 5 mm wide strip instead of a 1 mm diameter wire would be $10/(\pi\beta)$ which (depending on the value of β) is between ~2 and ~3 or between 3 and 4.8 dB. And because of Eq. 14 for small values of *P.F.*, this gives a similar difference in the radiation efficiency. This may seem a very useful improvement, however as discussed in subsection "Far Field Noise," often such differences in antenna performance make little difference to the overall performance of a receiver.

DOI 10.1007/978-981-4560-75-7_26-1

For body-borne VHF and UHF loop applications, a rectangular loop is particularly of interest (see subsection "Proximity Effects and Detuning"). Then as $p_{\mathrm{LA}} = 2\left(l_x + l_y\right)$ where l_x is the length across the loop and l_y is the width across the loop (see Fig. 2), the formula for Ohmic losses simplifies to

$$P_{\Omega \text{ rectangular strip loop}} = \left(l_x + l_y\right) \rho_S \, \beta \frac{|I_0|^2}{l_z} \tag{38}$$

Combining this with Eq. 26 gives

$$P.F._{\text{ rectangular strip loop}} = \frac{\dfrac{8Z_0\pi^2}{3}\left(\dfrac{|I_0|l_x l_y}{\lambda^2}\right)^2}{\left(l_x + l_y\right)\rho_S \, \beta \dfrac{|I_0|^2}{l_z}} = \frac{1.48 \times 10^{-23} f^{\frac{7}{2}} l_z \left(l_x l_y\right)^2}{\beta\sqrt{\rho_r}\left(l_x + l_y\right)} \tag{39}$$

where f is the frequency (in hertz); l_x, l_y, and l_z are the loop dimensions in meters; ρ_r is the bulk resistivity relative to that of annealed copper (1.72×10^{-8} Ω m); and the formula for surface resistivity in terms of bulk resistivity ρ has been applied:

$$\rho_S = \sqrt{\pi f \rho \mu} \tag{40}$$

Equation 39 has been used in industry for early evaluation of design choices in pager receiver design. In this context, it has been found that the losses associated with the tuning capacitors can also be accounted for by increasing the estimate for β to around 3 (Massey 2001).

Electrically small coils. The electric field from coils can be approximated by considering them as a collection of small loops spaced along the coil axis parallel to the z-axis. For an N-turn coil, the radiated field from the coil is given by

$$E_{\phi\text{coil}} = N c_{\text{rect}} I_0 A_{\text{LA}} \sin\theta \tag{41}$$

and

$$P_{\text{Rad coil}} = \left(\frac{N\pi|I_0|A_{\text{LA}}\sin\theta}{\lambda^2 R}\right)^2 \tag{42}$$

The total power radiated is given by

$$P_{\text{Rad}T\text{ coil}} = \frac{8Z_0\pi^3}{3}\left(\frac{NI_0A_{\text{LA}}}{\lambda^2}\right)^2 \tag{43}$$

The directivity is given by

$$D_{\text{coil}} = \frac{4\pi \, P_{\text{Rad coil}}}{P_{\text{Rad}T\text{ coil}}} = \frac{3\sin^2\theta}{2} \tag{44}$$

This is the same as the formula for the directivity of an electrically small dipole. As the above formula applies for all N, including $N = 1$, a loop has the same directivity as a coil. And as for loops and coils, P_{Rad}

DOI 10.1007/978-981-4560-75-7_26-1

and $P_{\mathrm{Rad}T}$ depend only on the total current I_0 and are independent of conducting wire or strip's cross section; the directivity is also independent of wire or strip size and cross section.

The Ohmic losses are

$$P_{\Omega\ \mathrm{coil}} = N\rho_w p_{\mathrm{LA}}\ |I_0|^2 \tag{45}$$

So,

$$P.F._{\mathrm{coil}} = \frac{8NZ_0\pi^3}{3\rho_w p_{\mathrm{LA}}}\left(\frac{A_{\mathrm{LA}}}{\lambda^2}\right)^2 \tag{46}$$

At first sight, Eq. 46 appears to state that coils have the advantage over loops that their power factor is improved by a factor of N, where N is the number of turns. While this is true if one was restricted to only using a particular wire, to see that this is not generally true, consider if instead of using a loop with one strand of wire in the turn, one had N strands. The total current I_0 stays the same, and Eq. 27 holds. However, assuming that the wire diameter is significantly more than the skin depth, then the Ohmic losses are proportional to the inverse of the perimeter of the conductor cross section and are reduced by a factor of N. So an N-turn coil made with one strand of wire has no performance advantage over a loop made from N strands of wire.

In practice loop antennas are rarely made from multiple strands of wire. Using metal strips often makes better use of the space that would be occupied by the multiple wire strands.

The reason that coils are popular is that their impedance is higher than loops. This reason was particularly important for wireless receiver applications when valves were used. The alternative to using a coil antenna for those applications was to include an impedance transformer, which is itself made using coils and is relatively expensive.

Because the radiation from an electrically small loop or coil is proportional to the loop or coil cross section's area squared, while the radiation from a dipole is proportional to the dipole length squared, electrically small loops rapidly become more inefficient than dipole antennas as the antenna dimensions are reduced. However, despite the better efficiency of the dipole-type structure, loop antennas find uses because they have a number of advantages. These advantages are related to:

- **Man-made electrical noise**: The near fields of human-generated interference are primarily electrical. Therefore, antennas which are insensitive to electrical near fields pick up less noise.
- **Quality factors of tuning components**: Electrically small loop antennas require capacitors for tuning components. Generally these have higher quality factors than the inductors used by electrically small dipole antennas and therefore introduce less loss.
- **Proximity detuning**: Nearby objects such as metal plates and human bodies can detune an electrically small antenna. The amount of detuning depends upon the type and orientation of the antenna, and the shape and preferred orientations of some loop antennas are better for use in many VHF and UHF body-mounted applications.

The following sections go into these topics in more detail.

Receiving Antennas and Man-Made Electrical Noise

When Marconi made his first successful transatlantic communications in 1901, for the receiving antenna he used a long wire antenna (effectively an electric monopole) suspended from a kite. Yet by the 1930s, loop antennas were used in practically all consumer radio receiver sets. The reason for this change in

DOI 10.1007/978-981-4560-75-7_26-1

antenna type was that in the interim three decades, man-made electrical noise had increased enormously. When this noise is from nearby sources and the receiver is in the near field of the sources, the noise usually has a much higher electric field, and loop antennas have a clear advantage because of their insensitivity to electric fields – see subsection "Near Field Noise." Noise sources further away reduce the performance advantages of larger and less lossy antennas – see subsection "Far Field Noise."

Near Field Noise

For noise sources closer than the order of a wavelength away, the noise is predominantly electric field. Therefore, a loop antenna, being more sensitive to the magnetic field, picks up less of the near field noise (Blok and Rietveld 1955). The excess of electric field in near field noise is particularly strong at long and medium wavelengths and is sometimes called the "aerial effect."

In suppressing near field noise, it is very important to ensure that the antenna is truly behaving as a loop antenna and that it is not inadvertently coupling to nearby conductors in such a way to form a dipole antenna. This issue is discussed in subsection "Proximity Effects and Detuning."

Far Field Noise

Electrically small loop and coil antennas are generally less efficient (more lossy) than long wire antennas. However, by the 1930s, the high levels of man-made environmental noise were making the performance reductions due to antenna losses much less significant. A full analysis of this would require a discussion of noise figures and their application to system noise analysis [see, e.g., ITU (2001)], which is beyond the scope of this chapter. However, the mechanism by which high levels of environmental noise reduce the effects of antenna losses can be explained with some examples.

The ability of a receiver to accurately detect a signal transmission is limited by how much the signal's power level P_{SO} is at the receiver input compared to the random noise power level P_{NO} at the input. If the antenna were lossless, then these powers would correspond to the signal power P_{SI} and the noise power P_{NI} picked up by the antenna. However, antenna losses degrade the ratio P_{SO}/P_{NO}. Therefore, it is of interest to examine how the signal-to-noise changes with antenna losses. One is interested in

$$f_a = \frac{\dfrac{P_{SI}}{P_{NI}}}{\dfrac{P_{SO}}{P_{NO}}} = \frac{P_{SI}P_{NO}}{P_{SO}P_{NI}} \tag{47}$$

(If the input and output powers of a two-port circuit were being discussed, the ratio f_a would be called the noise factor, and its value in dB would usually be called the noise figure. However, the term "antenna noise figure" is normally applied to different quantity that describes the excess of environmental noise over thermal noise, and so to avoid confusion, the terms "antenna noise factor" and "antenna noise figure" will not be used in the remainder of the subsection.)

With a perfect antenna, the signal incident upon the antenna would be transferred from space to the antenna terminals, and no additional noise would be introduced: $P_{SO} = P_{SI}$, $P_{NO} = P_{NI}$, and $f_a = 1$. Unfortunately, real antennas have attenuation due to resistive losses. This degrades both the signal and the noise from the atmosphere. It also introduces noise that is proportional to the temperature of the antenna. Consequently, for real antennas, $f_a > 1$. If the attenuation is represented by $g < 1$, then $P_{SO} = gP_{SI}$, and the noise power at the output transferred from space is $= gP_{NI}$. The total noise power at the output is that transferred from space plus the noise created by the antenna resistance: $P_{NO} = gP_{NI} + (1-g)kT_0B$ where k is Boltzmann's constant, T_0 is the temperature of the antenna

DOI 10.1007/978-981-4560-75-7_26-1

structure, and B is the bandwidth across which the power is being measured. Substituting into the formula for f_a gives

$$f_a = \frac{1}{g}\frac{gP_{NI} + (1-g)kT_0B}{P_{NI}} = 1 + \frac{(1-g)kT_0B}{gP_{NI}} \tag{48}$$

Suppose a well-matched receiving antenna is lossy – e.g., it is only 10 % efficient. Then $g = 0.1$ and $f_a = 1 + 9kT_0B/P_{NI}$. If the incident environmental noise power is comparable to the antenna structure's noise temperature: $P_{NI} = kT_0B$, then $f_a = 1 + 9 = 10$, or expressed in dB, the antenna losses reduce the signal-to-noise ratio by 10 dB. So for this low environmental noise example, the signal is attenuated by 10 dB, and the 10 dB attenuation of the environmental noise attenuation is made up by the noise introduced by the antenna resistance.

Now consider the same receiving antenna in a high environmental noise environment. If the environmental noise level $P_{NI} = 9kT_0B$ then $f_a = 1 + 9 \times (1/9) = 2$. Expressed in dB, the signal-to-noise level has degraded by 3 dB. The presence of high environmental noise reduces the increase in signal-to-noise level due to the antenna. In order to achieve the same 3 dB degradation level with $P_{NI} = kT_0B$, the antenna efficiency would have to be 50 %.

In both urban and rural areas throughout the populated parts of North America, Europe, and in many other regions, man-made electromagnetic noise has reached significant levels. At 100 MHz in these regions, the noise power that an antenna captures is often a hundred times or 20 dB above kT_0B. For a 10 % efficient antenna in this environment, the signal-to-noise ratio degrades by just 0.37 dB. In order to achieve this limited degradation with $P_{NI} = kT_0B$, the antenna efficiency would have to be 92 %.

For the reason explained in the next paragraph, man-made noise power contributing to P_{NI} increases as the frequency reduces. So the contribution of man-made noise to reducing the performance degradation caused by low antenna efficiency is more marked in the lower frequency bands. Conversely, for the upper UHF band and higher frequencies, man-made noise power is so low that the performance of a receiving antenna is strongly affected by its antenna efficiency – i.e., an ndB antenna loss increases the signal-to-noise level by ndB.

Atmospheric man-made radio frequency noise has a power density spectrum (measured in watt/m^2/Hz) with a frequency dependency that varies with location. However, the amount of man-made noise power (measured in watt/Hz) picked up by a receiving antenna is the product of both the power density spectrum and the antenna's capture area, and P_{NI} is the noise power received before the antenna losses are accounted for. The reciprocity relations between a transmitting and a receiving antenna and the Friis equation show that a lossless receiving antenna's capture area is proportional to the wavelength squared or equivalently to the inverse of the frequency squared. This inverse square dependency attenuates P_{NI} with increasing frequency faster than any growth in power density spectrum with frequency and means that regardless of location, the amount of man-made noise power P_{NI} increases quickly as the frequency is reduced. See Wagstaff and Merricks (2003) for a range of examples of how P_{NI} varies with frequency.

Tuning Components and Quality Factors

This subsection is about quality factors of components and circuits and why they are significant in discussing the performances of electrically small dipoles and loops. It also contains a discussion of how the inductance of the electrically small loop antenna and its tuning capacitance is found.

Quality Factors

Inductors are required to tune electrically small dipoles, and capacitors are required to tune electrically small loop antennas. The resistive losses associated with these tuning components have a detrimental

DOI 10.1007/978-981-4560-75-7_26-1

effect upon the antenna performance. Component manufacturers specify the losses in terms of quality factors as follows. The quality factors Q_c of a capacitor and Q_L of an inductor are defined as:

$$Q_C = \frac{2\omega E_C}{P_C} = \frac{1}{\omega C R_{SC}}\ ,\ Q_L = \frac{2\omega E_L}{P_L} = \frac{\omega L}{R_{SL}} \tag{49}$$

where E_C is the time-averaged energy stored in the capacitor, P_C is the time-average power dissipated by the capacitor, C is the capacitance, R_{SC} is the resistance that dissipates power losses P_C when put in series with a lossless capacitance C, E_L is the time-averaged energy stored in the inductor, P_L is the time-average power dissipated by the inductor, L is the inductance, and R_{SL} is the resistance that dissipates power P_L when put in series with an ideal lossless inductance L.

The quality factor of a circuit is the ratio of its stored energy to the energy dissipated per cycle. Since for a series or parallel LC circuit the total power dissipated P_T is

$$P_T = P_C + P_L \tag{50}$$

Then

$$\frac{P_T}{\omega\, E_T} = \frac{1}{Q_T} = \frac{1}{Q_C} + \frac{1}{Q_L} \tag{51}$$

where E_T is the energy stored within the circuit, and as this energy moves between the inductor and capacitor, $E_T = 2E_C = 2E_L$.

The LC circuit is of significance because:

- An electrically small dipole behaves like a capacitor, which has Ohmic and radiation loss resistances associated with it. It is tuned using an inductor.
- An electrically small loop or coil behaves like an inductor, which has Ohmic and radiation loss resistances associated with it. It is tuned using a capacitor.

With this in mind, Eq. 50 can be written as

$$P_T = P_{\text{antenna}} + P_{\text{tune}} = P_\Omega + P_{\text{Rad}T} + P_{\text{tune}} \tag{52}$$

where P_{tune} is the Ohmic losses of the tuning component, and as in subsection "Radiation and Losses," P_Ω is the Ohmic loss of the antenna and $P_{\text{Rad}T}$ is the radiated power from the antenna. Then, Eq. 52 can be rewritten as

$$\frac{1}{Q_T} = \frac{1}{Q_{\text{antenna}}} + \frac{1}{Q_{\text{tune}}} = \frac{1}{Q_\Omega} + \frac{1}{Q_{\text{Rad}T}} + \frac{1}{Q_{\text{tune}}} \tag{53}$$

Then, the ratio of the increase in Ohmic losses due to the tuning component to the Ohmic losses with a perfect tuning component is

$$\frac{P_\Omega + P_{\text{tune}}}{P_\Omega} = Q_\Omega\left(\frac{1}{Q_\Omega} + \frac{1}{Q_{\text{tune}}}\right) = 1 + \frac{Q_\Omega}{Q_{\text{tune}}} \tag{54}$$

DOI 10.1007/978-981-4560-75-7_26-1

The quality factors of most commercially available capacitors and inductors are quoted in the manufacturers' data sheets, and commercially available capacitors typically have quality factors of a few thousand. Commercially available inductors typically have quality factors ranging from 20 to around 200. Because electrically small antennas are usually significantly bigger than tuning components, the currents are spread across larger conducting surfaces, and so the Ohmic loss quality factor Q_Ω of electrically small dipole is usually a little better than Q_C of a capacitor, and factor Q_Ω of electrically small loop or coil is usually a little better than Q_L of an inductor. So one finds that for an electrically small dipole,

$$\frac{Q_\Omega}{Q_{\text{tune}}} \approx \frac{\sim 2000}{20 \text{ to } 200} \text{ and } \frac{P_\Omega + P_{\text{tune}}}{P_\Omega} > \sim 11 \tag{55}$$

And for an electrically small loop,

$$\frac{Q_\Omega}{Q_{\text{tune}}} \approx \frac{20 \text{ to } 200}{2000} \text{ and } \frac{P_\Omega + P_{\text{tune}}}{P_\Omega} \sim 1 \tag{56}$$

So the capacitor used to tune an electrically small loop or coil usually increases the losses much less than the inductor used to tune an electrically small dipole.

Finding the Inductance of an Electrically Small Loop or Coil Antenna

There are several methods for finding inductance. There are formulae for a variety of loop shapes and coil configurations, e.g., see Balanis (2005) for a simple circular cross section wire loop and Grover (2009) for a large selection of loop and coil configurations. In recent years, electromagnetic simulators have been useful and often more accurate than formulae in calculating inductance and can model realistic loops in their environment, e.g., noncircular shapes and varying cross sections that fit within the space available within their receiver, accounting for the effect of nearby metalwork within the receiver. However, often in practice, none of these theoretical methods account for all the contributions to the loop/coil's inductance, which may include manufacturing tolerances and construction variations. Consequently, measurement is the most reliable method of determining the inductance. At radio and microwave frequencies, a practical method of determining the inductance of the antenna loop/coil is to place tuning capacitance across the ends of the coil and search using a network analyzer for the lowest frequency resonance of the antenna. The inductance L is then calculated from the resonant frequency f_0 and the known capacitance value of the tuning capacitor(s) C:

$$L = \frac{1}{(2\pi f_0)^2 C} \tag{57}$$

The way in which the network analyzer is used to determine the resonant frequency depends on what connections are available on loop/coil antenna. If the network analyzer is connected across the ends of the loop/coil, then a search is done for the lowest frequency at which the magnitude of the impedance peaks. N.B. in this situation, it is very important that the connection between loop/coil and network analyzer uses a balanced line or balun; otherwise, the results will be contaminated by the currents traveling down the outside conducting surfaces of an unbalanced feed.

Alternatively, if a matching circuit is already in place (see subsection "Matching" for discussion of matching circuit types), then the network analyzer can be used to find the lowest frequency at which there is a peak in the insertion loss.

DOI 10.1007/978-981-4560-75-7_26-1

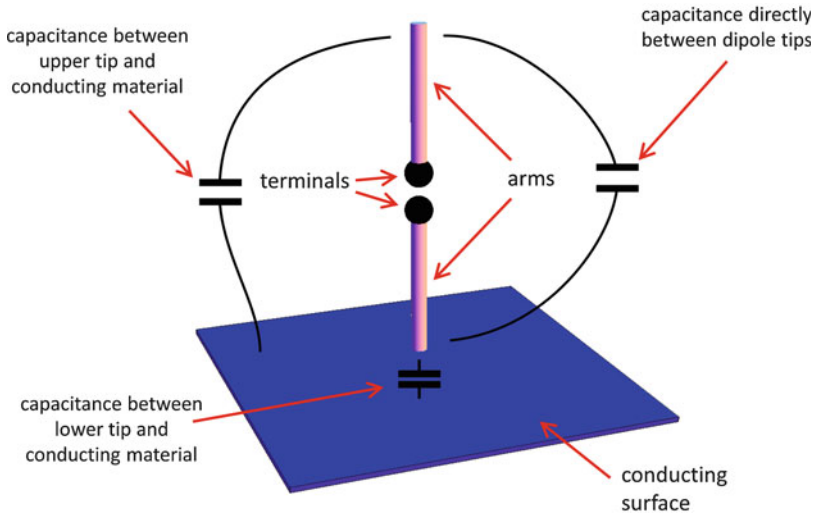

Fig. 3 Dipole perpendicular to the surface of a conducting body. The *black lines* show the approximate route of field lines between the tips and from the tips to the conducting surface. The distance along the field lines across space from one tip to the other tip via the conducting surface (the path on the *left* + the path in the *lower center*) is greater than the distance across space running directly between the tips. This indicates that the additional capacitance between the tips due to the presence of the conducting surface is less than the capacitance between the tips in free space

The accuracy of the resonance search method described above to determine the antenna inductance is often limited by the tolerances on the value of the tuning capacitor(s). These vary with capacitor type and series but typically lie between 2 % and 10 %. These tolerances also limit the accuracy to which the operating frequency of an electrically small loop/coil antenna can be preset using off-the-shelf fixed capacitors. For fixed frequency antennas, it is a good practice to use an adjustable trimmer capacitor in parallel with a fixed capacitor, so that the antenna's frequency can be adjusted prior to deployment.

Proximity Effects and Detuning

In this section, proximity detuning for a dipole is discussed first in order to set the scene for explaining the benefits of a loop antenna.

For both electrically small dipoles and for electrically small loops and coil antennas, detuning can occur through:

1. Capacitive coupling to nearby objects – This additional capacitance increases the tuning capacitance.
2. Inductive coupling to nearby objects – Nearby metal surfaces support currents that move in opposition to currents on the loop and act to reduce the inductance.

So capacitive proximity coupling lowers the resonant frequency, and inductive proximity coupling raises the resonant frequency. Some examples are described below.

All the following examples show a conducting sheet in their diagrams. These are included to represent the surface of a conductor, which could be a thin sheet (as shown) or a thick conducting body such as a block of metal. As the human body is composed of high dielectric lossy conducting fluids and tissues, it also has a similar effect upon the antennas.

Figure 3 shows a dipole perpendicular to the surface of a conducting body. The body couples capacitively to the dipole via the high electric fields at the dipole's lower tip. However, this capacitance has little effect upon the tuning as the conducting body is relatively far away from the upper arm.

DOI 10.1007/978-981-4560-75-7_26-1

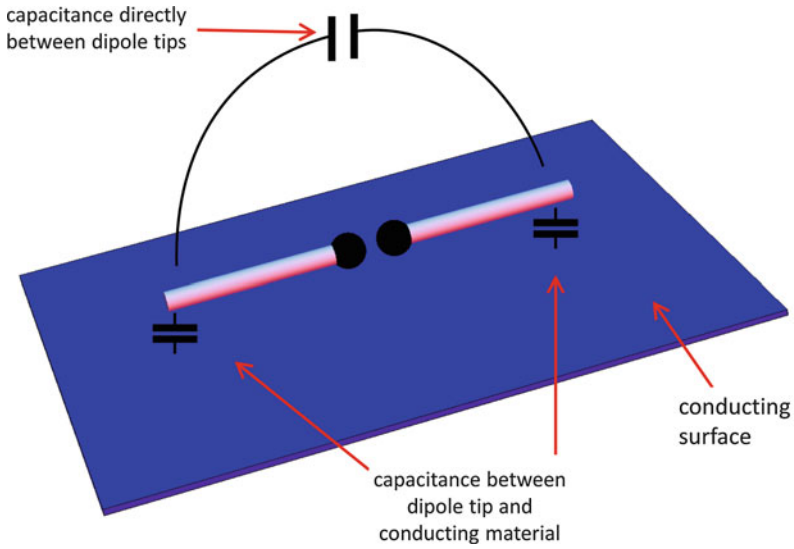

Fig. 4 Dipole parallel to the surface of a conducting body. The *black lines* show the approximate route of field lines between the tips and from the tips to the conducting surface. The distance along the field lines across space from one tip to the other tip via the conducting surface (the path on the *left* + the path on the *right*) is much shorter than the distance across space running directly between the tips. This indicates that the additional capacitance between the tips due to the presence of the conducting surface is much greater than the capacitance between the tips in free space

In contrast, Fig. 4 shows the situation when a dipole is placed parallel to the surface of a conducting body. The capacitance between each of the tips and the conducting body is much higher than the capacitance between the tips. Therefore, the presence of the conducting body provides a high capacitance path between the tips that detunes the antenna. Moreover, the current excited in the conducting body flows in the opposite direction to the current in the dipole and so cancels out its radiation.

The consequence of the above is that dipole-type antennas are suitable for use near conducting bodies, providing that they are oriented perpendicular to the surface of the body. For human body-mounted devices, this would mean that the antenna sticks out, which is generally considered undesirable. As is discussed below, loop antennas offer an alternative that gives a low profile above the body.

Figures 5 and 6 show some examples of proximity coupling in electrically small loops. The figures use a loop that is long and relatively narrow, which is a common shape as it is suited for fitting in devices such as pagers that fit in pockets next to a user's body. See Fig. 9 for an example on how this type of loop is installed in a radio pager.

When mounting loop antennas in body-worn devices, to avoid the detrimental effects of the inductively induced currents discussed in Fig. 5, it is important that the plane of the loop is perpendicular to the body's surface. And to avoid the capacitive detuning seen in the arrangement shown in Fig. 6, it is important that the tuning capacitor is mounted at the end of the long side of the loop. Figure 7 shows the preferred location for the tuning capacitor and for the orientation of the loop when next to a conducting body.

Besides the issues of detuning and of reduction in radiation, proximity coupling can also increase the coupling to noise. This can occur in two ways. The first is if the nearby structures are carrying noise. Mains cables are a common example; besides carrying 50–60 Hz mains signals, their currents can be contaminated with radio frequency noise picked up from connected equipment. The second way is if capacitive coupling adds a dipole-type antenna structure to the loop/coil. Then the dipole structure will pick up electric near field, and the near field noise-reducing advantage of using a loop (section "Near Field Noise") is diminished.

The capacitance available for capacitive proximity coupling is proportional to the size of the loop/coil. The effect of the proximity capacitance is dependent upon the inductance of the loop/coil and its tuning

DOI 10.1007/978-981-4560-75-7_26-1

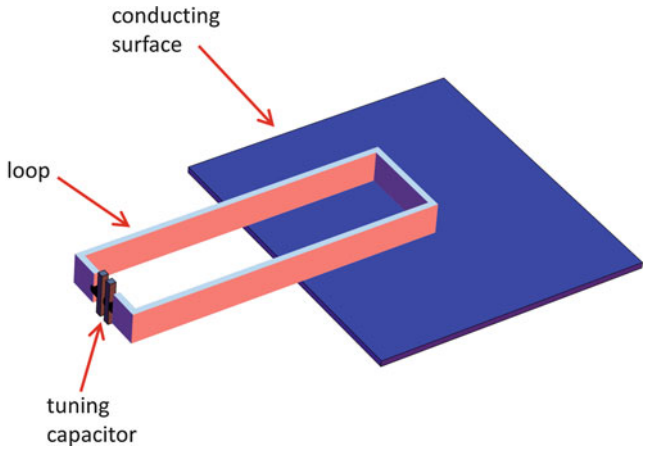

Fig. 5 Inductive proximity coupling to loops. The presence of a conducting sheet parallel to the plane of the loop (or perpendicular to the axis of a coil) reduces the loop's (or coil's) inductance because currents are excited in the sheet that travel in the opposite direction to those in the loop. Therefore, the antenna's resonant frequency increases

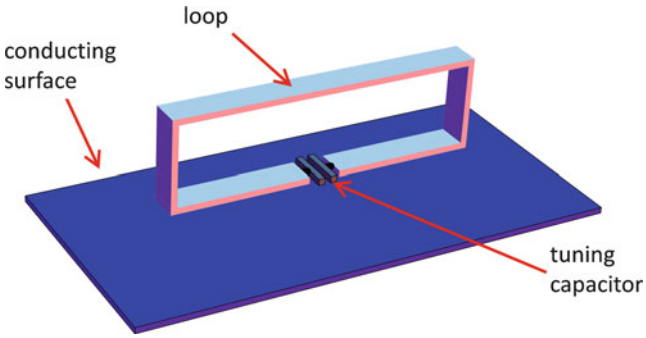

Fig. 6 Capacitive proximity coupling to loops. Capacitance between the loop and the conducting sheet adds to that of the tuning capacitor, reducing the resonant frequency. Placing the tuning capacitor in the middle of a long side of a loop antenna is the worst location for it, because of the propensity of the antenna to suffer from detuning due to capacitive coupling, by the same mechanism as shown in Fig. 4. This can even happen if the sheet is placed next to the long side without the tuning capacitor. For this reason, the tuning capacitor is normally placed at or near a narrow side

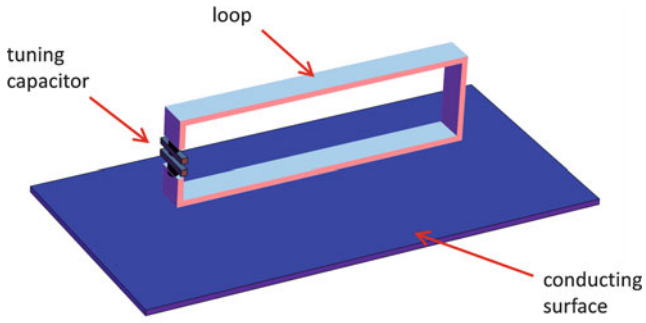

Fig. 7 Preferred configuration and orientation of electrically small loop next to conducting body

capacitance. If it is a large loop or a coil with a large number of turns, then the tuning capacitance will be less, and the proximity capacitance will be more significant. The large amount of metal wire associated with the high number of turns also increases the proximity capacitance compared with a few turns or a single turn of the same gauge of wire.

DOI 10.1007/978-981-4560-75-7_26-1

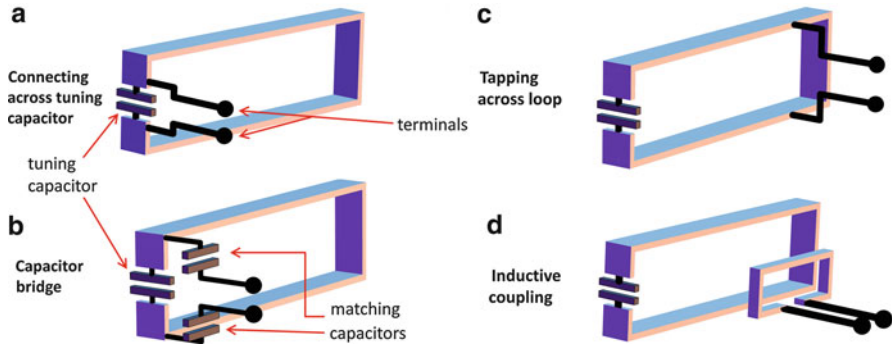

Fig. 8 Some matching arrangements for a loop or coil antenna

In the early twentieth century, multi-turn coils were used to provide the maximum voltage and high impedance across the tuning capacitor in order to directly drive the grid of the valve of a broadcast radio receiver. It was known that using a single-turn loop would reduce the effects of the proximity capacitance and reduce the amount of near field noise. However, in order to meet the impedance requirements for the input stage of the valve, a transformer would have been required, which would have added cost to the consumer product [see Blok and Rietveld (1955)]. The incorporation of a soft ferrite high-permeability core permitted a reduction in the diameter of the coil, which reduced the amount of proximity capacitance.

Advice on the use of soft ferrite cores can be found in Blok and Rietveld (1955) and Snelling (1988).

Soft ferrite has been successfully used to boost the performance of coil and loop antennas at frequencies up to VHF. However, the permeability of soft ferrite reduces, and the losses increase with increasing frequency (van der Zaag 1999), and beyond VHF air-cored loops and coils give the best performance.

Matching

Figure 8 shows some possible matching arrangements. It can be shown that most of these have very similar properties [see Massey (2009)], and therefore the choice of matching arrangement is determined by considerations other than which gives the best radio frequency (RF) performance. As examples:

- The direct connection across the tuning capacitor shown in Fig. 8a gives the highest impedance.
- The capacitor bridge shown in Fig. 8b is easily implemented as a circuit on a printed circuit board (PCB) to which the end of the loops is attached. See Fig. 9.
- Directly tapping across the loop or coil in Fig. 8c is very practical for experimental work, as the impedance match can be adjusted by moving the tap points. See Fig. 10.
- Inductively coupling into the loop using a small coupling loop in Fig. 8d builds the balun into the coupling structure. This is usually achieved at the cost of a small loss (~1 dB or less typically) due to the imperfect trapping of the magnetic flux between the antenna and the coupling loop.

The first three of these examples require either that they are connected to a balanced port or that a balun is used.

Full-Wave Loops

Introduction

The electrically small antennas of the last section always have to be tuned with a capacitor to make them work at the required frequency. This section discusses loops that are large enough to be self-resonant, i.e.,

DOI 10.1007/978-981-4560-75-7_26-1

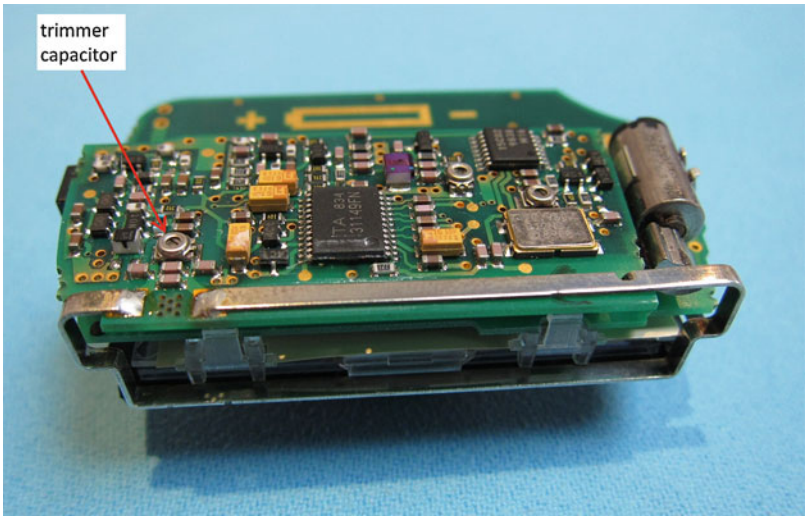

Fig. 9 Implementation of a capacitor bridge circuit in a pager receiver. The picture shows a radio pager with its casing and battery removed. The loop antenna is silver plated for maximum conductivity. The matching circuit is basically that shown in Fig. 8b, and the receiver has a balanced input port. However, in order to allow the tuning capacitance and matching capacitors to be mounted on the upper PCB, the ends of the loop are soldered to tracks on the PCB. The tuning capacitance consists of fixed capacitors in parallel with the trimmer capacitor. This is done because **a** fixed capacitors usually have greater Q than adjustable capacitors, and, **b** as most of the tuning capacitance is supplied by the fixed capacitors, the tuning range just covers the range necessary for adjustment (rather than a range of perhaps twice the center frequency, which would the case if the trimming capacitor was relied on to provide all the tuning capacitance). Therefore, the change in tuning frequency with rotation angle of the trimmer is less, and it is easier to bring the antenna into tune. The vibrator motor and its weight to the right of the PCB are mounted with the weight nearest the loop. This is because the permanent magnet in the motor introduces significant losses if placed close to the loop antenna

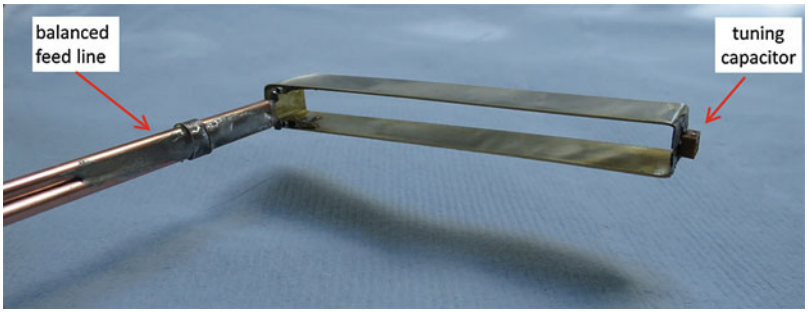

Fig. 10 Directly tapping across a loop using a balanced feed. The balanced line consists of two 50 Ω coaxial semirigid cables soldered together. The inners of the cables are fed from a 3 dB 180° splitter that converts an unbalanced 50 Ω feed into two 50 Ω signals that are 180° out of phase with each other, giving a balanced impedance of 50 + 50 = 100 Ω. To enable easy connection and disconnection between line and antenna, some sockets have been soldered onto the antenna, and wires which fit into the sockets have been soldered to the ends of the inner conductors of the coaxial cables. This arrangement is used for measuring the performance of different shapes of loops and for measuring the effects of bringing components close to the loop. The single adjustable tuning capacitor gives a very large tuning range but is very sensitive. For mass production, tuning using fixed capacitors in parallel with an adjustable capacitor is preferred. See Fig. 9

have a finite resistance and very low reactance between terminals that are across a gap in the loop. As the loop size is increased, self-resonance first occurs when the perimeter of the loop is around one wavelength long, i.e., the full-wave loop. In contrast to electrically small loops, full-wave loops generally have good efficiency and can be used for efficient transmission as well as for reception.

DOI 10.1007/978-981-4560-75-7_26-1

This section is arranged as follows. Subsection "Resonant Full-Wave Loop" discusses the basic full-wave loop structure, emphasizing that its radiation resistance is typically ~200 or more Ohms. The subsequent subsections detail how other features can be added to optimize full-wave loop behavior and tune the performance.

Subsection "Resonant Full-Wave Loop in Close Proximity to Metallic Structures" describes how the full-wave loop's natural resonant impedance can be reduced to values suitable for directly connecting to low-impedance (e.g., 50 Ω) ports by placing the loop around a conducting structure. To demonstrate the principle, a flat conducting structure, such as the electronics of a tablet computer, is used as an example. Then methods for frequency tuning (subsection "Tuning Resonant Loop Antennas") and creating circular polarization (subsection "Circularly Polarizing the Resonant Loop Antenna") are demonstrated.

Next, parasitic loops are introduced to modify the frequency coverage (subsection "Dual Banding the Resonant Loop Antenna"). These can be combined with the method for creating circular polarization as described in subsection "Dual Banding and Circular Polarizing the Resonant Loop Antenna."

The remaining subsections are devoted to describing methods for creating directive antennas with loops. Firstly, a loop over a ground plane is considered in subsection "Resonant Loop Over Planar Reflector." Subsection "Directive Resonant Loop Array" discusses the spacing of parasitic elements to create a Yagi-Uda like array with high directivity.

Another method of creating an efficient and relatively compact directive antenna is to mount shared feed loops about a quarter wavelength above a ground plane. Both linear (also known as biquad, described in subsection "Dual Rhombic/Circular Loop Antenna Over Planar Reflector (Biquad Antenna)") and circular polarized versions (described in subsection "Circularly Polarized Dual Rhombic/Circular Loop Antenna Over Planar Reflector") are detailed. Finally, methods for bandwidth extension are described in subsection "Wideband Circularly Polarized Dual Rhombic Loop Antenna with Parasitic Loops."

Resonant Full-Wave Loop

A full-wave loop structure can be almost any shape, for example, circular, square, rhombic, and triangular, as illustrated in Fig. 11. The full-wave loop can be constructed in three dimensions (e.g., from wire or a tube); it can have a planar structure, for example, being manufactured from a sheet of metal or etched onto the conductor of a printed circuit board. The full-wave resonant loop antenna is often approximated by a pair of (often bent) half-wave dipoles connected in parallel, as their current and voltage distributions are comparable to the full-wave loop. The dipole pairs resonate in phase and are connected at their tips where the current is almost zero. In Fig. 11, these points are denoted by red dots and labeled as $I_{\min}$.

Resonant Full-Wave Loop in Close Proximity to Metallic Structures

The moderately large characteristic impedance of the resonant loop at its feed point (denoted as the loop characteristic impedance from here onward) can be exploited to create an efficient radiator of significant bandwidth and low volumetric profile, by intentionally coupling the loop to surrounding structures such as circuit boards or metallic cases. To explain how this works, first consider a full-wave large loop antenna in isolation designed to operate at 500 MHz, fed from a 50 Ω feed. The top left diagram in Fig. 12 shows a rectangular loop example. In the figure, the loop is a track shown in yellow against an FR4 printed circuit board shown in green, and the location of the antenna feed is shown in red. The printed circuit board is 200 mm long by 100 mm high.

At 500 MHz, it can be seen that the feed impedance is over 150 Ω, the return loss is > -5 dB, and the realized gain is suboptimal at about +1 dBi. The large mismatch between the antenna impedance and the 50 Ω impedance of the feed accounts for a significant proportion of the low realized gain. (Realized gain is defined as radiated power in a given direction compared to the power radiated by an ideal perfectly

DOI 10.1007/978-981-4560-75-7_26-1

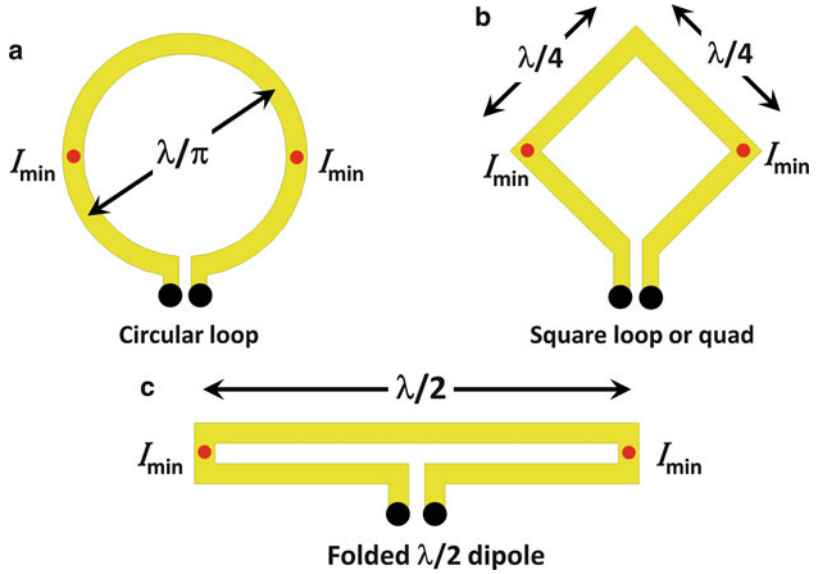

Fig. 11 Some examples of full-wave loop antennas. Around resonance, the radiation resistances of the circular and square loop antennas are approximately 200 Ω, and the radiation resistance of the folded half-wave dipole is approximately 300 Ω. The directivity is usually at a maximum perpendicular to the antenna plane (perpendicular to the plane of the figure). For all the antennas depicted, the radiation pattern is doughnut shaped, with its axis of minimum radiation running horizontally across the figure. The radiation varies slightly with shape, and consequently the maximum directivities are around 1.5 (1.76 dBi) for the circular loop, 1.7 (2.3 dBi) for the square loop, and 1.64 (2.15 dBi) for the folded half-wave dipole

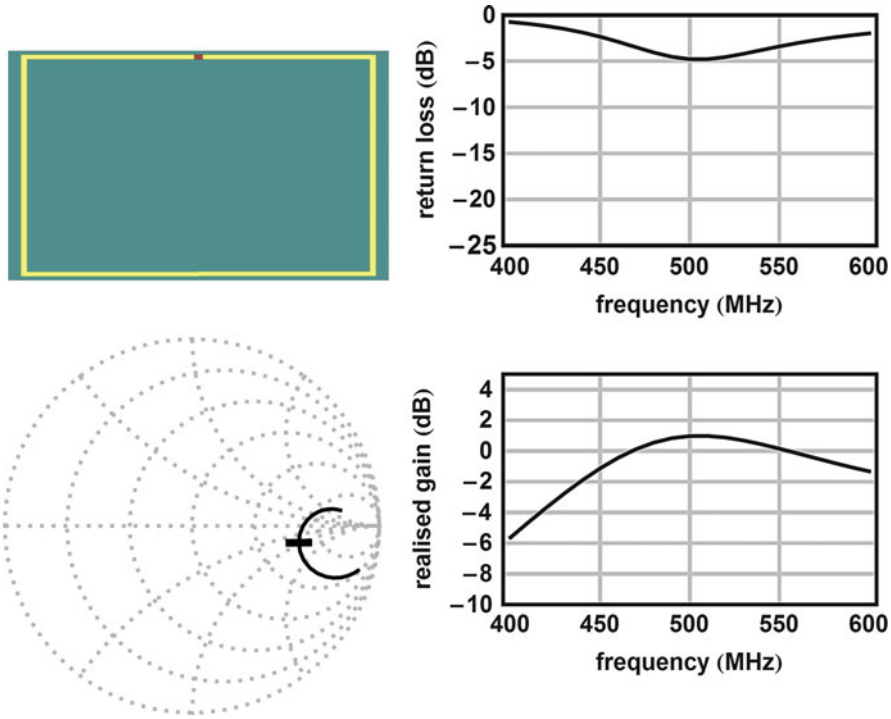

Fig. 12 Basic rectangular full-wave loop on FR4 sheet. The figure shows, in clockwise order from top left, the antenna (see text for description), the return loss response, the realized gain perpendicular to the antenna's board, and the reflection coefficient response between 400 and 600 MHz on a Smith chart whose center is normalized to 50 Ω. In the Smith chart, a marker has been put at 500 MHz

DOI 10.1007/978-981-4560-75-7_26-1

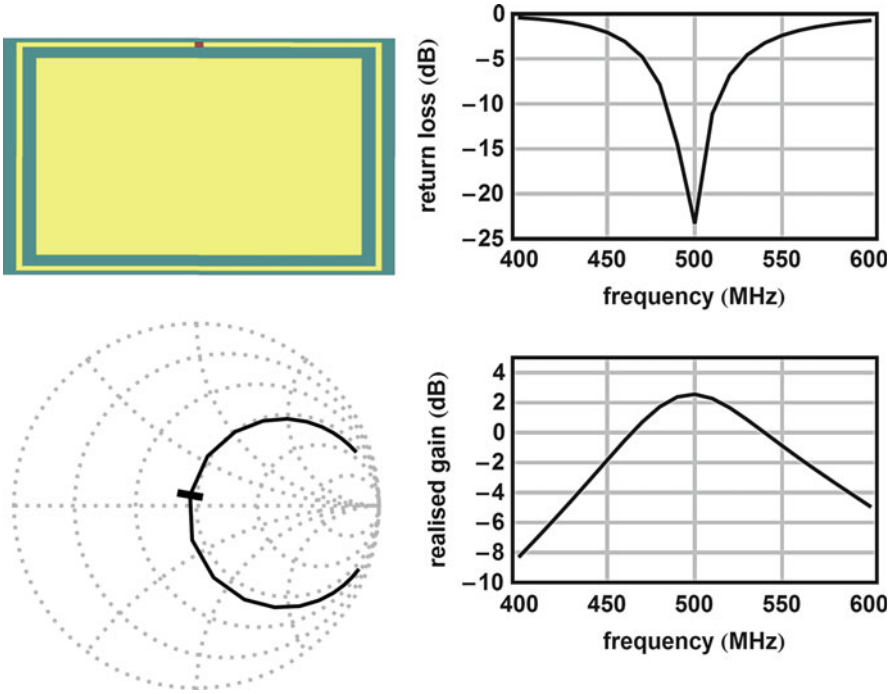

Fig. 13 Basic full-wave loop on FR4 sheet with impedance modification. For key to diagrams, see text below Fig. 12

matched ideal isotropic antenna fed with the same signal.) It should also be noted that the size of the antenna at 500 MHz is such that it takes up a significant area.

Now consider the same antenna operating in the presence of other components. As an example, Fig. 13 shows a copper ground plane (represented by the large yellow rectangle) filling much of the antenna's interior, which in this case represents a circuit board. However, this structure could also be a metallic case or other component part which is conductive in nature. The coupling which occurs between the loop and in this case the copper ground plane results in modification of the loop characteristic impedance. It is therefore possible to use this additional structure to improve the loop antenna's performance; hence, it is considered to be a cooperative structure.

Considering the example of Fig. 13 and comparing the responses to Fig. 12, it can be seen that the addition of the ground plane has led to a significant modification in loop characteristic impedance. The resulting impedance is now much closer to the desired 50 Ω of the feed, and thus the cooperative structure results in an improvement in both match and overall performance of the antenna. Examining the remaining results of Fig. 13 shows that at the design frequency of 500 MHz, the resonance is significantly stronger resulting in a return loss of < -20 dB. The realized gain has also increased to over 2.5 dBi.

Application Example

Applying the principle of what is illustrated in Fig. 13 to a real-life example, consider a small tablet computer. For this example, a single-turn resonant loop antenna has been inserted around the perimeter of the tablet. For this instance, the loop antenna is designed to operate at around 400 MHz. The loop has been positioned to closely couple to the remaining structures in the tablet, in order to modify the impedance appropriately. A simplified computer aided design (CAD) view of the antenna incorporated into the tablet computer is illustrated in Fig. 14, where the loop is highlighted in yellow and closely follows the perimeter of the tablet computer's case.

In the Smith chart, a marker has been at 410 MHz, which corresponds to the resonant frequency realized by this antenna configuration

DOI 10.1007/978-981-4560-75-7_26-1

For this demonstration example, the loop has been designed to operate in the presence of the touch screen, battery, circuit board, and the rear case containing Wi-Fi antennas and a large NFC (Near Field Communication) antenna.

The top left-hand corner in Fig. 15 shows a more detailed CAD image of the tablet computer with the main board populated with circuitry and battery. The "chassis" component shown in Fig. 15 was in its original unmodified incarnation manufactured in a lightweight metallic alloy; however, to implement the perimeter loop antenna, a structural plastic has been used for this component, which prevents shorting out of the loop antenna's fields. The remainder of Fig. 15 shows the simulated results obtained from the installed antenna.

In this demonstration example, and without additional matching, the impedance of the antenna is approximately 25 Ω at the center frequency (410 MHz), and the realized gain is 0.7 dBi, with a −3 dB gain bandwidth in excess of 50 MHz. Four hundred and ten megahertz corresponds to the natural resonant frequency for this particular antenna. Tuning to other frequencies is possible and is discussed in subsection "Tuning Resonant Loop Antennas."

Tested Example and Range Plots

A real-life demonstration example was manufactured consisting of a tablet computer with a retro-fitted loop antenna, as illustrated in Fig. 16a. The tablet computer is shown with its back cover and NFC antenna removed for clarity. The realized gain of the installed antenna configuration is measured and illustrated in Fig. 16b. Figure 16a also indicates the orientation of the axes used in the measurement. For the purposes of the measurement, the antenna is mounted "upside down" compared to the image in Fig. 16a so that its test cable hangs down and runs to the chamber's feed cable without crossing the loop antenna.

The actual resonant frequency of this structure occurs at 425 MHz which is slightly higher in frequency than predicted. This is because several simplifications have been made in the simulation, in order to be able to realize an initial design. Much of the detail, which is present in practice, has not been replicated in simulation. However, the measured magnitudes of the return loss and gain responses (not shown) are similar to those of the simulated model. For the purposes of demonstrating the principle of cooperative structures, the realized gain patterns at 425 MHz are illustrated in Fig. 16b.

It can be seen from both the simulation results in Fig. 15 and the measurement results in Fig. 16 that the full-wave loop structure with its naturally high impedance is ideally suited to applications where an antenna is asked to coexist with metallic structures. These metallic structures can be used in a cooperative manner with loop structures to enable a good installed antenna performance. For other more conventional antennas such as patches or printed inverted F antennas (PIFAs), the presence of metallic structures has a more detrimental impact on the installed antenna performance.

Tuning Resonant Loop Antennas

It has already been shown that a resonant loop antenna can be considered as behaving like a pair of connected dipole antennas (see subsection "Resonant Full-Wave Loop"). This concept can be thought of as the motivation for the following strategy to reduce the resonant frequency of a large loop antenna. The two high-current nodes of the loop antenna are in the centers of its constituent dipole antennas. As illustrated in Fig. 17, i.e., they are at the feed and at a point about halfway around the antenna from the feed.

Placing an inductor at the high-current node halfway around the loop from the feed increases the electrical length of the antenna and lowers its resonant frequency. An example of this arrangement is shown in Fig. 18. If the inductor had been placed closer to the left or right sides of the example in Fig. 18, its effects upon the current distribution and electrical length would have been less.

DOI 10.1007/978-981-4560-75-7_26-1

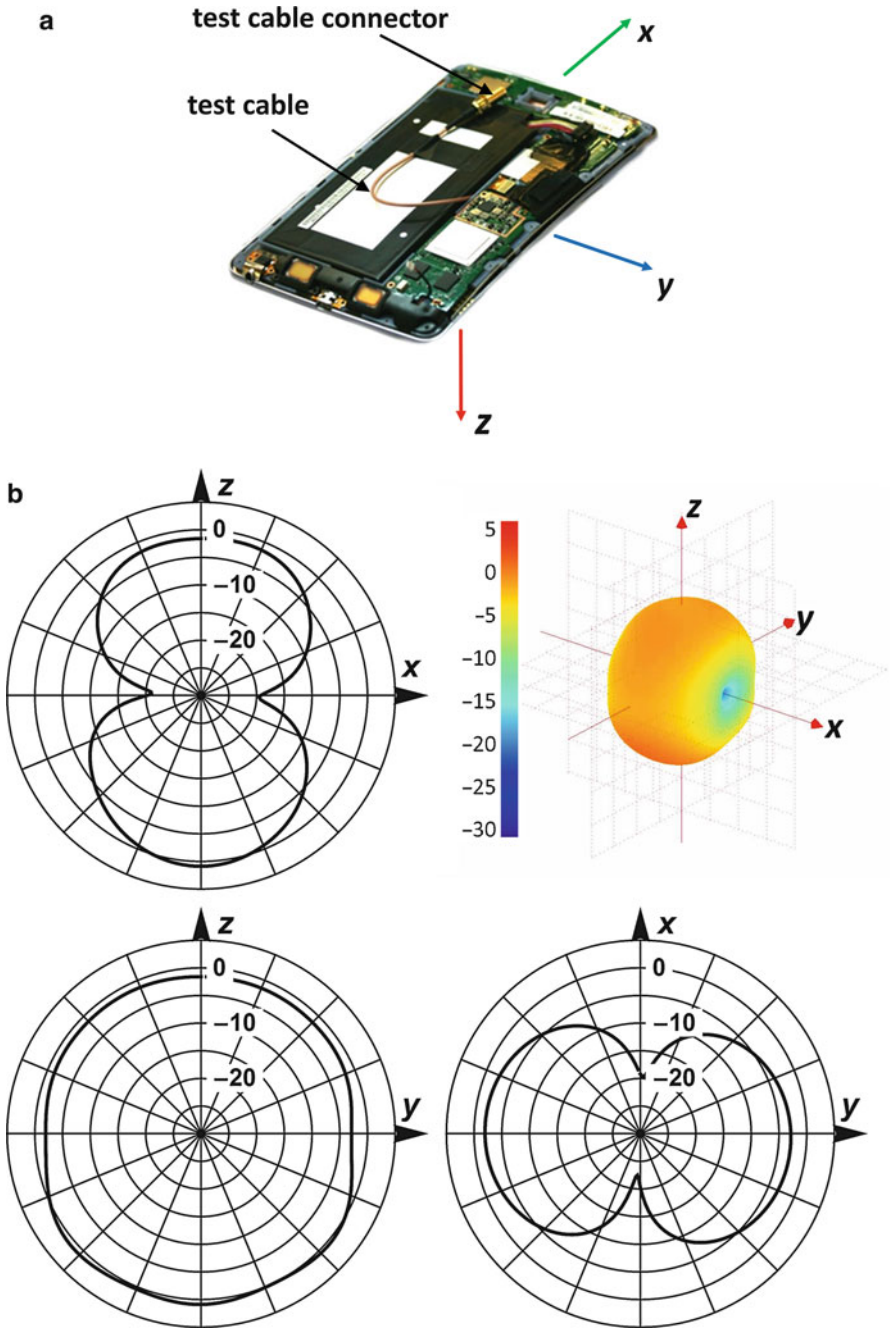

Fig. 16 Tablet computer and its radiation measurement results. See text for description of the figure

The effect of inductor values upon the return loss of the loop is illustrated in Fig. 19. A change in the resonant frequency of the antenna is clearly seen.

It can be seen in Fig. 19 that the impedance modified full-wave loop structure responds well to inductive loading, retaining useful matched bandwidth at all illustrated tuned frequencies. Of course, in a real-life example, the loop to structure coupling would be set with a best match at the center of the tunable frequency range in order to ensure the best possible match at all operating frequencies.

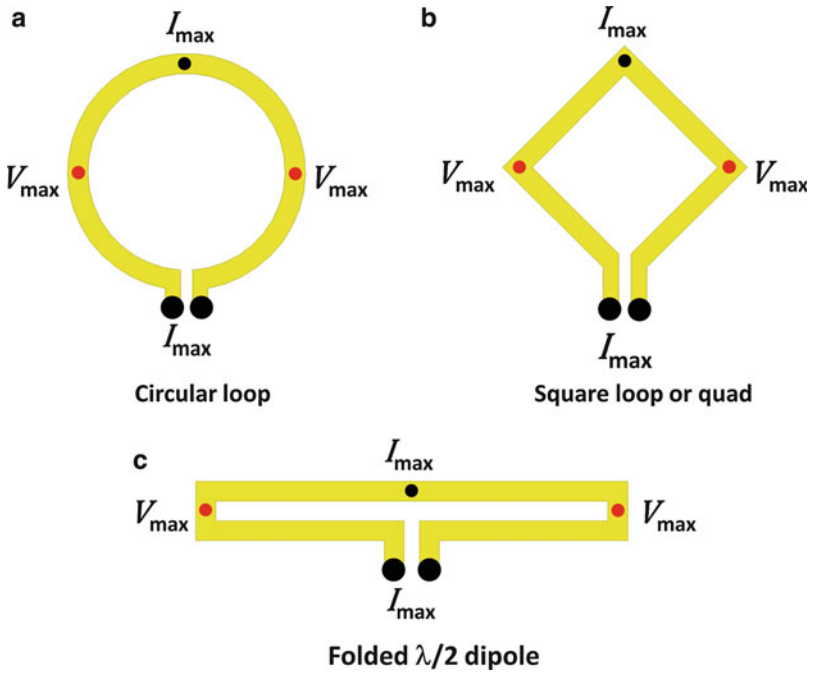

Fig. 17 High voltage and current points on full-wave dipole antennas

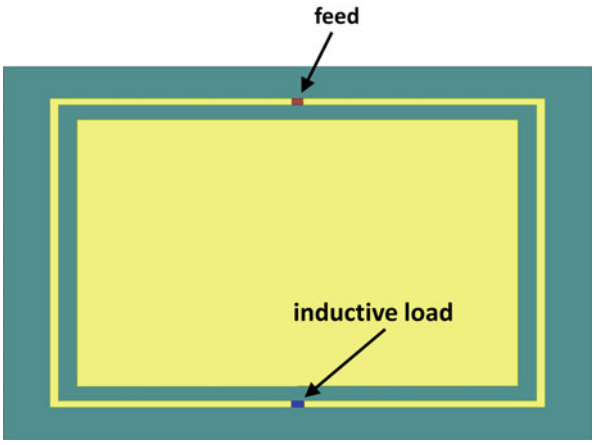

Fig. 18 Location of inductive load at high-current node

Circularly Polarizing the Resonant Loop Antenna

The resonant loop antenna can be further adapted to include a circular polarization response by the inclusion of capacitive gaps in the tracking as illustrated in the example of Fig. 20. These capacitive breaks in the loop structure give rise to a traveling wave current distribution of constant amplitude and linearly changing phase. Circular polarization is normally achieved by breaking the tracking in one place in the loop. For the case shown in Fig. 20, the single break version would retain the break that is closest to the feed point. However, Fig. 20 shows a variation with a pair of breaks as this allows the designer greater scope for adjustment. In this uncluttered example, the antenna's loop is almost exactly one wavelength in circumference, and the capacitors' respective positions are typically at −1/6 λ and +1/3 λ from the feed point, i.e., λ/2 apart. It is important to note that these locations will be significantly influenced by the

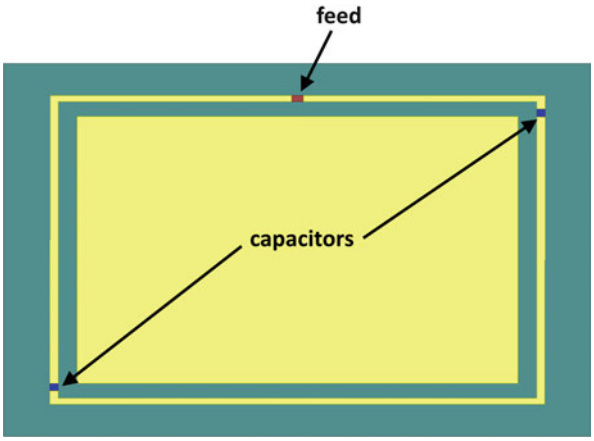

Fig. 20 Capacitor placement for a circularly polarized loop antenna

coupling of the loop to the structure and also by the impact of the substrate and surrounding materials, so should be taken as guidance only.

It is possible to flip the polarization between right and left handed by mirroring of the capacitive breaks in the loop structure from the lower to the upper half of the loop and vice versa. The circularly polarized response can be tuned simply by varying the value of the capacitance and is achieved electronically using varactor diodes or similar devices. The gain and reflection coefficient plots for the circularly polarized loop illustrated in Fig. 20 are shown in Fig. 21.

Dual Banding the Resonant Loop Antenna

One method for dual banding the resonant loop antenna is to proximity couple one or sometimes more secondary loops to the primary driven loop. Secondary loops can be placed either inside, outside, or both inside and outside the driven loop and effectively act as parasitic resonant structures. The example shown below builds on the cooperative structure-loaded loop described at the start of subsection "Resonant Full-Wave Loop in Close Proximity to Metallic Structures" and uses a secondary loop outside the primary loop that has been inductively loaded to further reduce the frequency of the secondary band.

Note that the secondary loop is coupled predominantly along the high-current sections of the antenna, with the high-voltage (low current) sections to the driven loop more widely separated from the secondary

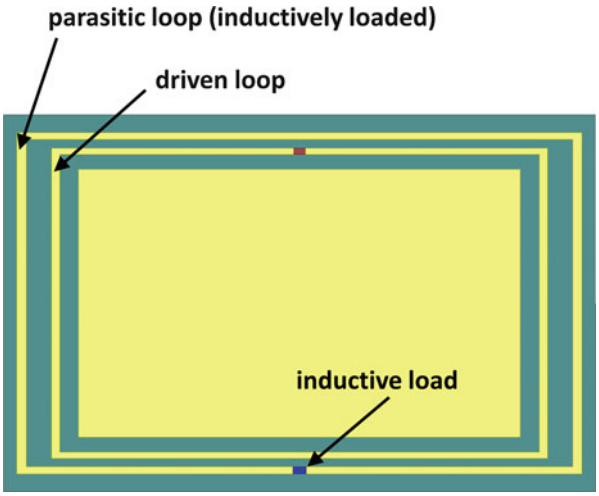

Fig. 22 Dual banding the resonant loop antenna

loop; this prevents the collapse of the electric field at the high-voltage nodes of the primary loop. Figure 23 illustrates the realized gain of the dual loop structure, compared with the single-loop response taken from Fig. 13.

It can be seen in the gain versus frequency plot in Fig. 23 that the lower-frequency response is typically of a higher quality factor (has a narrower peak) than that of the higher frequency band. This is due not only

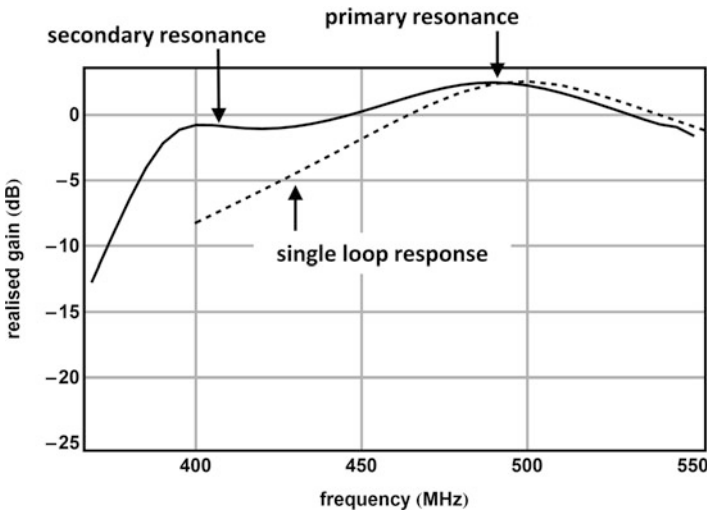

Fig. 23 Realized gain of single and dual loops showing the two resonances realized by the dual loop configuration shown in Fig. 22. The single-loop response is taken from the results shown in Fig. 13

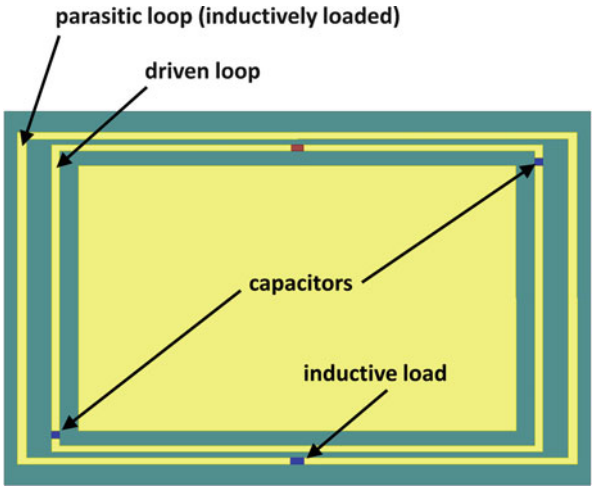

Fig. 24 Dual banding and circularly polarizing the resonant loop antenna

to a reduction in the antenna's electrical size (size in free-space wavelengths) at lower frequencies but is also a function of the coupling action between the loops.

Dual Banding and Circular Polarizing the Resonant Loop Antenna

It is possible to combine two or more of the methods described in the preceding subsections, namely, inductive loading, dual banding, and circularly polarizing. An example is illustrated in Fig. 24. It should be noted here that the parasitic loop has not been capacitively loaded, as the circularly polarized wave from the primary loop couples strongly into the secondary (parasitic) loop. In other instances to obtain circular polarization where the coupling is less strong, it will be necessary to capacitively load the parasitic loop.

Figure 25 illustrates the gain versus frequency response of the antenna illustrated in Fig. 24. The gain is reported for the direction out of the plane of the antenna in Fig. 24 towards the viewer. If the plot were done for the opposite direction into the plane of the antenna, the red and blue traces would be interchanged.

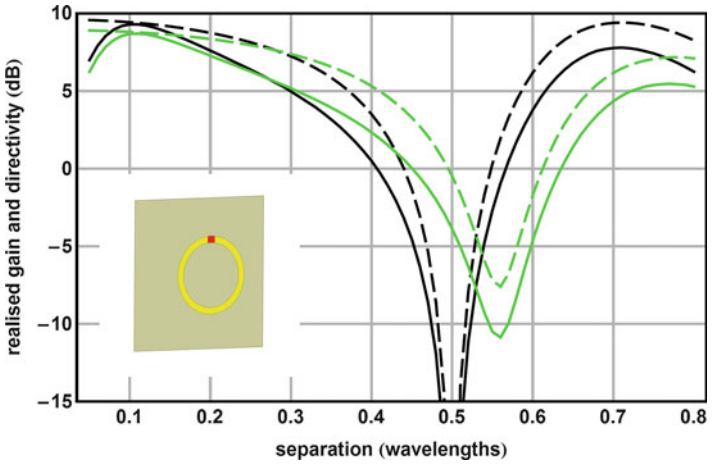

Fig. 26 Directivity and realized gain of resonant loop over infinite ground plane and over planar reflector. See text for the key to the plots and for details of the antenna and reflecting plane

Resonant Loop over Planar Reflector

The full-wave resonant loop element is often used over a ground plane in order to increase its performance in both directivity and gain. The moderately large real input impedance of the loop element in free space is useful, as the proximity of the reflector can be used to adjust the feed impedance of the antenna without adjusting the loop circumference. This allows easy matching to 50 Ω, and thus to being fed from a standard coaxial cable. Figure 26 shows the gain and directivity perpendicular to the reflecting plane, where the radiation is plotted for the loop side of the reflecting plane, in the direction perpendicular to the plane. The directivity is depicted using dashed lines and the realized gain with solid lines. As can be seen in Fig. 26, the single-turn resonant loop has a significantly improved directivity when placed over a reflecting surface.

In Fig. 26, the response over an infinite ground plane is shown in black, and the response over a 2λ/3 long square planar reflector is shown in green. The loop is a flat ring with interior diameter of 0.28λ and exterior diameter of λ/3. The loop and reflecting surface have parallel planes, which are separated by the separation distance, shown on the figure's horizontal axis. Some interesting phenomena can be seen in Fig. 26:

DOI 10.1007/978-981-4560-75-7_26-1

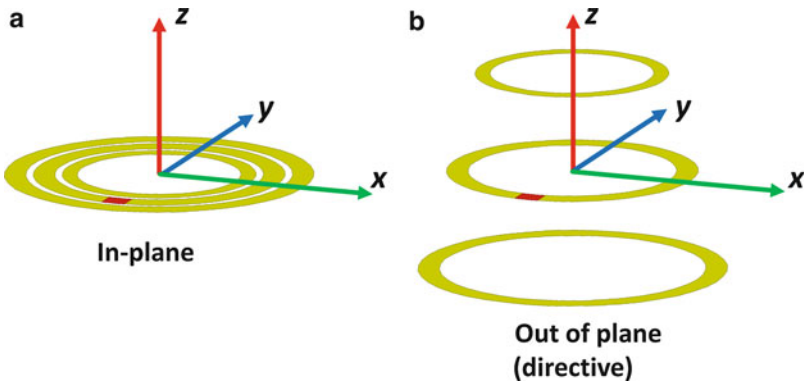

Fig. 27 In-plane coupled loops and the directive out-of-plane derivative

- The loop is best matched to 50 Ω when it is around 0.11 wavelengths from the reflecting surface.
- At small separations, the realized gains and the directivities of the infinite plane and finite reflector cases are very similar, but for a given separation the infinite plane values are slightly higher.
- At half-wavelength separation, the radiation vanishes for the infinite ground plane.
- The radiation of the finite ground case has a minimum at a slightly higher separation but never completely vanishes.
- With increasing separation, the next maximum in gains and directivities is at just over 0.7λ separation. For the infinite ground plane, its magnitude is similar to that of the 0.11 wavelength peak, but in the finite reflector case, it is somewhat reduced.

Directive Resonant Loop Array

So far, only coupled loops lying in the same plane have been discussed, such as that shown on the left-hand side in Fig. 27, which shows a central loop as the driven element, with the outer loop being the low-frequency parasitic element and the inner loop being the higher-frequency parasitic element. Moving the parasitic loops away from the driven loop, as shown on the right-hand side in Fig. 27, gives opportunities for enhanced gain. In a manner similar to parasitic elements in conventional Yagi-Uda arrays of dipoles, the lower-frequency loops become reflectors and the higher-frequency loops act as directors. The reflector can also take the form of a plate (as illustrated in Fig. 26).

It is possible to give some typical rule of thumb sizes for the circumferences of the different elements in order to achieve a directive resonant loop array. They are:

- Reflector: 1.05 wavelengths
- Driven element: 1 wavelength
- Directors: 0.95 wavelengths

The reflector to driven element spacing and driven element to director spacing are highly dependent on the number of elements, and the spacing follows closely the pattern set for the design of a conventional Yagi-Uda antenna of linear elements. In the Yagi-Uda configuration, the reflector is separated from the driven element by approximately 0.15 wavelengths, and there is approximately 0.2 wavelength separation between both adjacent directors and also between the driven loop and its nearest director.

Dual Rhombic/Circular Loop Antenna over Planar Reflector (Biquad Antenna)

The biquad takes several forms, the most notable of which are the parallel- and series-fed variety, shown in Fig. 28. These antennas have a higher gain than the equivalent area patch antenna, and, because of their

DOI 10.1007/978-981-4560-75-7_26-1

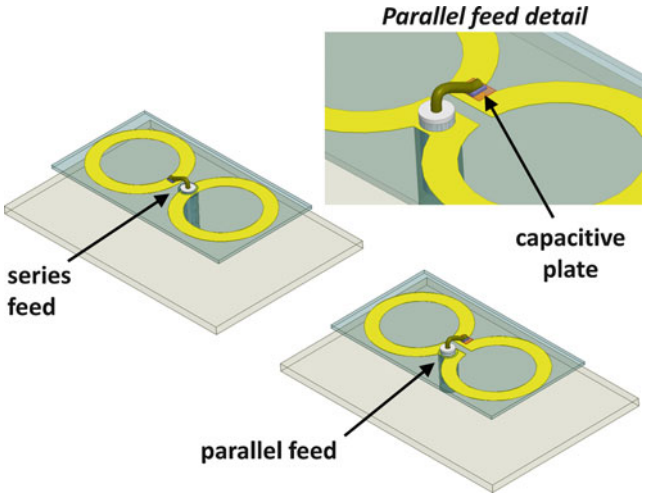

Fig. 28 Series- and parallel-fed versions of the biquad antenna

depth (i.e., distance between the loops and their ground reflector, which is set to optimize the feed impedance), they have significant bandwidths. This coupled with their ease of construction has contributed to their widespread adoption by the hobbyist radio community for the Wi-Fi band. Each loop is typically one wavelength in circumference (measured around the outside of the loop) at the lowest design frequency, with the inner circumference setting the higher part of the resonance band.

Figure 28 also shows two possible feed configurations: a directly connected feed as shown in the series configuration and a capacitive feed as illustrated in the expansion of the parallel configuration. In the capacitive feed arrangement, the center pin of the feed coax is connected to a small capacitive plate, which is located on the opposite side of the board to the metallization which forms the loop (underside of the PCB in Fig. 28). Thus the loop is fed by capacitive coupling to this plate. This configuration provides additional capacitance at the feed point which can be useful for canceling out the additional inductance which results from the exposed center conductor of the feed cable. This additional inductance can be particularly substantial at higher frequencies; thus the capacitive feed variant is highly applicable here. It should be noted that either feed configuration can be used with both the series and parallel versions of the biquad.

Circularly Polarized Dual Rhombic/Circular Loop Antenna over Planar Reflector

The rhombic version of the full-wave loop antenna has four linear sides each measuring about 0.3 wavelengths long. To induce circular polarization, capacitive breaks are introduced into the loop structure, similar to those discussed in subsection "Circularly Polarizing the Resonant Loop Antenna," and a traveling wave current distribution of constant amplitude and linearly changing phase is realized. Capacitor position is typically at $\pm 1/6$th loop length from the feed point (depending on the polarization required). The capacitance can be realized by breaks in tracking or wiring or by using lumped components depending upon construction techniques being employed.

Two circularly polarized rhombic loops are combined to form a dual rhombic loop. The antenna is illustrated in Fig. 29, which shows two possible feed configurations. For clarity, the examples are depicted without showing the ground plane that lies below the loops.

In Morishita et al. (1998), axial ratio bandwidths (<2 dB) of more than 20 % are achieved for both parallel and series feed antennas, with gains of 10 dBi for the parallel-fed version and 11 dBi for the series-fed antenna.

DOI 10.1007/978-981-4560-75-7_26-1

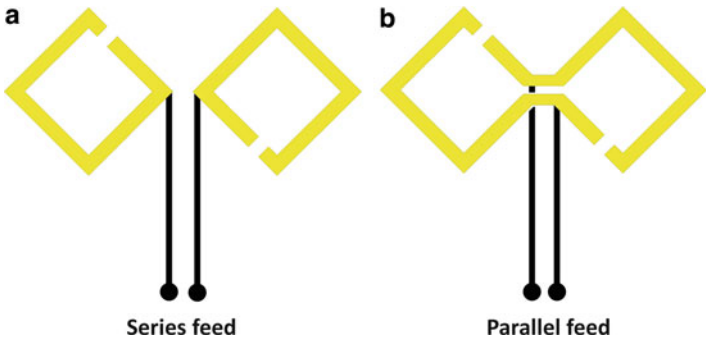

Fig. 29 Circularly polarized biquad concept. See text for description

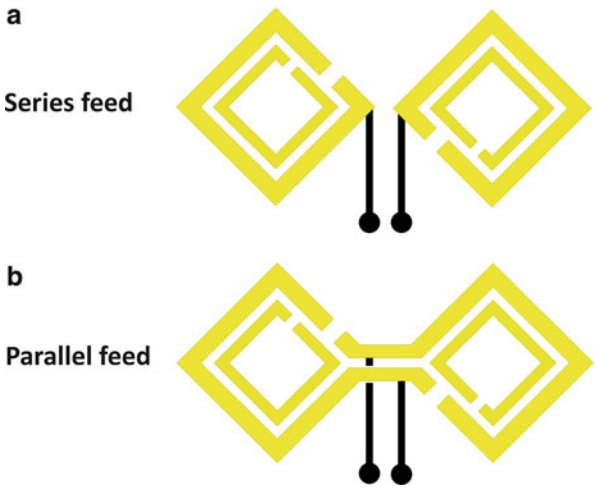

Fig. 30 Wideband circularly polarized resonant loop antennas

Wideband Circularly Polarized Dual Rhombic Loop Antenna with Parasitic Loops

This antenna design expands on the concept of the circularly polarized dual rhombic loop discussed above and introduces a set of smaller parasitic elements within the main driven loops, shown in Fig. 30 (see Li et al. 2005). The parallel-fed structure has a significantly wider circular polarization bandwidth (measured as the −2 dB axial ratio) of 50 %, compared to 25 % for the series-fed arrangement.

Reconfigurable Multi-feed Loops and Their Arrays

Introduction

The previous section on full-wave loop antennas and their derivatives described how loops can be fitted around or near the conducting structures of a device to increase efficiency while adding very little extra volume to the device. This section describes another way in which space can be saved, by reusing the radiating structure of a loop antenna for several different radiation patterns by switching between feeds. In order to have a directive high-gain steering performance, the loop is placed above a ground plane. Further, this section discusses how high-impedance surfaces can be used to reduce the distance between the loop and the ground plane, while keeping good efficiency and controlling the beam shape. Finally, the latest research on array of beam steering loop antennas for achieving high-gain scanning range will be presented.

Background

As mobile communications migrate up from 4G systems to 5G systems and beyond with a promise of enabling consumer end devices (phones, tablets, etc.) to work in excess of 1 giga bit per second, there is a tremendous focus on the development of beam steering antenna technology in order to solve some of the channel problems. The pattern reconfigurable antennas have the ability to generate multiple radiation patterns and are capable of directing the beam toward the intended direction of signal arrival and evade the noise sources. From a transceiver perspective, this means a higher signal-to-noise system capable of offering a higher data throughput capacity. The follow-on benefits include mitigation of multipath effects, reduction in transmitted power levels, longer battery life, range enhancement, reduction in co-channel interference (jamming avoidance), and faster handover. Single-element reconfigurable antennas as presented here are of special significance as they do not require multiple antenna elements with complex phase shifters as in the case of a conventional phased array antenna (Liberti and Rappaport 1999; Pozar 1986). For a near equivalent performance scenario, a single-element adaptive antenna compared with a conventional phased array antenna normally is 75 % smaller, ten times faster, and 95 % cheaper.

Early research and development on single-element beam steering/beam switched/pattern reconfigurable antennas started around 2003–2004 (Huff et al. 2003; Mehta and Mirshekar-Syahkal 2004). Various architectures (Huff and Bernhard 2006; Jung et al. 2006; Mehta et al. 2006), mainly traveling wave types, to realize the single-element steerable antennas were explored. These antennas employed multiple switches to vary the current distribution along the peripheral length for achieving reconfigurable radiation patterns. These early designs had three major restrictions. Firstly, due to the different current distributions, the antenna polarization differs from one switch configuration to another,

DOI 10.1007/978-981-4560-75-7_26-1

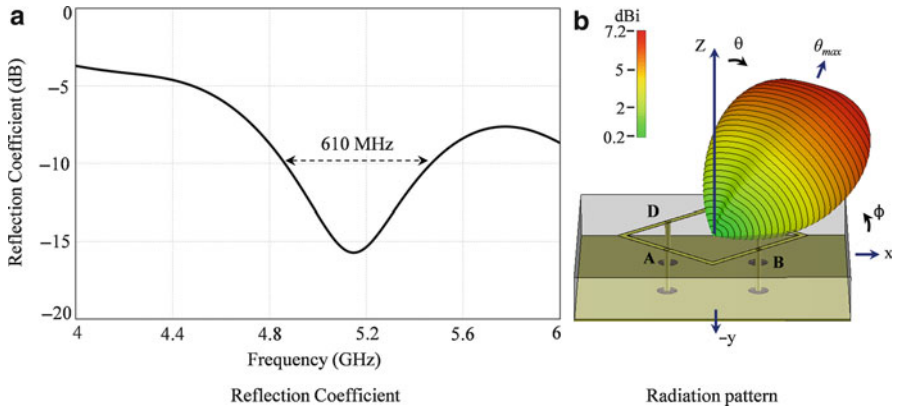

Fig. 32 Frequency response of reflection coefficient of the SLA and radiation pattern at 5.2 GHz

which in effect causes polarization randomness. In situations where a link is polarization sensitive, the polarization randomness can simply make beam steering futile. Secondly, some configurations had many switches which introduced significant RF loss. And finally, none of these designs offered radiation uniformity from one pattern to another.

To overcome these limitations, another form of traveling antenna called symmetric planar square loop antenna (SLA) for switched beam steering applications (Mehta and Mirshekar-Syahkal 2007; Pal et al. 2008) was proposed (Fig. 31). Its structural symmetry offered reconfigurable radiation pattern without any polarization and pattern variation from one beam to another. Since then, that particular SLA has evolved into a much more compact and efficient array configuration. A step-by-step evolution of the antenna for achieving beam steering is presented next.

Radiation Mechanism for Beam Steering

On a ground backed square loop antenna (SLA) of a periphery length greater than 2 × guide wavelength (λ_g), the traveling wave phenomenon dominates, and the antenna radiates a tilted beam ($\theta_{\max} \approx 32^\circ$) in the direction of flow of current. The larger is the periphery in terms of guide wavelength, λ_g, the higher is the beam tilt. For current flowing on a strip backed by substrate of relative permittivity ε_r on one side and air on the other, $\lambda_g = \lambda_0/\sqrt{(1+\varepsilon_r)/2}$ where λ_0 is the free-space wavelength. Figure 31 shows the SLA with four feeding points designed for beam steering applications for the 5 GHz Wi-Fi band. The center and test frequency of the loop is 5.2 GHz. The metal square loop has a periphery length of 120 mm and is etched on Rogers 4350 B substrate whose relative permittivity ε_r is 3.48. The antenna is backed by a ground plane which is at a distance of 9.6 mm. For the center (test) frequency of 5.2 GHz, $\lambda_0 = 57.6$ mm, and for current flowing on 120 mm metal loop, $\lambda_g = 38.7$ mm. Thus, the loop periphery is $3.1\lambda_g$. The antenna has a height of 9.6 mm with planar dimensions of 60.3 × 60.3 mm.

