and eventually the polarization of the antenna will be linear. However, if the sequential rotation can be enforced, not by physically rotating the parasitic ring, rather by introducing the cuts along the other diagonal corners, as shown in Fig. 31, this will correct the phase relationship between the two waves generated from the two rings and ensure the RHCP. Moreover, cutting corners from the bigger parasitic ring reduces the overall antenna size. The antenna shows wide impedance bandwidth of 152 MHz (9.5 %), as well as broad 3 dB *AR* bandwidth of 77 MHz (4.9 %), as observed in Fig. 32. The antenna also demonstrates RHCP gain over 7 dB in the entire bandwidth. The optimized dimensions of these antennas and a summary of these results are tabulated in Table 1.

Microstrip antennas typically have a narrow CP beamwidth that is restricted around the antenna boresight direction, limiting its use in applications where wide angular coverage is required, such as the Global Positioning System. This hybrid perturbation technique provides a wider angular coverage in the upper hemisphere, similar to a sequentially rotated array (Teshirogi et al. 1985). When compared to different perturbation schemes, the hybrid perturbation scheme provides the largest angular coverage, as illustrated in Fig. 33. The antenna with negative corner perturbations has a 3 dB axial ratio beamwidth of only 118°, in the $\phi = 0°$ plane. However, the antenna with the hybrid perturbations has a wider angular

DOI 10.1007/978-981-4560-75-7_36-1

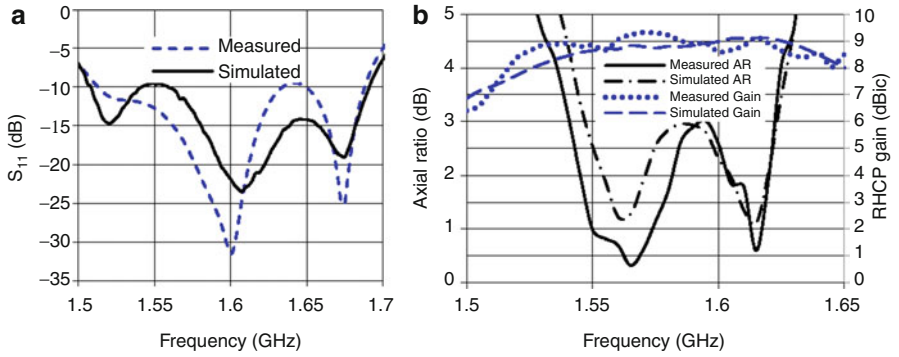

Fig. 34 Comparison between simulated and measured (**a**) reflection coefficient and (**b**) axial ratio and RHCP gain of the stacked ring antenna, with positive perturbation (shown in Fig. 27). The antenna parameters are $\varepsilon_r = 3.2$, $h_1 = 1.6$ mm, $h_2 = 11$ mm, $L_1 = 59$ mm, $L_2 = 37$ mm, $L_3 = 44.5$ mm, $L_4 = 14.5$ mm, $p_a = 5$ mm, $q_a = 6$ mm

coverage with 3 dB axial ratio beamwidth of 154°, from −77° to +77° off the boresight. In the other principal plane, all perturbation types have similar performances.

These results are confirmed by experimental verifications. First, the stacked square-ring antenna with outward positive perturbations, shown in Fig. 27, was fabricated where the driven ring was excited at $X_F = 21$ mm, $Y_F = 0$ mm, using a 50Ω SMA probe. The sizes of the main dielectric substrate ($\varepsilon_r = 3.2$; thickness = 1.6 mm) and the foam, which is the substrate for the parasitic ring, were chosen to be the same, and the rings were placed at the center of the respective substrates for easy alignment. A finite ground plane (160×160 mm^2) was used for the antenna. The fabricated antenna was tested in the Antenna Laboratory at the University of Manitoba. The reflection coefficient was measured by ANRITSU ME7808A Network Analyzer and compared in Fig. 34a with the simulation results. The measured S_{11} is slightly different from simulation, which is due to the difference in dimensions in the handmade antenna. However, the variations are below −10 dB, making the corresponding bandwidths about the same.

The measured and simulated axial ratio and RHCP gains are compared in Fig. 34b. The measured 3 dB axial ratio bandwidth is larger (81 MHz) than the simulated one (76 MHz), and it also has lower minima, as low as 0.32 dB at 1.565 GHz. In other words, the fabrication tolerances have improved the axial ratio performance. The measured RHCP gains are somewhat higher at low frequencies, as seen in the same figure. There are small oscillations in the measured gain, which are due to interactions between the antenna and its support. A sample of the measured radiation patterns, using a rotating linear source, is shown in Fig. 35. The boresight CP performance is quite good, but deteriorates gradually with increasing angle, which is a common characteristic of CP antennas.

Secondly, the stacked square-ring antenna with hybrid perturbation, as shown in Fig. 31, was fabricated and tested, and the comparison with the simulated ones is presented in Fig. 36, which shows good agreement as the first example. Measurement of radiation patterns also confirms the wide angular coverage from this antenna in the $\phi = 0°$ plane, as shown in Fig. 37.

Effects of Finite Ground Plane on CP Performance of Stacked Square-Ring Antenna

Ground Plane Size The effect of the finite ground plane size on the CP performance of the stacked square-ring antenna is also studied. Figure 38 shows the variation of the axial ratio of the antenna with the outward positive perturbation, shown in Fig. 27, versus frequency for different ground plane sizes. Here, the antenna is symmetrically placed at the center of the ground plane. The axial ratio deteriorates as the ground plane size decreases. Between the two dips in the axial ratio plot, caused by the perturbations on both rings, the second dip suffers the most, which moves to higher frequencies with a poor axial ratio. This

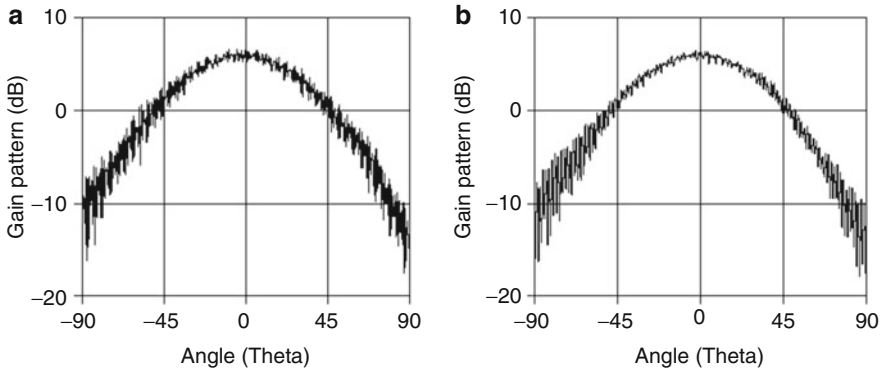

Fig. 35 The measured gain patterns in (**a**) $\phi = 0°$ and (**b**) $\phi = 90°$ planes at 1.56 GHz of the DLSRA antenna, with positive perturbation on both driven and parasitic rings (shown in Fig. 27)

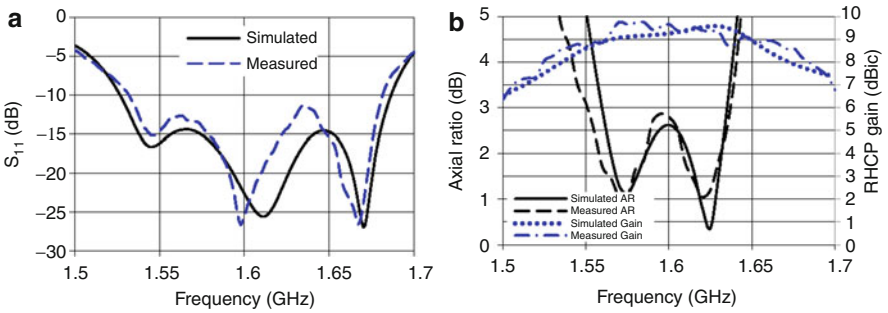

Fig. 36 Comparison between (**a**) simulated and measured reflection coefficient and (**b**) axial ratio and RHCP gain of the stacked square-ring antenna, with hybrid perturbations (shown in Fig. 31). The antenna parameters are $\varepsilon_r = 3.2$, $h_1 = 1.6$ mm, $h_2 = 11$ mm, $L_1 = 59$ mm, $L_2 = 37$ mm, $L_3 = 44.5$ mm, $L_4 = 14.5$ mm, $p_a = 5$ mm, $q_a = 6$ mm

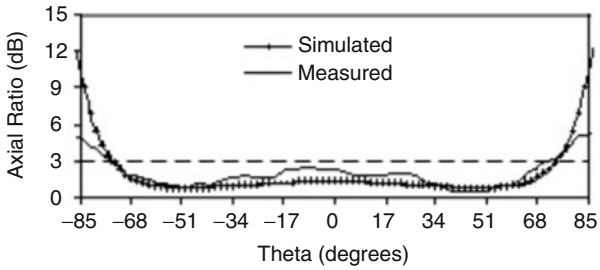

Fig. 37 Measured and simulated axial ratios with elevation angle, in the $\phi = 0°$ plane, of the stacked square-ring antenna with hybrid perturbations in Fig. 31

axial ratio can be improved by adjusting the size of the driven ring that causes this dip and the foam thickness as well. It is also increased to achieve lower values of the axial ratio. The parasitic ring size and perturbations are kept fixed in this case. The simulation results are tabulated in Table 2 for the optimized cases for different ground plane sizes. Figure 39a shows the variation of the axial ratio, and Fig. 39b shows the variations in RHCP gain for different ground plane sizes. As the ground plane size decreases, the RHCP gain decreases. For a ground plane size of 80 × 80 mm^2, the peak RHCP gain is 7.89 dBic, whereas it is 9.2 dBic when the ground plane size is 160 × 160 mm^2.

Asymmetric Antenna Position on the Ground Plane In the study of finite ground plane size discussed above, a symmetric antenna position on the ground plane was considered. In order to see the effects of asymmetric locations, the circularly polarized stacked square-ring antenna with positive perturbations is positioned asymmetrically on the ground plane as shown in Fig. 40a. Considering O as the global origin which is the center of the ground plane, and C(X_g, Y_g) as the center of stacked rings, when the antenna on

DOI 10.1007/978-981-4560-75-7_36-1

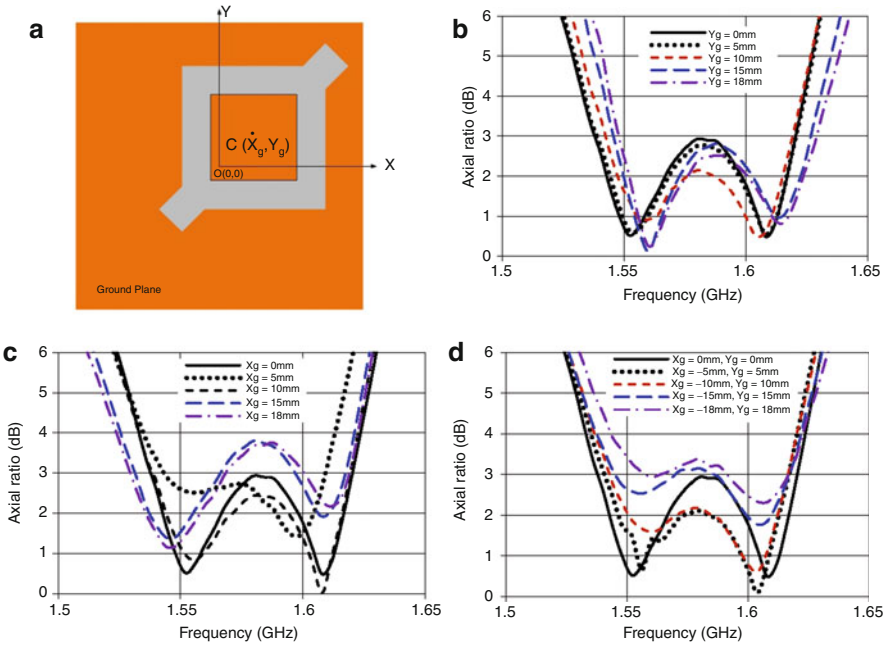

Fig. 40 The effects of asymmetric antenna position on the ground plane on the axial ratio of the stacked square-ring antenna with positive perturbations in Fig. 27. Antenna parameters (in mm) are $L_1 = 59$, $L_2 = 37$, $L_3 = 44.9$, $L_4 = 14.9$, $P_a = 5$, $q_a = 6$, $\varepsilon_r = 3.2$, $h_1 = 1.6$, $h_2 = 12.8$. Ground plane size $= 100 \times 100$ mm^2. (**a**) Geometry, (**b**) when the antenna is asymmetric about *y*-axis, with $X_g = 0$, (**c**) when asymmetric about *x*-axis, and with $Y_g = 0$, (**d**) when asymmetric about both *x*- and *y*-axes

the ground plane is asymmetric about the *y*-axis (with $X_g = 0$ mm), the axial ratio performance does not deteriorate much, as can be seen in Fig. 40b. Here, $X_g = 0$ mm, $Y_g = 0$ mm indicates the symmetric case, and $X_g = 0$ mm, $Y_g = 18$ mm means the stacked ring antenna is at one side of the ground plane. When the antenna is asymmetric about the *x*-axis (keeping $Y_g = 0$ mm), the axial ratio performance degrades significantly, as shown in Fig. 40c. Similarly, when the antenna is asymmetrically positioned about both *x*- and *y*-axes, the axial ratio suffers significantly, as shown in Fig. 40d.

Conclusion

Circularly polarized antennas, categorized into their current sources of radiation, were well elucidated in this chapter. Mathematical expressions and important definitions were first reviewed. The condition of circularly polarized radiation was analytically stated for one-dimensional current sources in the form of crossed electric dipole antennas. It was later extended to four sequentially rotated dipoles, mathematically proving the formation of circularly polarized radiation with beamwidths as wide as 170°. Antennas with two- and three-dimensional current sources were presented. In particular, microstrip patch antennas and dielectric resonator antennas were thoroughly discussed, corresponding to the aforementioned current sources. Different methods for generating circularly polarized waves were given for each of the antennas. More specifically, circularly polarized radiation properties of square-ring microstrip patch antenna were extensively investigated, and the corresponding results were presented for different antenna parameters. The square-ring microstrip antenna was selected as it closely approximates the sequentially rotated currents, and also it has not been widely studied in the literature. The idea presented in this chapter can be applied to other antenna structures for different applications. In summary, circularly polarized antennas

DOI 10.1007/978-981-4560-75-7_36-1

with their attractive features are vital radiating components in most modern satellite communications, radars, and Global Positioning Systems.

Phased Arrays

Takashi Maruyama*, Kazunari Kihira and Hiroaki Miyashita
Antennas Technology Department, Information Technology R&D Center, Mitsubishi Electric Corporation, Kamakura, Kanagawa, Japan

Abstract

This chapter explains the fundamental issues in designing phased array antennas (PAAs). At first, the structure and functions of the PAAs are introduced. Pattern synthesis, which is a feature of array antennas, and array calibration methods are explained. It includes some methods, minimax algorithm, element thinning algorithm, and genetic algorithm. For array calibration, rotating element electric field vector method is also explained. Digital beam forming (DBF) including signal processing and MIMO (multiple input multiple output) techniques are shown in a later part of this chapter.

Keywords

Phased array antennas; Antenna pattern synthesis; Array antenna calibration; Rotating element electric field vector method; Digital beam forming

Introduction

Antennas are defined as devices that convert energy between electromagnetic waves and electric currents in circuits. To increase an antenna's conversion efficiency, it is necessary to ensure the antenna has directivity and align its maximum directivity toward the direction of arrival (or direction of radiation) of the desired radio waves. Such pattern control is performed in aperture antennas and linear antennas by mechanically changing the antenna direction. Phased array antennas (PAAs), which arrange multiple radiating elements on either flat or curved surfaces, have greatly changed this antenna pattern control method. These antennas change the beam direction by controlling the excitation phase and amplitude of the individual antennas. Control of the excitation phase is achieved by adjusting the phase of the signal received at each element (or the signal radiated) using a device called a phase shifter. This opens up the possibility of electronic pattern control in antennas. It also makes high-speed pattern control possible regardless of antenna size or weight.

PAAs were originally developed for radar application. Compared to conventional mechanically driven antennas, they offer dramatically faster beam scanning. As a result, PAAs have become the main type of mobile and fixed radar antennas. Recently, they have been applied to radio communications due the benefits offered by beam scanning, miniaturization of antenna elements and feeding circuits, and cost reduction. Examples reported include an on-satellite beam reforming antenna that switches between beams based on fluctuations in demand, for example, in international satellite communications, and a mobile station antenna for mobile satellite communications. An additional of PAA advantage is their ability to conform to the structure of the items on which they are mounted. This means that the antenna can

*Email: t-maru@ieee.org

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_37-1

be mounted on a satellite or moving vehicle without mechanically altering its form. An even more advanced form of PAA is the active phased array antenna (APAA), which not only has phase shifters for each element but also active elements such as low-noise amplifiers and high-power amplifiers.

The APAA has triggered new changes in antenna control methods.

When the APAA is designed so as to receive the microwave signals of each element and to digitalize them by an analog-to-digital converter, it enables beam forming by using a digital signal processor. A phased array antenna with this kind of functionality is referred to as a digital beam-forming (DBF) antenna. A further extension of the adaptive array technology that has appeared in recent years is MIMO (multiple input multiple output), which uses array antennas to both transmit and receive signals.

Thus, the arrival and subsequent development of PAAs have helped antennas evolve from simple energy converters to comprehensive systems that include such features as control technology, signal processing, and modulation and demodulation technology, the culmination of which are DBF antennas (adaptive array and MIMO).

This chapter explains the fundamental issues in designing PAAs. At first, the structure and functions of the PAAs are introduced. Pattern synthesis, which is a feature of array antennas, and array calibration methods are explained. DBF including signal processing and MIMO techniques are explained in a later part of this chapter.

Function of Array Antenna

The basic structure of an array antenna is depicted in Fig. 1. Each radiating element of the array is called an "element antenna." An array antenna consists of element antennas and a feed network. Various antennas have been used as element antennas, e.g., wire antennas or dipole antennas, slot antennas, microstrip antennas, and even horn antennas. The feed network includes signal distribution/combining circuits, phase shifters, high-power amplifier, low-noise amplifier, etc. Unlike a single antenna, an array antenna can offer a variety of functions by changing antenna type, grid type, and excitation provided by the feed network.

A flagship feature of the array antenna is pattern synthesis; the radiation pattern is optimized so as to meet some requirement. Pattern synthesis offers the following attributes:

(1) Desired radiation pattern
(2) Arbitrary width of main beam
(3) Reduced and controlled sidelobe levels
(4) Designated null point
(5) Desired gain

Using the above attributes allows us to improve the signal-to-noise (S/N) ratio or desired-to-undesired (D/U) ratio.

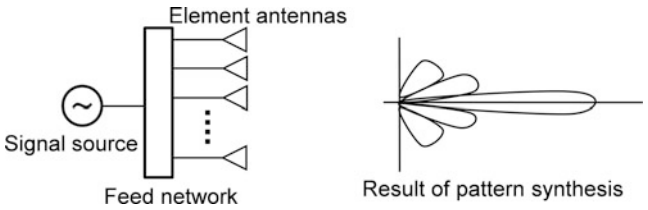

Fig. 1 Fundamental configuration of the array antenna

DOI 10.1007/978-981-4560-75-7_37-1

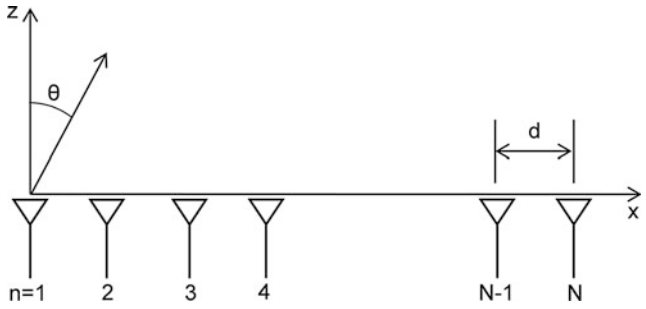

Fig. 2 Linear array antenna with N elements

Another feature of the array antenna is beam scanning which allows the main beam to be arbitrarily directed. For beam scanning, the phases of each element antenna are changed but not their positions. Several methods are available to change the excitation phase:

(1) Inserting phase shifters into the feed networks
(2) Changing frequency by altering length differences in the feed network
(3) Selecting the beam-forming network that corresponds to the desired direction

(1) yields the "phased array antenna (PAA)," which is the de facto choice for electronically scanning antennas.

A phase shifter, either analog or digital, is added to each element feed line. The latter is the main choice recently because of its controllability. Another approach to control the phases of each element antenna is digital beam forming (DBF) (Steyskal 1988; Chiba et al. 1997). In DBF, an intermediate frequency (IF) signal or a baseband signal is converted into a digital signal, and the phase is controlled in the digital stage. The key advantage of DBF is that arbitrary phase and amplitude can be set and multiple beams can be simultaneously created because of the digital operation. The optically controlled array antenna, whose phase and amplitude are controlled in the optical domain, has been also researched (Marpaung et al. 2011; Sumiyoshi et al. 2010). It enables to create multiple beams with small size and light weight.

Characteristics of Array Antenna

Linear Array Antenna

Figure 2 shows a linear array antenna consisting of N element antennas placed in a straight line with equal spacing of d (Hansen 1966; Mailloux 2005). The linear array antenna is the simplest array antenna, and many examples of practical use have been described.

The radiation patterns or input impedance or current distribution (in the case of dipole antennas) of each element antenna is not identical even if all element antennas are excited with the same amplitude and phase. The reason is mutual coupling between element antennas. However, the basic characteristics of array antennas can be explained without addressing these differences. If all element antennas are assumed to receive the same current distributions, the radiation pattern of each element antenna can be expressed by the same function. Given this assumption, the radiation pattern of an array antenna is determined by the radiation pattern function and the phase difference of each element antenna. The phase difference is determined by the position of each element antenna. The radiation pattern of array antenna $F(\theta, \phi)$ is expressed by

DOI 10.1007/978-981-4560-75-7_37-1

$$F(\theta,\phi) = f(\theta,\phi)\sum_{n=1}^{N} a_n \exp(j\varphi_n) \times \exp(jk\mathbf{r}_n \cdot \mathbf{R}) \tag{1}$$

where $\mathbf{r}_n = (x_n,0,0)$ is the position vector of the nth element antenna, a_n is excitation amplitude, p_n is excitation phase, $f(\theta, \phi)$ is the radiation pattern of a single element antenna, vector of observation point is $\mathbf{R} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$, $k = 2\pi/\lambda$ is wave number in free space, and λ is wavelength in free space. For simplicity, $F(\theta, \phi)$ of the linear array antenna in Fig. 2 is expressed as

$$F(\theta,\phi) = f(\theta,\phi)\sum_{n=1}^{N} a_n \exp(j\varphi_n) \times \exp[jk(n-1)d\sin\theta] \tag{2}$$

If the element antenna type is changed, e.g., from dipole antenna to microstrip antenna, radiation pattern $f(\theta, \phi)$ in Eq. 2 is changed. On the other hand, the summation term is unchanged. Therefore, features of the array antenna are determined by the summation term. In order to analyze the basic performance of the array antenna, the pattern that eliminates $f(\theta, \phi)$ is used. It is the same as $f(\theta, \phi) = 1$, the ideal isotropic antenna. This radiation pattern is called the "array factor."

In the array antenna of Fig. 2, assuming that the array antenna is far from the observation point, if all element antennas are excited so that phases from all element antennas are identical at direction $\theta = \theta_0$, excitation phase of the nth element antenna, φ_n, is

$$\varphi_n = -n \cdot u_0 \tag{3}$$

$$u_0 = kd\sin\theta_0 \tag{4}$$

These phases are called "co-phase" and are used when the peak of the radiation pattern is directed to a desired angle. In this case, the array factor is expressed by

$$F(u) = \sum_{n=1}^{N} a_n \exp(jnu) \tag{5}$$

u is used instead of θ,

$$u = kd(\sin\theta - \sin\theta_0) \tag{6}$$

Dropping the radiation pattern of element antenna, $f(\theta, \phi)$, from Eq. 2 yields Eq. 5. θ, d, and θ_0 are determined by just one variable u. This is convenient when analyzing the characteristics of an array antenna.

When all element antennas of the linear array antenna are excited with identical amplitude and co-phase, from Eq. 5, the radiation pattern of the array antenna is expressed as

$$F(u) = \frac{\sin\left(\frac{Nu}{2}\right)}{N\sin\frac{u}{2}} \tag{7}$$

DOI 10.1007/978-981-4560-75-7_37-1

From Eq. 7, F takes maximum value 1 at $u = 2\,m\pi(m = 0, \pm 1, \pm 2, \cdots)$. Local maxima in F, called sidelobes, are found at $Nu/2 = (2\,M + 1)\,\pi/2$ $(M = 0, \pm 1, \pm 2, \cdots)$.

In case of $u \ll 1$, Eq. 7 is approximated by

$$F(u) = \frac{\sin\left(\frac{Nu}{2}\right)}{\frac{Nu}{2}} \tag{8}$$

This approximation is valid when element antenna spacing d is smaller than wavelength or the range of θ is limited. Equation 8 yields the same pattern as that created by an aperture emitting a continuous wave with uniform amplitude distribution. Therefore, the array antenna of this case can be replaced by an aperture antenna with uniform amplitude distribution. Reversing this assumption allows an array antenna to be designed: First, aperture size and amplitude distribution of a continuous wave source are determined so as to satisfy service requirements like gain, beamwidth, and sidelobe level. Second, the number of elements and element antenna spacing are determined by placing the element antennas at the aperture determined in the first step.

Figure 3 is an example of the array factor of a linear array antenna with nine elements. This is a periodic function and yields maximum value 1 at $u = 2\,m\pi(m = 0, \pm 1, \pm 2, \cdots)$. Local maxima are sidelobes.

If the main beam is directed to the z-axis in Fig. 2, the antenna becomes a broadside array, i.e., the main beam and the axis of elements are perpendicular. In this case, θ_0 becomes 0. Because $|\sin(\theta)| \leq 1$, the range of u becomes

$$-kd \leq u \leq kd \tag{9}$$

For antenna spacing $d = \lambda/2$, $|u| \leq \pi$ corresponds to the actual space $|\sin(\theta)| \leq 1$, i.e., $-\pi/2 \leq \theta \leq \pi/2$. This range where the pattern appears in actual space is called the "visible region." Other region is called the "invisible region."

For antenna spacing $d = 1.5\ \lambda$, $|u| \leq 3\pi$ becomes the visible region. In this case, in addition to $u = 0$, two peaks at $|u| = 2\pi$ fall on the visible region. These large radiations correspond to the periodic diffraction fringe caused by the optical diffraction grating effect. They are called "grating lobes."

In array antennas, if the spacing between element antennas is expanded, mutual coupling between element antennas is reduced and narrow beams are obtained. If spacing between element antennas is

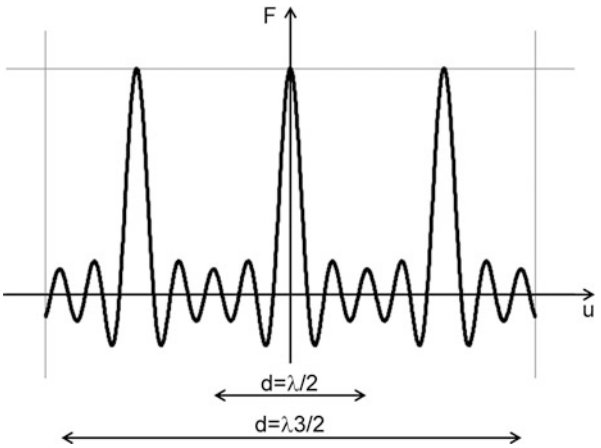

Fig. 3 Array factor of 9 element linear array antenna and visible region for each antenna spacing

DOI 10.1007/978-981-4560-75-7_37-1

expanded within a fixed aperture size, the number of elements is reduced and feeding circuits are accordingly simplified and manufacturing costs are lowered. Thus, antenna designs that offer the widest possible spacing are preferred. Unfortunately, excessively wide antenna spacings trigger grating lobes. Radiation occurs on undesired angles, gain is degraded on the desired angle, and signal-to-noise ratio (S/N) is degraded along with the input impedance of the element antenna. Array antenna designs basically widen the spacing up to the point that grating lobes appear in the visible region.

For a one-dimensional PAA whose main beam is to be scanned, antenna spacing d is calculated as described below. First, the relationship between variable u and main beam angle θ_0 is given by Eq. 6:

$$u = kd(\sin\theta - \sin\theta_0) \tag{6}$$

If $\theta_0 \geq 0$ is assumed, |u| is maximized at $\theta = -\pi/2$, which yields the following equation:

$$|u|_{maz} = \frac{2\pi}{\lambda} d(1 + \sin\theta_0) \tag{10}$$

The first grating lobe appears at $|u| = 2\,\pi$. Grating lobes do not appear in the visible region if the following inequality is satisfied:

$$\frac{2\pi}{\lambda} d(1 + \sin\theta_0) \leq 2\pi \tag{11}$$

From Eq. 11, the upper limit of d without grating lobes can be determined:

$$d = \frac{\lambda}{1 + \sin\theta_0} \tag{12}$$

If d is selected so as to satisfy Eq. 12, where θ_0 is the upper limit of scanning angle, no grating lobe appears within the visible region. If, however, the element spacing d determined from Eq. 12 is used, the peaks of the first grating lobes lie on the edges of the visible region. In order to eliminate the grating lobes completely, including their shoulder, antenna spacings that are 5–10 % smaller than Eq. 12 are generally adopted.

Using Eq. 12, the relationship between antenna spacing and main beam angle with the first grating lobe at $\theta = -\pi/2$ is plotted in Fig. 4. When $d/\lambda = 0.5$ is used, no grating lobe appears within the scan angle $\pm\pi/2$.

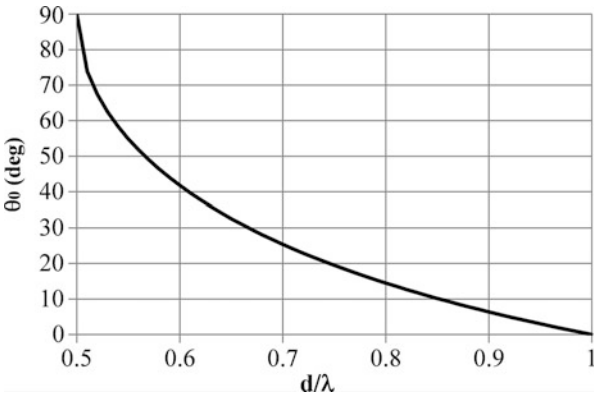

Fig. 4 Relationship between the antenna spacing and main beam angle with the first grating lobes at the visible region edges

DOI 10.1007/978-981-4560-75-7_37-1

If grating lobes in the visible region are permitted, the relationship between grating lobe angle θ_g and main beam angle θ_0 is given by

$$\frac{2\pi}{\lambda} d\left(\sin\theta_g - \sin\theta_0\right) = -2\pi \tag{13}$$

$$\sin\theta_g = \sin\theta_0 - \frac{\lambda}{d} \tag{14}$$

This is illustrated in Fig. 5.

Planar Array Antenna

While linear array antennas have radiation patterns that take the form of a dish or circular cone, planar array antennas have pencil beam-like radiation patterns (Mailloux 2005). Therefore, planar array antennas are widely used as practical array antennas.

Most planar array antennas use either a rectangular grid array or a triangular grid array; see Fig. 6. The rectangular grid array is realized by expanding the linear array to two dimensions. Its feeding circuit is easier to design than that of the triangular grid array antenna. On the other hand, the triangular grid array

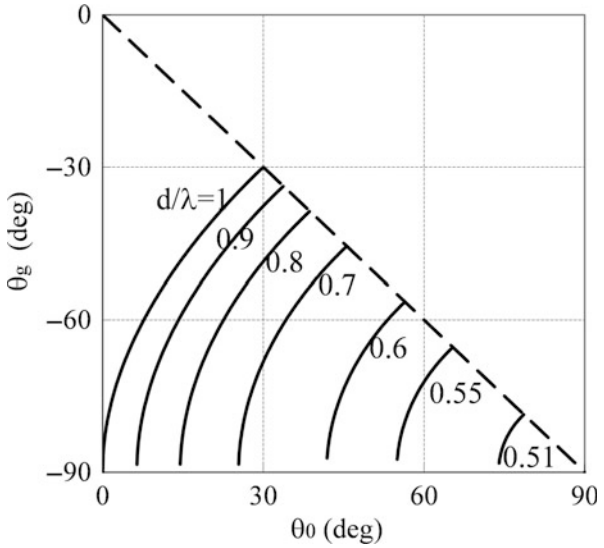

Fig. 5 Relationship between main beam angle and grating lobe angle for different antenna spacings

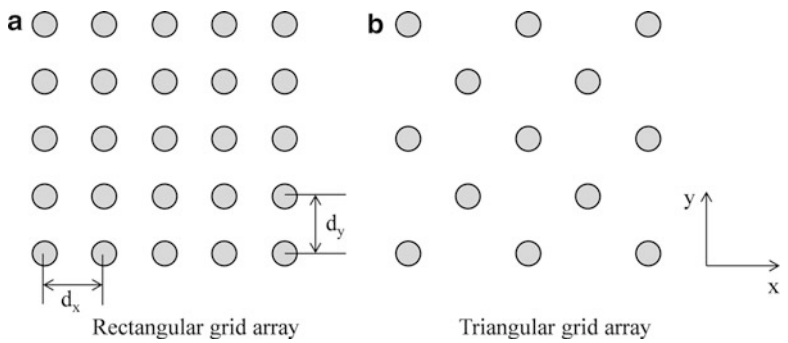

Fig. 6 Rectangular grid array and triangular grid array

DOI 10.1007/978-981-4560-75-7_37-1

allows element antenna spacing to larger than the rectangular grid array. The triangular grid array allows fewer element antennas to be used than the rectangular grid array for the same aperture size and gain and coverage. Additionally, mutual coupling between element antennas is reduced because of wide antenna spacing. So the triangular grid array antennas are widely used.

In the case of the rectangular grid array, the complex amplitude of the element antenna on the nth column (x-direction) and the mth row (y-direction) is defined as A_{mn} ($=a_{mn}$ exp[j(nu + mv)]). Element antenna spacing in x-direction is d_x, and element antenna spacing in y-direction is d_y. The radiation pattern is given by

$$F(\theta, \phi) = \sum_n \sum_m A_{nm} \exp[j(nu + mv)] \tag{15}$$

where

$$u = kd_x \sin\theta \cos\phi \tag{16}$$

$$v = kd_y \sin\theta \sin\phi \tag{17}$$

If the complex amplitude of the element on nth column and mth row, A_{mn} is expressed as the product of x-direction term A_n and y-direction term A_m, that is,

$$A_{nm} = A_n A_m \tag{18}$$

Equation 15 is rewritten as

$$F(\theta, \phi) = \sum_n A_n \exp[jnu] \sum_m A_m \exp[jmv] \tag{19}$$

It means that the radiation pattern of a rectangular grid array antenna is the product of the radiation pattern of the x-directional linear array and the radiation pattern of the y-directional linear array. Basically, rectangular grid array antennas are excited in accordance with Eq. 18. In the case, characteristics of the planar array antenna are those of the linear array antenna. Radiation patterns described by Eq. 19 are called separable patterns. On the other hand, radiation patterns that do not follow Eq. 19 are called non-separable patterns.

The rectangular grid array and the triangular grid array have different grating lobe characteristics. In Fig. 6, the two designs have the same element antenna spacing on the x-axis and on the y-axis, so the incidence of grating lobes on the xz-plane and yz-plane is also the same. However, grating lobe characteristics on the diagonal direction are not the same. A grating lobe chart, based on the reciprocal lattice of crystallography, helps us to analyze the grating lobes of planar array antennas. An example of a grating lobe chart is shown in Fig. 7 for both the rectangular grid array and the triangular grid array; the main beam is directed to the boresight (z-axis).

The grating lobe chart has two axes: axis Tx plots term $\sin(\theta)\cos(\phi)$, while axis Ty plots term $\sin(\theta)\sin(\phi)$; length from the origin is $\sin(\theta)$ and circumferential angle is ϕ. The visible region lies inside the circle of $\sin(\pi/2) = 1$. The grating lobes of the rectangular grid array lie on the reticular pattern of λ/d_x and λ/d_y in the grating lobe chart. The triangular grid array outputs the grating lobes on a triangle lattice in the grating lobe chart. If element antenna spacing is constant, the grating lobes of the triangular grid array are more widely separated than those of the rectangular grid array. Thus, triangular grid array antennas are widely used.

DOI 10.1007/978-981-4560-75-7_37-1

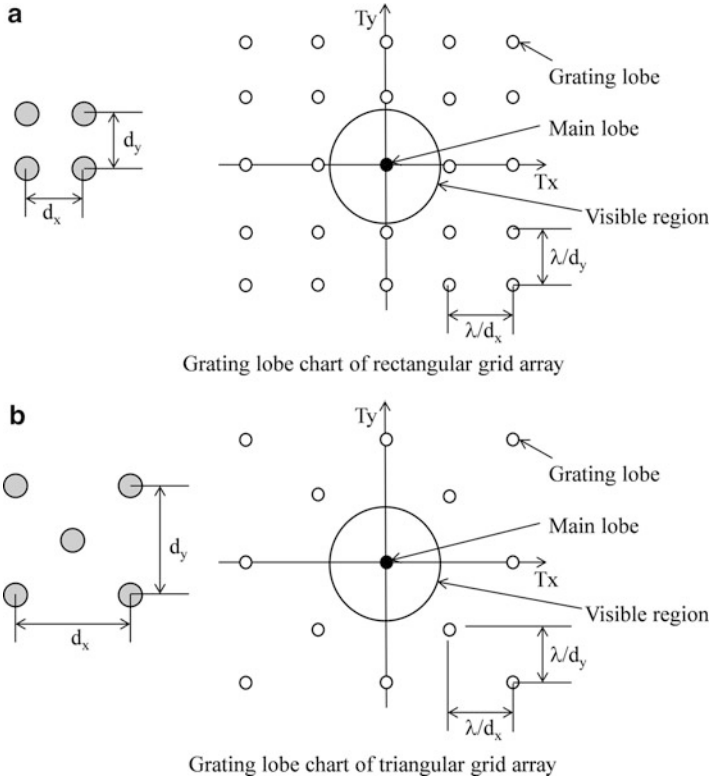

Fig. 7 Grating lobe chart at main beam angle $\theta = 0°$

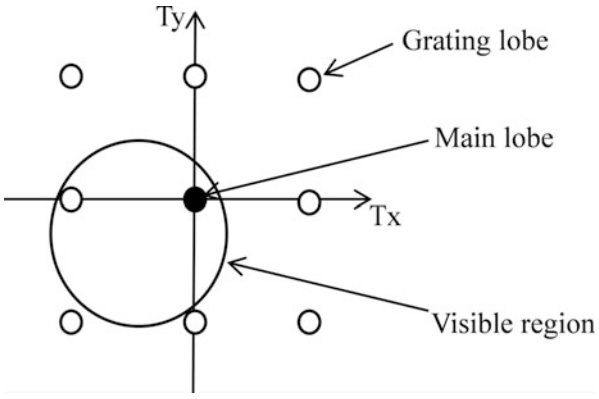

Fig. 8 Grating lobe chart at main beam angle $\theta = 60°$, $\phi = 60°$

The grating lobe chart is helpful in analyzing grating lobes even if the beam is scanned. Figure 8 is an example of the grating lobe chart when the main beam of a rectangular grid array is directed to $\theta = 60°$, $\phi = 30°$.

When the main beam is scanned, its point moves in the grating lobe chart. All grating lobe points move in parallel with that of the main lobe. In the case of Fig. 8, one grating lobe appears in the visible region due to beam scanning.

DOI 10.1007/978-981-4560-75-7_37-1

Gain, Beamwidth, and Sidelobe Level

Directivity of array antennas is approximated as follows (Elliott 2003)

Linear Array Antenna When the element antennas in Fig. 2 are point wave sources, their amplitudes are uniform, their number (N) is large, and antenna spacing d is selected so as to exclude grating lobes; the directivity of the resulting linear antenna, D_l, is given by

$$D_l \approx \frac{2Nd}{\lambda} \tag{20}$$

The directivity is determined by the radiation pattern. Loss of feeding circuits and efficiency of element antennas are not included in this expression.

Planar Array Antenna When aperture size is sufficiently larger than wavelength, and element number N is large, the directivity of a planar array, D_p, is given by

$$D_p \approx D_e N \cos\theta_0 \tag{21}$$

$$D_e = \frac{4\pi A_e}{\lambda^2} \tag{22}$$

where θ_0 is main beam angle, D_e is directivity of arrayed element antenna, and A_e is efficient aperture size of the element antenna. If directivity of stand-alone element antenna D_0 is higher than D_e, that is, $D_0 \geq D_e$ and $A_0 \geq A_e$ (A_0: efficient aperture size of stand-alone element antenna), A_e is limited by the area occupied by one element antenna. Thus, $A_e \times N$ is nearly equal to aperture size of total antenna size A. This condition is basically satisfied in the case of array antennas with standard element antenna spacings. Using this approximation, D_p becomes

$$D_p \approx \frac{4\pi A}{\lambda^2} \cos\theta_0 \tag{23}$$

This is equal to the directivity of a planar wave source with aperture size A and with phase distribution so as to direct the main beam to θ_0. If the amplitude distribution of element antennas is unequal to obtain a radiation pattern with low sidelobe levels, the directivity will be reduced since the aperture efficiency is determined by the amplitude distribution.

Actual Gains

The actual gain of a PAA is not equal to the directivity determined from the radiation pattern (Mailloux 2005). The one factor is the impedance mismatch of element antennas and mutual coupling between element antennas. When the number of elements is N, and the aperture efficiency determined from amplitude distribution is η, the actual gain is given by

$$G(\theta_0) = g(\theta_0) N \eta \tag{24}$$

g is the element gain function given by

DOI 10.1007/978-981-4560-75-7_37-1

$$g(\theta_0) = D_e \cos\theta_0 \left(1 - |\Gamma(\theta_0)|^2\right) \tag{25}$$

D_e is the directivity of the arrayed element antenna given by Eq. 22. Γ is reflection coefficient where all elements are excited, that is, active reflection coefficient is defined as

$$\Gamma_n(\theta_0) = \frac{1}{a_n} \sum_{i=1}^{N} S_{i,n} a_i \exp[j(\psi_i(\theta_0) - \psi_n(\theta_0))] \tag{26}$$

Subscript n means element number. $S_{n,n}$ is the self-reflection coefficient of element n. $S_{i,n}$ is mutual coupling from element i to element n. a_i is excitation amplitude of element i. $\psi_i(\theta_0)$ is the excitation phase of element i. Because $\psi_i(\theta_0)$ varies according to main beam angle θ_0, active reflection coefficient Γ is also a function of θ_0.

Beamwidth and Sidelobe Level

From Eq. 8, directivity of a linear array with element number N and uniform amplitude distribution is approximately (Mailloux 2005)

$$F(\theta) = \frac{\sin(u)}{u} \tag{27}$$

where

$$u = \frac{\pi}{\lambda} L(\sin\theta - \sin\theta_0) \tag{28}$$

L is aperture length, $L = Nd$ (d is element antenna spacing). Beamwidth Θ (which is defined as the angle at which gain decreases −3 dB from main lobe peak) of this linear array antenna is directly calculated from Eq. 27. Its approximation is given by

$$\Theta \approx \frac{50}{(L/\lambda)\cos\theta_0} (\text{deg.}) \tag{29}$$

The beamwidth increases with scan angle θ_0.

The directivity of a circular planar array with high enough element number and uniform amplitude distribution is approximately equal to a circular aperture with continuous wave source and uniform amplitude distribution. It is given as follows:

$$F(\theta) = \frac{2J_1(u)}{u} \tag{30}$$

$$u = \frac{\pi}{\lambda} D(\sin\theta - \sin\theta_0) \tag{31}$$

J_1 is the Bessel function order 1. Beamwidth is approximated by

$$\Theta \approx \frac{60}{(D/\lambda)\cos\theta_0} \ (\text{deg.}) \tag{32}$$

DOI 10.1007/978-981-4560-75-7_37-1

From Eqs. 29 and 32, beamwidth of the circular planar array is about 1.2 times greater than that of the linear array or the rectangular planar array.

Sidelobe level can be easily obtained from Eqs. 27 and 30. First sidelobe level of the linear array with uniform amplitude distribution is about −13.3 dB. That of the circular planar array with uniform amplitude distribution is about −17.6 dB.

Mutual Coupling

Mutual coupling between element antennas, a characteristic of array antennas, causes various problems. If the mutual coupling level is not zero, the active reflection coefficient of an arrayed element antenna is not equal to that of a stand-alone element antenna as per Eq. 26. The impedance of an arrayed element antenna where all elements are excited is called the active impedance. From Eq. 26, the active impedance varies according to beam-scanning angle. In large-scale arrays, there is a risk that the active impedance becomes infinite (the active reflection coefficient becomes 1) or the active impedance becomes zero (the active reflection coefficient becomes −1). In such cases, no signal is radiated. This phenomenon is called scan blindness. One example of scan blindness is as follows: element antenna spacing d is larger than $\lambda/2$, and the main beam is widely angled away from the boresight. Scan blindness may arise when the grating lobe appears at a visible region edge. Figure 9 shows a dipole antenna that is $\lambda/4$ above a metal reflector. This antenna is used as the elements of an infinite array antenna. Because antenna spacing in the y-direction is $\lambda/2$, a grating lobe appears at $\phi = 90°$ and $\theta = -90\,°$, when the main beam is directed to $\phi = 90°$ and $\theta = 90°$. Figure 10 is its active impedance plot. When main beam direction is the boresight ($\phi = 90°$, $\theta = 0°$), the impedance is almost matched. When the main beam direction is scanned 90° from the boresight ($\phi = 90°$, $\theta = 90°$), the impedance is rapidly degraded.

Scan blindness can arise without grating lobes. One example is an array antenna from which some elements have been eliminated to create a tapered amplitude distribution, which is explained later. Because some element antennas may not have symmetrical partners, mutual coupling cannot be fully canceled.

One method to estimate the degradation in active impedance is the array-element pattern measurement; the radiation pattern of a single element is measured when only that element is excited and all other elements are terminated. The array-element pattern is the element gain function given by Eq. 25. The gain at the angle at which the scan blindness occurs decreases to zero at worst.

To counter the impedance mismatch due to beam scanning, one approach is to reduce the mutual coupling by changing the element antenna type or the array configuration. Other approach is to add matching circuits to the element antennas. There is no general, deterministic solution to this problem. So computer simulations or experimental techniques with parameterized antenna parameters are used. Note that the edge effect should be considered because element number is finite.

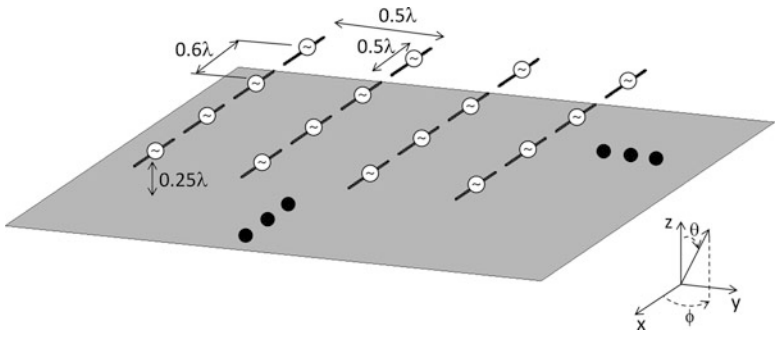

Fig. 9 Antenna configuration

DOI 10.1007/978-981-4560-75-7_37-1

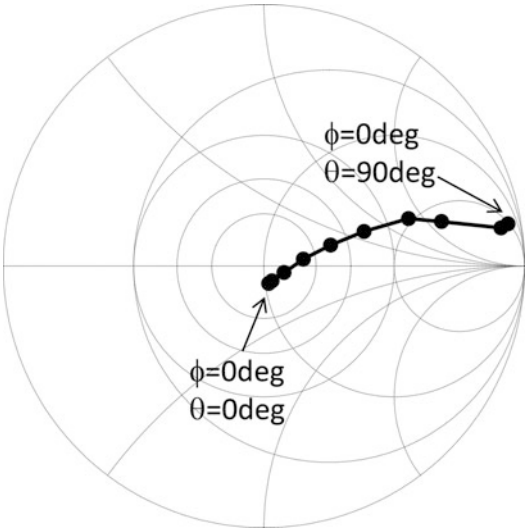

Fig. 10 Active impedance (*circles* are plotted at θ intervals of 10°)

Mutual coupling produces various problems like impedance variation, gain degradation, and radiation pattern degradation. Therefore, it is important for the array antenna designer to determine the antenna type and the array configuration so as to reduce mutual coupling as much as possible.

The Analysis of Infinite Array by Using Periodic Boundary Conditions

When large-scale array antenna is analyzed, simulating the actual array size allows various antenna characteristics, like the impedance of each element antenna, mutual coupling, array-element pattern, and total pattern, to be obtained. Unfortunately, such simulations are usually impossible due to constraints on computer memory resources and calculation time. One approach is to use a subarray, a subset of the full array. However, it is difficult to judge whether the modeled subarray well replicates the characteristics of the full array. Other analysis methods of infinite arrays (Ren et al. 1994; Turner and Christodoulou 1999; Holter and Steyskal 1999) use periodic boundary conditions (Amitay et al. 1972). The analytical region matches the element spacing, but a periodic boundary condition is added. This approach method can simulate one- or two-dimensional infinite arrays by modeling just one element antenna.

Antenna Pattern Synthesis

Amplitude Distribution Yielding Low Sidelobe

In the previous chapter, it was shown that the first sidelobe level of the linear array antenna and the rectangular aperture array antenna is about −13.3 dB, while that of the circular aperture array antenna is about −17.6 dB. In APAA for radar application, lower sidelobe level is required so as to reduce interference and noise from the environment.

It is important to achieve both sidelobe level reduction and gain maintenance. The amplitude distribution yielding the sidelobe level of a defined value (or lower) and minimum beamwidth is the Chebyshev distribution (or Dolph-Chebyshev distribution) (Dolph 1946). The radiation pattern of an array antenna with this amplitude distribution is expressed as the following polynomial:

$$E(u) = T_{N-1}\left(z_0 \cos\frac{u}{2}\right) \tag{33}$$

DOI 10.1007/978-981-4560-75-7_37-1

All sidelobe levels are identical. Z_0 is a constant that defines the sidelobe level. Its value is greater than 1. The ratio of main lobe level to sidelobe level is

$$R = T_{N-1}(z_0) \tag{34}$$

$$z_0 = \cosh\left[\frac{1}{N-1}\cosh^{-1}R\right] \tag{35}$$

The Chebyshev distribution, both ends of which are normalized to 1, is given as

$$a_n = \begin{cases} (n-1)\alpha^2 \sum_{m=0}^{n-1} \dfrac{(n-m)_m (N-n-m-1)_n}{m!(m+1)!}\alpha^{2m} & \left(0 \le n \le \dfrac{N-1}{2}\right) \\ 1 & (n=0) \end{cases} \tag{36}$$

$$\alpha = \frac{\sqrt{z_0^2 - 1}}{z_0} \tag{37}$$

In Eq. 36, $(\beta)_l$ means the following product:

$$\beta_l = \beta(\beta+1)(\beta+2)\cdots(\beta+l-1)$$

$$\beta_0 = 1$$

When the Chebyshev distribution is applied to a large-scale array with element number N, amplitudes of edge elements become discontinuous. The radiation pattern is very sensitive to errors in the amplitude distribution. In such case, the Taylor distribution, which has no such inconvenience, is commonly used.

The Taylor distribution is explained as follows. At first, the Chebyshev distribution of N elements follows the equation below when entire array length $a = (N-1)d$ is kept constant and N approaches infinity:

$$E_1(u) = \cos\left[\pi\sqrt{u^2 - A^2}\right] \tag{38}$$

$$u = \frac{2a}{\lambda}\sin\theta \tag{39}$$

A is a parameter of the sidelobe level, $1/\cosh(\pi A)$. Radiation patterns with Chebyshev distribution have constant sidelobe levels. On the other hand, from Eq. 8, the radiation pattern of a continuous wave source with uniform amplitude distribution is

$$E_2(u) = \frac{\sin(\pi u)}{\pi u} \tag{40}$$

It becomes zero when u is integer. The sidelobe level is reduced by $1/u$.

Here integer number $\overline{n}$ is defined. The Taylor radiation pattern has zero point of E_2 for $u \ge \overline{n}$ and zero point of E_1 for $u \le \overline{n}$ (Taylor 1955).

DOI 10.1007/978-981-4560-75-7_37-1

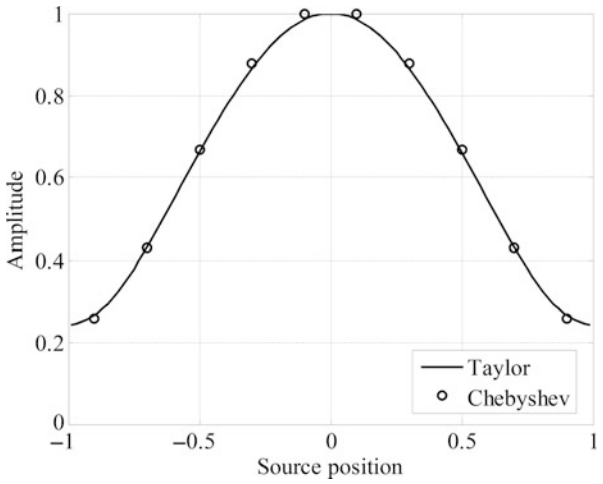

Fig. 11 Taylor distribution (*solid line*) and Chebyshev distribution (*circles*)

The amplitude distribution that yields the Taylor radiation pattern is the Taylor distribution. The Taylor distribution with sidelobe level of -30 dB and $\overline{n}$ =4 is shown in Fig. 11. The Chebyshev distribution with sidelobe level of −30 dB and ten elements is also plotted. Its values are similar to the sampled values of the Taylor distribution.

Discrete values of the Taylor distribution are generally used in designing large-scale array antennas with element number N. Compared to the Chebyshev distribution, the Taylor distribution yields high gain.

Plane-Wave Synthesis

Plane-wave synthesis yields desired radiation pattern by superposition of multiple radiation patterns (Chiba and Mano 1987).

In Fig. 12, the angle of the desired signal is θ_s, and its radiation pattern with main beam angle θ_s is $E_s(\theta)$, which is the initial pattern. The angles forming nulls are θ_m ($m = 1 \cdots M$), and radiation pattern with main beam angle θ_m is $E_m(\theta)$ ($m = 1 \cdots M$). In plane-wave synthesis, null points are formed by superimposing the initial patterns E_s and E_m with multiplication by an appropriate complex factor. When complex amplitudes of element antenna n to form E_s and E_m are A_{sn} and B_{mn}, respectively, from Eq. 1, E_s and E_m are as follows:

$$E_s(\theta) = \sum_{n=1}^{N} A_{sn} \exp(jk\mathbf{r}_n \cdot \mathbf{R}) \tag{41}$$

$$E_m(\theta) = \sum_{n=1}^{N} B_{mn} \exp(jk\mathbf{r}_n \cdot \mathbf{R}) \tag{42}$$

When complex factor multiplied to E_m is a_m, desired radiation pattern yielding desired angle θ_s and null angle θ_m is given as

$$E(\theta) = E_s(\theta) + \sum_{m=1}^{M} a_m E_m(\theta) = \sum_{n=1}^{N} \left(A_{sn} + \sum_{m=1}^{M} a_m B_{mn} \right) \exp(jk\mathbf{r}_n \cdot \mathbf{R}) \tag{43}$$

DOI 10.1007/978-981-4560-75-7_37-1

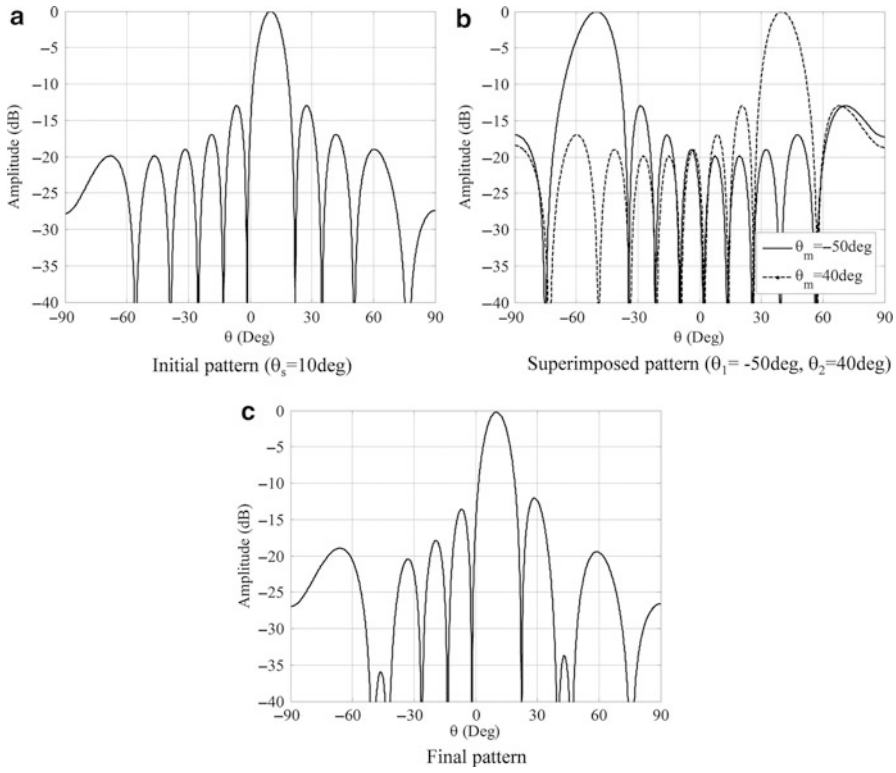

Fig. 12 Plane-wave synthesis

Amplitude distribution A_n to form the desired radiation pattern is expressed by using A_{sn} and B_{mn}:

$$A_n = A_{sn} + \sum_{m=1}^{M} a_m B_{mn} \tag{44}$$

From Eq. 43, the condition that yields nulls on θ_m ($m = 1 \cdots M$) is

$$E(\theta_m) = E_s(\theta_m) + \sum_{m=1}^{M} a_m E_m(\theta) = 0 \tag{45}$$

a_m is the solution of the following simultaneous equation:

$$\mathbf{Ea} = \mathbf{e} \tag{46}$$

$$\mathbf{E} = \begin{bmatrix} E_1(\theta_1) & E_2(\theta_1) & \cdots & E_M(\theta_1) \\ E_1(\theta_2) & E_2(\theta_2) & \cdots & E_M(\theta_2) \\ \vdots & \vdots & \ddots & \vdots \\ E_1(\theta_M) & E_2(\theta_M) & \cdots & E_M(\theta_M) \end{bmatrix} \tag{47}$$

$$\mathbf{a} = [\, a_1 \quad a_2 \quad \cdots \quad a_M \,] \tag{48}$$

$$\mathbf{e} = [\, -E_s(\theta_1) \quad -E_s(\theta_2) \quad \cdots \quad -E_s(\theta_M) \,] \tag{49}$$

DOI 10.1007/978-981-4560-75-7_37-1

If A_{sn} and B_{mn} are array factors for θ_s and θ_m, that is, the conjugate of the electric field from element antenna, A_n becomes the complex amplitude that maximizes gain for θ_s and sets nulls on θ_m. Because A_{sn} and B_{mn} are amplitudes that form a plane wave, this method is called plane-wave synthesis. Figure 12 is an example of plane-wave synthesis when the number of element antennas is 10. In (a), θ_s is 10°. In (b), θ_1 and θ_2 are −50° and 40°, respectively. The resulting pattern, (c), has two nulls at −50° and 40°.

Plane-wave synthesis gives a unique complex value that includes amplitude and phase information for each element. This method requires both amplitude and phase control. Because standard PAA has only phase control, the desired pattern may not be obtained. In such cases, antenna pattern synthesis with only phase control, which demands nonlinear optimization like the minimax method, is used.

Minimax Algorithm

When plane-wave synthesis or other analytical synthesis algorithms are not applicable, or the amplitude distribution cannot be analytically obtained due to the complexity of the desired radiation pattern, nonlinear optimization algorithms are used. One example, the minimax algorithm, addresses array antenna power (Klein 1984). It is effective when the reference point number of the radiation pattern, M, is larger than element antenna number, N.

Parameters are commonly defined as follows:

N: Element antenna number
M: Reference point number of radiation pattern
E_{mn}: Radiated electric field amplitude of element antenna n, angle θ_m
ϕ_{mn}: Radiated electric field phase of element antenna n, angle θ_m
a_n: Excitation amplitude of element antenna n
φ_n: Excitation phase of element antenna n
P_{0m}: Desired power for θ_m
W_m: Weight of each reference point

The evaluation function is defined as

$$F = \sum_{m=1}^{M} W_m \left(\left| \sum_{n=1}^{N} a_n \exp(j\varphi_n) E_{nm} \exp(j\phi_{nm}) \right|^2 - P_{0m} \right)^2 \tag{50}$$

Excitation amplitude and phase yielding desired radiation pattern can be obtained by minimizing F by calculating its gradient.

The minimax algorithm can be applied to any requirement. However, the following important points must be noted:

(1) F has many local minima due to its nonlinearity, and it is difficult to judge if an F value is the absolute or local minimum. Moreover, the iteration number for convergence depends on initial excitation amplitude and phase. In order to ease these inconveniences, plane-wave synthesis can be conducted first and its results used as the initial condition.
(2) In the case of an antenna with fixed radiation pattern, feeding circuits cannot be constructed because calculated values of excitation amplitude and phase may be scattered.

DOI 10.1007/978-981-4560-75-7_37-1

Element Thinning Algorithm

In many APAA designs, transmitting power of each element antenna is constant because high-power amplifiers are driven in their saturated region for efficiency. This prevents excitation amplitude of each element from being controlled to obtain radiation patterns with low sidelobe levels. In order to realize low sidelobe levels in this situation, element density distribution is controlled by thinning element antennas. A deterministic approach to the thinning algorithm that attains the element density distribution yielding desired radiation pattern has been proposed (Numazaki et al. 1987).

It has no ambiguity and does not depend on probability.

When element position is P_i and desired amplitude distribution is f, weight f_i of element at P_i is defined as

$$f_i = Cf(P_i)\,\Delta S_i \tag{51}$$

$f(P_i)$ is the amplitude distribution value at P_i. ΔS_i is the exclusive area of point P_i. C is a coefficient such that the upper limit of f_i is 1. An example of P_i is the grid of a linear array, and f is the Taylor distribution. When the order of element position is determined, the thinning function, $T(P_i)$, is given by the cumulative value of f_i:

$$T(P_i) = \left[\sum_{j=1}^{i} f_j + 0.5\right] - \left[\sum_{j=1}^{i-1} f_j + 0.5\right] = 0 \text{ or } 1 \tag{52}$$

$[\cdot]$ is a floor function. Equation 52 outputs 0 or 1. The value means excitation or non-excitation of each element. The difference between the cumulative value of the weight and that of excitation element number is 0.5 or less. An example of thinning is shown in Fig. 13. The number of elements is 20 and the amplitude distribution follows a Taylor distribution with sidelobe of -30 dB and $\overline{n} = 4$. In the figure, the solid line is the cumulative value of f_i, and circle plots are the cumulative value of $T(P_i)$. No difference exceeds 0.5.

In planar array antennas, the radiation pattern on an observing plane is determined by element number distribution vertically projected onto the plane. Let's consider optimizing the x-plane radiation pattern to yield the desired pattern. While P_i has coordinates of (x, y), order of P_i is given lexicographically, that is, x is sorted in ascending order. If multiple elements have identical position according to x, y is sorted in

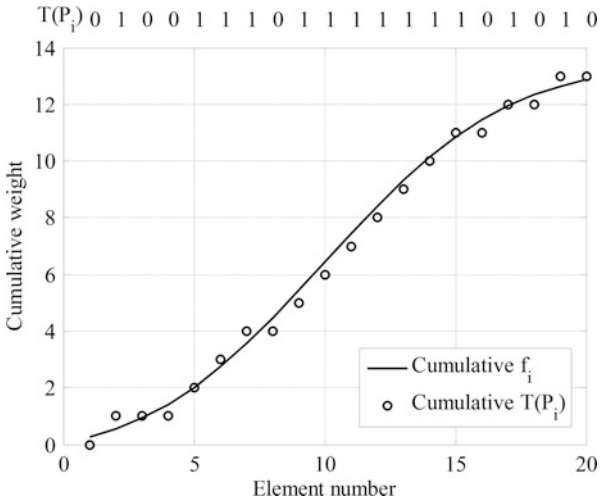

Fig. 13 Element thinning algorithm

DOI 10.1007/978-981-4560-75-7_37-1

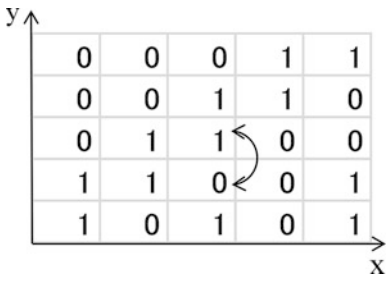

Fig. 14 Interchange of excitation elements

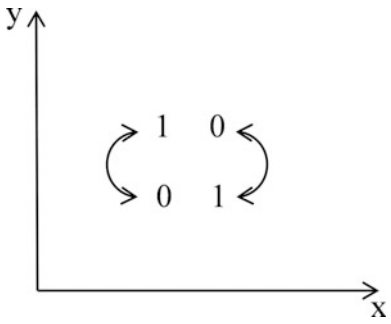

Fig. 15 Interchange of two pairs

ascending order. The thinning function, T_x, for the x-plane pattern is determined from P_i. From T_x, P_{xj}, which is the number of the excitation element at jth position for the x-plane, is calculated. Similarly, T_y and P_{yk} are calculated for the y-plane. When T_x is calculated for x-plane, resulting Q_{yk}, which is the excitation element number at kth position on the y-plane, is also calculated. Difference between ideal distribution P_{yk} and distribution Q_{yk} is calculated as D_k:

$$D_k = Q_{yk} - P_{yk} \tag{53}$$

The summation of D_k must be zero. If all D_k are zero, the desired distribution is obtained for x- and y-plane.

If D_{k1} is positive, D_{k2} having negative value must exist. If the thinning function yields 1 on row k_1 and 0 on row k_2 at position x_1, and 0 on row k_1 and 1 on row k_2 at position x_2, values are interchanged as shown in Fig. 14. D_{k1} and D_{k2} increase or decrease by 1, while P_{xk} is unchanged. This operation enables the thinning function to approach the desired distribution. Though multiple interchangeable pairs may be found, the existence of interchangeable pairs is not assured. When no interchangeable pair is found, two pairs can be interchanged as shown in Fig. 15. After the operation, above changeable pair is searched.

Here one calculated example of the thinning algorithm is shown. A planar array antenna with 10 × 10 elements, rectangular grid, and Taylor distribution with sidelobe level of −25 dB and $\overline{n} = 3$ is assumed. The excitation elements for the x-plane are determined as per Fig. 16a. In the 10 × 10 matrix, "0" means unexcited element. "1" means excited element. P_{xj}, the sum of each column, is the result and has no ambiguity. Resulting Q_{yk}, sum of each row, differs from ideal P_{yk}. Here "0" and "1" are interchanged in each column. Q_{yk} approaches P_{yk} while P_{xj} is unchanged. Interchanged result is shown in Fig. 16b. From the results, the calculated radiation pattern is shown in Fig. 17. Solid line is the result achieved by the thinning algorithm. Broken line is the result gained by an ideal Taylor distribution. The plots are nearly identical.

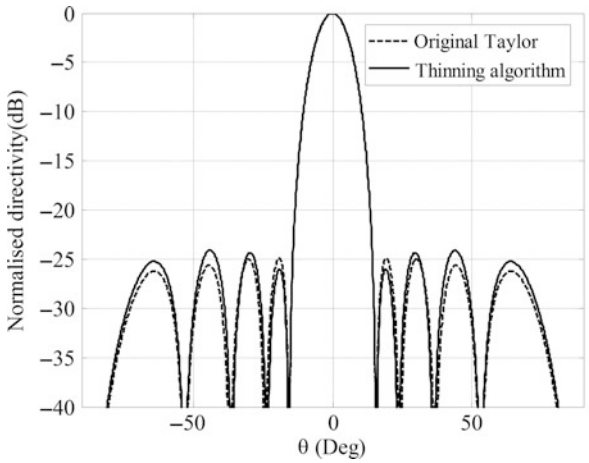

Fig. 17 Radiation pattern

Genetic Algorithm

Introduction of Genetic Algorithm

Though the element thinning algorithm determinately selects elements to excite, there is low flexibility in changing the exciting elements for adjusting the radiation patterns on the two axes. It is not always true that the element thinning algorithm yields the desired pattern. Here the genetic algorithm (GA) (Holland

DOI 10.1007/978-981-4560-75-7_37-1

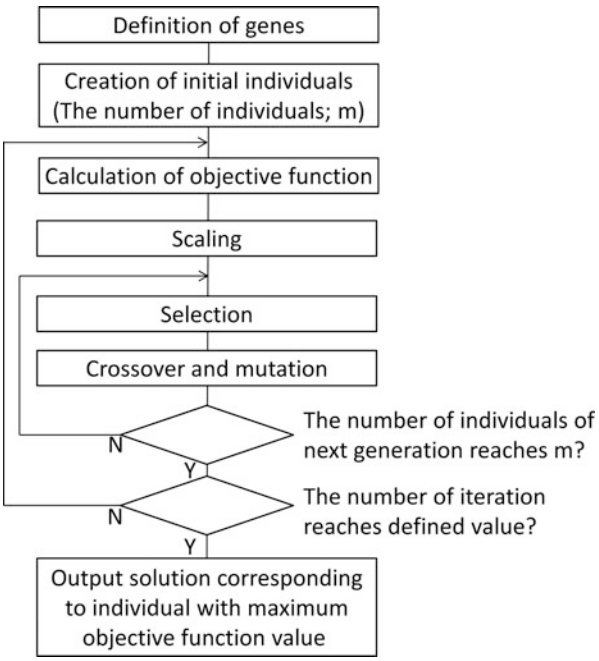

Fig. 18 Flowchart of optimization process of GA

1975), which simulates the process of biological evolution, is a powerful tool for optimization. Features of GA are as follows:

- GA can be applied to many applications by changing genes (input) and objective function (output).
- Full search of space is possible; it is not local solution.
- Multiple-point search is possible.
- Gradient information is not required for optimization.

Non-array antennas have been designed by the GA approach (Altshuler and Linden 1997; Jones and Joines 1997). GA is also applicable to array antennas, element thinning (Haupt 1994), and antenna pattern synthesis (Shimizu 1994; Yan and Lu 1997; Fujita 1999).

A flowchart of the optimization process based on standard GA is shown in Fig. 18. The GA identifies the optimum solution by creating multiple individuals that yield solutions and repeating the GA processes of selection, crossover, and mutation.

Process of GA

Definition of Genes In order to solve a problem by using GA, at first, input variables should be expressed by genes. One set of genes is called an individual. An example of an individual is

$$g_i : 01101010 \tag{54}$$

In this case, the individual consists of 8 genes. In the element thinning problem, each gene corresponds to an element antenna. A value of 0 means a thinned element, and a value of 1 means an excited element.

Initial Individuals A population consisting of multiple individuals is required for GA optimization. The first-generation population is created by random numbers. For example, when each individual has n-genes

DOI 10.1007/978-981-4560-75-7_37-1

and the population consists of m-individuals, $n \times m$ random numbers are generated. If a value close to optimal is already known, the optimal solution can be found more rapidly by using the value and its vicinity as first-generation individuals rather than random numbers.

Objective Function In GA, a new individual, which is closer to the optimal solution, is created as the next generation. In order to determine this criterion quantitatively, an objective function is defined. Though an arbitrary function can be used as the objective function, it outputs larger values as the population more closely approaches the optimal solution.

As one example of the objective function, in order to reduce sidelobe level, the objective function f can be defined as

$$f = -\max(\{S(P_i) \ \ | i = 1 \cdots k\}) \tag{55}$$

where $S(P_i)$ is sidelobe level and P_i is sampling points of angle within the sidelobe region. The solution that maximizes this objective function yields the lowest sidelobe level.

Scaling In GA, two individuals are selected, and new individuals related to them are created as the next generation. Individual selection is based on a probability that corresponds to the value of the objective function (fitness). However, when all individuals have almost the same fitness, individuals will be selected with virtually the same probability. The solution is to transform fitness so as to realize more effective selection. The procedure used for this is scaling. One approach is linear scaling. When original fitness is f and scaled fitness is f', linear scaling is expressed as

$$f' = af + b \tag{56}$$

a and b are constants and are determined so as to satisfy the following equations:

$$f'_{\text{avg}} = f_{\text{avg}} \tag{57}$$

$$f'_{\max} = Cf_{\text{avg}} \tag{58}$$

where f_{avg} is the average value of original fitness, f'_{avg} is average value of scaled fitness, and $f'_{\max}$ is the upper limit of scaled fitness. Equation 57 is introduced to ensure that the next generation includes the average individual.

Selection In GA, an individual superior to others creates many individuals in the next generation. Typical selection methods are explained.

The first one is the roulette rule. Individuals are selected with probability proportional to their fitness. When the number of individuals is n and fitness of the ith individual is f_i, the probability that this individual will be selected is

$$P_i = \frac{f_i}{\sum_{i=1}^{n} f_i} \tag{59}$$

Cumulative probability is calculated from P_i:

DOI 10.1007/978-981-4560-75-7_37-1

$$Q_i = \sum_{j=1}^{i} P_j \quad (i = 1, 2, \cdots, n) \tag{60}$$

By setting a random value r ($0 \leq r \leq 1$), minimum i satisfying $r < Q_i$ is determined, and the ith individual is selected.

The second approach is ranking. Individuals are sorted in descending order of fitness and are selected according to the ranking for the next generation.

Crossover In the crossover process, two individuals swap some of their genes. Gene position is determined in a random manner. In one-point crossover, genes are interchanged at one switching point. In multiple-point crossover, genes are interchanged at multiple switching points. In uniform crossover, all genes are randomly interchanged. Though uniform crossover has the best performance, it is complicated to implement. Note that the crossover process is conducted based on probability. Original genes are passed to the next generation if the crossover is ignored. When original individuals are g_i, g_j, and the individuals that result from crossover are g'_i, g'_j, examples of crossover are as follows.

One-Point Crossover Genes are interchanged at one switching point as per Fig. 19. The switching point is randomly determined.

Multiple-Point Crossover Genes are interchanged at multiple switching points as per Fig. 20. Following is an example of two-point crossover.

Uniform Crossover Random sequence R whose length equals that of the individuals and whose values are 0 or 1 is generated. Genes are interchanged at the positions as per Fig. 21 where the value of the random sequence is 1.

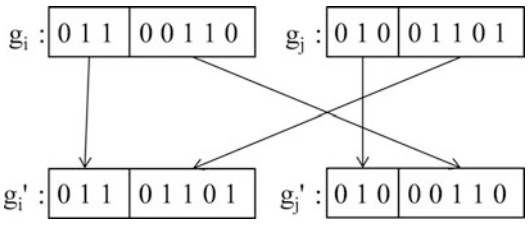

Fig. 19 One-point crossover

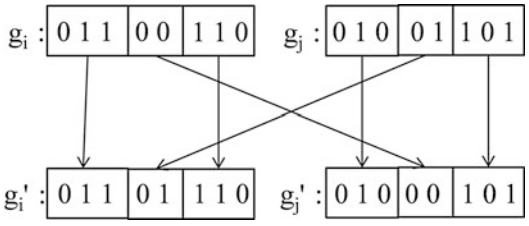

Fig. 20 Multiple-point crossover

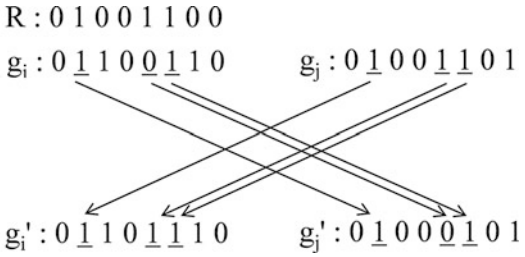

Fig. 21 Uniform-point crossover

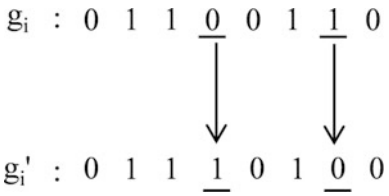

Fig. 22 Mutation

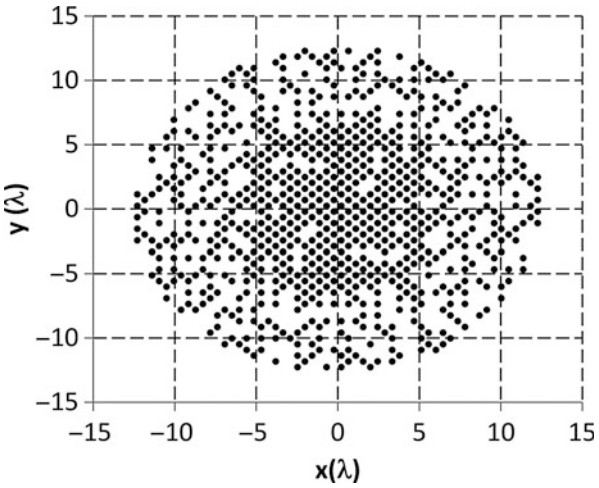

Fig. 23 Thinned aperture by using GA

Mutation The mutation process varies genes at arbitrary positions. Mutation probability per gene is defined. All genes are randomly varied according to the probability. An example of mutation is shown in Fig. 22.

Calculation Example

One example of thinning by using GA is shown. Original aperture is a circle with radius of 12.3λ. The objective is the sidelobe level of −25 dB. Moreover, the algorithm attempts to reduce the sidelobe level as much as possible.

The thinned aperture is shown in Fig. 23. Its radiation patterns are shown in Fig. 24. Radiation patterns with sidelobe level of −28 dB or lower are obtained.

Array Antenna Calibration

This chapter explains the rotating element electric field vector (REV) method, which measures the electric field from each element of an array antenna (Mano and Katagi 1982). The REV method can be adopted for array antenna calibration. It has the following features:

(1) Element electric field can be measured in the state of all elements being driven.
This means that the electric field can be measured in actual environments and so covers manufacturing error, mutual coupling, scattering from surrounding area, etc.
(2) Amplitude and phase of the element electric field can be obtained by measuring the summed power of all elements.
Amplitude and phase of the element electric field can be measured without explicit phase measurement. This feature is very effective in the millimeter wave band.

System Configuration and Measurement Principle

Typical system configuration for REV measurement is shown in Fig. 25. Received element electric field vector of each element and the summed array electric field vector are shown in Fig. 26. Here, the initial amplitude and initial phase of the summed array electric field are defined as E_0 and ϕ_0, respectively. Similarly, the initial amplitude and initial phase of the element electric field of the mth element antenna are

DOI 10.1007/978-981-4560-75-7_37-1

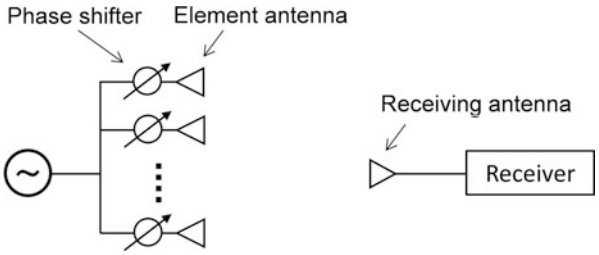

Fig. 25 System configuration for REV measurement

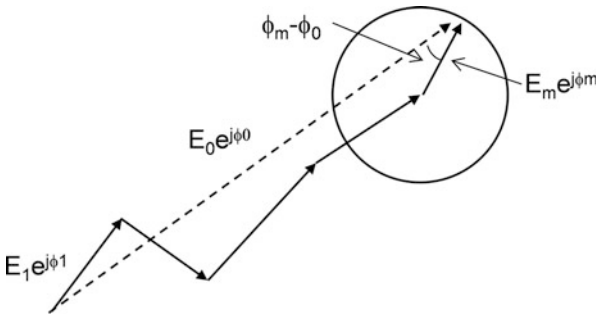

Fig. 26 Summed array electric field and element electric field

E_m and ϕ_m, respectively. Summed array electric field where the phase of the mth element antenna is rotated by Φ_m becomes

$$E = E_0 e^{j\phi 0} - E_m e^{j\phi m} + E_m e^{j(\phi m + \Phi m)} \tag{61}$$

Dividing both sides of Eq. 61 by the initial summed array electric field yields the following equation:

$$\hat{E} = \frac{E}{E_0 e^{j\phi 0}} = 1 - k_m e^{jXm} + k_m e^{j(Xm+\Phi m)} \tag{62}$$

k_m and X_m are relative amplitude and relative phase of mth element from the initial summed array electric field, respectively:

$$k_m = \frac{E_m}{E_0} \tag{63}$$

$$X_m = \phi_m - \phi_0 \tag{64}$$

From Eq. 62, relative value of the summed array electric field becomes

$$f = \left|\hat{E}\right|^2 = \left(Y^2 + {k_m}^2\right) + 2k_m Y \cos\left(\Phi_m + \Phi_{m,0}\right) \tag{65}$$

where

DOI 10.1007/978-981-4560-75-7_37-1

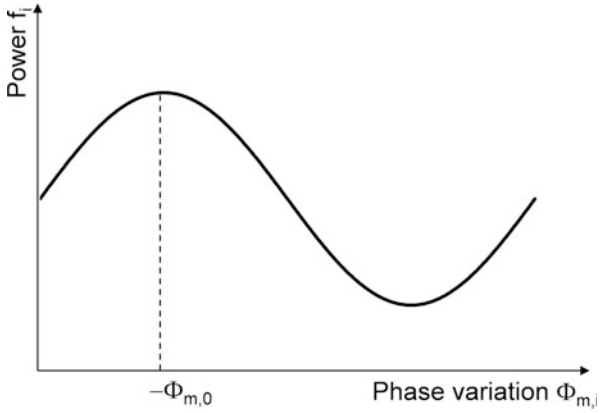

Fig. 27 Power variation of summed array electric field

$$Y^2 = (\cos X_m - k_m)^2 + \sin^2 X_m \tag{66}$$

$$\tan \Phi_{m,0} = \frac{\sin X_m}{\cos X_m - k_m} \tag{67}$$

Therefore, the "phase variation of one element" creates a "cosine-shaped power variation in the summed array electric field." The power variation is shown in Fig. 27. $-\Phi_{m,0}$ in the figure is the phase when the power of the summed array electric field is maximized. In the REV method, relative amplitude k_m and relative phase X_m of the mth element can be estimated from the phase, $-\Phi_{m,0}$, and the ratio of maximum power of the summed array electric field to its minimum, r^2. r^2, is expressed as

$$r^2 = \frac{(Y + k_m)^2}{(Y - k_m)^2} \tag{68}$$

and so r has two solutions:

$$r = \pm \frac{Y + k_m}{Y - k_m} \tag{69}$$

Due to the double sign of Eq. 69, two candidates of relative amplitude k_m and relative phase X_m are obtained:

(A) Solution with plus sign

$$k_m = \frac{\Gamma}{\sqrt{1 + 2\Gamma \cos \Phi_{m,0} + \Gamma^2}} \tag{70}$$

$$\tan X_m = \frac{\sin \Phi_{m,0}}{\cos \Phi_{m,0} + \Gamma} \tag{71}$$

(B) Solution with minus sign

DOI 10.1007/978-981-4560-75-7_37-1

$$k_m = \frac{1}{\sqrt{1 + 2\Gamma \cos \Phi_{m,0} + \Gamma^2}} \tag{72}$$

$$\tan X_m = \frac{\sin \Phi_{m,0}}{\cos \Phi_{m,0} + 1/\Gamma} \tag{73}$$

Γ in Eqs. 70, 71, 72, and 73 is

$$\Gamma = \frac{r-1}{r+1} \tag{74}$$

There is an ambiguity in determining the sign in Eq. 69. The ambiguity is eliminated by obtaining solutions for both signs under two different initial phase distribution states. The solution in the first state and the solution in second state will be identical. They are assumed to be the true solution. This method requires only amplitude measurement. If both amplitude and phase measurement are available, the sign ambiguity be resolved with a single measurement.

Application of REV Method to Actual System

From the previous section, in the REV method, amplitude and phase of electric field of mth element can be estimated from the phase, $-\Phi_{m,0}$, that maximizes the power of the summed array electric field and the ratio r of maximum power of the summed array electric field to its minimum. $-\Phi_{m,0}$ and r are obtained by changing the excitation phase of element antennas. However, it's not always true that the maximum power and minimum power of the summed array electric field can be measured exactly, because actual APAAs use digital phase shifters, which output discrete phases. Additionally, the phase shifter has output phase error for each input phase. Therefore, measured power of the summed array electric field fluctuates from the ideal cosine-shaped curve as per Fig. 28.

A cosine term can be obtained from measured values by using Fourier series expansion. When the excitation phase of element m is $-\Phi_{m,\mathrm{i}}$ and its measured power of the summed array electric field is f_i, the cosine curve yielded by Fourier series expansion is expressed as

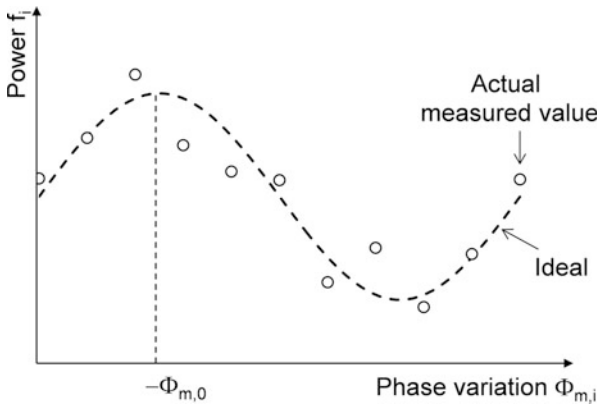

Fig. 28 Example of the power variation of summed array electric field using digital phase shifter

DOI 10.1007/978-981-4560-75-7_37-1

$$f_i = \frac{\alpha}{2} + c\cos\Phi_{m,i} + s\sin\Phi_{m,i} \tag{75}$$

Fourier coefficients are given as follows:

$$\alpha = \sum_{i=1}^{N} f_i \tag{76}$$

$$c = \sum_{i=1}^{N} f_i \cos\Phi_{m,i} \tag{77}$$

$$s = \sum_{i=1}^{N} f_i \sin\Phi_{m,i} \tag{78}$$

N is the number of measurements made while changing excitation phase. N is generally the number of states of the phase shifter. r and $-\Phi_{m,0}$ are calculated as follows:

$$\tan\Phi_{m,0} = -\frac{s}{c} \tag{79}$$

$$r^2 = \frac{\alpha + 2\sqrt{c^2+s^2}}{\alpha - 2\sqrt{c^2+s^2}} \tag{80}$$

Measurement Time Reduction for REV Method

The basic REV method, explained in detail in the previous chapter, has been enhanced in several ways. As one example, measurement time reduction (Takahashi et al. 2008) is introduced. While element phases are changed one at a time in the basic REV method, an enhancement changes the phases of multiple elements with different phase cycles, and the power variation of the summed array electric field is measured. The amplitudes and phases of the elements are estimated by calculation. The time taken to conduct measurements, a significant problem of the basic REV method, is drastically shortened. Though this method does increase measurement error, it is not of practical importance because the error of the original REV is very small. However, this method should be applied with reference to the theoretical error.

True Time Delay Calibration

Previous chapters explained the "phase" calibration method. Array antennas for large aperture and wideband systems suffer from main beam squint. The ideal excitation phase of each element antenna differs with frequency because k in Eq. 4 varies according to frequency (or wavelength). Unfortunately, a standard phase shifter outputs constant phase within the frequency bandwidth. Squint is prevented if signal transmission timing is controlled instead of phase. Such timing control is called true time delay (TTD). Due to cost limitations, TTD is generally applied only to subarrays of element antennas, while phase shifters are set to all element antennas. Such systems require both phase calibration for each element antenna and delay calibration for each subarray. For phase calibration, the REV method explained in the previous chapter can be used. For delay calibration, a method of estimating the delay difference between two subarrays through space has been proposed (Maruyama et al. 2014). Two subarrays transmit a signal, while an already known delay is given to one subarray. When the transmitting frequency is swept, a cosine-shaped response is output. Total delay difference between the subarrays is estimated from the

DOI 10.1007/978-981-4560-75-7_37-1

response. Subtracting the already-known delay from the total delay difference yields the original delay difference. This method does not require phase measurement, while received level variation is referenced. This characteristic is similar to that of the REV method.

Digital Beam Forming (DBF)

Overview and Functions of DBFs

DBF antennas combine array antennas with digital signal processing (Steyskal 1987; Farina 1992; Litva and Lo 1996). Such an antenna can perform a variety of intelligent processes because it uses digital signal processing for beam forming, etc. The major functions that DBFs can provide are listed below:

(1) High-precision beam pointing
(2) Spatial filtering
(3) Spatial division multiplexing

(1) is a function for pointing the main lobe with high precision in the desired signal's direction and a function that ensures low sidelobe levels. DBFs can reproduce signals more easily than APAAs and so can easily realize multibeam forming.

(2) is a function for spatially eliminating an undesired signal by pointing a null in the antenna pattern in the appropriate direction. This results in the receiver achieving a better signal-to-noise ratio (SNR).

(3) refers to transmitting different information from multiple antennas and receiving signals on multiple antennas; this is called the MIMO (multi-input multi-output) technique. This can help expand transmission capacity and improve frequency usage efficiency.

Basic Configuration of DBF Antennas

Figure 29 shows the basic configuration of a DBF antenna. The receiving antenna consists of antenna elements, low-noise amplifiers, down converters, analog-to-digital converters, and digital signal processors.

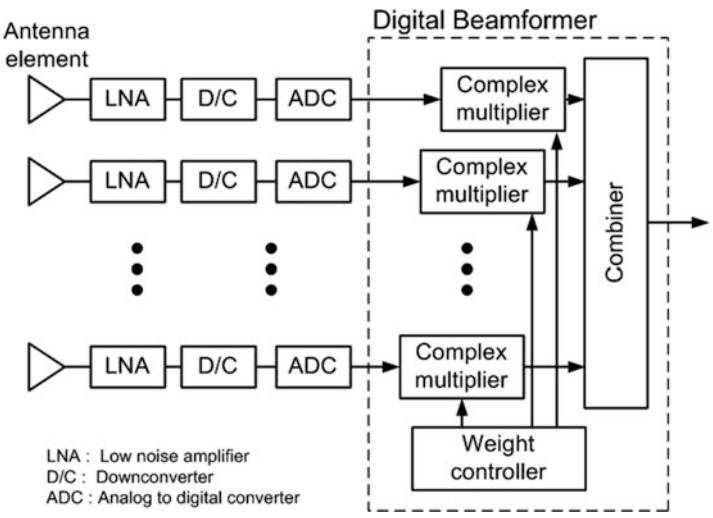

Fig. 29 Configuration of DBF antenna (receiving side)

DOI 10.1007/978-981-4560-75-7_37-1

Antenna Elements

The antenna elements and element arrangement basically follow APAA designs. However, depending on the operating mode (such as whether to achieve high directionality or antenna diversity), element spacing may be about one wavelength.

Low-Noise Amplifiers (LNAs)

LNAs amplify the received signals; they are essential to DBF antennas. They are usually located immediately after the antenna elements. The NF (noise figure), an indicator of input deterioration, and the output signal-to-noise ratio (SNR) determine the performance in the vicinity of the receiving sensitivity point.

Down Converters

A down converter uses local signals generated inside the receiver to convert the received signals in the carrier wave frequency band into intermediate frequencies, etc. A low-pass filter is placed immediately after it because a high-frequency component is generated by frequency conversion.

Analog-to-Digital Converters

An analog-to-digital converter is located at the last stage of an analog circuit. It converts analog signals to digital ones. Sampling frequency and bit precision are important parameters. The analog-to-digital converter adopted is selected based on factors such as the degree of deterioration in receiving performance, based on received signal bandwidth and quantum error.

Digital Signal Processors

The digital signal processor provides two functions. The first is calculating the weight (that is, the amplitude phase adjustment value) to be applied to the signal received on each element. Specifically, this includes calculating the phase value applied to each element in order to make the wave front of the received signal uniform in the main beam direction and calculating the amplitude phase value to point nulls in the direction of arrival of undesired signals. The second function is multiplying the weight to each element's output to get the synthesized output.

There are two ways of implementing the hardware for digital signal processing. The first is the use of an ASIC (application-specific integrated circuit). An ASIC is a dedicated circuit with a particular use. Its wiring is physically fixed, so it cannot be changed once it is produced, but using such a circuit can lower the energy consumption. The other way is to use an FPGA (field-programmable gate array). FPGA circuits are built by hardware programming. The circuits can be rewritten, which makes them more flexible than ASICs. Software-based digital signal processing is also possible by using a DSP (digital signal processor) or a CPU/MPU (central/micro processing unit).

The above has briefly explained the structure of DBF receiving antennas. To make a transmitting DBF antenna, one need only replace the low-noise amplifiers with high-power amplifiers, the down converters with up converters, and the analog-to-digital converters with digital-to-analog converters.

Characteristics of DBF Antennas

One advantage of that DBF antennas is that they can provide a wide variety of functions because they use digital signal processing. They also allow for a simpler feed network and suffer less loss than is the case with APAA technology. Functions can be consolidated into digital devices, enabling a high degree of integration. As digital devices become more advanced, moreover, DBF antennas can also take advantage of lower costs. One disadvantage is that the processing bandwidth is limited by the performance of the analog-to-digital converter or digital-to-analog converter. High-speed analog-to-digital converters have

DOI 10.1007/978-981-4560-75-7_37-1

been developed in recent years, and their communications bands are widening. This is generally costly, however, because each antenna element requires an analog-to-digital or digital-to-analog converter and a down converter or up converter. Because there are so many digital devices and the amount of data processed is growing, digital signal processors are consuming more energy. For that reason, array antennas with a large number of elements often have a subarray structure such that they first synthesize multiple antenna elements at the analog stage and then perform DBF.

Adaptive Arrays

Overview of Adaptive Arrays

If the antenna element can independently find the correct weight and set it automatically, the optimal communications environment becomes possible at all times. This idea was proposed a long ago. Starting in the 1960s, there were many reports, starting with the topic of the sidelobe canceler (SLC) (Howells 1965; Applebaum 1976). At first, the idea was certainly interesting and seemed effective theoretically, but implementing such technology required massive computers and microwave circuits, so in most cases, it did not advance much beyond the theoretical stage.

However, digital technology is advancing rapidly, and the integration of microwave circuits made them less costly and more compact. At the same time, mobile communications were developing, making the radio environment more challenging by the day. These events are highlighting adaptive array technology more and more.

The sidelobe canceler, which might be called the origin of adaptive arrays, was devised by Howells. The sidelobe canceler was intended to enable radar to operate even when there was strong interference. As shown in Fig. 30, it consists of a main, high-gain antenna and K auxiliary antennas. The auxiliary antenna gains are designed to approximate the average sidelobe level of the main antenna gain pattern. The amount of desired signal received by the auxiliary antennas is negligible compared to the desired signal in the main antenna. By controlling the weights on the auxiliary antennas, an interference in the sidelobe of the main antenna may be nulled out.

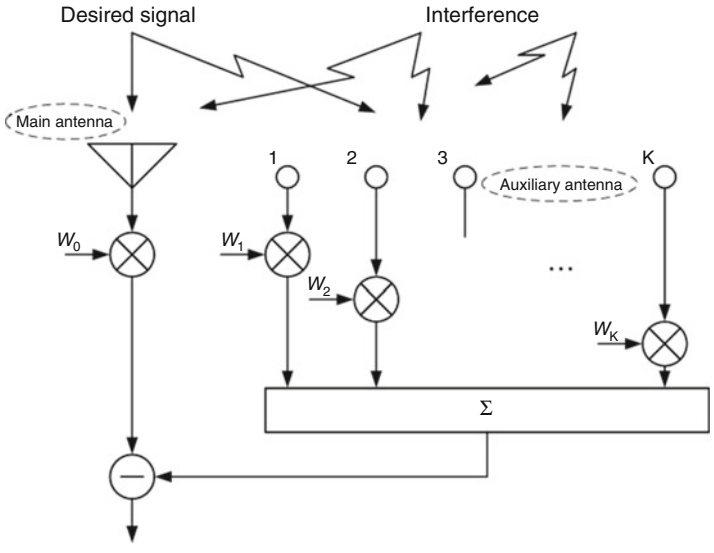

Fig. 30 Configuration of sidelobe canceler

DOI 10.1007/978-981-4560-75-7_37-1

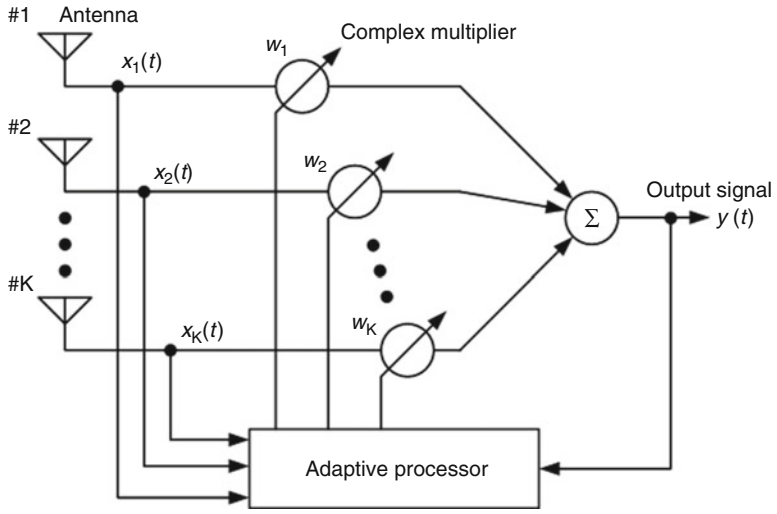

Fig. 31 Configuration of an adaptive array

Functions of Adaptive Arrays

Figure 31 shows the configuration of an adaptive array made up of K elements (Compton 1988; Monzingo and Miller 1980; Widrow et al. 1967; Kikuma and Fujimoto 2003; Ogawa and Ohgane 2001). Weight is first applied to each antenna element's input signal. An adder then synthesizes these into the array output. Each weight is a complex value that can control the amplitude and phase of the antenna elements' input signal.

Vector notation is used in the following formulas, with the desired signal, interference, and thermal noise at kth element labeled $s_k(t)$, $i_k(t)$, and $n_k(t)$, respectively:

$$\begin{aligned} \mathbf{S}(t) &= [s_1(t)\ s_1(t)\ \cdots\ s_K(t)]^T \\ \boldsymbol{I}(t) &= [\mathrm{i}_1(t)\ \mathrm{i}_2(t)\ \cdots\ \mathrm{i}_K(t)]^T \\ \boldsymbol{N}(t) &= [\mathrm{n}_1(t)\ \mathrm{n}_2(t)\ \cdots\ \mathrm{n}_K(t)]^T \end{aligned} \tag{81}$$

Here, subscript t refers to transposition.

Using these formulas, input signal vector $\boldsymbol{X}(t)$, with input signals in vector notation, is given by the following formula:

$$\mathbf{X}(t) = [\,x_1(t) \quad x_2(t) \quad \cdots \quad x_K(t)\,]^T = \mathbf{S}(t) + \mathbf{I}(t) + \mathbf{N}(t) \tag{82}$$

Similarly, given weight w_k, the vector notation yields the following formula:

$$\mathbf{W} = [\,w_1 \quad w_2 \quad \cdots \quad w_K\,]^T \tag{83}$$

Array output $y(t)$ is therefore expressed as the following formula:

$$\mathrm{y}(t) = \mathbf{W}^{\mathrm{H}}\mathbf{X}(t) \tag{84}$$

Subscript H represents complex conjugate transposition. Output power P_{out} is found as in the following formula:

DOI 10.1007/978-981-4560-75-7_37-1

$$P_{out} = \frac{1}{2}E\left[|y(t)|^2\right] = \frac{1}{2}\mathbf{W}^{H}R_{xx}\boldsymbol{W} \tag{85}$$

$\mathbf{R}_{xx}$ is the correlation matrix of the input signal vector and is defined by the following formula:

$$\mathbf{R}_{xx} = E\left[\mathbf{X}(t)\mathbf{X}^{\boldsymbol{H}}(t)\right] \tag{86}$$

$E[]$ represents the expected value.

The output SINR (signal-to-interference-plus-noise ratio) is defined by the following formula. This is normally used as a metric for evaluating an array's output characteristics. The higher the value, the better its characteristics:

$$SINR = \frac{\text{Desired signal power}}{\text{Interference power} + \text{Noise power}} \tag{87}$$

The functions of an adaptive array can be classified into the following two, depending on the objective:

(1) Adaptive beam forming
(2) Adaptive null steering

The first enables automatic tracking of the array's main beam, even if the direction of arrival of the received signal (desired signal) is unknown or changes with time. The second automatically forms the antenna pattern's null points in the direction of interference. There have been many examples of research into null steering. The sidelobe canceler mentioned earlier was the result of some of the earliest research.

Optimization Algorithm

An adaptive array changes directivity and frequency characteristics to conform to the radio environment as it acquires information about that environment. Therefore, it is not necessary to know the undesired signals (interference) in advance. However, extracting just the desired signal from a poor radio environment that also contains undesired signals and noise does require some a priori information of the desired signal. Data needed include the signal's center frequency, direction of arrival, modulation method, polarization used, and training signals used. The following is an explanation of the main optimization algorithms.

Maximal Ratio Combining

Maximal ratio combining (MRC) detects the envelope level and phase information of the signal received on each antenna element (Miura et al. 1999; White 1976). Each received signal is set to the same phase and weighted according to its envelope level. This maximizes the SNR after combining. This was developed as a diversity reception technology to mitigate the effect of fading. It can scan for the main beam to track incoming waves, but it does not suppress interference. Several methods proposed such as closed loop control using a receiving level monitor, control using a direction sensor, and phase control using a feedback loop (PLL system). Moreover, it is important to achieve stable operations in environments with low SNR (Kihira et al. 2006).

MMSE

The development of adaptive arrays based on the minimum mean square error (MMSE) method started when Widrow proposed an adaptive filter in the 1960s. Widrow applied adaptive array technology and

DOI 10.1007/978-981-4560-75-7_37-1

established the least mean square (LMS) algorithm (Widrow et al. 1967). MMSE adaptive arrays work to minimize the error signal, that is, the difference between a reference signal and the actual array output signal. This system can perform the two major functions of adaptive arrays (adaptive beam forming and adaptive null steering) simultaneously and is not limited by the element arrangement. Strictly speaking, the desired signal itself is required as a reference signal, but in actuality, this system works by using something, such as a known training symbol that is inserted, for example, in front of the data.

The error signal of reference signal $r(t)$ (desired time response) and array output signal $y(t)$ can be written as the following formula:

$$\begin{aligned} e(t) &= r(t) - y(t) \\ &= r(t) - \mathbf{W}^H \mathbf{X}(t) \end{aligned} \tag{88}$$

The expected value of the square of this error signal (mean square error) is given by the following formula:

$$\begin{aligned} E\left[|e(t)|^2\right] &= E\left[|r(t) - y(t)|^2\right] = E\left[\left|r(t) - \mathbf{W}^{\mathrm{H}}\mathbf{X}(t)\right|^2\right] \\ &= E\left[|r(t)|^2\right] - \mathbf{W}^T \mathbf{r}^*_{xr} - \mathbf{W}^{\mathrm{H}}\mathbf{r}_{xr} + \mathbf{W}^{\mathrm{H}}\mathbf{R}_{\mathbf{xx}}\mathbf{W} \end{aligned} \tag{89}$$

$\boldsymbol{r}_{xr}$ is the correlation vector of the reference signal and input signal vector and is defined by the following formula:

$$\mathbf{r}_{xr} = E[\mathbf{X}(t) r^*(t)] \tag{90}$$

In this formula, the weight vector is a quadratic function, and to minimize its mean square error, it is necessary to satisfy the following formula:

$$\frac{\partial}{\partial \mathbf{W}} E\left[|e(t)|^2\right] = -2\mathbf{r}_{xr} + 2R_{xx}\mathbf{W} = \mathbf{0} \tag{91}$$

Therefore, the optimal weight is given by the following formula:

$$\mathbf{W}_{opt} = \mathbf{R}_{\mathbf{xx}}{}^{-1}\mathbf{r}_{xr} \tag{92}$$

Several optimization techniques using digital control have been proposed, such as the LMS algorithm based on the steepest descent method (Haykin 2002); sample matrix inversion (SMI), which uses sample values to find a solution directly; and recursive least squares (RLS) (Compton 1988).

Figure 32 shows an example of an antenna pattern after convergence in a four-element, two-incoming wave model. The main beam is formed in the direction of arrival of the desired signal (0°), and a deep null is pointed at the direction of arrival of interference (60°). Figure 33 shows the output power after array synthesis of each signal in the LMS algorithm. The horizontal axis is the number of weight updates (iterations). The results clearly show that the desired signal's output power is maintained, while the interference's output power is diminished.

Having a reference signal is a precondition for the MMSE adaptive array, so it is more effective as a means for achieving a spatially optimized filter in a communication system than in radar. A training symbol inserted into a data signal in a communications system using TDMA can be used as a reference signal. This potential is gaining MMSE attention for applications in mobile communications.

MSN

Applebaum took the sidelobe canceler developed by Howells and developed it into the MSN (maximum SNR method) adaptive array; this is also referred to as the Howells-Applebaum (HA) adaptive array (Applebaum 1976). Because MSN adaptive arrays were applied to radar systems, a precondition is that the direction of arrival of the desired signal must already be known.

This algorithm finds the weight that maximizes output SNR. The desired signal power, interference power, and thermal noise power in the array output are expressed in the following formula:

$$\begin{aligned} P_{Sout} &= \frac{1}{2}E\left[|y_s(t)|^2\right] = \frac{1}{2}\mathbf{W}^H\mathbf{R}_{SS}\mathbf{W} \\ P_{Iout} &= \frac{1}{2}E\left[|y_i(t)|^2\right] = \frac{1}{2}\mathbf{W}^H\mathbf{R}_{ii}\mathbf{W} \\ P_{Nout} &= \frac{1}{2}E\left[|y_n(t)|^2\right] = \frac{1}{2}P_n\mathbf{W}^H\mathbf{W} \end{aligned} \tag{93}$$

DOI 10.1007/978-981-4560-75-7_37-1

Here, $\mathbf{R}_{ss}$ and $\mathbf{R}_{ii}$ are the correlation matrices for the desired signal and interference, respectively, while P_n is the thermal noise power per antenna element. If the direction of arrival of the desired signal is known, the following formula can be established if it is assumed that the desired signal's bandwidth is narrow enough:

$$\begin{aligned}\mathbf{S}(t) &= s(t)\mathbf{V}_s \\ \mathbf{V}_s &= \left[v_{s1}\ v_{s2}\cdots v_{sK}\right]^T \\ \mathbf{R}_{ss} &= E\left[\mathbf{S}(t)\mathbf{S}^H(t)\right] = P_s\mathbf{V}_s\mathbf{V}_s^H\end{aligned} \tag{94}$$

Here, P_s is the desired signal power per element.

Therefore, the output SINR can be found using the following formula:

$$SINR = \frac{P_{Sout}}{P_{Iout} + P_{Nout}} = \frac{\mathbf{W}^H\mathbf{R}_{SS}\mathbf{W}}{\mathbf{W}^H\mathbf{R}_{nn}\mathbf{W}} \tag{95}$$

Here, R_{nn} is the correlation matrix for the undesired signal component as expressed below:

$$\mathbf{R}_{nn} = \mathbf{R}_{ii} + \mathbf{P}_n\mathbf{I} \tag{96}$$

Note that $\mathbf{I}$ is the identity matrix of dimension K.

The optimal weight, W_{opt}, that maximizes the SINR satisfies the following equation:

$$\nabla\left(\frac{\mathbf{W}^H\mathbf{R}_{ss}\mathbf{W}}{\mathbf{W}^H\mathbf{R}_{nn}\mathbf{W}}\right) = \mathbf{0} \tag{97}$$

Solving this yields the following formula:

$$\mathbf{W}_{opt} = \alpha\mathbf{R}_{nn}^{-1}\mathbf{V}_s \tag{98}$$

Here, α is a constant.

Finding the optimal weight requires separating the desired signal from the interference and then finding their correlation matrix $\mathbf{R}_{\mathrm{nn}}$. With radar, assuming that interference is much greater than the desired signal, one can take as a substitute the correlation matrix of the received signal (a signal that contains both the desired signal and interference).