For achieving steering at one time, the antenna is excited at one of the four points, labeled as Ae, and the other three ports (Bo, Co, and Do) are left open circuited. This feeding arrangement creates an asymmetric traveling wave current distribution along the square loop with respect to the whole antenna structure and generates a tilted beam directing to the opposite space quadrant ($0^\circ \leq \phi \leq 90^\circ$) of the excited feed. This is shown in Fig. 32 which also shows that the impedance bandwidth of the antenna is over 12 % (610 MHz). This particular property of tilted beam generation is exploited for beam steering. Since the four feeds are symmetric to each other, by exciting and switching one feed at a time, the tilted beam can be moved in four quadrants of the space in front of the antenna. This concept is depicted in Fig. 33.

DOI 10.1007/978-981-4560-75-7_26-1

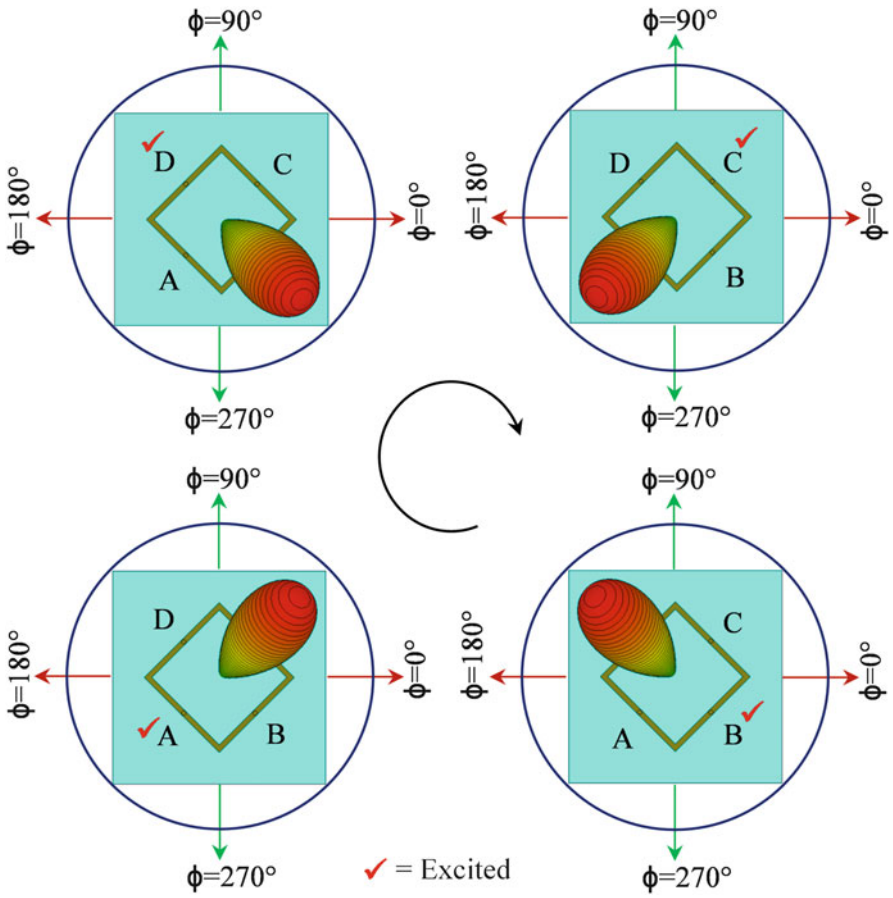

Fig. 33 Demonstration of beam steering by four feeds of SLA. Beam points away from the excited feed

Using High-Impedance Surfaces for Height Reduction

For many modern devices, antennas must be low profile. However, with a height of 9.6 mm, the example presented above is quite thick for implementation in most of the modern portable wireless devices. To overcome this problem, a hybrid high-impedance surface (HHIS) is used for reducing the height by a factor of approximately 50 % (Deo et al. 2010). HHIS is essentially an EBG (electromagnetic bandgap) structure that allows the ground plane to be kept close to the square metal loop without affecting the antenna radiation performance. For this, a two-layer stratified model of substrate is used. The top layer has a height 1.5 mm and is of Rogers's substrate which has $\varepsilon_r = 3.48$ and has the square loop printed on it. This layer is placed over a HHIS substrate layer. That HHIS substrate layer has a height of 3.2 mm and is composed of a 6×6 array of square metal patches on its top surface. Each square has a side length of 8.8 mm with a gap of 1.5 mm between two neighboring patches. The squares on the outer periphery of the HHIS structure are shorted to the ground by metal vias, each having a diameter of 3 mm. The vias are inserted only to the outermost patches to reduce the side lobes emanating from the sides which can cause reduction in directivity. The HHIS layer is then backed by the ground plane and from there four feeding pins go vertically upward toward the loop strip at the top for excitation. This architecture not only reduces the height of the original SLA from 9.6 mm down to 4.7 mm, but it also provides extra bandwidth and higher directivity of 8.8 dBi at $\theta_{\max} = 32°$ and $\phi_{\max} = 45°$. This is shown in Fig. 34.

DOI 10.1007/978-981-4560-75-7_26-1

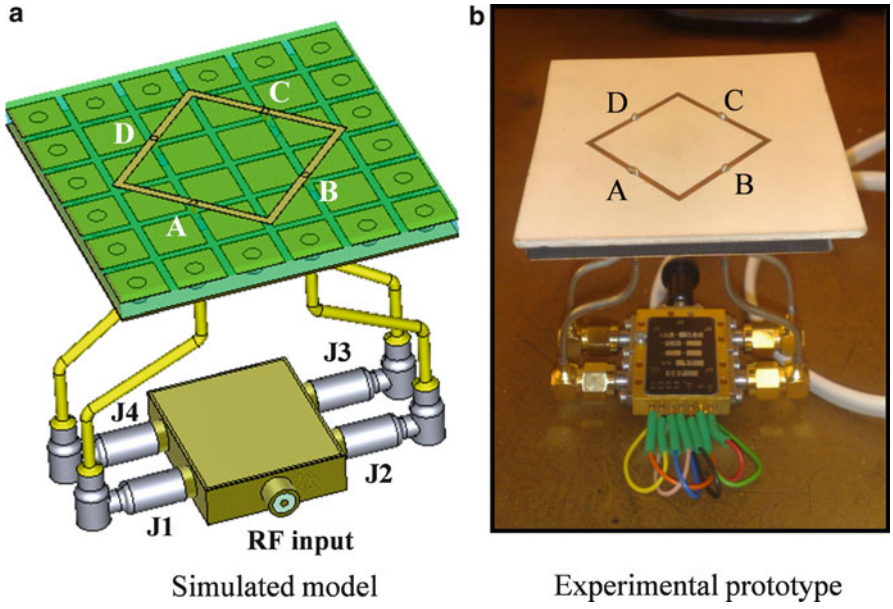

Fig. 35 Simulated and experimental model of the HHIS-based SLA integrated with RF switch (Deo et al. 2011)

Incorporating Electronic RF Switching Circuitry for Electronic Beam Switching

Figure 35 shows the experimental and simulated model for the HHIS-based SLA with the RF switching network. Experimentally, a PIN diode-based RF switch (Deo et al. 2011) is used to connect RF main input to any of the four ports (J1–J4). The selection of one of the four SMA (subminiature version A) connector ports generally can be done via binary control logic from microcontroller providing switching DC voltages linked with a desktop computer running the c algorithm/logic code. For multipath mitigation, the algorithm for the port selection could be fast scan all four ports, measure the received signal/interference (S/I) on all the four ports, compare all four S/I and lock on the port with the highest S/I, and keep monitoring. As mentioned above, by selecting one feed at a time, the SLA can steer its tilted radiation beam in four different space quadrants ($0° \leq \phi \leq 90°$, $90° \leq \phi \leq 180°$, $180° \leq \phi \leq 270°$, and $270° \leq \phi \leq 360°$). With the current developments in PIN diodes, there are PIN diodes available that have: switching speeds in the tens of nanoseconds, low insertion loss (1–2 dB), and high power handling capabilities.

DOI 10.1007/978-981-4560-75-7_26-1

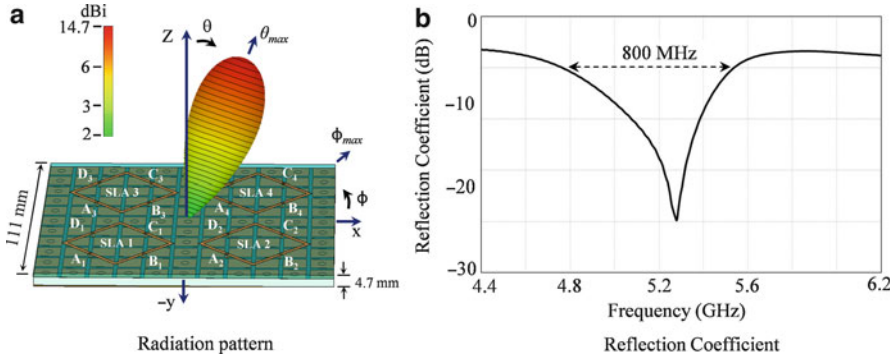

Fig. 36 Radiation pattern of 2 × 2 array of SLA and reflection coefficient for a unit antenna with port A_1 excited and others open circuited

In addition to the four tilted beams in four quadrants, the SLA can also generate a circularly polarized axial (Pal et al. 2013) and a semi-doughnut beam (Pal et al. 2011). For axial, the four ports of the SLA need to be simultaneously excited with quadrature phase shifts. The axial beam would be useful for communicating with vertically located communication systems such as satellites, unmanned aerial vehicles (UAVs), planes, etc. The semi-doughnut can be generated when the four ports of the SLA are simultaneously excited with the same phases. The semi-doughnut pattern is suitable for applications where signal is coming from all the directions but from the top and bottom. Examples for this include receiving radio and digital television from terrestrial station in a moving car/vehicle.

Array of SLAs for High-Gain Wide-Angle Steering, Wide Null Scanning, and Low Grating Lobes

In a phased array antenna system, multiple antenna elements are excited coherently with variable phase to steer the beam in a particular direction and to suppress radiation in undesired directions. They have been traditionally used in several military applications for many years; however, recent advances in wireless communication are drawing attention for utilizing array antenna systems for commercial applications such as 5G, 60 GHz, satellite TV, and cellular base stations as well. The conventional phased array antenna system deploys a grid of ground backed patch or dipole antennas with a fixed radiation pattern, generally axial with typically broadside directivities of 6–7 dBi for patch antennas. According to the phased array theory, the net pattern of an array system is given by multiplication of the unit pattern with the array factor. Thus, the scanning angle and radiation gain of phased array systems are determined by the unit radiation pattern of the single antenna element. The radiation gain of the array decreases by at least 3 dB when the scanning angle of the array increases beyond the half power beam width (HPBW) of the unit pattern. Due to this phenomenon, for such axial systems, the typical 3 dB scanning range is confined within the range from $-40°$ to $+40°$ from the zenith (including a grating lobe < -10 dB criteria). This limited scanning range inhibits the extensive commercial and defense applications of phased array systems which need high-gain signals at off-boresight (tilted) angles as well. This problem can be solved by deploying a pattern reconfigurable SLA as a unit element, which is capable of producing a tilted steerable beam as its fundamental pattern. In essence, the SLA array consisting of pattern reconfigurable unit elements can provide an extra degree of freedom for net pattern formation. Recently, some good work has been published to exploit pattern adaptive behavior of unit element for various applications (Roach et al. 2007; Wu et al. 2010).

As seen from Figs. 32b and 34a, the SLA main radiation is tilted in one direction (high gain on one side and low gain in opposite direction); therefore, its array system will offer a much higher gain in off boresight. Further, in arrays grating lobes start to come into play as the system steers the beam away from

DOI 10.1007/978-981-4560-75-7_26-1

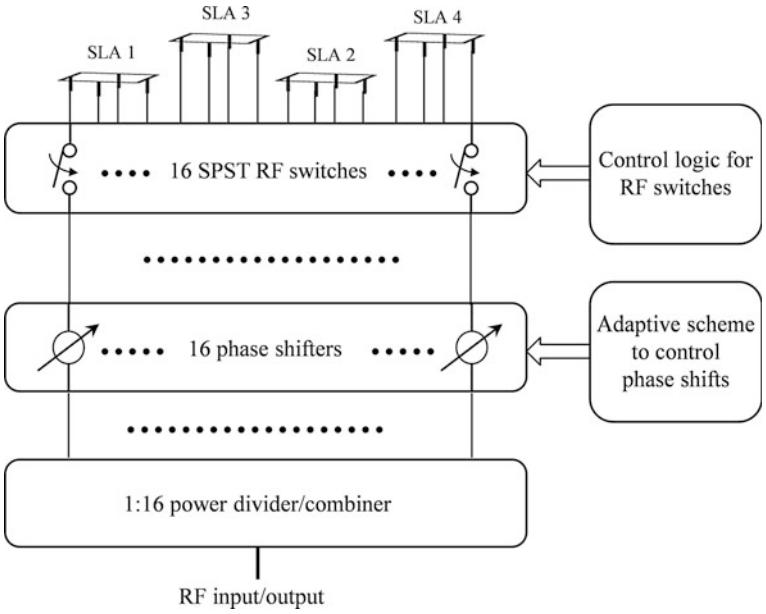

Fig. 37 Block diagram of the feeding network of 2 × 2 array

the unit pattern. For a patch antenna with axial unit pattern, the grating lobes start to get dominant for steering beyond $\theta_{max} > 40°$. However, in the SLA-based array, its antenna elements have tilted beams to begin with: $\theta_{max} \approx 32°$, and hence the array's grating lobes would only appear when the beam is steered beyond $\theta_{max} > 60°$. Besides providing high gain in tilted direction, the SLA can also adapt for boresight steering. As mentioned earlier, Pal et al. (2013) show that the SLA can change its fundamental pattern from tilted to a circularly polarized axial beam by sequential phasing of the four ports. Hence, by combining the SLA tilted beam scanning and axial beam, a complete high-gain scanning range can be achieved, which is not possible with conventional patch or dipole antenna elements. This concept is elaborated next using array of HHIS-based SLA.

HHIS-Based SLA for Demonstrating Gain Beam Steering Using Tilted and Axial Modes

A similar configuration to that described below is presented in Pal et al. (2014).

Figure 36 shows a 2 × 2 array for four HHIS-based square loops. Each SLA loop has the same specification as that of shown in Fig. 34. Again, for side lobe suppression, vias of 3 mm run around the four sides and through the middle of the array for shorting the HHIS patches to the ground. In addition, there are also two via lines that go through the middle of the structure which separates the four individual SLAs. The net planar size of the array is 111 × 111 mm with height staying the same at 4.7 mm. Furthermore, with four feeding ports for each SLA, the net array system has a total of 16 ports which are fed from the bottom side. These ports are labeled as (A_1, B_1, C_1, D_1), (A_2, B_2, C_2, D_2), (A_3, B_3, C_3, D_3), and (A_4, B_4, C_4, D_4). The antenna array operates over 5 GHz Wi-Fi band, and, for port A_1 excited, it has a reflection coefficient bandwidth of 800 MHz (16 %), as shown in Fig. 36b.

This array has two modes of operation: one is for producing steerable high-gain off-boresight tilted beams and the other is for producing a steerable high-gain axial beam. For tilted beam steering, depending upon the quadrant, only four ports are excited at a time and others are left open circuited. For example, for generating a steerable beam in the first quadrant of $0° < \phi < 90°$, the four A ports (A_1–A_4) need to be excited. For axial beam mode, all of the 16 ports need to be excited at the same time, with condition that the four ports of every individual SLA are in phase quadrature with each other. The selection of both these modes can be achieved using a feeding network shown below (Fig. 37). For axial mode, all of the 16 SPST

DOI 10.1007/978-981-4560-75-7_26-1

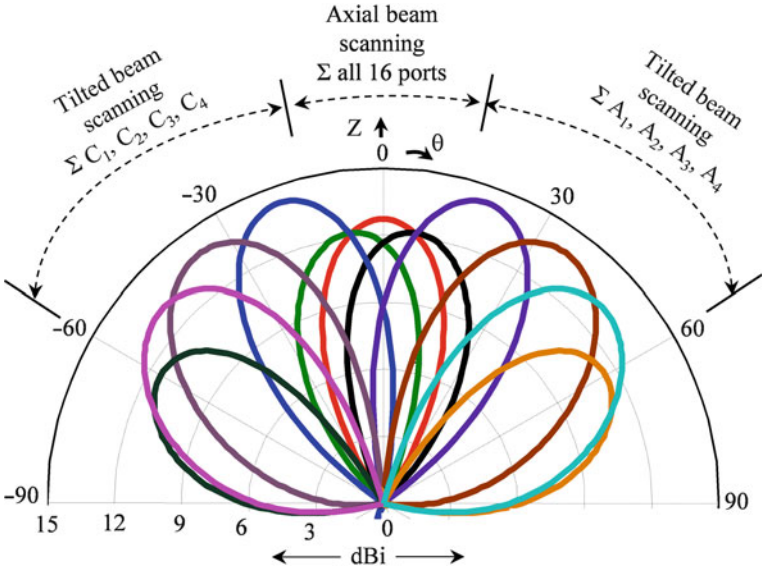

Fig. 38 Block diagram of the scanning of the radiation beam at $\phi_{max} = 45°$

(single pole single throw) RF switches should be on, and for tilted mode, only four SPST should be on and others open circuited. The automated selection of the switch settings and the phase shifts can be done using computer control.

For this 2 × 2 configuration, the antenna array factor is given by Balanis (2005):

$$AF(\theta,\phi) = \frac{1}{4}\left\{\frac{\sin(\psi_x)}{\sin\left(\frac{\psi_x}{2}\right)}\right\}\left\{\frac{\sin\left(\psi_y\right)}{\sin\left(\frac{\psi_y}{2}\right)}\right\} \tag{58}$$

Where:

$$\psi_x = kd_x \sin\theta\cos\phi + \beta_x$$
$$\psi_y = kd_y \sin\theta\sin\phi + \beta_y$$
$$k = 2\pi/\lambda$$
$$d_x = \text{Distance between two elements in } x \text{ direction}$$
$$dy = \text{Distance between two elements in } y \text{ direction}$$
$$\beta_x = \text{Phase shift between two elements in } x \text{ direction}$$
$$\beta_y = \text{Phase shift between two elements in } y \text{ direction}$$
$$\lambda = \text{Wavelength}$$

The maximum radiation beam and grating lobes are located at

$$\begin{aligned} (kd_x \sin\theta\cos\phi + \beta_x) &= \pm 2m\pi \qquad m = 0,\ 1,\ 2,\ \ldots \\ \left(kd_y \sin\theta\sin\phi + \beta_y\right) &= \pm 2n\pi \qquad n = 0,\ 1,\ 2,\ \ldots \end{aligned} \tag{59}$$

DOI 10.1007/978-981-4560-75-7_26-1

To direct the main beam along $\theta = \theta_{\max}$ and $\phi = \phi_{\max}$, the phase shift between the two elements in x- and y-directions must be equal to

$$\begin{aligned} \beta_x &= -kd_x \sin\theta_{\max} \cos\phi_{\max} \\ \beta_y &= -kd_y \sin\theta_{\max} \sin\phi_{\max} \end{aligned} \tag{60}$$

For the 2×2 SLA array, shown in Fig. 36, $d_x = d_y = 51\ \text{mm} = 0.9\lambda_0$. Using the equations above, both the tilted and axial beam maximums were steered in the space for various maximums at different $\theta_{\max}$, and the results for elevation cut at $\phi_{\max} = 45^\circ$ are shown in Fig. 38. It was found that, for tilted beam configuration, a maximum directivity of 14.7 dBi was achieved at $\theta_{\max} = 32^\circ$, and, for an axial beam configuration, a directivity of 13.6 dBi was achieved in the boresight. Hence, together both tilted and axial mode can provide a near constant high-gain (14.7–12.7 dBi) scanning range from -60° to $+60^\circ$ (for pattern having $\leq$10 dB grating lobes). This high-gain wide scanning range is extremely difficult to achieve from a non-reconfigurable phased array system. For example, an array using patch antenna elements (6dBi gain) would need approximately 9 elements to provide a similar boresight gain but still will not be able to provide 14dBi gains at tilted angles. Hence, the proposed system here is of a huge significance when the systems are deployed for covering wide sky, especially for airborne and marine applications.

Conceptual Examples

Problem 1 The concept of radiation resistance R_r is very useful in various applications especially in matching wire antennas including dipole and wire loop antennas to transmitter or receiver circuit. It is defined by the following expression:

$$R_r = \frac{P_{\text{Rad}T}}{|I_0|^2} \tag{61}$$

where I_0 is the rms current and $P_{\text{Rad}T}$ is the power radiated by the antenna, as denoted in subsection "Radiation and Losses."

(a) Considering that the total power radiated by a single-turn small loop antenna is given by

$$P_{\text{Rad}T\text{loop}} \frac{8Z_0\pi^3}{3} \left(\frac{|I_0|A_{\text{LA}}}{\lambda^2}\right)^2 \tag{62}$$

show that the radiation resistance of the loop antenna can be calculated using

$$R_{r\text{loop}} = 31171 \left(\frac{A_{\text{LA}}}{\lambda^2}\right)^2 \tag{63}$$

or using

DOI 10.1007/978-981-4560-75-7_26-1

$$R_{r\text{loop}} = 20\pi^2\left(\frac{C}{\lambda}\right)^4 \tag{64}$$

where C = $2\pi a$ is the perimeter of the loop of radius a.

What would be the expression for the radiation resistance of an n-turn small loop antenna?

(b) Considering that the radiation efficiency of an antenna (Eq. 14) is defined as

$$R.E. = \frac{P_{\text{Rad}T}}{P_{\text{Rad}T} + P_\Omega} \tag{65}$$

show that, for the loop antenna, it reduces to

$$R.E. = \frac{R_{r\text{loop}}}{R_{r\text{loop}} + R_{\Omega\text{loop}}} \tag{66}$$

where $R_{\Omega\text{loop}}$ is known as the Ohmic loss resistance of the loop antenna.

(c) Show that the Ohmic loss resistance of a single-turn loop antenna of radius a and wire diameter d larger than the current skin depth δ (i.e., $d > \delta$ where $\sqrt{2/(\omega\mu_0\sigma)}$) is given by

$$R_{\Omega\text{loop}} = \left(\frac{a}{d}\right)\rho_S \tag{67}$$

where $\rho_S = \sqrt{\omega\mu_0/(2\sigma)}$ is the surface resistance. Note σ is the conductivity of the loop metal/alloy and related to the resistivity ρ through $\sigma = 1/\rho$.

(d) Calculate the radiation resistance, the loss resistance, the efficiency, the Q factor, and the input impedance of a single-turn loop antenna made of a silver wire of conductivity $\sigma = 6.3 \times 10^7$S/m. This loop antenna has a radius of $a = \lambda/30$ and a wire radius of $d = \lambda/3000$, and is designed to operate at 200 MHz.

(e) In order to operate (resonate) the loop antenna at 200 MHz, a capacitor is connected in parallel across the two terminals of the loop. Calculate the value of the capacitor and the input impedance of the antenna at resonance. What would happen to the resonant frequency and the input impedance of the antenna if the capacitor is connected in series with the loop?

Solutions

(a) Inserting $P_{\text{Rad}T\text{loop}} = 8Z_0\pi^3\left(|I_0|A_{\text{LA}}/\lambda^2\right)^2/3$ in the radiation resistance definition leads to

$$R_r = \frac{P_{\text{Rad}T}}{|I_0|^2} = \frac{8Z_0\pi^3}{3}\left(\frac{A_{\text{LA}}}{\lambda^2}\right)^2 \tag{68}$$

i. Since the intrinsic impedance of air $Z_0 = 120\pi = 377\Omega$, the expression for R_r transforms to the following equation: $R_r = 8 \times 120\pi \times \pi^3\left(A_{LA}/\lambda^2\right)^2/3 = 31171\left(A_{\text{LA}}/\lambda^2\right)^2$.

ii. Since the loop area $A_{\text{LA}} = \pi a^2$, the expression for R_r can be written as follows:

DOI 10.1007/978-981-4560-75-7_26-1

$$R_r = \frac{8Z_0\pi^3}{3}\left(\frac{\pi a^2}{\lambda^2}\right)^2 = \frac{120\pi \times \pi}{2 \times 3}\left(\frac{2\pi a}{\lambda}\right)^4 \tag{69}$$

Substituting for the perimeter, $C = 2\pi a$, in the above equation gives $R_r = 20\pi^2(C/\lambda)^4$

When the loop antenna is n-turn, the current can be assumed to have weighted by a factor of n, i.e., $I_0 \rightarrow nI_0$. Therefore, the radiated power increases by a factor of n^2 (see the expression for radiated power). This means that R_r of an n-turn loop antenna is n^2 of that of the single-turn loop antenna.

(b) Using the definition of the radiation resistance $R_r = P_{\mathrm{Rad}T}/|I_0|^2$, the total power radiated by the loop antenna is

$$P_{\mathrm{Rad}T} = R_{r\mathrm{loop}}|I_0|^2 \tag{70}$$

Similarly, the total Ohmic power loss born by the single loop antenna is

$$P_\Omega = R_{\Omega\mathrm{loop}}|I_0|^2 \tag{71}$$

Inserting these equations in the expression for radiation efficiency, $R.E. = P_{\mathrm{Rad}T}/(P_{\mathrm{Rad}T} + P_\Omega)$, leads to

$$R.E. = \frac{P_{\mathrm{Rad}T}}{P_{\mathrm{Rad}T} + P_\Omega} = \frac{R_{r\mathrm{loop}}|I_0|^2}{R_{r\mathrm{loop}}|I_0|^2 + R_{\Omega\mathrm{loop}}|I_0|^2} = \frac{R_{r\mathrm{loop}}}{R_{r\mathrm{loop}} + R_{\Omega\mathrm{loop}}} \tag{72}$$

(c) The surface resistance, ρ_S, is in Ohms per square (Omega/sq). As the current flows along the loop, the loss resistance of the loop is obtained as follows:

$$R_{\Omega\mathrm{loop}} = \frac{\rho_S}{2\pi d}2\pi a = \frac{a}{d}\rho_S \tag{73}$$

It should be noted that the loss resistance of a loop antenna with n turns is not simply n times of that of its single loop. This is because there is an interaction between the fields of the loops, changing the current distribution and hence the value of the loss resistance. However, if the loops are sufficiently separated, the n-time approximation can be used.

(d) To find the radiation resistance of the antenna, the radius of the loop, $a = \lambda/30$, is used to find the area of the antenna:

$$A_{\mathrm{LA}} = \pi a^2 = \pi\left(\frac{\lambda}{30}\right)^2 \tag{74}$$

Then, this area is inserted in the expression for the radiation resistance:

DOI 10.1007/978-981-4560-75-7_26-1

$$R_{r\text{loop}} = 31171\left(\frac{A_{\text{LA}}}{\lambda^2}\right)^2 = 31171\left[\frac{\pi\left(\frac{\lambda}{30}\right)^2}{\lambda^2}\right]^2 = 31171\left(\frac{\pi}{30^2}\right)^2 = 0.38\,\Omega \tag{75}$$

To calculate the loss resistance, first the surface resistivity is determined:

$$\rho_S = \sqrt{\frac{\omega\mu_0}{2\sigma}} = \sqrt{\frac{\pi \times 200 \times 10^6 \times 4\pi \times 10^{-7}}{6.3 \times 10^7}} = 3.54 \times 10^{-3}\,\Omega \text{ per square.} \tag{76}$$

Then, the surface resistance; the loop radius, $a = \lambda/30$; and the loop wire radius, $d = \lambda/3000$, are inserted in the expression for the loss resistance:

$$R_{\Omega\text{loop}} = \left(\frac{a}{d}\right)\rho_S = [(\lambda/30)/(\lambda/3000)] \times 3.54 \times 10^{-3} = 0.35\Omega \tag{77}$$

Therefore, the radiation efficiency of the antenna is

$$R.E. = \frac{R_{r\text{loop}}}{R_{r\text{loop}} + R_{\Omega\text{loop}}} = \frac{0.38}{0.38 + 0.35} = 52\% \tag{78}$$

To calculate the Q factor of the antenna, the value of the inductance of the loop is required. This inductance, L, is the sum of the external inductance, $L_{ext\text{loop}}$, and the internal inductance, $L_{int\text{loop}}$, of the loop:

$$L = L_{ext\text{loop}} + L_{int\text{loop}} \tag{79}$$

The external inductance, associated with the storage of the magnetic field external to the loop wire, is obtained using an approximate expression (Johnson and Jasik 1993):

$$L_{ext\text{loop}} = \mu_0 a\left[\ln\left(\frac{8a}{d}\right) - 2\right] = 4\pi \times 10^{-7}\left(\frac{1.5}{30}\right)\left[\ln\left(\left(\frac{\lambda}{30}\right)/\left(\frac{\lambda}{3000}\right)\right) - 2\right] = 2.94 \times 10^{-7}\text{H} \tag{80}$$

The internal inductance, associated with the storage of the magnetic field within the loop wire, is obtained using

$$L_{int\text{loop}} = \frac{1}{\omega}\left(\frac{a}{d}\right)\rho_S = \frac{1}{\omega}R_{\Omega\text{loop}} = \frac{0.35}{2 \times \pi \times 200 \times 10^6} = 2.8 \times 10^{-10}\text{H} \tag{81}$$

As can be seen, $L_{ext\text{loop}} \gg L_{int\text{loop}}$ and this is normally the case and hence $L_{int\text{loop}}$ can be ignored. Therefore, the Q factor of the loop antenna is

$$Q = \frac{\omega L}{R_{r\text{loop}} + R_{\Omega\text{loop}}} \cong \frac{2\pi \times 200 \times 10^6 \times \left(2.94 \times 10^{-7}\right)}{0.38 + 0.35} = 506 \tag{82}$$

To calculate the input impedance of the antenna, the equivalent circuit of the loop antenna is used. In

DOI 10.1007/978-981-4560-75-7_26-1

this circuit, the radiation and loss resistance are in series with the inductance of the loop antenna. Therefore,

$$Z_{in\text{loop}} = R_{r\text{loop}} + R_{\Omega\text{loop}} + j\omega L \cong 0.38 + 0.35 + j2\pi \times 200 \times 10^6 \times 2.94 \times 10^{-7} = 0.73 + j369.5\Omega \tag{83}$$

As expected, the input impedance is very inductive.

(e) To find the capacitance C of the capacitor, the input admittance of the antenna is formed as the capacitor is connected in parallel with the loop:

$$Y_{in} = jC\omega + \frac{1}{R + jL\omega} \tag{84}$$

where $R = R_{r\text{loop}} + R_{\Omega\text{loop}}$ and $L = L_{ext\text{loop}} + L_{int\text{loop}}$. This can be written as follows:

$$Y_{in} = \frac{R + j\left\{C\omega\left[R^2 + (L\omega)^2\right] - L\omega\right\}}{R^2 + (L\omega)^2} \tag{85}$$

At resonance, the imaginary part of the input admittance vanishes. Therefore,

$$C\left[R^2 + (L\omega)^2\right] - L = 0 \tag{86}$$

from which the value of capacitance is obtained:

$$C = \frac{L}{\left[R^2 + (L\omega)^2\right]} \cong \frac{1}{L\omega^2} = \frac{1}{2.94 \times 10^{-7} \times \left(2\pi \times 200 \times 10^6\right)^2} = \frac{1}{0.464 \times 10^{12}} = 2.15\text{pF} \tag{87}$$

In the above and following calculations, the resistance is ignored as it is much smaller than the reactance.

The input impedance of the antenna at resonance is found using the input admittance at resonance:

$$Y_{in} = \frac{R}{R^2 + (L\omega)^2} \tag{88}$$

$$Z_{in} = \frac{R^2 + (L\omega)^2}{R} \cong \frac{(L\omega)^2}{R} = \frac{\left(2.94 \times 10^{-7} \times 2\pi \times 200 \times 10^6\right)^2}{0.38 + 0.35} = 187\,\text{k}\Omega \tag{89}$$

When the capacitor is connected in series with the loop, the resonant frequency of the antenna stays nearly the same as before (200 MHz). However, the input impedance at resonance changes drastically to a small value and is equal to

$$R = R_{r\text{loop}} + R_{\Omega\text{loop}} = 0.38 + 0.35 = 0.73\Omega \tag{90}$$

DOI 10.1007/978-981-4560-75-7_26-1

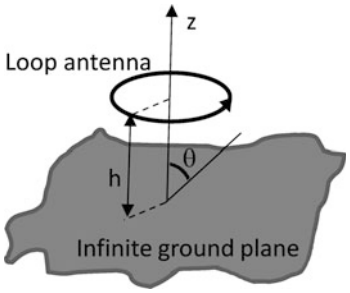

Fig. 39 Loop antenna parallel to and above an infinite perfectly conducting plane, discussed in problem 2

Comments

1. Capacitors have quality factors Q_C that are typically in the range of ~200 (for low-cost variable capacitors) to ~2,000 for high-quality capacitors. For the 2.15 pF capacitor of this example, using the relation $Q_C = 1/(\omega C\, R_{Sc})$ where R_{SC} is the effective series resistance of the capacitor, gives R_{SC}~2 Ω (for Q_C~200) to R_{SC}~0.2 Ω (for Q_C~2,000). These values are comparable to those of $R_{r\text{loop}}$ and $R_{\Omega\text{loop}}$ of the loop antenna and shows that in practice the losses associated with nonideal capacitors should be considered in the design calculations. The details of the mathematics for this are beyond the scope of these examples. However, by an extension of the analysis described above, it can be shown that, in general, the effect of the finite quality factor of a real-life capacitor is to reduce the resonant impedance of the loop tuned with a capacitor in parallel and to increase the resonant impedance of the loop tuned with a capacitor in series.
2. Transmitters and receivers generally require impedances that lie between the two extremes calculated above for series and parallel capacitor tuning. This observation can be thought of as an inspiration for the combined series and parallel capacitor tuning arrangement shown in Fig. 8b, which is capable of giving any impedance between the very low-impedance case with series capacitors only (parallel capacitance vanishes) to the very high-impedance case with the parallel capacitor providing practically all of the tuning and the series capacitors having such high capacitances that they appear to have negligible reactance.

Problem 2 Consider a small loop antenna horizontally placed at a distance h over an infinite size perfect conductor (Fig. 39). Assuming that the radiation pattern of this antenna in the absence of the ground plane varies according to the following expression:

$$E_\phi = k \sin(\theta) \tag{91}$$

where k is constant, find an expression for the radiation pattern of this antenna when the ground plane is present.

Solution As the ground is a perfect conductor, it can be replaced by the image of the loop antenna. This image is another loop antenna at distance h from the surface of the ground plane, and it carries a current opposite to that of the original loop antenna. In other words, there is a phase shift of π between the currents of the two elements. The system can be assumed as a linear array of two loop antennas. In un-normalized form, the array factor for a linear array of N elements is

DOI 10.1007/978-981-4560-75-7_26-1

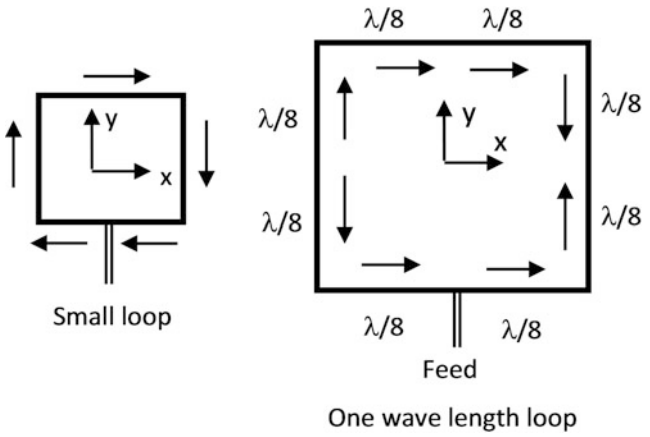

Fig. 40 Current distribution on a square loop antenna

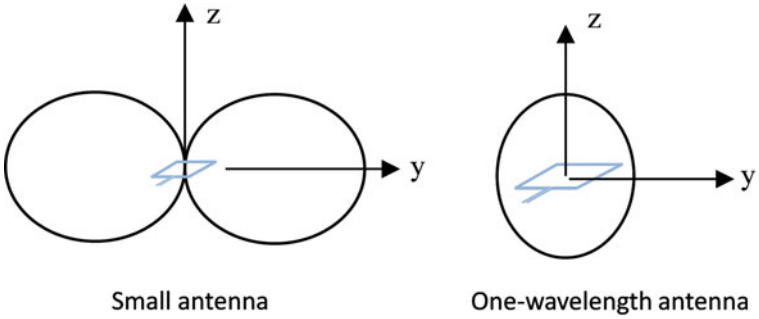

Fig. 41 The yz-cut of the radiation pattern of square loop antenna

$$AF = \frac{\sin\left(\frac{N}{2}\Psi\right)}{\sin\left(\frac{1}{2}\Psi\right)} \tag{92}$$

where $\Psi = \beta s \cos\theta + \alpha$. In this case, the separation between the elements $s = 2h$, the number of elements $N = 2$, and the progressive phase $a = \pi$. Therefore, the array factor simplifies to

$$AF = \frac{\sin\left[\frac{2}{2}\left(\frac{2\pi}{\lambda}2h\cos(\theta)+\pi\right)\right]}{\sin\left[\frac{1}{2}\left(\frac{2\pi}{\lambda}2h\cos(\theta)+\pi\right)\right]} = \frac{\sin\left[\frac{2\pi}{\lambda}2h\cos(\theta)+\pi\right]}{\sin\left[\frac{1}{2}\left(\frac{2\pi}{\lambda}2h\cos(\theta)+\pi\right)\right]}$$
$$= 2\cos\left[\frac{1}{2}\left(\frac{2\pi}{\lambda}2h\cos(\theta)+\pi\right)\right] \tag{93}$$

Then, the overall radiation pattern is found using the pattern multiplication rule:

$$E_{\phi T} = \text{antenna (element) pattern} \times \text{array factor} = 2k\sin(\theta)\cos\left[\left(2\frac{h}{\lambda}\cos(\theta)+\frac{1}{2}\right)\pi\right] \tag{94}$$

DOI 10.1007/978-981-4560-75-7_26-1

From this expression, several conclusions can be made:

i. $E_{\phi T} = 0$ along the loop axis ($\theta = 0$).
ii. $E_{\phi T} = 0$ over the ground plane ($\theta = \pi/2$).
iii. $E_{\phi T}$ has beam direction and directivity which varies with h/λ.

Problem 3 Assume that a square loop antenna fed as shown in Fig. 40 lays in the x-y plane with its center at the origin of the coordinate system. Sketch the radiation pattern of the antenna in the y-z plane for the two cases of small square loop antenna and one-wavelength square loop antenna.

Solution Since the current is approximately uniform on the wire of the small square loop antenna (Fig. 40; left), the radiation pattern is similar to that of the small circular loop antenna. Therefore, the pattern is omnidirectional with its yz-cut shown in Fig. 41 (left).

The pattern of the one-wavelength square loop antenna is more complex if one considers the current distribution of this antenna at the first resonance as shown in Fig. 40 (right). Since the currents in the left and right arms of the antenna are opposite, they contribute little to the radiation. The currents in the top and bottom arms are the main contributors. These arms can be considered as the array of two dipole antennas separated by a distance of quarter wavelength. In this case, the yz-cut of the pattern has the maximum radiation occurring along the z-axis (due to the constructive interference of the fields of the two dipoles) (Fig. 41; right). In the y-direction, the radiation strength is about half of that in the z-direction (due to the vector sum of the two fields of the dipoles with 90° phase shift) (Fig. 41; right). The cuts of the radiation pattern in the two other principle planes can also be predicted. In the x-z plane, the radiation has nulls in the ±x-directions and is maximum in the ±z-directions. In the x-y plane, the radiation has nulls along the x-axis and has a value about half of that along the z-axis (as explained earlier). Also, see Fig. 16 of subsection "Tested Example and Range Plots" for the radiation pattern of an antenna example similar to that in this problem.

Conclusion

This chapter describes three classes of loop antennas in order of their size in wavelengths: electrically small loop (and coil) antennas, full-wave loop antennas, and reconfigurable multi-feed loops. This ordering also reflects the historical development of loop antennas, with the electrically small loop antennas coming early in the history of wireless development and reconfigurable multi-feed loops still being a current research topic.

Throughout loop antenna history, their ubiquity has inevitably led them being combined with other innovations. For example, electronically small loop antennas were among the first to be used in a commercial product with antenna diversity – by the early 1950s, radios were sold with a pair of loops angled away from each other, and the user could switch between loops for the best reception (Blok and Rietveld 1955). After World War II, electrically small loop antennas were combined with the then very new soft ferrite material to give smaller antennas with similar sensitivity and less noise reception through reducing the aerial effect. Today, reconfigurable multi-feed loops are placed above high-impedance surfaces, to reduce the distance between the loop and its backing ground plane, and also because the high-impedance surface is found to improve isolation between a loop's feeds.

Loop antenna research continues to be a very active field. A search of the IEEE Xplore database for articles published between the beginning of 2014 and June 2015 (the date when the search was conducted) revealed 123 papers with "loop antenna" in their titles, and over three times this number in which loop

DOI 10.1007/978-981-4560-75-7_26-1

antennas played a significant role. Over the last few years, popular research and application areas have included:

1. Creating loops from metamaterial structures (e.g., Nakano et al. 2013a; Zhang et al. 2015)
2. Loop antennas in medical on-body and implant applications (e.g., Alrawashdeh et al. 2014; Lee and Jung 2015)
3. Loop antennas in handheld multiband mobile phone devices (e.g., Ban et al. 2015)
4. Using loops as circularly polarized elements in arrays (e.g., Nakano et al. 2013b; Hirose et al. 2012, 2015a, b)

In view of the recent nature of the newer publications, it is difficult to predict how these topics would develop and which developments would prove to be the most significant. However, what is certain is that electrically small loop antennas will continue to have a significant role in antennas for products designed to be worn against the user's body and in other portable devices. In addition, the unique ability of traveling wave loops to provide broad impedance bandwidth and adaptive antenna element pattern will enable the realization of wideband reconfigurable arrays for communications and sensor networks.

Microstrip Patch Antennas

Kai Fong Lee[a]* and Kin-Fai Tong[b]
[a]Department of Electrical Engineering, The University of Mississippi, University, USA
[b]Department of Electronic and Electrical Engineering, University College London, London, UK

Abstract

The basic geometry of a microstrip patch antenna (MPA) consists of a metallic patch which is either printed on a grounded substrate or suspended above a ground plane. The antenna is usually fed either by a coaxial probe or a stripline. In the coaxial case, the center conductor is directly connected to the patch and the outer conductor to the ground. In the stripline case, energy is coupled to the patch in several ways: by direct connection, by proximity coupling, and by aperture coupling. The patch antenna idea appeared to be originated in the early 1950s, but there was little activity for almost two decades, mainly due to its inherent narrow bandwidth. It began to attract the serious attention of the antenna community in the 1970s, as antenna designers began to appreciate the advantages offered by this type of antennas, which include low profile, conformability to a shaped surface, ease of fabrication, and compatibility with integrated circuit technology. In the last three decades, extensive studies have been devoted to improving the bandwidth and other performance characteristics. This chapter begins with a brief description of the modeling techniques and basic characteristics of the MPA. Methods for broadbanding are then discussed, followed by dual- and multiband designs, size reduction techniques, circularly polarized patch antennas, and frequency-agile and polarization-agile designs. The chapter ends with some concluding remarks.

Keywords

Microstrip antennas; Wideband patch antennas; Patch antennas for circular polarization; Small-size patch antennas; Dual- and multiband patch antennas

Introduction

The idea of microstrip patch antennas arose from utilizing printed circuit technology not only for the circuit components and transmission lines but also for the radiating elements of an electronic system. The basic geometries are shown in Fig. 1. It consists of a metallic patch which is either printed on a grounded substrate or suspended above a ground plane and fed against the ground at an appropriate location. The patch shape can in principle be arbitrary. In practice, the rectangle, the circle, the equitriangle, and the annular ring are common shapes. Feeding is usually by a coaxial probe or a stripline. The latter can be directly connected to the patch, or proximity coupled to the patch, or coupled through an aperture. These are illustrated in Fig. 2 for the rectangular patch. Electromagnetic energy is first guided or coupled to the region under the patch, which acts like a resonant cavity with open circuits on the sides. Some of the energy leaks out of the cavity and radiates into space, resulting in an antenna.

The advantages and disadvantages of the four feeding methods are listed in Table 1. Of the four, the coaxial feed and the direct stripline feed are the most common.

	Advantages	Disadvantages
Coaxial feed	Easy to match Low spurious radiation	Large inductance for thick substrate Soldering required
Microstrip line	Monolithic Easy to fabricate Easy to match by controlling insert position	Spurious radiation from feed line, especially for thick substrate when line width is significant
Proximity coupled	No direct contact between feed and patch Can have large effective thickness for patch substrate and much thinner feed substrate	Multilayer fabrication required
Aperture coupled	Use of two substrates avoids deleterious effect of a high dielectric constant substrate on the bandwidth and efficiency No direct contact between feed and patch avoiding large probe reactance or wide microstrip line No radiation from the feed and active devices since a ground plane separates them from the radiating patch	Multilayer fabrication required Higher back lobe radiation

DOI 10.1007/978-981-4560-75-7_29-1

The patch antenna idea appeared to be proposed by Deschamps in the early 1950s (Deschamps and Sichak 1953), but there was little activity for some two decades. It was not until the late 1970s that this type of antenna attracted serious attention of the antenna community, due to the recognition of the many advantages it offered. These include low profile, conformability to a shaped surface, ease of fabrication, and compatibility with integrated circuit technology, since active and passive circuit elements can be etched on the same substrate. Its main drawback is narrow bandwidth, typically less than 5 %. Research in the last several decades has resulted not only in patch antennas with double digit bandwidths but a host of techniques for designing dual- and multiband, dual- and circular polarization characteristics, size reduction, and reconfigurable designs. The MPA has found extensive applications in the wireless industry, both commercial and military, and it is probably not an exaggeration to say that this type of antennas has become the favorite of antenna designers. The literature on MPAs is vast, comprising thousands of research articles in archival journals. There were also several review articles, handbook chapters, and more than a dozen books, a partial list of which are given in the references [Bahl and Bhartia (1980); Chen and Chia (2005); Debatosh and Antar (2010); Garg (2000); Huang (2008); James and Hall (1981, 1989); Kumar and Ray (2003); Lee and Tong (2012); Lee and Chen (1997); Richards et al. (1981); Pozar (1992); Shafai (2007);Wong (2002); Zurcher and Gardiol (1995)].

In this chapter, a brief description of the modeling techniques and basic characteristics of the MPA is given in section "Modeling Techniques and Basic Characteristics." Section "Broadbanding Techniques" presents four major broadbanding techniques. Dual- and triple-band designs are discussed in section "Dual- and Multiband Designs." Methods for size reduction and circular polarization are the topics of sections "Methods of Reducing the Patch Size" and "Designs for Circular Polarization," respectively. Section "Frequency-Agile and Polarization-Agile Patch Antennas" presents examples of frequency-agile and polarization-agile patch antennas. Concluding remarks are given in section "Conclusion." To keep the chapter within the allotted length, dual-polarization designs and the subject of microstrip antenna array are not addressed in this chapter.

Modeling Techniques and Basic Characteristics

Brief Description of Modeling Techniques

There are two approaches to deducing the performance characteristics of microstrip patch antennas. One is to devise a physical model based on a number of simplifying assumptions; the other is to attempt to solve Maxwell's equations subject to the boundary conditions.

For the coaxial feed microstrip patch antenna shown in Fig. 1a, a physical model, known as the cavity model (Lo et al. 1979), has been developed to deduce the characteristics of the antenna. It is based on a number of simplifying assumptions which are valid for thin substrates. These assumptions enable the fields between the patch and the ground plane to be determined analytically for a number of patch shapes. From these, radiation and impedance characteristics of the basic MPA geometry can be calculated. Basic characteristics obtained from the cavity model are presented in section "Basic Characteristics."

More general methods which aim at solving the full set of Maxwell's equations without relying on the thin substrate assumption are known as full-wave methods. One such method treats the currents on the antenna structure to be the unknowns to be solved. By requiring the fields produced by the currents to satisfy the boundary and excitation conditions, integral equations are obtained for the unknown currents, which are solved by some numerical method, such as the moment method (Mosig and Gardiol 1985). Another approach of the full-wave method converts Maxwell's equations into difference equations, which, together with appropriate models for the boundary conditions, are solved numerically in the time domain (Reineix and Jecko 1989). This is known as the finite difference time domain (FDTD)

method. Still another method, known as the finite element method, solves Maxwell's eq. in the form of the vector wave eq. by the Rayleigh-Ritz variational method (Salon and Chari 1999).

The cavity model provides physical insight, but works well only for the basic geometry of the MPA, namely, a conducting patch on a thin, grounded substrate, with the patch shape amenable to the method of separation of variables. The full-wave methods have the advantages of being able to handle thick substrates, various feeding methods, and thick complicated structures such as multilayers, multiple patches with or without parasitic elements, shorting walls, and shorting pins, as well as slots cut in patches. However, they require extensive computation time and provide little physical insight.

In the last two decades, many commercial simulation software based on full-wave methods are available. These software have played a key role in the rapid advancement of microstrip antenna research. They have become indispensable tools in the design of these antennas. Some of these are listed in Table 2. Many of the results to be presented in this chapter were based on IE3D and HFSS. Some were obtained using moment method and FDTD codes developed in-house.

Basic Characteristics

The basic characteristics of microstrip patch antennas can be obtained by applying the cavity model to a coaxially fed microstrip patch antenna. The basic assumption in the cavity model is that the thickness of the substrate is much smaller than the wavelength. The region under the patch can then be considered as a cavity bounded by electric walls on the top and bottom ($E_t = 0$) and, as a consequence of the thin substrate assumption, bounded by a magnetic wall ($H_t = 0$) on the sides. The fields under the patch are transverse magnetic (TM), with the electric field perpendicular to the patch. These fields are determined by solving the wave equation subject to the conditions on the boundary and the feed. By virtue of the equivalence principle, the fields outside the cavity can be calculated from the equivalent sources on the exit region of the cavity.

Using this approach, the performance characteristics of the probe-fed rectangular, circular, annular-ring, and equitriangular patch antennas were predicted theoretically and verified experimentally in the late 1970s and 1980s (Lee and Dahele 1989). While differing in detail, there are a number of similar features, irrespective of the shapes of the patch. These are delineated below for the rectangular patch shown in Fig. 3. The rectangular patch is probably the most commonly used microstrip patch antenna.

(A) The fields under the cavity are transverse magnetic, with the electric field in the z direction and independent of z. There are an infinite number of modes, each characterized by a pair of integers (m, n):

DOI 10.1007/978-981-4560-75-7_29-1

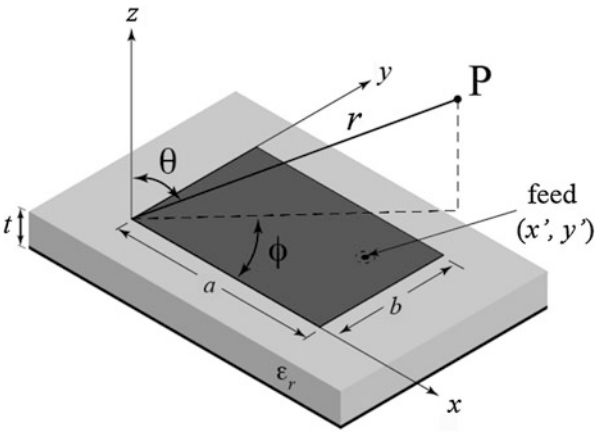

Fig. 3 Geometry of a rectangular patch antenna

$$E_z = E_0 \cos\frac{m\pi x}{a} \cos\frac{n\pi y}{b} \quad m, n = \text{integers} \tag{1}$$

(B) For the cavity bounded by electric walls on the top and a magnetic wall on the side, the resonant frequency of each mode is governed by the dimensions of the patch and the relative permittivity of the substrate ε_r. It is given by

$$f_{mn} = \frac{k_{mn} \cdot c}{2\pi\sqrt{\varepsilon_r}} \tag{2}$$

where

$$k_{mn} = \left[\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2\right]^{\frac{1}{2}} \tag{3}$$

c = velocity of light in free space.

(C) Because of fringing fields at the edge of the patch, the patch behaves as if it has a slightly larger dimension. Semiempirical factors are usually introduced in the cavity model-based design formulas to account for this effect, as well as the fact that the dielectric above the patch (usually air) is different from the dielectric under the patch. These factors vary from patch to patch.

For the rectangular patch, with a > b, a commonly used formula for the fundamental mode, accurate to within 3 % of measured values, is

$$f_r = \frac{c}{2(a+t)\sqrt{\varepsilon_e}} \tag{4}$$

where

$$\varepsilon_e = \frac{(\varepsilon_r + 1)}{2} + \frac{(\varepsilon_r - 1)}{2}\left[1 + \frac{10t}{b}\right]^{\frac{-1}{2}} \tag{5}$$

is the effective permittivity (Schneider 1969).

DOI 10.1007/978-981-4560-75-7_29-1

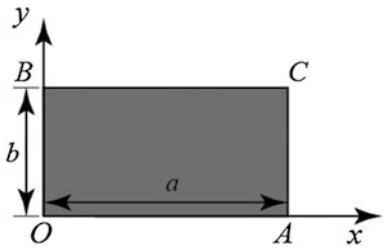

Fig. 4 Top view of the rectangular patch

(D) The equivalent sources at the exit region (the vertical side walls) are the surface magnetic current densities, related to the tangential electric fields in those locations. Referring to Fig. 4, they are:

Along the wall OA,

$$\vec{M}_s = -\hat{n} \times \vec{E} = +\hat{y} \times \hat{z} \times E_0 \cos\frac{m\pi x}{a} = +\hat{x}E_0\frac{m\pi x}{a}. \tag{6}$$

Along the wall AC,

$$\vec{M}_s = -\hat{n} \times \vec{E} = -\hat{x} \times \hat{z} \times E_0 \cos m\pi \cos\frac{n\pi y}{b} = +\hat{y}E_0 \cos m\pi \cos\frac{n\pi y}{b}. \tag{7}$$

Along the wall CB,

$$\vec{M}_s = -\hat{n} \times \vec{E} = -\hat{y} \times \hat{z} \times E_0 \cos\frac{m\pi x}{a} \cos n\pi = -\hat{x}E_0 \cos\frac{m\pi x}{a} \cos n\pi. \tag{8}$$

Along the wall BO,

$$\vec{M}_s = -\hat{n} \times \vec{E} = +\hat{x} \times \hat{z} \times E_0 \cos\frac{n\pi y}{b} = -\hat{y}E_0 \cos\frac{n\pi y}{b}. \tag{9}$$

The effect of the infinite ground plane is to double the strength of each $\vec{M}_s$ source. The electric field and magnetic surface current distributions on the side walls for the TM_{01} and TM_{10} modes are illustrated in Fig. 5. For the TM_{10} mode, the magnetic currents along b are constant and in phase, while those along a vary sinusoidally and are out of phase. For this reason, the b edge is known as the radiating edge since it contributes predominately to the radiation. The a edge is known as the non-radiating edge. Similarly, for the TM_{01} mode, the magnetic currents are constant and in phase along a and are out of phase and vary sinusoidally along b. The a edge is thus the radiating edge for the TM_{01} mode.

(E) To satisfy the boundary condition imposed by the feed, the fields under the patch are expressed as a summation of the various modes. The amplitudes and phases of these modes are determined by the excitation. The mode with resonant frequency equal to the excitation frequency will be at resonance and has the largest amplitude.

(F) Each resonant mode has its own characteristic radiation pattern. For the rectangular patch, the commonly used modes are TM_{10} and TM_{01}. However, the TM_{03} mode has also received some attention. These three modes all have broadside radiation patterns. The computed patterns for a = 1.5b and two values of ε_r are shown in Fig. 6. In the principal planes, the TM_{01} and TM_{03} modes have similar linear polarizations, while that of the TM_{10} mode is orthogonal to the other two.

DOI 10.1007/978-981-4560-75-7_29-1

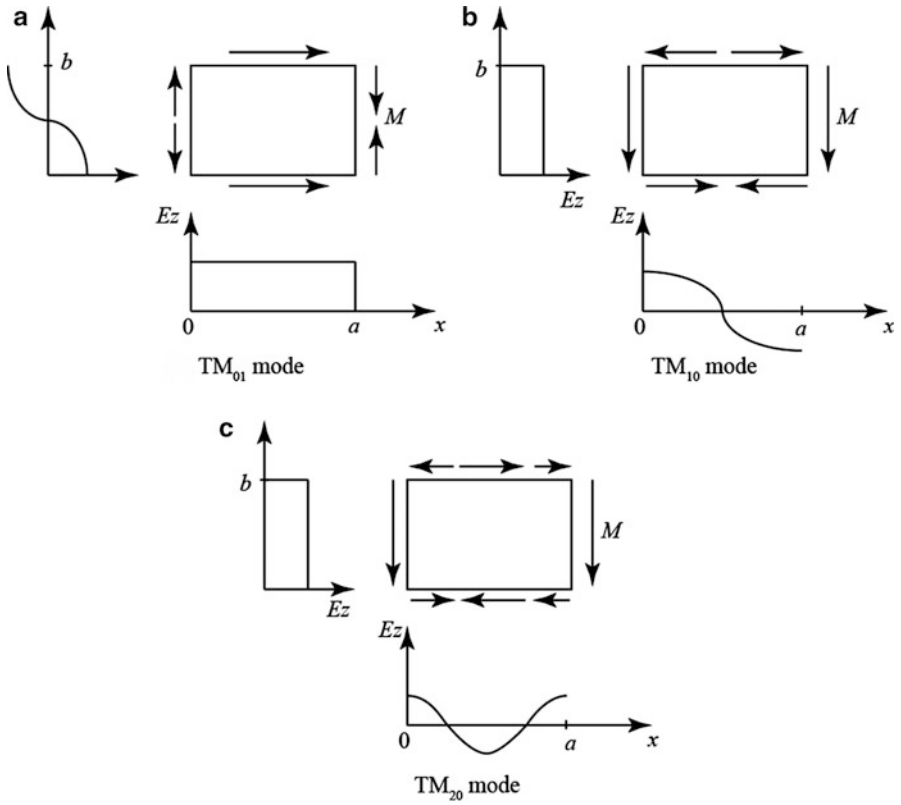

Fig. 5 Illustrations of the magnetic current density distribution on the side walls

The patterns do not appear to be sensitive to a/b or t. However, they change appreciably with ε_r. Typical half-power beamwidths of the TM_{10} and TM_{01} modes are of the order of 100° and the gains are typically 5 dBi. The patterns of most of the other modes have maxima off broadside. For example, those of the TM_{11} mode are illustrated in Fig. 6g.

Figure 7 shows the computed and measured radiation patterns of the TM_{10} and TM_{01} modes obtained by Lo et al. (1979) for a rectangular patch with a $= 11.43$ cm, b $= 7.6$ cm, $\varepsilon_r = 2.62$,and t $= 0.159$ cm. Both $\overrightarrow{E_\theta}$ and $\overrightarrow{E_\phi}$ were measured in each of the two cuts, $\phi = 0^{\circ}$ and $\phi = 90^{\circ}$. It was found in their experiment that, in each case, one component polarization was negligible when compared to the other and is not shown. The dominant component is called the co-polarization, and the component orthogonal to the dominant component is called the cross polarization. For thin substrates, cross-polarization fields are mainly due to the excitation of higher-order modes. A study of the dependence of the cross-polarized fields on aspect ratio (a/b), feed position, and relative permittivity can be found in Huynh et al. (1988).

For each mode, there are two orthogonal planes in the far-field region – one designated as E-plane and the other designated as H-plane. The far-zone electric field lies in the E-plane and the far-zone magnetic field lies in the H-plane. The patterns in these planes are referred to as the E- and H-plane patterns, respectively. For the TM_{01} mode, the contributions to the far fields are from the magnetic surface current densities on the side walls containing the radiating edges. Referring to Figs. 3 and 5, one can show from the directions of these magnetic currents that the E-plane is the y-z plane ($\phi = 90^{o}$) and the H-plane is the x-z plane ($\phi = 0^{o}$).

For the TM_{10} mode, again referring to Figs. 3 and 5, one can show that the E-plane is the x-z plane ($\phi = 0^{o}$) and the H-plane is the y-z plane ($\phi = 90^{o}$).

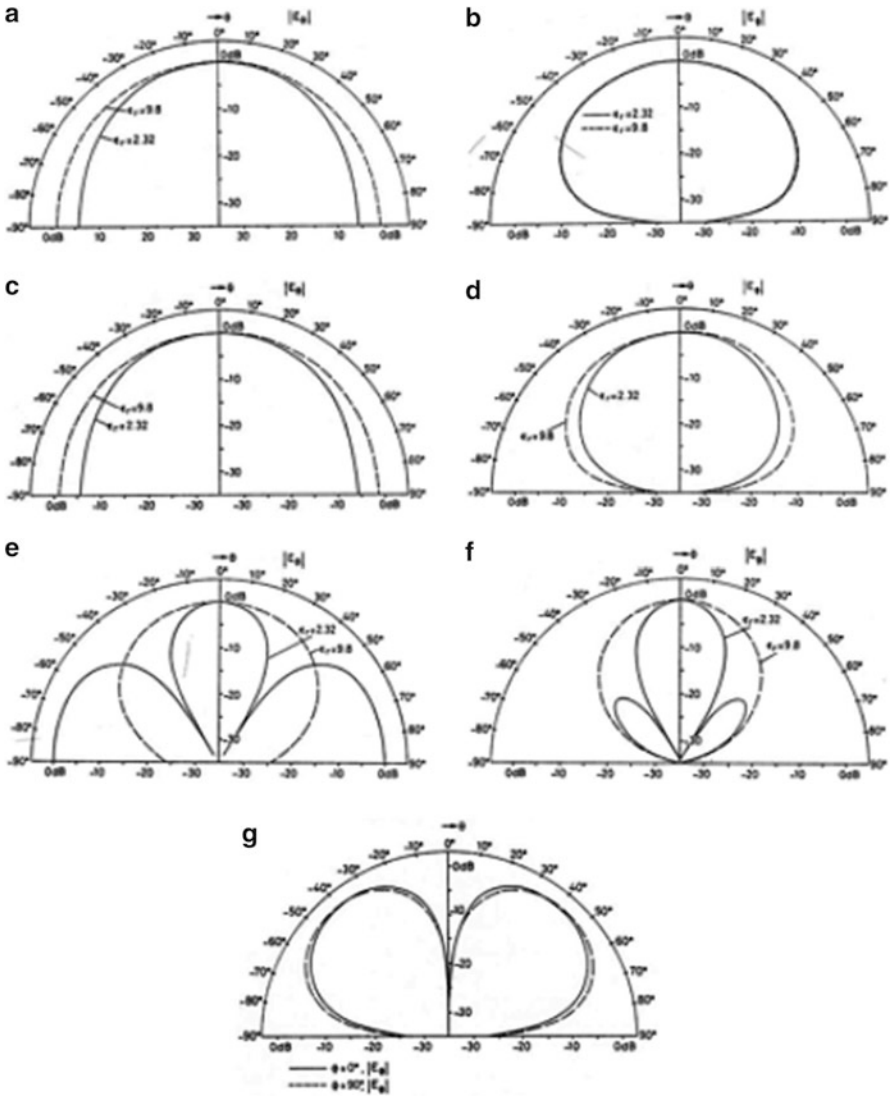

Fig. 6 Relative field patterns for a rectangular patch with a/b = 1.5, f_{nm} = 1 GHz, and (i) $\varepsilon_r = 2.32$, t = 0.318, 0.159, 0.0795 cm; (ii) $\varepsilon_r = 9.8$, t = 0.127, 0.0635, 0.0254 cm. (**a**) TM_{10}, $\phi = 0°$. (**b**) TM_{10}, $\phi = 90°$. (**c**) TM_{01}, $\phi = 90°$. (**d**) TM_{01}, $\phi = 0°$. (**e**) TM_{03}, $\phi = 90°$. (**f**) TM_{03}, $\phi = 0°$. (**g**) TM_{11}, $\varepsilon_r = 2.32$

With appropriate design, circular polarization can be achieved by utilizing two modes. This will be discussed in detail in section "Designs for Circular Polarization."

(G) At resonance, the input reactance is small for thin substrates, while the input resistance is largest when the feed is near the edge of the patch and decreases as the feed moves inside the edge. The decrease follows the square of a cosine function for the TM_{10} and TM_{01} modes of a coaxial-fed rectangular patch. Figure 8 shows the theoretical and measured values of the resonant resistances of the first two modes of a coaxial-fed rectangular patch.

(H) By choosing the feed location properly, the resonant resistance can be matched to the feed line resistance, while the use of thin substrates (thickness $t \leq 0.03\ \lambda_0$) will minimize the feed inductance at resonance, resulting in a very near unity voltage standing wave ratio (VSWR or SWR). As the frequency deviates from resonance, VSWR increases. For linear polarization, a common definition of impedance bandwidth is the range of frequencies for which VSWR is less than or equal to two, corresponding to 10 dB return loss or −10 dB for the reflection coefficient (scattering parameter S_{11}).

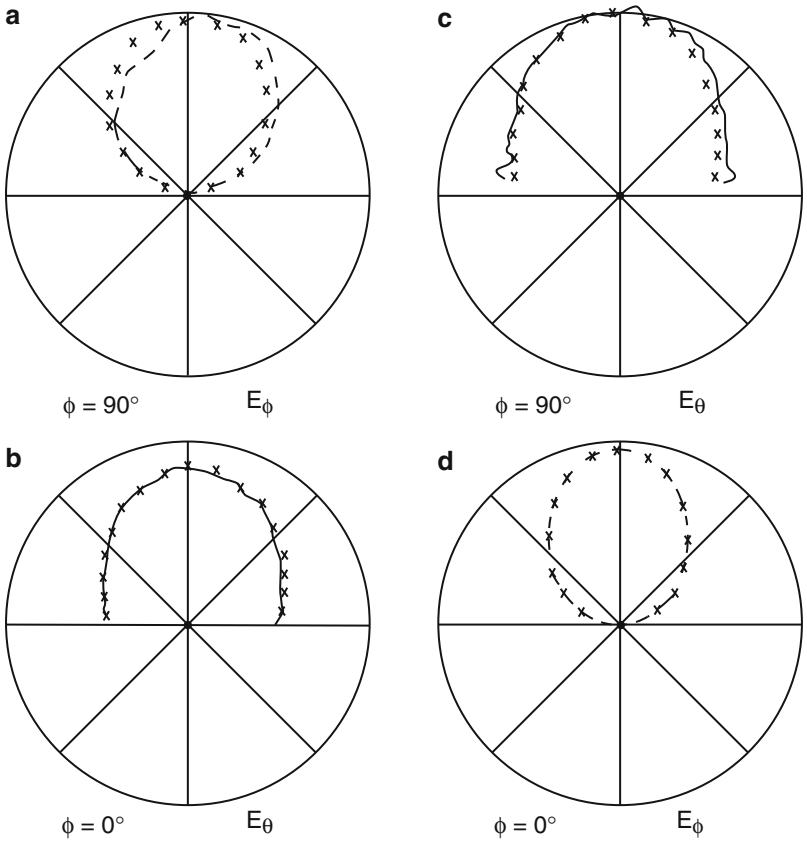

Fig. 7 Theoretical (x) and measured (*solid or dashed line*) radiation patterns in $\phi = 0°$ and $\phi = 90°$ planes of a rectangular patch antenna with a = 11.43 cm, b = 7.6 cm, $\varepsilon_r = 2.62$, t = 0.159 cm. (**a**) and (**b**) at resonant frequency 804 MHz of (1, 0) mode; (**c**) and (**d**) at resonant frequency 1,187 MHz of (0, 1) mode (From Lo et al. (1979). © 1979 I.E. Reprinted with permission)

This is usually also the antenna bandwidth, as the patterns are much less sensitive to frequency. For circular polarization, bandwidth is determined by both VSWR ≤ 2 and axial ratio $\leq$3 dB.

(I) The losses in the patch antenna comprise radiation, copper, dielectric, and surface-wave losses. For thin substrates, surface wave can be neglected. According to Wood (1981), it is required that $t/\lambda_o < 0.07$ for $\varepsilon_r = 2.3$ and $t/\lambda_o < 0.023$ for $\varepsilon_r = 9.8$, if the antenna is to launch no more than 25 % of the total radiated power as surface waves. The quality factor Q of a particular mode is determined by the ratio of the stored to loss energy and determines the impedance bandwidth of the antenna.

(J) In general, the impedance bandwidth is found to increase with substrate thickness t and inversely proportional to $\sqrt{\varepsilon_r}$. However, the use of low-permittivity substrates can lead to high levels of radiation from the feed lines, while for higher permittivities, an increase in substrate thickness can lead to decrease in efficiency due to surface-wave generation. Additionally, when the substrate thickness exceeds about 0.05 λ_o, where λ_o is a free-space wavelength, the antenna cannot be matched to the feed line. As a result, for the basic MPA geometry, the impedance bandwidth is limited to about 5 %.

Broadbanding Techniques

General Remarks

The operating frequencies of some wireless communication systems are shown in Table 3.

While the bandwidths of several systems (e.g., GPS) are quite narrow, five of the systems shown in Table 3 require bandwidths in excess of 8 %. As discussed previously, the microstrip patch antenna in the basic form of a conducting patch in a grounded substrate is inherently narrow band and is not able to meet the requirements of these systems. While bandwidth can be increased by using lossy substrates, this is usually not desirable as efficiency will be reduced. In the last three decades, a number of techniques have been developed to broaden the bandwidths of microstrip patch antennas, without compromising efficiency. The various designs provide bandwidths in the range of 10–60 %. Note that a 20 % bandwidth will be able to cover the first two applications in Table 3, while a 30 % bandwidth will cover the third, fourth, and fifth applications combined.

The methods developed for efficient wideband patch antenna design are based on one or more of the following principles:

(A) By means of parasitic elements or slots, additional resonances are introduced so that, in conjunction with the main resonance, an overall broader band response is obtained.
(B) Thick substrates of low permittivity are used.
(C) A scheme is devised to reduce the mismatch problem associated with thick substrates.

[a]Precision (P)
[b]Coarse-acquisition (C/A)

Several wideband designs based on the above principles will now be presented.

Stacked Patches

A popular method for increasing the bandwidth of microstrip patch antennas is to use parasitic elements to create dual or multiple resonances. If these resonances are suitably arranged, the resulting overall frequency response can be significantly broader than the case when only a single resonance is present. This is similar to the situation in coupled tuned circuits. There are two arrangements: the stacked geometry in which the fed and parasitic patches are on separate layers (Sabban 1983; Lee et al. 1987, 1995; Barlately et al. 1990) and the coplanar geometry in which all patches are on the same layer (Kumar and Gupta 1984). Thin substrates are used. The coplanar geometry increases the lateral area occupied by the patches and is not as popular as the stacked geometry and will not be discussed further.

One of the first journal papers on two-layer stacked patches is that by Lee et al. (1987), who studied the configuration shown in Fig. 9.

The substrate has relative permittivities, $\varepsilon_r = 2.17$ and thickness $t = 0.254$ mm. They are separated by a distance s by means of spacers. The dimensions of the patches are identical, with $a = 1.5$ cm and $b = 1.0$ cm. It is found that when the patches are excited at the TM_{01} mode, with resonant frequency approximately 10 GHz, the impedance bandwidth is about 13 % when the spacing is around 0.0508 cm ($0.017\ \lambda_0$). This is almost an order of magnitude larger than the case when there is no parasitic patch.

Subsequently, Lee et al. (1995) developed a full-wave moment method analysis and a computer program for multilayer microstrip antennas. Using this program, representative design guides for the configuration of Fig. 10, operating at the center frequency of 5 GHz, are shown in Table 4. In Table 4,

DOI 10.1007/978-981-4560-75-7_29-1

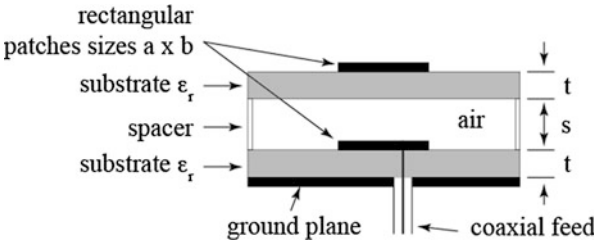

Fig. 9 Geometry of rectangular electromagnetically coupled stacked patch antenna

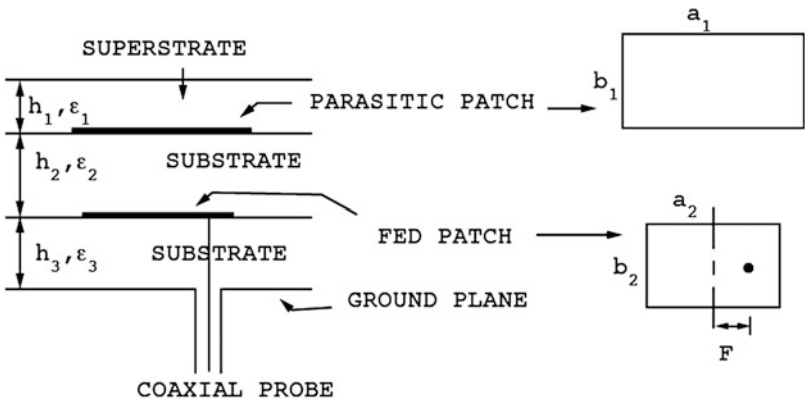

Fig. 10 Geometry of the stacked electromagnetically coupled microstrip antenna with superstrate

Table 4 Design examples for stacked electromagnetically coupled patch antennas at the center frequency of 5 GHz

	12 %	12 %	15 %
BW (VSWR $\leq$ 2)	Design 1	Design 2	Design 3
ε_1	1.0	2.2	1.0
ε_2	1.2	1.2	1.2
ε_3	2.2	2.2	2.2
h_1 (mm)	0.0	0.26	0.0
h_2 (mm)	3.580	3.630	3.500
h_3 (mm)	0.493	0.486	1.200
a_1 (cm)	2.296	2.198	2.300
b_1 (cm)	1.275	1.465	1.278
a_2 (cm)	2.000	2.027	2.000
b_2 (cm)	1.111	1.351	1.111
F (cm)	0.928	0.940	0.900

design 1 gives the parameters which achieve a bandwidth of 12 % for the case when there is no superstrate (dielectric cover). When a superstrate of thickness of 0.26 mm and relative permittivity of 2.2 is placed on top of the parasitic patch, the parameters which yield 12 % impedance bandwidth are given by design 2. Design 3 provides the antenna parameters which result in a bandwidth of 15 % when no superstrate is present. If the center frequency is changed, it is only necessary to scale the length parameters accordingly (patch dimensions, substrate and superstrate thickness, feed location).

DOI 10.1007/978-981-4560-75-7_29-1

The patterns of stacked patches are stable across the impedance bandwidth. Typical E- and H-plane half-power bandwidths are 76° and 86°, respectively. This is to be compared with 92° and 86° for the single patch. The gain of the stacked patches is about 6.0 dBi and that of the single patch is about 5.2 dBi.

It is obvious that, by extending the stacked patch geometry to multiple parasitic patches in multiple layers, additional resonances can be introduced, further broadening the bandwidth of the antenna. However, the antenna becomes very thick when there are more than two layers.

Aperture-Coupled Patches

General Remarks About Aperture-Coupled Feed

While the most popular methods for feeding a patch antenna are directly connecting a coaxial probe or stripline to the patch, a method which has a number of advantages is to couple energy from the stripline through an aperture (slot) in the ground plane, as shown in Fig. 1d. The open-ended microstrip line is located on a dielectric slab below the ground plane, while the patch antenna is formed on a separate dielectric slab above the ground plane. The two structures are electromagnetically coupled through an aperture in the ground plane between them. In the original paper by Pozar (1985), the aperture was in the form of a small circular hole. Subsequently, a more common shape of the aperture was in the form of a narrow rectangular slot.

As listed in Table 1, one advantage of this feeding method is that the feed network is isolated from the radiating element by the ground plane, which prevents spurious radiation. Another advantage is that active devices such as phase shifters and amplifiers can be fabricated in the feed substrate with high dielectric constant for size reduction, while the radiating patch can be mounted on low dielectric constant substrate in order to increase bandwidth and radiation efficiency.

The slot that couples energy from the stripline to the patch can be either resonant or nonresonant. The bandwidth achievable by nonresonant slot excitation is typically 6–7 % but can be as large as 10–13 % by utilizing thick substrates, since the problem of probe inductance is not applicable here. If the slot is resonant, it provides another resonance in addition to the patch resonance, resulting in an antenna with impedance bandwidth in excess of 20 %. However, the resonant slot has a strong back lobe radiation which reduces the gain of the antenna and causes interference problems in certain applications.

As with coaxially fed microstrip antennas, the impedance bandwidth of aperture-coupled patch antennas can be further enhanced by using stacked or coplanar elements.

In the next section, an example of a wideband aperture-coupled patch antenna utilizing a resonant slot is presented.

Example of a Wideband Aperture-Coupled Patch Antenna

By using a resonant slot and relatively thick foam substrate for the patch, Croq and Papiernik (1990) studied the aperture-coupled patch antenna shown in Fig. 11. Note that there was a dielectric cover (radome) protecting the patch.

The measured and computed impedances showed that, in the frequency range 4.85–6.1 GHz, the VSWR was less than 1.5, corresponding to a bandwidth of about 22 %.

The antenna gain was found to be about 8 dB for the entire bandwidth. The maximum back to front level was about −14 dB at the frequency of 5.6 GHz and was about −12 dB over the band. The strong back radiation is a major disadvantage of a resonant slot aperture-coupled patch antenna.

The Wideband U-Slot Patch Antenna

The stacked patch geometry with one fed patch and one parasitic patch can provide up to about 20 % bandwidth, while the aperture-coupled patch utilizing a resonant slot can yield up to about 25 %

DOI 10.1007/978-981-4560-75-7_29-1

bandwidth. The former involves more than one layer and more than one patch, while the latter also involves more than one layer, as well as a more complicated feeding arrangement and strong back lobe radiation. A wideband design which is single layer and single patch is the U-slot patch antenna shown in Fig. 12, first introduced in 1995 by Huynh and Lee (1995). A number of studies by Lee and coworkers, as well as by others, followed (Lee et al. 1997, 2010; Tong et al. 2000; Clenet and Shafai 1999; Weigand et al. 2003). It was firmly established that the U-slot patch antenna can provide impedance bandwidths in excess of 30 % for an air substrate of thickness about 0.08 λ_0 and in excess of 20 % for material substrates of similar thickness.

Air Substrate

In the original study of Huynh and Lee (1995), the wide-bandwidth characteristics of the antenna were demonstrated experimentally. It was pointed out in their paper that the factors contributing to the wideband behavior were (1) the air substrate; (2) a relative thick substrate (about 0.08 λ_0); (3) the capacitance introduced by the U-slot, which countered the feed inductance; and (4) the additional resonance introduced by the U-slot, which combined with the patch resonance to produce a broadband response. Subsequently, Lee et al. (1997) produced a more comprehensive experimental and FDTD modeling of the air-substrate U-slot patch antenna. Results for the VSWR response of one such antenna are shown in Fig. 13. The impedance bandwidth is about 30 %. The measured patterns (not shown here) were stable across the band. The E-plane and H-plane beamwidths were about 70° and 65°, respectively. The gain of the antenna was around 7.5 dBi, about 2 dB higher than the traditional microstrip antenna. The cross polarization was negligible in the E-plane. It was about 12 dB below the co-polarization level in the H-plane at the center of the band, but it increased to about 8 dB at the outer edges of the band.

While the abovementioned studies, as well as others, have shown that more than 30 % impedance bandwidth can be obtained when an air-substrate thickness of about 0.08 λ_0 is used, it should be pointed out that some applications do not need such a wide bandwidth. For example, referring to Table 3, in Advanced Mobile Phone Service (AMPS), about an 8.1 % bandwidth is sufficient. Likewise, in Global

System for Mobile Communications (GSM), only an 8.7 % bandwidth is needed. While such bandwidths cannot be realized by the traditional patch antenna (Lee and Luk 2010), it has been demonstrated that these can be realized by a U-slot patch antenna only 0.033 λ_0 thick, which has a 12 % bandwidth. The dimensions of the antenna used in this study are shown in Table 5, and the results are summarized in Table 6.

Material Substrate

Although the first series of investigations of the U-slot patch antenna used an air or foam substrate, subsequent investigations have confirmed that this wideband design can also be implemented with material substrates. As expected, the bandwidth of an antenna on a material substrate is smaller than an antenna on an air or foam substrate.

Tong et al. (2000) presented both experimental study and FDTD analyses of two antennas on a substrate with relative permittivity $\varepsilon_r = 2.33$. The dimensions of one of these antennas are shown in Table 7. The operating frequencies and bandwidths of this antenna are shown in Table 8. The 3 dB gain bandwidths were about the same as the impedance bandwidths, and the average gains of the antennas were about 7 dBi across the matching band.

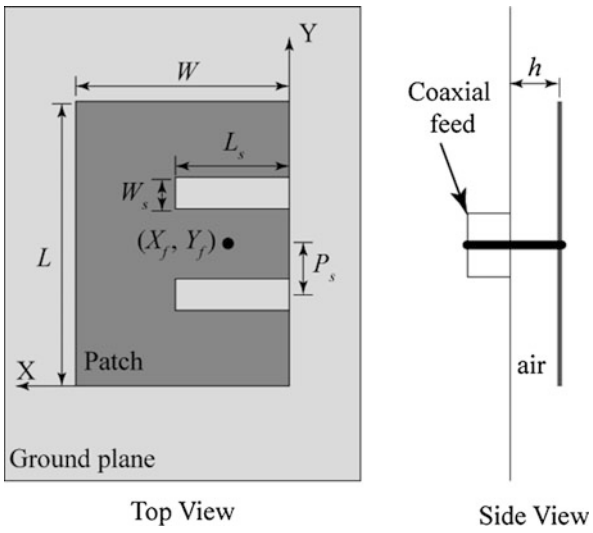

Fig. 14 Geometry of the E-patch antenna

Variations of the U-Slot Patch Antenna and the E-Patch

The use of the U-slot to achieve wideband performance is not limited to a rectangular patch. Wideband circular patch antennas with a U-shaped slot have been reported (Bhalla and Shafai 2002). The shape of the slot can also take on other forms, such as a circular slot and a V-slot (Rafi and Shafai 2004). By letting the width of the horizontal slot go to zero and extending the two vertical slots to the edge of the patch, an E-patch is obtained (Yang et al. 2001a). This geometry is shown in Fig. 14. As in the U-slot, the parallel slots provide an additional path for the currents, giving rise to a second resonance. The parallel slots can also introduce a capacitance which compensates for the probe inductance, thus enabling the use of relatively thick substrates. In Yang et al. (2001a), impedance bandwidths of about 30 % were obtained for E-patches operating at the center frequency of around 2.4 GHz, using air substrate of about 0.08 λ_0. The antenna parameters for one such antenna are listed below, in mm: L = 70, W = 30, h = 15, $X_f = 35$, $Y_f = 6$, $L_s = 40$, $W_s = 6$, and $P_s = 10$. Ground plane size = 14 × 21 cm.

The Wideband L-Probe Coupled Patch Antenna

Shortly after the publication of the first paper on the wideband U-slot patch antenna, another wideband single-layer single-patch antenna was introduced. This design achieves wideband operation using an L-shaped probe feeding method. The L-probe feed was first used by Nakano in the electromagnetically coupled curl antenna (Nakano et al. 1997). Its use in patch antennas was due to Luk et al. (1998a). The geometry is shown in Fig. 15. This design uses low-permittivity substrate (air or foam) of thickness about 0.1 free-space wavelength. The feed is a modified version of the coaxial probe. Instead of the center conductor extending vertically to the patch and connected to it, a portion of it is bent in the horizontal direction. The horizontal arm of the probe is approximately a quarter of a wavelength long. It provides a capacitance to counteract the inductance due to the vertical part. In the experiment of Luk et al. (1998a), the rectangular patch had a width $W_x = 30$ mm and a length $W_y = 25$ mm. The L-shaped probe, connected to the inner conductor of a 50 Ω SMA launcher, had a parallel arm $L_h = 10.5$ mm and a perpendicular arm $L_v = 4.95$ mm. It was excited in the TM_{01} mode of the patch antenna. The patch was supported by a foam layer of thickness H = 6.6 mm with a dielectric constant close to unity. Within the matching band, this thickness corresponded to 0.08–0.12 λ_0. The distance between the lower edge of the patch and the perpendicular arm of the L-probe was D = 2 mm. The probe radius R = 0.5 mm. The measured VSWR and gain as a function of frequency are shown in Fig. 16. The bandwidth (VSWR < 2)

DOI 10.1007/978-981-4560-75-7_29-1

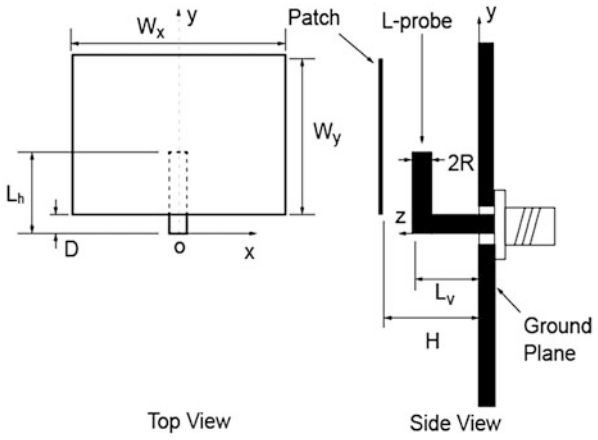

Fig. 15 Geometry of the patch antenna with an L-probe feed

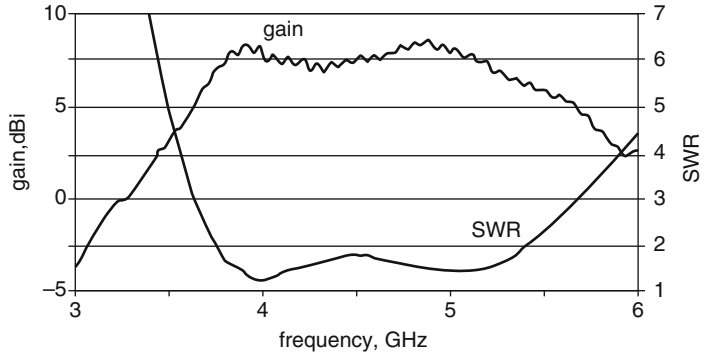

Fig. 16 Measured gain and SWR against frequency (From Luk et al. (1998a). © 1998 IET, Reprinted with permission)

was 36 % and the average gain was 7.5 dBi. The measured radiation patterns at 4.53 GHz are shown in Fig. 17. It is seen that the co-polarization patterns were symmetrical with respect to the broadside direction. The cross polarization was negligible in the E-plane (y-z plane). It was quite high in the H-plane (x-z plane) in the direction around $\theta = 30°$. Simulation results of this antenna using the software IE3D were in good agreement with experimental results.

Subsequent related studies included the use of twin L-probes to increase gain and reduce cross polarization (Mak et al. 2005) and the T-probe-fed patch antennas (Mak et al. 2000).

Dual- and Multiband Designs

Introductory Remarks

There are many applications in wireless communications that involve two or more distinct frequency bands. It is sometimes possible that a broadband microstrip antenna can cover the frequencies of interest. However, the disadvantage of using a broadband antenna is that it also receives non-desired frequencies unless some kind of filtering network is introduced to reject such frequencies. On the other hand, the advantage of a dual- or multiband design is that it focuses only on frequencies of interest and is thus more desirable. The frequency bands can be relatively close or relatively far apart. A variety of designs have been developed to provide the desired characteristics: by providing multi-resonances, by using multi-

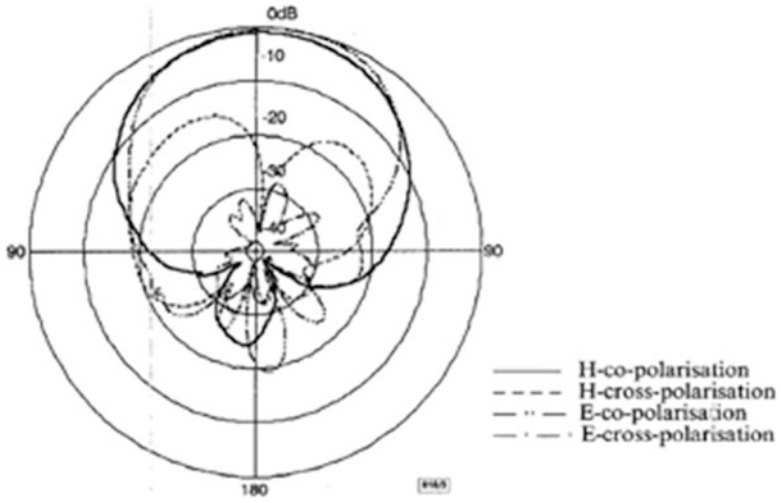

Fig. 17 Measured radiation pattern at 4.53 GHz (From Luk et al. (1998a). © 1998 IET, Reprinted with permission)

modes, or by introducing band notches in a broadband antenna. Long and Walton(1979) and Dahele et al. (1987) used stacked circular and stacked annular-ring patches for dual-band designs. This technique was extended to multibands by Anguera et al. (2003). Dual- or triple-band characteristics can also be realized by loading a rectangular patch with one or two stubs (Deshmukh and Ray 2010), by utilizing the TM_{01} and TM_{03} modes of a rectangular patch (Zhong and Lo 1983) or the TM_{10}, TM_{20}, and TM_{11} modes of the equilateral-triangular patch (Lee et al. 1988). Recently, it was found that the U-slot patch geometry, originally introduced for broadband operation, can be suitably modified for dual- and multiband operations (Lee et al. 2008, 2011). This method is discussed in detail in the next section.

The Use of U-Slot Patches

Most of the studies of the U-slot patch antenna were concerned with its broadband capabilities. However, recent studies have shown that it can be also used for dual- or multiband designs. There are two approaches, depending on whether the frequency ratios are larger than or less than about 1.5. The two cases will be referred to as large frequency ratio and small frequency ratio, respectively.

Large Frequency Ratios

For the case when the frequency ratio is larger than about 1.5, the approach to dual-band design is to use a coaxial feed and adjust the U-slot dimensions so that the patch resonance and the slot resonance do not merge to yield a broadband response. Figure 18 shows a U-slot patch antenna which operates at a band centered at 2.0 GHz and another band centered at 4.8 GHz. The patch dimension L (54 mm) determines the lower resonance, while the upper resonance is governed by the dimensions of the U-slot. The simulated reflection coefficient (S_{11}) versus frequency is shown in Fig. 19. The impedance bandwidths at the lower and upper bands are 3.5 % and 18.2 %, respectively. The radiation patterns are similar to those of the broadband U-slot patch antenna.

To achieve triple-band operation, two slots are necessary. While it is possible to use two U-slots, it was found that the second slot in the form of an H-slot offers better flexibility. Figure 20 shows a U-slot in combination with an H-slot to produce resonances at 1.94, 4.16, and 5.44 GHz. Figure 21 shows the reflection coefficient (S_{11}) response curve. The impedance bandwidths at the three bands are 2.6 % for the lower band, 9.8 % for the middle band, and 10.4 % for the upper band. The radiation patterns at the three bands are shown in Fig. 22. The co-polarization patterns are stable. The cross-polarization levels are 20 dB below the co-polarization at the lower band. At the center frequency of the middle band (4.2 GHz)

and high band (5.4 GHz), it becomes very high at oblique angles, as the antenna is electrically thick ($>0.08\ \lambda_o$) and radiation from the vertical coaxial feed becomes significant.

Rather than cutting a second slot in the patch, a triple-band antenna can also be realized by placing an open circuit stub on the radiating edge of a dual-band U-slot rectangular patch antenna. Quadruple-band response results if two stubs are used. An example is shown in Fig. 23a (ground plane not shown). The substrate is glass epoxy ($\varepsilon_r = 4.3$, h = 0.159 cm, and $\tan\delta = 0.02$). The measured VSWR of the triple-

band antenna is shown in Fig. 24. The measured resonant frequencies agree well with the simulated values of 770, 952, and 1,100 MHz and corresponding bandwidths 16, 18, and 22 MHz. Finally, quadruple-band response can be obtained with a stub-loaded rectangular patch with two unequal-length half U-slots cut into it, as illustrated in Fig. 23b.

Small Frequency Ratios

A simple approach to designing dual- and triple-band patch antenna with frequency ratios less than about 1.5 was introduced in Lee et al. (2008, 2011). The method starts with a broadband antenna. When a suitably located U-slot of the appropriate dimensions is cut in the patch, it introduces a band notch at a frequency within the original broadband. The broadband antenna is turned into a dual-band antenna. When a second U-slot is cut in the patch, two band notches can be introduced and a triple-band antenna results.

Antenna	W	L	H	H_L	L_L	U_{a1}	U_{d1}	U_{x1}	U_{y1}	U_{a2}	U_{d2}	U_{x2}	U_{y2}
a	22	18	5	3.5	8.5								
b	22	18	5	3.5	8.5	0.8	2	7.5	10.8				
c	22	18	5	3.5	8.5	0.8	2	7.5	10.8	0.8	3.5	4.5	10.8

The original broadband antennas can be an L-probe-fed patch, an M-probe-fed patch, coax-fed stacked patches, aperture-coupled stacked patches (Lee et al. 2011), or a U-slot patch (Mok et al. 2013). In what follows, the use of an L-probe-fed patch is presented in detail.

Figure 25a shows the wideband L-probe-fed rectangular patch. When a U-slot is cut in the patch (Fig. 25b), a notch is introduced within the matching band and a dual-band antenna results. With two U-slots (Fig. 25c), two notches are introduced and a triple-band antenna results.

In Lee et al. (2008), these antennas with the dimensions shown in Table 9 were fabricated. Air substrate was used. Simulation results, using IE3D software, were obtained, as well as measured results. The simulated and measured return losses are shown in Fig. 26, and the impedance bandwidths ($S_{11} < -10$ dB) are summarized in Table 10. Reasonable agreement was obtained between the simulated and measured results. The discrepancies between the results were due to the fabrication tolerance of the fabricated antenna prototypes. Figures 27, 28, and 29 show the measured radiation patterns for the three antennas. The patterns are broadside and the polarization is linear.

For antenna b, the U-slot introduced a notch at around 5.5 GHz. The relationship between the band notch frequency and the total U-slot length is shown in Table 11. The total length of the slot is approximately half wavelength for the two proposed U-slot(s) antennas. The resulting dual-band antenna has a frequency ratio $f_2/f_1 = 1.30$, where f_2 and f_1 are the center frequencies of the upper and lower bands, respectively. For antenna c, the two U-slots introduced a notch at around 5.5 GHz and another notch at around 6.2 GHz. The resulting triple-band antenna has frequency ratios $f_3/f_1 = 1.34$ and $f_2/f_1 = 1.16$, where f_3, f_2, and f_1 are the center frequencies of the upper, middle, and lower frequencies. It should be noted that the frequency ratios are determined by the bandwidth of antenna a, which was 30 % for this case. If one starts with an antenna with broader bandwidth, e.g., 40 %, the frequency ratios of the dual- and triple-band antenna will be larger.

A patch antenna with quadruple-band characteristics can be realized by cutting three half-wavelength long U-slots on the patch. Another method is to use stacked patches in multiple layers (Anguera et al. 2003).

Methods of Reducing the Patch Size

General Remarks

In many applications, it is desirable for the dimensions of the patch to be a small fraction of the free-space wavelength. The resonant length of the microstrip patch antenna is approximately λ/2, where λ is the wavelength in the dielectric substrate. It follows that the size of the patch can be reduced by using a substrate material with high dielectric constant. However, the resulting patch antenna will have narrow impedance bandwidth. This motivated the search for other size reduction methods.

By placing a shorting wall along the null in the electric field across the center of the patch, the resonant length can be reduced by a factor of two (Pinhas and Shtrikman 1988; Chair et al. 1999; Lee et al. 2000). The area occupied by the patch will be reduced by a factor of four, if the aspect ratio is kept the same. Another technique to reduce the resonant length is to add a shorting pin in close proximity to the feed (Waterhouse et al. 1998). The shorting pin is capacitively coupled to the resonant circuit of the patch, effectively increasing the permittivity of the substrate. It has been shown that a suitably placed shorting pin can reduce the resonant length of a circular patch by a factor of three and the area of the patch by a factor of nine. Broadbanding techniques such as stacked patches, U-slot patch, and L-probe feed can be applied to obtain small-size wideband patch antennas (Shackelford et al. 2003). All these methods result in radiation patterns with high cross polarization. This may not be a disadvantage in indoor mobile communication applications. A low cross-polarization design is that of the folded patch, which, however, is thicker and more difficult to fabricate (Luk et al. 1998b).

In what follows, the use of shorting wall, shorting pin, and the U-slot patch with shorting pin is discussed in detail.

The Use of Shorting Wall: Quarter-Wave Patch

Chair et al. (1999) presented experimental results of the quarter-wave patch shown in Fig. 30. The substrate between the patch and the ground plane is foam, with thickness h and relative permittivity 1.08. The sides of the patch are a = b = 3.06 cm long, with one side shorted. The patch is fed by a coaxial probe, with the feed point at x = 0 and y = d, where d is the distance between the feed point and the open edge and is adjusted for best match.

Resonant frequency, pattern, and bandwidth (VSWR < 2) measurements were performed for several thicknesses h, from 2 to 7 mm. Resonant frequencies ranged from 2.19 to 2.46 GHz, while the bandwidths ranged from 3.59 % for h = 2 mm (0.017 λ_o) to 17.66 % for h = 7 mm (0.058 λ_o). The corresponding bandwidths for a half-wave regular patch on the same thickness and the same width but double in length were 1.57 % and 5.55 %, respectively. These results were confirmed qualitatively by simulation software. That the quarter-wave shorted patch has a wider bandwidth than the half-wave patch is due to its smaller volume and therefore less stored energy, leading to a smaller Q and larger bandwidth. This conclusion was found to hold only for air/foam substrate and not for material substrate which supports surface waves.

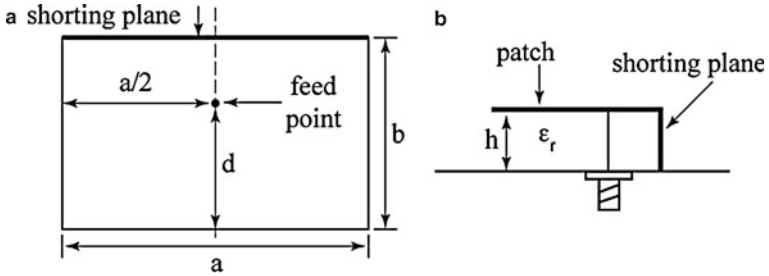

Fig. 30 Geometry of the shorted patch. (**a**) Top view; (**b**) side view

DOI 10.1007/978-981-4560-75-7_29-1

Table 12 Measured gains of the shorted square patch of Fig. 31

h (mm)	f_o (GHz)	Gain (dBi) at broadside	Maximum gain and direction
3	2.06	2.5	2.5 at 0°
5	2.17	2.5	3.5 at 30°
7	2.46	0.2	2.2 at 45°

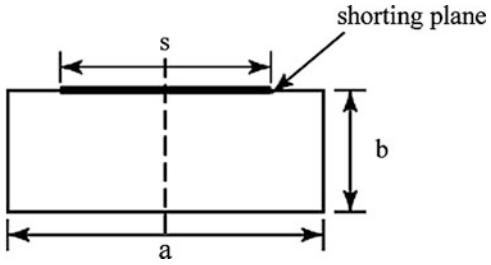

Fig. 31 Geometry of partially shorted patch

In Lee et al. (2000), it was found that shorted patches on substrates with $\varepsilon_r = 2.32$ and $\varepsilon_r = 4.0$ had smaller bandwidths than their half-wave counterparts. This was attributed to the fact that the surface-wave loss was considerably more in a half-wave patch than a quarter-wave patch, leading to a larger bandwidth for the former.

The measured patterns by Chair et al. (1999) showed large cross polarization in the E-plane. They also showed that, depending on the thickness, the maximum radiation could occur off broadside. The measured gains for h = 3, 5, and 7 mm at the resonant frequencies in the broadside direction as well as in the maximum direction are summarized in Table 12. It is seen that typical values of the maximum gain were in the range 2–3.5 dBi. This is about half that of the regular half-wave patch.

Maximum gain direction is measured from the perpendicular direction in the E-plane (perpendicular to the shorting plane).

Partially Shorted Patch and Planar Inverted-F Antenna

Figure 31 shows the geometry in which the shorting wall, instead of extending fully across the width of the patch a, has a width s, where $s \leq a$.

It was shown in Hirasawa and Haneishi (1992) that the use of a partially shorted wall had the effect of reducing the resonant frequency of the antenna. Lee et al. (2000) showed that this was accomplished at the expense of bandwidth. Their calculated results using IE3D simulation software for an antenna with a = 3.8 cm, b = 2.5 cm, h = 3.2 cm, and $\varepsilon_r = 1.0$ showed that as s/a decreased from 1.0 to 0.1, the resonant frequency decreased from 2.69 to 1.61 GHz, representing a 60 % reduction in frequency or size. However, the bandwidth was reduced from 7.4 % for s/a = 1.0 to 3.7 % for s/a = 0.1.

The partially shorted patch in the form shown in Fig. 32 is known as the planar inverted-F antenna (PIFA), because the side view looks like an inverted F. The width of the shorting wall w is approximately 0.2 L_1, while the dimensions of L_1 and L_2 are on the order of 1/8 λ_o.

The Use of Shorting Pin

Another technique for reducing the patch size, very similar to the inverted-F method, is to use a shorting pin (Waterhouse et al. 1998). This is illustrated in Fig. 33.

The shorting pin causes the fields underneath the patch to bounce back and forth. The field starts to radiate once the bouncing distance reaches half wavelength. As a result of the multiple bounces, the

DOI 10.1007/978-981-4560-75-7_29-1

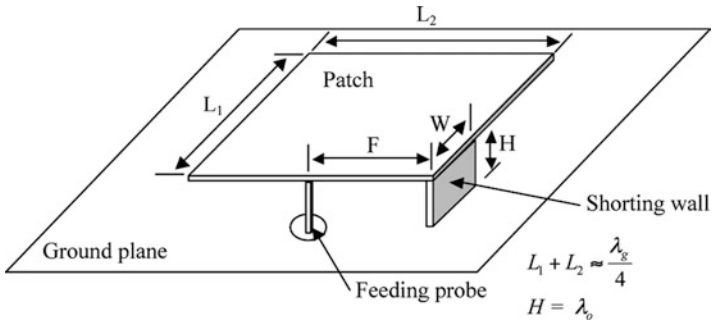

Fig. 32 Size reduction by using an inverted-F patch

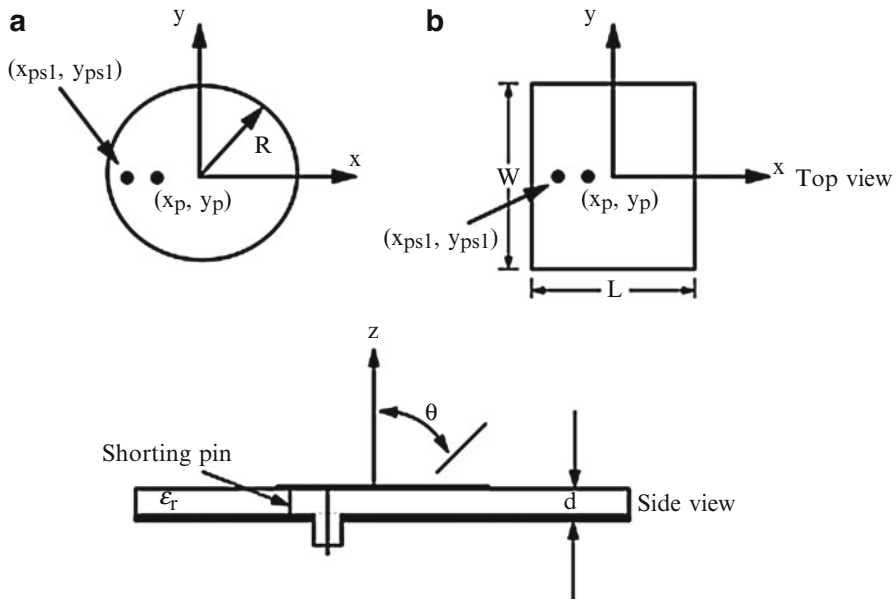

Fig. 33 Circular (**a**) and rectangular (**b**) patches with shorting pin

physical size of the patch is reduced. Since the bounces are non-unidirectional, the fields can radiate out from almost all edges of the patch, resulting in high cross polarization. However, for certain applications such as cellular phone communication in a multipath environment, high cross-polarized fields are not a concern.

If the shorting pin is close to the feed, the resonant circuit of the patch is capacitively coupled to the pin. This is equivalent to increasing the permittivity of the substrate, which further contributes to reduction in frequency or size of the patch (measured in wavelength).

The solid curve of Fig. 34 shows the simulation results for return loss for the circular patch shown in Fig. 34a with $x_p = 6.2$ mm, $x_{ps} = 8.3$ mm, and $y_p = y_{ps} = 0$, on a foam substrate with $\varepsilon_r = 1.07$ and $t = 10$ mm. IE3D simulation software was used. The radius of the patch is reduced by a factor of 3 and the area by a factor of 9 when compared to the case of no shorting pin. The thickness of the foam substrate is 0.06 λ_o, and the impedance bandwidth is about 6.3 %. The simulated radiation patterns at 1.9 GHz are shown in Fig. 35. As noted earlier, the cross polarization of this type of antenna is very high. The simulation results are consistent with the experiments reported in Waterhouse et al. (1998).

The bandwidth can be slightly improved by using multiple shorting pins. A circular patch with two and three shorting pins is shown in Fig. 36. The reflection coefficient (S_{11}) for these cases is shown in the

broken curves of Fig. 34. The impedance bandwidths are 7.9 % for the patch with two pins and 10 % for the patch with three pins.

Wideband U-Slot Patch Antenna with Shorting Pin

The shorting pin technique can be applied to the wideband U-slot patch discussed in section "Aperture-Coupled Patches." An example of the U-slot patch with shorting pin is shown in Fig. 37a

DOI 10.1007/978-981-4560-75-7_29-1

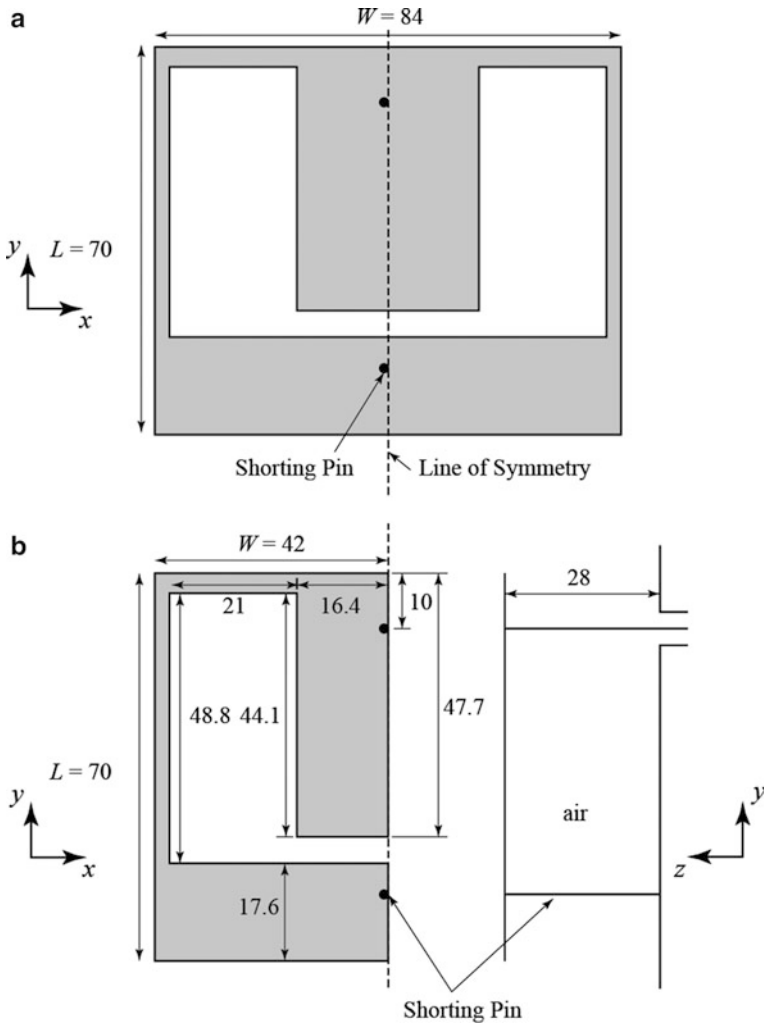

Fig. 37 (**a**) U-slot patch with shorting pin; (**b**) half U-slot patch with shorting pin

(Shackelford et al. 2001). The U-slot patch has a length L = 70 mm (0.2 λ_o) and a width W = 84 mm (0.24 λ_o) where λ_o is the free-space wavelength at the center frequency 0.86 GHz of the U-slot patch. The patch is supported by the shorting pin and the probe wire in air. The radii of the shorting pin and the probe feed are 4.65 and 2 mm, respectively. The shorting pin and the probe feed are located at the non-radiating edge of the U-slot patch, which is placed on a 1 × 1 λ_o ground plane. Figure 38 shows the measured and simulated SWR of this antenna. The matching frequency range is from 0.75 to 0.97 GHz with an impedance bandwidth of 25.6 %. The area of the U-slot patch is only 0.055 λ_o. Figure 39 shows the simulated x-z and y-z plane radiation patterns at 0.85 GHz.

Studies of the U-slot patch with shorting pin on material substrates have been reported in Shackelford et al. (2003). It was also possible to further reduce the size of the patch by removing half of the structure along the plane of symmetry (Chair et al. 2005). Such an antenna is shown in Fig. 38b and its VSWR response is also shown in Fig. 39. The corresponding bandwidth is 20 %.

Discussion on Finite Ground Plane Size Effect

The papers from which the above examples were drawn, as well as most of the papers in the literature on patch size reduction techniques, did not address the ground plane size effects. Based on the recent study for the shorted patch on foam substrate using CST Microwave Studio simulation software, it was found

DOI 10.1007/978-981-4560-75-7_29-1

that, when compared to the infinite ground case, the center resonant frequency, bandwidth, and gain will deviate less than 5 % and 10 % and 1.5 dB, respectively, until the ground plane is reduced to smaller than $0.5\times\ 0.5\ \lambda_o$ (Tong et al. 2011).

In general, the ground plane size effects have to be considered with care, as they are dependent on the particular antenna and the locations of the antenna and the feed (Best 2009).

Designs for Circular Polarization

Basic Principles of Circularly Polarized Patch Antennas

The designs described in the previous sections are for linear polarization. There are many circumstances, such as multipath/fading environments and in communication with space vehicles above the earth's ionosphere, in which it is more reliable to use circular polarization. Circularly polarized patch antennas can be broadly classified into three types – single feed, dual feed, and sequentially rotated feed. Figure 41 shows four single-feed designs.

Figure 40a and b shows an almost square patch and an almost circular (elliptical) patch. Figure 40c and d shows a square patch with truncated corners and a circular patch with indentations. Although coaxial feeds are shown in Fig. 40, the patches can also be fed by a microstrip line or by coupling through an aperture.

At the appropriate frequency, all four configurations will generate two orthogonal linearly polarized waves which are in phase quadrature in the broadside direction. This design is simple, but suffers from very narrow axial ratio bandwidth for thin substrates. By using the U-slot or L-probe for relatively thick substrates or the use of stacked patch techniques, the axial ratio bandwidth can be increased to over 10 %.

The basic principle of the single-feed CP patch antenna is that a perturbation of the dimensions be introduced such that, by feeding the patch at the appropriate location, two modes with orthogonal

DOI 10.1007/978-981-4560-75-7_29-1

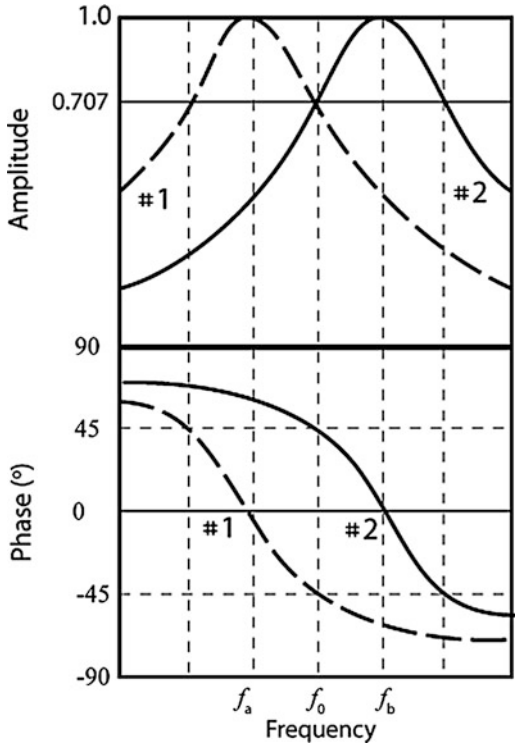

Fig. 41 The amplitudes and phases of two orthogonal modes

polarizations are generated with resonant frequencies which are slightly different. In the almost square patch and the almost circular patch, the perturbation is in the form of one of the dimensions being slightly different from the other. In the square patch with truncated corners and the circular patch with indentations, the perturbation is in the form of two slightly different diagonal lengths.

In the broadside direction, the amplitudes and phases of the radiated electric fields of the two orthogonal modes generated are illustrated in Fig. 41. The resonant frequencies of these modes are f_a and f_b, respectively.

At the frequency f_o, approximately midway between f_a and f_b, the amplitudes of the two modes are equal and the phases differ by 90°, resulting in circular polarization. This condition for perfect CP occurs only at f_o and in the broadside direction. As the frequency deviates from f_o and/or the direction is off broadside, elliptical polarization results.

The antenna is only useful for the range of frequencies within which both the return loss is less than 10 dB (RLBW) and the axial ratio is less than 3 dB (ARBW). This overlapping region will be referred to as the CP bandwidth.

Broadbanding of Single-Feed Circularly Polarized Patch Antennas

As with the case of the RLBW, the ARBW is found to increase as the substrate thickness increases. However, this thickness is very limited if the ARBW is to overlap with the RLBW. For the single-feed patch antennas of Fig. 40, achievable CP bandwidth is less than 1 %. For thicker substrates, the use of the U-slot patch, the E-patch, stacked patches, as well as the L-probe feeding techniques is found to be effective not only in increasing the RLBW and the ARBW but also to enable them to overlap. The truncated square patch with U-slot, the CP modified U-slot patch, and the CP modified E-patches will now be discussed in detail.

5	4 mm	0.06 λ_o	6.9	4.3

The Truncated Square Patch with U-Slot

A circularly polarized antenna can be designed using a square patch with truncated corners. One of the requirements for the CP antenna is that the axial ratio bandwidth (ARBW) should be within the return loss bandwidth (RLBW) or, equivalently, the impedance bandwidth. This overlapping bandwidth is very narrow for the square patch with truncated corners. Typically, it is about 0.8 %, for an air-substrate thickness of around 0.02 λ_o. Yang et al. (2008) have shown that, while increasing the substrate thickness can increase axial ratio bandwidth and the impedance bandwidth individually, this increase is very limited if the ARBW is to be within the RLBW. On the other hand, by using a U-slot patch with truncated corners and using substrates of thickness around 0.1 λ_o, the axial ratio bandwidth can be as wide as 6.1 % and still stay within the impedance bandwidth. The antenna geometry studied by Yang et al. (2008) is shown in Fig. 42.

The patch has dimensions 28.6 mm (W) $\times$ 28.6 mm (L) and the ground plane is 100 $\times$ 100 mm. It is fed by a coaxial probe and the substrate is air. Using the IE3D simulation software, the RLBW and ARBW are studied for five thicknesses. For each case, the truncation parameter a and the feed position d are adjusted for best performance and are shown in Table 13. The simulation results are shown in Table 14.

It is seen that, as the substrate thickness increases from 1 mm (0.016 λ_o) to 3 mm (0.046 λ_o), the RLBW increases from 4.0 % to 7.4 % while the ARBW increases from 0.82 % to 3.1 %. When the thickness increases further to 4 mm (0.06 λ_o), the RLBW drops to 4.0 % while the ARBW continues to increase to 3.8 %. The important point to note is that, beginning with case 2, the two frequency bands do not overlap. Thus, only in case 1 the ARBW lies within the RLBW, and the useful frequency band is determined by the ARBW, from 4.90 to 4.94 GHz, corresponding to 0.82 %.

Table 15 Parameters of the antenna as shown in Fig. 44. Units for a, d, U_a, U_d, U_x, and U_y are in mm

Case	Substrate thickness (H)		a	d	U_a	U_d	U_x	U_y
6	4 mm	0.05 λ_o	5.7	12.6	1	9.8	12	14
7	6 mm	0.08 λ_o	7.7	9.6	1	9.8	12	14
8	7.5 mm	0.1 λ_o	8.2	5.6	1	9.8	11	14

Figure 43 shows the geometry when a U-slot is added to the square patch with truncated corners. Three thicknesses are studied. The dimensions of the antenna are shown in Table 15, and the simulation and measurement results are shown in Table 16.

The following is observed:

1. When the U-slot is added on the patch, the resonant frequency is lowered compared to the case without the U-slot.
2. By adjusting the dimensions of the U-slot, the RL and AR bandwidths can be tuned to overlap.
3. The measured overlapping bandwidth is 5.23 % for H = 6 mm (0.08 λ_o). This is to be compared to 0.82 % achievable for the case of no U-slot. This is achieved, of course, at the expense of increasing the thickness of the antenna.

The CP Modified U-Slot Patch and the CP Modified E-Patch

Instead of truncating the corners of a square patch, circular polarization can also be generated by the use of an asymmetric U-slot (unequal arms) etched on a square patch (Tong and Wong 2007) or a modified E-patch in which the two parallel slots are unequal (Khidre et al. 2010). The geometries of these are shown in Figs. 46 and 47, respectively. By using relatively thick substrates (0.08 λ_o), the CP bandwidths achievable are comparable to the truncated U-slot square patch.

DOI 10.1007/978-981-4560-75-7_29-1

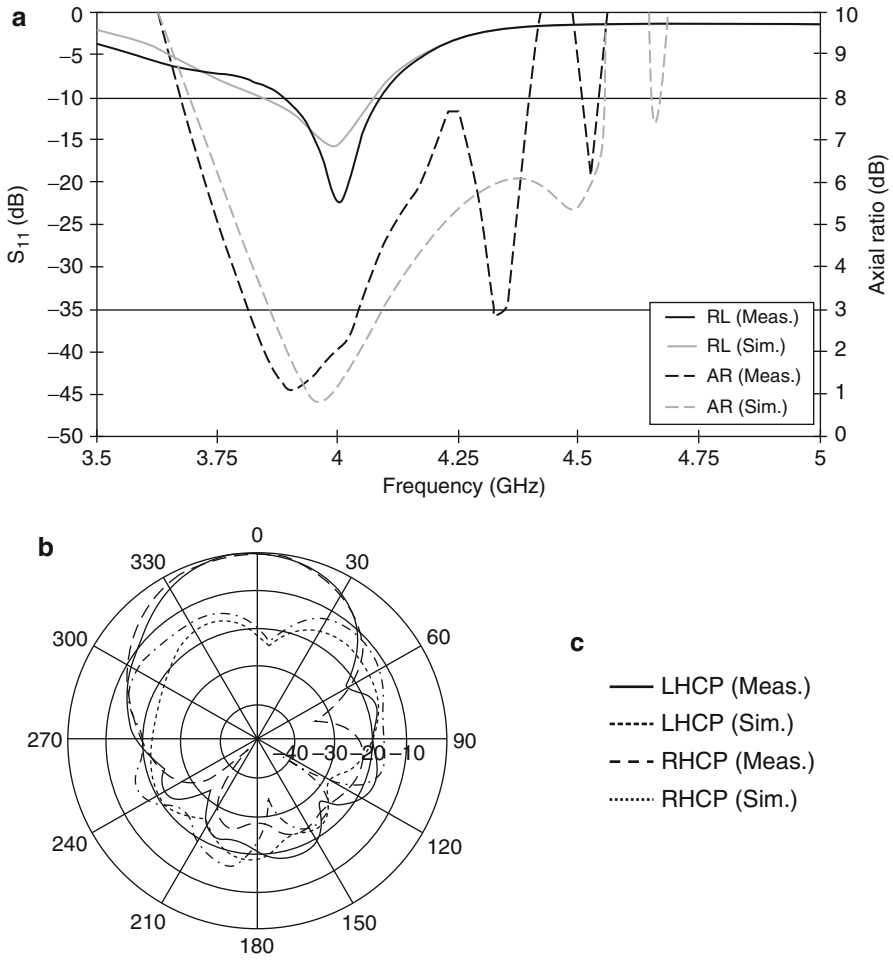

Fig. 45 Simulated and measured performance of case 8, radiation patterns are at 4 GHz

In Khidre et al. (2010), a study was made of the three designs using both air substrate and a substrate with $\varepsilon_r = 2.2$.

The optimized dimensions of the designs to work at IEEE 802.1 lb/g band (2.4–2.5 GHz) are tabulated in Tables 17, 18, and 19. The simulated S_{11} and axial ratios of the three air-substrate antennas are shown in Figs. 48 and 49, respectively. From the results, the modified E-patch exhibits 10.1 % impedance bandwidth (2.35–2.6 GHz), while unequal arms U-slot has 9.25 % (2.37–2.6 GHz) and truncated corner U-slot has 9.65 % (2.27–2.5 GHz). It is clear that all ARBW are aligned with the corresponding RLBW, resulting in CP bandwidths of 6.5 % (2.38–2.54 GHz) for the modified E-patch, 4 % (2.39–2.49 GHz) for the unequal arms U-slot, and 4.5 % (2.39–2.5 GHz) for the truncated corner U-slot.

The simulated S_{11} and axial ratios of the material substrate antennas are shown in Figs. 50 and 51, respectively. From the results, the modified E-patch exhibits 10.6 % impedance bandwidth (2.39–2.66 GHz), while unequal arms U-slot has 6.9 % (2.38–2.65 GHz) and truncated corner U-slot has 13.1 % (2.41–2.75 GHz). Again, all AR bandwidths are aligned with the corresponding S_{11} bandwidth, resulting in CP bandwidths of 3.6 % (2.41–2.5 GHz) for the modified E-patch, 2.8 % (2.36–2.55 GHz) for the unequal arms U-slot, and 3.3 % (2.39–2.5 GHz) for the truncated corner U-slot.

The CP characteristics of the three designs were verified experimentally in Yang et al. (2008), Tong and Wong (2007), and Khidre et al. (2010).

Designs for Wider CP Bandwidth

In Yang et al. (2008), a truncated square patch fed by an L-probe with an air substrate attained a usable bandwidth of 16 %. In Chung and Mohan (2003), truncated corner stacked square patches achieved a usable bandwidth of 17 %. Both antennas are relatively thick.

For thin substrates ($<0.03\ \lambda_0$), good CP bandwidth can be obtained by the use of dual feeds to provide the 90° phase difference for the two orthogonal modes, as illustrated in Fig. 52. This feeding method can attain about 10 % axial ratio bandwidth while keeping the substrate thin, although at the expense of more complexity in the feed circuitry (Hall and Dahele 1997).

The dual-feed design can be considered a special case of multi-feed design. It was shown that sequentially feeding a patch at suitable multiple locations with appropriate phasing leads to the cancelation of the cross circularly polarized components, resulting in improved axial ratio bandwidth (Hall and Dahele 1997).

As in the case of linear polarization, it is desirable in many situations to reduce the size of CP patch antennas, and a number of methods have been developed. Because of page limitations, they are not

described here. The reader is referred to the article on "Small Antennas in Wireless Communications" (Wong et al. 2012).

Frequency-Agile and Polarization-Agile Patch Antennas

In some applications, it is desirable to be able to tune the operating frequency of the patch antenna without having to fabricate a new antenna. In other applications, the ability to alter the polarization of the antenna will enable more efficient use of the allocated frequencies. The methods for designing frequency-agile patch antennas and polarization-agile patch antennas include tuning using varactor diodes, shorting pins, adjustable air gap, patch antenna with switchable slots, and U-slot and E-patches with switchable slots. Several of these will be described in this section.

Frequency-Agile Microstrip Patch Antennas

Tuning Using Varactor Diodes

For a given set of patch dimensions, the resonant frequency is primarily governed by the value of the relative permittivity ε_r of the substrate. If some means is available to alter ε_r, the resonant frequency will change. One method of achieving this is to introduce varactor diodes between the patch and the ground plane, as shown in Fig. 53. The diodes are provided with a bias voltage, which controls the varactor capacitance and hence the effective permittivity of the substrate. Bhartia and Bahl (1982) performed an experiment on this method and the results are shown in Fig. 54. The resonant frequency (f_r) of the lowest mode of the rectangular patch increases with the bias voltage, which changes the diode capacitance. It is seen that, in this experiment, a tuning range of some 20 % was achieved with a 10 V bias. The range

DOI 10.1007/978-981-4560-75-7_29-1

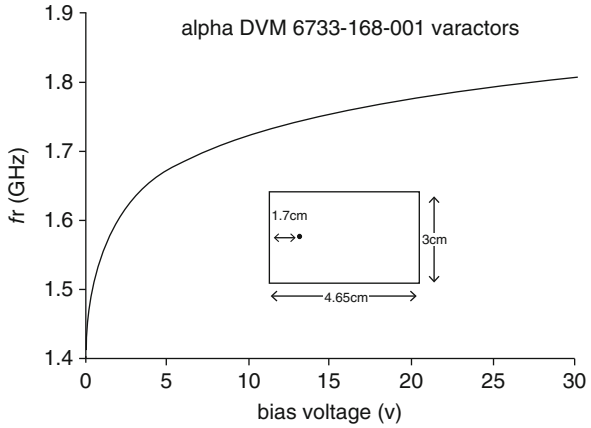

Fig. 54 Resonant frequency versus bias voltage for a varactor-loaded rectangular patch antenna

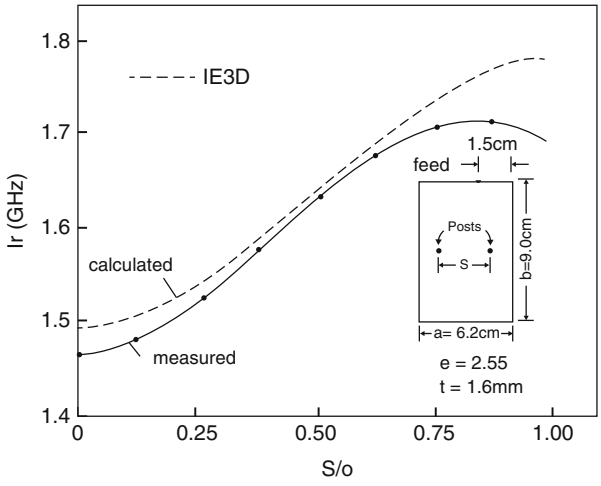

Fig. 55 Resonant frequency versus separation of posts for 6.2 × 9.0 cm rectangular patch antenna with $\varepsilon_r = 2.55$, t = 1.6 mm

increased to about 30 % with a 30 V bias. Note that the curve of frequency versus bias voltage is not a linear one. Similar results were obtained in Waterhouse and Shuley (1994) and Kalialakis and Hall (2007).

Tuning Using Shorting Posts (Pins)

The value of ε_r can also be changed by introducing shorting posts (pins) at various points between the patch and the ground plane. These shorting posts present an inductance and therefore affect the effective permittivity of the substrate. The method appeared to be first introduced by Schaubert et al. (1981), who performed an experiment on a rectangular patch using two pins, as shown in Fig. 55.

The solid curve in Fig. 55 was measured results, which shows that the resonant frequency is dependent on the separation of the two posts. A tuning range of some 18 % is obtained as the separation varies between 0 mm and the whole width of the patch.

It is not possible to analyze the rectangular patch with shorting pins using the cavity model. Full-wave analysis is necessary and a number of commercial software can be used to obtain simulation results.

The results using the Zeland IE3D simulation software are shown in the dashed curve in Fig. 55 for resonant frequency and in Fig. 56 for S_{11}.

DOI 10.1007/978-981-4560-75-7_29-1

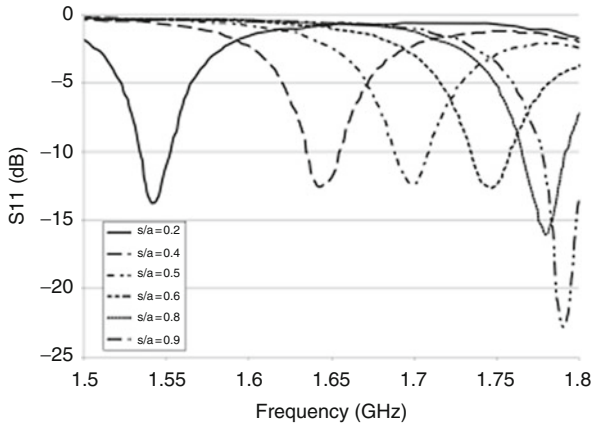

Fig. 56 Simulated reflection coefficient (S_{11}) versus frequency for six values of pin spacing

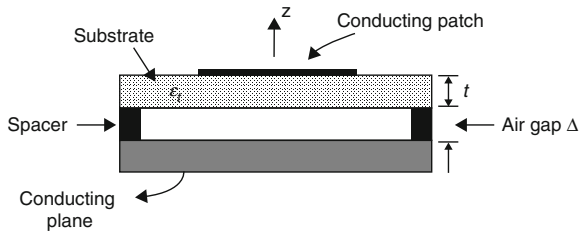

Fig. 57 Geometry of a microstrip patch antenna with an air gap

Tuning by Means of an Adjustable Air Gap

By introducing an air gap between the substrate and the ground plane in a microstrip patch antenna, the effective permittivity of the cavity will change. This can be used to tune the resonant frequency (Dahele and Lee 1985).

The geometry of a microstrip patch antenna with an air gap is shown in Fig. 57. The feed is not shown and will be discussed shortly.

Consider the cavity under the conducting patch. It is made of two layers: a substrate of thickness t and an air region of thickness Δ. Compared to the case with no air gap, the effective permittivity of the cavity is smaller. As a result, the resonant frequencies of the various modes will increase. Since the effective permittivity decreases as Δ increases, tending toward the free-space value of unity as $\Delta \to \infty$, it follows that the resonant frequencies can be tuned by adjusting the air gap with Δ. As a by-product, the bandwidth will also increase partly due to the increase in the height of the dielectric medium and partly because the effective permittivity is smaller. It is also to be noted that substrate and etching tolerances can be compensated by adjusting Δ.

A heuristic derivation of the effective permittivity and the resonant frequency of the two-layer cavity can be obtained by considering the capacitance of a capacitor with two dielectric layers, as shown in Fig. 58.

The overall capacitance is the two capacitors in series:

$$C = \frac{\varepsilon_1 \varepsilon_2 A}{\varepsilon_1 d_2 + \varepsilon_2 d_1} = \frac{\varepsilon_{\text{eff}} A}{d_1 + d_2} \tag{10}$$

where

DOI 10.1007/978-981-4560-75-7_29-1

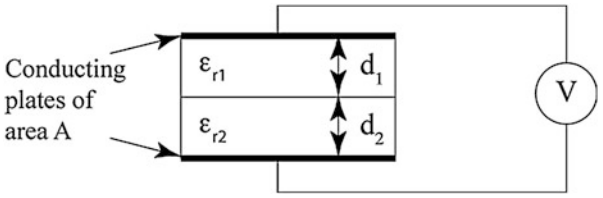

Fig. 58 A capacitor consisting of two dielectric layers

$$\varepsilon_{\text{eff}} = \frac{\varepsilon_1 \varepsilon_2 (d_1 + d_2)}{\varepsilon_1 d_2 + \varepsilon_2 d_1}. \tag{11}$$

Applying this result to the geometry of Fig. 58,

$$\varepsilon_{\text{eff}} = \frac{\varepsilon \varepsilon_0 (t + \Delta)}{\varepsilon_r \varepsilon_0 \Delta + \varepsilon_0 t} = \frac{\varepsilon (t + \Delta)}{(t + \Delta \varepsilon_r)} \tag{12}$$

Since $\varepsilon_r > 1$,

$$\varepsilon_{\text{eff}} < \varepsilon \qquad \text{when} \quad \Delta > 0$$

$$\varepsilon_{\text{eff}} = \varepsilon \qquad \text{when} \quad \Delta = 0$$

If the effective permittivity is used in the formula for the resonant frequency, we obtain, for the TM_{nm} mode,

$$f_{nm}(\Delta) = f(0) \sqrt{\frac{\varepsilon}{\varepsilon_{\text{eff}}}} \tag{13}$$

where $f_{\text{nm}}(0)$ is the resonant frequency when there is no air gap.

The formula for f_{nm} applies to any patch shape. As the air gap width increases, ε_{eff} decreases and the resonant frequency increases. The dependence of f_{nm} on Δ, however, is not a linear one.

Rectangular, circular, and annular-ring patches with air gaps fed coaxially had been studied by Lee and coworkers by means of the cavity model as well by full-wave analysis (Dahele and Lee 1985). The results were validated by an experiment. Typical tuning range is from 0 % to 20 %.

The disadvantage of applying the adjustable air gap method to coaxially fed patches is that, every time the air gap width is changed, the coaxial probe has to be de-soldered and resoldered to the patch. This disadvantage can be avoided if the patch is fed using coupling through an aperture or stripline, which was demonstrated in Mao et al. (2011).

Discussion Compared to the methods of using varactor diodes, or shorting pins, or switchable slot (Yang and Rahmat-Samii 2001b), the air gap method has the following advantages:

1. It can be applied to patches of any shape.
2. There is no need to add components or etch a slot in the patch.
3. The method is particularly attractive for an array consisting of many elements. If the elements are fed by apertures or strip lines, the resonant frequencies of all the elements, and therefore of the array, can be tuned by a single adjustment of the air gap width.

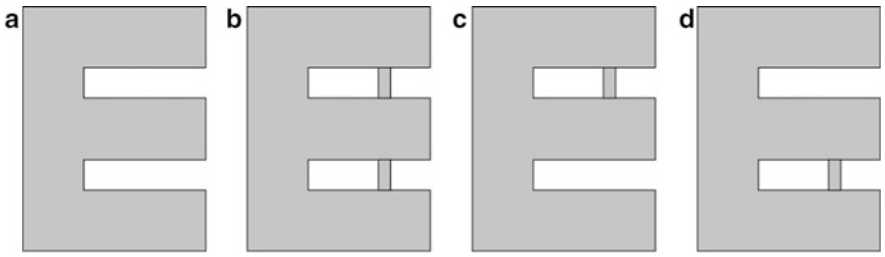

Fig. 59 Switching states of the reconfigurable E-shaped patch antenna: (**a**) LP state 1; (**b**) LP state 2; (**c**) LHCP state 3; and (**d**) RHCP state 4

Table 20 Antenna possible configurations (From Khidre et al. (2013). © 2013 IEEE, Reprinted with permission)

State	Switch 1	Switch 2	Frequency	Polarization
1	OFF	OFF	f_L	LP
2	ON	ON	f_H	LP
3	ON	OFF	f	LHCP
4	ON	OFF	f	RHCP

The disadvantage is that the air gap has to be changed mechanically. However, a MEMS-based electrostatically tunable circular patch antenna has been developed (Jackson and Ramadoss 2007).

Polarization-Agile E-Shaped Patch Antenna

Polarization-agile antennas are antennas whose polarization characteristics can be altered. They are also called polarization reconfigurable antennas and have received increasing attention in the last decade. Polarization agility is a desirable feature for wireless applications because it can double the system capacity through frequency reuse with two orthogonal polarizations without the need of integrating several individual antennas, thus rendering the wireless devices lighter and more compact. Reconfigurable circularly polarized antennas also provide a powerful modulation scheme for microwave tagging systems. They also have potential applications in multiple-input multiple-output (MIMO) systems. Polarization switching could be accomplished with the aid of switching devices such as PIN diodes and RF-MEMs.

Using switchable slots, Yang and Rahmat-Samii (2002) demonstrated a reconfigurable patch antenna for circular polarization diversity. The CP bandwidth obtained was 3 %. By using PIN diodes in U-slot patches, Qin et al. (2010) built two antenna prototypes; the first enables switching between linear and circular polarization, and the second switches between the two circular polarizations, with a CP bandwidth of 2.8 %. Khidre et al. (2013) designed and built CP polarization-agile patch antennas incorporating PIN diodes in an E-shaped patch and obtained CP bandwidth of 7 %. The operation principle, design, and performance of the polarization-agile antenna studied by Khidre et al. (2013) are presented below.

Operation Principle

When an E-shaped patch antenna is loaded with two switches on the slots as shown in Fig. 59, the antenna will have four possible states listed in Table 20. At state 1, the resonant frequency of the original E-shaped patch would be f_L and radiate linear polarized (LP) fields (Yang et al. 2001a). At state 2, the two switches are ON which allows the surface currents to pass through them, making the current path around the slots become shorter. Thus, the electrical length is smaller and the resonant frequency f_H would be higher ($f_H > f_L$). Due to the symmetry of the antenna structure, at state 2, the polarization would also be linear.

DOI 10.1007/978-981-4560-75-7_29-1

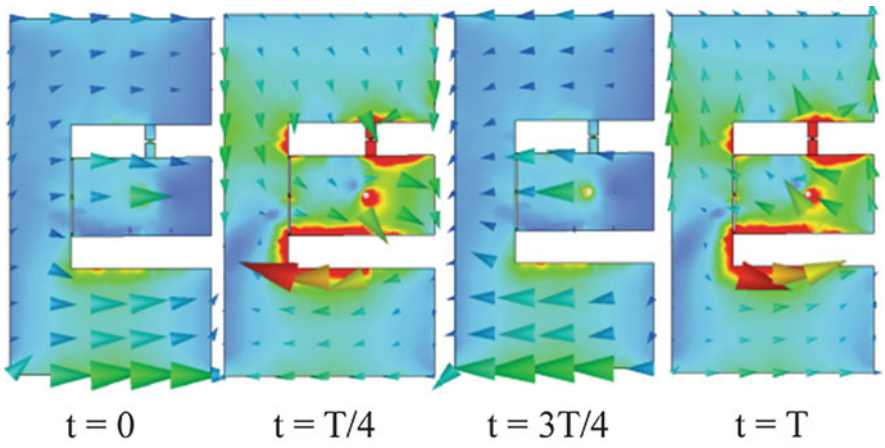

Fig. 60 Current distribution on the E-shaped patch antenna in state 3 during one-time cycle *T* (From Khidre et al. (2013). © 2013 IEEE, Reprinted with permission)

Consequently, going from state 1 to state 2 or vice versa is a frequency reconfigurable E-shaped patch antenna with linear polarization.

Recently, it has been shown that CP fields could be excited by E-shaped patch antenna with a wide effective bandwidth (9.27 %) (Khidre et al. 2010). Letting one of its slots shorter than the other would introduce asymmetry and perturb the field beneath the patch, thus producing CP fields. Therefore, an E-shaped patch antenna at state 3 effectively has the upper slot shorter than the lower one, and at an appropriate switch position on the upper slot, LHCP could be attained at resonant frequency f ($f_L < f < f_H$). In a similar fashion, state 4 gives RHCP. According to the above mechanism, wideband polarization reconfigurable E-shaped patch antenna is realized. The current distribution of an E-shaped patch antenna in state 3 is shown in Fig. 60, where the current rotates clockwise which implies LHCP.

Antenna Design

The reconfigurable E-shaped patch antenna geometry with labels is shown in Fig. 61. It is printed on a thin sheet of RT/duroid 5880 dielectric substrate with $\varepsilon_r = 2.2$ and thickness t = 0.787 mm. The substrate is mounted 10 mm above the ground plane by a coaxial single-feed pin. Although the antenna is built over air substrate for wide bandwidth, the thin dielectric substrate facilitates mounting the microwave components. The dimensions of the antenna are obtained through the procedure described in Khidre et al. (2010).

Two RF PIN diodes are inserted on the slots of the E-shaped patch antenna. A narrow slit of width $s = 0.5$ mm is incorporated on the E-shaped patch surface to avoid DC short across the diodes' terminals. Therefore, the E-shaped patch is divided into two parts: inner and outer one. Three DC block capacitors are inserted on the narrow slit to maintain RF continuity. The outer part of the E-shaped patch is DC grounded through a narrow shorted λ/4 transmission line, and the short circuit is realized by a vertical via as shown in Fig. 62b. This ensures high impedance at the edge of the E-shaped patch and hence keeps the RF current unperturbed on the E-shaped patch surface. The ground plane is common for both the DC and the RF signals. Its size is 200 × 100 mm. The RF and DC control signals are supplied to the antenna via the coaxial pin feed and are superimposed together through a tee bias for RF/DC isolation. Thus, the D2 diode would be ON and the D1 diode would be OFF when the inner part of the E-shaped patch is positively charged, resulting in RHCP. For LHCP, the terminals of the DC source have to be reversed; hence, the D1 diode would be ON and the D2 diode would be OFF.

Table 21 Antenna bandwidth simulated versus measured results at states 3 and 4 (From Khidre et al. (2013). © 2013 IEEE, Reprinted with permission)

Parameter	Simulation	Measured
S_{11} (*<–10 dB*)	2.39–2.6 GHz (8.4 %)	2.4–2.575 GHz (7 %)
Axial ratio(*<3 dB*)	2.4–2.6 GHz (8 %)	2.38–2.6 GHz (8.8 %)

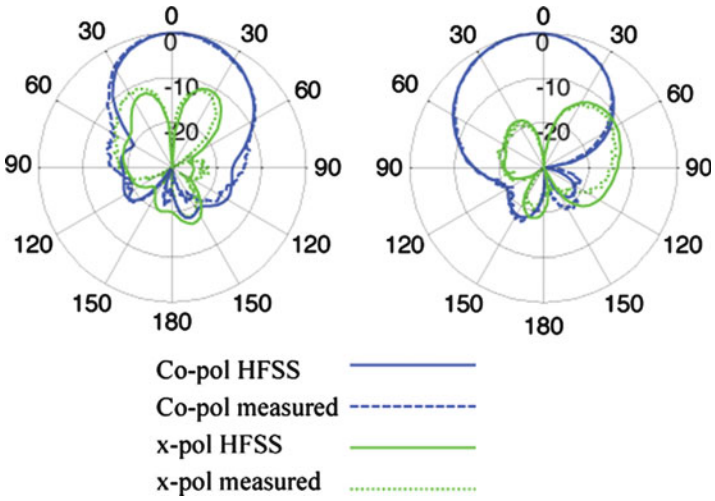

Fig. 64 Simulated and measured radiation pattern of the proposed antenna at 2.45 GHz: (**a**) x-z plane at state 3; (**b**) y-z plane at state 3; (**c**) x-z plane at state 4; and (**d**) y-z plane at state 4 (From Khidre et al. (2013). © 2013 IEEE, Reprinted with permission)

Antenna Performance

The simulated versus measured results of S_{11} and axial ratio in both switching states 3 and 4 are shown in Figs. 62 and 63, respectively. Good agreement between simulated and measured results is observed. Due to the structure symmetry, S_{11} and axial ratio are maintained along switching between the two states, which is an advantage of this design. This can be observed from Fig. 62, where S_{11} in state 3 is almost the

DOI 10.1007/978-981-4560-75-7_29-1

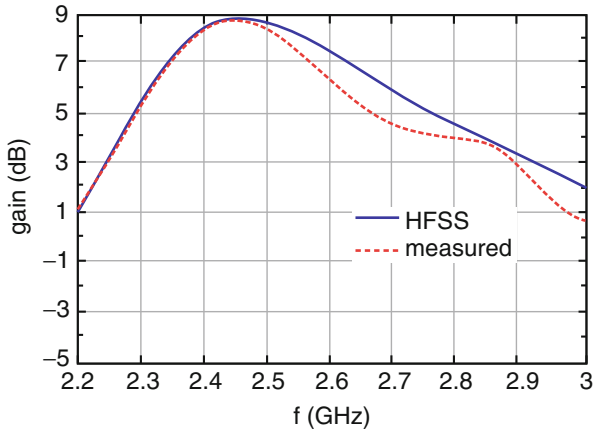

Fig. 65 Simulated and measured gain of the proposed antenna in either state 3 or state 4 (From Khidre et al. (2013). © 2013 IEEE, Reprinted with permission)

same as in state 4. Similarly, in Fig. 63 the axial ratio is kept the same in both switching states. The achieved impedance and axial ratio bandwidths calculated from simulation in comparison to measurements are tabulated in Table 21. From Table 21, the measured effective overlapped bandwidth (−10 dB S_{11} and 3 dB axial ratio) is 7 % (2.4–2.575 GHz), which is wideband for single-feed polarization-agile microstrip antenna designs.

Antenna radiation pattern at 2.45 GHz is shown in Fig. 64, where good agreement between the simulated and measured results is observed. The radiation pattern in y-z plane remains the same after switching, whereas in x-z plane, the radiation pattern is mirrored due to the symmetry of the structure. Experimental results along with the simulated one for the antenna gain versus frequency are shown in Fig. 65. Again, because of the symmetry, the broadside gain is the same in both modes of the antenna. To avoid redundancy, only RHCP mode is shown. Maximum realized gain is 8.7 dBi at 2.45 GHz according to both simulation and measurement, whereas the 3 dB gain bandwidth is 2.31–2.63 GHz (13 %) from measurement which covers the S_{11} and axial ratio bandwidths shown in Table 21.

Conclusion

This chapter began with descriptions of the basic geometry of the microstrip patch antenna, feeding methods, operation principles, and performance characteristics. The chapter then proceeded to present its development into a sophisticated and versatile antenna which is used in numerous military, space, commercial, and medical applications.

While the advances of the last three decades have been impressive, a number of challenges remain. For example, in size reduction, most of the methods developed focused on reducing the patch size, while useful guidelines on the effects of ground plane size on antenna characteristics have not been adequately developed. In broadbanding, the efficient methods developed all result in increased volume, which somewhat mitigate the low-profile advantage of microstrip patch antennas. The search for wideband, efficient, and low-profile patch antennas remains an area of active research.

Other than the basic geometry, there is a lack of design guides for most of the structures discussed in this chapter, such as the wideband U-slot patch, the L-probe-fed patch, or the patch with shorting pin. Antenna

designers have to rely on trial and error using a simulation software. It will be very helpful to develop useful formulas/guidelines/procedures which enable the designer to arrive at the first cut parameters, without relying on trial and error.

It is instructive to end this chapter by showing the photos and a sketch of several microstrip patch antennas used in space, military, commercial, and medical applications.

Reflector Antennas

Trevor S. Bird*
Antengenuity, Eastwood, NSW, Australia

Abstract

Reflector antennas are in widespread use in communications and radar applications in the twenty-first century. They are seen on towers for point-to-point telecommunication links, on houses for pay tv and in news items of spacecraft travelling to distant galaxies. This chapter provides an introduction to reflector antenna fundamentals for design and analysis. The history of the focusing properties of reflectors extends back to ancient times, but some of the more intricate properties such as defocusing have not been realised until recent times. Some basic reflector geometries are considered initially through a review of geometric optics. The basic design principles of a reflector are established from a rigorous point of view through a study of the paraboloid geometry, its radiation pattern and focal region fields. Practical reflectors have imperfections due to surface errors or misalignments, and how these impact the reflector radiation pattern is outlined. The means of feeding a parabolic reflector is outlined through a description of the dipole, waveguide and horn feeds. Some other reflector configurations are discussed including the offset parabolic reflector, the symmetrical and offset Cassegrain geometries and the spheroid. An introduction to reflector shaping is given through a description of two techniques. The chapter concludes with a description of three typical reflector applications in satellite communications, weather radar and radio astronomy.

Introduction

Reflector antennas are ubiquitous in communications and radar applications in the twenty-first century. They are seen on towers for point-to-point telecommunication links, on houses for pay tv and in news items of spacecraft travelling to distant galaxies. For many in society, they have become symbolic of progress and advancement in technology. Whilst the design and operation of reflectors is of crucial interest to many, for some the concepts are considered well established and lack interest for further study. Indeed, many of the basic concepts are known, but like many areas there are detailed topics of vital importance that require detailed knowledge for future designs to meet the ever-increasing performance criteria. The purpose of this chapter is to provide an introduction to the design principles of reflector antennas. In this approach, important techniques and concepts are introduced to assist the reader with basic reflector design principles and also to assist in suggesting improvements in design approaches. It could be part of a first lecture course on advanced antennas.

In transmission, a reflector antenna concentrates signals received from another antenna, called a feed, into a narrow beam of radiation in the far field. Close by, and in front of the reflector, the resulting aperture field is reasonably uniform. This field falls away rapidly normal to the reflector edge. Depending on the feeding arrangement, the beam can be scanned, or it can be broadened to cover a defined two-dimensional region, such as on the earth's surface from space. In reception, an incoming signal is directed by the reflector to the feed and the receiving electronics. As a result of the principle of reciprocity (Balanis 1982), the means of operation is the same whether in transmit or receive operation.

In the next section, a short history is given of reflector antennas up to recent times. This is followed by a description of some basic reflector geometries by means of geometric optics. The standard methods used in the analysis of reflector antennas are then reviewed as background. This is followed in the section "Introduction to Reflector Antennas" by basic design principles of a reflector from a rigorous point of view through study of the paraboloid. The impacts of reflector imperfections such as surface errors and misalignments on the reflector radiation pattern are outlined. The means of feeding a reflector is described where simple feed antennas and techniques are also discussed in the section "Introduction to Reflector Antennas." Other reflector configurations, such as the offset parabolic reflector and the Cassegrain geometry, are discussed later in the section as well as an introduction to reflector shaping. The chapter concludes with a description of three typical reflector applications, namely, satellite communications, dual-polarized weather radar and radio astronomy.

Background

Brief History of Reflector Antennas

The history of reflector antennas commences with basic configurations taken from optical astronomy such as the parabolic reflector and the Newtonian and Cassegrain geometries. The parabola has been well known from ancient times for its ability to focus rays from the sun. For example, it has been claimed that Archimedes in the third century BC, who had made a study of paraboloidal reflectors, used them to set the Roman fleet alight during the Siege of Syracuse. In the early experiments conducted by Heinrich Hertz in the late 1800s to verify the predictions of James Clerk Maxwell, a cylindrical parabolic reflector was used with his spark gap generator at an estimated operating frequency of about 450 MHz. The reflector was made of zinc sheet metal supported by a wooden frame and had a spark-gap excited dipole along its focus as shown in Fig. 1. The aperture size was 2 m high by 1.2 m wide, with a focal length of 0.12 m. Some of these antennas still exist today (see Fig. 1). Other early workers such as Bose employed plane reflectors in 1895 as part of their experiments on the electrical properties of materials. Following these early experiments, reflectors appear to have been little used until the 1920s when UHF and microwave sources became more readily available and experiments were conducted on communications and radar. During the 1930s, Marconi used a parabolic reflector on his ship *Electra* for investigations of UHF transmission. In March 1931, a 1.67 GHz microwave relay telephone link, called Micro-Ray, was demonstrated across the English Channel between Calais, France, and Dover, UK, using 10 ft (3 m) parabolic dishes (see Fig. 2a). As a result of this demonstration, a permanent link was established in 1934 between Lympne, France, and St Inglevert, UK. Also in the 1930s, Bell Technical Laboratories (BTL), USA, worked on a range of equipment, including reflectors operating at frequencies up to 500 MHz, for potential radio relay links operating at these frequencies. These advances would have to wait until efficient sources became available and higher frequencies were required. In 1937, a 9 m dish was built by pioneering radio astronomer Grote Reber in his backyard, where he undertook a sky survey that resulted ultimately in the new field of radio astronomy. About this time, in 1938, early airborne radar experiments were conducted in the UK using the 30 cm wavelength and a 2 ft (60 cm) square cylindrical parabola. The invention of the resonant magnetron

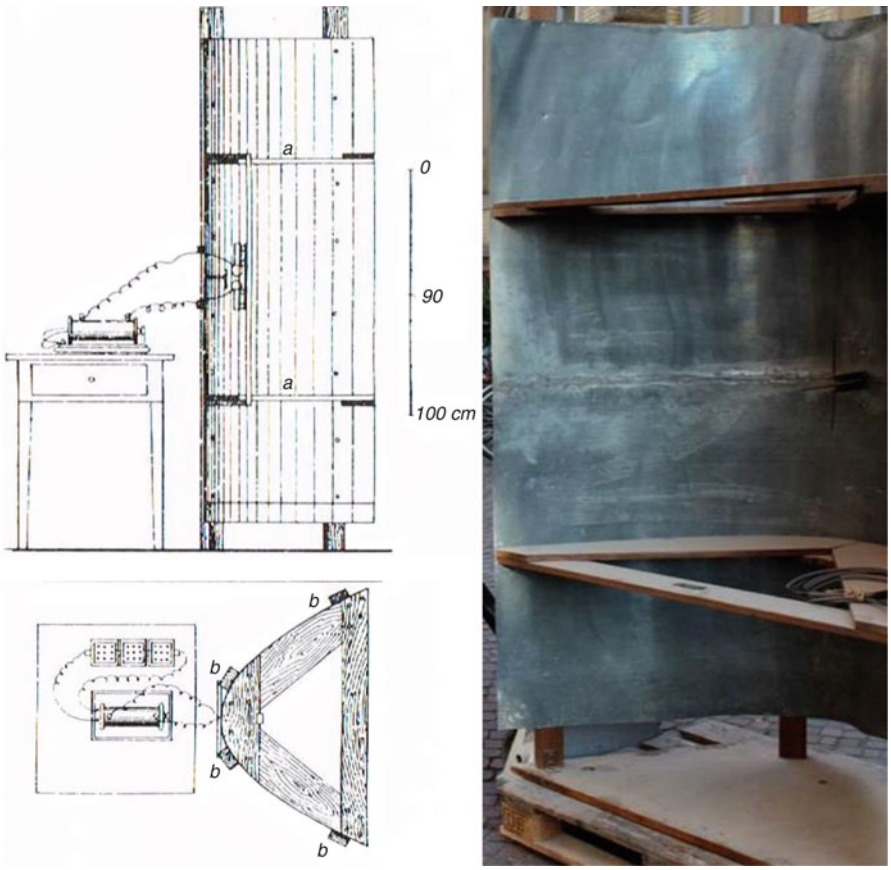

Fig. 1 The Hertz cylindrical parabolic reflector or mirror used for experiments on 'electric radiation' at Karlsruhe, Germany (Hertz 1892)

by Boot and Randall in 1940 made centimetre-wave radar technically feasible, as well as communications. The former application resulted in the evolution of air interception radar and the use of dishes in aircraft from 1941 onwards in Britain and the USA. Other defence equipment employing reflectors were developed at this time (e.g., gun-laying radar). Theoretical aspects of reflectors were not neglected. The development of techniques beyond geometric optics in occurred in several institutes in the 1940s and particularly the MIT Radiation Laboratory in the USA, where technical reports and notes were disseminated after 1945 in textbooks. In particular, the book by Samuel Silver (1985) on microwave antennas contained a detailed description of reflector antenna design that was the definitive statement on the topic for upwards of 30 years and is still a very major reference. Thus, during the early 1940s, radar provided a great incentive for reflector antenna research, and this resulted in many new developments such as improved feeding techniques and shaped-beam antennas, in which the reflector is shaped differently in two orthogonal planes to produce a beam of a particular shape. The consolidation of the concepts in the 1950s resulted in further applications such as terrestrial links, and also advances in radio astronomy saw the construction of three large parabolic reflectors over 60 m in diameter at Jodrell Bank, UK, Parkes, Australia, and Greenbank, USA. The introduction of geostationary satellites for global communications in the 1960s witnessed the wide use of many types of dish antennas for communication networks, which conveyed telephone calls and television programmes across continents. One of the first parabolic reflector antennas used for commercial satellite communications was constructed in 1962 at Goonhilly Downs, Cornwall, England, to communicate with the Telstar satellite. The stabilized satellites that then became available were able to point a narrow beam continuously towards the earth (with a despun platform, for

example) with the result that high-gain reflectors were introduced on-board satellites. On the ground, with the increased signal, smaller and cheaper reflectors (e.g., 30 m) could be used. Many countries around the world consolidated the dishes for this purpose at a central location, now referred to as teleport. The first reflector with a dual-reflector Cassegrain configuration (see Fig. 2e) was installed in Japan in 1963. These were assisted by improvements in understanding of reflector design and associated design techniques. The widespread use of computers in the 1960s and the advent in the 1970s of computer design tools as well as the further development of techniques such as the geometrical theory of diffraction led to improved design accuracy and reflector performance. Some of these techniques will be described in this chapter. There are two major reviews of developments in reflector antenna design and application that contain valuable information, one in the 1980s (Rusch 1984) and another at the end of the 1990s (Bird and James 1999), both of which are worth consulting for further details of reflectors.

Basic Reflector Geometries

The basic reflector geometries are shown in Fig. 2. Most configurations shown arose in optical astronomy and are designed to maximize the signal in one direction only, which is determined by the amplitude and phase distribution across the aperture. The paraboloid in Fig. 2a is the most commonly occurring type of reflector configuration. An offset version is shown in Fig. 2b. Another reflector shape that is used is the spherical reflector Fig. 2d, which does not have a single point focus but a focal line along its axis. The use of a subreflector with a parabola in a Cassegrain configuration as shown in Fig. 2c, e can have enhanced performance such as increased antenna gain because feed lines can be short, which also assists to reduce the antenna noise temperature. A disadvantage of any axisymmetric reflector antenna system is the blockage created by the feed or the subreflector and any associated strut supports. These obstructions have a deleterious effect on the antenna gain and, often more importantly, on sidelobe levels. Blockage

DOI 10.1007/978-981-4560-75-7_30-1

effects can be avoided by means of the offset-fed reflector configurations shown in Fig. 2b, e, f. Although the lack of symmetry creates a number of design problems, these antennas are capable of performance which is superior to that of their axisymmetric counterparts. A difficulty of single offset reflectors Fig. 2b is the high cross-polarization due to the offset feed. However, this can be largely overcome in Fig. 2e, f by means of a subreflector, which, along with the feed offset angle, can be adjusted to cancel out the cross-polarization due to the offset feeding. A spherical reflector equivalent is the Gregorian configuration which has a concave subreflector illustrated in Fig. 2f. In reception, the secondary reflector, which is located axially outside of the primary focus, forms a properly oriented final focus by refocussing the diverging wave emanating from the primary reflector. Furthermore, if the subreflector is shaped, the primary and subreflector combination can be arranged to have a point focus. There are other well-known reflector configurations that are not shown here but which are most suitable for some applications such as the Schwartzfeld system for beam steering.

Geometric Optics and Ray Tracing Description of Reflectors

The laws of reflection at a perfect conductor require the incident and reflected ray directions, $\mathbf{s_i}$ and $\mathbf{s_r}$, to satisfy the following:

$$(\mathbf{s_i} - \mathbf{s_r}) \times \hat{n} = 0 \tag{1a}$$

$$(\mathbf{s_i} + \mathbf{s_r}) \cdot \hat{n} = 0 \tag{1b}$$

where $\hat{n}$ is the normal to the reflector surface, Σ, so that

$$\mathbf{s_r} = \mathbf{s_i} - 2\hat{n}(\hat{n} \cdot \mathbf{s_i}). \tag{1c}$$

Thus, Eq. 1 indicates $\mathbf{s_i}$ and $\mathbf{s_r}$ lie in the same plane and also the angle of incidence relative to the normal equals the angle of reflection after taking into account that one angle is 360° minus the angle for the other ray.

The boundary condition at the surface requires the total net tangential electric field to be zero and for continuity of the normal components of the electric field. Referring to Fig. 1.2.1, if $\mathbf{E_i}$. is the incident electric field and $\mathbf{E_r}$ is the reflected field, these require

$$(\mathbf{E_i} + \mathbf{E_r}) \times \hat{n} = 0 \tag{2a}$$

and

$$(\mathbf{E_i} - \mathbf{E_r}) \cdot \hat{n} = 0. \tag{2b}$$

Taking the cross-product of Eq. 2a and $\hat{n}$ results in $(\mathbf{E_i} + \mathbf{E_r}) - \hat{n}[(\mathbf{E_i} + \mathbf{E_r}) \cdot \hat{n}] = 0$.

Utilizing Eq. 2b, it is found that

$$\mathbf{E_r} = 2\hat{n}(\hat{n} \cdot \mathbf{E_i}) - \mathbf{E_i}. \tag{3}$$

Equation 3 gives the reflected electric field at the surface, Σ, in terms of the incident field. The field reflected from a paraboloid is a plane wave, and extra phase shift must be included to account for the plane wave path s_r (Fig. 3) from the reflector to the aperture. Since the total path length is $2f$ and the ray path length from the focus to the reflector is ρ,

DOI 10.1007/978-981-4560-75-7_30-1

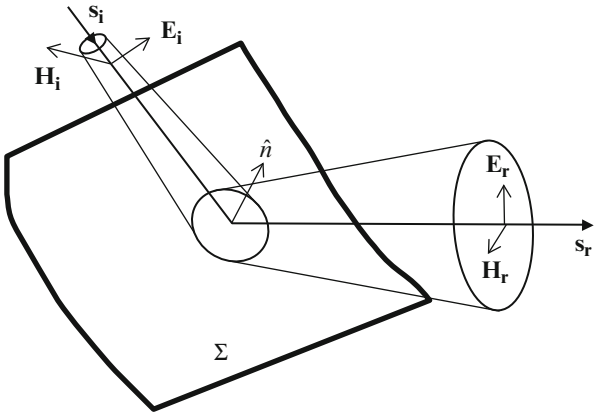

Fig. 3 Reflection at a conducting surface Σ

$$s_{\mathbf{r}} = 2f - \rho.$$

Therefore, the approximate aperture field in the plane at $z = 0$ due to an arbitrary incident field is

$$\mathbf{E}_a = \left[2\hat{n}\left(\hat{n} \cdot \mathbf{E}_f\right) - \mathbf{E}_f\right] e^{-jk(2f-\rho)} \tag{4a}$$

$$\mathbf{H}_a = \frac{1}{\eta_o}\hat{z} \times \mathbf{E}_a \tag{4b}$$

Suppose the feed antenna radiates an incident electric field at the reflector in the following form:

$$\mathbf{E_i} = \left(\hat{\psi}' F_\psi(\psi', \xi') + \hat{\xi}' F_\xi(\psi', \xi')\right) \exp(-jk\rho')/\rho' \tag{5}$$

where the primed coordinates (ρ', ψ', ξ') are coordinates relative to the feed phase centre. Many feed types such as waveguides and horns can be represented by the feed functions

$$F_\psi(\psi', \xi') = A(\psi') \cos \xi' \text{and } F_\xi(\psi', \xi') = -B(\psi') \sin \xi'. \tag{6}$$

If $A(\psi) = B(\psi)$, Eq. 5 becomes

$$\mathbf{E_i} = A(\psi')\left(\hat{\psi}' \cos \xi' - \hat{\xi}' \sin \xi'\right)\Big) \exp(-jk\rho')/\rho' = \hat{x}' A(\psi') \exp(-jk\rho')/\rho'$$

indicating the incident field is linearly polarized and the radiation pattern is axisymmetric.