As indicated above, MSN adaptive arrays require setting the desired signal's direction of arrival in advance, and so one important question is how to get correct direction information for the desired signal. Techniques have been proposed in recent years that estimate the direction of arrival with high precision; examples include MUSIC (multiple signal classification) (Schmidt 1986) and ESPRIT (estimation of signal parameters via rotational invariance techniques) (Roy et al. 1986). These estimates can be used for preprocessing MSN control. This, it is believed, would make it possible to use MSN adaptive arrays even in such applications as mobile communications. However, the direction of arrival estimation errors causes the performance of MSN adaptive arrays to degrade sharply. The so-called tamed adaptive antenna, which adds "pseudo"-noise to the correlation matrix, offers greater resistance to these errors (Takao and Kikuma 1986).

DCMP

This algorithm was proposed by Frost (Frost 1972) and further expanded by Takao et al. (Takao et al. 1972). If the direction of arrival, frequency, and array arrangement is decided, then the array

DOI 10.1007/978-981-4560-75-7_37-1

response vector is decided. In DCMP, this is treated as constraint vector **C**, and the following formula's constraint conditions are imposed.

$$\mathbf{C}^T\mathbf{W}^* = H \tag{99}$$

Here, H is called the constraint response value; it is a constant that determines the array response value in direction θ_s.

The DCMP adaptive array determines the weight vector that minimizes output power under these conditions. In other words, if the array response in the direction of arrival of the desired signal is constrained and the output power is minimized, then interference is suppressed. The weight vector that satisfies this is given by the following formula:

$$\mathbf{W}_{opt} = \mathbf{R}_{xx}^{-1}\mathbf{C}\left(\mathbf{C}^H R_{xx}^{-1}\mathbf{C}\right)^{-1}H^* \tag{100}$$

Moreover, if constraint conditions must be imposed in multiple directions, this can be handled by using a constraint matrix in place of a constraint vector and by rendering the constraint response value into vector form.

DCMP adaptive arrays work with the direction of arrival of the desired signal already known, but in reality, there are cases when there is some variance between the designated direction of arrival and the actual angle of arrival, for example, because of the error introduced when the antenna was installed or because of the movement in the antenna itself. Similar problems can also be caused by mutual coupling between antenna elements. It is possible to suppress this problem by using a tamed adaptive antenna (Takao and Kikuma 1986), which, as mentioned above, adds pseudo noise to the correlation matrix.

Power Inversion

Conditions for applying a power inversion adaptive array (PIAA) (Compton 1979) are as follows:

- The array's degrees of freedom (one less than the number of elements) must be the same as the number of interference signals.
- The desired signal's output power must be (sufficiently) smaller than the interference power.

Power inversion can be used if the above conditions are satisfied. In other words, the desired signal and interference are distinguished from each other merely from the difference in their input powers, so a priori information, such as the reference signal needed in MMSE, is not required.

Under the above conditions, minimizing the output power is a direct way of suppressing the unnecessary component. As is, however, this means that all weights are zero, which does not allow the antenna to receive even the desired signal. Under PIAA, the simplest conditions are imposed in order to eliminate trivial solutions. Under this rule, in other words, the minimal output power is achieved when one antenna element's weight is set at a fixed value. Thus, PIAA is a kind of output power minimization method with constraints. Following this principle, the greater the power of the interference is, the more strongly it is suppressed.

The optimal weight when the weight of element 1 is fixed is given by

$$\begin{aligned}\mathbf{W}_{opt} &= \mathbf{R}_{xx}^{-1}\overline{\mathbf{S}} \\ \overline{\mathbf{S}} &= [1,\, 0, \cdots,\, 0]^T\end{aligned} \tag{101}$$

DOI 10.1007/978-981-4560-75-7_37-1

Here, $\overline{\mathbf{S}}$ is a constraint vector.

Its application in mobile communications is also being studied because PIAA is a blind algorithm that does not use a priori information, which allows simpler configurations and processing (Kihira et al. 2003).

CMA

Whereas MMSE adaptive arrays require a reference signal, phase modulation signals like PSK, which are currently widely used for mobile communications, basically have a constant envelope characteristic. Taking advantage of this feature, CMA controls antenna weights by making the array output signal's envelope a desired fixed value (Treichler and Agee 1983). Therefore, it is possible to obtain the optimal weight by minimizing the evaluation function expressed by the following formula:

$$Q(\mathbf{W}) = E[|\,|y(t)|^p - \sigma^p\,|^q] \tag{102}$$

Here, σ is the desired envelope value, and p and q are positive integers, usually 1 or 2. The solution $\mathbf{W}$ that minimizes evaluation function Q cannot be found analytically, and so repeated operations are needed using a nonlinear optimization method. If the steepest descent method is used as the operation algorithm, weight updates follow the following formula ($p = q = 2$):

$$\mathbf{W}(m+1) = \mathbf{W}(m) - \mu 4\mathbf{X}(m)y^*(m)\left(|y(m)|^2 - \sigma^2\right) \tag{103}$$

Here, μ is a constant that expresses the feedback step size, and m is the number of times (iterations) a weight is updated.

CMA adaptive arrays allow blind processing; no a priori information is needed. Therefore, many studies have been performed on applications for mobile communications.

MIMO Technology

MIMO technology uses multiple antennas (that is, an array antenna) for both the transmitter and receiver (Foschini and Gans 1998; Telatar 1999). This makes it possible to achieve either (i) faster transmission speed or (ii) greater reliability or both (Paulaj et al. 2003). In the case of (i), the technology is described as spatial division multiplexing (SDM). In the case of (ii), it is described as spatial diversity (SD). Particularly in the case of (i) SDM, multiple different signal data streams are transmitted from multiple antennas, meaning that they are spatially multiplexed. At the receiving side, the multiple signals are separated by signal processing technology. With SDM, as the number of antennas at both the transmitting and receiving sides is increased, the frequency usage efficiency increases at a rate that is proportional to the number of antennas. These results have been demonstrated experimentally (Nishimori et al. 2005; Taoka et al. 2007). MIMO technology is now indispensable to wireless communication systems.

In recent years, furthermore, there has been much study of multiuser MIMO (MU-MIMO) technology (Spencer et al. 2004). This technology uses many antennas at the base station to enable MIMO communication among multiple users and a base station. MU-MIMO is being studied in terms of IEEE 802.11 ac (which is being studied as the next-generation LAN standard) and LTE-Advanced (which is being studied as the next-generation mobile communications standard), among others. For MU-MIMO comparison purposes, a scenario in which one user communicates by MIMO with a base station is called single-user MIMO (SU-MIMO).

DOI 10.1007/978-981-4560-75-7_37-1

MIMO technology, originally developed for communication, is now also being studied for applications in radar (Robey et al. 2004). This research into MIMO radar is also gaining much attention.

Conclusion

This chapter has introduced the fundamental points of PAAs. One of the important features of PAAs is pattern synthesis. Some methods of pattern synthesis were explained. In order to operate PAAs correctly, element antenna calibration is an essential procedure. Array calibration methods were also explained. In the later part of this chapter, DBF including signal processing and MIMO techniques were introduced. All types of devices have advanced in recent years, and the various DBF prototypes and DBF use in practical fields have earned high praise. This has created fertile ground for practical applications of DBF. Very recently, products have appeared that apply MIMO technology. This is one example of how research and development for the large-scale diffusion of this technology is speeding up.

Dielectric Lens Antennas

Carlos A. Fernandes[a]*, Eduardo B. Lima[a] and Jorge R. Costa[b]
[a]Instituto de Telecomunicações, Instituto Superior Técnico, Universidade de Lisboa, Lisbon, Portugal
[b]Instituto de Telecomunicações, Instituto Universitário de Lisboa (ISCTE-IUL), Lisbon, Portugal

Abstract

Dielectric lens antennas are attracting a renewed interest for millimeter- and submillimeter-wave applications where they become compact, especially for configurations with integrated feeds usually referred as integrated lens antennas. Lenses are very flexible and simple to design and fabricate, being a reliable alternative at these frequencies to reflector antennas. Lens target output can range from a simple collimated beam (increasing the feed directivity) to more complex multi-objective specifications.

This chapter presents a review of different types of dielectric lens antennas and lens design methods. Representative lens antenna design examples are described in detail, with emphasis on homogeneous integrated lenses. A review of the different lens analysis methods is performed, followed by the discussion of relevant lens antenna implementation issues like feeding options, dielectric material characteristics, fabrication methods, and a few dedicated measurement techniques. The chapter ends with a detailed presentation of some recent application examples involving dielectric lens antennas.

Introduction

The use of a dielectric lens as part of an antenna is almost as old as the demonstration of electromagnetic waves by Hertz. In fact, in 1888, Oliver Lodge used a dielectric lens in his experiments at 1-m wavelength (Lodge and Howard 1888). However, it was not until World War II that research on lens antennas has progressed further. Lenses were used to transform the radiation pattern of the primary feed into some high-gain radiation pattern, either for fixed or scanning beam applications. But at that time, they were supplanted by reflector antennas, less bulky and lighter at microwaves.

With the fast advances on the millimeter and submillimeter waves' circuit technology for the past two decades, there has been a renewed interest on lens antennas, which present a more acceptable size at these frequencies. Lenses are being explored for imaging applications, for fixed and mobile broadband communications, and for automotive radar applications, among others. In most cases, the target radiation pattern continues to be the collimated beam type (plane wave output), either fixed or scanning. But interesting highly shaped beams conforming to demanding amplitude templates have also been explored.

Lenses can be used to modify the phase or the amplitude (or both) of the primary feed radiation pattern in order to transform it into a prescribed output radiation pattern. In this sense, lenses are equivalent to reflectors. However, instead of reflection, the lens operation principle is based on the refraction of

DOI 10.1007/978-981-4560-75-7_40-1

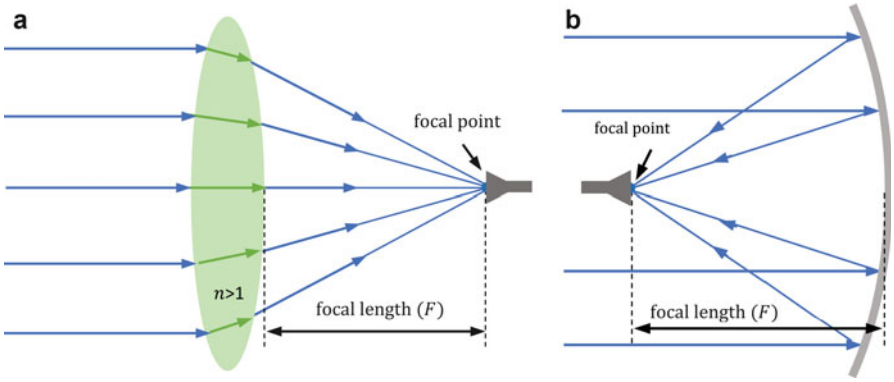

Fig. 1 Focusing antennas: (**a**) lens; (**b**) reflector

electromagnetic waves at the lens surfaces (in the case of isotropic homogenous lenses) or within the lens dielectric material in the case of nonuniform refractive index lenses. For instance, in one of its most basic configurations (Fig. 1a), parallel rays of an incident plane wave are refracted at the lens surfaces in such a way that all output rays intersect at a point, the lens focal point. All these rays have the same electrical path length, that is, they arrive in phase at the focal point (Fermat's principle), despite their different physical lengths which are compensated by a slower phase velocity ($v = c/n$) in different portions of the lens. In most designs, lens dimensions are large in terms of wavelength, enabling the use of quasi-optical design methods. Large lenses share with reflectors its inherent large bandwidth, which is limited only by the feed bandwidth.

One main advantage of lenses over reflectors is that the feed and its supporting structure do not block the antenna aperture. This back-feeding feature was key for the development of the millimeter- and submillimeter-wave integrated lens antenna concept where the lens base is positioned directly in contact with the feed, such as an integrated circuit front end, to produce a directive radiation pattern, either single beam or multiple beam. The integrated lens structure is very flexible to accommodate demanding output radiation pattern specifications, while multiple shells can be added, for instance, to increase the design degrees of freedom maintaining a compact structure. This contrasts with multi-reflector systems where blockage issues force large complex structures.

The existence of powerful software simulation tools, numerically controlled machines, 3D additive manufacturing technologies, low-loss dielectric materials, and an exploding knowledge on artificial dielectrics is favoring the development and fabrication of very sophisticated high-performance lens antennas, namely, integrated lens antennas, that are easily accessible to most laboratories or companies and affordable for mass-market products.

Lens Theory

This section starts with a brief overview of different types of known lenses and presents a possible classification. This is followed by some basic concepts applicable for quasi-optical lens design, assuming that the lens dimensions and radius of curvature at every point of the surfaces are large compared to the wavelength. Finally this section presents some alternative lens design approaches, involving a combination of iterative algorithms and lens analysis methods.

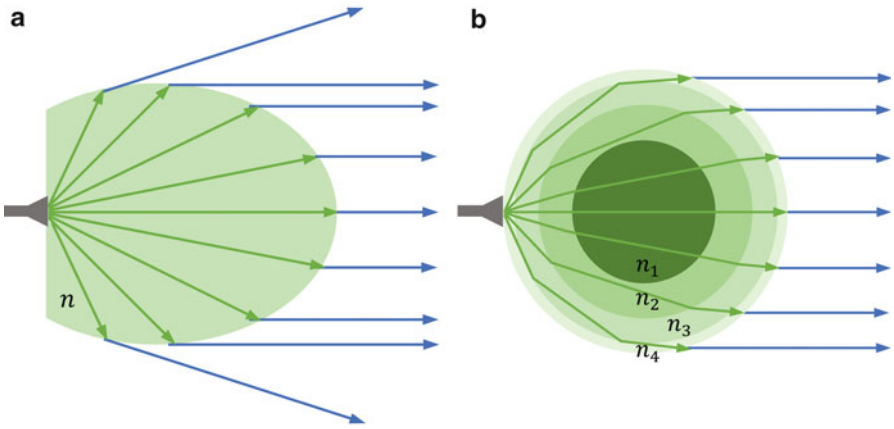

Fig. 2 Examples of integrated lens antennas

Lens Types

The lens classification adopted in this chapter is based on three different physical characteristics: the feed position relative to the lens body (far from the lens or in direct contact), refractive index profile (constant/stepped or nonuniform), and number of refraction surfaces (see Table 1). For each of these categories, the lenses can be further classified according to the type of output radiation pattern: fixed beam (collimated or shaped) or scanning beam (usually collimated).

In early lenses and in a few current designs, the focal point is located well away from the lens, at a distance comparable with its diameter as in Fig. 1a. These lenses are named in this chapter the off-body fed lenses and all examples found in the literature are axial-symmetric.

Lenses can alternatively be designed to have the feed in direct contact with the lens body (or within the body or at a fraction of the wavelength away). These are referenced in the literature as integrated lens antennas (ILA). These lenses can be made with one or more shells although the most common designs use a single layer (Fig. 2).

The concept of integrated lenses started with single-material hemispherical lenses added on top of integrated circuit antennas to eliminate substrate modes and increase radiation efficiency (Rebeiz 1992). This has evolved to the use of other fixed canonical shapes like the elliptical or extended hemispherical to further enhance gain, producing collimated output beams (Filipovic et al. 1993).

But the integrated lens configuration is especially flexible to satisfy more elaborate output beam specifications like secant square type of radiation patterns using more complex lens surfaces (Fernandes 1999), which can have an arbitrary 3D shape in the general case to produce nonsymmetrical radiation patterns (Bares and Sauleau 2007). In Fernandes and Anunciada (2001), the lens shape is adapted to transform the radiation of the circular-symmetrical source into an output shaped beam with square or rectangular footprint when pointed at the ground.

DOI 10.1007/978-981-4560-75-7_40-1

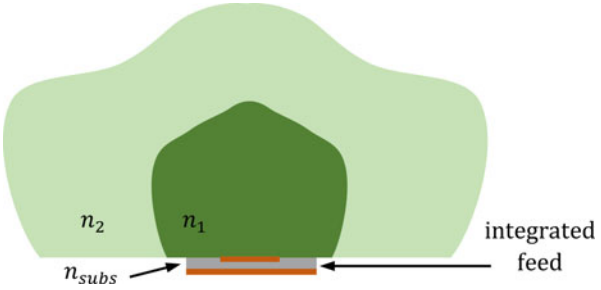

Fig. 3 Shaped integrated dielectric lens antenna

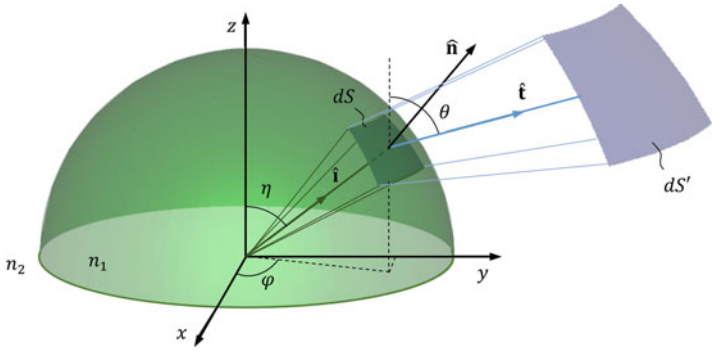

Fig. 4 Geometry of the lens and ray tube for GO formulation

Adding a further shell to the integrated lens adds a second refracting surface offering a supplementary degree of freedom to impose another design condition without sacrificing too much the lens compactness (see Fig. 3). For instance, in Costa et al. (2008a), a double-shell lens is designed to satisfy both a beam-scanning condition and maximum power transfer across the lens surfaces.

The Luneburg lens is a special case of integrated lenses, with nonuniform refractive index, where ideally an incident plane wave is focused on the antipodal point on the lens surface (see Fig. 2b).

Geometrical Optics for Lens Design

Geometrical optics (GO) is a very convenient formulation for lens (or reflector) design. It derives from the asymptotic solution of Maxwell's equations in the high-frequency limit (Kay 1965). As long as the overall lens dimensions and surface radius of curvature at any point are much larger than the wavelength, wave propagation inside a homogenous isotropic lens may be conveniently modeled in terms of elementary ray tubes. These emanate from the phase center of the source (see Fig. 4) along straight lines, with the amplitude weighted by the radiation pattern of the source and decaying with path length in the inverse proportion of the square root of the tube cross section and with phase given by the electrical path length. Reflection and transmission at an interface are made according to Snell's law (which derive from the Fermat's principle), and ray amplitude is affected by Fresnel coefficients and a divergence factor.

Assuming that the interface between two dielectric media can be considered locally plane, the reflection of an incident plane wave occurs in the same medium, with equal incident and reflected angles – Snell's law for reflection. The refraction is governed by the following Snell's law:

$$n_1 \sin(\theta_{\text{inc}}) = n_2 \sin(\theta_{\text{trans}}) \tag{1}$$

DOI 10.1007/978-981-4560-75-7_40-1

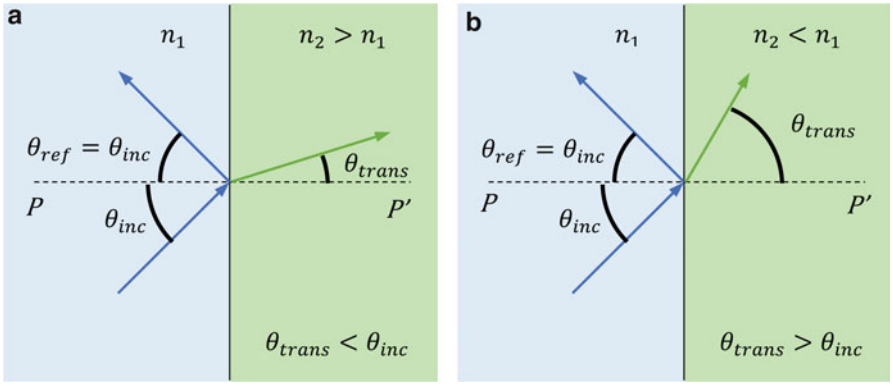

Fig. 5 Plane wave incident at an interface between two dielectrics; (**a**) incidence from the lower index medium; (**b**) incidence from the higher index media

where n_1 and n_2 are the refraction indexes of each medium and θ_{inc} and θ_{trans} are the incidence and transmission angles defined with respect to the interface normal (see Fig. 5). If the two media present the same magnetic permeability of air (most of the usual lens materials do), then $n_1 = \sqrt{\varepsilon_{r1}}$ and $n_2 = \sqrt{\varepsilon_{r2}}$ where ε_{r1} and ε_{r2} are the relative electric permittivity of each media. The refracted wave is bent toward the surface normal if the wave enters a medium with higher dielectric constant (see Fig. 5a), and it is bent away from the normal when exiting a medium with higher dielectric constant (see Fig. 5b).

In the general case, the lens surface has an arbitrary curved shape, although with large curvature radius (compared to the wavelength) at any point, and so it is convenient to present Eq. 2 in a more general form:

$$\left(n_1\,\hat{\mathbf{i}} \;-\; n_2\,\hat{\mathbf{t}}\right) \;\times\; \hat{\mathbf{n}} \;=\; 0 \tag{2}$$

where $\hat{\mathbf{i}}$ and $\hat{\mathbf{t}}$ represent the incident and refracted wave number vectors, respectively (see Fig. 4), and $\hat{\mathbf{n}}$ represents the surface normal. By expressing these three unit vectors in spherical coordinates centered at the feed phase center, Eq. 2 for an axial-symmetric lens takes the form:

$$\frac{dr}{d\eta} = \frac{n_2\, r \sin\left(\theta - \eta\right)}{n_1 \;- n_2\, \cos\left(\theta - \eta\right)} \tag{3}$$

where $r(\eta)$ represents the unknown lens profile while the output angle function $\theta(\eta)$ is the other unknown to be specified by some design condition involving phase or amplitude or eventually polarization. This condition may be given by an algebraic equation or by a differential equation. The simultaneous equations must be integrated in the interval $\eta \in [0,\ \eta_{max}]$ with applicable initial conditions $r(0)$ and $\theta(0)$ and final value η_{max}. This integration is usually performed numerically, taking only a few seconds to provide the final lens shape.

If other dielectric interfaces are involved in the ray paths, each one must conform to its Snell's equation equivalent to Eq. 3. Additional interfaces allow the enforcement of additional radiation pattern specifications which translate into corresponding equations involving the radius $r_n(\eta)$ of the n^{th} interface and the ray exit angle $\theta_n(\eta)$. The system of all the involved equations is solved by generalizing the procedure described above for the single interface. It is noted however that the formulation is different for spherical lenses like the Luneburg or Maxwell fish-eye lenses where the unknown function is no longer $r(\eta)$. The refractive index profile $n(r)$ is the unknown function in these lenses. These types of lenses are not the main focus of the present chapter and are treated as specific cases ahead.

DOI 10.1007/978-981-4560-75-7_40-1

The characterization of multiple internal reflections becomes intricate with the increase in the number of lens shells, but in general, there is no significant advantage in including its effect in the lens synthesis process. The design formulation must include however the transmission coefficients, divergence factor, and material dissipation losses where applicable. Internal reflection analysis can be performed a posteriori when evaluating the lens performance.

Because of lenses' large dimensions in terms of wavelength, dissipation losses are also an important aspect to mind. The material permittivity is a complex-valued function of the form $\varepsilon_r(1 - j\ \tan\delta)$ where the imaginary part inside the parenthesis is the loss tangent. A spherical wave propagating inside the lens material has the form:

$$E_0(\theta,\varphi)\frac{e^{-j2\pi\sqrt{\varepsilon_r(1-j\tan\delta)}\frac{r}{\lambda}}}{r} \tag{4}$$

So the total dissipation loss depends on lens dimensions, its shape, and feed illumination function. For low-loss materials, loose bounds for the dissipation loss in a homogeneous lens can be calculated for the minimum and maximum radius r of the lens using

$$L = 27.3\sqrt{\varepsilon_r}\frac{r}{\lambda}\tan\delta\ [dB] \tag{5}$$

Considering that typical lens radius that copes with the geometrical optics approximation ranges from 10 to 30 λ, a value of tan $\delta = 10^{-3}$ corresponds to dissipation losses ranging from about 0.4 to 1.3 dB.

A simple procedure to verify the lens design is to perform a ray tracing, by shooting rays from the feed point at equal angular intervals and using Snell's law to trace the rays' propagation inside and outside the lens (see Fig. 6). This can reveal, for instance, the shape of the output phase front, the phase center position, or the existence of caustics. The lens radiation pattern in the optical limit can be easily obtained by representing throughout the solid angle the ratio dS/dS' of the ray tubes, defined in Fig. 4, weighted by the feed radiation pattern.

GO-based lens synthesis has been used in the literature for different design specifications ranging from simple phase correction problems (Olver et al. 1994) or with additional aperture taper specification to multi-beam or beam-scanning problems (Kelleher 1961) or to stringent beam-shaping problems (Fernandes 1999). It has been applied for axial-symmetric lens synthesis as well as for any arbitrarily shaped lens (Salema et al. 1998; Fernandes and Anunciada 2001; Sauleau and Bares 2006; Bares and

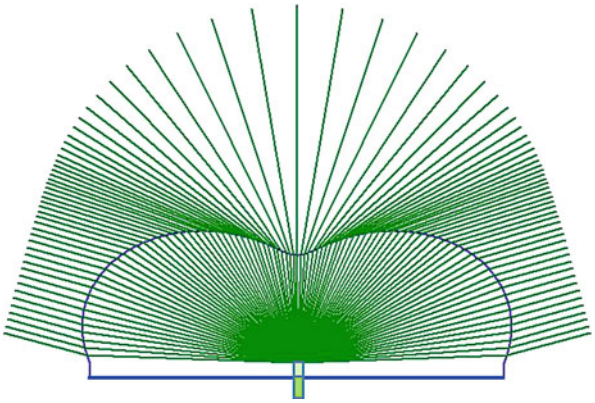

Fig. 6 Ray tracing in a secant-squared lens antenna example with embedded feed

DOI 10.1007/978-981-4560-75-7_40-1

Sauleau 2007), for multiple-shell lenses (Silveirinha and Fernandes 2000), for nonuniform refractive index lenses (Cornbleet 1994), or, in fact, for any combination of the previous cases.

The exact solution for the generic 3D structures using GO is numerically involved but feasible (Salema et al. 1998; Sauleau and Bares 2006; Bares and Sauleau 2007). Perturbation methods like the one proposed in Fernandes and Anunciada (2001) may be simpler to implement for specific types of nonsymmetrical target radiation patterns, and it allows to find the appropriate shape for the required nonsymmetrical lens. In this reference, the lens shape is adapted to transform the radiation of the circular-symmetrical source into an output shaped beam with square or rectangular cross section. An adaptation of the same principle can be used to adjust the lens shape to produce an axial-symmetric output beam.

Other Lens Design Methods

The advantage of the direct GO synthesis method presented in the previous section is that it provides the lens shape that satisfies the design requirements after elementary numerical evaluation of closed-form analytical expressions, without the need for any trial and error iterations. Required memory and CPU resources are really modest in the case of axial-symmetric lenses. Although the direct GO synthesis is enough for a large number of applications, the method is asymptotic, valid in the optical limit, thus neglecting diffraction effects that become important as the lens size reduces.

Alternative lens design methods can be considered when a more accurate lens solution is required for given specifications. They are typically based on a trial and error process involving a parameterized lens model and a lens performance analysis method. The accuracy of the design depends on the accuracy of the numerical modeling and a number of required iterations, conditioned by available computational resources. The efficiency of the design process depends very much on how smart the optimization procedure is, due to lens-specific issues which are detailed ahead. Using the direct GO synthesis lens as the first guess for the iterative process may enhance its efficiency.

Before describing the alternative iterative lens design method, it is worth summarizing the following concepts:

- A *closed-form lens synthesis* method (like the GO method described in the previous section) starts from a list of input parameters and design specifications and directly provides an appropriate lens shape based on a closed-form formulation, without the need for trial and error iterations. In this sense, this can be further classified as a direct synthesis method. In general the verification of the lens performance requires the subsequent single-time use of a lens analysis method.
- In *iterative lens synthesis* methods, the lens shape is described by some analytical or numerical representation with unknown coefficients which are determined inside an iterative optimization cycle that tests each generated lens using an appropriate lens analysis method until the target specifications are met by trial and error.
- A *lens analysis method* is intended to evaluate the performance of an existing lens either using an approximate method or a full-wave solver. Its output is the lens performance, not the lens shape.

Unlike direct synthesis methods, the list of available analysis methods is considerably larger. The most used are presented in Table 2, grouped according to the type of electromagnetic modeling. A brief description of these methods is provided in section "Lens Design, Fabrication, and Test."

Figure 7 presents a schematic diagram of the two mentioned approaches for lens design – the direct synthesis method on the left and the iterative synthesis methods on the right. Naturally both start from the definition of the target specifications, lens material, and primary feed characteristics. The path on the left provides a fast first guess of the solution, which can be enough for certain problems or can be fed for refinement through the iterative process on the right.

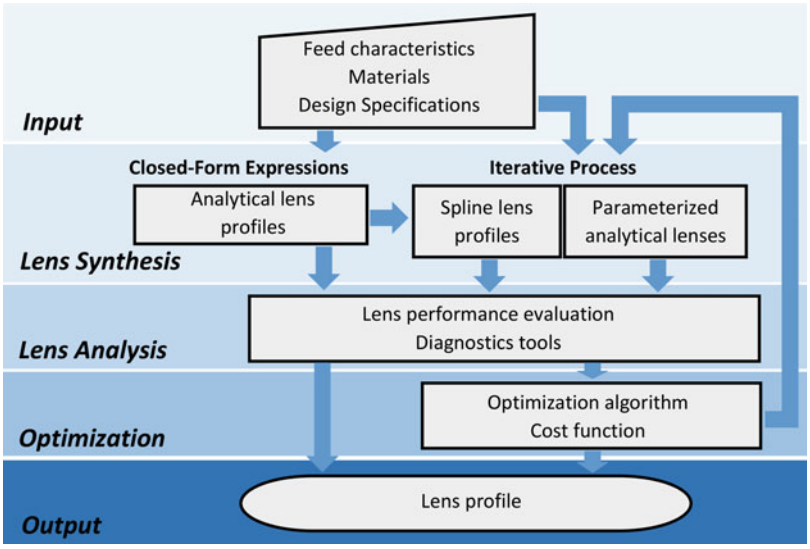

Fig. 7 Block diagram of lens design steps

Two alternative approaches are considered for the parametric modeling of the lens. A polynomial-type representation can be adopted, where the coefficients are the unknowns to be optimized in the loop instead of the large collection of the lens surface coordinates. This solution is very flexible allowing the representation of arbitrary shapes. The disadvantage is that the optimization algorithm may generate an unnecessary number of useless lenses, not because the geometry is impossible (it can be checked before starting the lens analysis and removed from the test population) but because randomly generated lenses can easily originate total internal reflection, surface wave modes, and caustics, especially for integrated multiple-shell lenses which can only be detected after the analysis process.

In the second approach (Lima et al. 2008), the search space can be narrowed to specific classes of lenses by using the analytical lens profiles from the GO synthesis method but letting the involved parameters be managed by the optimization algorithm. The analytical-based solutions ensure the electromagnetic viability of all the solutions tested in the iterative process. There is a convergence time versus design flexibility trade-off between these two approaches.

The described procedures and the workflow presented in Fig. 7 are implemented in a freeware lens design, analysis, and optimization tool – the ILASH software tool (Lima et al. 2008). It was developed for circular-symmetric-shaped integrated lens antennas with single or double layer and can handle multiple target specification definitions. The lens analysis method is based on the GO/PO, and the optimization is based on genetic algorithms. A screenshot of the ILASH user interface is presented in Fig. 8. It allows simple interaction with the kernel, to generate and manipulate lens design data, to fully characterize the

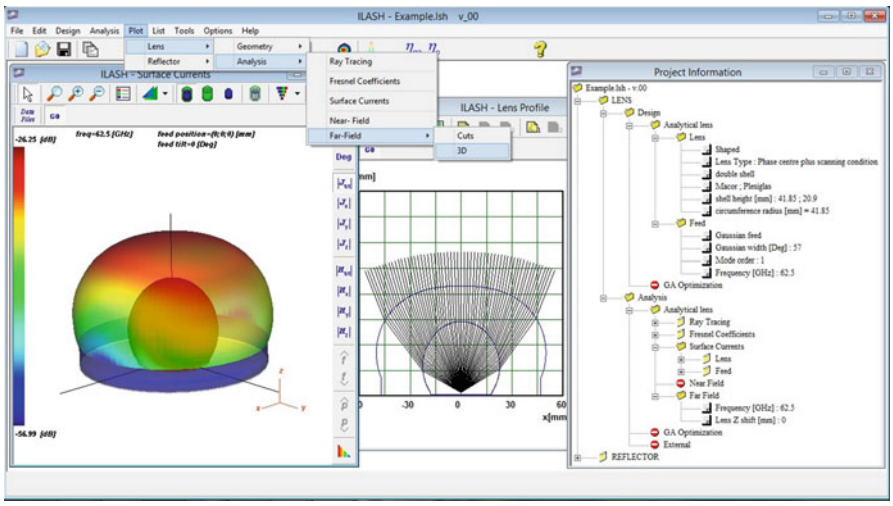

Fig. 8 Screenshot of the user interface of the freeware ILASH software

lens performance, and to export and import results. It is also possible to monitor in real time several aspects of the optimization process like the cost function value, lens parameter evolution, and convergence. ILASH was used to design the lens examples described in section "Applications."

Lens Design, Fabrication, and Test

This section presents a few representative examples of lens design, organized according to the lens classification introduced in section "Lens Theory." In most of the cases, the design is based on GO formulation. The section includes also a discussion of the steps that follow the lens design toward fabrication and test.

Off-Body Fed Lens Design Examples

Early works on dielectric lens antennas were based upon the concepts of optical lenses. Most of the late 1800 and early 1900 tests were conducted with off-body fed lenses which were used to collimate the radiation of a plane wave into the feed placed at the focal point in the opposite side of the lens. Also most off-body fed lenses have an axial-symmetric shape, and, at least during design, the feed radiation pattern is considered also circularly symmetric. These assumptions remove the dependence of the lens with the φ angle, the angle of rotation about the antenna axis of symmetry. Off-body fed lens antennas are usually made of a single material and can have either one or two refracting surfaces.

Single Refraction Lenses

The simpler lens configurations with a single refracting surface are the elliptical and the hyperbolic lenses (see Fig. 9). In an elliptical lens, the surface closer to the feed (inner surface) has a spherical shape and does not refract the rays. The collimation of the rays is achieved from the elliptical surface farther away from the feed (outer surface). In a hyperbolic lens, the refraction occurs in the hyperbolic lens surface closer to the feed. In this configuration, the outer lens surface is planar and does not refract the rays.

The shape of the outer surface of the elliptic lens in polar coordinates can be obtained by imposing the path length collimation condition:

$$r_1 + n\, l(\eta) + \; s(\eta) = r_1 + n\, T \tag{6}$$

DOI 10.1007/978-981-4560-75-7_40-1

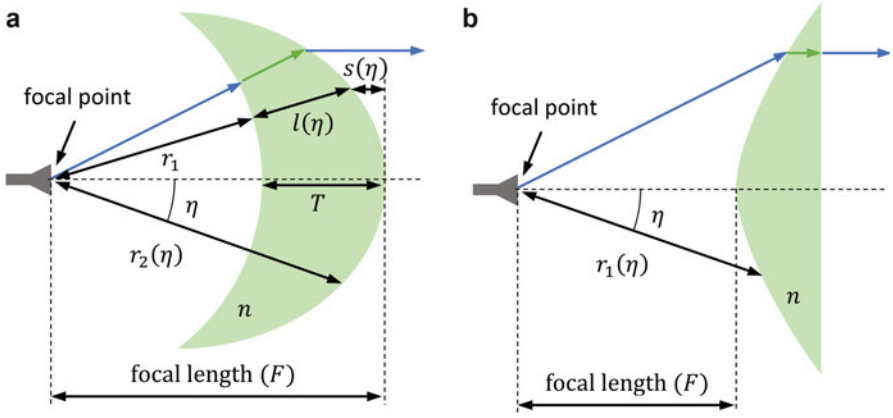

Fig. 9 Off-body fed lens examples. (**a**) Elliptical lens; (**b**) hyperbolic lens

and the following physical length condition:

$$[r_1 + l(\eta)]\cos(\eta) + s(\eta) = r_1 + T \tag{7}$$

where T is the lens selected thickness at the axis. Subtracting the two equations and noting that $r_1 + l(\eta) = r_2(\eta)$ and that $r_1 + T = F$ where F represents the lens focal distance, the outer surface profile is expressed as

$$r_2(\eta) = \frac{F(n-1)}{n - \cos(\eta)} \tag{8}$$

where n is the refraction index of the lens material and F is the lens focal distance. Snell's equations are implicitly satisfied by the collimation condition (which translates Fermat's principle).

The inner shape of the hyperbolic lens can be obtained using a similar set of equations and is defined by

$$r_1(\eta) = \frac{F(n-1)}{\cos(\eta) - 1} \tag{9}$$

Note that the design is based solely on phase considerations, assuming a point source. In the ideal case when both lens types with identical diameters are fed with a point source, the elliptical lens presents higher directivity and lower side lobe levels. In fact, all the inner surface points of the elliptical lens are at the same distance from the source and are illuminated with identical amplitude. The main disadvantage of the elliptical lens is that the reflection at the inner surface of the lens, due to the contrast between the air and the dielectric permittivity, is normal to the spherical surface and is reflected back toward the feed (Piksa et al. 2011). In the hyperbolic lens, the diffraction effects at the edges of the lens tend to influence more the main beam of the radiation pattern and increase the side lobe level (Piksa et al. 2011). The hyperbolic lens however may be simpler to manufacture since it presents one planar surface.

Double Refraction Lenses

Lenses with two refracting surfaces allow more control of the radiation pattern characteristics as discussed in section "Geometrical Optics for Lens Design." In fact, based upon geometrical optics, a set of differential and linear equations can be obtained to determine the coordinates of one of the surfaces

DOI 10.1007/978-981-4560-75-7_40-1

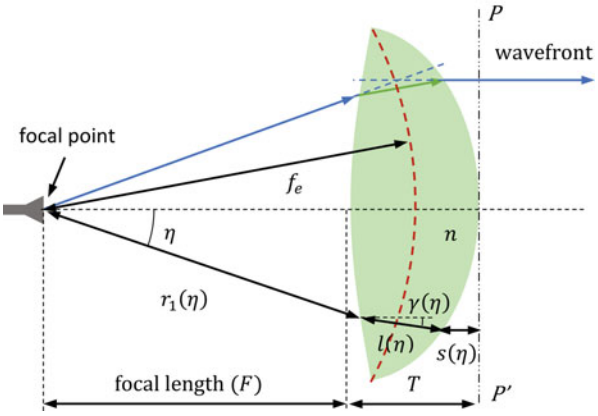

Fig. 10 Geometry of a two refracting surface lens for Abbe sine condition enforcing

(Silver 1984). However, those equations are not sufficient to determine uniquely both surfaces, so another design condition must be imposed.

One interesting use for the extra degree of freedom provided by the second refracting surface is in scanning beam applications. If the feed in the previous elliptical or hyperbolic lenses is shifted off the focus on a plane normal to the lens axis, the beam tilts linearly for very small shifts and with a more complex dependence for larger shifts along with increasing beam deformations. In fact the phase front of the output beam is no longer plane for off-axis feed positions. Expanding it in Taylor series reveals a linear term responsible for the linear tilt and nonlinear terms responsible for different types of superimposed beam deformations (Born and Wolf 1959).

It is possible to extend the linear tilt angle range for scanning beam applications by imposing the so-called Abbe sine condition for the design of the second available lens-refracting surface. This enables designing a collimating lens which is free from comma aberration when the feed is transversely displaced away from the lens axis (Born and Wolf 1959). The inner surface of the lens can be defined by the unknown function $r_1(\eta)$ and the outer surface by the unknown length $l(\eta)$ and angle $\gamma(\eta)$ represented in Fig. 10. The lens focal length is F and the axial thickness is T. The Abbe sine condition is verified when the intersections of the extended $r_1(\eta)$ rays departing from the lens focal point and the corresponding extended transmitted $s(\eta)$ rays all lie over an arc of circumference with a certain radius f_c centered at the focal point. This is represented by the thick dashed line in Fig. 10. In view of the geometry presented in Fig. 10, the Abbe sine condition can be written as

$$(f_e - r_1)\sin(\eta) = l\sin(\gamma) \tag{10}$$

Snell's law at the inner surface of the lens implies that (Eq. 3)

$$\frac{dr_1}{d\eta} = \frac{n\, r_1 \sin(\gamma - \eta)}{1 - n\,\cos(\gamma - \eta)} \tag{11}$$

In order that the electrical path length of every ray is the same at the exiting wavefront, it is required that

$$r_1 + nl + s = F + nT, \tag{12}$$

$$s + r_1\cos(\eta) + l\cos(\gamma) = F + T \tag{13}$$

DOI 10.1007/978-981-4560-75-7_40-1

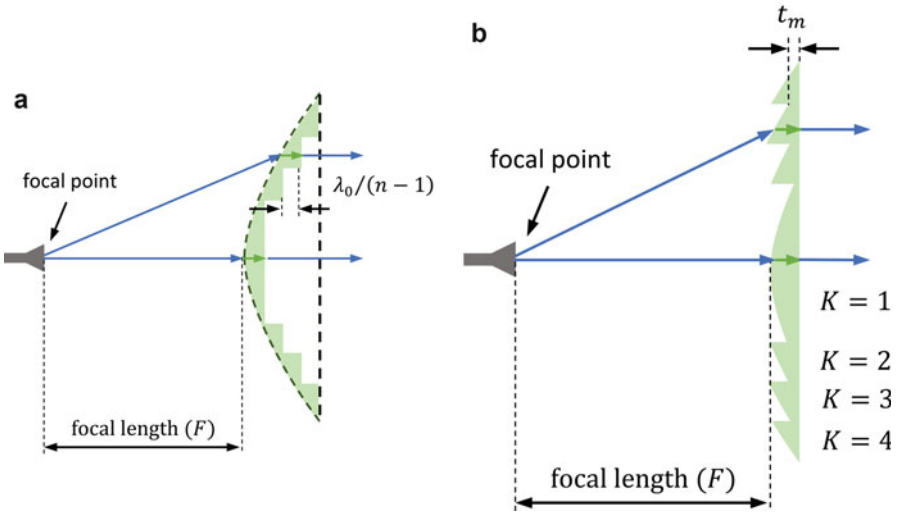

Fig. 11 Zoning of a hyperbolic lens. (**a**) Original outer hyperbolic shape; (**b**) corresponding zoned lens

Equations 10, 11, 12, and 13 can be solved simultaneously for $r_1(\eta)$, $l(\eta)$, $s(\eta)$, and $\gamma(\eta)$ taking η as the independent variable and the initial conditions $r_1(0) = F$, $l(0) = T$, $s(0) = 0$, and $\gamma(\eta) = 0$. The outer surface of the lens can be calculated from the previous four functions.

Zoning

Usually lenses are several wavelengths thick, particularly near the lens axis. For microwave applications, this may lead to a very bulky antenna and originate non-negligible dissipation losses in the dielectric. To attenuate those effects, rings of material with a thickness equal to an integer multiple of the wavelength can be removed from the lens, a process called zoning. Figure 11 shows an example for the hyperbolic lens discussed in section "Single Refraction Lenses" with four zones ($K = 4$). A minimum physical lens thickness t_m needs to be maintained in the zoned lens to provide structural support, as indicated in Fig. 11. The thickness of the zoned lens is independent of the number of zones K, and it is given by $t_m + \lambda_0/(n-1)$, which for the example in Fig. 11 represents about a quarter of the original lens thickness.

The downside of zoned lens is the associated frequency dependence which becomes more important as the lens diameter increases and more zones are used. A criterion to estimate the bandwidth of zoned lenses is given by Silver (1984): under uniform aperture distribution and lens aperture phase error smaller than $\pi/4$

$$\text{Bandwidth} \approx \frac{25\%}{K-1} \tag{14}$$

If the zoning is performed in the non-refracting surface of the lens, shadowing losses can appear at the transition regions, and this effect is stronger for lenses with larger ratios between the focal length and the lens diameter F/D (Petosa and Ittipiboon 2000).

Integrated Lens Design Examples

This section addresses briefly two classical examples of nonuniform refractive index lenses – the Luneburg and the Maxwell fish-eye – and focuses more on the homogeneous shaped lenses. Other nonuniform refractive index lenses have also gained interest with the recent advances in the fields of transformation optics and metamaterials, but these exceed the scope of this chapter.

Homogeneous integrated lenses are very effective for integration with low-cost millimeter-wave circuits, allowing low form-factor solutions with sophisticated radiation pattern characteristics owing to

DOI 10.1007/978-981-4560-75-7_40-1

the great design flexibility this lens configuration provides. However, internal reflections may critically influence the lens performance and must be properly analyzed in each design. This section presents some representative design examples of canonical lenses as well as some more recent shaped lenses based on GO.

Nonuniform Index Spherical Lenses

In the classical nonuniform spherical lenses, the dielectric constant of the material has only radial variation. Therefore, the lens is symmetric in relation to any axis passing the center of the lens. As a consequence, these spherical lenses do not present a unique focal point but rather a spherical surface concentric with the lens where the focal point can be located depending on the direction of the incident wave.

The most known of the spherical lenses is the Luneburg lens (Luneburg 1943) where the lens material permittivity profile varies with the square of the r distance from the lens center:

$$\varepsilon_r(r) = 2 - \left(\frac{r}{R}\right)^2 \tag{15}$$

R being the outer radius of the lens. This formulation results in a focal region located at the outer surface $r = R$ of the lens. Therefore, a point source located at any point of the lens surface originates a collimated beam in the opposite direction (Fig. 12). This property is independent of the lens diameter. The Luneburg lens is particularly adequate for multi-beam applications since the symmetry ensures that all beams are equally independent of the feed position on the lens surface.

Luneburg did not have the opportunity to demonstrate such antenna experimentally since no suitable lens materials were available at the time. Nowadays, Luneburg lenses are formed by a discrete number of concentric dielectric layers that approximate the ideal permittivity law of Eq. 15. It is expected that as the number of discrete layers increases, the performance of the lens improves; however, the manufacturing complexity increases as well as the influence of possible air gaps between the layers (Kim and Rahmat-Samii 1998). It has been demonstrated that a quite small number of shells is enough to obtain a directivity and side lobe level close to the ideal case (Fuchs et al. 2007a). Nevertheless, the recommended number of discrete layers increases with the lens diameter compared to the wavelength. For example, just six layers were required to achieve adequate performance with an $8\lambda_0$-diameter Luneburg lens (Fuchs et al. 2007a). Even lesser number of layers is possible by optimizing both the permittivity and thickness of the layers (Mosallaei and Rahmat-Samii 2001; Boriskin et al. 2011).

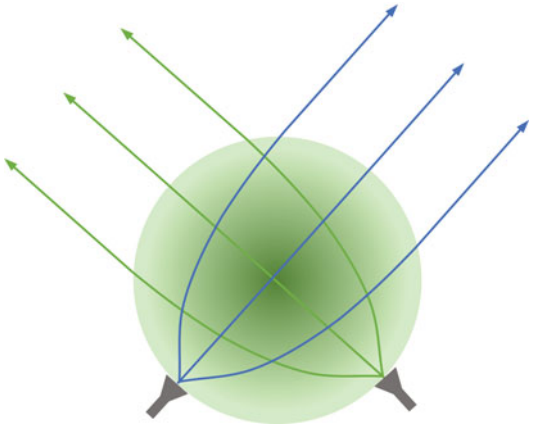

Fig. 12 Luneburg lens with darker color representing increasing permittivity

DOI 10.1007/978-981-4560-75-7_40-1

There are also examples of Luneburg lenses fabricated from a single material with controllable dielectric constant. For instance, in Min et al. (2014), a 3D rapid prototyping machine was used to achieve the desired permittivity value by controlling the filling ratio of a polymer/air-based unit cell. Alternatively, it is possible to use foam material and press it to obtain the desired dielectric constant. In fact, when the pressure increases and the foam is compacted, the quantity of air in the material decreases, increasing the permittivity. This technique has been tested for the fabrication of a Luneburg lens in Bor et al. (2014). It is also possible to control the dielectric constant in the Luneburg lens by drilling holes into the material and varying either the diameter of the holes or their density (Sato and Ujiie 2002; Xue and Fusco 2007).

One of the major disadvantages of the Luneburg lens is its high profile. Transformation optics (Do-Hoon and Werner 2010) can be used to change the shape of the lens into a much lower cylindrical profile. However, common solutions end up resulting in materials that are anisotropic and/or must have relative permeability different than unity forcing the use of metamaterials that are usually narrowband, lossy, dispersive, and sometimes cumbersome to manufacture. A reasonable performance has been achieved with a compacted Luneburg lens with cylindrical geometry, formed by discrete layers with step permittivity variation along the radius and along the height (Mateo-Segura et al. 2014). Although a height reduction was obtained, permittivity values as high as 12 are required, and the structure presents some scanning loss.

A commonly used solution to reduce the profile of the Luneburg lens by a factor of 2 is to combine half of the lens with a flat ground plane (Fig. 13). The ground plane creates an image of the upper hemisphere and simulates the complete Luneburg lens. The size of the ground plane must be adequate to produce the required image, and the necessary dimensions are the function of the elevation angle of the beam in relation to the ground plane. An insufficient ground plane size will reduce the directivity of the beam and cause scanning loss. This hemispheric lens solution also suffers from feed blockage for high elevation angles. One advantage of this configuration is that it is easier to mechanically stabilize than the complete spherical lens. Recently a quarter Luneburg lens with a 90° corner ground plane has been demonstrated (Nikolic et al. 2012).

A similar configuration to the Luneburg spherical lens is the cylindrical one (Fig. 14) where the variation of the dielectric constant occurs only in the radial direction. In this solution, the beam collimation is obtained only in one plane, leading to fan-shaped beams instead of pencillike beams (Komljenovic et al. 2010).

Another classical nonuniform index spherical lens is the Maxwell fish-eye lens, which predates the Luneburg lens (Maxwell 1860). The dielectric constant of the lens material is given by

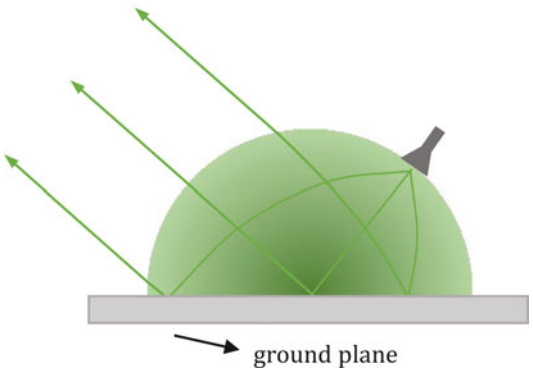

Fig. 13 Half hemisphere Luneburg lens

DOI 10.1007/978-981-4560-75-7_40-1

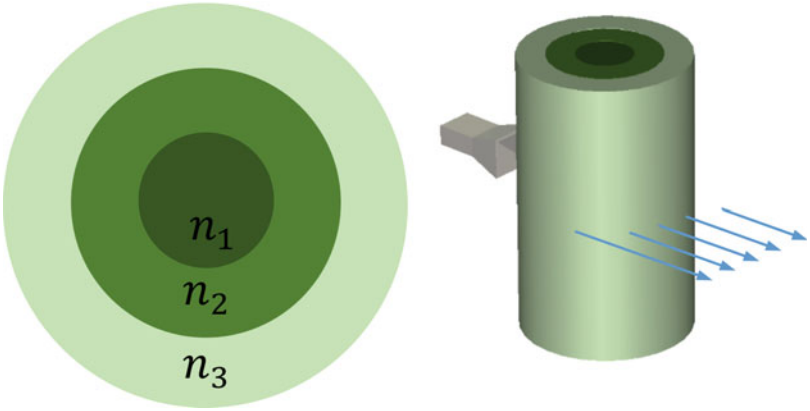

Fig. 14 Cylindrical Luneburg lens

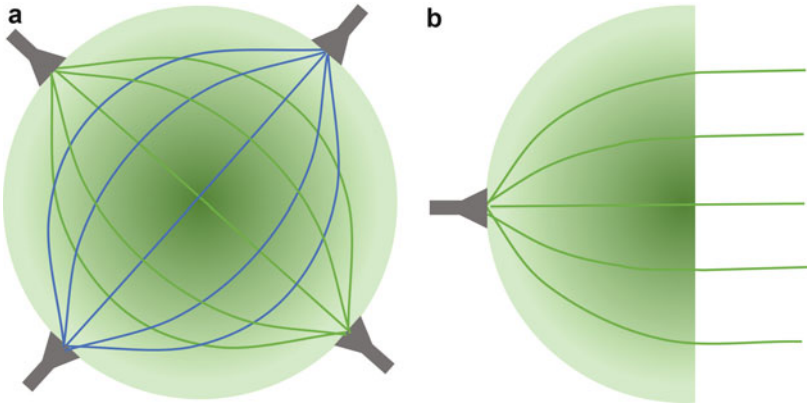

Fig. 15 (**a**) Maxwell fish-eye lens; (**b**) half Maxwell fish-eye lens. The darker color represents higher values of permittivity

$$\varepsilon_r(r) = \left(\frac{4}{\left[1 + \left(\frac{r}{R}\right)^2\right]^2} \right) \tag{16}$$

where R is the outer radius of the lens. When a point source is placed on the surface of the lens, the radiation is focused at the antipodal point of the lens as represented in Fig. 15a. Due to the lens symmetry, the source radiation is converted into a local plane wave at the center of the lens. Therefore, if the Maxwell fish-eye lens is cut in half, it can be used as a collimating lens that focuses a plane wave into a focal point on the surface of the lens, which becomes unique in this case (Fig. 15b). The half Maxwell fish-eye (HMFE) lens has lower profile than the Luneburg lens and is easier to flush mount. Practical implementation of the HMFE has been done using a few discrete layers (Fuchs et al. 2006), and the performance was shown to be comparable with the Luneburg lens when the feed is centered with the lens (Fuchs et al. 2008a).

Unlike the Luneburg lens, the HMFE lens loses interest for scanning beam applications since scanning losses appear as the feed is moved over the lens surface (Fuchs et al. 2007b).

Elliptical and Hemispherical Lenses

The homogeneous elliptical integrated lens, just like its off-body fed counterpart treated in section "Single Refraction Lenses," is used to transform the radiation pattern of a feed placed at the focal point of the lens

DOI 10.1007/978-981-4560-75-7_40-1

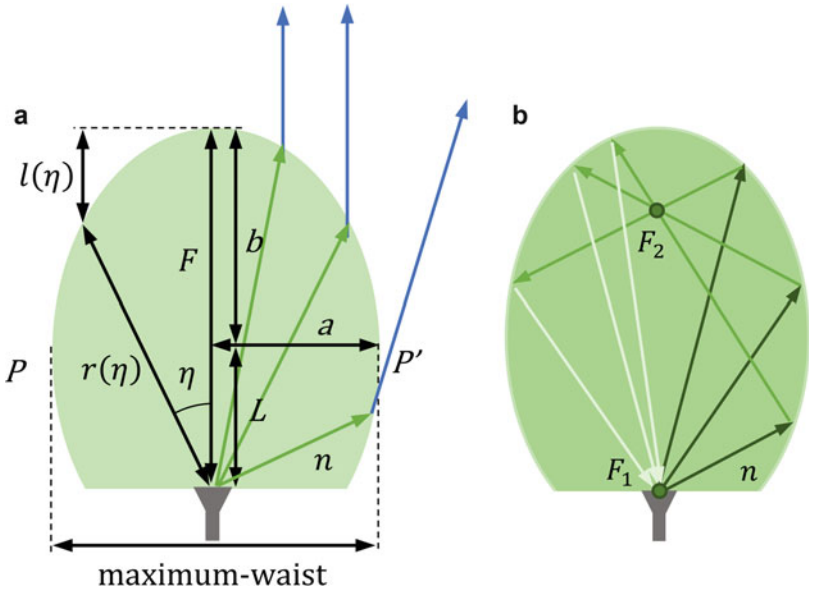

Fig. 16 (**a**) Design variables of an elliptical integrated lens antenna; (**b**) rays' reflection inside the lens

into a plane wave in the air medium, propagating along the lens axis (Fig. 16). It can be viewed as the limit when r_1 tends to zero in Eqs. 6 and 7 from section "Single Refraction Lenses":

$$n\, r(\eta) + l(\eta) = n\, F \tag{17}$$

Also the following physical length condition can be imposed:

$$r(\eta)\cos(\eta) + l(\eta) = F \tag{18}$$

Eliminating $l(\eta)$ between the two equations leads to the same elliptical lens profile found in section "Single Refraction Lenses":

$$r(\eta) = \frac{F(n-1)}{n - \cos(\eta)} \tag{19}$$

It is a simple matter to show that this corresponds in rectangular coordinates to

$$\left(\frac{x}{a}\right)^2 + \left(\frac{z-L}{b}\right)^2 = 1 \tag{20}$$

where a is the radius along the x-axis, b is the radius along the z-axis, L is the position of the focal point in relation to the center of the lens, and $b + L = F$ (Fig. 16a). The eccentricity of the elliptical lens is related to the dielectric constant of the material. The following relations hold (Filipovic et al. 1993):

$$b = \frac{a}{\sqrt{\frac{1-1}{n^2}}} \tag{21}$$

DOI 10.1007/978-981-4560-75-7_40-1

$$L = \frac{b}{n} \tag{22}$$

The value of a is chosen to define the lens size and consequently the aperture size required to achieve a certain directivity of the beam.

Only the rays that hit the lens surface above the plane of maximum waist PP' are focused (Fig. 16b). The feed radiations intersecting the lens below the maximum waist are not collimated but rather propagate along undesired directions or excite surface wave modes (Pasqualini and Maci 2004) giving rise to side lobes or other perturbations in the lens radiation pattern. For this reason, proper feed configurations should be used to minimize the illumination of the lower part of the lens surface.

Internal reflections may be especially critical in integrated lens antennas. For instance, if the feed is at the center of a hemispherical lens, all reflected rays travel back along the same path of the corresponding incident rays, concentrating at the focal point, usually causing a substantial mismatch at the feed impedance. A similar effect occurs in the elliptical lens; all reflected rays concentrate at the feed point after traveling through the second focal point of the elliptical lens, originating a second-order reflection at another point of the lens surface (Fig. 16b) (Neto et al. 1998, 1999; Van Der Vorst et al. 1999, 2001). Again, this causes feed impedance mismatch. Part of the second-order ray is transmitted to the air at an undesired direction causing side lobes in the lens radiation pattern. These undesired effects increase with the contrast between the material and the air refraction indexes. For other integrated lens shapes, the reflected rays may not be all reflected back into the feed; nevertheless, they may be responsible for transmission of higher than first-order rays along undesired directions, reducing the main beam efficiency or causing ripple.

The problem of internal reflections can be tackled, at least within a limited bandwidth. For normal incidence on a planar interface between two dielectric media with refraction index n_1 and n_2, it is possible to cancel the reflected ray by adding an appropriate intermediate layer, Fig. 17a. Its dielectric refraction index n^{match} must be

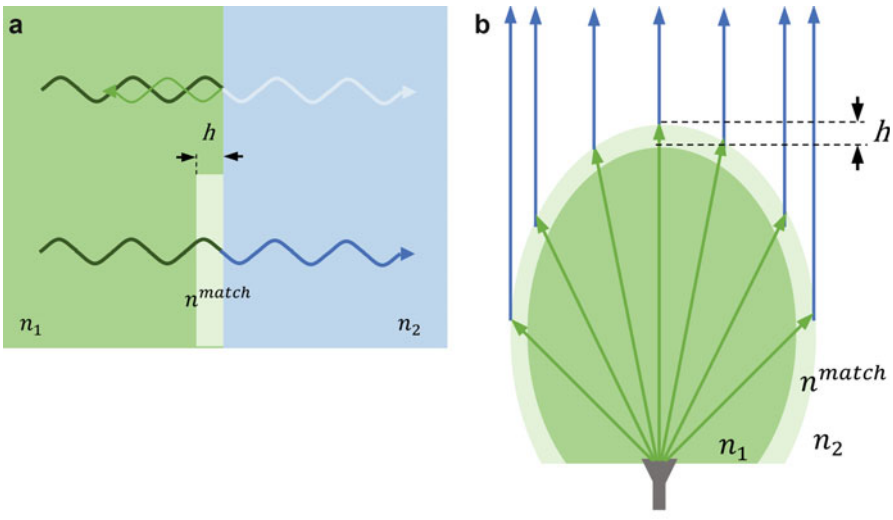

Fig. 17 Matching layer (**a**) in a planar dielectric-air interface. The intensity of ray color is proportional to the wave power density; (**b**) in an elliptical integrated lens antenna

$$n^{\text{match}} = \sqrt{n_1 n_2} \tag{23}$$

and a thickness h

$$h = \frac{\lambda_0}{4n^{\text{match}}} \tag{24}$$

where λ_0 is the free-space wavelength. This intermediate layer is usually called the matching layer.

By adding a matching layer to the lens surface, it is possible to alleviate the effect of internal reflections (Fig. 17b). It is a fact that the rays do not hit the lens surface along the normal direction, and therefore the thickness of the matching layer should not be given by Eq. 24. Instead it should vary along the surface of the lens according to the ray incident angle. In a study presented in Van Der Vorst et al. (1999) for an elliptical integrated lens of silicon ($\varepsilon_r = 11.7$), it was demonstrated that there is no major improvement on the lens radiation performance by using the optimum-thickness matching layer. Therefore, a constant thickness layer given by Eq. 24 is generally used, facilitating the manufacturing process. Because it is not easy to find natural materials with specific permittivity values, it is common to synthesize an effective medium layer by periodically removing a fraction of the dielectric material from the lens surface, such as drilling holes or cutting groves (Ngoc Tinh et al. 2010).

The matching layer thickness is frequency dependent and, therefore, reduces the bandwidth of the lens antenna. To improve the bandwidth, multiple consecutive matching layers can be used, performing a gradual transition between the two dielectric constants at the interface (Ngoc Tinh et al. 2009).

The extended hemispherical lens is another classical configuration of integrated lens, owing to its simple shape for fabrication. It consists of a half sphere of radius R with a cylindrical extension of height L. The feed is located at the base of the lens (Fig. 18b).

If the length of the cylindrical extension is chosen to be

$$L = \frac{R}{n-1} \tag{25}$$

most of the spherical part of the hyper-hemispherical lens coincides with an elliptical lens (Fig. 18a). This lens is usually called synthesized elliptical lens (Filipovic et al. 1993) although it tends to present a slightly lower directivity when compared to a true elliptical lens with the same diameter.

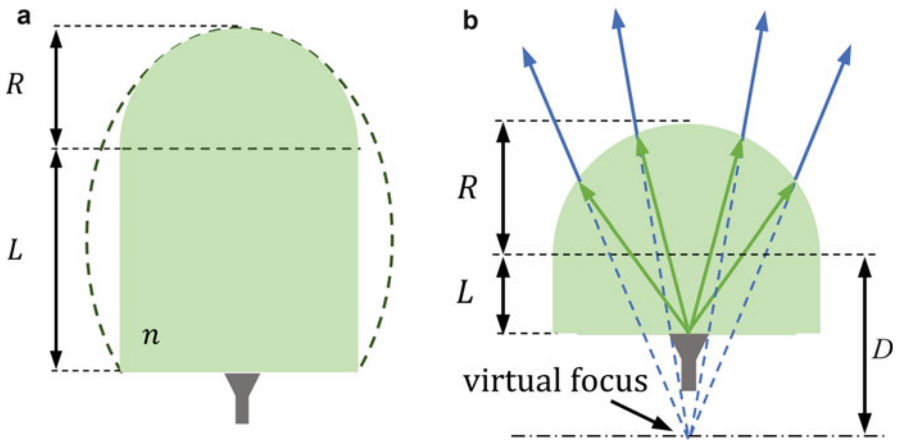

Fig. 18 Extended hemispherical integrated lens antenna: (**a**) synthesized elliptical; (**b**) hyper-hemispherical

DOI 10.1007/978-981-4560-75-7_40-1

A second type of extended hemispherical lens is the hyper-hemispherical (Rebeiz 1992) where the cylindrical extension length is

$$L = \frac{R}{n} \tag{26}$$

For this particular type of lens, the output beam is not collimated, presenting a much broader (and sometimes multilobed) radiation pattern when compared to an elliptical lens with the same radius. Nevertheless, the hyper-hemispherical lens bends the rays radiated by the feed toward the axis of the lens (Fig. 18b). The lens sharpens the radiation pattern, effectively increasing the gain of the feed by a factor n^2 (Rebeiz 1992). However, unlike collimated lenses, the directivity of this lens does not increase with lens size (or aperture size).

The hyper-hemispherical lens satisfies the Abbe sine condition (Born and Wolf 1959). Therefore, this lens is free from comma aberration when the feed is transversely displaced within certain limits away from the lens axis. This type of lens is particularly useful for beam-scanning applications. Another interesting characteristic of hyper-hemispherical lenses is that all the rays transmitted into the air focus in a virtual point behind the lens at a distance:

$$D = Rn \tag{27}$$

from the center of the spherical part of the lens. This means that the radiation pattern of this lens presents a very stable phase center position coincident with this virtual focus and its position does not shift with the frequency (in the optical limit).

There are several other types of shaped dielectric integrated lens antennas with profiles not given by canonical expressions like the elliptical and extended hemispherical lenses. In section "Applications" of this chapter, several design and implementation examples of noncanonical shaped lenses will be given in more detail.

Lens Designed to Match an Output Power Template

Integrated lenses can also be used to conform the output radiation pattern to some far-field power template $G(\theta)$. The formalism of a GO direct synthesis method is described for an axial-symmetric single-material lens with refraction index n, fed on-axis at the base of the lens as shown in Fig. 19 (Fernandes 1999).

The lens design requires the knowledge of the feed power pattern $U(\eta)$ when the feed is inside the lens material. This can be obtained using a full-wave analysis of the feed radiating into an unbounded medium with the same permittivity as the lens. Alternatively it can be obtained experimentally using the procedure described in section "Lens Measurements."

The unknown lens profile is represented by the $r(\eta)$ function. As before, Snell's equation for refraction at the dielectric interface is written as

$$\frac{\partial r}{\partial \eta} = \frac{r(\eta)\sin(\theta - \eta)}{n - \cos(\theta - \eta)} \tag{28}$$

In order to enforce the output power pattern template, the elementary ray tube concept introduced in section "Geometrical Optics for Lens Design" is used (Fig. 4). Power conservation in the elementary ray tube is expressed as

$$U(\eta)T\sin(\eta)d\eta = KG(\theta)\sin(\theta)d\theta \tag{29}$$

DOI 10.1007/978-981-4560-75-7_40-1

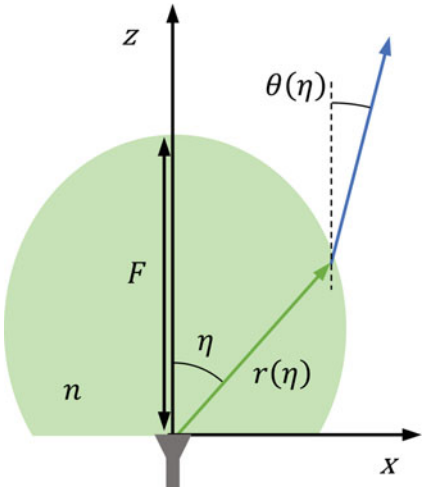

Fig. 19 Geometry of a single-shell lens

or rearranging

$$\frac{d\theta}{d\eta} = \frac{T}{K}\frac{U(\eta)}{G(\theta)}\frac{\sin(\eta)}{\sin(\theta)} \tag{30}$$

where $T(\eta)$ represents the transmissivity, that is, the ratio of the power P_t transmitted across dS to the incident power P_i (Fig. 4).

$$T = \frac{U_{\parallel}\left|t_{\parallel}^2\right| + U_{\perp}\left|t_{\perp}^2\right|}{U}\frac{1}{n}\frac{\cos(\beta)}{\cos(\alpha)}T \tag{31}$$

$$\cos(\alpha) = \hat{\mathbf{i}} \cdot \hat{\mathbf{n}} \tag{32}$$

$$\cos(\beta) = \hat{\mathbf{t}} \cdot \hat{\mathbf{n}} \tag{33}$$

where $t_{//}$ and $t_{\perp}$ represent the Fresnel transmission coefficients for parallel and perpendicular polarization, respectively. K is a normalization constant to be determined from the balance between the total power inside the lens and total power outside the lens:

$$K = \frac{\int_0^{\eta_{\max}} T(\eta)U(\eta)\sin(\eta)d\eta}{\int_0^{\theta_{\max}} G(\theta)\sin(\theta)d\theta} \tag{34}$$

$\eta_{\max}$ being the maximum feed aperture and $\theta_{\max}$ the maximum output angle.

The unknowns $r(\eta)$ and $\theta(\eta)$ are obtained by integrating the system of equations formed by Eqs. 28 and 30 from $\eta = 0$ to $\eta_{\max}$ (typically 90°) using the initial condition $r(0) = F$ and $\theta(0) = 0$. F acts as a scaling factor not affecting the lens shape. However, the larger is this value, the larger is the lens size. Inherent to the design, increasing the size also improves the lens radiation pattern compliance with the target $G(\theta)$.

DOI 10.1007/978-981-4560-75-7_40-1

Function $T(\eta)$ in Eqs. 28, 29, 30, and 31 depends indirectly on the unknown function $r(\eta)$. An iterative process can be adopted, repeating successively the integration of Eqs. 28 and 30 considering $T(\eta) =$ constant in the first step. The obtained solution $r(\eta)$ can then be used to calculate $T(\eta)$ for the next evaluation of Eqs. 28, 29, 30, and 31, and the process is repeated until convergence; usually two or three iterations are enough.

The presented formulation assumes φ-independent feed and target template power patterns $U(\eta)$ and $G(\eta)$. In most cases, the feed radiation pattern is not axial-symmetric, but an approximation can be generated as an average of the co-components in the main planes for the lens synthesis purpose.

Frequency-Stable Radiation Pattern and Phase Center Position

This section presents the design of a double-shell axial-symmetric lens that complies with two design conditions: a well-defined phase center located behind the lens (outside its body) and a target far-field amplitude template (Fernandes et al. 2010). This type of virtual focus lens can be useful as a reflector primary feed as it will be discussed in the "Applications" section ahead. Lens dimensions are assumed to be large relative to the wavelength, so direct GO synthesis will be used for the lens design.

Considering the geometry from Fig. 20, n_1 and n_2 are the refraction indexes from the inner and outer lens shells, respectively, and S and F are the corresponding axial depths. The lower value of the refraction index is used at the outer shell to favor lower reflections at the air interface. The two lens surfaces are defined by the unknown functions $r_1(\eta)$, $\theta(\eta)$, and $R(\eta)$ and are obtained by solving a system of three differential equations as explained next.

One of the equations derives from the power conservation condition in an elementary ray tube crossing the lens system, the same discussed in section "Lens Designed to Match an Output Power Template":

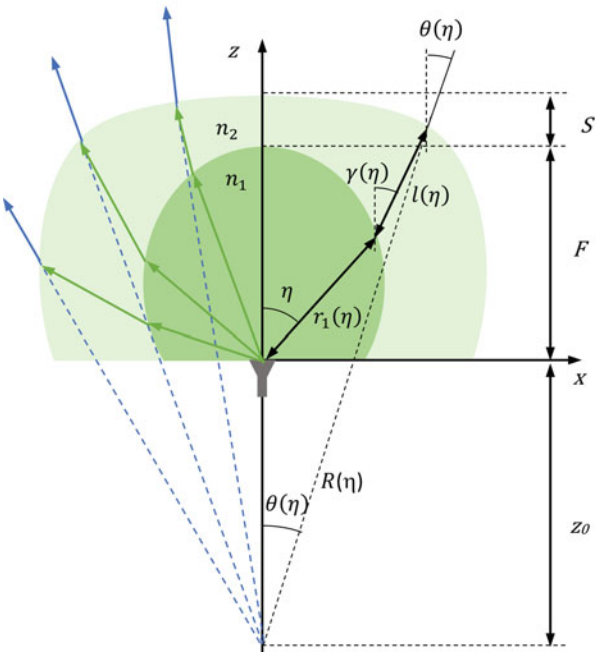

Fig. 20 Geometry for the lens design

DOI 10.1007/978-981-4560-75-7_40-1

$$\frac{d\theta}{d\eta} = \frac{T(\eta)U(\eta)\sin(\eta)}{KG(\theta)\sin(\theta)} \tag{35}$$

where $U(\eta)$, $G(\theta)$, $T(\eta)$, and K maintain the previous definition. Further imposing Snell's law for refraction at the inner interface results in (Eq. 3)

$$\frac{dr_1}{d\eta} = \frac{r_1(\eta)\sin(\gamma-\eta)}{\frac{n_1}{n_2} - \cos(\gamma-\eta)} \tag{36}$$

while imposing Snell's law at the outer interface results in

$$\frac{dR}{d\eta} = \frac{dR}{d\theta}\frac{d\theta}{d\eta} = \frac{Rn_2\sin(\gamma-\theta)}{1-n_2\cos(\gamma-\theta)}\frac{T(\eta)U(\eta)\sin(\eta)}{KG(\theta)\sin(\theta)} \tag{37}$$

Finally, the following path length conditions are imposed:

$$\begin{cases} r_1 n_1 + l n_2 = R \\ R\cos(\theta) = r_1\cos(\eta) + l\cos(\gamma) + z_0 \end{cases} \tag{38}$$

The lens profile is obtained by solving the system of three differential equations, Eqs. 35, 36, and 37, with respect to η integrating from $\eta = 0$ to $\eta = \eta_{max}$. The γ angle required in Eqs. 36 and 37 is obtained from the following explicit expression derived from Eq. 38:

$$\gamma = \cos^{-1}\left[\frac{n_2(R\cos(\theta) - r_1\cos(\eta) - z_0)}{R - n_1 r_1}\right] \tag{39}$$

The initial conditions at $\eta = 0$ are

$$\begin{cases} \theta = 0 \\ r_1 = F \\ \gamma = 0 \\ l = S \\ R = n_1 F + n_2 S \end{cases} \tag{40}$$

The distance from the phase center to the base of the lens z_0 is settled once the lens shells' refraction index and axial depths are chosen. In fact, from Eq. 40, one has

$$z_0 = R(\eta = 0) - F - S = F(n_1 - 1) + S(n_2 - 1) \tag{41}$$

Equation 35 is numerically undetermined at $\eta = 0$. To obtain its value at $\eta = 0$, the following relation is written from

$$\int_0^{\theta} KG(\theta)\sin(\theta)d\theta = \int_0^{\eta} T(\eta)U(\eta)\sin(\eta)d\eta \tag{42}$$

DOI 10.1007/978-981-4560-75-7_40-1

and evaluated in the limit as $\theta \to 0$ and $\eta \to 0$. The result is

$$\theta = \sqrt{\frac{T(\eta)U(\eta)}{KG(\theta)}}\eta \tag{43}$$

where $T(\eta)$, $U(\eta)$, and $G(\theta)$ are assumed constant near $\eta = 0$ and $\theta = 0$. Finally, from the above equation, the corresponding limit value for Eq. 35 is given by

$$\frac{d\theta}{d\eta} = \sqrt{\frac{T(\eta)U(\eta)}{KG(\theta)}} \tag{44}$$

This result is also used in the related part of Eq. 37 for $\eta = 0$.

The GO lens synthesis is inherently broadband as long as lens dimensions are large compared to the wavelength and as long as the feed radiation pattern remains constant and coincident with the used $U(\eta)$ template.

Multi-beam Lens

An integrated lens configuration, formed by two embedded shaped shells, can be designed for multi-beam or scanning applications (Costa et al. 2008a). The possibility to shape two lens surfaces enables that two independent design goals can be specified (in a single-material lens, only one design goal can be defined):

- A beam collimation condition, i.e., the output rays emerging from the lens are required to be parallel to each other
- A condition that minimizes aberrations of the output beam for off-axis feed positions

The lens geometry is presented in Fig. 21. The structure is axial-symmetric, formed by two embedded shells of different materials; the inner shell presents the higher refraction index value n_1 and the outer shell the lower value n_2. An array of feeds is distributed at the planar base of the lens within a small area centered with the lens axis.

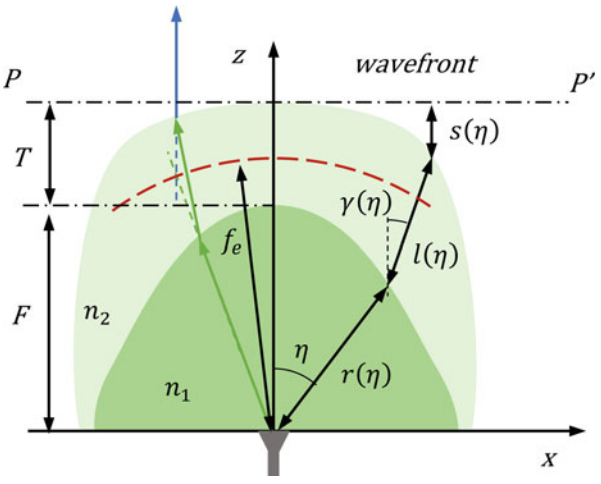

Fig. 21 Geometry for the lens design

DOI 10.1007/978-981-4560-75-7_40-1

The inner lens surface is defined by the (unknown) function $r(\eta)$, and the outer lens surface is defined by the (unknown) length $l(\eta)$ and angle $\gamma(\eta)$ (Fig. 21). The lens axial thickness is F and T for the inner and outer shells, respectively.

It is well known that a lens satisfying the so-called Abbe sine condition is free from comma aberration for a small off-axis transversal displacement of the feed (Born and Wolf 1959). The Abbe sine condition is verified when the intersection points of the extended $r(\eta)$ rays departing from the on-axis feed and the corresponding extended transmitted $s(\eta)$ rays all lie over an arc of circumference with a certain radius f_e centered at the sensor (Born and Wolf 1959). This is represented by the thick dashed arc in Fig. 21. In view of the geometry of Fig. 21, the Abbe sine condition can be written as

$$(f_e - r)\sin\eta = l\sin\gamma \tag{45}$$

Snell's law at the inner interface implies that

$$\frac{dr}{d\eta} = \frac{r(\eta)\sin(\gamma-\eta)}{\frac{n_1}{n_2} - \cos(\gamma-\eta)} \tag{46}$$

In order that the optical path length of every ray is the same at the exiting wavefront, it is required that

$$n_1 r + n_2 l + s = n_1 F + n_2 T \tag{47}$$

$$s = F + T - r\cos(\eta) - l\cos(\gamma) \tag{48}$$

Equations 45, 46, 47, and 48 can be solved simultaneously to determine both the inner and the outer shell profiles, taking η as the independent variable. The initial condition for $\eta = 0$ is $r = F$, $l = T$, and $\gamma = 0$, and the integration is extended up to $\eta = \eta_{edge}$, where generally $\eta_{edge} < \pi/2$. The calculation is stopped at the point where the outer shell intersects the f_e circle or where the total internal reflection condition is reached.

For a given combination of n_1, n_2, F, and T values, the f_e parameter can be adjusted between F and $F + T$ to control the shape of the lens surfaces (and indirectly the lens scanning characteristics). In the optical limit, the lens shape obtained with the above GO-based formulation is independent of the absolute dimensions and thus, for instance, F, can be taken as a scaling factor.

It is noteworthy that, in line with the classical Abbe formulation for single-material lenses (Born and Wolf 1959), the above design equations consider only the central feed. The imposed Abbe condition implicitly determines the scanning behavior for off-axis feeds.

Beam-Steering Lens

In the traditional approach for mechanical beam steering, the primary feed is displaced over the focal arch of the focusing element (lens or reflector) originating a corresponding beam tilt. Alternatively the feed can be fixed and the lens (or reflector) tilted in such a way that its focal arch passes always through the feed. Off-axis feed displacement leads to increased phase error at the aperture, originating progressive beam degradation. These become unacceptable typically beyond 25° beam tilt (notable exception is the Luneburg lens; section "Nonuniform Index Spherical Lenses").

This section presents an alternative approach where the axis for lens tilting is coincident with the lens focus and consequently coincident with the feed phase center (Fig. 22) (Costa et al. 2009). In this way, phase errors associated with the lens tilting are eliminated, and in principle, a larger beam-scanning range can be reached, provided that proper illumination of the lens is maintained for all lens tilt angles. The feed

DOI 10.1007/978-981-4560-75-7_40-1

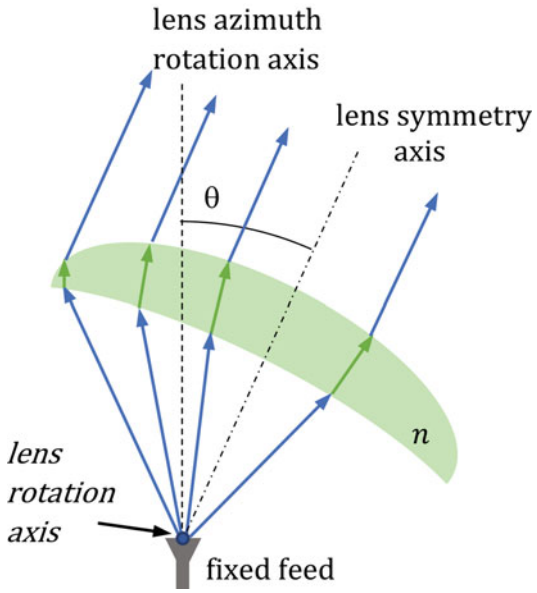

Fig. 22 Working principle of the beam-steering lens

remains stationary. An application example of this lens is presented in section "Mechanical Beam-Steering Lenses."

A collimated beam lens is used for this concept, so, by definition, all output rays emerge always parallel to the lens symmetry axis, making the θ beam tilt angle coincident with the lens tilt angle. The azimuth beam scanning is obtained by simultaneous rotation of the lens about the feed axis.

Of course in this case the feed cannot be in contact with the lens. But the system is designed to have the feed as close to the lens base as possible (in the order of one wavelength) to favor proper lens illumination for all lens tilts. Issues to consider when designing the collimated beam lens are the maximum achievable beam tilt angle, the maximum gain, and the minimum gain scan loss. These characteristics are determined by the lens profile, but they are in part limited by reflections at the dielectric interfaces and by feed illumination spillover as lens tilt increases. An appropriate feed must be designed for proper lens illumination.

This is a case where numerical optimization is required for the lens design. However, instead of brute force optimization of a spline representation of the lens, an alternative hybrid approach is considered (section "Other Lens Design Methods") where GO design equations are combined with a parametric representation of the lens base surface to narrow the search space. The two refraction surfaces of the lens must be designed maximizing the portion of the output lens surface that is able to collimate the feed's radiation. This is equivalent to maximize the lens η_{max} value defined in Fig. 23. The two lens surfaces play a role to broaden this maximum angle.

The lens geometry is shown in Fig. 23. Using Snell's refraction law at the bottom lens interface leads to

$$\frac{\partial r(\eta)}{\partial \eta} = \frac{r(\eta)\, n\, \sin(\gamma - \eta)}{1 - n\, \cos(\gamma - \eta)} \tag{49}$$

where η is the independent variable. On the other hand, by imposing an electrical path length condition, one gets

$$r + n\, l + s = F + n\, T \tag{50}$$

DOI 10.1007/978-981-4560-75-7_40-1

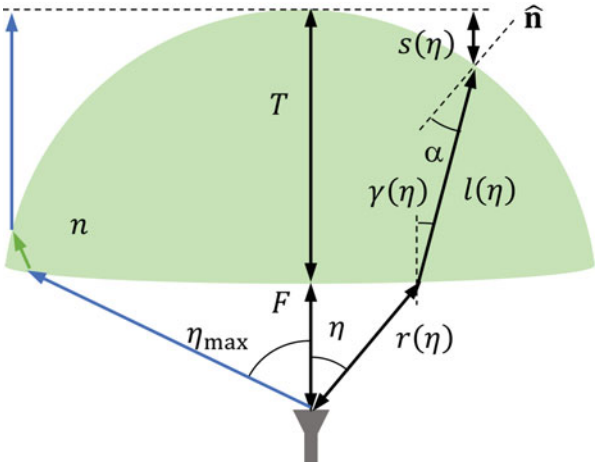

Fig. 23 Geometry for the design of the beam-steering lens

where

$$s = F + T - r\cos(\eta) - l\cos(\gamma) \tag{51}$$

F and T are input constants, whereas $r(\eta)$, $l(\eta)$, and $\gamma(\eta)$ are unknown functions. A third design condition is required to define a unique solution. For that, $r(\eta)$ is analytically written as a Taylor series expansion in η:

$$r(\eta) = \sum_{n=0}^{8} C_n \eta^n \tag{52}$$

So the left-hand side of Eq. 49 can also be written analytically. The following values are set $C_0 = F$ and $C_1 = 0$ in order to impose $\partial r/\partial \eta = 0$ at $\eta = 0$. This ensures null refraction for the central ray. Coefficients C_2 to C_8 are generated by using the genetic algorithm (GA) optimization method. Setting the C_n coefficients defines the $r(\eta)$ function in Eq. 52 so $\gamma(\eta)$ can be calculated from Eq. 49 and then $l(\eta)$ can be calculated from Eqs. 50 and 51. The latter functions define the lens upper surface.

As mentioned, the above formulation is integrated with a GA loop to test different shapes of the bottom lens surface $r(\eta)$, with the goal to maximize the η_{max} angle of the lens, subject to the following constraints:

(a) $r(\eta)$ must be large enough to ensure that the edges of the feed never touch the bottom lens surface when the lens is tilted.
(b) The bottom lens surface cannot cross the upper surface except at the edge of the lens.
(c) Ray incidence angle at the upper lens interface must be below 95 % of the critical angle α_c.

This latter constraint minimizes the excitation of a lateral wave (Pasqualini and Maci 2004) along the lens upper surface. This can happen when ray's incidence angle α, measured with respect to lens local normal $\hat{\mathbf{n}}$, approaches the total reflection condition:

$$\alpha_c = asin\left(\frac{1}{n}\right) \tag{53}$$

DOI 10.1007/978-981-4560-75-7_40-1

As previously referred, the surface wave tends to deflect part of the lens radiation away from the main beam direction reducing the directivity.

Lens Analysis Methods

Geometrical Optics/Physical Optics (GO/PO) Analysis Method

The hybrid GO/PO method is certainly the most used approach for lens (reflector and other open structures) analysis. It takes as input the lens shape and material permittivity, the feed position, and the far-field pattern radiated by the feed when immersed in an unbounded media that has the same permittivity as the lens. The GO/PO procedure involves two steps, as implied by the acronym.

In the first step, GO formulation, as explained in section "Geometrical Optics for Lens Design," is used to compute the field distribution at the inner face of the lens interface; Fresnel coefficients are then used to compute the fields at the outer face of the lens. When one or more dielectric interfaces are crossed by the ray tubes originated at the feed phase center, appropriate Fresnel coefficients and divergence factors must be used.

From the field distribution obtained in the first step, equivalent currents are calculated over the outer face of the lens, and these are Kirchhoff-Huygens (KH) integrated over the lens aperture S to provide the lens far-field radiation pattern:

$$\mathbf{E}(P) = \frac{je^{-jkR}}{2\lambda r}\int_S [Z(\hat{\mathbf{n}} \times \mathbf{H}(P')) \times \mathbf{R}_1 + (\hat{\mathbf{n}} \times \mathbf{E}(P'))] \times \mathbf{R}_1 e^{jk\boldsymbol{\rho}\cdot\mathbf{R}_1} dS \qquad (54)$$

$\mathbf{E}(P')$ and $\mathbf{H}(P')$ represent the field produced by the feed over the lens outer surface, calculated in the first step. $\mathbf{R}_1$ is a unit vector directed from the origin toward the observation point P, $\boldsymbol{\rho}$ is a vector directed from the origin toward the integration point P' on the lens surface, and $\hat{\mathbf{n}}$ is the outward normal to the lens surface. This second step is referred in the literature as the physical optics (PO) integration (Fig. 24).

The GO/PO approach provides very good results for most large aperture antenna problems, provided that the accuracy of the aperture field description is also good. While in the GO direct synthesis approach discussed in the previous section it is enough to consider only the forward propagating rays to define the aperture fields (as already discussed), in the analysis process all the multiple reflected and transmitted rays must be properly accounted. Ling et al. (1989) propose a general procedure for tracing the rays in complex arbitrarily shaped structures in the context of radar cross-section problems, which is referred as the shoot and bounce ray (SBR) method. The SBR method was used for computation of the internally reflected rays in an integrated elliptical lens (Neto et al. 1998) or in an off-axis feed extended hemispherical lens (Pavacic et al. 2006).

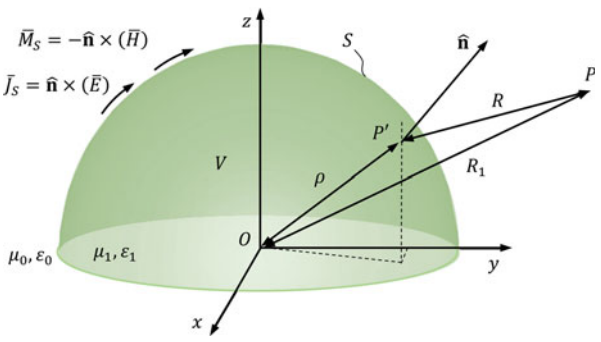

Fig. 24 Geometry for the PO aperture integration

DOI 10.1007/978-981-4560-75-7_40-1

The computation time for the GO/PO method becomes really insignificant when structures are axial-symmetric. Even if the source fields are not axial-symmetric, an appropriate decomposition of those source fields in terms of a series of azimuthal harmonics may transform the nonsymmetrical problem into a superposition of solutions for axial-symmetrical problems.

Memory requirements for the GO part of the procedure are reasonably modest, especially for circular-symmetric structures. A similar comment is valid in general also for the PO part of the procedure, having in mind that in some approaches the far-field pattern can be calculated as the superposition of the sequentially calculated closed-form KH integrations of all exit ray tube fields.

Physical Optics/Physical Optics (PO/PO) Analysis Method

This is again a two-step analysis method, like the previously studied GO/PO, but now the calculation of the aperture fields in the first step is based on the PO formulation. This allows circumventing two GO limitations:

- GO cannot be used in the first step for small lenses, where the feed can no longer be accurately represented by a point and by its far-field radiation pattern.
- GO fails to predict the fields near the caustics. This aspect becomes critical when caustics approach the edge of the lens affecting the correct evaluation of edge diffraction effects or when the caustics approach the feed region, thus affecting significantly the feed impedance (Neto et al. 1998).

With the a priori knowledge of the source currents, a free-space dyadic Green's function can be used to calculate the fields in an unbounded media with the same permittivity as the lens. The fields are calculated at a fictitious surface S with the shape of the lens to represent the incident field ($\mathbf{E}_{inc}$, $\mathbf{H}_{inc}$) at a lens dielectric-air interface. Fresnel coefficients are used to calculate the reflected and transmitted fields at the interface, and equivalent electric and magnetic surface currents are then calculated on both sides of the interface. PO integration of the equivalent currents at the inner face of the lens allows calculating the reflected fields everywhere inside the lens. The far-field radiation pattern of the lens is determined from PO integration of the equivalent surface currents defined outside the interface from the fields obtained in the previous steps (Fig. 25).

The asymptotic expressions that are commonly used for the PO evaluation of the far field cannot be used in general for the evaluation of the interior fields, since the observation point may lie close to the aperture. The use of the general PO formulation valid for near field is a little more cumbersome and more

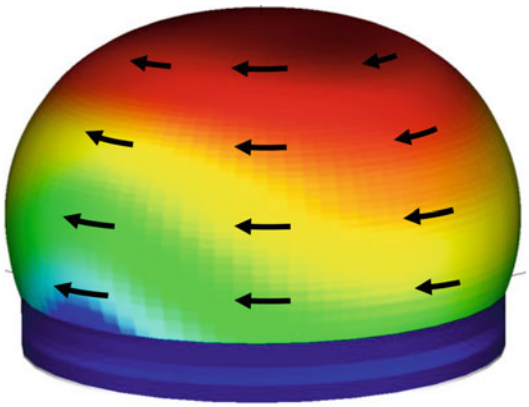

Fig. 25 Equivalent currents on the lens surface

DOI 10.1007/978-981-4560-75-7_40-1

CPU time-consuming. This point aggravates for more complex structures like multiple-shell lenses where more than one PO integration would have to be performed for complete evaluation of the internal fields.

This is clearly a less flexible method and more CPU-intensive than GO/PO. The insertion into an optimization loop is similar to what was discussed before for the GO/PO method, but each iteration takes longer.

Spectral Domain Methods (SDMs)

Spectral domain methods (SDMs) are a possible alternative to GO/PO for the analysis of integrated lens antenna. They are particularly interesting for small lens with only a few wavelengths in size where the classic geometrical optics approach fails.

In SDMs, the lens far field is determined from the decomposition of the feed aperture fields at the lens base into given basis functions. These functions can be, for example, plane waves or Gaussian beams (Maciel and Felsen 1989). The main advantage of Gaussian beams is that they are both spatially and spectrally limited. The estimation of the near field at the lens base requires the use of another method, like the method of moments. The Gaussian decomposition presents several beam parameters that can set the beam width, tilt, and spatial and spectral separation between basis functions.

In Hailu et al. (2009, 2011), a spectral domain decomposition combined with ray tracing is used to analyze an extended hemispherical lens. Results are compared against a full-wave commercial software tool and measurements.

Spherical Wave Modal Method

The spherical wave modal method is based on the discretization of the electromagnetic field in a set of base functions, which are solutions of the wave equation in spherical coordinates. An example of this approach is found, for instance, in Sanford (1994) and Fuchs et al. (2008b) for the analysis of a spherical homogenous or stratified Luneburg lens.

For each layer of the lens, the interior and exterior fields are discretized in spherical modes. A mode-matching technique is used to obtain the expansion coefficients. A priori, the only known coefficients are those of the incident wave at the exterior layer of the lens. All the other coefficients have to be determined from imposing the boundary conditions at the layer interfaces. The application of the boundary conditions creates a series of linear equations that once solved provide the coefficients of all the fields in each region.

To apply the modal method to an integrated lens antenna, the first step is to decompose the radiated field from the planar feed. First, the feed is replaced by its planar representation in terms of equivalent electric and magnetic surface currents. Then that plane is meshed, and each segment is considered as an independent elementary radiator with a known discretization in spherical modes. Therefore, an initial knowledge of the feed's current is needed. Since the modal method is a full-wave method, it implicitly takes into account the internal reflections at the lens interfaces.

The spherical wave mode approach is especially adequate for perfect spherical shapes. For arbitrarily shaped lenses, the boundary conditions of the fields are much more difficult to express in the spherical coordinate system. It is also expected that the convergence of the series becomes unacceptably slow especially when the feed off-axis distance increases.

Method of Moments (MoM)

One of the most popular methods for the full-wave analysis of arbitrary electromagnetic structures is the method of moments (MoM) (Peterson et al. 1998). This method is intended for the evaluation of electric and magnetic field integral equations (EFIE and MFIE, respectively) that describe the EM problems. Those equations may be written in the form $Lf = g$, where L is the integral operator, f the unknown, and g the excitation. An approximate solution may be obtained by MoM in the form:

DOI 10.1007/978-981-4560-75-7_40-1

$$f \cong \sum_{n=1}^{N} \alpha_n B_n \tag{55}$$

where functions B_n are known basis functions defined on the domain of L and the scalars α_n are unknown coefficients to be determined. Equation 55 is then substituted into $Lf = g$, and a system of linear equations is obtained by forcing the residual

$$L\left(\sum_{n=1}^{N} \alpha_n B_n\right) - g = \sum_{n=1}^{N} \alpha_n L B_n - g \tag{56}$$

to be orthogonal to a set of test functions $\{T_1, T_2, \ldots, T_N\}$. The result will be the matrix equation $L\alpha = \beta$ with the entries

$$l_{mn} = \langle T_m, LB_n \rangle \tag{57}$$

and

$$\beta_m = \langle T_m, g \rangle \tag{58}$$

where $\langle , \rangle$ represents the inner product operator. The unknown coefficients can be determined by inverting the matrix (Peterson et al. 1998).

The size of this matrix may become prohibitive for large electromagnetic objects. As previously referred, lenses are usually large in terms of wavelength, so there is not much work reported in the literature about MoM analysis of dielectric lenses.

Finite-Difference Time-Domain (FDTD)

The FDTD technique utilizes a second-order central-difference scheme to approximate Maxwell's curl equations on a representative grid of discrete time and space. The electric and magnetic fields' components are successively updated by repeated implementation of the finite-difference equivalents of the curl equations until the desired transient or steady-state response is achieved. This process is known as leapfrog time marching. Because the solution in the FDTD method is built up through time, it alleviates the need to form a large system of equations and thereby turns an otherwise intractable problem into one of patience.

As with MoM, the use of traditional 3D FDTD as an iterative analysis algorithm is restricted to lenses with dimensions similar to the wavelength. In fact, the number of variables of the algorithm increases cubically with the radius of the lens leading to impractical computation times for most common optimization problems. However, for structures with axial symmetry, it is possible to reduce the 3D problem to a simpler 2D one and implement a faster algorithm called body of revolution (BOR)-FDTD. BOR-FDTD can be used even if the symmetric lens is fed by an asymmetric source (Van Der Vorst and De Maagt 2002). In that case, the feed's current or its radiated field may be discretized into a Fourier expansion. Each element of the expansion is separately analyzed by the BOR-FDTD algorithm, and the final result is obtained by the vector sum of all the partial BOR-FDTD analysis.

BOR-FDTD can be implemented for small lenses where, for instance, the GO/PO method cannot be used. In fact, the smaller the lens, the faster the BOR-FDTD will converge for the solution since the number of space grid elements reduces with the size of the lens. BOR-FDTD can easily handle internal

DOI 10.1007/978-981-4560-75-7_40-1

reflections since it is a full-wave method and can also be implemented for multiple-layer or varying dielectric constant lenses.

Lens Materials

There are a few aspects to be taken into consideration when selecting dielectric materials for lens fabrication. Usually the materials are selected based upon their dielectric constant or relative permittivity, and the usual values range from 1.2 to 11. A second important parameter is the dielectric loss tangent (tan δ) which measures the material dissipation loss. The lower the loss tangent value, the lower the material losses per wavelength. Acceptable values of the loss tangent depend upon the application; nevertheless, in most cases, a value lower than 10^{-3} is usually considered adequate. It is also important to know if the dielectric materials are isotropic and homogenous. There are also mechanical considerations like material hardness, fracture toughness, or melting temperature which may be relevant for the selection of the lens fabrication technology and thermal expansion coefficients which may be relevant for multi-shell lenses.

The electromagnetic properties of dielectric materials at millimeter wave may vary between manufacturers and even between material batches. For demanding specifications, it is advisable to accurately measure the dielectric properties of a sample of the material that will be used for the lens fabrication. Evaluation of the complex permittivity of dielectric materials usually involves vector network analyzer measurement of the frequency response of a test millimeter-wave circuit (it can be a resonator or not) when loaded with a dielectric sample and when empty (Chen et al. 2005). Two classical methods are described next: the waveguide method and the open Fabry-Perot resonator method.

Parallelepiped samples of the dielectric material are required for the waveguide method, precisely cut with the same length of the short-circuited waveguide sample holder and filling completely its cross section (Chen et al. 2005). These waveguide sections operate in single-mode TE_{10} conditions. The complex permittivity of the material is deembedded from the measured s_{11} frequency response at the open port of the sample holder, both filled with the dielectric sample and when empty (Silveirinha et al. 2014). Two sample holders with different lengths may be used for redundant permittivity determination and detection of eventual measurement uncertainties (Fig. 26).

One advantage of this method is that it is quite precise, provided that the air gap between the dielectric sample and the involved five walls of the waveguide sample holder is negligible. Another advantage is that it requires very small samples of the material (typically $3.9 \times 1.9 \times 5.0$ mm^3 in the V-band) which enables to detect material inhomogeneity or anisotropy by cutting samples from different parts and different orientations of the bulk material. Besides, it can be shown that some fortuitous measurement errors or the appearance of higher-order modes can be easily perceived during the measurements, indicated by abnormal irregularities in the measured s_{11} frequency response

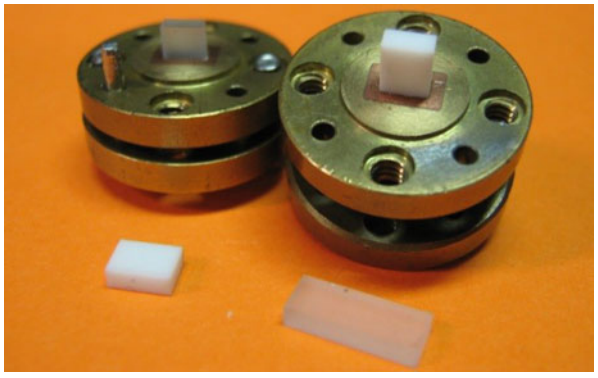

Fig. 26 Example of waveguide short-circuited sample holder for V-band and a few dielectric samples

DOI 10.1007/978-981-4560-75-7_40-1

(Silveirinha et al. 2014). Another interesting point with this method is that it allows measuring loss tangents in the range up to 10^{-2}.

The method presents however limitations for high dielectric constant values (typically larger than 6), associated with the excitation of higher-order modes in the dielectric-filled sample holder. This introduces significant error in the complex permittivity evaluation, especially in the loss factor.

The Fabry-Perot resonator method does not present the previous limitation for high permittivity samples. Its theory and operation principles are very well known (Afsar et al. 1990; Komiyama et al. 1991; Hirvonen et al. 1996). There are different possible configurations for the resonator. The plane-concave configuration is commonly used since it involves only one spherical mirror and allows precise positioning of the dielectric samples at the Gaussian beam waist without the need for perturbing holders. The material samples are typically cut as disks with a diameter typically three times larger than the Gaussian beam waist and thickness of the order of half the wavelength in the material under test (Hirvonen et al. 1996).

In the example shown in Fig. 27 for the V-band (Fernandes and Costa 2009), the spherical mirror is made of aluminum, with 160.3-mm curvature radius and 240-mm projected diameter. A linear translation is allowed for the planar mirror, and a 10-μm precision gauge is associated with this translation. When the central distance between mirrors is around 157.3 mm, this enables a good compromise at 63 GHz between a narrow beam waist of the fundamental Gaussian mode at the planar mirror ($w_0 = 5.7$ mm) and the Gaussian beam width at the spherical mirror ($w_z = 42.9$ mm). This choice makes it possible to measure material samples with diameters as small as 20 mm. Increasing the distance between mirrors reduces w_0 but increases w_z with consequent risk of spillover at the edges of the spherical mirror and consequent reduction of the cavity quality factor.

Measurements can be performed using the fixed mirror distance approach. A vector network analyzer sweeps the frequency within the V-band and acquires the s_{12} transfer function between the two waveguide ports connected to the back of the spherical mirror. In a first run, the resonator is measured without any sample. Then a second measurement is performed with a dielectric disk sample placed at the center of the plane mirror. The dielectric constant of the sample is determined from the frequency shift in the resonator modes, and the loss tangent is obtained from the resonance bandwidth of a given mode (Komiyama et al. 1991).

This method also allows evaluating the anisotropy of the material by performing successive measurements where the sample is rotated in relation to the spherical mirror axis of symmetry. In fact, since the cavity is operated with linearly polarized modes, the s_{12} transfer functions depend on the material

Lens Fabrication

Several techniques exist to manufacture a dielectric lens antenna. The most common approaches use either computer numerical control (CNC) milling machine, molding, or 3D additive manufacturing.

CNC enables to produce physical objects from its digitized 3D description, by automatically excavating the object shape out from a block of raw material (Fig. 28). This type of fabrication process is especially appropriate for antennas with complex shapes, tight dimensional tolerances, and good surface finish as happens, for instance, with shaped lens antennas at millimeter waves. It is more indicated for small series production or for lab prototyping as opposed, for instance, to the injection molding process, which is cost-effective for mass production. CNC milling may, however, be used for mold production for the latter technology.

There are no special limitations on the materials that can be used for CNC milling, except that they must be machineable. Some examples of commercially available machineable dielectrics are listed in Table 3. The cutting tool and its rotation speed, cutting speed, feed rate, and cutting depth must be appropriate for

DOI 10.1007/978-981-4560-75-7_40-1

Fig. 29 Lens fabrication by molding technique

the selected material. The specific values for these cutting parameters can be found in manufacturers' material data sheets. Depending on the dielectric material and CNC milling machine characteristics, 50-μm fabrication accuracies can be achieved. For some types of materials, it is possible to fabricate the lens using a molding technique (Fig. 29). In this case, a mold with the shape of the lens has to be manufactured where the dielectric, in liquid phase, is poured or injected into. Usually, the assembly must be left for a few hours before the mold can be removed. Depending on the material, the lens dimensions may change marginally after material curing; this has to be considered when designing the mold. Molding is generally considered a cost-effective technique for mass production, but it is of limited advantage for lens lab prototyping due to the mold manufacturing cost. Furthermore, it is not easy to avoid trapped gas bubbles or to control the homogeneity of the mixture as it becomes solid without an appropriate facility.

In the case of multilayer lenses, particular attention has to be given to the matching and alignment of the layers produced by milling or molding technologies. Air gaps between the layers should be avoided when assembling the lens. The presence of air gaps as small as 0.03 wavelengths in multilayer lenses can reduce the antenna gain and increase side lobe level of the radiation pattern. This effect is more intense with the increase of the number of layers (Kim and Rahmat-Samii 1998) or with higher-permittivity materials (Nguyen et al. 2010). A glue can be used to mitigate the effect of the air gaps as long as it has approximately the same dielectric constant of one of the adjacent layers.

3D printing is becoming an attractive technique to fabricate elaborate dielectric prototypes at relatively low cost. As with CNC, it starts with a 3D digitized model of the object, but the rendering is based on an additive process where successive layers of a material are laid down dot by dot to construct the desired shape. Various materials can be considered, but thermoplastic-based 3D printers are the most popular. Although the commonly used materials tend to have moderately high losses and the fabrication tolerance of low-end printers is presently of the order of 200 μm, the viability of a 3D-printed lens antenna made of ABS ($\tan \delta = 0.008$) for short-range indoor wireless link at 60 GHz has been recently demonstrated (Bisognin et al. 2014). A similar technique can be used to manufacture lenses using higher-permittivity lower-loss materials like alumina (Ngoc Tinh et al. 2010).

Lens Feeds

The main requirements for a lens feed are a reasonably uniform radiation pattern within the lens aperture subtended angle, minimum energy spillover at the lens edges, and a well-defined phase center coincident with the lens focal point. The most common families of lens feeds are either patches, slots, or horns/waveguides. Patches and slots have the advantage of low profile and in some cases can be made conformal with the lens surface. However, they tend to have a broad radiation pattern which may lead to excessive spillover losses particularly in off-body fed lenses. Patches and slots are thus more appropriate for integrated lens feeding. Waveguides, although bulky, may present some advantages for lab testing of

DOI 10.1007/978-981-4560-75-7_40-1

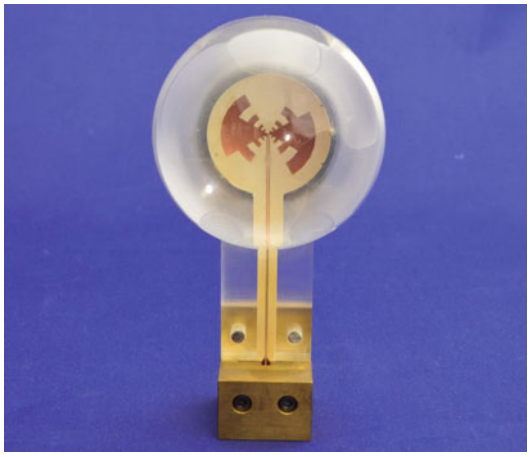

Fig. 30 Integrated lens antenna fed by a planar self-complementary log-periodic feed

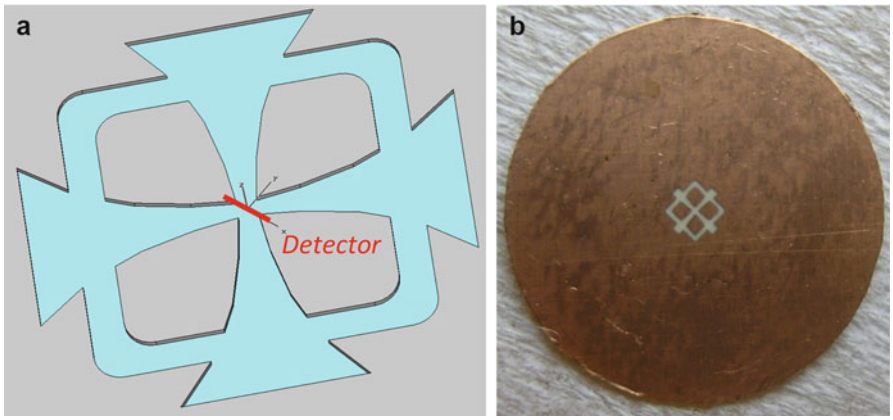

Fig. 31 (**a**) Configuration of a crossed exponentially tapered slot (XETS) antenna; (**b**) prototype of the XETS for operation from 40 to 75 GHz

integrated lens prototypes as they allow reusing the same feed in several lens prototypes while ensuring measurement repeatability. Horns tend to have a much more directive beam than all the previous types of feeds and are more common as off-body lens feeds.