Suppose the feed phase centre is coincident with the focus of the reflector. For illustrative purposes, assume the reflector is a perfect paraboloid, in which case $\rho = 2f/(1 + \cos\psi)$ is the distance from the focus to the surface of the paraboloid. By elementary methods, the normal to the surface can be shown to be given by

DOI 10.1007/978-981-4560-75-7_30-1

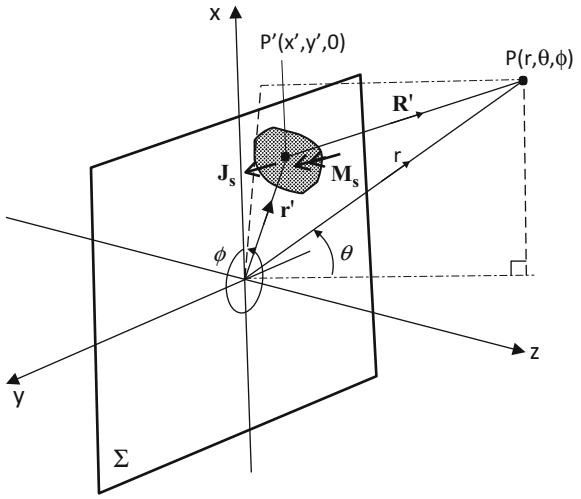

Fig. 4 Calculation of radiated fields at observation point P from aperture currents at source point P′

$$\hat{n} = \hat{\rho}\cos\frac{\psi}{2} + \hat{\psi}\sin\frac{\psi}{2}.$$

Substituting this and Eq. 5 into Eq. 4a results in electric fields in the aperture plane as

$$\mathbf{E}_a = -\left[\hat{\rho}F_\psi \sin\psi + \hat{\psi}F_\psi \cos\psi + \hat{\xi}F_\xi\right](1 + \cos\psi)\frac{\exp(-jk2f)}{2f}.$$

When expressed in rectangular coordinates, the field is

$$\mathbf{E}_a = -\left[\hat{x}\left(F_\psi \cos\xi - F_\xi \sin\xi\right) + \hat{y}\left(F_\psi \sin\xi + F_\xi \cos\xi\right)\right](1 + \cos\psi)\frac{\exp(-jk2f)}{2f}. \tag{7}$$

Introducing Eq. 25 into Eq. 26, the aperture field reduces to

$$\mathbf{E}_a = -\left[\hat{x}\left(A(\psi)\cos^2\xi + B(\psi)\sin^2\xi\right) + \hat{y}\sin 2\xi\left(\frac{A(\psi) - B(\psi)}{2}\right)\right](1 + \cos\psi)\frac{\exp(-jk2f)}{2f} \tag{8}$$

Further, for a feed with an axisymmetric pattern, the aperture field is also linearly polarized:

$$\mathbf{E}_a = -\ \hat{x}A(\psi)(1 + \cos\psi)\frac{\exp(-jk2f)}{2f} \tag{9}$$

Aperture Fields and Fourier Transforms

It will be shown that fields radiated by a planar antenna from a surface on which currents are specified can be determined by means of aperture integration. In general, the antenna can be represented by both electric and magnetic currents on its aperture plane. Suppose these currents are denoted by $\mathbf{J_s}$ and $\mathbf{M_s}$ on a surface Σ as shown in Fig. 4. These currents can be estimated or calculated from either approximate or rigorous analysis methods. In the far field of the surface Σ on which the currents are located, the radiated fields are given by

DOI 10.1007/978-981-4560-75-7_30-1

$$\mathbf{E} \approx \frac{jk}{4\pi}\frac{e^{-jkr}}{r}\hat{r} \times \int_{\Sigma}\left[\mathbf{M_s} - \eta \mathbf{J_s} \times \hat{R}\right]\exp(jk\hat{r}\cdot\mathbf{r}')dS' \tag{10a}$$

and

$$\mathbf{H} = \frac{1}{\eta_o}\hat{r} \times \mathbf{E} \tag{10b}$$

where $\hat{r}$ is a unit vector in the radial direction, $\hat{R}$ is a unit vector from the source point (in primed coordinates) to the far-field point as shown in Fig. 4. $\eta_o = \sqrt{\mu_o/\varepsilon_o}$ is the free-space wave impedance, where μ_o and ε_o are the permeability and permittivity of free space, respectively. Equation 10b implies that the field radiated by the aperture is a wave with a spherical wave front. In the far-field region, the field is polarized tangential to the radiation sphere since there are no radial components (i.e., $E_r = 0 = H_r$). For a plane aperture coincident with the x-y plane, the surface currents are given by

$$\mathbf{J_s} = \hat{n} \times \mathbf{H_a} \text{ and } \mathbf{M_s} = -\hat{n} \times \mathbf{E_a} \tag{11}$$

where ($\mathbf{E_a}$, $\mathbf{H_a}$) are the total fields on the aperture. From Eq. 9a, the radiated field is

$$\mathbf{E} \approx -\frac{jk}{4\pi}\frac{e^{-jkr}}{r}\hat{r} \times \int_{A}[\hat{z} \times \mathbf{E_a} + \eta(\hat{z} \times \mathbf{H_a}) \times \hat{r}]\exp(jk\hat{r}\cdot\mathbf{r}')dS'. \tag{12}$$

Using the standard vector relationships between rectangular and spherical coordinate systems, namely,

$$\hat{x} = \hat{r}\sin\theta\cos\phi + \hat{\theta}\cos\theta\cos\phi - \hat{\phi}\sin\phi$$

$$\hat{y} = \hat{r}\sin\theta\sin\phi + \hat{\theta}\cos\theta\sin\phi + \hat{\phi}\sin\phi$$

$$\hat{z} = \hat{r}\cos\theta - \hat{\theta}\sin\theta$$

from which Eq. 31 can be expressed in spherical components as

$$E_r = 0 \tag{13a}$$

$$E_\theta \approx \frac{jk}{4\pi}\frac{e^{-jkr}}{r}\left[\left(N_x\cos\phi + N_y\sin\phi\right) - \eta_o\cos\theta\left(L_x\sin\phi + L_y\cos\phi\right)\right] \tag{13b}$$

$$E_\phi \approx \frac{jk}{4\pi}\frac{e^{-jkr}}{r}\left[\cos\theta\left(-N_x\sin\phi + N_y\cos\phi\right) + \eta_o\left(L_x\cos\phi + L_y\sin\phi\right)\right] \tag{13c}$$

where N_x, N_y, L_x and L_y are the components of the vectors

$$\mathbf{N}(u,v) = \int_{A}\mathbf{E_a}(x',y')\exp(j2\pi(ux' + vy'))dx'dy' \tag{14a}$$

DOI 10.1007/978-981-4560-75-7_30-1

$$\mathbf{L}(u,v) = \int_A \mathbf{H_a}(x',y')\exp(j2\pi(ux' + vy'))dx'dy'. \tag{14b}$$

The functions

$$u = \frac{1}{\lambda}\sin\theta\cos\phi \tag{15a}$$

and

$$v = \frac{1}{\lambda}\sin\theta\sin\phi \tag{15b}$$

are variables in the u-v plane, which is often preferred over the standard spherical angles for presenting the far fields in two dimensions. It can be seen from Eq. 14 that the components of **N** and **L** are two-dimensional Fourier transforms of the aperture field components between the x-y and u-v planes. When the magnetic field in the aperture is related to the electric field through Eq. 4b, **L** is related to **N** as follows:

$$\mathbf{L} = \frac{1}{\eta_o}\hat{z} \times \mathbf{N}.$$

Consequently, Eqs. 13b and 13c simplify to

$$E_\theta \approx \frac{jk}{4\pi}\frac{e^{-jkr}}{r}(1 + \cos\theta)\left(N_x\cos\phi + N_y\sin\phi\right) \tag{16a}$$

and

$$E_\phi \approx \frac{jk}{4\pi}\frac{e^{-jkr}}{r}(1 + \cos\theta)\left(-N_x\sin\phi + N_y\cos\phi\right) \tag{16b}$$

Through Eqs. 16 or 13, it is apparent that the far-zone fields are related to the Fourier transforms of the aperture field distributions. Some relationships for simple aperture distributions are illustrated in Fig. 5.

Physical Optics Method

A powerful approach to analysing radiation from reflectors involves estimating the currents on the actual reflector surfaces and by means of Maxwell's equations transforming these into the far field. The field expressions given in the previous section are modified to suit the change in summation of the elementary currents – for a reflector, either the main or a subreflector, which are usually large in terms of wavelengths. A good approximation is to assume that at any point on the reflector, the current that is induced is the same as if for an infinite plane conductor. This principle is called physical optics (PO). Relevant to the previous equations, on a conducting surface there are no magnetic currents.

If the feed radiates a magnetic field $\mathbf{H_f}$ at the reflector surface, the surface current is given by

$$\mathbf{J_s} = 2\hat{n} \times \mathbf{H_f}|_{reflector\Sigma} \tag{17}$$

DOI 10.1007/978-981-4560-75-7_30-1

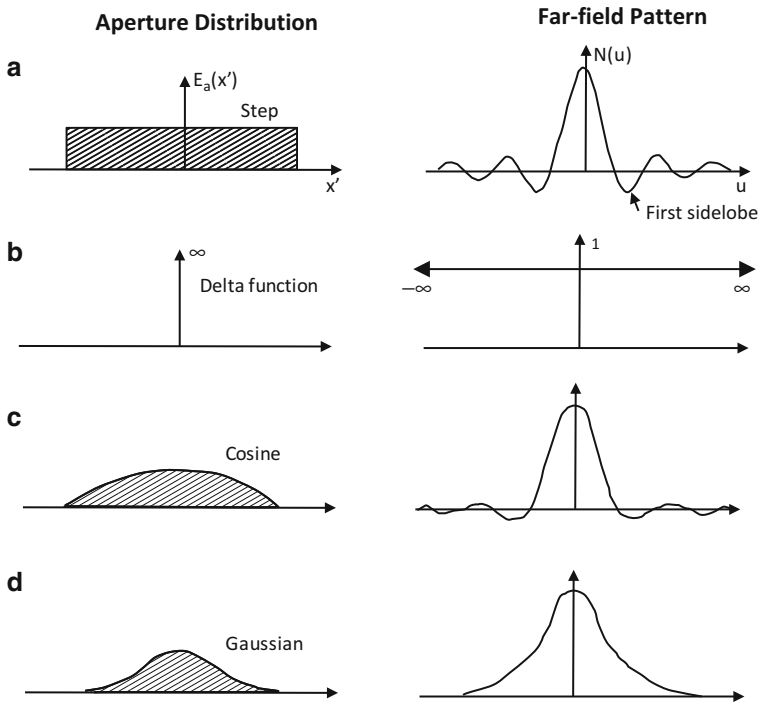

Fig. 5 Fourier transform relationships for simple aperture distributions and the resulting transforms. (**a**) Unit step; (**b**) delta function; **c** cosine; and Gaussian distributions.

where $\hat{n}$ is the unit outward normal to the reflector surface Σ. The factor of 2 appears in Eq. 17 because the total magnetic field at a plane conductor is twice the incident field.

Equation 17 may be used in Eq. 10 to calculate the radiated fields. There is no magnetic surface current on the surface Σ, and as a result, the radiated electric field can be rewritten as

$$\mathbf{E}(r,\theta,\phi) = -\frac{jk\eta_o}{4\pi}\frac{e^{-jkr}}{r}[\mathbf{F}(\theta,\phi) - \hat{r}(\mathbf{F}(\theta,\phi)\cdot\hat{r})] \tag{18}$$

where

$$\mathbf{F}(\theta,\phi) = \int_{\Sigma} \mathbf{J_s}\exp(jk\,\hat{r}\cdot\mathbf{r}')dS'. \tag{19}$$

The primed coordinates in this instance refer to the source components on the reflector surface. The purpose of the second term inside the square brackets of Eq. 18 is to cancel out a radial vector component produced by the first term because there is no radial component in the far-field region.

Introduction to Reflector Antennas

With some fundamentals in hand and awareness of some basic reflector geometries in Fig. 2, some of the basic properties of the radiation from reflector antennas will now be investigated. Before commencing this, there are some standard terms that require definition.

DOI 10.1007/978-981-4560-75-7_30-1

Elementary Terminology

Feed

A basic component of a reflector is the feed antenna. The aim is to illuminate the reflector to give the desired energy distribution because as the Fourier transform relations show, if the illumination is highly tapered, the antenna beam is broader than when the illumination is uniform. In addition, the amplitude of the first sidelobe is higher for a uniform distribution compared with a tapered one. When the phase has a gradient across the aperture, the beam will be steered at some angle from boresight.

The most common type of feed is a waveguide or horn although the dipole is sometimes preferred at frequencies below about 1 GHz. Without some type of reflector or cup at the rear of the dipole, a significant amount of power is radiated as a backlobe, which combines with the radiation of the reflector to fill in the sidelobe nulls and also raises the levels of the odd-numbered sidelobe levels. The horn has low levels of rear radiation and can have a low input reflection coefficient over a broad range of frequencies.

Beamwidth and Radiation Patterns

The beamwidth of a reflector antenna is very strongly dependent upon the feed illumination over its surface. Based on Fourier relationships, a circular aperture of diameter D that is uniformly illuminated has a half-power beamwidth (HPBW) approximately equal to $1.02/(D/\lambda)$. With a $\left(1-(2r/D)^2\right)^p$ aperture distribution where r is the distance from the aperture centre, the HPBW increases for $p \geq 1$ as $\approx \left[1.27^{(p+1)/2}\right](\lambda/D)$. The radiation patterns are usually presented in the form of pattern cuts through the far-field sphere for the radiation from a reflector that has two planes of symmetry. For a reflector producing a shaped beam over a surface, it is usual to make a two-dimensional plot of the radiation. For a reflector excited by a feed with radiation given by Eq. 25, the radiation patterns in the two principal planes corresponding to the planes parallel to the electric field polarization, the E-plane, and also the pattern cut orthogonal to it, the H-plane, are of interest. Also of interest is the cross-polarized radiation in the

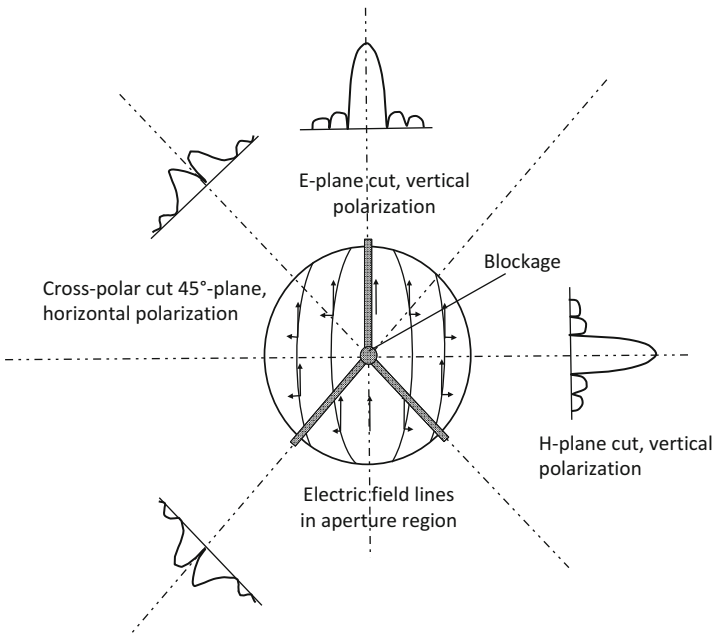

Fig. 6 Relationship of aperture field to radiation pattern cuts.

DOI 10.1007/978-981-4560-75-7_30-1

45-degree planes (see Fig. 6). How these patterns are defined shall be described in more detail later in this section.

Reflector Antenna Gain and Efficiency

Antenna gain is defined as the ratio of the power received at (θ,ϕ) if this same power were radiated isotropically as compared with the total input power. Thus, when P_r is the power density radiated at (θ,ϕ), and P_T is the total input power; the gain at (θ,ϕ) is defined as

$$G(\theta,\phi) = \frac{4\pi r^2 P_r}{P_T}. \tag{20a}$$

Furthermore, the power density in the far field is given by $P_r = |\mathbf{E}\cdot\mathbf{E}|/2\eta_o$ where the electric field is $\mathbf{E}(r,\theta,\phi) = \left(\hat{\theta}E_\theta(\theta,\phi) + \hat{\phi}E_\phi(\theta,\phi)\right)\exp(-jkr)/r$. Also in the far field, the magnetic field is given by $\mathbf{H}(\theta,\phi) = (\hat{r}\times\mathbf{E})/\eta_o$. Therefore, Eq. 20a reduces to

$$G(\theta,\phi) = \frac{2\pi\left(|E_\theta|^2 + |E_\phi|^2\right)}{\eta_o P_T}. \tag{20b}$$

Maximum gain occurs at directions close to the axis either in the boresight direction or in a steered direction at some angle not far from it.

Under conditions of uniform aperture and phase across the aperture, a reflector of diameter D has a maximum gain of

$$G_o = \left(\frac{\pi D}{\lambda}\right)^2 \tag{21}$$

The reflector illumination is usually tapered in order to keep sidelobes to acceptably low levels. As a result, the gain is less than that given by Eq. 21. To include illumination tapering, the maximum gain is usually defined as

$$G_{\max} = \eta_a G_o \tag{22}$$

where η_a is the aperture efficiency as compared with uniform illumination.

Equation 22 neglects losses in the reflector system due to feed spillover, mismatch, reflector surface errors, etc. These power losses can be accommodated in Eq. 20 by introducing efficiency factors for each loss mechanism. Initially, consider one of these losses called feed spillover. The power density radiated by a feed is

$$P_f = \frac{1}{2\eta}|\mathbf{E_f}|^2.$$

which results in a total radiated power

$$P_T = \int_0^{2\pi} d\xi \int_0^{\pi} P_f \rho \sin\psi d\psi. \tag{23}$$

DOI 10.1007/978-981-4560-75-7_30-1

Not all the power in Eq. 23, however, is intercepted by the reflector. Some of it falls outside the reflector causing power loss. This power loss is called spillover. The power collected by a reflector subtending an angle ψ_c is

$$P_c = \frac{1}{2\eta}\int_0^{2\pi} d\xi \int_0^{\psi_c} |\mathbf{E_f}|^2 \rho \sin\psi d\psi. \tag{24}$$

By conservation of power, the power lost due to spillover is

$$P_s = P_T - P_c = \frac{1}{2\eta}\int_0^{2\pi} d\xi \int_{\psi_c}^{\pi} |\mathbf{E_f}|^2 \rho \sin\psi d\psi.$$

The spillover efficiency is defined as the ratio of the power that is collected by the reflector and the total radiated power ie.

$$\eta_s = \frac{P_c}{P_T} = 1 - \frac{P_s}{P_T}. \tag{25}$$

By means of Eqs. 23 and 24, this is expressed as

$$\eta_s = \frac{\int_0^{2\pi} d\xi \int_0^{\psi_c} |\mathbf{E_f}|^2 \rho \sin\psi d\psi}{\int_0^{2\pi} d\xi \int_0^{\pi} |\mathbf{E_f}|^2 \rho \sin\psi d\psi}. \tag{26}$$

Ideally, η_s should be close to 1; typically, it has a value around 80–90 %. The maximum antenna gain given by Eq. 22 now becomes

$$G_{\max} = \eta_a \eta_s \left(\frac{\pi D}{\lambda}\right)^2 = \eta_a \eta_s G_o. \tag{27}$$

In the same way, efficiency factors may also be defined for other losses. Let

$\eta_f =$ feed mismatch efficiency
$\eta_c =$ conductor efficiency
$\eta_r =$ reflector surface roughness efficiency

These efficiencies may be included in the gain function in much the same way as described for spillover. To include all such losses, it is convenient to define an overall efficiency factor as the product of all efficiencies as

$$\eta_T = \eta_a \eta_s \eta_f \eta_c \eta_r. \tag{28}$$

Finally, the maximum antenna gain is expressed as

$$G_{\max} = \eta_T G_o. \tag{29}$$

DOI 10.1007/978-981-4560-75-7_30-1

Gain will be discussed in connection with specific reflector geometries in the following sections.

Edge Taper and Edge Illumination

As the feed illuminates the reflector from some distance, depending on the type of reflector, this illumination can vary with angle. For example, for a paraboloid, the distance from the focus to the reflector edge is greater than to the centre of the reflector. As has been discussed, the radiation pattern is closely related to the aperture illumination and in particular the tapering. It is, therefore, common practice to refer to the level of the field at the edge of the reflector as a rule of thumb for the antenna beamwidth and sidelobe levels. Two different terms are used, often interchangeably.

1. Edge illumination (i.e., illumination at the edge) is the ratio of the field strength radiated by the feed in the direction of the edge and its level at the reflector vertex when both are measured on the surface of a sphere (of radius given by the distance from the focus to the vertex).
2. Edge taper is the ratio of the feed field strength at the actual reflector edge and the corresponding level at the reflector vertex. The difference between edge illumination and edge taper is the freespace loss due to the additional distance δ from the sphere of radius f to the reflector rim. If E is the edge illumination, by definition edge taper, T, is

$$T = E/L_e$$

where $L_e = (f+\delta)/f$ is the edge taper loss. For a paraboloid, $\delta = f/(4f/D)^2$ and, therefore, $L_e = 1 + \left[1/(4f/D)^2\right]$. In dB, the relationship is

$$\text{Edge taper (dB)} = \text{Edge illumination(dB)} - \text{L}_\text{e}\text{(dB)}. \tag{30}$$

For example, a paraboloid with $f/D = 0.35$ is illuminated by a feed with an edge illumination of -10 *dB;* the edge taper is -13.58 *dB*.

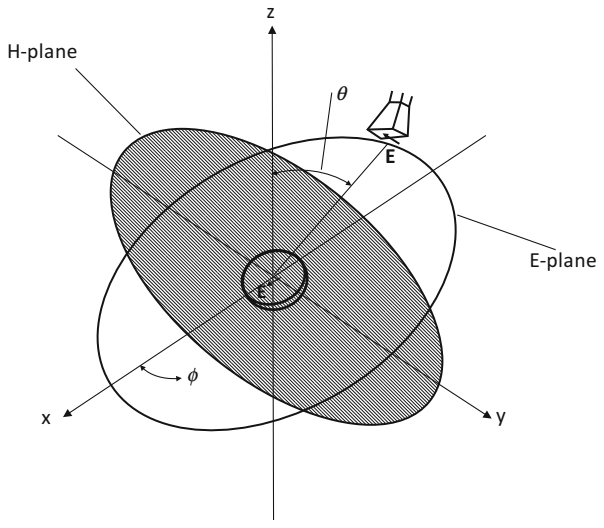

Fig. 7 Principal plane radiation pattern cuts

DOI 10.1007/978-981-4560-75-7_30-1

Co- and Cross-Polarized Radiation Patterns

The far fields of an antenna are tangential to the surface of a sphere centred on the antenna since $E_r = 0$ as illustrated in Fig. 7. Thus, the remaining field components on the surface are aligned in the $\hat{\theta}$ and $\hat{\varphi}$ directions. The field is linearly polarized if the components, E_θ and E_ϕ, are everywhere in constant phase difference in time. When the field components are $\pm 90^\circ$ out of phase in time, the field is circularly polarized. The field is elliptically polarized for an arbitrary phase difference.

The polarization generally varies over the surface of the far-field sphere, and as a consequence, it is important to control the polarization in the main directions required for the application. The principal plane cuts in the E- and H-directions, shown in Fig. 7, usually provide sufficient information about a reflector and/or feed that have two planes of symmetry. Furthermore, it is useful to understand the field components relative to the chosen field polarization. To do this, consider a field given by **E**. Let a unit vector in the direction of the reference polarization, or the co-polarized component, be **p,** and let a unit vector in the orthogonal or cross-polarized direction be **q**. As a result,

$E_p = \mathbf{E} \cdot \mathbf{p}$ – co-polarxized component of the electric field

$E_q = \mathbf{E} \cdot \mathbf{q}$ – cross-polarized component of the electric field.

With this definition of the **p** and **q** vectors, the two components of **E** on the surface are expressed as

$$\begin{bmatrix} E_p(\theta) \\ E_q(\theta) \end{bmatrix} = \begin{bmatrix} \cos(\phi - \phi_o) & \sin(\phi - \phi_o) \\ \sin(\phi - \phi_o) & -\cos(\phi - \phi_o) \end{bmatrix} \cdot \begin{bmatrix} E_\theta(\theta, \phi) \\ E_\phi(\theta, \phi) \end{bmatrix} \tag{31}$$

where ϕ_o is the reference direction. For example, if the reference polarization is oriented at $\phi_o = 0^\circ$, the E-plane corresponds to the $\phi = 0^\circ$ plane where

$$E_p(\theta) = E_\theta(\theta, 0) \text{and} E_q = -E_\phi(\theta, 0) \tag{32a}$$

while the orthogonal H-plane corresponds to the $\phi = 90^\circ$ plane where

$$E_p(\theta) = E_\phi\left(\theta, \frac{\pi}{2}\right) \text{and} E_q = E_\theta\left(\theta, \frac{\pi}{2}\right). \tag{32b}$$

The components of the field in the $\phi = 45^\circ$ plane relative to the reference are

$$E_p(\theta) = \frac{1}{\sqrt{2}}\left[E_\theta\left(\theta, \frac{\pi}{4}\right) + E_\phi\left(\theta, \frac{\pi}{4}\right)\right] \tag{33a}$$

$$E_q(\theta) = \frac{1}{\sqrt{2}}\left[E_\theta\left(\theta, \frac{\pi}{4}\right) - E_\phi\left(\theta, \frac{\pi}{4}\right)\right]. \tag{33b}$$

The E-plane pattern is measured or calculated by aligning the reference or test antenna with the electric field and then rotating the antenna under test (AUT) in that plane whilst measuring the received signal. The H-plane pattern is found by rotating the AUT in the plane orthogonal to the reference but with the AUT aligned with the reference. Similarly, the co-polar pattern in the 45 ° plane is obtained by aligning the reference parallel to the electric field while the AUT is rotated in the 45 ° plane. The cross-polarization in

DOI 10.1007/978-981-4560-75-7_30-1

an arbitrary $\phi -$ plane is found by initially rotating the AUT to coincide with the polarization of the reference. Then the reference is rotated by 90 °, and the pattern is then measured in the $\phi -$ plane.

Paraboloidal Reflector

Radiation from a Paraboloid

The aperture field predicted by geometric optics is given by Eq. 8. The field radiated by this distribution is obtained by substituting this field into Eq. 12 and carrying out the Fourier transform. This can be done numerically using quadrature methods such as Simpson's rule or by means of a two-dimensional fast Fourier transform. In making use of the latter, only the fields on the aperture should be used as input. The rest of the matrix should be filled with zeros. If a grid point is outside the aperture by less than a quarter of a wavelength, a non-zero estimate could be used which has a value that is half the value on the field on the rim of the aperture. If the feed functions F_ψ and F_ξ are integrable functions, the integral may be evaluated in closed form from Eqs. 16 and 14a. The transform in this case is

$$\mathbf{N}(\theta, \phi) = \int_0^{2\pi} d\xi \int_0^{D/2} \mathbf{E_a}(t, \xi) \exp(jwt \cos(\phi - \xi))\, t\, dt. \tag{34}$$

$w = k \sin\theta, t = \rho \sin\psi$ and $\rho = 2f/(1 + \cos\psi) = f \sec^2\psi/2$, for a paraboloid.

Consider initially the aperture field given by Eq. 9. The multiplier corresponds to an illumination function $F(\psi) = A(\psi)(1 + \cos\psi)$. Suppose also $A(\psi)$ has an inverse taper so that the aperture illumination is uniform, i.e., $F(\psi) = 1$. Equation 34 gives

$$N_x(\theta, \phi) = -\frac{\exp(-jk2f)}{2f} \int_0^{2\pi} d\xi \int_0^{D/2} \exp(jwt \cos(\phi - \xi))\, t\, dt.$$

Making use of the Bessel identity

$$\int_0^{2\pi} \begin{matrix}\cos \\ \sin\end{matrix} p\phi' \Bigg\} e^{jz\cos(\phi - \phi')} d\phi' = 2\pi j^p J_p(z) \Bigg\{ \begin{matrix}\cos \\ \sin\end{matrix} p\phi \tag{35}$$

where $J_p(z)$ is an ordinary Bessel function of order p with argument z, the transform simplifies to

$$N_x(\theta, \phi) = -\pi \frac{\exp(-jk2f)}{f} \int_0^{D/2} J_0(wt) t\, dt.$$

Since $\int_0^1 J_0(at) = J_1(a)/a$ then

$$N_x(\theta, \phi) = -\pi \left(\frac{D}{2}\right)^2 \frac{\exp(-jk2f)}{f} \frac{J_1(X)}{X} \tag{36}$$

where $X = \frac{\pi D}{\lambda} \sin\theta$. A plot of the electric field radiated by the paraboloid with uniform illumination is shown in Fig. 8. The first sidelobe level occurs at −17.6 dB relative to the peak, and the beamwidth is $1.02\lambda/D$.

DOI 10.1007/978-981-4560-75-7_30-1

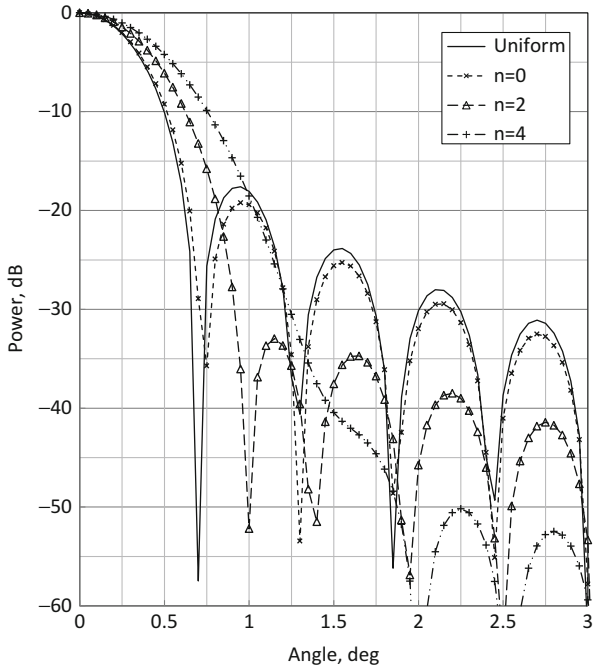

Fig. 8 Radiation patterns of a paraboloid with $D = 100\ \lambda$ and $f/D = 0.4$ with a feed with a symmetric pattern. Order of feed taper is n. Also shown is the pattern for uniform aperture illumination

A tapered illumination is considered next. Suppose $A(\psi) = \cos^n\psi = B(\psi)$ where n can have arbitrary values. Large positive values of n correspond to higher edge taper. Negative values correspond to inverse tapers. Following from Eq. 9

$$N_x(\theta,\phi) = -\pi\frac{\exp(-jk2f)}{f}\int_0^{D/2} J_0(wt)\cos^n\psi(1+\cos\psi)t\,dt$$

where $t = \rho\sin\psi = 2f\tan(\psi/2)$. Therefore, $dt = f\sec^2(\psi/2)d\psi$. Let $\psi_c = 2\tan^{-1}(D/4f)$. Then

$$N_x(\theta,\phi) = -2\pi f\exp(-jk2f)\int_0^{\psi_c} J_0(2f\,w\tan[\psi/2])\sin\psi\cos^n\psi\sec^2(\psi/2)d\psi. \tag{37}$$

Also, making a further substitution, $u = \tan(\psi/2)$ where $du = (1/2)\sec^2(\psi/2)\,d\psi$, and also $\sin\psi = 2u/(1+u^2)$ and $\cos\psi = (1-u^2)/(1+u^2)$. Therefore,

$$N_x(\theta,\phi) = -8\pi f\exp(-jk2f)\int_0^{D/4f} J_0(2f\,w\,u)\left(\frac{1-u^2}{1+u^2}\right)^n\frac{u\,du}{(1+u^2)}. \tag{38}$$

The integral can be evaluated by replacing the zero-order Bessel function with its series and then integrating term by term. However, it is usually more convenient to evaluate the integral numerically. Plots of the far field obtained from Eqs. 38 and 36 are shown in Fig. 8 for a 100 λ diameter dish with $f/D = 0.4$ for a feed with tapers defined by $n = 0$, 2 and 5. These results are compared with uniform aperture illumination of a circular aperture. As the taper is increased, the beamwidth increases, and the sidelobes reduce. The first sidelobe level for the first two cases $n = 0$ and 2 is, respectively, -19.2 dB and -34.0 dB. For $n = 4$, the widened main beam and the first sidelobe have merged. The radiation patterns of a paraboloid with specific feed antenna types will be discussed in the next section.

DOI 10.1007/978-981-4560-75-7_30-1

A paraboloidal reflector and a feed with an axisymmetric pattern radiates power at boresight direction given by

$$P_r = \frac{2}{\eta}\left(\frac{kf}{r}\right)^2 \left| \int_0^{\psi_c} A(\psi) \tan\frac{\psi}{2} d\psi \right|^2 \tag{39}$$

The substitution $t = \rho \cos\psi$ was made in Eq. 23 to obtain this equation. The power collected by the reflector from the feed is

$$P_c = \frac{\pi}{\eta} \int_0^{\psi_c} |A(\psi)|^2 \sin\psi d\psi. \tag{40}$$

Let the maximum gain be $G_{\max} = \eta_a \eta_s G_o$. That is,

$$G_{\max} = \eta_s \left(\frac{\pi D}{\lambda}\right)^2 2\cot^2\frac{\psi}{2} \frac{\left| \int_0^{\psi_c} A(\psi) \tan\frac{\psi}{2} d\psi \right|^2}{\int_0^{\psi_c} |A(\psi)|^2 \sin\psi \, d\psi} \tag{41}$$

The aperture efficiency is given by

$$\eta_a = 2\cot^2\frac{\psi}{2} \frac{\left| \int_0^{\psi_c} A(\psi) \tan\frac{\psi}{2} d\psi \right|^{12}}{\int_0^{\psi_c} |A(\psi)|^2 \sin\psi d\psi} \tag{42}$$

Blockage due to the feed and its supporting struts can be included in an approximate manner by altering the limits of integration. For example, feed blockage of diameter a is introduced in Eq. 34 by changing the lower limit of integration. Thus,

$$\begin{aligned} \mathbf{N}(\theta,\phi) &= \int_0^{2\pi} d\xi \int_{a/2}^{D/2} \mathbf{E_a}(t,\xi) \exp(jwt\cos(\phi-\xi)) t\, dt \\ &= \int_0^{2\pi} d\xi \left\{ \int_0^{D/2} - \int_0^{a/2} dt\, t \right\} \mathbf{E_a}(t,\xi) \exp(jwt\cos(\phi-\xi)). \end{aligned} \tag{43}$$

This shows that the vector transform is the difference of two transforms. The domain of one transform is over the full diameter, and the other domain is only over the blocked area. Therefore, for a uniform illumination,

$$N_x(\theta,\phi) = -\pi \frac{\exp(-jk2f)}{f} \left[\left(\frac{D}{2}\right)^2 \frac{J_1(X)}{X} - \left(\frac{a}{2}\right)^2 \frac{J_1(X')}{X'} \right] \tag{44}$$

where $X' = \frac{\pi a}{\lambda} \sin\theta$. The field radiated by a 100 λ diameter dish with $f/D = 0.4$ and central blockages of 5 λ and 10 λ are shown in Fig. 9. Also shown is the effect of blockage on a symmetric tapered feed with

DOI 10.1007/978-981-4560-75-7_30-1

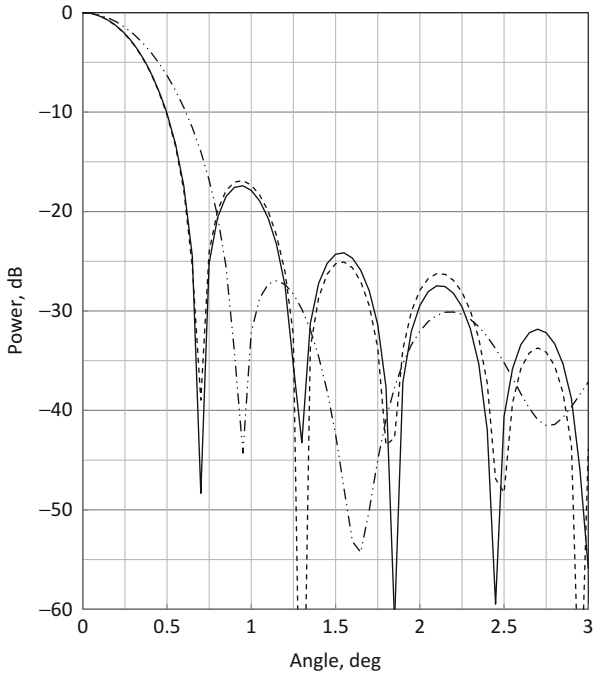

Fig. 9 Radiation patterns of a $D = 100\ \lambda$ paraboloid with central blockage. The reflector has $f/D = 0.4$ and the aperture is uniformly illuminated. *Solid line*: blockage diameter $a = 5\ \lambda$ and uniform illumination; *short dashed line*: blockage diameter $a = 10\ \lambda$; *long dashed line*: blockage diameter $a = 5\ \lambda$ with tapered feed $n = 2$

$n = 2$. Comparing this figure with Fig. 8, it is seen that central blockage has had a major impact on the radiation pattern of the reflector with a tapered feed, indicating that low sidelobes can be badly affected by blockage.

Struts can be handled in an approximate manner using a similar technique. Suppose that a feed is supported by three struts that are separated by 120° apart. These struts can be approximated by angular segments of width 2Δ. Then,

$$\begin{aligned}\mathbf{N}(\theta,\phi) &= \left\{\sum_{m=1}^{3}\int_{2(m-1)\pi/3+\Delta}^{2m\pi/3-\Delta} d\xi\right\}\int_0^{D/2}\mathbf{E_a}(t,\xi)\exp[jwt\cos(\phi-\xi)]t\,dt\\ &= \int_0^{2\pi} d\xi\int_0^{D/2}\mathbf{E_a}(t,\xi)\exp[jwt\cos(\phi-\xi)]t\,dt\\ &\quad-\left\{\sum_{m=1}^{3}\int_{2m\pi/3-\Delta}^{2m\pi/3+\Delta} d\xi\right\}\int_0^{D/2}\mathbf{E_a}(t,\xi)\exp(jwt\cos(\phi-\xi))t\,dt.\end{aligned}\tag{45}$$

With an axisymmetric illumination function, the integral over ξ can be expressed in closed form as

$$\begin{aligned}I &= \left\{\sum_{m=1}^{3}\int_{2m\pi/3-\Delta}^{2m\pi/3+\Delta} d\xi\right\}\int_0^{D/2}\mathbf{E_a}(t,\xi)\exp(jwt\cos(\phi-\xi))t\,dt\\ &= 2\Delta\sum_{m=1}^{3}\sum_{k,\,l=-\infty}^{\infty} j^k\exp\left[\frac{2m\pi}{3}(l-k)\right]S[\Delta(l-k)]\int_0^{D/2}\mathbf{E_a}(t,\xi)J_k(wt\cos\phi)J_l(wt\sin\phi)t\,dt\end{aligned}\tag{46}$$

DOI 10.1007/978-981-4560-75-7_30-1

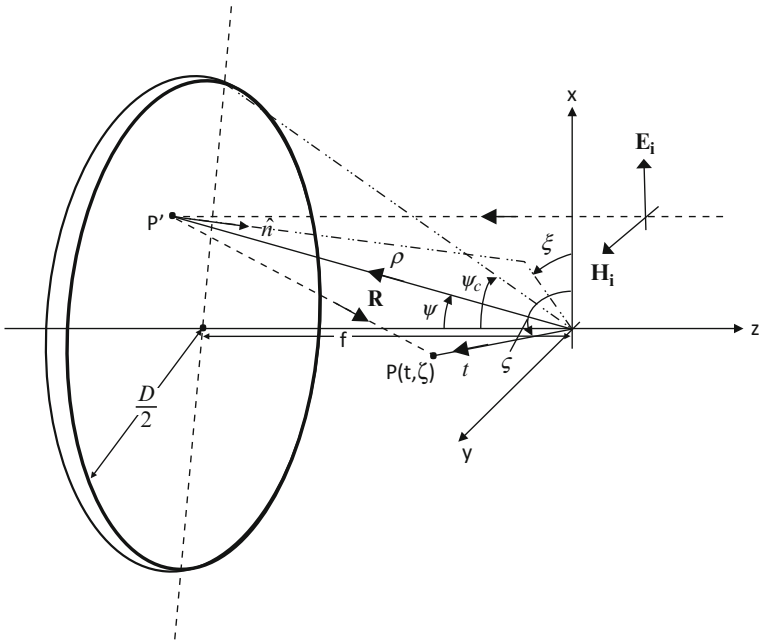

Fig. 10 Focal region of a paraboloid

where $S(x) = \sin x/x$. In most cases, it is preferable to evaluate the integrals in Eq. 43 directly by numerical means rather than by Eq. 45.

Focal Region Fields of a Paraboloid

The fields in the vicinity of the focus of a reflector are of particular importance as they indicate the most appropriate excitation from the feed for a desirable excitation and hence highest efficiency. The focal fields can be calculated from geometric optics or from physical optics. In both cases, the reflector is illuminated by a plane wave, and the field arriving at the focus is determined by each method. The PO method will be used here. An incident plane wave is assumed to propagate towards the reflector parallel to the z-axis as illustrated in Fig. 10. The incident fields are

$$\mathbf{E_i} = \hat{x} E_o \exp(jkz) \tag{47}$$

and

$$\mathbf{H_i} = \frac{1}{\eta_o} \hat{z} \times \mathbf{E_i}.$$

An electric current induced on the paraboloid is

$$\mathbf{J_s} \approx \hat{n} \times \mathbf{H_i} = \frac{2E_o}{\eta_o} (\hat{n} \times \hat{y}) \exp(jkz) \Big|_{\text{reflector } \Sigma}. \tag{48}$$

Introducing the normal to the paraboloid, in rectangular co-ordinates the surface current is

$$\mathbf{J_s} = \frac{2E_o}{\eta_o} e^{jkz} \left(\hat{x} \cos \frac{\psi}{2} + \hat{z} \sin \frac{\psi}{2} \cos \xi \right). \tag{49}$$

DOI 10.1007/978-981-4560-75-7_30-1

The fields in the focal region (at $z = 0$) are obtained by means of the PO expression Eq. 10 where the surface of integration is the reflector and in this instance there are no magnetic currents.

Although the focal region is not always in the far field of the reflector, approximations to the scattered field included in Eq. 10a are applicable. As shown in Fig. 10, the vector $\mathbf{R} = \mathbf{t} - \boldsymbol{\rho}$ is a vector from a point P′ on the reflector to P in the focal region. For a large reflector, in the vicinity of the focus, consider distances $|\mathbf{t}| << |\boldsymbol{\rho}|$. Further, let $R = |\mathbf{R}| \approx |\boldsymbol{\rho}| = \hat{\rho} \cdot \mathbf{t}$ in the phase function of the integrand of Eq. 10a and $\hat{R} \approx \hat{\rho}$ in the amplitude function of the integrand. Thus, Eq. 10a can be expressed as

$$\mathbf{E}_F(t,\zeta) \approx -\frac{jk\eta_o}{4\pi}\int_\Sigma [\mathbf{J_s} - (\hat{\rho}\cdot\mathbf{J_s})\hat{\rho}]\frac{e^{-jk\rho}}{\rho}\exp(jk\hat{\rho}\cdot\mathbf{t})dS'. \tag{50}$$

For a paraboloid, the surface element is given by $dS' = \rho^2 \sec(\psi/2)\sin\psi d\psi d\xi$.

The amplitude function of Eq. 50 is expanded as follows:

$$[\mathbf{J_s} - \hat{\rho}(\mathbf{J_s}\cdot\hat{\rho})]\rho\, d\psi d\xi = -\frac{2fE_o}{\eta_o}e^{jkz}\hat{x}\left(1 - \tan^2\frac{\psi}{2}\cos 2\xi\right)\sin\psi - \hat{y}\sin\psi\tan^2\frac{\psi}{2}\sin 2\xi + \hat{z}2\sin\psi\tan\frac{\psi}{2}\cos\xi. \tag{51}$$

The phase function inside the integrand is given by

$$\begin{aligned}\exp[jk(-\rho + z + \hat{\rho}\cdot\mathbf{t})] &\approx \exp[jk(-\rho(1+\cos\psi) + (x_F\cos\xi + y_F\sin\xi)\sin\psi)] \\ &= \exp[jk(-2f + t\sin\psi\cos(\zeta - \xi))]\end{aligned} \tag{52}$$

where, as shown in Fig. 10, $x_F = t\cos\zeta$ and $y_F = t\sin\zeta$ are rectangular coordinates in the focal plane on which (t,ζ) are the polar coordinates. With these approximations and substitutions, the components of Eq. 50 become

$$E_{Fx} = -\frac{jkfE_o}{2\pi}e^{-jk2f}\int_0^{2\pi}d\xi\int_0^{\psi_c}\left(1 - \tan^2\frac{\psi}{2}\cos 2\xi\right)\sin\psi\exp[jkt\sin\psi\cos(\zeta - \xi)]d\psi \tag{53a}$$

$$E_{Fy} = \frac{jkfE_o}{2\pi}e^{-jk2f}\int_0^{2\pi}d\xi\int_0^{\psi_c}\sin\psi\tan^2\frac{\psi}{2}\sin 2\xi\exp[jkt\sin\psi\cos(\zeta - \xi)]d\psi \tag{53b}$$

$$E_{Fz} = -\frac{jkfE_o}{\pi}e^{-jk2f}\int_0^{2\pi}d\xi\int_0^{\psi_c}\sin\psi\tan\frac{\psi}{2}\cos\xi\exp[jkt\sin\psi\cos(\zeta - \xi)]d\psi. \tag{53c}$$

The integration with respect to ξ can be completed by means of the integral identity Eq. 35, which allows Eq. 53 to be simplified to

$$E_{Fx}(t,\zeta) = \Omega_0(t) + \Omega_2(t)\cos 2\zeta \tag{54a}$$

$$E_{Fy}(t,\zeta) = \Omega_2(t)\sin 2\zeta \tag{54b}$$

$$E_{Fz}(t,\zeta) = -2j\Omega_1(t)\cos\zeta \tag{54c}$$

wherein

DOI 10.1007/978-981-4560-75-7_30-1

$$\Omega_n(t) = \kappa \int_0^{\psi_c} J_n(kt\,\sin\psi)\tan^n\frac{\psi}{2}\,\sin\psi d\psi \tag{55}$$

and

$$\kappa = -jkf\,E_o e^{-jk2f}.$$

For a long–focal length paraboloid, Eq. 54 can be simplified further by virtue of the small angle to the rim, ψ_c, leading to

$$\Omega_0(t) \approx 2\kappa\,\sin^2\frac{\psi_c}{2}\left[2\frac{J_1(U)}{U}\right] \tag{56a}$$

$$\Omega_1(t) \approx 2\kappa\,\sin^2\frac{\psi_c}{2}\left[\psi_c\frac{J_2(U)}{U}\right] \tag{56b}$$

$$\Omega_2(t) \approx 0 \tag{56c}$$

where $U = kt\sin\psi_c$. Thus, the transverse component of the focal field is

$$E_{Fx}(t,\zeta) \approx -j2kE_o e^{-jk2f}\left[2\frac{J_1(kt\sin\psi_c)}{(kt\sin\psi_c)}\right].$$

The field consists of a series of high- and low-intensity bands known as Airy rings. The latter correspond to the zeros of the $J_1(U)$ Bessel function. The first two of these occur at $U = 3.85$ and 7.02. The peaks occur at the maxima of the function $2J_1(U)/U$. The first two peaks occur at $U = 0$ and $U = 5.14$. A contour plot of the electric field focal region given by Eq. 53 for a paraboloid with diameter $D = 100\ \lambda$ and $f/D = 0.35$ is shown in Fig. 11. The low-intensity rings are clearly evident and are close to the approximations of Eq. 52 ($t = 0.66\ \lambda$ and $1.21\ \lambda$) even though the focal length is relatively short. It can be seen that close to optimum excitation could be achieved with a feed with a uniform aperture distribution and a radius α approximately equal to $0.66\ \lambda$.

Imperfect Reflectors

Up to this point, it has been assumed that the reflector surface is a smooth function with no surface imperfections or misalignments in the structure. In practice, due to manufacturing tolerances and physical variations, a reflector system has some imperfections. In this section, two types of imperfections are considered. The first is due to surface errors, and the second is related to various misalignments that result in aberrations in the radiated pattern.

Surface Errors

Random surface errors, if small, can be considered to add a phase function to the aperture field. Let the aperture field with phase error be approximated by

$$\mathbf{E_a}' = \mathbf{E_a}e^{-j\alpha} \tag{57}$$

DOI 10.1007/978-981-4560-75-7_30-1

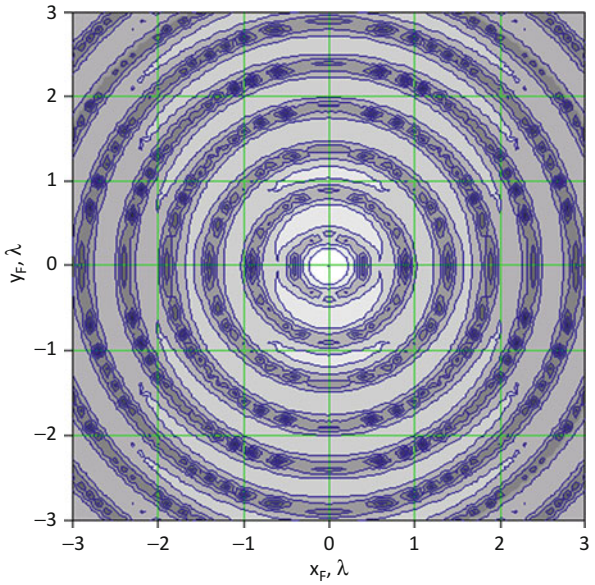

Fig. 11 Focal region field of a paraboloid reflector with diameter $D = 100\ \lambda$ and $f/D = 0.35$

where α is a small random function in the surface profile, and $\mathbf{E_a}$ is the aperture field with no reflector surface errors. Since $\alpha \ll 1$, let $\exp(-j\alpha) \approx (1 - \alpha^2/2) + j\alpha$. For simplicity, consider a paraboloid with a feed having an axisymmetric pattern. With the aperture distribution given by Eq. 57, the aperture efficiency is modified to

$$\eta_a{}' = \frac{1}{2\pi^2}\cot^2\frac{\psi}{2}\frac{\left|\int_0^{2\pi} d\xi \int_0^{\psi_c}\left(1 - \frac{\alpha^2}{2} + j\alpha\right)A(\psi)\tan\frac{\psi}{2}d\psi\right|^2}{\int_0^{\psi_c}|A(\psi)|^2\sin\psi d\psi} \approx \eta_a\left(1 - \overline{\alpha}^2 + (\overline{\alpha})^2\right) \tag{58}$$

where η_a is the aperture efficiency with no surface errors. The quantities $\overline{\alpha}^2$ and $(\overline{\alpha})^2$ are the mean-square phase error and average phase error weighted by the aperture illumination function $A(\psi)\tan(\psi/2)$. The phase reference plane can be chosen arbitrarily so that latter quantity $(\overline{\alpha})^2 = 0$. Therefore,

$$\eta_a{}' \approx \eta_a\left(1 - \overline{\alpha}^2\right). \tag{59}$$

Another more sophisticated model of surface errors has been developed (Ruze 1966), which is valid for large surface errors that are Gaussian distributed. If the errors are completely uncorrelated in small regions of the aperture of dimensions much less than D, the aperture efficiency is

$$\eta_a{}' \approx \eta_a \exp\left(-\overline{\delta}^2\right) \tag{60}$$

where $\overline{\delta}^2$ is the mean square error of the Gaussian distribution. For small errors, Eq. 60 is almost identical to Eq. 59 with the exception that $\overline{\alpha}^2$ is a weighted quantity. A useful indicator for practical

DOI 10.1007/978-981-4560-75-7_30-1

reflectors is the rms surface error ε, which is equivalent to the rms error of a sinusoid of period $2\pi/k = \lambda$, is given by

$$\varepsilon = \frac{\sqrt{\overline{\delta^2}}}{2k} = \frac{\lambda}{4\pi}\sqrt{\overline{\delta^2}}. \tag{61}$$

As an example, a reflector was designed to have an aperture efficiency of 70 % at 30 GHz. When the reflector was fabricated, the rms surface error was found to be 50 μm. Therefore in practice, the effective aperture efficiency is about 66 % and the gain 0.28 dB below what was expected. As a rule of thumb, a surface tolerance as high as $\lambda/30$ may be acceptable in many applications. This results in a gain loss of up to 1.8 dB. In other applications, this loss may not be acceptable, and a smaller surface error, typically $\lambda/50$, may be required. This error corresponds to a gain loss of about 1 dB.

Aberrations

The radiation pattern of an aperture antenna is sensitively dependent upon the phase distribution of the aperture field. Variation from an ideal uniform phase distribution can cause aberrations. These aberrations can also occur inadvertently during antenna design and manufacture. Sometimes they arise intentionally when, for example, beam shaping or for beam steering. Due to aberrations, the ideal aperture field $\mathbf{E_a}$ can be considered to have a phase distribution superimposed on it; thus,

$$\mathbf{E_a}\exp(j\Phi(x',y')) \tag{62}$$

where for a circular aperture, the polar coordinates $x' = t\cos\xi$ and $y' = t\sin\xi$ allow the aberration function to be expressed as

$$\Phi(x',y') = \Phi(t,\xi) = \sum_{m,\,n=0}^{\infty} \Delta_{mn} t^n \cos m\xi. \tag{63}$$

From Eq. 63, it is possible to see the effect of each term by letting all coefficients be zero apart from the desired one. The primary aberrations are illustrated in Table 1. They are referred to as linear ($n = 1$, $m = 0$), quadratic ($n = 2$, $m = 0$), coma ($n = 3$, $m = 1$), astigmatic ($n = 2$, $m = 2$) and spherical ($n = 4$, $m = 0$) aberration. Linear aberration in Table 2 shifts the direction of the main beam by an amount $\alpha = \sin^{-1}(\Delta_{11}/k)$ without changing the structure of the beam. Quadratic phase error causes a reduction in antenna gain and increases both the beamwidth and sidelobe level. Another effect is that the nulls in the pattern are filled in. Cubic phase error, or coma, causes the beam to shift an angle $\alpha = \arcsin(2\Delta_{31}a^2/3k)$ and also reduces gain. In addition, the pattern is asymmetrical in the plane containing the shifted beam and the central axis (the plane of 'scan'). The sidelobes closest to the central axis are lower than the sidelobes without coma, and those in the direction of scan are higher than without coma. The effect of astigmatism is similar to a quadratic phase error. When astigmatism and quadratic phase error occur together, the width of the main beam and the sidelobes are different in the two principal planes. Finally in Table 1, spherical aberration produces a symmetrical distortion of the radiation pattern with an effect similar to quadratic phase error.

The gain of an aperture affected by aberration, G_a, is approximately given by

$$G_a = \frac{1}{1+\kappa\Delta_e^2}G \tag{64}$$

DOI 10.1007/978-981-4560-75-7_30-1

Table 1 Aberrations on a circular aperture of unit radius

Aberration	Order n, m	Aperture phase	Radiation pattern
Linear	1,0	$\Phi = \Delta_{11} t$	 $\alpha = \sin^{-1}(\Delta_{11}/K)$
Quadratic	2,0	$\Phi = \Delta_{20} t^2$	Coma	1,3	$\Phi = \Delta_{31} t^3 \cos\xi$	 $\alpha = \tan^{-1}(2\Delta_{21}/3K)$
Astigmatism	2,2	$\Phi = \Delta_{22} t^2 \cos 2\xi$	Spherical	4,0	$\Phi = \Delta_{40} t^4$	
where G is the gain without aberration, Δ_e is the phase error in radians at the edge of the aperture and K is a constant the value of which depends on the type of aberration and equals 0 for linear, 1/12 for quadratic, 1/72 for coma, 1/6 for astigmatism and 4/45 for spherical aberration.

In any practical antenna, all types of aberrations can occur, some to a greater extent than others. For example, a method commonly used to scan the beam of a reflector antenna is to displace the feed laterally from the reflector axis in order to produce a linear phase shift across the aperture. As well as the desired linear aberration (beam shift), coma is strongly represented in the radiation pattern. Astigmatism is also produced, but it is of lesser importance than coma for small lateral shifts. However, when the feed is moved from the focus in the axial direction, either towards or away from the reflector vertex, quadratic and spherical aberrations occur.

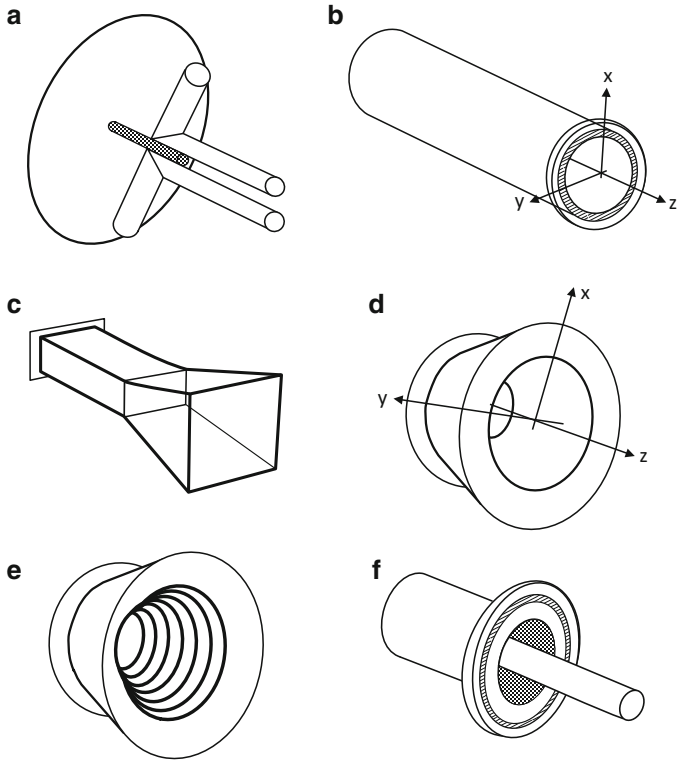

Fig. 12 Feeds for reflectors. (**a**) Dipole with reflector; (**b**) circular waveguide; (**c**) pyramidal horn; (**d**) conical horn; (**e**) corrugated horn; and (**f**) cup feed

Feeds for Reflectors

The feed antenna for a reflector is a vital part of the overall system operation and performance, and therefore, its design requires careful attention. It should have low input reflection over the desired frequency band, efficiently illuminate the reflector and have low spillover and in some applications it should have low cross-polarization. The latter is important in applications such as communications, radar and polarimetry that use orthogonally polarized signals for different bands. The types of feed vary significantly as shown in Fig. 12. As has been mentioned previously, the dipole feed was the first feed that was used, and it still is a common solution where bandwidth may not be significant and at frequencies where weight and size preclude other methods. As shown in Fig. 12a, the dipole can be fitted with a small reflector to improve the directionality of its beam. An option as a feed for a front-fed reflector instead of a dipole is the cup feed as illustrated in Fig. 12f, which can have a bandwidth of about 20 %. The advantage of the dipole or the cup feed is that they are self-supporting so that struts are not required, which improves pattern symmetry and does not reduce gain. A waveguide feed, which is either a circular waveguide as in Fig. 12b or a rectangular horn as shown in Fig. 12c, are suitable in some situations. Aperture slots or tuning rings are often included to improve the radiation pattern of the feed. For the efficient illumination of a reflector system with a subreflector, a feed with a narrow beam is usually required. Hence in dual-reflector applications, a tapered horn is frequently employed. These come in the form of a smooth wall conical horn as in Fig. 4.1d, an optimized profile or one with corrugations as shown in Fig. 4.1e.

Dipole

One of the simplest feeds to construct and connect to an amplifier or power source is the dipole. Consider the dipole shown in Fig. 12a minus the reflector. The electric field radiated by a half-wave dipole oriented parallel to the x-direction is

DOI 10.1007/978-981-4560-75-7_30-1

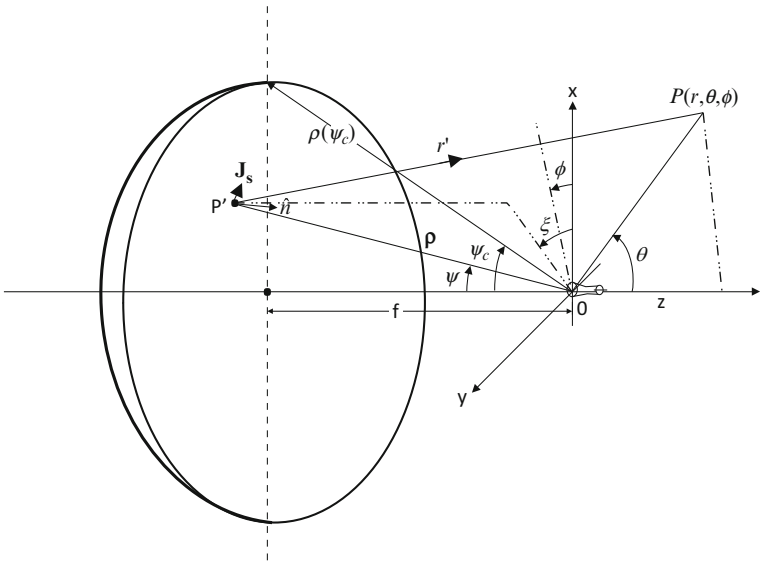

Fig. 13 Geometry of reflector and feed in transmit mode

$$\mathbf{E}_f = E_o \frac{e^{-jkr}}{r} A(\theta, \phi)\left[\hat{r}\ \sin\theta\cos\phi + \hat{\theta}\cos\theta\cos\phi - \hat{\phi}\sin\phi\right] \tag{65a}$$

$$\mathbf{H}_f = \frac{1}{\eta_o}\hat{r} \times \mathbf{E}_f \tag{65b}$$

where E_o is a constant and

$$A(\theta, \phi) = \frac{\cos\left(\frac{\pi}{2}\sin\theta\right)}{\cos\theta}$$

is the pattern function for a half-wave dipole. The pattern function is kept general in the present example for extension to an array of dipoles as a feed in a later chapter of this book ("▶ Applications of Phased Array Feeders for Reflector Antennas." In the E-plane ($\phi = 0$ or π) and H-plane ($\phi = \pm\,\pi/2$), the patterns are different.

The radiation from a paraboloid with a dipole feed can be found from PO or the aperture field method. The former approach will be used here. The geometry of the reflector and feed is shown in Fig. 13. When the reflector is illuminated by the feed, surface currents are created, and these can be approximated by PO as described above. To do this, Eq. 65b is substituted into Eq. 17, and from Eq. 19, it is found that

$$\mathbf{F}(\theta, \phi) = -\frac{2}{\eta_o}\int_0^{2\pi}\int_0^{\psi_c} \hat{n} \times \left(\hat{\rho} \times \mathbf{E}_f\right)\exp(jk\ \hat{r}\cdot\boldsymbol{\rho})\rho^2 \sec\left(\frac{\psi}{2}\right)\sin\psi\, d\psi\, d\xi \tag{66}$$

where $\hat{r}\cdot\boldsymbol{\rho} = \rho(\sin\theta\sin\psi\cos(\phi - \xi) - \cos\theta\cos\psi)$. Now,

DOI 10.1007/978-981-4560-75-7_30-1

$$\begin{aligned}\hat{n}\times\left(\hat{\rho}\times\mathbf{E}_f\right) &= \left(\hat{\rho}\cos\frac{\psi}{2}+\hat{\psi}\sin\frac{\psi}{2}\right)\times\left(\hat{\xi}\cos\psi\cos\xi+\hat{\psi}\sin\xi\right)E_o\frac{e^{-jk\rho}}{\rho}A(\psi,\xi)\\ &= E_o\frac{e^{-jk\rho}}{\rho}A(\psi,\xi)\left(\hat{\rho}\sin\frac{\psi}{2}\cos\psi\cos\xi-\hat{\psi}\cos\frac{\psi}{2}\cos\psi\cos\xi+\hat{\xi}\cos\frac{\psi}{2}\sin\xi\right).\end{aligned} \tag{67}$$

In order to express Eq. 66 in the global coordinate system, the vector components of Eq. 67 must be transformed by means of

$$\begin{aligned}\hat{\rho} = \hat{r}(\sin\theta\sin\psi\cos(\phi-\xi)-\cos\theta\cos\varphi)+\hat{\theta}(\cos\theta\sin\psi\cos(\phi-\xi)+\sin\theta\cos\psi)\\ -\hat{\phi}\sin\psi\sin(\phi-\xi)\end{aligned} \tag{68a}$$

$$\begin{aligned}\hat{\psi} = \hat{r}(\sin\theta\cos\psi\cos(\phi-\xi)-\cos\theta\cos\varphi)+\hat{\theta}(\cos\theta\cos\psi\cos(\phi-\xi)-\sin\theta\sin\psi)\\ -\hat{\phi}\cos\psi\sin(\phi-\xi)\end{aligned} \tag{68b}$$

and

$$\hat{\xi} = -\hat{r}\sin\theta\sin(\phi-\xi)+\hat{\theta}\cos\theta\sin(\phi-\xi)+\hat{\phi}\cos(\phi-\xi). \tag{68c}$$

As a result, the vector triple product becomes

$$\hat{n}\times\left(\hat{\rho}\times\mathbf{E}_f\right) = E_o\frac{e^{-jk\rho}}{\rho}A(\theta,\phi)\left(-\hat{r}\sin\frac{\psi}{2}\cos\psi\cos\xi+\hat{\theta}\cos\frac{\psi}{2}\cos\psi\cos\xi-\hat{\phi}\cos\frac{\psi}{2}\sin\xi\right). \tag{69}$$

The radial components of the electric field in Eq. 18 cancel leaving the following far-field components

$$E_\theta = \frac{jkfE_o}{\pi}\frac{e^{-jkr}}{r}B(\theta,\phi) \tag{70a}$$

and

$$E_\phi = \frac{jkfE_o}{\pi}\frac{e^{-jkr}}{r}C(\theta,\phi) \tag{70b}$$

where

$$\begin{aligned}B(\theta,\phi) = \int_0^{2\pi}d\xi\cos\xi\int_0^{\psi_c}d\psi A(\psi,\xi)\exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi)-(1+\cos\theta\cos\psi))]\times\\ \left[\cos\theta(\cos\psi\cos\xi\cos(\phi-\xi)-\sin\xi\sin(\phi-\xi))-\sin\theta\tan\frac{\psi}{2}\cos\phi\cos\xi\right]\tan\frac{\psi}{2}\end{aligned} \tag{71a}$$

$$\begin{aligned}C(\theta,\phi) = \int_0^{2\pi}d\xi\sin\xi\int_0^{\psi_c}d\psi A(\psi,\xi)\exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi)-(1+\cos\theta\cos\psi))]\times\\ [\cos\psi\cos\xi\sin(\phi-\xi)+\sin\xi\cos(\phi-\xi)]\tan\frac{\psi}{2}.\end{aligned} \tag{71b}$$

DOI 10.1007/978-981-4560-75-7_30-1

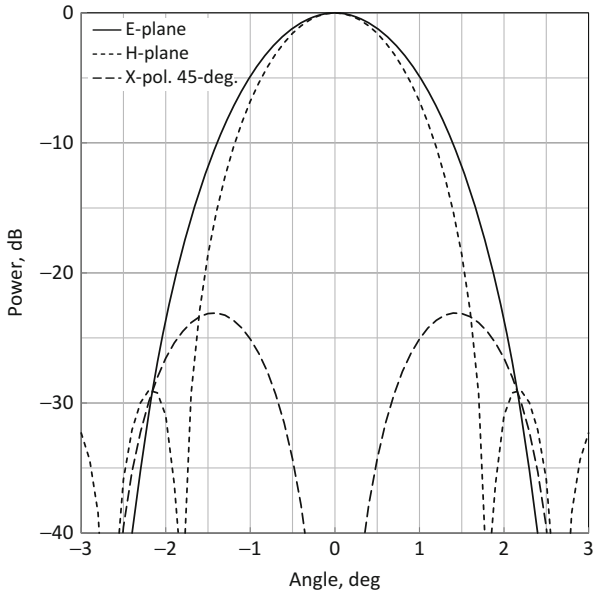

Fig. 14 Principal radiation patterns of a paraboloid reflector with a half-wavelength dipole feed at an operating frequency of 10 GHz. Reflector diameter $D = 1.5\ m$ and $f/D = 0.35$ i.e., $\psi_c = 71.075°$. *Solid line*: E-plane; *short-dashed line*: H-plane; *long-dashed line*: X-polar 45°-plane

The radiation patterns of a reflector with a diameter 50 λ and $f/D = 0.35$ that is fed with a half-wave dipole have been computed, and these are shown in Fig. 14. The E-plane field corresponds to $E_\theta(\theta, 0)$ and the H-plane pattern to $E_\phi(\theta, \pi/2)$, which are given by the functions $B(\theta, 0)$ and $C(\theta, \pi/2)$, respectively. The computed gain is 41 dBi, which gives an aperture efficiency of 51.1 %. The cross-polar level in the 45°-plane is relatively high and is due to deformation of the polarization vector from the far-field sphere to the parabolic surface as well as variation on the surface of the feed field pattern from one principal plane to the other. When the feed pattern is axisymmetric, the latter variation is not present.

Waveguides and Horns

A range of waveguide feeds have been devised for prime focus reflector and also have been flared or profiled into horns for more directive feeding of dual-reflector systems. A basic type of waveguide feed for a paraboloid is a circular waveguide, of which there are many variations devised often through modifying the flange at the aperture plane as illustrated in Fig. 12b.

The reflector geometry is as shown in Fig. 13, and PO will be used once again to determine the far fields of the reflector. Consider a circular waveguide shown in Fig. 12b with a radius α and a smooth flange. Here the electric field radiated by this circular aperture is assumed to have its principal polarization parallel to the x-axis. Therefore, the electric field in the far zone is given by

$$\mathbf{E}_f = \frac{jkaE_o}{2}\frac{e^{-jkr}}{r}\left[\hat{\theta}A(\theta)\cos\phi - \hat{\phi}B(\theta)\sin\phi\right] \tag{72}$$

where

$$A(\theta) = \left(1 + \frac{\beta}{k}\cos\theta\right)\frac{J_1(k_c a)}{k_c}\frac{J_1(wa)}{wa} \tag{73a}$$

and

$$B(\theta) = \left(\frac{\beta}{k} + \cos\theta\right) J_1(k_c a) \frac{k_c J_1'(wa)}{k_c^2 - w^2} \tag{73b}$$

are the feed pattern functions in which $w = k\sin\theta$, $\beta = \sqrt{k^2 - k_c^2}$ is the TE_{11} mode propagation constant and $k_c a = 1.84118$ is the cut-off wavenumber. The associated magnetic field is given by Eq. 4.1b.

The surface current on the paraboloid due to feed radiation given by Eq. 72 is

$$\begin{aligned}
\mathbf{J}_s &= \frac{2}{\eta_o}\hat{n} \times \left(\hat{\rho} \times \mathbf{E}_f\right) = \frac{jkaE_o}{\eta_o}\frac{e^{-jk\rho}}{\rho}\left(-\hat{\rho}\cos\frac{\psi}{2} + \hat{\psi}\sin\frac{\psi}{2}\right) \times \left(\hat{\xi}A(\psi)\cos\xi - \hat{\psi}B(\psi)\sin\xi\right) \\
&= \frac{jkaE_o}{\eta_o}\frac{e^{-jk\rho}}{\rho}\left(\hat{\rho}\,A(\psi)\sin\frac{\psi}{2}\cos\xi + \hat{\psi}A(\psi)\cos\frac{\psi}{2}\cos\xi - \hat{\xi}B(\psi)\cos\frac{\psi}{2}\sin\xi\right) \\
&= \frac{jkaE_o}{\eta_o}\frac{e^{-jk\rho}}{\rho}\cos\frac{\psi}{2}\left\{\hat{r}\left[A(\psi)\cos\xi\cos(\phi-\xi)\left(\sin\theta - \cos\theta\tan\frac{\psi}{2}\right) + B(\psi)\sin\theta\sin\xi\sin(\phi-\xi)\right]\right. \\
&+ \hat{\theta}\left[A(\psi)\cos\xi\cos(\phi-\xi)\left(\cos\theta - \sin\theta\tan\frac{\psi}{2}\right) - B(\psi)\cos\theta\sin\xi\sin(\phi-\xi)\right] \\
&\left. + \hat{\phi}\left[-A(\psi)\cos\xi\sin(\phi-\xi) + B(\psi)\sin\xi\cos(\phi-\xi)\right]\right\}.
\end{aligned}$$

The radial components in the integrand cancel out, and therefore, the radiated electric field is given by

$$\begin{aligned}
E_\theta(r,\theta,\phi) = \frac{k^2 af E_o}{2\pi}\frac{e^{-jkr}}{r}\int_0^{2\pi} d\xi \int_0^{\psi_c} d\psi \exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi) - (1+\cos\theta\cos\psi))] \times \\
\left[A(\psi)\cos\xi\cos(\phi-\xi)\left(\cos\theta - \sin\theta\tan\frac{\psi}{2}\right) - B(\psi)\cos\theta\sin\xi\sin(\phi-\xi)\right]\tan\frac{\psi}{2}
\end{aligned} \tag{74a}$$

and

$$\begin{aligned}
E_\phi(r,\theta,\phi) = -\frac{k^2 af E_o}{2\pi}\frac{e^{-jkr}}{r}\int_0^{2\pi} d\xi \int_0^{\psi_c} d\psi \exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi) - \\
(1+\cos\theta\cos\psi))][A(\psi)\cos\xi\sin(\phi-\xi) + B(\psi)\sin\xi\cos(\phi-\xi)]\tan\frac{\psi}{2}.
\end{aligned} \tag{74b}$$

The maximum gain of paraboloid with a circular waveguide feed can be calculated by means of Eqs. 20b and 74. It may be shown that the total power radiated by a circular waveguide operating in the TE_{11} mode is

$$P_T = \frac{|E_o|^2 \pi a^2}{4\eta_o} J_1^2(k_c a)\left(1 - \frac{1}{(k_c a)^2}\right).$$

The maximum gain then follows from Eq. 20b where the field components of the electric field are obtained from Eq. 74 that are evaluated in the boresight direction at (0°,0°).

As an example of a prime-focus reflector and circular feed, consider a parabolic reflector of diameter $D = 100\ \lambda$ and $f/D = 0.35$ excited by a circular waveguide with a radius of $a = 0.66\ \lambda$, which corresponds

DOI 10.1007/978-981-4560-75-7_30-1

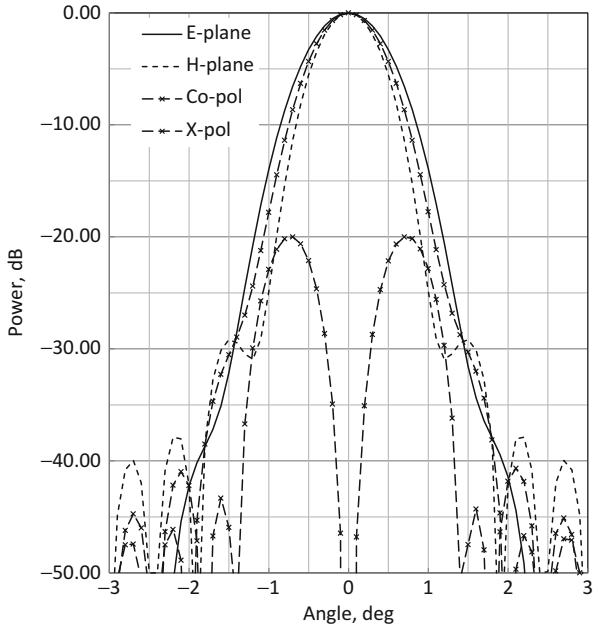

Fig. 15 Radiation patterns of paraboloid with a circular waveguide feed. Reflector dimensions $D = 100\ \lambda$ and $f/D = 0.35$. Circular waveguide feed radius is $a = 0.66\ \lambda$, *Solid plot*: E-plane; *dashed plot*: H-plane; *long dash* – x-: co-polar in the 45° plane; and *short dash* – x-: cross-polar in the 45° plane

to the radius of the first Airy ring in the focal region. The principal plane radiation patterns and co- and cross-polarized patterns are shown in Fig. 15. The computed gain was 48.1 dBi where the aperture efficiency is 65.8 %. This corresponds close to the peak gain for this reflector. Variations in the waveguide diameter either smaller or larger produce a reduction in gain.

Other waveguide feed types can also be studied by means of Eq. 74 as long as the feed radiation can be represented by variations of Eq. 72. For example, a corrugated waveguide operating in the HE_{11} mode at the balanced hybrid–hybrid condition the feed pattern functions Eq. 73 are replaced by

$$A(\theta) = \frac{2\pi k_\rho a}{\left(k_\rho^2 - w^2\right)}\left(1 + \frac{\beta}{k}\cos\theta\right)J_1(k_c a)J_0(wa) \tag{75a}$$

$$B(\theta) = \frac{2\pi k_\rho a}{\left(k_\rho^2 - w^2\right)}\left(\frac{\beta}{k} + \cos\theta\right)J_1(k_c a)J_0(wa) \tag{75b}$$

where $k_\rho a = 2.4048$ and $w = k\sin\theta$. The radiation pattern of the corrugated waveguide is axisymmetric about the boresight direction except for the Huygen's factors. However, in usual operation, $\beta \approx k$. This enables some simplifications to be made to the field radiated by the reflector in Eq. 74. The co- and cross-polarized radiation patterns of the previous reflector of diameter $D = 100\ \lambda$ with a corrugated waveguide of radius $a = \lambda$ are shown in Fig. 16. It is observed that the cross-polarization level is significantly lower than in the case of the circular waveguide feed with a peak of −43 dB and the principal plane patterns are almost identical. Even though the feed cross-polarization is low, there is still some cross-polarization with the reflector. This is due to diffraction that occurs at the reflector rim, which produces a slight depolarization of the radiated field.

DOI 10.1007/978-981-4560-75-7_30-1

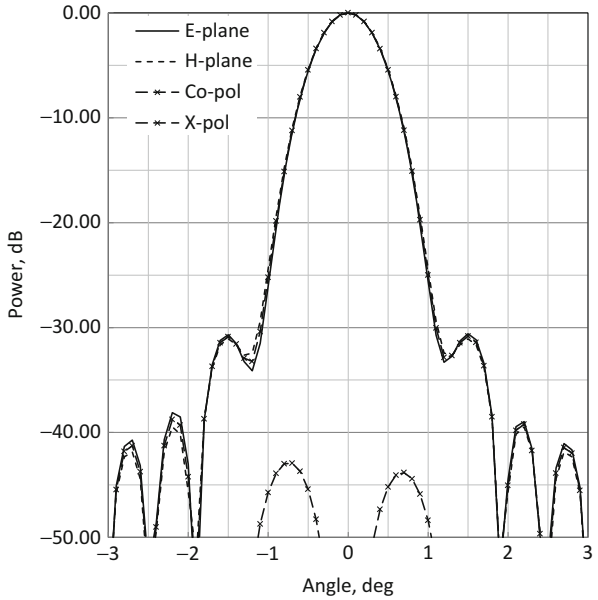

Fig. 16 Radiation patterns of a paraboloid with a corrugated waveguide feed. Reflector dimensions $D = 100\ \lambda$ and $f/D = 0.35$. Waveguide feed radius is $a = 0.66\ \lambda$, *Solid plot*: E-plane; *dashed plot*: H-plane; *long dash* – x-: co-polar in the 45° plane; and *short dash* – x-: cross-polar pattern in the 45° plane

Linear flared horns can also be modelled approximately with Eqs. 72 and 74 provided Eq. 73 can be modified by adding a quadratic phase factor to account for the expansion of the wavefront. For example, a conical horn has an approximate radiated field that is given by the fields radiated by a circular horn multiplied by the quadratic phase factor

$$\exp\left(\frac{k}{2}\frac{\rho'^2}{L}\right)$$

where $\rho' = \sqrt{x'^2 + y'^2}$ is the radial distance to the source point and L is the distance from the horn apex to the aperture. By introducing this factor into the field of the TE_{11} mode of circular waveguide, the far-field of the conical horn is obtained as

$$\begin{Bmatrix} E_\theta \\ E_\phi \end{Bmatrix}(r,\theta,\phi) = \pm\frac{jkE_o}{4}\frac{e^{-jkr}}{r}\ (Q_0(k_c,\theta) \mp Q_2(k_c,\theta))(1+\cos\theta)\ \begin{Bmatrix} \cos\phi \\ \sin\phi \end{Bmatrix} \tag{76}$$

where

$$Q_m(\xi,\theta) = \int_0^a J_m(\xi\rho')J_m(k\rho'\sin\theta)\exp\left(-jk\rho'^2/L\right)\rho' d\rho' \tag{77}$$

and $k_c a = 1.841184$. Equation 77 is sufficiently accurate for most applications providing the cone semi-angle, θ_o, is less than about 30°.

It is assumed in Eq. 76 that $\beta \approx k$. The half-power beamwidth of a conical horn can be shown to be $HPBW \approx 0.6 * 180\lambda/(\pi a)$, where a is the radius at the aperture. Thus, if the feed radius at the aperture is $a = 1\ \lambda$ the $HPBW \approx 34^\circ$. Suppose conical horn is used as a feed in a paraboloid with $D = 50\ \lambda$ and $f/$

DOI 10.1007/978-981-4560-75-7_30-1

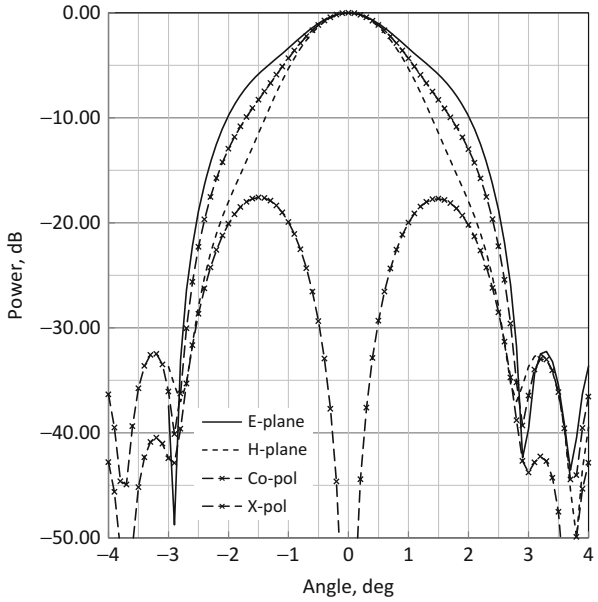

Fig. 17 Radiation patterns of paraboloid with a conical horn feed. Reflector dimensions $D = 50\ \lambda$ and $f/D = 0.5$. Waveguide feed radius is $\alpha = 1\ \lambda$, *Solid plot*: E-plane; *dashed plot*: H-plane; *long dash* – x-: co-polar in the 45° plane; and *short dash* – x-: cross-polar pattern in the 45° plane

$D = 0.5$. The co-polar and cross-polar patterns of this reflector with the conical horn shown in Fig. 17. Obviously the cross-polar level is quite high and this frequently the case with smooth wall conical horns. The cross-polar peak is reduced as in Fig. 16 with a corrugated conical horn. Similarly, a quadratic phase factor can be applied to a corrugated waveguide to model the radiated field of a corrugated horn. The result is

$$\begin{Bmatrix} E_\theta \\ E_\phi \end{Bmatrix}(r,\theta,\phi) = \pm\frac{jkE_o}{2}\frac{e^{-jkr}}{r}(1+\cos\theta)Q_0(k_\rho)\begin{Bmatrix} \cos \\ \sin \end{Bmatrix}\phi \tag{78}$$

where Q_0 is given by Eq. 77.