The earlier works on integrated lens antennas at submillimeter waves used a double-slot antenna as the lens feed (Filipovic et al. 1993, 1997). This type of feed is particularly indicated for integration, for instance, with bolometers, in applications where the lens is used only as an amplitude receptor like in radio astronomy. However, the double-slot antenna is narrowband and therefore limits the inherent wideband nature of the lens. Wideband feeds like the sinuous antenna (Edwards et al. 2012) and log-spiral or log-periodic antennas (Semenov et al. 2007) have been used for radio astronomy lens applications (Fig. 30).

One problem with the previous wideband feeds is that the polarization is not stable with frequency. An alternative wideband planar feed that solves that problem is the crossed exponentially tapered slot (XETS) antenna (Costa and Fernandes 2007a). It presents a frequency-stable linearly polarized radiation pattern versus frequency with stable phase center position at the center of the antenna. The operation bandwidth is 1:3 (or 100 %). The antenna geometry is presented in Fig. 31: it is formed by a single metal layer with two crossed exponentially tapered slots, intersected by a square (or star)-like slot. The antenna is fed between two opposite petals, as shown in Fig. 31a, which define the antenna E-plane. The antenna perfect

DOI 10.1007/978-981-4560-75-7_40-1

symmetry with respect to the feed point ensures perfect symmetry of the antenna currents with respect to the E-plane and perfect anti-symmetry with respect to the H-plane, irrespective to frequency. Consequently, pure linear polarization is obtained versus frequency at least in the main planes.

A slot feed with an extremely wide band of more than 1:10 has been presented in Neto (2010) and Neto et al. (2010). It is composed by a long leaky slot line fed at the middle by an orthogonal microstrip line printed in the other face of the substrate. An air gap smaller than 1/16 of the wavelength is placed between the slot and the base of the lens in order to improve the feed radiation performance. This concept has recently been extended to a square array of leaky slots (Yurduseven et al. 2014).

All of the above single-layer antennas present a bidirectional radiation pattern due to the absence of a ground plane. This is attractive for THz applications to ease the feed fabrication. However, when attached to the base of a dielectric lens, most of the feed radiation is pulled into the lens body. In fact, the fraction of power that is coupled to the lens increases with the permittivity as $\varepsilon_r^{3/2}$ (Rutledge et al. 1983). Thus, the lens material permittivity tends to be high to operate with these uniplanar feeds. Higher reflection is thus expected at the air/dielectric interface, but it can be overcome with the matching layer approach or with the double-shell lens configurations discussed in section "Integrated Lens Design Examples."

Classical patch antennas are also used as integrated feeds. For example, an integrated lens with an array of aperture-coupled rectangular patches is fed by a microstrip feeding network at 28 GHz (Nguyen et al. 2011) or at 60 GHz (Artemenko et al. 2013a, b).

An open-end waveguide aperture is sometimes preferable for integrated lens antenna feeding, as it is easier to couple the full power to the lens without the need to increase the lens permittivity as it happens with uniplanar printed antennas. However, the standard waveguide open end has to be modified to avoid excessive return loss and asymmetrical radiation pattern between E- and H-planes. The inclusion of an edge-tapered dielectric filling with the same permittivity of the lens material can mitigate the return loss problem (Ngoc Tinh et al. 2010); however, it may originate higher-order modes that affect the lens performance. To avoid this difficulty, the cross-section dimensions of the dielectric-filled waveguide must be conveniently tapered to enable single-mode operation (Fernandes 2002; Fernandes et al. 2011). When appropriately designed, the waveguide open end itself is enough to reproduce the radiation pattern inside the lens body comparable to that of a printed or slot broadband antenna. Although the operation band of the waveguide feed may not be wide enough, the broadband characteristic of the lens can still be tested using separate waveguide feeds, each one designed for partial bands. Figure 32 presents an example of the layout and photograph of two similar waveguide feeds for Q- and V-band (Fernandes et al. 2011). Due to the outer thread, these feeds can be easily attached or removed from the lens and reused in other lenses ensuring repeatable measurements.

For off-body fed lenses, it is common to use horn feeds. The requirements and the used configurations are exactly the same as for reflectors, so ample literature exists (Olver et al. 1994). In order to avoid excessive spillover losses, usually it is required that the illumination at the edge of the lens is 10 dB below the power level at the center of the lens.

Lens Measurements

Most of the lens antenna measurement techniques are no different from those used for reflector antennas or for any other large aperture antennas. So the most common measurement procedures are not repeated here. This section addresses only two specific issues which are relevant for integrated lens antenna measurements.

Feed Radiation Pattern in Unbounded Dielectric Media

Integrated lens antenna design requires the knowledge of the actual radiation pattern of the feed when it is embedded in the lens material. This is of course different from the radiation pattern of the same feed in air.

DOI 10.1007/978-981-4560-75-7_40-1

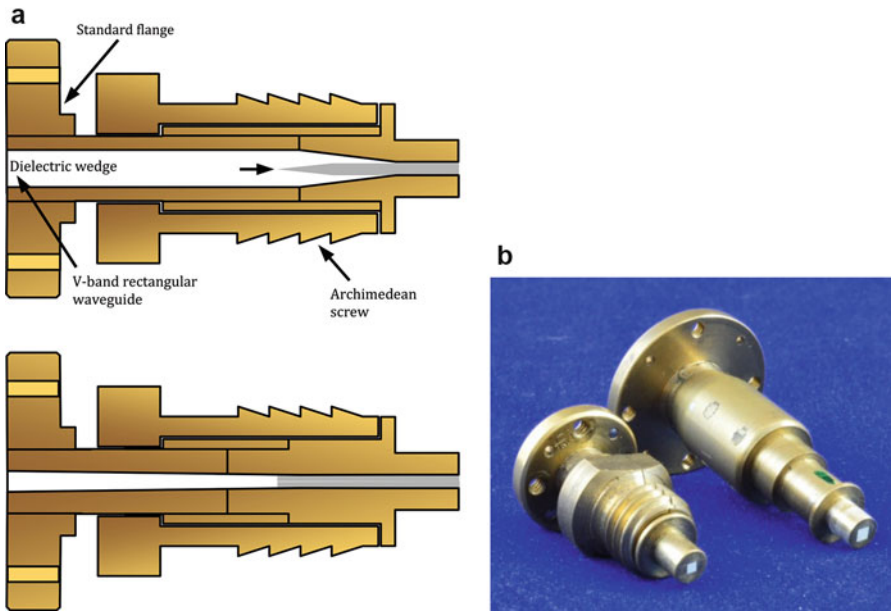

Fig. 32 (**a**) Schematic view of the feed prototype (not to scale). *Above*, longitudinal cut in the H-plane; *below*, E-plane; (**b**) photograph of the fabricated feeds. *Left*, for V-band operation; *right*, for Q-band operation

Although the feed radiation pattern in unbounded dielectric medium can be obtained from some full-wave EM solvers, the direct measurement is not possible.

One practical solution that provides a reasonably good approximation is to use a spherical lens of the same dielectric material and measure at its surface the tangential fields produced by the centered embedded feed. The lens radius must be large enough to ensure the predominance of the transverse field components of the feed radiation at the lens surface. Noting that the tangential components are continuous across the dielectric-air interface and that there is no refraction in this configuration, the measured tangential fields can be considered a fair estimation of the feed radiation pattern inside the dielectric. Internal reflections may generate some ripple but generally do not preclude the procedure.

Figure 33 shows the application of the method for the waveguide feed presented in the previous section. The feed is embedded in a MACOR hemispherical lens, and the near-field scanning probe is also a waveguide open end (Fig. 33a). The near-field measured result is presented in Fig. 33b, superimposed on the simulated far field of the feed in the dielectric, computed with WIPL-D EM solver (Kolundzija and Djordjevic 2002). The agreement is quite acceptable.

Phase Center Evaluation

Phase center knowledge is required when integrated lenses are used, for instance, as primary feeds in focusing systems. Unlike horns, where the phase center position is normally located close to the aperture plane, the phase center of integrated lenses is very dependent upon the lens shape and may even be far out from the lens body. It is a simple matter to determine it when the radiation pattern phase $\phi(\theta, \varphi)$ can be measured. Considering the geometry of Fig. 34a, it can be shown that the distance d between the phase center and the rotation axis in a constant ϕ-plane cut is given by

$$d = -\frac{\lambda}{2\pi} \frac{\partial \phi}{\partial(\cos(\theta))} \tag{59}$$

DOI 10.1007/978-981-4560-75-7_40-1

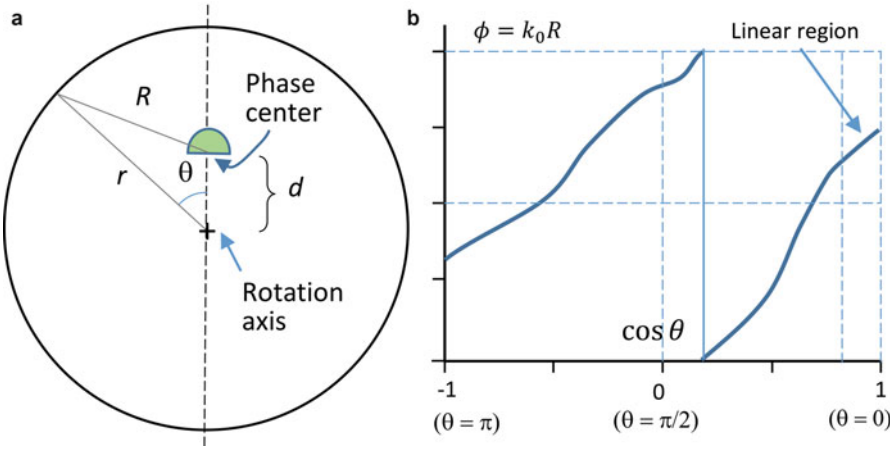

Fig. 34 (**a**) Geometry for phase center determination; (**b**) representation of the radiation patter phase ϕ versus cos θ

DOI 10.1007/978-981-4560-75-7_40-1

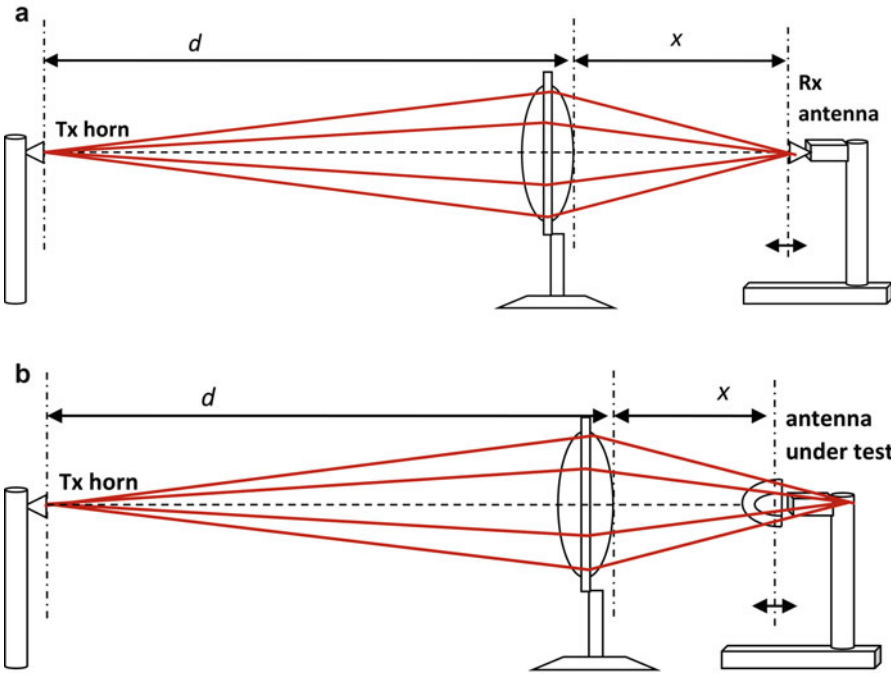

Fig. 35 Schematic setup for phase center determination based on power measurements: (**a**) reference measurement; (**b**) antenna under test measurement

assuming that $d \ll r$. So, when the phase center exists, d is proportional to the slope of the linear variation of ϕ versus cos (θ). This allows calculating d using just a single radiation pattern measurement.

However, when bolometers or other detectors are used as integrated lens feeds (Filipovic et al. 1993), only amplitude radiation patterns can be measured, preventing the application of the previous phase center determination method. The obvious alternative is to place the lens in the focal plane of a simple focusing system. An auxiliary convergent lens (ACL) can be interposed at a fixed position between the transmitting antenna and the lens under test (LUT), while the latter is translated along the link axis until the received power is maximized. That would correspond to coincident ACL and LUT phase centers. An additional reference measurement is required with the lens replaced by an antenna with known phase center to determine the absolute phase center of the LUT (Costa et al. 2010; Fig. 35).

The advantage of using a lens (instead of a reflector) is that it does not need to be very large. An example is presented below where the ACL lens diameter is only three times larger than the LUT diameter, so the procedure is very convenient for small anechoic chambers. If such a small reflector was used instead, the LUT would interpose between the Tx horn and the reflector producing severe aperture blockage and consequent perturbation of the measurement.

Figure 36 shows an example of the setup where the ALC, made of Teflon ($\varepsilon_r = 1.96$ at 62.5 GHz), has a 300-mm diameter and its focal points are located 350 mm to the Rx side and d = 4.550 mm on the Tx side. The LUT is a double-shell lens fed by a waveguide (Fernandes et al. 2010) to allow verification of the amplitude-based method against the phase-based method. The reference antenna is a waveguide probe with the phase center practically coincident with its open-end aperture. The difference between values from phase measurements and power measurements is of the order of 2 mm at 62.5 GHz which is much smaller than the depth of field of practical focusing systems at this frequency.

Applications

Overview of Applications

This section focuses on the recent trends of dielectric lens applications, mostly involving the integrated lens configuration for microwave and millimeter-wave applications where the lens size and weight are reduced. Some of the examples listed below and associated lenses are detailed in the subsequent sections.

The most common function of an integrated lens is to focus the radiation of the feed and increase the overall gain while keeping with a lower profile than what can be achieved with a reflector. This is particularly important in applications at millimeter waves like high bit rate communications at 60 GHz (Bisognin et al. 2014) or automotive anti-collusion radar at 77 GHz (Ka Fai et al. 2014). Alternatively, the integrated lens can be used to shape the radiation pattern of the feed into a desired pattern. For example, for 60-GHz indoor wireless networks, it is required to have base stations with adequately shaped radiation patterns like flat-top (Ngoc Tinh et al. 2011; Rolland et al. 2011) or secant-squared (Fernandes and Anunciada 2001; Bares and Sauleau 2007).

Lenses are inherently wideband so they are interesting feed candidates for some reflector focusing systems in radio telescope applications, where a wideband frequency-stable radiation pattern and phase center position are required for reflector illumination. Integrated lenses have been proposed for stable

DOI 10.1007/978-981-4560-75-7_40-1

performance with either multilayer (Fernandes et al. 2010) or dome (Ngoc Tinh et al. 2013) configurations. In both cases, noncanonical lens shapes were obtained after proper design and/or optimization.

Lenses can be used in imaging applications, where the image of the target is focused through the lens into an array of sensors (or detectors) at the other side of the lens (Filipovic et al. 1997). The spacing between sensors should satisfy the Nyquist sampling criterion (typically two detectors per wavelength) in order to recover the original target image. Security screening and medical imaging are examples of applications using lens antennas. For example, in Trichopoulos et al. (2010, 2013), a hemispherical lens is used with 31 by 31 detectors at its base to detect the object image. Alternatively it is possible to use an array of closely spaced lenses with one detector per lens (Llombart et al. 2013; Naruse et al. 2013). However, in this case, the Nyquist criterion is not fulfilled. There are also some applications requiring multi-beam antennas but with a lower density of detectors like for a lens with an electrically reconfigurable beam shape (Nguyen et al. 2011) or some degree of electrically controlled discrete beam steering (Costa et al. 2008a; Artemenko et al. 2013a, b).

Communications between a movable vehicle and high-altitude platform or satellites require a ground terminal antenna with a beam-steerable capability. Some of the few examples in the literature that use lenses for satellite-on-the-move (SOTM) applications adopt Luneburg-based configurations with mechanical beam-steering capability. For example, companies like Lun'tech in France are selling commercial solutions. Alternatively, integrated lens antennas can also be used for mechanical beam steering in SOTM applications (Costa et al. 2008b). In those configurations, the inner shell of the lens is air, allowing the lens to move freely above the fixed feed to steer the direction of the main beam.

Lens Application Examples

Constant Flux and Flat-Top Lenses for Millimeter-Wave WLAN

Pioneering work on millimeter-wave cellular mobile communications started in the early 1990s (Fernandes 1995) at that time aiming at 150 Mbit/s per channel. Oxygen attenuation is extremely high in this band (15 dB/km), free-space attenuation is also very high, and the same happens with obstacle attenuation. Altogether, these factors intrinsically confine radio coverage to very small cells, so unlicensed spectrum is available for emerging broadband applications.

The 60-GHz band is recently being explored for short-range multi-gigabit wireless local area networks. In indoor scenarios (Fig. 37a), the difference in free-space attenuation for different locations in the same room may represent a high dynamic range which can be compensated with an appropriately shaped antenna radiation pattern. A shaped dielectric lens antenna can be used at the base station (BST) hanging from the ceiling that produces a secant-squared ($\sec^2\theta$) type of radiation pattern in the elevation plane in order to compensate for the free-space attenuation at each direction. The target radiation pattern can be expressed as

$$G(\theta) = \begin{cases} G(\theta_{\max}) \frac{\sec(\theta)}{\sec(\theta_{\max})} & \theta \le \theta_{\max} \\ 0 & \theta > \theta_{\max} \end{cases} \tag{60}$$

The maximum elevation angle $\theta_{\max}$ is selected according to the desired cell radius. A sharp fall of the radiation can be imposed for $\theta > \theta_{\max}$ to conserve power and to prevent excessive reflections from the walls. An estimation of $G(\theta_{\max})$ can be obtained from Fig. 37b which presents the directivity of an ideal radiation $\sec^2$ pattern versus the maximum illumination angle $\theta_{\max}$ (Fernandes 1999).

The BST antenna must be paired with a flat-top radiation pattern antenna at the mobile terminal (MT) so that the average received power remains reasonably constant for all positions of the mobile or portable terminal within the cell. Many antenna technologies can be used to obtain such type of radiation pattern.

DOI 10.1007/978-981-4560-75-7_40-1

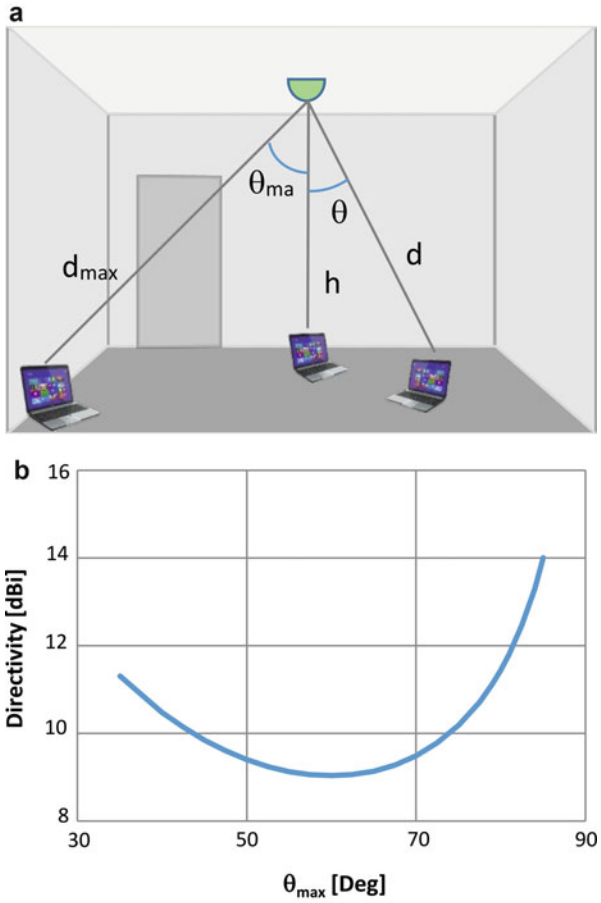

Fig. 37 (**a**) Millimeter-wave wireless LAN scenario; (**b**) directivity of an ideal $\sec^2$ elevation radiation pattern with azimuth symmetry versus θ_{max}

Here a shaped lens is demonstrated, due to its possibility to reduce sharply the radiation beyond θ_{max} and thus reduce multipath pickup. Although the radiation patterns of the BST and MT lens antennas are circular symmetric in the present example, a square coverage footprint could also be obtained for the BST with a 3D-shaped lens, if required (Fernandes and Anunciada 2001).

The design of these axial-symmetric amplitude shaping lenses followed the GO formulation presented in section "Lens Designed to Match an Output Power Template." Plexiglas material ($\varepsilon_r = 2.53$, $\tan\delta = 0.012$) was used for both lenses, although other lower-loss commercially available materials like polystyrene ($\varepsilon_r = 2.53$, $\tan\delta = 10^{-4}$) might also be possible. Both lenses were fed by the aperture of circular metallic waveguides embedded in the lens body, carrying a circular polarized TE_{11} mode. The lens radiation pattern dropout was fixed at $\theta_{max} = 75°$ for both lenses. This corresponds roughly to 11-mm cell radius for h = 3 m BST antenna height with respect to MT.

Figure 38a shows the fabricated prototype of the BST $\sec^2$ lens, with 66-mm radius. Its measured radiation pattern at 62.5 GHz is presented in Fig. 38b. The nadir (the floor in this case) corresponds to $\theta = 0$, and $\theta_{max} = 75°$ corresponds to the maximum gain direction.

The fabricated flat-top lens is shown in Fig. 39. In this case, the lens radius is 35 mm, considerably smaller then for the $\sec^2$ lens where the sharp features of the target pattern were more pronounced. The MT elevation pattern is presented in Fig. 40b, showing a good coincidence with the desired flat-top characteristic. The zenith (ceiling in this case) corresponds to $\theta = 0$. This flat-top characteristic and the pattern circular symmetry favor free movement of the MT within the cell limits and even some tilting.

DOI 10.1007/978-981-4560-75-7_40-1

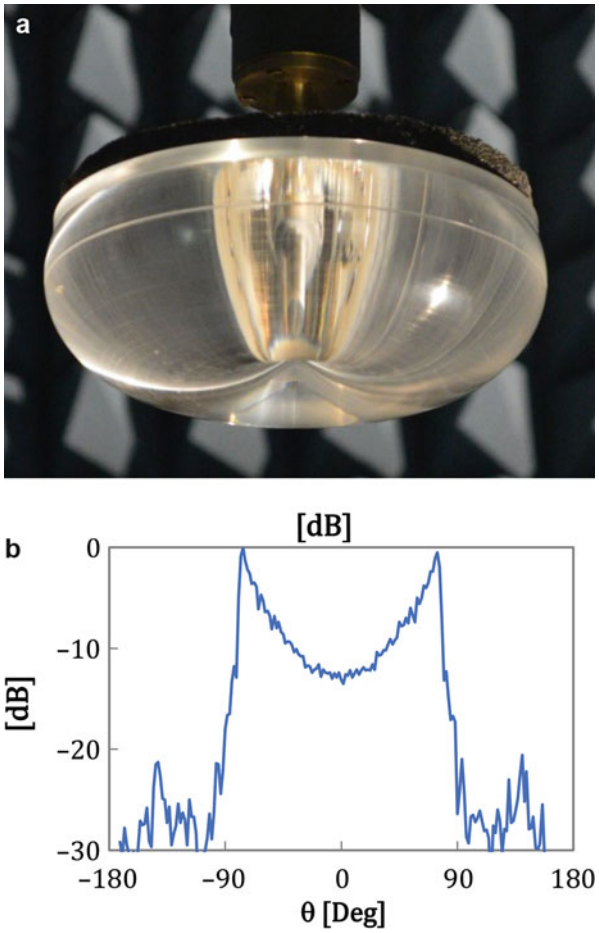

Fig. 38 (**a**) Prototype of the $\sec^2$ lens; (**b**) measured circular polarization radiation patterns at 62.5 GHz

Considering that the link budget is affected by the product of the two antenna gain functions, this lens combination further provides very sharp cell boundaries at θ_{max}, with negligible radiation outside the cell limits. A remarkable characteristic of $\sec^2$ patterns is that cell dimensions are scaled to the antenna height. This provides a simple means to control the illumination of the walls at the cell edges and maintaining an adequate compromise between multipath effects and the need for alternative paths in case of line of sight (LOS) blockage.

Broadband Lens for Constant Illumination of a Reflector

The most common reflector feeds are based on horn antennas. Despite many variants that horns may have, they all share the same feature of aperture antennas, which is a radiation pattern that increases its directivity with the frequency. When large bandwidths are involved, this may represent an important reduction of the reflector aperture illumination efficiency. This problem is often circumvented by splitting the wide band into multiple sub-bands, each with its own feed horn; but then a complex setup is required to minimize aberrations due to off-axis positioning of the multiple horns.

A challenging specification for a reflector feed is the ability to maintain a constant radiation pattern beam width with stable phase center over a 1:3 bandwidth. A double-shell shaped dielectric lens can be designed to meet such specification using the formulation from section "Frequency-Stable Radiation Pattern and Phase Center Position" (Fernandes et al. 2010). The lens is intended to feed a 90° offset

DOI 10.1007/978-981-4560-75-7_40-1

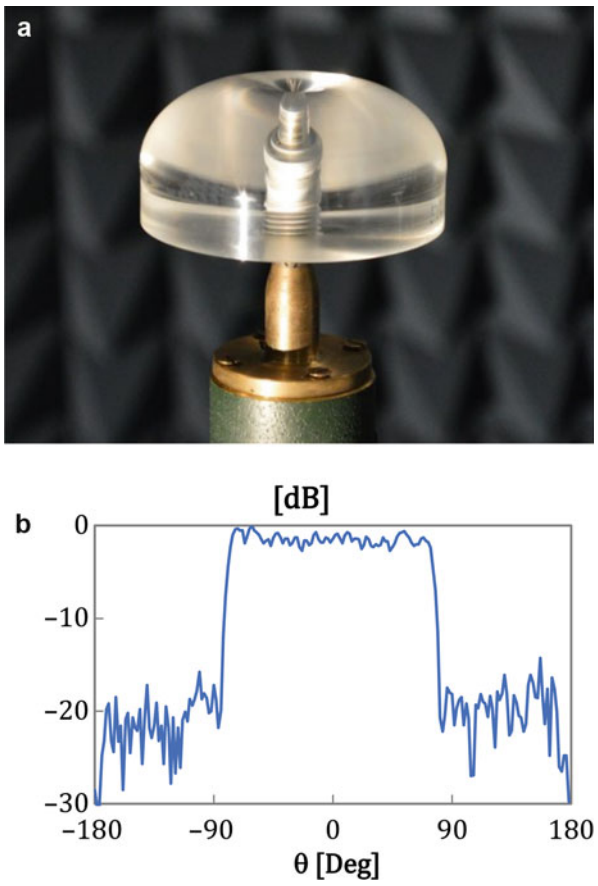

Fig. 39 (**a**) Prototype of the flat-top lens; (**b**) measured circular polarization radiation patterns at 62.5 GHz

reflector. The lens output beam produces a virtual focus located far below the lens and close to the corresponding reflector focal point (Fig. 40a).

A 20 λ diameter lens prototype was designed and fabricated using MACOR and acrylic (Fig. 40b). The optical transparency of the acrylic reveals the inner shell, which appears distorted due to refraction effects. The lens is fed by the waveguide device described in section "Lens Feeds" (Fig. 32). The measured lens radiation patterns are shown in Fig. 41a for two distinct frequencies in the Q- and V-band (40 GHz and 62.5 GHz). The measured lens radiation pattern agrees very well with the Gaussian template with $\alpha_0 = 23^\circ$ Gaussian width (dashed curve). It is possible to see that the shape and beam width of the lens radiation pattern are identical in both bands as desired. The same behavior was demonstrated by full-wave simulation between 30 and 90 GHz (Fernandes et al. 2010). The lens output beam Gaussicity is better than 94 % over the band. The measured phase center position of the lens agrees with the value imposed during the design ($z_0 = 68.7$ mm), and it is identical in both frequencies. Full-wave simulations confirm phase center stability over the 1:3 bandwidth.

The performance of the lens-reflector assembly was simulated using the ILASH software (Lima et al. 2008). Figure 41b shows that the aperture efficiency is practically constant versus frequency as required, and, in agreement with that property, the reflector directivity in dB increases almost linearly with logarithm of the frequency.

Multi-beam Lens

Two examples of compact integrated lens antennas are presented here for multi-beam applications operating over a 40 % bandwidth from 40 to 60 GHz. The first example is intended to demonstrate the

DOI 10.1007/978-981-4560-75-7_40-1

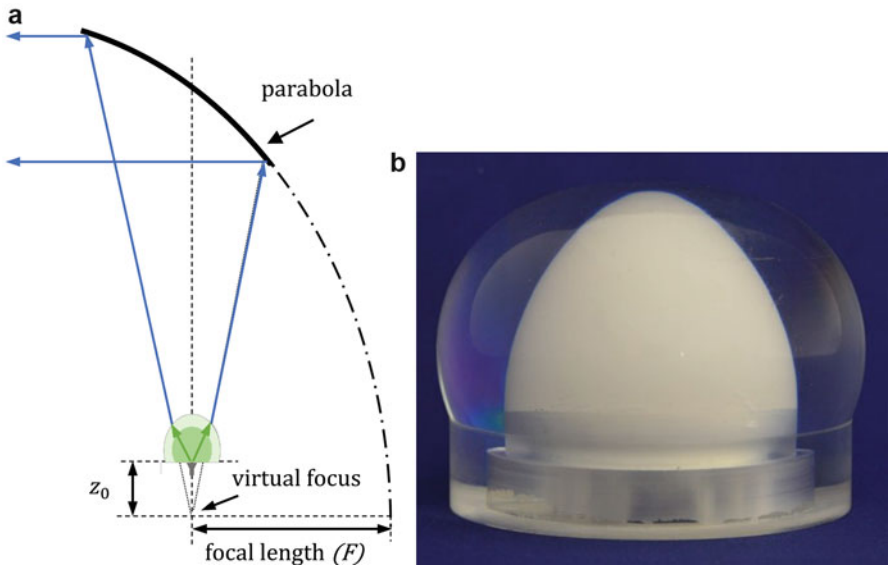

Fig. 40 (**a**) Problem geometry; (**b**) fabricated lens prototype with a MACOR^{TM} inner shell and an acrylic outer shell

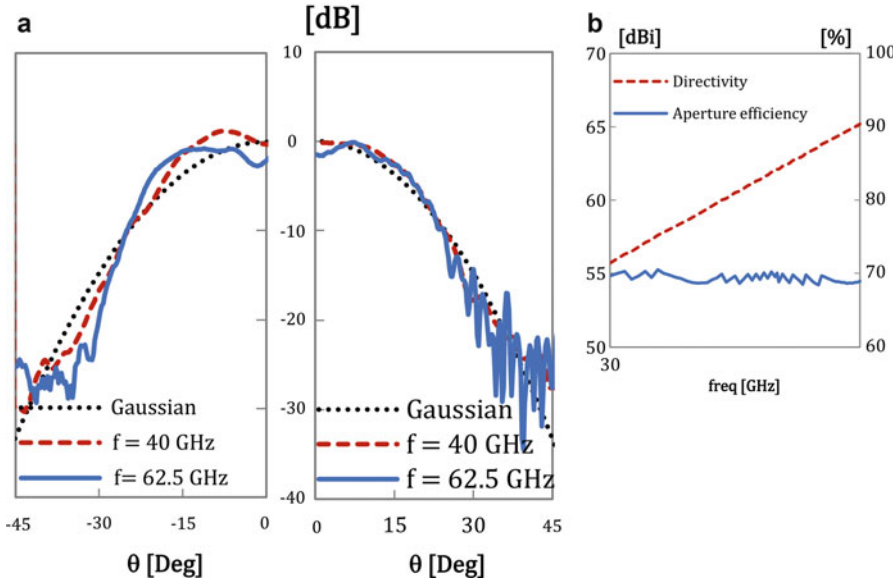

Fig. 41 (**a**) Measured radiation patterns of the lens at 40 and 62.5 GHz; (**b**) calculated directivity and aperture efficiency of the reflector with frequency plotted on log scale

potential of a double-shell lens to produce 11 beams within ±20° scan intervals with 6° beam width at 60 GHz, gain scan loss lower than 1 dB, and better than 95 % Gaussissity throughout the 40 % bandwidth. In this example, the lens is fed by a waveguide. The main purpose of the second example is to demonstrate the viability of the broadband XETS antenna introduced in section "Lens Feeds" as an effective uniplanar linear polarization lens feed for multi-beam applications. Its configuration allows very tight antenna packing at the lens base for proper adjacent beam overlap. The tight packing does not preclude the integration of each XETS element with its Schottky diode for operation as a mixer. A canonical integrated lens is used for this feed demonstration.

DOI 10.1007/978-981-4560-75-7_40-1

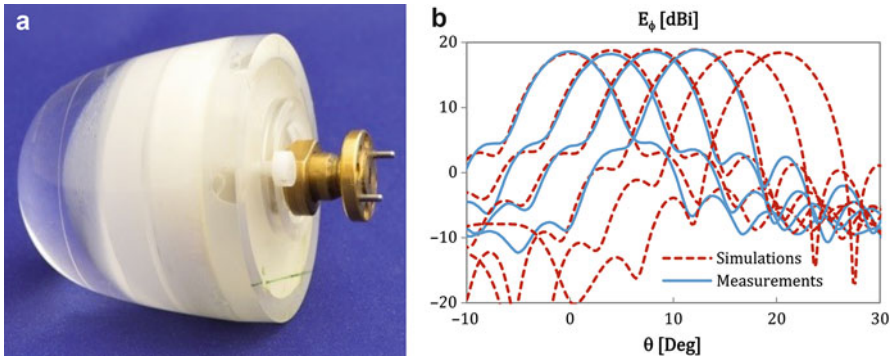

Fig. 42 (**a**) Fabricated MACOR™/acrylic lens prototype, showing the attached 60-GHz band waveguide feed; (**b**) simulated and measured gain radiation patterns at 62.5 GHz, in the H-plane, with feed at 0, 1.1, 2.2, 3.3, 4.4, and 5.5 mm from the lens axis

The scarce integrated lens configurations reported in the literature for scanning or multi-beam applications are based only on extended hemispherical or elliptical lens configurations (Filipovic et al. 1997; Wu et al. 2001). In these canonical structures, the lens shape is fixed, and so the available degree of freedom for design is just the feed distance to the lens radiating surface which does not allow enforcing any condition to reduce the aperture phase errors for off-axis feed positions. A double-shell configuration was adopted in this example to allow imposing the Abbe sine condition. The selected lens materials were the MACOR^{TM}/acrylic combination (permittivity 5.5/2.53), and the selected feed was the waveguide device described in section "Lens Feeds" for 40-GHz and 62.5-GHz operation; see Fig. 32.

Figure 42a shows the fabricated lens antenna prototype (Costa et al. 2008a) which was designed using the GO formulation from section "Multi-beam Lens" implemented in the ILASH software (Lima et al. 2008). The lens dimensions are 60 mm in diameter at the base and 37 mm in height. Figure 42b shows the measured and simulated radiation patterns for different feed positions at 1.1-mm steps along the lens base in the H-plane. This produces overlapping of consecutive beams near −1.5-dB level with respect to maximum. Beam overlap at −3 dB occurs for wider separation between consecutive feeds, compatible with the used feed aperture size (not shown). The figure shows excellent agreement between ILASH predictions and measurements and confirms the effectiveness of the proposed double-shell lens concept regarding beam scan linearity, internal reflections, beam shape, and Gaussissity preservation with extremely low scan loss up to 20° elevation. The achieved gain was of the order of 18–19 dBi and the scan loss better than 1 dB for 43–62 GHz. As a consequence of the GO-based lens design, the scan angle dependence on the feed off-axis position was practically independent of frequency, and the beam Gaussissity was better than 95 %.

The following example is intended to demonstrate the viability of the wideband XETS printed antenna with simple integral mixer described in section "Lens Feeds" as an integrated multi-beam lens feed and to show the effectiveness of the IF signal retrieval setup. Despite the tightly packed assembly of the XETS elements at the lens base, the proposed feed still offers good isolation between adjacent elements both at RF and IF, providing very stable radiation pattern and linear polarization over the bandwidth.

The above objectives can be demonstrated using a canonical single-material lens, the conclusions remaining valid for more sophisticated lens designs. A 68-mm diameter MACOR elliptical lens was used in this case (Costa and Fernandes 2007b) (Fig. 43a). The lens was designed to scan the angular interval from 0 to ±18° with beam overlap approximately at −3 dB for 43 GHz and at −4.5 dB for 62.5 GHz. The overlap level at the higher frequencies could have been improved with other lens designs, but this type of optimization exceeded the established objective for this example.

DOI 10.1007/978-981-4560-75-7_40-1

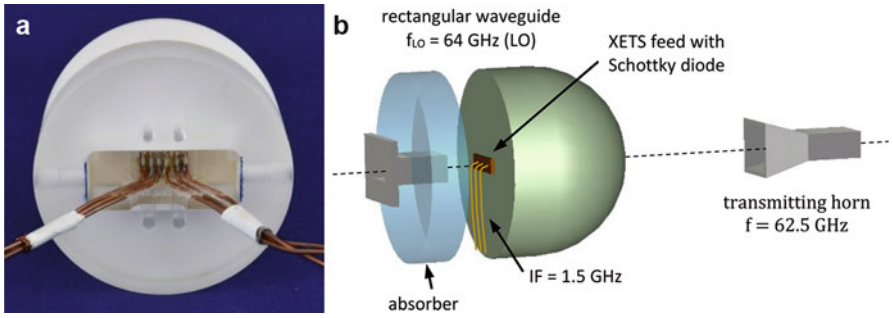

Fig. 43 (**a**) *Bottom* view of a MACOR elliptical lens fed by a multi-XETS assembly with an integrated mixer; (**b**) radiation pattern measurement setup at 62.5 GHz, using an integrated mixer at the base of the lens

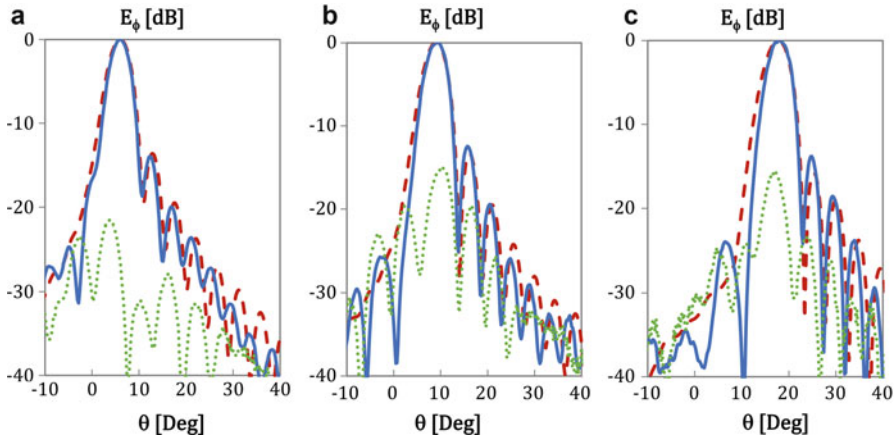

Fig. 44 Comparison between simulated and measurements radiation pattern at 62.5 GHz in the H-plane (*red dashed line*, simulations Co-pol; *blue line*, measurements Co-pol; and *green dotted line*, measurements X-pol) for a feed displacement of: (**a**) x = 2 mm; (**b**) x = 3 mm; (**c**) x = 6 mm

The radiation pattern measurement configuration is shown in Fig. 43b. The Schottky diode integrated into the XETS receives both the 62.5-GHz far-field Tx signal (through the lens) and the 64-GHz LO signal (through the air from the back), producing the desired 1.5-GHz IF signal. The LO assembly is fixed with respect to the lens, so that the LO signal amplitude illuminating the XETS does not change with lens rotation, whereas the IF signal amplitude changes only in response to lens radiation pattern at the TX frequency.

Examples of the H-plane measured and simulated radiation patterns are depicted in Fig. 44 at 62.5 GHz for three XETS elements (#2, #3, and #6). The curves are normalized to the respective maximum. The main lobe shape is quite stable, with the correct beam inclination despite the very close position of the XETS elements. Cross-polar level is below −15 dB, which is much better than what can be obtained, for instance, with the self-complementary log-periodic feed. This validates the expected feed performance.

Mechanical Beam-Steering Lenses

Mechanical beam-steering antennas tend to be superseded by electronic beam-steering antennas because the latter usually offer more compact and flexible solutions. But at millimeter waves, this trend is not so clear as losses and cost of phased arrays increase considerably. The main drawbacks of the mechanical beam-steering solutions are the mechanical complexity and the expensive millimeter-wave rotary joint.

DOI 10.1007/978-981-4560-75-7_40-1

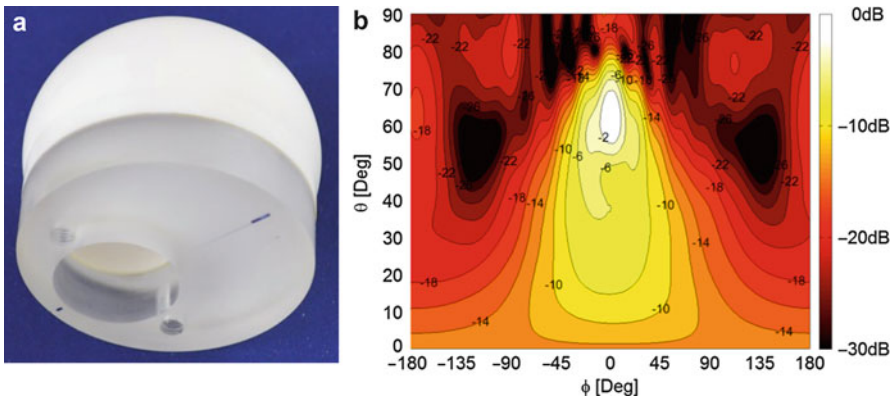

Fig. 45 (**a**) MACOR^{TM} axial-symmetric 50-mm diameter shaped lens; (**b**) radiation performance of the lens computed with the GO/PO method

A new approach for mechanical beam steering has been proposed in Costa et al. (2008b, 2009) where the feed remains stationary, while the beam tilt is obtained just by rotating or tilting an appropriately shaped dielectric lens that is held by a very simple mechanical structure in the near field of the fixed feed aperture.

One example of this configuration was intended for low Earth orbit satellite telemetry link at 26 GHz. The lens was required to produce a sector beam with shaping in elevation and to enable a simple mechanical azimuth scanning. The target gain versus elevation angle θ is given approximately by Sec(kθ). With an appropriate choice of the k shaping parameter, this elevation radiation pattern compensates path loss attenuation taking into account the Earth's curvature.

The designed shaped lens is axial-symmetric, but a spherical air cavity is excavated through its base at a calculated offset distance with respect to the lens symmetry axis (Fig. 45a). The feed aperture is at the center of this offset spherical air cavity. The asymmetry introduced by the feed position produces an adequate directive beam in the azimuth plane with Sec(kθ) shaping in elevation. This is an extremely simple solution where the feed is fixed and the lens rotates about the eccentric feed axis to provide the required beam scanning. This contactless feeding avoids the need for fault-prone rotary joints in long continuous usage. The assembly is very compact and lightweight (lens diameter is less than 5 wavelengths and height is less than 3 wavelengths) complying with mass and volume restrictions for satellites.

The same concept of a moving lens with fixed feed was extended for azimuth plus elevation mechanical scanning in a different application context (Costa et al. 2009). Wireless indoor transmission of uncompressed HD video signal between a video device like a camcorder and a HD TV display may soon become a requirement for mass-market home applications. Emerging standards are proposing to use the unlicensed spectrum from 57 to 66 GHz for such applications. For mass consumer applications, the radio link must use inexpensive low-power sources, and hence high-gain antennas (>20 dBi) are required to favor the link budget. The narrow beam needs to be steered to allow for the user mobility. Using the design formulation described in section "Beam-Steering Lens," a new configuration of a mechanical steerable beam antenna has been developed where a dielectric lens pivots in front of a single stationary moderate gain feed (Fig. 46a). Again, the feed is not in physical contact with the lens. As previously discussed, this eliminates the need for rotary joints and the associated drawbacks. The designed lens is made of polyethylene and is such that both the input and output lens surfaces are shaped to accommodate a beam collimation condition and a scan angle maximization condition. The lens output beam is aligned with the lens axis for all lens orientations within the operation cone. Thus, pivoting the lens around two of its main axis allows steering the beam in elevation and azimuth. The important difference with respect to conventional scanning lenses is that for all lens inclinations the focus is always exactly coincident with the

DOI 10.1007/978-981-4560-75-7_40-1

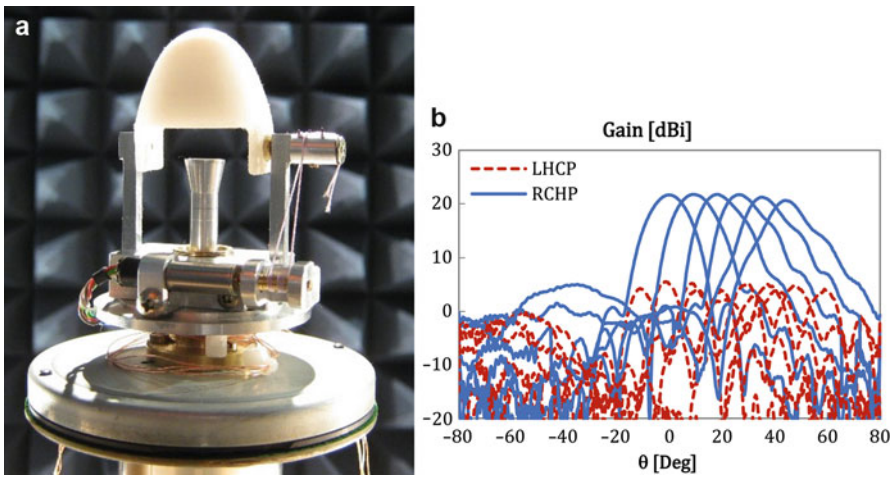

Fig. 46 (**a**) Photograph of the manufactured polyethylene lens plus horn feed; (**b**) measured radiation patterns of the lens antenna for several lens tilt angles

aperture phase center. In this way, aberrations are strongly reduced allowing wider scan angles than conventional solutions. The fabricated lens assembly demonstrated a −45° to +45° elevation scan capability over full azimuth, with 21-dB gain and better than +1.1-dB gain scan loss (Fig. 46b). The radiation efficiency is always above 95 %.

Conclusion

Rapid prototyping techniques and the trend to move into millimeter and submillimeter waves are bringing back the interest on dielectric lens antennas, namely, on integrated lens antenna configurations, taking advantage of the fast parallel advancements on low-cost fabrication of millimeter-wave integrated circuits. This integration prompts for mass-market applications at these bands.

It was shown in this chapter that dielectric lenses are very flexible to accommodate demanding specifications and lens design is reasonably simple. Although a fast progress is being made on low-profile planar antennas employing phase-shifting cells and metamaterials, dielectric lenses will remain a strong competitor at very small wavelengths owing to its effectiveness and simplicity for design and fabrication.

Self-Complimentary and Broadband Antennas

Kunio Sawaya*
Innovation Center for Creation of a Resilient Society, Tohoku University, Sendai, Miyagi Prefecture, Japan

Abstract

Frequency independent and broadband antennas are reviewed form the view points of the self-complementarity and self-similarity. The theory of self-complementary antenna, original and modified self-complementary antennas, and so-called log-periodic antennas are discussed. Then the frequency independent antennas based on the self-similarity and other broadband antennas are presented.

Introduction

Frequency independent antennas can be divided into two types of antennas: one is the self-complementary type and the other is the self-similar type antennas. Self-complementary antennas are based on the Mushiake relationship and have the constant input impedance with respect to frequency (Mushiake 1949). Since there is an infinite variety of self-complementary structures, many self-complementary and modified self-complementary antennas have been proposed. So called log-periodic antennas are considered to be derivatives of the self-complementary antennas. Some broadband antennas are based on both the self-complementarity and self-similarity such as the two-arm spiral antennas.

Self-similar object is defined by the fact that the structure is similar to a part of itself. Antennas having self-similar structures are called "self-similar antennas." If the linear dimensions of the self-similar antenna are reduced by a given factor, the electromagnetic properties remain the same, as long as the wavelength is reduced by the same ratio. Self-similar structures are divided into two types: one is the continuous structure composed of continuous shape, and the other is the log-periodic type or fractal structure composed of log-periodic elements. When the end effects of the self-similar antenna having continuous structure can be negligible, the electromagnetic properties are the same at all frequency, and the continuous self-similar antennas have the frequency-independent properties. On the other hand, the electromagnetic characteristics of the log-periodic or fractal self-similar antennas remain in the same, merely at the discrete points of the wavelength that have the same ratio with the self-similar ratio of the structure, and they cannot be the frequency-independent antennas.

In this chapter, the theory of self-complementary antenna, original and modified self-complementary antennas, and so-called log-periodic antennas are reviewed. Then frequency independent antennas based on the self-similarity and other broadband antennas are presented.

Self-Complementary Antenna

Theory of Self-Complementary Antenna

There is a duality property between electromagnetic fields ($\boldsymbol{E}_1$, $\boldsymbol{H}_1$) in structure #1 and ($\boldsymbol{E}_2$, $\boldsymbol{H}_2$) in structure #2 shown in Fig. 1, which is expressed by

$$\boldsymbol{E}_1 = Z_0^2 \boldsymbol{H}_2, \boldsymbol{H}_1 = -\boldsymbol{E}_2, \tag{1}$$

if all electric walls S, magnetic walls S_m, electric currents $\boldsymbol{J}_0 = \boldsymbol{N}$, and magnetic currents $\boldsymbol{J}_{0m} = \boldsymbol{M}$ in structure #1 are respectively interchanged for magnetic walls S_m, electric walls S, magnetic currents $\boldsymbol{J}_{0m} = \boldsymbol{N}$, and electric currents $\boldsymbol{J}_0 = -\boldsymbol{N}/Z_0^2$ in structure #2, where $Z_0 = \sqrt{\mu/\varepsilon}$ is the intrinsic impedance of the medium.

Let us consider a structure #1 composed symmetric sources of electric currents with a conducting plane S placed in xy plane shown in Fig. 2a and another structure #2 composed anti-symmetric sources of magnetic currents with a conducting plane $\overline{S}$ in xy plane shown in Fig. 2b. The surface $\overline{S}$ in Fig. 2a and the

surface S in Fig. 2b are considered to be magnetic walls because of the symmetric electric currents and anti-symmetric magnetic currents, respectively. By applying the duality property, the relation between the electromagnetic fields in Fig. 2a, b is expressed by

$$\boldsymbol{E}_1 = \pm Z_0^2 \boldsymbol{H}_2,\ \boldsymbol{H}_1 = \mp \boldsymbol{E}_2,\ z \gtrless 0. \tag{2}$$

This relation is called "Babinet's principle" to electromagnetic fields, which had been derived in Japan during mid-1940s.

Mushiake applied Babinet's principle in electromagnetic fields to the analysis of a slot antenna having arbitrary shape shown in Fig. 3a. Let the slot antenna having voltage V_1 and current I_1 at the driving point generate electromagnetic field $\boldsymbol{E}_1$ and $\boldsymbol{H}_1$ as shown in Fig. 3a, which is equivalent to a slot antenna fed by magnetic current shown in Fig. 3b. The complementary planar antenna with driving voltage V_2 and current I_2 generate electromagnetic field $\boldsymbol{E}_2$ and $\boldsymbol{H}_2$ as shown in Fig. 3c. The driving point voltages V_1 and V_2 are expressed in terms of the driving currents I_1 and I_2 as

$$\begin{aligned} V_1 &= -\int_a^b \boldsymbol{E}_1 \cdot d\boldsymbol{s} = \int_a^b \boldsymbol{H}_2 \cdot d\mathbf{s} = \frac{I_2}{2} \\ V_2 &= -\int_d^c \boldsymbol{E}_2 \cdot d\boldsymbol{s} = -Z_0^2 \int_d^c \boldsymbol{H}_1 \cdot d\boldsymbol{s} = \frac{Z_0^2 I_1}{2}, \end{aligned} \tag{3}$$

where

$$Z_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} \cong 120\pi \ \ [\Omega], \tag{4}$$

is the intrinsic impedance in vacuum space.

By using Eq. 3, the input impedance of the slot antenna Z_s shown in Fig. 3a can be obtained by the following equation (Mushiake 1949; Uda and Mushiake 1949)

DOI 10.1007/978-981-4560-75-7_41-1

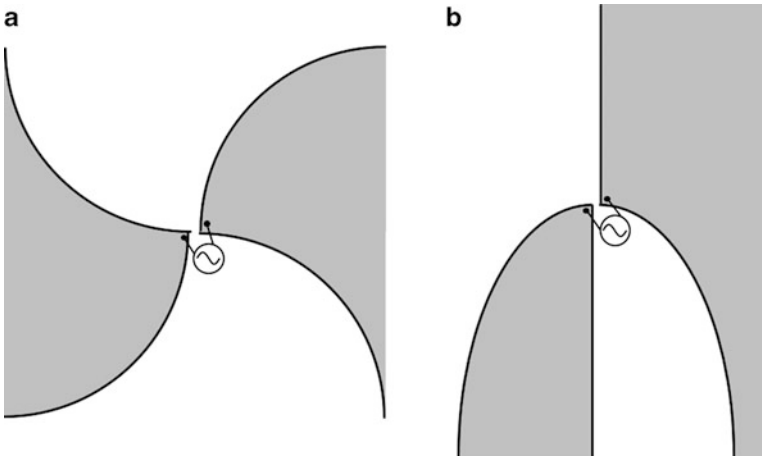

Fig. 4 Self-complementary antennas. (**a**) Balanced and rotationally symmetric type. (**b**) Unbalanced and axially symmetric type

$$Z_s = \frac{(Z_0/2)^2}{Z_d}, \tag{5}$$

where Z_d is the input impedance of complementary planar antenna shown in Fig. 3c.

Equation 5 had been already obtained in Japan to obtain the input impedance of slit antennas earlier than the paper of Booker (1946) as pointed out by Mushiake (2004), and the paper by Asami et al. (1947) was a more detailed report of the unpublished earlier paper. (The slot antenna was called the slit antennas in Japan at that time.) However, the structures reported in these papers had been restricted for the thin slot antennas and the thin wire antennas. On the other hand, Eq. 5 derived by Mushiake and Uda (Mushiake 1949; Uda and Mushiake 1949) does not have such limitation and can be applied for slot antennas and planar antennas with arbitrary shape.

Mushiake also originated the self-complementary structures and discovered that the input impedance of the antennas shown in Fig. 4 is constant independent of the frequency and given by

$$Z_{in} = \frac{Z_0}{2} \cong 60\pi \ \ [\Omega], \tag{6}$$

since arbitrarily shaped four lines for the boundary of two conducting sheets are exactly identical and the complementary structure in Fig. 4 is exactly the same to the original structure in Fig. 4 (Mushiake 1949; Uda and Mushiake 1949). Equation 6 is known as "Mushiake relationship" and this antenna is called "self-complementary antenna" (Rumsey 1957; 1966). The principle of the constant impedance of the self-complementary antennas is called the "principle of self-complementarity."

Modification of Self-Complementary Antennas

The self-complementary antennas are very interesting since there is an infinite variety of self-complementary structures as shown in Fig. 5. Although infinite structures are required for the constant impedance of the self-complementary antennas, the structures having teeth or notches and monopoles shown in Fig. 5a, b can realize the constant impedance with a finite conducting plane, because teeth or notches and monopoles radiate electromagnetic power and the truncation effect can be reduced for the finite structures. Archimedean spiral structure shown in Fig. 5c can also reduce the truncation effect because of the radiation from the spiral arms. Figure 5d is a self-complementary antenna called "alternate-

DOI 10.1007/978-981-4560-75-7_41-1

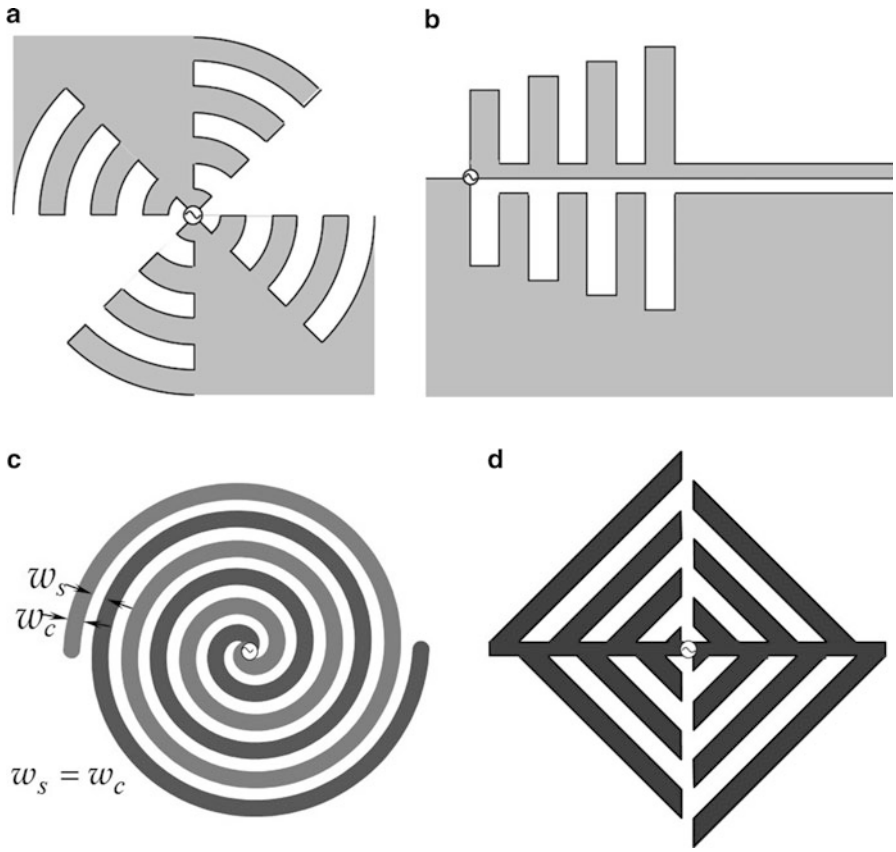

Fig. 5 Examples of self-complementary structures. (**a**) Balanced type with "teeth-type" structure. (**b**) Unbalanced type with notches and monopoles. (**c**) Archimedean-spiral structure. (**d**) Alternate-leaved structure

leaved structure" developed by Furuya et al. (1977). Since there is a lot of flexibility of the shape of the self-complementary antennas, it could be possible to obtain antennas having desired gain and/or desired radiation pattern maintaining the constant input impedance, e.g., an antenna having desired frequency dependence of gain.

Rumsey and DuHamel found the importance of the principle of self-complementarity (Rumsey 1957, 1966). DuHamel and Isbell (1957) proposed a self-complementary antenna with log-periodically spaced teeth as shown in Fig. 6 and showed that the input impedance is almost equal to 188 Ω under the condition that the operating frequency is higher than the frequency at which the length of the longest tooth is a quarter wavelength.

The most important structure for the broadband characteristics is the self-complementary structure. Nakano (2006) performed a numerical analysis of the toothed log-periodic antennas shown in Fig. 7 by using FDTD method. Figure 7a is a modified self-complementary antenna having trapezoidal log-periodic and point-symmetric structure. Figure 7b is another trapezoidal log-periodic and anti-complementary antenna having line-symmetric structure and is not a modified self-complementary antenna. Figure 8 shows the input-impedance of these antennas. In the case of modified self-complementary antenna shown in Fig. 7a, the input impedance is approximately $60\pi \approx 188\ \Omega$, although the structure is not an exact self-complementary structure. On the other hand, the input impedance of the anti-complementary antenna shown in Fig. 7b exhibits periodically oscillating behavior with respect to the logarithm of frequency and broadband characteristics are not obtained.

Deschamps (1959) proposed self-complementary multiterminal planar antennas having the input impedance depending on the structure. Mushiake and his colleagues also developed other types of self-

complementary antennas, such as rotationally symmetric four-terminal planar self-complementary antennas (Mushiake 1965), three-dimensional multi-planar self-complementary antennas, stacked self-complementary antennas, and monopole-slot antenna. Figure 5d is alternate-leaved self-complementary antenna (Furuya et al. 1977), which has not only the broadband input impedance but also frequency independent radiation pattern. Figure 9 shows the monopole-slot array antenna, whose input impedance was obtained theoretically as $Z_{in} = \sqrt{2}30\pi \cong 133\ \Omega$ by Ishizone et al. (1983). The details of these antennas are presented in the paper and book by Mushiake (1992, 1996). Also, the numerical investigation of the monopole-notch antennas shown in Fig. 5b was performed by Yamamoto et al. (1982) to obtain the relation between the structure parameters and the characteristics such as input impedance and the gain of the array.

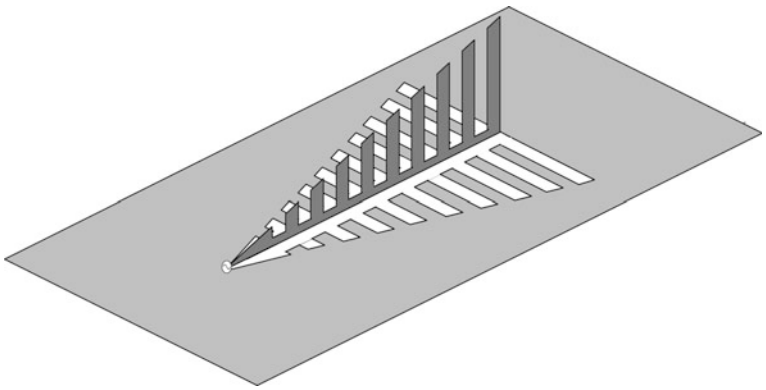

Fig. 9 Monopole-slot array antenna (Ishizone et al. 1983)

Modified Self-Complementary Antennas Having Log-Periodic Shape

The first structure of self-complementary antenna having log-periodic shape was the planar structure shown in Fig. 6. DuHamel and Ore (1958) deformed the self-complementary antenna and developed a planar antenna shown in Fig. 10, where the planar antenna is the original self-complementary antenna under the condition of $\alpha + \beta = \pi$. Since the planar structures radiate bidirectionally and unidirectional antenna was desired, they tried to deform the structure by folding the planar antenna and obtained a modified self-complementary type antenna called "log-periodic antenna" shown in Fig. 11. They also developed a log-periodic antenna composed of thin wires shown in Fig. 12, which is a wind-resistant structure.

The log-periodic antennas were further deformed to the log-periodic dipole array (LPDA) antenna by Isbell (1960) shown in Figs. 13 and 14, and design procedure of the LPDA was proposed by Carrel (1961), where theoretical investigation using sinusoidal current distribution on the dipole elements was performed. The parameters of the LPDA are the scale factor τ and space factor σ given by

DOI 10.1007/978-981-4560-75-7_41-1

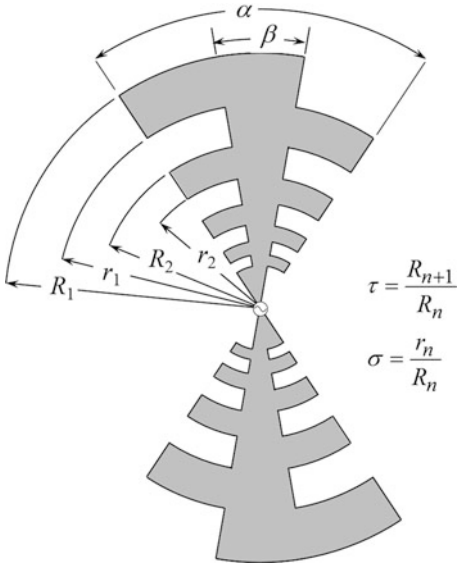

Fig. 10 Modified self-complementary antenna with log-periodic shape (DuHamel and Ore 1958)

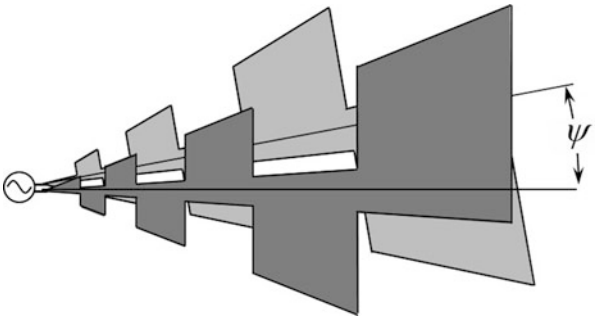

Fig. 11 Modified self-complementary antenna with log-periodic shape having directional radiation pattern (DuHamel and Ore 1958)

$$\tau = \frac{L_{n+1}}{L_n}$$
$$\sigma = \frac{d_n}{2L_n} = \frac{1-\tau}{4}\cot\alpha, \tag{7}$$

respectively. Carrel (1961) showed numerical results of the relation among the directivity, the scale factor τ and space factor σ as well as the consideration of the bandwidth and the input impedance. Peixeiro (1988) also showed the design method of the LPDA using numerical method and improved the Carrel's numerical results.

The LPDA has been widely used for extremely wide frequency operation in communications, TV reception and measurements, especially in the EMC measurements. Figure 15 shows the numerical and experimental input impedance of LPDA (Kim et al. 2001), where the numerical results were obtained by the method of moments using piece-wise sinusoidal basis and test functions (Richmond and Greary 1975; Tilston and Balmain 1990). As can be seen in Fig. 15, the input impedance of LPDA is approximately 50 Ω and the broadband characteristics of LPDA are demonstrated.

DOI 10.1007/978-981-4560-75-7_41-1

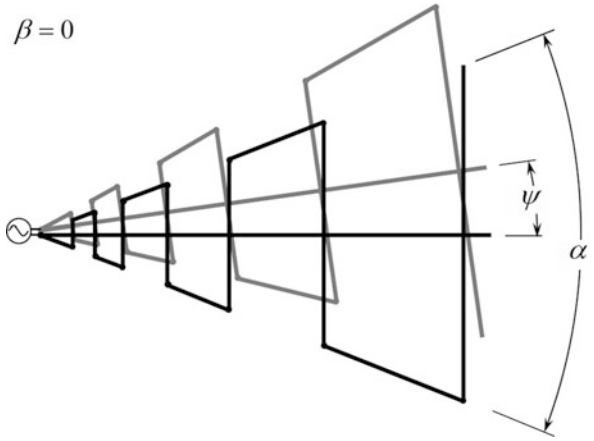

Fig. 12 Modified self-complementary antenna with log-periodic shape composed of thin wires (DuHamel and Ore 1958)

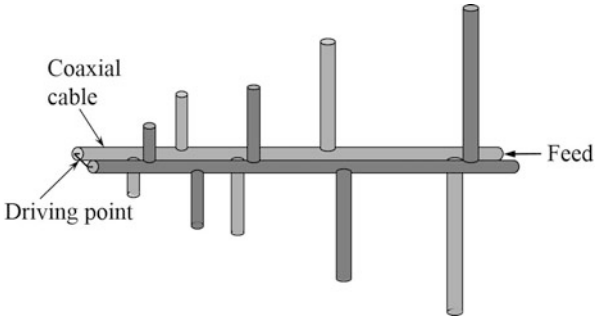

Fig. 13 Log-periodic dipole array (LPDA) (Isbell 1960)

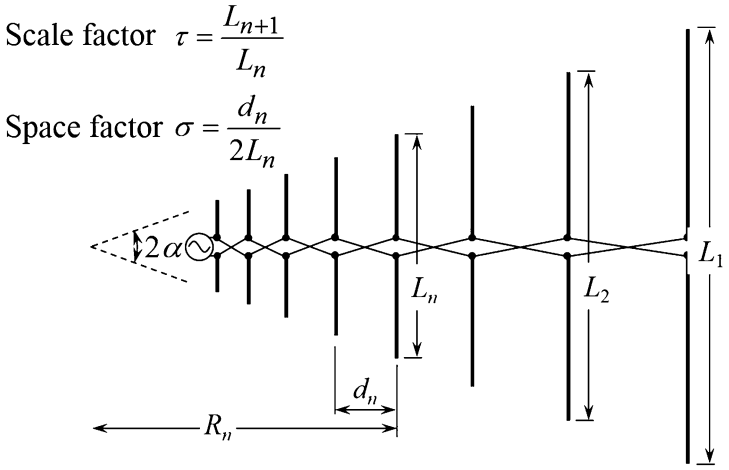

Fig. 14 Parameters of log-periodic dipole array (LPDA) (Isbell 1960)

As mentioned above, so-called log-periodic antennas were developed based on the principle of the self-complementarity. The broadband characteristics of the log-periodic antenna are obtained by the principle of self-complementarity rather than the log-periodic structure (Mushiake 1992, 1996). The most important structure in these broadband antennas is the transposed excitation shown in Fig. 14 (Mushiake 1999).

DOI 10.1007/978-981-4560-75-7_41-1

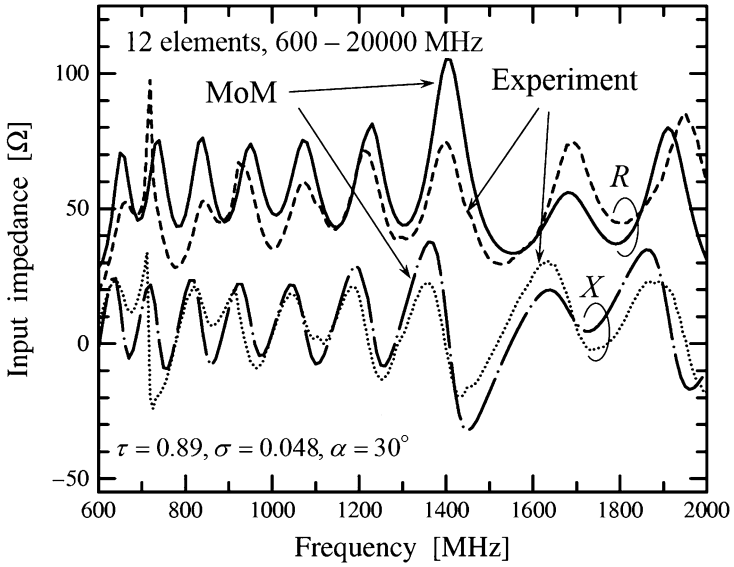

Fig. 15 Input impedance of log-periodic dipole array (LPDA). Comparison of numerical data by method of moments and experimental results (Kim et al. 2001)

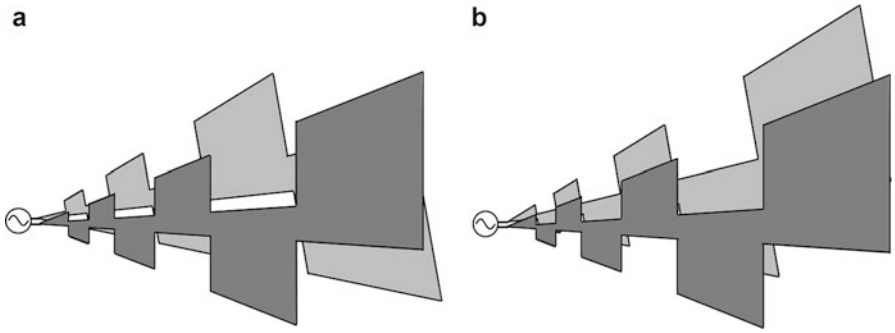

Fig. 16 Self-complementary type and anti-complementary log-periodic antennas (Folded trapezoidal shape) (Mushiake 1965)

Figure 17 shows a comparison of measured input resistance of self-complementary type log-periodic antenna shown in Fig. 16a and anti-complementary type log-periodic antenna shown in Fig. 16b (Mushiake 1965). In the case of anti-complementary type, frequency-independent characteristics are not obtained, whereas broadband property can be observed in the case of self-complementary type log-periodic antenna. Nakano (2006) also presented a numerical analysis of LPDA shown in Fig. 18, where Fig. 18a shows LPDA with transposed excitation and Fig. 18b is that with non-transposed excitation. The input impedance of the LPDA with transposed excitation shows almost constant impedance of about 100 Ω, but LPDA with non-transposed excitation shows strongly oscillatory curves as can be seen in Fig. 19. The broadband property of LPDA comes from transposed excitation of the folded up self-complementary antenna. The transposed excitation is inevitable outcome of the modification, and it is essential for the broadband LPDA. However, the log-periodic shape does not provide with broadband property to antennas (Log-periodic antenna "Any one of a class of antennas having a structural geometry such that its impedance and radiation characteristics repeat periodically as the logarithm of frequency." (IEEE Std 100-1992, Copyright © 1993, IEEE)). Therefore, LPDA is actually a modified self-complementary dipole array (MSCDA) with log-periodic shape (see Wikipedia "Self-complementary antenna" https://en.wikipedia.org/wiki/Self-complementary_antenna). Fractal antenna is another type of

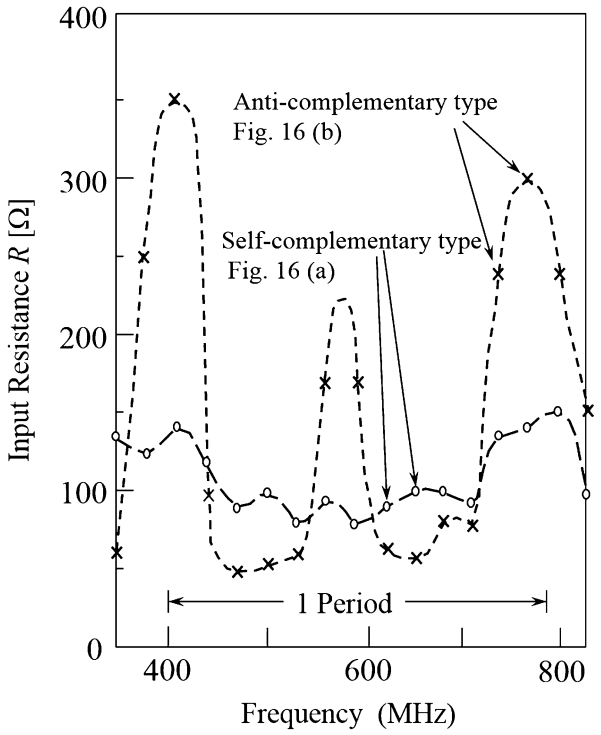

Fig. 17 Comparison of measured input resistance of log-periodic antennas (Mushiake 1965). (**a**) Transposed excitation. (**b**) Non-transposed excitation

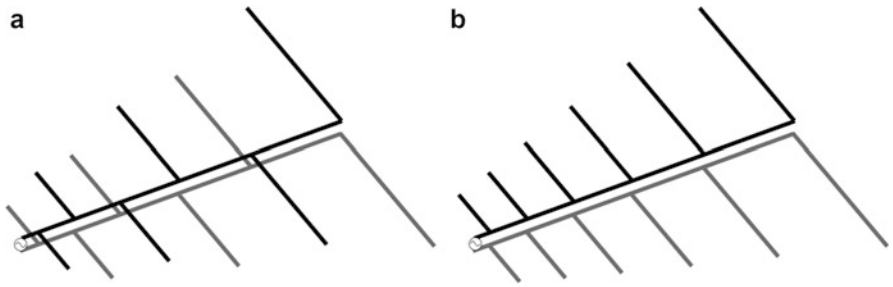

Fig. 18 Log-periodic dipole antennas. Comparison of transposed and non-transposed antennas (Nakano 2006)

log-periodic antenna but it has periodically oscillating characteristics with respect to the logarithm of frequency rather than the broadband properties (Puente et al. 1998).

Because of the broadband characteristics of the LPDA, several types of log-periodic antennas were proposed as described by Jordan et al. (1964). One of the log-periodic dipole array antennas is the log-periodic V array (LPVA) proposed by Mayes and Carrel (1960), where the V-shaped dipole array shown in Fig. 20 was employed and not only the λ/2-resonance of the V dipole elements but also the higher order resonance modes such as the 3λ/2-resonance and 5λ/2-resonance are utilized to maintain the unidirectional radiation pattern and increase the bandwidth. The characteristics of LPVA operating in the 3λ/2-resonance mode was analyzed numerically by Chan and Silvester (1975). LPVA is actually obtained by folding up of the square alternate-leaves type self-complementary antenna which has log-periodic shape in quite a large dimension with respect to the wavelength. Then, some tooth may be resonant at a frequency, by the basic property of the self-complementary antenna. The broadband property of LPVA

DOI 10.1007/978-981-4560-75-7_41-1

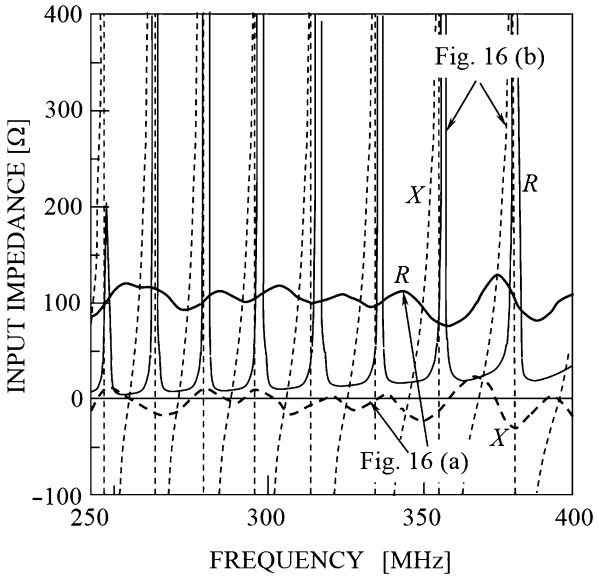

Fig. 19 Input impedance of log-periodic dipole array antenna. Comparison of transposed and non-transposed antennas (Nakano 2006)

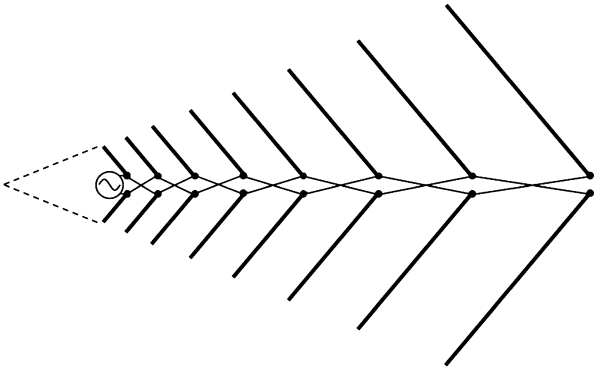

Fig. 20 Log-periodic V array (LPVA) antenna (Mayes and Carrel 1960)

actually comes from transposed excitation of the folded up self-complementary antenna. Further modification of LPVA leads to LPDA. Balmain and Mikhail (1969) proposed an inductively coupled log-periodic dipole array antenna, where the dipole elements are inductively coupled with transposed transmission line and do not have feeding gaps for unbroken dipoles. Since anomalous behavior of this antenna was observed, Oakes and Balmain (1973) optimized the structure in order to remove such behavior. Rojarayanont and Sekiguchi (1977) proposed a log-periodic loop array (LPLA) antennas shown in Fig. 21, where loop elements were employed and a bandwidth of about 2.5:1 is obtained. In these log-periodic antennas, transposed excitation is employed which yields the broadband characteristics.

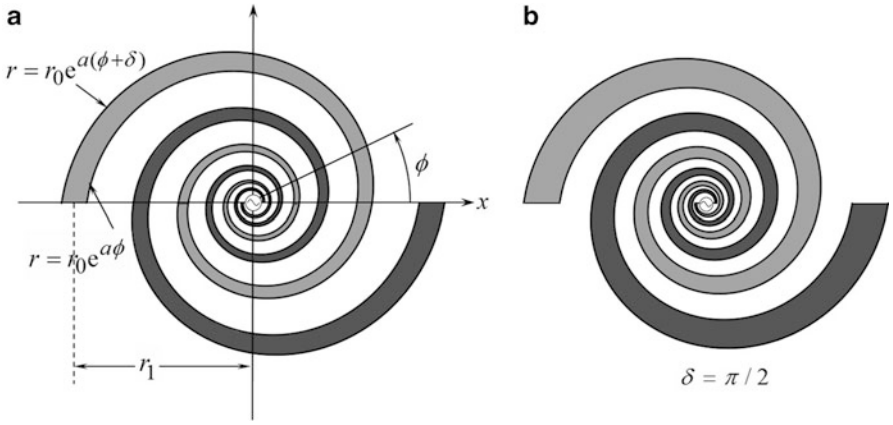

Fig. 22 Two-arm equiangular spiral antennas. (**a**) General equiangular spiral antenna. (**b**) Self-complementary and equiangular spiral antenna

Spiral Antennas

Planar Spiral Antennas

Planar log-periodic spiral antenna is one of the self-similar antennas. It radiates circularly polarized wave bidirectionally. Figure 22 illustrates the two-arm equiangular spiral antenna or log-spiral antenna (Dyson 1959a), where the outer and inner sides of the strip conductor are defined by

$$\begin{aligned} r &= r_0 e^{a(\phi+\delta)} \\ r &= r_0 e^{a\phi}, \end{aligned} \tag{10}$$

and δ is the parameter expressing the width of the strip conductor. The planar log-spiral antenna is the self-similar antennas and has the frequency independent properties. It is also noted that the structure becomes the original self-complementary antenna in the case of $\delta = \pi/2$ as shown in Fig. 22b.

An infinite structure is required for the complete self-similar antenna and truncation effect occurs in the cases of realistic finite structure. The lowest operating frequency of the log-spiral antennas may be given by

$$f_{\text{low}} = c/(2\pi r_1), \tag{11}$$

DOI 10.1007/978-981-4560-75-7_41-1

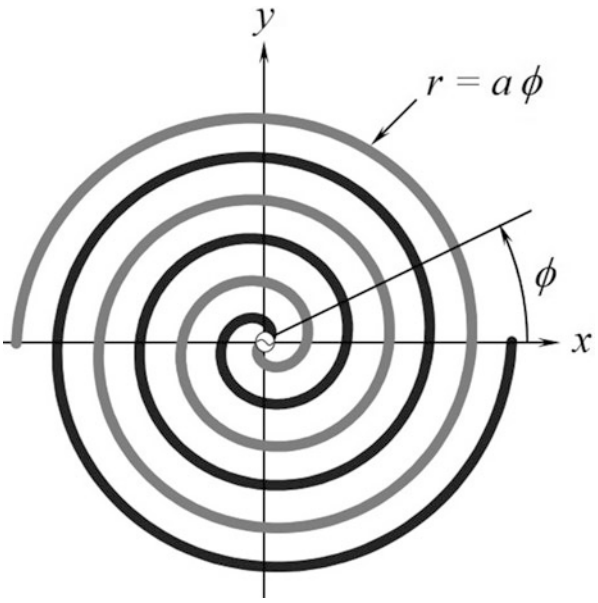

Fig. 23 General two-arm Archimedean-spiral antenna

where r_1 is the outer radius of the spiral and c corresponds the speed of light.

It could be possible to design four-arm or multi-arm spiral antennas, but multi-arm log-spiral antennas are not easy to fabricate because planar log-spiral antennas are composed of strip conductors with finite width.

Archimedean-Spiral Antennas

Archimedean-spiral antenna is another type of spiral antenna (Kaiser 1960). It also radiates circularly polarized wave bi-directionally. The shape of the conductors composing antenna is defined by

$$r = a\phi, \tag{12}$$

as shown in Fig. 23. When the width of the conducting strip w_c is equal to the width of gap between conducting strips w_s, the structure becomes the original self-complementary one as shown in Fig. 5c and constant impedance can be obtained. In the case of $w_c \neq w_s$, the Archimedean-spiral antennas are not self-complementary antenna or self-similar antenna, but broadband property is obtained, e.g., 10:1 bandwidths. This antenna radiates circularly polarized wave, but linearly polarized wave can be obtained by a pair of Archimedean-spiral antennas (Kaiser 1960). Four-arm Archimedean-spiral antenna is also available and was numerically analyzed by Nakano et al. (1983).

Conical Spiral Antennas

The planar spiral antennas are bidirectional antennas, and unidirectional antennas are desired. A method to obtain unidirectional antenna is a combination of the spiral antennas and reflecting plane or conducting cavity, but the presence of the reflector narrows the bandwidth significantly.

DOI 10.1007/978-981-4560-75-7_41-1

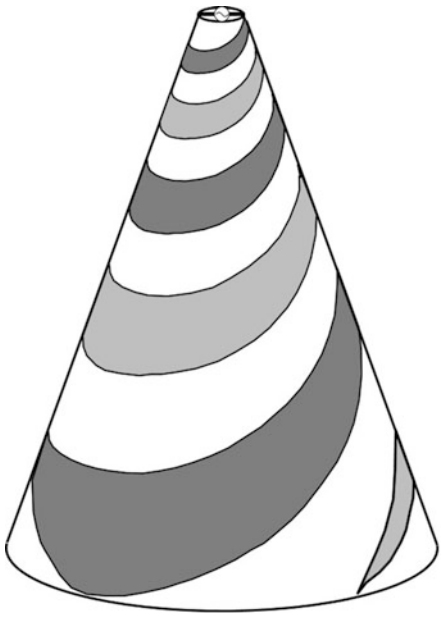

Fig. 24 Two-arm conical spiral antenna

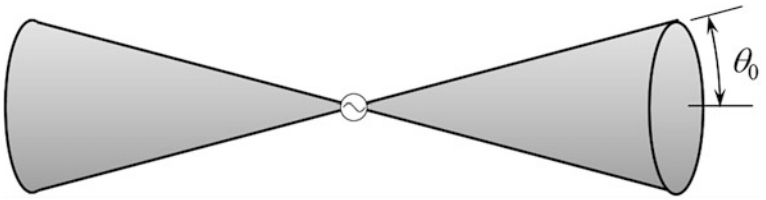

Fig. 25 Biconical antenna

Another method to realize the unidirectional radiation is the introduction of conical spiral antenna, where the log-spiral antenna is placed on a conical surface. Figure 24 shows the two-arm conical log-spiral antenna (Dyson 1959b). The conical spiral is one of the self-similar antennas and broadband characteristics can be obtained. The analysis of the conical log-spiral antenna was reported by Dyson (1965). Multi-arm conical log-spiral antennas were theoretically analyzed by Deschamps and Dyson (1971).

Other Broadband Antennas

Biconical and Bow-Tie Antennas

One of the continuous self-similar antennas is biconical antenna shown in Fig. 25. When the length of biconical antenna is infinite, it can be regarded as a TEM transmission line (Schelkunoff 1951; Tai 1948), and its characteristic impedance is given by

$$Z = \frac{1}{\pi}\sqrt{\frac{\mu_0}{\varepsilon_0}}\cot\frac{\theta}{2} \approx 120\cot\frac{\theta}{2}\,[\Omega], \tag{8}$$

DOI 10.1007/978-981-4560-75-7_41-1

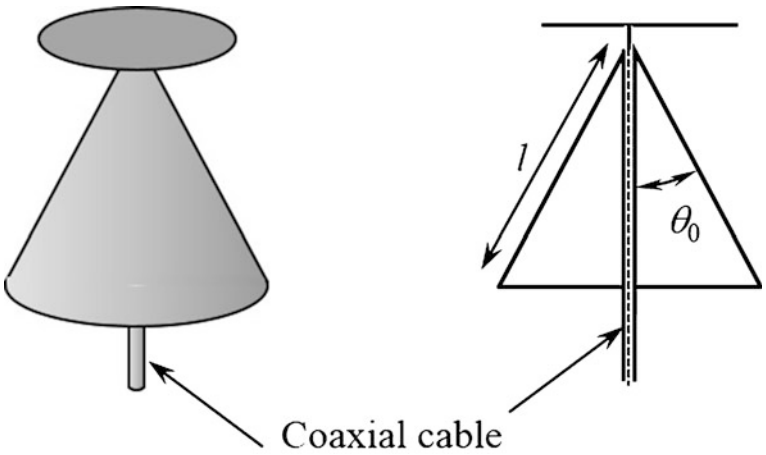

Fig. 26 Discone antenna (Kandoian 1946)

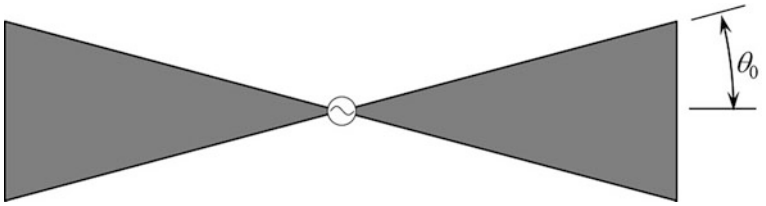

Fig. 27 Bow-tie antenna

In the case of finite length, the input impedance differs from the value of Eq. 8 but is almost constant as long as the total length is sufficiently large.

Figure 26 is the discone antenna composed of a disc and a cone proposed by Kandoian (1946). This antenna is considered to be a modification of biconical antenna and very convenient because of the small size and omni-directional pattern. Typical value of the cone angle is $\theta_0 = 30^\circ$ and the lowest operating frequency of the discone antenna is given by

$$f_{\text{low}} = c/(4l) \tag{9}$$

where l is the length of the cone.

Bow-tie antenna shown in Fig. 27 is another example of the continuous self-similar antennas. It is noted that this antenna becomes the planar self-complementary antenna when the angel is $\theta_0 = 45^\circ$. Bow-tie antennas are often used as pulse transmission and reception because the pulse distortion is small (Shlager et al. 1994). Resistively loaded bow-tie antenna are also used to improve the bandwidth, especially in the case of small bow-tie antenna (Shlager et al. 1994).

Tapered Slot Antennas

One of the other broadband antennas are tapered slot antenna (TSA). TSA is well known for the features of thin structure, low weight, easy to fabricate, broadband, and suitable for microwave integrated circuits. Figure 28 shows the linearly tapered slot antenna (LTSA) fabricated on a dielectric substrate (Yngvesson et al. 1985). LTSA is one of the self-similar antennas having broadband characteristics and unidirectional

DOI 10.1007/978-981-4560-75-7_41-1

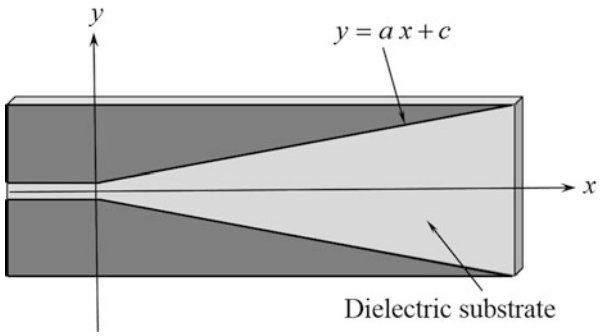

Fig. 28 Linearly tapered slot antenna (LTSA)

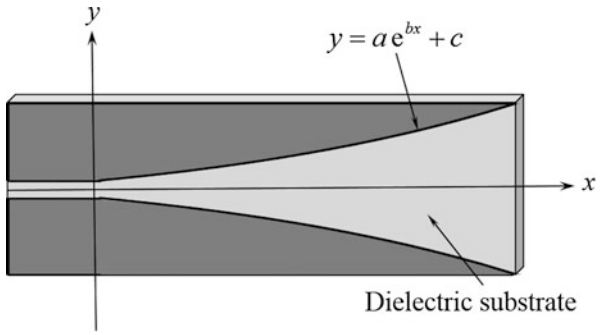

Fig. 29 Vivaldi antenna (Gibson 1979)

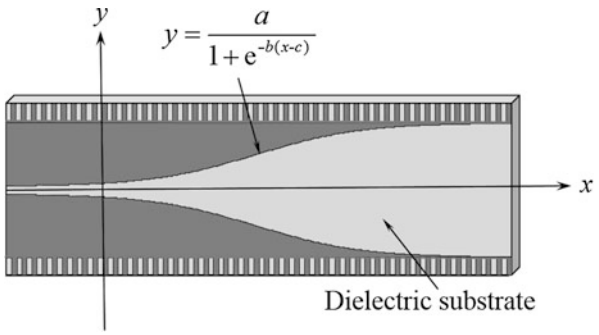

Fig. 30 Fermi antenna (Sugawara et al. 1997)

radiation pattern. In order to extend the bandwidth, Vivaldi antenna shown in Fig. 29 having exponential taper was proposed (Gibson 1979). TSAs were applied to the sensors of millimeter imaging and the elements of array antennas (Yngvesson et al. 1989).

Sugawara et al. (1997, 1998) proposed a TSA called "Fermi antennas" having a profile defined by the Fermi-Dirac function and the corrugation on the side of the substrate shown in Fig. 30. Fermi antenna have many parameters and it is not easy to design the Fermi antennas. Sato et al. (2005) analyzed the Fermi antenna using FDTD method and clarified the relation between the parameters and characteristics. They also showed that the Fermi antenna can yield almost the same radiation patterns in E-plane and H-plane, which are suitable for the millimeter-wave imaging using lens (Sato et al. 2003).

DOI 10.1007/978-981-4560-75-7_41-1

Summary

In this chapter, frequency independent and broadband antennas are reviewed form the view points of the self-complementarity and self-similarity. The theory of self-complementary antenna, original and modified self-complementary antennas, and so-called log-periodic antennas are discussed, where the transposed excitation based on the principle the self-complementarity is the most important to obtain the broadband antennas. Then the frequency independent antennas based on the self-similarity and other broadband antennas are presented.

The ultrawide band antennas described in this chapter are considered to be more and more important for the uses of the new wireless communications such as UWB (ultra wide band) communications and the cognitive radio communications.

Fresnel Zone Plate Antenna

H. D. Hristov*
Department of Electronic Engineering, Federico Santa Maria University of Technology, Valparaiso, Chile

Abstract

The classic Fresnel zone plate has the advantage of being a flat, two-dimensional structure with a small thickness, light and easy to manufacture compared to the bulky refraction lens. In some cases, however, the zoned plate can be fabricated as a three-dimensional curvilinear assembly standing alone or conformal to some man-made or natural formation.

This chapter is devoted to aperture antennas based on flat or curvilinear Fresnel zone plate lenses or reflectors. It is written as a self-sufficient text, which brings together most of the standard knowledge and recent research on the Fresnel zone plate antennas.

Keywords

Diffraction; Focusing; Lens; Fresnel zones; Fresnel zone plate; Fresnel zone plate antenna

Introduction

The Fresnel zone plate antenna is a lens or reflector antenna consisting of two basic components: feed (dipole, horn, etc.) and Fresnel zone plate (FZP). The FZP can be transmissive (lens) or reflective (reflector) in the case of lens or reflector antenna, respectively. FZP lens or reflector is based on the Huygens-Fresnel diffraction principle and focuses an incident plane wave by diffraction, rather than by refraction. While trying to explain the free-space light propagation Fresnel proposed the concept of half-wave zones (known as Fresnel zones) outlined at a wave front plane. He disclosed that the light emitted from the nearby half-wave zones should be in a phase opposition (Fresnel 1866). A. J. Fresnel's portrait is pictured in Fig. 1.

The first optical half-wave FZP lens was designed and examined by J. L. Soret and was intended for the visible light focusing (Soret 1875). The original glass zone plate lens consisted of adjacent transparent and opaque circular Fresnel zones. Soret found that such a zone plate illuminated normally by a plane light wave produced infinite number of spherical waves focused at different focal spots (foci): primary ones with a focal distance (length) $F_1 = F = a_1^2/\lambda$ and secondary ones with focal distances $F/3, F/5$, etc., where a_1 is the radius of the first (central) zone circle and λ is the design light wavelength. The Soret-type lens is usually known as a binary-amplitude or simply binary FZP lens.

In 1871 Lord Rayleigh wrote in his laboratory notepad that the light intensity at the FZP focus could be increased four times if the opaque zones are made transparent and constructive. It was R. W. Wood, however, who put in practice Rayleigh's idea. He manufactured from glass and studied experimentally the so-called phase-reversing FZP lens, where all alternative zones were made transparent and productive, retarded or advanced in phase by 180°. Besides, Wood did the first ever practical application of two FZP

lenses serving as the objective and eyepiece of a light telescope. By means of this telescope Wood managed to see distinctively the lunar craters (Wood 1898, 1934).

Since the focusing principle of the FZP lens is valid for any frequency this lens can be operative not only in the optical range but also in the radio or quasioptical bands (here the term *radio* implies microwave, millimeter and terahertz (submillimeter) wave. The basic references on the theory, design, and production of the optical Fresnel zone plates and systems are collected in a book edited by Ojeda-Castañeda and Gómes-Reino (1996).

The radio wave FZP lenses originated directly from the optical ones and had similar characteristics and applications. From the very beginning the main efforts in studying radio-wave FZP lenses and antennas have been dedicated toward the growth of their focusing efficiency and resolution. The flat binary FZP lens is easy converted into a phase-reversing one if its opaque (metal or absorber) rings are replaced by transparent phase-shifting rings (dielectric, for example), having the same zone pattern but different profile thickness (depth). For making the flat zone plate competitive in focusing efficiency to the ordinary refraction lens different multiple phase-correcting techniques have been employed. Also, by placing a plane reflector behind the flat Fresnel zone lens, a FZP reflector (or folded FZP lens) is realized. And finally, at the expense of a bigger volume, the equal-in-aperture curvilinear FZP lenses or reflectors show the biggest possible focusing efficiency, much better imaging, and scanning properties. A futuristic view of a satellite communication FZP lens antenna conformal to a building cupola is illustrated in Fig. 2.

The early binary radio lens and reflector FZP antennas were patented about 80 years ago (Clavier and Darbord 1936; Bruce 1939, 1946). During the next three decades extensive studies and applications were carried out by numerous researchers. Both binary and dielectric phase-correcting FZP lenses were designed as focusing microwave antenna elements (Maddaus 1948; Van Buskirk and Hendrix 1961). Wiltse and Sobel headed several research projects resulting in the first effective millimeter and submillimeter (terahertz) phase-correcting FZP lenses and antennas (King et al. 1960; Sobel et al. 1961; Cotton et al. 1962; Wiltse 1985, 1998).

More about the evolution of radio wave FZP antennas until today, and about their present technological level and feasible applications are found in many journal and conference publications, and in several books (Goldsmith 1998; Hristov 2000; Guo and Barton 2002; Minin and Minin 2004, 2008a, Wiltse 2012, unpublished).

Flat Fresnel Zone Plates in Antenna Mode

Half-Wave (Binary and Phase-Reversing) FZP Lenses Depending on the zone pattern, profile shape, and plate structure, various radio FZP lens and reflector designs are possible. The flat half-wave FZP lenses, binary (Soret-type) and phase-reversal (Wood-type) have similar zone patterns but different cross section profiles and constructions. In general, each lens transforms a given curved wave front into another curved wave front, and therefore, it has two foci: transmitting and receiving, and two focal distances (lengths), F_1 and F_2, respectively. The lens antenna, however, is converting a plane wave front with $F_1 = \infty$ to a curved (spherical, for instance) wave front with F_2=F. It is understood that the lens with a single finite focal length is operating as a lens antenna in receive or transmit mode.

Zone Patterns of Binary FZP Lenses Figure 3 illustrates a binary FZP lens illuminated by an incident paraxial plane wave. This lens is acting like a receiving antenna (or in antenna receive mode). The binary FZP is named positive or negative if the odd zones are open or closed, respectively. The basic design parameters of the binary FZP lens are wavelength λ, total number of zones N, n^{th} zone outer radius b_n, lens diameter $D = 2b_N$, primary focal length F, and outmost zone width $\Delta b = \Delta b_N$. In the phase-correcting FZP lenses total lens thickness w is calculated.

Diffracted by the round FZP lens the plane wave is transformed into a spherical wave converging to a small spot or primary focal point P at $z = F$. More exactly, the focusing effect is a result of two wave phenomena: diffraction by the open zones and interference of diffracted waves in the focal region. Almost half of the electromagnetic energy illuminating the binary FZP lens is blocked by the obstructed Fresnel zones. Also, the phase in the open zones changes from 0° to 180°. Thus, compared to the ordinary refraction lens with the same aperture size, the binary FZP lens has much lower focusing efficiency.

DOI 10.1007/978-981-4560-75-7_42-2

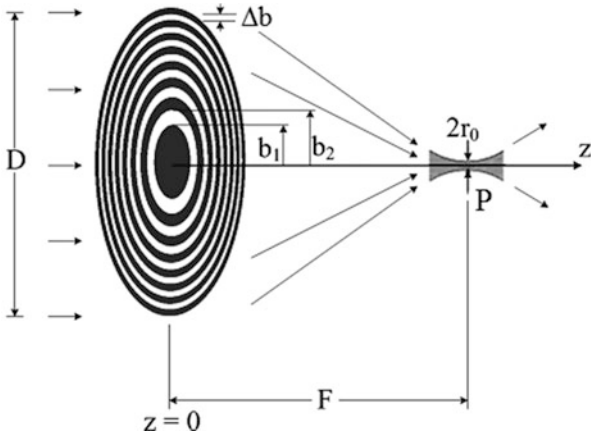

Fig. 3 Binary negative FZP lens operating in receive antenna mode

Zone patterns (front views) of circular, elliptic, and linear binary FZP lenses are shown in Fig. 4. For a paraxial plane wave the FZP patterns have symmetric shapes (circular, Fig. 4a, or linear, Fig. 4b). For an oblique plane wave incidence the zone patterns become asymmetric (elliptic, Fig. 4c, or linear, Fig. 4d). While the ring-shape lenses, circular or elliptical, focus the plane wave at a point (or make a plane-to-spherical wave conversion), the strip-shape lenses focus the plane wave along a focal line, or they convert the plane wave into a cylindrical wave. The opaque zones in the FZP lenses are usually metallized (covered by thin metal rings, strips, etc.) and are normally printed on a low-loss dielectric substrate.

Two identical linear zone plates crossed at right angle form the so-called linear FZP cross, Fig. 5a. More complex FZP planar patterns have also been investigated, as for example the hyperbolic FZP cross, Fig. 5b.

Profiles of Binary and Phase-Correcting FZP Lenses Figure 6 shows the transverse cross sections (profiles) of several flat half-wave FZP configurations. Fig. 6a displays the profile of a binary positive zone plate consisting of open (+) Fresnel zones and opaque (−) metal zone rings. Fig. 6b shows a binary negative zone plate. The binary FZP lens is typically manufactured by means of a microprinting technology, as illustrated in Fig. 6c, where a positive metal FZP rings are printed unilaterally on a thin, low-loss dielectric substrate. In Fig. 6d, e the phase reversing is made by means of Fresnel zone annular grooves cut in a flat dielectric plate with a permittivity ε. As a result, each groove with a depth w is alternated by a dielectric edge.

A microwave variety of Wood's zone plate is the invented by J. C. Wiltse zone plate of dielectric rings, Fig. 6f. This is a smooth, biplanar plate with increased focusing efficiency. The Wiltse lens is designed as a double-dielectric combination of Fresnel zone rings having equal thickness w. In Fig. 6f the permittivities of alternate dielectric rings are specified as ε_1 and ε_2. For $\varepsilon_1 = \varepsilon_0$ the double-dielectric phase-reversing lens becomes simpler and lighter, but some techniques for ring fixing are necessary. For example, in Fig. 6g, the rings are firmly fixed and encapsulated by two thin outer disks with a permittivity ε, which slightly increase the attenuation through the lens (Hristov 1996).

A bigger increase in the focusing efficiency is achieved by means of multiple phase corrections. For example, each full-wave zone, incorporating two Fresnel (half-wave) zones, can be subdivided into four subzones, and thus, a quarter-wave phase-correcting FZP lens can be realized. Four levels of stepwise phase correction per full-wave zone are completed by four stepped, annular grooves cut in a flat, single-permittivity dielectric plate, Fig. 7a, (Sobel et al. 1961; Garrett and Wiltse 1991).

A quarter-wave FZP lens with four distinct-permittivity dielectric rings is sketched in Fig. 7b, while Fig. 7c shows the profile of refraction plane-hyperbolic lens, which is obviously much thicker and

weighty, and lossy as well. A traditional zoned refraction lens is shown in Fig. 7d. It comprises many small curved teeth-shaped edges, which at millimeter and terahertz frequencies become very problematic for production. Fig. 7e is a picture of a quarter-wave four-permittivity phase-correcting lens made by an

appropriate subzone drilling of single-dielectric disk plate (Petosa and Ittipiboon 2003; Petosa et al. 2006).

Phase Correction in Flat FZP Lenses and by Use of Composite/Meta Media Additional thickness and weight reduction in the FZP lenses is possible by employing composite phase correction subzone rings, i.e., metal-dielectric structures instead of pure dielectric ones. Often such composite media are made as grid layers of metal obstacles or slots. The grid metal elements (dipoles, disks, rings, ordinary and Jerusalem crosses, etc.) are usually printed or embedded in a dielectric plate. Such a metal-dielectric plate is narrowband, frequency-selective surface (FSS) structure. Some technological examples are shown in Fig. 8, where (a) is a profile of double-metal grid embedded in a dielectric slab and (b) and (c) are front and profile views of metal double-square printed FSS array.

A thin phase-shifting surface (PSS) that consists of three metallic and two dielectric layers is described in Gagnon et al. (2010), Fig. 8d. The metallic layers consist of conducting elements, which are tuned to introduce the desired phase shifts. Such a frequency-selective surface structure has been applied for constructing phase-correcting zone plate lenses and lens antennas (Gagnon et al. 2012, 2013). The operations of the new FSS structures and FZP lenses/antennas based on them are well validated by measurements.

A low-profile Wood zone plate metalens based on the fishnet metamaterial is proposed in (Orazbayev et al. 2015). It is characterized by a refractive index less than unity (n = 0.51). The metalens is made of alternating dielectric and fishnet metamaterial concentric rings. The use of fishnet metamaterial allows reducing the reflections from the lens, while maintaining low profile, low cost and ease of manufacturing.

Profiles of FZP Reflectors By placing a plane reflector at a distance $d = \lambda/4$ behind the binary Fresnel zone plate the incident wave is brought back in antiphase, and the combination of FZP and reflector works as a FZP reflector (or folded binary FZP). Its cross-sectional view is sketched in Fig. 9a. An alternative FZP reflector is sketched in Fig. 9b, where a metal sheet is shaped in a zigzag manner for making the required phase-reversing steps. A similar FZP cross-sectional view of a metal quarter-wave stepped plate is shown in Fig. 9c. These two zone plate reflector structures can be encapsulated in a dielectric foam or honeycomb.

DOI 10.1007/978-981-4560-75-7_42-2

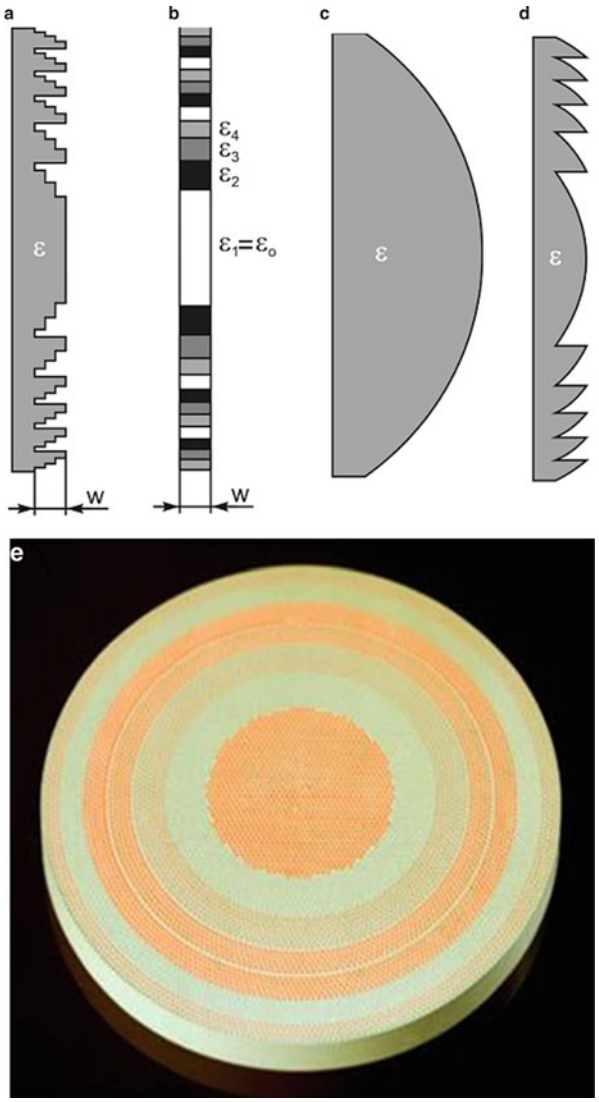

Fig. 7 More effective dielectric lenses: (**a**) grooved quarter-wave FZP lens, (**b**) quarter-wave four- dielectric ring FZP lens, (**c**) ordinary refraction lens, (**d**) zoned ordinary refraction lens and (**e**) drilledsingle-dielectric quarter-wave FZP lens

A printed millimeter-wave design of a FZP reflector is described in Huder and Menzel (1988). As shown in Fig. 9d it is fabricated by use of printed technology and consists of a ground plane disk reflector and FZP rings etched on a dielectric substrate, w_1 in width.

Based on the half-wave and quarter-wave grooved single-dielectric zone FZP lenses, FZP reflectors sketched in Fig. 9e and Fig. 9f, respectively, can be constructed. Similarly, the multi-dielectric quarter-wave FZP lens is transformed into FZP reflector (with a thickness $w_1 = w/2$, Fig. 9g. Obviously, the grooved and multi-dielectric FZP reflectors are roughly twice thinner compared to the respective FZP lenses.

FZP Design Considerations Cross-sectional design and building of phase-correcting dielectric zone plates involves the choice of the following structural features:

1. $\bar{f}$-focal number: FZP lens is characterized by its focal number $\tilde{f} = F/D$, where D is the lens diameter and F is the primary focal length. Typically, the optical FZP lenses have very big $\bar{f}$-number. The radio wave Fresnel zone plates have much smaller focal number and require more exact design equations and

DOI 10.1007/978-981-4560-75-7_42-2

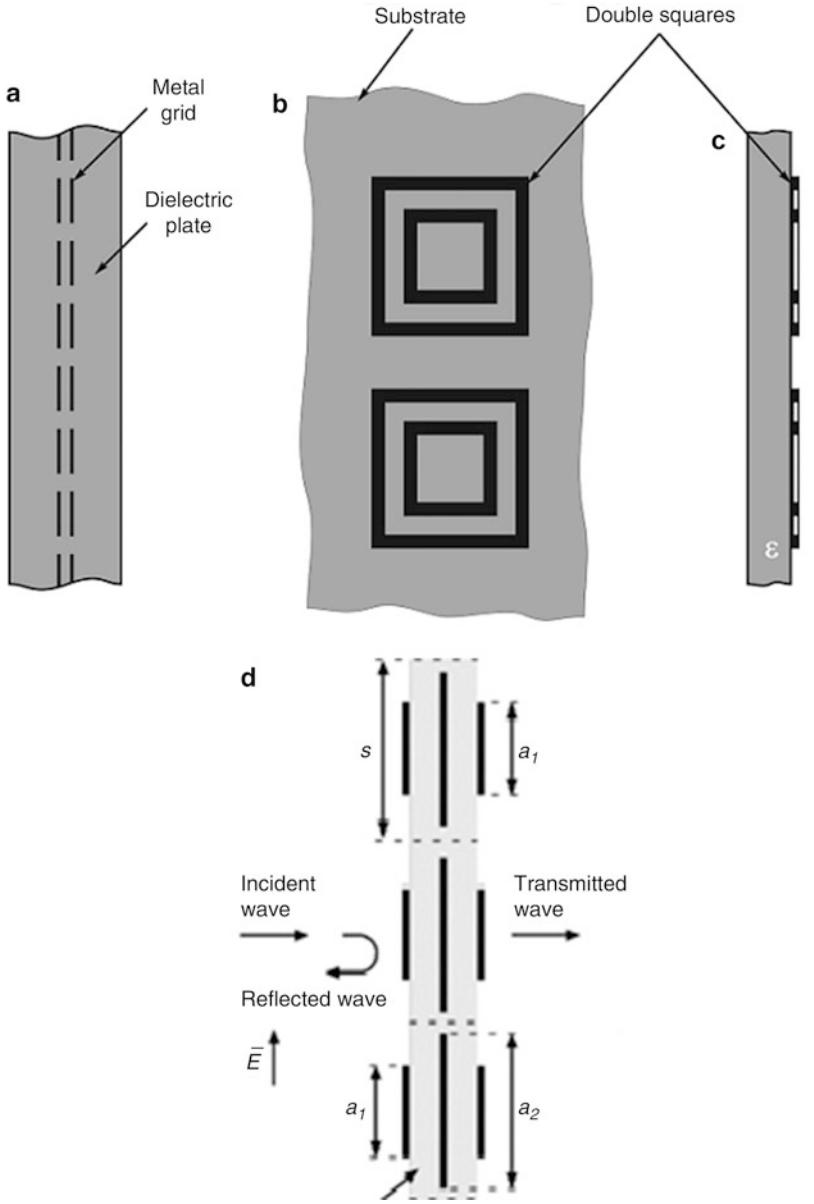

Fig. 8 Metal-dielectric phase-shifting media: (**a**) double-metal grid in dielectric slab, (**b**) front and (**c**) profile views of phase-correcting FSS of printed double-square metal rings, and (**d**) phase-correcting FSS of three metallic and two dielectric layers

methods for electromagnetic analysis. This is especially valid for the short-focal zone plates, with $\tilde{f} < 0.5$.

2. Zone pattern: number of FZP zones/subzones and their outlines (circular, elliptical, linear, cross-type, etc.).
3. FZP profile: straight-line or curvilinear (spherical, parabolic, conical, etc.).
4. Phase correction structure: selected according to the required focusing gain, focusing aperture efficiency, frequency bandwidth, lens wall thickness, and others.

FZP Fabrication Different precise technologies are employed for production of radio wave Fresnel zone plate lenses, especially of those for millimeter waves and terahertz frequencies:

DOI 10.1007/978-981-4560-75-7_42-2

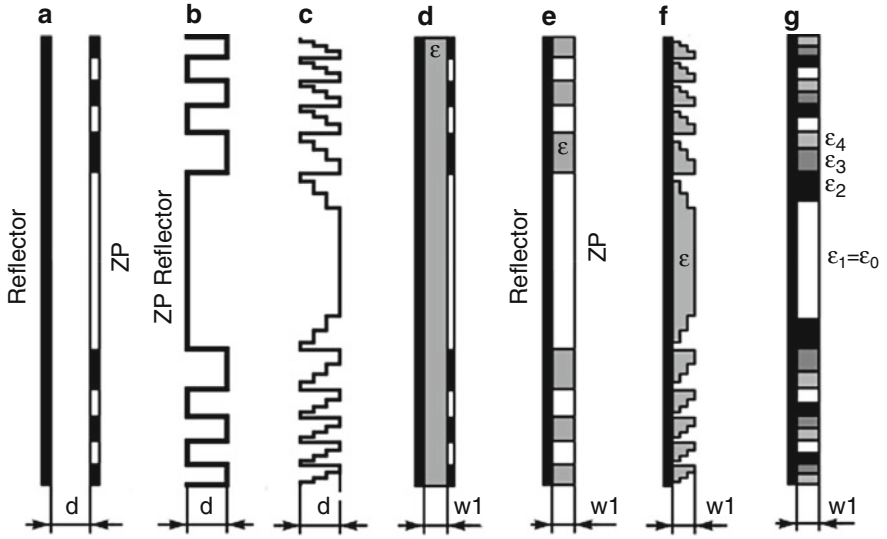

Fig. 9 Profiles of flat FZP reflectors: (**a**) FZP in front of reflector (folded binary FZP), (**b**) binary zigzag reflector, (**c**) quarter-wave zigzag reflector, (**d**) folded half-wave FZP printed on dielectric substrate, (**e**) half-wave dielectric FZP with reflector, (**f**) quarter-wave dielectric FZP with reflector and (**g**) multi-dielectric quarter-wave FZP with reflector

1. Metal (foil) zone elements printing on a thin dielectric substrate without a ground (FZP lenses) or grounded (FZP reflectors)
2. Cutting and milling for making phase-correcting steps or grooves, having in mind that at 1 THz and above an eighth-wavelength correction step can be less than 50 μm
3. Creation by drilling of multipermittivity zones in single-dielectric zone plates
4. Assembling of dielectric rings in multi-dielectric zoned plates
5. Making composite metal-dielectric or solid-state zone structures by use of microelectronic technologies (for instance, photolithography or chemical depositing)

The dielectric material for FZP fabrication has to be a low-loss one, with a proper design permittivity. The internal losses in the dielectric FZP lenses increase significantly with the frequency, especially over the millimeter and terahertz ranges. Typical dielectric materials include polymers, like polystyrene (Rexolite), Teflon, TPX, Tsurupica, etc., and dielectric crystals, like quartz, sapphire, and silicon (Goldsmith 1998).

Zone Radius of Half-Wave FZP Lens Geometry of plane-wave illuminated half-wave FZP is presented in Fig. 10a. Diffracted by the receiving FZP lens plane wave is transformed into infinite in number primary and secondary spherical waves converging to the respective primary and secondary foci. Because the energy at the primary focus $P(0, 0, F)$ is predominant, the secondary foci of the Fresnel zone plate are neglected. Thus, it is supposed that there is only one focus, the primary one. The reverse (transmit) wave transformation is taking place as follows: the spherical wave front radiated from a focal point source is transformed by the FZP lens into a plane wave. As was mentioned before, the phase in each Fresnel zone is not a constant but varies from 0 deg at the origin O to 180 deg at point Q_n. Thus, the half-wave (Fresnel zone) ray path difference is $\mathrm{RPD} = \overline{Q_nP} - \overline{OP} = \left(F^2 + b_n^2\right)^{1/2} = n\lambda/2$. If $b_n^2 << F^2$, the outer radius b_n of the n^{th} half-wave zone is easily found by

DOI 10.1007/978-981-4560-75-7_42-2

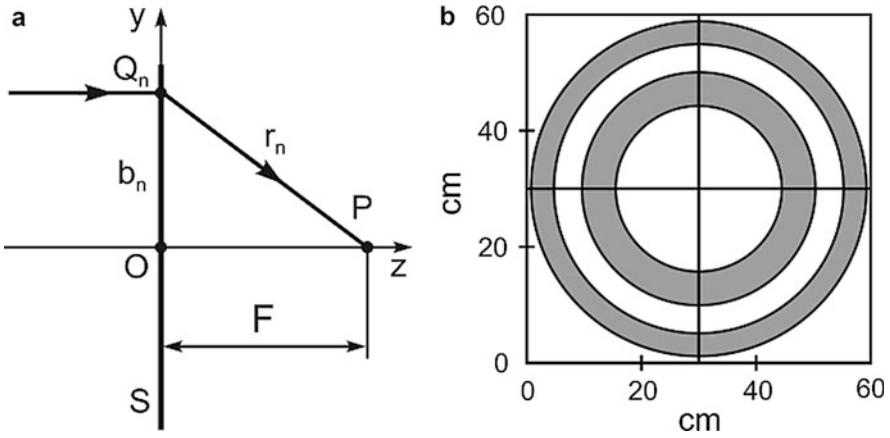

Fig. 10 Half-wave planar FZP axially illuminated by plane wave: (**a**) converging geometry and (**b**) Fresnel zone pattern

$$b_n = \sqrt{n\lambda F + \left(\frac{n\lambda}{2}\right)^2}, \quad n = 1,\ 2,\ 3,\ \ldots, N \tag{1}$$

where N is the total number of half-wave zones.

Equation 1 is usually applied to radio Fresnel zone plate lenses. For the optical waves, $(n\lambda/2)^2 << n\lambda F$, and Eq. 1 is further approximated to

$$b_n = \sqrt{n\lambda F} \tag{2}$$

The circular zone pattern drawn in Fig. 10b is calculated from Eq. 1 for λ =3.2 cm and $F = D = 60$ cm, or $F/D = 1$ and $D/\lambda = 18.75 >> 1$.

Zone Radius of Full-Wave FZP Lens Two adjacent half-wave (Fresnel) zones numbered by m and (m-1) form a full-wave zone, which corresponds to a ray path difference $RPD = m\lambda$, where $m = 1, 2, \ldots, M$, $m = n/2$, and $M = N/2$. Thus, the m^{th} full-wave zone has an outer radius b_m found by Eq. 3, similar to Eq. 1

$$b_m = \sqrt{2m\lambda F + (m\lambda)^2} \tag{3}$$

Zone Radius of Half-Wave FZP Lens with Reference Phase Recently, the classical concept for the zero initial phase at the FZP origin O is reconsidered (Webb 2003). An extra initial phase θ_{ref} named reference phase is introduced as a new variable, which for the positive FZP lens is changed from 0 to 180 deg, and for the negative FZP lens – from 180 to 360 deg. If the reference phase is expressed as $\theta_{ref} = 360\Delta_{ref}/\lambda$, the path ray difference RPD is increased by $\Delta_{ref} = \lambda\theta_{ref}/360$ or $RPD = \sqrt{F^2 + b_n^2} - F = n\lambda/2 + \Delta_{ref}$. In result, the zone radius equation, or Eq. 1, obtains a more general form

$$b_n(\theta_{ref}) = \sqrt{2F\left(\frac{n\lambda}{2} + \frac{\lambda\theta_{ref}}{360}\right) + \left(\frac{n\lambda}{2} + \frac{\lambda\theta_{ref}}{360}\right)^2} \tag{4}$$

DOI 10.1007/978-981-4560-75-7_42-2

For $n = 0$, an initial reference zone is defined with a radius $b_0 = b_{ref}$ given by

$$b_{ref} = \sqrt{2F\frac{\lambda\theta_{ref}}{360} + \left(\frac{\lambda\theta_{ref}}{360}\right)^2} \tag{5}$$

Obviously, a zero reference radius ($b_{ref} = 0$) corresponds to $\theta_{ref} = 0$, which matches the classical Fresnel-Soret half-wave zone plate. In fact, this extra free parameter, the variable radius $R_0 = b_{ref,}$ was introduced about 15 years earlier than the parameter reference phase (Minin and Minin 2004, 2008a). By changing the reference phase or radius, valuable improvement in the FZP lens/antenna performance is obtained. Also, there is a difference in frequency and phase response between the main lobe and sidelobes. This new finding can be utilized for multipath-fading and radar sidelobe clutter reductions and communication security enhancement (Webb et al. 2011).

Zone Radius of FZP Lens with Multiphase Correction In contrast to the traditional refractive lens the diffractive FZP lens does not make smooth phase-error compensation but a discrete or step-phase one. In other words, the FZP lens is acting as a stepwise zone/subzone phase converter. Each full-wave zone is divided into $Q = 2, 4, 8$, etc. (usually even in number) subzones, and the corresponding lenses are termed as half-wave, quarter-wave, eighth-wave, etc. The phase in each s^{th} subzone differs by $2\pi/Q$ relative to the phase in the adjacent subzone (Guo and Barton 1993b). More details for the phase-correcting mechanism in the FZP lens are found in Guo and Barton (2002). For $Q \to \infty$ the Fresnel zone plate is converted into the well-known Fresnel zone refractive lens, Fig. 7d.

In the classical subzone FZP lens, where $\theta_{ref} = 0$ and $RPD = \lambda s/Q$, the s^{th} subzone radius b_s is computed by

$$b_s = \sqrt{2F\left(\frac{s\lambda}{Q}\right) + \left(\frac{s\lambda}{Q}\right)^2} \tag{6}$$

where $s = 1, 2, 3, \ldots S$, $s = mQ,$, $S = MQ$, m and M are the current and total number of the full-wave zones, respectively.

If the extra reference phase is included (or if $\theta_{ref} \neq 0$) the subzone radius equation becomes

$$b_s = \sqrt{2F\left(\frac{s\lambda}{Q} + \frac{\lambda\theta_{ref}}{360}\right) + \left(\frac{s\lambda}{Q} + \frac{\lambda\theta_{ref}}{360}\right)^2} \tag{7}$$

For $\theta_{ref} = 0$ and $Q = 2$, $s = n$ and $S = N$, the multi-half-wave subzone FZP becomes a half-wave lens, and Eq. 7 converts to Eq. 1.

Thickness of Binary Metal FZP Lens The binary FZP is usually produced by a skinny metal sheet printed on a thin nongrounded dielectric substrate, Fig. 6c, while in the case of corresponding reflector the printed FZP lens is backed by the substrate ground, Fig. 9d.

Thickness of Grooved-Dielectric Multiphase-correcting FZP Lens The FZP phase correction structures are made most frequently of low-loss dielectric plates. The plates are grooved in a stepwise manner as shown in Fig. 7a, for lenses, and in Fig. 9f, for reflectors, where the phase is changed as a staircase of Q levels and $Q-1$ steps. Each step has a width w_1 given by

DOI 10.1007/978-981-4560-75-7_42-2

$$w_1 = \frac{\lambda}{Q(\sqrt{\varepsilon} - 1)} \tag{8}$$

where λ is the free-space design wavelength and ε is the relative dielectric permittivity.

In the case of phase reversal dielectric lens with one grooved step or two phase levels ($Q = 2$), the FZP lens thickness w is

$$w = \frac{\lambda}{2(\sqrt{\varepsilon} - 1)} \tag{9}$$

The total grooved-dielectric FZP lens of $Q-1$ steps per full wave has a thickness $w = (Q-1)\, w_1$, or

$$w = \frac{(Q-1)\lambda}{Q(\sqrt{\varepsilon} - 1)} \tag{10}$$

The supporting substrate slab of the FZP lens can be made with the same permittivity ε or distinct permittivity ε_s. As in the refraction lenses, the thickness w_s of the FZP supporting structure can be chosen to make a negligible influence on the FZP operation and better interface match between the lens and free space, and thus to improve the FZP efficiency.

According to Eq. 9, for $\varepsilon = 4$, the phase reversal FZP thickness is equal to the free-space half wavelength or $w = \lambda/2$. For a quarter-wave grooved-dielectric FZP lens ($Q = 4$) with a permittivity $\varepsilon = 4$, the Eq. 10 gives $w = 3\lambda/4(\sqrt{\varepsilon} - 1) = 0.75\lambda$.

For a better impedance match between the lens and free space, the permittivities of the lens ε and supporting layer ε_s are connected by the equation $\varepsilon_s = \sqrt{\varepsilon}$. In addition, the thickness of the supporting layer is given by the approximation $w_s \approx \lambda/4\sqrt{\varepsilon_s}$. Having depths w and w_s calculated, the total thickness w_t of the grooved-dielectric FZP lens is

$$w_t = w + w_s \tag{11}$$

Thickness of Multi-Dielectric Ring FZP Lens Consider initially the thickness (depth) equation for double-dielectric FZP lens illuminated by a paraxial plane wave (Black and Wiltse 1987)

$$w = \frac{\lambda}{2\left(\sqrt{\varepsilon_2} - \sqrt{\varepsilon_1}\right)} \tag{12}$$

where ε_2 and ε_1 are the relative permittivities of the two dielectrics (plastics).

It is evident from Eq. 12 that for a given design wavelength the minimum depth corresponds to the maximum ratio between ε_2 and ε_1. These relations are displayed graphically in Fig. 11a, (Wiltse 2012), where ε_r corresponds to ε_2. The FZP lens depth of cut (in cm) versus the frequency (in GHz) is plotted for three permittivity ratios: $\varepsilon_2/\varepsilon_1 = 1.6$, 2.1, and 2.54.

Particular depths of two plane-convex ordinary lenses, plane-spherical and plane-hyperbolic, Fig. 11b, are compared to the depth of same-diameter phase-reversing FZP lens, Fig. 11c. All lenses are designed for $f = 140$ GHz, $F = 200$ mm, and $D = 200$ mm. The hyperbolic and spherical refraction lenses are 8 and 11 times thicker, compared to the FZP lens, respectively. They are also much heavier and difficult to manufacture in comparison to the FZP lens. These advantages are at the expense of about two and half times smaller focusing efficiency.

DOI 10.1007/978-981-4560-75-7_42-2

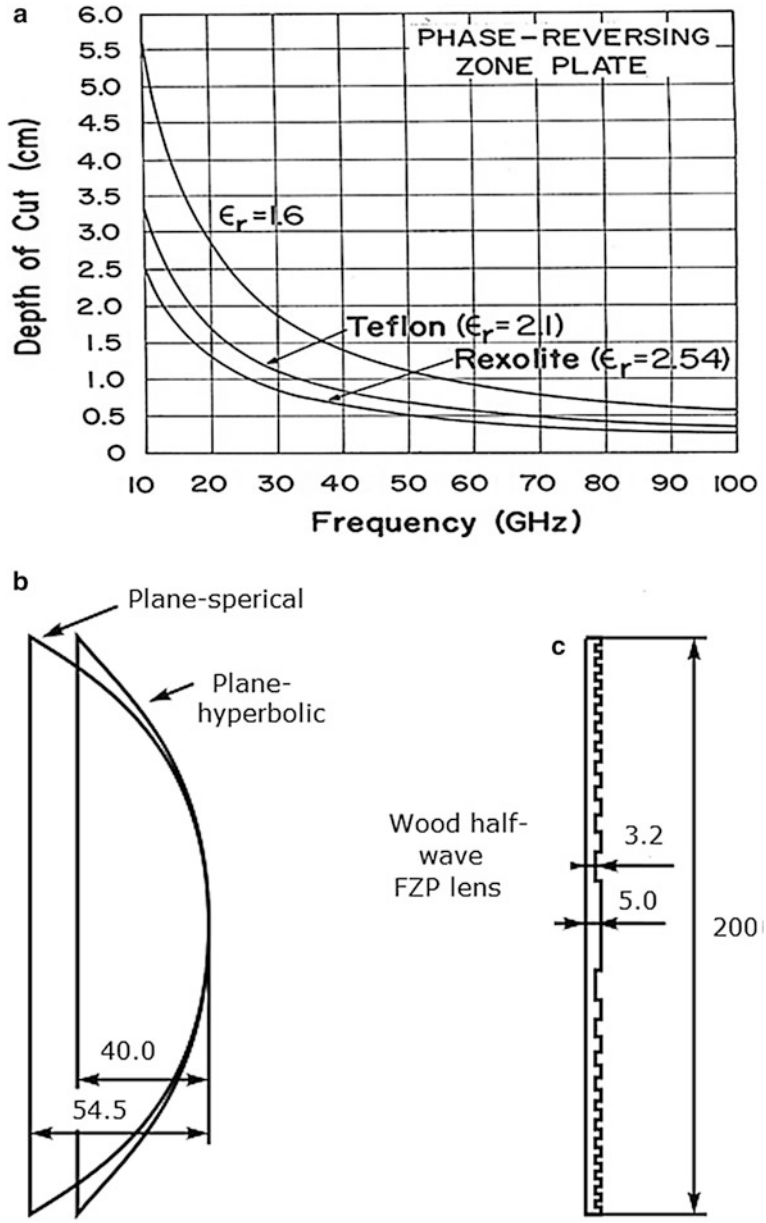

Fig. 11 Depths of refraction and diffraction lenses: (**a**) phase-reversing FZP depth of cut versus frequency, (**b**) ordinary refraction lenses and (**c**) grooved phase-reversing zone plate

Unlike the staircase grooved-dielectric FZP the thickness of flat multi-dielectric FZP lens (or Wiltse lens) is preserved constant. A general permittivity equation for the Wiltse lens was derived and published recently in Hristov and Rodriguez (2013). For a normal plane wave incidence (antenna receive mode) the wave goes through the first subzone thickness without reflection if the following standing-wave condition is met: $w_1 = \kappa\lambda/(2\sqrt{\varepsilon_1})$, where λ is the free-space design wavelength. The optimum ratio $\xi_{s,1}$ between the permittivities of s^{th} and 1st zone ring dielectrics is found by

$$\xi_{s,1} = \frac{\varepsilon_s}{\varepsilon_1} = \left[1 + \frac{2}{k}\left(1 - \frac{s-1}{Q}\right)\right]^2 \tag{13}$$

DOI 10.1007/978-981-4560-75-7_42-2

Here $s = 1, 2, 3, \ldots$ is a current subzone number in the first full-wave zone and $k = 1, 2, 3$, etc. is an integer number of half-waves in the s^{th}dielectric ring. Also, for a minimum FZP lens depth, k is set to 1 and the lens thickness w is fixed equal to that of the first zone/subzone, or $w = w_1$.

Equation 13 is valid for ideal, loss-free dielectrics. If the FZP lens is made of realistic microwave dielectrics, and the s^{th} subzone dielectric ring has a complex transmission coefficient $\tilde{T}_s = |\tilde{T}_s|\exp(j\Phi_t)$, where the attenuation A_s of the s^{th} dielectric ring is given by $A_s = 10\log\left(1/|\tilde{T}_s|^2\right)$ in decibels. This attenuation factor should include both the internal dielectric losses and losses due to the multiple reflections.

For a quarter-wave multi-dielectric FZP lens with $Q = 4$, $\varepsilon_1 = 1$, and $k = 1$ the ring permittivities are found by Eq. 13 as follows: $\varepsilon_2 = 6.25, \varepsilon_3 = 4$, and $\varepsilon_4 = 2.25$. Due to the radial phase periodicity, Eq. 13 is correct and recurrently applicable to all full-wave zones of the lens. Thus, for the second full-wave zone $\varepsilon_5 = 1$, $\varepsilon_6 = 6.25$, $\varepsilon_7 = 4$, and $\varepsilon_8 = 2.25$.

Essentials in Fresnel Zone Plate Operation

Multifocal Action of Binary FZP Lens Suppose a zone plate lens illuminated by a plane wave with a design wavelength λ_1 as shown in Fig. 3. According to the solution in Sussman (1960) the zone plate diffraction lens produces multiple foci at $z = \pi F/w$, primary and secondary. Here $w = \pm(2k + 1)\pi$, $k = 0, 1, 2, \ldots$ The multifocal action is illustrated in Fig. 12a, where the plus signs correspond to the real foci, $P_1(+F_1)$, $P_3(+F_3)$, $P_5(+F_5)$, etc., located at the points $z = F_1 = F$, $z = F_3 = F/3$, $z = F/5$, and so on. Along the + z axis the Fresnel zone plate behaves as a multifocal converging lens. On the other hand, the foci $P_1'(-F)$, $P_3'(-F/3)$, $P_5'(-F/5)$ are virtual images of the real foci. Thus, the binary or Soret zone plate acts simultaneously as two ray-converging multifocal lenses. The points P_1 and P_1' are the first-order or primary foci, and all others are high-order (secondary) foci. The Fresnel zone plate of metal rings has no virtual but only real foci, corresponding to the transmitted and reflected waves.

The normalized intensity versus the real focus number is graphed in Fig. 12b. The intensity maxima are found at the odd foci: $I_1(w = \pi) : I_3(w = 3\pi) : I_5(w = 5\pi), \ldots = 1: (1/3)^2: (1/5)^2$, etc. Thus, the high-order foci 3, 5, and so on have much smaller focal intensities compared to the primary focus intensity. On the other hand, the intensity at the primary focus is $1/\pi^2$ times weaker than the focal intensity of the equal-in-diameter refraction lens.

If the fields focused at the two primary foci $z = +F$ and $z = -F$ are received and brought together in phase, the focusing efficiency of the binary zone plate will be increased twice (or by 3 dB). In practice, such in-phase combination can be done by one of the following techniques: (i) feed-line power combining by use of two feeds, feed lines, phase shifter, and power combiner and (ii) free-space power combining by means of folded binary FZP reflector with diameter $D = 2b_N$ as shown in Fig. 9a.

Multifrequency Focusing of Binary FZP Lens This phenomenon corresponds to the axial multiple focusing of the Fresnel zone plate. Both phenomena are linked by Eq. 1 and can be easier explained by Eq. 2. From Eq. 2 follows that for a given FZP diameter the change of the focal distance F for $\lambda = \lambda_1 =$ const or the change of wavelength λ for $F =$ const leads to the multifocal or multifrequency effect, respectively.

Initially, the multifrequency phenomenon will be discussed taking as an example a binary FZP lens of four Fresnel zones designed for a focal length F and wavelength λ_1. Fig. 13a illustrates the Fresnel zone assembly with all zones open. The plane waves going through the positive and negative zones will cancel at P_1 and will not produce a focusing effect, i.e., the wave is propagating without any change. In Fig. 13b

DOI 10.1007/978-981-4560-75-7_42-2

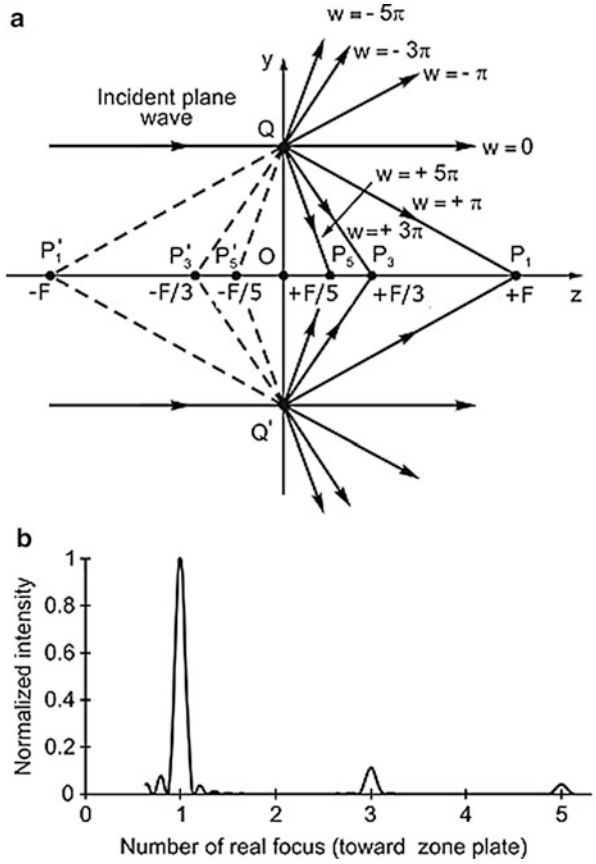

Fig. 12 Diffraction mechanism of binary zone plate illuminated by plane wave with design frequency f_1 wavelength λ_1: (**a**) forming primary and secondary foci, and (**b**) focusing intensity at the primary and secondary foci

the negative (even) zones are blocked by metal (or thin absorbing) rings (Soret lens). The focusing is produced by the open (white) zones only, which fields add in phase at the primary focus P_1.

Now consider the same FZP lens construction illuminated by a plane wave with a wavelength λ_3 equal to the third harmonic wavelength, or $\lambda_3 = \lambda_1/3$. According to Eq. 2, for the same lens diameter D and design focal length F, the threefold smaller wavelength λ_3 requires three times bigger number of subzones S, or $S = 3N$. This means that in each real half-wave zone corresponding to the design wavelength λ_1, three virtual λ_3 subzones are enclosed: two positive (in white) and one negative (in gray), Fig. 13c. Thus, for the s^{th} subzone radius Eq. 2 can be rewritten as follows:

$$b_s = \sqrt{s\lambda_3 F} = \sqrt{3n\lambda_3 F} \tag{14}$$

Thus, the subzone radii can be calculated by Eq. 14, where $s = 3n$ is the current subzone number. In Fig. 13c the fields produced by the 2nd (gray) and (white) subzones will cancel leaving only the 1st subzone to contribute at P_1. Similar physical explanations are valid for all other odd harmonic wavelengths: λ_5, λ_7, and so on.

Theoretically, for each odd wavelength harmonic the FZP lens produces one and the same field intensity (focusing gain) at the primary focus P_1. Nevertheless, the FZP aperture efficiency for the higher harmonics is dropping rapidly compared to the efficiency at the design wavelength λ_1. If the FZP focusing efficiency at λ_1 is set to $\eta_1 = 100\ \%$, the higher odd harmonics will be focused at P_1 with much lesser efficiencies: $\eta_3 = \eta_1(1/3)^2 \approx 11\ \%$, $\eta_5 = \eta_1(1/5)^2 \approx 4\ \%$, and so on Hristov (2011).

Phase Correction Mechanism Detailed theory and interpretation of the phase correction mechanism is exposed in Guo and Barton (1993a, b, 1995, 2002). As was explained above, the zoned plate is a stepwise phase front converter, where each full-wave Fresnel zone is usually divided into half-wave, quarter-wave, eighth-wave, and so on subzones.

Consider first the phase correction procedure for the half-wave or Wood phase-reversing zone plate. Suppose that the zone plate is illuminated by a spherical wave front from a point source P at a focal distance F from the plate. The radial phase variation (or phase error) in the outer plane of the zone plate is described by a quadratic function Φ_1 that can be expressed as a function of Fresnel zone number as follows:

$$\Phi_1(n) = -\frac{2\pi}{\lambda}\left(\sqrt{F^2 + b_n^2} - F\right) \tag{15}$$

where b_n is the Fresnel zone radius calculated for a given F and λ by Eqs. 1 or 2.

The calculated Φ_1 is drawn as a dash-dotted line in Fig. 14a. The conversion of spherical phase front into a plane one makes zero phase error in the aperture. Ideally, this can be achieved by a refractive, plane-convex (or convex-plane) dielectric lens, which creates a phase-reversed quadratic function $\Phi_2(n) = -\Phi_1(n)$, drawn by the dashed line. Thus, the sum of the initial phase function $\Phi_1(n)$ and the lens phase correction function $\Phi_2(n)$ will be zero, and thus, the spherical phase error in the lens aperture will be entirely compensated. However, the Fresnel zone plate makes incomplete phase compensation. For example, the phase reversal zone plate produces staircase compensation (dotted line) with steps of 180 deg each. The sum of the spherical phase error function and staircase compensation function is a tooth-shape phase error curve (solid line), which varies within each Fresnel zone from 0 to −180 deg.

DOI 10.1007/978-981-4560-75-7_42-2

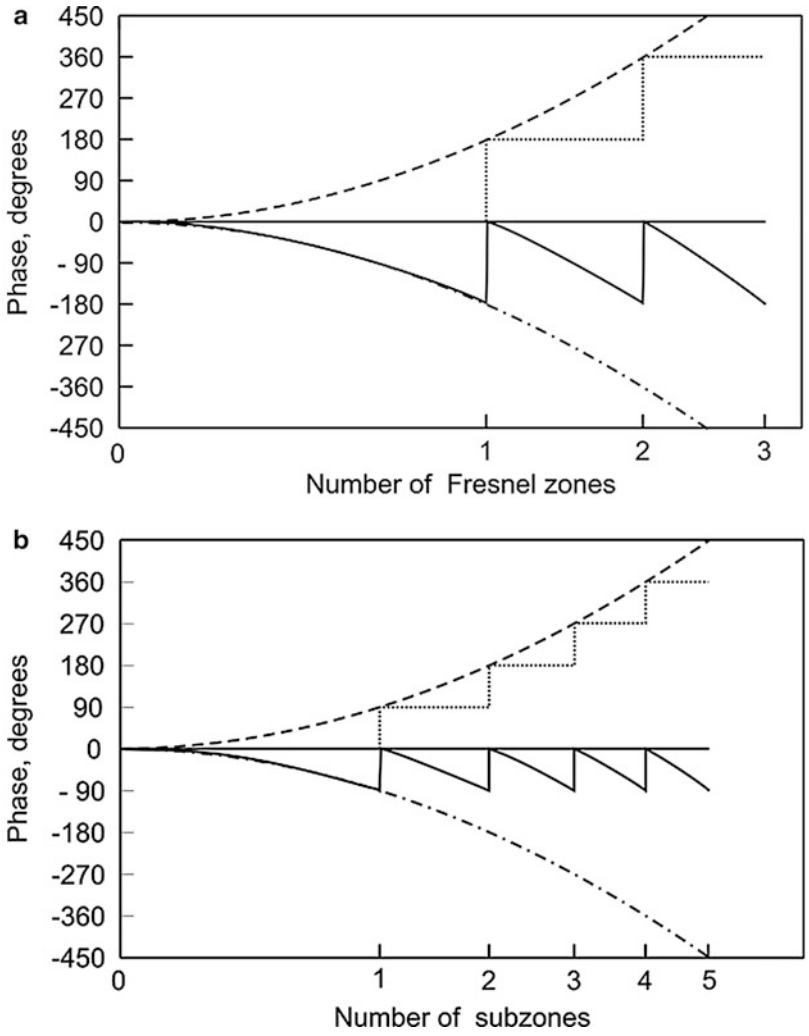

Fig. 14 Stepwise phase-front correction in (**a**) half-wave (phase-reversing) and (**b**) quarter-wave zone plates

Similar reasoning is valid for the quarter-wave zone plate, illustrated graphically in Fig. 14b. There, the resultant aperture phase error function does not exceed −90 deg within each subzone.

Diffraction Focusing Efficiency of FZP Lens Consider the focusing efficiency of ideal FZP lens, free of material and polarization loss. This efficiency depends only on the phase increment in the compensation staircase function and is expressed by the simplified equation (Garrett and Wiltse 1991)

$$\eta_f = \frac{\sin^2(\Delta\Phi/2)}{(\Delta\Phi/2)^2} \tag{16}$$

where $\Delta\Phi$ is a step increment in the staircase phase correction function. From Eq. 16 is easy calculated that the diffraction efficiency of the stepwise phase-corrected half-wave, quarter-wave, and eighth-wave zone plate lenses is equal to 40.5 %, 81 %, and 95 %. If $\Delta\Phi \to 0$ the zone plate diffraction efficiency tends to unity. Therefore, a good efficiency enhancement is obtained for $\Delta\Phi \leq 90$ deg. Actually, if the material, polarization, and reflection loss factors are taken into account the realistic FZP lens focusing efficiency becomes rather smaller.

DOI 10.1007/978-981-4560-75-7_42-2

Resolution of Binary FZP Lens A high resolution is needed when the lens is used for imaging and narrow-beam antenna design. By definition, the so-called Rayleigh resolution criterion is commonly expressed by the resolving (resolution) angle δ_0, in radians (Myers 1951)

$$\delta_0 = \chi \frac{\lambda}{D} \tag{17}$$

In case of the binary FZP $\chi = 1.22$ for number of zones N is bigger than about 200. For smaller N, say $N < 50$, the resolution constant χ varies with N. It is found that $\chi(N) < 1.22$ for the positive FZP lenses (odd zones open), and $\chi(N) > 1.22$ for the negative FZP lenses (even zones open).

According to the axial Airy diffraction pattern the resolving angle δ_0 is directly related to the first null radius r_0 and primary focal length F by the equation $\tan\delta_0 = r_0/F$. For a high resolution δ_0 is small enough and Eq. 17 is approximated to $\delta_0 \approx r_0/F$. Thus, taking into account Eq. 17 and the previous approximate equation for δ_0, the lens radius r_0 can be expressed as $r_0 = \chi(M)\lambda F/D$. The outmost zone width Δb is related to the resolving lens radius by the equation $r_0 = \chi(M)\Delta b$ (Sun and Cai 1991; Hristov 2011).

Curvilinear Fresnel Zone Plates in Antenna Mode

Axially Symmetric Zone Plate Structures For improving the focusing, resolving and frequency properties of the FZP lens it can be made like a thin bent plate (shell) with zone shapes similar to those in the plane FZP lens. In general, the curved FZP can be fabricated with an arbitrary shape provided the Fresnel zones are drawn in accordance with the Fresnel-zone/subzone ray path difference (RPD) condition (Hristov 2000).

From practical and theoretical points of view the most appropriate is a zone plate surface expressed mathematically as an axially rotational curve profile function. Examples of FZP lenses with simple rotational profiles are shown in Fig. 15a for spherical and in Fig. 15b for conical FZP lenses. The conical zone plate is especially suitable for building of collapsible umbrella-like FZP lens/reflector antennas.

Cylindrical Zone Plate Structures Figure 16 illustrates the zone patterns of (a) cylindrical rim ring-type and (b) strip-type FZP lenses. The cylindrical rim-type arrangement consists of circular Fresnel zone rims (rings) and converges the incident plane wave to a focal point P(z = F), while the strip-type FZP structure focuses the plane wave along the focal line P′P″.

Zone Pattern of Spherical Phase-Correcting FZP Lens Figure 17a is the geometry of a radio wave spherical zone plate (shell) with a radius R and sphere center at point C. Here the half-wave FZP lens is considered, with a zone pattern consisting of N half-wave (Fresnel) zones, specific for the binary (Soret-type) and phase reversal (Wood-type). The zone plate is convex-side illuminated by a plane wave and is operating in antenna mode. The approximate equation for the outer radius b_n of the n^{th} zone is derived on the basis of the Fresnel zone ray path difference condition

$$\mathrm{RPD} = \sqrt{\left[F - \left(R - \sqrt{R^2 - b_n^2}\right)\right]^2 + b_n^2} - F = \frac{n\lambda}{2} \tag{18}$$

where $n = 1, 2, 3, \ldots, N$.

From Eq. 18 the half-wave zone radius b_n is obtained (Dey and Khastgir 1973a, b, c)

DOI 10.1007/978-981-4560-75-7_42-2

DOI 10.1007/978-981-4560-75-7_42-2

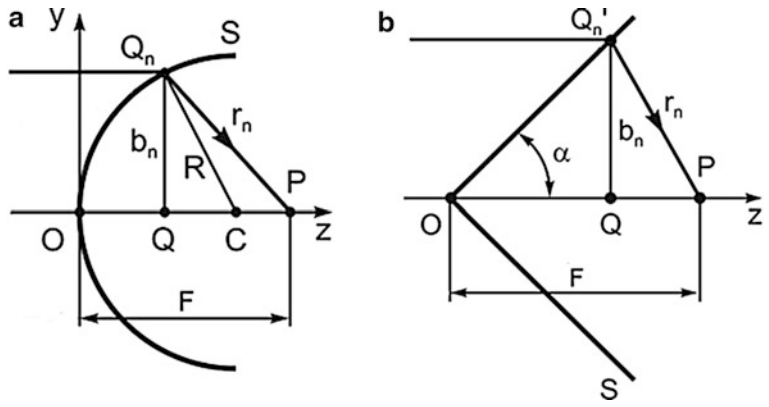

Fig. 17 Half-wave curvilinear FZP lens convex-side illuminated by plane wave: (**a**) spherical lens converging geometry and (**b**) conical lens converging geometry

$$b_n = \sqrt{R^2 - \left(\sqrt{R^2 + n\lambda(R - F)} - \frac{n\lambda}{2}\right)^2} \tag{19}$$

Equation 19 is simplified considerably for $F = R$. In this particular occasion the plane wave is focused at the sphere center C

$$b_n = \sqrt{n\lambda F - \left(\frac{n\lambda}{2}\right)^2} \tag{20}$$

The latter formula is very similar to the flat FZP zone radius Eq. 1, and therefore, both equations can be combined in one

$$b_n = \sqrt{n\lambda F \pm \left(\frac{n\lambda}{2}\right)^2} \tag{21}$$

where the plus and minus signs are valid respectively for the half-wave flat and spherical FZP lenses, with the same diameters and primary focal lengths. And finally, for a paraxial optical/quasioptical FZP $F >> \lambda$ and $n\lambda F >> (n\lambda/2)^2$, and Eq. 21 is converted to Eq. 2.

For the multiphase correcting FZP lens each full-wave zone is subdivided into s subzones, with $s = 1, 2, 3, \ldots S$, $s = mQ$, and $S = MQ$; Q is the number of subzones in a single full-wave zone; m and M are the current and total number of the full-wave zones, respectively. Thus, the FZP RPD condition becomes equal to $s\lambda/Q$, and the equation for the s^{th} radius is found as follows:

$$b_s = \sqrt{R^2 - \left(\sqrt{R^2 + 2(R - F)\left(\frac{s\lambda}{Q}\right)} - \frac{s\lambda}{Q}\right)^2} \tag{22}$$

Zone Pattern of Conical Phase-Correcting FZP Lens Figure 15b represents a rotational conical FZP lens convex-side illuminated by an axially incident plane wave. Here, for the half-wave phase-correcting conical FZP a specific design parameter is defined: cone opening semi-angle $\alpha = \text{atan}(s_n/OQ) = \text{const}$.

DOI 10.1007/978-981-4560-75-7_42-2

The n^{th} outer Fresnel zone radius b_n in the half-wave zone pattern projected in the plane $z = OQ$ is given by the following equation (Minin and Minin 2004):

$$b_n = \sqrt{2F\frac{n\lambda}{2} + \left(\frac{n\lambda}{2}\right)^2 + \left(\frac{n\lambda}{2\tan\alpha}\right)^2} - \frac{n\lambda}{2\tan\alpha} \tag{23}$$

For the general case of conical zone plate, the s^{th} subzone radius b_s is easy found from Eq. 23 after replacing b_n by b_s and $n\lambda/2$ by $s\lambda/Q$

$$b_s = \sqrt{2F\frac{s\lambda}{Q} + \left(\frac{s\lambda}{Q}\right)^2 + \left(\frac{s\lambda}{Q\tan\alpha}\right)^2} - \frac{s\lambda}{Q\tan\alpha} \tag{24}$$

where $s = 1, 2, 3, \ldots S$, $s = mQ$, and $S = MQ$ are parameters and relations similar to those for the spherical FZP lens.

The conical FZP lens with a half-opening angle $\alpha = 90$ deg becomes a flat FZP lens. If in addition $Q = 2$, and $s = n$, Eq. 24 reduces to Eq. 1.

The spherical and conical Fresnel zone plates can be turned also to the incident plane wave by their concave sides. Such FZP lenses are specified as concave lenses operating in antenna mode.

Fresnel Zone Plate Focusing Methods

Optical Diffraction Method for Focusing Analysis Classically, the FZP focusing and imaging or FZP antenna radiation analysis is completed by use of optical methods (GO, UTD, Kirchhoff's diffraction integral (KDI), etc.). Next is described an approximate diffraction focusing theory valid for any axially symmetric curvilinear zone plate with a specified profile function according to Hristov (2000). The zone plate geometry with a profile curve function $y(z)$ illuminated by a plane wave is illustrated in Fig. 18a. All open zone arcs are approximated by the corresponding chords. P is an axial running point illuminated by the elementary area $dS = y(z)d\varphi(dz/\cos\alpha_n)$.

According to the diffraction theory the field produced by the n^{th} zone at point P can be written as $dE_n = jE(Q)I(\vartheta_n, \vartheta_n')\exp(-j\beta r(z))dS/\lambda r(z)$, where the inclination factor is approximated as in the case of planar zone plate, or $I(\vartheta_n, \vartheta_n') \approx (1 + \cos\vartheta_n)/2, \beta = 2\pi/\lambda\, dz/dl = \cos\alpha_n = \sin\eta_n$. The n^{th}-zone field at point P is found as a surface integral, which after integration with respect to the rotational coordinate φ reduces to the next linear integral

$$E_n(P) = j\frac{\pi E_0}{\lambda}\int_{z_{n-1}}^{z_n} y(z)\frac{1+\cos\vartheta_n}{\cos\alpha_n}\frac{\exp[-j\beta(r(z)+z)]}{r(z)}dz \tag{25}$$

with $r(z) = \sqrt{(z_p - z)^2 + y(z)^2}$.

The integration limits z_n and z_{n-1} are calculated by the approximated RPD condition

$$z_{n,n-1} = z_p - b_{n,n-1} + \sqrt{(n, n-1)\lambda b_{n,n-1} - b_{n,n-1}^2} \tag{26}$$

where $b_{n,n-1}$ can be calculated in advance for each specific zone plate profile.

DOI 10.1007/978-981-4560-75-7_42-2

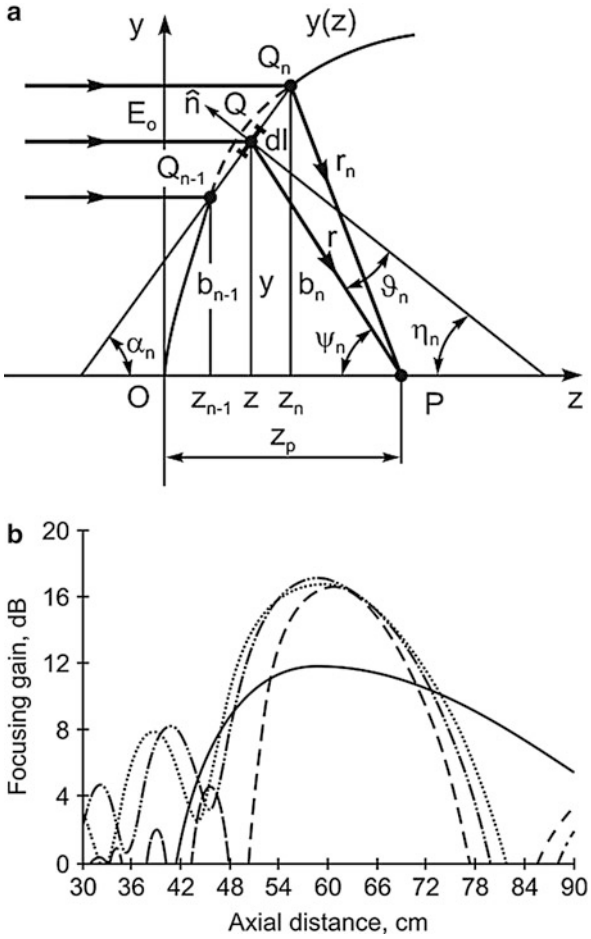

Fig. 18 Axial focusing of plane and curved FZP lenses: (**a**) geometry for derivation of general focusing theory, and (**b**) focusing gain versus axial distance from the lens for planar (*solid line*), spherical (*dotted line*), parabolic (*dashed-dotted line*) and conical (*dashed line*) zone plates

According to Fig. 18a, the total focused field at the focal point P is created by the odd open zones, or

$$E(P) = \sum_{n-1}^{N} E_n(P), \tag{27}$$

with $n = 1, 3, 5, \ldots, N$

The zone plate focusing gain G_f in decibels is found by the equation $G_f = 10\log|E_f(P)/E_0(P)|^2$, where $E_f(P)$ is the FZP focused electric field and $E_0(P)$ is the plane-wave electric field at P if the FZP lens is not present.

The profile functions of three studied curved zone plates are: $y(z) = \sqrt{R^2 - (R - z)^2}$ for a spherical zone plate, $y(z) = \sqrt{4f_P z}$ for a parabolic zone plate, where f_P is the parabolic surface focal length, and $y(z) = z\tan\alpha$ for a conical zone plate, Fig. 17b, with $\alpha = \alpha_n = \text{const}$. The flat zone plate is defined as a limiting case of the conical zone plate, or for $\alpha \to \pi/2$.

The above equations have been applied for numerical computations and comparison between the focusing properties of the planar, spherical, parabolic, and conical convex zone plates. All zone plates have the same focal length ($z_p = F = 60$ cm) and aperture diameter $D = 2b_N = 60$ cm. The spherical surface radius R is also set to 60 cm, the parabolic surface has a focal length $f_p = 15$ cm and an opening

DOI 10.1007/978-981-4560-75-7_42-2

conical half-angle is $\alpha = \pi/4$. The plane zone plate is defined for $\alpha = \pi/4 - 10^{-3}$, all lenses are designed for the wavelength $\lambda = 3.2$ cm. For the listed dimensions and design wavelength the binary flat and curved FZP lenses have two and three open zones, respectively. From Fig. 18b is concluded that for the same in size apertures and focal lengths, the focusing superiority of the curved zone plates over the plane zone plate is well expressed. On the other hand, the focusing gains of the curved FZP lenses do not differ considerably one from another, while the conical zone plate lens displays the best focusing resolution.

Full Electromagnetic Simulation Methods For the binary FZP with noncircular outline (square or hexagonal) or more complex phase-correcting dielectric/metal-dielectric zone plates and antennas, the more precise full-wave electromagnetic methods are preferable. These are mainly the integral equation method (IEM), method of moments (MoM), finite-element method (FEM), finite-difference time-domain method (FDTD) and its varieties. The full electromagnetic methods give very realistic simulation outcomes for any FZP lens focal number F/D, while the KDI theory is an appropriate tool only for the FZP lenses with F/D equal or bigger than about 0.5–1.0.

The body-of-revolution (BOR)-FDTD method was applied recently in Reid and Smith (2006, 2007) for a full electromagnetic analysis of binary or grooved-dielectric microwave and millimeter wave FZP lenses and antennas. In the cited papers precise sets of design and optimization graphs for the FZP lenses and antennas are given.

In Fig. 19a, b, two sets of design graphs for the binary and quarter-wave FZP lens antennas are illustrated. From these graphs is easy found that for $F/\lambda = 40$ and $D/\lambda = 60$, the focusing gain FG of the binary FZP lens is 26 dB. dB, while of the quarter-wave FZP lens is 32 dB.

Flat FZP Lens Antennas

Diffraction Radiation Theory In this section the radiation theory of the flat FZP antennas is based on the vector Kirchoff's diffraction integral (Jackson 1975; Black and Wiltse 1987; Leiten and Herben 1992; Baggen and Herben 1993; Van Houten and Herben 1994; Hristov and Herben 1995; Hristov 2000). The diffraction integral is applied here to the lens antennas based on the simplest doublet of microwave half-wave FZP lenses: binary FZP lens, Fig. 6a, and phase-reversing FZP lens, Fig. 6e. The binary FZP lens consists of coaxial thin metal rings, while the phase reversal FZP is an assembly of solid dielectric phase-shifting rings of permittivity $\varepsilon = 4$, loss tangent $\tan\delta = 0.001$, and ring thickness $w = \lambda/2$. Both FZP lens antennas, illustrated in Fig. 20a, b, respectively, are illuminated by equal round corrugated feed-horns with phase centers set on the z-axis at a focal point $z = -F$. Here, by F is labeled the FZP lens antenna primary focal length.

Each FZP antenna has rotational symmetry around the z-axis and radiation aperture centered in the xOy plane. The odd half-wave (Fresnel) zones are left open (positive lens) and even ones are covered by metal/dielectric rings. The zone radii $b_1, b_2, b_3, \ldots$, are calculated by Eq. 1. The horn radiation pattern is modeled by the cosine scalar equation $G_f(\psi) = 2(q+1)\cos^q\psi$ (Silver 1984). The feed radiation pattern is shaped by changing the parameter q depending on the lens aperture edge illumination (EIL) taper, which is typically from -8 to -12 dB down to the center field maximum.

From structural and theoretical points of view the phase reversal dielectric FZP antenna is a more complex configuration. The theory of the binary FZP antenna is regarded as a particular case of the phase reversal FZP antenna theory.

The incident free-space ray $\rho(\psi)$ associated with the feed-horn spherical wave propagates through the phase-shifting dielectric ring as a refraction ray. The ray tracing through this phase reversal FZP lens, containing solid-dielectric and air-transparent rings, is illustrated in Fig. 20b.

DOI 10.1007/978-981-4560-75-7_42-2

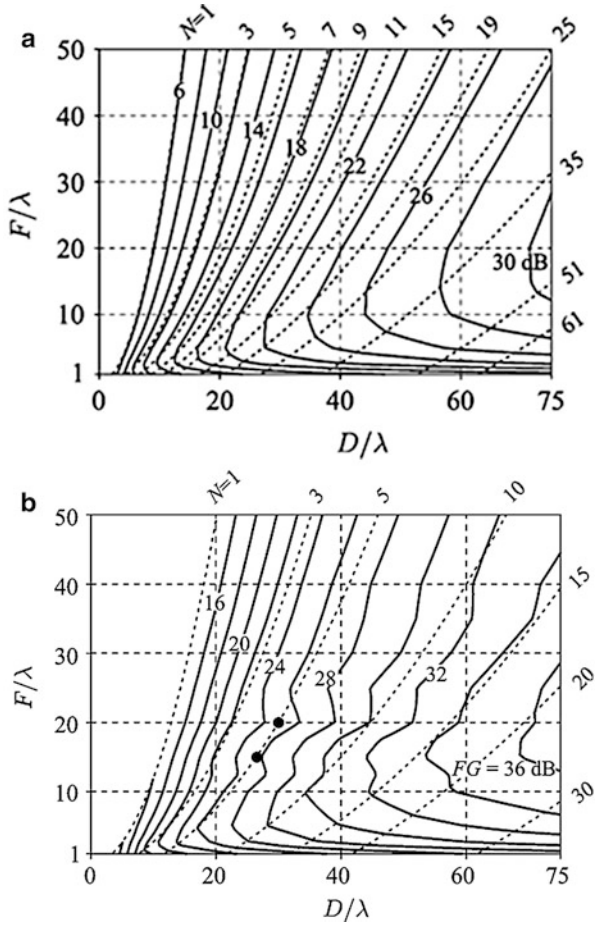

Fig. 19 Design graphs for (**a**) binary and (**b**) quarter-wave phase-correcting FZP lenses. *Solid lines* are contours of constant focusing gain FG, in decibels, *dashed lines* are for constant N

The refraction through the dielectric ring of a linearly polarized wave is characterized by multiple complex transmission coefficients: $T^{||} = \left|T^{||}\right|\exp\left(j\Phi_t^{||}\right)$ (for a parallel or magnetic polarization) and $T^{\perp} = |T^{\perp}|\exp\left(j\Phi_t^{\perp}\right)$ (for a perpendicular or electric polarization). In the lens output (aperture) plane $II - II'$ the refracted ray gives rise to an electric field $\mathbf{E}_d(\psi,\ \xi)$, which can be expressed as

$$\mathbf{E}_d(\psi,\ \xi) = C_f\sqrt{G_f(\psi)}\frac{\exp(-j\beta L(\psi))}{F + w}\cos\psi\ \mathbf{p}'_d(\psi,\ \xi) \tag{28}$$

where $\mathbf{p}'_d(\psi,\ \xi) = s_d\left(-T^{||}\cos\xi\hat{\mathbf{e}}_\psi + T^{\perp}\sin\xi\hat{\mathbf{e}}_\xi\right)$, $C_f = \sqrt{P_t Z_0/2\pi}$, and $L(\psi) = F/\cos\psi + \varepsilon w/\sqrt{\varepsilon - \sin^2\psi}$.

The multiple transmission coefficient $T^{||,\perp}$ of a dielectric ring is supposed equal to that of an infinite-in-extent dielectric plate with the same thickness w and is calculated according to Burnside and Burgener (1983).

The far electric field components $E_\theta^{(d)}$ and $E_\varphi^{(d)}$ are found as follows (Van Houten and Herben 1994):

DOI 10.1007/978-981-4560-75-7_42-2

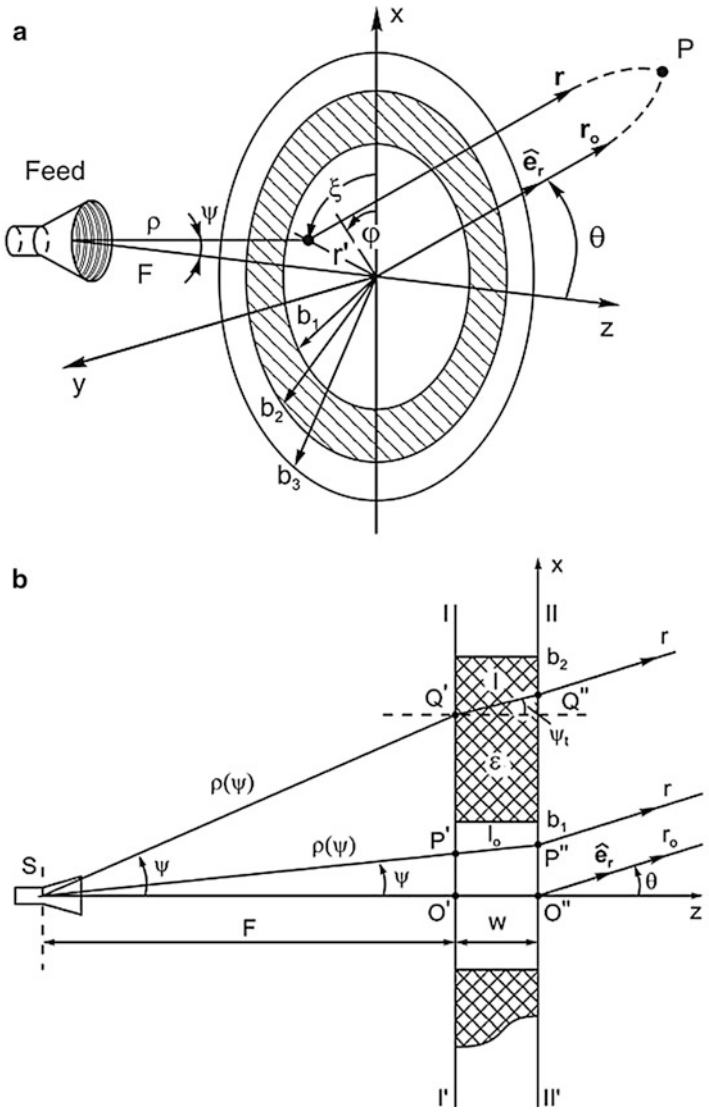

Fig. 20 Radiation geometry of: (**a**) binary and (**b**) phase-reversal FZP lens antennas fed by corrugated circular horns

$$E_{\theta}^{(d)}(\theta,\varphi) = -\pi C \cos\varphi \sum_{n} \int_{\psi_{n-1}}^{\psi_n} \exp(M_d(\psi)) O_d(\psi) I_{\theta}^{(d)}(\theta,\psi) d\psi \tag{29}$$

$$E_{\varphi}^{(d)}(\theta,\varphi) = -\pi C \sin\varphi \cos\theta \sum_{n} \int_{\psi_{n-1}}^{\psi_n} \exp(M_d(\psi)) O_d(\psi) I_{\varphi}^{(d)}(\theta,\psi) d\psi \tag{30}$$

where C, $\psi_{n,n-1}$ and the integral functions $O_d(\psi)$, $M_d(\psi)$, $N_d(\theta,\psi)$, $I_{\theta}^{(d)}(\theta,\psi)$, and $I_{\varphi}^{(d)}(\theta,\psi)$ can be also found in Hristov and Herben (1995), Hristov (2000).

DOI 10.1007/978-981-4560-75-7_42-2

The components $E_\theta^{(o)}(\theta, \varphi)$ and $E_\varphi^{(o)}(\theta, \varphi)$ of far field radiated by the open apertures are easily obtained from Eqs. 29 and 30 having in mind that the ray tracing is through the air rings with $\varepsilon = 1$ and $T^{||} = T^{\perp} = 1$. Thus, the above integral functions are considerably simplified.

The far-field E_θ and E_φ of the phase reversal FZP antenna are sums of the air-ring and dielectric-ring far fields

$$E_\theta(\theta, \varphi) = E_\theta^{(o)}(\theta, \varphi) + E_\theta^{(d)}(\theta, \varphi) \tag{31}$$

$$E_\varphi(\theta, \varphi) = E_\varphi^{(o)}(\theta, \varphi) + E_\varphi^{(d)}(\theta, \varphi) \tag{32}$$

The total far-field electric vector is a sum of the FZP antenna E_θ and E_φ vector components

$$\mathbf{E}(\theta, \varphi) = \hat{\mathbf{e}}_\theta E_\theta(\theta,\varphi) + \hat{\mathbf{e}}_\varphi E_\varphi(\theta, \varphi) \tag{33}$$

and the antenna directive gain pattern is calculated by

$$G(\theta, \varphi) = 10 \log\left(\frac{2\pi r^2}{Z_0 P_t}|\mathbf{E}(\theta, \varphi)|^2\right) \tag{34}$$

The quarter-wave FZP antenna comprising four dielectric rings in a full-wave zone is treated similarly. The numerical comparison between 30-GHz flat binary, phase-reversing, and quarter-wave FZP lens antennas with dimensions $F/\lambda = 15$, $D/\lambda = 18$, $EIL = -10$ dB gives roughly the following antenna radiation efficiencies: 12 %, 30 %, and 50 %. The efficiencies of the phase reversal and quarter-wave FZP lenses are for the following dielectric permittivities: $\varepsilon = [1,\ 4]$ and $\varepsilon = [1,\ 6.25,\ 4,\ 2.25\ ]$, respectively. All dielectric rings have delta tangent equal to 0.001.

Some Numerical Results for Flat FZP Lens Antennas Following the diffraction theory applied to the flat binary and dielectric phase reversal FZP lens antennas some numerical and experimental results for exemplary FZP antenna models are displayed in graph and table forms. The binary FZP antennas are made of positive or negative FZP lenses, which are supposed to have similar focusing characteristics. This opinion is checked numerically on 11.1-GHz flat FZP antennas with a lens aperture diameter $D = 100$ cm and a focal length $F = 200$ cm (or for $\tilde{f} = F/D = 2$). The lenses are illuminated by corrugated feed horns producing edge illumination level $EIL = -11$ dB.

In Fig. 21a are drawn the E-plane directive gain radiation patterns of both binary positive (solid line) and binary negative (dashed line) FZP lens antennas, in comparison with the phase reversal (dotted line) FZP lens antenna (Hristov 2000). It is evident that there is no notable difference between the pattern main lobes. The pattern distinction is bigger in the sidelobe areas. The positive FZP lens antenna with odd open zones has 0.6 dB higher peak gain, while the negative one with even open zones has a narrower beamwidth and lower near sidelobes. The positive zone plate has a central zone open that ensures a minimum reflection from the plate to the feed, better feed matching and somewhat larger frequency bandwidth. In Fig. 21b are contrasted the normalized radiation patterns of phase-reversal (dashed line) and quarter-wave (solid line) FZP lens antennas equal in diameter and focal length.

A combination of the Kirchhoff diffraction theory (for the main-lobe region) with the uniform theory of diffraction (UTD) for the sidelobe regions, leads to much closer simulated and measured radiation patterns (Baggen and Herben 1993; Sluijter et al. 1995). In Fig. 22a, the measured far-field pattern (solid line) is compared to the computed one (dotted line). Directive gain function versus frequency for the

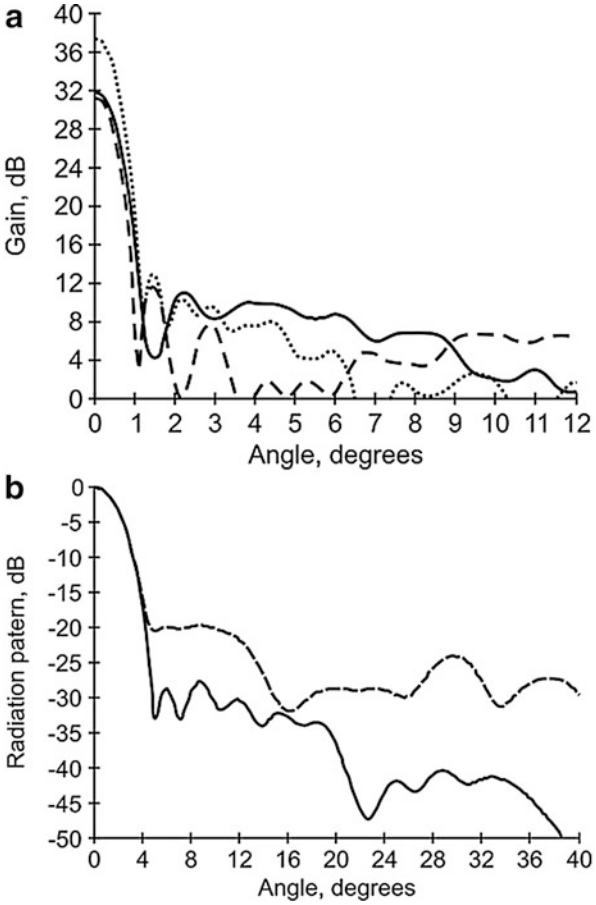

Fig. 21 Directive gain radiation patterns of: (**a**) binary FZP lens antennas, positive FZP (*solid line*), negative FZP (*dashed line*) and phase-reversal FZP lens antenna (*dotted line*), and (**b**) phase-reversal (*dashed line*) and quarter-wave (*solid line*)

same binary FZP lens antenna (D = 1.12 m, F = 0.71 m and design frequency f = 11.5 GHz) is illustrated in Fig. 22b. The theoretical graph is drawn with a solid line and measured data are shown as spread circles.

As is described above in the text, the binary FZP lens holds a multiharmonic focusing behavior. Similar actions hold also the binary, phase-reversing, and other phase-correcting FZP lens antennas. In Fig. 23 is demonstrated the harmonic gain and efficiency behavior of the phase-reversing (solid line) and quarter-wave (dashed line) FZP lens antennas, designed for a frequency f = 30 GHz, focal length F = 264 mm, aperture diameter D = 301.5 mm, and edge illumination level EIL = −10 dB (Hristov 2000). The gain curves are drawn in Fig. 23a and the aperture efficiency curves are shown in Fig. 23b, both in the range 10–180 GHz. The phase-reversing FZP lens antenna has almost constant directive gain of about 37.5 dB but very different efficiency maxima at 30 GHz, 90 GHz, 150 GHz, etc., or similarly to the binary FZP lens antenna. It is evident that the phase-reversing FZP lens antenna behaves as a frequency-selective antenna with a multiple-frequency ratio 1:3:9, ... The antenna aperture efficiency is 38.2 % at the design frequency of 30 GHz and quickly goes down for the harmonic frequencies of 90 GHz, 150 GHz, and so on.

Rather different is the frequency performance of quarter-wave FZP lens antenna with first three periodic gain maxima of about 41 dB taking place at 30 GHz, 60 GHz, and 90 GHz, or according to the multiple-frequency ratio 1:2:3. . . The antenna has a satisfactory efficiency of about 60 % at 30 GHz and 37.3 % at 60 GHz.

Some Early FZP Lens Antennas and Applications One of the first binary microwave FZP antenna is published in Van Buskirk and Hendrix (1961). These authors built and measured X-band FZP antennas comprising binary FZP lenses with one, two, or three open half-wave zones. Two types of feeds, a half-wave dipole and turnstile, have been explored. Fig. 24 shows the full 360-degree experimental radiation pattern of the FZP antenna with a binary lens of three open zones. This radiation pattern is of great interest because clearly shows the forward (transmission peak) and backward (reflection peak) pattern areas. Both transmission (front) and reflection (back) beams have almost the same peak levels and 3-dB beamwidth of about 4 deg, which is nearly identical to the beamwidth of parabolic antenna with the same aperture diameter. As expected, the aperture radiation efficiency of the binary FZP antenna is very low, only about 10 % versus 55–70 % for the typical parabolic antenna.

A polyethylene phase reversal zone plate lens fed by a rectangular horn is integrated in a 33-GHz simple and low-cost homodyne Doppler radar, Fig. 25 (Lazarus et al. 1979). The zone plate had the following dimensions: $w = 9$ mm, $F = 180$ mm, and $D = 300$ mm ($\tilde{f} = F/D = 0.6$).

A 21-inch-diameter single-dielectric quarter-wave FZP lens antenna is utilized in a millimeter-wave radio transceiver, Fig. 26 (Norden Systems 1984; Thornton and Strozyk 1983). At 37.8 GHz the transceiver FZP antenna has a gain of 41.5 dB, beamwidth of 1.1 deg, and sidelobes less than −24 dB.

Off-Axis Scanning in Flat Zone Plate Lens Antenna with Circular Fresnel Zones Scanning properties of the folded zone plate and antenna were initially discussed in Van Buskirk and Hendrix (1961), where is supposed that the maximum scan (off-axis) angle should not exceed ±20 deg. The first application of FZP antenna for scanned satellite TV reception is described in Shuter et al. (1984). The antenna main lobe was pointed to the satellite simply by scanning the feed-horn ±15 degrees off axis with a signal loss not more than 1 dB.

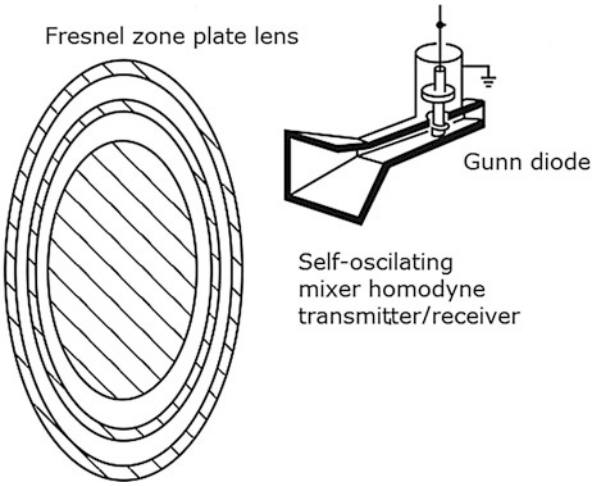

Fig. 25 Doppler radar antenna with phase-reversing FZP lens antenna

Fig. 26 Millimeter-wave radio transceiver with quarter-wave FZP lens antenna

A comprehensive theoretical study comparing the scan performances of a binary round-zone FZP antenna and a parabolic dish antenna is completed in Baggen et al. (1993). The main beam scanning is illustrated in Fig. 27. There, by displacing the feed instead of rotating the whole antenna, TV signals from different satellites are received. It is proved that the binary FZP lens with circular zones has nearly circular scan curve, while the scan curve of the parabolic reflector is the so-called Petzval line. From this follows that the main lobe scan angle of the FZP antenna is somewhat bigger than that of the parabolic antenna.

Flat Offset Antenna with Elliptical Zone Plate For realizing a more efficient off-axis scanning in a larger angular sector the circular zone plate should be redesigned to an elliptical zone plate.

A binary elliptical zone plate made of metal (foil) zone rings and attached to an office window or wall is illustrated in Fig. 28 (Mawzones Ltd Leaflet 1992). The FZP antenna consisting of attached zone plate and a feed-horn could be applied, for example, as a terminal device in a direct communication satellite link.

Beam-Scanning in Binary FZP Antenna Based on Photoconductivity A binary FZP antenna lens studied in Hajian et al. (2003) includes a semiconductor wafer (silicon or gallium arsenide) in which a

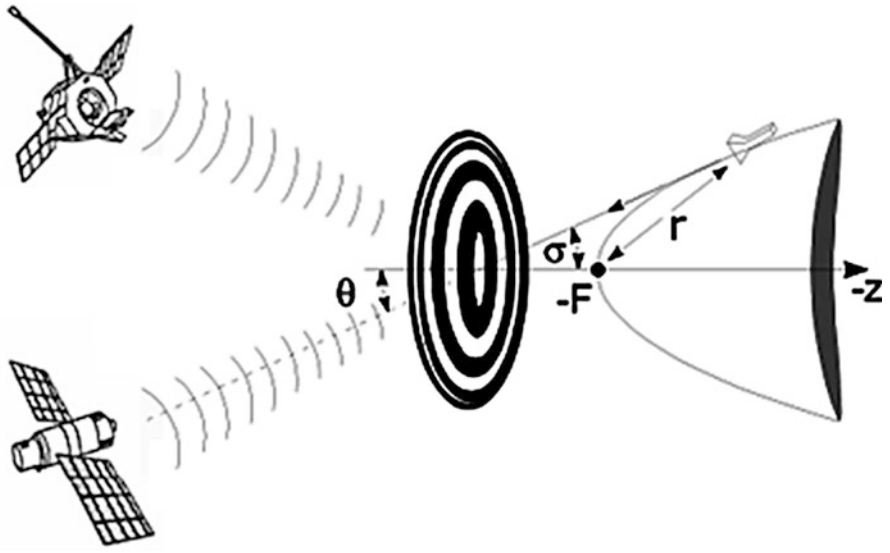

Fig. 27 Defocused Fresnel zone plate antenna for satellite scan purposes

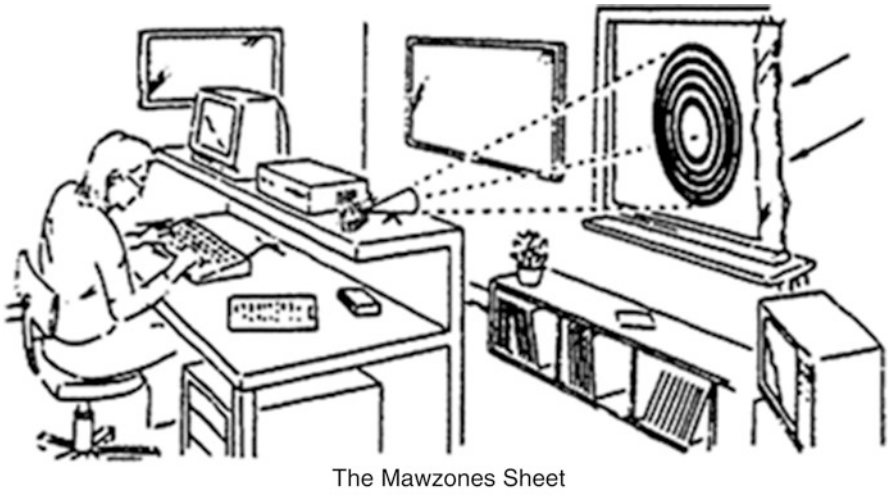

Fig. 28 Attached to window off-set binary Fresnel zone plate as an element of computer satellite link antenna

spatially variable density of the charge carriers is realized through a selective optical (laser) illumination. It is proved theoretically that the beam of such a circular-zone FZP antenna can be scanned by reconfiguring the wafer masking simply by changing the wafer conductivity in the zones by a variable laser illumination.

Low-Profile Fresnel Zone Plate Antenna Arrays

The microwave and millimeter wave FZP lenses are (i) high-profile (or long-focal) for a focal factor $\tilde{f} = F/D \geq 0.5 - 1.0$ or (ii) low-profile (short-focal) if $\tilde{f} = F/D \geq 0.25 - 0.5$. The low-profile lens antennas have a small overall volume of the combined lens and feed, and are suitable for effective IC (integrated circuit) arraying.

DOI 10.1007/978-981-4560-75-7_42-2

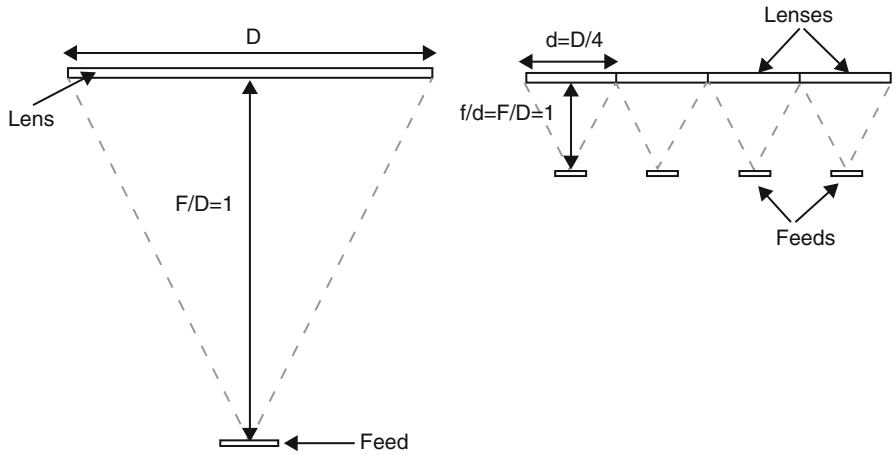

Fig. 29 Profile comparison between big single FZP lens antenna (*left*) and array of small FZP lens antennas (*right*)

A concept for the FZP lens antenna depth reduction involves replacing a single large-diameter lens with an array of small-diameter FZP lens antennas 2006 ili 2004??? Koi publkatcii sa tuk? This concept is illustrated in Fig. 29.

Let the single big FZP lens has a focal factor $\tilde{f} = F/D = 1$, and the same ratio $f/d = 1$ is fixed for the linear array of small FZP lenses. The array lens diameter is $d = D/x$, where $x = 4$ is the number of array lens elements. Thus, the antenna depth reduction of the lens antenna is made possible because each array element diameter is a portion of the big antenna diameter or d=D/4.

The research and applications of FZP antenna arrays are still in their initial stage. Almost all new original ideas and results related to this topic along with many others like the aperture shapes of FZP antenna array elements, FZP reference phase, FZP subwavelength resolution, etc. can be found in the recently published book (Minin and Minin 2008a).

Flat FZP Reflector Antennas

Folded (Reflector) FZP Antenna: Initial Arrangement The antenna based on the binary FZP lens of metal rings is a simple but not effective lens. It has two principal foci: one for transmission through the open zones and another for reflection by the metal zone rings. By placing a plane quarter-wavelength reflector behind the metal zone plate the incident plane wave transmitted through the open zones is turned back and interferes constructively at the reflection focus P_1, Fig. 30a (Van Buskirk and Hendrix 1961). This folded binary FZP lens acts like a phase reversal zone plate antenna. Fig. 30b is an artistic view of the Van Buskirk's and Hendrix's feasible construction of a simple and cheap radio telescope based on the FZP reflector.

By simple changes Eqs. 29 and 30 for the far-field components are transformed to similar equations for the folded zone plate antenna, as follows:

$$E_\theta(\theta,\varphi) = -\pi C\cos\varphi \sum_{n=1}^{N} (-1)^n \int_{\psi_{n-1}}^{\psi_n} O(\psi) e^{M(\psi)} I_\theta(\theta,\psi) d\psi \tag{35}$$

$$E_\varphi(\theta,\varphi) = -\pi C\cos\varphi\cos\theta \sum_{n=1}^{N} (-1)^n \int_{\psi_{n-1}}^{\psi_n} O(\psi) e^{M(\psi)} I_\varphi(\theta,\psi) d\psi \tag{36}$$

with n = 1, 2, 3,. . . N.

FZP Antennas with Machined and Printed Reflectors A typical FZP reflector antenna consisting of precisely machined grooved-dielectric zone plate with a disk reflector and a feed-horn is drawn in Fig. 31a.

Most likely, the first printed zone plate reflector antenna is described by Huder and Menzel (1988). This is a single-layer 94-GHz folded zone plate antenna manufactured by means of a standard microstrip technology, comprising a ground plane 125 mm in diameter and Fresnel-zone metal rings spaced from the ground plane by a dielectric substrate 0.508 mm in depth. The antenna is fed by an open-ended waveguide WR-10 with an aperture placed at a focal distance of 80 mm. The measured antenna parameters for an amplitude edge taper of −10 dB are: directive gain of 35 dB, 3-dB beamwidth of 1.6 deg, sidelobe levels less than −19 dB, cross-polar level less than −25 dB, and mismatch loss equal to 15dB.

A printed three-layer zone plate reflector is illustrated in Fig. 31b (Guo and Barton 1991, 1992, 2002). Shown above is the reflector front view, and below is drawn its cross-sectional view. More exactly, the plate consists of three layers metal rings separated by three dielectric substrates. On the basis of this quarter-wave zone plate a reflector antenna has been developed, fed by a polyrod feed that yields about −11 dB EIL level. The maximum antenna gain of 34.75 dB occurs at 11.8 GHz, and a 3-dB frequency bandwidth of about 13 % is estimated from the measured gain versus frequency curve.

Figure 32a illustrates a printed resonant-ring structure of quarter-wave FZP reflector (Guo 1993). The first three subzones are covered by arrays of different in diameter rings and the last one is left blank. A reflector FZP prototype has a diameter of 594 mm and focal length of 475.2 mm. The FZP reflector fed by a helical antenna forms an 11.4-GHz reflector antenna with a circular polarization, gain of 33.4 dB, radiation efficiency of 43 %, and frequency bandwidth of about 10 %.

Figure 32b shows a 9.375-GHz folded zone plate fed by a monofiliar backfire helical antenna (BHA) with the following design parameters: pitch angle of 26 deg, helical circumference C = 0.83 λ, number of turns N = 6, and small reflector diameter of 7.9 mm (Yamauchi et al. 1990). The backfire helix plus FZP reflector antenna has a focal length of 40 mm, diameter of 260 mm, and the next measured parameters: a peak gain of 21 dB at 9.375 GHz and a gain greater than 20 dB in the frequency range from 9 to 9.8 GHz. The axial polarization ratio is less than 1.5 and VSWR is less than 1.6 over the same frequency range.

A FZP-FSS compound lens, Fig. 33a, consisting of a binary Fresnel zone plate (FZP) and frequency-selective screen (FSS) was proposed and studied recently (Fan et al. 2010). The FZP has eight circular zones totally, four open and four closed, and the FSS is a square array of 40 × 40 four-leg loaded elements, Fig. 33b, cut in a thin metal sheet. The FZP-FSS lens is designed for a paraxial plane-wave illumination at the frequency of 12 GHz (λ = 2.5 cm), with a focal length F = 15 cm. The compound lens square side is 16λ = 40 cm. Both lenses, FZP and FZP-FSS, are simulated and analyzed numerically

by means of a specially developed hybrid PSTD-FDTD algorithm and software. The PSTD-FDTD results are contrasted with those obtained by lens prototype measurements, Fig. 34a. Some attractive focusing and spectral properties of the FZP-FSS lens compared to the same-size FZP lens have been found: (i) frequency filtering enhancement, (ii) about 2 dB increase in the peak focusing intensity, and (iii) more than 4 dB reduction in the first off-axis maximum.

The compound FZP-FSS lens has somewhat better 3dB focal resolution δ equal to 5.5 deg versus 5.8 deg for the single FZP lens. As seen in Fig. 34b the intensity of FZP-FSS lens at focal point ($Z = F$, $X = Y = 0$) is 19.1 dB.

Offset Reflector FZP Antenna Designs An effective X-band four-layer offset antenna is reported in Guo et al. (1994). Fig. 35a shows the front and sectional view of the antenna FZP reflector, which produces five phase shifts ($Q = 5$) in each full-wave zone: 0°, 72°, 144°, 216°, and 288°. The substrate layer depth d is calculated by $d = \lambda\sqrt{1 - \sin^2\theta_{off}/\varepsilon}/Q\sqrt{\varepsilon}$, where ε is the relative permittivity of each dielectric substrate and θ_{off} is the offset angle. Measured prototype of this offset FZP antenna is designed for 10.39 GHz and has a reflector 320 × 320 mm^2 in size and 20-degree offset angle. Its focal length is 190 mm. The antenna is fed by a rectangular horn with aperture dimensions 41 mm and 28 mm. The measured antenna radiation efficiency is 61 %, which is a very good value for such a complicated design.

A simple 1.5 × 1.5 m^2 offset antenna with a phase-reversing zone plate outside antenna is described in Sazonov (1999). The antenna receives 12.5-GHz DBS TV signals with a similar quality as a standard 1.2-m parabolic antenna.

Curvilinear FZP Antennas

Axially Symmetric FZP Antennas The binary 2D or 3D curvilinear (3D) Fresnel zone plate lens can be formed on an arbitrary-shaped surface, but the zone plate lens with a rotational silhouette is most simple and efficient. The spherical, cylindrical, and conical FZP lenses are next in simplicity to the flat Fresnel zone plate. The 3D or curvilinear FZP lens has more degrees of freedom for parametric optimization compared to the flat FZP lens. For example, in the axially symmetric conical lens a third dimension is the lens length (thickness) t, which is related to the cone semi-angle α.

DOI 10.1007/978-981-4560-75-7_42-2

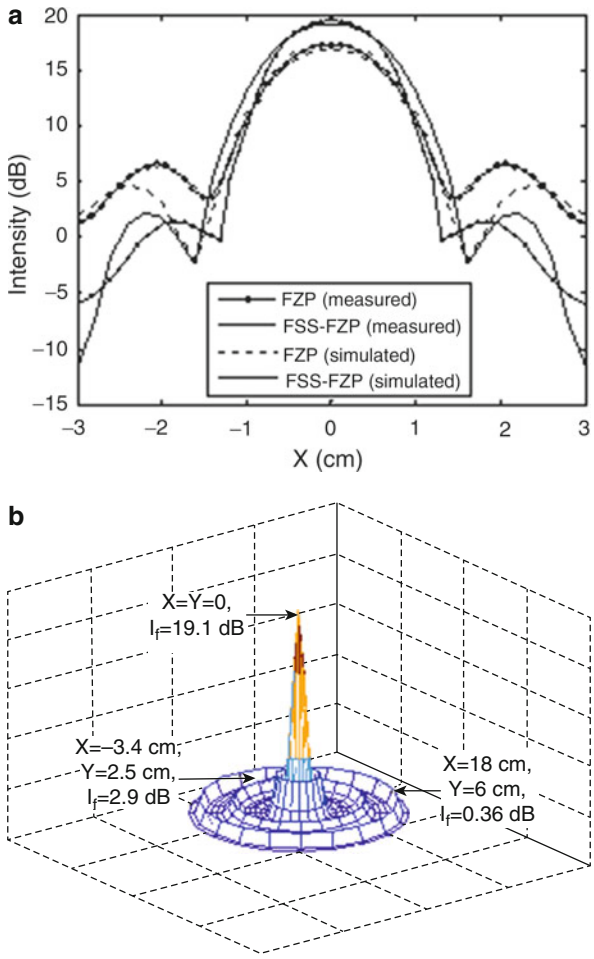

Fig. 34 Intensity distribution: (**a**) of FZP and FZP-FSS lenses along *X*-axis, (simulated and measured) and (**b**) 3D graph of intensity versus axes X and Y. Both intensity figures are valid for the transverse focal plane Z = F

Typically, the known curvilinear dielectric FZP configurations consist of phase-correcting elements (ribs/corrugations) that follow the FZ surface curvature and are difficult to produce especially at millimeter wave and terahertz frequencies.

First most comprehensive analytical studies of the curvilinear FZP lenses and antennas go back to the early 1970s, when K. Dey and P. Khastgir developed the diffraction theory of microwave curvilinear zone plate antennas. Rigorous theoretical investigations of the spherical and parabolic zone plate antennas has been made on the basis of the Kirchhoff diffraction integral (Dey and Khastgir 1973a, b, c; Khastgir et al. 1973). It has been shown that for a given antenna aperture the microwave spherical and paraboloidal zone plate lenses/antennas are superior to the flat zone plate lenses/antennas in two aspects: (i) greater number of zones can be constructed, and in result, (ii) bigger focusing gain and resolution can be attained along the zone plate axis. The problem of determining the off-axis defocus of curvilinear zone plate in the specific case of paraboloid of revolution has been analyzed later on in Khastgir and Bhomwmick (1978).

In order to obtain exact solutions Dey and coauthors have completed their theoretical studies for each zone plate curvature separately. An approximated universal solution of the Kirchhoff diffraction integral (KDI) for any lens profile shape is presented in Kamburov et al. (2005). This KDI theory is valid for a half-wave axially symmetric FZP antenna and is based on the conical-segment lens profile approximation. Vector equation for the electric far field is derived from which follow expressions for the antenna co- and

DOI 10.1007/978-981-4560-75-7_42-2

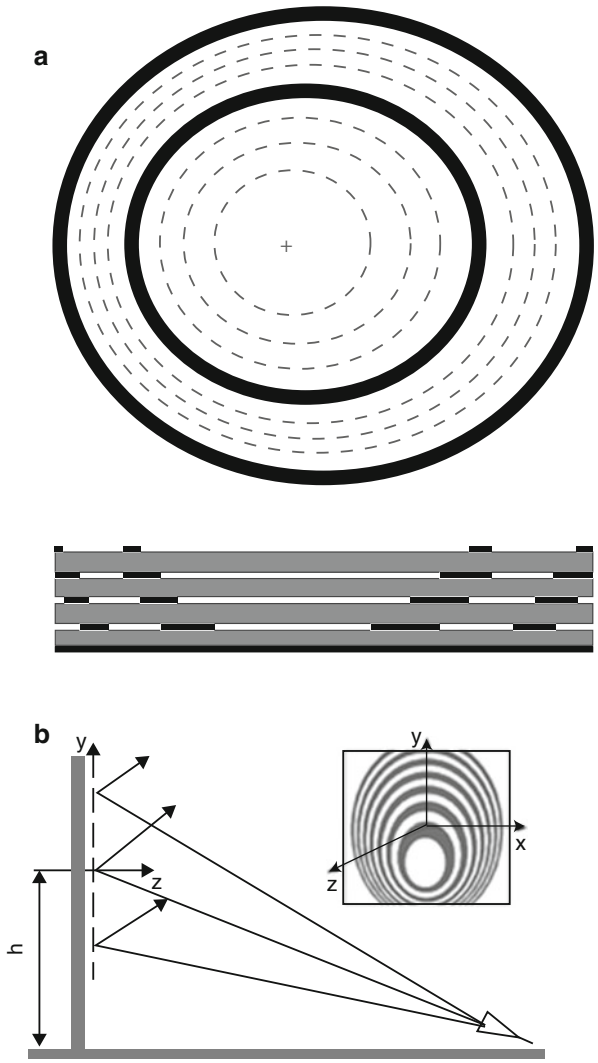

Fig. 35 Offset zone plate reflector antennas: (**a**) printed four-layer offset reflector and (**b**) offset FZP reflector antenna with elliptic zones

cross-polar radiation patterns, directive gain, and radiation efficiency. The proposed theory is utilized for the numerical analysis and comparison of 140-GHz curvilinear half-open FZP lens antennas with flat, conical, parabolic, and spherical apertures with the same diameter.

Figure 36a shows the geometry of the curvilinear half-open FZP lens antenna with a feed located at the lens primary focus P_1 (Hristov et al. 2005). The curvilinear FZP lens is assumed with an axially symmetric surface. The focal length of the lens is $F = F_a + t$. It is concave-side lens illuminated by a spherical wave from the feed at P_1. The m^{th} and $(m-1)^{th}$ zone radii b_m and b_{m-1} and are calculated by Eq. 24. Figure 36b shows the numerical copolar radiation patterns of two FZP lens antennas designed for a frequency of 2 GHz (Hristov and Feick 2001). Each antenna is fed by a scalar horn. The first antenna lens is a big flat zone plate, 30 m in diameter. The second FZP lens is a semispherical plate (shell) with the same aperture diameter. The flat and spherical FZP lenses also have equal radii and focal lengths or $R = F = 15$ m.

Table 1 displays the main parameters of both antennas. Due to the surface curvature the semispherical FZP lens has 1.65 times bigger number of zones than the flat FZP lens. For achievement of one and the same field edge illumination of −10 dB, the feed gains of both antennas should be different. From Table 1

DOI 10.1007/978-981-4560-75-7_42-2

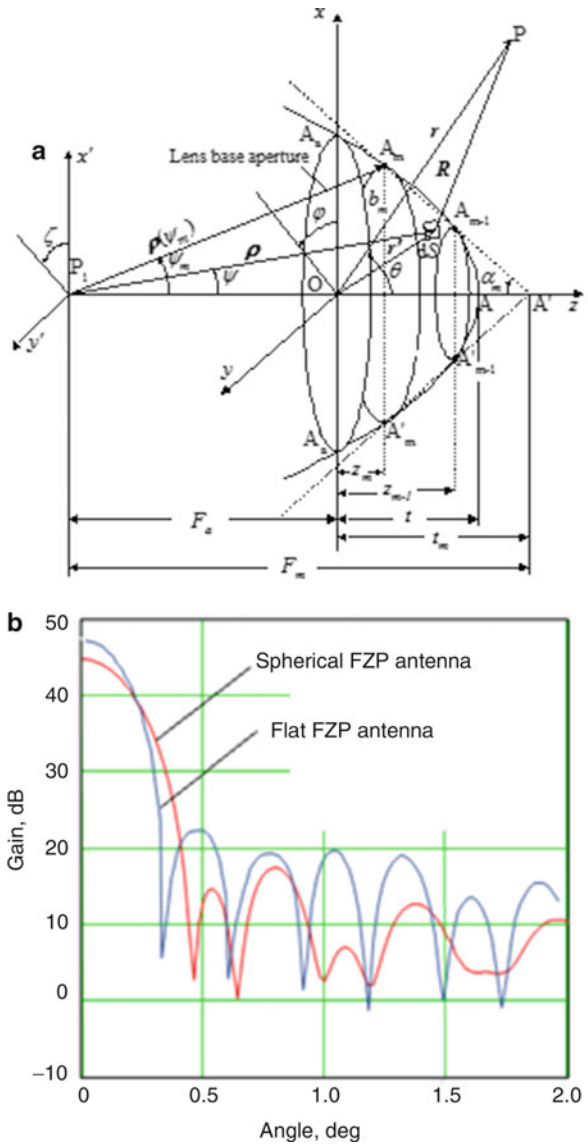

Fig. 36 Far-field of FZP lens antenna: geometry of curvilinear of flat antenna surface and (**b**) gain radiation patterns of flat (*blue line*) and spherical (*red line*) binary FZP lens antennas

Table 1 Comparative table for flat and semi-spherical FZP lens antennas

Parameters/FZP antennas	Number of zones	Feed gain (dB)	Antenna gain (dB)	Beamwidth (deg)	Antenna efficiency (%)
Flat FZPlens antenna	82	10.6	44.8	0.33	7.7
Semi-spherical FZP lens antenna	135	4.3	47.7	0.28	15.2

it is concluded that for the same-size aperture the curvilinear FZP lens antenna has much bigger gain and efficiency, and slightly narrower main beam compared to the corresponding flat FZP lens antenna.

A parabolic FZP antenna comprising metal zone-plate rings in front of a solid parabolic reflector was proposed, fabricated, and reported in Delmas et al. (1993). More exactly, the parabolic zone plate reflector antenna is designed and built to have two symmetric diffraction focal points P_1 and P_2 with an angular

Table 2 Characteristics of parabolic dish and FZP antennas

Characteristics	**Parabolic (dish) antenna**	**FZP (diffractive) antenna**
Optic schematics	Reflector antenna	Lens or reflector antenna
Feed blockage	Yes	Yes or no
Surface shape	Fixed (parabolic)	Arbitrary
Building material	Metal or carbon	Lowloss dielectric (plastic)
Precision in machining	$\pm\lambda/32$	in the range $\pm\lambda/5 - \pm\lambda/10$
Satellite pointing	By whole antenna rotating	By moving receiver only
Multi-beam mode	Constrained	$\pm$ 15–20 deg
Frequency band	Wide	Variable narrow bands

spacing of about 40° between them. The antenna prototype is utilized for simultaneous reception of TV programs from two different geostationary satellites. At a design frequency of 12 GHz, the basic antenna dimensions and parameters of the single-layer zone plate backed by a parabolic reflector of 900 mm in diameter are: parabolic surface focal length $F_p = 290$ mm, lateral diffraction focal length $= 620$ mm, total number of zones $N = 10$, zone plate height above the parabolic reflector $= 6.25$ mm, peak gain $= 35$ dB, 3-dB beamwidth $= 2°$, sidelobe level $= -20$ dB, and cross-polar level $= -22$ dB.

Important theoretical and practical progress in the area of curvilinear FZP lenses and antennas is done by I. Minin and O. Minin. These researchers have developed and examined experimentally many spherical, parabolic, and conical dielectric FZP lenses and antennas in the frequency range 40–95 GHz (Minin and Minin 1988, 1989, 2004, 1990, 2005a, 2008a). One of the studied FZP antenna models has a half-wave phase reversal spherical zone plate with $D/\lambda = 36$ and $D/F = 1.48$. The measured antenna gain is 34 dB, and the H- and E-plane sidelobe levels are less than -28 dB and -18 dB, respectively.

Composite conical-parabolic lens antenna consisting of two portions, conical and parabolic, is pictured in Fig. 37a. A semispherical FZP lens antenna mounted on a car roof, Fig. 37b, serves for satellite TV signal reception. The shown FZP antenna prototypes are fabricated from grooved-dielectric shells, which serve simultaneously as FZP lenses and antenna radomes.

A very useful table comparison between the parabolic (reflective) antenna and FZP (diffractive) antennas is found in Minin and Minin (2008a). Slightly altered, the table is presented here as Table 2. The characteristics included are mainly related to the antennas for satellite TV reception and communications.

DOI 10.1007/978-981-4560-75-7_42-2

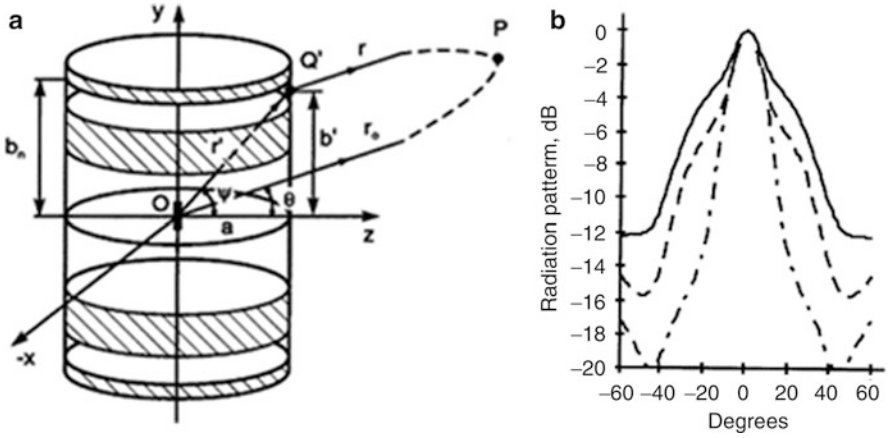

Fig. 38 Cylindrical FZP antennas: (**a**) geometry of original cylindrical FZP lens antenna and (**b**) yOz-plane radiation patterns of binary (*solid line*), phase-reversing (*dashed line*) and quarter-wave (*dash-dotted line*) FZP antennas

Cylindrical FZP Lens Antennas Cylindrical FZP lens antenna with an uniform horizontal radiation pattern is proposed and examined in Ji and Fujita (1996). The rim height b_n, Fig. 38a, is calculated by the corresponding to the flat FZP zone radius equation, Eq. 2. I. Minin and O. Minin suggested more exact empiric equation for the rim height, which leads to antenna gain increase.

By virtue, the binary cylindrical FZP antenna is a low-efficiency radiation structure. The opaque Fresnel zones in the examined antenna are thin circular metal rings and the feed is a half-wave dipole located at the mid-point O, Fig. 38a.

Based on the original binary FZP configuration several modifications with enhanced radiation efficiency are examined numerically (Hristov 1999). As in the flat FZP lens the efficiency is grown by replacing the binary zone plate structure with a phase-reversing or quarter-wave phase-correcting one. A 9-GHz cylindrical Fresnel zone antenna 80 mm in diameter is studied numerically. The vertical yOz-plane radiation patterns with main-beam maxima in the horizontal plane xOz are illustrated in Fig. 38b. The antenna directive gain corresponding to each antenna pattern is 5.1 dB, 6.4 dB and 7.7 dB for the binary, phase-reversing and quarter-wave phase-corrected lens antenna.

If the upper half of the cylindrical Fresnel zone antenna is set on a ground plate and fed by a quarter-wavelength monopole, an asymmetric zone-lens antenna is realized (Hristov 1999). As expected, the asymmetric antenna has a pattern beam slightly tilted above the horizon.

Both symmetric and asymmetric cylindrical Fresnel zone antennas are quite suitable as base station or car mobile antennas in wireless communication and broadcasting radio systems.

FZP Antennas for Terahertz Frequencies

Introduction Text The terahertz frequencies range from 100 to 10,000 GHz or from 0.1 to 10 THz (Lee 2009). Often, the frequencies between 100 and 1000 GHz are called low-terahertz or sub-terahertz frequencies to which correspond free-space wavelengths between 3 and 0.3 mm. Two significant problems arise at terahertz wavelengths: one is keeping losses low, which leads to the use of low-loss solid dielectrics or low-permittivity, foamed dielectric materials (Wiltse 2012). Depending on the number of phase correction steps the groove dielectric FZP lens might be small fractions of the wavelength.

Example: for a frequency of 500 GHz (or $\lambda = 600$ μm) and dielectric permittivity $\varepsilon = 2.1$ (Teflon), the height w_1 of each quarter-wave groove calculated by Eq. 8 is equal to 333 μm. This groove size is still likely for machining. At higher frequencies and finer phase correction a plastic with a permittivity around

DOI 10.1007/978-981-4560-75-7_42-2

1.03–1.05 (a dense foam, for instance) might be more appropriate. For the same frequency and a permittivity of 1.05 the groove depth is 6 mm, or the FZP lens becomes easy for machining but rather thick. For higher terahertz frequencies special microelectronic technologies like a chemical deposition might be necessary. Examples of terahertz FZP lenses produced by use of lithography and reactive ion etching on high-resistivity silicon are demonstrated in Walsby et al. (2002), Wang et al. (2002).

The design and practical basics of millimeter-wave and low-terahertz phase-correcting zone plates for constructing wireless transmission antennas were reported half a century ago (Sobel et al. 1961; Cohn et al. 1962; Cotton et al. 1962). More recently, important theoretical and design methods have been developed and described in Goldsmith and Moore (1984), Wiltse (1994, 2004), Goldsmith (1998).

Low-Terahertz FZP Antenna for Integrated-Circuit (IC) System A folded FZP lens antenna integrated with a bolometer device is proposed, fabricated, and studied in detail in Gouker and Smith (1992). The binary zone plate lens is printed on a grounded fused silica substrate, where the ground metal plane is serving as a FZP reflector. On the opposite side a strip dipole is printed at the focal point $z = F$. The energy collected by the resonant feed-dipole antenna is detected by a bismuth bolometer at the dipole terminals. All components are made by use of simple integrated-circuit (IC) fabrication technique. Another feature of the FZP antenna design is the small focal length–to–aperture diameter ratio (F/D ranges from 0.1 to 0.5). The antenna models described are designed for a frequency of 230 GHz ($\lambda \cong 1.3$ mm). Based on the diffraction Kirchhoff integral the authors developed a far-field theory for the prediction of antenna radiation pattern. Measurements of FZP antenna prototype with $F = 10$ mm and $D = 21.4$ mm have shown a good agreement with the diffraction theory. The average experimental gain is 23.3 dB, and the E-plane 3-dB beamwidth is 4.2 deg.

Low-Terahertz Cavity-Backed FZP Lens Antenna A compact 270-GHz cavity-backed binary Fresnel zone plate lens antenna integrated in a low-temperature cofired ceramic (LTCC) is proposed, fabricated, and studied in Xu et al. (2013), Fig. 39, cross-section and face views. The gain of this low-terahertz FZP lens antenna is enhanced by using a back cavity formed via sidewall and ground plane. A compact feed transition is realized for a broader-band input match.

The measured results show that the cavity-backed FZP antenna achieves a peak gain of 20.8 dB at 270 GHz and a 3-dB gain bandwidth of 9.1 GHz (or about 4 %). These results reasonably validate the design concept, fabrication, and measurement. The proposed compact FZP antenna is a candidate for the future terahertz substrate-integrated planar antenna systems.

Microwave FZP Antenna Operation at Terahertz Frequencies The frequency and space domain antenna harmonic operation of a binary 90-GHz FZP lens antenna is studied by use of vectorial Kirchhoff-Fresnel diffraction theory in the frequency band 50–1550 GHz (Hristov 2011). The lens is made of ten thin metal rings printed on a thin low-loss substrate, whose material loss is taken into account in the process of calculation. The lens antenna has a diameter $D = 100$ mm and focal length $F = 66.7$ mm. The outmost (10th) Fresnel zone is obstructed by a narrow ring of width $\Delta b = 2.83$ mm. The feed horn is supposed to preserve its directive gain function $G_f(\psi) = 2(q + 1)\cos^q\psi$ one and the same in the whole frequency band. The binary FZP lens of the numerically studied antenna produces at primary (design) frequency $f_1 = 90$ GHz and all odd secondary terahertz harmonics ($3f_1 = 270$ GHz,$5f_1 = 450$ GHz f_0, etc.) one and the same directive gain of about 29 dB, Fig. 40a. The comb-shaped frequency response promises attractive filtering capacity of FZP lens antenna, because for the present FZP design all harmonic gain peaks are identical in shape, bandwidth (16.5 GHz), and top values. As expected, the antenna aperture efficiency rapidly goes down with the frequency, following the square of the reverse odd harmonic ratio 1, $(1/3)^2$, $(1/5)^2$and so on. It is clear that at the terahertz harmonic frequencies the antenna

DOI 10.1007/978-981-4560-75-7_42-2

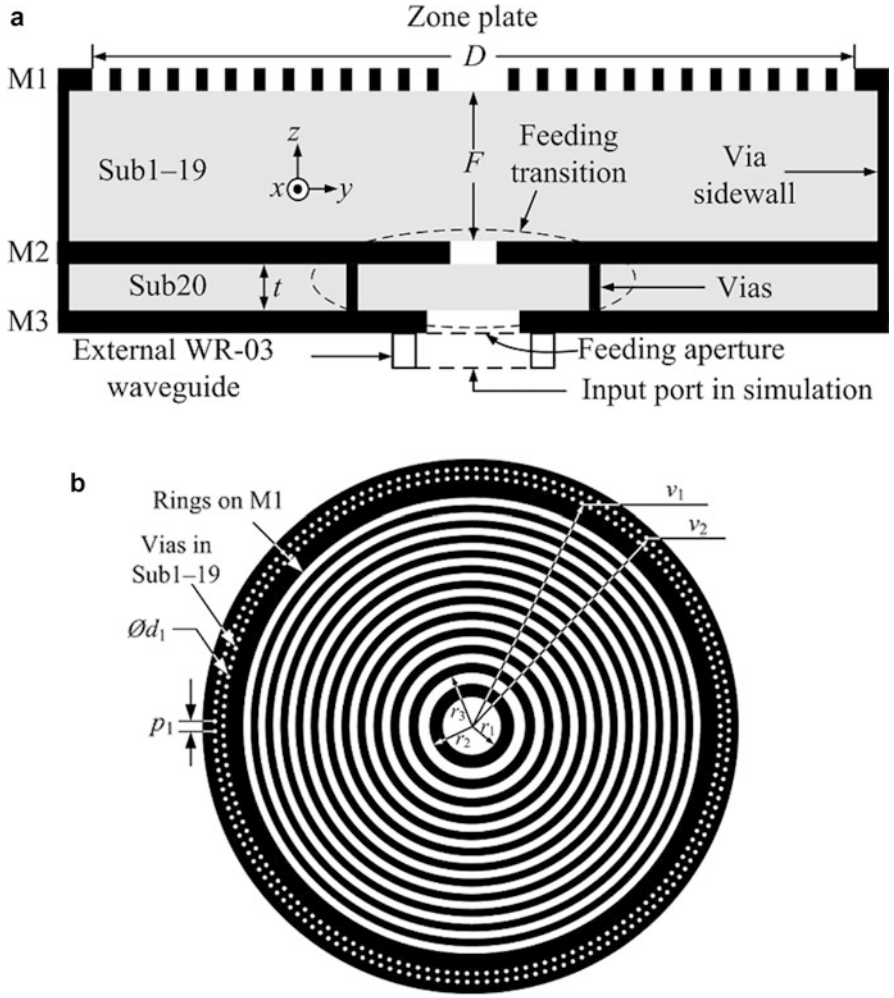

Fig. 39 Cavity-backed FZP lens antenna for 270-GHz frequency band: (**a**) cross-sectional view and (**b**) face view

radiation aperture is not utilized efficiently. Such a low-efficiency performance, however, is typical for all ultrawide band or frequency-independent antennas. For instance, the Archimedean antenna designed for the microwave band 1–20 GHz at the frequency of 10 GHz has about 0.5 % aperture efficiency only.