Advanced Feeds

The feeds illustrated in Fig. 12 represent canonical feeds although extensions shown in Fig. 18 are now in general use. These feeds provide several improvements such as increased efficiency, pattern symmetry, low cross-polarization, increased bandwidth, well-defined phase centre and low input mismatch, which increased the performance of suitable reflector systems. A short summary of these feeds is given in this section. Further details on them as well as other feeds can be found in the references (Olver et al. 1994; Bird and Love 2007).

A simple extension of the circular waveguide in Fig. 12b is to corrugate the output flange as shown in Fig. 18a. This enables the patterns for pipes of smaller diameter, and therefore wider beamwidth, to be axisymmetric, which is useful for deep dishes (i.e., f/D < 0.35). In addition, the number of corrugations may be reduced so that there is only one (as shown in Fig. 18c) or two ring slots and these can be tuned to give low cross-polarization at several narrow frequency bands. The depth of the slot varies from about 0.2 to 0.375 λ depending on the aperture diameter and the distance the slot(s) needs to be placed for the chosen edge illumination. Another option as a feed for deep reflectors is to use a coaxial waveguide.

DOI 10.1007/978-981-4560-75-7_30-1

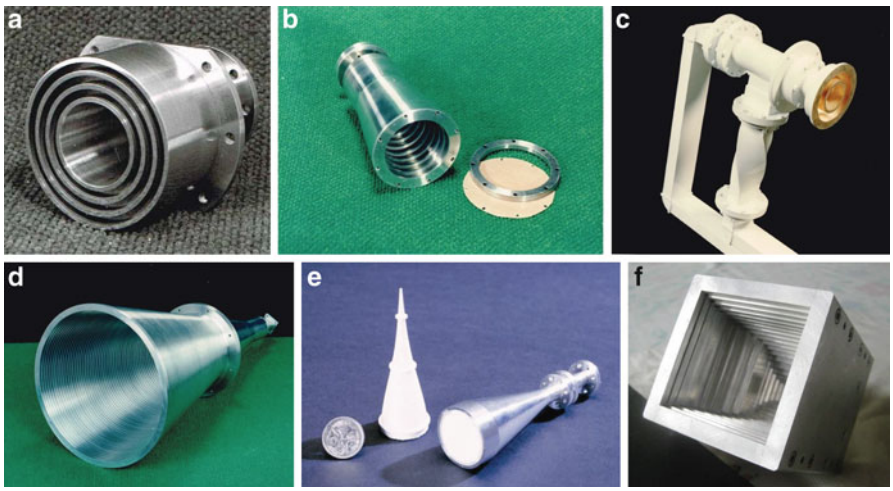

Fig. 18 Advanced feeds for reflector antennas. (**a**) Circular waveguide with corrugated flange; (**b**) corrugated horn for an offset parabolic reflector; (**c**) dual-polarized circular waveguide with ring slot flange; (**d**) wideband corrugated horn for a symmetrical Cassegrain reflector; (**e**) dielectric-lined horn with profiled dielectric insert; and (**f**) profiled rectangular horn feed (Pictures (**a**) to (**e**) courtesy CSIRO Australia)

A coaxial feed works best when the inner-to-outer conductor radii are close to 0.3. When this ratio is larger, the H-plane pattern becomes narrow and the E-plane pattern broadens. A flange with ring slots can also be used to adjust the pattern for coaxial feeds.

The corrugated horns illustrated in Fig. 18b, d continue to be an effective feed option for long–focal length reflectors (i.e., f/D >0.5) and for dual reflectors. Its excellent characteristics such as beam symmetry, bandwidth, low cross-polarization and good input reflection coefficient make it an attractive option for many applications. Fabrication can still be a problem as it is important to have accurate corrugations, which can be obtained with numerical machining.

Dielectric-lined horns as shown in Fig. 18e are another option in place of corrugated horns. The dielectric constant can be profiled transversely or have a central core of material with dielectric constant of about 1.2 and a small air gap between the core and the metal wall. When properly designed, a dielectric-lined horn can have very large bandwidths sometimes in excess of 30:1. There are practical issues around the use of dielectrics such as moisture trapping and outgassing in a vacuum. They have to be suitable for the operating environment either on the ground or in space as well as structurally stable. Nonetheless, their wide bandwidth makes them an attractive possibility.

The performance of standard rectangular and circular horns can be improved with a number of steps along their profile to generate higher-order modes. This has been used for many years to obtain incremental improvements. This process has been extended recently by introducing many steps to profile the horn from a desired input waveguide diameter to an output diameter that is able to achieve the desired beamwidth, input match and cross-polar maximum. A rectangular horn designed by this method is shown in Fig. 18f. The profile is created by computer optimization in much the same way described in a later section ("Reflector Shaping") for profiling reflectors. By this means, a horn's performance can be tailored to suit the intended application including a desired bandwidth, edge illumination and input reflection coefficient.

The feed geometries referred to above enable high-performance reflector systems to operate reliably. The references should be consulted (Olver et al. 1994; Bird and Love 2007) for further details as well as information of other feed types.

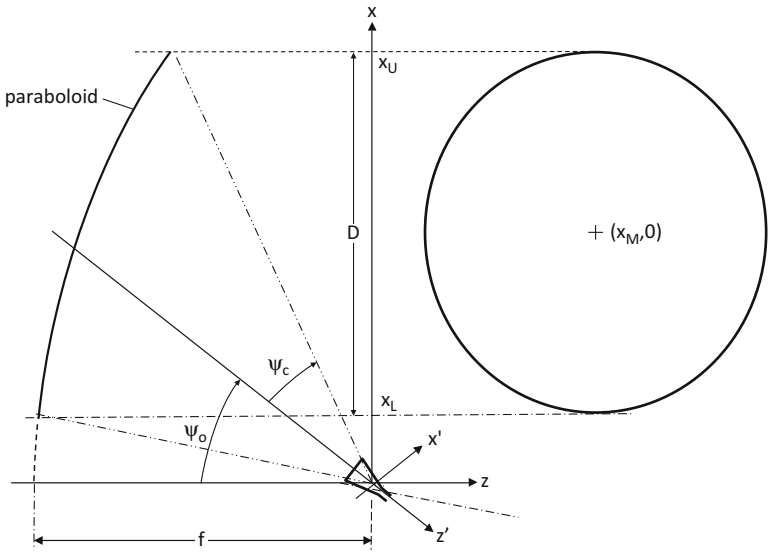

Fig. 19 The offset parabolic reflector geometry and its rotated co-ordinate system {X′} for the feed along with the projected aperture

Other Reflector Geometries

While the paraboloid is the most common type of reflector in everyday use, there are other reflector geometries that are used. In this section, the basic properties of the offset parabolic reflector are described as are the properties of the classical symmetrical Cassegrain and its offset equivalent. The radiation from the prime-focus fed spherical reflector is described, and focal fields of this reflector are studied. Finally, some basic techniques for designing shaped reflectors will be outlined.

Offset-Fed Parabolic Reflector

Blockage by the feed and feed support struts in a paraboloidal reflector reduces the gain and increases the sidelobe level. This can be overcome with the offset-fed configuration as illustrated in Fig. 19. The advantage of offset reflecting systems is that the offset parabolic antenna is formed by rotating the feed through an angle as shown in Fig. 19, which illuminates only part of the paraboloid and allows the feed to be supported by a mount below the reflector. The feed and reflector are contained within a cone of half-angle ψ_c with the feed at its apex and the reflector rim lying on its surface. The projection of the rim onto the x-y plane is a circle of diameter

$$D = \frac{4f \sin \psi_c}{\cos \psi_o + \cos \psi_c} \tag{79}$$

which is centred at (x_m, 0) where

$$x_m = \frac{2f \sin \psi_o}{\cos \psi_o + \cos \psi_c}. \tag{80}$$

f is the focal length of the original paraboloid and ψ_o is the rotation angle ("offset angle") of the primed coordinate system about the focus. The cone angle ψ_c lies between the rotated axis of the feed and the rim of the offset reflector. The angles are given by

DOI 10.1007/978-981-4560-75-7_30-1

$$\psi_{o,c} = \tan^{-1}\left(\frac{x_m + D/2}{2f}\right) \pm \tan^{-1}\left(\frac{x_m - D/2}{2f}\right).$$

Feed blockage is avoided if the largest feed upper extremity in the positive x-direction is less than the clearance, x_L, between the lower rim and the z-axis, where

$$x_L = 2f \tan\left[\left(\frac{\psi_o - \psi_c}{2}\right)\right] \tag{81}$$

From the focus along the offset axis, the reflector rim lies on the projected elliptical cone that has major and minor axes of length

$$a = \frac{D}{2\sin\gamma};\ b = \frac{D}{2} \tag{82}$$

where $\gamma = \tan^{-1}\frac{2f}{x_m}$. The centre of the ellipse is (x_m,0,z_m), where $x_m$is given by Eq. 80 and

$$z_m = f\left[\frac{\sin^2\psi_o + \sin^2\psi_c}{(\cos\psi_o + \cos\psi_c)^2} - 1\right]. \tag{83}$$

With respect to the rotated axes, the spherical polar co-ordinates in this system are (ρ, ψ, ξ) and a point on the paraboloid has coordinates

$$x' = \rho\sin\psi\cos\xi; y' = \rho\sin\psi\sin\xi; z' = -\rho\cos\psi \tag{84}$$

where

$$\rho = \frac{2f}{1 - \cos\xi\sin\psi\sin\psi_o + \cos\psi\cos\psi_o} \tag{85}$$

The relation between the two coordinate systems is

$$x = x'\cos\psi_o - z'\sin\psi_o; y = y'; z = x'\sin\psi_o + z'\cos\psi_o. \tag{86}$$

The normal is expressed

$$\hat{n} = -\sqrt{\frac{\rho}{4f}}\{-\hat{x}(\cos\xi\sin\psi\cos\psi_o + \cos\psi\sin\psi_o) - \hat{y}\sin\xi\sin\psi + \hat{z}(1 - \cos\xi\sin\psi\sin\psi_o + \cos\psi\cos\psi_o)\}.$$

A geometric optics approximation to the aperture field is obtained by the approach for symmetrical reflectors leading up to Eq. 27. Clearly, feed rotation does not alter the paraboloid's basic properties, viz. the distance from the focus to the aperture plane at $z = 0$ to the reflector and back to the aperture is $2f$; also there is no z-component of the aperture field because the output is a plane wave. These properties allow the aperture field expressions to be simplified. For the incident field from the feed expressed by Eq. 25, the rectangular components of the aperture field in the projected aperture are given by Eq. 47:

DOI 10.1007/978-981-4560-75-7_30-1

$$E_{ax} = g_o\left[a_1 F_\psi(\psi,\xi) - b_1 F_\xi(\psi,\xi)\right] \tag{87a}$$

$$E_{ay} = g_o\left[b_1 F_\psi(\psi,\xi) + a_1 F_\xi(\psi,\xi)\right] \tag{87b}$$

where

$$a_1 = \cos\xi(1 + \cos\psi\cos\psi_o) - \sin\psi\sin\psi_o,$$

$$b_1 = \sin\xi(\cos\psi + \cos\psi_o)$$

and

$$g_o = -\exp(-2fk)/2f.$$

The far fields are obtained from Eq. 87 by applying Eq. 16 in the aperture plane. To do this, define polar co-ordinates $(t,\ \zeta)$ centred on $(x_m,\ 0)$ in the aperture such that $x = x_m + t\cos\zeta$, $y = t\sin\zeta$ and $z = \left(x^2 + y^2 - 4f^2\right)/4f$. The resulting integrals are evaluated on the projected circle, Fig. 19. To obtain the angle co-ordinates relative to the rotated feed coordinates, the inverse of Eq. 86 are used to express $\psi = \text{asin}(z'/\rho)$ and $\xi = \text{atan}(y'/x')$ where $\rho = \sqrt{x^2 + y^2 + z^2}$. When the feed pattern is axisymmetric (i.e., $F_\psi(\psi,\xi) = A(\psi)\cos\xi$ and $F_\xi(\psi,\xi) = -A(\psi)\sin\xi$ the aperture fields will be symmetric about the vertical (x-) axis. However, compared with the symmetrical paraboloid there is cross-polarization. This is maximum in the plane of asymmetry ($\xi = 90°$ and 270°). Cross-polarization results because the feed has been rotated and the field illuminating the reflector is no longer symmetrically located. In general, a feed with asymmetric patterns has maximum cross-polarization between the 90 and 45° planes, depending on the level of feed cross-polarization. Special feeds have been designed to introduce low levels of cross-polarization to cancel out the cross-polarization of the offset paraboloid (Rudge and Adatia 1975).

As described above, the radiation field is obtained by substituting Eq. 87 into Eq. 16 and evaluating the required transform either numerically or by means of the FFT. An example of the radiation patterns possible for an offset parabolic reflector is shown in Fig. 20. The E-, H-, co- and cross-polar patterns in the 90°-plane are shown for an offset reflector with $\psi_{o=44°}$, $\psi_c = 30°$ and $D = 100\ \lambda$. The reflector is fed with a rectangular waveguide having aperture dimensions $1.57\lambda \times 2.14\ \lambda$. Its E-plane pattern is obviously coincident with the x-z plane. The dimensions of the waveguide and the operating frequency result in edge illuminations in both the E- and H-planes of about −12 dB. The computed gain is 37.67 dBi, and the aperture efficiency is 72 %. The peak cross-polar level is −23.6 dB below the co-polar maximum in the $\phi = 90°$-plane. The results given in Fig. 20 were computed from Eq. 87 by numerical integration and they agree well with experimental values (Rudge 1975).

The feed can be modified from Eq. 5.9 to one with pattern axial symmetry given by the Gaussian function

$$A(\psi) = \exp\left(-\alpha\psi^2\right).$$

where the coefficient α is chosen to give an edge illumination of −12 dB. Thus, $\alpha = -EdB/\left(20\psi_c^2\log_{10}e\right)$ wherein EdB is the edge illumination $EdB = -12$. With this axisymmetric feed, the offset antenna gain has an increased gain of 38.0 dBi and an efficiency of 77.9 %. The radiation patterns are similar to those shown in Fig. 5.2 except that first sidelobe is lower at −29.6 dB below the peak and the cross-polar maximum is slightly lower at −24.1 dB. The peak cross polarization occurs near to the 45° plane for an asymmetric feed and is at a higher level than in the axisymmetric case, which occurs

DOI 10.1007/978-981-4560-75-7_30-1

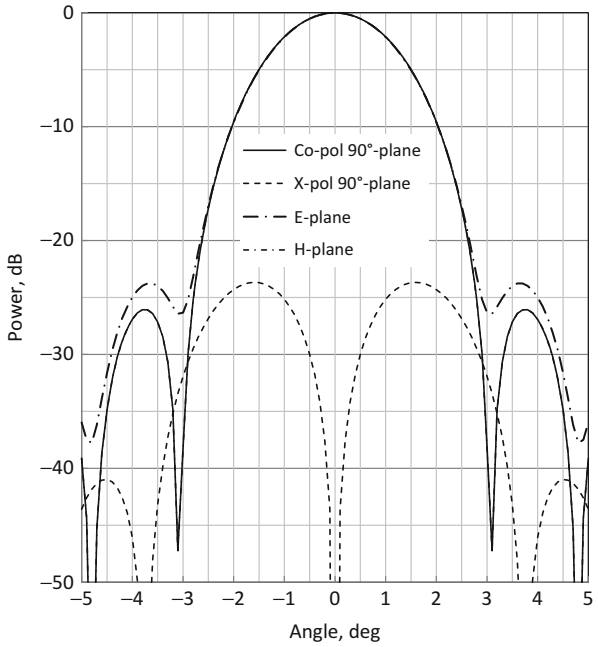

Fig. 20 Co- and cross-polarized radiation patterns of an offset reflector antenna with $\psi_o = 44°$, $\psi_o = 30°$ and $D = 100\ \lambda$ and that is fed with a rectangular waveguide of aperture dimensions $a = 1.57\ \lambda$ and $b = 2.14\ \lambda$

in the 90° plane. However, the maximum level of cross-polarization is approximately the same for both feeds.

An estimate of the HPBW of an offset parabolic reflector in the E-plane is approximately

$$HPBW\ \ (\text{deg.}) = (0.9\,E_{dB}\ \ +\ \ 58)\ \ (\lambda/D) \tag{88}$$

where E_{dB} is the edge illumination in dB. Thus, in the previous example, where the edge illumination is −12 dB, Eq. 5.10 predicts a HPBW of 2.4°, which agrees closely with the HPBW of the pattern in Fig. 20.

In the design of offset parabolic reflectors, the useful concept for establishing 'ball-park' figures and designing the co-polar pattern is that of the 'effective paraboloid.' The offset parabolic reflector is assumed identical to a symmetrical paraboloid of the same diameter but with an effective focal length

$$f_{eff} = \frac{2f}{1 + \cos\psi_o} \tag{89}$$

For the effective paraboloid, the focal length to diameter ratio is f_{eff}/D.

As an example, consider the design of an offset paraboloid to produce a beam in the far-field at the elevation and azimuth angles θ_b and ϕ_b. Assume θ_b is close to reflector boresight and consider an incoming ray from (θ_b, ϕ_b). In the effective paraboloid, the reflected ray makes an angle β with respect to the axis, where

$$\beta \approx \theta_b \left(1 + \frac{1}{32\left(f_{eff}/D\right)^2}\right) \tag{90}$$

DOI 10.1007/978-981-4560-75-7_30-1

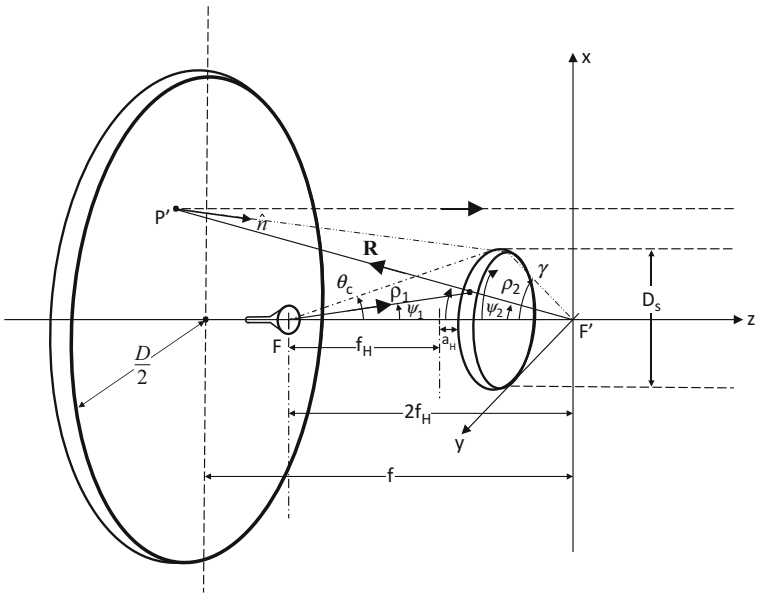

Fig. 21 Symmetrical Cassegrain antenna with hyperboloidal subreflector

which comes from the small angle estimate for a paraboloid. The position for the location of feed in the focal plane is estimated as

$$x_{oeff} = f_{eff} \sin\beta \cos\phi_b y_{oeff} = f_{eff} \sin\beta \sin\phi_b. \tag{91}$$

The accuracy of the estimates given by Eq. 91 is usually quite good, but they become less accurate as the angle from boresight increases due to the original estimate Eq. 90.

Cassegrain Antennas

The Cassegrain antenna as illustrated in Fig. 21 had its origins in an optical telescope that was devised in the seventeenth century. In its classical form, it consists of a paraboloidal main reflector and a smaller hyperboloidal subreflector. The hyperboloid has real and virtual foci, labelled F and F′ in Fig. 21, and it is symmetrical about the axis FF′. From the focus F the distance to the surface is given by

$$\rho_1 = \frac{-e\beta}{1 - e\cos\psi_1} \tag{92}$$

where $\beta = f_H(1 - 1/e^2)$ and $e = f_H/a_H$ is the hyperboloid' s eccentricity. Alternatively, from the virtual focus the surface is given by

$$\rho_2 = \frac{e\beta}{1 + e\cos\psi_2}. \tag{93a}$$

The relation between the angles from the axis to the reflector is

$$\tan\frac{\psi_2}{2} = M\tan\frac{\psi_1}{2} \tag{93b}$$

DOI 10.1007/978-981-4560-75-7_30-1

where $M = \frac{e+1}{e-1}$ is the magnification factor. The cone angle from the focus to the rim is given by

$$\theta_c = \tan^{-1}(-1/\alpha) + \left(\frac{\alpha/e}{\sqrt{\alpha^2+1}}\right) \tag{93c}$$

where $\alpha = 2\beta/D_s$. D_s is the diameter of the subreflector. The relation between the cone angles from the foci is

$$\cot\theta_c + \cot\gamma = f_H/D_s \tag{93d}$$

In the Cassegrain configuration, F′ of the hyperboloid is coincident with the paraboloid's focus, while the feed is located at F. When a source of spherical waves is located at the focus, the hyperboloid creates a reflected wave that for the paraboloid appears also to emanate from a source located at F′. The main advantages of the Cassegrain over a single reflector antenna are that the feed can be located close to the main reflector and the receiving/transmitting electronics and, also, feed spillover is directed toward the cold sky not towards a hot earth. In the classical symmetrical Cassegrain (Fig. 21) blockage still occurs due to the subreflector and the subreflector supports.

However, there is sufficient flexibility in the dual reflector system to shape the profiles of both reflectors in such a way that subreflector blockage is reduced. Reflector shaping applied to both surfaces allows the aperture illumination to be selected to enhance performance. This makes the symmetrical shaped Cassegrain superior in most respects to front-fed reflectors and is the reason for their widespread use in large earth stations.

Blockage can also be avoided by adopting an offset Cassegrain configuration, which is illustrated in Fig. 22. Feed spillover is an important contributor to the far-out sidelobes of all types of Cassegrain antennas, and to minimise this contribution, the feed sidelobes in particular should be small. Usually, subreflector edge illumination needs to be ≤ -16 dB to keep the spillover contributions to the sidelobes of the Cassegrain to an acceptable level.

The properties of Cassegrain antennas can be analysed by means of the techniques described in the section "Background." Ray tracing by geometric optics (GO) can be used at both reflectors to determine the aperture field. Although this approach is not accurate for small subreflectors (diameter less than about 10 λ) because of diffraction at the rim. GO is sufficiently accurate for most purposes when the diameter of the reflectors is large ($>10\ \lambda$). Considerable improvement in accuracy results for smaller reflectors when diffraction is included through methods such as the geometrical theory of diffraction (GTD). Accurate results are also possible by applying the physical optics approximation at both reflectors or by combining the techniques of GTD and physical optics.

Application of GO to the offset Cassegrain configuration shown in Fig. 22 enables an approximation to be found for the aperture fields. A feed with an axisymmetric pattern function $F(\psi)$, which is also polarized parallel to the plane of symmetry (x-z plane), results in aperture fields

$$E_{ax}(\psi',\zeta') = g_o(\psi',\zeta')[A\sin\psi'\cos\zeta' + B\left(\sin^2\zeta' + \cos\psi'\cos^2\zeta'\right) + C(1+\cos\psi')] \tag{94a}$$

$$E_{ay}(\psi',\zeta') = -g_o(\psi',\zeta')\sin\zeta'[A\sin\psi' + B(\cos\psi' - 1)\cos\zeta'] \tag{94b}$$

where

DOI 10.1007/978-981-4560-75-7_30-1

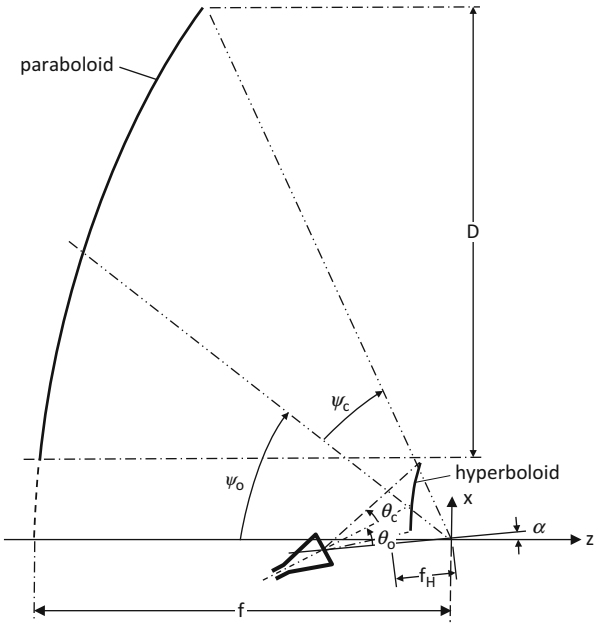

Fig. 22 Offset Cassegrain antenna

$$A = L\sin\alpha\cos\theta_o - \sin\theta_o(K + \cos\alpha)$$

$$B = L\sin\alpha\sin\theta_o + \cos\theta_o(K + \cos\alpha) - C$$

$$g_o(\psi', \zeta') = \frac{F(\psi')}{2fL}\exp\left[-2jk\left(f + \frac{f_H}{e}\right)\right]/(B\cos\psi' + A\sin\psi'\cos\zeta' + C(1 + \cos\psi'))$$

$C = 1 + K\cos\ \alpha$, $L = (e^2 - 1)/(1 + e^2)$ and $K = -2e^2/(1 + e^2)$. Also (Ψ', ζ') are the elevation and azimuth angles of a spherical coordinate system at the feed phase centre. Equation 5.16 are in an identical form to the single offset reflector except for the latter, $A = \sin\theta_0$, $B = 1 - \cos\theta_0$, $C = -1$ and D=exp$(-2jkf)/2f$. The aperture fields for a symmetrical Cassegrain are obtained from Eq. 94 by letting $\phi_0 = 0$, $\theta_0 = 0$ and $\alpha = 0$.

The offset Cassegrain can have low cross-polarization compared with a single offset by the appropriate selection of the feed and reflector offset angles. GO predicts zero cross-polarization, but due to subreflector diffraction cross-polarization has a small but finite level. Zero cross-polarization is predicted by Eq. 94 when the feed and hyperboloid offset angles satisfy the condition

$$\tan\frac{\theta_0}{2} = M\tan\frac{\alpha}{2}. \tag{95}$$

where M is the magnification factor defined for the Cassegrain (Eq. 93b).

Under this condition, the reflector pattern is axisymmetric also. When the feed pattern is not axisymmetric, Eq. 95 is the condition for zero cross-polarization in the plane of asymmetry (y-z plane). Furthermore, in that case the principal component of the aperture field is elliptical and maximum cross-polarization occurs between the 45 and 90° planes. The aperture field of an offset antenna with a feed with an axi-symmetric pattern that does not satisfy Eq. 95 is shown in Fig. 23. In this example, $D = 150\ \lambda$, $\psi_o = 53.553°$, $\psi_c = 20.511°$, $f = 160.77\ \lambda$, $\theta_o = 28°$, $\theta_c = 11$, e = 2.4575, $f_H = 41.054\ \lambda$ and $\alpha = 6°$ The feed pattern is a Gaussian function, which results in a subreflector edge illumination of −10 dB. As might

DOI 10.1007/978-981-4560-75-7_30-1

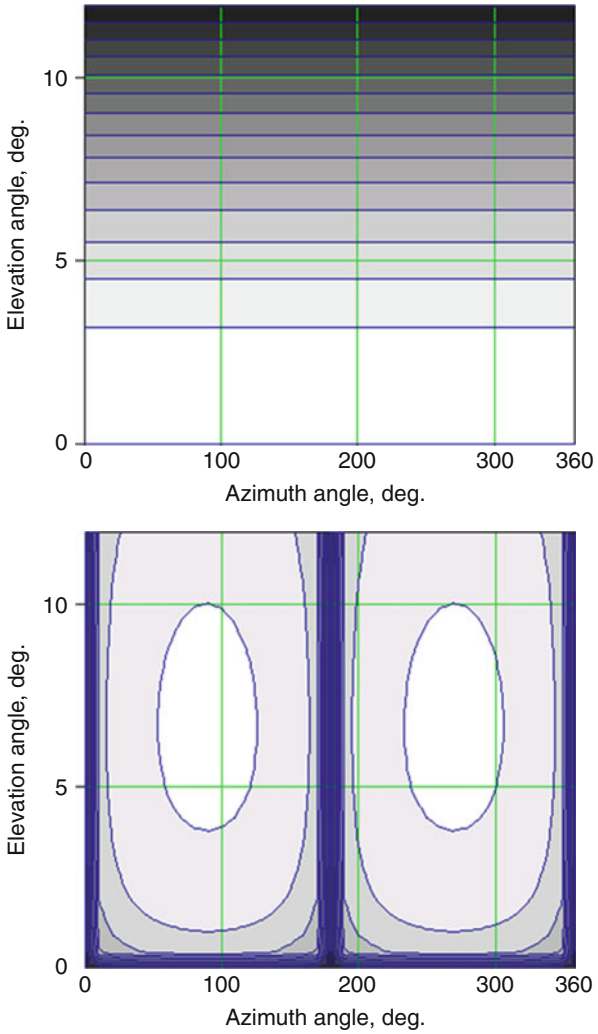

Fig. 23 Principal and cross-polar field components obtained by geometric optics in the aperture plane of an offset Cassegrain antenna defined by $D = 150\ \lambda$, $\psi_o = 53.553$, $\psi_c = 20.511°$, $\theta_o = 28°$, $\theta_c = 11°$, $e = 2.4575$, $f_H = 41.054\ \lambda$, $\alpha = 6°$. Feed has axisymmetric pattern with edge illumination of 10 dB. The electric field is polarized parallel to plane of symmetry

be expected, the co-polar contours are almost invariant with azimuth angle and peak cross-polarization occurs in 90 and 270° planes.

The radiation patterns can be obtained from Eq. 16 and the aperture fields in Eq. 94 by a series of coordinate changes from the aperture plane through to the local co-ordinate system of the feed. The geometric optics formulation described above does not take into account the diffraction from the subreflector, which contributes particularly to the cross-polarization. For example, in the plane of asymmetry (i.e., $\phi = \pm 90°$), a rigorous analysis of the antenna described in Fig. 23 has been shown that the cross-polar peak level at the angle α predicted by Eq. 95 varies from about -45 dB for a 10 λ diameter subreflector to about -30 dB for one with a subreflector 5 λ in diameter.

Spherical Reflectors

The spherical reflector is employed in many different applications, from satellite communications to scanning beams for radar tracking. The latter is achieved quite simply by rotating the feed at the chosen focal point as the surface appears identical over a limited angular range. However, the complication is that

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_30-1

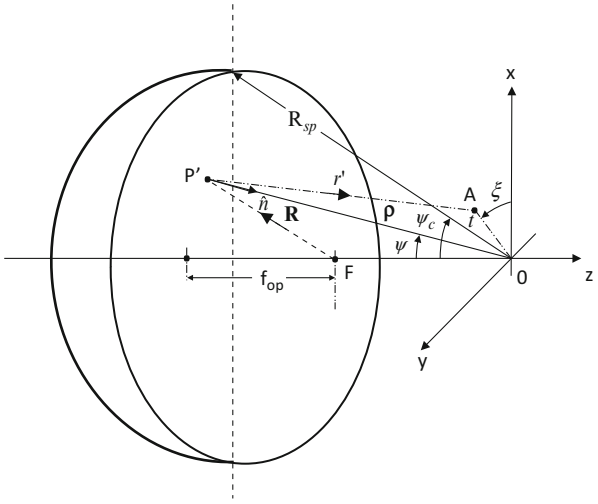

Fig. 24 Geometry of spherical reflector

without correction, a conventional feed horn provides poor illumination of a spheroid compared with a paraboloid. The classical location for a point source of a spherical reflector of radius R_{sp} is $f_{op} = R_{sp}/2$. However, marginal rays do not intersect this classical point but do so elsewhere along the paraxial region, i.e., close to the z-axis shown in Fig. 24. As a result, the optimum location focal point F can be closer to the reflector than the classical location (Ashmead and Pippard 1946). It has been shown that, to keep the phase error in the aperture to within $\pm\lambda/16$, the diameter of the aperture should not exceed $D = 256\lambda(f/D)^3$. Three approaches are commonly used for feeding a spherical reflector. These are an array of dipoles or waveguides, a correcting concave reflector known as a Gregorian-corrected configuration, and a line source in which a travelling wave feed radiates a field along the axis towards the reflector. To understand the spherical reflector further, the radiation from this reflector analysed by means of geometric optics. Through this analysis the optimum location can be estimated for a single feed. A waveguide feed is then used to excite a spherical reflector and the radiation pattern obtained. Finally, the focal region field of a spherical reflector is discussed.

The geometry of a spherical reflector is shown in Fig. 24. The distance from the focal point to the aperture plane at $z = 0$ is given by

$$s = FP' + P'A = \sqrt{t^2 + \left[\sqrt{\rho^2 - t^2} - \left(\rho - f_{op}\right)\right]^2} + \sqrt{\rho^2 - t^2} \tag{96}$$

where $\rho = R_{sp}$ the radius of the sphere, t is the radial distance from the z-axis and f_{op} is the distance from the vertex to the focal point at F. The path difference between a paraxial ray and a non-axial ray is given by

$$\Delta = R_{sp} + f_{op} - s$$

In wavelengths, this difference is

DOI 10.1007/978-981-4560-75-7_30-1

$$\frac{\Delta}{\lambda} = \frac{R_{sp}}{\lambda}\left(1 + \frac{f_{op}}{R_{sp}} - \sqrt{\left(\frac{t}{R_{sp}}\right)^2 + \left[\sqrt{1 - \left(\frac{t}{R_{sp}}\right)^2} - \left(1 - \frac{f_{op}}{R_{sp}}\right)\right]^2} - \sqrt{1 - \left(\frac{t}{R_{sp}}\right)^2}\right). \tag{97}$$

The total phase error over a prescribed aperture is least when the phase error at the aperture edge is zero. If the aperture radius is D/2, which describes a cone of angle $\psi_c = \sin^{-1}\left(\mathrm{D}/2\mathrm{R}_{\mathrm{sp}}\right)$ at O, the optimum focal length when $\Delta/\lambda = 0$ is

$$f_{op} = \frac{1}{4}\left(R_{sp} + \sqrt{R_{sp}^2 - \left(\frac{D}{2}\right)^2}\right). \tag{98}$$

Whilst this is the optimum location for a uniform illumination, it is not necessarily the most suitable location for a tapered pattern when the feed needs to move further away from the reflector vertex. Correspondingly there is a given aperture size for a total phase error. Thus, the phase error tolerance limits the aperture size. It has been determined that the maximum allowable total phase error $(\Delta/\lambda)_{\max}$ for a given aperture diameter D is

$$\left(\frac{D}{R_{sp}}\right)^4_{\max} = 75\pi\frac{(\Delta/\lambda)_{\max}}{(R_{sp}/\lambda)}. \tag{99}$$

For example, a spherical reflector with a radius of $R_{sp} = 1.52\ m$ is required to produce an aperture field with maximum total phase error of $(\Delta)_{\max} = \lambda/16$ at 11.2 GHz. The maximum possible aperture diameter predicted by Eq. 99 is $(D)_{\max} = 1.08m$.

The aperture field of the spherical reflector can be obtained from Eq. 4, where $\hat{n} = -\hat{r}$. It is assumed the feed radiates an incident electric field in the form given by Eq. 6, which results in

$$\mathbf{E_i} = \left(\hat{\psi}F_\psi(\psi,\xi) + \hat{\xi}F_\xi(\psi,\xi)\right)\exp(-jkR)/R$$

where, as shown in Fig. 24, R is the distance from the focus to the reflector surface. Therefore the aperture field is given by

$$\mathbf{E}_a = -\left(\hat{\psi}F_\psi(\psi,\xi) + \hat{\xi}F_\xi(\psi,\xi)\right)\exp(-jks)/R \tag{100}$$

where $s = R + r'$ is the total distance, $r' = \sqrt{R_{sp}^2 - t^2}$ and

$$R = \sqrt{t^2 + \left[\sqrt{R_{sp}^2 - t^2} - \left(R_{sp} - f_{op}\right)\right]^2}. \tag{101}$$

To calculate the radiated field from a spherical reflector, Eq. 100 is substituted in Eqs. 16. An asymmetrical feed is assumed so that $F_\psi(\psi,\xi) = A(\psi)\cos\xi$ and $F_\xi(\psi,\xi) = -B(\psi)\sin\xi$. The integral over ξ in this case can be completed in closed form by means of Eq. 35. The resulting transform functions are

DOI 10.1007/978-981-4560-75-7_30-1

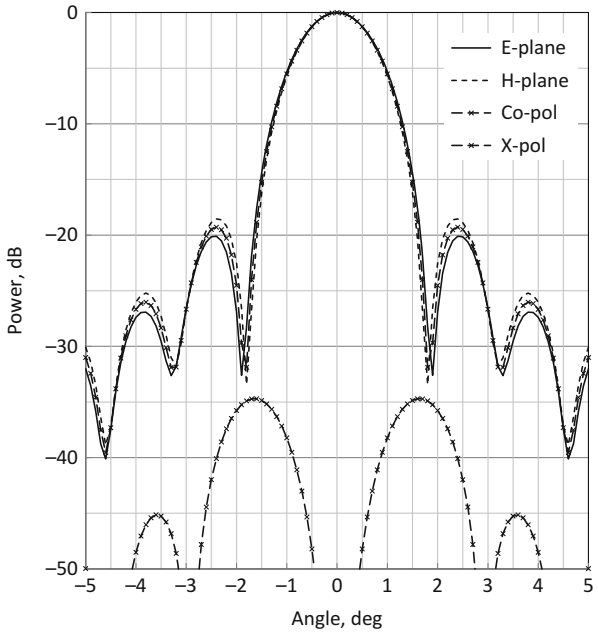

Fig. 25 Radiation patterns of a spherical reflector with a circular waveguide feed at an operating frequency of 11.2 GHz. The diameter of the spheroid is 305.8 cm, aperture diameter 108 cm, focal length 73.7 cm and $\psi_c = 20.89°$. Aperture radius of the circular waveguide feed is 1.87 cm

$$N_x(\theta,\phi) = -\pi\int_0^{D/2} dt\ \ t\left[A(\psi)\cos\psi(J_0(w) - J_2(w)\cos 2\phi) + B(\psi)\left(J_0(w) + J_2(w)\cos 2\phi\right)\right]\exp(-jks)/R \tag{102a}$$

$$N_y(\theta,\phi) = \pi\sin 2\phi\int_0^{D/2} dt\, tJ_2(w)[A(\psi)\cos\psi - B(\psi)]\exp(-jks)/R. \tag{102b}$$

where $w = kt\sin\theta$. It is convenient to integrate over the angle ψ in Eqs. 102 in the range $0 < \psi < \psi_c$. Substituting for $t = R_{sp}\sin\psi$ and

$$N_x(\theta,\phi) = -\frac{\pi R_{sp}^2}{2}\int_0^{\psi_c} d\psi\sin 2\psi[A(\psi)\cos\psi(J_0(w) - J_2(w)\cos 2\phi) + B(\psi)(J_0(w) + J_2(w)\cos 2\phi)\Big]\exp(-jks)/R \tag{103a}$$

$$N_y(\theta,\phi) = \frac{\pi R_{sp}^2}{2}\sin 2\phi\int_0^{\psi_c} d\psi\sin\psi J_2(w)[A(\psi)\cos\psi - B(\psi)]\exp(-jks)/R \tag{103b}$$

where $s = R_{sp}\cos\psi + R$ and $R = \sqrt{R_{sp}^2 + \left(R_{sp} - f_{op}\right)^2 - 2\cos\psi R_{sp}\left(R_{sp} - f_{op}\right)}$. Note that when $\psi = 0, R = f_{op}$, It can be seen from Eq. 103 that when the feed is axisymmetric, i.e., $A(\psi) = B(\psi)$, the contribution of the terms $J_2(w)\cos 2\phi$ and $J_2(w)\sin 2\phi$ to the far field will be small. These terms contribute to the cross-polarization so, therefore, for low cross-polar applications, an axisymmetric feed is preferred.

DOI 10.1007/978-981-4560-75-7_30-1

As an example, Fig. 25 shows the radiation patterns obtained with a 4.05 m diameter spherical reflector that is fed with a circular waveguide of radius 0.7 λ. The aperture diameter for a total phase error is given by Eq. 99 is $D = 108.7$ cm. The focal distance has been computed from Eq. 5.20 and also 74.7 cm. The edge illumination at $\psi_c = 20.89°$ in the E- and H-planes are -4.1 and -2.1 dB respectively. Good pattern symmetry is achieved and the first sidelobe levels lie near the -20 dB level. The cross-polar level is seen to have a peak of -35 dB relative to the co-polar peak. The computed peak gain is 39.76 dBi. The same reflector with a square-aperture horn feed with a sidelength of 4.9 cm is reported to have a measured gain of 39.4 dBi and comparable sidelobe levels (Li 1959) to those predicted in Fig. 25.

Although not mentioned earlier, wide-angle scanning is possible with a spherical reflector when a suitable feed – usually with a broad main lobe – is rotated at the focal distance. The scan angle width of the 4.05 m reflector reported above (Li 1959) was found to be 70°, which is typical for a spherical reflector.

The focal region fields of a spherical reflector can be obtained in the same way as described for the paraboloidal reflector in the section "Paraboloidal Reflector." The results can be used to design a feed that best matches these fields to obtain a high efficiency. The electric field in the axial region of a spherical reflector at a point (t, ξ, z) has been derived (Thomas et al. 1969) and is expressed

$$E_\rho(t,\xi,z) = G_\rho(t)\sin\xi \tag{104a}$$

$$E_\xi(t,\xi,z) = G_\xi(t)\cos\xi \tag{104b}$$

$$E_z(t,\xi,z) = G_z(t)\sin\xi \tag{104c}$$

where

$$G_\rho(t) = -jkR_{sp}E_o\sin^2\psi_c[A(t)+B(t)]$$

$$G_\xi(t) = -jkR_{sp}E_o\sin^2\psi_c[A(t)-B(t)]$$

$$G_z(t) = -2kR_{sp}E_o\sin^2\psi_c\,C(t)$$

$$A(t) = \frac{1}{2}\csc^2\psi_c\int_0^{\psi_c}\kappa(\psi)(1+\Gamma)J_0(wt)\exp(-j\phi)d\psi$$

$$B(t) = \frac{1}{2}\csc^2\psi_c\int_0^{\psi_c}\kappa(\psi)(1-\Gamma)J_0(wt)\exp(-j\phi)d\psi$$

$$C(t) = \frac{1}{2}\csc^2\psi_c\int_0^{\psi_c}\kappa(\psi)\frac{\sin\psi}{\zeta}J_1(wt)\exp(-j\phi)d\psi$$

in which $\kappa(\psi) = \frac{\sin\psi}{\zeta}\left(1-\frac{z}{R_{sp}}\cos\psi\right)$, $\zeta = \sqrt{1+\left(\frac{z}{R_{sp}}\right)-2\frac{z}{R_{sp}}\cos\psi}$, $w = \frac{k\sin\psi}{\zeta}$, $\Gamma = \frac{\zeta\cos\psi}{\left(1-\left(z/R_{sp}\right)\cos\psi\right.}$, and $\phi(\psi) = kR_{sp}(\cos\psi+\zeta)$. A contour plot of the focal fields that are predicted by Eq. 104 is shown in Fig. 26 for a spheroid of radius 1.52 m at a distance $z = 78.7$ cm from the vertex, which corresponds to the point F in Fig. 23 where $f_{op} = 73.7$ cm. The operating frequency is 11.2 GHz. The plot clearly shows the Airy rings and that a waveguide of radius about 1.8 cm would be a good starting point for feeding the reflector. This may mean exciting a number of waveguide modes to create the precise Airy rings. For example, Thomas et al. (1969) have shown that an efficiency >80 % is possible for

DOI 10.1007/978-981-4560-75-7_30-1

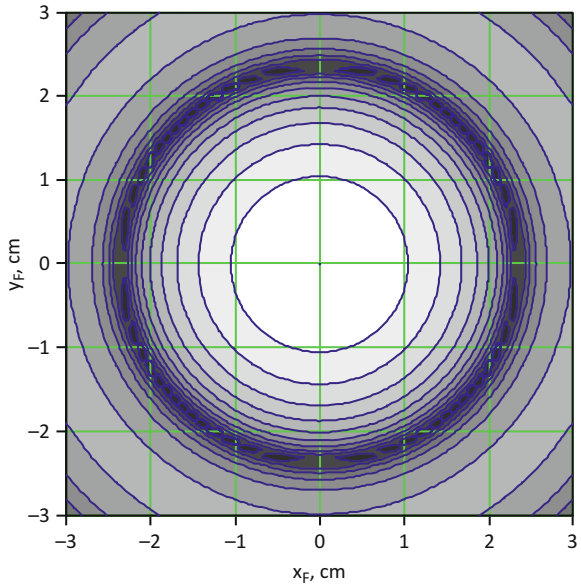

Fig. 26 Focal region fields at a distance $z = 78.7$ cm from the origin of a spherical reflector of radius 1.52 m. The operating frequency is 11.2 GHz

a spherical reflector with $R_{sp} = 400\ \lambda$ and $\psi_c = 20°$ for $z = 0.515R_{sp}$ with a feed having $ka > 15$, where α is the aperture radius, providing the correct combination of modes has been excited in the aperture.

A subreflector can be designed to completely correct for the spherical aberration (Holt and Bouche 1964) or numerically using the methods of the section "Reflector Shaping." which can also correct other deficiencies such as subreflector mismatch.

Reflector Shaping

All reflectors considered so far have been given in a closed form either as a parabola or a sphere. In this section, the objective is to achieve a desired radiation pattern through the shaping of the reflector surface. Two approaches are described. The first is a classical approach based on geometrical optics (Silver 1946). The second and more recent approach is based on numerical optimization. This latter approach is potentially more flexible because it allows the possibility of inclusion of diffraction effects, the mounting structure as well as limitations of the feed antenna. Accurate analysis methods can also be included such as physical optics, providing their implementation is fast enough for use with a standard optimization methods.

Reflector Synthesis by Geometric Optics

Reflector shaping or reflector synthesis by geometric optics methods was originally developed in the 1940s (Silver 1946) for a single reflector and has been extended to two reflectors (Galindo 1964) and later to more reflectors by continued application of the GO.

Consider the axisymmetric reflector shown in Fig. 27 for which the profile is required. The z_1-axis is taken as the axis of rotation of the reflector. The focus of the reflector is located at F a distance f from the reflector vertex, and also the reflector has a maximum dimension in the vertical direction specified by $x_{1\max}$. Let $\rho_1(\theta_1)$ be the radial distance from F to a point on the reflector at an elevation angle of θ_1 where clearly $\rho_1(0) = f$. An incident ray from the feed at F undergoes reflection and exits at an angle θ_2 to the z_1-

DOI 10.1007/978-981-4560-75-7_30-1

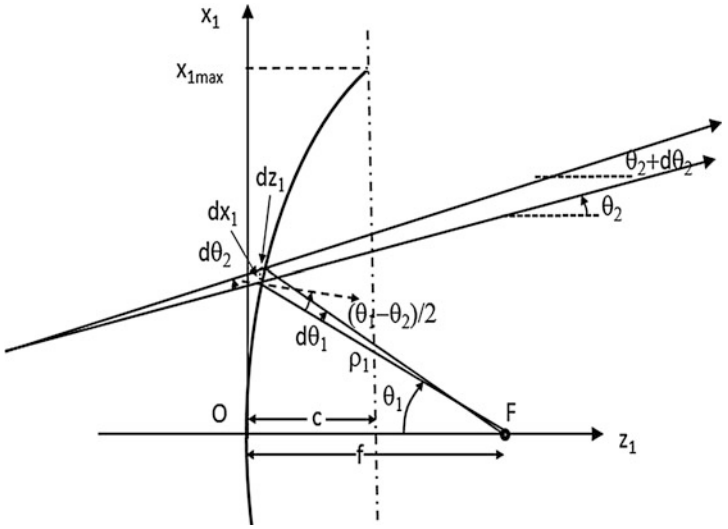

Fig. 27 Ray paths at a single reflector fed from the focus F

axis. By means of the second law of reflection, the angle between the normal to the curve and the incident and reflected rays is $(\theta_1 - \theta_2)/2$ as can be seen in Fig. 27. Application of Snell's law results in the following differential equation

$$\frac{dx_1}{dz_1} = \frac{1}{\rho_1}\frac{\partial \rho_1}{\partial \theta_1} = \tan\left(\frac{\theta_1 - \theta_2}{2}\right). \tag{105}$$

Integrating both sides of Eq. 105 with respect to θ_1 results in

$$\int_0^{\theta_1} \frac{1}{\rho_1}\frac{\partial \rho_1}{\partial \theta_1} d\theta_1 = \int_0^{\theta_1} \tan\left(\frac{\theta_1 - \theta_2}{2}\right) d\theta_1$$

and, therefore,

$$\rho_1(\theta_1) = f \exp\left[\int_0^{\theta_1} \tan\left(\frac{\theta_1 - \theta_2}{2}\right) d\theta_1\right]. \tag{106}$$

The solution of ρ_1 as a function of θ_1 through Eq. 106 gives the profile of the reflector.

As an example, if $\theta_2 = 0$ the exit ray is parallel to the z_1-axis. Setting this in Eq. 5.27 results in $\rho_1(\theta_1) = f \exp(2\ln|\sec(\theta_1/2)|)$, which simplifies to $\rho_1(\theta_1) = 2f/(1 + \cos\theta_1)$, the equation of a paraboloid.

In general, the angles θ_1 and θ_2 should be chosen to allow the energy to disperse into the secondary radiation pattern. This is done by ensuring that conservation of energy occurs from the feed to the aperture field. Incrementally, this energy is contained in the angular wedges $d\theta_1$ and $d\theta_2$. Thus, if $P(\theta_1)d\theta_1$ is the energy incident from the primary feed located at F, where $P(\theta_1)$ is the feed pattern function, and $I(\theta_2)d\theta_2$ is the reflected power, where $I(\theta_1)$ is the desired illumination function, then, for conservation of energy, it is required that

$P(\theta_1)d\theta_1 = I(\theta_2)d\theta_2$.

Therefore, over all angles this becomes

DOI 10.1007/978-981-4560-75-7_30-1

$$\int_0^{\theta_1} P(\theta_1)\sin\theta_1\,d\theta_1 = K\int_{\theta_{2\min}}^{\theta_2} I(\theta_2)\sin\theta_2\,d\theta_2 = K\int_{x_{2\min}}^{x_1} I(x_2')x_2'dx_2' \tag{107}$$

where $\theta_2 = \tan^{-1}\left(\frac{x_2-x_1}{z_2-z_1}\right)$, $\theta_{2\min}$ and $\theta_{2\max}$ are the minimum and maximum angles over which $I(\theta_2)$ is known or specified. $\theta_{2\max}$ can be chosen from almost zero through to several beamwidths. The constant K can be evaluated from Eq. 107 at the upper limits i.e., $\theta_1 = \theta_{1\max}$ and $\theta_2 = \theta_{2\max}$. This results in

$$K = \frac{\int_0^{\theta_{1\max}} P(\theta_1)\sin\theta_1\,d\theta_1}{\int_{\theta_{2\min}}^{\theta_{2\max}} I(\theta_2)\sin\theta_2\,d\theta_2}. \tag{108}$$

Equation 108 is substituted back into Eq. 107 to give

$$\frac{\int_0^{\theta_1} P(\theta_1)\sin\theta_1\,d\theta_1}{\int_0^{\theta_{1\max}} P(\theta_1)\sin\theta_1\,d\theta_1} = \frac{\int_{\theta_{2\min}}^{\theta_2} I(\theta_2)\sin\theta_2\,d\theta_2}{\int_{\theta_{2\min}}^{\theta_{2\max}} I(\theta_2)\sin\theta_2\,d\theta_2} \tag{109}$$

Equation 109 is a relationship between θ_2 and θ_1 that can be used in conjunction with Eq. 105 to determine $\rho_1(\theta_1)$. Alternatively, both $P(\theta_1)$ and $I(\theta_2)$ could be specified from measured data and a relationship obtained in order to solve Eq. 105.

A feed pattern that is quite useful for representing many practical feeds is $P(\theta_1) = \cos^n\theta$ where n is the index of the power pattern. In that case Eq. 107 becomes

$$\frac{\int_0^{\theta_1} \cos^{n+1}\theta_1\,\sin\theta_1\,d\theta_1}{\int_0^{\theta_{1\max}} \cos^{n+1}\theta_1\,\sin\theta_1\,d\theta_1} = \frac{\int_{\theta_{2\min}}^{\theta_2} I(\theta_2)\sin\theta_2\,d\theta_2}{\int_{\theta_{2\min}}^{\theta_{2\max}} I(\theta_2)\sin\theta_2\,d\theta_2}.$$

That is:

DOI 10.1007/978-981-4560-75-7_30-1

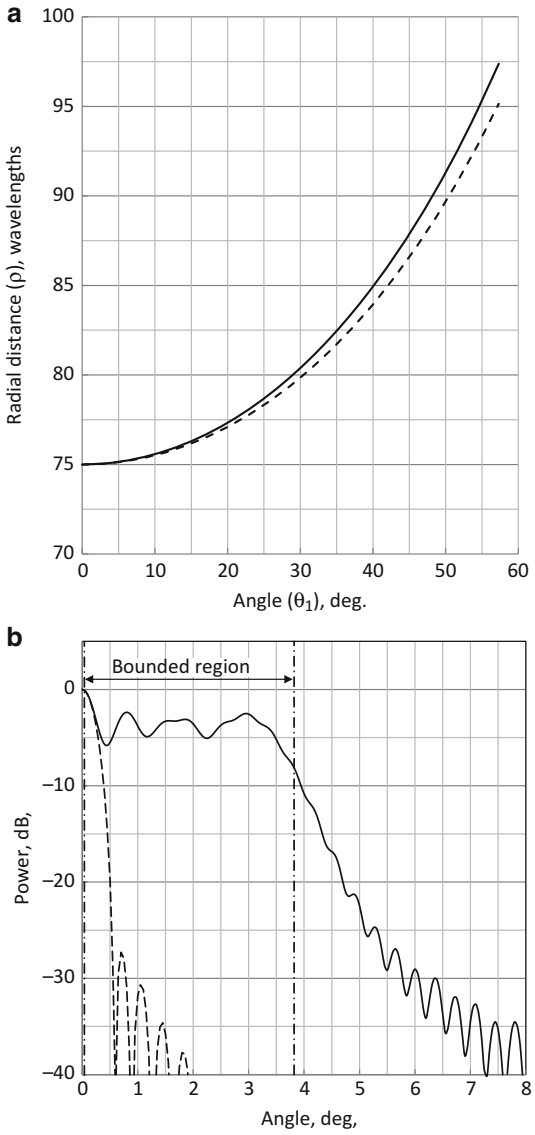

Fig. 28 Shaped reflector design for uniform illumination over the range $\lambda/10D \leq \theta \leq 10\ \lambda/D$(indicated by vertical *dashed lines*). $D = 150\ \lambda$ and $f/D = 0.5$ feed pattern index $n = 1.5$. (**a**) Reflector profile radial distance versus angle; (**b**) radiation pattern for synthesized reflector. Key – synthesized (*full curve*) and parabola (*dashed*)

$$\frac{(1 - \cos^{n+1}\theta_1)}{(1 - \cos^{n+1}\theta_{1\max})} = \frac{\int_{\theta_{2\min}}^{\theta_2} I(\theta_2)\sin\theta_2 d\theta_2}{\int_{\theta_{2\min}}^{\theta_{2\max}} I(\theta_2)\sin\theta_2 d\theta_2} \tag{110}$$

Continuing, suppose a uniform illumination is required over an angular range, i.e., $I(\theta_2) = 1$ for $\theta_{2\min} \leq \theta_2 \leq \theta_{2\max}$. Carrying out the integrations in Eq. 110 and reorganizing, the result is

DOI 10.1007/978-981-4560-75-7_30-1

$$\theta_2(\theta_1) = a\cos\left[\cos\theta_{2\min} + (\cos\theta_{2\max} - \cos\theta_{2\min})\frac{(1 - \cos^{n+1}\theta_1)}{(1 - \cos^{n+1}\theta_{1\max})}\right]. \tag{111}$$

This relation can be used in conjunction with Eq. 105 to obtain the reflector profile $\rho_1(\theta_1)$.

As an example, consider the design of the profile of reflector with a diameter of 150 λ and focal length $f = 75$ λ. A feed with $n = 1.5$ is chosen to give an edge illumination of about −7 dB. Suppose a uniform illumination function is required over the angular range of $\lambda/10 \leq \theta \leq 10\lambda/D$, i.e., in this case $0.030° \leq \theta \leq 3.8°$. The profile that is predicted by Eq. 106 along with Eq. 51 is shown in Fig. 28a. The resulting radiation pattern calculated from physical optics is shown in Fig. 28b. The average relative power level is −3.9 dB between the bounds indicated in Fig. 28b, which corresponds to an average gain of 28.7 dBi over the angular range. By comparison the profile and radiation pattern of a parabolic reflector with the same diameter and $f/D = 0.5$ is also shown in Fig. 28a, b produces a maximum gain on boresight of 52.5 dBi. The two profiles diverge as the edge approached and when $\theta_{2\max}$ is reduced the synthesized profile approaches the parabolic profile.

The approach described above is readily extended to two reflectors through the Galindo method (Galindo 1964). It was found that if an upper reflector limit equivalent to $x_{1\max}$ is chosen to be +1 (an arbitrary scale), a Cassegrain-type solution results. On the other hand, if $x_{1\max}$ is chosen as −1, a Gregorian-type reflector geometry is created, i.e., a spheroid with a concave reflector.

Reflector Synthesis by Numerical Optimization

The geometric optics approach described in the previous section has limitations as the number of physical constraints and requirements increase. The synthesis problem can be broadened to include accurate methods and more variables to be optimized through the use of numerical methods. There are several ways of doing this, both directly and indirectly. There are several direct techniques for reflector shaping that include effects such as diffraction, blockage and accurate feed modelling. One such approach is the method of successive projections. An indirect approach is to use standard numerical methods. A numerical representation of the reflector surface is used in concert with accurate radiation and feed models to meet the various system requirements. In this section a reflector synthesis approach is described which uses standard optimization methods.

A synthesis of a reflector surface by optimization is described in the flowchart shown in Fig. 29. The procedure uses a PO transmit-mode radiation-pattern analysis in conjunction with a standard optimization method. An important requirement for efficient optimization is the choice of representation of the surface and also the analysis methods so that each iteration can be quickly undertaken. One approach for representing the surface that has proved effective is with the basis-spline or B-spline functions. The degree of the spline function can be selected as required although, in many applications, a third-order basis spline has proved sufficient in both accuracy and computation time. The reflector surface $z = f(x, y)$ is represented by the B-spline series, the coefficients of which become the optimization variable in order to meet the performance requirements. A surface given in terms of B-splines of the same order in both dimensions is

$$f(x,y) = \sum_{i=0}^{m}\sum_{j=0}^{n}\alpha_{ij}B_{i,k}(x)B_{j,k}(y);\ 2 \leq k \leq m, n+1 \tag{112}$$

where $B_{i,k}(x)$ and $B_{j,k}(y)$ are standard B-spline basis functions of order k with $m + 1$ and $n + 1$ control points, respectively, and α_{ij} are the control point coefficients. A B-spline in a variable x is a piecewise polynomial function of degree $k - 1$ that is defined over a range $t_1 \leq x \prec t_m$ where $m = k + 1$. The points

DOI 10.1007/978-981-4560-75-7_30-1

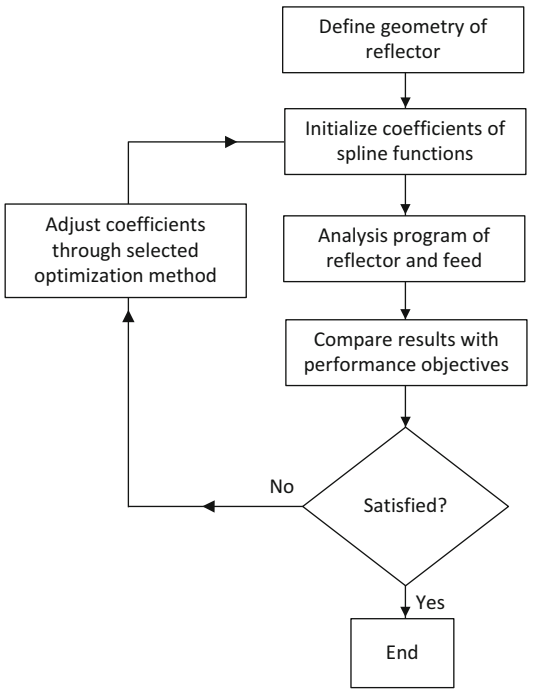

Fig. 29 Reflector shaping through numerical optimization.

where $x = t$ are known are called knots or break points, and these are arranged in ascending order. The number of knots is the minimum for the degree of the B-spline, which has non-zero values only in the range between the first and last knot. Each piece of the function is a polynomial of degree $k - 1$ between and including adjacent knots. The surface given by Eq. 5.33 has a set of $(m + 1)(n + 1)$ control points, which is in common with most other interpolation methods, except that the surface does not generally pass through the central control points. Expressions for the polynomial pieces are easily generated by means of available recursion formulae such as, for example, the Cox- de Boor formula for a k-spline which is given by

$$B_{i,k}(x) = \frac{(x - t_i)B_{i,k-1}(x)}{(t_{i+k-1} - t_i)} + \frac{(t_{i+k} - x)B_{i+1,k-1}(x)}{(t_{i+k} - t_{i+1})}$$

where t_i is the knot value at I and $t_i < t_{i+1}$.

The control point coefficients α_{ij} of Eq. 112 are the unknowns in the reflector synthesis, and in Fig. 28 they are determined by the optimization. If there is more than one reflector, all surfaces are expressed similarly to Eq. 112 and, therefore, the remaining coefficients could be included in the optimization as well.

Returning now to Fig. 29, after the coefficients of Eq. 112 have been initialised, an analysis method is used to determine the performance of the antenna with the initial surface. There are some standard reflector profiles that can be selected as a starting point for the optimization. The computed performance with the initial surface is compared with the performance objectives. These are usually included in a single objective functional for which a minimum is required. If the functional is not a minimum, the coefficients of the surface are adjusted further by the optimization method. The antenna is analysed once again with the revised coefficients and once again the performance is compared with the specifications through the functional. This process is repeated until a reflector shape is found where the computed performance meets the system requirements or a limit on the iterations is reached. The reflector-shaping procedure

DOI 10.1007/978-981-4560-75-7_30-1

could use a PO transmit-mode radiation-pattern analysis based on numerical integration of the surface current, within a search for an optimum reflector shape via variation of the coefficients, α_{ij}. A positive definite functional to be minimized by the optimizer could be sum of least-squares or a higher index between the actual and desired specifications. In addition, a combination of search methods can be useful. For instance, a genetic search algorithm has been found effective for arriving into the vicinity of a minimum of a functional and a gradient search such as a quasi-Newton search method can be usefully applied to reach the minimum in fewer functional evaluations.

Some Reflector Applications

As has been mentioned previously, reflectors occur in many areas of daily living, from communications, the weather and in understanding the wider universe such as through radioastronomy. Three examples of applications of reflector antennas in each of these areas are outlined in the following section.

Satellite Communications

Reflector antennas in satellite communications are used both on the ground and in space. The size and type of reflector vary significantly depending on the distance to the satellite and the level of available power. A satellite in geostationary orbit is located at a distance of 36,000 km from the earth while those in orbit about the earth may only be 800 km away. An earth station at a teleport of major earth station facility may have to transmit and receive to both types of satellite. The size of the reflector used in the home or at a business premises may be only 20–30 wavelengths in diameter while the earth stations used in network hubs and in satellite control may be over a hundred times larger. In this discussion the emphasis is on the latter antennas. In space, the reflector size is often determined by the size of the launch vehicle. A fully-formed shaped reflector at launch may have only a maximum diameter of 2 m whereas an unfurlable parabolic dish can be 30 m diameter or larger.

Antennas for major earth stations for international communications via lNTELSAT satellites are typically up to 32 m in diameter. They usually consist of dual shaped reflectors in an axi-symmetrical configuration. A recent trend has been towards greater use of 18 m or smaller diameter antennas for major earth stations as the power and sensitivity of the space borne antennas has increased. The major bands used by INTELSAT are the 6/4 GHz bands, where the 6 GHz band is for the uplink (transmitting) and 4 GHz for the downlink (receiving). The bandwidth in each link direction is 580 MHz, and both senses of circular polarization are used to double the communication capacity. Where a transmit beam is involved a number of additional specifications have to be met. These usually include the following:

1. The G/T on receive is important but on transmit the effective isotropic radiated power level (EIRP) in the direction of the satellite is specified depending on the type of service.
2. In both transmit and receive, the isolation in decibels (dB) between orthogonal polarizations is important. For a dual-polarized system a value of approximately ≤ -30 dB is typically specified for angles within 1 dB of the main beam.
3. The peak level of the radiation pattern sidelobes is specified for all angles greater than from boresight. This is specified as a function of $P(\theta)$ given in dBi. Most telecommunications administrations use the CCIR sidelobe recommendations and these depend on the diameter of the main reflector in wavelengths (D/λ) as follows:

(a) $D/\lambda > 100$

DOI 10.1007/978-981-4560-75-7_30-1

Fig. 30 An 11 m X-band earth station antenna that was designed for low profile and high isolation so as to meet the CCIR sidelobe specifications (Bird et al. 1995)

$$P(\theta) \leq \begin{cases} 32 - 25\log\theta\,\text{dBi}, & 1^\circ < \theta \leq 48^\circ \\ -10\,\text{dBi}, & \theta > 48^\circ \end{cases} \tag{113}$$

although in some applications the tighter specification 29-25log(theta) is used out to 48 degrees.

(b) $D/\lambda < 100$

$$P(\theta) \leq \max\begin{cases} 52 - 10\log(D/\lambda) - 25\log\theta\,\text{dBi}, & \theta > 1\text{st sidelobe} \\ -10\,\text{dBi} \end{cases}. \tag{114}$$

The latter requirement (i.e., Eq. 114) recognizes the fact that it is more difficult to achieve low sidelobe levels with small antennas.

As an example, the design of an axisymmetric dual-shaped reflector antenna with a diameter of <18 m is outlined. Figure 30 shows this dual-reflector antenna, where the feed-horn, polarizer-diplexer unit (feed-system), and low-noise receiver (LNA) are situated in the cone housing at the vertex. The antenna operates at X-band and consists of an 11 m diameter main reflector and a 1.2 m diameter subreflector. The reflector surfaces were shaped to maximize the antenna G/T and to meet the 29–25logθ CCIR sidelobe recommendation (Bird et al. 1995). The smaller reflector size than usual was specified in order to meet important environmental considerations. The antenna transmits right-hand circularly polarized signals in the frequency band 7.9–8.4 GHz and receives left-hand polarized signals in the 7.25–7.75 GHz band. The proximity of the two bands, combined with an upper limit on the antenna gain due to environmental factors, placed a stringent requirement on the isolation requirements of the feed system. In order to

DOI 10.1007/978-981-4560-75-7_30-1

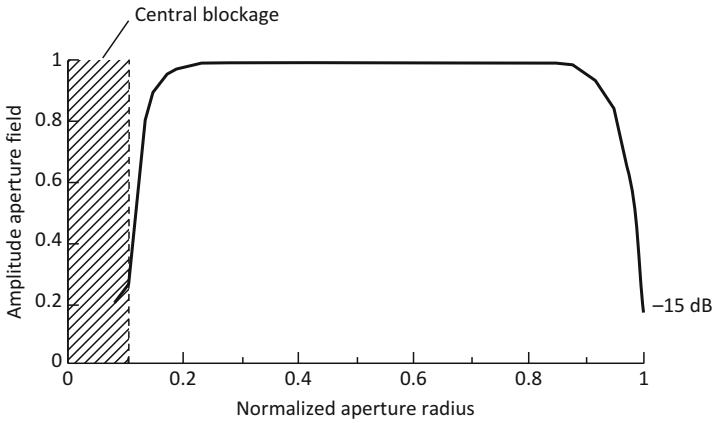

Fig. 31 Optimum aperture distribution for maximum G/T and low sidelobe levels

maximize the G/T, the transmit/receive filters had to have low insertion loss. This limits the order of the filters, and consequently the out-of-band performance. To achieve the desired high transmit/receive isolation, the feed system and the reflector had to have low reflections across the band. Low reflection from the reflector system was achieved by including a shaped matching cone at the centre of the subreflector (Wood 1980). The cone blends in smoothly with the remainder of the shaped subreflector and extends only over that the centre of the subreflector, which was already blocked by the feed. In this step, it is important to combine the feed mismatch and sidelobe designs together as the sidelobes have a large influence on the overall design.

Other improvements to existing earth stations can bring important advantages. This may be necessary to ensure that the expensive earth–station infrastructure meets any extension of the standards to permit access to any new satellites. Improvements to the input match of the feed to cover a wider bandwidth can have a significant impact. Also, as long as the new feed geometry fits the original feed enclosure, there will be minimum down-time for the earth station when the feed is replaced. Also, the optics of the antenna could be modified, for example, by replacing the usual uniform illumination over the full circle with other illuminations such as that shown in Fig. 31. By optimizing the taper at the upper edge of the illumination the spillover of energy is reduced past the edge of the main reflector and also of energy scattered by diffraction at the reflector rim. In addition, the reduction of energy in the central blocked region also minimizes the signal scattered by the secondary reflector. These changes can be included in an existing earth station by machining of the new subreflector and some re-setting of the surface panels so that any new sidelobe levels can be achieved.

Antennas on the satellite orbiting the earth operate in a very different environment and have objectives which usually differ significantly from those of earth station antennas. The communication antennas produce one or more beams, each beam defining a coverage region or “footprint” on the earth’s surface. Signals are either transmitted to or received from these footprints. The type of beams generated may be a single pencil, or a spot, beam over a major city, or a contoured beam designed to follow the boundary of a region or country, as illustrated in Fig. 32. An extreme case of this is a simple circular beam of angular width 17.4° to cover the entire earth from the geostationary orbit.

Apart from making the best use of the available satellite transmitter power, a contoured-beam antenna reduces interference to adjacent coverage regions and makes possible a more uniform coverage in the desired region. The isolation achieved between neighboring regions allows a common frequency band to be assigned, thus conserving the available frequency spectrum.

Ideally, a single shaped beam antenna produces the desired beams, both on transmit and receive. This may not be possible, and as a result transmit and receive functions are separated, which can be an

DOI 10.1007/978-981-4560-75-7_30-1

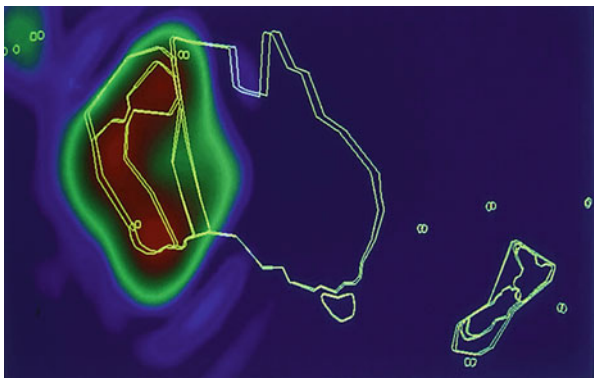

Fig. 32 Contoured beam design for Western Australia with a low-level illumination of the Cocos Islands

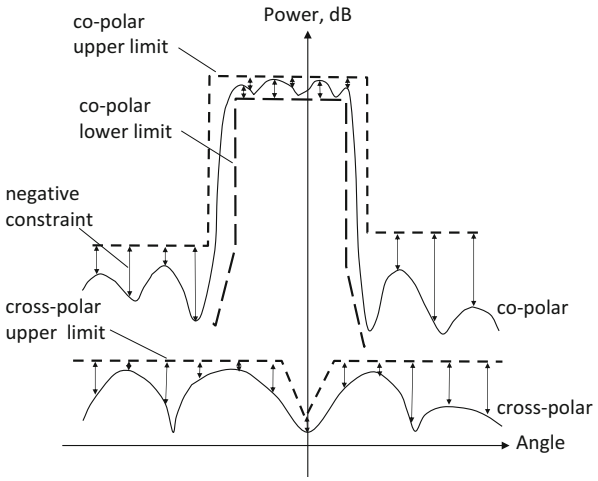

Fig. 33 Outline of constraints on a pattern for optimization through reflector shaping

advantage for isolation between bands. Currently, for each frequency band, a pair of antennas is used to generate all desired spot and area coverage beams, in two orthogonal polarizations. The type of antenna most commonly used for producing spot and contoured beams is a shaped offset reflector, which enables the feed and any beamforming network to be located close to the body of the spacecraft.

The procedure used to design shaped beams by numerical optimization is similar, irrespective of whether an array of feeds or reflector shaping is used. At first it is necessary to define maximum and minimum power levels at selected points inside the coverage region, and maximum levels outside of it, as depicted in Fig. 33. These levels define an envelope within which the radiated power must be contained.

It is important to know the relationship between the radiated power density in the defined area and the geometry of the reflector. This information is obtained by analysing the shaped reflector as described in the chapter on "► Applications of Phased Array Feeders for Reflector Antennas". The reflector surface or the feed excitation coefficients are adjusted by the optimizer so that the constraints on the power pattern could be satisfied. This is carried out by means of computer optimization. It may be impossible to determine all the unknowns automatically and some parameters may need to be selected on the basis of experience.

Fig. 34 A paraboloid reflector with high performance dual – polarized feed for a radar application (Hayman et al. 1998)

Table 2 Summary of dual-polarized meteorological radar reflector

Antenna type	Prime focus fed paraboloid
Diameter (D)	5.2 m
Focal ratio (f/D)	0.34
Beamwidth	0.9°
Gain	45.5 dBi
Sidelobes	<-21 dB
Cross-polarization	<-32 dB
Frequency	5,600–5,650 MHz

Dual-Polarized Weather Radar

Another important application for reflectors is in weather radar. The radar beams usually are required to have low-level sidelobes to avoid the clutter from signals scattered from the ground. In applications involving dual-polarization, high isolation is required between the polarization of two orthogonally polarized channels. The latter may be addressed with a shaped reflector but in some instances it can be addressed through a new feed system with high isolation. As an example of the latter, there has been an increased use of dual polarization in meteorological radars. The additional data provided by dual polarization has improved understanding of clouds and precipitation. For instance, droplet size can be estimated using the difference between the vertical and horizontal reflectivities, which can be assessed from radar returns of dual-polarized signals. Larger droplets are more oblate and will have a greater differential reflectivity than smaller droplets.

One approach that is sometimes adopted is the upgrade of an existing single-channel Doppler radar antenna to operate in two linear polarizations. In a dual-linear polarization approach the important measurement variables are horizontal (Z_{HH}) and vertical radar reflectivities (Z_{VV}). These are defined by

DOI 10.1007/978-981-4560-75-7_30-1

Fig. 35 Reflectors antennas in the Australian SKA pathfinder (ASKAP) (Courtesy CSIRO). This array consists of 36 12 m-diameter antennas, which are fed with 188 element phased array feeds, operate over a frequency range from 0.7 to 1.8 GHz (Picture courtesy CSIRO Australia)

$$Z_{pp} = \frac{32}{k^5|\chi|^2}\int \sigma_{pp} N(D) dD \tag{115}$$

where p is either the horizontal (H) or vertical (V), σ_{pp} is the radar cross section for either co-polar state, $N(D)$ is the particle-size distribution, and $\chi = (\varepsilon_r - 1)/(\varepsilon_r + 1) - 1$ where ε_r is the dielectric constant of the particle. Of importance is the differential reflectivity, which is defined by

$$Z_{DR} = 10\log\left(\frac{Z_{HH}}{Z_{VV}}\right) \tag{116}$$

and the linear depolarization ratio

$$LDR = 10\log\left(\frac{Z_{HV}}{Z_{VV}}\right). \tag{117}$$

Therefore, to accurately measure all parameters, Eqs. 115, 116, and 117, it was important for the upgraded antenna to have low cross-polarization relative to the co-polarized in both vertical and horizontal planes. A way of ensuring this is to have a symmetrical feed system with low cross-polarization in both diagonal planes. It is useful also to have similar antenna pattern in V- and H-directions to ensure Z_{DR} is a true measure of the differential reflectivity.

An existing single-channel Doppler radar was upgraded by introducing a dual-polarized feed that would give overall low cross-polarization. The antenna consisted of a paraboloid reflector and rotating mount. In the upgrade it was decided to design a new high performance axially symmetric feed with a ring slot flange (shown in Fig. 18c). As well, the two orthogonally polarized signals were transmitted from the same source with a short time delay, and, therefore, the upgrade included a high-power-microwave switch, and also an orthomode transducer (OMT) with high isolation between transmit and receive ports. The resulting reflector antenna is shown in Fig. 34 (Hayman et al. 1998). The target performance for the

DOI 10.1007/978-981-4560-75-7_30-1

antenna was specified by the end-user and included well matched co-polarized beam patterns, low sidelobes, low cross polarization taken in the diagonal planes and high isolation between channels. It was found for the feed that a worst case cross-polar isolation of −28 dB in the diagonal planes was sufficient to meet the required isolation in the V- and H-directions. The overall performance obtained from the antenna system is summarized in Table 2. The antenna has been used for a number of years in regions north of Australia to monitor tropical thunderstorms to use polarimetric measurements to provide quantitative rainfall data.

Radio Astronomy

As in astronomy at optical frequencies, microwave reflectors find significant use is in radio astronomy. There are a number of major radio astronomy observatories around the world. For observations above 800 MHz, reflectors are invariably involved. They can vary in size from around 20 m to over 300 m for the Arecibo spherical reflectors. Sometimes they can involve basic geometries such as a paraboloid, sphere or Cassegrain. Some antennas such as the Australia telescope array use a shaped dual reflector system. There are advantages and disadvantages of reflector shaping. One is that shaping can increase the gain and hence sensitivity for a point focus and use with a single feed. Reduced sidelobes and interference from nearby directions can be accommodated in the design as well. However, such a design may limit the possibilities for improvement by methods such as an extended array feed in the focal. Such feeds will have very poor gain performance for off-axis feeds than say a paraboloid or a classical Cassegrain antenna. The development of the international square kilometre array (SKA) observatory has stimulated much work on reflectors both in design and in manufacture as many antennas of a particular type need to be fabricated. Techniques being trialed vary from standard approaches with shaped aluminium panels and steel construction to a combination of steel backing structure and a carbon fibre reflector surface to reduce weight. There is competition between standard reflector shapes and some shaping. A range of feed options are available and this may ultimately resolve this as well as adaptability in the future. Figure 35 shows the Australian SKA pathfinder (ASKAP) system, which uses low-cost, low-power reflectors and phased array feeds. The 36 12 m-diameter antennas provide a 30 square degree field-of view of the southern sky over a frequency range from 0.7 to 1.8 GHz. The digital beamformer, which has a significant 300 MHz bandwidth, also has the potential for zooming the beam.

An earlier development was the introduction of array feeds in radio astronomy. In the first instance with an array of N elements, it enabled the data collection time for significant survey of the sky to be reduced by a factor of 1/N. In addition, they enabled through cross-correlation techniques to uncover additional information about the region of the sky. Phased array feeds became possible with the use of beamforming techniques that did not significantly contribute to the noise temperature. Details of both approaches with individual and phased array feeds are given in a chapter of this book entitled "► Applications of Phased Array Feeders for Reflector Antennas".

Conclusion

This chapter is an introduction to the theory and practice of reflector antennas. The material provided could find use in an advanced course in antennas at the advanced undergraduate or postgraduate level as well as for the practising telecommunications engineer. Also, the fundamentals are provided to allow the reader to understand the current literature on reflectors and to consider making initial progress on their own either in research or engineering design. The brief history shows that many of the basic reflector

DOI 10.1007/978-981-4560-75-7_30-1

geometries have been known from ancient times. However, many improvements have been made in the last 80 years. These vary over a considerable range of topics and include new reflector geometries as well as shaping, methods of feeding, computational methods, integrated design, correction of imperfections that result from manufacturing or misalignment and, of course, the materials used.

Advances in reflector system design have been steady, and this has often come with improvements in computational tools, which have been fundamental to many of the developments mentioned in the previous paragraph. With improved speed and accuracy of computation, there is no less reliance now on measured results than in earlier times. However, measured results may indicate unexpected difficulties due to certain assumptions, and, of course, they are important for confirming the accuracy or otherwise of the modelling. There are some specific algorithms for reflector shaping, but most of these use assumptions about the geometry; e.g., the geometrical optics method covered in this chapter neglects edge diffraction. Integrated design comes through the use of rigorous methods together to produce a specific design. For example, this may involve both reflector as well as horn profile shaping, both of which take into account interactions with a support structure. Correction of reflector misalignments, possibly over time, through adjustment of the structure is also possible through techniques such as in situ sensors and measurement processes of an operating reflector system. Finally, and most importantly, the progress being made in other areas with advanced materials, both physical and electromagnetic-based structures, opens up the potential of lightweight, rigid structures that are less prone to manufacturing tolerances than in the past. For example, fibre glass and carbon fibre reflectors have been in use for many years in several applications, but they have proved less reliable than might have been expected. Nevertheless, the fact that normally unwieldy reflectors made lightweight can alter the cost structure of the whole system particularly with the possibility of the use of less expensive towers is an important option. Taking just some of these possibilities into account indicates that the area of reflector antennas will continue into the future to be an exciting field to work in.

Spiral, Helical, and Rod Antennas

Hisamatsu Nakano* and Junji Yamauchi
Faculty of Science and Engineering, Hosei University, Koganei, Tokyo, Japan

Abstract

Various antennas radiating a circularly polarized wave are reviewed on the basis of numerical techniques. The method of moments, the finite-difference time-domain method, the beam-propagation method, and the finite element method are employed to clarify the operation principles of spiral, helical, and rod antennas. A novel type of spiral antenna (a metamaterial-based spiral antenna) can provide a dual-band counter-circularly polarized wave. Since the operation principle of an endfire-mode helical antenna is very close to that of a dielectric rod antenna, the so-called discontinuity-radiation concept of a surface-wave antenna is discussed using a dielectric rod. Modification of the dielectric rod is studied to achieve a higher gain. A rod antenna based on an artificial dielectric is also investigated using a periodic structure of circular metal disks.

Introduction

One of the broadband radiators of a circularly polarized (CP) wave is a spiral antenna, whose geometry is classified into Archimedean and equiangular types. An almost complete frequency independency can be realized by the equiangular spiral (Mushiake 1996; Rumsey 1966), and similar wideband characteristics are also achieved by an Archimedean spiral (Kaiser 1960). In addition to the frequency independency, its advantage of a low-profile structure encourages us to employ the spiral for a space-constraint case, such as mobile and spacecraft applications. Although a slot spiral also operates as an efficient radiator of the CP wave, an emphasis is primarily put on a spiral antenna consisting of conducting wires. In section "Spiral Antennas," the wideband operation of the Archimedean spiral antenna is discussed on the basis of the numerical analysis using the method of moments (Harrington 1968; Mei 1965; Nakano 1987), followed by the introduction of a metamaterial-based spiral antenna of a left-handed property (Nakano et al. 2011, 2013).