It is also proved that the FZP antenna pattern beamwidth closely follows the Rayleigh resolution criterion for all terahertz harmonics. It is clarified that if the antenna resolution is of a primary

importance and the low efficiency is not a vital limitation, or may be increased by additional amplification, the microwave FZP lens antenna can be appropriate for terahertz applications too. The FZP resolution increases for the higher harmonics, Fig. 40b, and is 2.4 deg, 0.26 deg, and 0.15 deg for the frequencies 90, 810, and 1350 GHz, respectively. Also, the studied FZP lens antenna has very high axial polarization ratio (AR >55 dB at 90 GHz and >75 dB at 1350 GHz).

Unique and expensive microtechnology is not required for producing the simple and regular-size FZP microwave structure. Applications where the spatial and frequency resolutions are key factors already have been set up in the terahertz metrology, imaging tomography for medical and security use, spectral analysis of organic and nonorganic materials, and radio astronomy among many others.

Microwave and Terahertz FZP Lens Antennas Contrasted to Ordinary Lens Antenna Compared to the bulky and heavy ordinary dielectric lens the grooved-dielectric FZP lens has the very important

DOI 10.1007/978-981-4560-75-7_42-2

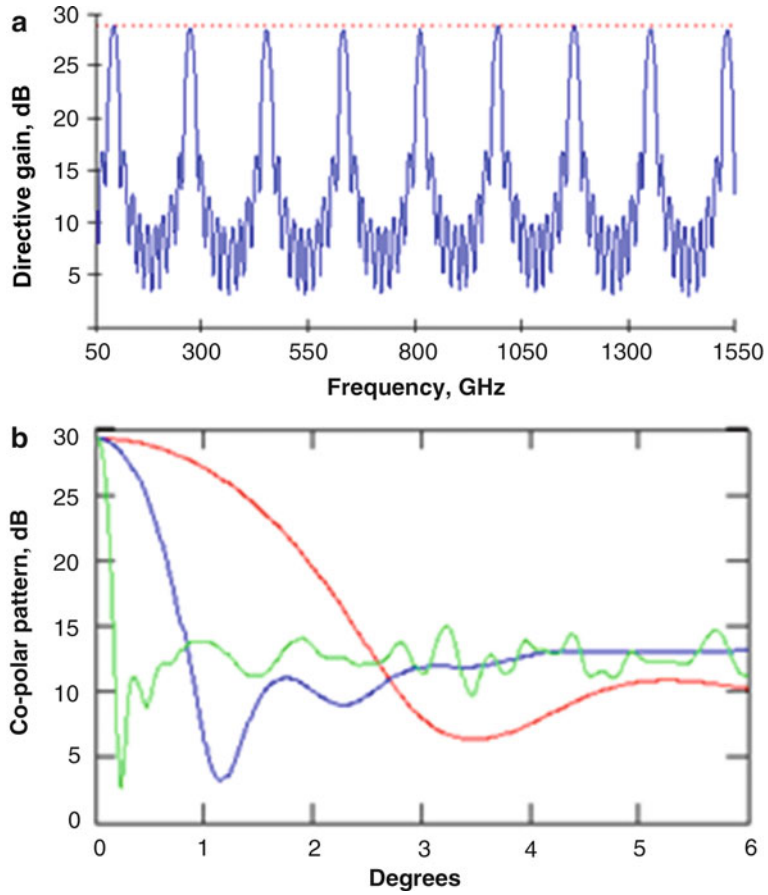

Fig. 40 Frequency- and space-domain action of binary FZP lens antenna: (**a**) directive gain versus frequency and (**b**) radiation co-polar patterns for three harmonic frequencies, f1 = 90 GHz (*red line*), f9 = 810 GHz (*blue line*) and f15 = 1350 GHz (*green line*)

advantage of being thin, light, and easy for production, Fig. 41a. Computer-simulated model of quarter-wave FZP antenna is shown in Fig. 41b. The terahertz design data for the ordinary and FZP lens antennas subject of comparison are $f = 1.5$ THz or $\lambda = 0.2$ mm, $F = 4.55$mm and $D = 4.83$ mm (Rodriguez et al. 2011; Hristov and Rodriguez 2013). The terahertz lenses are modeled for TPX polymer with $\varepsilon = 2.09$ and $\tan\delta = 0.0132$. Similar microwave lenses are designed for $f = 38$ GHz and have $F = 180$ mm and $D = 190.7$ mm. For the design microwave frequency the same TPX polymer has $\varepsilon = 2.13$ and $\tan\delta = 0.0043$. Both antennas are fed by round 16-dB each corrugated horns. A number of terahertz and microwave FZP lens antennas are numerically studied and contrasted to an ordinary plane-hyperbolic lens by use of CST Microwave Studio software. It is found by Fig. 42 that for four or more FZP phase correction steps both antenna types, FZP and ordinary, have close realized gains, similar beamwidths, and comparable cross-polar and mismatch qualities. For example, at the microwave frequency of 38 GHz the eight-step microwave FZP antenna gives way to the ordinary lens antenna by 1.7 dB, Fig. 42b, while for the corresponding 1.5-GHz antenna the gain difference is very small as seen by Fig. 42a. The FZP lens antennas (microwave or terahertz) are narrowband compared to the ordinary ones. Nevertheless, at 1.5 THz the absolute frequency band is more than 500 GHz, which in fact is a very big frequency range for most wireless applications.

Flat-Ring Conical Fresnel Zone Antenna: Low-Terahertz Antenna Project

 # 1. Introduction A lens antenna based on a cone-like Fresnel zone (CFZ) lens consisting of flat dielectric rings is subject to a recently completed project (Rodriguez et al. 2011; Hristov et al. 2012). The 3D lens originates from Wood's flat phase reversal FZP. A low-terahertz CFZ flat-ring lens assembly conformal to a truncated conical surface is designed and studied by CST computer simulation. Each CFZ lens is characterized by the cone semi angle α in degrees and number of rings ν. For a shortness, each cone-shape FZ lens is abbreviated as CFZ.ν.α. The CFZ lens antenna is compared to flat FZP and ordinary lens antennas same in aperture size and focal length.

 # 2. Lens Geometry and Antenna Model The geometry for analysis of conical Fresnel zone lens with two flat dielectric rings is shown in Fig. 43a. The lens convex side is illuminated by an axial plane wave. CFZ.6.75 lens antenna fed by a rectangular open waveguide (OWG) is shown in Fig. 43b.

 # 3. Design Equations for CFZ Lens For a given design wavelength λ_0, cone semi-angle α, and focal length F, the n^{th} zone radius R_n and axial zone location Z_n are calculated by the next system of equations

$$R_n = \sqrt{2\Lambda(n)F + \Lambda^2(n) + \left(\frac{\Lambda(n)}{\tan\alpha}\right)^2} - \frac{\Lambda(n)}{\tan\alpha} \tag{37}$$

$$Z_n = \frac{R_n}{\tan\alpha} \tag{38}$$

DOI 10.1007/978-981-4560-75-7_42-2

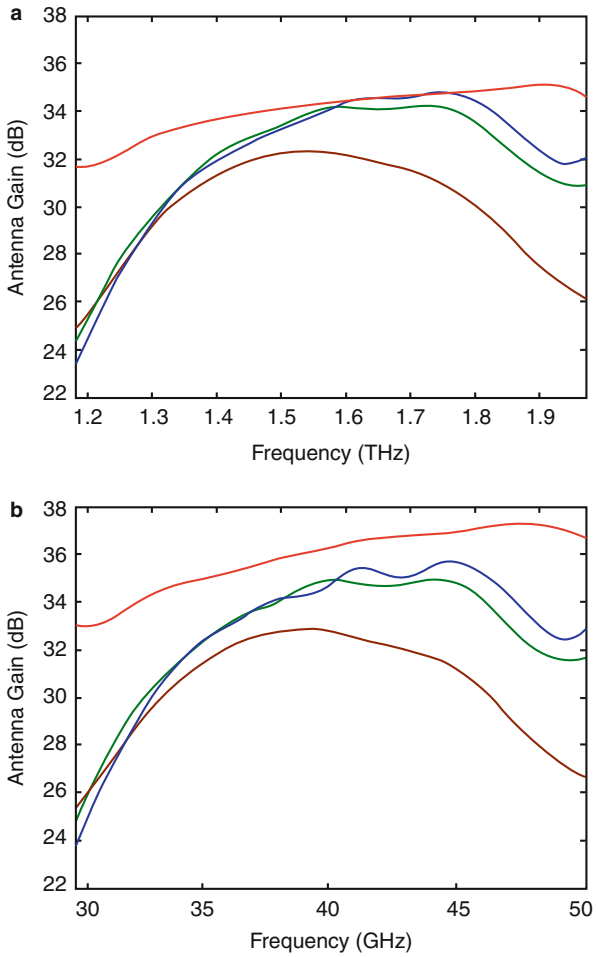

Fig. 42 Realized antenna gain graphs versus frequency for : 2-step FZP (*brown line*), 4-step FZP (*green line*), 8-step FZP (*blue line*) and plane-hyperbolic (*red line*) lenses, for (**a**) terahertz and (**b**) microwave bands, respectively

where $n = 1, 2, \ldots, N$ is an integer sequence, $N = 2\nu$ is the number of all half-wave (Fresnel) zones, and $\Lambda(n) = n\lambda/2$ is a half-wave zone function.

The odd zones in the CFZ lenses are open apertures with an air permittivity $\varepsilon_1 = 1$. The phase-reversing rings on the even zone apertures are made of low-loss dielectric with a preferable permittivity $\varepsilon_2 \geq 2$. In the conical lenses made of flat dielectric rings in air the ring thickness d is calculated by $d = \lambda/2\left(\sqrt{\varepsilon_2 - 1}\right)$. Except in the air, the dielectric ring assembly can be embedded in a low-permittivity solid or liquid media, with $1.03 < \varepsilon_1 < 1.07$.

 # 4. Design Data for Projected CFZ Antennas Design frequency $f = 229$ GHz, focal length $F = 30$ mm, ≈ 42.6 mm ($\tilde{f} = F/D = 0.704$), $\alpha = 75$ deg, $\varepsilon = 2.25$, and $\tan\delta = 0.0004$. For the listed design frequency and dimensions the CFZ lens has six dielectric rings of depth $d = 1.1$ mm each. According to the above abbreviation the lens is marked as CFZ.6.75.

 # 5. Lens Focusing Field Intensity Plots The yOz-plane computer-simulated focusing plots of the plane-wave illuminated lens CFZ.6.75 and classical plane-hyperbolic (PH) lens are displayed in Fig. 44a, b, respectively. It is evident that the lens CFZ.6.75 has a slightly smaller resolving angle δ_0 (transverse

DOI 10.1007/978-981-4560-75-7_42-2

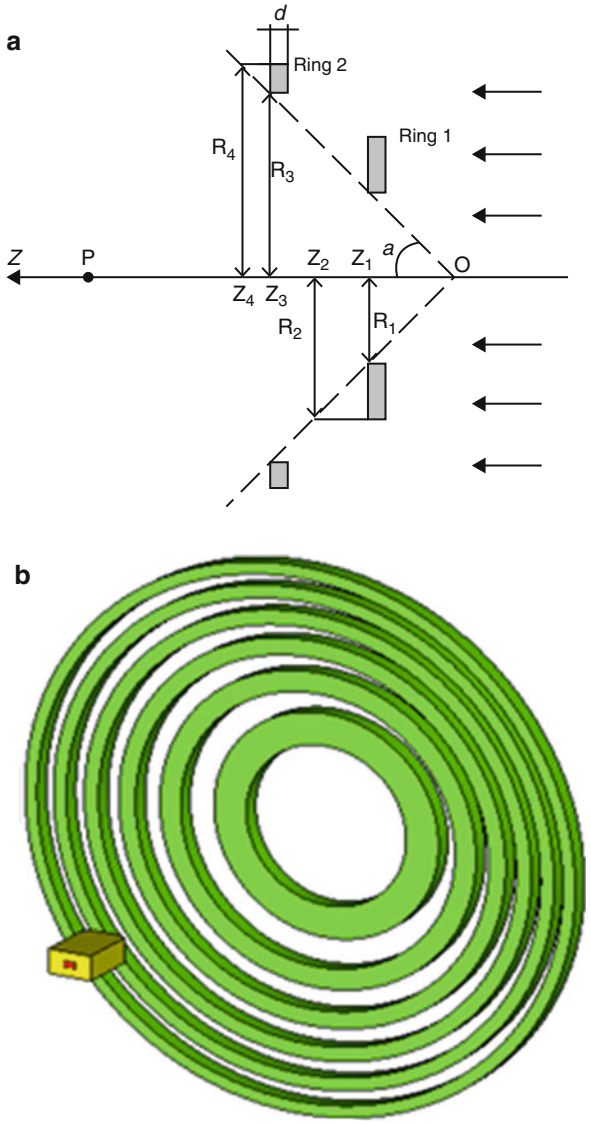

Fig. 43 Conical flat-ring FZ lens antennas: (**a**) lens geometry and (**b**) 3D CFZ.6.75 antenna with OWG feed

resolution) and much better axial resolution. Such a big axial focusing enhancement leads to a smaller spherical aberration and 3D focusing spot compared to the classical PH lens.

 # 6. Lens Antenna with CFZ.6.75 Lens The E-plane (red line), H-plane (blue line), and 45-degree-plane (green line) radiation patterns of the CFZ.6.75 and corresponding plane-hyperbolic lens antennas are contrasted in Fig. 45. The E- and H-plane radiation patterns of each antenna are well overlapping.

In Table 3 are listed the main radiation parameters of the three antennas with: equal in aperture and in focal length (i) flat FZP lens, (ii) cone-shape CFZ.6.75, and (iii) classical PH lens. The abbreviations for the main antenna parameters are: G is the normalized gain, HPBW-half-power beamwidth, SL-maximum sidelobe level, and XP-maximum cross-polarization level.

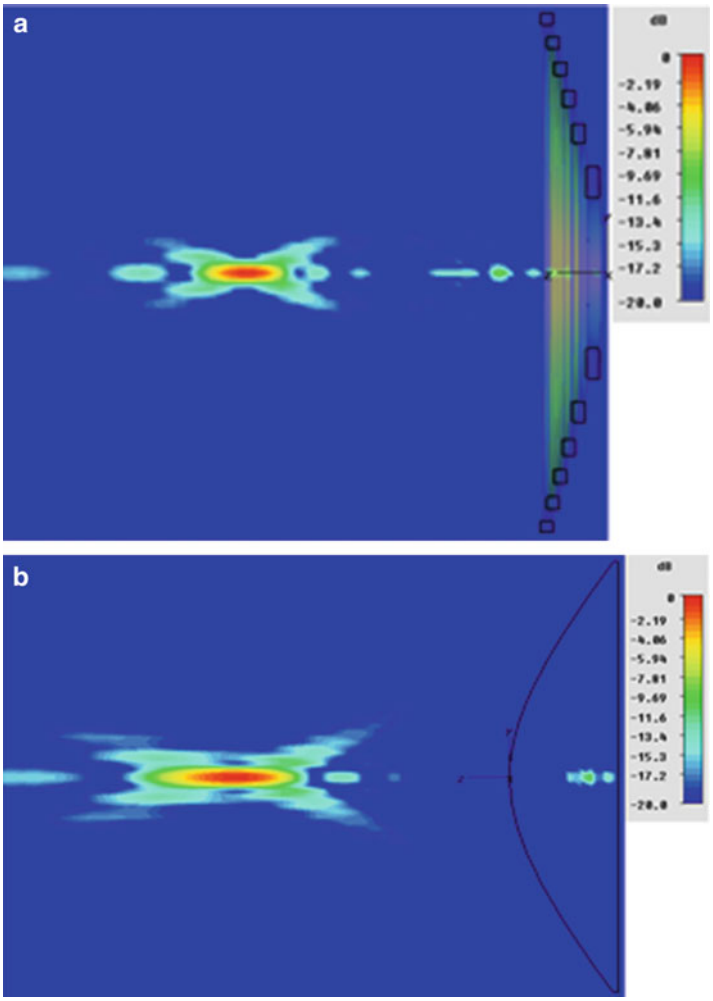

Fig. 44 Plots of yOz-focusing gain of plane-wave illuminated (**a**) curvilinear lens CFZ.6.75 and (**b**) plane-hyperbolic (PH) lens

 # 7. Conclusions For the same design wavelength of 1.31 mm, focal length of 30 mm, and aperture diameter of about 42.6 mm the studied flat FZP lens antenna is inferior in gain compared to both phase-reversing CFZ.6.75 and PH lens antennas. The latter two antennas feature similar radiation characteristics, but the CFZ.6.75 antenna is much lighter and has important structural and technological advantages. Certainly, the CFZ lens antenna with finer lens phase correction (quarter-wave, eight-wave, and so on) will become superior in radiation compared to the corresponding ordinary refraction lens. The main disadvantage of the conical lens antenna is its bigger length and occupied volume.

Optical Nanoantennas

Robert D. Nevels* and Hasan Tahir Abbas
Department of Electrical and Computer Engineering, Texas A&M University, College Station, TX, USA

Abstract

An overview of the field of optical plasmonic antennas is presented in this chapter. After a brief introduction and historical review, the theory of surface plasmon polaritons which leads to a set of overall observations as to the requirements and restrictions placed on the operation of plasmonic waveguides and antennas is presented. Both a single metal-dielectric interface and two interfaces between a metal sheet with dielectrics on either side are considered. In the second section the physical principles of operation and mathematical design criteria are presented for several common optical antennas including on-surface metallic structures and free standing particles. The third section covers the basic theory of aperture radiators along with a more detailed description of some popular designs. Current applications of optical nanoantennas are presented along with a discussion on some future directions in optical nanoantenna research.

Keywords

Optical antenna; Nanoantenna; Surface plasmon polaritons; Plasmonics; Negative dielectric constant; Near infrared; Electromagnetic; Propagation

Introduction

Optical nanoantennas are nano-size objects that transmit or receive electromagnetic fields through their intrinsic plasmonic behavior in the optical or near infrared range. Optical antennas have become the object of great interest to engineers due to advancements in nano device construction technologies. In particular, commercial computer aided design (CAD) programs that allow the characterization of materials with a negative real part permittivity and the lower cost and advancements in electron beam (e-beam) etching machines permitting the creation of nanocircuits with line widths on the order of 10 nm or smaller have made it possible for universities and research labs to not only numerically simulate, but also build models and measure the properties of optical antennas. The fact that practical research and development is now available to the academic and industrial community has led to several new applications and technologies including dramatically improved spectroscopy (Ouyang et al. 1992; Nie and Emory 1997; Kneipp et al. 1997), disease and toxin sensors (Arduini et al. 2010; Nevels et al. 2012), wireless communication with nano-circuitry (Adato et al. 2011), and the creation of nanocircuits using subwavelength lithography (Sotomayor Torres et al. 2003; Ishihara et al. 2006). The opportunities for antenna engineers in this vast new landscape are great, but much work remains to be done on analytical and numerical characterization as well as in developing an understanding as to how electromagnetic and quantum processes can be incorporated into a coherent mathematical theory that will allow ready design of such devices.

DOI 10.1007/978-981-4560-75-7_43-1

Dimensions of optical antennas are in the nanometer (nm) range of visible and near infrared light. Typical antenna element shapes include the dipole, bowtie, aperture, and sphere, as shown in Fig. 1. Figure 1d illustrates the oscillating dipole like behavior produced by plasmonic action in a nanometer scale gold sphere illuminated at 800 nm where gold has a dielectric constant $\varepsilon_r = -20.277 - j2.07$. Optical antennas are always fabricated out of noble metals, most commonly gold and silver and less commonly with aluminum, chromium, and copper. Unfortunately there are some negative aspects of these materials that make them difficult to work with in engineering applications. In an ambient environment silver can form a silver sulfide layer that inhibits the propagation of plasmon waves (Nevels and Michalski 2014) and as such is not always a good candidate for an optical antenna. Aluminum has a higher dielectric function imaginary part than does gold, increasing from a small difference at 550 nm to a significantly larger value at 830 nm where it becomes exceptionally lossy. During the construction of a nanoantenna, ion beam bombardment can cause gold to melt making it hard to form a smooth metallic structure that is true to its intended design (Farahani 2006). Nevertheless, noble metals are necessary for the applications described in this chapter because their plasma frequency, a crucial element of the design, lies in the wavelength range of visible light.

The majority of current research papers center on free space designs, but for most practical applications nanoantennas will be etched on a substrate. The type of substrate depends on the particular application, to some extent determined by the mechanism used to excite the antenna, but for many industrial applications cost and availability considerations have driven the move to silicon dioxide (SiO_2), often described in technical papers simply as "glass." Typical signal generation is via off-board laser light or by an on-board transmission line. Unlike classical antenna signals which can be generated at virtually any microwave carrier frequency, there are a select few frequencies where low cost optical sources are available, although specialized lasers can operate at frequencies throughout the optical spectrum. In optical terminology the signal has traditionally been specified in wavelengths rather than frequency, however here both terms will be used. Some common wavelengths where research is being carried out are in the neighborhood of 550, 630, and 820 nm. A more complete list of various laser types along with their operating frequencies can be found (Weber 2001).

In the optical realm, in addition to referring to "wavelength" rather than "frequency," other commonly encountered terms can at first seem odd or even incorrect to someone accustomed to working in the classical microwave domain. The term "antenna" itself is generally associated with the radiator or receiver component of a circuit, but in the nanometer regime it is also often used when describing a resonator, a device that is not intended for transmission or reception of signals. Also, the term "field intensity" is usually associated with the electric or magnetic field intensity in a microwave system, but in optics it is

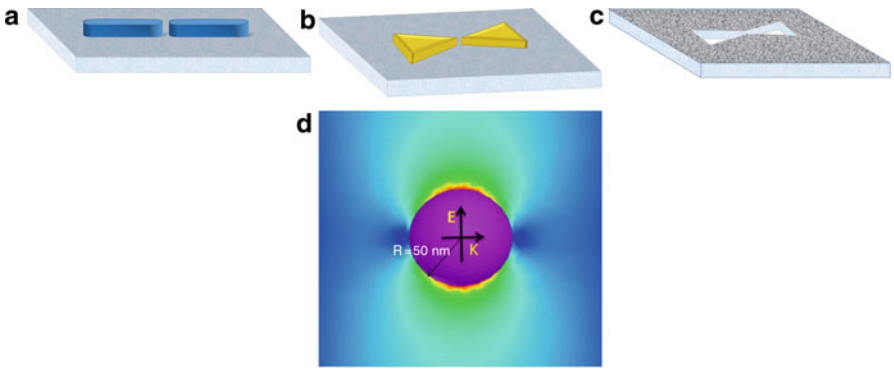

Fig. 1 Common nanoantenna elements (**a**) dipole (**b**) bowtie (**c**) aperture and (**d**) sphere. The dipole, bowtie, and aperture antennas are typically etched on a low loss substrate such as silicon dioxide while spheres may be mounted at the tip of a cone shaped substrate or arranged in some fashion on a flat substrate

DOI 10.1007/978-981-4560-75-7_43-1

used to describe what an antenna engineer would refer to as the "radiation intensity," which is power density multiplied by r^2.

A counter-intuitive oddity of noble metals at optical frequencies is that they are no longer perfect conductors, but rather they have some of the properties of a dielectric with, as mentioned above, a permittivity whose real part is negative. This turns out to be a remarkable advantage over dielectrics with a positive real part, due to the fact that the wavelength of the current in these metals can be much less than the wavelength of the free space incident field. A solid nanorod still resonates around one-half wavelength of its surface current but, given an incident field frequency, one must use numerical or approximate analytical methods to determine the shorter than free space wavelength of the antenna at resonance. While optical antennas make excellent resonators, due in part to a tightly bound plasmon current, the wavelength mismatch between air and metal, which does not exist at microwave frequencies, is a significant factor hampering their radiation and receiving properties. To understand how the radiation efficiency of an optical antenna can be improved it is necessary to first study the unusual properties of waves on metals at optical frequencies. The essentials of optical wave propagation and radiation are presented in the following section.

Electromagnetic Theory of Surface Plasmon Polaritons

The physical mechanism for wave propagation at optical frequencies is very different from that of propagating waves at microwave frequencies although the mathematics for determining the wave behavior is virtually the same and can be laid out in a classical Sommerfeld integral analysis. At optical frequencies surface plasmon polaritons (SPPs), electromagnetic surface waves created by coherent charge oscillations in an electron gas in a metal, propagate at a metal-dielectric interface (Ritchie 1957; Otto 1976; Raether 1988). Resonant plasmonic oscillations can also occur in the confined space of nanoparticles (Nie and Emory 1997). Fortunately, in most cases where optical antennas are concerned the quantum mechanisms which create SPPs or local confined plasmons can be expressed in terms of the material properties of metals and nanoparticles, such as shape, size and permittivity (Kelly et al. 2003). Because the study of nanoantennas relies on the behavior of plasmonic waves, it resides in the research area described as "plasmonics," a subfield of nanophotonics (Maier and Atwater 2005; Park 2009). In this section some of the basic theory of SPPs will be presented in order to aid the reader in understanding the underlying principles that determine the behavior of nanoantennas. First, the fundamental problem of electromagnetic propagation on a planar dielectric-metal interface at optical frequencies is considered, followed by a discussion on the role played by quantum effects in determining the allowable frequency range and loss mechanisms in nano-device design. This presentation does not require an understanding of quantum mechanics, but occasionally the language of quantum electronics is used to describe the effects that determine the properties of the constitutive parameters at optical frequencies.

Single Boundary Structure

Assuming a metal can have a complex permittivity at optical wavelengths, the propagation constants k_{xi} and k_{zi} at the planar interface between dielectric and metal half-spaces, $i = 1,2$ respectively, can be found starting with expressions for transverse magnetic (TM) plane waves in these two regions as shown in Fig. 2. The electromagnetic field expressions in region 1 where

DOI 10.1007/978-981-4560-75-7_43-1

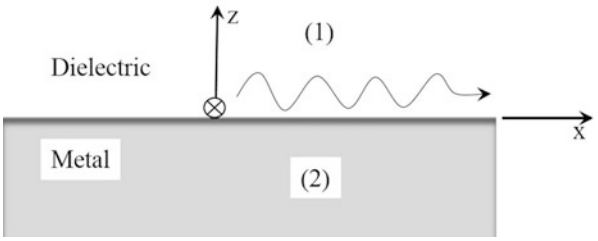

Fig. 2 Dielectric and metal half-spaces with a planar boundary

$z \geq 0$ are,

$$\mathbf{E}_1 = (E_{x1}\hat{\mathbf{x}} + E_{z1}\hat{\mathbf{z}})e^{-j(\mathrm{k}_x x + k_{z1} z)} \tag{1a}$$

$$\mathbf{H}_1 = H_{y1}e^{-j(k_x x + k_{z1}\mathrm{z})}\hat{\mathbf{y}} \tag{1b}$$

and in region 2 where $z \leq 0$,

$$\mathbf{E}_2 = (E_{x2}\hat{\mathbf{x}} + E_{z2}\hat{\mathbf{z}})e^{-j(\mathrm{k}_x x - k_{z2} z)} \tag{2a}$$

$$\mathbf{H}_2 = H_{y2}e^{-j(k_x x - k_{z2}\mathrm{z})}\hat{\mathbf{y}} \tag{2b}$$

A positive sign is chosen for k_{z2} to ensure propagation in the negative z direction. The Im(k_z) must therefore be negative in order to be bounded at infinity.

Ampere's law, $\nabla \times \mathbf{H} = j\omega\varepsilon\mathbf{E}$, applied to Eqs. 1 and 2 yields the boundary conditions

$$k_{z1}H_{y1} = \omega\varepsilon_1 E_{x1} \tag{3a}$$

$$k_{z2}H_{y2} = -\omega\varepsilon_2 E_{x2} \tag{3b}$$

where $\varepsilon_{1,2}$ are the permittivities of the dielectric and metal regions respectively. Since metal at optical frequencies has the behavior of a lossy dielectric, continuity of tangential electric and magnetic fields, $E_{x1} = E_{x2}$ and $H_{y1} = H_{y2}$, can be applied at the boundary along with Eq. 3. This gives the dispersion relation for waves on the metal-air boundary

$$\frac{k_{z1}}{\varepsilon_1} + \frac{k_{z2}}{\varepsilon_2} = 0 \tag{4}$$

Helmholtz equation, $\nabla^2\mathbf{E} + k_i^2\mathbf{E} = 0$, where $i = 1,2$, and assuming the permeabilities of all regions are that of air, lead to the dispersion equations for the two regions,

$$k_x^2 + k_{zi}^2 = \varepsilon_i\left(\frac{\omega}{c}\right)^2 \doteq \varepsilon_i k_o^2 \tag{5}$$

where c is the speed of light in air. Equations 4 and 5 are combined to produce the SPP propagation constant

DOI 10.1007/978-981-4560-75-7_43-1

$$k_x = k_o \left(\frac{\varepsilon_{r1}\varepsilon_{r2}}{\varepsilon_{r1} + \varepsilon_{r2}} \right)^{1/2} \tag{6}$$

Where k_o is the free space wavenumber and the subscript r is used to indicate a dielectric constant quantity. If the permittivity of the dielectric is real and that of the metal is complex, $\varepsilon_2 = \varepsilon_2' - j\varepsilon_2''$, and $|\varepsilon_2'| \gg \varepsilon_2''$ the complex propagation constant in Eq. 6 can be expressed as (Raether 1988).

$$k_x = k_o \left(\frac{\varepsilon_1 \varepsilon_2'}{\varepsilon_1 + \varepsilon_2'} \right)^{1/2} - jk_o \frac{\varepsilon_2''}{2(\varepsilon_2')^2} \left(\frac{\varepsilon_1 \varepsilon_2'}{\varepsilon_1 + \varepsilon_2'} \right)^{3/2} = k_x' - jk_x'' \tag{7}$$

Similarly, from Eqs. 5 and 6, k_{zi} becomes approximately,

$$k_{z1} = k_o \left(\frac{\varepsilon_1{}^2}{\varepsilon_1 + \varepsilon_2'} \right)^{1/2} + jk_o \frac{\varepsilon_1 \varepsilon_2''}{2(\varepsilon_1 + \varepsilon_2')^{3/2}} = k_{z1}' + jk_{z1}'' \tag{8}$$

$$k_{z2} = k_o \left(\frac{\varepsilon_2'{}^2}{\varepsilon_1 + \varepsilon_2'} \right)^{1/2} - jk_o \frac{\varepsilon_2''(2\varepsilon_1 + \varepsilon_2')}{2(\varepsilon_1 + \varepsilon_2')^{3/2}} = k_{z2}' - jk_{z2}'' \tag{9}$$

From Eqs. 4, 5, 6, 7, 8, and 9 some very important conclusions can be drawn concerning the nature of the two half-space materials and the properties of nano surface waves on their intersecting boundary:

(a) First, if loss is neglected ($\varepsilon'' \simeq 0$), a valid assumption for noble metals over significant segments of the optical range, so that the permittivities of both regions are real, the equality in Eq. 4 will not hold if these permittivities are both positive or both negative. But, if the permittivity in the dielectric region (1) is positive, $\varepsilon_1 > 0$, and the real part of the permittivity in the metal region (2) is negative, $\varepsilon'_2 < 0$, then it is possible to satisfy Eq. 4.

(b) Nevertheless, a wave still cannot exist if the term under the square root in Eq. 7 is negative because this would lead to a totally complex k_x, which would mean the fields in Eqs. 1 and 2 will exponentially grow or decay rather than propagate along the boundary. However, if

$$\varepsilon_1 > 0,\ \varepsilon_2' < 0 \ \text{ and } \ |\varepsilon_2'| > \varepsilon_1 \tag{10}$$

then the term under the square root in Eq. 7 is positive and propagation of a wave at the boundary is assured. This condition (10) causes the signs of the terms under the square roots in Eqs. 8 and 9 to be negative, but Eq. 4 will still hold as long as same sign for $\sqrt{-1}$ is chosen for both square roots.

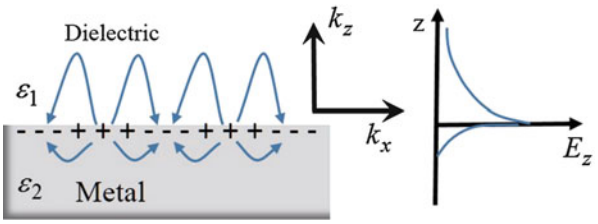

Fig. 3 Surface plasmon propagation along a dielectric-metal boundary and exponential decay perpendicular to the boundary

DOI 10.1007/978-981-4560-75-7_43-1

(c) If the conditions in Eq. 10 are met then from Eq. 6 $k_{x>} k_o$ and therefore k_z in Eq. 5 must be complex. According to Eqs. 1 and 2 this results in exponential decay of the field away from the boundary in both the positive and negative z-directions as long as $\sqrt{-1} = -j$ is chosen for the square root terms in Eqs. 8 and 9. Exponential decay of the surface plasmon wave into the dielectric and metal is illustrated in Fig. 3.

(d) According to Snell's law the component of the wavenumber k_x tangential to the boundary is the same in both mediums. If medium 1 is air, the x-component of a plane wave incident upon the boundary at an angle θ from normal is $k_{x1} = k_o \sin\theta$, which is less than k_o. However, according to Eqs. 6 and 10 surface plasmons cannot exist unless $k_x > k_o$. Therefore, surface plasmons cannot be excited by shining light on a flat metal surface.

(e) From Eq. 7 the velocity of a surface plasmon wave on a planar boundary is

$$v_{sp} = \omega/k'_x = c\left(\frac{\varepsilon_1 + \varepsilon'_2}{\varepsilon_1\varepsilon'_2}\right)^{1/2} \tag{11}$$

and its wavelength is

$$\lambda_{sp} = \frac{2\pi}{k'_x} = \lambda_o\left(\frac{\varepsilon_1 + \varepsilon'_2}{\varepsilon_1\varepsilon'_2}\right)^{1/2} \tag{12}$$

(f) The exponential decay of a plasmon along its propagation direction is determined by the second term in Eq. 7. The "propagation length" of a plasmon wave is the distance $x = L$ at which the wave decays to $1/e$ of its initial value. The plasmon propagation length on a planar surface is therefore

$$L = 1/k''_x = \frac{2\left(\varepsilon'_2\right)^2}{k_o\varepsilon''_2}\left(\frac{\varepsilon_1 + \varepsilon'_2}{\varepsilon_1\varepsilon'_2}\right)^{3/2} \tag{13}$$

(g) If the conditions in Eq. 10 hold, the second term on the right hand side in Eqs. 8 and 9 are small so, neglecting these terms, perpendicular to the boundary the 1/e decay distance is (Raether 1988)

$$z_1 = \left|\frac{1}{k'_{z1}}\right| = \frac{1}{k_o}\left|\left(\frac{\varepsilon_1 + \varepsilon'_2}{{\varepsilon_1}^2}\right)^{1/2}\right| \tag{14}$$

into the dielectric and

$$z_2 = \left|\frac{1}{k'_{z2}}\right| = \frac{1}{k_o}\left|\left(\frac{\varepsilon_1 + \varepsilon'_2}{{\varepsilon'_2}^2}\right)^{1/2}\right| \tag{15}$$

into the metal.

(h) Power and energy relationships can be found by assuming a value for the magnetic field amplitude and by using Amperes law to determine the electric field.

The conditions described in Eq. 10 are met by noble metals in air for the optical and near-infrared ranges in the case of a TM polarized wave. A similar analysis will show that a transverse electric (TE) polarized wave cannot exist at a dielectric-metal boundary.

DOI 10.1007/978-981-4560-75-7_43-1

In practical applications one should take care in the selection of the metal to be used in a nanoantenna design. Some metals, such as silver, tend to develop an oxidation layer, which can severely decrease propagation length and increase the antenna impedance. For a more detailed discussion concerning the effect of a silver sulfide oxidation layer on a silver substrate plasmon wave, the reader is referred to (Nevels and Michalski 2014).

Figure 4 shows the propagation length as a function of wavelength for three metals, gold, silver and aluminum (Homola 2006). The practitioner is cautioned that although the propagation length of a surface plasmon does increase as frequency decreases, the analysis leading to this figure is based on an idealization of the physical problem. Here, a pure wave propagation condition was assumed in the formulation of equations 1 and 2. In the practical case a source, such as the feed point of an antenna, must be included in the problem formulation. If the source is included, one sees that as the frequency decreases less energy is transferred into the surface plasmon wave and more into the space wave – the field that is radiated directly into space from the source point. In the far infrared range the surface plasmon essentially ceases to exist. Plasmon wave behavior is discussed in more detail in the section of this chapter concerning aperture antennas.

Quantum Effects

The above analysis considers only the classical electromagnetic aspects of propagation on a dielectric metal boundary. However, quantum mechanical effects inherent in metals and dielectrics enter the picture through the permittivity, thereby determining its value as well as the frequency range over which surface plasmon polaritons can propagate. Essentially quantum processes reveal the frequency range over which the metal has a permittivity with a negative real part and where losses begin to have a serious effect on wave propagation within that frequency range. In the following the influence of plasma resonance and atomic collisions on SPP propagation are briefly explored. Although the properties described below are best understood using quantum mechanics, the mathematics below is classical, primarily developed by concatenating harmonic oscillator models. However, the differences in the results of the two theories is small, allowing classical electromagnetic calculations without the necessity of delving into quantum theory.

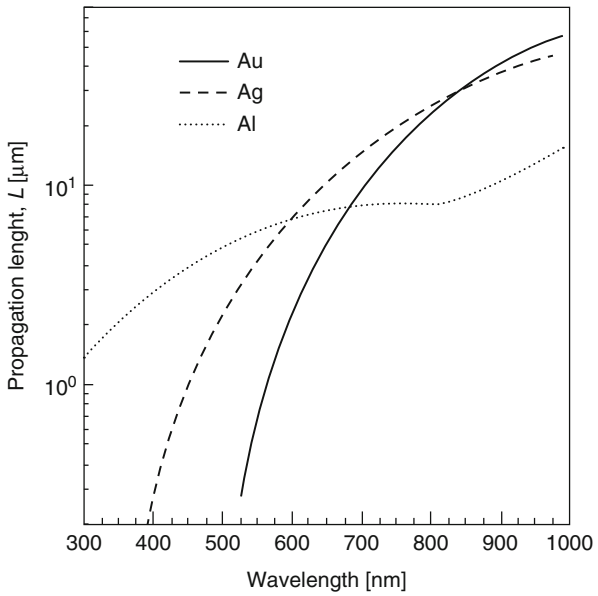

Fig. 4 Propagation length of a surface plasmon propagating along the interface between a dielectric (refractive index 1.32) and a metal as a function of wavelength calculated for gold (Au), silver (Ag), and aluminum (Al)

DOI 10.1007/978-981-4560-75-7_43-1

Free electrons can exist near the top of the energy band distribution in a metal. The interaction of these electrons with photons and the long-range Coulomb force of atoms create an electron oscillation known as a plasmon. Taking these effects into account, the dielectric function of metal can be expressed in terms of the Drude model (Born and Wolf 1970),

$$\varepsilon(\omega) = \left(1 - \frac{\omega_p^2}{\omega(\omega - j\nu)}\right) = \left(1 - \frac{\omega_p^2}{\omega^2 + \nu^2}\right) - j\frac{\nu\omega_p^2}{\omega(\omega^2 + \nu^2)} = \varepsilon_r - j\varepsilon_i \tag{16}$$

where $\nu = 1/\tau$ is the collision frequency, τ is the time between collisions, and ω_p is the plasma frequency

$$\omega_p = \sqrt{\frac{Ne^2}{\varepsilon_o m_e}} \tag{17}$$

where e and m_e are the electron charge and mass respectively and N is the concentration of free electrons. Plasma frequencies for metals are in the visible and ultraviolet ranges. Typical values of plasma and collision frequencies are $\omega_p = 0.2321 \times 10^{16}$Hz and $\nu = 5.513 \times 10^{12}$Hz for gold and $\omega_p = 0.2068 \times 10^{16}$Hz and $\nu = 4.449 \times 10^{12}$Hz for silver, however impurities and other factors can affect these numbers so the literature does not have a unique set of values for these parameters. A comprehensive list of plasma and collision frequencies published by a variety of researchers for gold, silver and other noble metals can be found at (Moroz 2009).

Collisions are primarily between electrons and relatively large lattice vibrations (phonons), so for most metals at room temperature $\nu \ll \omega_p$ (Bohren and Huffman 2004), which reduces Eq. 16 to approximately

$$\varepsilon(\omega) \simeq 1 - \frac{\omega_p^2}{\omega^2} \tag{18}$$

This important expression shows that when $\omega < \omega_p$ then $\varepsilon(\omega) < 0$ which in part satisfies the conditions in Eq. 10. Therefore surface plasmon polaritons can only exist below the plasma frequency. Equation 18 substituted into Eq. 6 gives a simplified Drude model for the plasmon wave vector:

$$k_x \simeq k_1 \left(\frac{\left(\omega^2 - \omega_p^2\right)}{\omega^2\varepsilon_{r1} + \left(\omega^2 - \omega_p^2\right)}\right)^{1/2} \tag{19}$$

The Drude model in the form given in Eq. 16 is widely used in nanoantenna analytical and numerical calculations for determining the permittivity, and therefore the propagation constant, of the plasmon polariton of noble metals. However, this free electron model fails at frequencies higher than about 850 THz (Archambault et al. 2009), due to bound charge effects, and must be modified by incorporating additional terms (Bohren and Huffman 2004). This becomes a tedious process but reasonable accuracy can be achieved. Another option, preferred by the authors, is to use measured data (Lynch and Hunter 1998) with a partial fraction fit (Michalski 2013). Figure 5 shows the dielectric function for gold and silver over the frequency range from 0.5 eV (120 THz) to 6.5 eV (1.57 PHz) obtained from measured data via a partial fraction fit. The solid lines are the partial fraction fit for the real part, ε', and the dashed lines are for the imaginary part, ε'', of the dielectric function.

DOI 10.1007/978-981-4560-75-7_43-1

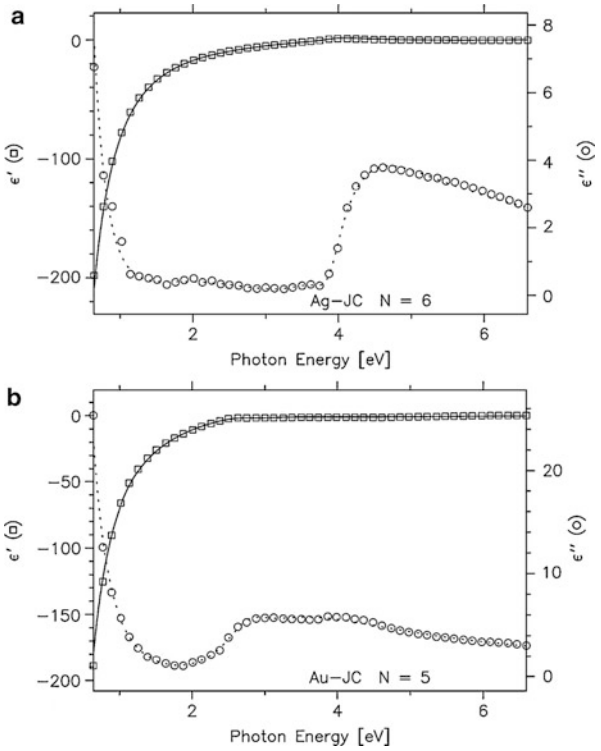

Fig. 5 Dielectric function for (**a**) Silver and (**b**) Gold as a function of photon energy $E = hf$ where f is frequency and $h = 6.626068 \times 10^{-34} \mathrm{m}^2\,\mathrm{kg/s}$ is Planck's constant. The solid lines are the partial fraction fit for ε' and the dashed line is for ε''. The circles and squares are from measured data originally supplied by (Johnson and Christy 1972)

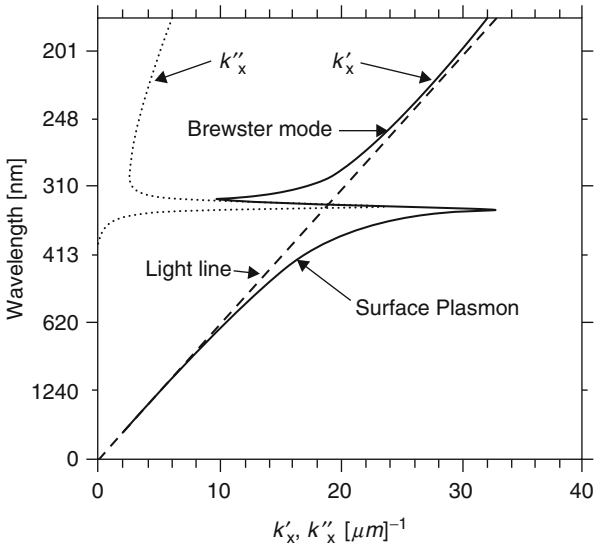

Fig. 6 SPP dispersion curve for ω versus k'_x and k''_x for an air-silver interface. The lower part of the curve is the non-radiative surface plasmon region which is capped by a high loss backbending region, and a Brewster mode radiative region above

The significance of the data in Fig. 5 becomes clearer in Fig. 6 where the surface plasmon dispersion curve for frequency versus the propagation, k'_x, and attenuation, k''_x, constants at an air-silver boundary are plotted. The lower part of the curve is the non-radiative surface plasmon region followed above by an anomalous dispersion region and above that a Brewster mode radiative region. The slanted dashed line is

DOI 10.1007/978-981-4560-75-7_43-1

the free space light line $k = \omega/c$. The Brewster mode portion of the dispersion curve is in the fast wave region to the left of the light line. It is the locus of the values of k_x of the plane wave incident on the boundary at the Brewster angle. These waves do not set up a surface wave, but rather carry their power directly into the metal without reflection. Below the Brewster mode section is a region of anomalous dispersion, often described in the literature as "backbending," which has a group velocity that is virtually zero, and is accompanied by high loss.

The surface plasmon portion of the dispersion curve is of primary importance to nanoantenna design. The plasmon region lies to the right of the light line and therefore it is a slow wave since the phase velocity here is less than the speed of light. Because surface plasmons have a shorter wavelength than light they are prevented from radiating from a flat planar surface. Of particular significance is the decreasing slope of the dispersion curve, tending toward horizontal near where it joins the anomalous dispersion segment. In the plasmon region the surface plasmon propagation constant increases dramatically with a small increase in frequency. The horizontal dashed line at 380 nm intersects the light line at approximately $k_o = 17$ rad/μm while at the same wavelength $k_x' = 21$ rad/μm, which means the surface plasmon wavelength can be much less than the free space wavelength. Therefore, a resonant half-wavelength nano-dipole antenna can be much smaller than a half-wavelength measured in air at the same frequency. As the plasmon wavelength decreases near the anomalous dispersion region the propagation constant approaches a limiting value. The Drude model provides the estimate for this limiting frequency,

$$\omega_{sp} \simeq \omega_p / \sqrt{1 + \varepsilon_{r1}} \tag{20}$$

obtained by setting the denominator in Eq. 19 equal to zero, which is equivalent to assuming the propagation constant in Eq. 19 approaches infinity. This is not what happens to the propagation constant, as can be seen in Fig. 6 where real data is used, but it does provide a reasonable estimate of the limiting frequency. Nanoantennas must be designed to operate below this frequency, thereby avoiding a group velocity approaching zero and dramatically increased losses.

Although several key aspects of wave propagation on nano-structures have been presented here, all analysis has been performed assuming propagation is on a surface between two half spaces. However, most nanoantennas have air above and are etched in a noble metal, such as gold, on a dielectric substrate, such as silicon dioxide. The metal antenna therefore lies between two different materials. Nanoantennas are typically excited at a corner or edge where both upper and lower surfaces are exposed to the incoming electromagnetic field. Because the plasmon propagation constant (7) is a function of the permittivity in the regions above and below an interface, it will be helpful to understand how different phase velocities (Eq. 11) and wavelengths (Eq. 12) on the two sides of a nano-antenna will affect its performance. This issue is briefly addressed in the following paragraphs.

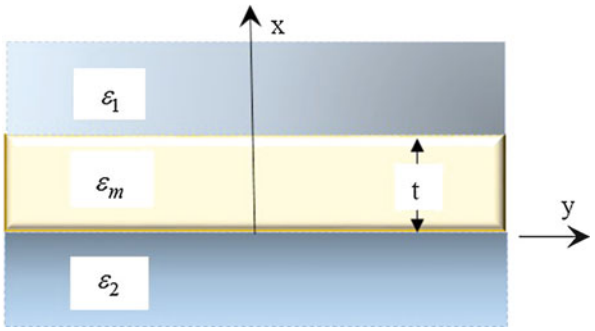

Fig. 7 Thin metallic film between two dielectric regions with different permittivities

DOI 10.1007/978-981-4560-75-7_43-1

Two Boundary Structures

Surface plasmon polaritons on a metal film have properties that do not exist on an interface between metal-dielectric half spaces. To analyze the mode configuration on a metal strip of thickness t consider the configuration shown in Fig. 7 where the dielectrics are assumed to extend from the surface of the metal to infinity and possess different permittivities, ε_1 and ε_2. The permittivity of the metal is ε_m and all three regions have the permeability of free space. The waves in each region are assumed to be TM polarized with a magnetic field component in the y-direction in each region given by

$$\mathbf{H}_1 = H_{y1} e^{-k_{z1} z - j k_x x} \hat{\mathbf{y}} \text{ dielectric region 1 } (z \geq t) \tag{21a}$$

$$\mathbf{H}_m = \left(H_{ya} e^{k_{zm} z} + H_{yb} e^{-k_{zm} z}\right) e^{-j k_x x} \hat{\mathbf{y}} \text{ metal region } m \text{ (t} \geq z \geq 0) \tag{21b}$$

$$\mathbf{H}_2 = H_{y2} e^{k_{z2} z - j k_x x} \hat{\mathbf{y}} \text{ dielectric region 2 } (z \leq 0) \tag{21c}$$

The dispersion relations for the three regions are,

$$k_{zi}^2 = k_x^2 - k_o^2 \varepsilon_i \text{ and } i \doteq 1, 2, m \tag{22}$$

and the boundary conditions satisfied by $\mathbf{H}_m$ at each interface are

$$H_{ym} = H_{yi} \tag{23a}$$

$$\frac{1}{\varepsilon_m} \frac{\partial}{\partial z} H_{ym} = \frac{1}{\varepsilon_i} \frac{\partial}{\partial z} H_{yi} \tag{23b}$$

Where $i = 1,2$. Each of these conditions are applied to Eq. 21 at each boundary yielding a set of four homogeneous linear equations which can be combined to produce

$$\frac{H_{yb}}{H_{ya}} = \frac{\left(\frac{\varepsilon_2 k_{zm}}{\varepsilon_m k_{z2}} - 1\right)}{\left(\frac{\varepsilon_2 k_{zm}}{\varepsilon_m k_{z2}} + 1\right)}, \frac{H_{yb} e^{-k_{zm} t}}{H_{ya} e^{k_{zm} t}} = \frac{\left(\frac{\varepsilon_1 k_{zm}}{\varepsilon_m k_{z1}} + 1\right)}{\left(\frac{\varepsilon_1 k_{zm}}{\varepsilon_m k_{z1}} - 1\right)} \tag{24}$$

The equations in 24 are equated to produce the dispersion relation

$$\left(\frac{\varepsilon_m k_{z1}}{\varepsilon_1 k_{zm}} + 1\right)\left(\frac{\varepsilon_m k_{z2}}{\varepsilon_2 k_{zm}} + 1\right) = \left(\frac{\varepsilon_m k_{z1}}{\varepsilon_1 k_{zm}} - 1\right)\left(\frac{\varepsilon_m k_{z2}}{\varepsilon_2 k_{zm}} - 1\right) e^{-2 k_{zm} t} \tag{25}$$

for a metal sandwiched between two different dielectrics. Equation 25 can be verified by allowing the metal thickness to become large, $k_{zm} t \gg 0$, in which case the right hand side goes to zero. This yields the pair of equations

$$\frac{\varepsilon_m k_{z1}}{\varepsilon_1 k_{zm}} + 1 = 0, \cdots \frac{\varepsilon_m k_{z2}}{\varepsilon_2 k_{zm}} + 1 = 0 \tag{26}$$

recognized from Eq. 4 to be the dispersion equations for surface plasmon polaritons at the boundaries between two individual dielectric-metal half-spaces.

DOI 10.1007/978-981-4560-75-7_43-1

If ε_1 and ε_2 are positive and $\varepsilon_m < 0$, the right hand side of Eq. 25 is positive, which means the left hand side must also be positive. This is possible if $\left(\frac{\varepsilon_m k_{z1}}{\varepsilon_1 k_{zm}} + 1\right)$ and $\left(\frac{\varepsilon_m k_{z2}}{\varepsilon_2 k_{zm}} + 1\right)$ are both positive or both negative. Under the assumption that both are negative, that $\varepsilon_1 > \varepsilon_2$, and $|\varepsilon_m| > \varepsilon_1$ the characteristic Eq. 25 becomes (Durach et al. 2004),

$$k_{zm}t = \coth^{-1}\left(\frac{|\varepsilon_m| k_{z1}}{\varepsilon_1 k_{zm}}\right) + \coth^{-1}\left(\frac{|\varepsilon_m| k_{z2}}{\varepsilon_2 k_{zm}}\right) \tag{27}$$

Similarly, assuming that both expressions in brackets on the left hand side of Eq. 25 are positive and $|\varepsilon| < \frac{\varepsilon_1 \varepsilon_2}{\varepsilon_1 - \varepsilon_2}$ the characteristic equation becomes (Durach et al. 2004),

$$k_{zm}t = \tanh^{-1}\left(\frac{|\varepsilon_m| k_{z1}}{\varepsilon_1 k_{zm}}\right) + \tanh^{-1}\left(\frac{|\varepsilon_m| k_{z2}}{\varepsilon_2 k_{zm}}\right) \tag{28}$$

Equations 22 together with 27 or 28 can be used to solve for the wavenumbers in the even and odd mode cases, referring respectively to the symmetric or asymmetric form of the tangential (z-directed) component of the electric field about the center of the metal layer (Burke et al. 1986).

When the metal plate is thick the waves on the two sides of the metal slab do not interact, as indicated in Eq. 26. However, as the slab becomes thinner the electromagnetic fields on the two sides do interact and the frequency splits into a low frequency even mode (Eq. 27) and a higher frequency odd mode (Eq. 28). Although the tangential electric field is not entirely symmetric in the metal region when $\varepsilon_1 \neq \varepsilon_2$, more of the field lies inside the metal in the even mode case (Eq. 27) than it does in the basically asymmetric odd mode case (Eq. 28). As the metal layer becomes thinner the damping of the odd mode decreases, approximately as the square of the thickness, allowing this mode to travel a greater distance than a plasmon polariton on the interface between two half spaces. However, the basically symmetric mode damping decreases with decreasing thickness, allowing propagation distances one or two orders of magnitude greater than those of thick metal construction (Sarid 1981). The physical reason attributed to this phenomena is that in the asymmetric case, where the null is in the center of the metal, more of the field resides outside as the thickness of the metal decreases lessening the presence of the tangential electric field in the metal thereby reducing Joule heat which in turn decreases the electron collision rate resulting in less damping of the wave. This analysis suggests that the efficiency of an optical antenna can be improved by decreasing the thickness of the metallic material with which it is constructed and operating in the higher odd mode frequency range.

When the metal width is finite and the environment is symmetric ($\varepsilon_1 = \varepsilon_2$), there are four fundamental modes and a number of higher order modes. These modes can be classified according to the cross-sectional width and thickness, similar to a rectangular waveguide and will become successively cut off as the thickness decreases leaving one Gaussian like mode. Efficient optical fiber coupling to this plasmonic mode in a metal guide has been demonstrated (Berini 2000), raising the possibility of similar coupling between optical antennas and metal strip plasmonic waveguides designed with the appropriate width and thickness so as to operate in this particular mode. Closer to the nanoantenna case, in an asymmetric environment ($\varepsilon_1 \neq \varepsilon_2$) there is no pure TM mode. It has been shown that modes in this case can change their symmetry properties with changes in both transverse directions, width and thickness, and that all modes show a cutoff height that increases both with decreasing width and increasing dielectric mismatch between the sub- and superstrate (Berini 2000, 2001). Unfortunately, this includes air-metal-glass configurations commonly used in the design of optical antennas and waveguides. Thus the complicated

DOI 10.1007/978-981-4560-75-7_43-1

spatial profiles shown in modes in an asymmetric environment prohibit efficient excitation techniques (Maier and Atwater 2005; Yang et al. 1991).

In this section it has been shown that in the optical frequency range electromagnetic wave propagation, which is via a surface plasmon polariton, can take place on an air-dielectric boundary if one of the two materials has a dielectric constant with a negative real part obeying the conditions in Eq. 10. The dispersion equation for this wave is given in Eq. 7 and presented graphically in Fig. 6, which shows that a surface plasmon is a slow wave, i.e., slower than the speed of light in the dielectric medium. The Drude model, which is relatively accurate below, and not too close to, the plasma frequency ω_p and useful for analytical calculations, was given in Eq. 16. This model, or its approximation in Eq. 17, is commonly used to obtain approximate velocity (Eq. 11), wavelength (Eq. 12), propagation distance (Eq. 13), and exponential decay distance away from the boundary (Eqs. 14 and 15) of the plasmon wave. It also provides an estimate of maximum frequency (Eq. 20) at which a plasmon wave can propagate. Although Fig. 6 shows that the surface plasmon wavelength can be much less than the free space wavelength, close to the maximum frequency the plasmon wave will experience severe attenuation.

Because optical antennas are operated in a frequency range which is at the overlapping boundary between electromagnetic and quantum theories, in the paragraphs above some of the quantum justification for the unusual behavior of materials in the near infrared and optical domains has been presented. This discussion was then followed by an asymmetric two boundary case development of the dispersion equations modeling a typical optical antenna structure in cross-section, showing that the interaction between the plasmon waves on the two boundaries breaks into symmetric and asymmetric modes, (Eqs. 27 and 28). The symmetric mode is preferred when coupling to another device and the asymmetric mode is preferred for long distance propagation in a plasmon waveguide. This section then concluded with a discussion of the finite width metal guide that has been shown to have a complicated mode structure, hampering efforts to obtain a mathematical expression for impedance matching. Current attempts at obtaining a mathematical model and along with design methods that improve impedance matching and enhance optical antenna radiation will be covered in the individual antenna discussions that follow.

Design of Optical Antennas

The plasmonic nature of nanoantenna operation prevents the designer from describing antenna performance with formulas that have been developed over many decades at microwave and lower frequencies. Dielectric properties of metals are only one factor preventing a direct correspondence between established antenna theory and actual optical antenna operation. A traditional antenna concept that the wave vector for the current is the same as the free-space wave vector must be abandoned, dispersion effects must be accounted for and losses not generally expected in a microwave frequency "perfect conductor" become dependent on the size and shape of the antenna.

The optical antenna, although not a traditional perfect conductor, cannot be analyzed as though it is a pure dielectric rod as would be the case for an optical fiber. But even if an optical antenna could be modeled as a pure dielectric, the tips of a rod represent the famous unsolved dielectric wedge problem. As described above, the fast wave current on a perfect conductor must be replaced by a slow wave plasmon current tightly coupled to the antenna surface. Radiation on an optical dipole still occurs at the tips of the rods and can still be viewed as current induced. The primary difficulty that must be faced when attempting an analytical analysis is that for practical reasons the design requires placing the antenna on an interface between a dielectric below, such as a silicon dioxide substrate, and air above. Although numerical techniques can be used to accurately analyze the characteristics of the structure, similar to microstrip

DOI 10.1007/978-981-4560-75-7_43-1

patch antennas, no exact analytical methods are available. Analytical approximations and numerical attempts to obtain the basic characteristics of an optical antenna, the resonant frequency, input impedance, gain, directivity and efficiency, are presented in this section.

Dipole and Patch Antennas

Size and shape can affect the design frequency of an optical antenna in ways not typically expected in microwave frequency antenna engineering. For example a rectangular microstrip patch is expected to resonate when the incident field is polarized in the direction of the $\lambda/2$ dimension of the patch, while the transverse dimension is flexibly left to something greater or less than $\lambda/2$. However, as shown in Fig. 8 both the width and length of a metal plate must be considered in designing an optical antenna. A narrow nanodipole resonating at a particular frequency, as shown in Fig. 8a, does not maintain resonance when widened. However, the first resonance can be regained by changing both the length and width of the dipole as shown in Fig. 8b. The mechanism causing this phenomena has to do with the manner in which surface plasmons are excited. The incident wave with a free space wavenumber transfers energy into the plasmon wave having a much larger wavenumber at locations where the interaction between the incident wave and the antenna produce the largest concentration of higher order modes, which will couple energy into the plasmon mode. This interaction is primarily seen on the corners of the dipole in Fig. 8b. Similar to plane waves in a waveguide, plasmon waves fan out from the corners taking a circuitous route bouncing from the edges of the plate before phase matching produces a resonance condition. Further complicating the picture is the chemical potential and the "lighting rod" effect whereby opposite charges form a high concentration of the field across the antenna center gap. However, plasmons in the narrower dipole, Fig. 8a, follow a shorter more direct route to resonance than does the plasmon wave on the wider dipole Fig. 8b thereby experiencing less attenuation and ultimately creating a region of higher field enhancement in the gap than does the wide dipole. Figure 8c shows that as the dipole widens the resonant frequency shifts and the enhancement decreases. Enhancement is defined as the ratio of the total to the incident

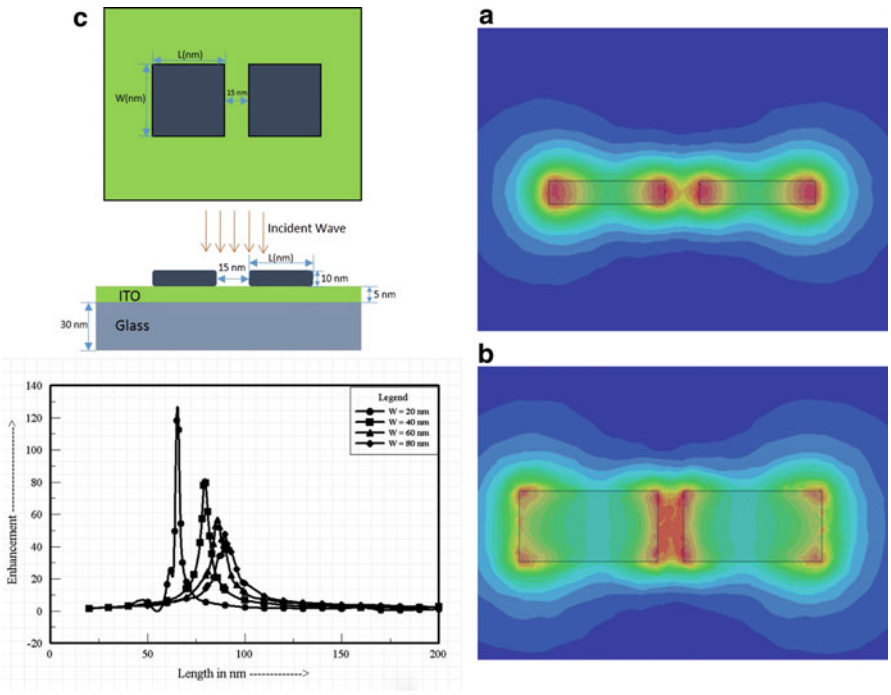

Fig. 8 Maximum enhancement of a gold nanodipole excited at 550 nm (**a**) narrow and (**b**) wide profile. A narrow structure does not maintain resonance when widened without also changing its length

DOI 10.1007/978-981-4560-75-7_43-1

electric field in the gap region, although in some publications this ratio is squared and therefore described as intensity enhancement.

The behavior of the narrower dipole shown in Fig. 8a is more closely aligned with what one would expect at microwave frequencies whereby increasing the length of each nanorod in plasmon half-wavelength intervals will produce successive resonance and antiresonance in the gap input impedance. Notice that the total length of the dipole is a full plasmon wavelength λ_p plus the gap separation distance, as opposed to the typical $\lambda_o/2$ dipole first resonance of a perfectly conducting microwave antenna with a negligible gap width. In terms of plasmon wavelengths, a first resonance does occur in an isolated $\lambda_p/2$ nanorod or a vertical $\lambda_p/4$ nanorod on a metal substrate (Taminiau et al. 2007).

Although an exact determination of the plasmonic wavelength in a dielectric nanorod is not mathematically feasible, (Novotny 2008) has derived an effective wavelength λ_{eff} based on the assumption that the antenna is a thin dielectric cylinder operating in the TM_0 cylindrical waveguide mode. The antenna is immersed in a material with dielectric constant ε_s, a Drude dielectric function is used to describe the metal rod material and the apparent increase in the antenna length at the rod ends is accounted for by an additional reactance term. This scaling law is

$$\lambda_{eff} = n_1 + n_2\left(\frac{\lambda}{\lambda_p}\right) \tag{29}$$

Where λ is the wavelength of the external region, λ_p is the metal plasma wavelength, and n_1, n_2, coefficients with dimensions of length that depend on antenna geometry and static dielectric properties, are

$$n_1 = 2\pi R[13.74 - 0.12(\varepsilon_\infty + \varepsilon_s 141.04)/\varepsilon_s - 2\pi]; n_2 = 0.24\pi \mathrm{R}\sqrt{\varepsilon_\infty + \varepsilon_s 141.04}/\varepsilon_s \tag{30}$$

In Eq. 30 R is the radius of the cylinder, and ε_∞ is the dielectric constant correction in the Drude formula for $\omega \gg \omega_p$. For gold $\varepsilon_\infty \simeq 11$, $\lambda_p = 138\,\mathrm{nm}$ and for silver $\varepsilon_\infty \simeq 3.5$, $\lambda_p = 135\,\mathrm{nm}$ (Novotny 2008).

In the case of an optical patch or dipole antenna it is necessary to account for a phase shift acquired by the surface plasmon polariton upon reflection at rod, strip, or gap terminations. The resonance wavelength λ of metal strip resonators of thickness t and width w are determined approximately by (Søndergaard and Bozhevolnyi 2007)

$$w\frac{2\pi}{\lambda}n_{slow} = m\pi - \phi \tag{31}$$

where n_{slow} is the real part of the mode index of surface plasmon polaritons propagating in a metal film with the same thickness t as the strip, $m = 1,2,3,\ldots$ is the order of the resonance, and ϕ is the phase of the reflection coefficient at strip terminations. For a symmetric structure where $\varepsilon_d = \varepsilon_1 = \varepsilon_2$, once t, and ε_m are selected and the phase shift ϕ determined, n_{slow} can be obtained from Eqs. 22 and 26 or 27 or for thin strips one can use the approximation (Søndergaard et al. 2008)

$$n_{slow} \simeq \sqrt{n_d^2 + \frac{4n_d^4}{k_0^2 t^2 n_m^4}} \tag{32}$$

where n_d and n_m are the indices of refraction of the dielectric and metal and $k_o = 2\pi/\lambda$. The wavelength of the slow surface plasmon polariton is then given by $\lambda_{slow} = \lambda/n_{slow}$.

DOI 10.1007/978-981-4560-75-7_43-1

Analytical models are preferable because clear trends in antenna performance can be seen by adjusting mathematical parameters that represent physical quantities such as the antenna width or length and the excitation frequency. On the other hand numerical techniques can provide both the accuracy and flexibility needed to model complex antenna structures. However, purely mathematical solutions can become clouded with long complex expressions and special functions while a purely numerical analysis provided by the powerful commercial codes that have become available these last few years, while furnishing useful visual data in terms of graphs and charts, do not always provide a way to understand the multifaceted interaction between the variables of an antenna system. Recently a compromise approach for optical antennas has been advanced, advocated primarily by Engheta and Alù (Engheta et al. 2005; Alù et al. 2007; Zhao et al. 2011; Agio and Alù 2013), whereby the antenna and field excitation are replaced by an equivalent lumped circuit model based on numerical analysis data. The basic model, shown in Fig. 9, is centered on a Thévenin equivalent circuit for the antenna with a capacitance accounting for a non-negligible gap impedance Z_g along with the intrinsic impedance Z_a of the dipole. The parallel combination of these two impedances forms the input impedance of the circuit. The input impedance is calculated, by driving the antenna at the gap with an arbitrary source voltage V_g and calculating, with full-wave simulations, the displacement current I_g flowing across the arms at the terminals in the region of the gap $Z_{in} = V_g/I_g$.

The intrinsic antenna impedance Z_a is extracted from the input impedance by first taking the parallel combination of the gap and load impedances according to

$$Z_{in} = \frac{1}{1/Z_a + 1/Z_g};\ Z_g = 1/j\omega C;\ C = \varepsilon_0 S/g \tag{33}$$

where S and g are respectively the gap cross-sectional area and gap height. Setting $Z_a = R_a + jX_a$ and $Z_{in} = R_o + jX_o$, Eq. 33 is rearranged to give:

$$R_a = \frac{R_o}{1 + \omega C\left(2X_o + \omega C\left(R_o^2 + X_o^2\right)\right)} \tag{34}$$

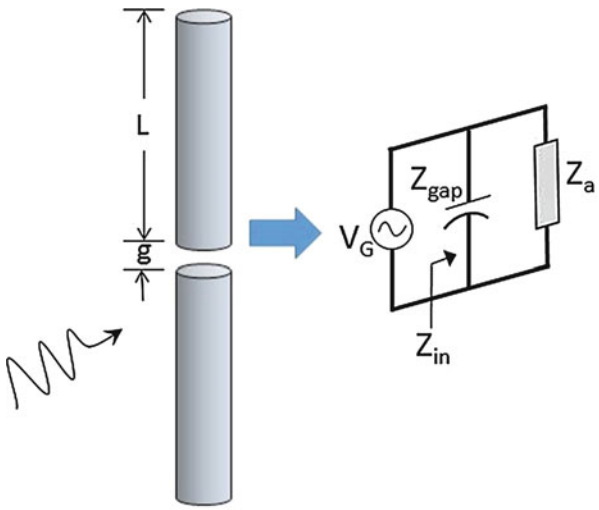

Fig. 9 Optical antenna with equivalent circuit model. The driving voltage could be an incident electromagnetic field, a transmission line connected to the antenna, or a quantum emitter

DOI 10.1007/978-981-4560-75-7_43-1

$$X_a = \frac{X_o + \omega C\left(R_o^2 + X_o^2\right)}{1 + \omega C\left(2X_o + \omega C\left(R_o^2 + X_o^2\right)\right)} \tag{35}$$

Since full wave simulations have provided the Z_{in} components R_o and X_o the dipole intrinsic impedance is determined mathematically from Eqs. 34 to 35. The intrinsic impedance Z_a, which is unaffected by antenna loading either by a transmission line or by altering the gap capacitance, is now completely determined.

The antenna is resonant when the input reactance $X_o = 0$ which from Eq. 35 is

$$\omega_0 = \frac{X_a}{C\left(R_a^2 + X_a^2\right)} \tag{36}$$

The "open circuit" or first resonance has been shown to have a very low value, whereas the "short circuit" or antiresonance has a high impedance, on the order of kilo-ohms. The feed line or other loading conditions will determine which operating frequency is selected. In the event of loading the capacitance becomes $C = \varepsilon_L S/g$, the new resistance and reactance terms in the input impedance $Z_{in} = R_{in} + jX_{in}$ are again found numerically and the equivalent dielectric constant ε_L can be calculated from Eq. 33 with ε_0 replaced by ε_L. Extra circuit elements can be added to account for the transmission feed line or a quantum radiator such as is the case in molecular spectroscopy, or a different circuit can be created for single quantum radiators without a gap (Agio and Alù 2013).

Efficiency is an important measure used to characterize antenna performance. The overall antenna efficiency can be broken down into the product of several measures of efficiency, the most important of which are the radiation efficiency and the reflection efficiency, $\eta = \eta_{rad}\,\eta_{ref}$, where the maximum value of each efficiency is one. The reflection efficiency determines how well the transmission feed line characteristic impedance is matched to the antenna input impedance. Its value, given in terms of the transmission line reflection coefficient Γ, is $\eta_{ref} = 1 - |\Gamma|^2$ where $|\Gamma| \leq 1$. The radiation efficiency is ratio of the total power radiated P_{rad} to the power received P_{in} by the antenna. The input power is assumed to be the sum of the radiated power and the power losses on the antenna. Provided the antenna is fed at the antenna maximum current point, which is most often the case with optical antennas operating at or below the lowest resonant frequency. At the first antiresonance, the radiation efficiency can be expressed in terms the radiation resistance R_{rad} and the ohmic loss resistance R_L experienced by the current flow in the antenna elements. The radiation efficiency is therefore

$$\eta_{rad} = \frac{R_{rad}}{R_{rad} + R_{in}\sin^2\left(\pi L_{eff}/\lambda_{eff}\right)}; R_{rad} = 2P_{rad}/I_{\max}^2 \tag{37}$$

The ohmic loss resistance R_{in} is the real part of the input impedance. The optical dipole radiation resistance can be determined analytically by first hypothesizing the current at resonance. Taking into account the effective length and wavelength of an optical antenna, L_{eff} and λ_{eff} respectively which can be calculated using Eq. 29, the standard microwave expression for a dipole current is modified to become (Alù et al. 2007),

$$I(z) = \frac{I_o \sin\left[\pi\left(L_{eff} - 2|z|\right)/\lambda_{eff}\right]}{\sin\left(\pi L_{eff}/\lambda_{eff}\right)} \tag{38}$$

DOI 10.1007/978-981-4560-75-7_43-1

Where I_o is the numerical displacement current at the feed point $z = 0$. This current Eq. 38 is used to find an analytical expression for the power radiated by the optical dipole P_{rad} which is then substituted into Eq. 37 to find the efficiency.

Antenna directivity defined as $D_o =$ (time average power density maximized with angle)/(average total power radiated through a sphere), can again be analytically calculated with the formulas above as can gain which is the product of the efficiency times the directivity, $G_o = \eta_{rad} D_o$. Keep in mind that this exercise has been a combination of numerical and analytical calculations, forming a hybrid approach that seems best suited for understanding complex interactions as well as for overall engineering optical antenna design. Although the example of a dipole has been used here, many other structures have been successfully investigated using this equivalent technique (Zhao et al. 2011; Agio and Alù 2013). For design data for the dipole based on measurements the reader is referred to references (Schuck et al. 2005; Fischer and Martin 2008; Muskens et al. 2007).

Bowtie Antenna

Compared to a dipole antenna, the bowtie antenna has the advantage of broadband operation yet it is a simple design. The feed point of a bowtie antenna is a gap at the vertex of two tip to tip apposal triangular electrically conducting arms. If extended to infinity while the angles of the triangle vertices remain unchanged this antenna would be frequency independent. When the incident field polarization is perpendicular to the gap, the antenna can be driven into resonance. Figure 10 shows the intensity distribution for a 520 nm resonant bowtie design made out of gold on a SiO_2 substrate and excited by a normally incident plane wave. The numerical simulation in Fig. 10a shows that a high field intensity distribution occurs not only at corners and in the gap region but also along each of the sides, likely due to the sharp edge design. In Fig. 10b a plot of the electric field vectors immediately above the surface of antenna indicate the largest field components are just above the gap region but tend to decrease in amplitude as they spread out and terminate at the wider ends of the antenna arms where a much lower intensity is seen in Fig. 10a. The intensity of the field in the bowtie gap has been shown to be strongly dependent upon the gap width (Schuck et al. 2005). For the design presented in (Schuck et al. 2005), starting on the order of 50 nm the resonant intensity climbs exponentially as the gap separation narrows, however as the gap separation widens the intensity tends to level out at around 100 nm. Although very little work has been carried out concerning mathematical design criteria for the construction of on-surface optical antennas, optimal design dimensions can be obtained through published data gathered in experiments. For optical frequency design data based on measurements for the bowtie antenna the reader is referred to reference (Fischer and Martin 2008). Studies have also been carried out to determine optimum

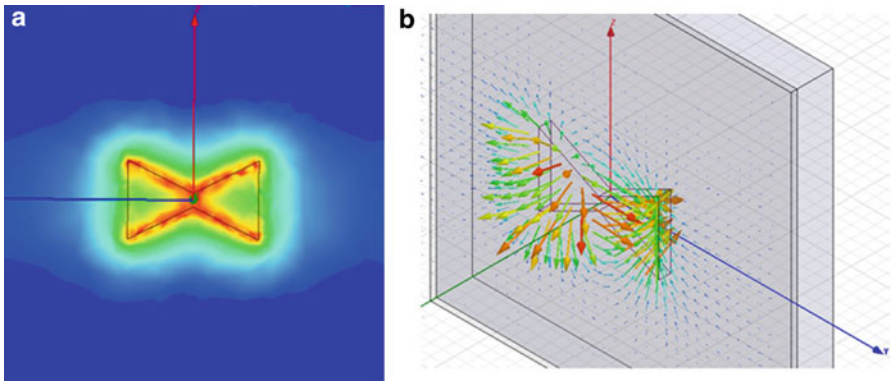

Fig. 10 Bowtie antenna with (**a**) highest field intensity shown in red around the edges and corners of the triangular arms and (**b**) electric field vectors where the largest amplitude field is displayed in red occurs in the gap between the two arms

DOI 10.1007/978-981-4560-75-7_43-1

bow angle, the outside angle formed by the edges of the two apposal arms of a bowtie antenna. It has been reported that the strongest enhancement can be obtained with a bow angle of 90° (Fischer and Martin 2008).

Unlike microstrip antennas printed on a thin substrate with a metal backing focusing radiation into the air region above, optical antennas are a single metal radiator lying on a dielectric-air interface. There can be no ground plane below because there are no perfect conductors at optical frequencies. Although radiation is in both directions, most of the energy radiated from an optical antenna tends to couple into the higher density substrate. In the microwave case a TM_0 mode surface wave can be launched into the substrate because this mode has no cutoff wavelength, but the fundamental mode in a typical microwave patch antenna is not conducive to launching TM modes. As long as the substrate is thin a microwave patch antenna suffers little substrate induced loss. As the substrate thickens energy from the microwave patch antenna is coupled into surface wave modes, seriously degrading the efficiency of the antenna. However, an optical antenna radiates in both directions regardless of the substrate thickness, making it in any case less efficient than its microwave counterpart. One measurement study carried out in the infrared range (Fischer and Martin 2008) concluded that the dipole and bowtie efficiencies are respectively 20 % and 30 % whereas a typical microstrip patch antenna has an efficiency of 60 %. A similar conclusion was reached in a more recent study (Agio and Alù 2013) that included the optical dipole, bowtie, and dimer constructions. A dimer, which has two pancake shaped arms, has an efficiency level close to the bowtie design. Numerical investigations of the optical Yagi-Uda design show a strong emission into the substrate and a much smaller emission lobe into the air side of the surface (Hofmann et al. 2007; Kosako et al. 2010). Although most of the electromagnetic radiation is emitted into the critical angle below, the above surface emission still shows a strong directivity.

Yagi-Uda Antenna

The dipole and bowtie nanoantennas described above are most often used in applications where a wide beamwidth or broadband transmission is the primary objective. However as nano-science progresses, achieving highly directional beams in the optical regime will be necessary in order to, for instance, transmit signals from nanocircuits to a receiver above the surface with a minimum power load on the electronic system. Another significant application is the possibility of enhancing and directing the radiation from a nano-emitter, which will be discussed in the Applications section below. At the microwave level the Yagi-Uda antenna shown in Fig. 11 has proven to be highly directional for radiation of radio waves yet simplistic in construction. One would expect that basically similar design principles can be used to obtain directionality with an optical Yagi-Uda design. Over the last few years this has been shown to be the case primarily due to the fact that the elements of the Yagi antenna are nanorods, the

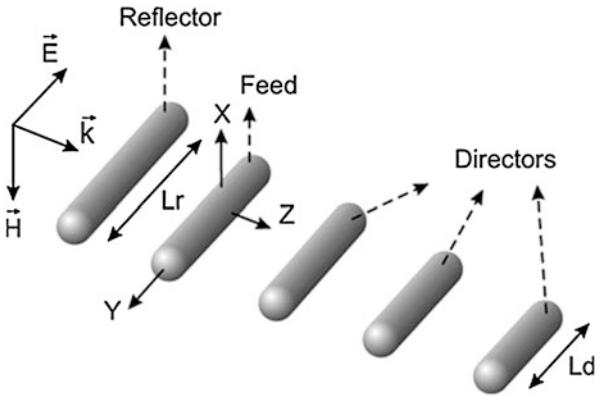

Fig. 11 Yagi-Uda optical antenna constructed with nano rods

DOI 10.1007/978-981-4560-75-7_43-1

properties of which have been the subject of extensive study by the optics community over the last 30 years.

The essential Yagi-Uda design consists of a resonant driven element flanked on one side by a longer passive reflector element and on the other by a series of shorter director elements, all of which lie in the same plane. Researchers have studied a variety of element types for the Yagi, including spheres and prolate spheroids, but low efficiency and difficulties in achieving smooth surfaces and precise positioning on the nano level has focused attention on the classical cylindrical rod design. In addition to surface smoothness and the precise rod length and positioning needed for optimum array performance, other difficulties encountered in the optical regime are the loss of energy coupled into the substrate, the difference in wavelength between free-space and the metallic rods, and field interaction with the air-substrate boundary causing a phase difference between surface plasmons on the two sides of the antenna. Naturally these effects can be modeled by pure numerical calculations but preventing unwanted consequences such as the substrate energy loss are still left open for future research. However detailed design rules have been developed (Hofmann et al. 2007) for the optical Yagi. As a rough estimate high directivity can be obtained with separation distances of about 0.25λ between the feed and the reflector and about 0.3λ between the feed and the director and between each of the director elements (Kosako et al. 2010). The length of the feed element is the effective resonant wavelength λ_{eff} of the antenna rods which is related to the incident free space wavelength λ by a simple relation $\lambda_{eff} = n_1 + n_2(\lambda/\lambda_p)$ given in Eq. 29 above with an accompanying discussion.

A scanning near-field optical microscope (SNOM) has been used to simultaneously image the amplitude and phase of the normal E-field component on a working Yagi-Uda nanoantenna (Dorfmuller et al. 2011). This data was processed to produce a time evolution animation of the fields of the antenna during reception, providing an unusual opportunity to check time domain numerical simulations of the received fields. These measurements showed that illumination of the antenna from the forward direction resulted in constructive interference of scattered light by the antenna elements which leads to a strong field enhancement in the feed element. Measurement data taken when illumination is from the rear of the antenna reveal that the destructive interference by the feed element suppresses strong fields.

Log-Periodic Antenna

To date most theoretical and experimental studies on directional optical antennas have focused on the Yagi-Uda design, shown in Fig. 11, which provides good directivity for a specific design frequency with a limited bandwidth. A possibility of improving both bandwidth and directivity may be met with a log-periodic antenna design. The name is derived from a progressive spacing between the elements of the antenna based on a logarithmic scale. A number of log-periodic design schemes have been employed at microwave frequencies. At optical frequencies several graded size and spacing designs have been proposed with elements varying in shape from spheres and ellipses to the classical elongated rod. Due to difficulties in creating precise size and shapes at the nano level most implementations are only approximations of the true log-periodic requirement.

In a log-periodic antenna arrangement (Balanis 2005) the arm lengths (l_n), spacing between arms (R_n) and rod diameters (d_n), increase logarithmically as defined by the inverse of the geometric ratio τ as given by

$$\frac{1}{\tau} = \frac{l_{n+1}}{l_n} = \frac{R_{n+1}}{R_n} = \frac{d_n}{d_{n+1}} \tag{39}$$

DOI 10.1007/978-981-4560-75-7_43-1

Another parameter associated with the array, but independent of the geometric ratio, is the scaling factor. The scaling factor is often expressed normalized by the element length and as such it is given by $\sigma = d_n/2l_n$. The half angle at the antenna apex is determined by the parameters τ and σ according to $\alpha = \tan^{-1}[(1-\tau)/4\sigma]$.

In one study (Pavlov et al. 2012) carried out measurements on an optical log-periodic antenna with gold elements on a glass substrate strictly following the design criteria above. However unlike other optical array designs, a gap was placed in the middle of each arm in order to enhance the field produced by plasmonic action. It was observed that the directionality of the antenna reaches a maximum with $N = 10$ elements but the optimum field enhancement value of $|E|^2_{FB}$ for the forward beam electric field is obtained between $N = 6$ and $N = 10$. A decrease of the intensity enhancement values, defined as $|E_{total}|^2/|E_{inc}|^2$ with increasing numbers of elements is associated with increasing plasmonic losses incurred in the addition of elements. Adding a gap did not affect the antenna patterns, however a significant increase in beam intensity was observed. As with other on-surface plasmonic antennas a significant portion of the radiated power is coupled into the substrate.

One of the drawbacks of the log-periodic design is that the currents in the optical version have the same phase in each element. In addition the elements are closely spaced producing a phase progression of the current in the direction of the longer elements. This produces an endfire beam in the direction of the longer elements and interference effects in the pattern. The standard design for a log-periodic antenna calls for crisscrossing the feed between adjacent elements thereby adding a 180^o degree phase shift to the terminal of each element. Since the shorter elements are spaced closer together and opposite in phase, very little energy is radiated from them and interference effects are minimal. The radiation pattern in this crisscross case tends to be toward the shorter elements (Balanis 2005). In the previous paragraph the design calling for dipoles rather than solid rods appears to be a step in the right direction. The plasmonics of optical frequency materials and construction methods on the nano level will determine the efficacy of adapting the standard microwave design where alternate dipoles are connected.

Subwavelength Particles

The spheroid is the basic subwavelength plasmonic particle employed in optical antennas. It is usually described in terms a major axis with diameter $2a$ and two minor axes with diameters $2b$ and $2c$. The electrical behavior of metallic particles can deviate remarkably from their bulk form, particularly in terms of their resonant behavior when illuminated by an electromagnetic field. Typically the imaginary part of a bulk form dielectric function will go through a maximum at resonance. However, the imaginary part of the dielectric function of a metal particle will have no maximum, but rather decreases monotonically in magnitude as the frequency increases. Nevertheless, when $\varepsilon_m = -2\varepsilon_s$, where ε_m is the real part of the particle dielectric function and ε_s is the dielectric constant of the surrounding medium, a small spherical metal particle will have a peak in its absorption cross-section at ω_F, which corresponds to the particle resonant or Fröhlich frequency (Bohren and Huffman 2004). If the damping coefficient is small the real part of the Drude model dielectric function in Eq. 16 gives a resonant frequency

$$\omega_{\mathrm{F}} = \frac{\omega_p}{\sqrt{1+2\varepsilon_s}} \tag{40}$$

for a small spherical particle. For metallic ellipsoids the absorption cross-section is a maximum when

$$\omega_{\mathrm{F}} = \omega_p \sqrt{\frac{L}{\varepsilon_s - L(\varepsilon_s - 1)}} \tag{41}$$

DOI 10.1007/978-981-4560-75-7_43-1

where L is a geometric function that takes into account the shape of the ellipsoid. Most nanoantennas are prolate spheroids, which have the property $b = c$ and a geometric function

$$L = \frac{1-e^2}{e^2}\left(-1 + \frac{1}{2e} ln \frac{1+e}{1-e}\right); e = 1 - \frac{a^2}{b^2} \tag{42}$$

The shape of a prolate spheroid ranges from a needle ($e = 1$) to a sphere ($e = 0$). For a sphere $L = 1/3$, which reduces Eqs. 40 to 39. For a more detailed discussion and formulas for other shapes, such as disk and associated variations, see (Bohren and Huffman 2004).

Various particle shapes have been discussed in the literature with the idea of creating an enhanced field concentration. Typically single solid particles, for example constructed with gold or silver, have the low field enhancement (see Fig. 1d). It was later found that dielectric spheres covered with a gold or silver shell exhibited stronger enhancement of the incident field. However no single particle has shown the promise of exceptionally high field concentration seen in the dimer configuration pictured in Fig. 12a.

Although enhancement schemes with multiple nanoparticles produce strong fields between particles many applications require the concentration of strong fields at locations where the antenna structure is removed from the high intensity area of the enhanced field. To this end there has been a good deal of research on self-similar particles. The Yagi-Uda and log-periodic antennas are two examples. Another example is shown in Fig. 12b, c, likely motivated by the Yagi-Uda design. When two self-similar gold spheres containing different radii are connected together, an enhanced field is produced at the end of the smaller sphere as shown in Fig. 12b, c is a continuation of this idea with additional spheres containing successively smaller radii. Although successful in design due to a considerably improved enhancement exterior to the tip, this antenna, like many free standing designs, does not offer enhancements exceeding that of the gold coated cone tip commonly used in SNOM applications described below.

Purcell Factor

Light emission from an optical quantum emitter such as a quantum dot or a nano-crystal can be enhanced when in close proximity to an intense electromagnetic source. This effect was first discovered at radio frequency by E. M. Purcell in 1946, when he observed an increase in the probability of spontaneous emission of an emitter placed in a resonator (Purcell 1946). However, controlling the degree of enhancement of a quantum emitter remains a major challenge. Optical microcavities or microresonators such as optical nanoantennas, generally used for emission enhancement can be mathematically quantified by what has become known as the Purcell factor F (Vahala 2003), defined as:

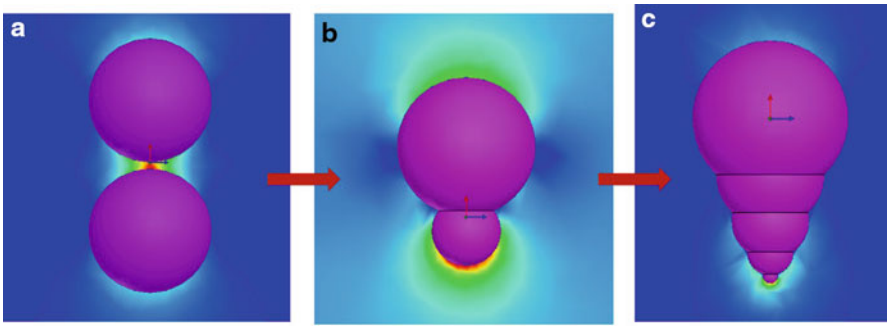

Fig. 12 Spherical particle nanoantennas arranged in (**a**) a two-sphere dimer configuration and as (**b**) two and (**c**) multiple attached self-similar spheres. An enhanced field region is seen to exist external to the self-similar configuration at the end of the smallest sphere

DOI 10.1007/978-981-4560-75-7_43-1

$$F = \frac{3}{4\pi^2}\left(\frac{\lambda}{n}\right)\left(\frac{Q}{V}\right) \tag{43}$$

where λ is the wavelength of the emitted photon, Q and V are the quality factor and mode volume respectively, and n is the refractive index of the surrounding medium. The Q corresponds to the temporal confinement while the mode volume V represents the spatial confinement. Although cavity based structures can provide very high Q (~10^4) (Song et al. 2005), they are consequently narrow bandwidth devices. This spectral limitation is a problem for contemporary solid-state quantum emitters which, despite many efforts in research, still have a broad spectral emission due to stability issues (Gaebel et al. 2004).

Optical nanoantennas, on the other hand have a much lower Q (~100) (Curto 2013) and hence are suitable for applications involving broadband sources. However, due to surface plasmon polaritons, they have the capability to highly confine the light source volume well beyond the diffraction limit (Maier 2006; Barthes et al. 2011). Coupling optical nanoantennas with quantum structures like quantum dots can result in highly directive quantum emitter intensity pattern, but with a mode volume as low as 0.002 $(\lambda/n)^3$ (Curto 2013) and therefore, a very high Purcell factor.

Aperture Antennas

So far in this chapter on-surface optical antennas have been emphasized primarily because there is considerable current scientific and industrial interest in the design of antennas for optical and near infrared communications. However, there is also significant industrial interest in antennas that are effective in focusing light to sub-wavelength dimensions. A primary application lies in the possibility of extending current photolithographic techniques to produce circuit chips on a sub-wavelength scale using relatively inexpensive optical equipment as compared to ion beam etching machines. Nano-aperture antennas have been the key component in sub-wavelength lithographic research and also been a key element in the development of several other technologies that will be discussed in the Applications section. Below a brief treatment of the theory of optical aperture antennas is presented followed by an overview of selected designs that have received popular attention in the literature.

Optical Aperture Antenna Theory

Although important nano level aperture optics was carried out in the study of fluorescence molecules in the 1980s (Fischer 1986), the report by (Ebbesen et al. 1998) of dramatically enhanced transmission through sub-wavelength holes in metal films, was an event that spurred widespread interest in optical aperture antennas. Because this phenomena, now known as extraordinary optical transmission (EOT), seemed to fly in the face of the widely accepted classical electromagnetic analysis by (Bethe 1944) and (Bouwkamp 1950), there has been considerable scientific interest in the subject reaching to the core of surface plasmon theory. According to the classical theory, the power transmitted through an aperture in an infinitely thin metallic screen scales as the inverse fourth power of the aperture size in terms of wavelengths. If the screen is made to be of finite thickness, then an additional reduction in the transmitted field strength will result, due to the below-cutoff dimensions of the slot. However, it was discovered, first experimentally and then confirmed by numerical analysis, as shown in Fig. 13, that for metals at optical frequencies there are situations where remarkable amounts of energy pass through sub-wavelength slits and holes. Figure 13 illustrates a cross-sectional view of a metallic sheet made of silver with two slots passing through the sheet. This nanostructure is excited by a plane wave from below. The magnitude of the field intensity shows a complicated structure with significant field at the slot corners, an interaction resulting in strong standing waves in the horizontal direction below, some weak field transmission through the slots, and a standing wave pattern on top of the center plate.

DOI 10.1007/978-981-4560-75-7_43-1

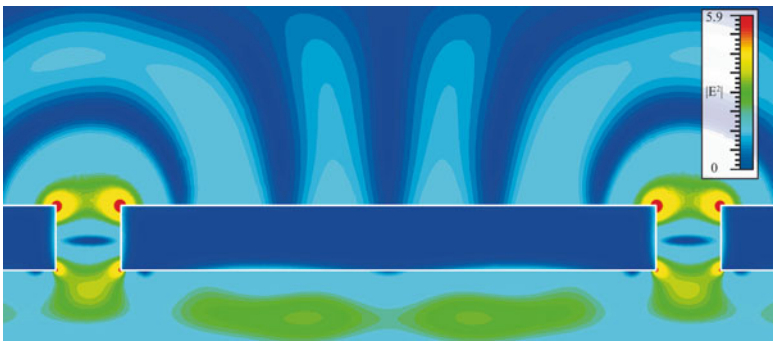

Fig. 13 Numerical calculation (CST©) showing a surface plasmon standing wave E^2 pattern on a thin silver plate with dielectric constant $\varepsilon_r = -18.242 + j1.195$ between two slots illuminated by a 660 nm plane wave from below. The center plate has a length $5/2\lambda_{spp}$ (1,650 nm) and each aperture has a width and thickness of $\lambda_{spp}/3$ (200 nm)

Although (Ebbesen et al. 1998) explained EOT in terms of surface plasmon polaritons, others (Lezec and Thio 2004; Gay et al. 2006) questioned the existence of surface plasmons and asserted that the observed phenomena could be explained by the existence of evanescent waves arising in a classical electromagnetics analysis not used by Bethe and Bouwkamp. However, a more detailed study that evolved through a series of technical papers confirmed the original EOT hypothesis (Lalanne and Hugonin 2006; Nevels and Michalski 2014). In the following a purely mathematical analysis is presented revealing the nature of transmission through sub-wavelength holes including the surface plasmon, a space wave in the vicinity of the aperture, and a lateral wave behavior on the metal surface at distances over 100 surface plasmon wavelengths removed from the aperture. The importance of this analysis lies in the fact that surface plasmon radiation plays a more significant role in optical aperture radiation than does diffraction. Also because many applications require optical apertures with narrowly focused beams it is important to know that significant energy is carried in surface plasmon polaritons on the surface of the metal on the side opposite the aperture excitation.

A thin slot aperture is modeled by placing a 2-D magnetic line current on the air-metal interface along the y-axis perpendicular to the page, as shown in Fig. 1. This arrangement gives rise to a transverse magnetic (TM) field, which has three non-zero electromagnetic field components H_y, E_x and E_z. A straightforward analysis yields the magnetic field along the air-metal boundary:

$$H_y(x) = -\frac{k_o}{2\pi\eta_o}\int_{-\infty}^{\infty}\tilde{G}(k_x)e^{-jk_x x}dk_x \tag{43}$$

$$\tilde{G}(k_x) = \frac{1}{\tilde{D}(k_x)}, \tilde{D}(k_x) = \frac{k_{z2}}{\varepsilon_2} + \frac{k_{z1}}{\varepsilon_1}, k_{z1,2} = \sqrt{k_{1,2}^2 - k_x^2} \tag{44}$$

where $\tilde{G}(k_x)$ is the Green function in terms of the spectral variable k_x, ε_1 is the dielectric constant of the upper half-space and ε_2, containing a negative real part, is the dielectric constant of the metal lower half-space. Assuming the permeabilities of the two regions are the same as that of free-space, the location of the surface wave pole k_{xp}, which can be found analytically by setting $\tilde{D}(k_x)$ to zero, is $k_{xp} = k_o\sqrt{\varepsilon_1\varepsilon_2/(\varepsilon_1+\varepsilon_2)}$ as predicted by Eq. 6. The corresponding residue is

DOI 10.1007/978-981-4560-75-7_43-1

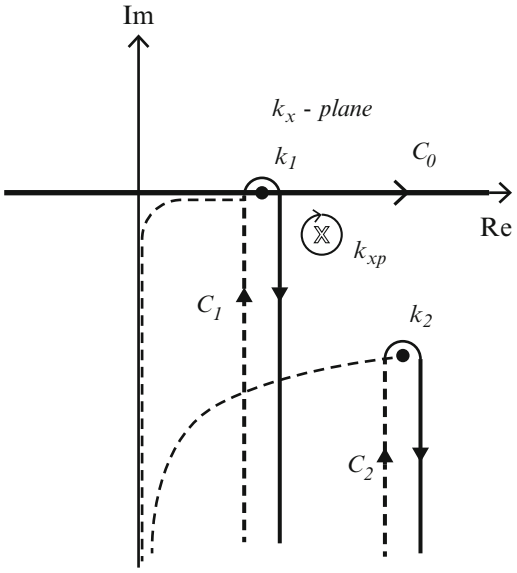

Fig. 14 Complex plane integration path around branch cuts connecting the branch points k_1 and k_2, the wavenumber for air and metal respectively, and the SPP pole k_{xp}

$$R_p = \frac{1}{\tilde{D}'(k_{xp})}, \tilde{D}'(k_x) = -k_x\left(\frac{1}{\varepsilon_2 k_{z2}} + \frac{1}{\varepsilon_1 k_{z1}}\right) \tag{45}$$

The spectral domain Green function $\tilde{G}(k_x)$ has branch points at k_1 and k_2, respectively the wavenumbers of air and the metal at optical frequencies. Air is lossless, so k_1 is real and therefore lies on the real axis, as shown in Fig. 14, whereas metal has significant loss, so k_2 is far removed from and below the real axis. The field can be obtained by integrating in the k_x-plane along the real axis, path C_0, from minus to plus infinity by means of the definitions $\mathrm{Im}(k_{z1}) < 0$ and $\mathrm{Im}(k_{z2}) < 0$ on the top sheet of the complex plane for both branch cuts. Integration on the real axis can be improved upon by deforming the integration path vertically so that C_0 is replaced by C_1 and C_2, paths of steepest descent in the k_x-plane. An important consequence of the optical properties of a noble metal is that the position of the pole k_{xp} is such that it is captured by the vertical path deformation. Had the real part of the dielectric constant of metal been positive, the pole would reside to the left of the integration path below k_1 and therefore it would not be captured by the integration path. It has been shown that poles captured by the steepest descent path are physical waves, in this case a surface plasmon wave, whereas poles not captured are not actual waves although they do influence the behavior of the field through their proximity to the integration path (Collin 2004). The contribution from the integral C_2 around the branch point at k_2 is negligible because the branch point lies well below the real axis so exponential decay due to the imaginary part of k_x is significant. The spatial domain Green function can now be expressed in terms of its pole and branch point components as,

$$G(x) = \underbrace{\int_{C_1} \widetilde{G}(k_x)\, e^{-jk_x x} dk_x}_{\text{Composite Wave}} + \underbrace{\int_{C_2} \widetilde{G}(k_x)\, e^{-jk_x x} dk_x}_{\text{Negligible}} - \underbrace{2\pi j R_p e^{-jk_{xp}x}}_{\text{SPP Wave}} \tag{46}$$

A careful analytical study of the composite wave shows that subtracting the surface plasmon polariton pole from the C_1 integrand yields a negligible result. However, when the pole is added back the resulting analytical expression yields the following limiting case forms (Nevels and Michalski 2014),

DOI 10.1007/978-981-4560-75-7_43-1

$$I_p(x) \sim \begin{cases} x^{-1/2} \text{ for small and moderate distance } x \\ x^{-3/2} \text{ for sufficiently large distance } x \end{cases} \tag{47}$$

At small or moderate distances from the aperture (magnetic line source) the magnetic field has a $x^{-1/2}$ behavior, the same as the small argument behavior of a Hankel function for a line source in free space and is often referred to as the "space wave". At large distances the $x^{-3/2}$ decay is typical of lateral wave behavior.

Numerical results displaying the composite wave (solid line) and surface plasmon polariton wave (dashed line) where the metal is silver and the line source is radiating at 633 nm and 2,500 nm are shown in Fig. 15 below. As predicted the dominant behavior of the magnetic field near the aperture is the $x^{-1/2}$ space

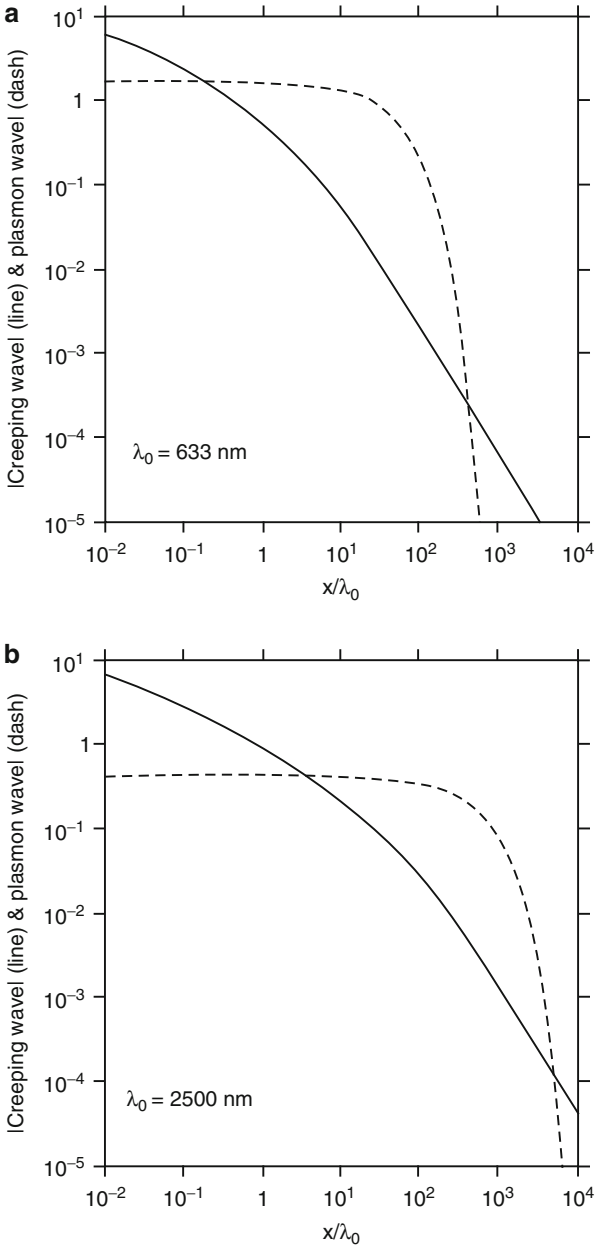

Fig. 15 Logarithmic scale comparison of composite wave and surface plasmon polariton wave normalized amplitude for an air-silver interface as a function of distance from the source at (**a**) 633 nm (**b**) 2,500 nm

DOI 10.1007/978-981-4560-75-7_43-1

wave. However at greater distances the plasmon wave becomes dominant, and in Fig. 15a close to 500 wavelengths where the plasmon wave tends to rapidly decay the lateral wave behavior $x^{-3/2}$ dominates. Figure 15b shows that at 2,500 nm the surface wave amplitude is reduced due to losses that enter the numerical calculation through the dielectric function given in Fig. 5. Eventually, at frequencies below the near infrared range, the metal begins to behave more like a perfect conductor and the space wave completely dominates the behavior of the field.

This exercise confirms the existence of the plasmon wave and displays its relationship to other wave phenomena produced in the aperture of a sub-wavelength slot and on the air-metal interface. More important from an antenna engineering standpoint is that energy carried by the plasmon wave through the slot does radiate into the space wave above the slot. The question, "Can a plasmon wave pass through a slot?" is answered by the analysis at the beginning of this chapter and in an excellent review covering analytical methods used to determine the properties of subwavelength apertures (Garcia-Vidal et al. 2010). Because a surface plasmon wave is tightly bound to the metal surface, decaying to $1/e$ at distances far less than a wavelength above the metal walls, its expression in a waveguide is not governed by the typical waveguide boundary conditions. Plasmon waves in the two walls of the slot, although not entirely independent of one another, are not subjected to cutoff conditions and can therefore carry much more energy than a waveguide evanescent mode or even an infinite sum of evanescent modes. The conclusion that can be drawn from this analysis is that at optical wavelengths a significant amount of plasmon energy can be transported through a metallic slot with a sub-wavelength width. Because the slot is sub-wavelength in width it is therefore possible to form an array of plasmonic radiators to focus an intense beam to a sub-wavelength line or spot.

Bowtie Aperture Antenna

Many aperture antennas are a simple Babinet equivalent of their metal counterpart. The aperture bowtie, also known as the diabolo antenna, is one such design. The aperture bowtie shown in Fig. 2c differs from the well-known metal bowtie nanoantenna in that the opposing pair of aperture triangles are connected through an aperture extension of the facing triangular tips. Thus instead of a large charge density accumulating between the triangles across the air gap, a high optical current density develops within the gap but between the narrowly spaced metal sides of the gap. A high intensity enhanced field component is achieved in the gap connecting the apposal triangular arms by polarizing the incident light parallel to the narrow gap connecting the arms. Polarizing the incident field across the narrow dimension of the gap will produce little or no field enhancement. One of the interesting properties of the aperture bowtie is that the magnetic field rather than the electric field is enhanced in the gap. By analogy, the metal bowtie behaves more like an electric dipole and the aperture bowtie more like a magnetic dipole. Numerical simulations have shown a 2,900-fold enhancement of the magnetic field at a wavelength of 2,540 nm, confined to a 40-by-40 nm region near the center of the nanoantenna.

Although in general aperture antenna enhancement is not as high as can be achieved with a similar metallic structure, apertures are easier to make and have the advantage of providing a visual objective. The aperture bowtie has been shown to have sufficient enhancement and confinement to be effective in nanolithography applications (Wang et al. 2006). The effectiveness of the aperture bowtie nanoantenna in nanolithographic applications is attributed to the fact that the magnetic field created in the aperture gap above the photoresist mask enters the mask in the perpendicular direction, easily penetrating into the metal, thereby leading to noticeable dissipation effects (Grosjean et al. 2011).

Optical tweezers are instruments that use light to move microscopic particles. Most often this requires a high powered focused laser beam to provide the necessary force to trap and move the particle. Optical tweezers are often needed in biological applications and are expected to have important applications in the construction of nano-machines. A variant on the bowtie design has been shown to create an optical vortex

DOI 10.1007/978-981-4560-75-7_43-1

in the electromagnetic field (Kang et al. 2011). The unusual field pattern is such that a small particle moving away from the center of the vortex experiences increasingly higher forces pointing back towards the center. The aperture bowtie provides the user the ability to see the particle while manipulations are carried out.

Concentric Rings

Perhaps the most useful aperture antenna enhancement design is a concentric ring structure. In cross-section the ring has the appearance of a shallow trough etched into the metallic surface. Concentric rings have been incorporated around a variety of aperture designs with the goal of concentrating the transmitted signal into a narrow beam or to gain maximized reception. A single radiating aperture must be large in terms of wavelengths and contain a flat planar phase-front in order to concentrate the signal. A common example at microwave frequencies is a parabolic dish antenna which in practice will have an aperture size of at least ten wavelengths. However, a typical single sub-wavelength aperture antenna will have a large beamwidth. In order to provide directionality, an optical aperture antenna can be modified by adding the concentric ring structure which in essence provides a Bragg reflection condition for plasmon current waves traveling out from center. Another way of looking at the concentric ring design is that it provides an external impedance match condition for the source driven aperture.

Again, because metal at optical frequencies has a behavior similar to that of a dielectric, at least in terms of boundary conditions, numerical solutions provide the only route to design criteria for concentric rings. The number of grooves, groove width, groove depth, periodicity of the grating, hole diameter, and the distance between the first groove and the driven aperture all play a role and are strongly interlinked in the design. However, a basic optimization criteria for bull's eye structures has been formulated based on extensive numerical studies. What follows is repeated from an excellent discussion on the subject, which can be found in more detail in a paper by (Mahboub et al. 2010): The first item to define is the desired resonance wavelength which in turn determines the period of the structure. The choice of the hole diameter will then be determined by whether one would like optimal efficiency as normalized to hole area or highest absolute transmission. For the former, the diameter should be about half the period, but for the latter the aperture size can be increased. It should be noted that as the hole size increases relative to the period, the spectrum will eventually broaden which is a trade-off. The groove width should also be around half the period with a depth to width ratio at 0.4. The number of grooves should be just enough to reach saturation, typically around six to ten grooves depending on the geometrical parameters.

Arrays

Many other specialized aperture designs have been reported in the literature, although design information is scarce. Usually the designer can refer to the current microwave antenna literature as a starting point for a numerical parameter investigation to determine that proper dimensions for an optical antenna design. External to the antenna the array factor and standard microwave array methods will typically be applicable to optical antenna array design, assuming the aperture field information is known. That is, a computer code must be used to determine the near-field and a suitable array factor can be applied to the aperture near-field information to find the far-field. The array elements can be square or circular or any one of the antennas discussed above. Rectangular shaped apertures are of particular interest since they are the Babinet equivalent of a dipole antenna. The half-wavelength resonance condition applies to the slot antenna of high conductivity and a half-wave slot leads to a resonantly enhanced and aperture confined electric field (Park 2009).

Applications of Optical Antenna

SNOM

Scanning near-field optical microscopy (SNOM), an important technique for visualizing biological systems, involves obtaining high resolution topographic and optical images with a cone shaped probe that scales down to the nano level at the tip. The need for high spatial, temporal and resolving power with subwavelength resolution was the driving factor in a move to the fiber aperture probe, essentially a tapered optical fiber with a nanoscale tip. Evanescent or non-propagating fields that exist only near the surface of the object carry the high frequency spatial information about the object and have intensities that drop off exponentially with distance from the object. Because of this, the detector must be placed very close to the sample in the near-field zone, typically a few nanometers. However, the aperture probe suffers from diffraction of light at the tip, which reduces its imaging resolution. Present research is centered on finding an antenna design that reduces the fiber beamwidth, thereby improving resolution. Although fabrication of tips true to the design criteria and surface smoothness are significant challenges to be overcome, a number of antenna structures such as the bowtie, Yagi and several plasmonic nanosphere probes have been tried out showing successful improvement in many cases.

Photon Emitters and Optical Fluorescence

Single photon emission from a quantum emitter generates a stream of photons. Single photons can be used in a number of technologies such as Computed Tomography, which is an imaging technique able to provide 3D information. A single quantum emitter positioned inside the subwavelength size feed gap of an optical antenna couples to the antenna, radiating in such a way as to be considered to be an impedance matching device. The density of the emitted photons thereby increases, improving the tomographic image.

Solid state light-emitting devices are expected to eventually replace fluorescent tubes as illumination sources. Quantum dot nanocrystals are very promising for light-emitting sources. However, their light-emission efficiencies are still substantially lower than those of fluorescent tubes. It has been observed that quantum emitters in close proximity to a plasmon producing metal surface causes plasmonic fluctuations of the free electron gas. The associated currents radiate, in many cases with a significant increase in intensity. Antenna structures such as the bowtie have been designed, optimized in size, shape, and material properties to increase the radiation efficiency of a nanoscopic optical source. However, for visual appeal, sources with greater optical bandwidth are needed (Farahani 2006; Curto et al. 2010).

Raman Spectroscopy

Molecules vibrate, rotate and translate in a number of ways when exposed to an electromagnetic field. Raman spectroscopy is an optical technique used to detect the vibrational modes. It relies upon detection of a very low intensity portion of the scattered wave spectrum called inelastic or Raman scattering. Because molecules of a particular type, such as anthrax or mold aflatoxins, have a certain Raman spectra they can be identified by this method. However, because the Raman spectra is very small, very intense laser light is required in order to move the Raman signal above the noise level. Plasmonic nanoantennas create highly enhanced local fields when pumped resonantly, leading to increased Raman scattering (Felidj et al. 2003).

Communication with Nanocircuitry

As circuit chips become smaller and processer speeds increase, wire leads to the circuitry become less practical and less efficient. However, nanoantennas can overcome these drawbacks, with more efficient and on-chip created optical antennas communicating over wireless links to external circuitry. Cross-talk

DOI 10.1007/978-981-4560-75-7_43-1

and the many problems with computer interconnects can be eliminated. One of the properties of on-surface optical antennas is that most of the radiated energy travels downward into the chip substrate. This can become an advantage where the construction of a via through the nanochip is impractical. A proper nanoantenna design would allow the circuitry to rapidly communicate back and forth directly through the substrate.

Conclusion

In this chapter an overview of the field of optical antennas has been presented along with some of the basic theory of plasmonics, the underpinning concept governing electromagnetic wave behavior at optical frequencies. It was shown that surface plasmon polaritons lead to a set of requirements and restrictions placed on the design of antennas constructed out of noble metals at optical and near infrared frequencies. An unusual aspect of plasmonic waves in metals is their subwavelength behavior, an advantage when detecting small particles but it can cause added difficulty when impedance matching an optical antenna to free space. It was shown that the surface plasmons explain the unusual amount of radiation coupled through a subwavelength aperture and that as a consequence aperture optical antennas are remarkably efficient, behaving in a manner similar to their Babinet equivalent counterpart. Spectroscopy, disease and toxin sensors, wireless communication with nano-circuitry and the creation of nano-circuits using subwavelength lithography are some of the early beneficiaries of this new technology. The field of nanoplasmonics offers great opportunities for optical frequency circuit and antenna engineers with the future easily as bright as it is for the modern day wireless engineer.

Grid Antenna Arrays

Mei Sun[a]* and Yue Ping Zhang[b]
[a]Institute for Infocomm Research, A*STAR, Singapore, Singapore
[b]School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore, Singapore

Abstract

Grid antenna array (GAA) is a kind of planar array antenna with multiple rectangular loops. It can flexibly function either as a traveling-wave or non-traveling-wave antenna. This chapter lists clearly the different variations of the GAA and reviews briefly its theory development as well as applications. With a focus of the resonant GAA for 60-GHz millimeter-wave applications, the basic theory and operation are explored for the basic single-feed, dual-feed, and sub-array structures. More importantly, the further integration of the GAA as an antenna-in-package (AiP) module is presented with the design, fabrication, and test details at 60 GHz. The chapter finally reviews the state-of-the-art GAA millimeter-wave applications showing that the GAA really has wide applications from low microwave frequencies even to 120-GHz millimeter-wave frequencies.

Keywords

Grid antenna arrays; Array antenna; Microstrip grid array antenna; Millimeter-wave grid array antenna; Cross-mesh array antenna

Introduction

The grid antenna array (GAA) was first proposed by Kraus in 1964 (Kraus 1964a). It was a traveling-wave antenna of scanning beam in the backward direction against frequency. In 1966, Kraus filed a patent on his invention (Kraus 1966). Figure 1 shows the basic grid arrangement and its variations most in microstrip technology. The basic structures shown in Fig. 1a, b consist of rectangular meshes of microstrip lines on a dielectric substrate or metal lines in the air ($\varepsilon_r \geq 0$) and backed by a metallic ground plane. It can be fed at the mesh cell center as in Fig. 1a or at the mesh cell edge as in Fig. 1b with the other end terminated. The antenna can be fed by a metal via through an aperture on the ground plane such as by coaxial cable. Depending on the electrical length of the sides of the meshes, the grid antenna array may be resonant or nonresonant. Taking grid antenna array on a substrate as an example, for a resonant grid antenna array like in Fig. 1a, the sides of the meshes should be one wavelength by a half-wavelength in the dielectric and the instantaneous currents would be out of phase on the long sides of the meshes and in phase on the short sides of the meshes, respectively. As a result, the long sides of the meshes behave essentially as microstrip line elements and the short sides act as both radiating and microstrip line elements producing the main lobe of radiation in the boresight direction, while for a nonresonant traveling-wave grid antenna array like in Fig. 1b, the length of the short side of the meshes can be slightly more than one-third wavelength and the length of the long side of the meshes should be two times longer but three times shorter than the length of the short side of the meshes in the dielectric. Assuming that it is fed from one end, the currents in the

*Email: msun@i2r.a-star.edu.sg

DOI 10.1007/978-981-4560-75-7_44-1

short sides of the meshes follow a phase progression producing the maximum radiation in a backward angle-fire direction.

The work on GAA had been silent for years since its invention until M. Tiuri proposed a "chain antenna" in 1974 (Tiuri et al. 1974a) as in Fig. 1d. It was also a traveling-wave antenna with a scanning beam. Different from Kraus's design, Tiuri applied absorbing load at one end of the radiating array (Tiuri et al. 1974b). The world saw the first non-traveling-wave GAA in 1981 from R. Conti et al. (1981; Toth et al. 1983). He adopted four GAAs as in Fig. 1o with fixed broadside beams for the monopulse radar. Figure 1c shows their methods of amplitude control through control of microstrip line impedances to lower the first side lobe.

The grid antenna array has caught considerable attention of Nakano and his associates. Since the middle of 1990s, they have reported the design and analysis of various grid array antennas. Figure 1f shows their proposed center-fed dual-linearly polarized GAA by crossing the meshes in 1995 (Nakano et al. 1995); Fig. 1e shows a derivative of the GAA with transformed hexagonal loops, which was named honeycomb wire antenna, appeared from Nakano's group (Nakano et al. 1996, 1997); Fig. 1g shows their miniaturized grid antenna array by meandering the long sides of the meshes (Nakano and Kawano 1997; Nakano et al. 1998a); Fig. 1h shows the first circularly polarized GAA from Nakano's group realized by placing C-figure element above the radiating array in 1998 (Kawano and Nakano 1998); Fig. 1i also shows their circularly polarized grid antenna array by modifying the short sides of the meshes in 2007 (Nakano et al. 2007; Iitsuka et al. 2012); Fig. 1n shows their cross-mesh array, and with C-figure elements on top, this GAA can have multiple polarizations (namely, vertically linear polarization, horizontally linear polarization, and circularly polarization) (Kawano and Nakano 1999, 2000; Nakano et al. 2001a, b);

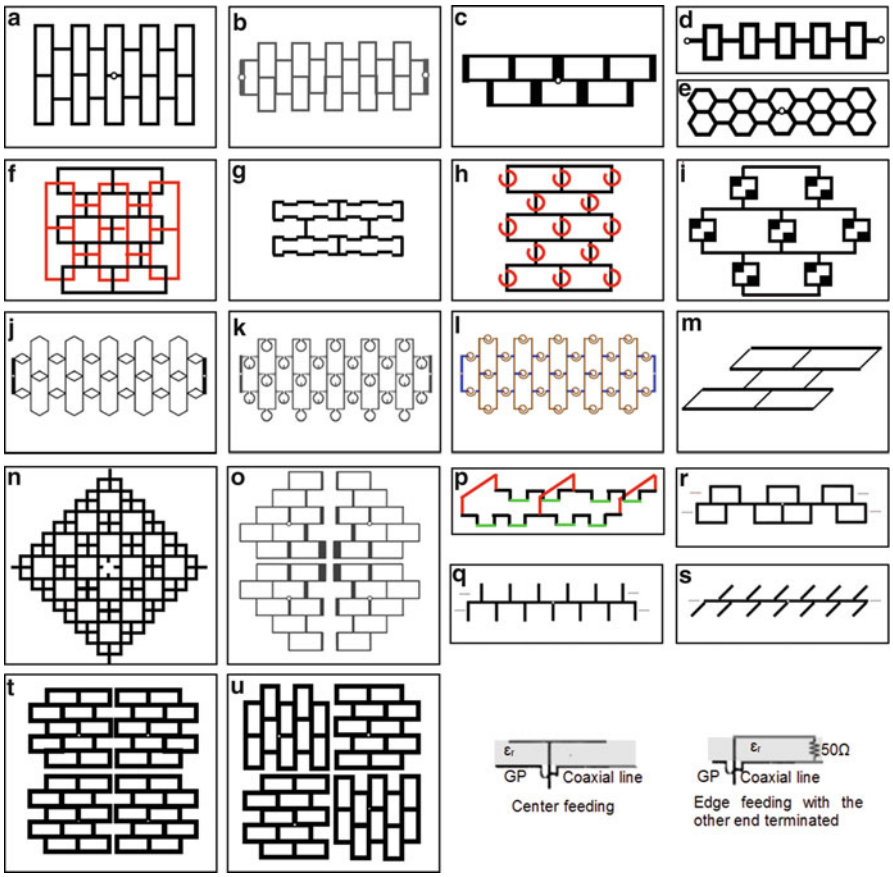

Fig. 1 The basic grid antenna array (**a**, **b**) and its variations (**c**–**u**)

DOI 10.1007/978-981-4560-75-7_44-1

Fig. 1j shows their proposed rhombic grid antenna array (RGAA) that has numerous bent radiation elements contributing to a more stable gain (Iitsuka et al. 2009a; Nakano et al. 2013a); Fig. 1k shows their loop-based GAA that can achieve a seamless CP frequency-scanning beam with perturbation elements added to the loops (Nakano et al. 2013b; Iitsuka et al. 2010); and Fig. 1l shows their tilted frequency-scanning CP GAA realized by adopting spiral elements as the radiation elements in 2010 (Iitsuka et al. 2010).

The above studies were all conducted at lower microwave frequencies. Zhang's group, for the first time, brought the GAA onto the stage of millimeter-wave application. They managed to implement a basic GAA as in Fig. 1a at 60 GHz on low temperature co-fired ceramic (LTCC) substrate to yield a standard surface-mounted chip package in 2008 (Sun and Zhang 2008; Zhang and Sun 2008). This antenna was the first millimeter-wave GAA and also was considered as an excellent antenna candidate for "antenna-in-package" technology (Sun and Zhang 2008). The idea of using GAA as a 60-GHz packaged antenna was further elaborated in Sun et al. (2009a, b). Targeted at millimeter-wave and integration purpose, they advocated GAA with a novel balanced feeding that eliminates the necessity of an extra lossy balun when the antenna is to be used in a differential system in 2011 (Zhang et al. 2011c). They also propose a new 45° linearly polarized grid antenna array by adjusting the angle between the long and short sides of the meshes as in Fig. 1m and a miniaturized grid antenna array by meandering the long sides and bending the short sides of the meshes in a multilayer metal structure as in Fig. 1p (Zhang and Sun 2008; Zhang et al. 2011c). The bending makes the large part of the short sides of the meshes further away from the ground plane, which may improve the radiation. Besides the millimeter-wave application, they also found the application of the GAA for automotive radar sensor and derived a comb array antenna for this purpose (Zhang et al. 2011a, b, 2012) as in Fig. 1r, q, s. In 2012, they also successfully adopt the GAA as a sub-element to further form a bigger array as an example in Fig. 1t (Zhang and Zhang 2012a, b, 2013). By dividing the large radiating array into small sub-grid arrays with multiple feedings, the accumulated phase error was minimized which resulted in more desirable radiation. The packaging scheme of such antennas was introduced in Zhang and Zhang (2012a) and Zhang et al. (2013a), and it was further integrated with a dual-band monopole as a mobile terminal antenna (Zhang et al. 2013d). More successfully, they realize a novel circularly polarized GAA by sequentially rotating the sub-GAA arrays as shown in Fig. 1u (Zhang and Zhang 2010, 2012a) and made into a package of such antennas in 2013 (Zhang et al. 2013b).

The analysis and synthesis of the GAA antenna has a long record. Wave velocities of the antenna were first analyzed in Kraus (1964b). In 1992, L. Hildebrand conducted his master thesis on the analysis of GAAs by the method of moments (MoM), which was the first attempt to analyze the characteristics of GAA (Hildebrand 1992). H. Nakano first analyzed the GAA by MoM in the GHz range in 1994 (Nakano et al. 1994). Later in mid-2000s, he also developed a fast MoM calculation technique for its analysis (Nakano et al. 1998b, 2001c, 2005). K. Palmer made the first attempt of GAA synthesis in 1997 (Palmer and Cloete 1997). The devoid of a systematic analysis and synthesis method of GAA had been lasting for 50 years until 2011, when the GAA's performance was characterized and a synthesis method was proposed by Zhang's group (Zhang and Zhang 2011). Radiation mechanism of the GAA was verified for the first time by pattern synthesis (Zhang et al. 2013c).

The literature review shows that GAA has wide applications in microwave frequencies. Zhang's group has made it an excellent antenna candidate for millimeter-wave "antenna-in-package" technology by providing various elegant package solutions as mentioned above. In addition, they successfully developed GAA for automotive radar sensor applications at 24 GHz (Zhang et al. 2011a, b, 2012). Inspired by their work, W. Menzel adopted the GAA for 79-GHz automotive radar (Bauer and Menzel 2011; Frei et al. 2011; Bauer et al. 2013), and T. Zwick implemented a D-band 120-GHz GAA on liquid crystal polymer (LCP) substrate as a lid of a surface-mounted chip package (Beer et al. 2013). All these demonstrate GAA's wide applications from microwave to millimeter-wave frequencies.

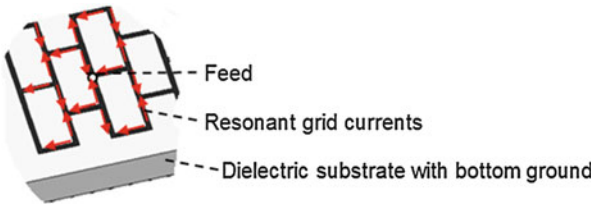

Fig. 2 Basic theory of the resonant grid array antenna

In this book chapter, although both resonant and nonresonant grid array antennas are useful for many applications, it will only focus on the more advanced technologies of the resonant GAA on the substrate at millimeter-wave frequencies. The basic theory and operation are presented in section "Basic Theory and Operation." The designs especially for integration purpose are presented in section "Design for Integration." The applications are presented in section "Millimeter Wave Applications." The chapter is summarized in section "Summary."

Basic Theory and Operation

Basic Theory

The GAA features a spatial scanning beam against input signal's frequency when designed as a traveling-wave antenna. Currents on the short side of each loop are in phase, which are responsible for the modulated equal phase front and co-polarization. Currents on the long side are out of phase so that they can cancel each other mostly in the far-field region and bring about cross-polarization. As a result, the short side of each loop is referred to as radiator or radiating element. As a traveling-wave antenna, it is usually excited at one end of the radiating array, while the other end of the radiating array is terminated either without (as in Kraus's design (Kraus 1964a)) or with an absorbing load (as in Tiuri's design (Tiuri et al. 1974a)). Phase shifting is generated when the input signal propagates from one end of radiating array to the other, which brings about a tilted equal phase front, hence a tilted beam. Because of the fixed dimensions of the loop, input signals at different frequencies can generate respective phase shifting, resulting in a modulated equal phase front against frequencies.

Though scanning beam can be achieved by a traveling-wave GAA without the requirement for an extra phase shifting or beam-forming network, it neither provides precise beam control in which a beam can appear at a specific locus nor a scanning beam at a fixed frequency. Hence, the GAA is not very popular as a traveling-wave antenna but finds wide application as a non-traveling-wave antenna.

As a non-traveling-wave antenna, the GAA is usually fed near its geometrical center. Because of the uniform phase degradation of EM waves that propagate from the feeding point to the periphery of the radiating array, the non-traveling-wave GAA features a fixed beam in the broadside direction. In this case, the short sides of each loop also carry in-phase current for effective radiation, while the currents on the long side are out of phase as shown in Fig. 2.

To elaborate the operation of the non-traveling-wave resonant GAA, the design of the single-feed, dual-feed, sub-array structures will be presented respectively in the following parts. Based on the A6 LTCC from Ferro, the grid array antennas are designed to operate in the 60-GHz band. The A6 ceramic tape has the dielectric constant of 5.9 and loss tangent of 0.0015 after firing, and the metallic paste is either silver or gold with good conductivity. The design determines the dielectric substrate dimensions, the number of meshes, the microstrip line impedances, and the excitation location with the associated diameters of the metal via and the aperture through the analysis of the HFSS simulations. It is demonstrated that the grid

DOI 10.1007/978-981-4560-75-7_44-1

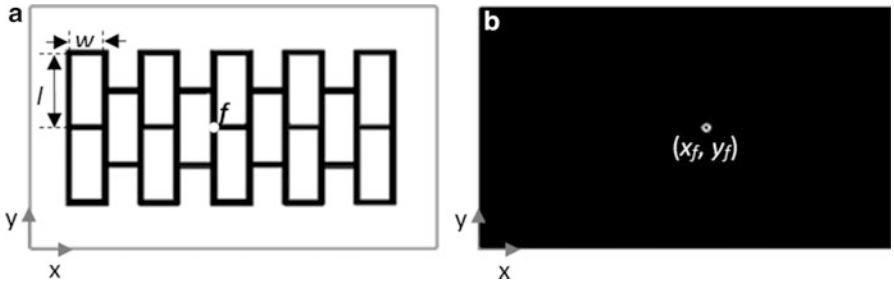

Fig. 3 The 60-GHz grid array antenna: (**a**) top and (**b**) bottom views

antenna array is easy to design, and more importantly, the grid antenna array is particularly suitable for fabrication in LTCC as its meshed structure avoids microfractures or warpage.

Basic Single-Feed Structure

The 60-GHz microstrip grid antenna array as shown in Fig. 3 consists of rectangular meshes of microstrip lines on a dielectric substrate backed by a metallic ground plane. It is fed at one of the nodes by a coaxial pin through an aperture on the ground plane. Based on the Ferro A6-S LTCC, the microstrip grid antenna array is designed to operate at 61.5 GHz with the maximum gain of ≥13.5 dBi, the impedance and radiation bandwidth of 7 GHz, and the efficiency of ≥80 %.

Given the specified gain value of 13.5 dBi and considering the various losses, one can find the required number of meshes to be at least 14, which leads to an estimation of the length and width of the substrate as 11.5 mm by 5 mm, respectively. The thickness of the substrate should be chosen to avoid the excitation of the TE_1 mode surface wave. Hence, a body size of $13.5 \times 8 \times 0.375$ mm^3 is finally determined by also taking the LTCC layout rule into account. For the sake of low cost and easy fabrication, the width and thickness of the microstrip lines are kept uniform as 0.15 and 0.01 mm, respectively. The mesh dimensions and the location of excitation f as well as the associated diameters of the metal via d_v and the aperture a_v on the ground plane are obtained from the HFSS simulations. They are $l = 2.5$ mm $\approx \lambda_g$, $w = 1.365$ mm $\approx \lambda_g/2$, $d_v = 0.1$ mm, $a_v = 0.3$ mm, $x_f = 4$ mm, and $y_f = 6.075$ mm, where λ_g is the guided wavelength.

Figure 4a, b shows the simulated antenna $|S_{11}|$ and peak realized gain as a function of frequency, respectively. The 10-dB impedance bandwidth is 13 GHz from 51 to 64 GHz or 26.7 % at 60 GHz. The maximum peak realized gain is 15 dBi at 61 GHz. The efficiency is also found to be better than 85 % over the required 7-GHz bandwidth. Figure 4c, d shows the simulated antenna radiation patterns in the xz- and yz-planes at 60 GHz, respectively. As expected, the antenna radiation patterns have the main beam of radiation in the boresight direction with side lobes lower than 20 dB and weak cross-polarization radiation components.

Basic Dual-Feed Structure

A basic dual-feed grid antenna array is shown in Fig. 5. The differential feeding scheme here is different from those in Kraus (1964a) and Nakano et al. (2005) where a gap is made on the short side of a mesh to connect to the differential source. The targeted specifications are the maximum gain of ≥15 dBi, the impedance and radiation bandwidth of 7 GHz, and the efficiency of ≥80 %. With the design steps similar to the single-feed one, the number of meshes of 14, substrate size of$13.5 \times 8 \times 0.385$ mm^3, the width and thickness of the microstrip lines are initially determined. Through HFSS simulation, the optimized mesh dimensions and the location of dual feeds as well as the associated diameters of the metal vias d_v and the apertures a_v on the ground plane are determined as $l = 2.5$ mm $\approx \lambda_g$, $w = 1.365$ mm $\approx \lambda_g/2$, $d_v = 0.1$ mm, $a_v = 0.3$ mm, $x_{f1} = 7.3$ mm, $y_{f1} = 3.98$ mm, $x_{f2} = 8.08$ mm, and $y_{f2} = 3.98$ mm.

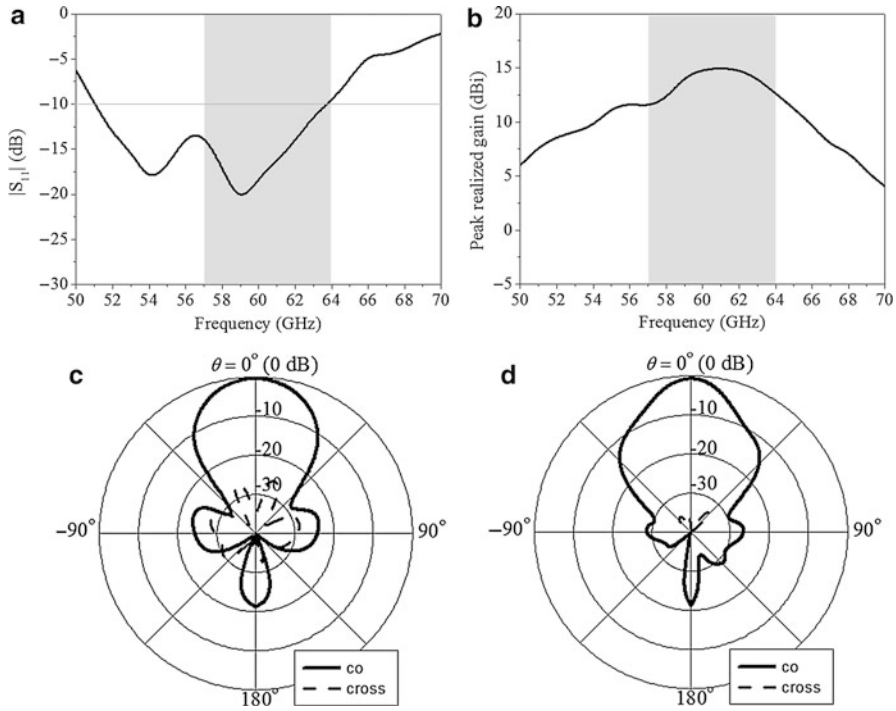

Fig. 4 Simulated grid antenna array performance: (**a**) $|S_{11}|$, (**b**) peak realized gain, (**c**) the xz-plane, and (**d**) the yz-plane radiation patterns at 60 GHz

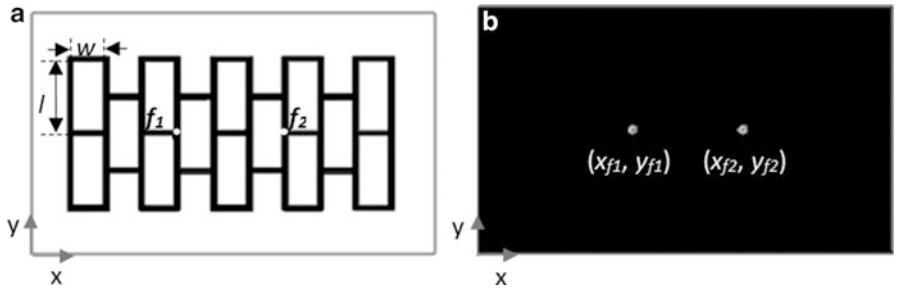

Fig. 5 The dual-feed grid array antenna: (**a**) top and (**b**) bottom views

Figure 6a compares the simulated current distributions on the grid at 61.5 GHz for the differential feed case with its single-feed counterpart. Note that the instantaneous currents do not distribute as shown in Kraus (1964a), Conti et al. (1981), and Palmer and Cloete (1997), that is, they are out of phase on the long sides of the meshes and in phase on the short sides of the meshes, respectively. Rather, they are only truly out of phase on the long sides of the meshes and in phase on the short sides of the meshes near the feeding points. This is because at such a high frequency, a slight mesh dimension change will cause a big change in signal phase over transmission, for example, at 60 GHz, a 70-μm variation in w will cause ~10° signal phase difference, thus making the control over phase synchronization of the far meshes from the source more difficult. The grid antenna array excited for differential operation has two source points, so it has more meshes of desirable current distributions than that excited for single-ended operation.

Figure 6b compares the simulated $|S_{11}|$. The impedance bandwidth is 10 GHz (16.7 %) from 53 to 63 GHz for the single end and 8 GHz (13 %) from 57 to 65 GHz for the differential operations, respectively. The wider impedance bandwidth for the single-ended antenna is the result of less number

DOI 10.1007/978-981-4560-75-7_44-1

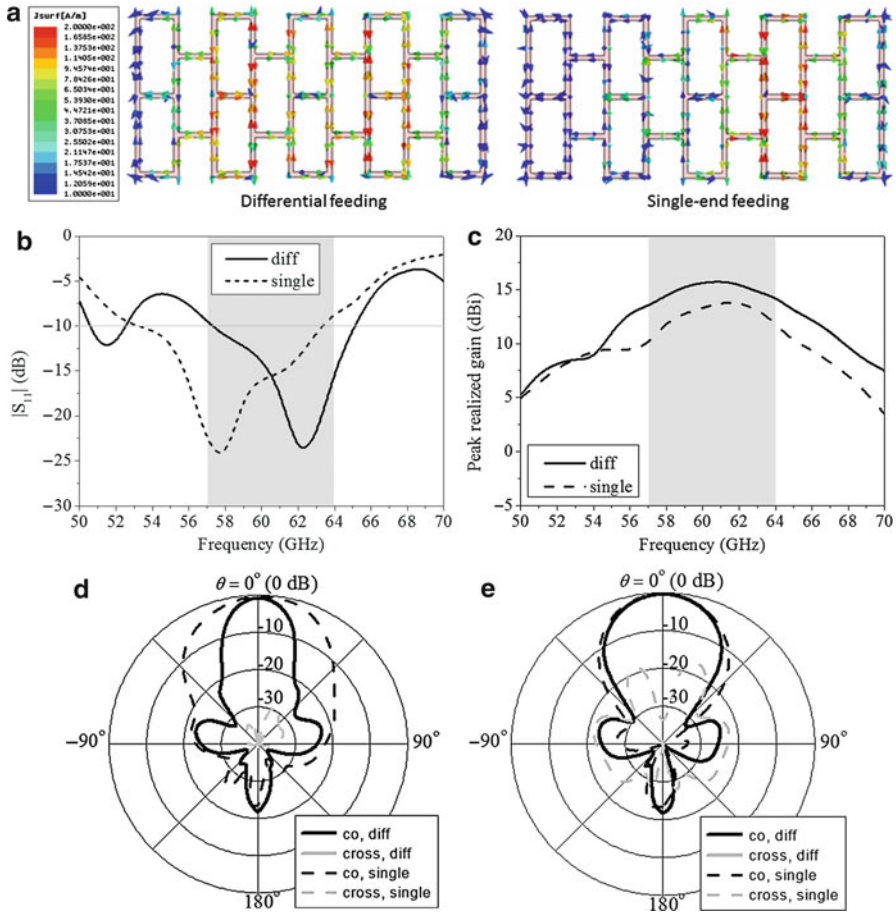

Fig. 6 The simulated results of the dual-feed grid antenna array compared with the single-feed one: (**a**) current distributions at 61.5 GHz, (**b**) $|S_{11}|$, (**c**) peak realized gain, (**d**) xz- and (**e**) yz-plane patterns at 61.5 GHz

of radiating elements that have in-phase currents. Figure 6c shows the simulated antenna peak gain. They are 16 and 13.5 dBi at 61.5 GHz for differential and single-ended operations, respectively. The 3-dB gain bandwidths are enough. The simulated efficiency is found better than 90 % for both cases. Figure 6d, e compares the simulated antenna radiation patterns in the xz- and yz-planes at 61.5 GHz. As expected, the main lobe and deep null of radiation appear in the boresight direction for the co- and cross-polarization fields, respectively. The differential excitation yields a sharper main beam in the xz-plane and a similar main beam in the yz-plane and much weaker cross-polarization field in both planes as compared with the single-ended operation, due to the current distributions shown in Fig. 6a. The front-to-back ratio is 21 dB.

Sub-array Structures

This section will introduce the GAA sub-array operation. Figure 7 shows the different structures formed by GAA sub-array element of (a). It is designed at 61.5 GHz as detailed in Zhang and Zhang (2014). It is interesting to note that on the sub-grid array, the currents on each short side are indeed in phase, while the currents on each long side are out of phase. As expected, the main beams of radiation are in the broadside direction as plotted in Zhang and Zhang (2014).

The formation of a large array with four sub-grid arrays and multiple feeds not only improves the unsynchronized current but also introduces more design flexibilities. For example, a linearly polarized (LP) GAA can be realized when sub-grid arrays in the upper and lower quadrants are fed out of phase simultaneously. Figure 7b shows the simulated current distribution at 61.5 GHz of the LP GAA of

DOI 10.1007/978-981-4560-75-7_44-1

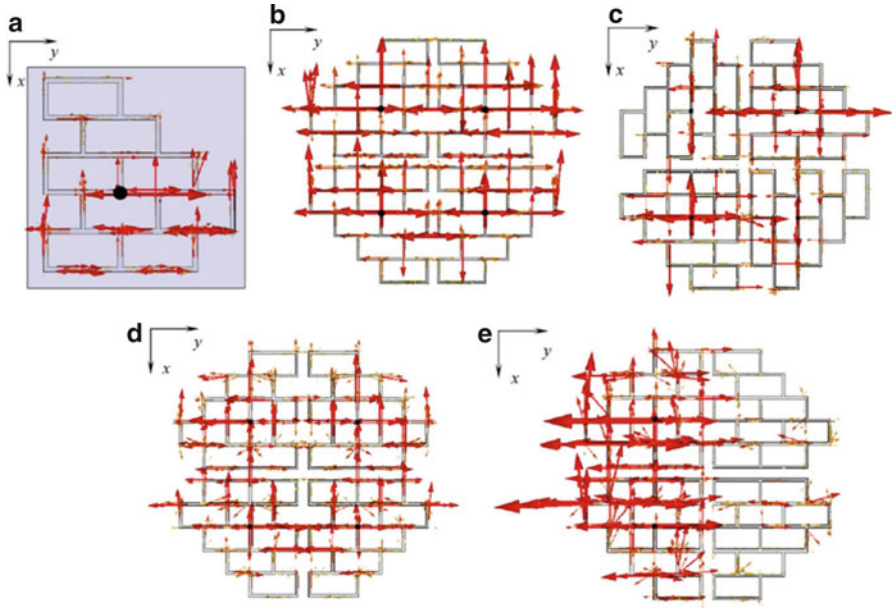

Fig. 7 The resonant GAA sub-array structures with denoted current distribution: (**a**) a GAA sub-array element, (**b**) a linearly polarized GAA, (**c**) a circularly polarized GAA, (**d**) a single balanced GAA, and (**e**) a single unbalanced GAA with four sub-arrays

32 loops formed by 4 sub-grid arrays and 4 feeds. It is clear from the figure that the current distribution is more satisfactory than that shown in Fig. 7a. The improvement is due to the fact that one feed excites 8 loops rather than 32 loops, leading to a smaller accumulated phase error. Although there are still incorrect current probably caused by the coupling between the sub-grid arrays and multiple feeds, the radiation patterns are improved with maximum radiation still in the broadside direction as detailed in in (Zhang and Zhang 2012b, 2013, 2014; Zhang et al. 2013a).

By sequential rotation, either a right-handed (RH) or left-handed (LH), the circularly polarized (CP) GAA can be realized. Figure 7c shows the current distribution at 61.5 GHz of the CP GAA of 32 grids formed by 4 sub-grid arrays and 4 feeds as detailed in (Zhang and Zhang 2010, 2012a; Zhang et al. 2013b), where good CP performance is achieved with satisfied axial ratio bandwidth and maximum radiation in the broadside direction.

Moreover, when the sub-grid arrays in the upper quadrants are driven with 0° phase and those in lower quadrants with 180° phase simultaneously in Fig. 7d, a single balanced antenna is realized which is compatible with a system of balanced output. While if the sub-grid arrays in the left quadrants and in the right quadrants are respectively driven differentially (that is to say, the sub-grid arrays in the left quadrants are driven by a differential pair and those in the right quadrants are driven by the other differential pair), two balanced antennas with one for transmission and the other for reception are realized. Figure 7d shows the simulated current distribution of the single balanced GAA at 61.5 GHz. Figure 7e shows the simulated current distribution when one of the dual balanced GAAs is excited at 61.5 GHz. Both radiation patterns have maximum radiation in the broadside direction (Zhang and Zhang 2014).

The peak realized gain results of the above GAAs are presented in Zhang and Zhang (2014). It is found that the GAA in Fig. 7b has the narrowest 3-dB gain bandwidth. The 3-dB gain bandwidth of the single unbalanced LP GAA in Fig. 7e is much wider, so is the single balanced LP GAA. Both the maximum gain values are enhanced by about 2 dB as compared with the GAA in Fig. 7b because of improved current distribution. As expected, the maximum gain values of the CP and dual balanced LP GAAs are about 3 dB lower.

Design for Integration

GAA Integrated in a Grid Array Package

Figure 8 illustrates the ball grid array package with a microstrip grid antenna array connected to a 60-GHz receiver die. Figure 8a shows the simplified block diagram of the 60-GHz receiver die, including its critical input/output pads. The receiver uses a dual-conversion superheterodyne architecture with a 57–64 GHz RF range, 8.1–9.1 GHz IF range, and 16.3–18.3 GHz VCO range. The bandwidth of the in-phase/quadrature (I/Q) baseband signal is currently limited by the IF bandwidth of ±1 GHz. The critical input/output pads are in ground-signal-ground (GSG) coplanar configurations. The input pads require the package interconnection with 50-Ω characteristic impedance from 57 to 64 GHz, while the output pads also require 50-Ω characteristic impedance but at much lower frequencies up to 2 GHz as determined by the maximum bandwidth of the I/Q baseband signals. The receiver die size is 3.4 × 1.7 × 0.46 mm^3 (Pfeiffer et al. 2006).

Note that the package features standard wire bonding and there are four co-fired laminated ceramic layers for the package. The first ceramic layer is 0.385 mm thick, the second ceramic layer is 0.285 mm thick with an opening 3.8 × 2 mm^2, the third layer is 0.21 mm thick with an opening 5 × 3.2 mm^2, and the fourth layer is 0.385 mm thick with an opening 5 × 3.8 mm^2. These openings form the three-tier cavity that can house the 60-GHz receiver die. There are also five metallic layers for the package. The top layer provides the metallization for the microstrip grid array antenna, the first buried layer the metallization for the solid ground plane, the second buried layer the metallization for the antenna feeding traces and signal traces, the third buried layer the metallization for the signal traces, and the bottom exposed layer the metallization for the package ground plane and solder ball pads. The package has 58 input/outputs with a JEDEC standard solder ball pitch of 0.65 mm. Two dummy solder balls are attached to the two corners of

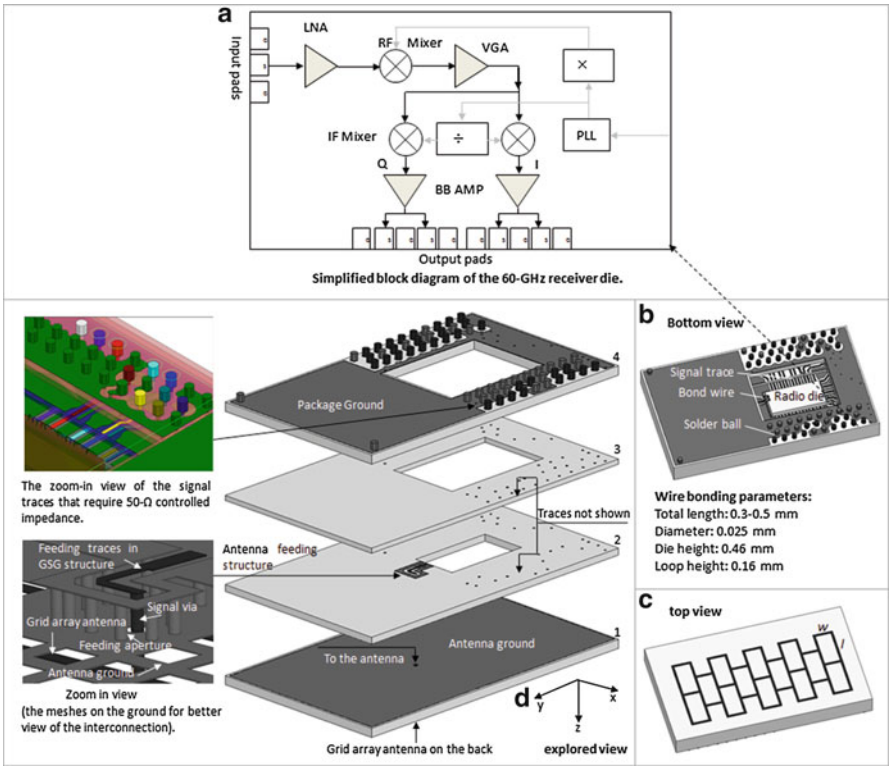

Fig. 8 The views of the ball grid array package with a grid antenna array and a 60-GHz die: (**a**) the simplified block diagram of the 60-GHz receiver die, (**a**) top view, (**b**) bottom view, and **c** explored view of the whole package

DOI 10.1007/978-981-4560-75-7_44-1

the package, respectively, for an enhanced attachment on the system PCB. The size of the whole package is $13.5 \times 8 \times 1.265$ mm^3.

Bond wires are used for chip-package interconnection. The input pads of the chip carrying RF signals from 57 to 64 GHz are connected to the antenna in package. The output pads of the chip carrying baseband signals up to 2 GHz are connected to signal traces in package. Here, bond wires between the receiver die and the antenna are the most critical because the discontinuity introduced by bond wires can significantly affect the performance of the entire 60-GHz radio. Nonetheless, the wire-bonding technique, well established in consumer electronics, remains a very attractive solution since it is robust and inexpensive. In addition, it has the advantage of being tolerant on die and package thermal expansion, an important requirement for many applications. There are methods to compensate the discontinuity on either or both sides of the die and package for millimeter-wave applications (Budka 2001; Sun et al. 2006). Figure 8 also shows wire-bonding parameters. The wire profile is based on the JEDEC standard. Note that the shortest bond wires are 300 μm long, which is almost a doubled length of the shortest bond wire supported by the current technology and would thus greatly improve the yield of assembly of the chip with the package.

A microstrip patch antenna array designed for 60-GHz applications has been reported (Lamminen et al. 2008). A complex feeding network, sophisticated process techniques, and embedded cavity are required to achieve enhanced bandwidth and efficiency. To avoid the problems of the microstrip patch array antenna, the microstrip grid antenna array is adopted. It operates in a resonant mode that requires the sides of the meshes one wavelength by one-half wavelength in the dielectric. Thus, the instantaneous current distribution would be out of phase on the long sides of the meshes and in phase on the short sides of the meshes, respectively. The resulting radiation would be broadside to the grid and linearly polarized parallel to the short sides of the meshes. For the sake of low cost and easy fabrication, the width and thickness of the microstrip lines are kept uniform as 0.15 and 0.01 mm, respectively. The mesh dimensions are $l = 2.5$ mm $\approx \lambda_g$, $w = 1.365$ mm $\approx \lambda_g/2$, where λ_g is the guided wavelength at 60 GHz.

Figure 8 also shows the zoom-in view of the antenna feeding network. It consists of such packaging elements as a coplanar waveguide (CPW) line cascaded first with a 90°-angled stripline and then vias in a GSG arrangement. It is known that the GSG arrangement not only minimizes potential electromagnetic interference but also improves the feeding performance. The signal via is finally fed to the antenna through an aperture in the antenna ground. The CPW feed line is designed to be 50 Ω with a pitch of 0.25 mm and a line width of 0.15 mm. The signal via, the aperture, and ground via have diameters of 0.1 mm, 0.3 mm, and 0.1 mm, respectively.

Figure 8 also shows the zoom-in view of the signal traces that require 50-Ω controlled impedance up to 2 GHz. These signal traces involve bond wires, CPW lines, vias, and solder balls. The signal traces in purple, red, aqua, and blue are denoted as signal traces 1, 2, 3, and 4, respectively. Signal traces 1 and 2 in a GSGSG configuration connect the on-chip Q signal output pads to the system board, so do signal traces 3 and 4 for the on-chip I signal output pads.

The package was fabricated in FERRO A6 LTCC ($\varepsilon_r = 5.9$ and $\tan\delta = 0.002$) with nine green tapes and gold metal in a panel size of 100×100 mm^2 by LTCC Boutique Foundry in Singapore Institute of Manufacturing Technology. Figure 9 shows the photo of a sample. The antenna function of the package was tested with a probe-based measurement setup (Zwick et al. 2004). Figure 9 also illustrates the test fixture to hold the package for testing. The package is supported by an FR4 fixture, which provides the good support for the probe to touch the antenna CPW feeding lines for measurement. This will also avoid the direct contact of the package on the metal probe station. A photo of a probe touching example is also shown in Fig. 9. The probe pitch is 250 μm to agree with the pitch of tested antenna CPW lines.

Figure 10 shows the simulated results with the measured results of the microstrip grid antenna array in the ball grid array package. No de-embedding was made to the measured results. It is evident from Fig. 10a that the measured 10-dB impedance bandwidth is 8.7 GHz from 56.3 to 65 GHz, which covers

DOI 10.1007/978-981-4560-75-7_44-1

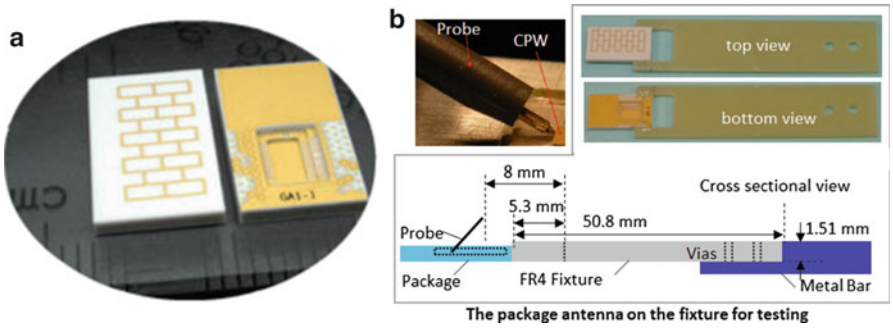

Fig. 9 Photo of the ball grid array package with the microstrip grid antenna array and illustration of the package antenna on the fixture for testing

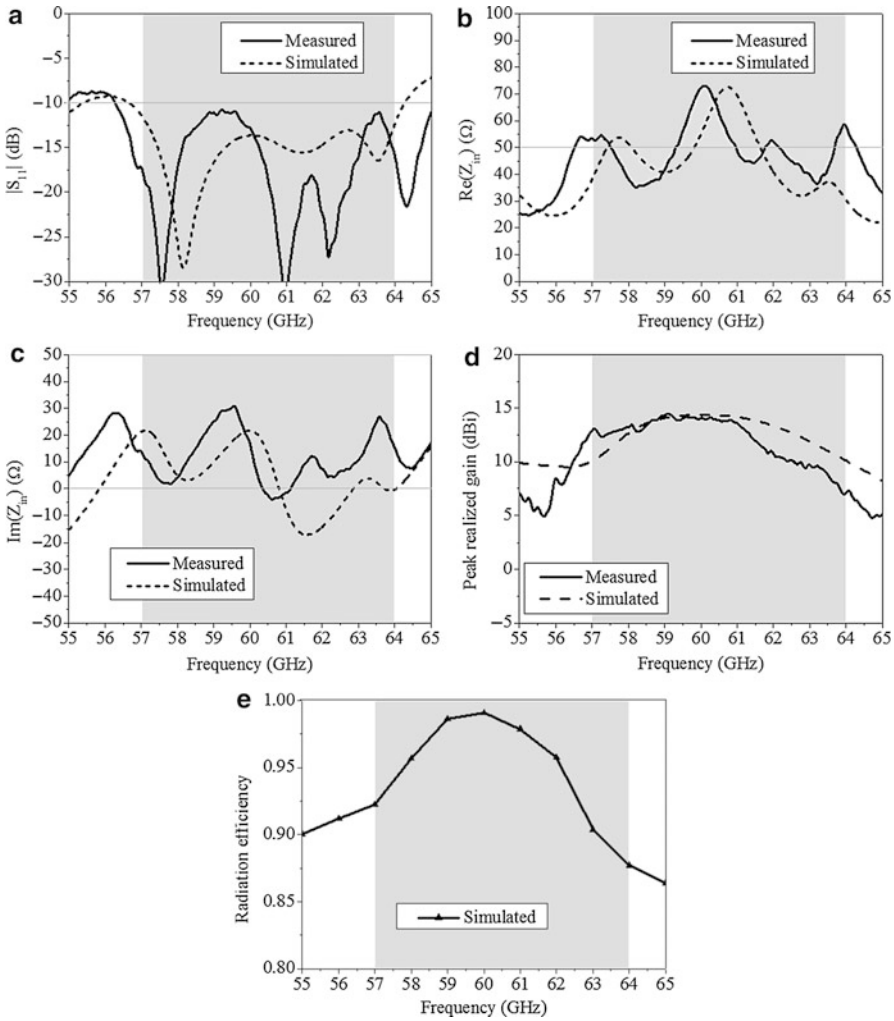

Fig. 10 Simulated and measured performance of the microstrip grid antenna array in the ball grid array package: (**a**) $|S_{11}|$, (**b**) input resistance, (**c**) input reactance, and (**d**) peak gain and efficiency as a function of frequency

the whole band of 57–64 GHz. By comparing with the simulated results in Fig. 10b, c, it is noted that the measured resonance frequencies shift down and the impedance becomes more inductive. This is attributed to the difference between the wave-port excitation in the simulation and the probe excitation in the measurement. In addition, the measured and calculated peak gain values in the main beam direction are

DOI 10.1007/978-981-4560-75-7_44-1

both 14.5 dBi as shown in Fig. 10d. It is achieved at 60 GHz in the simulation while 59 GHz in the measurement. Figure 10e also shows estimated efficiency $\eta > 88$ % over 57–64 GHz.

Figure 11 compares the simulated with the measured radiation patterns of the microstrip grid antenna array in the ball grid array package. They reveal that both xz- and yz-plane patterns have the main beam of radiations in the boresight directions with small cross-polarization radiation components. Note that the simulated and measured co-polar patterns at 60 GHz agree very well and both have small back radiations, while the back radiation levels increase at 57 and 64 GHz. This explains why the peak realized gain decreases at these frequencies as shown in Fig. 10d. Also note that the co-polar patterns on the xz-plane in the main radiation direction are more insensitive to the frequency than those on the yz-plane. This is because the grid antenna array has more meshes in the yz-plane making the control over phase synchronization of the far meshes from the source at different frequencies more difficult.

It should be mentioned that the performance of the microstrip grid antenna array in the ball grid array package landed on a system FR4 PCB with a top ground plane that was also simulated. It was found that the impedance matching performance is insensitive to the PCB and its further extended ground size. In addition, the peak realized gain showed a negligible decrease of 0.2 dB, while the gain performance over the whole bandwidth remains almost unchanged. Hence, one can conclude that the microstrip grid antenna array is an excellent antenna array candidate for 60-GHz radios.

Figure 12 shows the simulated insertion loss characteristics from 100 MHz to 5 GHz for 50-Ω controlled impedance signal traces. It can be observed that the signal loss is very low up to 5 GHz and the 3-dB insertion loss bandwidth is found to be much greater than 5 GHz, satisfying the 2-GHz bandwidth requirement easily. Figure 12 also shows the simulated return loss from 100 MHz to 5 GHz for 50-Ω controlled impedance signal traces. It is evident that the return loss values higher than 22 dB are

achieved over the 5-GHz bandwidth, indicating excellent wideband impedance matching to 50-Ω sources. Regrettably, no measurement was made to the frequency characteristics of these signal traces due to the limitation of our existing measurement setup and wire bonder. Nevertheless, the simulated insertion and return losses should be correct. They were obtained as each signal trace end was connected to a 50-Ω port while ground lines were short-circuited to the ground plane, and a single port was excited while other ports were tied to 50-Ω match loads.

Dual GAA Integrated in a Single Package

Figure 13 illustrates the concept of assembling the highly integrated 60-GHz radio in the chip-scale package to the system printed circuit board (PCB). A cavity or even an opening needs to be created in the PCB to house and protect the radio die. The lands on the chip package are soldered to the PCB to finish interconnect from the chip to the PCB through the package. This is believed to be a very cheap solution to highly integrated 60-GHz radios with the rather thin profile.

Figure 13 also illustrates the chip-antenna interface solutions for highly integrated radios. The highly integrated 60-GHz radio chip should be first discussed. Traditional commercialized 60-GHz radios have been designed as an assembly of several microwave monolithic integrated circuits (MMICs) in gallium arsenide (GaAs) semiconductor technology. They have been used for Gigabit Ethernet (1.25 Gb/s) bridges between local area networks (Maruhashi et al. 2001; Ohata et al. 2003). Recently, integrated

DOI 10.1007/978-981-4560-75-7_44-1

transmitter (Tx) and receiver (Rx) MMICs in 0.15-μm GaAs pHEMT and mHEMT processes have been realized to support data rates of several Gb/s for 60-GHz short-range applications (Gunnarsson et al. 2005, 2007). However, the 60-GHz radios in GaAs MMICs are expensive and bulky. In order for 60-GHz radio chips to have mass deployment and meet consumer marketplace requirements, the cost and size of any solution must be low and compact. That implies silicon, not GaAs as the better technology choice. In fact, designs toward low-cost, highly integrated 60-GHz radio chips have been realized in silicon technologies. For example, Floyd et al. have demonstrated a 60-GHz Tx and Rx chipset in a 0.13-μm silicon-germanium (SiGe) technology (Floyd et al. 2006) and Tanomura et al. in a 90-nm complementary metal oxide semiconductor (CMOS) technology (Tanomura et al. 2008). An examination of the above works and many other reported 60-GHz highly integrated radio chips in SiGe and CMOS reveals that two types of antenna-circuit interfaces as shown in Fig. 13 can be identified in the current solutions. The first type features the 50-Ω single-ended and the second type the 100-Ω differential antenna-circuit interfaces. For the first type, the 60-GHz on-chip input/output pads are designed as the ground-signal-ground (GSG) pads while for the second type the ground-signal-ground-signal-ground (GSGSG) pads. The GSG pads are bonded to an off-chip but in-package single-ended antenna while the GSGSG pads to a differential antenna with either flip-chip or wire-bonding techniques (Pfeiffer et al. 2006; Zhang et al. 2008a, 2009; Sun et al. 2008).

A single-chip solution of a 60-GHz radio transceiver (TRX) in CMOS has been attempted (Tomkins et al. 2009), where differential Tx and Rx are integrated on the same die. It is known that CMOS scaling improves amplifier noise performance and gain but exacerbates the difficulty of generating sufficient output power by the power amplifier (PA) at 60 GHz (Doan et al. 2004). Theoretically, a differential PA yields 3 dB more output power than a single-ended one does. Hence, the differential antenna-circuit interface in Fig. 13c is preferred to the single-ended antenna-circuit interface in Fig. 13a for the Tx integration of the TRX. Furthermore, the differential antenna-circuit interface in Fig. 13d is the better choice than the single-ended antenna-circuit interface in Fig. 13b for the Rx integration of the TRX because the differential low noise amplifier (LNA) can achieve higher linearity, lower offset, and better immunity to common-mode noise due to power supply variations or substrate coupling than the single-ended LNA does (Huang et al. 2006). The advantage of the fully differential architecture from the antenna to the circuit has been well understood for modern single-chip solutions of radio transceivers (Zhang et al. 2008b).

Regardless of the antenna-circuit interfaces, two antennas, one for transmission and the other for reception, are required for current highly integrated 60-GHz radios. The use of two antennas is not a problem as the antenna form factor at 60 GHz is on the order of millimeters. However, it may become a problem for the highly integrated 60-GHz radio that employs multiple antennas for beam steering to search the available path to enhance the link quality (Zhang and Liu 2009). This is because multiple antennas not only require corresponding multiple electrostatic discharge circuits that consume substantial die area but also make the whole radio bulky. It is known that the number of multiple antennas can be reduced to half by using transmit/receive (T/R) switches or circulators. Unfortunately, the T/R switches in CMOS in the 60-GHz band are still too lossy to be used (Tomkins et al. 2009; He and Zhang 2008) and information on circulators for highly integrated 60-GHz radios is unknown. In this section, the integration of the grid array antennas into a chip package in LTCC for highly integrated 60-GHz radio chipsets is described. As an example, a dual-feed grid antenna array is integrated for the differential Tx antenna-circuit interface and another single-feed grid antenna array for the single-ended Rx antenna-circuit interface.

As previously discussed, current highly integrated 60-GHz radios require dual antennas. Nakano et al. designed dual-grid array antennas in a double-layer structure (Nakano et al. 1995). A perpendicular orientation was arranged for the upper and lower grid array antennas. In this way, the

DOI 10.1007/978-981-4560-75-7_44-1

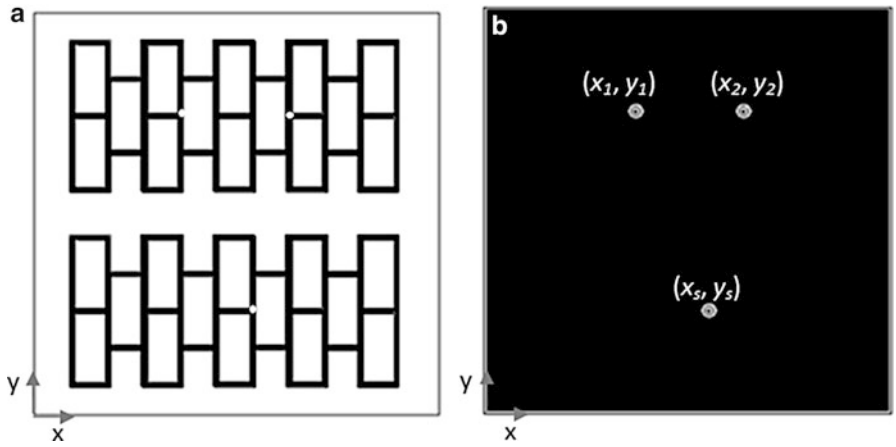

Fig. 14 The dual-grid array antennas: (**a**) top and (**b**) bottom views

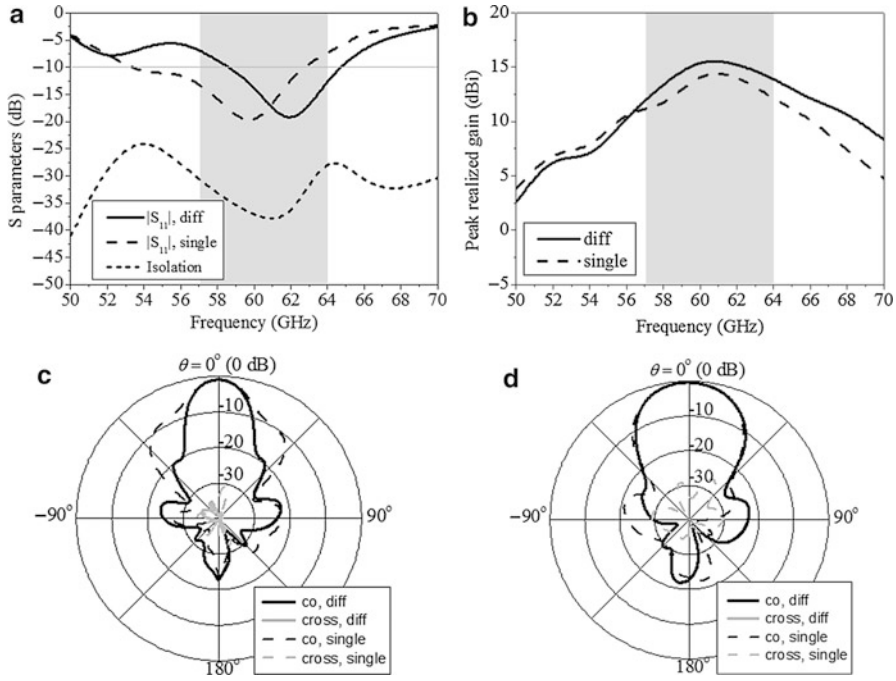

Fig. 15 The simulated results of the dual-grid array antennas with one for differential and the other for single-ended operations: (**a**) $|S_{11}|$ and isolation, (**b**) peak realized gain, and xz- and (**c**) yz-plane patterns at 61.5 GHz

upper grid antenna array radiates a horizontally polarized wave, while the lower grid antenna array does a vertically polarized one. A high isolation between both centrally located feeding terminals can be guaranteed. Figure 14 shows the dual-grid array antennas in a single-layer structure. It is formed by two grid array antennas of the basic structure that has a body size of $13.5 \times 13.5 \times 0.385$ mm^3. A parallel orientation is arranged for the dual-grid array antennas. Both grid array antennas radiate the wave of the same polarization. The single-layer structure simplifies the fabrication process. The parallel orientation reduces the outrage probability of 60-GHz radio links, which are usually deployed in line-of-sight environments, due to the polarization loss.

Figure 15 compares the simulated results of the grid antenna array with the dual feeds for differential operation and the grid antenna array with a single feed for single-ended operation. As this is a transitional

DOI 10.1007/978-981-4560-75-7_44-1

step, no performance enhancement is made and no patterned ground plane is used. When one grid antenna array is excited, the other grid antenna array acts as a parasitic element and vice versa. Figure 15a shows that the impedance bandwidth is 5.3 GHz (8.6 %) from 59 to 64.3 GHz for the differential antenna and 9.7 GHz (15.8 %) from 52.5 to 62.2 GHz for the single-ended antenna. With reference to Fig. 6c–e, one can find from Fig. 15b–d that the radiation patterns and the maximum gain of the single-ended antenna are improved more noticeably than those of the differential antenna by the parasitic element. For example, the beamwidth in the E-plane is narrowed, and the radiation of cross-polarization in the H-plane is suppressed, so the gain is improved to 15 dBi for the single-ended antenna. Figure 15a also shows the simulated isolation level between the dual-grid array antennas. For the sake of simulation simplicity, both grid array antennas are fed for single-ended operation. Note the isolation is high because of the large physical separation between the two feeding terminals.

Figure 16 illustrates the integration of dual-grid array antennas in a flip-chip package as sample A. Note that the package features standard flip-chip bonding, and there are three co-fired laminated ceramic layers for the package. The first ceramic layer is 0.385 mm thick, and the second to the third ceramic layers are both 0.095 mm thick. There are four metallic layers for the package. The top layer provides the metallization for the dual-grid array antennas, the first buried layer metallization for the patterned ground plane, the second buried layer the metallization for the antenna feeding traces, and the bottom exposed layer the metallization for the signal traces. The package has 48 input/outputs with a JEDEC standard pitch of 0.25 mm. The size of the whole package is $13.5 \times 13.5 \times 0.585$ mm^3.

Figure 16 also illustrates the zoom-in view of the feeding networks of the dual-grid array antennas of sample A. For the dual-feed one, it consists of such packaging elements as two quasi-coaxial cables cascaded first with two striplines, then another two quasi-coaxial cables, and finally vias through two apertures on the ground plane in a GSGSG arrangement. It is interesting to note that the differential

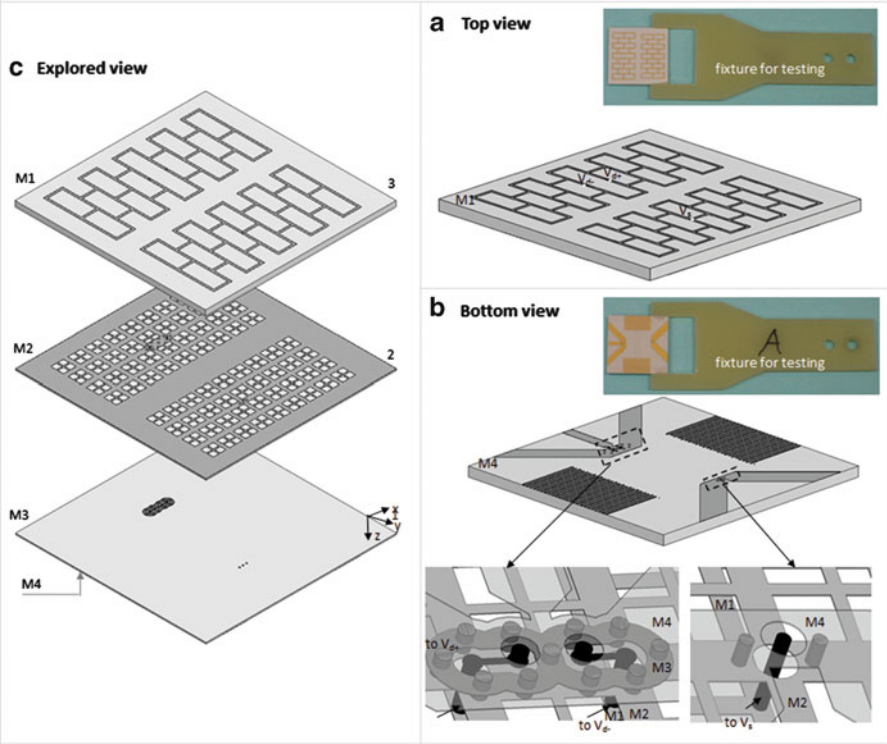

Fig. 16 Photos of the dual-grid antenna array A in the package with illustrations of **a** top view, **b** explored view, **c** bottom view with signal traces, as well as the zoom-in view of its feeding networks

DOI 10.1007/978-981-4560-75-7_44-1

feeding ports in Fig. 16 are brought closer to each other as compared with those in Fig. 14, due to the requirement of flip-chip bonding to the on-die GSGSG pads. The radiating element between the differential feeding ports is removed to enhance their isolation. For the single-feed one, it consists of a quasi-coaxial cable cascaded with via through one aperture on the ground plane in a GSG arrangement. It is known that the GSG and GSGSG arrangements not only minimize potential electromagnetic interference but also improve the feeding performance. The GSG and GSGSG feeding networks are designed together with the grid array antennas. Both GSG and GSGSG pads have a pitch of 0.25 mm.

Figure 17 shows the bottom view of the package sample B without the signal traces but with the integrated balun for testing the differential grid antenna array with the single-ended equipment. The package with the dual microstrip grid array antennas was fabricated in FERRO A6 LTCC in Singapore Institute of Manufacturing Technology. Figure 17 also illustrates the test fixture to hold the package for testing.

Figure 18 compares the simulated and measured results of the single-ended antenna for sample B. The return losses agree very well from 56 to 58.5 GHz. The agreement becomes poor for higher frequencies, due to the following reasons: dimension tolerance control, material property variation, and the difference between the wave-port excitation in simulation and the probe excitation in measurement. The measured return loss is higher than 10 dB from 56.4 to 61.7 GHz and 8 dB from 55 to 63.4 GHz indicating acceptable matching to 50-Ω sources at these frequencies. The simulated and measured radiation patterns are in close agreement at 61.5 GHz. The measured maximum gain is 13.5 dBi at 59 GHz with 3-dB gain bandwidth of 4.5 GHz. The simulated radiation efficiency is better than 85 %.

Figure 18 also compares the simulated and measured results of the differential antenna for sample B. The discrepancies between the simulated and measured return losses are due to the same reasons explained above for single-ended antenna. The measured return loss is higher than 8 dB from 56.2 to 63.2 GHz indicating acceptable matching to 50-Ω sources at these frequencies. Again, the simulated and measured radiation patterns at 61.5 GHz are in close agreement. The larger side lobes in the back side are caused by the balun. The measured maximum gain is 13.5 dBi at 57.5 GHz with 3-dB gain bandwidth of 5.3 GHz. If the additional loss of 1 dB from the integrated balun is de-embedded, the maximum gain of the differential antenna becomes 14.5 dBi. The simulated radiation efficiency is also better than 85 %. Generally, the measured results confirm the simulated ones. For instance, the differential grid antenna array exhibits a sharper radiation beam in the E-plane, a similar radiation pattern in the H-plane, and a higher gain as compared with those of the single-ended grid array antenna.

Millimeter-Wave Applications

The literature review shows that GAA has wide applications in microwave frequencies. Zhang's group has made it an excellent antenna candidate for millimeter-wave "antenna-in-package" technology by providing various elegant package solutions especially at 60-GHz band as mentioned in the above sections. In addition, they successfully developed GAA for automotive radar sensor applications at 24 GHz (Zhang et al. 2011a, b, 2012) as mentioned in the introduction part.

DOI 10.1007/978-981-4560-75-7_44-1

Inspired by the work done by the Zhang's group, W. Menzel adopted the GAA for 79 GHz automotive radar (Bauer and Menzel 2011; Frei et al. 2011; Bauer et al. 2013), where the wide band GAA with a broadside beam is designed to cover 77–81 GHz of the sensor operating frequency. A total of four SIW-fed GAA are integrated in a LTCC package with a four-channel SiGe transceiver chip on the back, which offers four TRX channels with a very compact LTCC RF frontend size of only 23 × 23 mm. The radar measurement results are presented and the feasibility of the concept is verified in Bauer et al. (2013).

T. Zwick implemented D-band 120 GHz GAAs on liquid crystal polymer (LCP) substrate as a lid of a surface-mounted chip package (Beer et al. 2013). Two prototypes are fabricated to demonstrate the feasibility of the package concept. Prototype 1 consists of three parts: a multilayer LCP GAA antenna as a lid, a $2 \times 2 \times 0.254$ mm^3 MMIC dummy, and an $8 \times 8 \times 0.4$ mm^3 LTCC package base with a $5 \times 5 \times 0.3$ mm^3 cavity to hold the MMIC. The D-band RF signal from MMIC dummy is flip-chip interconnected to the top GAA lid for further radiation. The other low-frequency signals from dummy MMIC are flip-chip interconnected to the top GAA lid signal traces and then distributed to connect to the bond pads of the LTCC package base and finally connected to the outside circuits through signal vias and solder pads on the bottom side of the LTCC package base. The LTCC package base uses Hirai Precision LTCC process with a tape material CS71 from Japan. The MMIC dummy uses thin film technology with high permittivity Alumina material from Hightec MC AG, Switzerland, and its stud bumps with a challenging diameter of ~60 μm and height of 30 μm placed by Hybrid SA, Switzerland. The LCP substrate uses the challenging dimension with a line width of 60 μm and a spacing of 40 μm. The whole prototype is assembled using a Finetech Fineplacer Pico in the lab at Karlsruhe Institute of Technology (KIT), Germany. The cutout in the LCP substrate enables the MMIC feeding lines to be probe touched for testing. The $|S_{11}|$, antenna gain, patterns are finally measured showing the feasibility of the package concept. A Prototype with two GAA integrated in the same LCP lid is also demonstrated targeted to connect to a 122-GHz bistatic radar IC with both transmitter and receiver circuits in a single die (Beer et al. 2013).

Summary

It is concluded that GAA has wide applications from microwave to millimeter-wave frequencies. It demonstrates an excellent antenna candidate for millimeter-wave "antenna-in-package" technology as seen from the 60-GHz, 79-GHz, and 120-GHz application examples. Using multilayer millimeter-wave fabrication technologies, such as LTCC, LCP, etc., the GAA can provide various elegant package solutions with wide choice of differential feeding or single feeding, CP or LP radiation scheme, as well as good mechanical property resistant to the warpage.

Reflectarray Antennas

Shenheng Xu[a]* and Fan Yang[a]
[a]Department of Electronic Engineering, Microwave and Antenna Institute, Tsinghua University, Beijing, China
[b]Department of Electronic Engineering, Tsinghua University, Beijing, China

Abstract

The reflectarray is a novel type of high-gain antennas, which combines some of favorable features of reflectors and arrays. It consists of a space-feeding primary source and an array of reflecting elements with individually predesigned phases to collimate or shape the high-gain beam in the desired direction. In this chapter, the operating principles of reflectarray antennas will first be introduced. Then the design procedure and analysis methods of both reflectarray elements and systems will be explained in detail and some practical design considerations will be discussed. Finally, some latest developments and applications, such as broadband and multiband techniques, reconfigurable reflectarray designs, shaped-beam and multi-beam reflectarrays, etc., will be presented.

Keywords

Antenna; Array; Electronic beam scanning; Gain; Microstrip array; Pattern; Phased array; Radar; Reflectarray; Satellite communication; Spaceborne

Introduction

High-gain antennas are crucial components in satellite communications, radar detection and tracking, remote sensing, military and defense applications, and so on. The most widely used high-gain antennas are reflectors because of the high radiation efficiency and well-developed design and analysis procedures. However, their radiation performances are not versatile enough to meet the ever-increasing demands of modern applications. The slow beam scanning capabilities heavily rely on mechanical structures due to its severe off-focus degradation. The specifically curved metallic surfaces are difficult to fabricate at high frequencies and even become prohibitive in some shaped-beam designs. The bulky reflectors also render it inapplicable where mass, volume, and conformal structure are of great consideration.

Microstrip arrays have been successfully applied in many advanced applications due to its versatile radiation performances, planar and low profile, and lithographic etching technique for accurate fabrication. With the integration of phase shifters and transmit/receive (T/R) modules, phased arrays also excel at fast electronic beam scanning, shaped-beam, and multi-beam applications. The major disadvantages, on the other hand, are the considerable loss in the beam-forming network (BFN), especially for high-gain antennas at high frequencies. Its design also becomes formidably difficult for large-scale beam-forming networks. The added controlling modules are expensive, prohibiting it from massive adoption. In addition to the power inefficiency, they also increase the overall mass and volume and require specially designed heat ventilation structures in high-power systems.

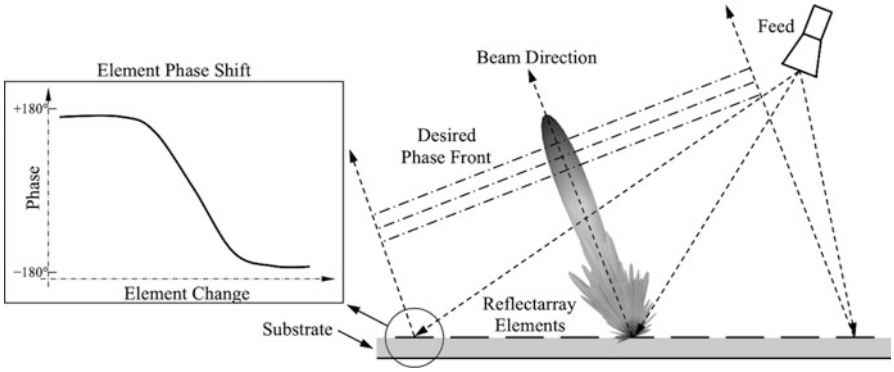

Fig. 1 General configuration of a reflectarray antenna

The reflectarray antenna (Huang and Encinar 2008; Shaker et al. 2014), as its name implies, is a hybrid of reflectors and arrays, which combines some favorable features of both antennas while mitigating their disadvantages. Its most general configuration is illustrated in Fig. 1, which consists of a space-feeding primary source (feed) and an array of reflecting elements with individually predesigned phases to collimate or shape the high-gain beam in the desired direction. The key parameter in a reflectarray is the phase shifts provided by the reflectarray elements arranged in array lattice, which are specifically designed to compensate for the differential spatial phase delays from the feed and form a planar (or shaped) phase front on the reflectarray aperture. The phase shift is usually achieved by varying one or more geometrical parameters of the element. By adding low-loss tuning devices or special substrate materials to each element, reconfigurable reflectarrays are also capable of generating electronically adjustable phase shifts and producing some of versatile functionalities as phased arrays.

As an alternative novel high-gain antenna configuration, the reflectarray technology has developed rapidly in recent years. Some favorable features, which successfully distinguish it among many candidates, are summarized as follows:

- Similar to reflectors, space-feeding mechanism is adopted so that the complicated and lossy beam-forming networks are avoided. Therefore, reflectarray antennas are usually able to achieve high radiation efficiency of more than 50 % (Huang and Encinar 2008).
- With proper analysis methods, the phase shift provided by each reflectarray element can be accurately designed. Similar to arrays, the phase adjustability of individual element allows the reflectarray to produce versatile radiation characteristics, including a high-gain beam in a desired direction, shaped-beam and multi-beam patterns, improved wide-angle beam scanning capability, etc.
- Combined with various phase synthesis or optimization methods, complex phase shift distributions can be readily designed and precisely achieved, thus producing very accurate shaped patterns. On the contrary to the difficulties in fabricating shaped reflectors with stringent accuracy, the fabrication process of shaped-beam reflectarrays is the same as simple single-beam reflectarrays without increasing the complexity or cost in fabrication. Furthermore, dual-linearly polarized elements can provide independent phase shifts for each polarization to obtain more flexible performance.
- The electronic phase adjustability can be achieved on the element level by incorporating low-loss and low-cost PIN diodes, RF MEMS switches, special substrate materials, or other tuning devices, in reflectarray element designs. Without using the lossy beam-forming network and expensive phase shifters (or T/R modules), electronically reconfigurable reflectarrays can provide fast electronic beam scanning capability with high efficiency and low cost.

DOI 10.1007/978-981-4560-75-7_45-1

- The array of reflectarray elements is usually fabricated on a grounded substrate using lithographic etching technology, which is a very matured process and ensures massive and low-cost manufacture with excellent accuracy. The reflectarray technology can readily cover the entire microwave and millimeter wave frequencies without significantly increasing fabrication complexity or cost.
- Reflectarrays are extremely low profile and light weighted. The reflectarray aperture is usually planar (or slightly curved or multifaceted), making it easily conformal to various mounting platforms.
- A large reflectarray aperture can be divided into small segments and assembled on site later, making fabrication, packaging, and shipment more convenient and keeping the cost low. Especially for spaceborne applications, compared to the conventional doubly curved reflectors, the planar structure of reflectarrays requires a much simpler and reliable folding mechanism to achieve a large-aperture deployable antenna with satisfactory surface accuracy. An inflatable reflectarray with elements printed on a large, flat, thin membrane can even further reduce its mass and stowing volume.

As a result, reflectarray antennas have been attracting growing interests in the recent years and a variety of research progresses have been accomplished. In this chapter, the fundamentals of reflectarray antennas, such as the operating principles, design procedure, and analysis methods, will be introduced. One of the main limitations of the reflectarray technology is its limited bandwidth. Hence, special attention will be paid to various broadband and multiband designs. And finally, some latest developments, innovations, and applications will be presented.

Reflectarrays: A Hybrid of Reflector and Array Antennas

The concept of reflectarray antennas was first conceived by Berry, Malech, and Kennedy in 1963, where short-ended waveguides with variable lengths illuminated by a horn feed were used to control the phase of the reflected wave (Berry et al. 1963). However, the structure was too bulky at lower microwave frequency so the related research was stalled for decades. With the development of microstrip arrays and lithographic etching technology, microstrip reflectarrays, in typical forms as seen nowadays, were introduced and intensively investigated in the late twentieth century (Huang 1991; Pozar and Metzler 1993; Pozar et al. 1997, 1999; Huang and Pogorzelski 1998). In the past 10 years or so, the increasing computational power enabled more rigorous analysis methods and phase synthesis/optimization approaches for reflectarray designs. Combined with driving demands of satellite communications, more diversified researches on reflectarrays were boosted and a variety of novel reflectarray technologies and designs have been accomplished.

As previously noted, a reflectarray is a hybrid of reflector and array antennas consisting of a feed and an array of many different elements printed on a grounded substrate. Considering the relatively complex structure, a systematic procedure is developed to accurately analyze and appropriately design a reflectarray antenna, as given in Fig. 2. It is usually carried out in several stages, and the two main stages are the element design and the system design, which will be discussed in detail in the following sections.

Reflectarray Elements

Similar to microstrip arrays, microstrip reflectarray elements are usually lithographically printed on a planar grounded substrate. Some typical reflectarray elements are illustrated in Fig. 3, which are patches with variable-length phase delay lines (Huang 1991), patches with variable sizes (Pozar and Metzler 1993), and split rings with variable rotation angles (Han and Chang 2003). They can take various forms and shapes but usually share the same property: the reflectarray elements are an array of reflecting microstrip elements arranged in a lattice configuration.

DOI 10.1007/978-981-4560-75-7_45-1

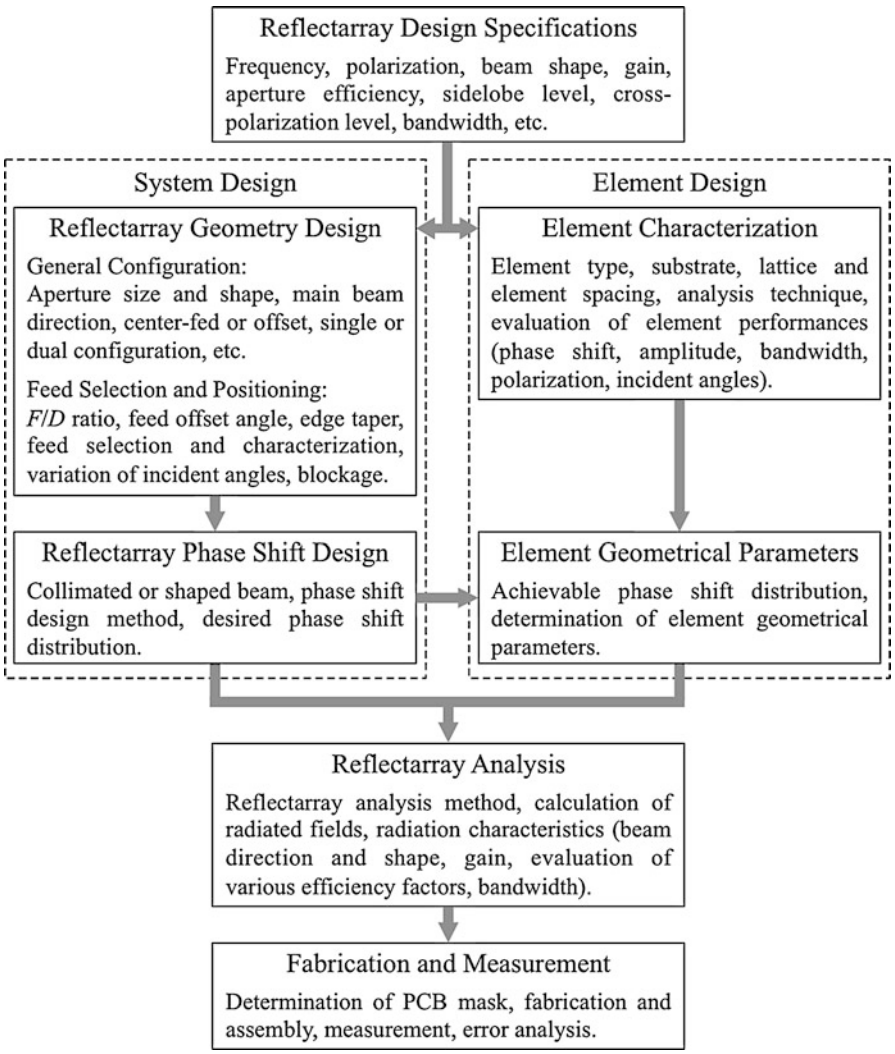

Fig. 2 Flowchart of the reflectarray antenna design and analysis procedure

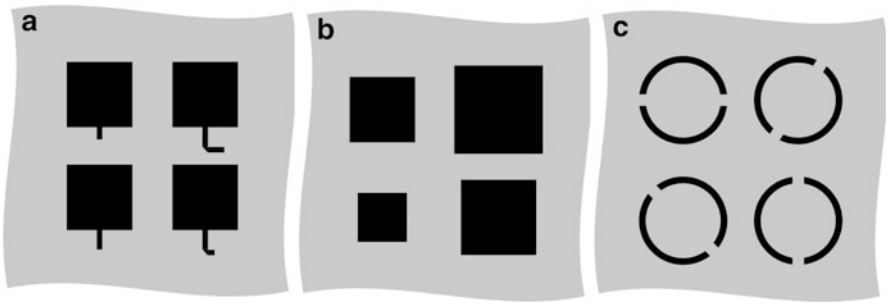

Fig. 3 Typical reflectarray elements: (**a**) patches with variable-length phase delay lines, (**b**) patches with variable sizes, (**c**) split rings with variable rotation angles

Unlike reflectors, which utilize specifically curved metallic surfaces to adjust the spatial phase delays and form the desired phase front, reflectarrays rely on the phase shift provided by individual element to form a specific phase front. Therefore, accurate characterization of a reflectarray element's response to the electromagnetic wave incident upon it is one of the most critical steps in the design procedure.

DOI 10.1007/978-981-4560-75-7_45-1

Element Analysis Techniques

The reflectarray element can be treated as an isolated element based on the assumption that each element works the same as an isolated element on a large grounded substrate and the mutual coupling between adjacent elements is negligible (Javor et al. 1995). However, it may not hold because the typical spacing between elements is so small that the mutual coupling effect can be strong enough to cause considerable errors. An improved surrounded-element approach is proposed, which considers the actual mutual coupling for a realistic configuration by including the surrounding nonidentical elements in element evaluations (Milon et al. 2007), but the enormous computational expenses it requires are hindering in practice.

Based on the observation that reflectarray elements form a quasiperiodic structure with similar elements surrounding each other, an infinite-array approach, which analyzes the reflection by an infinite array of identical elements with mutual coupling, is proposed (Pozar and Metzler 1993). This assumption is acceptable since the progressive phase distribution of the reflectarray aperture usually results in adjacent elements with similar shapes or sizes, except for those at the edges or with abrupt phase variation. Because of the similarity between the quasiperiodic structure of a reflectarray and the periodic structures of microstrip arrays and frequency selective surfaces (FSS), the analysis techniques from those fields can be directly borrowed and benefit the characterization of reflectarray elements. Specifically, by applying Floquet's theorem, the analysis of an infinite array with mutual coupling is dramatically reduced to only one unit element, thus resulting in extremely high efficiency and good accuracy (Huang and Encinar 2008). Therefore, the infinite-array approach has been widely adopted in reflectarray element analysis.

Various full-wave numerical methods, including the spectral domain method of moments (MoM), finite element method (FEM), and finite-difference time-domain (FDTD) method, have been employed to implement the infinite-array approach. Other than certain difference in computational cost, they all are able to yield accurate results. Some commercial full-wave electromagnetic simulators, such as Ansoft HFSS (HFSS 2014) and CST Microwave Studio (CST 2014), are also capable of fulfilling this purpose with built-in periodic boundaries and Floquet mode excitations. A crucial step in successfully applying these methods is to appropriately surround the unit cell with electric and magnetic walls (or periodic boundaries), which properly replicate it and span the desired infinite periodic structure. As an example, the numerical analysis model of a square microstrip patch with variable size using Ansoft HFSS is shown in Fig. 4. The unit cell is surrounded by the periodic boundaries. The port is set up with Floquet mode and de-embedded onto the patch surface. A plane wave with specific polarization and propagation direction is excited at the port, and by calculating the complex scattering parameter, the phase shift and amplitude response of the element can thus be achieved.

Other than the approaches mentioned above, the equivalent circuit method has also been used to speed up the calculation process (Bozzi et al. 2004; Shaker et al. 2014). For instance, a parallel *RLC* equivalent circuit model (Bozzi et al. 2004) can be utilized to characterize a lossy patch with variable size, as shown in Fig. 5, which provides useful insight into the physics of the reflectarray element. However, the construction of an equivalent circuit is usually based on a particular configuration, and its applicability is limited.

Evaluation of Element Performances

A reflectarray element reacts to the electromagnetic wave incident upon it and scatters it according to its design parameters. Its reflection characteristics directly affect the performances of the whole antenna. A careful evaluation of the element performances is important and critical, which helps determine the criteria for the selection of element configurations and optimization of element parameters to meet the design requirements. The characterization of a reflectarray element can be accomplished using one of the element analysis techniques mentioned above. Several key element performance parameters need to be

DOI 10.1007/978-981-4560-75-7_45-1

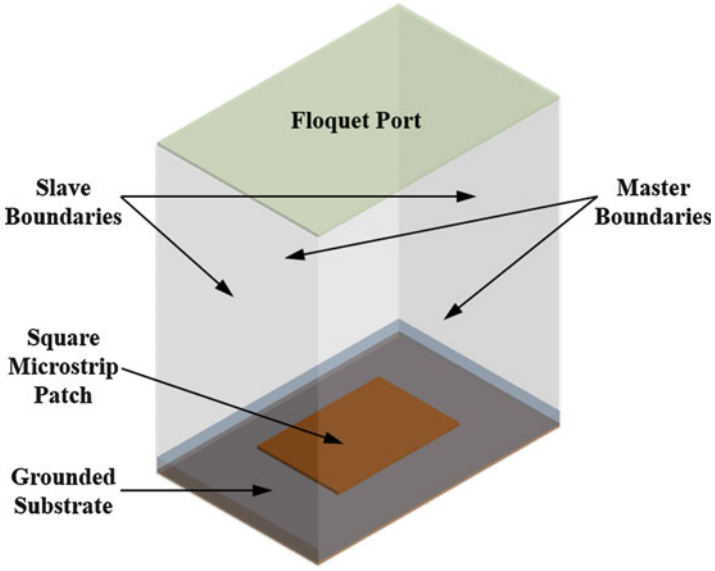

Fig. 4 Element analysis using Ansoft HFSS

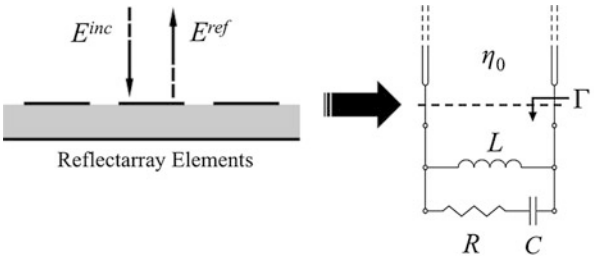

Fig. 5 Equivalent circuit model for a lossy reflectarray element

carefully evaluated, such as the phase shift, the reflection amplitude, the element bandwidth, and the element's responses to different polarization and different incident angles.

A detailed discussion on those parameters is carried out through a case study. As an example, a square microstrip patch with variable size at Ka-band is analyzed using the infinite-array approach in Ansoft HFSS, as shown in Fig. 4. The operating frequency is 32.5 GHz. The unit cell size is 4.6 mm in both directions, approximately half wavelength at the operating frequency. The thickness of the grounded substrate is 0.51 mm, with the dielectric constant ε_r of 2.55 and the loss tangent tanδ of 0.0019. A plane wave polarized in x direction is excited at the Floquet port and normally incident unto the patch. By de-embedding the port and calculating the complex scattering parameters, the reflection characteristics of the element are obtained, from which the element performance parameters can thus be achieved.

First and most importantly, the element phase shift is defined as the phase jump between the phases of the reflected and incident waves of the element, which equals the phase of the complex scattering parameter S_{11}. Different element phase shift is achieved by varying one or more geometrical parameters of the element. And in this case, it is the patch size. By changing it from 1 to 4 mm, the element phase shift versus the patch size can be obtained and plotted in Fig. 6a, which is known as the phase curve. Because of its typical S-shaped nonlinear variation, the phase curve is often called the S-curve as well. It is a measure of the phase adjustability of the element and is the fundamental ground on which the entire reflectarray concept is built. According to the required phase shift distribution of the reflectarray to form the desired phase front, the element sizes can be determined using the phase curve.

DOI 10.1007/978-981-4560-75-7_45-1

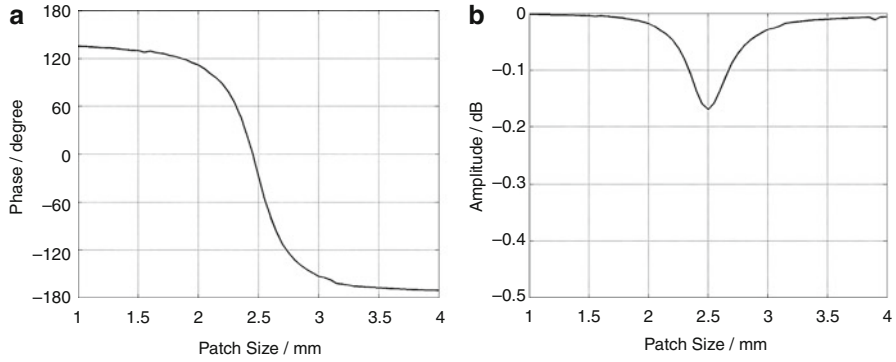

Fig. 6 (**a**) Phase curve and (**b**) reflection amplitude of square microstrip patches with variable sizes

The phase curve is one of the most crucial design curves in reflectarray designs and requires close attention. Two parameters are usually employed to examine the goodness of a phase curve. The first parameter is the maximum phase shift swing, which defines the phase range a set of reflectarray elements can possible cover. An ideal phase shift swing should cover at least 360°, and a smaller coverage inevitably results in phase errors. In Fig. 6a it is seen that the phase shift of the patches with variable sizes swings from −170° to +135°, so the phase range is approximately 305°. Although less than ideal, this coverage is often considered acceptable in practice and the resultant phase error is within an allowed range. There is no standard guideline on the minimum phase shift swing, and it is up to a designer's empirical knowledge and the trade-off among different performance parameters. The second one is the slope of the phase curve when it crosses 0°. It represents the resonance of the infinite-array structure and can be considered as a representative of the element bandwidth. A more gradual slope leads to a wider element bandwidth. Moreover, a steep slope causes the element phase response overly sensitive to the element change, and a minor fabrication error can cause considerable phase error.

The element reflection amplitude is plotted in Fig. 6b, which equals the amplitude of the complex scattering parameter S_{11}. Due to the existence of the ground plane, all the incident energy is scattered back, except for the part dissipated in the lossy substrate and nonideal conductors. The dielectric and conductor loss reduces radiation efficiency. The element amplitude response exhibits a maximum dip at the resonance of the structure where the maximum current flow on the element is excited and loss is maximized. The width of the dip also matters. A wider dip corresponds to a larger group of elements with high loss, leading to inefficiency of the reflectarray.

The back-scattered energy can be further divided into three components: the reradiated field due to the resonant activity of the patch, the specular reflected field due to the ground plane, and the scattered field due to the nonresonant structure of the patch. When the reradiated field does not coincide with the specular reflections, the latter components can cause higher sidelobes and reduced efficiency (Huang and Encinar 2008).

Both the phase and amplitude responses of the elements can be profoundly affected by the material properties. Firstly, as the thickness of the substrate increases, the element phase shift swing reduces as shown in Fig. 7a, leading to large phase error and reduced efficiency. The increased loss in thicker lossy dielectric substrates may also reduce efficiency. On the other hand, a thicker substrate reduces the Q-factor of the resonant structure. Hence, the slope of the phase curve becomes more gradual, improving the element bandwidth. Secondly, when the dielectric constant increases, the resonance of the structure shifts towards smaller patches and the slope of the phase curve becomes steeper, negatively impacting the element bandwidth, as shown in Fig. 7b. Thirdly, it is obvious that the increased loss tangent causes higher dielectric loss and reduced efficiency. And lastly, the finite conductivity of nonideal metallic materials

DOI 10.1007/978-981-4560-75-7_45-1

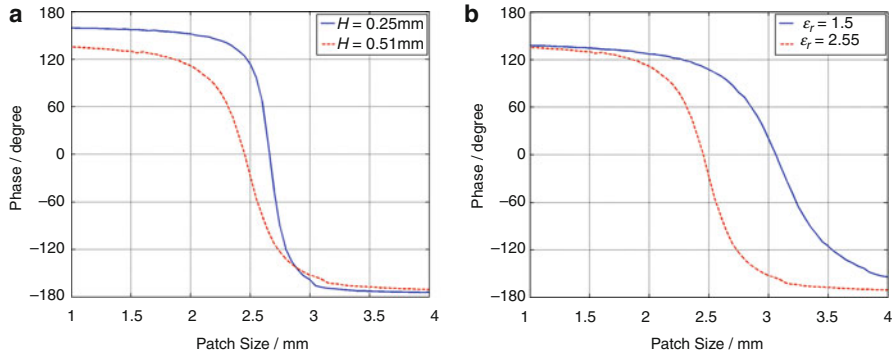

Fig. 7 Phase curves for (**a**) different thicknesses and (**b**) different dielectric constants of the substrate

increases the conductor loss (An et al. 2014a). Although mostly negligible at microwave frequencies, it becomes an important issue at terahertz (THz) and optical frequencies and requires special attention (Yang et al. 2012).

The unit cell size, or the element spacing in the quasiperiodic structure, is also an important design parameter of a reflectarray element. As a rule of thumb, it should be properly chosen to avoid grating lobes, which can be described as

$$\frac{d}{\lambda} \leq \frac{1}{1 + \sin\theta} \tag{1}$$

where d is the element spacing, λ is the wavelength in free space, and θ is either the incident angle or the main beam tilt angle from the broadside direction, whichever is larger (Huang and Encinar 2008). In practice, an element spacing of half wavelength is commonly employed. More recently, subwavelength element spacing is also adopted, where electrically small elements are closely spaced with element spacing less than half wavelength (Pozar 2007; Nayeri et al. 2010, 2011). The phase and amplitude responses for different unit cell sizes in this case study are presented in Fig. 8. It is observed that a coupled resonance is excited by the closely spaced elements. As the element spacing decreases to $\lambda/3$ and $\lambda/4$, both the slope of the phase curve and the amplitude loss improve, but the phase shift swing is considerably reduced. The subwavelength element spacing can substantially improve the bandwidth performance of the reflectarray antenna. However, the small patches and gaps also tighten the fabrication tolerance.

Another important element performance parameter is the element bandwidth. Reflectarray elements are intrinsically narrowband. As an example, the microstrip patch element with variable size generally has a bandwidth of 3–5 %. Its phase curves at different frequencies are shown in Fig. 9. Generally speaking, an element can achieve better bandwidth performance if the phase curves are smooth with gradual slopes and the variation between them is similar with element change. As briefly discussed above, careful tuning of element parameters can help improve the element bandwidth, such as using thick substrate with low dielectric constant and adopting subwavelength element spacing. For instance, using a thick layer of air or foam as substrate is a common way in practice. More recently, a lot of efforts have been devoted to this issue and various innovative broadband and multiband designs and techniques have been proposed.

A reflectarray element should also be able to properly respond to a polarized incident wave with correct phase and amplitude. Different element designs have different polarization performances, such as single- or dual-linear polarization and circular polarization, and appropriate selection of elements is critical. For instance, a square patch with variable size is suitable for single-linear polarization or circular polarization. Its side lengths can also be independently tuned so that the rectangular patch element can provide dual-linear polarization performance.

Lastly, a reflectarray element scatters differently the incident wave from different directions. The incident angle of the element can be determined in receive mode or transmit mode, depending on how the reflectarray operates (Rengarajan 2009). Using a single pencil-beam reflectarray as an example, whose general configuration is depicted in Fig. 1, in receive mode a plane wave is incident from the main beam direction. The incident angle of the element is simply the main beam tilt angle and all elements have the same incident angle. In transmit mode, it becomes more complicated. The spherical wave originated from the feed impinges on the element at a certain angle. Assuming the element is located in the far-field region of the feed, then the incident wave can be locally considered as a plane wave by revoking the local plane wave approximation, and the incident angle of the element is determined by its location with respect to the feed. In this case, all elements have different incident angles. This is a unique feature of reflectarrays and requires close attention in the element analysis and reflectarray design process.

The phase curves of square patch elements for different incident angles are plotted in Fig. 10. It is observed that the element phase shift changes with the incident angle. Ideally, the reflectarray element should be analyzed for each incident angle in order to accurately evaluate its phase characterization and minimize the potential phase error in reflectarray designs. Considering the large number of elements in a typical high-gain reflectarray, however, this process becomes extremely time-consuming and even prohibitive. On the other hand, the difference between the phase curves for normal and oblique incidences is relatively small within a certain angular range, i.e., 25° in this case. By appropriately designing the reflectarray geometry, the incident angles of the well-illuminated elements can be limited in that range. Therefore, only the normal incidence case is analyzed and all element parameters are determined using the phase curve for normal incidence. It is a common practice in most reflectarray designs, and the phase errors caused by this approximation are considered acceptable. However, in some advanced applications where optimal aperture efficiency for high gain or precise phase contour for shaped beam is required, an element-by-element analysis process should be adopted.

Representative Types of Elements

Various reflectarray elements have been developed to better meet different requirements of reflectarray designs, such as radiation efficiency, polarization, bandwidth, fabrication accuracy and cost, etc. Each has its own advantages and limitations. According to adopted phasing mechanism, most microstrip reflectarray elements are categorized into three representative types, namely, the resonant elements, the elements loaded with phasing structures, and the circularly polarized elements with variable rotation angles. Some designs are introduced and their performances are briefly discussed.

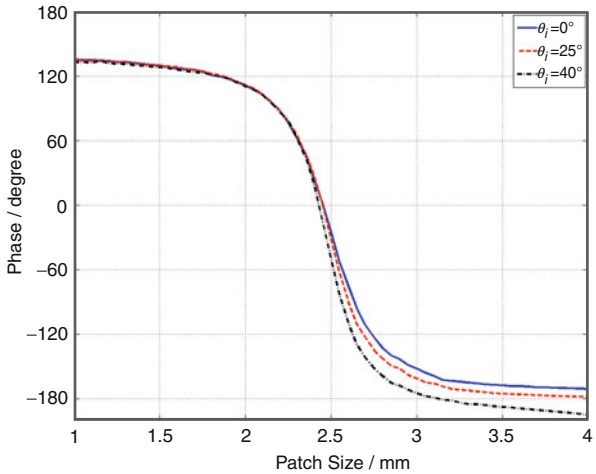

Fig. 10 Phase curves for different incident angles

DOI 10.1007/978-981-4560-75-7_45-1

The resonant elements employ the variable-size phasing mechanism to achieve the required phase adjustability. A patch element in an array environment is first designed to resonate at the operating frequency, and a small change in patch size results in substantial phase variation. The square patch with variable size, as shown in Fig. 3b, is the most widely used one in this category. Different shapes and forms, such as dipoles, square rings, and circular patches and rings, have also been investigated (Bialkowski and Sayidmarie 2008). They all have very simple configurations with a few geometrical parameters and can be easily fabricated using lithographic etching technology. The typical phase curve of the resonant elements is similar to that shown in Fig. 6a. The total phase shift swing is usually less than 360°, and the unobtainable phase range causes certain phase error and inefficiency. Because of the intrinsic resonant nature of the element, it exhibits a strong nonlinear variation with steep slope near the resonance and little change for extreme patch sizes. It limits the element bandwidth and makes it more sensitive to fabrication error. A large number of patches are off resonant, which may cause specular reflections, leading to higher sidelobes and reduced efficiency. More recently, a variety of multi-resonant elements have been proposed. By combining or stacking two or more simple resonant elements to create multiple resonance of the structure, they can effectively smooth the phase curve and substantially improve the element bandwidth performance (Encinar 2001; Chaharmir et al. 2009).

A different phasing mechanism is to load a resonant microstrip patch with variable-length phase delay lines, as shown in Fig. 3a (Huang 1991; Javor et al. 1995). The incident wave is coupled into the element, travels along the loading stub until it reflects back at the open end, and finally reradiates with a phase delay. The amount of phase delay varies approximately linearly with the length of the microstrip line, which can be calculated using an empirical formula (Javor et al. 1995). The stubs are usually bent to be able to fit within the limited space, which may cause spurious radiation in manifestation of higher cross-polarization and sidelobe levels. The long microstrip lines also increase dissipative loss in the elements. In order to mitigate these drawbacks, a multilayered slot-coupled patch element is developed (Bialkowski and Song 2001), and improved bandwidth performance can be achieved by using true-time delay lines (Carassco et al. 2008). In addition, slots can also be employed as loading structures (Chaharmir et al. 2003a). It is worthwhile to mention that the extra room in these elements allows the integration of tuning devices to achieve reconfigurable reflectarray designs (Rajagopalan et al. 2008; Carassco et al. 2012).

The circularly polarized elements with variable rotation angles produce desired phase shifts by physically rotating identical elements, and the phase shift is twice the angle of rotation because of the reflection process. This phasing mechanism can be applied to various circularly polarized elements, such as elements with loading stubs (Huang and Pogorzelski 1998), split rings as shown in Fig. 3c (Han and Chang 2003), single split rings (Yu et al. 2009), etc. A variation of this technique is to rotate the gaps of a square loop instead of the whole element itself in order to minimize the effectively occupied area by individual elements (Yu et al. 2012). The element rotation technique can achieve a full 360° phase shift swing. It also benefits the reflectarray performances in terms of sidelobe and cross-polarization levels because of the pseudorandomly arranged elements and improves radiation efficiency due to the suppression of specular reflection (Huang and Encinar 2008). It is crucial to note this technique is only applicable to circular polarization. And unlike the polarization reversal observed in other elements, the elements with variable rotation angles produce a same-sensed polarization response.

The above discussion only presents a commonly used method of categorization. Many novel reflectarray elements have been developed since the inception of reflectarray technology and may use one or a combination of various phasing mechanisms in its design. Other design parameters, such as the heights of the block elements (Nayeri et al. 2014; Deng et al. 2014) and the dielectric constant of the substrate material (Hu et al. 2008), can also be utilized to achieve the desired phase shifts. An appropriate selection of reflectarray element is the foundation of a reflectarray design.

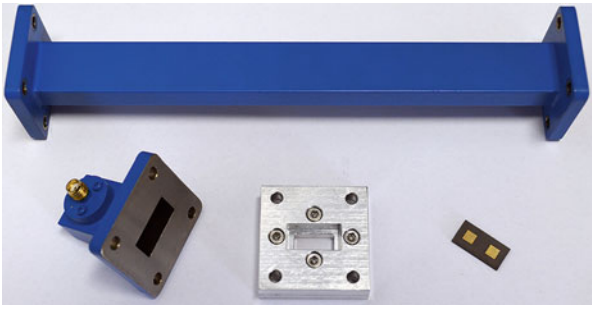

Fig. 11 Element measurement using a waveguide simulator

Element Measurement and Diagnosis

The phase shift and dissipative loss of a reflectarray element can be measured in a waveguide simulator (Hannan and Balfour 1965). An example of a Ku-band waveguide simulator is presented in Fig. 11, which includes a Ku-band standard waveguide, a coax-to-waveguide adapter, and a back plate. The element sample is inserted into the rectangular waveguide with the help of the back plate. The waveguide walls mirror the inserted sample and span an infinite array with specific element spacing. The opening on the back plate can be either sealed with conductive tape to ensure a total reflection or used for applying control signals in reconfigurable elements. The fundamental TE_{10} mode of the waveguide is excited, and the angle of incidence θ_0 of the impinging plane wave on the infinite array can be determined by

$$\sin\theta_0 = \frac{\lambda}{2a} \tag{2}$$

where λ is the free-space wavelength at the operating frequency and a is the longer dimension of the waveguide. The complex reflection coefficient is then measured using a vector network analyzer, from which the element phase and amplitude responses can be extracted. This measurement technique is easy to implement; however, there are several critical limitations that must be considered. The plane wave can only propagate in the H-plane with a fixed incident angle of θ_0. Only linear polarization can be excited with electric field parallel to the shorter waveguide walls. The element size and spacing are limited by the waveguide dimensions. And it may cause certain errors if the element responses in an actual configuration deviate from the quasi-infinite-array approximation.

It is sometimes desirable to check the accuracy of reflectarray element designs especially when the adjacent elements have abrupt phase variations or stringent performance requirements are demanded. Therefore, a visualization approach (Rajagopalan et al. 2012a) is proposed which can potentially assist the design, analysis, and diagnosis of reflectarrays. By properly interpreting the radiation mechanism of a reflectarray, the actual phase responses of an entire reflectarray are achieved through full-wave simulations and individual element performance in the actual configuration can be closely examined. Fine-tuning of element parameters can then be performed to achieve more accurate phase shifts as designed. However, the required computational expenses may limit its application in practice.

Reflectarray Design and Analysis

Reflectarrays utilize the same space-feeding mechanism as reflectors. Resemblance between them justifies that various theories and design guidelines from reflectors can be readily borrowed to facilitate the design and analysis of reflectarrays. On the other hand, reflectarrays rely on the phase adjustability of the array of elements, rather than specifically curved metallic surfaces in reflectors, to achieve the phase transformation of a spherical wavefront originated from the feed into a planar wavefront. This unique

DOI 10.1007/978-981-4560-75-7_45-1

feature gives more flexibility in reflectarray designs, but it also requires particular attention in analyzing its radiation characteristics.