A CP wave can also be efficiently radiated using a helical structure. There are several types of helical antennas; Kraus' helix invented in 1947 (Kraus and Marthefka 2002) can radiate the CP wave toward the endfire direction. The basic characteristics of an endfire helical antenna will be summarized in section "Helical Antennas." Note that the endfire helical antenna can also be categorized into a surface-wave

DOI 10.1007/978-981-4560-75-7_33-2

antenna such as a dielectric rod antenna, since the helical wire supports a traveling wave current with almost constant amplitude. Accordingly, the operation principle of both antennas are similar to each other, i.e., the radiation pattern can be viewed as a combination of direct radiation from the feed and surface-wave radiation from the transverse plane passing through the terminal discontinuity (Collin and Zucker 1969). In section "Rod Antennas," various rod antennas, constructed of a dielectric material or an artificial dielectric such as a corrugated-metal surface, will be reviewed. The finite-difference time-domain (FDTD) method (Taflove and Hagness 2005) is used for the numerical investigation. Section "Conclusion" concludes this chapter with the obtained results.

Spiral Antennas

A spiral antenna is known as a frequency-independent antenna which provides essentially constant directivity, gain, beamwidth, and impedance across a broad frequency range. For airborne applications, a compact, flush-mounted antenna is absolutely needed together with a wide CP beam across a broad bandwidth. A flat spiral antenna meets all of these requirements, so that the spiral antenna becomes irreplaceable components of many communication platforms. In the following, the basic characteristics of the Archimedean spiral antenna will be discussed. A finding is also provided on a new type of spiral antenna, so-called metamaterial-based spiral antenna (metaspiral), which is capable of radiating right- and left-handed CPs at different frequencies.

Archimedean Spiral Antenna

The radiation mechanism of a spiral antenna floating in free space was first qualitatively explained using current band theory (Kaiser 1960) and later quantitatively described using the current distribution (Nakano 1987). A round Archimedean spiral arm is defined by $r = a\phi$, where r is the radius from the spiral center, ϕ is the winding angle measured in radians, and a is the constant which controls a spiral pitch. A rectangular Archimedean spiral is also defined, as will be mentioned in the next subsection.

The current band theory is created on the basis of the fact that the two-wire spiral behaves as if it were a two-wire transmission line which gradually transforms itself into a radiating structure. For example, neighboring current elements start antiphase at the feed points and gradually come into phase as they proceed outward along the two-wire spiral line. These currents are precisely in phase when r is $\lambda/2\pi$ (λ: the wavelength at the operating frequency). It follows that radiation from the spiral is centered in an annular ring of turns of one wavelength mean circumference, often called an active region. This radiation is termed the first mode, since this represents the first occasion for which conditions are correct for radiation.

The spiral radiates a CP wave in the two directions normal to the spiral plane (bidirectional radiation), due to the outgoing current decaying from the feed point to the arm ends. The antenna exhibits almost constant input impedance across a wide frequency range. For practical applications, the bidirectional radiation is transformed into unidirectional radiation by placing a conducting reflector (or a cavity) behind the spiral. Generally, as the distance between the spiral and the reflector (antenna height) is decreased, the inherent wideband antenna characteristics degrade. However, this degradation can be mitigated by connecting resistors to the antenna arm ends or by placing an absorbing strip (ABS: see Fig. 1) behind the outermost portion of the arms. A spiral antenna having an antenna height of less than $\lambda/10$ attains a frequency bandwidth of more than 1:3, satisfying both a 3-dB axial ratio criterion and a VSWR = 2 criterion.

One of the interesting and practical features of the spiral antenna lies in generation of higher modes. In contrast to the conventional first mode with maximum radiation toward the axial direction (axial beam),

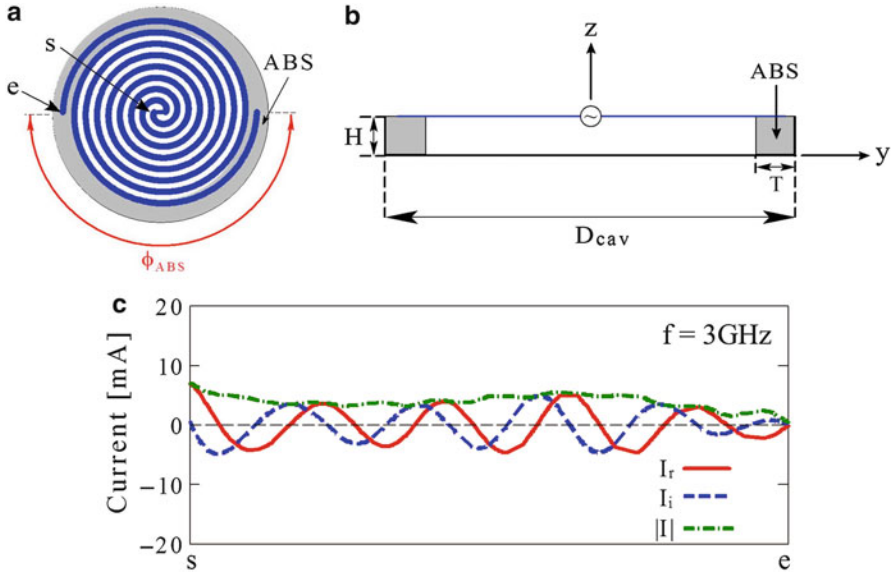

Fig. 1 Spiral antenna backed by a shallow cavity. (**a**) Perspective view. (**b**) Side view. (**c**) Current distribution

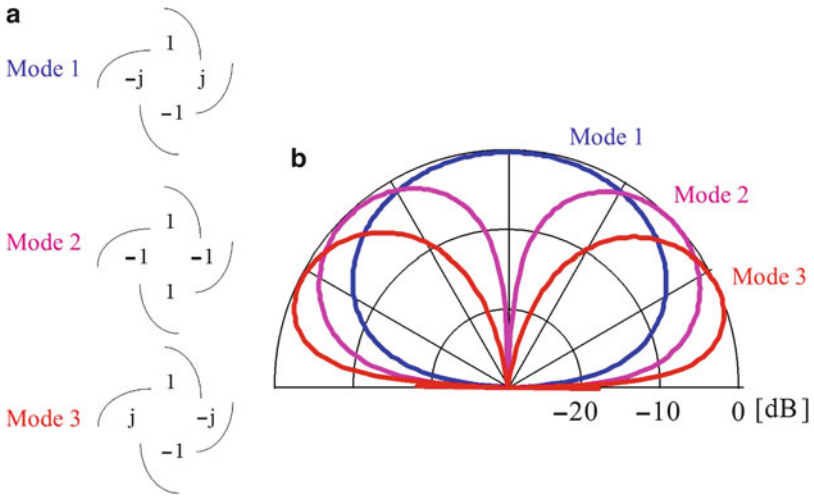

Fig. 2 (**a**) Excitation modes of a four-arm spiral. (**b**) Far-field patterns for respective modes versus elevation

the higher modes, such as the second and third modes, generate a conical beam. For example, the second mode can be generated when the two arms are excited in phase. The current band theory indicates that the axial beam is suppressed when the two arms are excited in phase. Note, however, that all the modes are active when a single-arm spiral is employed. Care, therefore, should be taken in the beam tilt for the single-arm spiral, since the conical beam generated from the second mode has the opposite phase relation with respect to the *z*-axis. Application of a single-arm spiral to a dual-band counter-circularly polarized wave will be described in the next subsection.

Another way of efficiently realizing the higher modes is to use a multi-arm spiral. As an example, the excitation condition of a four-arm spiral is illustrated in Fig. 2a. It should be noted that the first mode spiral generates a complete CP wave toward the axial direction due to the 90° phase difference in each arm. Furthermore, the third mode also generates a conical beam, like the second mode, but the field phase is the same with respect to the *z*-axis (Fig. 2b). Owing to the phase difference, the combination of the first and

second modes can be applied to radar direction finding of an incoming wave (Volakis 2007; Penno and Pasala 2001).

Metamaterial-Based Spiral Antenna (Metaspiral)

The rotational sense of the CP radiation from the conventional spiral antenna presented in the previous subsection is uniquely determined depending on the winding sense of the wire (single CP radiation). It is not possible for the conventional spiral to radiate a left-handed CP wave at a specific frequency f_{LH} and a right-handed CP wave at a different frequency f_{RH} ($f_{LH} \neq f_{RH}$). This limitation can be overcome when a new concept, a left-handed property (Nakano et al. 2011, 2013), is introduced.

Figure 3 shows a single-arm spiral antenna. The continuous straight strip filaments constituting the spiral arm have lengths L_1, L_2,. . ., L_M starting from the center. Let the current along the arm smoothly travel in only one direction, either from point T to point F (the coordinate origin) or from point F to point T, and that there is no reflected current.

First, a situation is considered where the current flows from point T to point F at frequency f_{LH}. This situation is designated as the TF case. Let points A and B be on the arm, both being on a straight line passing through the coordinate origin F and being quasi-point-symmetric with respect to point F (see Fig. 4a). If the path length along the arm from point A to point B is $\lambda_g/2$ (with λ_g being the guided wavelength), then the current elements at points A and B, illustrated by the arrows, are spatially in the same direction (i.e., the current elements are in phase), because of a 180° phase shift from point A to point B. As a result, the fields generated from these two current elements are added in the forward direction. The in-phase current elements travel along the arm near a square loop region of $1\lambda_g$ on the spiral plane, shown by a dotted line in Fig. 4b, and hence the polarization of the resultant field is LH in the $+z$ space.

Three facts are noted here: (1) current elements away from $1\lambda_g$ square loop region make less of a contribution to the resultant field, because they are not in phase; (2) the in-phase current elements are not located symmetrically with respect to the coordinate origin F due to the asymmetry of the spiral structure,

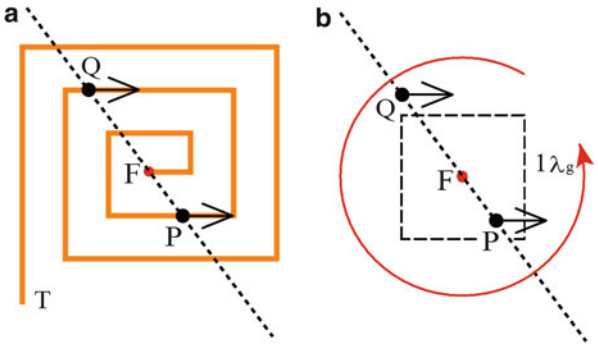

Fig. 5 FT case. (**a**) In-phase current elements. (**b**) RH CP radiation in the forward direction (*z*-direction). The length of the *dotted ring line* is one guided wavelength at frequency f_{RH}. The coordinate origin is denoted as F

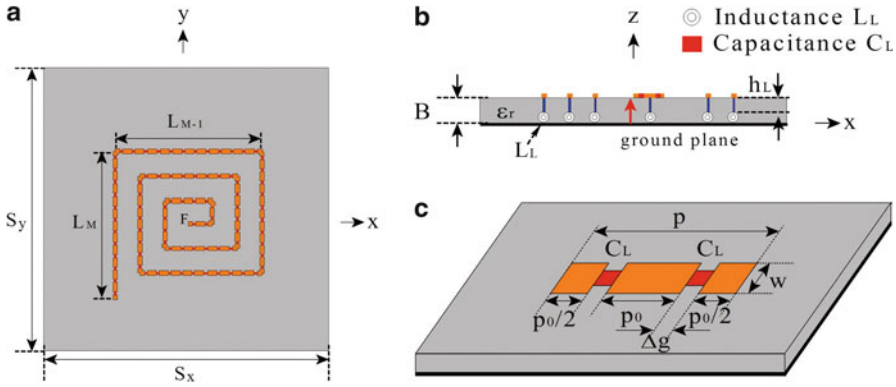

Fig. 6 Metamaterial-based single-arm spiral antenna (1-MTM-SPA). (**a**) Top view. (**b**) Side view. (**c**) Unit cell with inductance L_L and capacitance C_L loading

and hence, the radiation is not exactly symmetric with respect to the *z*-axis; and (3) the current experiences a *regressive* phase shift as it travels along the arm from point T to point F; conversely, the current experiences a *progressive* phase shift from point F to point T, i.e., the phase constant of the current along the arm, β, is negative with respect to the coordinate along the arm starting at point F and ending at point T (let us call this the arm coordinate).

Next, a case is considered where the current travels smoothly from point F to point T, opposite to the TF case. This is designated as the FT case. Figure 5a shows a $1\lambda_g$ loop region at frequency $f_{RH}(\neq f_{LH})$, where points P and Q are quasi-point-symmetric with respect to the coordinate origin F. Like the TF case, the current element arrows at P and Q are spatially in phase. These in-phase current elements rotate, producing CP radiation, whose rotational sense is RH in the forward direction. Note that the phase shift with respect to the arm coordinate (starting at point F and ending at point T along the arm, as already defined) is regressive, i.e., the phase constant β is positive with respect to the arm coordinate.

The aforementioned TF case (Fig. 4) is realized by locating the feed point at point T, while the FT case (Fig. 5) is realized by locating the feed point at point F. It follows that a switching circuit is needed to select the feed point for counter-CP radiation; it is not possible for a spiral having a single *fixed* feed point to realize counter-CP radiation. In order for the spiral with a single *fixed* feed point to realize dual-band counter-CP radiation, the phase constant β with respect to the arm coordinate must have a negative value within a specific frequency band and a positive value within a different frequency band. Based on this requirement for the phase constant, a novel spiral arm is introduced in the following.

	p	10 mm
	p_0	4 mm
	Δg	1 mm
	ρ	0.5 mm
	h_L	0.6 mm
Ground plane	s_x	110 mm
	s_y	110 mm
LH elements	C_L	1.07 pF
	L_L	3.74 nH
Transition frequency	f_T	3.0 GHz

As shown in Fig. 6, the antenna arm shown in Fig. 3 is modified, fixing the feed point at the innermost point F. Each filament is composed of numerous strip conductors and is printed on a dielectric substrate (of thickness B and relative permittivity ϵ_r) backed by a conducting ground plane having an area of $s_x \times s_y$. The cell, defined by length $p(=2p_0 + 2\Delta g)$ and width w, has a conducting pin (radius ρ) extending toward the ground plane. The p is designated as the cell periodicity. A shunt inductance is inserted between the end of the pin and the ground plane, and a capacitance is inserted between neighboring arm conductors. Thus, the spiral arm has a metamaterial (left-handed) property (Engheta and Ziolkowski 2006) together with its inherent right-handed property. This single-arm metamaterial-based spiral antenna is abbreviated as the 1-MTM-SPA. Note that the outermost point T is terminated with a Bloch impedance (Collin 1966).

Figure 7 shows the dispersion diagram for a unit cell, where $\beta(=2\pi/\lambda_g)$ is the phase constant of the current along the spiral arm and $k_0(=2\pi/\lambda)$ is the phase constant in free space. The lower and upper bound frequencies for a fast wave are marked by f_L and f_U, respectively, where $\beta/k_0 = -1$ at f_L and $\beta/k_0 = +1$ at f_U. The parameters used for this dispersion diagram are shown in Table 1, leading to a transition frequency

DOI 10.1007/978-981-4560-75-7_33-2

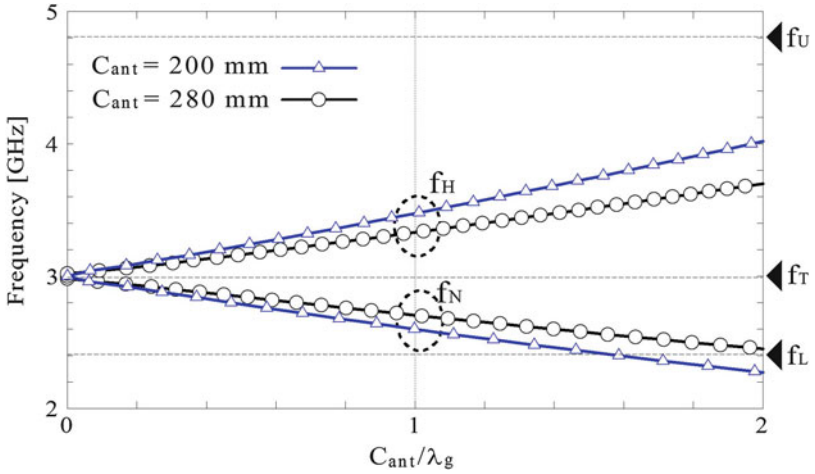

Fig. 8 Normalized antenna size C_{ant}/λ_g, where f_N and f_H denote the N and H frequencies, respectively, at which $C_{ant}/\lambda_g = 1$ is satisfied

of 3 GHz (Eleftheriades and Balmain 2005), which is denoted as f_T. Note that negative and positive phase constants for dual-band counter-CP radiation are prepared below and above f_T, respectively. Also note that the cell periodicity p in Table 1 is chosen to be less than $\lambda_g/4$ across a fast-wave frequency band of f_L to f_U, taking into account the homogeneity condition of a composite right- and left-handed transmission line (CRLH TL) (Caloz and Itoh 2006).

A square loop of $1\lambda_g$ (see the dotted lines in Figs. 4b and 5b) acts as an active region for CP radiation. Therefore, the 1-MTM-SPA must have an area sufficiently large to support this active region. For this, it is required that the last filament length L_M be larger than $\lambda_g/4$ so that the antenna size (defined by peripheral length $C_{ant} = 4L_M$) is larger than $1\lambda_g$.

Figure 8 shows the antenna size normalized to the guided wavelength, C_{ant}/λ_g, as a function of frequency, with the last filament length L_M as a parameter. A frequency that is below the transition frequency and satisfies $C_{ant}/\lambda_g = 1$ is designated as the N frequency (f_N), and a frequency that is above the transition frequency and satisfies $C_{ant}/\lambda_g = 1$ is designated as the H frequency (f_H). It is found that increasing the antenna size C_{ant} leads to a narrowing of the separation between f_N and f_H.

Based on the physical meanings of f_L, f_N, f_H, and f_U, the following four predictions are made: (1) the 1-MTM-SPA will exhibit maximum gain for LH CP radiation at a frequency between the lower bound frequency f_L and the N frequency; (2) the 1-MTM-SPA will exhibit maximum gain for RH CP radiation at a frequency between the H frequency f_H and the upper bound frequency f_U; (3) as the frequency is increased from the N frequency toward the transition frequency ($f_T = 3$ GHz), the gain for the LH CP radiation decreases, due to the disappearance of the active region for CP radiation, resulting from an increase in the guided wavelength; and (4) conversely, as the frequency is decreased from the H frequency toward the transition frequency f_T, the gain for the RH CP radiation decreases, again due to the disappearance of the active region for CP radiation.

For confirming the predictions mentioned above, a 1-MTM-SPA is analyzed, where a small number of filaments ($M = 12$) are used for the spiral arm to reduce the computation time. The filament lengths are denoted as $L_{2n-1} = L_{2n} = nL_1 (n = 1, 2 \ldots)$, where $L_1 = 10$ mm, and result in an $f_N = 2.7$ GHz and $f_H = 3.4$ GHz (note: $f_L = 2.4$ GHz and $f_U = 4.8$ GHz from Fig. 7).

Figure 9 shows the gain in the z-direction at frequencies below $f_T = 3$ GHz, which is obtained using the finite element method (HFSS 2015). Note that G_L and G_R denote the gains for LH CP radiation and RH CP radiation, respectively. These gains do not include the effect of input impedance mismatch. The actual gain is obtained by reducing the amount of input impedance mismatch from the G_L and G_R. For example,

DOI 10.1007/978-981-4560-75-7_33-2

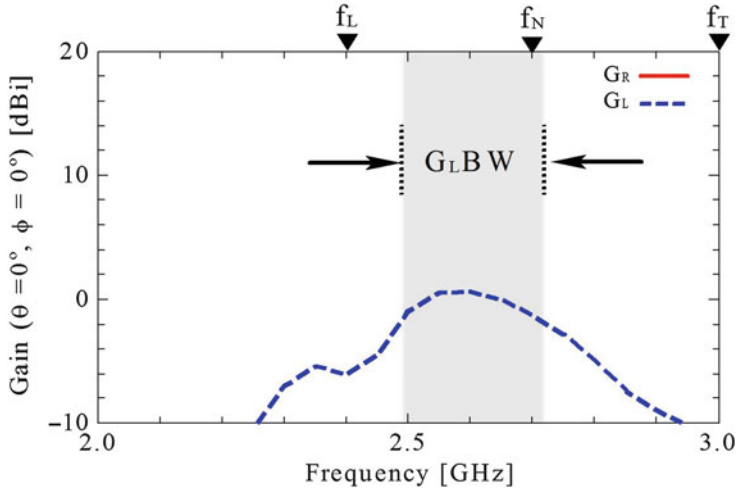

Fig. 9 Gain in the *z*-direction below $f_T = 3$ GHz. The LH CP radiation is dominant. G_LBW denotes a 3-dB gain reduction bandwidth for LH CP radiation. G_R is less than −10 dB and not illustrated

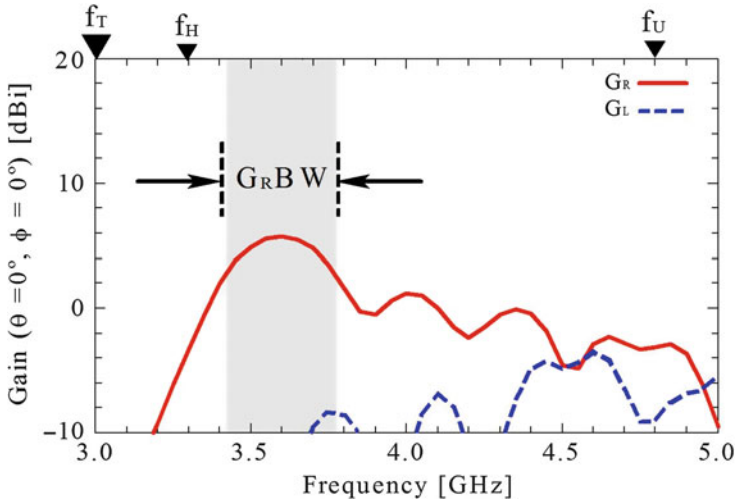

Fig. 10 Gain in the *z*-direction above $f_T = 3$ GHz. The RH CP radiation is dominant. G_RBW denotes a 3-dB gain reduction bandwidth for RH CP radiation

the amount of mismatch for VSWR = 2 is 0.51 dB. As predicted, the radiation at frequencies between the lower bound frequency f_L and the transition frequency f_T is dominated by LH CP radiation (G_R is less than −10 dB and is not illustrated), and the maximum gain of G_L for LH CP radiation, G_{Lmax}, appears between the lower bound frequency f_L and the N frequency f_N.

The prediction that as the frequency is increased from the N frequency f_N toward the transition frequency $f_T = 3$ GHz, the gain G_L will decrease is also confirmed. The 3-dB gain reduction bandwidth for LH CP radiation in the *z*-direction, G_LBW, is calculated to be 9.6 %.

Figure 10 shows the gain in the *z*-direction at frequencies above $f_T = 3$ GHz. Again, as predicted, the maximum gain of G_R for RH CP radiation, G_{Rmax}, appears at a frequency between the upper bound frequency f_U and the H frequency f_H. In addition, the gain G_R decreases with decreasing frequency toward the transition frequency f_T. The 3-dB gain reduction bandwidth for RH CP radiation in the *z*-direction, G_RBW, is calculated to be 9.7 %. Thus, the abovementioned RH CP radiation is confirmed. As a result, the

DOI 10.1007/978-981-4560-75-7_33-2

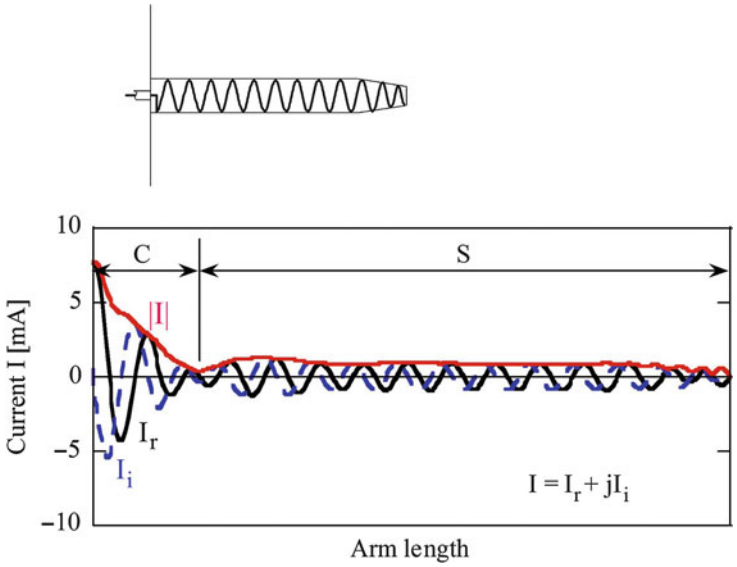

Fig. 11 Current distribution of an axial-mode helical antenna

predicted dual-band counter-CP radiation (LH CP radiation within a specific frequency band and RH CP radiation within a different frequency band) is numerically confirmed.

Helical Antennas

A helical antenna generally consists of a single wire or metallic strip wound into a helical shape. There are several operation modes, e.g., endfire (axial), backfire, sidefire, and normal modes. These modes basically depend on a difference in the size of the helix circumference. Since maximum CP-wave radiation along the helical axis is provided by the endfire mode, first, attention will be focused to this mode, which is closely related to the dielectric rod antenna described in later sections. Next, the CP-wave radiation toward the opposite endfire direction will be discussed, i.e., a backfire mode.

Endfire-Mode Helical Antenna

The current distribution of an axial-beam helical antenna has been analyzed using an integral equation (Nakano 1987). It is found that there are two distinct regions: one region (C-region) from the feed point to a point near the end of the second turn and the remaining region (S-region) just after the C-region, as shown in Fig. 11. The current distributed along the C-region generates backfire radiation toward the conducting flat reflector/plate. This backfire radiation is reflected by the flat reflector and then excites the S-region, inducing a traveling wave current whose amplitude is almost constant, except near the arm end. In other words, the C-region acts as an exciter and the S-region acts as a director (a waveguide element).

There are two findings for this antenna: (1) the helical antenna can work even when these two regions are disconnected, and (2) a helical antenna with a small number of turns constituting only the C-region radiates a CP wave. The latter finding leads to realizing a low-profile helix as a CP element, using the combination of a small number of turns and a low pitch angle.

The low-profile helices can be arrayed to construct a flat-type antenna, as shown in Fig. 12. The wave regarded as a local TEM mode in the radial direction propagates in the radial waveguide provided the spacing of the two parallel plates is sufficiently small compared with the wavelength, i.e., $S_w = 7.5\ \text{mm} = 0.3\lambda_{12}$ (λ_f: the wavelength at frequency f GHz). The feed wire of each helix is inserted

DOI 10.1007/978-981-4560-75-7_33-2

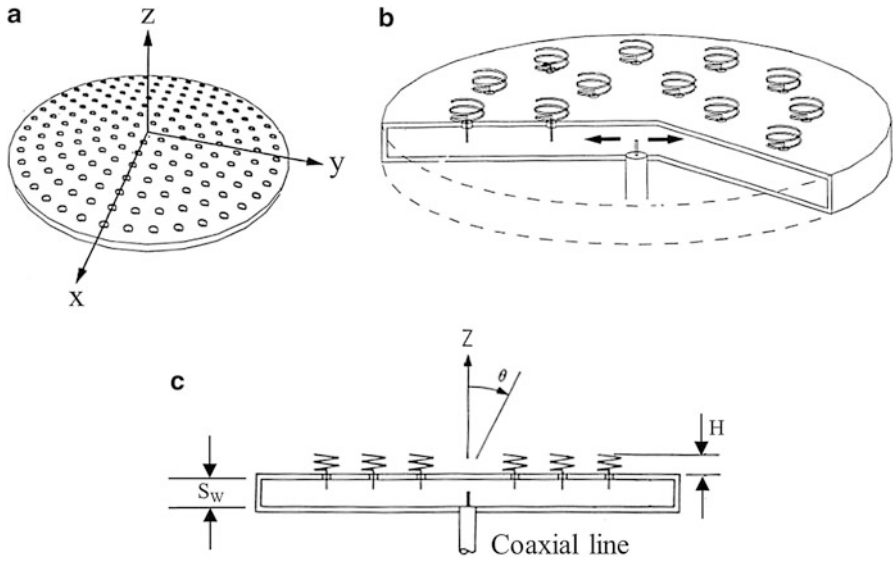

Fig. 12 Flat-type antenna consisting of low-profile helices

into the radial waveguide through a small hole and excited by a traveling wave flowing from the radial waveguide center (coaxial line) toward the waveguide edge. The radius of the feed wire is the same as that of the helix proper. It should be noted that the axial length H of the helical element above the surface of the radial waveguide is extremely low ($H = 4.7$ mm), so that the array antenna has a thickness of 15 mm ($\simeq S_w + H +$ plate thickness).

Using a two-turn helix of 4° pitch angle, which exhibits a 12 % bandwidth for a 3 dB axial ratio criterion, a flat-type antenna is fabricated for direct reception of the broadcasting satellite TV programs (DBS) in Japan (Nakano et al. 1992). The total number of helices is 368. It should be noted that the insertion length of the feed wire is adjusted to control an amplitude distribution. To minimize the backward traveling wave, the feed wires of the outermost helices are inserted at a distance of a quarter-wavelength from the waveguide edge, where the standing wave is maximal. The backward traveling wave can be absorbed by the outermost helices and becomes negligible over the waveguide except near the edge. In addition, it should be noted that the forward traveling wave in the waveguide decays as it progresses toward the edge. Therefore, to maintain a uniform amplitude distribution (or a uniform power distribution) on the array surface, the feed wires are gradually lengthened as the radial distance increases. Impedance matching to the feed coaxial line located in the center of the lower plate of the waveguide is made by appropriate insertion of the inner conductor of the coaxial line into the waveguide. As a result, good impedance matching is obtained, where the measured return loss is less than −18 dB in a frequency band of 11.7–12 GHz.

The radiation beam can be tilted by realizing the required phase condition. The amplitude distribution remains almost unchanged regardless of the helix rotation, so that there is no need to readjust the insertion length of the feed wire. Since the relative phase of each helix can be determined by measurement (Mano and Katagi 1982), the only thing to be done is to rotate each helix around its axis according to the phase requirement determined by the array theory. Figure 13 shows the gain at a frequency of 11.85 GHz, as a function of the beam tilt angle. The gain at a beam tilt angle of 30° is found to be only 1.1 dB lower than that without the beam tilt (normal beam).

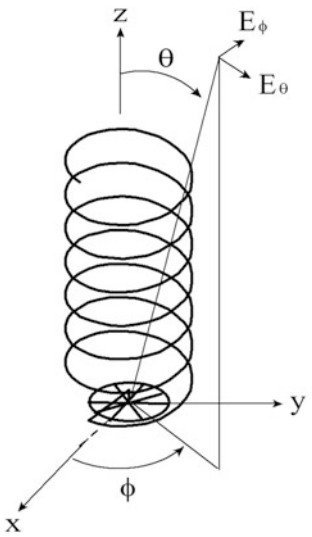

Fig. 14 Configuration and coordinate system of a helical antenna with a small ground plane

Backfire Helical Antenna

The endfire mode of operation in the previous subsection is most widely used. Another interesting mode of operation was reported by Patton in 1962 (Walter 1965). By using a bifilar helical antenna, he found a backfire mode, i.e., a CP wave radiated in the backward direction. It should be noted that the bifilar helix has an advantage over a conventional endfire helix in that a ground plane (reflector) is not needed. Attention is, therefore, directed toward a front-to-back (F/B) ratio. One of the means of realizing a sufficient F/B ratio is to modify the helix proper. A tapered backfire helix realizes a good F/B ratio across a wide frequency range, with smaller occupied space as compared with that of a conventional endfire helix mounted on a ground plane.

A similar effect is also observed in a monofilar helix with the small ground plane shown in Fig. 14 (Nakano et al. 1988). It should be recalled that the current in the C-region mainly radiates in the backfire direction. Since the reflector is small, the surface wave is not excited. This fact leads to another advantage that the phase center of the backfire helix is approximately and consistently fixed (note that the far-field from the endfire helix is composed of two fields radiated from spatially separated locations: the radiation from the feed and that from the open end). Thus, it is expected that the backfire helix be used as a primary feed for a paraboloidal reflector.

DOI 10.1007/978-981-4560-75-7_33-2

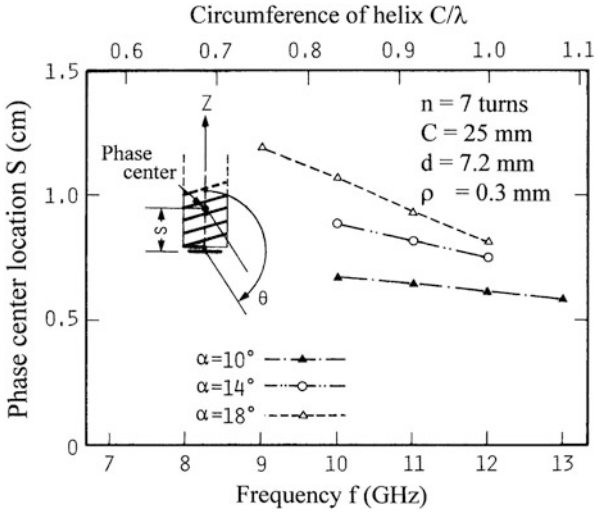

Fig. 15 Phase center location

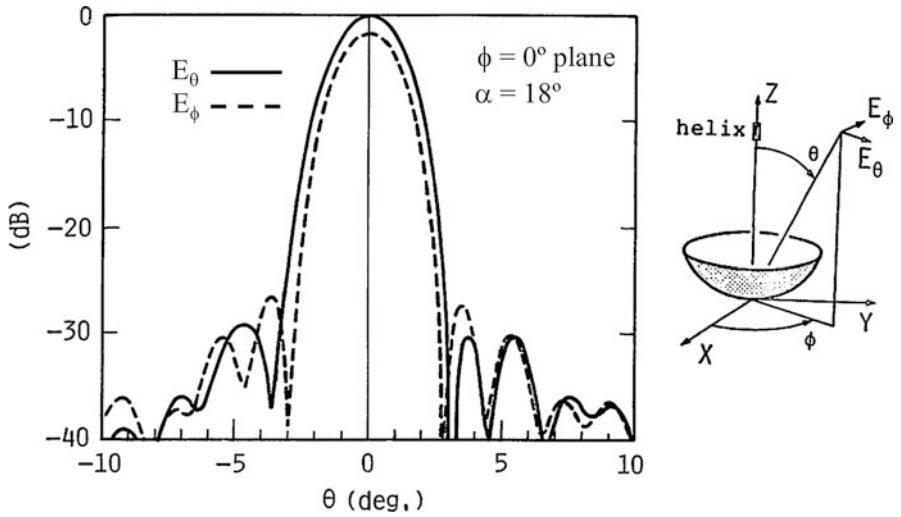

Fig. 16 Radiation pattern of a paraboloidal reflector antenna fed by a monofilar backfire helix

Now the monofilar backfire helix is employed as a primary feed for a symmetrical front-fed paraboloidal reflector. The reflector to be considered here has an aperture diameter of $D = 75$ cm and a focal length of $L = 22$ cm. The backfire helix is suitable for a feed of a front-fed reflector, since the configuration of the backfire helix is very small compared with a horn antenna and a conventional axial-mode helix with a ground plane. In addition, the backfire helix has an advantage that the feed line can be placed on the focal axis, resulting in a small aperture blockage.

To use the helix as an efficient feed for the reflector, it is imperative that the phase center location be known. The phase center is found by plotting the phase change of the radiation field against cos θ. The distance s from the helix origin to the phase center is shown in Fig. 15. Strictly speaking, the distance s varies according to the azimuth cut. Figure 15 presents the average of the two distances obtained in the $\phi = 0^\circ$ and 90° planes. As the frequency is increased, the distance s moves toward the feed point. This is due to the fact that the attenuation rate of the current becomes larger with an increase in frequency. The

DOI 10.1007/978-981-4560-75-7_33-2

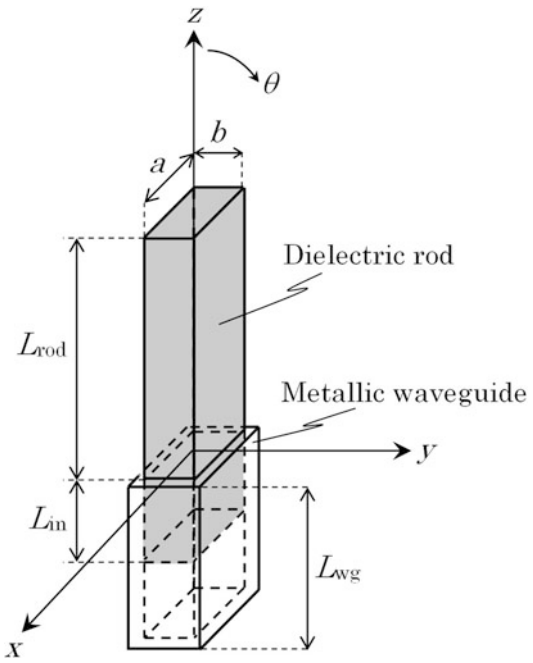

Fig. 17 Configuration of a dielectric rod fed by a metallic waveguide

change in the distance s as a function of frequency is small for a helix with a lower pitch angle, because the wire of the lower pitch helix is wound more tightly.

Figure 16 shows the radiation pattern of the paraboloidal reflector antenna. A seven-turn backfire helix with a pitch angle of $\alpha = 18^\circ$ and a ground plane diameter of 7.2 mm is situated at the focal point on the basis of the results shown in Fig. 15. The pattern calculation is performed at 12 GHz using the physical optics approximation. It is seen that the half-power beamwidth is 2.4° and that the first sidelobe level is less than −26 dB. The radiation field is circularly polarized with an axial ratio of 2.0 dB. The gain is calculated to be 37.2 dBi.

Rod Antennas

In this section, the characteristics of several rod antennas are described. First, the basic radiation properties of a rectangular rod antenna are studied. Emphasis is placed on the mechanism of the gain variation with rod length. The amplitude and phase distributions of the field near the rod are investigated. The gain increase with rod length is explained in terms of the expansion of the equiphase region in the terminal aperture regarded as a secondary Huygens plane. Then, a circular rod antenna is studied, since the circular geometry is preferable to radiate a CP wave. Modifications of dielectric rod antennas are discussed in terms of generation of a high gain, which exceeds the so-called Hansen-Woodyard condition (Hansen and Woodyard 1938; Andersen 1971). Final subsection is devoted to an artificial dielectric rod antenna consisting of a corrugated-metal surface.

Dielectric Rod Antenna

Figure 17 shows the configuration and coordinate system of a dielectric rod (Ando et al. 2002). A rectangular dielectric rod with a relative permittivity of $\epsilon_r = 2.05$ (Teflon) is fed by a metallic waveguide (WR-90) with internal dimensions of $(a, b) = (22.9\text{ mm}, 10.2\text{ mm})$. The length of the waveguide is fixed at $L_{wg} = 20$ mm for the analysis. The dimensions of the cross section of the rod are the same as the internal

DOI 10.1007/978-981-4560-75-7_33-2

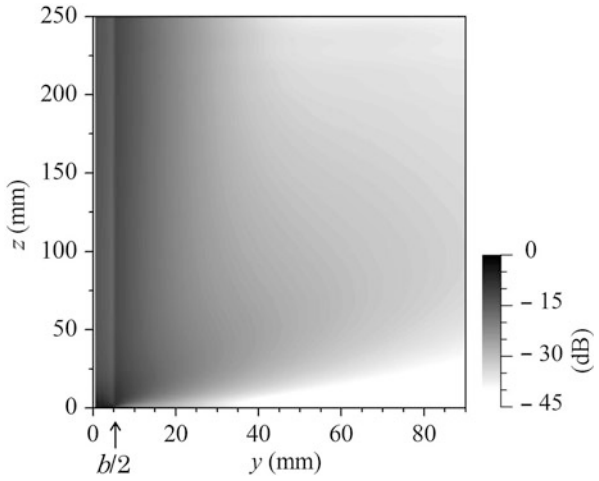

Fig. 18 Total field distribution of E_y in the y–z plane at $x = 0$ mm (half region) (From Ando et al. 2002, ©IET)

dimensions of the waveguide. The waveguide is excited with the TE_{10} mode, whose major electric field component is E_y. For impedance matching between the rod and the waveguide, a portion of the rod with length L_{in} is inserted into the waveguide without any modification. At the outer boundary of the computation region, the absorbing layers are placed to avoid spurious reflection toward the antenna.

The information on the field distribution near the rod is important to evaluate the radiation characteristics. For this, the field distribution is analyzed by the FDTD method. The field is decomposed into the surface and unguided waves, using a technique combining the FDTD method and the Yee-mesh-based beam-propagation method (YM-BPM) (Yamauchi 2003).

Figure 18 shows the total field distribution of E_y in the y–z plane at $x = 0$ mm. The field profile of the TE_{10} mode differs from that of the E_{11}^y mode, so that the power excited at the feed end is transformed into the surface- and unguided-wave power. At a sufficiently long z-distance, where the unguided-wave power is almost dissipated, the field along the rod can be regarded as the surface wave. At $z = 250$ mm, the ratio of power in the surface wave to the total radiation power is calculated to be approximately 52 %.

Figure 19a illustrates the distribution of the surface wave. By subtracting the surface wave in Fig. 19a from the field in Fig. 18, the unguided wave in Fig. 19b is obtained. As is well known, the phase velocity of the surface wave is slower than that of the unguided wave. Therefore, the phase interaction between the two waves occurs near the rod, as shown in Fig. 20. The phase interaction is used to interpret the gain variation with rod length L_{rod} in Fig. 24.

The directivity of a long dielectric rod with L_{rod} can be efficiently evaluated on the basis of the discontinuity-radiation concept (Collin and Zucker 1969). The radiation pattern is formed by superimposing the feed pattern onto the terminal pattern: the feed pattern generated from the unguided wave radiated near the feed end and the terminal pattern from the surface wave diffracted at the free end.

Figures 21 and 22 show the feed $D_{feed}(\theta)$ and terminal $D_{terminal}(\theta)$ patterns, which are calculated using the unguided and surface waves in Fig. 19, respectively. As can be seen, the unguided wave is diffracted in all directions, whereas the surface wave is in the endfire direction. Taking into account the phase relationship between the two patterns, the following superimposed pattern can be obtained:

$$D_{total}(\theta) = D_{feed}(\theta) + D_{terminal}(\theta)\exp[-j(\beta - k_0 \cos\theta)L_{rod}] \quad (1)$$

where k_0 is the wavenumber in free space and β is the propagation constant of the rod waveguide. Although not illustrated, good agreement is found to exist between the superimposed pattern and the

pattern calculated using the total fields. In other words, superimposing the feed pattern onto the terminal pattern forms the radiation pattern of the dielectric rod antenna.

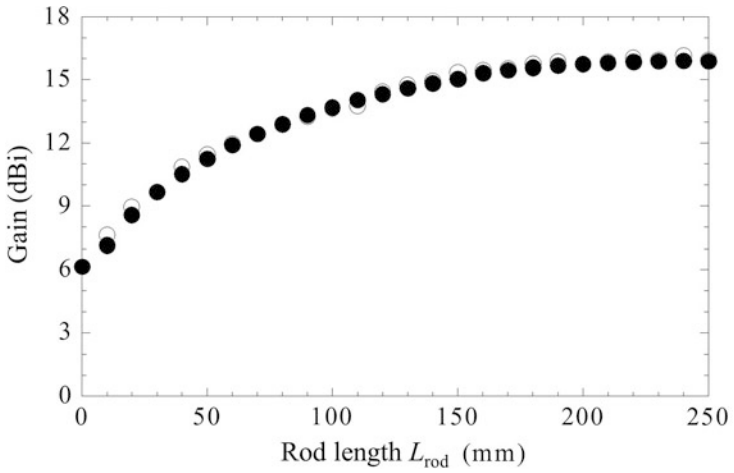

Fig. 24 Gain as a function of rod length L_{rod}; theoretical ●, experimental ○ (From Ando et al. 2002, ©IET)

The typical superimposed pattern for $L_{rod} = 150$ mm is shown as a solid line in Fig. 23. Needless to say, the pattern tends to have a sharper beam as L_{rod} is increased. The half-power beamwidth changes from $\pm 13°$ to $\pm 9°$ in the E- and H-planes, as L_{rod} is increased from 150 to 240 mm. The theoretical results agree well with the results measured in an anechoic chamber. A slight discrepancy in the backward radiation is due to the fact that in the experiment, a feeding system (including a waveguide to coaxial line transition) is located in the $-z$-axis direction.

It seems that the radiation pattern is also evaluated on the basis of the terminal aperture theory (Brown and Spector 1957): the x–y plane at $z = L_{rod}$ is regarded as a secondary Huygens plane where the source field composed of the surface and unguided waves exists. The unguided wave extends into the x–y plane (Fig. 19b), and hence the dimensions of the plane should be taken to be sufficiently large. Auxiliary calculations showed that the major lobes converge to those shown in Fig. 23, with an increase in the dimensions of the x–y plane. However, the minor lobes (in particular, the backward direction) disagree. This is because the source field in the secondary Huygens plane does not include the unguided wave diffracted toward the backward direction from the feed end (Fig. 21).

To take into account the effect of the unguided wave diffracted toward the backward direction on the radiation, the radiation pattern is calculated on the basis of the field on a closed surface containing the x–y plane at $z = L_{rod}$ around the rod. As a result, there is essentially no difference between the radiation pattern generated from the field on the closed surface and that in Fig. 23 obtained by the discontinuity-radiation concept, although the radiation pattern in the backward direction cannot be evaluated on the basis of the terminal aperture theory.

The gain computed from the field on the closed surface also agrees with that evaluated on the basis of the discontinuity-radiation concept. The computed gain in the $+z$-direction against L_{rod} is presented by solid circles in Fig. 24. It is observed that the gain increases from 15.1 to 15.9 dBi, as L_{rod} is lengthened from 150 to 240 mm. The gain variation with L_{rod} is validated by the experimental results presented by open circles.

As mentioned previously, the directivity in the endfire direction is dominated by the field in the secondary Huygens plane at the free end. Hence, the mechanism of the increase in the gain shown in Fig. 24 must be understood by the field distribution in the x–y plane at $z = L_{rod}$. Figure 25 illustrates the phase distributions of E_y ($x = 0, y, z = L_{rod}$) for several values of L_{rod}. The phase is normalized to a value at $y = \Delta y/2$ (Δy is the FDTD cell size in the y direction). The expansion of the equiphase region in the secondary Huygens plane corresponds to the gain increase observed in Fig. 24.

In summary, the terminal aperture theory is effective, provided that the diffracted wave toward the backward direction generated at the feed end is negligible.

Modified Dielectric Rod Antenna

It is known that the gradual taper of a dielectric rod leads to an increase in the gain. So far, the directivity of a tapered rod has been estimated using traditional design guidelines (Chatterjee 1985; Lo and Lee 1988). Zucker presented a design principle for a maximum-gain antenna, in which a tapered rod is regarded as an endfire array of discrete elements (Volakis 2007). James described a semiempirical approach to the selection of an optimum taper profile, in which a tapered rod is regarded as a series of noninteracting planar radiating apertures (James 1972). The attainable gain of a practical rod antenna may be limited to 20 dBi, although the traditional design guidelines predict the gain increase with an increase in rod length.

In this subsection, a tapered cylindrical-dielectric-rod fed by a metallic waveguide with a launching horn is analyzed, and the effect of the guided-mode conversion in the rod on the directivity is discussed (Ando et al. 2005). The waves propagating along linearly and curvilinearly tapered rods are evaluated using the body-of-revolution (BOR) FDTD method (Taflove and Hagness 2005). The use of the BOR technique enables us to efficiently calculate long cylindrical-dielectric rods.

Figure 26a shows the configuration of a cylindrical-dielectric rod fed by a circular metallic waveguide. The rod with a relative permittivity of $\varepsilon_r = 2.05$ (Teflon) is assumed to be a lossless medium and is composed of a uniform section (L_{uni}) and a tapered section (L_{tap}). The inner diameter of the metallic waveguide, which is the same as the diameter of the uniform rod, is $2\rho_{feed} = 17.475$ mm ($=0.64\lambda$) where λ ($=27.3$ mm) is the wavelength at a test frequency of $f = 11$ GHz. The metallic waveguide is excited with the TE_{11} mode, whose cutoff frequency is 10 GHz. The uniform rod operates as a single mode waveguide at the test frequency, since the cutoff frequency of higher-order modes (Balanis 1989) is 13 GHz.

To obtain smooth transition from the TE_{11} mode of the metallic waveguide to the HE_{11} mode of the uniform rod, the feeding system illustrated in Fig. 26b is introduced. A portion of the uniform rod is tapered and inserted into the metallic waveguide. A launching horn is placed at the feed end.

Typical taper profiles to be investigated are shown in Fig. 26c, in which the diameter at the free end is taken to be $2\rho_{free} = \rho_{feed}$ and the overall length of the tapered section is fixed to be $L_{tap} = 20\lambda$. The change in the radius of the tapered section, $\rho(z_{tap})$, is expressed as

$$\rho\left(z_{tap}\right) = \rho_{feed} - \left(\rho_{feed} - \rho_{feed}\right)\left(\frac{z_{tap}}{L_{tap}}\right)^{\frac{1}{n}}, \tag{2}$$

where z_{tap} is the axial distance of the tapered section (see Fig. 26a). The rod of $n = 1$ is linearly tapered and that of $n > 1$ is curvilinearly tapered. For the curvilinear taper, the change in the radius near the feed end

DOI 10.1007/978-981-4560-75-7_33-2

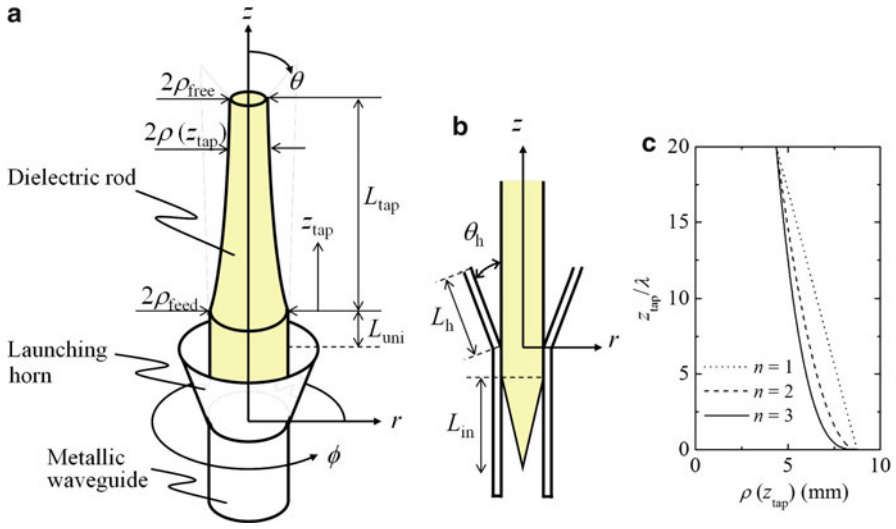

Fig. 26 Configuration of a tapered cylindrical-dielectric-rod antenna ($\varepsilon_r = 2.05$ (Teflon), $2\rho_{feed} = 17.475$ mm (=0.64λ), $2\rho_{free} = \rho_{feed}$, λ = 27.3 mm ($f$ = 11 GHz)). (**a**) Perspective view. (**b**) Feeding system. (**c**) Taper profiles for $L_{tap} = 20\lambda$; linear ($n = 1$) · · ·, curvilinear ($n = 2$) - - -, curvilinear ($n = 3$) —

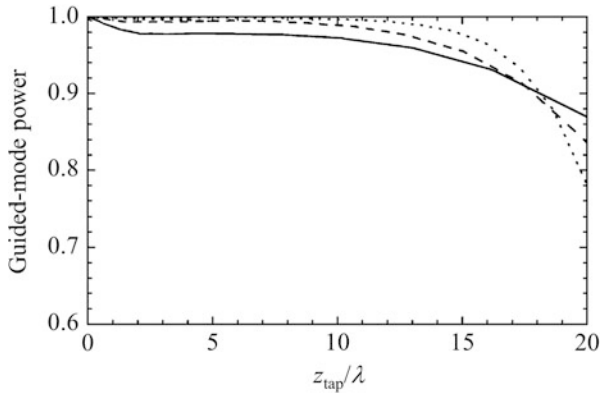

Fig. 27 Guided-mode power for $L_{tap} = 20\lambda$ as a function of z_{tap}; linear (n =1) . . ., curvilinear ($n = 2$) - - -, curvilinear ($n = 3$ —)

becomes large with an increase in n, while that near the free end becomes small. The guided-mode conversion properties and directivities will be evaluated for the linearly and curvilinearly tapered structures with $L_{tap} = 10\lambda$ and 20λ.

The gain of a dielectric rod increases with an expansion of the equiphase field region in the terminal aperture. As is well known, the field profile of the HE_{11} mode is extended into the air region by reducing the diameter of a rod. Hence, the enhanced gain is obtained, if the HE_{11} mode excited at the feed end is smoothly converted into that at the free end where the diameter is reduced. To achieve smooth guided-mode conversion, the diameter in the forward direction should be gradually reduced.

The diameter of the tapered rod connected with the uniform rod ($L_{uni} = \lambda$) is reduced from $2\rho_{feed} = 0.64\lambda$ to $2\rho_{free} = \rho_{feed} = 0.32\lambda$, in which the phase constant (k_z) of the HE_{11} mode wave at the free end is reasonably close to the free-space wave number (k_0), i.e., $k_z/k_0 = 1.005$. The directivity depends on a taper profile (James 1972), so that several profiles of tapered rods are investigated by changing the parameter n in Eq. 2.

DOI 10.1007/978-981-4560-75-7_33-2

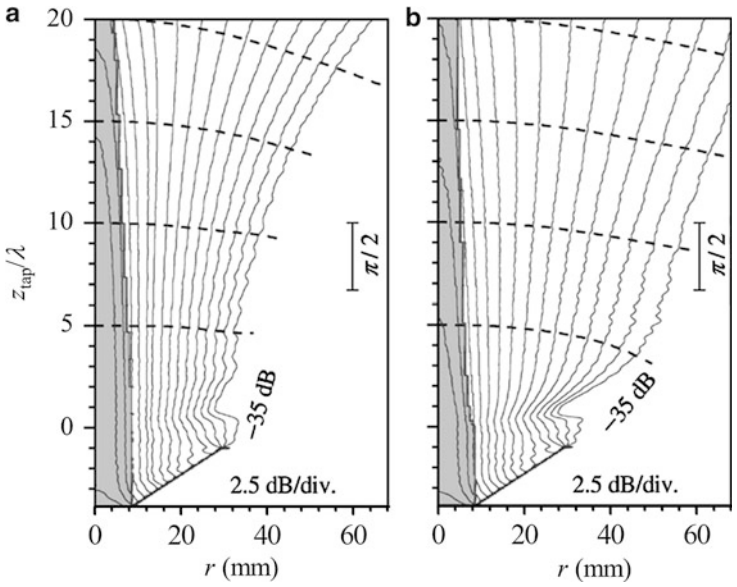

Fig. 28 Field distributions near tapered rods with $L_{tap} = 20\lambda$ (half region); amplitude —, phase - - -. (**a**) linear ($n = 1$). (**b**) curvilinear ($n = 3$)

Note that Ladouceur and Love (1996) intuitively described a low-loss criterion for the taper profile of a dielectric waveguide. Radiation loss will be small if the taper length is large compared with the coupling length between the fundamental guided-mode and the radiation field. The limit of the local taper angle [$\Omega(z_{tap})$] between the z-axis and the tangent to the dielectric interface was expressed as

$$\Omega(z_{tap}) = \tan^{-1}\frac{\rho(z_{tap})\left[k_z(z_{tap}) - k_0\right]}{2\pi} \simeq \frac{\rho(z_{tap})\left[k_z(z_{tap}) - k_0\right]}{2\pi}, \tag{3}$$

where $k_z(z_{tap})$ is the phase constant of the HE_{11} mode at z_{tap}. This equation implies that the change in $\rho(z_{tap})$ should become smaller for larger z_{tap}. Therefore, the guided-mode power is expected to be maintained in a curvilinear taper compared with a linear taper.

Figure 27 shows the guided-mode power along z_{tap} for $L_{tap} = 20\lambda$, in which the overlap integral between the eigenmode field of the tapered rod and the numerically determined field is used. The power is normalized to the HE_{11} mode power excited at the feed end. It is found that the guided-mode power for the linear taper drastically decreases near the free end. On the other hand, the guided mode for the curvilinear taper can smoothly be converted with an increase in L_{tap}, so that the considerable amount of the power is maintained at the free end. This tendency becomes more appreciable for a longer tapered rod. A value of 87 % is obtained in a curvilinearly tapered rod of $n = 3$ with $L_{tap} = 20\lambda$ (the reflected power generated in the tapered section is negligible and is calculated to be less than 0.05 %). As a result, smooth guided-mode conversion can be achieved in a curvilinearly tapered rod, whose radius slightly varies near the free end.

Figure 28a, b compares the field distributions along the tapered rods with $L_{tap} = 20\lambda$. The solid lines present the amplitude of $|E_r|$ and dashed lines present the phase at $z_{tap} = 5\lambda$, 10λ, 15λ, and 20λ. It is clearly observed that the fields along the curvilinearly tapered rods gradually extend into the air region near the free end in comparison to the field along the linearly tapered rod. The gradual extension of the field results in the expansion of the equiphase field region in the terminal aperture.

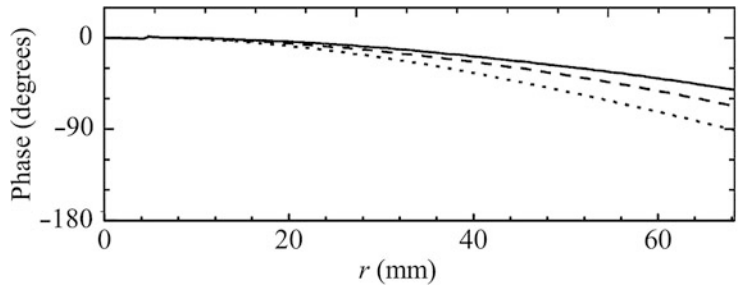

Fig. 29 Phase distributions for $L_{tap} = 20\lambda$ at free end (half region); linear ($n = 1$) · · ·, curvilinear ($n = 2$) - - -, curvilinear ($n = 3$ —)

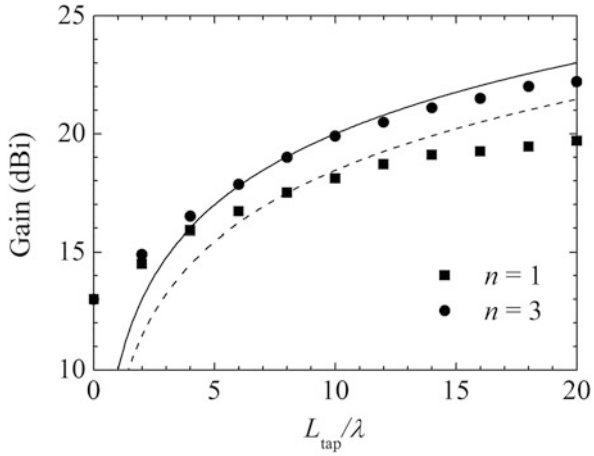

Fig. 30 Gain as a function of L_{tap}. HWG - - -, MG —

The phase distribution in the terminal aperture for tapered rods is plotted for $L_{tap} = 20\lambda$ in Fig. 29. The equiphase region is expanded, as n and L_{tap} are increased. The expansion of the equiphase region corresponds to an increase in the guided-mode power observed in Fig. 27. Owing to the expansion of the equiphase field region, a narrowed radiation pattern is expected with a subsequent higher gain.

Figure 30 plots the gain in the endfire direction ($\theta = 0°$) against L_{tap}. As can be seen, the gain increases with an increase in L_{tap}. The gain for $n = 3$ at $L_{tap} = 20\lambda$ is calculated to be 22.2 dBi, which is a 2.5 dB increase compared with that for $n = 1$. Auxiliary calculations show that a gain of greater than 20 dBi is maintained in a tapered rod of $n = 3$ with $L_{tap} = 20\lambda$ across a frequency range of 10–12.7 GHz (24 % bandwidth).

Finally, the gain obtained from the FDTD analysis is compared with that from the design guideline presented by Zucker (Volakis 2007). The gain variation with L_{tap} is expressed as

$$G \cong m\frac{L_{tap}}{\lambda}, \tag{4}$$

where m is a variable. The data for $m = 7$ corresponds to the so-called Hansen-Woodyard gain (HWG), and that for $m = 10$ corresponds to the maximum gain (MG). The HWG and MG are plotted by dashed and solid lines in Fig. 30, respectively. It is found that a value of higher than the HWG can be obtained in a curvilinearly tapered rod of $n = 3$. On the other hand, the MG indicates that the gain of a rod with $L_{tap} = 20\lambda$ is approximately 23 dBi. For further reference, curvilinearly tapered rods for larger values of n are also evaluated. Although not presented, the gain reaches a value of 22.6 dBi when n is chosen to be

DOI 10.1007/978-981-4560-75-7_33-2

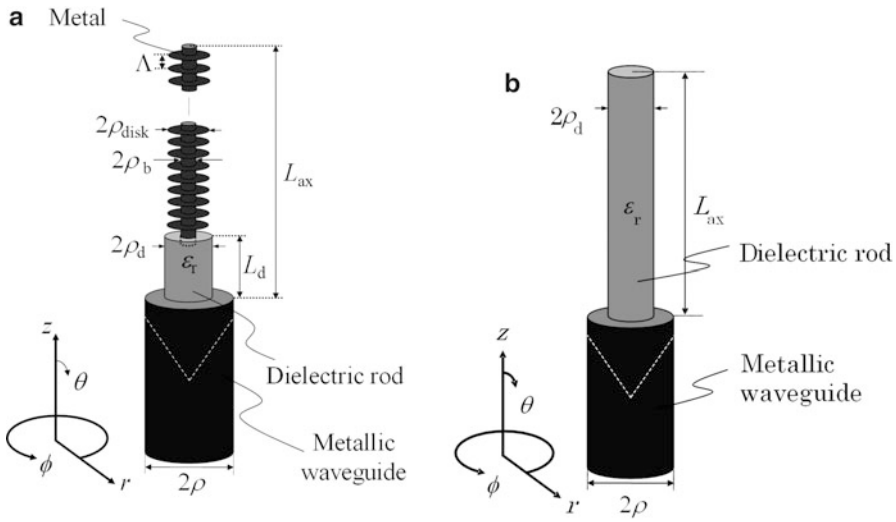

Fig. 31 Configurations of (**a**) a cigar antenna and (**b**) a reference dielectric rod antenna (From Yamauchi et al. 2011, ©KIEES)

5, while a guided-mode power of 82 % is maintained at the free end. Consequently, the design guideline is effective in predicting the gain increase with an increase in L_{tap} and roughly estimating the gain of a long tapered rod.

Artificial Dielectric Rod Antenna

A periodic structure consisting of an array of metal plates supports a surface wave. Therefore, an endfire antenna without using any real dielectric can be constructed. In other words, these metal structures can be viewed as an artificial dielectric that is often lighter than dielectrics such as Teflon and polyethylene. A pioneering work on the endfire antenna using a periodic structure of circular metal disks, called a cigar antenna, has been performed by Simon and Weill (1953). Although several works have been carried out experimentally and/or theoretically, recent numerical techniques such as the FDTD method allow more efficient and practical investigation of this type of antenna. The radiation characteristics regarding the cigar antenna will be summarized, where a circular metallic waveguide is adopted to excite a disk-on-rod structure.

Figure 31a shows the configuration of a cigar antenna fed by a metallic waveguide (WCI-120) whose inner diameter is $2\rho = 17.475$ mm. The waveguide is excited with the TE_{11} mode at a center frequency of 11 GHz ($\lambda_{11} = 27.3$ mm). The tapered dielectric rod whose relative permittivity is $\epsilon_r = 2.05$ is inserted into the metallic waveguide so that the impedance matching may be made between the air-filled and dielectric-filled regions.

The effective relative permittivity of the cigar structure depends on a period length Λ, a disk diameter $2\rho_{disk}$, and a boom diameter $2\rho_b$. These parameters are adjusted so as to realize almost the same effective relative permittivity as that observed in the reference dielectric rod antenna shown in Fig. 31b. Note that the cigar and dielectric rod antennas are compared under the condition of the same axial length L_{ax}. Two types of cigars #1 and #2 with $2\rho_b \simeq 0.11\lambda_{11}$ are treated: #1 is the model in which the periodicity is chosen to be small, while #2 is the model with a relatively large periodicity. To be specific, the parameters for #1 are $\Lambda = 0.09\lambda_{11}$ and $2\rho_{disk} \simeq 0.28\lambda_{11}$, while those for #2 are $\Lambda = 0.27\lambda_{11}$ and $2\rho_{disk} \simeq 0.32\lambda_{11}$. It is assumed that the cigar structure is perfectly conducting. To support the cigar, a short dielectric rod with a diameter of $2\rho_d \simeq 0.38\lambda_{11}$ and a length of $L_d = 0.54\lambda_{11}$ is introduced at the junction between the metallic waveguide and the cigar.

DOI 10.1007/978-981-4560-75-7_33-2

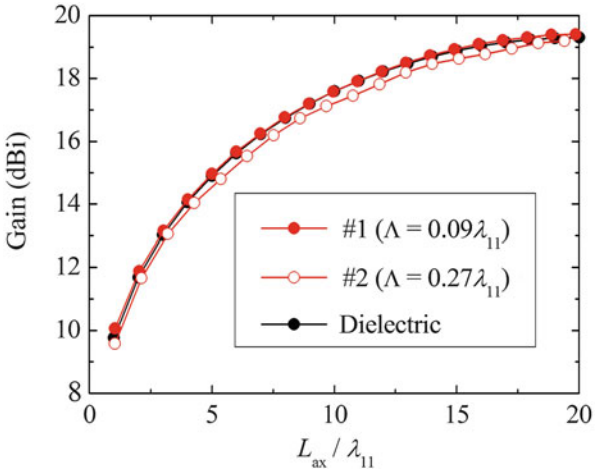

Fig. 32 Gain characteristics as a function of L_{ax} (From Yamauchi et al. 2011, ©KIEES)

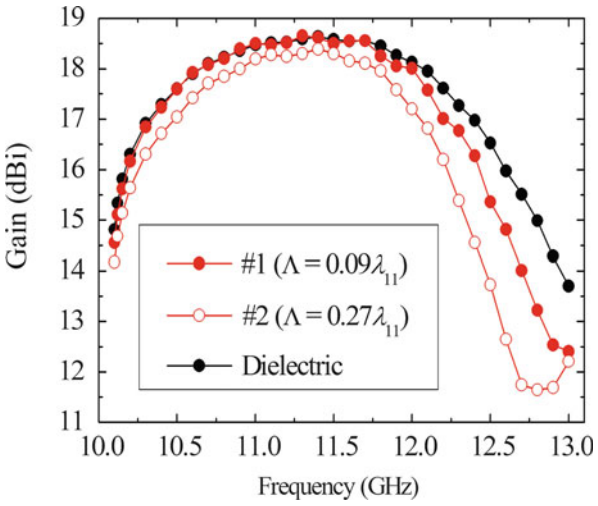

Fig. 33 Frequency response of gain (From Yamauchi et al. 2011, ©KIEES)

Figure 32 shows the gain characteristic at 11 GHz as a function of axial length L_{ax}. The data presented by red solid and open circles show the calculated gains for #1 and #2, respectively, while a black solid circle shows for the reference dielectric rod. In all the results, the gain increases as L_{ax} is increased. As can be seen, the gain property of the cigar is in a good correlation with that of the dielectric rod. It is confirmed that the cigar structure operates as an artificial dielectric. The gain reaches a maximum value of 19.4 dBi, when L_{ax} is taken to be around $20\lambda_{11}$. In the following analysis, the structures with $L_{ax} \simeq 13\lambda_{11}$ are treated.

The frequency response of the gain is shown in Fig. 33. A gain of more than 17 dBi is obtained for #1 across a frequency range of 10.4–12.2 GHz. A maximum gain of 18.6 dBi is obtained at 11 GHz. It is found that the gain bandwidth for #1 is wider than that for #2 and is close to that observed for the reference dielectric rod. In other words, when the periodicity of the circular disk is sufficiently small compared with the wavelength, the bandwidth becomes almost the same as that for the dielectric rod. The return loss for #1 is more than 15 dB across a frequency range of 10.5–13 GHz.

Figure 34a, b illustrates the currents $I(=I_r + jI_i)$ distributed along the cigar structure at 11 GHz and 13 GHz, respectively. For convenience, the current values obtained on the wall surfaces of disks are

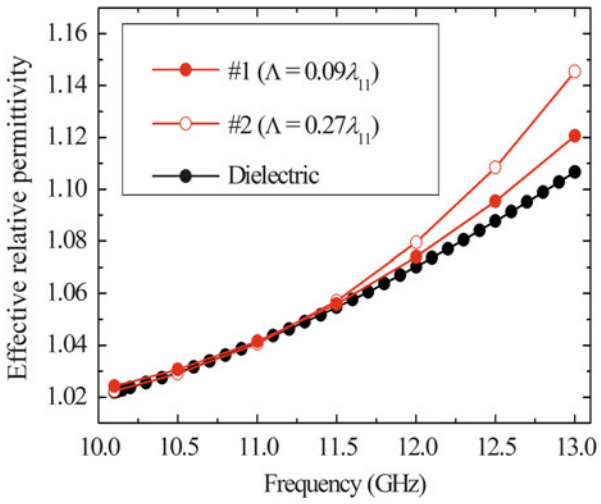

Fig. 35 Effective relative permittivity as a function of frequency (From Yamauchi et al. 2011, ©KIEES)

sampled and continuously plotted. It is found that the currents are of traveling wave type, as seen from the phase progressions. The amplitude tends to increase with subsequent generation of a standing wave, as the frequency is increased.

The effective relative permittivity as a function of frequency is shown in Fig. 35. The result for the cigar is estimated by the current distribution illustrated in Fig. 34. On the other hand, that for the dielectric rod is calculated from the eigenmode solver using the YM-BPM (Yamauchi 2003). Good agreement is found to exist between the results for #1 and for the dielectric rod. It should be noted that the values for #2 rapidly deviate from those of the dielectric rod as the frequency is increased. This results in the deterioration of the

radiation pattern with an increase in frequency. It can be said that the choice of a sufficiently short period length is extremely important for the wideband properties.

Conclusion

Antennas radiating a circularly polarized wave have been discussed. After reviewing the radiation mechanism of a flat Archimedean spiral antenna, a novel spiral structure is discussed, where a composite left- and right-handed transmission line is employed. The antenna radiates a dual circularly polarized wave. Then, discussion is made for a helical antenna radiating toward the endfire direction. Some applications of the helix to a flat-type antenna for direct reception of the broadcasting satellite TV programs have been introduced. An application of a backfire helix to the primary feed for a paraboloidal reflector has also been presented. Finally, the radiation properties of a dielectric rod antenna have been studied. The discontinuity-radiation concept has been confirmed by the numerical approach. A technique for obtaining a higher gain has been explained by introducing a tapered rod. As an artificial dielectric, a periodic structure of circular metal disks has been used, and their characteristics have been compared with those for the conventional dielectric rod antenna.

Abstract

Over the past 30 years, many interesting developments have been seen in the field of dielectric resonator antenna (DRA). Analytical and numerical models for different shapes of DRAs were established in the 1980s and 1990s to understand their radiation properties. A couple of excitation schemes have also been proposed so that the DRAs can be excited efficiently. With the rapid advancement of dielectrics and microfabrication technologies in recent years, the DRA can now be made very compact for applications in portable wireless communication and millimeter-wave systems. In the first part of this chapter, miniaturization techniques of the DRA are discussed. It is found that the DRA can be integrated with power dividers for designing the circularly polarized and differential DRAs. Use of ground miniaturization technique has enabled realization of the omnidirectional CP DRA and the quasi-isotropic DRA for the first time. A review of the recent achievements in millimeter-wave DRA is then given. In this chapter, different dielectrics such as polymer and glass are also explored for designing the DRA. Transmission lines such as microstrip and substrate-integrated waveguide are deployed for exciting the DRA in the millimeter-wave spectrum. Elucidation is made on the design procedures and other considerations of the miniature and millimeter-wave DRAs.

Keywords

Dielectric resonator antenna; Miniature DRA; Omnidirectional CP DRA; Quasi-isotropic DRA; Millimeter-wave DRA

Introduction

It was first shown in the late 1930s (Richtmyer 1939) that an unmetalized dielectric object can also behave like a metallic cavity resonator, and it was subsequently given the name of dielectric resonator (DR). But DR was only explored for designing various microwave circuits beginning in the 1960s when technologies for making low-loss and temperature-stable dielectrics were becoming more mature. Since then, the DR has been broadly used for designing filters and oscillators because it can provide high unloaded Q-factor (Abe et al. 1978; Cohn 1968; Fiedziuszko 1986; Kajfez and Guillon 1998; Plourde and Ren 1981), which is usually in the range of 20–10,000, making it an excellent candidate for designing energy storage components and for achieving high frequency selectivity. As the wavelength of electromagnetic waves in the DR is smaller by a factor of $1/\sqrt{\varepsilon_r}$ compared to that in free space, the component size can usually be scaled down when a DR is deployed. A higher degree of compactness is also achievable as the DR can be easily integrated with different microwave integrated circuits (MICs) using simple coupling

DOI 10.1007/978-981-4560-75-7_35-1

schemes (Trans-Tech 2013). Although it was first found in the 1960s (Gastine et al. 1967; Sager and Tisi 1968) that the Q factors of certain resonances in a spherical dielectric sphere can be very low, meaning that there is a possibility of coupling energy into an external medium, the pioneering work of exploring the DR as an electromagnetic radiating element was only reported in 1983 (Long et al. 1983), where Professor Long systematically showed that the TM and TE modes of a cylindrical DR could be easily excited to make it an efficient microwave radiator. Since then, the dielectric resonator antenna (DRA) has been explored for a myriad of applications at high frequencies due to the absence of conductive loss. The development of the DRA is always underpinned by the advancement of dielectrics technology. Among all dielectrics, ceramic is one of the most commonly used as it is able to provide a high dielectric constant (>20) and low-loss tangent. Ceramics, however, are very hard in nature, and machining them can be very tough. Glass is another good low-loss dielectric, but its permittivity range is only 4–8. Recently, different types of soft materials such as polymers and compounds (Rashidian and Klymyshyn 2010) have been developed for the DRA, even though their dielectric constants are usually less than 5. In the past decade, the advancement of microfabrication and nanoscale technologies (Madou 2011) such as ceramic stereography, optical lithography, and laser milling has also enabled significant miniaturization of the DRA, making it viable for millimeter waves or even higher.

In the first part of this chapter, the DRA is explored for making various miniature antennas. Here, the DRA is integrated with different microwave power dividers for designing the circularly polarized (CP) and differential antennas. Ground miniaturization techniques will subsequently be used for the design of the omnidirectional CP DRA and the quasi-isotropic DRA. In the second part, a study is performed to excite the DRA using different transmission lines at millimeter-wave frequencies. It is found that the higher-order modes of the DRA can be used to relax fabrication tolerances.

Developments and Issues

Since a couple of good reviews are already available on the theoretical and experimental developments of the DRA (Huitema and Monediere 2012; Kishk 2007; Luk and Leung 2003; Petosa 2007), this section will only briefly describe the important developments and milestones throughout the years. A good introduction of some of the early works conducted in the 1980s and 1990s can also be found in (Mongia and Bhartia 1994; Petosa et al. 1998). In the 1990s, research was conducted to analyze the characteristics of the cylindrical, hemispherical (Leung et al. 1993, 1995; McAllister and Long 1984), rectangular (Ke and Cheng 2001; Mongia 1992; Mongia and Ittipiboon 1997), and triangular DRAs (Lo et al. 1999). Studies were conducted to understand their resonance modes, radiation patterns, and excitation schemes. The hemispherical DRA was the earliest to receive attention because of the existence of exact solutions. With the use of method of moments (MoM) and Green's function, the input impedance of the hemispherical DRA can be determined in a rigorous way (Leung et al. 1993, 1995). Later, analytical methods were also applied to establish the theoretical foundations for the cylindrical (Junker et al. 1994, 1996) and rectangular (Liu et al. 2002; Takashi et al. 2004) DRAs, which are more complicated to be analyzed because they have more boundaries. With the availability of powerful computers, some of the memory-intensive numerical methods such as the finite-difference time domain (FDTD), finite volume time domain (FVTD), finite element method (FEM), etc., were widely used for characterizing various DRAs (Fumeaux et al. 2004; Li and Leung 2005; Sangiovanni et al. 2004). Commercial electromagnetic softwares such as Ansys HFSS and CST Microwave Studio, which are designed from numerical methods, have also become popular tools for designing and analyzing the radiation performances of various DRAs in the recent decades.

DOI 10.1007/978-981-4560-75-7_35-1

Many excitation schemes have been developed for the DRA, and they are quite straightforward. Most of the excitation methods for the microstrip antennas can also be used to excite a DRA, including the use of coaxial probe, microstrip-fed aperture, microstrip line, and coplanar waveguide. Their design considerations will now be discussed. Probe excitation method may require drilling a hole in the DR for efficient coupling. This is a tough job as the DR can be very hard in nature. Also, a metallic probe has a larger ohmic loss and self-reactance at millimeter-wave frequencies. Using the microstrip and aperture to feed a DRA is attractive as the DR can be directly placed on the top of the excitation source. Microstrip-based feeding methods can be easily integrated with the monolithic microwave integrated circuits (MMIC). Coplanar waveguide (Al-Salameh et al. 2002), which is made on a single layer of metal, is useful for exciting the DRA when the operating wavelength goes beyond millimeter. For all of the aforementioned excitation methods, however, the formation of air gap in between the DR and ground plane is sometimes unavoidable in practice, and it can seriously affect the coupling efficiency (Junker et al. 1995). To overcome this problem, the conformal-strip feeding method was proposed in (Leung 2000), where a metallic strip was closely attached on the DR surface to excite the DRA. This excitation scheme inherits most of the advantages of the coaxial-probe feeding method. Substrate-integrated waveguide is another new form of transmission line that can be used to excite the DRA at the millimeter-wave frequencies (Hou et al. 2014).

The DRA has been explored for designing a variety of linearly polarized (LP) and circularly polarized (CP) antennas (Luk and Leung 2003; Petosa 2007) to achieve wide bandwidth and to provide multiple frequency passbands. Bandwidth widening is no doubt one of the most popular research topics in the past decades. A number of techniques such as stacked- (Kishk et al. 1989; Chair et al. 2004), polygon- (Hamsakutty et al. 2007; Kishk 2003), embedded- (Ong et al. 2004; Sangiovanni et al. 1997), and hybrid-DR (Esselle and Bird 2005; Guha et al. 2006) were explored for achieving wide bandwidth in the linearly and circularly polarized DRAs. Perforated DRA was found to be able to produce higher antenna bandwidth (Chair and Kishk 2006) because of its low Q-factor. Also, excitation of multiple higher-order modes is also a good way that can be used to extend the impedance bandwidth of a DRA as much as 40 % (Li and Leung 2005). In the past, one of the challenges that deters the DRA from practical usage is inflexibility of frequency tuning. This is because it is almost not possible to change the shape of the DR once it is made. To solve this problem, it was shown in (Ng and Leung 2005, 2006) that the resonant frequency of a DRA can be easily tuned by adding in loading strips or caps.

In recent years, the applications of the DRA have extended to portable wireless communication systems, where compactness is one of the most important criteria. To miniaturize the RF frontends, multifunction DRAs (Lim and Leung 2012) that can be used as packaging cover, oscillator load, filter element, and light cover have been proposed. Having multiple functions in a single piece of DRA will not only reduce the circuit footprint, it will also reduce the hardware costs significantly.

Miniaturized and Integrated DRAs

It is always very desirable to make an antenna very compact. The circuit size of a DRA can be miniaturized by integrating it with other components such as circulators, filters, and couplers. Having a three-dimensional (3D) structure, the DRA can accommodate its feeding circuit beneath its DR or inside the hollow region of the DR. Such a design strategy is very desirable for the circularly polarized (CP) or differentially fed DRAs since a hybrid 90° or an 180° coupler is usually required to provide two forms of the signal, which have equal magnitude with quadrature or differential in phase. Embedding the coupler beneath the DRA does not increase the footprint of the antenna, thus making the system very compact. Design examples will now be presented for a CP DRA and a differentially fed DRA.

CP DRAs with Underlaid Quadrature Coupler

CP system allows a more flexible orientation between the transmitting and receiving antennas, and they are very popular for certain applications such as satellite communication and global positioning system (GPS). Therefore, various singly fed or dual-fed CP DRAs have been proposed and investigated in the past two decades (Haneishi and Takazawa 1985; Oliver et al. 1995). Generally, the singly fed CP DRAs including the chamfered-corner DRA (Haneishi and Takazawa 1985), cross-slot-fed DRA (Oliver et al. 1995; Huang et al. 1999), and strip-loaded DRA (Leung and Ng 2003; Leung et al. 2000) have simpler feed networks, but their axial-ratio (AR) bandwidths are relatively narrow, with a typical value given by ~4 % only. The dual-fed DRAs can provide much wider AR bandwidths, but they usually need external quadrature couplers and therefore have larger system sizes (Mongia et al. 1994).