Reflectarray Geometry Design

Similar to reflectors, reflectarray geometries can take various forms, such as a single reflectarray with a prime focus feed or an offset feed, in order to meet specific design requirements. For example, an offset geometry can avoid the feed blockage in a center-fed system and is widely adopted in practice. Moreover, unlike an offset reflector whose projected aperture is always smaller than its physical size, the main beam of an offset reflectarray can be aligned in the broadside direction so that the whole aperture is fully used. On the other hand, the variation of incident angles on the elements of an offset reflectarray is larger than that of a center-fed system, and some extremely large incident angles may occur for far-end edge elements. Under this circumstance, the actual element phase shift may considerably deviate from the phase curve for normal incidence, which is commonly assumed in reflectarray element analysis, resulting in phase errors and inefficiency. Meanwhile, less energy is intercepted and reradiated by those elements due to the element beamwidth effect (Huang and Encinar 2008), which may further reduce the radiation efficiency. Special attention needs to be paid to the design and analysis of those elements, making it more difficult to design offset reflectarrays. Therefore, a compromise can be made by reducing the feed offset angle while tilting the main beam away from the broadside. A blockage-free offset design with small feed offset angle is possible at the price of a reduced effective aperture size.

The reflectarray aperture is usually planar but can also be slightly curved for conformal designs. It can be circular, square, polygonal, or in other special shapes. The aperture's electrical size is determined by the system gain requirement. Generally speaking, the radiation performance in terms of sidelobe and cross-polarization levels and efficiency is better for reflectarrays of larger sizes, because the specular reflection, edge diffraction, and feed blockage effects become less noticeable compared to its desirable radiation from the elements.

A crucial design parameter F/D, the focal length to diameter ratio, must be properly chosen. A larger F/D usually can achieve better radiation performances in terms of cross-polarization level, bandwidth, and scan capability, but it may also increase the feed size and overall volume of the reflectarray antenna. A smaller F/D significantly increases the variation of spatial phase delays to the center and edge elements, which becomes a critical factor in bandwidth limitation. It may also result in extremely large incident angles for the edge elements. These are two distinctive differences compared to its reflector counterpart and require particular attention. In practice an F/D from 0.5 to 1 is commonly adopted.

The edge taper (ET) on the reflectarray aperture is another important parameter, which profoundly affects its radiation characteristics, such as beamwidth, sidelobe level, and efficiency, in the same way as it acts on reflectors. Generally speaking, the taper efficiency deteriorates and the spillover efficiency improves as the edge taper decreases, and optimal radiation efficiency can be achieved when the edge taper is around -10 dB. Therefore, the feed must be properly designed according to the chosen F/D so that it provides appropriate illumination on the reflectarray. Detailed derivations and calculations of these efficiency parameters will be presented in the following discussions.

Dual configurations have also been developed to fold the optics (Arrebola et al. 2008; Almajali et al. 2012; Tienda et al. 2012; Rajagopalan et al. 2013). Dual reflectarrays, as well as a combination of reflectarray and reflector, can be employed. Due to the unique phase controlling capability of reflectarray elements, some specific purposes, such as beam scanning (Hu et al. 2009), reflector surface distortion compensation (Xu et al. 2009; Rajagopalan et al. 2012b), and shaped beam for direct broadcast satellite (DBS) applications (Tienda et al. 2013), can be achieved. The complex structure, however, significantly increases the complexity in designing and analyzing a dual system.

DOI 10.1007/978-981-4560-75-7_45-1

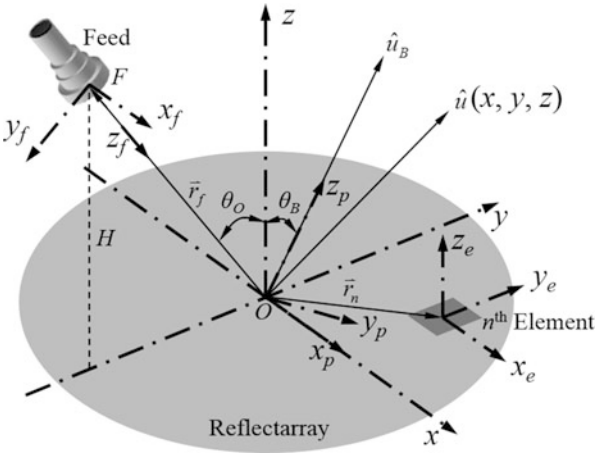

Fig. 12 The coordinate systems and configuration parameters of a reflectarray

Reflectarray Phase Shift Design

After the reflectarray geometry is determined, the phase shift distribution of the reflectarray required to produce the desired radiation characteristics can be obtained using a ray tracing method or a phase-only synthesis method. For a single high-gain beam design, the former is widely employed.

As illustrated in Fig. 12, four sets of coordinate systems are usually utilized to facilitate the analysis of a planar reflectarray with N elements. (x, y, z) refers to the reflectarray coordinates with its origin located at the center of the aperture O, and $\hat{u}$ is the observation direction. The one with subscript f refers to the feed coordinates with its origin located at the focus F. The phase center of the feed is positioned at the focus F, and the feed pattern is pointed toward the reflectarray aperture along the z_f axis. H is the feed height and θ_O is the feed offset angle. $\vec{r}_f$ is the position vector of the feed. The main beam is aligned in the $\hat{u}_B$ direction, which is also the z_p axis in the pattern coordinate system, and θ_B is the main beam tilt angle. The subscript e denotes the element coordinates whose origin is located at the center of each element, and $\vec{r}_n$ is the position vector of the nth reflectarray element. A coordinate transformation between different coordinate systems can be easily carried out using the Eulerian angles (Rahmat-Samii 1979).

Considering a reflectarray operating in transmit mode and assuming the reflectarray elements are in the far-field region of the feed, then the electromagnetic wave emanated from the feed can be considered as a spherical wavefront. The incident field on each element can be locally approximated by a plane wave with a phase proportional to the distance from the phase center of the feed to each element. To collimate the beam in the $\hat{u}_B$ direction, a uniform phase planar wavefront perpendicular to $\hat{u}_B$ is required. By using a simple ray tracing method, the desired phase shift φ_n of each element can be calculated as

$$\varphi_n = k\left(\left|\vec{r}_n - \vec{r}_f\right| - \vec{r}_n \cdot \hat{u}_B\right) + \Delta\varphi_0 + 2n\pi, n = 0, \pm 1, \pm 2, \cdots \tag{3}$$

where k is the free-space wave number, $\Delta\varphi_0$ is a constant reference phase, and the integer n is used to keep φ_n within 360° bound. It is critical to note that the phase shift relative to each other, rather than the absolute phase value of each element, is needed to fulfill the phase transformation. Hence, an arbitrary constant reference phase $\Delta\varphi_0$ may be added to all the elements. It is also observed that the main beam direction $\hat{u}_B$ is a design parameter independent of the feed position or the aperture geometry. For instance, a tilted pencil beam off the broadside can be achieved by a center-fed reflectarray. This is an example of the flexibility offered by reflectarrays that does not have an equivalent in reflectors.

Besides the reflectarrays that mimic parabolic reflectors to convert a spherical wavefront into a plane wave, the ray tracing method has also been successfully utilized to derive the closed-form expressions of

the required phase shifts of a reflectarray used as a hyperboloidal or ellipsoidal subreflector in a dual system (Almajali et al. 2012; Rajagopalan et al. 2013). Both full-wave simulations and measurements demonstrate that the reflectarrays are able to convert an incident spherical wave originated from one focus into another spherical wave from the secondary focus.

In reflectarrays, as opposed to active phased arrays with controllable phase and amplitude, only the phase shift of each element can be adjusted and its amplitude is determined by the illumination of the feed. Therefore, direct phase-only synthesis techniques from array designs can be borrowed, and various methods have been employed in advanced reflectarray designs, for example, the intersection approach for shaped-beam designs for DBS applications (Encinar et al. 2006, 2011), the alternating projection method (APM) for a quad-beam design (Nayeri et al. 2012), and the particle swarm optimization (PSO) method for improving scanned beam performance (Nayeri et al. 2013b). Generally speaking, these approaches are able to achieve satisfactory results, but the phase synthesis process is usually complicated and computationally extensive. Good understanding and *a prior* knowledge of the desired phase shift distribution of the reflectarray are needed to improve its effectiveness.

Reflectarray Analysis Methods

Assuming that the performances of the reflectarray elements can be accurately evaluated and the desired phase shift distribution or its closest values can be realized by the chosen element design, then the whole reflectarray can be analyzed to obtain its radiation characteristics such as the radiation pattern, gain, sidelobe and cross-polarization levels, bandwidth, etc. Three reflectarray analysis methods are widely adopted, namely, the array theory method, the aperture field method, and the full-wave analysis method.

The most straightforward approach to calculate the radiation pattern of a reflectarray is to compute the direct summation of the field radiated by each element using the array theory method (Chang and Huang 1995; Huang and Pogorzelski 1998; Nayeri et al. 2013a). To simplify the calculation, both the feed and reflectarray elements are modeled by an ideal $\cos^q(\theta)$-type point source with no azimuth dependence (Rahmat-Samii et al. 1981), and q_f and q_e are the matching q-factors controlling the feed and element patterns, respectively. Being located in the far-field region of the feed, the electric filed on each element originated from the feed can be expressed as

$$E^f = \frac{\cos^{q_f}\left(\theta_{f,n}\right)}{\left|\vec{r}_n - \vec{r}_f\right|} e^{-jk\left|\vec{r}_n - \vec{r}_f\right|} \tag{4}$$

where $\theta_{f,n}$ is the spherical coordinate of the nth element in the feed coordinate system. Taking into account the element beamwidth effect, the incident field intercepted by the element is modified as

$$E^i = \cos^{q_e}\left(\theta_{e,n}\right) \cdot E^f \tag{5}$$

where $\theta_{e,n}$ is the spherical coordinate of the feed in the nth element coordinate system. Assuming that by using a proper element analysis technique, the element's amplitude and phase responses are Γ_n and φ_n, respectively, the element excitation can then be written as

$$I_n = \frac{\cos^{q_f}\left(\theta_{f,n}\right)}{\left|\vec{r}_n - \vec{r}_f\right|} e^{-jk\left|\vec{r}_n - \vec{r}_f\right|} \cos^{q_e}\left(\theta_{e,n}\right) \Gamma_n e^{j\varphi_n} \tag{6}$$

Combined with the element pattern

DOI 10.1007/978-981-4560-75-7_45-1

$$A_n = (\theta, \phi) = \cos^{q_e}(\theta) e^{jk\left(\vec{r}_n \cdot \hat{u}\right)} \tag{7}$$

the radiated field of the reflectarray can be calculated by using a direct summation of the contributions from all the elements

$$E(\theta, \phi) = \sum_{n=1}^{N} \cos^{q_e}(\theta) \cos^{q_e}\left(\theta_{e,n}\right) \Gamma_n \frac{\cos^{q_f}\left(\theta_{f,n}\right)}{\left|\vec{r}_n - \vec{r}_f\right|} e^{-jk\left(\left|\vec{r}_n - \vec{r}_f\right| - \vec{r}_n \cdot \hat{u}\right) + j\varphi_n} \tag{8}$$

Obviously, Eq. 8 produces a uniform phase wavefront in the plane perpendicular to the $\hat{u}_B$ direction if the element phase shift φ_n is designed using Eq. 3, and a broadside radiation can be obtained if $\hat{u}_B$ coincides with the normal direction of the reflectarray aperture. It is also worthwhile to point out that if an appropriate element analysis technique, for instance, the infinite-array approach, is employed to obtain the element phase shift φ_n, the mutual coupling between elements is included in this calculation.

In general, the array theory method is able to yield a good prediction of some important radiation characteristics such as beam direction, main beamwidth, and general pattern shape of the first few sidelobes. The formulation of this approach is very simple and easy to implement. It requires little computational resources and computational time, making it suitable for integration with optimization techniques in phase synthesis applications. A 2-D inverse digital Fourier transform (IDFT) can be employed to further expedite the calculation (Huang and Encinar 2008). On the other hand, there also exist several noticeable limitations. The cross-polarization of the reflectarray cannot be obtained in this calculation, because the polarizations of the feed and elements are not accounted for in the simplified $\cos^q(\theta)$-type models. The effects of finite ground plane and edge diffraction are not taken into account, and the back radiations of the feed and reflectarray elements are ignored. Moreover, a careful loss analysis is required to improve the accuracy of gain calculation.

Based on the equivalence principle, the aperture field method has been developed to calculate the radiation pattern of a reflectarray from the tangential component of the reflected electric field on the reflectarray aperture (Pozar et al. 1997; Huang and Encinar 2008; Nayeri et al. 2013a). First, the incident field on the reflectarray aperture is obtained while considering the polarization of the feed. The radiated fields of x- and y-polarized feeds are given by Eqs. 9 and 10 (Rahmat-Samii 1988), respectively,

$$\vec{E}_x^f\left(\theta_f, \phi_f\right) = A_0 \left[\hat{\theta}_f C_E\left(\theta_f\right) \cos\phi_f - \hat{\phi}_f C_H\left(\theta_f\right) \sin\phi_f\right] \frac{e^{-jkr_f}}{r_f} \tag{9}$$

$$\vec{E}_y^f\left(\theta_f, \phi_f\right) = A_0 \left[\hat{\theta}_f C_E\left(\theta_f\right) \sin\phi_f + \hat{\phi}_f C_H\left(\theta_f\right) \cos\phi_f\right] \frac{e^{-jkr_f}}{r_f} \tag{10}$$

where A_0 is a complex constant and the subscript f denotes the feed coordinates. C_E and C_H are the E- and H-plane radiation patterns of the feed, respectively. They are typically modeled as $\cos^q(\theta)$-type functions as well

$$C_E\left(\theta_f\right) = \cos^{q_E}\left(\theta_f\right) \tag{11}$$

$$C_H\left(\theta_f\right) = \cos^{q_H}\left(\theta_f\right) \tag{12}$$

where q_E and q_H are the matching q-factors determined from the simulated or measured pattern data of the feed. Note that the above feed model could be further expanded to include cross-polarization fields.

DOI 10.1007/978-981-4560-75-7_45-1

Using the coordinate transformation (Rahmat-Samii 1979), the x- and y-components of the incident electric field on the reflectarray aperture can then be computed from these equations. Alternatively, the incident fields can be directly obtained from the full-wave simulation or measurement data of the feed. In this case, the near-field effect of the feed radiation may also be considered and the accuracy of reflectarray analysis may be improved.

Using the infinite-array approach for the element analysis, the generalized scattering matrix $[\boldsymbol{\Gamma}]$ relating the Cartesian components of the incident and scattered fields of the nth element in a periodic environment can be obtained

$$\begin{bmatrix} E^s_{x,n} \\ E^s_{y,n} \end{bmatrix} = \begin{bmatrix} \Gamma_{xx} & \Gamma_{xy} \\ \Gamma_{yx} & \Gamma_{yy} \end{bmatrix} \cdot \begin{bmatrix} E^i_{x,n} \\ E^i_{y,n} \end{bmatrix} \tag{13}$$

The radiated field of each element can then be readily calculated using the vector potentials (Balanis 2005), and the reflectarray pattern is achieved by summing the contributions from all the elements.

In general, the tangential electric field must be extended to an infinite plane containing the reflectarray aperture. However, it is always limited to the size of reflectarray aperture, and the field outside of its boundary is assumed to be zero. Another important approximation in this calculation is that the tangential components are assumed to be constant within each periodic cell, so the integration over the reflectarray aperture is approximated by a summation. Discontinuities at the border of each unit cell may result in erroneous radiation patterns. Only the fundamental Floquet harmonics are used in the element analysis, and the higher-order modes are ignored. It is also worthwhile to mention that to simplify the calculations, usually only the electric field is used in the computation. This corresponds to the second principle of equivalence, which implies that the reflectarray aperture is immersed in a perfect electric conductor. A more accurate computation is possible by using both tangential electric and magnetic fields on the reflectarray aperture, i.e., the first principle of equivalence, but the computational expenses also increase.

The aperture field method uses a more accurate feed model and takes into account both the co- and cross-polar components from the feed, the geometrical projection, and the elements. It allows an accurate prediction of the radiation pattern in a wider angular range as well as the cross-polarization level. The shortcomings of this approach are the significantly more complicated formulation and analysis program development. The computational time is also increased.

With the ever-increasing computational power nowadays, the full-wave analysis of the whole reflectarray also becomes possible. Some general-purpose commercial electromagnetic simulation software, such as Ansoft HFSS (HFSS 2014), CST Microwave Studio (CST 2014), FEKO (2014), etc., can be employed to design and analyze reflectarrays. They are able to provide accurate results by taking into account all approximations in reflectarray element design and mutual coupling, in addition to edge diffraction effects. Although having already been widely used in characterizing the element performances in an infinite periodic array, the applications of full-wave analysis methods are limited to small- or medium-size reflectarrays. The largest reflectarray size that can be handled by the software obviously depends on the available computational resources and the complexity of the software. Alternatively, useful information on the performance of the reflectarray can be obtained without simulating the whole structure. For instance, a good estimation of the reflectarray gain bandwidth is achieved by calculating the scattering from the center row of a large reflectarray surrounded by perfectly magnetic conductor (PMC) walls (Chaharmir et al. 2010).

Other approaches have also been developed to improve the accuracy or efficiency of the aforementioned reflectarray analysis methods. For instance, an improved technique based on the equivalent currents from a continuous plane wave spectrum and the spectral dyadic Green's function is proposed to account for the effect of finite ground plane (Zhou et al. 2011). An appropriate selection of reflectarray

DOI 10.1007/978-981-4560-75-7_45-1

analysis method must be carried out according to the requirements of reflectarray designs and the availability of computational resources.

Gain and Efficiencies of Reflectarrays

The ultimate goal of the design and analysis of a reflectarray is to obtain its important radiation characteristics, such as the radiation pattern, main beam direction, gain, aperture efficiency, sidelobe and cross-polarization levels, and bandwidth, to meet the design requirements. With the reflectarray geometry and element parameters determined, the radiation pattern of the reflectarray can be computed using the selected reflectarray analysis method, from which main beam direction, sidelobe, and cross-polarization levels can be readily extracted. Note that the radiated field of the reflectarray is usually expressed in the reflectarray coordinate system where the z axis is along the normal direction of the reflectarray aperture. A coordinate transformation to the pattern coordinate system whose z_p axis is along the main beam direction is needed to plot its far-field radiation patterns in two principal planes.

Among all characteristics, the antenna gain is of special importance. As an aperture radiator, the gain of a reflectarray antenna is defined by the classical formula

$$G = \frac{4\pi A_a}{\lambda^2}\eta_a \tag{14}$$

where A_a is the aperture area and η_a is the aperture efficiency. The aperture efficiency is a key parameter that dictates the effectiveness of a reflectarray's capability of converting transmitted or received power. It is usually expressed by the product of several efficiency factors. Some of them share similar definitions as their counterparts in a conventional reflector antenna, while others are unique to reflectarrays. And their calculations may be simplified due to the planar array structure of a reflectarray. Good understanding of these efficiency factors can greatly facilitate the design and optimization of a reflectarray's radiation performance.

The taper efficiency (or illumination efficiency) is a measure of the uniformity of the amplitude distribution I on the reflectarray aperture. Its mathematical expression is given by (Yu et al. 2010b)

$$\eta_t = \frac{1}{A_a}\frac{\left|\int_A I dA\right|^2}{\int_A |I|^2 dA} \tag{15}$$

where A denotes the reflectarray aperture. Specifically, to simplify the calculations in reflectarrays, the integrals can be replaced by summations

$$\eta_t = \frac{1}{A_a}\frac{\left(\sum_{n=1}^{N}|I_n|\right)^2}{\sum_{n=1}^{N}|I_n|^2} \tag{16}$$

where I_n is the element excitation given in Eq. 6.

For a reflectarray illuminated by a simple feed, its amplitude distribution usually has a peak in the central area and monotonically decays towards the rim, if the element loss is ignored. The edge taper (ET) is then defined as the ratio of the element amplitude at the rim to the maximum value over the reflectarray aperture. It is well known that as the edge taper decreases, the taper efficiency decreases, and the radiation pattern tends to exhibit a slightly broadened main beam with lowered sidelobe levels. It is worthwhile to note that on the contrary to reflectors, where the illumination taper is solely determined by the feed pattern and spatial path lengths, the amplitude distribution of a reflectarray also depends on the

radiation pattern of the elements. As implied in Eq. 5, the intercepted power by the element decreases as the incident field from the feed shifts away from its broadside. Therefore, the edge taper is further attenuated by the element pattern, which may negatively affect the taper efficiency, especially for reflectarrays with F/D smaller than 0.5. The amplitude loss of the elements adds variation to the amplitude distribution as well, but it is usually much less significant compared to the feed illumination.

The spillover efficiency defines the percentage of the radiated power from the feed that is intercepted by the reflectarray aperture. Its classical formula is

$$\eta_s \frac{\int_\sigma \vec{P}(\vec{r}) \cdot d\vec{S}}{\int_\Sigma \vec{P}(\vec{r}) \cdot d\vec{S}} \tag{17}$$

where $\vec{P}(\vec{r})$ is the Poynting vector from the feed, Σ denotes the entire spherical surface centered at the feed, and σ denotes the solid angle subtended to the reflectarray aperture. The direct approach to calculate the spillover efficiency is to perform the integrals over the specified areas analytically or numerically. In practice, however, it is not straightforward to determine the solid angle for σ, especially for an offset reflectarray with a square aperture. Alternatively, the integral in the numerator is performed over the reflectarray aperture

$$\eta_s = \frac{\int_A \vec{P}(\vec{r}) \cdot d\vec{S}}{\int_\Sigma \vec{P}(\vec{r}) \cdot d\vec{S}} \tag{18}$$

which is calculated in a coordinate system that accommodates the shape of the reflectarray aperture and the position of the feed (Yu et al. 2010b). For a center-fed reflectarray with circular aperture illuminated by a simplified $\cos^q(\theta)$-type feed, the spillover efficiency in a closed form is given by (Huang and Encinar 2008)

$$\eta_s = 1 - \cos^{2q_f+1}(\psi_0/2) \tag{19}$$

where ψ_0 is the subtended angle from the feed to the reflectarray rim.

Similar to reflectors, the spillover power from the feed decreases and the spillover efficiency increases as the edge taper decreases. The product of the taper efficiency and the spillover efficiency is the main factor that dictates the aperture efficiency. The spillover efficiency, taper efficiency, and their product versus the q-factor of the feed for a representative reflectarray are plotted in Fig. 13. An optimal aperture efficiency can be achieved if the feed provides an edge taper around -10 dB.

The element loss efficiency accounts for the dielectric and conductor loss in reflectarray elements. In the case of reflectors, only curved metallic surfaces are used where conductor loss is negligible at microwave frequencies. In reflectarrays, however, the dielectric loss is inherent due to the existence of lossy dielectric substrate and the resonance nature of the element design, as shown in Fig. 6b. Moreover, the finite conductivity of nonideal metallic materials increases the conductor loss (An et al. 2014a), and it becomes more pronounced at terahertz (THz) and optical frequencies (Yang et al. 2012). Both the dielectric and conductor loss are included in the element amplitude response, and the element loss efficiency can be readily quantified as

DOI 10.1007/978-981-4560-75-7_45-1

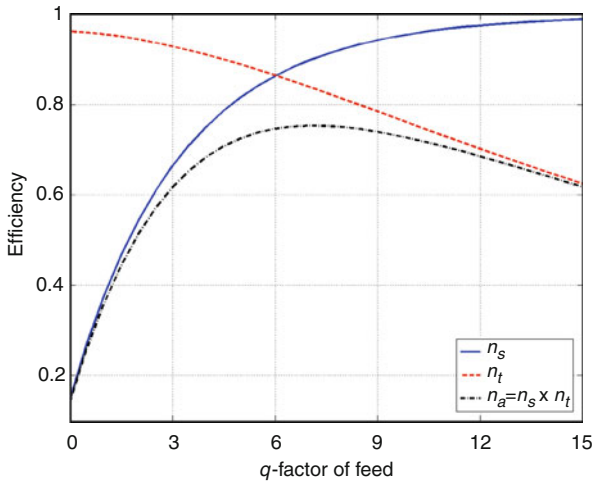

Fig. 13 Reflectarray efficiencies versus the q-factor of the feed

$$\eta_l = \frac{\sum_{n=1}^{N} |I_n|^2}{\sum_{n=1}^{N} |I_n/\Gamma_n|^2} \tag{20}$$

where Γ_n is the amplitude response of the nth element. Although Γ_n is present in the element excitation given in Eq. 6 and included in the calculation of taper efficiency in Eq. 16, it is canceled out in the numerator and denominator, especially when Γ_n is the same for all the elements. Hence, it is necessary to incorporate Eq. 20 in the product of efficiency factors and take into account the dielectric and conductor loss of elements.

The phase efficiency is a measure of the deviation from the uniform phase distribution (or the specifically shaped phase front) on the reflectarray aperture. The phase errors cause additional gain loss and degraded radiation pattern, which can be attributed to several factors. First and most importantly, it stems from the design and analysis of reflectarray elements. An infinite-array structure is usually assumed in the element analysis. The actual phase realized by each element in the actual reflectarray configuration may be different, especially where an abrupt phase variation occurs and adjacent elements have very different configurations. The simple element design process only based on the phase curve for normal incidence also introduces phase errors if the angle of incidence on the elements varies considerably. And for some element designs, the achievable phase shift swing is less than 360°; an approximate phase shift closest to its desired value is selected, leading to phase errors. Although it may be somehow mitigated by adopting more sophisticated element design and analysis technique, the phase error in the element phase response is usually inevitable in a practical reflectarray design. Secondly, the actual radiated field from the feed may deviate from the spherical wavefront, which is an important assumption commonly used in reflectarray element analysis and phase shift design. It can be circumvented by incorporating the actual incident field from the simulation or measurement data of the feed. Thirdly, the phase center of the feed wanders with changes in frequency. An axial defocusing effect is expected especially in broadband and multiband designs. This issue can be addressed by carefully choosing the feed or tuning the element phase responses at different frequencies to compensate for the movement of the phase center of the feed. Lastly, the fabrication error leads to deviation from desired phases. It is similar to the phase errors caused by the surface roughness in reflectors. However, the lithographic etching technique in reflectarray fabrication usually yields much better accuracy compared to those for reflectors. The phase deviation due to

DOI 10.1007/978-981-4560-75-7_45-1

fabrication error at Ka-band or lower frequencies is almost negligible and may be further alleviated if the element phase curve is more gradual.

The polarization efficiency represents the polarization purity of the reflectarray, and for a x-polarized antenna, it can be calculated as

$$\eta_x = \frac{1}{A_a} \frac{\left(\sum_{n=1}^{N} \left|E_{x,n}^{ref}\right|\right)^2}{\sum_{n=1}^{N} \left(\left|E_{x,n}^{ref}\right|^2 + \left|E_{y,n}^{ref}\right|^2\right)} \tag{21}$$

It measures the percentage of the power that is coupled into the co-polar component of the reflectarray radiation and is mostly affected by the polarization performances of both the feed and the element performance. A low cross-polarization performance can be achieved by adopting an appropriate element design such as dipoles with variable lengths to suppress the cross terms in Eq. 13. Therefore, an offset reflectarray is able to produce superior cross-polarization performance than its reflector counterpart as a result of the polarization selectivity of its elements.

The blockage efficiency accounts for the blockage effects of the feed assembly, subreflector, and other structural components on the aperture radiation. A simple estimation is to compute the percentage of unblocked aperture area projected in the main beam direction. Just like reflectors, an offset configuration is able to eliminate the feed blockage. Moreover, with the agile phase adjustment of reflectarray elements, the main beam can be properly set in an off-broadside direction to avoid the feed assembly, even for a center-fed system.

The return loss efficiency of the feed is mostly neglected in the computation of aperture efficiency and gain of a reflectarray. It is acceptable since the horn antenna is widely used as the feed and its reflection coefficient is usually below −20 dB. For reflectarrays with no feed blockage, the interference of the reflected wave from its aperture is also negligible.

In summary, various efficiency factors must be carefully evaluated. The aperture efficiency of a reflectarray can thus be computed by multiplying them altogether and its gain can be obtained using Eq. 14.

With the gain performance acquired at the frequency band of interest, the gain bandwidth of the reflectarray is simply defined as the frequency range of allowed gain drop from its designed value at the operating frequency. In practice, a gain drop of 1 dB or 3 dB is commonly used. The 1-dB gain bandwidth usually ranges from 3 % to 8 %, depending on the element design and the electrical size of the reflectarray aperture, and 10 % bandwidth, up to over 20 %, is possible in some broadband designs. The port impedance matching is usually very good if a horn feed is employed. Hence, the impedance bandwidth is not considered in reflectarrays.

An Example of Reflectarray Design

As an example, an offset single-beam reflectarray antenna operating at 32.5 GHz is designed, as shown in Fig. 14.

The reflectarray aperture is circular with a diameter of 516 mm. A moderate F/D value is selected to balance the feed illumination and the overall volume of the antenna. An offset configuration is utilized to mitigate the feed blockage effect. The x-polarized feed is located at 400 mm above the aperture, tilted toward the center of the aperture with a feed offset angle of 15°. By matching the $\cos^q(\theta)$-type function to the −10 dB beamwidth of the feed pattern, q_f is determined to be 5.5. In order to further reduce the blocked area, the main beam is tilted 15° as well, opposite to the feed offset direction.

DOI 10.1007/978-981-4560-75-7_45-1

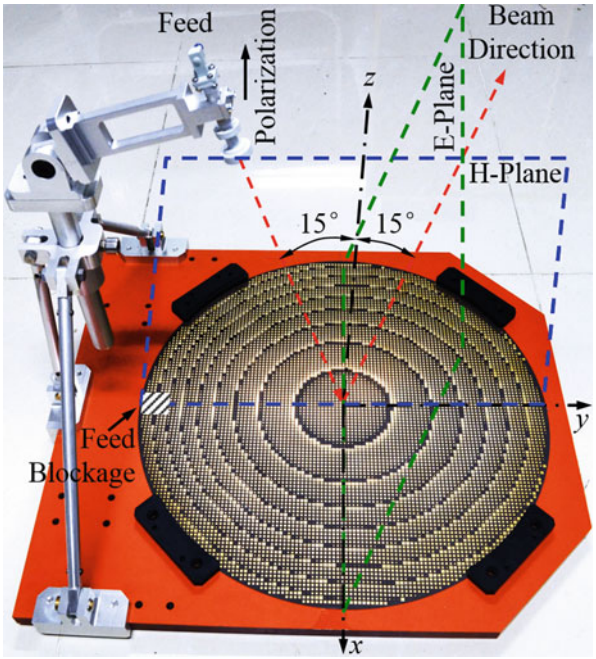

Fig. 14 Prototype of an offset reflectarray antenna operating at 32.5 GHz

Square microstrip patches with variable sizes are employed and arranged in a square lattice with element spacing of 4.6 mm. The thickness of the grounded substrate is 0.51 mm, with the dielectric constant ε_r of 2.55 and the loss tangent tanδ of 0.0019. The element is analyzed using the infinite-array approach. Its phase shift and amplitude response for the normal incidence are shown in Fig. 6. Based on the ray tracing method, the desired phase shift of each element φ_n can be obtained using Eq. 3 and plotted in Fig. 15a, where the phase shift is limited to one 360° cycle and the constant reference phase $\Delta\varphi_0$ is set to be zero. Because the achievable phase shift swing is less than 360°, the desired phase shift beyond this range is approximated by its closest value. The maximum angle of incidence on the far-end element is 42.4°; therefore, several phase curves for different incident angles are obtained and the element sizes are determined accordingly. The amplitude of the element excitation given in Eq. 6 is plotted in Fig. 15b. The edge taper is about −10.5 dB, well within the realm for optimized aperture efficiency. Note that a small area blocked by the feed is still present, although both the feed and main beam are tilted. However, its impact on the gain and pattern of the reflectarray is expected to be negligible because the blocked area is relatively small and the elements within the shadowed area are well under-illuminated.

The radiated field of the reflectarray is then computed using Eq. 8, and its calculated far-field radiation patterns in the pattern coordinate system are plotted in Fig. 16. The feed blockage effect is approximated by excluding those elements located within the shadowed area from the summation in Eq. 8. The reflectarray is also fabricated and measured in a compact-range anechoic chamber. The measured patterns are plotted and presented in Fig. 16 as well for comparison. It is observed that the main beam direction is well aligned in the designed direction. The main beam and first few sidelobes agree well, except the measured sidelobe levels are higher due to phase errors in element designs and system assembly. The array theory method predicts an overall pattern shape with lower sidelobe levels. The measured cross-polarization level is comparable to that of its reflector counterpart because the chosen elements are insensitive to polarizations.

The calculated and measured gains are 43.4 dBi and 43.0 dBi, respectively, which correspond to aperture efficiency of 70.9 % and 64.7 % using Eq. 14. It is worthwhile to point out that due to the tilted main beam, its effective aperture area is reduced by the amount of cos(θ_B). Taking into account this

DOI 10.1007/978-981-4560-75-7_45-1

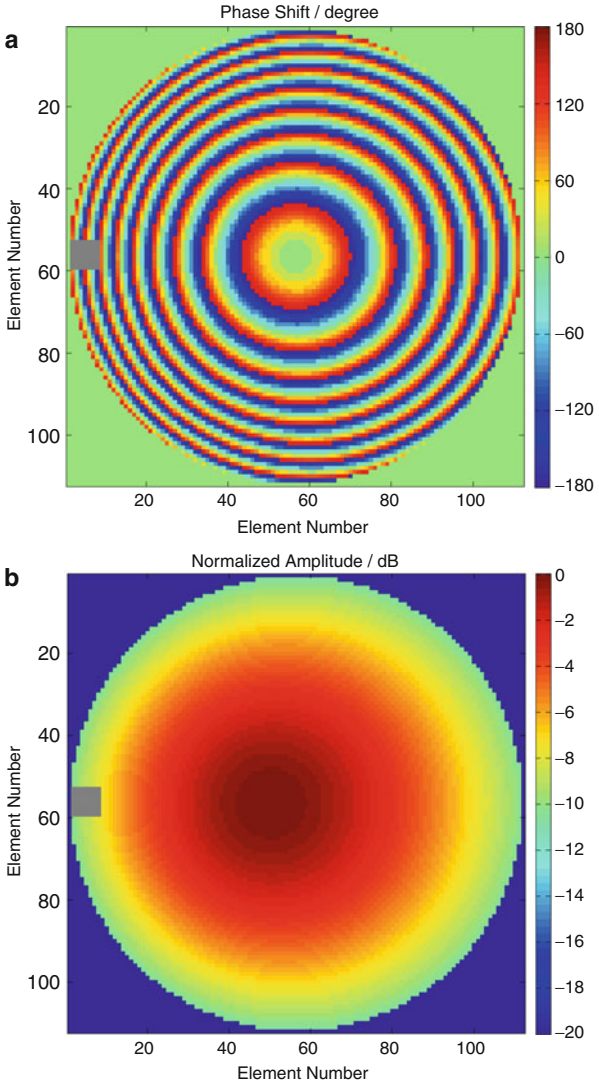

Fig. 15 (**a**) Desired phase shift distribution and (**b**) amplitude distribution of the reflectarray. The shadowed area represents the feed blockage

reduction, the calculated and measure aperture efficiency are modified to be 73.4 % and 67.0 %, respectively. This revision agrees with the convention in offset reflectors where the area of the projected aperture, instead of its physical aperture, is commonly used as the basis for aperture efficiency calculation. The simulation and measurement results are in good agreement. Although the achieved aperture efficiency is slightly suboptimal compared to that of reflectors, this example successfully demonstrates the superior radiation performance of a reflectarray as an efficient high-gain antenna.

The measured gain performance in the frequency band of interest is shown in Fig. 17. The ripple in the gain curve is mainly due to the imperfect frequency response of the anechoic chamber. The range of gain over 42 dBi is from 31.9 to 33.6 GHz, corresponding to a 1-dB gain bandwidth of 5.2 %. The moderate bandwidth performance is within expectation, given the simple element design and the large electrical size of the reflectarray. Improved bandwidth can be achieved if broadband techniques are adopted in the reflectarray design.

Latest Developments and Applications

With the development of numerical analysis tools, the integrated circuits and solid-state tuning devices, new materials, and fabrication technologies, a variety of novel reflectarrays have been investigated to satisfy the ever-increasing demands in satellite communications, spaceborne applications, defense and military areas, etc. More sophisticated elements and systems have been designed to fully exploit the feasibility and versatility provided by reflectarrays. Some latest developments and applications are briefly introduced in this section.

Broadband and Multiband Techniques

The most critical limitation in reflectarray technology is its limited bandwidth. It is attributed to two main factors. The first is the element bandwidth due to the intrinsic narrowband nature of reflectarray elements as previously discussed. It plays a more crucial role in the bandwidth performance of small- and medium-

DOI 10.1007/978-981-4560-75-7_45-1

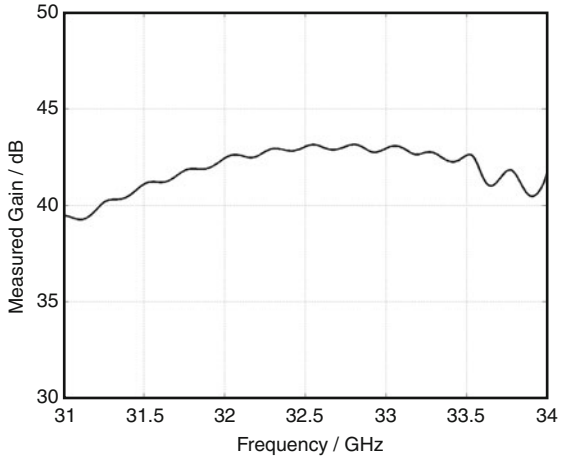

Fig. 17 Measured gain performance in the frequency band of interest

size reflectarrays with moderate or large F/D. The second is the differential spatial phase delay due to the different path lengths from the feed to the reflectarray plane where the desired phase front is located. It is obviously seen in Eq. 3 that the desired phase shift to collimate a beam is proportional to frequency. The reflectarray elements can no longer effectively compensate for the spatial phase delays if the realized element phase shift does not adapt to the change in frequency, leading to considerable phase errors. Its adverse impact on the bandwidth is more pronounced in large reflectarrays as well as those with small F/D where the variation in path lengths is large.

Multi-resonant structures are widely used to improve the bandwidth performance of reflectarray elements. One approach is to stack two or more layers of microstrip patches with variable sizes (Encinar 2001; Encinar and Zornoza 2003). Compared to the conventional single-layer patch elements with variable sizes, the additional layer introduces a second resonance to the structure, resulting in a smoother phase curve with more gradual slope. The achievable phase shift swing is extended beyond a full 360° range, and the element phase responses at different frequencies are considerably improved. A significant drawback of this design is its increased complexity in element structure, leading to a more complex and expensive fabrication process. The sizes of the elements on both layers change simultaneously, which also limits the flexibility in reflectarray designs.

Recently, more efforts have been devoted to develop single-layer multi-resonant elements. It is usually obtained by combining two or more simple structures with appropriate shapes, patches, rings, and crossed dipoles, for instance, in one element design. Various elements, such as double square rings (Chaharmir et al. 2009), double cross loops (Chaharmir et al. 2006), triple rectangular loops (Mohammadirad et al. 2012), the phoenix cell (Moustafa et al. 2011), etc., have been introduced in the literature. Alternatively, a secondary resonant structure such as a slot can be embedded in a simple patch element (Cadoret et al. 2005; De Vita et al. 2007) to obtain extra freedom in phase controlling.

Generally speaking, the multi-resonant elements can significantly broaden the element bandwidth, and a 1-dB gain bandwidth of more than 10 %, up to over 20 % (Chaharmir et al. 2009; Mohammadirad et al. 2012), may be achieved in a reflectarray design. The complex structures and controlling geometrical parameters in these elements considerably increase the complexity in element design and analysis as well as reflectarray fabrication. It is worthwhile to note that other design techniques such as a thick substrate with low dielectric constant, subwavelength element spacing (Pozar 2007; Nayeri et al. 2010, 2011), and optimization of feed position (Mohammadirad et al. 2012) are often adopted at the same time to further improve the element bandwidth.

DOI 10.1007/978-981-4560-75-7_45-1

To overcome the second issue in bandwidth limitation, the differential spatial phase delay, the desired phase shift, and the element phase response within the entire frequency band, rather than at a single operating frequency, need to be properly designed and analyzed. As observed in Eq. 3, if a frequency-dependent phase shift of the element described by

$$\frac{\varphi_n(f)}{f} = \frac{\varphi_n(f_0)}{f_0} \tag{22}$$

can be realized, where f_0 and f refer to the center and off-center frequencies, respectively, the same phase transformation can be achieved by the reflectarray within the entire frequency band, significantly improving its bandwidth performance. An ideal solution to compensate for frequency dispersion is to use the true-time delay element (Carassco et al. 2008). An aperture-coupled patch element is utilized and the length L of a U-shaped true-time delay line is adjusted to produce a phase shift of approximately $-2\beta L$, where β is the propagation constant at frequency f. A 1.5-dB gain bandwidth of more than 26 % can be achieved even for large reflectarrays. The only drawbacks are higher ohmic loss due to the long line covering $3 \times 360^\circ$ phase range and some distortion of the element phase response at extreme frequencies.

By using an appropriate phase optimization method, multi-resonant elements can be properly designed to alleviate the adverse impact of frequency dispersion as well (Encinar and Zornoza 2003; Chaharmir et al. 2010). It is achieved by taking into account the overall phase error between the desired and realized phase shifts of the element at the center frequency and two extreme frequencies at the same time. The flexibility in multi-resonant element configurations allows a number of elements to provide the same phase shift at the center frequency but different frequency dispersion characteristics. An optimization routine is then employed to minimize it by selecting the most suitable one from a pool of elements. A measured 1-dB gain bandwidth of 12 % is reported for a 1.2-m Ku-band reflectarray (Chaharmir et al. 2010), which successfully validates the effectiveness of the optimization method.

More recently, a novel phase synthesis approach for broadband reflectarray designs is proposed (Mao et al. 2012). The impact of selecting the constant reference phase $\Delta\varphi_0$ in Eq. 3, which has been overlooked since the inception of reflectarrays, is taken into account, and the sum of the phase errors of all the elements at two frequencies is minimized by an optimization algorithm. This phase synthesis process can be graphically described in the phase plane as in Fig. 18. By adjusting the constant reference phases at two frequencies independently, the straight line that represents the desired phase shifts at those frequencies is shifted in the phase plane to have a better matching with the achievable phase shifts provided by the elements, effectively reducing the overall phase errors of the reflectarray. A 1.5-dB gain bandwidth of 16.7 % is achieved by a reflectarray with simple square loop elements. Note that this approach can also be applied to reflectarrays with multi-resonant elements, whose achievable phase shifts can be optimized simultaneously to further improve the bandwidth performance.

An alternative approach to reduce the variation of path lengths in reflectarrays is the multifacet design. The reflectarray configuration is made of several small planar reflectarray panels arranged to approximate a parabolic surface (Huang and Encinar 2008). Several designs from simple one-dimensional arrangements to more complex circumferential structures have been reported. The complexity in fabrication and assembly as well as the deployment structure, however, is significantly increased. Hence, this technique is usually limited to some specific applications.

Several techniques in broadband reflectarray designs can be utilized to obtain multiband performances as well. Two sets of elements can be arranged on two stacked layers, and each one of them corresponds to one operating band (Encinar 1996; Han et al. 2004, Huang and Encinar 2008). The element configurations must be properly designed and arranged in order to minimize the mutual interference and blockage between the two layers of elements. Single-layer multiband designs have also been intensively

DOI 10.1007/978-981-4560-75-7_45-1

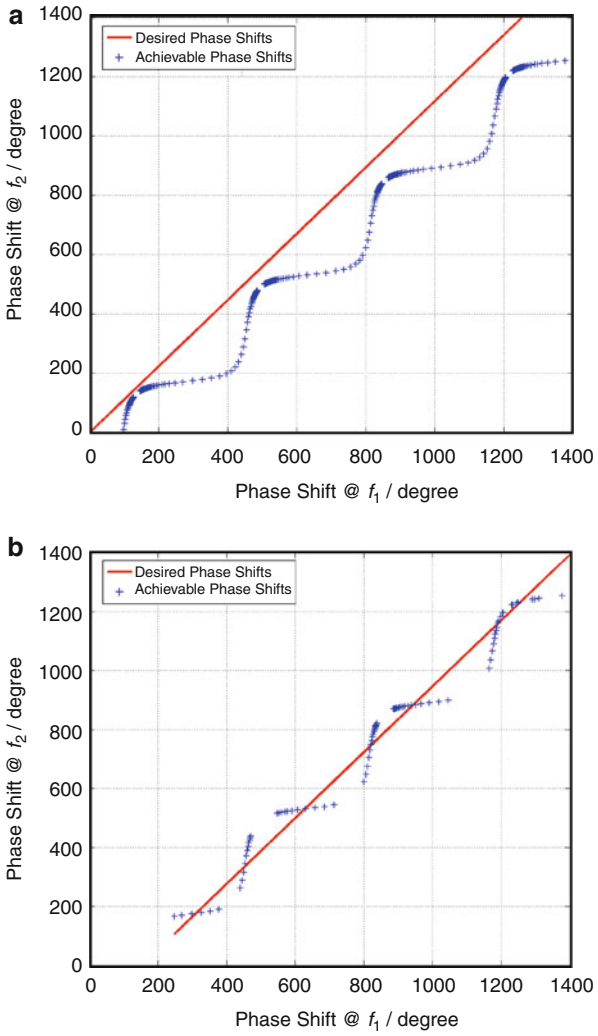

Fig. 18 Graphical illustration of the phase synthesis approach: (**a**) before and (**b**) after the optimization of the reference phases

investigated, which successfully circumvent the complex structure and blockage effects in multi-layer designs. For two widely separated frequencies, two sets of simple elements of appropriate forms are usually alternatively spaced without physically interfering with each other (Huang and Encinar 2008). Each set can be independently designed at one frequency with the presence of the other set of elements in the element analysis. Triple-band designs are also feasible (Yang et al. 2008; Yu et al. 2010a), but it becomes more challenging to choose the elements that are able to fit in the limited space. For two closely separated frequencies, multi-resonant elements such as a concentric dual split-loop (Smith et al. 2013) and a patch with embedded slots (Malfajani and Atlasbaf 2014) can be employed, with each of its substructure corresponding to one resonant frequency. Because the phase shifts at both frequencies are realized by the same element, the realized phase shift and amplitude loss of the element at one frequency may be interfered by the change in phase controlling parameters at the other frequency. A thorough element analysis is thus required to minimize the phase errors caused by this interference (Smith et al. 2013). The main drawback of single-layer multiband designs is the lack of flexibility in selecting element configuration, element spacing, and the thickness of substrate, which thus may not be optimized for all the elements.

DOI 10.1007/978-981-4560-75-7_45-1

Especially, the phase synthesis approach (Mao et al. 2012) is well suitable for dual-band designs. It inherently provides a dual-frequency element response. Moreover, in a single-layer multiband reflectarray, simple elements such as crossed dipoles and single loops are usually chosen in order to avoid physical interference between elements. Each set of elements typically exhibits narrow bandwidth due to its limited element performance. With no limitation on the selection of elements, this approach can be applied separately to optimize the bandwidth performance of each set of simple elements so that a broadband multiband reflectarray design becomes feasible.

Reconfigurable Reflectarrays

Beam scanning is a desired feature in many applications such as satellite communications, radar, remote sensing, etc. The most straightforward way is to mechanically rotate a fixed beam reflectarray as in reflectors. Although being low cost and with no loss in radiation performance, it suffers from the low beam scanning speed, which potentially limits its applicability in advanced applications. The vibration due to its mechanical rotation and the maintenance requirement may also adversely affect its reliability.

Owing to the independent phase adjustability of reflectarray elements as in phased arrays, electronic beam scanning becomes feasible (Shaker et al. 2014; Hum and Perruisseau-Carrier 2014). Especially, in the past 10 years or so, a lot of efforts have been devoted to the developments of a variety of reconfigurable reflectarrays. These designs can potentially provide exceptional radiation performance of high efficiency and fast beam scanning with low loss, low power consumption, and low cost. In addition, agile radiation characteristics such as shaped beam for coverage modification and anti-interference, multi-beam for multiple target detection, and dynamic beamwidth control can be achieved.

According to the adopted phase adjustment mechanism, reconfigurable reflectarrays can be categorized into three types. The most intensively investigated one is the electronically reconfigurable reflectarrays. It is typically accomplished by integrating solid-state tuning devices such as PIN diode, varactor diode, and RF MEMS switch into the element design (Hum et al. 2007; Perruisseau-Carrier and Skrivervik 2008; Rajagopalan et al. 2008; Sorrentino et al. 2009; Kamoda et al. 2011; Carassco et al. 2012). Various element configurations such as patches, dipoles, loops, and aperture-coupled elements have been studied, where the tuning devices can be integrated in the microstrip radiators, the embedded coupling slots, or the phase lines. The tuning devices vary in terms of loss, cost, speed, power consumption, power handling, mounting and biasing complexity, and technology readiness (Sorrentino et al. 2009). And the element performance also varies in terms of the achievable phase range, the number of phase states (or the number of bits), loss, polarization, etc. Generally speaking, these designs can achieve very fast beam scanning capability and reliable performance. Monolithic fabrication of the whole reflectarray along with the tuning devices and biasing network is also feasible (Perruisseau-Carrier and Skrivervik 2008). It is worthwhile to mention that a crucial issue for the element with PIN diodes or RF MEMS switches, which are controlled digitally, is the achievable number of phase states. It is shown that a simple 1-bit design typically causes over 3 dB gain loss due to quantization errors, while an average gain reduction of 0.2 dB with better beam pointing accuracy can be obtained for a 3-bit design (Wu et al. 2008). Particular attention is also required to properly design the biasing network, which may become overwhelming for an element design with a large number of tuning devices. A trade-off between the reflectarray performance and the complexity and cost of the system must be made according to the design requirements.

An alternative approach to design electronically reconfigurable reflectarrays is to use tunable materials such as liquid crystals (Hu et al. 2008; Gaebler et al. 2009), photo-induced plasma (Chaharmir et al. 2006), and ferroelectric materials (Romanofsky 2007) as the substrate or radiating elements. Under different biasing voltage or illumination intensity, the material properties such as permittivity, permeability, and conductivity change, resulting in a corresponding change of element phase. These designs are typically able to provide analog phase variation. However, it usually takes some time for the material to change its

DOI 10.1007/978-981-4560-75-7_45-1

properties so the respond speed is also relatively slow. More critically, the considerable loss in these materials may limit its wide application.

The phase reconfigurability may be obtained by mechanical methods as well. Different than the conventional mechanical rotation in reflectors, miniaturized actuators or motors are integrated into each element, so that the element phase is individually adjusted to produce the desired phase front (Gianvittorio and Rahmat-Samii 2006; Fusco 2005; Phillion and Okoniewski 2008; Cabria et al. 2009). Other methods such as a fluidic loading mechanism (Long and Huff 2011) and a three-state beam switching design (Chaharmir et al. 2003b) have also been developed. The typical loss and cost in tuning devices and tunable materials can be avoided, but the respond speed is the slowest among the three types of reconfigurable reflectarrays.

Some novel reconfigurable reflectarray designs with more flexibility have also been proposed in literature. Active amplifiers are incorporated in reflectarray elements, so the incident signal on each element can be amplified before being retransmitted (Bialkowski et al. 2002; Kishor and Hum 2012). Reconfigurable elements with capabilities of operating at variable frequencies (Rodrigo et al. 2013) and variable polarizations (Perruisseau-Carrier 2010) are also investigated. These designs further demonstrate the powerful flexibility that can be accomplished by the reflectarray technology.

Novel Applications of Reflectarrays

As a hybrid of reflector and array antennas, the reflectarray exhibits numerous favorable features and exceptional flexibility and versatility, making it suitable for a variety of advanced applications. With the latest developments in reflectarray technology, better designs in terms of radiation performance or fabrication complexity and cost may be achieved for some existing applications, while some previously unimagined scenarios now become feasible.

A large reflectarray aperture can be divided into small segments and assembled on site later, making fabrication, packaging, and shipment more convenient and keeping the cost low. In addition, its planar, low-profile, and light-weighted structure makes it more suitable for spaceborne applications. Compared to the conventional doubly curved reflectors, the planar structure of reflectarrays requires a much simpler and reliable folding mechanism to achieve a large-aperture deployable antenna with satisfactory surface accuracy. An inflatable reflectarray with elements printed on a large, flat, thin membrane can even further reduce its mass and stowing volume (Huang and Encinar 2008).

Specifically, reflectarrays with shaped beams have great potentials in direct broadcast satellite (DBS) applications (Encinar et al. 2006, 2011; Tienda et al. 2013). With various phase synthesis or optimization methods, complex phase shift distributions can be designed and precisely achieved, thus producing very accurate shaped patterns. Dual-linearly polarized elements can provide independent phase shifts for each polarization to obtain dual coverage with a single reflectarray. On the contrary to the difficulties in fabricating shaped reflectors with stringent accuracy, the fabrication process of shaped-beam reflectarrays is the same as simple single-beam reflectarrays without increasing the complexity or cost in fabrication.

The solar panels and high-gain antennas are usually the major components on a satellite platform with largest apertures. In order to reduce the volume, mass, cost, and complexity of a satellite, it is desirable to integrate them into one. The advent of planar reflectarray technology makes this integration feasible. By directly printing reflectarray elements with small footprint on solar cells (Huang and Zawadzki 2000; Dreyer et al. 2014; An et al. 2014b), the solar panels provide the required large aperture for high-gain antennas as well as solar energy harvesting for the satellite. It even becomes possible to install a high-gain antenna on a small satellite, which is previously prohibited due to the limited payload space and mass on this type of satellite.

The flexibility in element designs allows a reflectarray to provide independent phase shift distributions at different frequencies for different polarizations using the same aperture. It can effectively separate the

DOI 10.1007/978-981-4560-75-7_45-1

main beams and feeds, making the arrangement of a reflectarray system more convenient. The element phases can be optimized to produce multiple independent high-gain beams at the same time when being illuminated by a single feed (Nayeri et al. 2012). This capability makes it suitable for multiple target detection. More interestingly, this technique shows exceptional prospect in spatial power distributing/combining (Bialkowski and Song 2002), especially at high frequencies where the loss in traditional devices becomes prohibitively large.

Reconfigurable reflectarrays are able to provide similar functionalities as in phased arrays, for instance, electronic beam scanning, agile radiation pattern, and multiple target detection. Moreover, when monolithic fabrication of reconfigurable reflectarrays becomes available, better performance can be achieved with the reflectarray technology in terms of radiation efficiency, system complexity, fabrication cost, and power consumption. Wide applications of reconfigurable reflectarrays in satellite communications, radar, military and defense areas, etc., are hence expected.

Lastly, the planar quasiperiodic structure and the accuracy in fabrication make reflectarrays more suitable at high frequencies. The research has been extended to terahertz (THz) and optical frequency range (Ginn et al. 2007; Ahmadi et al. 2010; Yang et al. 2012; Niu et al. 2012; Carassco et al. 2013; Zainud-Deen et al. 2013; Nayeri et al. 2014; Deng et al. 2014). Potential applications in THz imaging, controlled beam forming, and power distributing/combining are some of the most cutting-edge research frontiers of the reflectarray technology.

Conclusion

The reflectarray antennas exhibit exceptional performance in both radiation characteristics and mechanical structures. As a hybrid of reflector and array antennas, it performs a phase transformation to produce a desired radiation pattern by properly designing the phase shifts of an array of quasiperiodic elements. Many important aspects of the reflectarray technology have been explored and great potentials in advanced applications have been well demonstrated, thanks to the flexibility and versatility arising from independent phase adjustability of reflectarray elements. Equipped with the fundamentals of reflectarrays and instructive design and analysis procedures presented in this chapter, the readers are encouraged to explore deeper into this novel and promising research frontier and to apply the reflectarray technology in practical engineering applications.

Abstract

Terahertz technology has been receiving expanding interest in the recent years. With the help of newly invented terahertz sources, terahertz systems have been developed for various applications. One important technology for terahertz systems is the design of efficient antennas for terahertz wave transmission and receiving. Accordingly, the terahertz antenna measurement technology is of equal importance as terahertz antenna design. This chapter gives an overview of the state-of-the-art terahertz antenna design and measurement for a range of applications including the photoconductive antennas and radioastronomy/remote sensing antennas.

Keywords

Terahertz; Antenna; Antenna Measurement; Photoconductive Antenna; Horn Antenna; Reflector Antenna; Far-field; Near-field; CATR

Introduction

The terahertz (THz) band is usually defined as the frequency range between 300 GHz and 10 THz. The wavelength of a THz wave is in the range of 1,000–30 μm (Lee et al. 2006; Grade et al. 2007). In the literature, an expanded range of 0.1–10 THz (Liu et al. 2008; Hoffmann and Fülöp 2011) may also be used for the THz band. The location of the THz band on the spectral diagram is shown in Fig. 1. It is interesting to see that below the THz band, electronic technologies can be employed to generate high-power RF/microwave radiation, while above the THz band, photonic methods are efficient to produce IR/visible waves. It had been a long period before the effective THz source was invented, leaving a gap (so-called THz gap) between microwave and light wave to be bridged.

An overview of the THz-power performance of different sources around the THz gap is given by Tonouchi (2007). Microwave methods encompass Gunn diode, resonant tunnel diode, and multiplexer impact ionization avalanche transit time diode. Quantum cascade laser and lead-salt laser are grouped as photonic methods. It has been observed that the output power level of the conventional RF/microwave techniques drops sharply down to 10 μW when the operating frequency approaches 1 THz. It is also true when optical methods are applied to generate THz waves. Such an awkward situation was not changed before the advent of the first photoconductive THz source (Auston and Smith 1983; Smith et al. 1988). Various compact THz systems spring up (Zhang 2002; Cai et al. 1997) of which the THz time domain spectroscopy (THz-TDS) is particularly worth mentioning (Schmuttenmaer 2004). More details of the THz-TDS system will be discussed in subsequent sections.

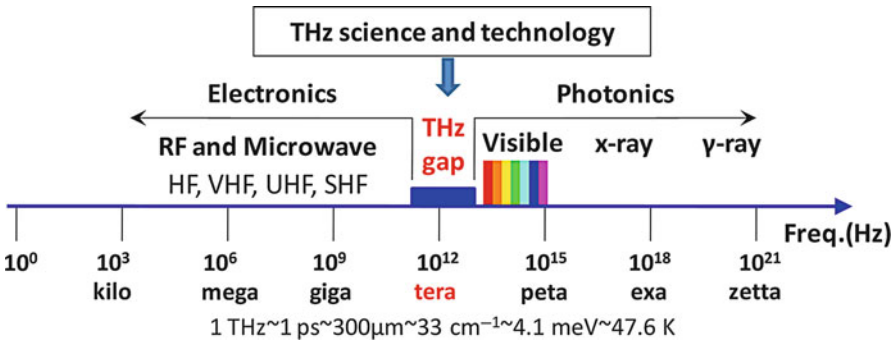

Fig. 1 Illustration of the location of the THz band. Below the THz band, electronic technologies dominate, while beyond the THz band, it is the photonic phenomenon that has to be considered

The reason that people invested huge efforts into the THz band lies in its rich scientific and practical potentials. For instance, about 98 % of the photons from the Big Bang are in the THz range (Blain et al. 2002); a variety of semiconductor phonons resonate in the THz range (Cho et al. 1999); macrobiomolecules have unique fingerprint lines in the THz range (Sushko et al. 2013); THz waves are less radioactive and do not cause ionization hazardous to human beings; THz waves provide better temporal resolution compared with RF/microwave and have larger penetration depth compared to IR/visible light, which bears the advantages in the applications of imaging and nondestructive inspection (Henry et al. 2013). These facts are self-evident in that THz is emerging as a promising field, spanning a wide range of disciplines.

As a matter of fact, an antenna is a key component for transmitting and receiving THz waves in the existing THz systems. In the conventional modality, the source and the antenna are usually considered as two parts. The distinct difference of a THz system is that the source and the radiation part may need to be considered as a whole, which is particularly true for a THz-TDS system. Nevertheless, one has to bear in mind that THz can still be generated by the conventional microwave ways such as multiplexer. Therefore, THz antennas are very versatile such as the photoconductive antenna developed in recent decades, the conventional horn antenna, and the reflector antenna. Also, terahertz antennas benefit from the development of nanotechnology (Bareiss et al. 2011) and metamaterials (Zhang et al. 2014). For photoconductive antennas, the major limitation is their power conversion efficiency, which though can be improved through many ways, while for horn and reflector antennas working in the THz band, the main technological issue is the fabrication precision.

Apart from the design and fabrication of efficient antennas, antenna measurement in the THz band is also a challenge that cannot be circumvented. For the photoconductive antenna scheme, antenna measurement is essentially the detection of THz waves. And therefore, photoconductive antennas are frequently utilized for THz antenna measurement (Zhang and Xu 2009). Details will be presented in the coming parts. It is, however, problematic for systems working on upconverting technology. There are many issues already identified associated with existing methods for antenna measurement. For instance, far-field method requires a long distance between the radiation source and antenna under test in the THz range (Balanis 2005). Such a condition is to ensure the phase uniformity in the test zone, which however brings in large signal losses, say path loss and atmospheric absorption loss. The path loss in the THz range is significant, as shown in Fig. 2. Near-field scanning method can be conducted in shielding environment, minimizing the possible issues in outdoor environment. Unfortunately, near-field method requires demanding stability of both electrical and mechanical systems. Moreover, the scanning time for

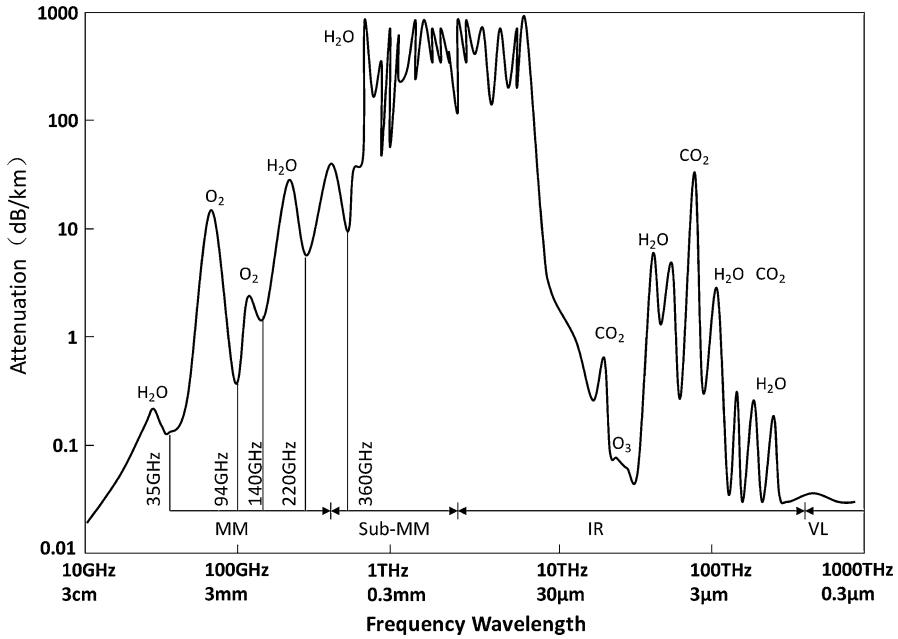

Fig. 2 Atmospheric absorption window (plotted by using the model in Klein 2000). MM stands for millimeter wave, VL denotes visible light

electrically large systems is in most cases extremely long (Tuoviizen 1993), sometimes maybe unacceptable. Recently, people have resorted to compact antenna test range (CATR) techniques aiming at providing a feasible approach to THz antenna measurement (Liu et al. 2011a, b; Rieckmann et al. 1999; Hirvonen et al. 1997). A CATR system transforms the field of a feed horn to a regional plane wave or pseudoplane wave in a very short distance, normally in several or several tens of meters, mimicking the far-field method effectively. Unlike conventional far-field method, a CATR works in an anechoic chamber, providing controlled all-whether measurement conditions and eliminating large path loss and atmospheric absorption loss. Compared with near-field method, measurement using CATR can be conducted in much shorter period. Many types of CATR are currently under investigation such as trireflector CATR, holographic CATR, and so on.

In addition to the aforementioned methods, many technologies are under development to enable on-orbit measurement (Forma et al. 2009). Also, precision measurement techniques have been introduced into antenna measurement to minimize the influence of noise or scattering effects (Paquay and Marti 2005; Paquay et al. 2007; Appel-Hansen 1979). Furthermore, mechanical–electrical combined method is also utilized (Dominic et al. 2009). Even more, simulation techniques are employed in combination with measurement for some cases where current technology cannot provide feasible measurement (Luis et al. 2010).

In this chapter, it is aimed to provide an overview of THz antennas and measurement. THz technology has been undergoing fast-evolving state in the past decades, when many novel types of THz antennas have been reported. The authors apologize to any contributors whose work is not included in this chapter due to limited space. The following parts are organized as follows: section "THz Antennas" introduces the fundamentals of THz antennas such as photoconductive antenna, horn antenna, and reflector antenna; section "THz Antenna Measurement" discusses different measurement technologies with four common methods (photoconductive detection method, far-field measurement, near-field measurement, and

compact antenna test range) and two infrequently used methods (defocusing method and electrical–mechanical combined method).

THz Antennas

Photoconductive Antennas

Photoconductive antennas are possibly the most used form in the THz-TDS. This method was first introduced by Auston and his colleagues in the early 1980s (Auston and Smith 1983; Smith et al. 1988). Later on, the photoconductive antennas were widely utilized in THz systems. A diagram of the THz-TDS is shown in Fig. 3. An 800 nm laser is directed to a beam splitter to divide the laser to a pump pulse and a probe pulse. The pump pulse shines on the photoconductive antenna to produce THz radiation, which is then refocused by an off-axis paraboloidal reflector. After passing through the sample, which can be biological species, semiconductor wafers, and other imaging objects, the THz wave is again refocused to the detector. The other path, the probe pulse, is delayed by a pair of delay mirrors to produce time delay to the pump pulse. Generally speaking, the laser pulse is much narrower in comparison with the THz wave, with the former on the order of femtosecond and the latter on the order of picosecond, ensuring sufficient time-resolved sampling rate.

It is clear that the photoconductive antenna is a key part of the whole system. As shown in Fig. 4a, a photoconductive antenna consists of several parts: a semiconductor substrate, two electrodes, and a bias voltage. It is well known that when a photon is incident on a semiconductor substrate, an electron may transit from the valence band to the conduction band if the bandgap E_g is smaller compared to the energy of the photon, as shown in Fig. 4b. In this way, an electron–hole pair is formed, with an electron in the conduction band and a hole in the valence band. If there is no further treatment, recombination of the newly created electron–hole pair is possible to happen. Therefore, a bias voltage is applied across the two electrodes, forming an electric field, which can efficiently separate the electron–hole pair. Therefore, an instant current takes place, producing THz radiation. In the literature, photoconductive antennas are also referred to as photoconductive switchers since the free carriers can only be generated when the photonic energy is higher than the bandgap.

It has been derived based on a dipole radiation model (Lee 2009), i.e., assuming the radiation of THz wave from a photoconductive antenna resembles the radiation field of an electric dipole, that the electric field is proportional to the second-order time derivative of the polarization (or dipole moment) within the substrate such that

DOI 10.1007/978-981-4560-75-7_47-1

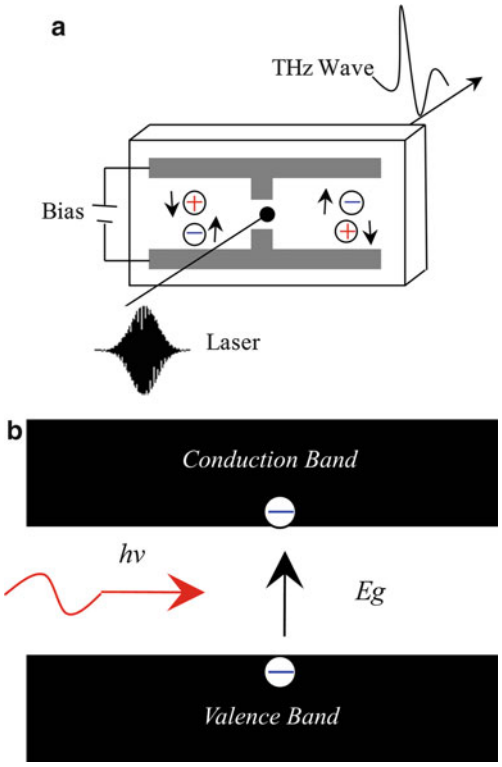

Fig. 4 The principle of a photoconductive antenna. Laser with photonic energy larger that the band gap of the substrate creates electron-holes pairs, which are accelerated by the bias voltage, and in this way producing terahertz wave

$$\vec{E}_{THz}(t) = \frac{\mu_0}{4\pi}\frac{\sin\theta}{r}\frac{d^2}{dt^2}\left[p\left(t-\frac{r}{c}\right)\right]\hat{\theta}, \tag{1}$$

where $\vec{E}_{THz}(t)$ is the time-dependent THz electric field, r is the distance from the dipole to the observation point, p is the polarization or dipole moment, and c is the light speed in the free space. It needs to be mentioned that the retarded time effect $(t-r/c)$ has to be involved when calculating the radiated field. As a matter of fact, under the condition of one-dimensional transport of the carriers, the photoconductive current can be written as

$$I_{PC} = \frac{dp(t)}{w_0 dt}, \tag{2}$$

where w_0 is the spot size of the laser beam. This immediately gives

$$\vec{E}_{THz}(t) = \frac{\mu_0 w_0}{4\pi}\frac{\sin\theta}{r}\frac{d}{dt}\left[I_{PC}\left(t-\frac{r}{c}\right)\right]\hat{\theta}, \tag{3}$$

showing that the radiated field is linearly proportional to the time derivative of photocurrent. The photocurrent can also be represented by the carrier density and carrier mobility as follows:

$$I_{PC} = e(n_e v_e + n_h v_h), \tag{4}$$

DOI 10.1007/978-981-4560-75-7_47-1

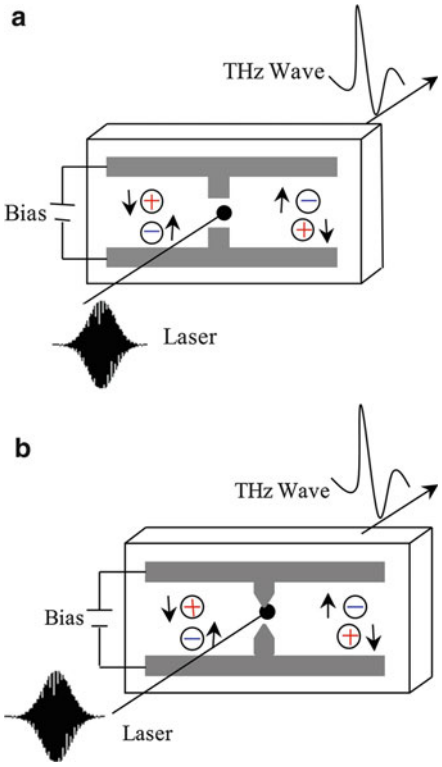

Fig. 5 Schematic diagram of (**a**) stripline and (**b**) sharp dipole structures

where n_e and n_h are the densities of electrons and holes respectively, while v_e and v_h are the average velocities of electrons and holes respectively. Normally, the carrier density under a pulse excitation can be modeled as

$$n = n_0 e^{-\frac{t}{\tau}}, \tag{5}$$

which implies that the carrier density is dependent on the carrier lifetime τ. Carrier lifetime and the velocity (also called mobility) significantly affect the radiated THz electric field. The mobility of the holes is approximately one order of magnitude lower than that of electrons. Therefore, the electrons dominate THz generation in photoconductive antennas (PCAs). A wide range of semiconductors can be employed in PCA fabrication. The main considerations include response time, carrier lifetime, and so forth. Unlike conventional microstrip antennas, where only the macroscopic dielectric property and loss tangent are considered, the design of PCAs needs to consider the microscopic property of semiconductors.

Of equal importance, the structure of PCAs is intensively investigated to create efficient THz radiation. Indeed, since the mobility of electrons is higher than that of holes, in a stripline structure, the laser spot is normally placed intentionally closer to the anode, shown in Fig. 5a. The distance between two electrodes is several tens of micrometers. It has been found that stripline structure produces narrower pulse than dipole structure (Fig. 4) under the condition of the same parameters for both structures. Subsequently, dipole structure has narrower bandwidth compared to stripline structure. However, dipole structure can produce higher radiation power under the same laser illumination and bias voltage. In general, the THz generation efficiency is very low, less than 0.01 %. Various structures have been investigated to enhance the efficiency, for instance, by sharpening the ends of the dipole, as shown in Fig. 5b. It has been reported that an average THz radiation power of 2–3 μW from the structure has been obtained under a 60-V bias voltage and a 20-mW optical excitation with a Ti:sapphire femtosecond oscillator (Cai et al. 1997).

DOI 10.1007/978-981-4560-75-7_47-1

Fig. 6 The geometry of photoconductive antennas common dipole and sharp dipole

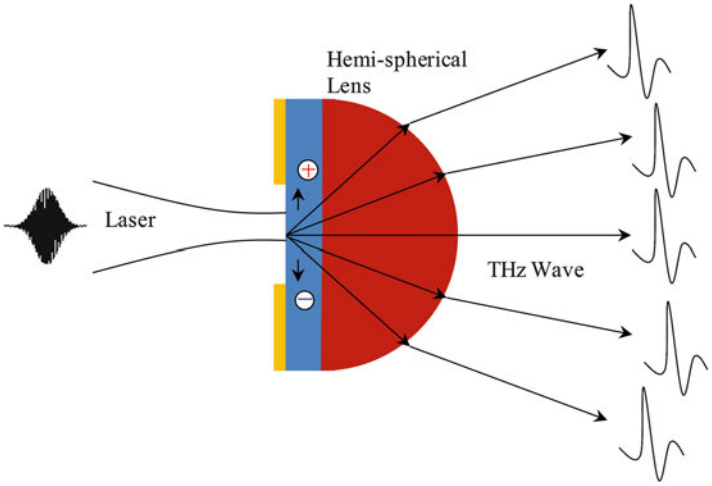

Fig. 7 Illustration of lens structure of a photoconductive antenna. With a hemi-spherical lens mounted on the substrate side, the terahertz wave would be more concentrated around the boresight direction of the photoconductive antenna, and therefore increase its directivity

Li and Huang (2006) theoretically investigated this phenomenon by comparing a dipole structure and a sharp dipole structure, see Fig. 6. The electric field generated by line charges can be expressed as

$$E_d = \frac{Q}{2\pi\varepsilon_0 r\sqrt{4r^2 + w^2}}, \tag{6}$$

where Q is the total charge of the dipole, w is the width of the dipole, as shown in Fig. 7, and r is the distance from the charge to the observation point. The electric field formed by point charge can be written as

$$E_s = \frac{Q}{4\pi\varepsilon_0 r^2}. \tag{7}$$

If one uses the same antenna substrate and bias voltage, it is reasonable to assume that the total charge Q for both structures is the same. Consequently, one has

DOI 10.1007/978-981-4560-75-7_47-1

$$\frac{E_s}{E_d} = \frac{\frac{Q}{4\pi\varepsilon_0 r^2}}{\frac{Q}{2\pi\varepsilon_0 r}} = \frac{\sqrt{4r^2 + w^2}}{2r}. \tag{8}$$

If the observation point is in the gap between the two electrodes, r is of the same order as the gap g. In this circumstance,

$$\frac{E_s}{E_d} = \frac{\sqrt{4g^2 + w^2}}{2g}. \tag{9}$$

In an experiment carried out by Cai et al. (1997), the width $w = 20$ μm, the gap $g = 5$um, which results in an electric field enhancement of

$$\frac{E_s}{E_d} = 2.25. \tag{10}$$

The measured results gave an enhancement of 2.34, showing great agreement with the theoretical prediction within an accuracy of 5 %.

Generally speaking, a dipole antenna provides relatively larger beamwidth. To narrow the beamwidth and increase the directivity, a hemispherical antenna is mounted on the surface of the photoconductive antenna and normally on the substrate side. To decrease the multireflection between the substrate and the lens, the material for the lens is so chosen that the refractive index of the lens is almost the same as that of the substrate. For instance, the refractive index of silicon in the terahertz band is approximately 3.4, which is nearly the same as that of GaAs. On the interface of lens and air, the curved surface makes the terahertz rays less divergent by the refraction law, leading to an increased gain. Such a structure is crucial to low-power-level THz applications. It has been reported that by using a silicon lens, the gain can be increased by 10 dB (Liu et al. 2013). A schematic diagram of lens-mounted THz antenna is shown in Fig. 7.

A log-periodic structure has been reported by (Mendis et al. 2005) where the outer diameter is 1.28 mm, as shown in Fig. 8. Generally speaking, a periodic structure provides relatively wide bandwidths. It is interesting, however, to find that the bandwidth of a log-periodic structure may be quite limited (Mendis

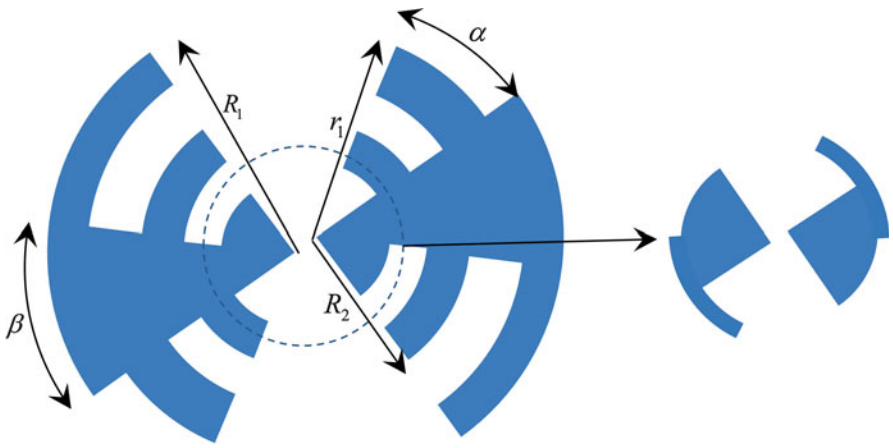

Fig. 8 The configuration of a log-periodic antenna. When working on high frequency side, a log-periodic antenna resembles a bow-tie antenna (Adapted from Mendis et al. 2005)

DOI 10.1007/978-981-4560-75-7_47-1

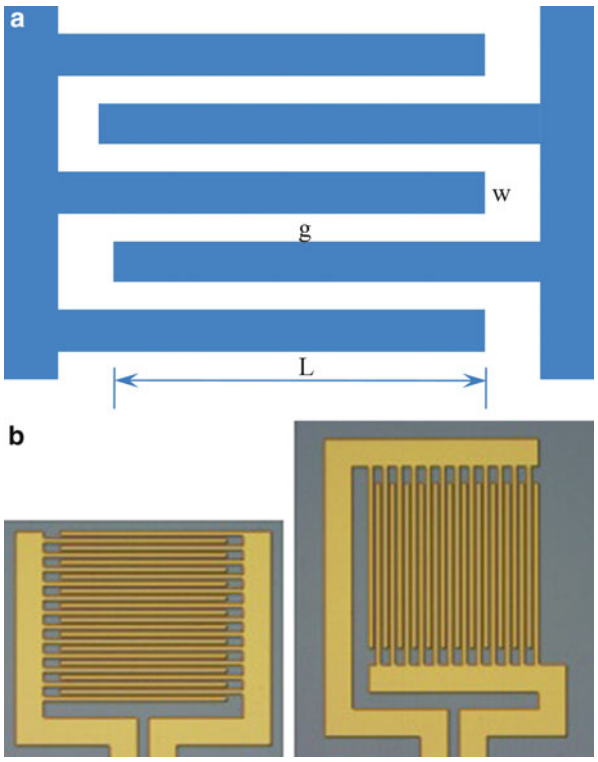

Fig. 9 Interdigital array. (**a**) Diagram; (**b**) Photography (By courtesy of Del Mar Photonics)

et al. 2005). A conventional strip structure may have a bandwidth from several fractions of THz to 2 THz, while the reported log-periodic structure works below 1 THz. Actually, a log-periodic antenna may provide wider bandwidth if properly designed. It is the outer radius that determines the low-resonant frequency. For higher frequency, a log-periodic antenna may act as a bowtie antenna.

The impedance matching is another issue with photoconductive antennas. Normally, the input impedance for a photomixer may be as high as 10 kΩ. However, the impedance for a dipole antenna may be much smaller. Impedance matching may be achieved through proper design of the structure. A Yagi-Uda antenna has been reported providing input impedance of 2.6 kΩ, which significantly improved impedance matching (Han et al. 2010). By further optimizing the driving unit, the input impedance may be increased to some 4–5 kΩ. Also, such a structure has relatively narrower beamwidth and hence higher directivity. The azimuthal plane has a 3-dB beamwidth of 49°, and the 3-dB beamwidth is 58°in the elevation plane. It is possible to increase the directivity by adding more director elements.

To increase radiation power, lens array has been investigated by many research groups, with some of the structures already commercialized. One lens array is based on interdigital structure, as shown in Fig. 9. Such structure provides higher radiation power than a conventional dipole structure. The interdigital structure forms an array of photoconductive antennas. An improved version may be achieved by mounting a silicon lens array on top of the interdigital structure.

Horn Antennas

A horn antenna is still one of the most popular types of antennas in THz bands. In most of the cases, a horn antenna is used in combination with reflector antennas, which will be discussed in later a section. Conventional horn antennas include pyramidal horn antenna, circular horn antenna, and corrugated horn antenna, as shown in Fig. 10.

DOI 10.1007/978-981-4560-75-7_47-1

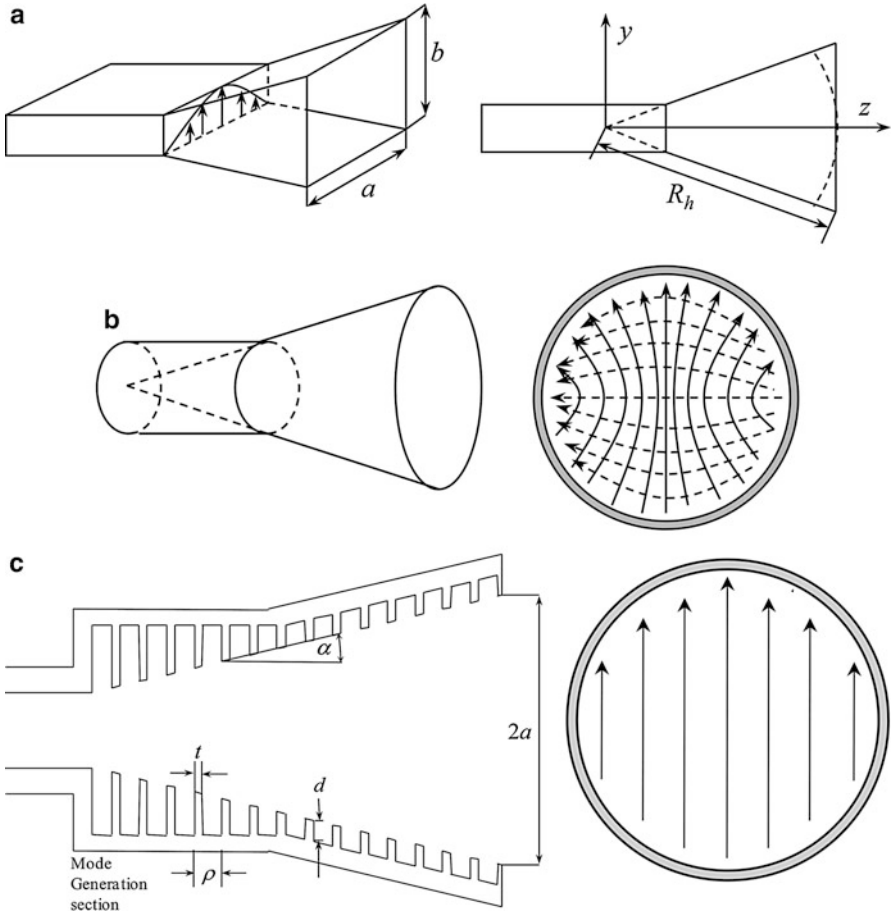

Fig. 10 Diagram of horn antennas. (**a**) Rectangular horn antenna; (**b**) Circular horn antenna; (**c**) corrugated horn antenna (Balanis 2005; Goldsmith 1997)

The most popular feed horns may be corrugated horns for their purity of polarization and scalar field distribution. The principle of operation of corrugated horns can be explained by considering the way in which the corrugated walls alter the field pattern in a corrugated waveguide to achieve symmetric main beam and low cross-polarization levels, which can only be met by an aperture with nearly linear-field distribution, as shown in Fig. 10c. Unfortunately, a linear electric field cannot be produced by waveguide supporting pure transverse-electric (TE) or transverse-magnetic (TM) modes. Therefore, in general cases, the corrugation is designed to generate a hybrid HE11 mode with almost linear electric field on the output aperture. Since the field distribution is independent on the azimuth angle, the radiation pattern will be symmetric with extremely good polarization purity.

The design of a corrugated horn has been reviewed by many researchers, and the interested readers are directed to a monograph on microwave horns (Olver et al. 1994). A well-designed corrugated horn can provide cross-polarization levels lower than −40 dB and first side lobe better than −40 dB as well as excellent fidelity to Gaussian distribution. The transverse component of the near field of a Gaussian beam propagating along z-axis can be described by

$$E_t(r,z) = \left(\frac{2}{\pi w^2}\right)^{0.5} \exp\left(\frac{-r^2}{w^2} - jkz - \frac{j\pi r^2}{\lambda R} + j\phi_0\right), \tag{11}$$

DOI 10.1007/978-981-4560-75-7_47-1

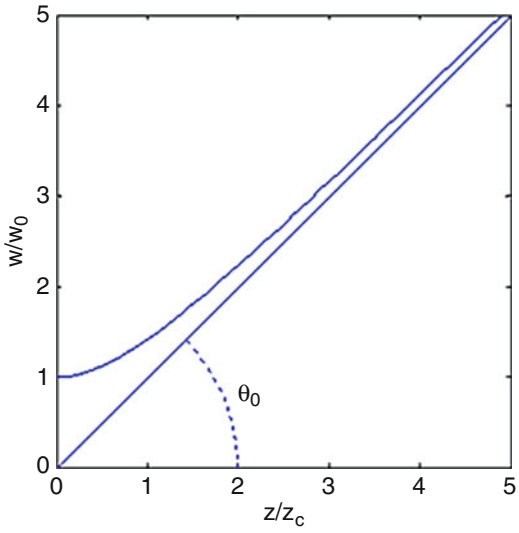

Fig. 11 The divergence angle of a corrugated horn antenna

where

$$R = z + \frac{1}{z}\left(\frac{\pi w_0^2}{\lambda}\right), \tag{12}$$

$$w = w_0\left[1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2\right]^{0.5}, \tag{13}$$

$$\tan\phi_0 = \frac{\lambda z}{\pi w_0^2}. \tag{14}$$

The far field can be written as

$$\frac{E_t(\theta)}{E_t(0)} = \exp\left(-\left(\frac{\theta}{\theta_0}\right)^2\right), \tag{15}$$

where

$$\theta_0 = \lim_{z \gg z_c}\left[\tan^{-1}\left(\frac{w}{z}\right)\right] = \tan^{-1}\left(\frac{\lambda}{\pi w_0}\right). \tag{16}$$

As shown in Fig. 11, the far field can be represented by the divergence angle. High-precision ultra-Gaussian beam horn antennas provide better than 40 dB cross-polarization isolation due to its scalar field distribution property and high Gaussian beam profile fidelity down to −40 dB (McKay et al. 2013; Adel et al. 2009). Such techniques enable one to calculate the far field and gain analytically, facilitating the prediction of the far field of a reflector antenna system. Horn antennas utilized as feeds are seen in ALAMA array and Planck telescope (Gonzalez and Uzawa 2012; Paquay et al. 2007), both arranged in a focal plane array with more than a dozen feeds working at different frequencies. Planck array horns

covering the frequency range of 27.5–870 GHz are centered at 30, 44, 70, 100, 143, 217, 353, 545, 857 GHz (Paquay et al. 2007). The feed array of the Planck satellite is shown in Fig. 12.

The difficulty of fabricating such horn antennas is again the accuracy. Note well that the corrugation of such antennas has a depth of a quarter of a wavelength and the teeth have a width of less than a quarter of a wavelength. The fabrication of such corrugated horns starts with fabricating a mandrel followed by electroforming on the surface of the mandrel a proper layer of copper. The mandrel was later on washed off by using strong base solution such as NaOH solution. Generally speaking, the mandrel is made of

DOI 10.1007/978-981-4560-75-7_47-1

aluminum, which reacts with NaOH solution. Several error sources can be identified during the fabrication. Firstly, the mandrel needs precision fabrication. Its precision directly affects the depth of slots and teeth of the horn. Secondly, the electroforming process is a time-consuming process, which is very likely to introduce the *fill-in error*, i.e., the imperfection when filling copper to the slots of the mandrel. Lastly, in the washing-off stage, residual aluminum may exist that distorts the radiation pattern or increases the reflection coefficient. A magnified mandrel fabricated in Rutherford and Appleton Laboratory is shown in Fig. 13.

Actually, THz horns are normally connected with waveguides, the previous international standards specifying the dimensions of which only to a maximum frequency of 330 GHz (Hesler et al. 2007). The newly approved standard rectangular metallic waveguide for THz applications has extended the operating frequency to 5 THz, shown in Table 1. It clearly shows that the physical dimensions of the waveguides working in the THz range lies in the micrometer range, which surely will impose challenges on fabrication.

Reflector Antennas

A reflector antenna is deployed in a wide scope of applications ranging from microwave communication to optical telescope. Most satellite communication systems are deployed with reflector antennas. Radioastronomy cannot have been so developed if a reflector antenna had not yet been invented. When the working frequency is high up to the millimeter wave range, the size of resonate type of antenna starts to decrease, leading to decrease in the effective receiving area. Reflector antennas are normally electrically large, from several wavelengths in diameter to tens of hundred wavelengths. Such electric size usually

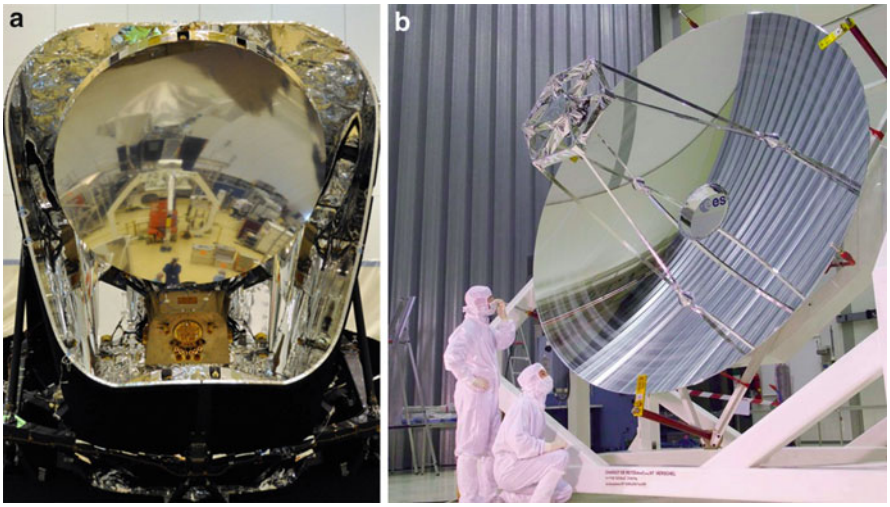

Fig. 15 The telescope of (**a**) Planck with a main reflector 1.5 m in diameter, and (**b**) Herschel with a main reflector of 3.5 m in diameter (Reproduced by permission of ESA)

bears high gain or high effective receiving area. In general, electrically large antenna provides very narrow beam, usually the 3 dB beam width being a couple of degrees or even narrower. Such a narrow beam provides one with high gain since the energy is very concentrated, which is very critical for remote sensing applications.

The surface profile of a reflector antenna is very versatile such as paraboloid, spheroid, ellipsoid, and hyperboloid surfaces, as shown in Fig. 14. The most popular one may be paraboloidal reflector. Launching from the focal point of a paraboloidal reflector, optical rays become parallely collimated after being reflected by the paraboloidal reflector. This attribute ensures equal phase on the output aperture plane. An improved structure is so-called Cassegrain antenna, where a hyperboloidal subreflector is employed to increase its effective focal length. An astronomy telescope may also in the form of spherical reflector receive signals from different incident angles. One example is the Five hundred meter Aperture Spherical Telescope (FAST) under construction in China (Nan and Li 2013).

Single paraboloidal reflector antenna used for THz application is rarely reported; one example is the main dish equipped on the payload of AMSU-B (Martin and Martin 1996). Examples of single reflectors, however, can be found in the microwave and millimeter wave range. In the THz range, paraboloidal reflectors are utilized in Cassegrain or Gregorian configurations. Offset structure was employed in Planck telescopes, while the Herschel telescope adopted a front-feed one. The Planck telescope has a main dish of diameter of 1.5 m, with its operating frequency high up to 870 GHz (Dominic et al. 2009). The Herschel telescope, in contrast, has a much larger main dish of 3.5 m in diameter (Dominic et al. 2009), shown in Fig. 15. Such electrically large antennas enable the detection of cosmic background radiation and deep space signal with gain up to 70 dB (Dominic et al. 2009). Ground base observatory also adapts electrically large-aperture reflector antenna or reflector array. The ALAMA antenna arrays have single antennas of diameter of 7 m or 12 m (Gonzalez and Uzawa 2012). Such array forms an interferometer that can detect signals from deep space with an angular resolution of 0.1 acres. The working frequency of the ALAMA array covers the range of 31–950 GHz. Spherical main dishes are also used such as the main reflectors of FAST under construction in China and Arecibo Observatory in Chili.

In quasioptical systems, paraboloid, spheroid, ellipsoid, and hyperboloid reflectors are all possibly employed for refocusing purpose. The equivalent focal length of an elliptical of hyperbolical reflector can be written as

DOI 10.1007/978-981-4560-75-7_47-1

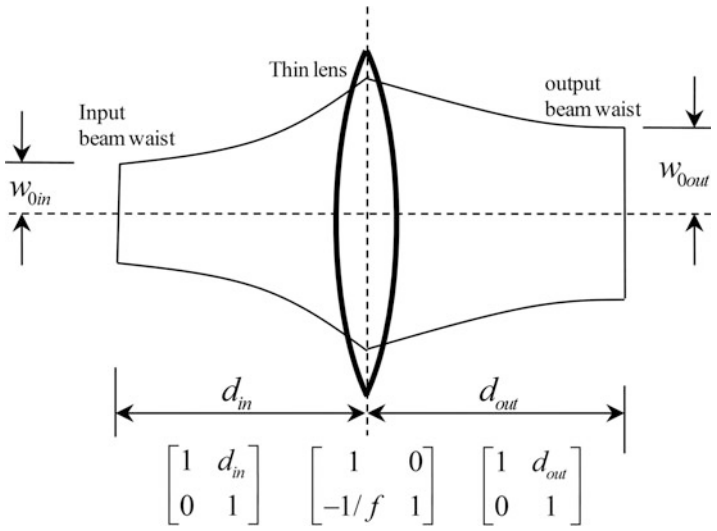

Fig. 16 Transform a Gaussian beam by thin lens

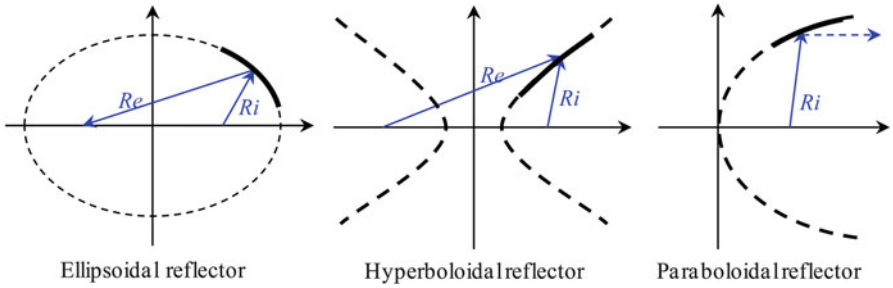

Fig. 17 Reflectors for quasi-optical systems. *Ri* stands for the distance from the incident focal point to the optical center of the reflector, and Re for the distance from the optical center to the emergency focal point

$$f = \frac{R_i R_e}{R_i + R_e}, \tag{17}$$

while the equivalent focal length for a parabolic reflector is

$$f = R_i. \tag{18}$$

These reflectors act as lenses transforming an incoming Gaussian beam to another one of different beam radius (Fig. 16). Such a transform can be implemented through ABCD matrix method for a preliminary design to determine the output beam profile. For practical applications, the size of the reflectors is normally four times o the beam radius to ensure 99.8 % of the power intersected by the reflectors (Goldsmith 1997). Normally, in a quasioptical system, the reflector is a section of an ellipsoidal, hyperboloidal, or paraboloidal surface, see Fig. 17. Such reflector surfaces are only a second-order approximation of thin lenses, suggesting that distortion may be introduced to the output beam. The distortion has been analyzed by Murphy (1987). Essentially, it is the coupling to higher Gauss-Hermit modes that cause distortion to the fundamental Gaussian mode. To characterize the distortion, a distortion parameter is defined and found as $U = 2^{-1.5} w_m \tan\theta_i f^{-1}$, showing a linear proportion to the tangent of the incident angle θ_i and the beam width at the mirror w_m and inversely proportional to the focal length of the mirror. Interestingly, the cross-polarization is also dependent of these factors and obeying the same rules.

DOI 10.1007/978-981-4560-75-7_47-1

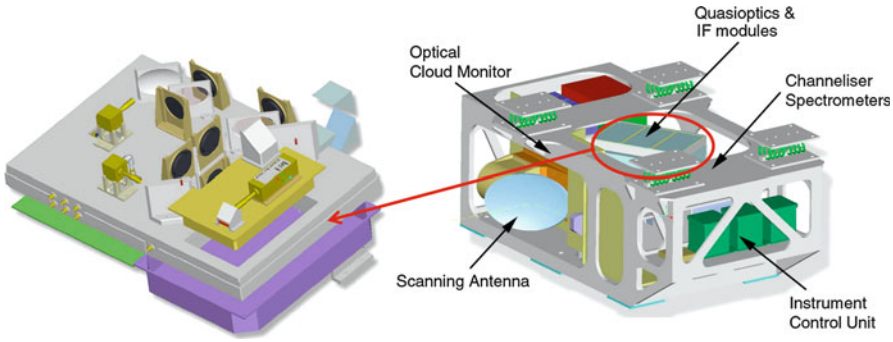

Fig. 18 An assembly model for the quasi-optical system equipped on MARSHAL limb-sounding unit (Reproduced with permission from Rutherford and Appleton Laboratory)

Such observations clearly indicate that to minimize the distortion and suppress the cross-polarization, the incident angle shall be as small as possible. Also, the beam width at the mirror should be controlled as small as possible. At last, one could choose long-focal length reflectors to ensure good performance. Nevertheless, such ideal conditions may not be met in a practical design. For instance, small incident angles may introduce blockage from other reflectors in a multichannel system. In this sense, the design of an optimized quasioptical system is a trade-off between many factors.

Since the designs of the reflectors are based on Gaussian beam theory, which is frequently encountered in a laser propagation textbook, the term *quasioptical technique* is often utilized to indicate its intermediating property between microwave and optical technologies. In the literature, quasioptical techniques are also referred to as beam waveguide techniques. Quasioptical techniques have been utilized in the MARCHAL limb-sounding unit (as shown in Fig. 18) and the receiver front end of the Herschel satellite.

Generally speaking, the fabrication of reflector antennas is not a concern. However, with the increase of operation frequency, the surface accuracy is a critical factor that affects the performance of an antenna working in the THz range. To ensure good performance, the surface accuracy in terms of root measure square (RMS) shall be better than $\lambda/20$ (18°), best $\lambda/100$ (3.6°). But such high accuracy is a challenge for reflector fabrication. Talking about 1THz, the corresponding wavelength is on the order of 300 μm; the requirement of $\lambda/20$ and $\lambda/100$ surface RMS accuracy would lead to 15 and 3 μm, respectively. For medium-sized systems, for example, the fabrication of quasioptical systems is less difficult. A high-precision numerical controlled machine can provide surface accuracy better than 5 μm. Two shaped reflectors of 300 mm in diameter have been machined in Thomas Keating (TK), UK, for an antenna measurement system in Beijing University of Posts and Telecommunications, with a surface accuracy better than 3 μm (Yu et al. 2013). However, for electrically large systems, say 3.5 m diameter reflectors, the accuracy is a critical issue to be considered.

In the fabrication of the Herschel telescope, a complicated procedure has been customized. The reflector of Herschel telescope is fabricated using silicon carbide. Due to the fact that the main dish is too large, the main dish was constructed by piecing up 12 separate petals (Tauber et al. 2005). It has to be mentioned that this is the first monolithic space mirror fabricated in a segmented fashion. The fabrication of such a big reflector is very complicated, involving SiC manufacturing (supplied by Boostec Industries, Tarbes, France), polishing of the main and secondary dishes (by Opteon, Finland, for the main dish and Zeiss, Germany, for the secondary dish), coating (Calar Alto observatory, Spain), and optical testing (Center Spatiale de Liege, Belgium) (Toulemont et al. 2004). Initially, it is intended to build the reflector as an all-composite (CFRP) telescope, which is however canceled due to funding issues. The final performance was eventually verified by measuring the wavefront error, which was measured to

DOI 10.1007/978-981-4560-75-7_47-1

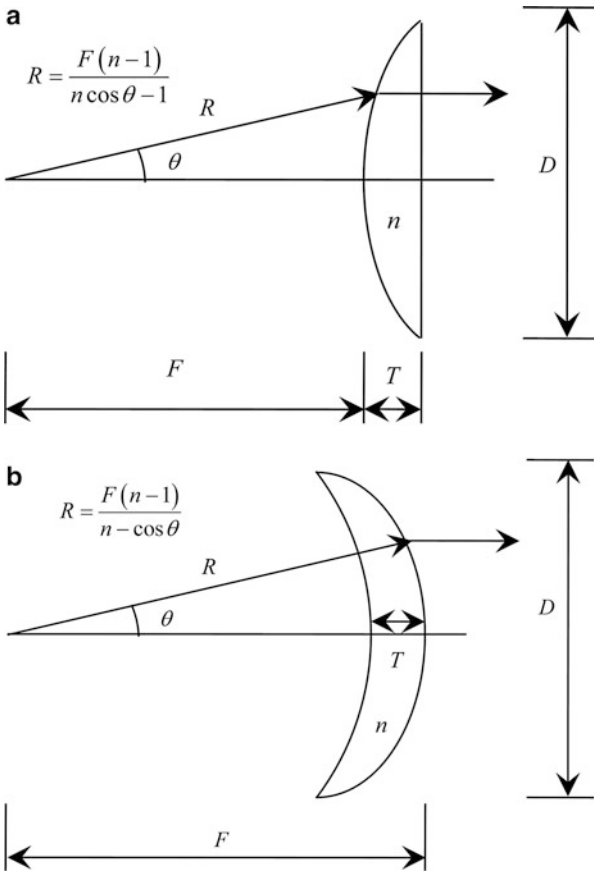

Fig. 19 Lens-based antennas. (**a**) Convex-planar structure; (**b**) concave-convex structure

be 5.5 μm at the edge of the reflector, better than the requirement, i.e., 6 μm (Dominic et al. 2009). Surface accuracy measurement seems too expensive, which however is possible using photogrammetry and interferometry techniques. These optical methods can be used in association with simulation and measurement techniques to predict in-orbit RF performance of electrically large antennas (Luis et al. 2010).

The Planck telescope is in aplanatic off-axis configuration, with both of the two reflectors made of sandwiched thermally stable carbon fiber-reinforced plastic (CFRP). To increase the reflectivity of the reflector, the front faces of both reflectors are coated with Al + Plasil. Such a fabrication technique leads to low coefficient of thermal expansion and high stiffness as well as low gross weight, 25 kg for the primary and 12 kg for the secondary. It is noted that in a reflector made of aluminum with diameter 1 m, the gross weight can be as high as 300 kg (Tauber et al. 2005; Toulemont et al 2004).

Other Antennas

The lens antennas have been widely utilized in the millimeter wave range. Lens antenna provides circular symmetrical radiation pattern due to its circular symmetrical structure. Particularly, this type of antenna is capable of generating Gaussian beam pattern and for this reason is frequently employed in a QO system. Two types of lens antenna are illustrated in Fig. 19. A lens antenna is usually made of polymer or silicon, correcting a spherical wave front to a planar one, at the same time calibrating the path length, i.e., ensuring equal phase distribution on the output plane.

In the THz range, a lens antenna is used in combination with photoconductive antenna. Or it can be used along in millimeter wave wireless communication system. One reported laboratory system working

DOI 10.1007/978-981-4560-75-7_47-1

at 300 GHz uses two polyethylene lens antennas of 5 cm in diameter, 12 cm focal length to compensate free-space path loss (Jastrow et al. 2008). Unavoidably, the fabrication error of a lens antenna produces uncertainty to the performance of its far field (Uvarov et al. 2007). In most cases, the side lobe level increases and the gain decreases as the surface accuracy decreases. For polymers, the machining of the curved surface with high precision is a challenge work. Also, temperature fluctuation makes the radiation pattern easily distorted. In addition, the reflection on the air-polymer surface decreases the efficiency depending on the refractive index.

With the development of nanotechnology, nanostructure has been investigated for THz wave radiation enhancement in photoconductive antennas (Gao et al. 2009; Park et al. 2012; Jornet and Akyildiz 2013). In most cases, THz radiation from nanostructure is attributed to surface Plasmon resonance (SPR). Strictly speaking, the THz radiation enhancement is due to field enhancement in nanostructure. It has been reported that by aid of nanostructure, the THz emission power can be doubled compared to a conventional photoconductive antenna (Jornet and Akyildiz 2013).

Also, metamaterials are also utilized for THz antennas (Zhang et al. 2014; Cong et al. 2012; Kyoung et al. 2011). Such structures can be designed for many uses such as polarization conversion, enhancement of radiation gain, and filtering. Due to the limitation of the space, this kind of antenna will not be covered in this chapter. Actually, there are other types of THz antennas not covered in this chapter for the same reason.

THz Antenna Measurement

Photoconductive Antenna Method

The measurement of a photoconductive antenna is usually conducted using the photoconductive antenna (PCA) scheme, as shown in Fig. 20.

The laser beam undergoing time delay will arrive at the photoconductor at Δt relative to the THz wave acting as the applied voltage, Fig. 20. In some THz-TDS systems, the induced current proportional to the magnitude of the THz wave is measured by a galvanometer. In this way, the THz wave is mapped out through delaying the reference laser by Δt relative to the THz wave, as illustrated in Fig. 21. To obtain the spectral information such as absorption fingerprint lines of biomolecules, Fourier transform can be applied. A frequently used scheme for measuring the current signal is electro-optical (EO) sampling by using an EO crystal, ZnTe for instance. EO crystal normally has different refractive index along different axes, which is referred to as birefringence phenomenon. In the EO sampling scheme, the THz field

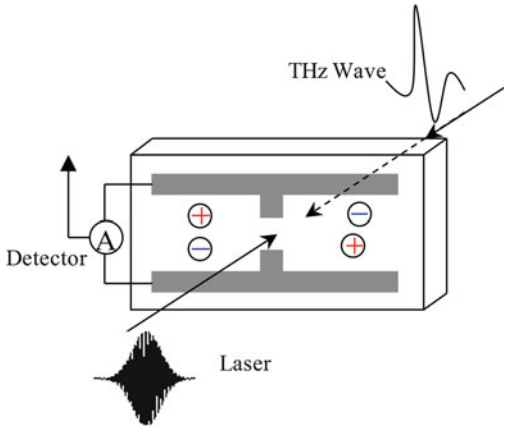

Fig. 20 Photoconductive antenna for THz wave detection

DOI 10.1007/978-981-4560-75-7_47-1

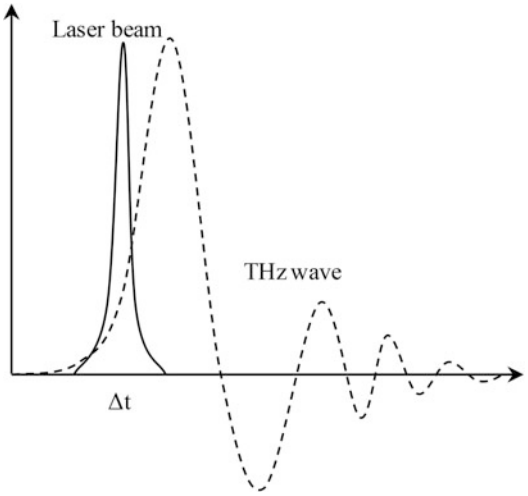

Fig. 21 The detection of the THz wave. The laser beam is at Δt relative to the THz wave. By changing Δt, the THz pulse can be detected

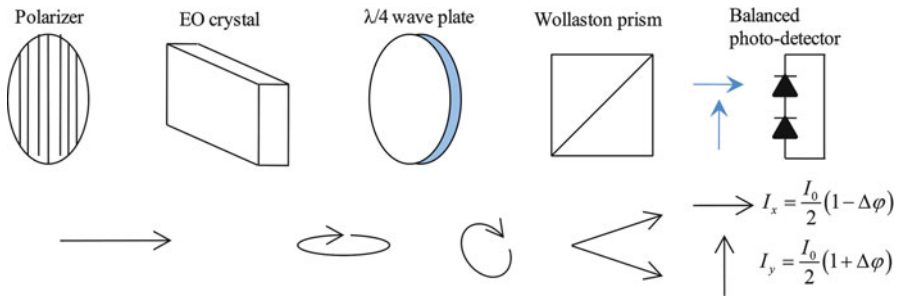

Fig. 22 Balanced detection method using EO crystal

changes the birefringence of the EO crystal. A linear polarized THz wave will be converted to a slight ellipsoidal polarized one. After going through the quarter-wave plate and a Wollaston prism, the THz wave will be eventually separated to a horizontally and a vertically polarized component, which can be detected using a balanced photodetector. The EO crystal detection scheme is illustrated in Fig. 22.