A compact CP rectangular DRA that employs an underlaid printed quadrature coupler was proposed in (Lim et al. 2011) for the first time. Figure 1 shows the antenna configuration. The rectangular DRA has a square cross section of side length $b = 31.8$ mm, a height of $h_2 = 20.5$ mm, and a dielectric constant of $\varepsilon_r = 10$. A hollow block with side length $a = 22$ mm and height $h_1 = 14$ mm is introduced at its bottom for housing a quadrature coupler, which is printed on a grounded substrate with a dielectric constant of $\varepsilon_{rs} = 6.15$ and a thickness of $d = 0.63$ mm. Since the coupler is located inside the hollow region of the

DOI 10.1007/978-981-4560-75-7_35-1

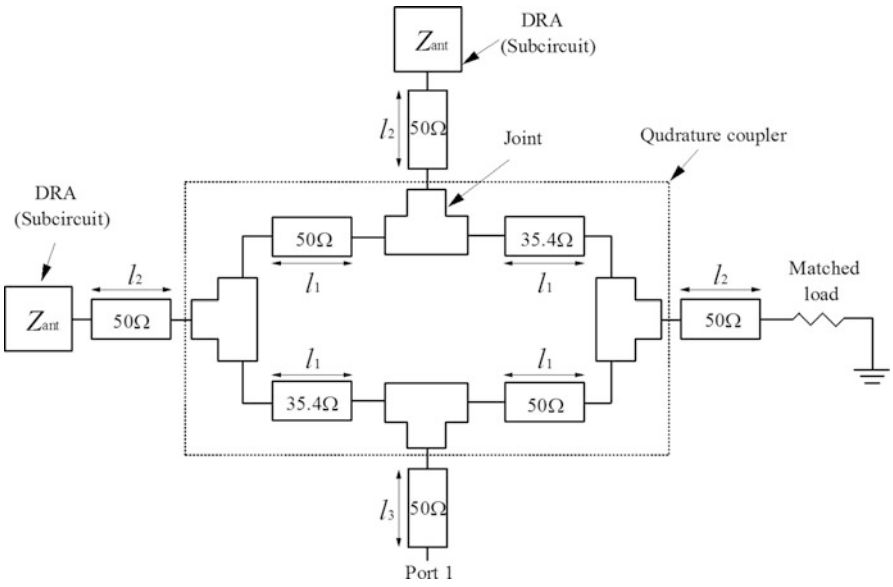

Fig. 2 Network model for the integrated CP DRA (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

DRA, it can be designed without affecting the structure of the DRA. Also, because virtually no extra space is needed for accommodating the coupler, the CP antenna is very compact. A pair of adhesive conducting strips which connect to the 0°- and 90°-output ports of the coupler are stuck on two adjacent side walls of the DRA to excite the degenerate TE^x_{111} and TE^y_{111} modes. Each strip has a width of $W_1 = 0.93$ mm and a length of $l_1 = 12.5$ mm. An external load of 50 Ω is used for the matching port of the coupler.

A network model has been obtained to simplify the design of the integrated CP antenna. Figure 2 shows the network model, in which the quadrature coupler is represented by its equivalent transmission lines and the functional block of the isolated DRA is extracted with the coupler removed. Using Ansys HFSS, the input impedance (Z_{ant}) is simulated by looking into one of the two excitation strips with the remaining excitation strip connected to a 50-Ω matched load. The whole model was then simulated in Microwave Office.

Figure 3 shows the measured and simulated reflection coefficients as a function of frequency. With reference to the figure, the reflection coefficient obtained by using the network model agrees reasonably well with the HFSS simulation and measurement. The discrepancy is expected because the network model does not take into account the mutual couplings. Since a hollow DRA is used, the measured 10 dB impedance bandwidth is as wide as 24.95 %. The measured and simulated ARs in the boresight direction ($\theta = 0^0$) are shown in Fig. 4. Also, a very wide 3-dB AR bandwidth of 33.8 % is obtained, ranging from 2.02 to 2.8 GHz. Figure 5 shows the antenna gains. The measured and simulated antenna gains are 6.18 dBi and 6.45 dBi at resonance frequencies, respectively. As can be seen from the figure, the measured gain is generally lower than the simulated one due to imperfections of the DRA and coupler. Figure 6 shows the broadside radiation patterns of the CP DRA at 2.40 GHz. The measured left-handed CP (LHCP) fields are stronger than the right-handed CP (RHCP) fields by 25 dB in the boresight direction.

Since a strip stuck on a DRA can inherently provide an impedance, the external 50-Ω resistor can also be replaced by a loading strip at the matching port (Lim et al. 2011). Figure 7 shows the proposed antenna configuration. In this case, a third strip that is attached on the corner of DRA is connected to the match port through an extended microstrip line. The strip has a width of $W_2 = 0.58$ mm and a length of $l_2 = 4$ mm. It was found that the impedance level can be easily adjusted by varying l_2, and a good match can be observed when a suitable l_2 is used. Figure 8 shows the simulated and measured ARs of the antenna. The measured

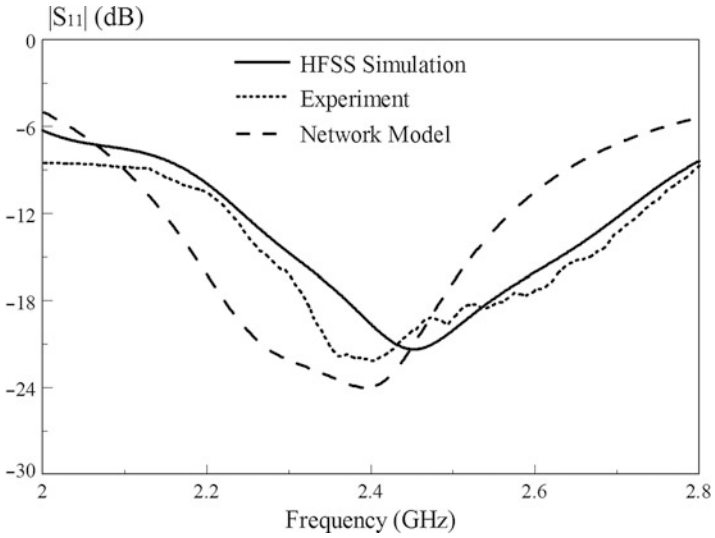

Fig. 3 Measured and simulated reflection coefficients of the CP DRA with external 50-Ω load (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

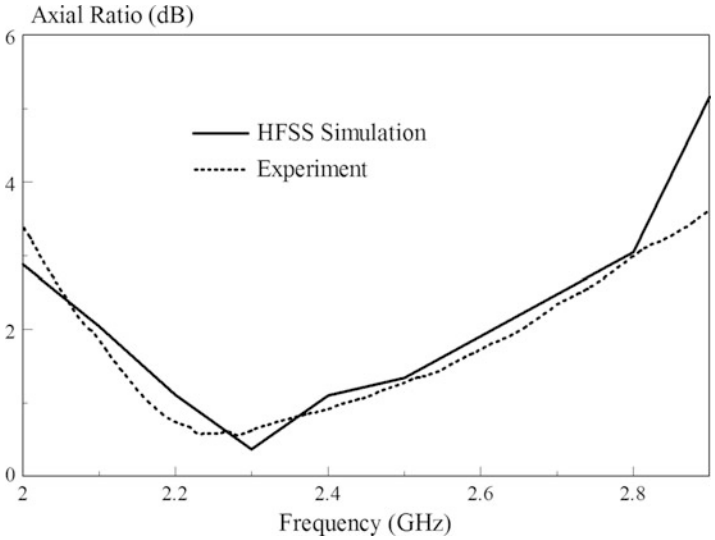

Fig. 4 Measured and simulated ARs of the CP DRA with external 50-Ω load (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

AR bandwidth is found to be ∼10 %, narrower than that for the former configuration. This is as expected since the DRA-loaded strip is unable to provide a constant 50-Ω load.

Differential DRA with Underlaid 180° Hybrid Coupler

The design idea was also used to realize a differential DRA (Fang et al. 2010), which is differentially fed by a 180° hybrid coupler to suppress the common-mode interference, and consequently to increase the signal-to-noise ratio. Figure 9 shows the antenna configuration. The hollow DRA with parameters of $a = 22$ mm, $b = 31.8$ mm, $d_1 = 14$ mm, $d_2 = 20.5$ mm, and $\varepsilon_r = 10$ is excited in its TE^y_{111} mode. In the hollow region of the DRA, there is a rat-race coupler printed on a Duroid substrate with a dielectric constant of $\varepsilon_{rs} = 6.15$ and a thickness of $h = 0.63$ mm. A pair of conducting strips of width $w = 0.58$ mm and length $l = 10.5$ mm are connected to the two output ports of the rat-race coupler.

DOI 10.1007/978-981-4560-75-7_35-1

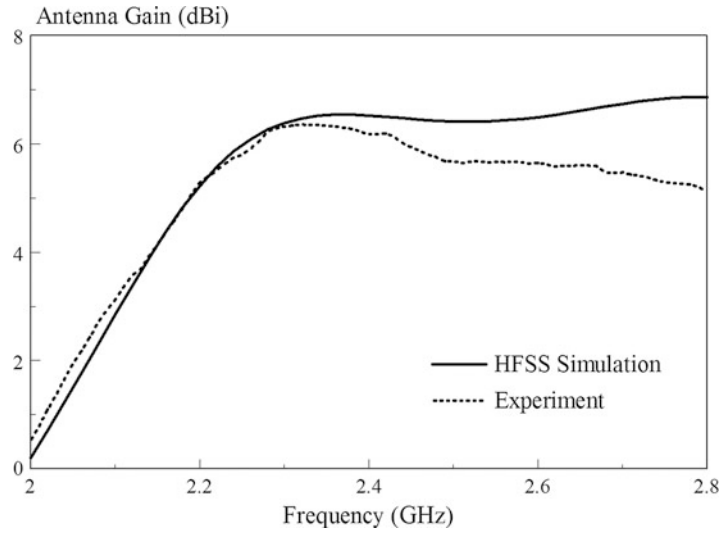

Fig. 5 Measured and simulated antenna gain of the CP DRA with external 50-Ω load (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

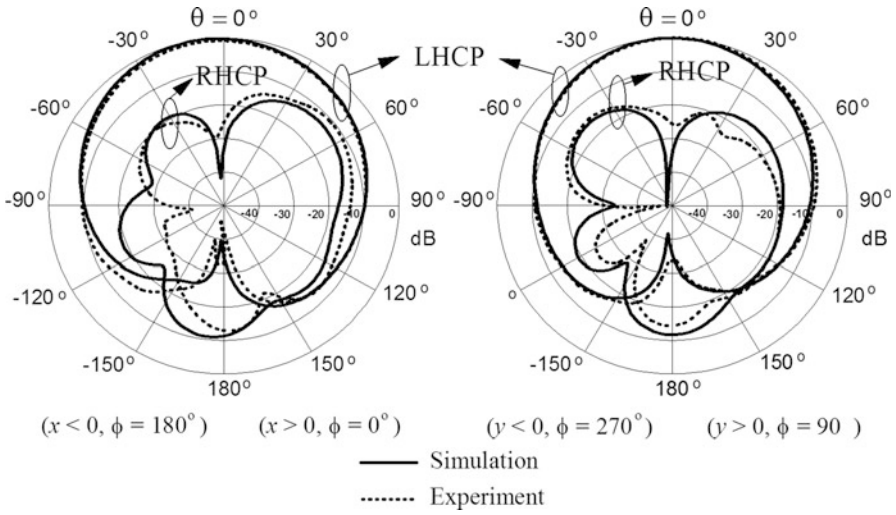

Fig. 6 Measured and simulated normalized radiation patterns of the CP DRA with external 50-Ω load (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

They are stuck on the two opposite walls of the DRA to feed the antenna differentially. The isolation port of the rat-race coupler is terminated by an external matched resistor of 50 Ω.

Figure 10 shows the measured and simulated reflection coefficients of the differential DRA as a function of frequency. As can be seen from the figure, the measured and simulated impedance bandwidths are given by 11.8 % (2.24–2.52 GHz) and 10.6 % (2.24–2.49 GHz), respectively. Figure 11 shows the measured and simulated radiation patterns at 2.4 GHz. Broadside radiation patterns are observed for both of the E- and H-planes as expected, since the fundamental TE^{y}_{111} mode is excited. In each plane, the cross-polarized field is weaker than its co-polarized counterpart by more than 26 dB in the boresight direction. For comparison, a single feeding strip was also used to feed the same hollow DRA. It was found that the cross-polarized fields of the differential DRA are generally lower than those of the single-ended design, especially for field pattern in the H-plane.

DOI 10.1007/978-981-4560-75-7_35-1

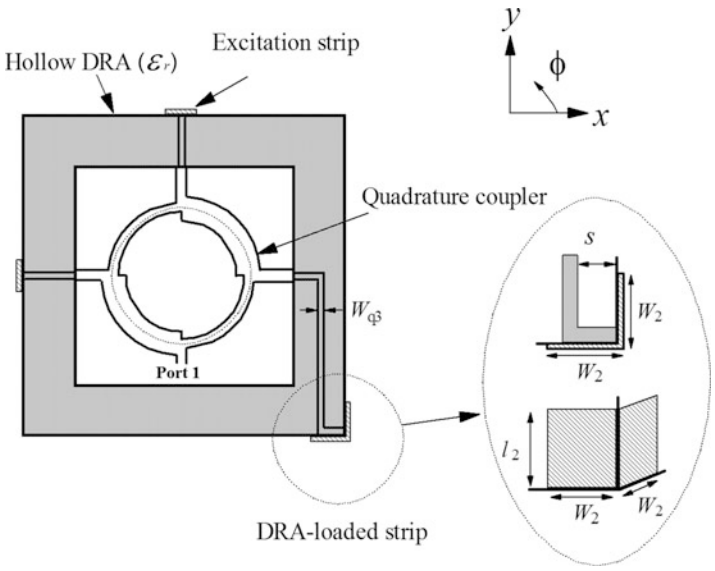

Fig. 7 *Top view* of the proposed CP DRA. A loading strip is added at the DRA corner to provide a 50-Ω load for the matching port of the coupler (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

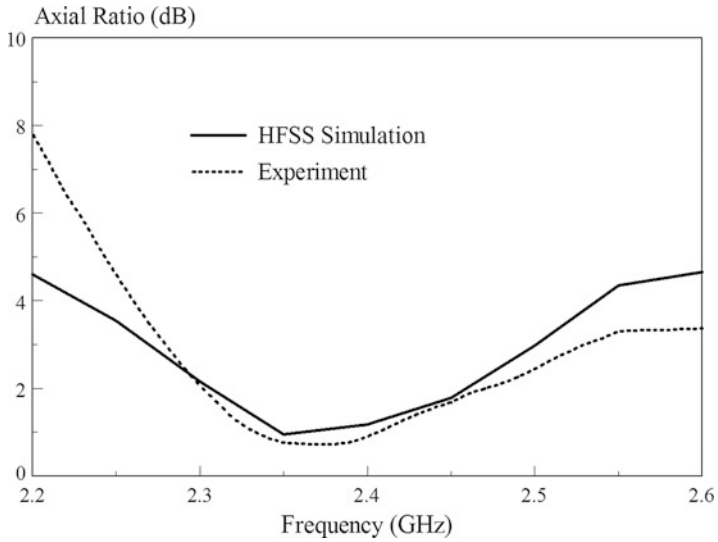

Fig. 8 Measured and simulated ARs of the CP DRA with DRA-loaded strip (From Lim et al. (2011), copyright © 2011 IEEE, with permission)

It should be mentioned that the underlaid technique can also be extended to solid DRAs. One factor to be noted is that the design of the coupler should take into account the loading effect of the upper DRA.

Compact-Ground DRAs

In the past three decades, various antenna geometries, excitation schemes, and bandwidth enhancement techniques for the design of DRA have been developed. Thus far, studies of the DRA have mainly focused on the main radiating element, and relatively much less attention has been paid to the other important constituent part – the ground plane. However, since the time-varying current formed on the ground plane

DOI 10.1007/978-981-4560-75-7_35-1

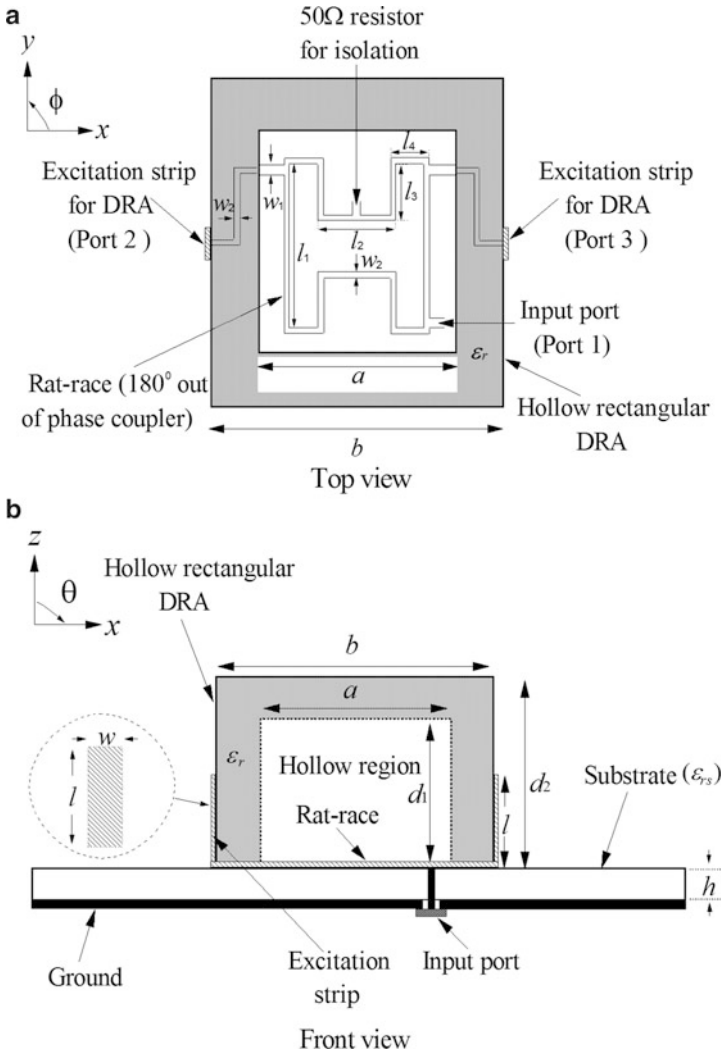

Fig. 9 Configuration of the differential rectangular hollow DRA with an underlaid rat-race coupler. (**a**) *Top view*. (**b**) *Front view* (From Fang et al. (2010), copyright © 2010 IEEE, with permission)

can also generate radiation, the dimension and shape of the ground plane may also play a crucial role on the antenna performance . Actually, it was found that very small ground planes are essential for some specific antennas such as the following omnidirectional CP DRA and isotropic DRA to provide a satisfactory performance. Having a smaller ground will also definitely make the DRA more compact.

Omnidirectional CP DRA

CP antennas are widely used in modern wireless communication systems because they can mitigate multipath and fading problems. On the other hand, omnidirectional radiation patterns are generally desirable since they can provide larger signal coverage and stabilize the signal transmission. As a result, the investigation of omnidirectional CP antennas has attracted increasing attention in recent years (Kawakami et al. 1997; Nakano et al. 2000; Park and Lee 2011; Quan et al. 2013; Row and Chan 2010).

Figure 12 shows the configuration of the first omnidirectional CP DRA (Pan et al. 2012), which is a rectangular DRA with four inclined slots fabricated on its sidewall. The DRA has a length of a, a width of b, a height of h, and a dielectric constant of ε_r, and each slot has a width of w and a depth of d. A coaxial probe of length l and radius r_1 is used to centrally feed the antenna. The probe is extended from the inner

DOI 10.1007/978-981-4560-75-7_35-1

conductor of an SMA connector. To enable maximum radiation around $\theta = 90^{o}$ and minimize the radiated fields from tilting, the flange of the SMA is used as the (small) ground plane. The working principle of the antenna is hereby explained. When a rectangular DRA is centrally fed by a coaxial probe, it will generate monopolar linearly polarized (LP) fields. By introducing a slot on each DRA sidewall, the vertical E_z field from the vertical monopole is perturbed and can be resolved into orthogonal $E_{\perp}$ and $E_{//}$ components which are perpendicular and parallel to the inclined slot. Since the slotted DR behaves effectively as an anisotropic dielectric (Kirschbaum and Chen 1957), the two components will travel at

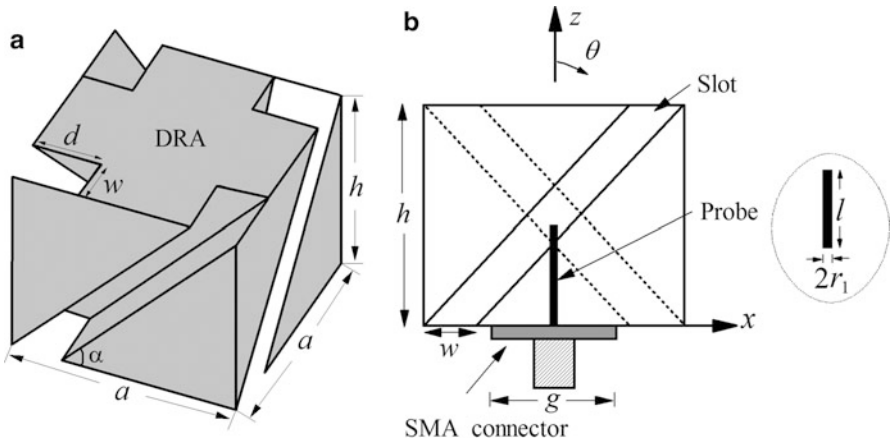

Fig. 12 Configuration of the omnidirectional CP DRA. (**a**) *Perspective view*. (**b**) *Front view* (From Pan et al. (2012), copyright © 2012 IEEE, with permission)

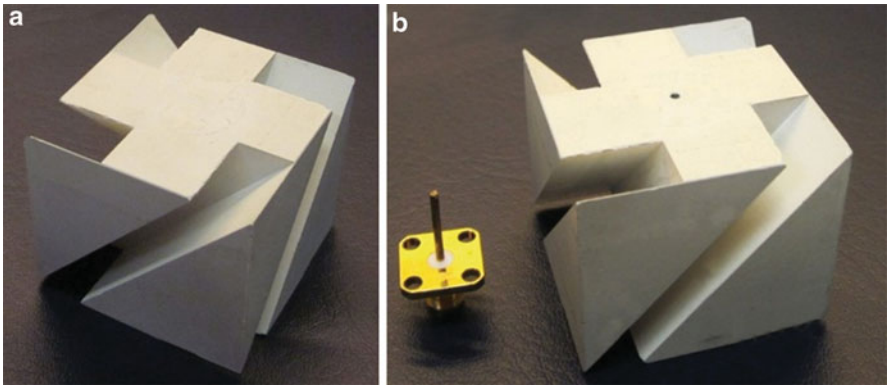

Fig. 13 Prototype of the proposed omnidirectional CP DRA. (**a**) Photograph showing the top face and sidewalls. (**b**) Photograph showing the bottom face of the DRA (From Pan et al. (2012), copyright © 2012 IEEE, with permission)

different velocities, causing a phase difference between them. When the phase difference reaches 90° and $|E_{\perp}| = |E_{/\!/}|$, a CP wave emerges from the DRA.

Figure 13 shows two photographs of a prototype operating at 2.4-GHz WLAN frequency range, with parameters given by $\varepsilon_r = 15$, $a = 39.4$ mm, $h = 33.4$ mm, $w = 9.4$ mm, $d = 14.4$ mm, $l = 12.4$ mm, $r_1 = 0.63$ mm, and $g = 12.7$ mm. The reflection coefficients and axial ratios of the proposed CP DRA are shown in Fig. 14a, b, respectively. With reference to the figures, the measured 10-dB impedance bandwidth and 3-dB AR bandwidth are 24.4 % (2.30−2.94 GHz) and 7.3 % (2.39−2.57 GHz), respectively. The measured AR passband falls within the impedance passband, and therefore the entire AR passband is usable. Figure 15 shows the simulated and measured radiation patterns in the elevation (*xz*) and azimuth (*xy*) planes. As can be observed from the figure, the elevation pattern has a null in the boresight direction and the maximum radiation occurs at $\theta = 90°$, whereas the azimuthal pattern is omnidirectional. In the whole azimuth plane, the co-polarized LHCP field is at least ~20 dB stronger than the corresponding cross-polarized RHCP counterpart, showing good CP performance.

For an omnidirectional CP antenna, the ground-plane size usually affects the antenna performance considerably. Figure 16 shows the results for different side lengths of ground plane. As can be observed from the figure, the impedance and AR bandwidths are reduced from 20.3 % to 10.6 % and from 8.2 % to 4.2 %, respectively, with an increase of g from 12.7 to 32.7 mm. But when g exceeds 42.7 mm, the AR

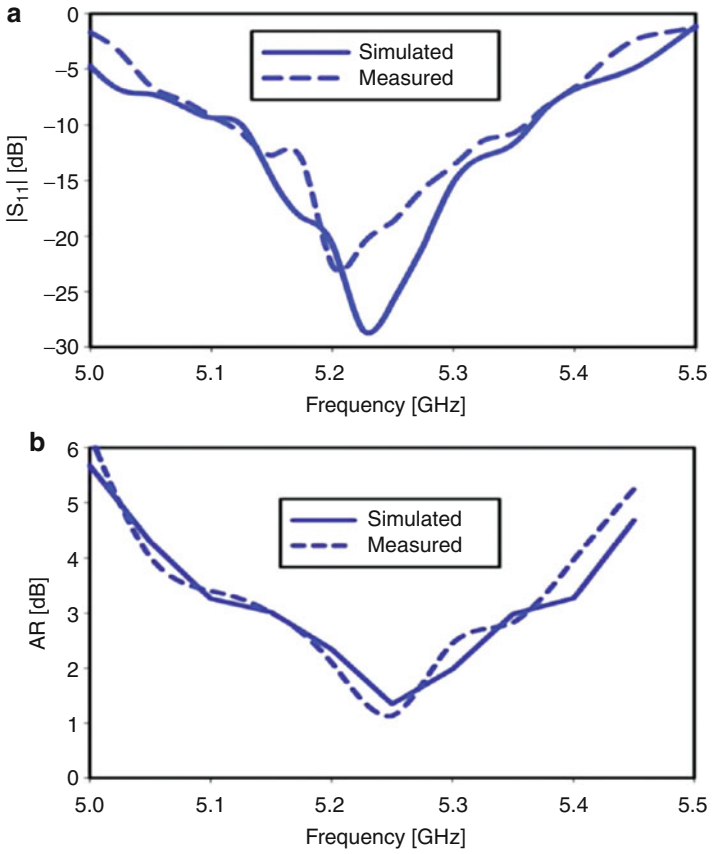

Fig. 18 Measured and simulated reflection coefficients and ARs of the omnidirectional CP DRA: $\varepsilon_r = 10$, $a = 31$ mm, $h = 24$ mm, $h_1 = 19$ mm, $w_1 = 5$ mm, $d_1 = 9.2$ mm, $w_2 = 10$ mm, $d_2 = 5$ mm, $l = 13.25$ mm, $r_1 = 0.63$ mm, and $g = 12.7$ mm. (**a**) Reflection coefficients. (**b**) ARs (From Khalily et al. (2014), copyright © 2014 IEEE, with permission)

deteriorates greatly, and the entire AR curve becomes higher than the 3-dB level. Poor AR is obtained because two orthogonal components are usually required to generate CP fields, but the boundary condition of a large ground plane requires that the tangential *E*-field component be zero on its surface and only the perpendicular *E*-field component remains. Therefore, a small ground plane is preferable in designing an omnidirectional CP antenna.

A similar slotted omnidirectional CP DRA has also been presented in (Khalily et al. 2014). Figure 17 shows the corresponding antenna configuration. In this case, vertical slots rather than inclined ones are introduced onto the sidewall of the DRA to generate CP fields. Again, the antenna is centrally fed by a coaxial probe, and the flange of the SMA acts as the small ground plane. Figure 18 shows the reflection coefficient and AR of the CP DRA. With reference to the figure, the measured 10-dB impedance bandwidth is given by 4.57 % (5.13–5.37 GHz), and the 3-dB AR bandwidth is 4.18 % (5.15–5.37 GHz). The omnidirectional radiation patterns of the DRA are similar to those shown in Fig. 15.

For the above two antennas, slots need to be fabricated on dielectric surfaces which can be difficult especially when a cylindrical or hemispherical DRA is used. Therefore, a novel omnidirectional CP DRA loaded with a modified Alford loop was proposed in (Li and Leung 2013). Figure 19 shows the configuration of the cylindrical DRA with a diameter of D, a height of H, and a dielectric constant of ε_r. The DRA is axially fed by a coaxial probe at the center of its bottom, exciting its fundamental $TM_{01\delta}$ mode. A modified Alford loop which consists of a center patch and four conducting curved branches is placed on top of the DRA for generating CP fields. The center piece of the patch has a diameter of d_1, and

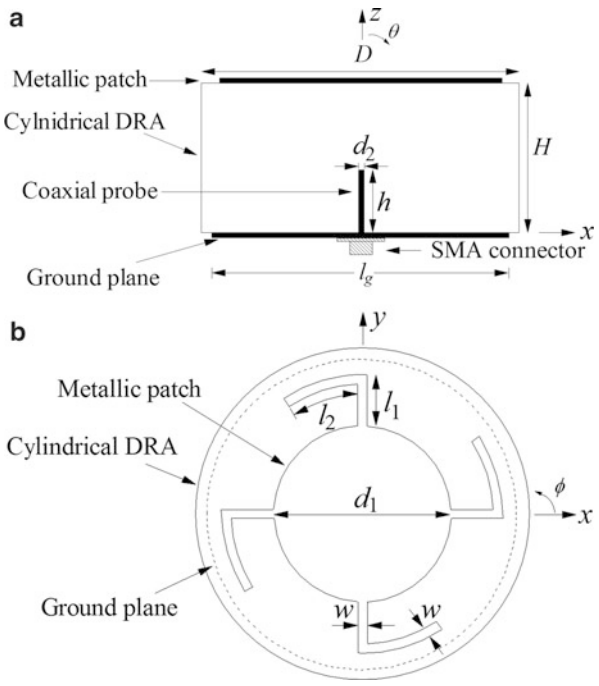

Fig. 19 Configuration of the omnidirectional CP cylindrical DRA. (**a**) *Side view* and (**b**) *top view* (From Li and Leung (2013), copyright © 2013 IEEE, with permission)

each of the extended branches has a width, radial length, and arc length of w, l_1, and l_2, respectively. Figure 20 shows the simulated and measured reflection coefficients and ARs of the CP antenna. Two modes, one is caused by the DRA while another is caused by the feeding probe, have merged together, giving an impedance bandwidth of 13.2 % (2.34–2.67 GHz). The measured 3-dB AR bandwidth is 10.5 % (2.26–2.51 GHz). Therefore, the usable overlapping bandwidth of the AR and impedance passbands is 7.0 % (2.34–2.51 GHz), which is almost the same as the previous slotted DRA (Pan et al. 2012).

Another omnidirectional CP DRA having parasitic patches on its sidewalls has been proposed in (Leung et al. 2013). Figure 21 shows the configuration of the proposed design. In this case, four patches are inclined along the diagonals of the sidewalls to effectively perturb the DRA fields, thus exciting nearly degenerate modes that lead to the generation of CP fields. As shown in Fig. 22, the measured impedance bandwidth and AR bandwidth of the CP DRA are comparable, given by 6.6 % and 6.9 %, respectively.

As shown in the above designs, both of the inclined slots and parasitic patches (or strips) can generate CP fields. Therefore, it is possible to obtain two CP modes by placing a parasitic strip inside each slot of the original slotted DRA (Pan et al. 2012). Figure 23 shows the configuration of the wideband omnidirectional CP antenna (Pan and Leung 2012). Four identical conducting strips of length l_s and width w_s are introduced at a depth of x_0 from the DR surface. It was found that by properly tuning the length and location of the strip, a new CP mode induced by the strips can be obtained and combined with the DRA CP mode to broaden the AR bandwidth. Moreover, a circular cylinder of radius r can be removed from the center of DR to accommodate the feeding probe and also to enhance the impedance bandwidth. The simulated and measured reflection coefficients and ARs are shown in Fig. 24. As can be seen from the figure, both of the impedance and AR bandwidths of the antenna read ∼24 %. The usable overlapping bandwidth of the antenna is given by 22.0 % (3.16−3.94 GHz), which is more than sufficient for many wireless communication applications. Furthermore, the omnidirectional radiation patterns are found to be very good and stable across the entire passband.

Compact Quasi-Isotropic DRA

For certain applications such as radio frequency identification (RFID) and wireless access points, it is very desirable to have an isotropic antenna which can provide full coverage to maintain good communication links at all angles. An isotropic antenna is usually obtained by arraying a number of discrete elements in a circle (Chen et al. 2012; Zhang et al. 2011) or by using two perpendicular half-wave linear dipoles with a

DOI 10.1007/978-981-4560-75-7_35-1

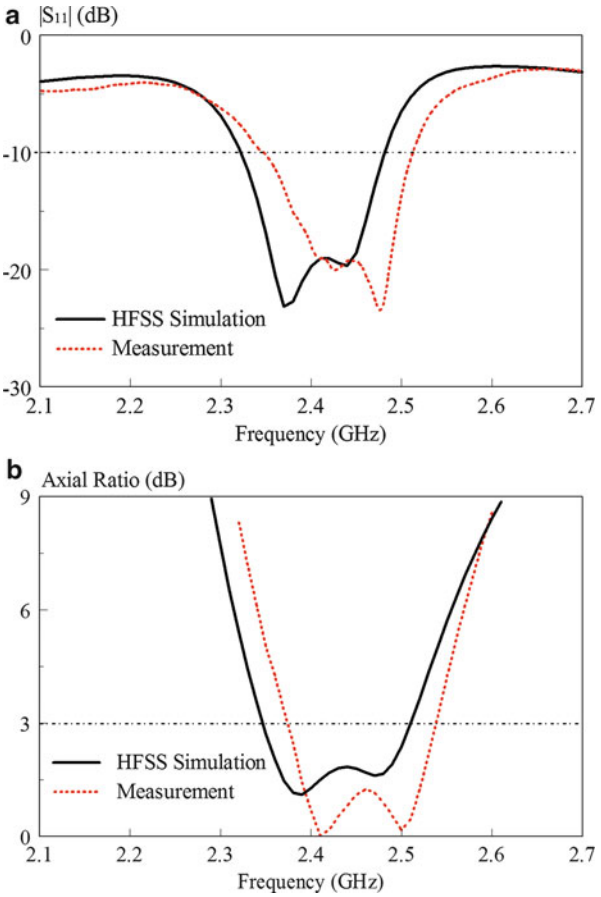

Fig. 22 Measured and simulated reflection coefficients and ARs of the omnidirectional CP DRA. (**a**) Reflection coefficients. (**b**) ARs (From Leung et al. (2013), copyright © 2013 IEEE, with permission)

phase difference of 90° (Radnovic et al. 2010; Kraus and Marhefka 2003), but the two methods involve either complex structures or complicated feeding networks.

A very simple quasi-isotropic DRA was investigated in (Pan et al. 2014) by using the idea of complementary antennas. The scheme of complementary antenna concept is shown in Fig. 25. From the figure, the E- and H-plane radiation patterns of an electric dipole are found to be of the figure-8 and figure-O shapes, respectively, and the two patterns are interchanged for a magnetic dipole. Therefore, when an electric dipole and a magnetic dipole are combined perpendicularly, the null-field direction of one of them is along the maximum-field direction of the other. Consequently, there is no blind spot, and it is possible to provide a quasi-isotropic antenna.

Figure 26 shows the configuration of the quasi-isotropic DRA. It is a rectangular DRA with a square cross section, which has a side length of a, a height of d, and a dielectric constant of ε_r. The DRA is fed by a coaxial probe of length l and radius r, located at a displacement of y_0 from the center. A small square ground plane with a side length of g is used for the antenna. The required equivalent magnetic and electric dipoles for obtaining a quasi-isotropic antenna are provided by the DR and ground plane, respectively. The working principle of the antenna is illustrated in Fig. 27, which shows the surface current on the ground plane and the fields in the DRA. With reference to Fig. 27a, the ground plane has a nearly uniform current distribution, and it can be approximated as an electric dipole along y axis. With reference to Fig. 27b, c, the fields of the DRA are very similar to those produced by a short x-directed magnetic dipole.

DOI 10.1007/978-981-4560-75-7_35-1

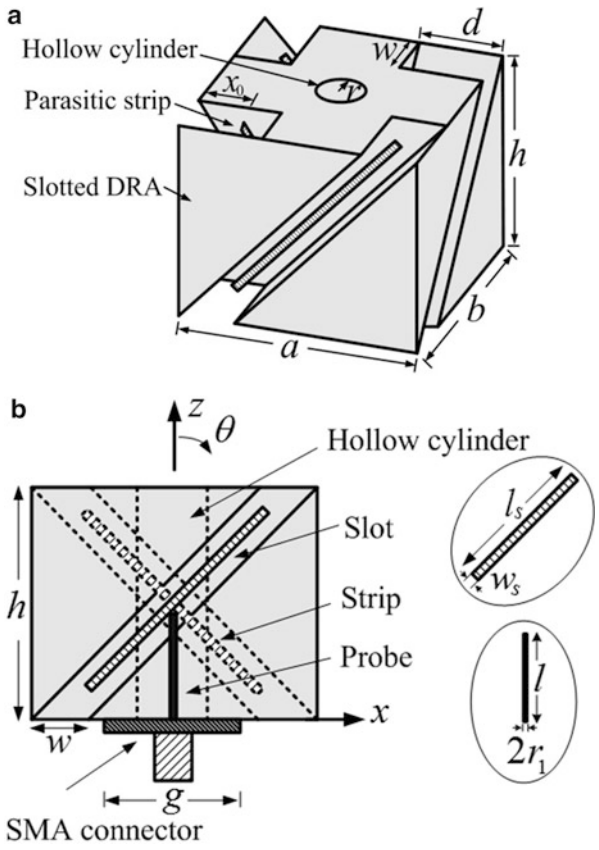

Fig. 23 Configuration of the proposed wideband omnidirectional CP DRA. (**a**) *Perspective view.* (**b**) *Front view* (From Pan and Leung (2012), copyright © 2012 IEEE, with permission)

As a result, the DRA with small ground plane is equivalent to a pair of perpendicular magnetic and electric dipoles, providing quasi-isotropic fields.

Figure 28 shows the measured and simulated reflection coefficients of the quasi-isotropic DRA. Since the coaxial feed line is an unbalanced structure, a choke (balun) is used to obtain a balanced current in the measurement. The measured 10-dB impedance bandwidth of the antenna is 6.9 % (2.38–2.55 GHz), agreeing well with the simulated result. Figure 29 shows the three-dimensional (3D) pattern of the total field E_T. It can be seen from Fig. 29a that the simulated E_T is independent of ϕ and the same field pattern is obtained for all elevation planes. The difference between the maximum and minimum radiation power densities is about 5.6 dB over the entire pseudo-spherical radiating surface, which is 2.6 dB higher than the theoretical value of 3 dB. This is because the two dipole sources are not ideal. Similar pattern has been obtained in the measurement, as shown in Fig. 29b. A much more isotropic pattern can be realized by using a narrower rectangular ground plane. Figure 30 shows the simulated surface current on the ground plane (24×6 mm^2) of the DRA with $\varepsilon_r = 10$, $a = 24$ mm, $d = 17$ mm, $l = 4.5$ mm, and $y_0 = 9$ mm. It can be clearly seen that the current distribution on the narrower ground plane is quite similar to that of a dipole antenna and thus the gain difference of the antenna can be reduced to 4.5 dB. An even smaller difference of 3.4 dB can be obtained using a DRA with a higher dielectric constant of ε_r=15 .

Millimeter-Wave Miniature DRAs

Millimeter-wave frequency ranges such as Ka (26.5–40 GHz), Q (40.5–43.5 GHz), V (40–75 GHz), and W (75–110 GHz) bands are traditionally used for military, astronomy, and remote sensing. Particularly, the International Telecommunication Union (ITU) has designated 30–110 GHz as the extremely high frequency (EHF) band. The key advantage of using millimeter-wave communication link is the possible availability of large amount of spectral bandwidth which may enable the transmission of high volume of data (Kay 1966; Rappaport et al. 2011). Nevertheless, millimeter waves are easily absorbed by rain, gases, and water vapor in the atmosphere (Weibel and Dressel 1967). Signals in the frequency range of 57–64 GHz can also be seriously attenuated by the resonances of oxygen molecules. As a result, in practice, millimeter-wave communication links require the use of high-gain antennas (Li and Luk 2014). This frequency range has already been successfully deployed for automotive radar sensing systems (Menzel and Moebius 2012) which do not require far radiation coverage. Parabolic reflectors and horn-fed lens are among the earliest nonplanar structures that are able to provide high antenna gain in the millimeter-wave ranges (Kay 1966). Later, planar antennas such as slots, microstrip patches, and printed dipoles were also explored (Pozar 1983; Vilar et al. 2014). Due to its small wavelength, the main challenges of making a millimeter-wave antenna are fabrication accuracy and feed line loss (Schwering 1992). Different from the microstrip-based resonators, the DR itself does not possess conductive loss. This feature is very desirable for enhancing radiation efficiency. Although it is stretching into a three dimensional, the DRA is still much more compact compared to reflectors and lenses.

The development of the DRA in the millimeter-wave ranges is boosted by the availability of microfabrication technology and low-loss dielectrics. Advancement in micromachining techniques such as photolithography and laser milling has enabled the fabrication of very small antenna structures. Ceramic stereography was deployed for fabricating periodic structures such as DRA arrays in (Buerkle et al. 2006; Brakora et al. 2007). Effort has also been made to explore low-loss materials for millimeter-wave applications. Ceramic is conventionally used for the DRA because it is able to provide high dielectric constant ($\varepsilon_r > 20$). However, ceramic material is hard in nature and difficult to be machined, making the fabrication and tuning processes extremely difficult. Soft materials such as polymer and plastic compounds have been developed for ease of machining, but such materials can only achieve a permittivity range of 3–5 (Zou et al. 2002; Wasylyshyn 2005; Koulouridis et al. 2006; Rashidian and Klymyshyn 2010). Having low dielectric constant may not be a problem as the antenna size is usually small at millimeter-wave frequency. It allows for the flexibility of making the antenna size larger to overcome fabrication imperfections. But the key issue is that a DRA with low dielectric constant may not be able to be excited efficiently.

Polymer materials such as liquid crystal polymer (LCP), polydimethylsiloxane (PDMS), and polyoxymethylene (POM) are among the low-loss dielectrics that can be used for making the

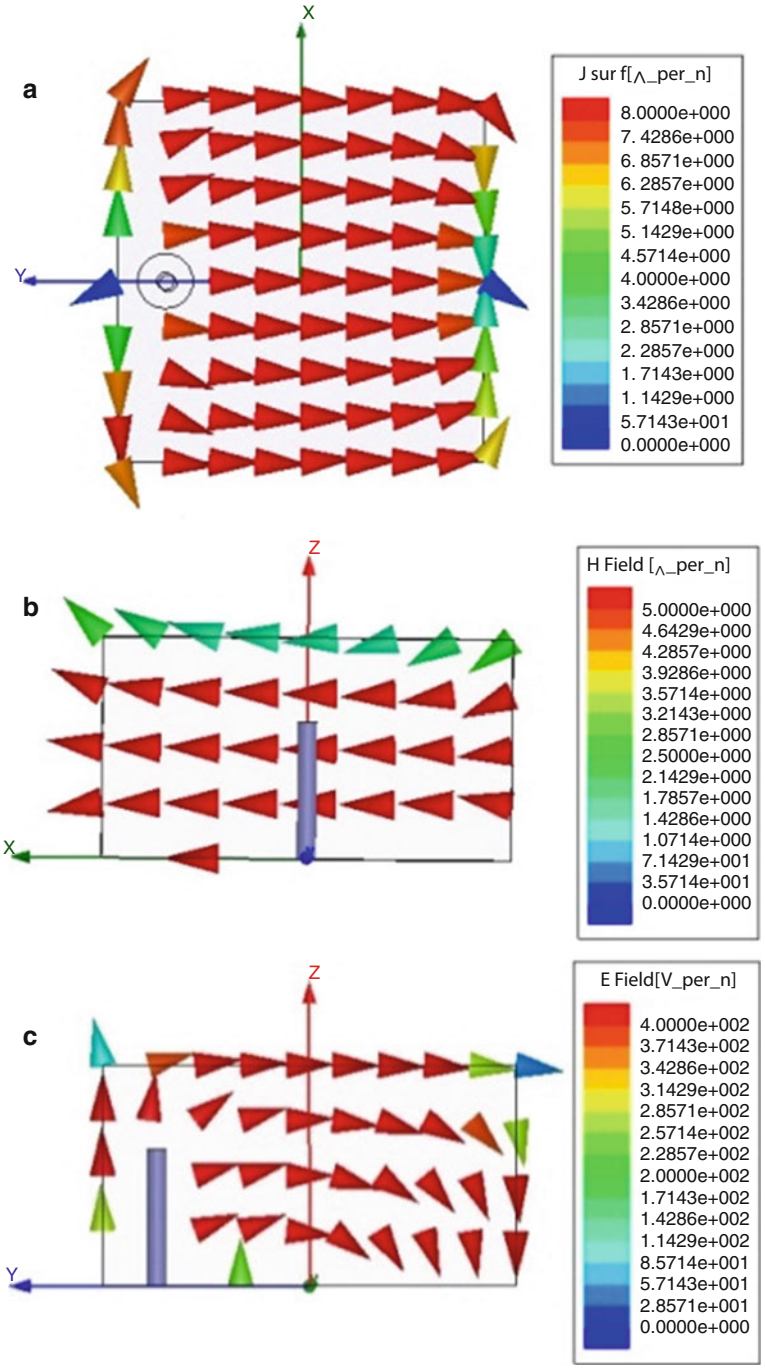

Fig. 27 Surface current on the ground plane and the fields in the quasi-isotropic DRA. (**a**) Surface current on the ground plane. (**b**) Magnetic field in the DRA. (**c**) Electric field in the DRA

DRA. Recently, one type of photosensitive polymer that can be processed using the X-ray lithography has been tested for designing a millimeter-wave DRA (Rashidian and Klymyshyn 2010). This section explores the possibility of applying low-permittivity dielectrics in the millimeter-wave spectrum. Figure 31 shows the configuration of the aperture-fed DRA, which has a dielectric constant of $\varepsilon_r = 4.2$, a footprint of $a = b = 5.7$ mm, and a height of $d = 2$ mm. Microwave signal is coupled from the 50-Ω microstrip feed line to the DRA through an aperture located on the reverse side of a piece of Duroid substrate with a dielectric constant of 2.2. The line stub L_s can be adjusted to improve the

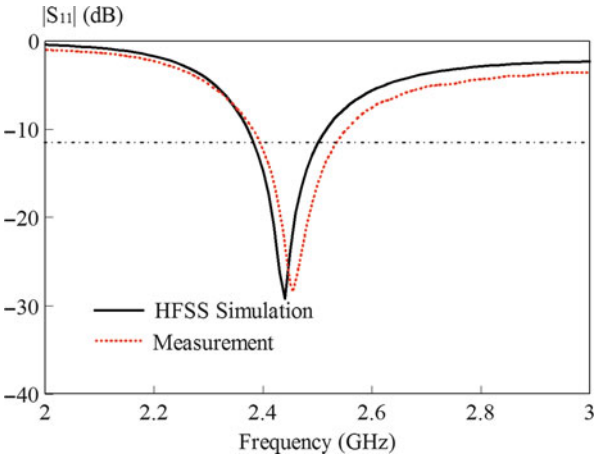

Fig. 28 Simulated and measured reflection coefficients of the quasi-isotropic DRA: ε_r=10, a = 27 mm, d = 14.5 mm, g = 27 mm, l = 9 mm, and r = 0.63 mm (From Pan et al. (2014), copyright © 2014 IEEE, with permission)

impedance matching. The antenna configuration was simulated using the commercial software HFSS simulator, and experiment was conducted on an Agilent 8722ES vector network analyzer. An Inter-Continental Microwave WK-3001-G test fixture is used for the measurement. As can be seen from the measured and simulated reflection coefficients in Fig. 32, the aperture-coupled DRA is able to provide a frequency passband from 21.25 to 29.25 GHz, covering a bandwidth of 32 %. In the same figure, for comparison, a ceramic DRA with ε_r = 10, $a = b$ = 5.7 mm, and d = 2 mm is also simulated and measured. It has a bandwidth of 9 % (covering 19–20.7 GHz) only, which is much less compared to that for the polymer. Figure 33 shows the measured and simulated radiation patterns in the *xz*- and *yz*-planes at the resonant frequency of 26.1 GHz. Broadside radiation has been observed for the TE_{111} resonance, where the co-polarized fields are at least 20 dB larger than their cross-polarized counterparts in both of the major cutplanes. The polymer DRA is found to have an antenna gain of 4.9 dBi in the boresight direction. This work shows that polymers can be used for designing the DRAs at millimeter-wave frequencies.

To work in the millimeter-wave ranges, the DRA has been conventionally incorporated with different transmission feed lines such as microstrip, image line, and waveguide. Recently, the DRA is incorporated with a new type of waveguide-like transmission line, called substrate-integrated waveguide (SIW), which works at the TE modes (Wu et al. 2012). The SIW structure was first proposed in 1998 (Uchimura et al. 1998), and it has a lower attenuation constant than microstrip since its propagating electric fields are confined in between the two backing metal plates and trenches of vias (Lai et al. 2009). But it has higher loss than the conventional metallic waveguide due to field leakage through the vias. To have compact size, as shown in Fig. 34, a half-mode substrate-integrated waveguide (HMSIW) is used to design a slot-coupled linearly polarized DRA (Lai et al. 2010), working at 60 GHz. The HMSIW is made on a Rogers 5880 substrate with a dielectric constant of ε_r = 2.2, a loss tangent of tanδ = 0.001, and a thickness of t = 0.127 mm. In this case, the DRA is machined from the TM10i dielectric material with $\varepsilon_r = 10.2 \pm 0.2$ and loss tangent of tanδ = 0.002. The DRA is placed on top of the slot using the Araldite resin which has a dielectric constant of 3.6 and a loss tangent of 0.06. The resin layer has a thickness of h_g = 15 μm. With reference to Fig. 34a, b, it can be seen that the HMSIW is fed by a tapered microstrip at one end on the bottom surface. Another end of the waveguide is shorted with a row of metallic vias. With a transverse slot etched on the top surface of the HSIW, as can be seen in Fig. 34a, a linearly polarized DRA can be easily designed. The optimized dimension of the linearly polarized DRA is w_{ms} = 0.35 mm, l_{ms} = 10 mm, w_{tr} = 0.9 mm, l_{tr} = 1.4 mm, w = 2.2, l = 8.9 mm, d = 0.4 mm, s = 0.5 mm,

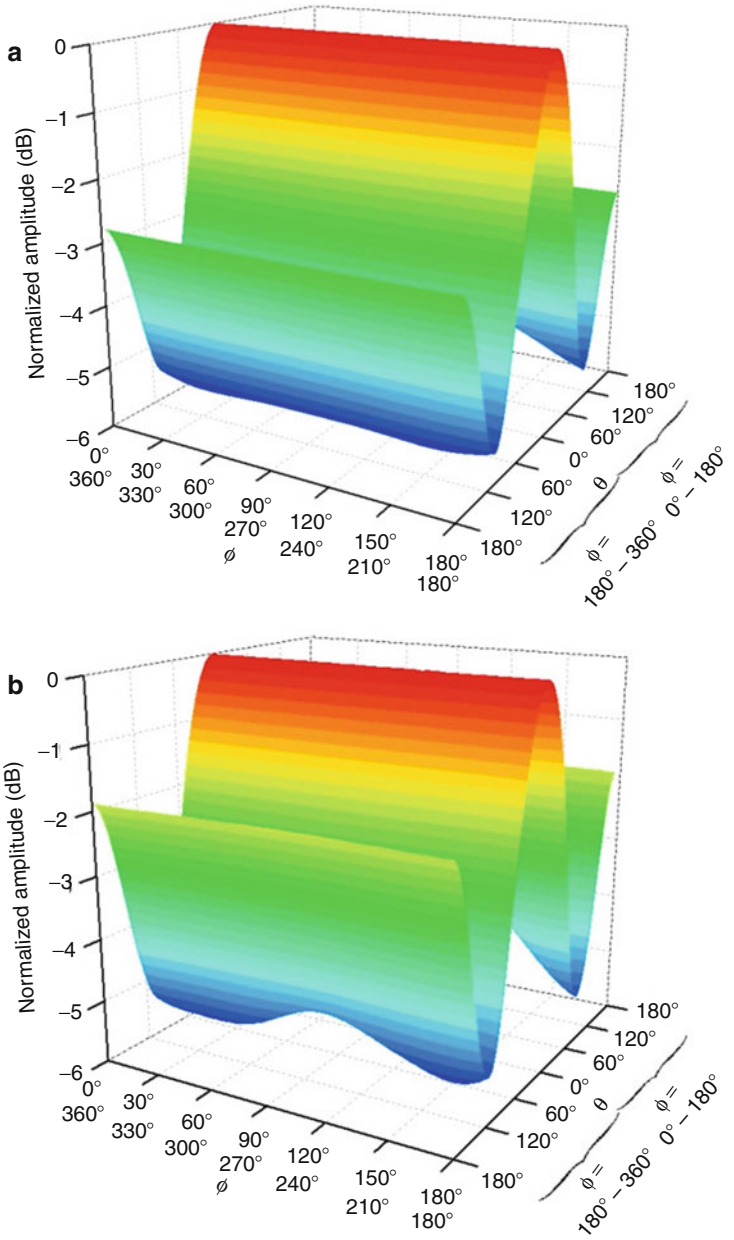

Fig. 29 Simulated (2.44 GHz) and measured (2.46 GHz) 3D radiation patterns of the quasi-isotropic DRA. (**a**) Simulation. (**b**) Measurement (From Pan et al. (2014), copyright © 2014 IEEE, with permission)

$D = 3$ mm, $h = 0.5$ mm, $x_{slot} = 1.0$ mm, $z_{slot} = 2.3$ mm, $w_{slot} = 0.2$ mm, $l_{slot} = 2.0$ mm, $h_g = 15 \pm 5$ μm, and $t = 5$mil. When a cross slot is used, as shown in Fig. 35, the same DRA can be made to generate circularly polarized waves. It has an optimized dimension of $w_{ms} = 0.35$ mm, $l_{ms} = 10$ mm, $w_{tr} = 0.$ m3m, $l_{tr} = 2.4$ mm, $w = 2.35$, $l = 8.55$ mm, $d = 0.4$ mm, $s = 0.5$ mm, $D = 2$ mm, $h = 0.7$ mm, $x_{slot} = 1.0 \pm 0.02$ mm, $z_{slot} = 2.75$ mm, $w_{slot} = 0.2$ mm, $l_{slot} = 2.0$ mm, $h_g = 15 \pm 5$ μm, and $t = 5$mil. Figure 36 shows the fabricated prototypes of the DRA samples.

The simulated and measured reflection coefficients of the linearly polarized DRA are shown in Fig. 37. Three resonances ($HEM_{11\delta}$ and slot modes) are clearly seen in the figure. It has a measured bandwidth of 24 %, which is slightly narrower than its simulated counterpart of 25 %. Figure 38 shows the simulated and measured antenna gains of the linearly polarized DRA, which are greater than 5.5 dBi in the frequency

range of 49–62 GHz. Broadside radiation pattern is observed at 55 GHz, as can be seen in Fig. 39, which is expected for the HEM and slot modes. An antenna gain of ∼5 dBi is obtained in the boresight direction ($\theta = 0°$). Figure 40 is the simulated and measured reflection coefficients of the circularly polarized DRA. The impedance matching has achieved its optimum point around ∼ 60 GHz, achieving a wide 10-dB impedance bandwidth of 2.7 GHz (4.5 %). The axial ratio in Fig. 41 shows that the CP antenna has a 3-dB AX bandwidth of 4.0 %, covering 58.6–61.0 GHz. Figure 42 shows the radiation patterns in the *xy*- and *yz*-planes at 59.4 GHz. The 3-dB beamwidth is 99° in the *xy*-plane and 81° in the *yz*-plane.

Most studies on the millimeter-wave DRAs mainly focus on the fundamental modes (Keller et al. 1998; Lai et al. 2008; Svedin et al. 2007; Wahab et al. 2009). For example, a rectangular DRA with a dielectric constant of $\varepsilon_r = 9.8$ has a dimension of 1.91 mm, 0.635 mm, and 1.91 mm at 40 GHz. It is not easy to fabricate the DRA precisely when the antenna size becomes very small, making such antenna structure

difficult to be realized at millimeter-wave frequencies. The use of the higher-order modes of the DRA has been proven to be useful for relaxing the precision problem in the fabrication of the DRA samples at high frequencies (Petosa et al. 2009, 2011; Pan et al. 2011; Hou et al. 2014).

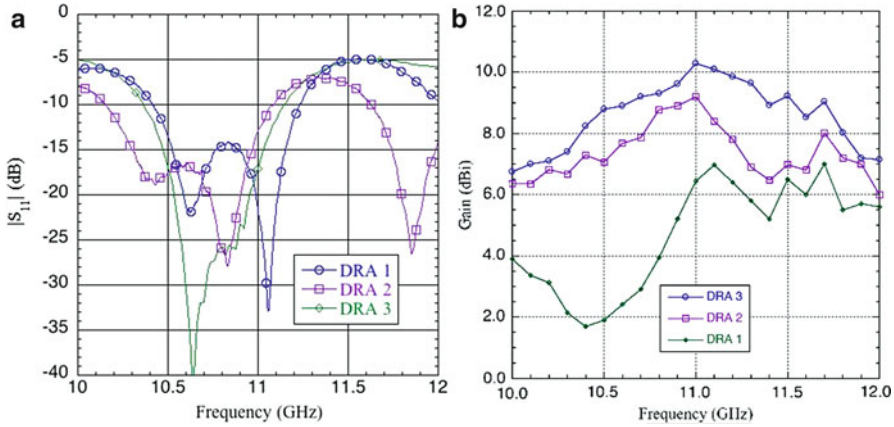

Fig. 43 (**a**) Reflection coefficients and (**b**) antenna gains of DRA1, DRA2, and DRA3 (From Petosa and Thirakoune (2011), copyright @ 2011 IEEE, with permission)

$d = 30$ mm) are studied in (Petosa et al. 2009; Petosa and Thirakoune 2011), where the higher-order $TE_{\delta 11}$, $TE_{\delta 13}$, and $TE_{\delta 15}$ modes are excited in the rectangular DRA1, DRA2, and DRA3, respectively. The measured reflection coefficients and antenna gains are depicted in Fig. 43. At 11 GHz, the respective antenna gains are found to be 5.5, 8.2, and 10.2 dBi. This work has shown that the rectangular DRA is able to provide higher antenna gain with the excitation of the higher-order modes. Figure 44a shows the magnetic field distribution of the $TE_{\delta 15}$ mode, which can be represented by a couple of equivalent magnetic dipoles, as shown in Fig. 44b. In this case, image theory is applied to remove the ground plane. Due to the existence of the ground plane, only odd modes are excitable. Even modes are not possible as they are short-circuited by the ground. The separation between the magnetic dipoles is determined by the dimension of the DRA. It can affect the antenna gain, beamwidth, and sidelobe directly. All of the DRA1, DRA2, and DRA3 are radiating in the broadside. Figure 45 shows the measured and simulated radiation pattern of the $TE_{\delta 13}$ mode, whose beamwidth is narrower than that for the $TE_{\delta 11}$ mode but broader than for the $TE_{\delta 15}$.

The properties of the higher-order TE^{y}_{pqr} modes of the DRA are further explored in (Pan et al. 2011) at the resonant frequency of 24 GHz. Again, the antenna structure shown in Fig. 31 is used for the design.

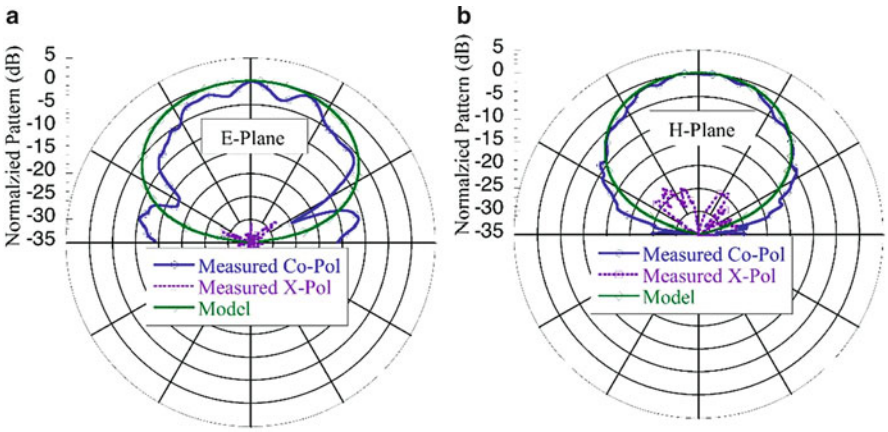

Fig. 45 Radiation patterns for the $TE_{\delta 13}$ mode. (**a**) *E*-plane. (**b**) *H*-plane

A *y*-directed slot is etched underneath the DRA for exciting it. For an aperture-fed rectangular DRA that is placed on a ground plane, it has been proven that the indices *p*, *q*, *r* have to be odd numbers. Figure 46 shows the reflection coefficient of an aperture-fed rectangular DRA with the design parameters of $a = 4.8$ mm, $b = 6.4$ mm, $d = 3$ mm, $\varepsilon_r = 10$, $W = 0.5$ mm, $L = 2.8$ mm, $W_m = 0.78$ mm, and $L_s = 2.6$ mm. Obviously, only odd modes are excitable. Resonant modes with even indices (TE^y_{211}, TE^y_{121}, TE^y_{112}) are not seen in the figure. Microstrip feed line has been used because it can be designed and fabricated easily. Coplanar waveguide and dielectric image guide can be used if the operating frequency goes higher.

The characteristics of the higher-order TE^y_{115} and TE^y_{119} modes are now studied (Pan et al. 2011). The optimized dimension for the DRA with the TE^y_{115} mode is $a = b = 4.0$ mm, $d = 6.1$ mm, $\varepsilon_r = 10$, $W = 0.5$ mm, $L = 2.2$ mm, $W_m = 0.78$ mm, and $L_s = 1.4$ mm, while the optimized dimension for the DRA with the TE^y_{119} mode is $a = b = 4.2$ mm, $d = 10.7$ mm, $\varepsilon_r = 10$, $W = 0.5$ mm, $L = 1.8$ mm,

$W_m = 0.78$ mm, and $L_s = 0.9$ mm. It can be observed from the reflection coefficients in Fig. 47 that the resonant frequencies are measured to be 23.86 and 23.87 GHz, respectively, for the TE^{y}_{115} and TE^{y}_{119} modes. The corresponding 10-dB bandwidths are 5.39 % (covering 23.30–24.59 GHz) and 3.87 % (23.58–24.51 GHz). Figure 48 shows the simulated and measured antenna gains of the DRAs,

DOI 10.1007/978-981-4560-75-7_35-1

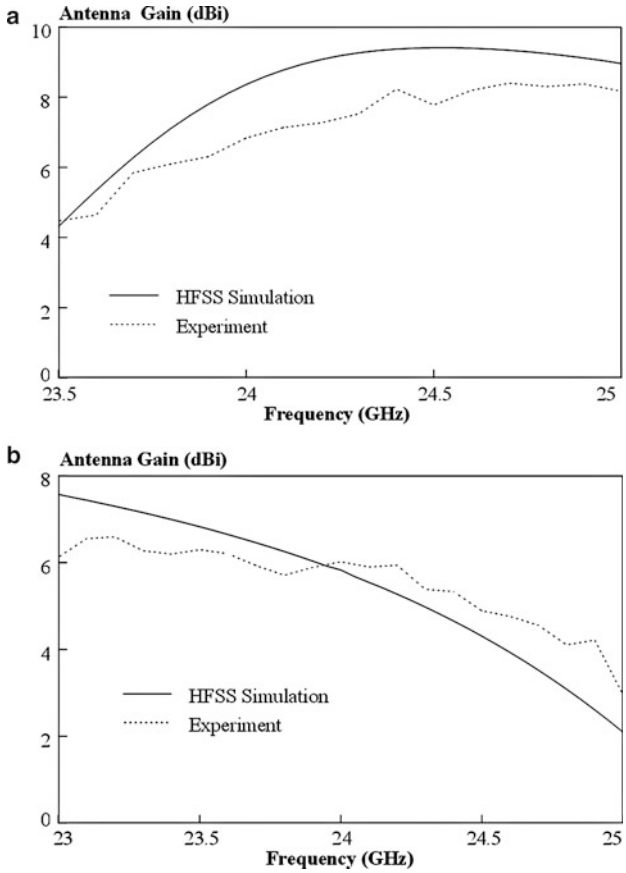

Fig. 48 Simulated and measured antenna gains of the DRAs excited in the (**a**) TE^{y}_{115} mode and (**b**) TE^{y}_{119} mode

which are ~5.8 dBi (TE^{y}_{115} mode) and ~6.3 dBi (TE^{y}_{119} mode) at around 24 GHz. Higher gain is observed in the latter. It should be mentioned that the beamwidth, sidelobe, and antenna gain of a higher-order mode can change with the DRA dimension. It can be seen from the measured and simulated radiation patterns in Fig. 49 that the higher-order modes are radiating into the boresight direction, as expected. For both of the E (xz-plane) and H (yz-plane) planes, the co-polarized fields are stronger than their cross-polarized counterparts by at least 20 dB.

Miniature DRAs can be combined with various integrated circuits (IC) for achieving compact footprint. Integrating an antenna directly on the RF circuit eliminates the use of interconnects, which may improve signal loss at high frequencies, especially in the millimeter-wave ranges. For a silicon-integrated antenna, the substrate conductivity is the most crucial parameter that decides its radiation efficiency. In (Hou et al. 2014), an on-chip DRA is integrated with a half-mode SIW cavity for the excitation of the higher-order $TE^{x}_{\delta 13}$ and $TE^{x}_{\delta 15}$ modes at the frequency of 135 GHz. Figure 50 shows the configuration of the on-chip DRA, and Fig. 51a shows the feeding half-mode SIW cavity. For comparison, the configuration of a standard full-mode SIW cavity is also depicted in Fig. 51b. It can be seen from the figures that the half-mode SIW cavity has the same resonance mode as the full-mode one. The entire structure is fabricated using the standard 0.18 μm CMOS technology. A DRA with a dimension of $a \times b \times h$ is directly placed on an aperture that is made on top of the feeding structure. Other design parameters are given here: $w = 10$ μm, $t = 300$ μm, $d = 100$ μm, $d_1 = 210$ μm, $d_2 = 160$ μm, $s = 30$ μm, $l = 750$ μm, $l_1 = 800$ μm, $th = 10$ μm, and $h_1 = 6.6$ μm. For the DRA that is working at the $TE^{x}_{\delta 13}$

mode, it has an optimized dimension of $a = 650$ μm, $b = 380$ μm, $h = 1300$ μm, and $d_3 = 140$ μm. The DRA that operates at the $TE^x_{\delta 15}$ mode has a dimension of of $a = 650$ μm, $b = 380$ μm, $h = 2200$ μm, and $d_3 = 140$ μm. The photographs of the DRA and its feeding structure are illustrated in Fig. 52. Two samples have been fabricated. The simulated and measured reflection coefficients for the $TE^x_{\delta 15}$ case are shown in Fig. 53. It has an antenna bandwidth of 8 %. With reference to (Hou et al. 2014), the simulated radiation efficiency and antenna gain are 42 % and 7.6 dBi, respectively. It is clear that the main challenge of the silicon antenna is always its low radiation efficiency.

Conclusion

In the first part of this chapter, the recent developments of the miniature DRA are discussed. Miniature DRAs that are designed by integrating the DRA with different power dividers are studied. It is found that the DRA can be integrated with a hybrid coupler for making a wideband CP antenna. When integrated with the rat-race coupler, a differential DRA can be easily obtained. In the second part, ground miniaturization technique has been explored for reducing the footprint of the DRA. Case studies are presented to show the design processes of the omnidirectional CP DRA and the quasi-isotropic DRA, with minimum ground area. Finally, the application of the DRA is explored for millimeter-wave ranges using different feeding methods. Higher-order modes of the DRA are found to be useful for relaxing the fabrication tolerances at millimeter-wave frequencies.

Abstract

This chapter is focused on circularly polarized antennas. Key definitions and governing equations of circular polarization are given. Infinitesimal dipole sources are considered to establish circularly polarized radiation. First, radiation patterns of cross dipoles are mathematically reviewed, from which the condition of circularly polarized waves is concluded. Later, the idea is extended to four displaced sequentially rotated dipole antennas, resulting in circularly polarized waves within a wide angular range in space. The extension of the concept to the magnetic source counterparts and Huygens sources is briefly discussed. Other than point sources, also known as one-dimensional current sources, sources of circularly polarized radiation are further investigated for two-dimensional cases, such as microstrip patch antennas, and three-dimensional structures, such as volumetric current sources existing in dielectric resonator antennas. For these cases, the creation of circularly polarized radiation using single-feed and dual-feed, perturbed structures and sequentially rotated method is described. As a design example, numerical and measurement results of circularly polarized square patch ring antennas are extensively discussed and presented in this chapter. The square-ring microstrip antenna is selected as it closely approximates the sequentially rotated currents, and also it has not been widely studied in the literature.

Keywords

Circular polarization; Antennas; Electric and magnetic sources; Sequential rotation technique; Axial ratio; Two- and three-dimensional current sources; Microstrip patches; Dielectric resonator antennas; Square-ring patch antennas

Introduction

This chapter presents circularly polarized antennas. Initially, circular polarization and its related field vectors, in both rectangular and spherical coordinate systems, are defined and presented in section "Basic Formulas and Definitions." Traditionally, circular polarization is defined in rectangular coordinates. However, antenna far-field radiation components are best described in spherical coordinates and are more natural for antenna applications. Thus, spherical components are used in this chapter for subsequent presentations. Following this section, the source concept is introduced, and elementary electric dipoles are used to develop the fundamental expressions for radiated field of electric-type sources. The results are used for determining the conditions for circular polarization. By way of these elementary sources, the quality of circular polarization is studied and compared, using the axial ratio of the polarization vector. Hybrid electric and magnetic sources are also presented and discussed. Next, the results are used to present practical circularly polarized antenna types with two-dimensional and three-dimensional current

DOI 10.1007/978-981-4560-75-7_36-1

distributions, using microstrip and dielectric resonator-type antennas, respectively. Finally, the case of a microstrip square-ring antenna is selected, as the most general radiation source, and studied in detail. A parametric study is conducted to relate the quality of circular polarization to the antenna dimensions and the substrate permittivity. Methods for improving the antenna impedance and axial ratio beamwidths are also studied and presented.

Basic Formulas and Definitions

Polarization of electromagnetic (EM) waves is simply specified by the behavior of the instantaneous electric fields in the time-space domain (Kraus 1988; Stutzman 1993). The tip of the electric field vector, as traveling along the direction of the propagation in time, leaves a spatial trace or footprint, which is called polarization. If the resultant trace is a line, the polarization is linear, which is the simplest case to visualize the polarization concept. The most general form of the aforementioned spatial trace is an ellipse, which defines the elliptical polarization. Under a special condition, where the axial ratio of the ellipse, i.e., the ratio of the major to minor axes, becomes unity, the polarization is circular, which is the main focus of this chapter. Mathematically, linear polarization is also a special case of elliptic polarization, when the axial ratio becomes infinity.

In antenna engineering, the polarization is determined by that of the radiated EM waves, and it plays an important role, as the polarization of transmit and receive antennas in any wireless communication must be matched in order to maximize the reception. For example, the reception of two orthogonally polarized antennas, such as vertical and horizontal dipoles, is zero. In order to attain a maximum signal in the receiver, the orientation of the dipoles must be parallel in either of the wireless-link terminals. Other than the loss due to the antenna misalignments, the Faraday rotation loss (Brookner et al. 1985) and the multipath interference loss (Counselman 1999) are inevitable, when a linear polarization is used for the wireless channel. The latter raises the noise floor of the system due to the detrimental summation of the unwanted received signals from multiple paths. The former is associated with the EM wave propagation in the Earth's ionosphere. Interestingly enough, the circular polarization (CP) can overcome all of these deleterious effects. This explains why CP antennas are in great demand in satellite communications, radars, and Global Positioning Systems.

Antennas radiate EM waves into the far-field zone, where they can locally be considered as plane waves containing only transverse fields, which are normal to the propagation direction. Generally, these waves can be decomposed into two orthogonal components. Assuming the plane waves propagate along the $+z$-axis and the time-harmonic term is $e^{j\omega t}$; the corresponding instantaneous electric field can be expressed in terms of x- and y-components as follows (Stutzman 1993):

$$\vec{E}\ (t,z) = E_x(t,z)\hat{x} + E_y(t,z)\hat{y} \tag{1}$$

where E_x and E_y are given by

$$E_x(t,z)\ = e_x \cos(\omega t - kz) \tag{2}$$

$$E_y(t,z)\ = e_y \cos(\omega t - kz + \delta) \tag{3}$$

where ω, k, and δ are the angular frequency, wave number, and the phase shift of the E_y component with respect to the E_x, respectively. Also, e_x and e_y are real numbers, representing the amplitudes of the x- and

DOI 10.1007/978-981-4560-75-7_36-1

y-components of the instantaneous electric fields. After substituting Eqs. 2 and 3 into Eq. 1 and enforcing z to zero for simplicity, one can write

$$\vec{E}(t) = e_x \cos \omega t \hat{x} + e_y \cos(\omega t + \delta)\hat{y} \tag{4}$$

In general, the tip of the above electric field, expressed by Eq. 4, forms an elliptical trace over a full period of 1/f, where f is the frequency. This is the most generalized case of EM polarization. Now, let us consider the special cases. If the phase shift between the decomposed electric field components is nπ, i.e., $\delta = n\pi$, where n = 0, 1, 2, . . ., the total electric field vector is expressed as

$$\vec{E}(t) = \cos \omega t \left(e_x \hat{x} \pm e_y \hat{y}\right) \tag{5}$$

which represents linear polarization.

The polarization is circular, when there is a quadrature phase shift between the y- and x-components of electric fields, i.e., $\delta = \pm(n + 0.5)\pi$, where n = 0, 1, 2, . . . and the magnitudes of them are equal, i.e., $e_x = e_y$. Thus, the corresponding total electric field vector traces a circle over a full oscillation period, and it is expressed as

$$\vec{E}(t) = e_x (\hat{x} \pm j\hat{y}) \tag{6}$$

Therefore, two orthogonal waves, which are 90° apart both spatially and electrically, with equal amplitudes, are required to create CP waves.

Since the focus of this chapter is on CP antennas, it is instructive to express the antenna polarization characterizations in terms of the spherical components of electric fields at the far-field region. First, let us define the senses of CP polarization. Based on the IEEE standard (IEEE Standard 1979), the sense of the polarization is determined by that of the rotation of the electric field tip forming the circle or the ellipse. It is right-handed (RH) if the electric field rotates clockwise, when one looks in the direction of the propagation. Similarly, it is left-handed (LH) if the rotation is counterclockwise (IEEE Standard 1979). Mathematically, based on Eq. 4, the RHCP and LHCP waves are realized when δ is equal to −90° and +90°, respectively. The far-field electric field can be expressed in terms of the spherical components as

$$\vec{E} = E_\theta \hat{\theta} + E_\phi \hat{\phi} \tag{7}$$

Thus, it can also be decomposed in terms of the RHCP and LHCP waves as (Milligan 2005)

$$\vec{E} = E_R \hat{a}_R + E_L \hat{a}_L \tag{8}$$

where $\hat{a}_R$ and $\hat{a}_L$ are the unit vectors of the RHCP and LHCL vectors. They are orthogonal to each other and expressed by

$$\begin{cases} \hat{a}_R = \dfrac{1}{\sqrt{2}}\left(\hat{a}_\theta - j\hat{a}_\phi\right) \\ \hat{a}_\mathrm{L} = \dfrac{1}{\sqrt{2}}\left(\hat{a}_\theta + j\hat{a}_\phi\right) \end{cases} \tag{9}$$

DOI 10.1007/978-981-4560-75-7_36-1

Then, E_R and E_L are simply obtained by projecting the electric field of Eq. 7 into the above unit vectors. That is, the inner product of Eq. 7 with the complex conjugate of either unit vectors given by Eq. 9. They are therefore expressed by

$$\begin{cases} E_R = \dfrac{1}{\sqrt{2}}\left(E_\theta + jE_\phi\right) \\ E_{\mathbf{L}} = \dfrac{1}{\sqrt{2}}\left(E_\theta - jE_\phi\right) \end{cases} \tag{10}$$

The axial ratio, denoted by AR, specifies the purity of the CP waves and is the ratio of the major axis to the minor axis of the polarization ellipse. The major and minor axes are maximum and minimum of the electric field, respectively, expressed by (Hollis et al. 1969)

$$E_{\max} = \frac{1}{\sqrt{2}}\left(|E_R| + |E_L|\right) \tag{11}$$

$$E_{\min} = \begin{cases} \dfrac{1}{\sqrt{2}}\left(|E_R| - |E_L|\right), & \text{RHCP} \\ \dfrac{1}{\sqrt{2}}\left(|E_L| - |E_R|\right), & \text{LHCP} \end{cases} \tag{12}$$

In antenna applications, the axial ratio is given in dB by the following expression:

$$AR(dB) = 20\log\left(\frac{E_{\max}}{E_{\min}}\right) \tag{13}$$

Therefore, a 0 dB axial ratio demonstrates pure CP field.

So far, a brief introduction on the circular polarization is provided. More in-depth material on the subject may be found in (Stutzman 1993; Hollis et al. 1969) for interested readers. The rest of the chapter deals with circularly polarized antennas. In particular, different techniques will be discussed to realize CP fields mainly using dipole, microstrip patch, and dielectric resonator antennas.

Sources of Circularly Polarized Radiation

The previous section provided the key definitions and fundamental field vectors that govern the circular polarization. In this section, the basic electric current sources that can radiate circularly polarized fields are presented. The magnetic current sources can similarly be defined and studied. However, their corresponding radiated field expressions can be easily inferred from the duality principle and using the results of the electric current sources. A unique case is the combination of both electric and magnetic sources, and for this reason, it is also presented and discussed. Apertures and slots are typical sources of equivalent magnetic currents. However, they radiate in the presence of the object they are located on. Other nonconducting sources, such as dielectric resonators, resemble the electric fields more closely and are thus more realistic magnetic sources.

Considering the electric current sources, different arrangements of the sources are considered and studied. The simplest case of two infinitesimal dipoles is first investigated, and then, it is generalized to two finite-sized electric currents. Subsequently, the case of four displaced electric currents is discussed,

DOI 10.1007/978-981-4560-75-7_36-1

and the concept of sequential rotation for improving the quality of circular polarization is introduced, by investigating the axial ratio of the radiated field. In each case, the magnetic vector potentials are derived and used to determine the field vectors. Since the circular polarization is normally defined and used in the far-field regions, only far-field vectors are determined and discussed.

Case I: Two Collocated Infinitesimal Electric Dipoles

Figure 1 shows the geometry of two orthogonal electric dipoles, along *x*- and *y*-axes. Their current vectors are

$$\boldsymbol{I}_1 = I_1 \hat{\boldsymbol{a}}_x \tag{14}$$

$$\boldsymbol{I}_2 = I_2 \hat{\boldsymbol{a}}_y \tag{15}$$

These sources are infinitesimal dipoles, and their magnetic vector potentials are given by

$$\boldsymbol{A}_1 = \frac{\mu I_1 \ell_1}{4\pi} \frac{e^{-jkr}}{r} \hat{\boldsymbol{a}}_x \quad \ell_1 << \lambda \tag{16}$$

$$\boldsymbol{A}_2 = \frac{\mu I_2 \ell_2}{4\pi} \frac{e^{-jkr}}{r} \hat{\boldsymbol{a}}_y \quad \ell_2 << \lambda \tag{17}$$

And at far-field zone, their radiated electric fields are

$$\boldsymbol{E}_1 = -j\omega \boldsymbol{A}_1 = \frac{-jk\eta I_1 \ell_1}{4\pi} \frac{e^{-jkr}}{r} \hat{\boldsymbol{a}}_x \quad r >> \lambda \tag{18}$$

$$\boldsymbol{E}_2 = -j\omega \boldsymbol{A}_2 = \frac{-jk\eta I_2 \ell_2}{4\pi} \frac{e^{-jkr}}{r} \hat{\boldsymbol{a}}_y \quad r >> \lambda \tag{19}$$

The total electric field then is

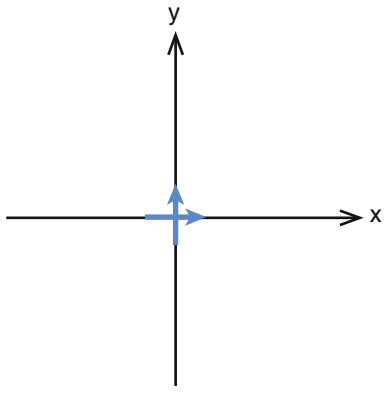

Fig. 1 Geometry of two orthogonal collocated electric dipoles, along *x*- and *y*-axes

DOI 10.1007/978-981-4560-75-7_36-1

$$\boldsymbol{E} = \boldsymbol{E}_1 + \boldsymbol{E}_2 = -\frac{jk\eta}{4\pi}\frac{e^{-jkr}}{r}\left[I_1\ell_1\hat{\boldsymbol{a}}_x + I_2\ell_2\hat{\boldsymbol{a}}_y\right] \tag{20}$$

Thus, from Eq. 6, the condition for circular polarization is

$$\begin{cases} |I_1\ell_1| = |I_2\ell_2| \ = I_o\ell \\ \angle I_1\ell_1 - \angle I_2\ell_2 = \pm\dfrac{\pi}{2} \end{cases} \tag{21}$$

Giving

$$E = -\frac{jk\eta I_o\ell}{4\pi}\frac{e^{-jkr}}{r}\left(\hat{a}_x \pm j\hat{a}_y\right) \tag{22}$$

One can also show that for two collocated magnetic dipoles, the condition for circular polarization is the same. That is,

> Two collocated orthogonal electric, or magnetic, dipoles will radiate a circularly polarized wave, if their magnitudes are equal, and their phase difference is ±90°. The phase difference of the field vectors remains the same as the source currents.

Since the radiation vectors are tangent to the radiation sphere, it is important to determine the circularly polarized vectors in spherical coordinates. They can be found from

$$\begin{aligned} \hat{\boldsymbol{a}}_x &= \hat{\boldsymbol{a}}_r \sin\theta\cos\phi + \hat{\boldsymbol{a}}_\theta \cos\theta\cos\phi - \hat{\boldsymbol{a}}_\phi \sin\phi \\ \hat{\boldsymbol{a}}_y &= \hat{\boldsymbol{a}}_r \sin\theta\sin\phi + \hat{\boldsymbol{a}}_\theta \cos\theta\sin\phi + \hat{\boldsymbol{a}}_\phi \cos\phi \end{aligned} \tag{23}$$

On the radiation sphere the radial component is zero, and thus the total electric field vector of Eq. 22 can be expressed as

$$E = -jk\eta\frac{I_o\ell}{4\pi}\frac{e^{-jkr}}{r}e^{\pm j\phi}\left(\cos\theta\,\hat{a}_\theta \pm j\hat{a}_\phi\right) \tag{24}$$

The RHCP and LHCP components can be found from Eq. 10 as

$$\begin{cases} E_R = \dfrac{1}{\sqrt{2}}\left(-jk\eta\dfrac{I_o\ell}{4\pi}\dfrac{e^{-jkr}}{r}\right)e^{\pm j\phi}(\cos\theta \mp 1) \\ E_L = \dfrac{1}{\sqrt{2}}\left(-jk\eta\dfrac{I_o\ell}{4\pi}\dfrac{e^{-jkr}}{r}\right)e^{\pm j\phi}(\cos\theta \pm 1) \end{cases} \tag{25}$$

Assume $l_1 = l_2 = l$; the resulting radiation will be RHCP if $I_2 = -jI_1$ and LHCP when $I_2 = +jI_1$. That is, when $I_2 = -jI_1$

$$\begin{cases} E_R = \frac{1}{\sqrt{2}}\left(-jk\eta\dfrac{I_o\ell}{4\pi}\dfrac{e^{-jkr}}{r}\right)e^{-j\phi}(\cos\theta\ + 1)\Big|_{\theta=0} \to \max \ \text{RHCP} \\ E_L = \frac{1}{\sqrt{2}}\left(-jk\eta\dfrac{I_o\ell}{4\pi}\dfrac{e^{-jkr}}{r}\right)e^{-j\phi}(\cos\theta\ - 1)\Big|_{\theta=0} = 0 \end{cases} \tag{26}$$

DOI 10.1007/978-981-4560-75-7_36-1

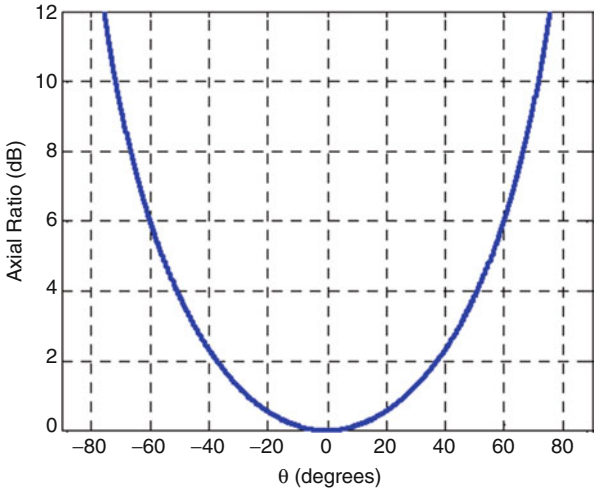

Fig. 2 Variation of AR as a function of θ, for two orthogonal crossed electric dipoles, with a phase difference of 90°

And for $I_2 = +jI_1$

$$\begin{cases} E_R = \frac{1}{\sqrt{2}}\left(-jk\eta\frac{I_o\ell}{4\pi}\frac{e^{-jkr}}{r}\right)e^{+j\phi}(\cos\theta\ -1)\Big|_{\theta=0} = 0 \\ E_L = \frac{1}{\sqrt{2}}\left(-jk\eta\frac{I_o\ell}{4\pi}\frac{e^{-jkr}}{r}\right)e^{+j\phi}(\cos\theta\ +1)\Big|_{\theta=0} \rightarrow \max\ \ \text{LHCP} \end{cases} \tag{27}$$

Thus, using Eq. 13, it becomes evident that a perfect circular polarization occurs only on the z-axis, where $\theta = 0$ with $AR = 1$ (0 dB). Away from the z-axis the axial ratio becomes

$$AR = \frac{|E_R| + |E_L|}{|E_R| - |E_L|} = \frac{|\cos\theta + 1| + |\cos\theta - 1|}{|\cos\theta + 1| - |\cos\theta - 1|} \tag{28}$$

Figure 2 shows a plot of the AR as a function of θ, the angle off the z-axis.

Case II: Two Finite Orthogonal Electric Currents

Figure 3 shows two orthogonal electric currents, along the x- and y-axes and centered at the origin. Their current distributions are assumed to be sinusoidal. For the x-oriented dipole, it can be written in the following form:

$$\begin{aligned} \boldsymbol{I}_x &= \hat{\boldsymbol{a}}_x I_0 \sin\left[k\left(\frac{\ell}{2} - x\right)\right] \quad 0 \le x \le \frac{\ell}{2} \\ &= \hat{\boldsymbol{a}}_x I_0 \sin\left[k\left(\frac{\ell}{2} + x\right)\right] \quad -\frac{\ell}{2} \le x \le 0 \end{aligned} \tag{29}$$

For the x-directed dipole, the magnetic vector potential is given by

DOI 10.1007/978-981-4560-75-7_36-1

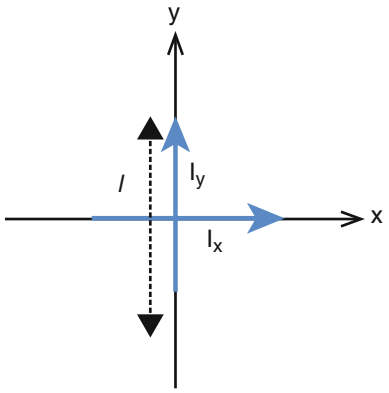

Fig. 3 Geometry of two orthogonal sinusoidal electric currents of finite lengths, centered at origin

$$A_x = \frac{\mu I_0}{4\pi}\frac{e^{-jkr}}{r}\left\{\int_{-\frac{\ell}{2}}^{0}\sin\left[k\left(\frac{\ell}{2}+x'\right)\right]e^{jkx'\,\sin\theta\,\cos\phi}\;dx' + \int_{0}^{-\frac{\ell}{2}}\sin\left[k\left(\frac{\ell}{2}-x'\right)\right]e^{jkx'\,\sin\theta\,\cos\phi}\;dx'\right. \tag{30}$$

After some manipulations one finds

$$A_x = \frac{\mu I_{o_x}}{2\pi k}\frac{e^{-jkr}}{r}\left[\frac{\cos\left(k\frac{\ell}{2}\,\sin\theta\,\cos\phi\right)-\cos\left(k\frac{\ell}{2}\right)}{1-\sin^2\theta\,\cos^2\phi}\right] = \frac{\mu I_{o_x}}{2\pi k}\frac{e^{-jkr}}{r}F_x \tag{31}$$

where F_x represents the angular-dependent function in Eq. 31 as

$$F_x = \frac{\cos\left(k\frac{\ell}{2}\,\sin\theta\,\cos\phi\right)-\cos\left(k\frac{\ell}{2}\right)}{1-\sin^2\theta\,\cos^2\phi} \tag{32}$$

Similarly for a finite-length dipole along the y-axis, the magnetic vector potential is expressed as

$$A_y = \frac{\mu I_{o_y}}{2\pi k}\frac{e^{-jkr}}{r}\left[\frac{\cos\left(k\frac{\ell}{2}\,\sin\theta\,\sin\phi\right)-\cos\left(k\frac{\ell}{2}\right)}{1-\sin^2\theta\,\sin^2\phi}\right] = \frac{\mu I_{o_y}}{2\pi k}\frac{e^{-jkr}}{r}F_y \tag{33}$$

where F_y is defined as

$$F_y = \frac{\cos\left(k\frac{\ell}{2}\,\sin\theta\,\sin\phi\right)-\cos\left(k\frac{\ell}{2}\right)}{1-\sin^2\theta\,\sin^2\phi} \tag{34}$$

and the far-field electric field vectors are

$$\begin{cases} E_x = -j\omega A_x \\ E_y = -j\omega A_y \end{cases} \tag{35}$$

Again the condition for circular polarization is

$$\begin{cases} |I_{o_x}| = |I_{o_y}| = I_o \\ \angle I_{o_x} - \angle I_{o_x} = \pm\dfrac{\pi}{2} \end{cases} \tag{36}$$

In terms of the spherical coordinate systems, the far-field electric field can be shown to be

$$\begin{cases} E_\theta = E_x \cos\theta \cos\phi + E_y \cos\theta \sin\phi \\ E_\phi = -E_x \sin\phi + E_y \cos\phi \end{cases} \tag{37}$$

After substituting Eqs. 31, 32, 33, 34, 35, and 36 into Eq. 37, the total electric field can be expressed as

$$E = -j\frac{\eta I_o}{2\pi}\frac{e^{-jkr}}{r}\left[\cos\theta\left(F_x \cos\phi \pm jF_y \sin\phi\right)\hat{a}_\theta \pm j\left(F_y \cos\phi \pm jF_x \sin\phi\right)\hat{a}_\phi\right] \tag{38}$$

which on the z-axis, i.e., $\theta = 0$, it is simplified to

$$E = -j\frac{\eta I_o}{2\pi}\frac{e^{-jkr}}{r}e^{\pm j\phi}\left[1 - \cos\left(k\frac{\ell}{2}\right)\right]\left[\hat{a}_\theta \pm j\hat{a}_\phi\right] \tag{39}$$

From Eq. 10, the corresponding circularly polarized vectors will have the following forms

$$\begin{cases} E_R = \dfrac{1}{\sqrt{2}}\left(-j\eta\dfrac{I_o}{2\pi}\dfrac{e^{-jkr}}{r}\right)e^{\pm j\phi}\left[\cos\theta\left(F_x \cos\phi \pm jF_y \sin\phi\right) \mp \left(F_y \cos\phi \pm jF_x \sin\phi\right)\right] \\ E_L = \dfrac{1}{\sqrt{2}}\left(-j\eta\dfrac{I_o}{2\pi}\dfrac{e^{-jkr}}{r}\right)e^{\pm j\phi}\left[\cos\theta\left(F_x \cos\phi \pm jF_y \sin\phi\right) \pm \left(F_y \cos\phi \pm jF_x \sin\phi\right)\right] \end{cases} \tag{40}$$

and the axial ratio can be calculated from Eq. 13. Figure 4 shows the effect of electric current length l on the axial ratio. The 3 dB axial ratio beamwidths are plotted in Fig. 5 against the dipole length. The beamwidth becomes narrower, as the dipole enlarges in length.

Case III: Four Displaced Sequentially Rotated Electric Dipole Sources

In this section, electric current sources displaced from the origin are considered. There are two possibilities in this case: Case IIIa when dipole currents are normal to the axes at their locations and Case IIIb when dipole currents are along the axes. Figure 6 shows Case IIIa, where four dipoles are located normal to x- and y-coordinate axes at their locations, and their parameters are given as

$$\begin{aligned} \boldsymbol{I}_1 &= \boldsymbol{I}_1\hat{\boldsymbol{a}}_y \\ \boldsymbol{I}_2 &= \boldsymbol{I}_2\left(-\hat{\boldsymbol{a}}_x\right) \\ \boldsymbol{I}_3 &= \boldsymbol{I}_3\left(-\hat{\boldsymbol{a}}_y\right) \\ \boldsymbol{I}_4 &= \boldsymbol{I}_4\hat{\boldsymbol{a}}_x \end{aligned} \tag{41}$$

DOI 10.1007/978-981-4560-75-7_36-1

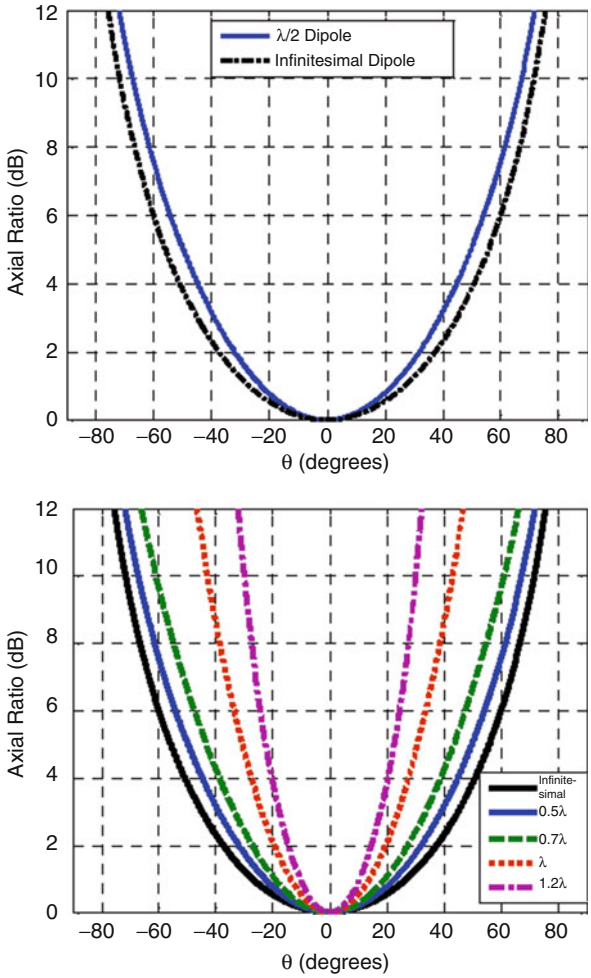

Fig. 4 Effect of electric current length on the axial ratio of two crossed dipoles of finite lengths

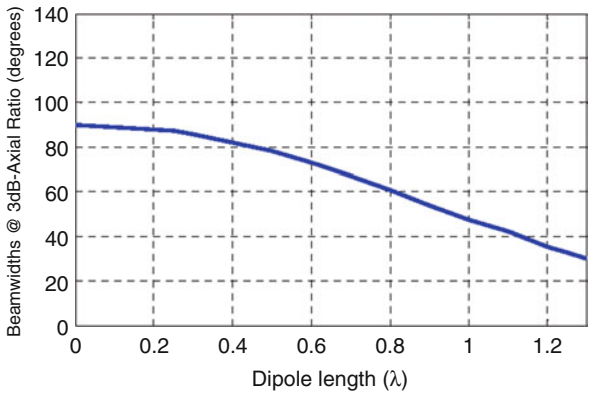

Fig. 5 Beamwidths of 3 dB *AR* of two crossed dipoles of finite lengths with sinusoidal current distributions

DOI 10.1007/978-981-4560-75-7_36-1

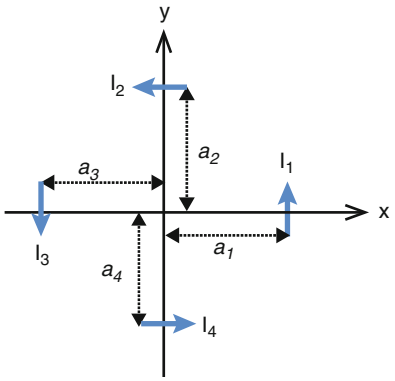

Fig. 6 Geometry of Case IIIa, four electric dipoles perpendicular to *x*- and *y*-axes at their locations

Their corresponding far zone electric fields are

$$\begin{cases} E_1 = -jk\eta \dfrac{I_1\ell_1}{4\pi}\dfrac{e^{-jkr}}{r} e^{jka_1 \sin\theta \cos\phi}\hat{a}_y \\ E_2 = jk\eta \dfrac{I_2\ell_2}{4\pi}\dfrac{e^{-jkr}}{r} e^{jka_2 \sin\theta \sin\phi}\hat{a}_x \\ E_3 = jk\eta \dfrac{I_3\ell_3}{4\pi}\dfrac{e^{-jkr}}{r} e^{-jka_3 \sin\theta \cos\phi}\hat{a}_y \\ E_4 = -jk\eta \dfrac{I_4\ell_4}{4\pi}\dfrac{e^{-jkr}}{r} e^{-jka_4 \sin\theta \sin\phi}\hat{a}_x \end{cases} \tag{42}$$

Thus, the total electric field is given by

$$E = -jk\eta \frac{e^{-jkr}}{4\pi r}\left[\left(I_1\ell_1 e^{jka_1 \sin\theta \cos\phi} - I_3\ell_3 e^{-jka_3 \sin\theta \cos\phi}\right)\hat{a}_y - \left(I_2\ell_2 e^{jka_2 \sin\theta \sin\phi} - I_4\ell_4 e^{-jka_4 \sin\theta \sin\phi}\right)\hat{a}_x\right] \tag{43}$$

It is clear that for finite radiated field on the *z*-axis, one must have

$$\begin{cases} |I_1\ \ell_1| = |I_3\ \ell_3| = I_1\ell \\ |I_2\ \ell_2| = |I_4\ \ell_4| = I_2\ell \\ \angle I_3\ \ell_3 - \angle I_1\ \ell_1 = \pi \\ \angle I_4\ \ell_4 - \angle I_2\ \ell_2 = \pi \end{cases} \tag{44}$$

With these conditions and $a_1 = a_3$ and $a_2 = a_4$, the electric field becomes

$$E = -jk\eta\ell \frac{e^{-jkr}}{2\pi r}\left[-I_2 \cos\left(ka_2 \sin\theta \sin\phi\right)\hat{a}_x + I_1 \cos\left(ka_1 \sin\theta \cos\phi\right)\hat{a}_y\right] \tag{45}$$

For equally displaced dipole sources, i.e., $a_1 = a_2 = a_3 = a_4 = a$, the condition for circular polarization is

$$\begin{cases} |I_1| = |I_2| = I_o \\ \angle I_2 - \angle I_1 = \pm\dfrac{\pi}{2} \end{cases} \tag{46}$$

DOI 10.1007/978-981-4560-75-7_36-1

Combining the conditions of Eqs. 44 and 46, one can arrive at the condition

$$\angle I_1 = 0, \angle I_2 = \pm\frac{\pi}{2}, \angle I_3 = \pm\pi, \angle I_4 = \pm\frac{3\pi}{2} \tag{47}$$

The condition for circular polarization is:

For four equally displaced electric currents around the z-axis the phase progression for the currents must be 2π.

It can be shown that this condition holds for any number of current elements around the z-axis. That is, if there are n numbers of equally displaced currents around the z-axis, as long as the total phase progression is 2π, the radiated field will be circularly polarized. In the limit, when n approaches infinity, the current elements converge to an electric current loop, i.e., a loop antenna.

In terms of the spherical coordinates, one can find the electric field

$$E = -jk\eta I_o \ell \frac{e^{-jkr}}{2\pi r} \left\{ \begin{array}{l} \cos\theta[\cos(ka\sin\theta\cos\phi)\ \sin\phi \mp j\cos(ka\sin\theta\sin\phi)\cos\phi]\,\hat{a}_\theta \\ +[\cos(ka\sin\theta\cos\phi)\ \cos\phi \pm j\cos(ka\sin\theta\sin\phi)\ \sin\phi]\,\hat{a}_\phi \end{array} \right\} \tag{48}$$

On the z-axis it becomes

$$E = k\eta I_o \ell \frac{e^{-jkr}}{2\pi r} e^{\pm j\phi}\left[\,\hat{a}_\theta \pm j\,\hat{a}_\phi\right] \tag{49}$$

In general for off z-axis points, Eq. 48 can be expressed in terms of the array factor terms, due to the displaced radiating elements along the x- and y-axes. They are defined as

$$\left\{ \begin{array}{l} AF_x = \cos(ka\sin\theta\cos\phi) \\ AF_y = \cos(ka\sin\theta\sin\phi) \end{array} \right. \tag{50}$$

Thus, one can write

$$E = -jk\eta I_o \ell \frac{e^{-jkr}}{2\pi r}\left\{\cos\theta\left(AF_x\sin\phi \mp jAF_y\cos\phi\right)\hat{a}_\theta + \left(AF_x\cos\phi \pm jAF_y\sin\phi\right)\hat{a}_\phi\right\} \tag{51}$$

Axial ratios for different element spacing d, i.e., $d = 2a$, between the dipoles are shown below in Figs. 7 and 8. As the dipole spacing increases, initially, the axial ratio beamwidth increases. The best spacing appears to be around $d = 0.443\lambda$, where the 3 dB axial ratio beamwidth becomes about 170° and covers nearly the entire half space, except for an angular range near the plane of the dipoles. This sequentially rotated dipole arrangement, therefore, appears to be the best source arrangement for circular polarization. It is also easy to implement using microstrip patch or other planar antennas. However, the finite size of the patch antenna will influence the axial ratio results, but the configuration is still the optimum source for a broad axial ratio beamwidth. This sequentially rotated configuration is also known to give much wider input impedance bandwidths, for the array elements, than other patch arrangements (Teshirogi et al. 1985; Huang 1986).

For Case IIIb, the geometry of the sequentially rotated elements is illustrated in Fig. 9, where the tip of the current vector of each element points toward the coordinate origin, i.e., each element is parallel to its respective axis. Under the condition given by Eq. 44, the corresponding electric field can be expressed as

DOI 10.1007/978-981-4560-75-7_36-1

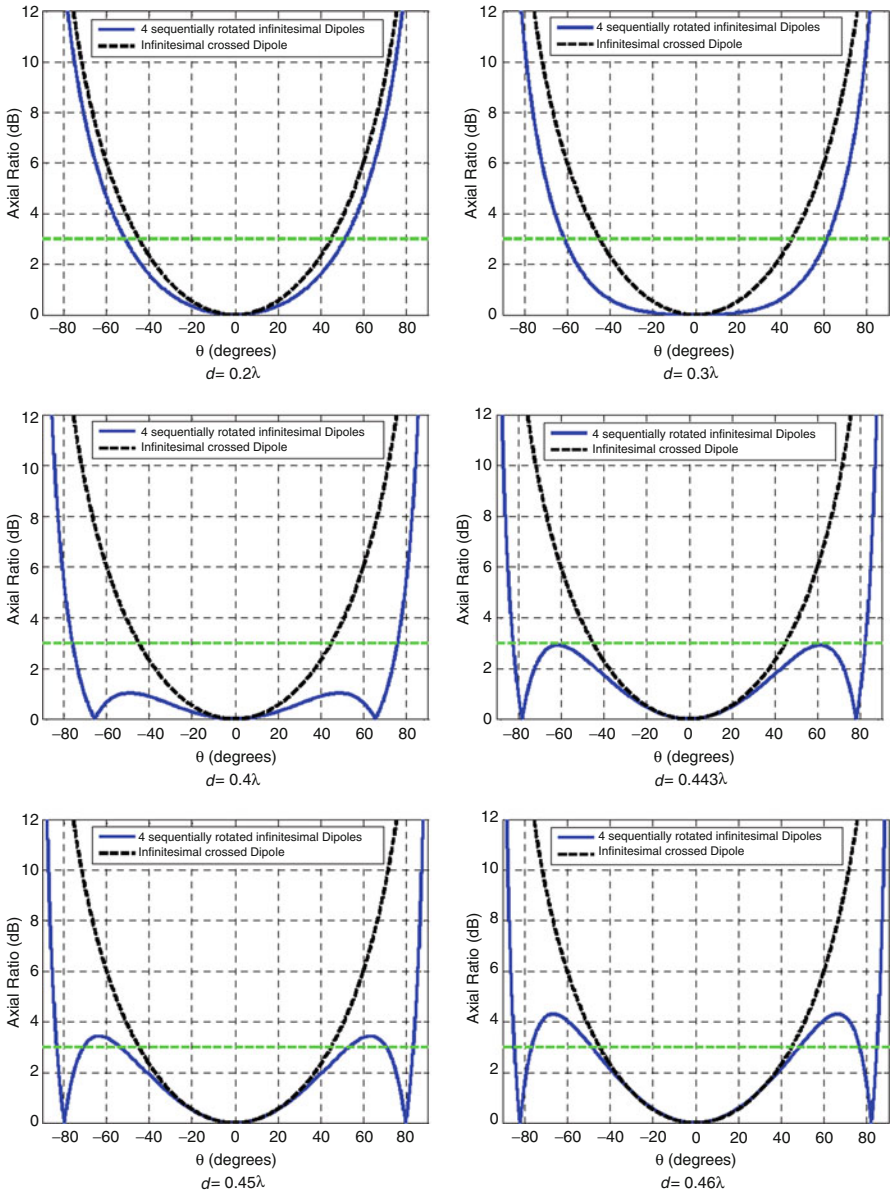

Fig. 7 *AR* of four sequentially rotated infinitesimal dipoles with different spacing, compared with crossed infinitesimal dipoles

$$E = jk\eta\ell \frac{e^{-jkr}}{2\pi r}\left[I_1 \cos\left(ka_1 \sin\theta \cos\phi\right)\hat{a}_x + I_2 \cos\left(ka_2 \sin\theta \cos\phi\right)\hat{a}_y\right] \tag{52}$$

Comparing the above equation with its counterpart electric field in Eq. 45, the magnitudes of the *x*- and *y*-components are swapped. The rest of the analysis can be carried out following Eqs. 46, 47, 48, 49, 50, and 51.

Case IV: Hybrid Electric and Magnetic Sources

An interesting antenna configuration is the combination of parallel electric and magnetic dipoles, collocated or adjacent. The far field of the electric dipole was provided earlier in Eqs. 16 and 24. The same can be generated similarly for a magnetic dipole, and in the spherical coordinate it is given by

DOI 10.1007/978-981-4560-75-7_36-1

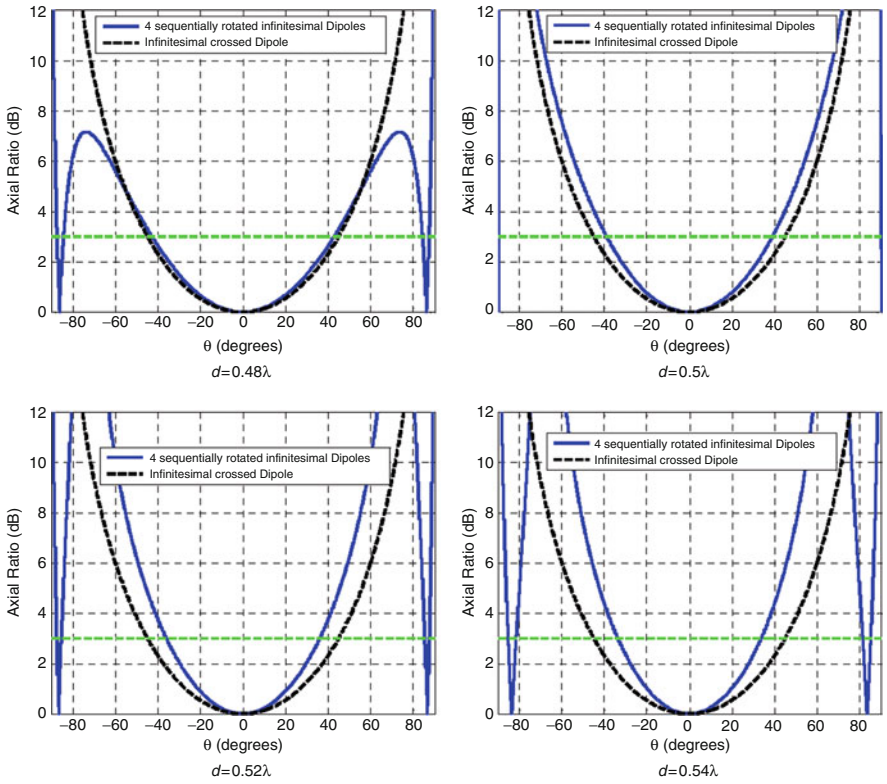

Fig. 8 *AR* of four sequentially rotated infinitesimal dipoles with different spacing, compared with crossed infinitesimal dipoles

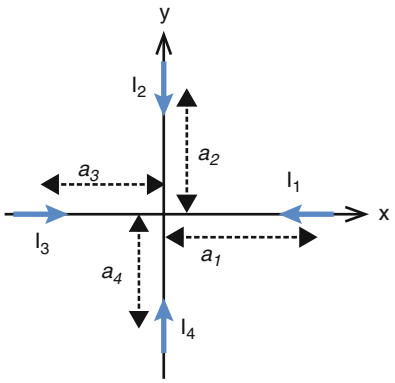

Fig. 9 Geometry of Case IIIb, four electric dipoles parallel to *x*- and *y*-axes, each element vector pointing toward the coordinate origin

$$\begin{aligned} \boldsymbol{I}^m &= \boldsymbol{I}^m\ \hat{\boldsymbol{a}}_x \\ \boldsymbol{E}^m &= \left(-\frac{jkI^m\ell}{4\pi}\frac{e^{-jkr}}{r}\right)\left[-\sin\phi\,\hat{\boldsymbol{a}}_\theta - \cos\theta\,\cos\phi\,\hat{\boldsymbol{a}}_\phi\right] \end{aligned} \tag{53}$$

If the magnetic source is related to the electric one by the characteristic impedance of space and a phase of 90°, the total field can be found from

$$\begin{aligned} E &= E^e + E^m \\ I^m &= j\eta I^e \end{aligned} \tag{54}$$

DOI 10.1007/978-981-4560-75-7_36-1

in the following form

$$\boldsymbol{E} = \left(-\frac{jk\eta I\ell}{4\pi}\frac{e^{-jkr}}{r}\right)(\cos\theta\cos\phi - j\sin\phi)\left(\hat{\boldsymbol{a}}_\theta - j\hat{\boldsymbol{a}}_\phi\right) \tag{55}$$

which is a circularly polarized wave in whole space. Thus, the conditions for circular polarization by a combination of electric and magnetic sources are

$$\begin{aligned} |I^m| &= \eta\,|I^e| \\ \angle I^m &= \angle I^e \pm \frac{\pi}{2} \end{aligned} \tag{56}$$

In practice the realization of a far field given by Eq. 55 is not realistic, since there are no perfect magnetic dipoles. It may be approximated by an aperture or more exactly by a narrow slot. However, slots are present on a conducting surface, and its presence alters the slot's radiation patterns. Thus, while the combination of an electric and magnetic dipole is an ideal source for circular polarization, its practical implementation is approximate and must be investigated for its axial ratio and impedance bandwidths, similar to other antennas.

Practical Implementations

Having established the mathematical foundations for circular polarization, the practical antenna configurations are now reviewed for generating circular polarization. From an electrical point of view, they can be divided into two different types:

- Traveling wave antennas
- Resonant antennas

From a current distribution point of view, they can be divided into three categories:

- One-dimensional currents
- Two-dimensional currents
- Three-dimensional currents

The traveling wave antennas are mostly made of continuous conducting structures, such as spirals, helices, and microstrip transmission lines over ground planes. Their current can be distributed in two dimensions such as planar spiral antennas, or in three dimensions similar to conical spiral antennas, and radiates as it travels along the structure. Thus, the shape of the antenna geometry is important for circular polarization. These antennas are covered in a separate chapter and will not be repeated here. For this reason, in this chapter, the second subdivision approach, i.e., the dimensional characteristic of the antenna currents, will be used for further discussion. In this manner, traveling wave antennas, based on microstrip transmission line, will be discussed as part of the two-dimensional magnetic current antennas.

Antennas with One-Dimensional Current Distributions

The case of one-dimensional currents is referred to one-dimensional antennas, which in practice are thin wire antennas. This case was already discussed in Case II above, for a general form of "two finite

DOI 10.1007/978-981-4560-75-7_36-1

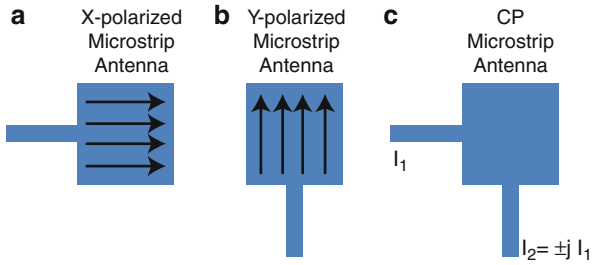

Fig. 10 (**a**) *x*-polarized and (**b**) *y*-polarized square microstrip patch antennas fed by transmission lines and (**c**) CP microstrip patch excited by two orthogonal transmission lines

orthogonal electric currents." A practical example of this case is "two orthogonal half-wave dipole antennas."

Antennas with Two-Dimensional Current Distributions

The two-dimensional current distribution can be generated from the one-dimensional case by using planar surfaces, in lieu of thin wires. The mathematical extension of two orthogonal wires to two orthogonal planar surfaces is obvious and will not be discussed here. Instead, the case of microstrip patch antennas will be considered as the example of two-dimensional currents, because of their popularity and ease of fabrication. The microstrip patch antenna is a resonant structure, similar to a wire antenna. Thus, its most common size is half-wave length, where the current distribution is sinusoidal, but distributed over its surface, as shown in Fig. 10a. For simplicity, the square patch of Fig. 10a is fed by a microstrip transmission line. However, as is well known, it can be also fed by other means such as a probe or a slot. The advantage of a microstrip patch is that it can also be fed in the orthogonal direction, for the orthogonal currents, as shown in Fig. 10b. Thus, for circular polarization a single square patch can be excited with two orthogonal feeds of Fig. 10c. It should also be noted that because of symmetry, one can also use a circular patch, in place of a square patch in Fig. 10.

The purity of CP radiation is measured by the axial ratio value, and the operating bandwidth is defined by the axial ratio bandwidth. For microstrip antennas, the axial ratio bandwidth is calculated using the following equation (Langston and Jackson, 2004):

$$BW_{CP}^{AR} = \frac{AR_{\max} - 1}{\sqrt{AR_{\max}}Q} \tag{57}$$

where $AR_{\max}$ is the maximum axial ratio value and Q is the quality factor.

Figure 11 shows different geometries for circular polarization. There are two fundamental approaches, the two-feed approach, which is discussed above, and a single-feed approach. The single-feed approach generates the orthogonal currents with a geometric deformation, which for symmetry reason is located at 45°, with respect to the feed. It is more advantageous in practical applications, because of its feed system simplicity. They are discussed separately below.

Dual-Orthogonal-Fed Circularly Polarized Patch

Dual-orthogonal feeds are used to generate two orthogonal modes with equal amplitude but in-phase quadrature. An external power divider is used in this case. Several power dividers have been successfully used for CP generation such as the quadrature hybrid, the Wilkinson power divider, the 180° hybrid, and the T-junction power divider (Garg et al. 2001). The configuration of dual-fed CP patches with a quadrature hybrid is shown in Fig. 12. Depending on the sense of CP rotation, one port is used as the

DOI 10.1007/978-981-4560-75-7_36-1

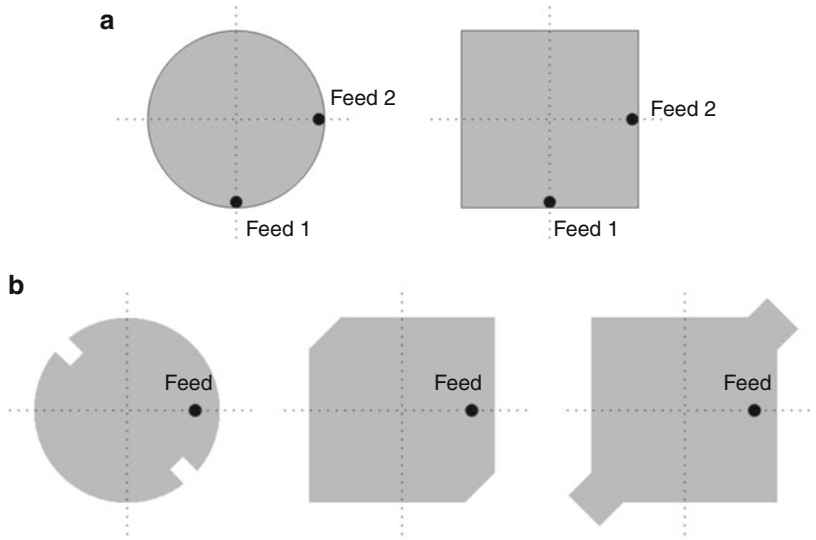

Fig. 11 (**a**) Dual-fed CP patch antenna requiring an external polarizer and (**b**) singly-fed CP patch antenna with perturbations

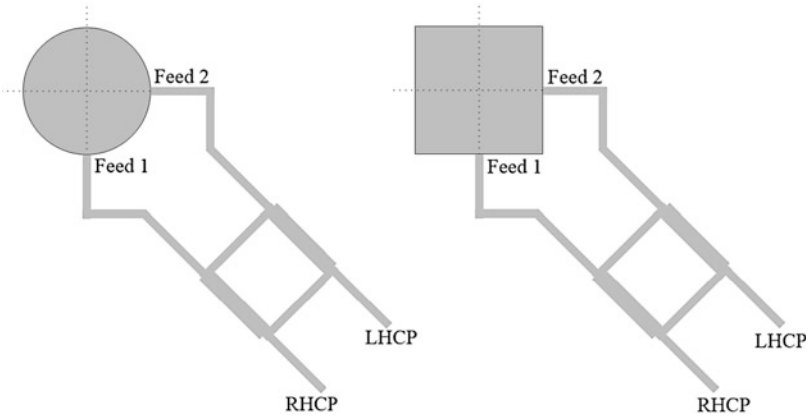

Fig. 12 Dual-fed CP patch antenna configuration with a quadrature hybrid power divider

input, and the other port is terminated with a matched load. The output ports are then connected to two feed points on the patch. The input signal is thus divided into two equal amplitudes, but in-phase quadrature, with good isolation, generally exceeding 20 dB, between two output ports. In dual-fed configurations, the 3 dB axial ratio bandwidth of the patch antenna is broad since a quadrature hybrid is broadband (Langston and Jackson 2004). Its operating bandwidth is limited by the impedance bandwidth of the patch antenna itself.

Singly-Fed Circularly Polarized Patch

Dual feed for CP requires external power dividers, thus needs extra space, and, in many cases, is difficult to accommodate. In these scenarios, a single-point feed patch capable of generating CP radiation is very attractive. A microstrip patch with a single feed generates linear polarization at the dominant mode. To induce two orthogonal patch modes with equal amplitude and in-phase quadrature, slight perturbation of the patch with respect to the feed is necessary. Various perturbation schemes for generating CP from patch antennas have been reported in the literature (Garg et al. 2001). However, the main principle in these schemes is the detuning of the degenerate mode in a symmetrical patch by introducing small perturbation segments at appropriate locations. The generated mode of a patch antenna can be separated into two

DOI 10.1007/978-981-4560-75-7_36-1

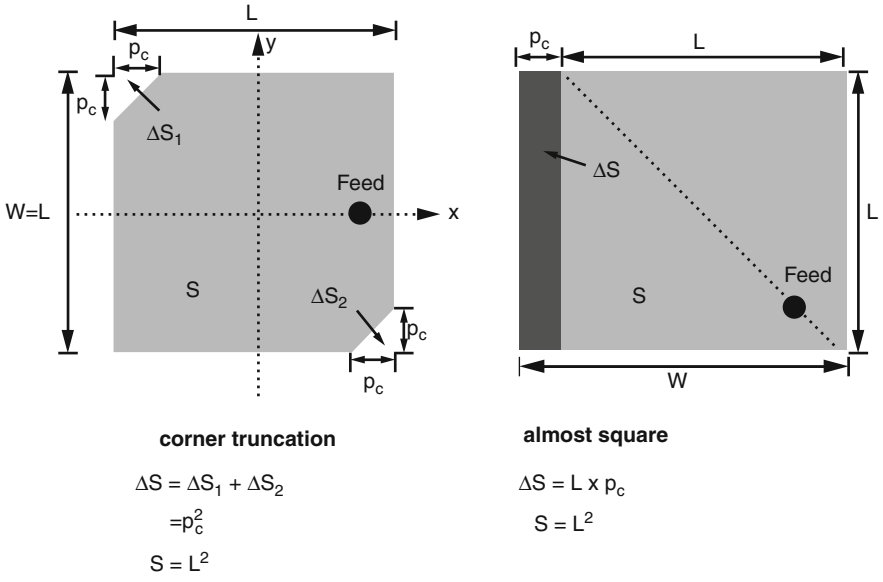

Fig. 13 Single feed CP patch antenna configuration with perturbations. Depending on the feed location, two types are possible: "corner truncation" and "almost square"

orthogonal modes by a perturbation segment in the form of a slit, a slot, a truncated segment, or an added stub. The radiation fields excited by these modes are typically perpendicular to each other. When the amount of perturbation is selected to the optimum value, these two modes are excited in equal amplitude and phase quadrature at the center frequency. This enables the CP radiation from the patch antenna even with a single feed.

The analysis for determining the amount of segmentation in the case of rectangular patch is described in detail in (Hall and James 1989). Two types of configuration based on the feed location, as shown in Fig. 13, are used in the analysis. In this figure, "corner truncation" is the configuration when the feed is either on the *x*- or *y*-axis, and it is "almost square" when the feed is located on the diagonal axis of the patch. ΔS represents the total sum of the perturbation segments, which may consist of a single (e.g., "almost square") or multiple segments (e.g., "corner truncation"). By introducing symmetric perturbations on opposite diagonal corners in a corner truncation patch, CP radiation can be obtained. In this type, the amount of perturbation can be determined using the simplified design equation

$$\left|\frac{\Delta S}{S}\right| = \frac{1}{2Q_o} \tag{58}$$

where S represents the total area of the patch and Q_o is the unloaded quality factor of the cavity resonator produced by the patch and the ground plane. Q_o depends on the dimension of the patch, the substrate thickness, and the substrate dielectric constant. For better accuracy, Q_o should be selected such that the patch radiation efficiency is greater than 90 % (Garg et al. 2001).

In the case of the "almost square" patch antenna, the perturbation is introduced by adding a strip to the patch, which, in fact, provides a nearly square patch antenna, and when it is fed diagonally, CP is generated. For this type, the amount of perturbation can be obtained using the following equation:

DOI 10.1007/978-981-4560-75-7_36-1

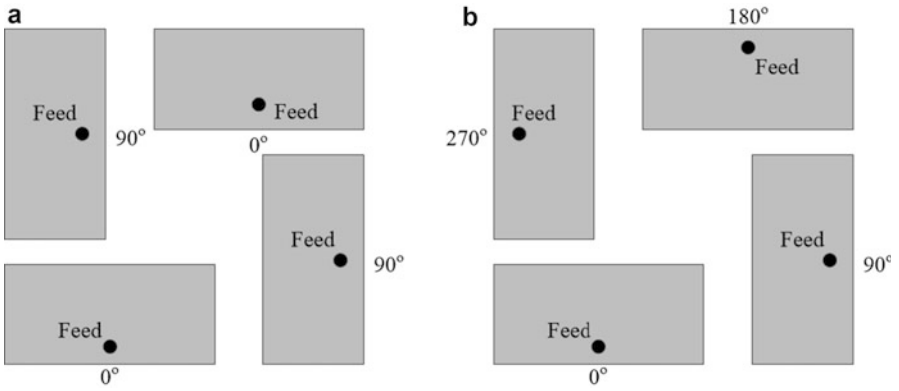

Fig. 14 Microstrip array with linearly polarized elements sequentially rotated for CP radiation: (**a**) narrow band arrangement and (**b**) wide band arrangement

$$\left|\frac{\Delta S}{S}\right| = \frac{1}{Q_o} \tag{59}$$

Sequentially Rotated Microstrip Arrays for CP Radiation

In section "Sources of Circularly Polarized Radiation," it was shown that four sequentially rotated dipoles can generate circular polarization with very broad axial ratio beamwidth, which is an ideal method for generating circular polarization. This configuration can easily be implemented with four microstrip patches, by replacing the dipoles with microstrip patches. It has been also shown that microstrip patches in this configuration have wide impedance bandwidths (Teshirogi et al. 1985; Huang 1986). Two arrangements are presented in Fig. 14, where an external power divider with appropriate phase shift is necessary to generate CP radiation from these linearly polarized patches. The configuration in Fig. 14a does not meet the phase requirement of Eq. 47 and has a narrow axial ratio beamwidth. The configuration of Fig. 14b, on the other hand, meets the phase requirement of Eq. 47 and has a substantially wider axial ratio beamwidth, with significantly low cross-polarization (Garg et al. 2001).

Sequentially Rotated Magnetic Dipoles

A simple way to produce a magnetic dipole is to bend a microstrip line, as shown in Fig. 15a. The electric field discontinuity at the bend, measured from the two sides of the line, generates an equivalent magnetic dipole, at 45° with each side of the angle. Thus, it radiates an electric field that bisects the corner. Since an undulated line has four corners, it is equivalent to four sequentially rotated magnetic dipoles. If four corners generate 90° and 180° phase shifts, the opposite corners are out of phase, and adjacent corners are at phase quadrature, and the four corners radiate circular polarization. This condition occurs when the lengths $h = \lambda/2$, $w = \lambda/4$, and $p = \lambda$. With these conditions the period of the corner unit cells becomes λ, and the corners of the undulated traveling line radiate in-phase circular polarization.

Hybrid Electric and Magnetic Dipole Antennas

A microstrip line can also be used to design hybrid electric and magnetic dipole antennas for circular polarization. Figure 15b shows one such case, where a straight microstrip line is etched on a substrate, over a ground plane. On the upper surface an electric dipole is placed orthogonal to the microstrip line. On the opposite side, a resonant slot is etched on the ground plane, which represents a magnetic dipole. If the spacing between the slot and dipole is $\lambda/4$, then the phase shift between the two will satisfy the condition for circular polarization. For better performance, the slot should be over a cavity, or a reflecting plate, to cause unidirectional radiation, similar to the dipole. In this design, the amplitude of the dipole and slot

DOI 10.1007/978-981-4560-75-7_36-1

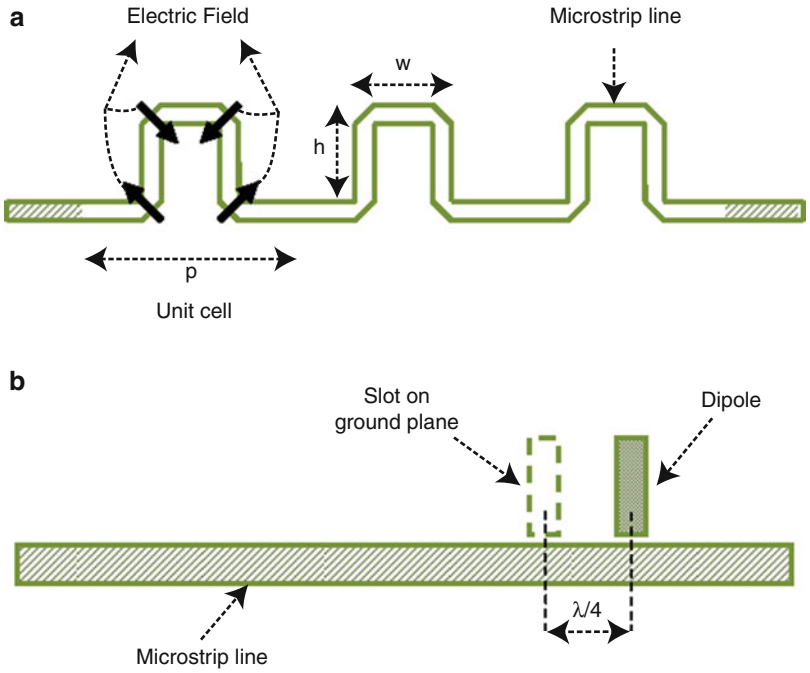

Fig. 15 (**a**) Geometry of a meandered microstrip line. *Solid arrows* at the corners of the line represent electric field. (**b**) Geometry of hybrid electric and magnetic dipoles

excitations can be controlled by adjusting their coupling with the microstrip line, i.e., adjusting their distance from the microstrip line. In this design, the slot and dipole are not collocated, and thus their circular polarization is not perfect, as the case of two hybrid electric and magnetic dipoles, but the antenna configuration is simple and can be designed satisfactorily.

Antennas with Three-Dimensional Current Distributions, Dielectric Resonator Antennas

Three-dimensional current distributions can be generated by volumetric antennas such as cones, spheres, and other shapes. However, in conducting shapes the currents are on the antenna surface and can be represented by the characteristic modes of the antenna. Circular polarization can therefore be generated similar to orthogonal wire antennas. An antenna that is unique in its electromagnetic characteristics is the *dielectric resonator* antenna, in which the characteristic modes resonate within the volume of the antenna. These antennas, depending on the resonating mode, can be equivalent to an electric or magnetic dipole antenna. In addition, since the entire antenna volume contributes to the resonance, more geometric possibilities exist for circular polarization. They are summarized in this section.

Dielectric resonator antennas (DRAs) are resonator-type antennas made of low-loss microwave materials and usually designed for single-mode operation with linear polarization. Different modes having specific internal and associated external field distribution can be excited in DRAs using different feeding methods such as microstrip, probe, and aperture. These modes are equivalent to electric and magnetic dipoles with different orientations. For instance, the field configurations inside the rectangular and cylindrical DRAs for the lowest-order modes are plotted in Fig. 16, where the subscript δ ($\delta = \sim 1$) (Luk and Leung, 2003) denotes the variation of fields along the axial direction inside the cylindrical resonator. These plots are very useful to predict the far-field radiation patterns and to design coupling schemes for various modes. To produce circular polarization, these equivalent dipoles should be considered in similar arrangements as described in section "Sources of Circularly Polarized Radiation."

DOI 10.1007/978-981-4560-75-7_36-1

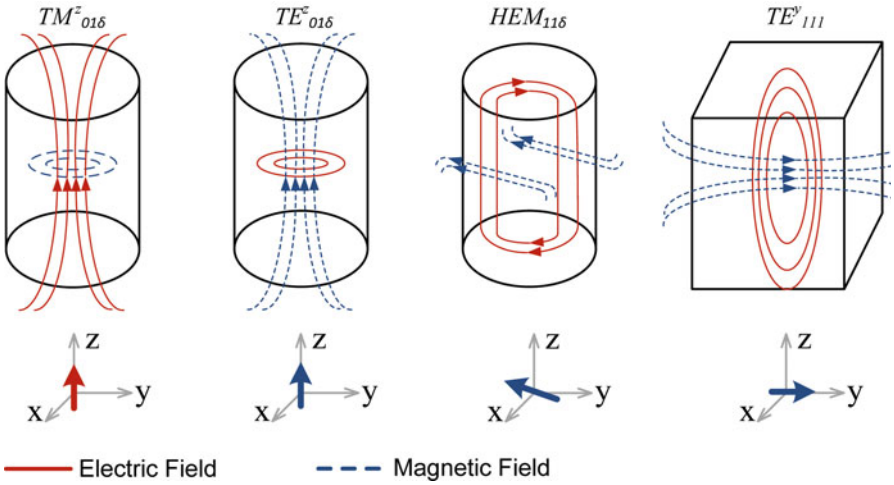

Fig. 16 Electromagnetic field distributions and equivalent dipoles of different modes in cylindrical and rectangular DRAs; δ ($\delta = \sim 1$) denotes the variation of fields along the axial direction inside the cylindrical resonator

An exact analytical closed-form solution does not exist for dielectric resonator geometries except hemispherical resonators, for which separation of variables is possible. For a dielectric resonator of arbitrary shape, general conclusions can be achieved to find approximate solutions. Most of these conclusions are based on the fundamental work of Van Bladel (Van Bladel 1975a, b). Numerical techniques such as finite element and finite difference time domain methods can produce more accurate electromagnetic solutions for these dielectric structures and are mostly used to achieve CP DRAs.

It is worth mentioning that achieving circular polarization usually requires special complicated geometries (e.g., cross shape) or minor changes in the resonator body which are difficult to realize due to the abrasive nature of ceramic, the number one material used for DRA applications. However, it has been recently investigated that DRAs can be fabricated by lithographic processes using ceramic-photoresist microcomposites (Rashidian et al. 2010, 2012). This fabrication technology can be very useful for CP DRAs in which special and complicated geometries may be required.

Similar to the microstrip case, circular polarization can be generated by three different ways, dual-feed system, single-feed system, and sequential rotation feed. For completeness, they are discussed again separately below, for the cases where a ground plane is used to support the antenna. Also, since the principle is the same for any volumetric resonator antenna, in the following the *dielectric resonator antenna* is simply referred to as *resonator antenna.*

Dual-Feed Approach

Dual-feed approach is the most straightforward method to realize CP radiations from inherently linearly polarized resonator antennas such as DRA. Two equal amplitude signals, 90° out of phase, are delivered in two different feed points on the resonator body to excite two orthogonal modes. The power divider splits the input signal into two outputs with equal amplitudes, and an extra quarter-wavelength transmission line is considered in only one of the outputs to generate a 90° phase difference. Alternatively, a directional coupler may be utilized to perform all these tasks.

Figure 17a shows a dual-feed system used to excite the two orthogonal $HEM_{11\delta}$ modes of a cylindrical ring dielectric resonator placed on a circular metallic ground plane (Mongia et al. 1994). A 3 dB quadrature coupler assembled in the backside was utilized to deliver equal amplitude and phase quadrature signals to two vertical probes. The probes are positioned in the proper places to excite the dominant hybrid mode ($HEM_{11\delta}$) in perpendicular directions. As shown in Fig. 16, the near-field distribution of this

DOI 10.1007/978-981-4560-75-7_36-1

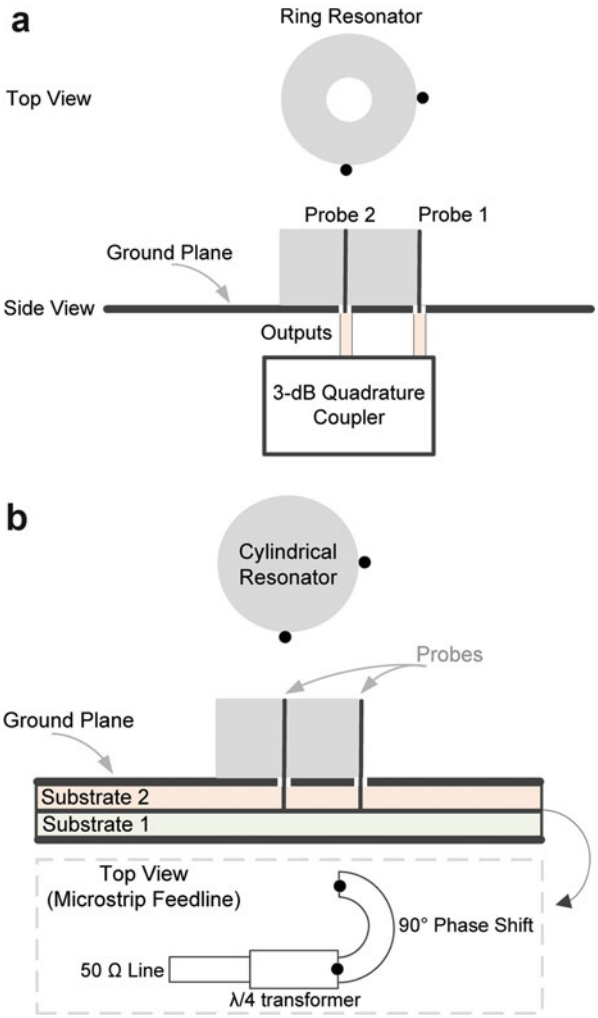

Fig. 17 (**a**) Configuration of a dual-feed ring CP DRA with an external coupler; (**b**) configuration of a dual-feed cylindrical CP DRA with microstrip feed line

type of mode is equivalent to a horizontal magnetic dipole, and since two of them are orthogonally excited with equal amplitudes and in-phase quadrature, CP radiations are resulted in the broadside direction. It should be noted that the 3 dB ellipticity bandwidth can be a large value and even more than the impedance bandwidth when a wideband directional coupler is used. In other words, the ellipticity bandwidth is proportional to the bandwidth of the external directional coupler, which provides in-phase quadrature signals of nearly equal amplitudes in a wide frequency band.

In Fig. 17b, the combination of microstrip line design and probe excitation is employed to achieve circular polarization from a cylindrical dielectric resonator antenna (Drossos et al. 1996). The 3 dB quadrature coupler is realized using a microstrip design. The two orthogonal $HEM_{11\delta}$ modes of the cylindrical resonator are excited by two vertical probes, which are connected to the microstrip design in the backside. A semicircle $\lambda/4$ microstrip line was designed to provide the 90° phase shift between the two excitation probes. Another $\lambda/4$ microstrip line was considered to transform the 50Ω input impedance to the 25Ω output impedance, which is because of the two 50Ω loads in parallel. Not a large ellipticity bandwidth is expected from this configuration due to the bandwidth limitation of the microstrip line design. To achieve a larger axial ratio bandwidth in the broadside direction, a microstrip 90° hybrid coupler can be designed to deliver the quadrature signals to the dual feeds.

DOI 10.1007/978-981-4560-75-7_36-1

Single-Feed Methods

Single-feed DRAs generally radiate linear polarization. To generate circular polarization in a single-feed configuration, three methods can be followed:

- Specific geometries such as cross shape or circular sector are employed, while the feed point position is adjusted so that two orthogonal modes with equal amplitudes and in-phase quadrature are excited.
- Regular shapes such as rectangles and circles that usually produce linear polarization in single-feed arrangements are slightly perturbed at proper locations with respect to the feed point. The perturbation configuration generates two orthogonal degenerate modes, one of which is detuned such that it is of the same magnitude but 90° out of phase with respect to the other mode.
- Feed mechanism is modified to excite two orthogonal modes and generate circular polarization. For instance, a cross-shaped aperture with unequal arms is used to initiate in-phase quadrature orthogonal modes.

The frequency distance between the resonant frequencies of two orthogonal modes must be adjusted so that the requirement of 90° phase difference between these modes can be properly fulfilled. To realize this condition, one can assume that at a particular frequency point between the resonant frequencies of these modes, the lower resonance is driven at its upper −3 dB point, and the upper resonance is driven at its lower −3 dB point. These provide +45°/−45° phase shift and therefore satisfy the 90° phase shift between modes in order to produce circular polarization. Therefore, if f_1 is the resonant frequency of the lower mode, f_2 is the resonant frequency of the upper mode, and Δf is the 3 dB bandwidth of the reflection coefficient of each resonant mode, the quadrature phase condition is fulfilled when

$$f_1 + \frac{\Delta f_1}{2} = f_2 - \frac{\Delta f_2}{2} \tag{60}$$

By choosing appropriate dimensions/geometry for the antenna, the above equation is satisfied, and a circular polarized antenna can be achieved in a single-feed configuration.

In the past several decades, numerous circularly polarized designs with a compact single feed have been reported. Microstrip line, probe, and slot are mostly used to feed these antennas. These designs are organized under different categories and briefly described in the following subsections.

Truncated (Perturbation) Shape Basic geometries such as rectangular and circular shapes with slight or no modifications in their structures can be utilized to generate circular polarization. Although narrow bandwidths for the axial ratio are achieved, the geometry is simple and compact due to single-feed excitation. Figure 18 shows the top view of several examples of this type of CP antennas fed by coaxial probe.

In Fig. 18a no modification is performed, and the coaxial feed is positioned at the corner of the rectangular resonator. In this case, if the ratio of the width to the length is slightly larger/smaller than one, two orthogonal modes of TE^{x}_{111} and TE^{y}_{111} with resonant frequencies in close vicinity are excited. As

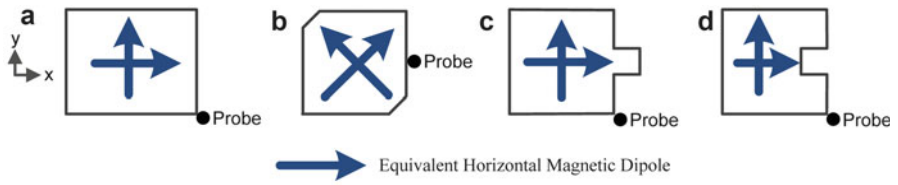

Fig. 18 Top view of probe-fed rectangular shape resonator antennas perturbed at certain locations to generate CP radiations

DOI 10.1007/978-981-4560-75-7_36-1

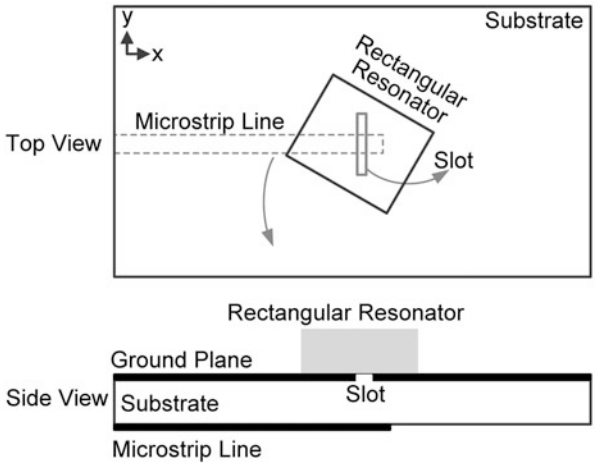

Fig. 19 Slot-fed CP rectangular dielectric resonator antenna

illustrated in Fig. 16, these modes are equivalent to magnetic dipoles in *x*- and *y*-directions, respectively. The aspect ratio bandwidth of the antenna is usually less than a few percent for the optimum design parameters (Malekabadi et al. 2008).

The rectangular-shaped antenna can be also excited using a single slot feed to produce circular polarization as shown in Fig. 19. A narrow nonresonant aperture in the ground plane side of a microstrip line is used to couple the electromagnetic energy to the rectangular-shaped resonator, which is inclined by around 45° with respect to the slot. The two orthogonal modes of TE^{x}_{111} and TE^{y}_{111} are simultaneously excited, and the length and the width of the dielectric resonator can be adjusted to optimize the resonant frequencies to achieve the required 90° phase difference between these modes for circular polarization. Generally, a near-square-shaped resonator provides the best result (Oliver et al. 1995).

The next structure, Fig. 18b, is a square resonator with two chamfered edges. In fact, by cutting two opposite corners of the dielectric resonator and locating the coaxial probe feed in the middle of one of the sidewalls, two near-degenerate orthogonal modes with similar magnitude and 90° phase difference can be excited to provide CP radiations. In this case, the equivalent horizontal magnetic dipoles of these modes are along the diagonal of the dielectric resonator. As the depth of the cut increases, the resonant frequency of the mode created along the chamfered edges increases, while the resonant frequency of the mode created along the unaltered corners stays constant. Therefore, the depth of the cut needs to be adjusted in order to achieve the maximum aspect ratio bandwidth.

Figure 18c and d shows the geometries of modified square resonators in which a rectangular perturbation segment and a rectangular notch are, respectively, introduced in the sidewall of the dielectric resonator. In these structures, the probe is located in the corner of the resonator. Two orthogonal resonant modes are excited along the *x*- and *y*-axes. In Fig. 18c, the first resonant belongs to TE^{x}_{111} as the rectangular perturbation in the *x*-direction creates a longer path for the mode in this direction. In Fig. 18d, the second resonant belongs to TE^{x}_{111} as the rectangular notch in the *x*-direction creates a shorter path for the mode in this direction. To achieve the maximum *AR* bandwidth, the rectangular perturbation/notch has to be optimized using numerical methods or simulation tools. Similar to the conventional rectangular-shaped antenna, all of these modified antennas present broadside radiation patterns. Similar perturbation ideas can be used for the circular-shaped antennas (Malekabadi et al. 2008).

Circular Sector Geometries Using a single feed with proper position, circular sector DRAs produce circular polarized radiations with axial ratio less than 3 dB over a wide frequency bandwidth. Figure 20 illustrates a plane view of the geometry of a circular sector antenna that is formed by removing a part (e.g.,

DOI 10.1007/978-981-4560-75-7_36-1

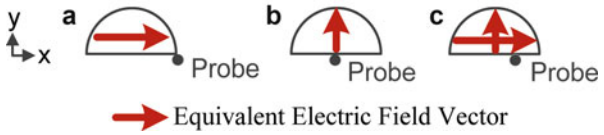

Fig. 20 Top view of circular sector dielectric resonator antennas excited by coaxial probes

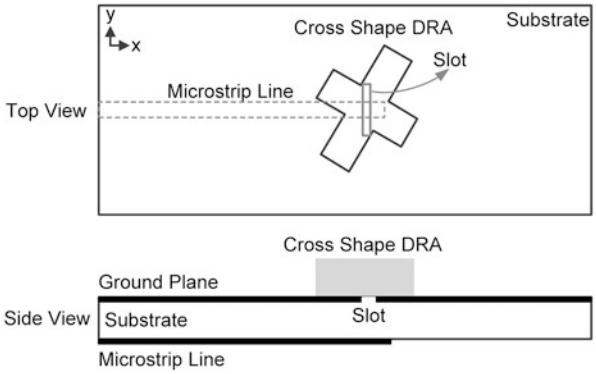

Fig. 21 Geometry of a cross-shaped dielectric resonator antenna excited by microstrip line slot

half) of a circular cylinder. A coaxial probe feed is used to excite the antenna. Two orthogonal modes with similar radiation patterns and 90° phase difference are required to achieve circular polarization from the circular sector antenna. As shown in Fig. 20a, when the feed is located in the corner of the geometry, the fundamental resonant mode of $TM_{11\delta}$ is excited. This mode is equivalent to an electric dipole with radiation polarization along the *x*-axis. Changing the feed position to the center of the geometry results in excitation of the next lowest-order mode of $TM_{21\delta}$ which is equivalent to an electric dipole with radiation polarization along the *y*-axis, as shown in Fig. 20b. These orthogonal dipoles are suitable to generate circular polarized radiation if they are excited simultaneously and are in-phase quadrature. To this end, a proper position for the feed point must be selected, and the antenna dimensions must be adjusted so that the resonant frequencies of these modes satisfy Eq. 60.

To achieve a wide axial ratio bandwidth, deviation from the 90° phase difference must be small over a wide range of frequency. Decreasing the permittivity of the antenna increases the individual bandwidths of the modes and minimizes the deviation over a wider frequency range. For example, an antenna with the radius of 18 mm, height of 15 mm, permittivity of 12, and excited using a probe located between the center and the corner of the geometry shows 3 dB axial ratio bandwidth of 10 % from 2.54 to 2.81 GHz in broadside direction (Tam and Murch 2000).

Cross Shape A cross-shaped dielectric resonator, which is composed of two crossing rectangles with different lengths, can generate CP radiations. Figure 21 shows the top and side view of this structure along with the feeding mechanisms. The cross-shaped dielectric resonator is excited using a single slot at the ground plane of a microstrip line. Due to a small change in lengths, the two crossing rectangular resonators support two orthogonal modes, which are equivalent to two magnetic dipoles operating in close vicinities. To produce maximum axial ratio bandwidth, the length of the crossing rectangles must be adjusted. Using a numerical optimization, over 5 % 3 dB axial ratio bandwidth was achieved when the ratio of the shorter length to the larger length was ∼0.6 (Esselle 1995).

Cross-Aperture Coupled Cross-aperture-coupled DRAs are capable of producing relatively wideband CP radiations. This method facilitates the fabrication procedure as a wide variety of geometries including

DOI 10.1007/978-981-4560-75-7_36-1

simple dielectric structures (e.g., rectangular or circular shapes) without any modification can be used in such an arrangement. Basically, it is relatively difficult to construct three-dimensional dielectric resonators with specific shapes or make small changes in the geometry due to the hardness of the dielectric material. Figure 22 shows different structures that can be examined for circular polarization. The microstrip feed line is printed on the substrate and the coupling cross-aperture of unequal arm lengths is centered on the ground plane of the substrate underneath the dielectric resonator. The cross-aperture is inclined by around 45° with respect to the microstrip feed line. Instead of changing or modifying the dielectric resonator structure, the arms of the cross-aperture are changed to excite two nearly degenerate orthogonal resonant modes with nearly equal amplitudes and 90° phase difference. These two modes are equivalent to orthogonal magnetic dipoles. Depending on which aperture arm is longer, left-hand or right-hand CP operation can be achieved. For instance, the fundamental mode of $HEM_{11\delta}$ in the circular-shaped

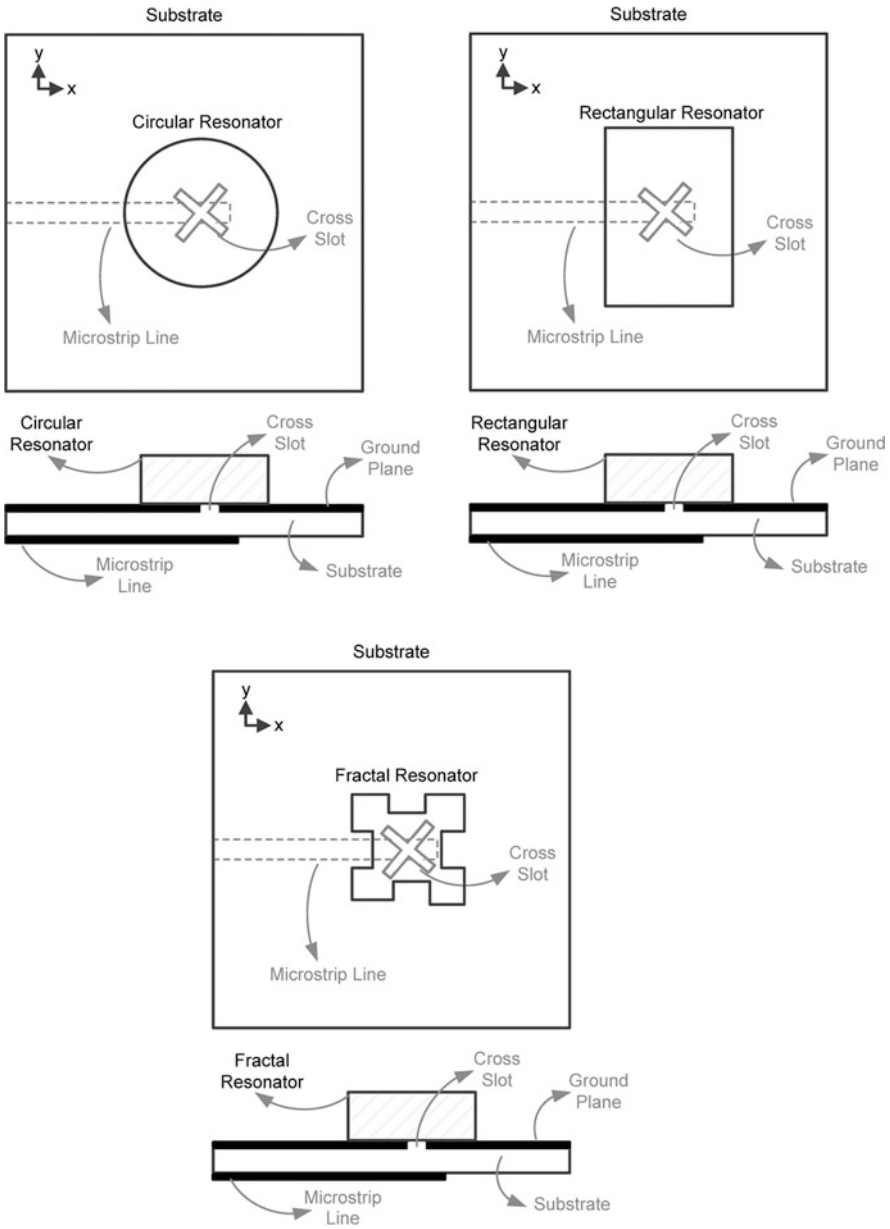

Fig. 22 Cross-aperture-coupled dielectric resonator antennas for circular polarization

DOI 10.1007/978-981-4560-75-7_36-1

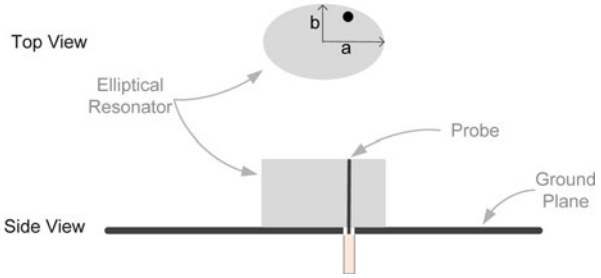

Fig. 23 Probe-fed elliptical dielectric resonator antenna

antenna, shown in Fig. 22, is split into two orthogonal modes and consequently two equivalent orthogonal magnetic dipoles in the slot directions. The resonant frequency of the mode in the direction of the shorter aperture is slightly lower than that of the other mode, and therefore, the right-hand circular polarization is obtained in this example (Huang and Yang 1999). More investigations can be found in (Dhar et al. 2013; Zhang et al. 2014).

Elliptical Shape Elliptical DRA with single feed can produce CP radiations. Figure 23 shows the antenna geometry. The dielectric resonator with elliptic cross section is placed above a finite ground plane and excited by a single coaxial probe feed. The ratio of the radius of the major axis a, to that of the minor axis b, is an important parameter to adjust the resonant frequencies of two orthogonal modes excited inside the resonator. The coaxial probe is located inside the resonator but near the surface and with angular positions around 40°–50° from the major axis. The length of the coaxial probe feed is adjusted to achieve wideband matching between the resonator and the 50Ω coaxial line. Depending on the resonator parameters such as height and permittivity, different optimized values can be achieved for a/b to maximize AR bandwidth. In most cases a/b should be around 1.5 to produce the optimum circular polarization (Kishk 2003; Malhat et al. 2012).

Sequential Rotation Technique

As described in section "Sources of Circularly Polarized Radiation," CP radiations can be achieved from displaced sequentially rotated electric dipoles. This technique can be easily applied for DRAs as they are equivalent to dipoles in their operational modes. Symmetrical geometries such as circular- or square-shaped resonators can also be used in this arrangement without any performance degradation. Since several antenna elements are used in this technique, higher antenna gain is achieved in comparison to the single-element CP antennas. One of the specific advantages of the orthogonal positioning of the adjacent elements in the sequential feeding technique is that the mutual coupling effects that disturb the array performance are considerably reduced. An example that uses aperture-fed cylindrical-shaped DRAs is shown in Fig. 24a. Rectangular slots are used to excite the dominant mode, which radiates like a linearly polarized horizontal magnetic dipole. The elements are employed in a 2 × 2 subarray design in which they are sequentially rotated with relative phases of 0°, 90°, 180°, and 270°.

Instead of linearly polarized, CP antenna elements can be also used in this feeding configuration to increase both the axial ratio bandwidth and the antenna gain (Huang 1986). For instance, the cross-aperture-coupled antenna elements, which generate CP radiations, are employed in a sequential feeding configuration (Pang et al. 2000). The feed network is similar to that shown in Fig. 24a. The only difference is that a cross-aperture of unequal length (e.g., $L_{long}/L_{short} = 1.22$), instead of a rectangular aperture, is used in excitation of the dielectric resonator elements to generate circular polarization. While the 3 dB axial ratio bandwidth is 5.6 % for the single element, it is over 16 % for the sequentially rotated 2 × 2

DOI 10.1007/978-981-4560-75-7_36-1

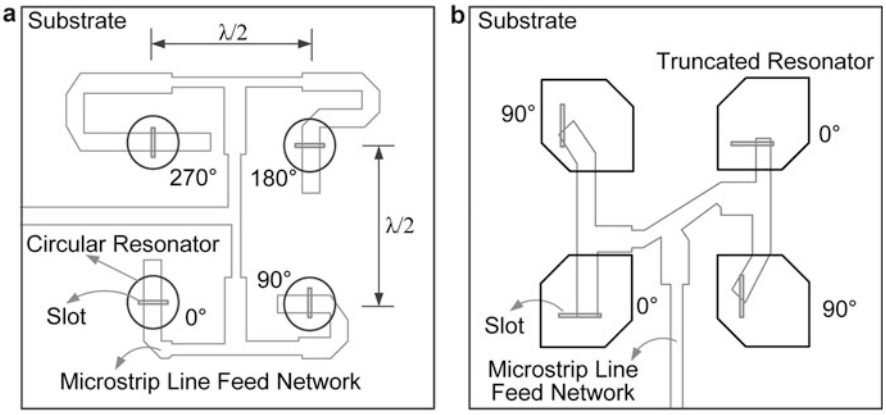

Fig. 24 Generation of circular polarization using sequential rotation technique from (**a**) linearly polarized aperture-coupled cylindrical DRA elements. (**b**) Truncated rectangular-shaped DRA elements

subarray system. Besides, the peak realized gain of the subarray antenna is around 12 dBi, which is 6 dB higher than that of the single CP antenna element.

Truncated rectangular-shaped DRAs result in narrow ellipticity bandwidths, usually not more than a few percent. By applying the sequential rotation technique, one can increase the 3 dB axial ratio bandwidth to the high value of 15 % and beyond (Haneishi and Takazawa 1985). Figure 24b shows the array configuration with microstrip slot-fed coupling. Each element is fed uniformly in amplitude and oriented orthogonally with respect to the neighboring element. The microstrip feed network on the rear plane of the substrate is designed to deliver the uniform power with 90° phase difference through the small apertures in the ground plane on the top of the substrate.

Design Example, Dual-Layer Microstrip Ring Antenna

This section provides a design example to show how the performance of a circularly polarized antenna can be improved. In section "Case III: Four Displaced Sequentially Rotated Electric Dipole Sources," Case IIIa, it was shown that four sequentially rotated currents provided a wide axial ratio beamwidth. Thus, as a design example, a square-ring microstrip antenna is selected, where currents flowing in the arms resemble Case IIIa. For simplicity, the single-feed case is selected, and corner truncation is used for circular polarization. Single layer patch antennas suffer from narrow impedance bandwidth. Although dual-fed patch antennas with external power divider provide wider axial ratio bandwidth, their bandwidth is limited by the impedance bandwidth of the patch. Stacked patches are commonly used to enhance the impedance bandwidth of patch antennas. By introducing appropriate perturbations to both the parasitic and driven patches, two orthogonal modes from each patch are generated. These four modes are combined, by adjusting the patch sizes and their separation, which eventually increase the impedance as well as the axial ratio bandwidths. A 3 dB axial ratio bandwidth of 8 % has been demonstrated in (Chung and Mohan 2003) with an impedance bandwidth equal to 43 % in the C-band.

Thus, a stacked square-ring antenna is selected to improve the bandwidth. What has not been shown so far is that with stacked configuration, one additional sequential rotation can be done, by rotating the upper-stacked patch 90° with respect to the lower patch. The performance of the antenna is provided for each case and discussed to show the reason and degree of improvement in the performance.

The square-ring patch is a miniaturized version of the patch antenna. In the ring patches the currents flow on the ring arms, which are similar to four displaced dipoles of section "Sources of Circularly Polarized Radiation." As it was shown in that section, the axial ratio beamwidth can be improved significantly by selecting the dipole separations of about 0.443λ. However, that requires the use of four

feeds, one for each arm of the ring, to accomplish the ultrawide axial ratio beamwidth. With a single feed the axial ratio beamwidth is lower, but as it will be shown later, the problem can be remedied with stacked configuration. The axial ratio bandwidths can also be increased which are shown in (Latif and Shafai 2012, 2005), for various perturbation schemes to obtain large axial ratio bandwidths in stacked square-ring patch antennas. They are discussed briefly below. Because of the similarity of this square-ring configuration to that of four dipoles of section "Sources of Circularly Polarized Radiation," it is chosen here for more detailed study.

Stacked Ring Patches for CP by Negative Perturbation

The common form of perturbation, corner truncation, is applied to the diagonal corners of both the driven and parasitic ring patches, as shown in Fig. 25. Corner truncations in the driven ring are denoted by q_c and those in the parasitic ring are by p_c. Here, foam is used to separate these patches, and a grounded dielectric substrate with permittivity, ε_r of 3.2, and thickness (h_1) of 1.6 mm is used for the driven ring patch. The feed is located on the x-axis following the "corner truncation" configuration to obtain right-hand CP. The judicial selection of the ring sizes, the separation between parasitic and driven rings, and the perturbation amount give wide axial ratio and impedance bandwidths. The optimized antenna parameters are tabulated in Table 1. Because of the diagonal corner perturbations on both ring patches, two orthogonal modes are excited on each ring, and the two central adjacent modes are merged together due to the optimized parameters. Thus, three resonances can be noticed on the simulated reflection coefficient plot of Fig. 26a. The simulation has been carried out in Ansoft Ensemble 8.0. The impedance bandwidth is 160 MHz (10.1 %). Due to the perturbation in both rings, the axial ratio plot, shown in Fig. 26b, has two dips close to each other, providing significantly wider 3 dB axial ratio bandwidth to 72 MHz (4.6 %), compared to the singly-fed CP patch antenna. The antenna has right-hand CP (RHCP) gain over 7 dB within this band. The gain patterns at two principal planes of this antenna at 1.6 GHz are shown in Fig. 26c. It shows a boresight RHCP gain of 8.9 dB with cross-polarization level 15 dB below the co-polarization. However, the RHCP gain drops rapidly away from the boresight.

Stacked Ring Patches for CP by Positive Perturbation (Outward)

Positive perturbations, in the form of added metal strips in the diagonal corner of both rings to the outward direction, also provide CP radiation. The diagonal line is at 45° with respect to the feed point in this case, as shown in Fig. 27, for the RH sense of CP. The antenna parameters, optimized for a wide *AR* bandwidth, are indicated in Table 1, and the simulated reflection coefficient and axial ratio with frequency are shown

in Fig. 28a. The $|S_{11}| < -10$ dB bandwidth is 173 MHz (10.8 %), and 3 dB *AR* bandwidth is 79 MHz (5 %), as shown in Fig. 28b, which are slightly larger than those of the previous case. Because of the added stubs, the overall size of the antenna increases by 25.4 %, with reference to the negatively perturbed case, which is the reason for wider bandwidths. It also slightly increases the RHCP gain with peak value of 9.2 dB at 1.62 GHz.

Stacked Ring Patches for CP by Positive Perturbation (Inward)

Ring patches have an added advantage of introducing positive perturbation by adding metal stubs to the inward direction of the diagonal corners of the square rings in the slot region, as shown in Fig. 29. Table 1 summarizes the optimized antenna parameters in this case, along with the obtained impedance and *AR* bandwidths. The simulated reflection coefficient, axial ratio, and RHCP gain plots are shown in Fig. 30. Both types of positive perturbations give similar results; however, in the inward positive perturbation case, the overall size of the antenna is not increasing.

Stacked Ring Patch for CP using Hybrid Perturbations

A similar perturbation type (either positive or negative) is commonly used to achieve CP from microstrip patch antennas. A combination of positive and negative perturbations or hybrid perturbations can also be used to generate CP radiation from the stacked patch antenna (Latif and Shafai 2007). Here, positive perturbation is introduced to the diagonal corners of the driven ring, and negative perturbation is applied to the parasitic ring. This configuration is essentially equivalent to the concept of sequential rotation used in arrays, where elements are physically rotated for correcting the axial ratio (Teshirogi et al. 1985). In other words, the stacked configuration introduces an additional sequential rotation, by rotating the upper-stacked patch 90° with respect to the lower patch. The stacked square-ring antennas can be considered as a two-element array. Instead of physically rotating the elements for phase compensation, the phase

correction is obtained here geometrically. The driven ring is smaller in size than the parasitic ring due to the higher permittivity of the related substrate, and metal stubs are added to diagonal corners of the driven ring for generating RHCP, without increasing the antenna size. The perturbations are located with respect to the feed point for "corner truncation" configuration, as shown in Fig. 31. If negative perturbations are introduced along the same diagonal corners of the parasitic ring, this will generate left-hand CP radiation,