The radiation pattern measurement of a photoconductive antenna resembles a near-field imaging system. In general, the images are obtained via raster scanning. Many methods have been developed to achieve high-resolution imaging; the interested readers are referred to (Adam 2011). Those methods aim at achieving subwavelength resolution. One commercial product worth mentioning is a freely positionable photoconductive probe tip manufactured by the group of Nagel in Germany. The gap between the two electrodes is only 1.5 μm, achieving a resolution of 6 μm for the bandwidth of 0.1–3THz. Such a probe in theory can also be utilized for far-field measurement (Wächter et al. 2009).

Far-Field Method

Ideally, for antenna measurement, the incident wave to the antenna under test (AUT) shall be a plane wave with uniform amplitude and phase. An approximate approach is placing the AUT far away from the radiating source. Normally, it is in the far field of the test and source antennas. In the far field of an antenna, the radiation wave has a spherical phase front. To ensure accurate antenna measurement, a rule of thumb

DOI 10.1007/978-981-4560-75-7_47-1

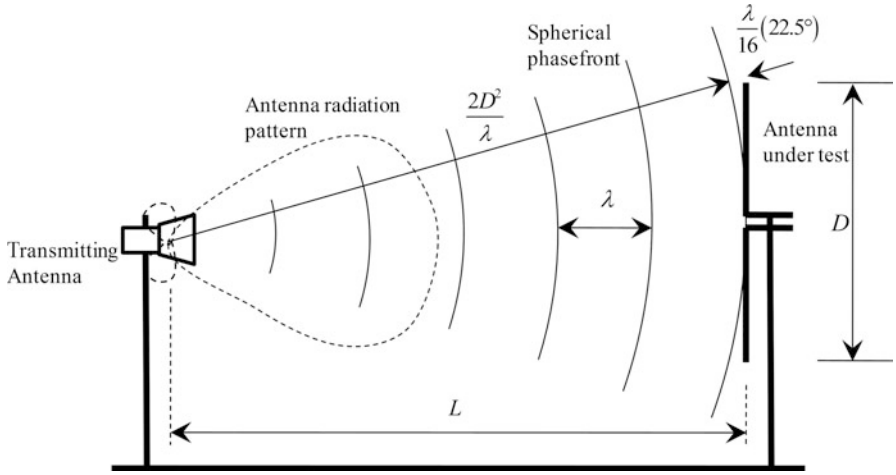

Fig. 23 Illustration of far-field measurement. The test antenna has to be far enough from the source antenna to ensure that the phase difference of any part of the test antenna shall be less than 22.5°

is that the phase difference of the phase front to a planar surface of diameter D is less than 22.5°, corresponding to λ/16 path difference. As shown in Fig. 23, the separation distance between the source and test antennas is L. The phase difference between the edge of the planar surface and the midpoint is

$$\Delta L = \sqrt{L^2 + \left(\frac{D}{2}\right)^2} - L \leq \frac{\lambda}{16}. \tag{19}$$

If L is much larger than D, the far-field condition becomes

$$L \geq \frac{2D^2}{\lambda}. \tag{20}$$

This is the minimal distance for far-field antenna measurement. However, it is a problem for most THz antennas since the distance may be as long as several tens of kilometers for electrically large antennas. For instance, a 1.5 m diameter antenna working at 0.3 THz requires L to be larger than 4.5 km.

One has to conduct this kind of far-field measurement outdoors. However, it is seen from Fig. 2 that the atmospheric attenuation beyond 0.3 THz is almost more than 10 dB/km, which imposes more than 45 dB absorption loss if the path length is 4.5 km. The atmospheric attenuation is even more pronounced in the range of 1–10 THz, more than 100 dB/km. For this reason, the far-field method is not feasible for electrically large antenna measurement.

The far-field method is only feasible for the measurement of small-aperture THz antennas, such as corrugated horns. A corrugated horn with center frequency 275 GHz has been measured using the far field in Queen Mary University of London with the measured results shown in Fig. 24. The aperture of the corrugated horn is around 8 mm in diameter. It is seen from the results that the far field of the corrugated horn has very good Gaussian profile, down to −40 dB, with high symmetry of the two cuts. The side lobe level of this corrugated horn is down to −36 dB, showing excellent Gaussian purity.

Near-Field Method

The near-field method is another technique frequently used for the measurement of millimeter antennas. The near-field method was introduced in the 1980s. In such a method, the near-field distribution over a

DOI 10.1007/978-981-4560-75-7_47-1

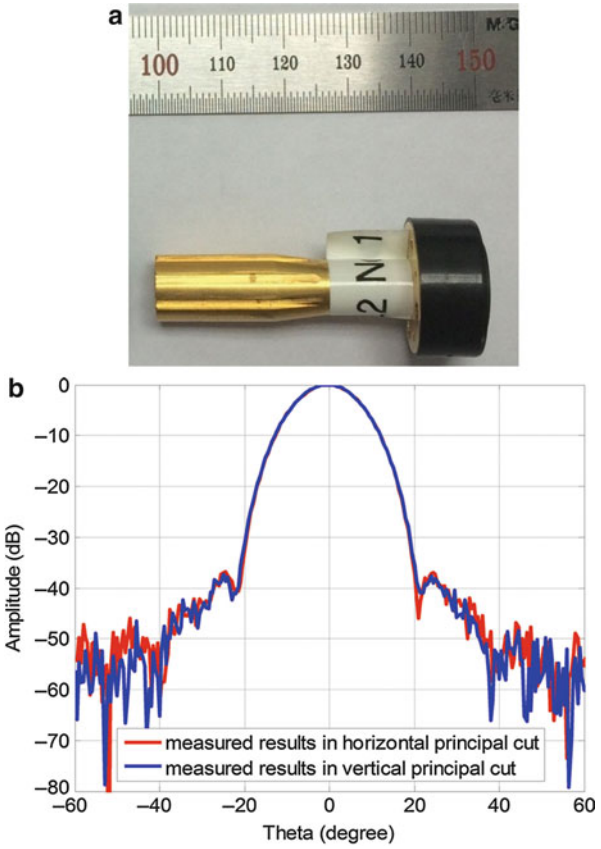

Fig. 24 Measurement of a 275 GHz corrugated horn using far-field method. (**a**) Photograph, (**b**) The radiation pattern

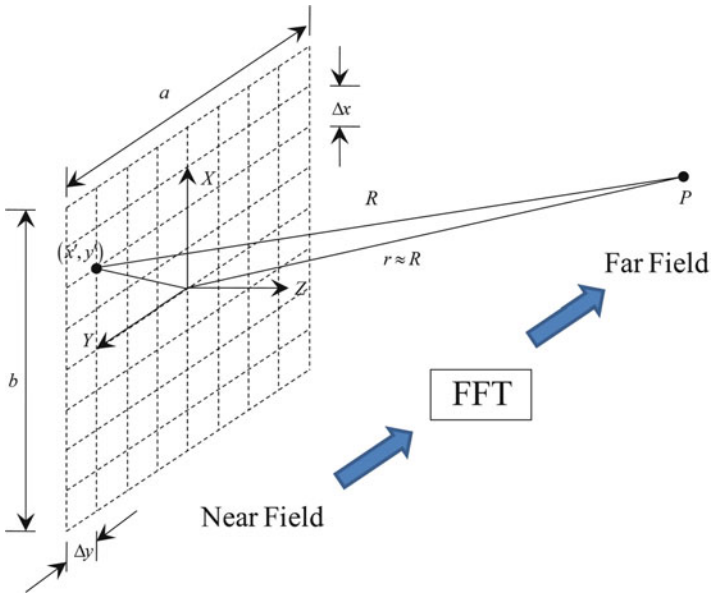

Fig. 25 The near-field scanning schemes

DOI 10.1007/978-981-4560-75-7_47-1

planar, cylindrical, or spherical surface is firstly picked up by using a probe. Then, the near-field-to-far-field (NF/FF) transform method is applied to obtain far-field radiation characteristics.

Generally speaking, planar scanning is suited for electrically large and high-gain reflector antennas. Data acquisition over such a planar scanning is usually conducted by raster scanning, as shown in Fig. 25. The maximal scanning interval for Δx and Δy is half a wavelength, which is dedicated by Niquist sampling rate.

Near-field transform to far-field transform is essentially Fourier transform. For planar scanning scheme, far-zone fields can be expressed as

$$\vec{E}\ (x,y,z) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\vec{f}\ (k_x,k_y)e^{-j\vec{k}\cdot\vec{r}}dk_xdk_y, \tag{21}$$

where

$$\begin{cases}\vec{f}\ (k_x,k_y) = f_x(k_x,k_y)\hat{x} + f_y(k_x,k_y)\hat{y} + f_z(k_x,k_y)\hat{z}\\ \vec{k} = k_x\hat{x} + k_y\hat{y} + k_z\hat{z}\\ \vec{r} = x\hat{x} + y\hat{y} + z\hat{z}\end{cases}. \tag{22}$$

The spectral components f_x and f_y are related to the near field by

$$\begin{cases} f_x(k_x,k_y) = \int_{-b/2}^{b/2}\int_{-a/2}^{a/2} E_x(x',y',z'=0)e^{j(k_xx+k_yy)}dx'dy' \\ f_y(k_x,k_y) = \int_{-b/2}^{b/2}\int_{-a/2}^{a/2} E_y(x',y',z'=0)e^{j(k_xx+k_yy)}dx'dy' \end{cases}, \tag{23}$$

where E_x and E_y are electric components along x and y axes. The far field can be approximated by using asymptotic evaluation to be

$$\begin{cases} E_\theta(r,\theta,\phi) \approx j\frac{ke^{-jkr}}{2\pi r}\cos\theta\left(f_x\cos\phi + f_y\sin\phi\right) \\ E_\phi(r,\theta,\phi) \approx j\frac{ke^{-jkr}}{2\pi r}\cos\theta\left(-f_x\sin\phi + f_y\cos\phi\right) \end{cases}. \tag{24}$$

Near-field scanning method has been employed to measure antennas of many satellite payloads or ground-based observation stations. Up to 950 GHz system has been measured by using near-field scanning. For instance, JPL Earth Observing System Microwave Limb Sounder working at 650–660 GHz (Slater et al. 2001) was measured using near-field method. And NSI's most recent submillimeter wave scanner was built in support of the Atacama Large Millimeter Array (ALMA) program at 950 GHz (Van Rensburg and Hindman 2008). One example of the near field of a corrugated horn working in the W band is shown in Fig. 26.

Although near-field method is successful for THz antenna radiation pattern measurement, the limitation of this method is also obvious in several aspects. The first aspect is the data acquisition time for electrically large antennas. By the Niquist sampling theorem, the maximal sampling interval shall be half a wavelength. For an aperture antenna, the scanning area would be slightly larger than the antenna aperture

DOI 10.1007/978-981-4560-75-7_47-1

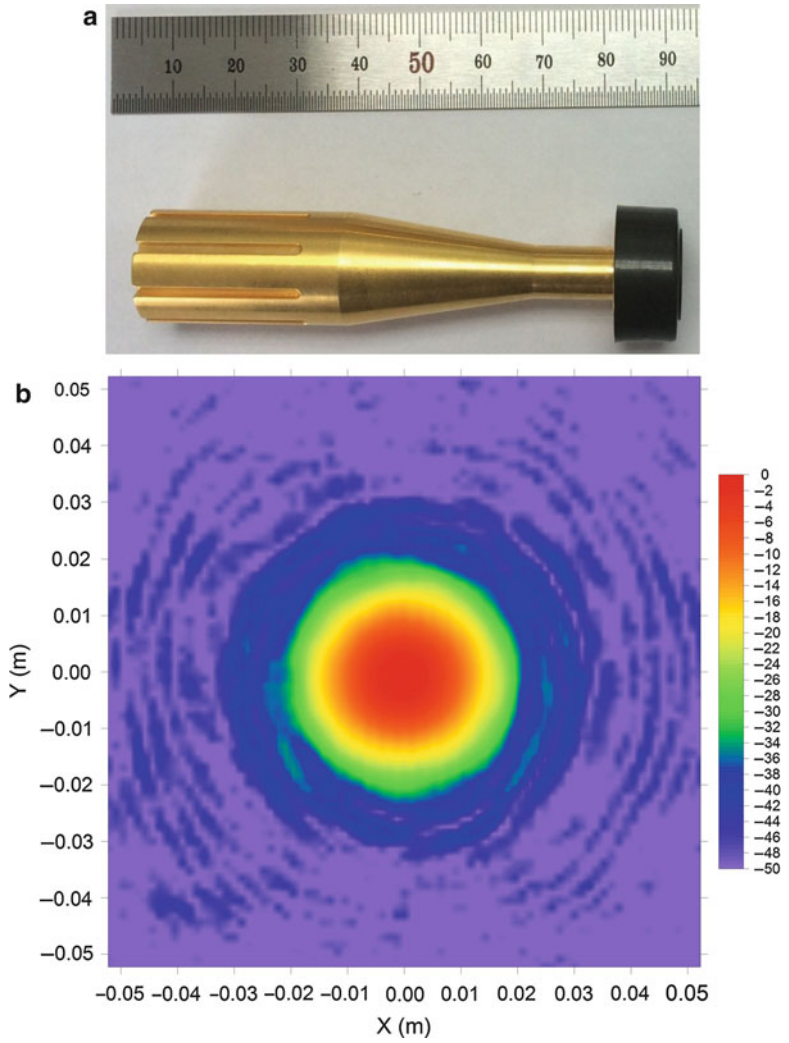

Fig. 26 Near-field measurement of a W-band corrugated horn using a NSI near-field scanning system in Queen Mary University of London. (**a**) Photograph, (**b**) The amplitude of the near-field

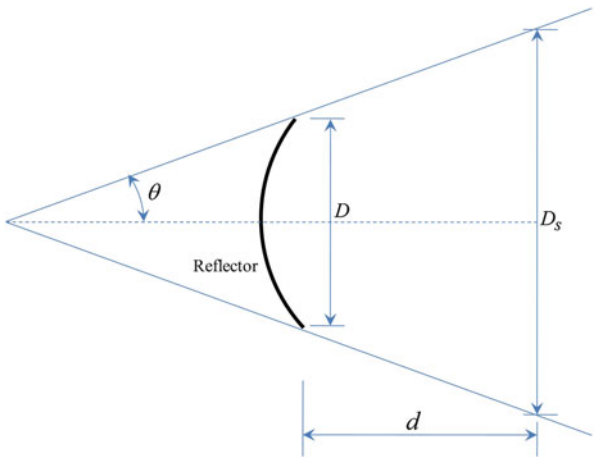

Fig. 27 The required measurement diameter in a near-field scanning system

DOI 10.1007/978-981-4560-75-7_47-1

depending on the far-field angle θ to be measured, as shown in Fig. 27. Suppose the diameter of the reflector is D, the distance between the probe and the aperture of the antenna is d, then the scanning area has a diameter larger than

$$D_s = D + 2d \tan\theta. \tag{25}$$

The number of scanning points N is calculated by

$$N = \left[\frac{2D_s}{\lambda}\right]^2, \tag{26}$$

where the bracket denotes the integer part of a number. For instance, for a 1 m diameter antenna working at 1 THz and 30° far-field angle, D_s is 2.15 m if d is 1 m. Even if the far-field angle is 10°, D_s will be 1.35 m. Then, the number of scanning points will be on the order of 10^8. Such a massive data collection needs tens or even hundreds of hours scanning. To reduce the data acquisition time, nonredundant data recovery techniques have been developed. Such a method can effectively reduce the sampling points by using postsignal processing techniques.

The second aspect is the planarity of the scanning structure. Working up to 1 THz, the wavelength will be on the order of 300 μm. The reported RMS planarity by NSI is 3 μm, corresponding to λ/100 or 3.6° phase error. Mechanical planarity of such is almost to its extreme. The reported working frequency of the NSI system is 950 GHz. Systems operating at higher will require better planarity, imposing a great challenge to mechanical system fabrication and installation.

The third aspect is the stability of the mechanical structure and the electronic systems. Inevitably, the mechanical structure is vibrating with the moving of the scanning arms. In addition, temperature variation causes thermal effect on the mechanical structure, which also causes stability issue to long-time scanning measurement. Electronic systems themselves are often noise sources. The signal stability over the whole period of measurement is also a source of error.

A fourth aspect is RF cable phase instability. This aspect may be one of the most concerned effects in the scanning method. With the movement of the scanning, the flexible cable causes extra phase fluctuation, which is difficult to overcome. Many techniques have been developed such as differential phase measurement method (Tuovinen et al. 1991) and pilot signal-based real-real time method (Saily et al. 2003).

The fifth aspect is probe translation during polarization rotation. Also, probe compensation has to be considered in the postprocessing stage (Leach et al. 1974). To overcome the phase issue, phaseless techniques have been proposed for near-field methods to recover the far field (Isernia et al. 1991; McCormack et al. 1990).

Compact Antenna Test Range

Compact antenna test range is the most feasible technique for THz antenna measurement. The reasons are obvious: its indoor nature making all-weather measurement in controlled environment possible; its system stability being better than near-field scanning; and its measurement time being relatively short.

The diagram of the working principle of a CATR system is demonstrated in Fig. 28. The incoming plane wave is generated through focusing elements such as lens and mirrors within a short distance. The plane wave is actually not a perfect one in a practical CATR but a regional pseudoplane wave where the antenna under test (AUT) is placed. The far field of the AUT can be measured by rotating the turntable by using a position controller.

DOI 10.1007/978-981-4560-75-7_47-1

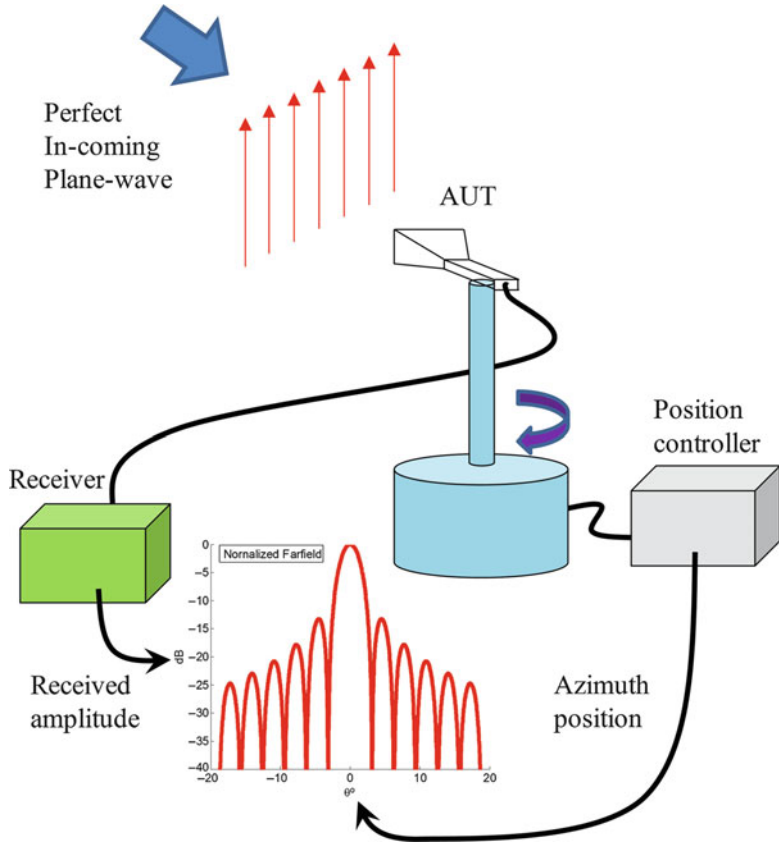

Fig. 28 The operating principle of a CATR system

The simplest CATR is a parabolic reflector antenna, see Fig. 29a, giving a 30 % quiet zone size of the dimension of the reflector. The quiet zone is the region where an EM wave can be approximated as a plane wave, with normally ±0.5 dB amplitude ripple and ±5°phase ripple. Generally speaking, ±0.5 dB amplitude ripple and ±5°phase ripple are the industrial convention, which is not an international standard. If the edge of the reflector is treated with serrated edge, the quiet zone can be increased to 50 %. Such a single-reflector scheme has disadvantage of low aperture usage ratio. To increase the aperture usage, a dual-reflector system has been developed in ASTRIUM, so called CPTR also, as shown in Fig. 29b. Such system can increase the aperture usage ratio to 60 % and even to 70 %. However, its drawback is that the two reflectors have to be of the same order of dimension.

Recently, a novel trireflector system has been proposed and developed in Queen Mary University of London, with the working frequency up to 325 GHz. The configuration of such is illustrated in Fig. 30a, with simulated quiet zone performance shown in Fig. 30b, c for amplitude and phase ripple, respectively. An improved version is being developed in Beijing University of Posts and Telecommunications in order to push the working frequency to 550 GHz. The trireflector CATR consists of a spherical main reflector with two-shaped relatively small subreflectors. Such a configuration gives one freedom manipulating both amplitude and phase distribution in the quiet zone. This novel CATR can achieve aperture usage ratio up to 80 %, a significant increase compared to single-reflector CATR. In addition, the fabrication cost is dramatically decreased due to the increase of the aperture usage ratio since a much smaller dish is needed. Note well that the fabrication cost of a reflector is not a linear function of the area but might be an exponential relationship. Furthermore, spherical mirrors are frequently used in telescope systems with a relatively lost fabrication cost. For the two-shaped subreflector, the surface is not a conic function but a numerically defined one, i.e., defined by a set of discrete points. The coordinates of these points are

DOI 10.1007/978-981-4560-75-7_47-1

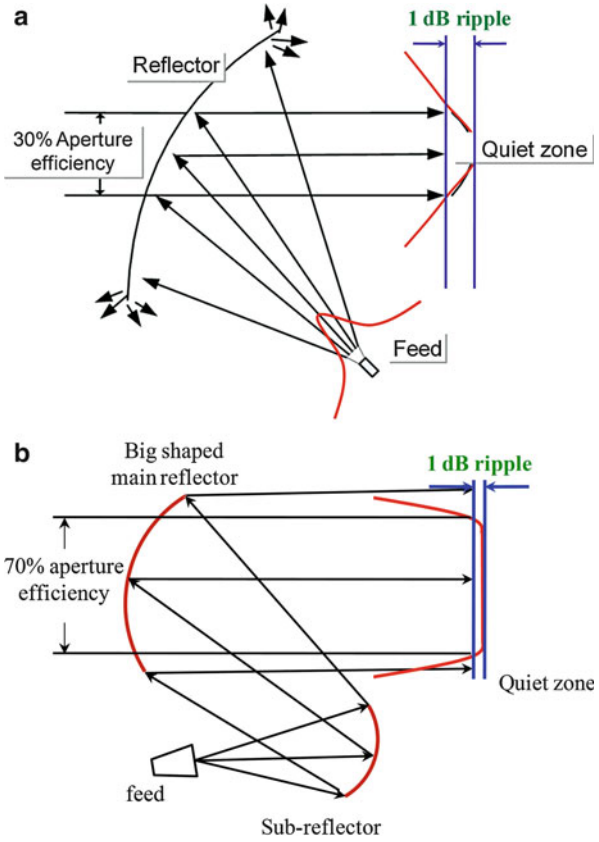

Fig. 29 Reflector based CATR, (**a**) Single reflector CATR; (**b**) dual-reflector CATR

synthesized by dynamic and kinematic ray tracing method (Kildal 1990) by gracefully incorporating both equal optical path condition and the law of conservation of energy to obtain uniform phase and amplitude distribution in the quiet zone, respectively. The size of the two subreflectors can be significantly smaller compared with the main dish, usually 10 % of the area of the main dish.

The configuration of trireflector CATR can be versatile, having at least four combination options, double-Cassegrain, Cassegrain-Gregorian, Gregorian-Cassegrain and double-Gregorian. The most useful two are Cassegrain-Gregorian and double-Gregorian configurations (Rieckmann et al. 2005). The other two configurations have the disadvantage of blockage from the first subreflector. Cassegrain-Gregorian normally produces smaller ripple in the quiet zone, while double-Gregorian has relatively better cross-polarization isolation. By adding diffraction stop in the caustic region, it is possible to reduce the amplitude of the ripple.

Ideally, a reflector CATR is expected to work over very wide bandwidth. However, two factors, i.e., electrical size and surface accuracy of dishes, determine the operation frequency range. The low frequency end is limited by the dish electrical size due to the edge diffraction while the high frequency end is determined by the dish surface accuracy for the reasons of scattering and phase error. The low-frequency limitation occurs when the size of the reflector is in the range of 25–30 wavelengths (Schluper et al. 1987). The dish surface accuracy is required to be better than 1/20 of the wavelength for high-frequency operation as a rule of thumb (Balanis 2005).

Another novel method in building CATRs for THz antenna measurement is a so-called hologram-based CATR (Hakli et al. 2005), as shown in Fig. 31. The hologram CATR is based on Fourier optics using a

DOI 10.1007/978-981-4560-75-7_47-1

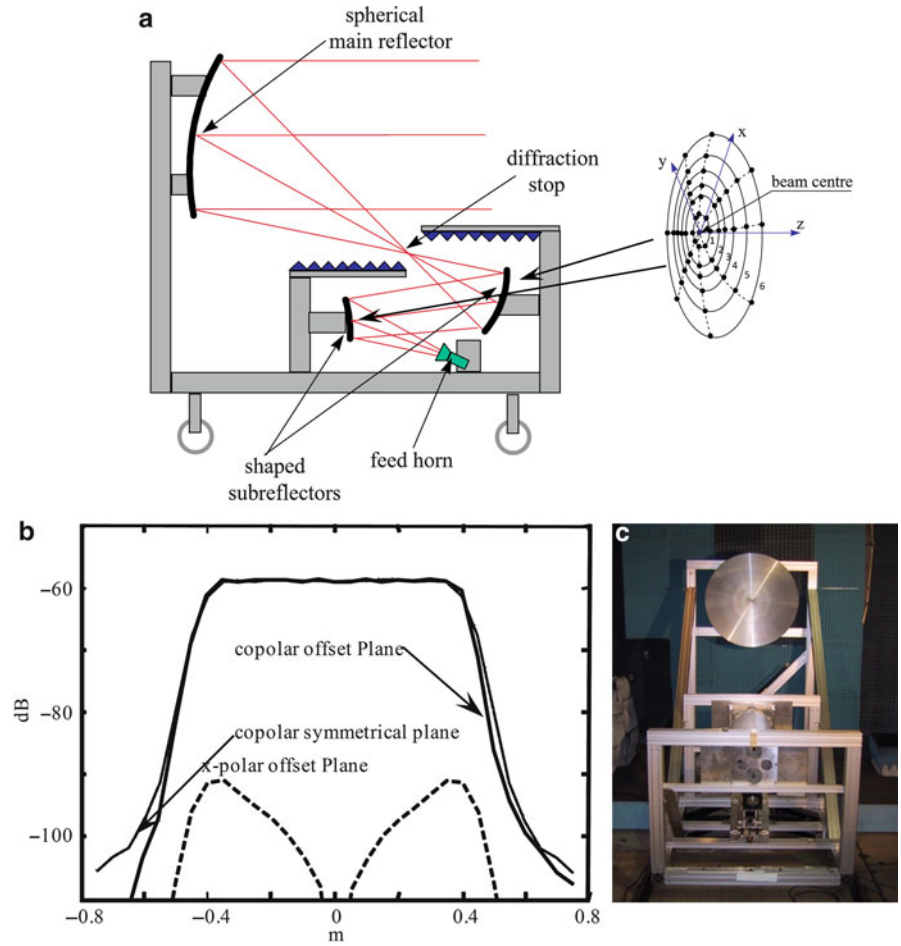

Fig. 30 Tri-reflector CATR. (**a**) configuration, (**b**) amplitude distribution in the quiet zone in the quiet zone at 200 GHz (Liu et al. 2011b), (**c**) Photograph of the tri-reflector CATR in Queen Mary University of London (Rieckmann et al. 2006)

hologram plane to transform spherical wave to plane wave, as illustrated in Fig. 31. The core technical part of a hologram CATR is the synthesis and fabrication of the hologram plane. It has been reported that a 650 GHz hologram-based CATR has been fabricated to measure a 1.5 m antenna operating at 650 GHz. The 3.16 m large hologram plate is pieced up by three plates to form a quiet zone of ±0.4 dB ripple in amplitude and ±6°ripple in phase (Karttunen et al. 2009). Unfortunately, such specifications were not achieved due to many factors such as the fabrication error, piecing up error, and so on. Such a structure, due to its nature, produces an asymmetrical quiet zone with low cross-polarization isolation (only −24 dB achieved). Also, the operating bandwidth of a hologram CATR is quite narrow. In addition, the chamber accommodating such a structure is relatively larger than a reflector-based CATR.

In the CATR measurement, one important procedure is the calibration of its quiet zone. Unless one uses near-field scanning to sample the whole area of the quiet zone, amplitude and phase ripple in the quiet zone is difficult to assess. But this again falls into near-field measurement. Alternative methods have been proposed (Griendt et al. 1996) such as using a standard antenna with much smaller electric size. Measuring such an electrical antenna is not an issue even using near-field measurement. But this method only gives one a ballpark estimation of the CATR, no details of the amplitude or phase ripples. One established method may evaluate the test zone (or quiet zone) of a CATR using a radar cross section (RCS) flat plate, which has been demonstrated at the compact payload test range at ESTEC, Noordwijk, the Netherlands.

DOI 10.1007/978-981-4560-75-7_47-1

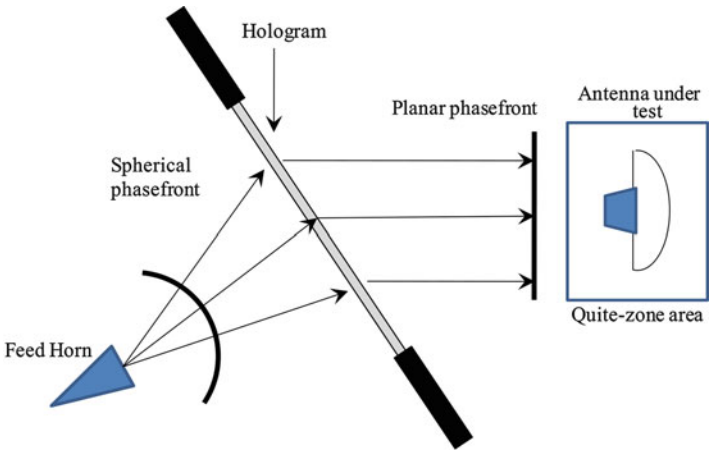

Fig. 31 Hologram based CATR

The underpinning principles are as follows. When a planar plate is illuminated by a nonplanar wave, the scattered field from this plate is a function of azimuth and elevation angle. The scattered field can therefore be represented by

$$E_s(\alpha,\beta) = \iint_A E_i(x,y)e^{2jk(x\sin\alpha + y\cos\alpha\sin\beta)}dxdy, \tag{27}$$

where $E_s(\alpha, \beta)$ is the scattered field, α and β are the azimuth and elevation angle, respectively, $E_i(x, y)$ is the incident angle, and A is the area of the flat plate. If one takes

$$\begin{cases} u = 2k\sin\alpha \\ v = 2k\cos\alpha\sin\beta \end{cases}. \tag{28}$$

then one has

$$E_s(\alpha,\beta) = \iint_A E_i(x,y)e^{j(xu+yv)}dxdy. \tag{29}$$

The inversion of the scattered field gives

$$E_i(x,y) = 4\pi^2\iint_{u,v} E_s(u,v)e^{-j(xu+yv)}dudv. \tag{30}$$

This method is particularly suitable for THz CATR evaluation since the scanning of such a large area is almost an impractical mission over a range of frequencies. In addition, electrically large plate only produces very large value of RCS in very narrow area of view of angle. It suffices to measure the RCS in a range of $(-20°, 20°)$. To further improve the measurement accuracy, the calibration of the RCS measurement could be implemented through single-reference, three-target calibration measurement technique (Wiesbeck and Kähny 1991).

DOI 10.1007/978-981-4560-75-7_47-1

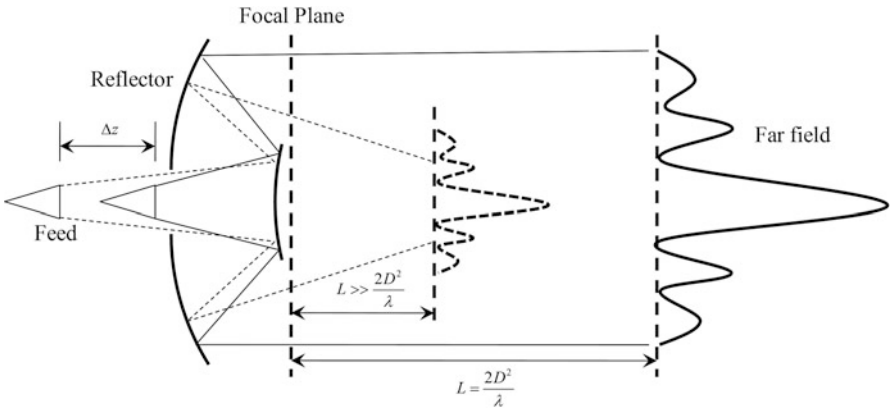

Fig. 32 Defocusing method

Other Methods

The far field of an antenna can be moved closer to its aperture plane by moving the feed out of the focal plane, as shown in Fig. 32 (Hohnsn et al. 1973). By using the thin-lens formula,

$$\frac{1}{d_2} = \frac{1}{F} - \frac{1}{d_1}, \tag{31}$$

where d_2 is the far-field distance, d_1 is the distance of the feed to the focal point, and F is the focal length of the antenna. If the feed is located at the focal point, then the far field will be infinite, while if the feed is displaced by a certain distance, the far field will be much closer to the antenna. Despite that this method enables one to measure the far field at the same distance of near field, the drawbacks are also apparent. For the THz systems, the movement of the feed may not be possible. In addition, it assumes that the defocusing of the feed affects the phase only. In fact, the amplitude may also need to be considered.

Actually, the measurement of antenna deployed on a THz system is a challenging task. To assess the performance of a THz antenna in the operating environment, one has to use an electrical and mechanical combined method. One example is the measurement of the antenna deployed on the Planck telescope. The test strategy employed is to measure the surface dimension of the antenna under the in-orbit condition using the optical methods photogrammetry and interferometry. Then, the measured dimension data are fed to GRASP for simulation at a relatively low frequency (320 GHz). The electrical measurement of the antenna is conducted using the near-field scanning at 320 GHz. Correlating the simulated and measured antenna performance at 320 GHz, the performance at even higher frequency is estimated using simulation alone. Though not ideal, this combined method has managed to predict the radiation pattern of the Planck telescope antenna in orbit.

There are several methods to measure the surface of a reflector antenna. A most straightforward method is using a three-coordinate gauging machine. Such a method is of course very time consuming for electrically large antenna and may have accuracy issues as well. The photogrammetry and interferometry techniques, however, provide an efficient and accurate method for electrically large reflector antenna measurement. In general, photogrammetry measures large-scale to medium-scale deformation, while interferometry measures small-small deformation. This kind of two-phase technique allows one to derivate the global shape as well as align the reflector. The cost of this method is also apparent. (1) Large arrays of cameras have to be employed. For instance, 250 camera stations were utilized in the Planck telescope verification; (2) Surface reconstruction has to be implemented based on a large set of data; (3) RF characterization using conventional antenna measurement techniques has to be conducted at low frequency; (4) Simulation using physical optical method is normally computational resource

DOI 10.1007/978-981-4560-75-7_47-1

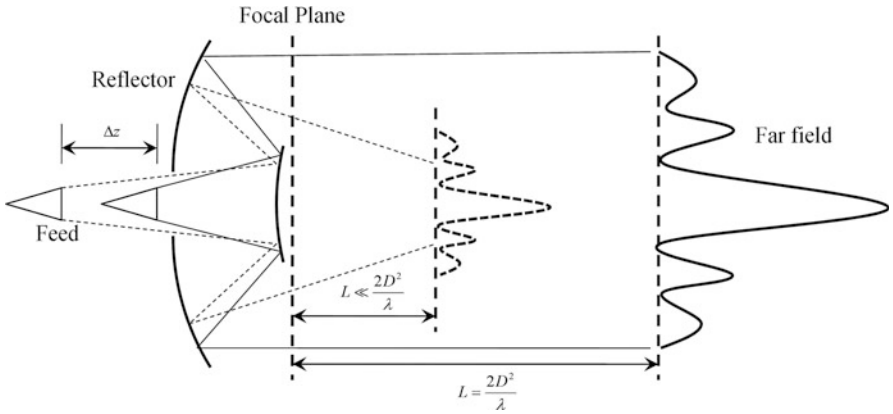

Fig. 33 The process of electrical–mechanical combined method

demanding. Nevertheless, before any other approaches are accessible to the THz RF verification of electrically large antenna, such a method after all provides a possibility. The procedures are illustrated in Fig. 33.

Summary

The antennas operating in the THz band and their associated measurements have been reviewed in this chapter with a focus on the basic concepts and operating principles.

In the THz range, the design of an antenna often has much more to consider than its lower-frequency counterpart such as sources and fabrication issues. The photoconductive antenna, though being called an antenna, is an integrated THz signal generator. Various methods have been explored in order to increase its directivity and the radiation power. Other high-gain antennas such as horn antennas and reflector antennas often have fabrication issues in the THz range due to its short wavelength.

Another challenge arises from the THz antenna measurement. The near-field and CATR measurement techniques are possible but not free of problems in the frequency range up to 1 THz. However, there is no feasible RF measurement method in the frequency range higher than 1 THz. For example, the 3.5 m diameter antenna on the Herschel telescope operating up to 5 THz wasn't measured electrically at all but was only simulated based on the surface shape measurement.

In the near future, the antennas and their measurement in the THz band remain as a technical challenge. It is hoped this challenge will be overcome with the development of high-power THz sources and advanced fabrication process in the long run.

Acknowledgment

The tri-reflector CATR presented in this Chapter is part of the work of the pre-research program (Funded by the Chinese Ministry of Industry and Information) led by Prof. Junsheng Yu with Beijing University of Posts and Telecommunications.

Small Antennas

Kyohei Fujimoto[a]* and Zhinong Ying[b]
[a]Institute of Applied Physics, University of Tsukuba, Tsukuba, Japan
[b]Research and Technology, Sony Mobile Communication, Lund, Sweden

Abstract

This chapter first provides basic treatment of small antennas (SAs), beginning with overview; definition, giving four types; discussions of the limitation related with the size and Q or the bandwidth; and significance of SA, in which a short history is included. Then, principles and methods of making antennas small based on those principles are described for four types of SA. Representative examples of practical SAs are introduced for the four types individually by referencing recent technical journals. Finally, the future prospective of SA is discussed.

Keywords

Electrically small antenna (ESA); Principles and methods of creating small antenna (SA); Definition of SA; Limitation in SA; Use of slow-wave structure; Metamaterial applied in SA; Integrated and composite SA; Space effectively used by SA

Introduction

With emergence of various wireless systems, including mobile phones, broadband systems, high-rate data transmission systems, radio-frequency identification (RFID) systems, body-centric communication systems, and wearable systems, requirements for small antennas (SAs) are rather urgent, and many SAs have so far been newly developed and practically applied to terminals of wireless systems. Because most wireless systems use small terminals, antennas mounted on such terminals are inevitably SAs. Practically, many small terminals require ESA; however, SAs used so far are not only those having small dimensions but also some functions to implement a variety of performances, including wideband, multiband, reconfigurable operation and other sophisticated operations (FSA). Practical SAs with low-profile structure (PCSA) and having simply physically small dimensions without regarding the operating frequency (PSA) are also significant in small wireless terminals. Each of these four types of SA is appropriately designed and applied to related systems.

This chapter intends to provide engineers and researchers in the fields of antennas and communications with basic concepts, fundamental treatment, methods, and techniques to make antennas small based on the principles; multiple examples are introduced showing practical modern SAs, which can guide design and development of newly required SAs.

This chapter consists of five parts: (1) general principles of SA, (2) short history of SA, (3) principles and methods of producing SA, (4) practical examples of SA, and (5) future perspectives for SA.

Small Antenna Generalizations

Overview of Modern Small Antennas

Many recent small antennas (SAs) are not only types of electrically small antenna (ESA), having much smaller dimensions with respect to the operating wavelength, but also other types that can be classified based on functions and dimensions with different aspects than the wavelength. All of those SAs have been used practically in various wireless systems not only for communications but also radio control, radio identification, data and video transmission, sensors, and so forth, as the indispensable component in the systems. Among those wireless systems, the most popular and significant wireless applications are mobile systems that deal with voice, data, and image transmission, radio identification, and wearable systems. Typical voice transmission mobile systems are cellular phones, which have presently advanced to smartphones and data tablets for transmitting information, images (both still and moving), large-quantity data, NFC (near-field communication) systems, and wearable systems including body-centric communication and biomedical systems.

Those wireless systems require small antennas, since the size of their equipment is generally small and the space to install antennas is restricted to a limited narrow area. In addition, antennas for some mobile terminals not only should be small but should facilitate wideband or multiband capability, because the relentlessly increasing trend in such mobile terminals is to equip them with multiband and other systems such as GPS, WLAN (wireless local area network), Wi-Fi (Wireless Fidelity), etc. as well as telephony. Although multiple operation is required, antennas must still necessarily be small.

Furthermore, the wireless world should expect emergence of a new system in the near future, cognitive radio, by which effective and flexible use of radio spectrum in wide frequency bands will be made feasible (Dudley et al. 2014). This system will urge further needs of ultra-wideband small antennas.

Nevertheless, small antennas play very significant roles in the wireless systems for various situations, as they are always indispensable components.

Design and development of small antennas need special considerations, especially when the dimensions become smaller and designers encounter difficult situations to conquer trade-offs between practical requirements and the fundamental limitation of SA. What the fundamental limitation addresses is relations of antenna size with the bandwidth in transmitting antennas and, in a similar way, relation of antenna size with the noise factor or SNR (signal-to-noise ratio) as well as the bandwidth in receiving antennas.

The fundamental limitation of SA was first treated by H. A. Wheeler in 1947 (Wheeler 1947). The discussion on the limitation is still continuing up through today to obtain reasonable conclusions.

The essential issues to realize a small antenna are to overcome difficulties based on the limitation and create a small antenna which can exhibit performance approaching the limitation as closely as possible. Nevertheless, modern small antennas have shown significant progress. Various novel functional and intelligent antennas, yet with small dimensions, have been developed. Design techniques have also advanced along with emergence of new wireless systems, for which novel antennas are required.

Small antennas have so far been used in numerous wireless systems in various fields; however, the importance of them may be overlooked as many of them are invisible, since they are installed inside the small units of wireless equipment.

Definition of Small Antenna

The term electrically small antenna (ESA), which is defined in terms of the operating wavelength, generally has been used as regards SA. However, there are numerous other types of small antennas defined in different aspects from the wavelength, that is, with respect to function and physical dimensions. When an antenna is constructed to have enhanced performance, with the size kept unchanged, the antenna

DOI 10.1007/978-981-4560-75-7_48-3

is considered effectively small, since the performance exhibited by the antenna may be that produced by a larger antenna. This type of antenna is defined in regard to the function and named as functionally small antenna (FSA). Other types of antennas made in low-profile or thin structure, the thickness of which is much smaller than the wavelength, can be defined from a dimensional point of view as physically constrained small antenna (PCSA), as a part of the antenna is constrained to be small. Typical example of PCSA is MSA (microstrip antenna).

Another type is an antenna having physically small dimensions, but not necessarily small in relation to the wavelength, for example, a physically small antenna that can be put on a human palm, even though it could be electrically large. This type of antenna is defined as physically small antenna (PSA). There is no exact physical meaning in PSA as there is with other types of small antennas. A small millimeter-wave horn antenna is one of the PSAs when the operating frequency is in the SHF region and the physical size of the antenna aperture is a few cm, which is a few wavelengths and not electrically small.

The classification of small antenna is not unique for an antenna, because one antenna can be included in two or more types of category; for instance, a PCSA can be an ESA, if the whole structure of a low-profile antenna is much smaller than the operating wavelength. ESA is defined from another aspect by taking account of a dimensionally numerical value, that is, when the whole antenna structure is put into a sphere of the radius a which satisfies $ka \leq 0.5$ ($k = 2\pi/\lambda$) (Fujimoto and Morishita 2013; Volakis et al. 2010a). This sphere is the minimum-sized one that encloses the whole structure of an antenna and is referred to the "Chu sphere."

Another example is a small multiband mobile terminal antenna, which is classified into an FSA and can be at the same time an ESA, if the maximum size of the antenna structure can be embraced by a sphere with radius a and ka is smaller than 0.5.

There are many small antennas which are not only electrically small but also functional, defined as FSA and another type, PCSA, when the thickness is very thin.

Limitation in Small Antennas

When the size of an antenna is made smaller, the bandwidth tends to grow narrower with reduction of the size. In turn, antenna Q is increased as the antenna size is reduced. As Q becomes large, the bandwidth becomes inversely proportional to Q, implying that the reduction of the antenna size gives rise to increased Q and makes the bandwidth narrower.

Now, it should be noticed that increase in the antenna Q with the antenna size reduction is not limitless but bounded by some value. This is the limitation inherently observed in small antennas; that is, the antenna Q or the bandwidth cannot take excess value over the limit value that corresponds to the antenna size. In other words, for a small antenna, a greater bandwidth or a lower Q that violates the limit value depending on the size cannot be achieved.

Wheeler first discussed limitations of small antennas in 1947 and showed that Q of a small antenna for the most limiting case was $Q = 1/(ka)^3$ where k is the wave number $2\pi/\lambda$ and a is the radius of the minimum-sized sphere which encloses the whole structure of an antenna. This indicates Q is inversely proportional to the three-dimensional antenna size, and hence the antenna size imposes a fundamental limitation on the bandwidth B, as when $Q > 1$, the fractional bandwidth B is considered approximately inversely proportional to the Q.

Chu followed Wheeler's work (Chu 1947) and studied the limitation by using spherical vector wave functions, from which the minimum possible Q for an antenna enclosed in the Chu sphere along with the maximum G/Q (G, gain) was derived.

Limitation of the small antenna was studied by many researchers with considerations on the antenna configuration, current distributions, gain, impedance, exciting modes, and polarizations (Volakis et al. 2010b; Fujimoto and Morishita 2013). Some representative expressions are McLean's (McLean

DOI 10.1007/978-981-4560-75-7_48-3

1996) and Thal's (Thal 2006. 2009). McLean presented the limitation of Q for a Chu antenna (antenna enclosed by the Chu sphere) as

$$Q \leqq (1/M)\left[1/(ka)^3 + M/(ka)\right] \tag{1}$$

where M refers to the excitation mode (linear polarization). M = 2 means equal excitation of both TE and TM modes (either linear or circular polarization), while M = 1 indicates when only either TE or TM mode (linear polarization) is excited. When M = 2, the absolute lowest Q is obtained by an antenna of a given size. Thal gave the minimum Q as $1.5/(ka)^3$ for TM_{10} mode radiation, $3/(ka)^3$ for TE_{10} mode radiation, and $1/(ka)^3$ for both TE_{10} and TM_{10} mode radiation assuming surface current distributions on the Chu sphere surface.

Hansen has shown a new formula for Q of a Chu antenna (Hansen and Collin 2009) as

$$Q \leqq 3/2(ka)^3 + 1/\sqrt{2}\,(ka) \tag{2}$$

These results can be compared with Wheeler's limitation,

$$Q \leqq 1/(ka)^3 \tag{3}$$

When the antenna size becomes smaller, Eq. 1 approaches to Eq. 3 and Eq. 2 becomes Thal's results.

Nevertheless, as Wheeler's limitation is understood as the lowest achievable Q for an antenna of given size, design of ESA is a sort of challenge to realize antenna having Q or bandwidth which can approach the limitation as closely as possible.

Significance of Small Antenna

Small antennas are crucial devices and recognized as being indispensable for any wireless systems. This understanding continues up through today since the earliest days of radio communications when ESAs began to be used. Antennas used first in communication systems were ESA, although the antenna dimensions were physically large, as the operating frequency bands were LF and MF. The communication range was gradually extended along with the progress in the communication systems from telegraphy to voice transmission. This progress was attributed greatly to the advancement of the antenna technology. Dimensions of antennas had gradually reduced as the frequency allocation progressed to higher bands like HF and VHF, by which long-range communication, even covering worldwide areas, was realized. In those days, antennas practically applied were not only ESA but also other types of small antennas, and though small, their role in communication systems was important. Advancement in antenna technology contributed to progress in communication systems, and in turn communication systems inspired progress in the advancement of antennas.

Recent communication systems cover wide ranges of transmission for voice, image, data, and radio control, radio identification, sensors, and wideband signal transmissions, including both moving and still images, wearable systems, and so forth. Most of those systems have mobile applications, where equipment is generally small, and antennas to be installed are inevitably small and mostly built into the equipment. In any wireless system, a small antenna is naturally indispensable. There may be cases, where small antennas would determine the system performance, when the RF front end of the wireless system is designed optimally, and to further improve the performance as is required is almost impossible.

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_48-3

The latest mobile systems widely used in public are smartphones, handheld tablets, and wireless broadband systems. Other mobiles are radio sensors, RFID (radio-frequency identification), and wearable systems, including body-centric communications. Types of antennas used for those systems can be any of ESA, FSA, PCSA, and PSA. There is growing need for mobile systems that operate multiband or wideband, as systems tend to include more than two subsystems like GPS, WLAN (wireless local area network), Wi-Fi (Wireless Fidelity), etc. that operate in different frequency bands. Thus, antennas for those systems are designed to perform multi- or wideband, corresponding to the systems, without significant change in the dimensions. Furthermore, some systems require antennas to have functions such as frequency or pattern reconfigurable operation, diversity, and so forth, keeping the antenna size increase as small as possible. In any case, importance of small antennas does not vary depending upon the system and will continuously grow with further prevalence and advancement of mobile systems.

The latest topic in the wireless world is expectation of practical cognitive radio in the near future, which will require small UWB (ultra-wideband) antennas. Antenna engineers who design small UWB antennas will overcome the fundamental limitation regarding antenna size related with bandwidth and efficiency/gain.

Each era has been lively with innovative antenna development along with progress in new social systems decade to decade. Obviously small antenna technologies will advance along with the progress in the wireless systems; in turn, progress of the small antenna technologies will inspire advancement of the wireless systems. Significance of small antennas will further be augmented generation to generation.

Short History of Small Antenna

Antenna history started with a small antenna in 1846, which was inaugurated by J. Henry, who experimented with spark-gap transmission and reception by using a small loop loaded with an induction coil (Fig. 1). Many pioneers like Edison, Hertz, and Lodge did experiments of radio-wave radiation and reception by using electrically small antennas (ESAs), although the dimensions were physically large, as the frequency bands used were LF and MF. Types of antennas used in those days were thin long wires, monopoles, biconical dipoles, loops, and so forth (Rumsey 1981). By replacement of the early

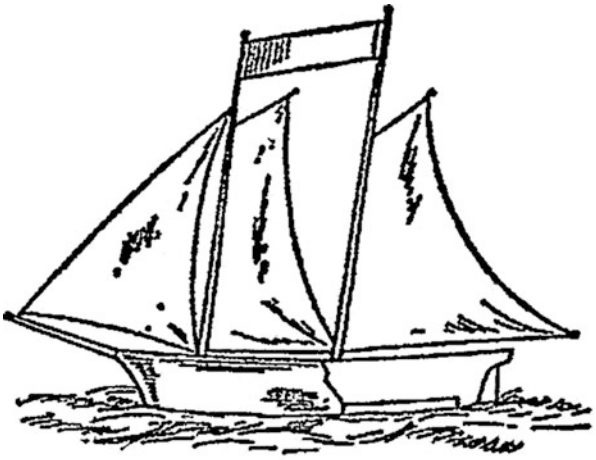

Fig. 2 Wire invented - L antenna used in ship

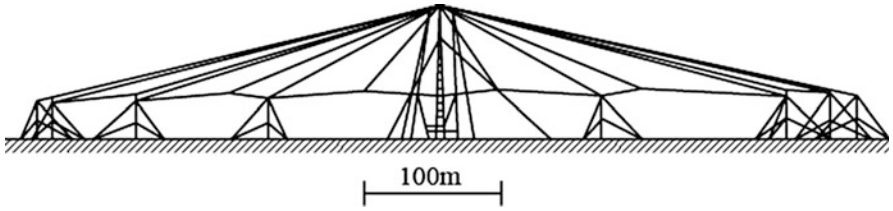

Fig. 3 Top- Loading technique applied umbrella type antenna

radiotelegraphy spark-gap transmitters, longer-distance communication was promoted, and various antenna technologies such as grounding of one antenna terminal to the earth, resonance by using LC circuits, and impedance matching were developed.

The world's first radio communication accomplished by Marconi in 1901 used also types of ESA, although they were physically quite large; the antenna at the England site was the fan type having dimensions of 48-m wide and 68-m high, but that is only several tenths of the operating wavelength about 3000 m (820 KHz). Since then, radio communications over the Atlantic Ocean spread to be used between ships and coasts in the early 1900s. Ship antennas were mostly thin long wires or wired inverted-L types (Fig. 2).

In 1906, the frequency spectrum for the radio communications was restricted to LF and MF bands for ships, long-distance land communications, and military use. Since then, many large, low-frequency antennas were developed. To shorten the long-wire antennas, top-loading technique was invented. Later, by applying the top-loading technique, a new flat-top antenna like an umbrella (Fig. 3) was developed. Since radiation efficiency of those antennas was very low, multiple tuning techniques were invented for improving the efficiency. Antenna technology had further advanced to achieve directional radiation by arraying antenna elements. The directional radiation was designed by using another technique, the use of a traveling wave on a long wire placed in parallel to the ground with low height. Other antenna types practically used in those days were (a) T shape, (b) inverted L, (c) harp shape, (d) rhombus, (e) flat top (Fig. 4), and so forth; all of those were ESA. In the late 1930s, slot antennas and ferrite antennas were put into practice.

With progress in generation, operating frequencies tended to be higher, and in the mid-twentieth century, HF was the major band, and aeronautical radio and marine radio were made feasible. Remarkable advancement of small antenna technology can be attributed to World War I (1914–1918) and World War II

(1939–1945) due to the needs for military communications for airplanes and airships, as well as for land systems. The type of antennas used in such communication systems during World War I was mainly a thin $\lambda/4$ wire monopole, which was installed on the equipment body (metal) that was considered as the ground. Significant progress seen in World War II was mobile systems, particularly for land mobiles used for military force and vehicles.

System advancement was accelerated by introduction of higher-frequency bands, VHF, and FM technology. After the war, application of mobile systems was further expanded to various new mobile systems for the public: telephones for personal use and on the airplane. Another notable subject in the 1940s was study of the fundamental limitation of small antennas, initiated by Wheeler in 1947. The discussion on the limitation has still been active in the present days.

In the 1950s, the UHF band was opened to the public and design concepts of antennas for mobile systems changed. The body of the small radio unit (metal) traditionally considered as the ground was changed to be treated as a part of the radiator, to which the ground was included. This result gave rise to improving the antenna performances. In the mid-1950s and later, spiral antennas were developed and applied to various wideband systems. By using spiral structures, design of a small antenna having wideband or UWB (ultra-wideband) characteristics has become feasible. Other antenna types used in those days were newly developed NMHA (normal-mode helical antenna), IFA (inverted-F antenna) (Fig. 5a, b), and various composite antennas, for instance, combination of a dipole and a loop.

DOI 10.1007/978-981-4560-75-7_48-3

In the 1960s, systems underwent changes through time with emergence of various new systems and services, which deployed according to the social needs; they were radar, space communication, TV broadcast, mobile systems, and so forth. Along with advancement of systems, antenna technologies progressed.

It should be noted that the design techniques of small antennas changed remarkably to treat an antenna with a comprehensive concept in which wireless system, propagation, and environmental conditions were included, and so the design concept of small antennas has advanced to treat an antenna as a "system." There were some occasions where the antenna performance, in particular with a small antenna, could finally dominate the system performance. Considerations of the environmental conditions, including wireless unit body and hardware nearby the antenna element within the unit, are vital in the design of a small antenna, because all of those factors affect system performance. When the system unit is a handset, influence of the unit operator's hand, head, and body affects antenna design as one of the crucial parameters.

The concept of integrated antennas was introduced in the late 1960s, which contributed to miniaturization of an antenna and to produce functional antennas. These are generally called IASs (integrated antenna systems) (Fujimoto 2005), since they work as a system, where their structures, being composed of passive or active devices, are dealt in total with systematic concepts. Among them, AIAS (active integrated antenna system) is devoted to small-sizing antennas, particularly in application to the matching. Very small antennas exhibit very large reactive components but very small resistive components in their input impedances, making proper matching difficult. An NIC (negative impedance converter) (Linvill 1953), which is one of the representative AIASs, is used for overcoming the matching problem in very small antennas. The NIC can be used at either the antenna load terminals or in the near field of a radiator. The latter is known as space matching (Stuart and Pilwerbetsky 2006; Billoti et al. 2000; Fujimoto and Morishita 2013), which is a recently introduced technology.

In the 1970s, public mobile phones called cellular phones were first introduced. That technology has progressed to the fourth-generation system from the first systems in the 1980s, and antenna systems used in mobile terminals (handsets) evolved from a wire monopole to planar types such as PIFA, MSA, and parallel plate, and they were at last entirely built into the equipment body. In some phones, functional performances such as diversity, frequency reconfigurable control, and pattern control were required and so facilitated. Those antennas were classified into the type of FSA.

In the 2000s, an increasing demand for access to information anywhere, anytime led to an explosive growth of wireless technologies and accelerated the emergence of various wireless broadband systems, such as Wi-Fi, WiMAX (Worldwide Interoperability for Microwave Access), WLAN, and the advanced mobile system LTE (Long-Term Evolution) evolved from cellular phones, which can deal with high-data-rate signals including both still and moving images, large amounts of digital data, and high-quality sounds as well as voice. Antennas for those wireless broadband systems had made remarkable progress along with the newly developed systems, where wideband operation covering wide frequency ranges are needed – several tens of MHz and UWB (ultra-wideband).

Most of the latest practical antennas have been no longer simple like just a dipole, a monopole, or a loop but constructed in composite structure with the shape transformed to perform wideband or multiband, integrated types to facilitate function, and combined arrangement of two or more types of antenna to operate adaptive control, even with the small dimensions as ESA. In the integrated antennas, active devices are used as AIAS (active integrated antenna system), which of course contributes to antenna small-sizing. NIC (negative impedance converter) is a representative AIAS. For a very small antenna, which exhibits difficulty in matching because of highly reactive and very small resistive impedance, an NIC can be applied to ease this difficulty, as it can compensate highly reactive components.

Contribution of electromagnetic materials to advance antenna technology is notable. Dielectric or magnetic materials have long been applied to antennas for making the dimensions small. In addition,

DOI 10.1007/978-981-4560-75-7_48-3

recently introduced metamaterials which exhibit either negative mu, negative epsilon, or both play an important role for creating such versatile antennas as miniaturized ones; functionalized ones; ones provided with enhanced performances, including reconfigurable control; and so forth. Those antennas can be any of ESAs, FSAs, PCSAs, and PSAs.

Principle and Method for Small-Sizing an Antenna

Principle in General

The fundamentals of small-sizing an antenna are to lower the resonance frequency, while the size of the antenna is kept much smaller than the operating wavelength. Another aspect is to either improve or enhance the performance of the antenna without varying its size significantly. The former is for producing ESA while the latter is for creating FSA. PCSA can be realized by lowering the profile of an antenna. The simplest way is to thin down the thickness of antenna much smaller than the operating wavelength. PSA is simply to compose an antenna physically small, regardless of the operating wavelength.

Following are methods of small-sizing antennas.

Methods of Small-Sizing an Antenna

Methods of small-sizing an antenna differ depending on the type of antenna.

ESA

The major principles for realizing an ESA are to:

(a) Lower the resonance frequency
(b) Extend/increase the current paths on the surface of the antenna element
(c) Occupy antenna space more effectively
(d) Increase number of radiation modes
(e) Make current distributions on the antenna element uniform

These are to be accomplished while the antenna size is kept unchanged. The following are practical methods for producing an ESA:

Lower the Antenna Resonance Frequency

Lowering the resonance frequency of an antenna while keeping the antenna size unchanged implies effectively small-sizing of an antenna, since the lower resonance frequency corresponds to that of a larger antenna.

There are various methods to lower the resonance frequency of an antenna without changing the antenna dimensions.

The use of a slow-wave structure

This is the typical method for lowering the resonance frequency of an antenna. Slow wave is a wave that travels a medium with slower phase velocity v_p than that of free space c; that is, $\mathbf{c} > v_p$. By applying the slow-wave concept to an antenna structure, the resonance frequency f_p of the antenna can be lowered. It can be explained by noting since $v_p = \boldsymbol{\omega}_p/\boldsymbol{\beta}_p$ ($\boldsymbol{\omega}_p = 2\pi\ f_p$ and $\boldsymbol{\beta}_p$ is the phase constant), $\boldsymbol{\beta}_p = 2\pi f_p/v_p$, and $\mathbf{c} = \boldsymbol{\omega}_0/k$ ($\boldsymbol{\omega}_0 = 2\pi f_0$ and k is free-space phase constant), then $v_p/\mathbf{c}$, and $f_p/f_0 < 1$. From this $f_p < f_0$, meaning that the resonance frequency of the antenna is lowered without changing the size by means of slow wave.

DOI 10.1007/978-981-4560-75-7_48-3

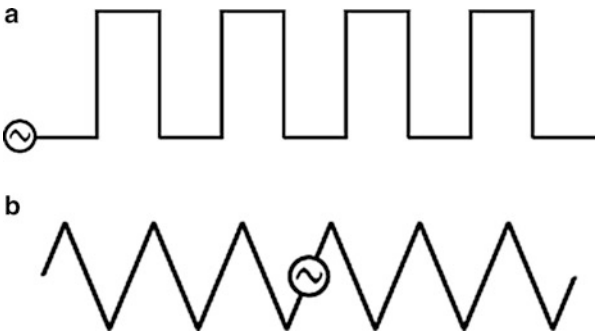

Fig. 6 Slow wave (SW) structures; a. Meander-line and b. Zigzag-line

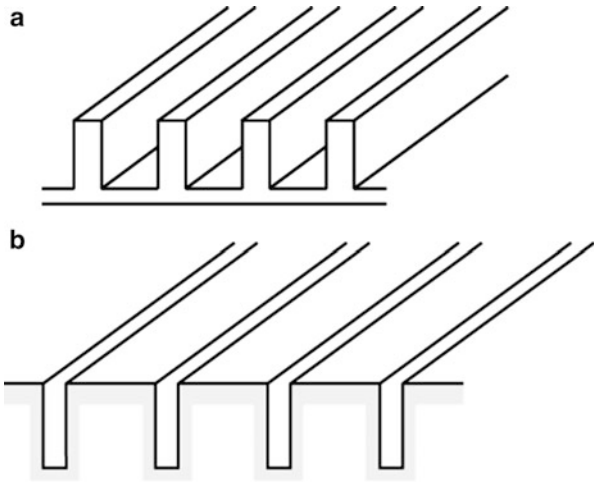

Fig. 7 3D SW structures: conductor with a. corrugation and b. trough on the surface

Practical examples of slow-wave structure are as follows:

1. Periodical structure

   The slow-wave structure is attained by periodical arrangement of wire or planar elements and solid material. Meander line, zigzag line, etc. (Fig. 6 (a) meander line, (b) zigzag) are examples of wire-type elements. Examples of solid structures or 3D type are those having corrugation or troughs on the surface of the materials (Fig. 7(a) Corrugation, (b) trough). Conducting sheet with holes on the surface is an example of planar type (Fig. 8).
2. Electromagnetic materials

   Electromagnetic (EM) materials such as dielectric or magnetic materials convey slow-wave properties and hence can be used for reducing antenna size. Within the EM materials with permittivity $\boldsymbol{\varepsilon_r}$ or permeability $\boldsymbol{\mu_r}$, an EM wave travels with phase velocity $v_p = \mathbf{c}/\sqrt{\boldsymbol{\mu_r}\boldsymbol{\varepsilon_0}}$ or $\mathbf{c}/\sqrt{\boldsymbol{\varepsilon_r}\,\boldsymbol{\mu_0}}$.

   In addition to ordinary EM materials, metamaterials (MMs), which exhibit properties of negative mu/epsilon, transport an EM wave with slower velocity v_p than that of light **c**, meaning that MMs have slow-wave properties and are useful for producing a small antenna.

DOI 10.1007/978-981-4560-75-7_48-3

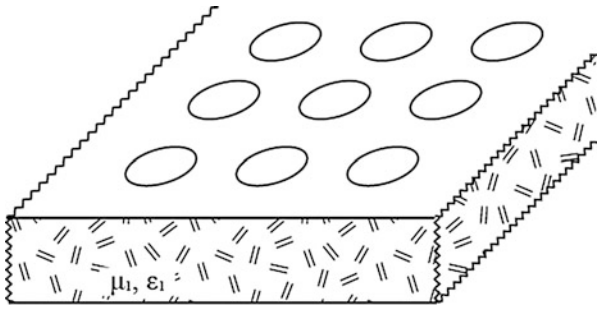

Fig. 8 2D SW structures: conducting sheet with holes on the surface

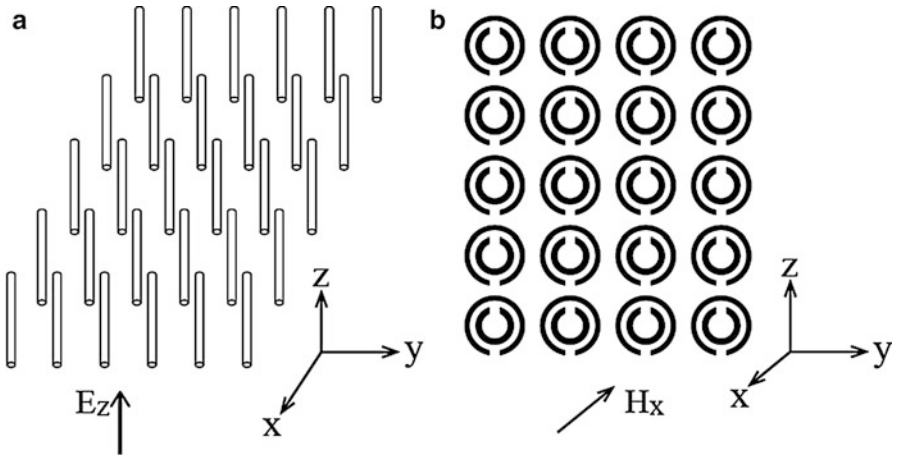

Fig. 9 Meta materials: a. dense array of wires exhibiting negative ε property and b. array of split- ring resonators (SRR) exhibiting negative μ property

The MMs are known as materials that are not available in nature, as they have uncommon properties. In practice, equivalent materials which have negative $\boldsymbol{\varepsilon}$ can be realized by using a dense array of wires (Fig. 9a) (Pendry et al. 1998), while a negative $\boldsymbol{\mu}$ property can be achieved by an array of SRRs (split-ring resonators) (Fig. 9b) (Pendry et al. 1999).

Another way to compose artificial MM structures is the use of a transmission line (TL), which can be devised to exhibit negative constitutive parameters ($-\boldsymbol{\varepsilon}$ and $-\boldsymbol{\mu}$), by arranging TL parameters (Lai et al. 2004). This TL is said to be a medium having left-handed (LH) property (Caloz and Itoh 2009) and is characterized by the property of negative propagation constant –k ($k = 2\pi/\lambda$) by the attributes of $-\boldsymbol{\varepsilon}$ and $-\boldsymbol{\mu}$. The term LH is originated from the concept of right-hand (RH) rule (Johnk 1975), derived from the use of a right hand to indicate the directions of the wave vector k and the Poynting vector $S = E \mathbf{x} H$ (E, the electric field; H, the magnetic field) as shown in Fig. 10a, b. In the LH media, the direction of the wave vector –k is opposite to that of S which is illustrated by Fig. 10c.

LH media can be realized equivalently by a transmission line (TL). A TL, on which a TEM wave propagates, is expressed by a model comprised of periodical connections of equivalent circuits with unit length *l*, consisting of a series per unit length impedance Z and a shunt per unit length admittance Y as shown in Fig. 11a, b, where dispersion characteristics on the β-ω coordinate are given. The

DOI 10.1007/978-981-4560-75-7_48-3

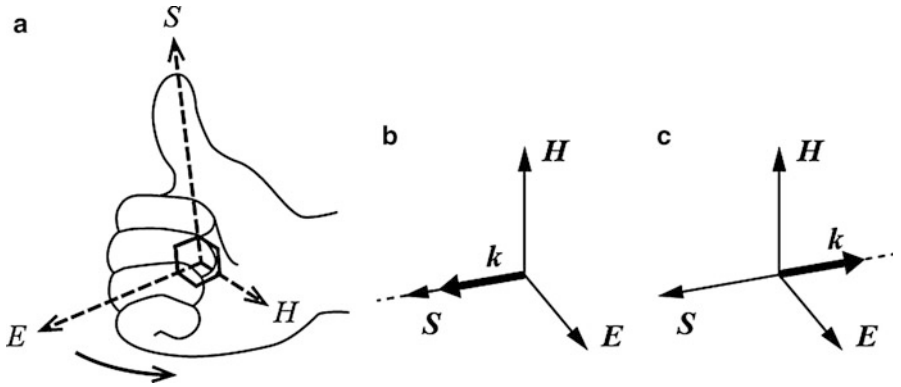

Fig. 10 (a) Explanation of Right -hand (RH) rule and direction of vectors, (b) RH case and (c) left-Hand (LH) case

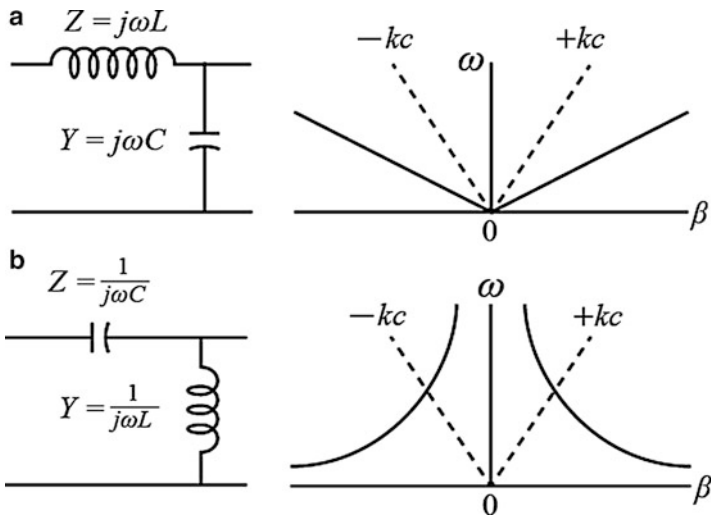

Fig. 11 Equivalent circuit of a transmission line unit cell consisting with a series impedance Z and a shunt admittance Y. (a) LC circuit and (b) CL circuit and dispersive characteristics of each circuit

immitances Z and Y, respectively, are given by using constitutive parameters $\boldsymbol{\varepsilon}$ and $\boldsymbol{\mu}$ of the propagation medium as

$$\mathrm{Z}(\boldsymbol{\omega}) = \mathrm{j}\boldsymbol{\omega}\boldsymbol{\mu}$$

$$\mathrm{Y}(\boldsymbol{\omega}) = \mathrm{j}\boldsymbol{\omega}\boldsymbol{\varepsilon} \tag{4}$$

The immitances Z and Y in Fig. 11 are expressed by lumped circuit parameters C and L. By using these parameters, the effective constitutive parameters $\boldsymbol{\varepsilon}_{\mathbf{eff}}$ and $\boldsymbol{\mu}_{\mathbf{eff}}$, respectively, of the circuit (a) are given by

$$\boldsymbol{\varepsilon}_{\mathbf{eff}} = \mathrm{C}/l$$

$$\boldsymbol{\mu}_{\mathbf{eff}} = \mathrm{L}/l \tag{5}$$

and in the circuit (b), they are expressed by

DOI 10.1007/978-981-4560-75-7_48-3

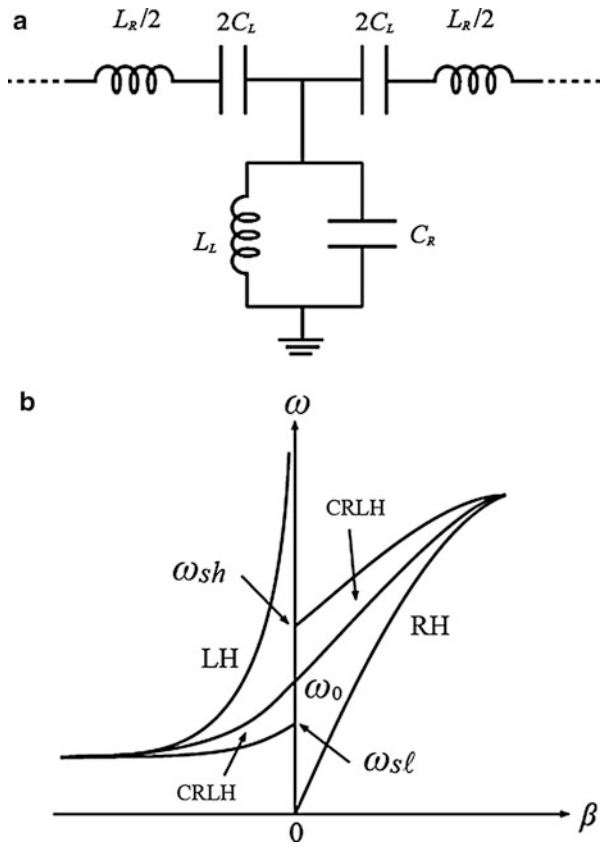

Fig. 12 (a) Unit of TL expressed by a T- circuit and (b) dispersive characteristic

$$\boldsymbol{\varepsilon}_{\mathbf{eff}} = -1/\left(\boldsymbol{\omega}^2 \mathrm{L}/l\right)$$

$$\boldsymbol{\mu}_{\mathbf{eff}} = -1/\left(\boldsymbol{\omega}^2 \mathrm{C}/l\right) \tag{6}$$

The TL with constitutive parameters given by Eq. 6 is considered an LH media as they are negative. The LH media has property of negative propagation constant –k, the attribute of $-\boldsymbol{\varepsilon}$ and $-\boldsymbol{\mu}$. The circuit model shown by Fig. 11b is characterized by negative phase constant –β as is observed in the dispersion characteristics given in Fig. 11. In the dispersion diagrams, dotted line gives k**c**, and the region below this dotted line is that where β is greater than k, indicating that in this media the phase velocity v_p is smaller than **c** (free-space velocity), meaning the media supports slow waves.

In practice, the complete equivalent circuit including a parasitic series inductance and a parasitic parallel capacitance is depicted by a T circuit composed of series reactance L_R and C_L and shunt reactance L_L and C_R as is shown in Fig. 12a, and the dispersion characteristic in the β-ω coordinate is also illustrated in Fig. 12b. In the figure, ω_{sh}, $\omega_{s\ell}$, and ω_0 are series resonance frequency, parallel resonance frequency, and the transition frequency, respectively. They are given by $\omega_{sh} = 1/\sqrt{L_R' C_L'}$, $\omega_{s\ell} = 1/\sqrt{L_L' C_R'}$, and $\omega_0 = \sqrt{\omega_{sh}\omega_{s\ell}}$, respectively. Prime (′) indicates parameters per unit length and times unit length. Which is higher ω_{sh} or ω_{se} depends on the circuit parameters. The circuit behavior appearing in the –β region in the diagram shows LH region, while that in the +β region expresses RH region. The CRLH line gives the circuit behavior having both LH and RH properties, and ω_0 is the frequency where the circuit property transfers from LH to RH or vice versa. This type of TL exhibits

DOI 10.1007/978-981-4560-75-7_48-3

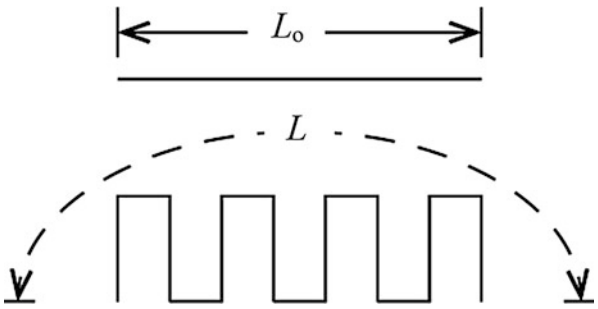

Fig. 13 Extension of current path by a meander-line compared with a straight line

behavior of either LH or RH or both depending on the parameters and is referred to as CRLH (composite RH/LH) TL (Caloz and Itoh 2005). The equivalent circuit shown in Fig. 12 is considered as the most general form of a CRLH TL structure of unit cell with LH attributes. By arranging the circuit parameters, the TL having either or both LH and RH behaviors can be designed.

By using the LH and RH behavior of a TL, the versatile application to develop novel antennas can be expected. For example, backward radiation can be realized by using the LH behavior, and beam sweeping can be obtained by switching RH and LH behaviors arranged on a TL.

3. Compose antenna by combining with different types of antenna

Resonance frequency can be lowered by composing an antenna with different types of antenna elements having different resonance frequencies. Modification of antenna geometry to a different shape is also a useful way to lower the resonance frequency. By modifying antenna geometry, the number of radiation current paths on the surface of the antenna increases so that resonance frequency is lowered. There is another modification of current paths with change in the direction of the current flows that will result in widening the bandwidth.

Extend/Increase the Path of Current Flows

Extension of current path on the surface of an antenna element makes the resonance frequency lower.

(a) Use of periodical structures

Previously introduced meander line, zigzag line, etc. are typical ones, as their length (extended length L) is longer than the length L_0 of the linear line (Fig. 13). In case of the planar antennas, the simplest way is to put slots/slits on the antenna surface so the current flow takes roundabout ways around the slot/slit (Fig. 14) so that current paths become longer and the resonance frequency becomes lower.

(b) Varying antenna geometry

Making the area of a planar antenna wider, the thickness of a linear element thicker, or antenna geometry to some different shapes will make the paths of current distributions longer or increase the number of paths so that the resonance frequency becomes lower or frequency bandwidth wider.

Efficient Use of Antenna Space

When an antenna structure occupies three-dimensional space fully where the antenna is located, the antenna may have a wider bandwidth compared with the case where the space is not effectively used by the antenna (Wheeler 1958). When an antenna can be made wider bandwidth without changing its size, the antenna is said to be a smaller one as the wider bandwidth is that of a larger antenna.

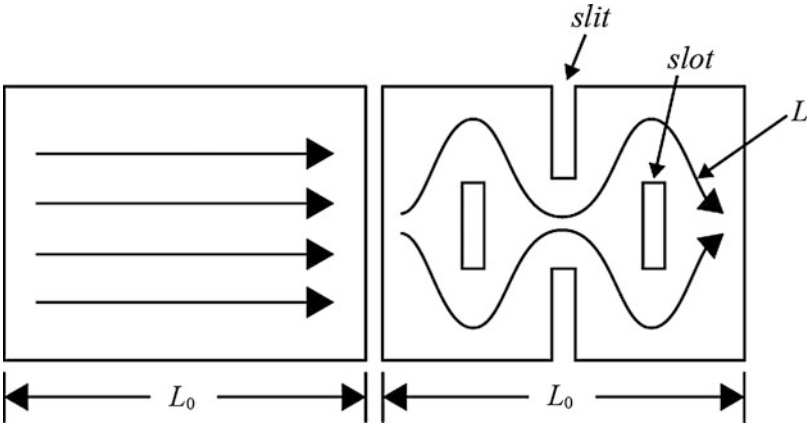

Fig. 14 Roundabout current path around the slits and slots composed with a plane surface

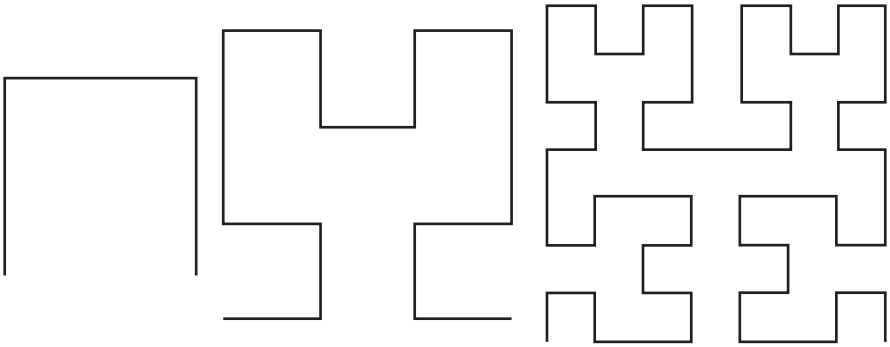

Fig. 15 Fractal geometry: Peano shape

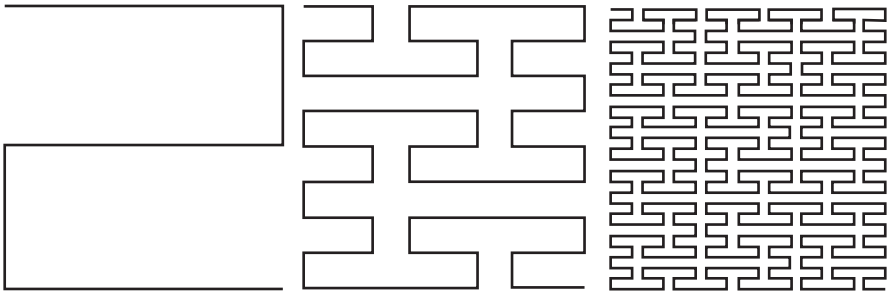

Fig. 16 Fractal geometry: Hilbert shape

To use space effectively, antenna geometry is arranged to occupy the space as much as possible. Easy ways of making antenna structures use the space effectively are applications of fractal geometries (Werner 2003) such as Peano shape (Fig. 15) (Sagan 1994; Zhu et al. 2004), Hilbert shape (Fig. 16) (Sagan 1994; Zhu et al. 2004), Minkowski (Fig. 17) (Gianvittoro 2002), and Koch (Fig. 18) (Baliarda et al. 2000). Examples of a dipole using Peano and Hilbert lines are shown in Figs. 19 and 20, respectively, where a dot is the feeding point.

A three-dimensional antenna, a sphere, in which an antenna is enclosed, is taken into consideration, and the antenna structure is composed to occupy space inside the sphere fully or as much as possible. The most

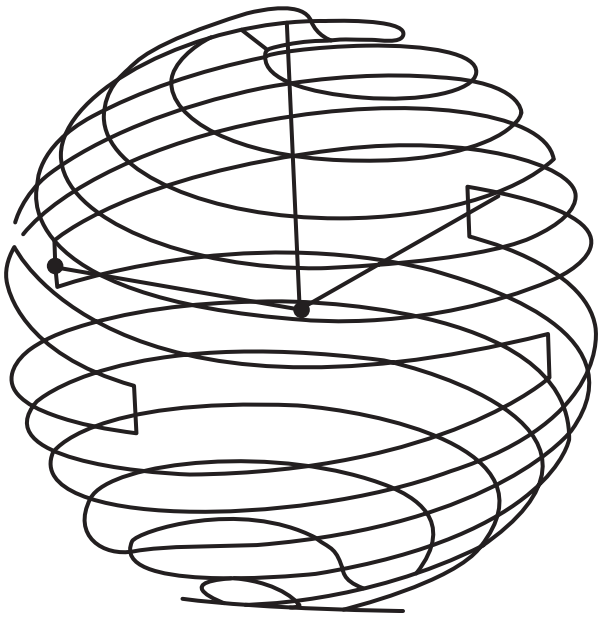

Fig. 21 Spherical helix occupying a sphere periphery © IEEE 2015

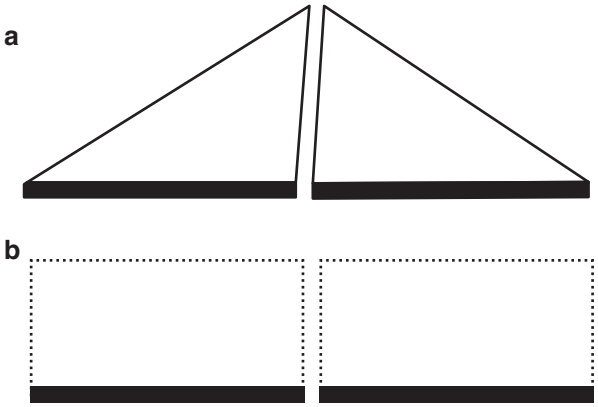

Fig. 22 (a) Triangular current distribution on a very small dipole and (b) uniform distribution

Increase of Radiation Modes

By combining an antenna with another type of antenna – for example, a TE-mode antenna and a TM-mode antenna combined – modes of radiation are increased, and antenna performance can be enhanced. Gain can be increased or bandwidth may be made wider. Enhancement of gain, bandwidth, etc. without significant increase in the dimensions from a single antenna qualifies the antenna as small sized.

Practical methods to increase radiation modes are to combine TE- and TM-mode antenna elements, for example, a dipole and a loop or the use of self-complementary concept (Mushiake 1996a) and conjugate structure. By the self-complementary structures, wideband performance – theoretically infinite if the ground plane is infinite – can be achieved; meanwhile by the conjugate structure, matching process becomes easier for a small-sized antenna, usually having very low resistive and very high capacitive input impedance, making the impedance matching difficult.

DOI 10.1007/978-981-4560-75-7_48-3

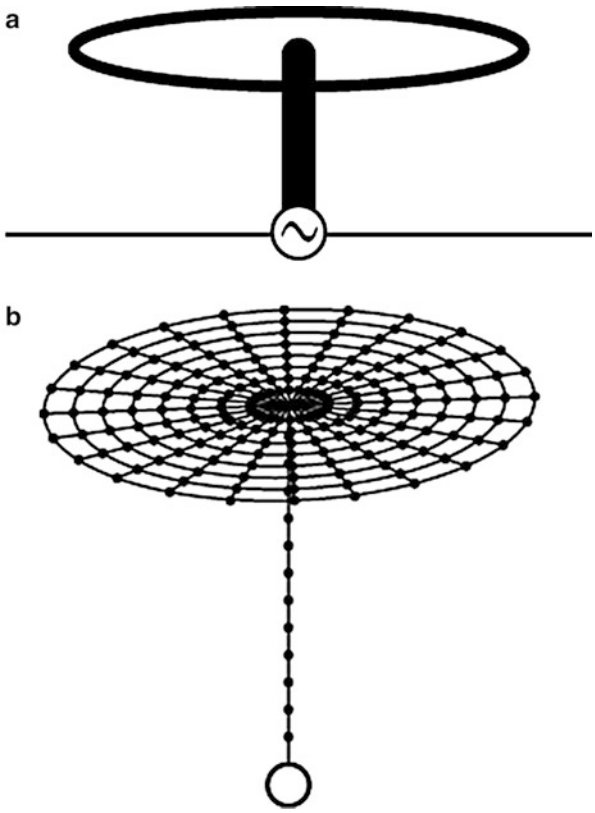

Fig. 23 Top-loaded monopole with (a) circular disk and (b) a circularly-wound disk on monopole top

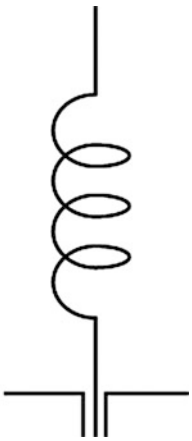

Fig. 24 A dipole loaded with an inductance in the middle

Make the Current Distributions on the Antenna Element Uniform

When the current distribution on the antenna element is uniform, the gain will be maximum with a given size of antenna. Practically, current distribution on a very small dipole is treated as triangular (Fig. 22a). To obtain maximum gain by that size of small dipole, current distribution on the dipole should be made uniform (Fig. 22b). To realize uniform current distribution on a small dipole, loading technique is often applied. The loading is done either on the top or the middle of the dipole. For example, a circular disk or circularly wound wire is used on the top loading (Fig. 23a, b), and a reactance component like an

DOI 10.1007/978-981-4560-75-7_48-3

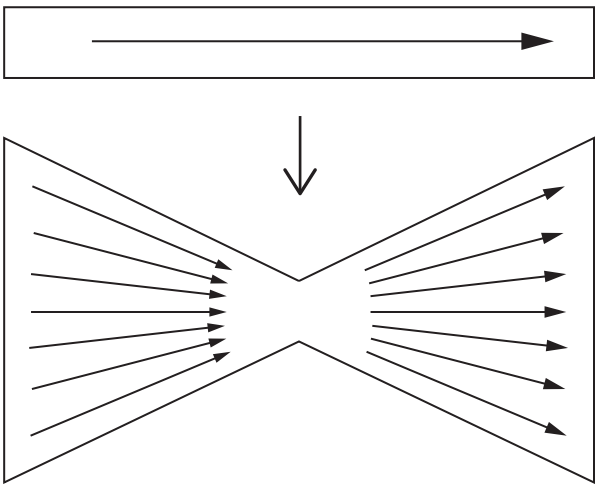

Fig. 25 Enlarging an antenna geometry to enhance the bandwidth in the figure a missing line on the top is added

inductance is loaded in the middle of the dipole (Fig. 24). Increased gain means effectively small-sizing of an antenna, because the higher gain may be obtained equivalently to a larger antenna.

FSA

To produce an FSA, essentials are either enhancement of antenna performance with the dimensions of the antenna unchanged or addition of some function by integrating either passive or active devices into the antenna structure. Typical methods for enhancing antenna performance are (1) modification of antenna geometry, (2) composing an antenna with different types of antenna elements, (3) use of HIS (high-impedance surface) (Sievenpiper et al. 1989), and (4) integration of an electronic device, either active or passive or both, into the antenna structure. Application of metamaterials (MMs) is also a useful means to enhance the antenna performance.

Among the wideband performances, UWB (ultra-wideband) is a specific one, which requires particular considerations to realize very wide bandwidth in small-sized antennas of inherently narrow bandwidth.

Modification of Antenna Geometry

Typical modification of antenna geometry is to augment the antenna surface or thickness. By doing so, the number of current flow paths on the surface increases so that the bandwidth is widened.

Figure 25 illustrates examples of modification of antenna geometry, and enlarging an antenna area to increase current flow paths on the antenna surface is depicted.

Composite Antenna

Combination of TE- and TM-mode antenna elements is one of the examples. As a practical example, composing a monopole (TE mode) with a slot having self-complementary structure (Fig. 26) to the monopole (TM mode) will result in an antenna of very wide bandwidth. With the slot monopole on the infinite ground plane, the bandwidth is theoretically infinite; however, the practical ground plane cannot be infinite but only finite, and hence the bandwidth is finite. Although it is finite, the bandwidth will still be very wide when the ground plane has effectively very large size, at least a few wavelengths.

Another type of composite antenna is constituted by using an antenna with its conjugate antenna. An antenna with capacitive impedance can be combined with an antenna having inductive impedance to achieve resonance within the antenna structure. A TM-mode antenna may be made conjugate against the TE-mode antenna. A combination of a short monopole having capacitive impedance with a slot antenna

DOI 10.1007/978-981-4560-75-7_48-3

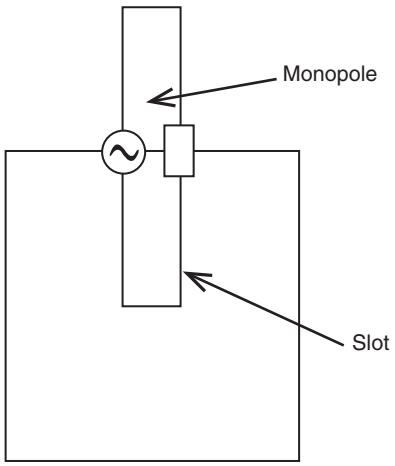

Fig. 26 An example of a combined TE and TM mode antenna: an L-shaped monopole (TE) and its complementary L- shaped slot (TM)

having inductive impedance is an example. Conjugate combination of two antennas, one of which is capacitive while the other is inductive, provides conjugate reactance corresponding to those antennas loaded to each of the two antennas.

Integrated Antennas

By integrating components, devices either passive or active, circuitry, and materials, including metamaterials, into an antenna structure – that is IAS – various notable modifications in the antenna structure can be expected. Some of those are improvement or enhancement of antenna performance, size reduction of antennas, and addition of functions into antenna structures that will create novel FSA. For instance, increase in gain is the result of constituting an antenna with different radiation modes that would add radiation power to that of the original antenna. Meanwhile, bandwidth can be increased by combining an antenna with another one having slightly different resonance frequency. The size reduction is an attribute of composing an antenna with slow-wave structure that lowers the resonance frequency.

Integration of active components into an antenna structure will produce various types of FSA. An antenna, to which oscillating circuitry is integrated, will act as a transmitting antenna with increased power compared to the original passive antenna. However, in designing the integrated antenna, noise produced by the circuit and nonlinear characteristics that may cause intermodulation can deteriorate the system performance. Factors like these should be carefully evaluated and excess noise and intermodulation should be eliminated.

By using passive components like capacitive or inductive reactance, antenna impedance can be varied, resulting in resonance in an antenna structure, and by using a varactor diode, which varies the capacitance by the bias voltage supplied to the diode, the resonance frequency of the antenna can be varied, and by utilizing this property, a frequency reconfigurable antenna is realized.

Application of Metamaterial (MM)

MM can be applied to an antenna structure or near field of the radiating antenna element for small-sizing antennas. Integration of MM, which exhibits negative reactance ($-$C or $-$L), into an antenna structure is a strong candidate for producing small antennas, wideband antennas, functional antennas, and other various sophisticated antennas. MM can be equivalently composed by various ways. The examples are the use of transmission line resonators constructed by split-ring structure (split-ring resonator, SRR), its complementary structure (complementary split-ring resonator, CSRR), and so forth.

DOI 10.1007/978-981-4560-75-7_48-3

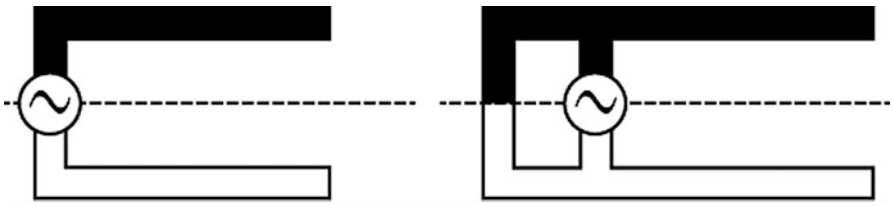

Fig. 27 An L-shape and inverted F shape antennas and their images beneath the PEC ground plane

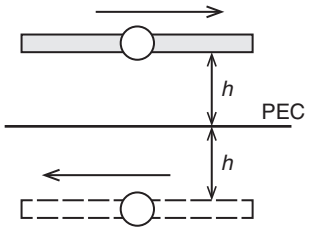

Fig. 28 Negative phase current on the image antenna beneath the PEC ground plane

PCSA

PEC Ground Plane

To realize a PCSA, an antenna is fabricated in low-profile structure with low height or narrow thickness. The thickness of PCSA is necessarily much smaller than the operating wavelength, whereas other antenna dimensions may be arbitrary. A TE-mode antenna like an inverted L or inverted F can be placed on the PEC ground plane in parallel. With the ground plane, the antenna will have an image of the original antenna symmetrically under the ground plane as shown in Fig. 27, where arrows indicate currents on the elements. A TM-mode antenna like a dipole will produce a negative-phase image element beneath the PEC ground plane when it is placed on the PEC ground plane in parallel as shown by Fig. 28.

The PEC ground plane should be infinite or equivalently infinite size, having at least a few wavelengths in one side of the plane from the feed point to the end. When the size of the ground plane is finite, some radiation current would flow on its surfaces, and the antenna performance will differ from that which is placed on the infinite ground plane due to the effect produced by the currents on the ground plane. In other words, antenna design should consider the effect of the ground plane as well as the antenna element when the size of the ground plane is finite.

Use of High-Impedance Surface (HIS)

The ground plane is not necessarily PEC, but HIS (Sievenpiper et al. 1989) can be used, with which a negative image will not be produced. A dipole antenna can be located close to the HIS ground plane with lower height h as shown in Fig. 29 and so the dipole can be a low profile antenna. In this case antenna impedance will be varied and radiation efficiency may be enhanced.

The input impedance Z_d of an antenna placed on the HIS is given by

$$Z_d = Z_{11} + Z_{12}e^{j\theta} \tag{7}$$

where Z_{11} is input impedance of the original antenna, Z_{12} is the mutual impedance between that of the original antenna and the image antenna, and θ is the reflection phase angle, which is 180° for the PEC surface.

DOI 10.1007/978-981-4560-75-7_48-3

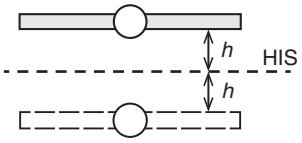

Fig. 29 A dipole antenna closely placed on the HIS ground plane with low height h

The surface impedance of the HIS is high so that the current flow on the surface can be suppressed. This will result in reducing the current flow to the rear side of the ground plane that will result in enhancing the radiation into the space and decreasing the radiation beneath the ground plane, contrary to the case of finite PEC ground plane. It also reduces the mutual coupling between two antennas placed on the HIS ground plane. Hence, two antennas can be placed with closer distance than the ordinary arraying space. By utilizing this effect, several antennas can be placed in a small limited area without higher mutual influence on each other. Practically this is applied to antenna settings for MIMO (multiple-input and multiple-output) systems, which employ several antennas in a limited small area, often in small mobile terminals.

Application of Electromagnetic (EM) Materials

EM materials, typically dielectrics, are often used as the substrate to assist thinning the thickness of an antenna. MSA (microstrip antenna) is the representative one.

Another example of EM material application is the use of HIS and EBG (electromagnetic band gap) (Rahmat-Samii and Mosallaei 2001), by which not only thinning of the antenna structure but also other various ways to create characteristic antennas can be brought out (Engheta and Ziolkowsy 2006). The HIS or EBG can be realized by periodical structure and geometrical patterns that exhibit resonance for certain frequency bands. A typical example of HIS is a metal slab with quarter-wavelength deep corrugations, shown previously in Fig. 8. This corrugation structure is considered as an array of quarter-wavelength transmission lines which exhibit a high-impedance boundary condition for electric fields polarized perpendicular to the grooves, because of the short circuit at the bottom of the grooves, whereas low impedance appears for parallel electric fields. This type of structure is known to have soft and hard surfaces (Kildal 1990) which depend on the polarization and direction of the propagating wave. A practical example of EBG material is the mushroom type shown in Fig. 30, which illustrates an external appearance on the top, cross section of several segments on the middle, and an equivalent circuit for one segment of the cross section on the bottom. In equivalent circuit, C is an equivalent capacitance due to a gap between the two surface plates and L is an inductance produced by a current flowing through the surface plate, the via, and the ground plane.

PSA

Microwave (MW) or Millimeter-Wave (MMW) Antennas

MW and MMW antennas are inherently small size as the frequency is very high. Design of those antennas is not specific, but recent antenna technology in MM and MMW regions has progressed to designing by using integration techniques, and antennas are constructed in a sophisticated structure, operating with some functions such as multi-mode, adaptive control, and so forth, keeping the dimensions small.

DOI 10.1007/978-981-4560-75-7_48-3

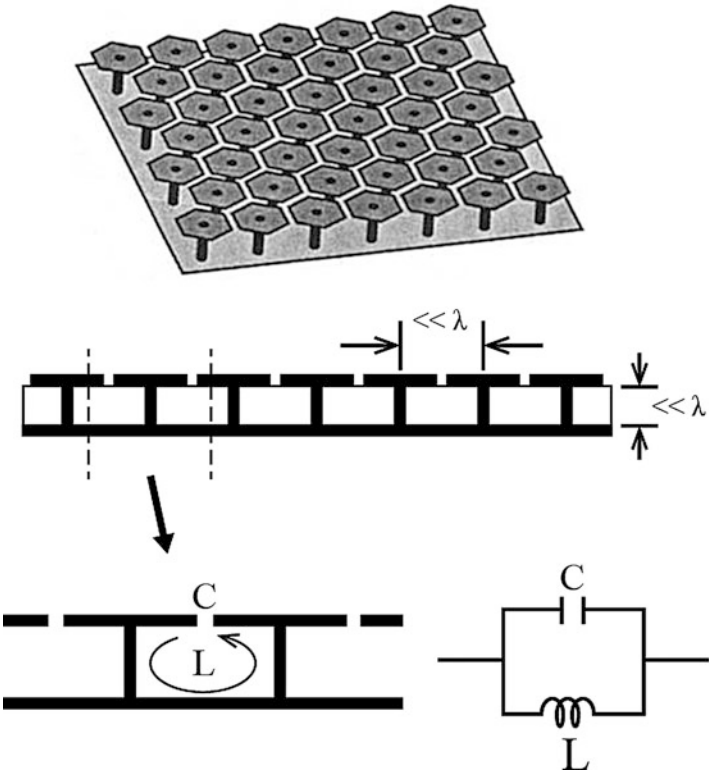

Fig. 30 An example of EBG material using mushroom structure - top: pictorial; bottom: cross-sections and equivalent circuit

Physically Small Antennas (PSAs)

Any type of antennas having physically small dimensions is called PSA. Other types of antennas, ESA, FSA, and PCSA, can be included in PSA, when their size is physically small. The term physically small means here that the size is smaller than 30 cm or so or something roughly comparable to the size of a human hand.

In recent wireless systems, antennas used are mostly PSA which are practically used in various wireless systems. Antennas applied to small RFID systems are the representative ones. Small wireless terminals used for RFID, NFC, and wearable systems, including body-centric communication and so forth, generally contain small antennas having physically small size, as the RFID terminals are generally small. Types of antennas belonging to PSA are not specific, but generally linear, planar, and three dimensional.

Of importance is antenna impedance matching in any case. When equipment is very small, any antenna installed in it is necessarily very small. There may be cases where the antenna is not properly matched to the load due to disturbance of environmental conditions near the antenna element. This kind of problem is often encountered when the evaluation of the antenna impedance is difficult because of no allowance of space for performing the measurement. The other case may be an awkward situation in placing a matching circuit. However, whatever the condition may be, matching should be properly made for any antenna and never omitted.

Taking an example in a small RFID case without appropriate matching, although the unit may be practically usable, transmitting power might be wastefully large, required sensitivity might be excessive,

DOI 10.1007/978-981-4560-75-7_48-3

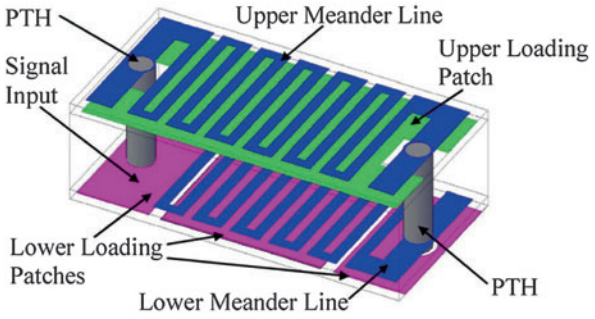

Fig. 31 Perspective view of the folded meander-line chip monopole antenna © IEEE 2015

the battery could require greater capacity than necessary, or its size may be larger than the normal one. On the contrary, if matching is properly done, the RFID unit could work with smaller power, lower sensitivity, and smaller capacity or smaller-sized battery. Or with the same power, the sensitivity might be higher or the working area broader. Also the battery capacity or size can be allowed to be smaller.

Practical Small Antennas

Practical examples of small antennas will be introduced in the next section, based on the four categories: ESA, FSA, PCSA, and PSA.

ESA

Slow-Wave Structure

Typical example is a use of meander line for an antenna element as Fig. 31 illustrates (Lee et al. 2014). The antenna element is constituted with a meander line, folded to make the size half of a normal dipole-type antenna, by which the impedance becomes a quarter of that of a dipole-type antenna. As a result, the antenna becomes very small and can be constructed as a chip. The physical dimensions of the antenna are only $3.2 \times 1.6 \times 0.83$ mm^3. The antenna is composed of a three-layered structure, two prepreg layers and one copper core layer. Side view of the antenna is shown (The exploded view is depicted) in Fig. 32. The upper meander-line element is placed on the top copper layer, and the lower one is folded inside the antenna block over the bottom copper layers. They are connected by two plated-through-hole (PTH) vias. The signal is fed into one end of the bottom meander line, and the top meander-line element is excited through the PTH vias. Reflection coefficient S_{11} measured for a prototype antenna when matched at 2.5 GHz is shown in Fig. 33, where the bandwidth is observed to be from 2.40 GHz to 2.59 GHz (7.6 %), although the antenna size is very small.

Extension/Increase of Current Paths

A small modified PIFA using a circular disk for the planar element and some meandered slots on the planar element (Fig. 34) is introduced (Kiourti and Nikita 2012). The use of the meandered slots increases the path lengths of the current on the surface of the planar element and leads to lowering the resonance frequency, achieving small-sizing of the antenna. The antenna is applied for telemetry operating at MICS (medical implant communications service) band (402.0–405.0 MHz) and ISM (industrial, scientific, and medical) band (433.1–434.8, 868–868.6, and 902.8–908 MHz). The antenna is composed of three thin circular plates, one with 6-mm-radius ground plane, and two of 5-mm radius with meander lines, as shown in Fig. 35, which gives from left to right, the bottom plate as the ground plane, the second plate and the

third plates. The three plates are vertically stacked as shown in the extremely right. The second plate has the feed point, and one end is shorted to form a PIFA planar element, and the third plate constitutes the additional upper planar element of the PIFA. Patches are plated on 0.6-mm-thick substrate layers. Between the two planar elements, dielectric substrates ($\boldsymbol{\varepsilon_r} = 10.2$ and $\tan \boldsymbol{\delta} = 0.003$) are used. The thickness of the antenna is 1.2 mm.

The antenna is in practice applied on a human head by being implanted in it and used as a medical implant device.

The antenna design is optimized for the implantation scenario under consideration. The optimization of the scalp-implantable antenna is performed so as to fit the PIFA for implantation inside the scalp of a 100-mm-radius three-layer spherical human head model consisting of (a) a 10-cm skin tissue cube, a scalp of (b) three-layer spherical human head model consisting of skin (scalp), cortical bone (skull), and gray

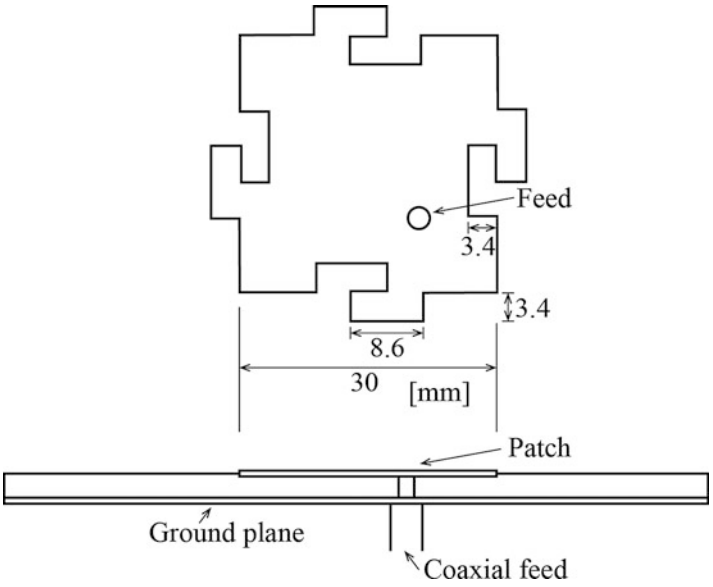

Fig. 38 Proposed Peano shape applied to a square patch antenna

matter (brain) tissue as Fig. 35 illustrates. Figure 35c depicts the anatomical human head model, a scalp consisting of 13 tissues, for which antenna performances are also investigated. Simulated reflection coefficients for the optimized antenna are shown in Fig. 36, which gives data for the three-layer head model and the anatomical head model. To provide realistic results, radiation performance of an optimized PIFA is evaluated for the case of the anatomical head scenario. Radiation patterns are studied; SAR (specific absorption rate), which should be within the specified value for safety when the device is allied to a transmitter, is evaluated; and communication links, either bidirectional or half duplex to be established between the optimized PIFA and exterior antennas, are discussed.

Efficient Use of Space

Geometrical patterns like Hilbert, Peano, and fractal shapes are applied to construct an antenna, which occupies a space efficiently, leading to small-sizing the antenna (Chen et al 2003). Here is an example of using Peano shape to modify an antenna geometry and realize a small antenna remaining yet broadband with higher gain compared with other antennas having the same area (Oraizi and Hedayati 2012).

The initiator (a line) and the generator of the Peano shape are depicted with its dimensions in Fig. 37. A proposed antenna, where the first-iteration Peano-shaped line is applied to the edge of a square patch, is

DOI 10.1007/978-981-4560-75-7_48-3

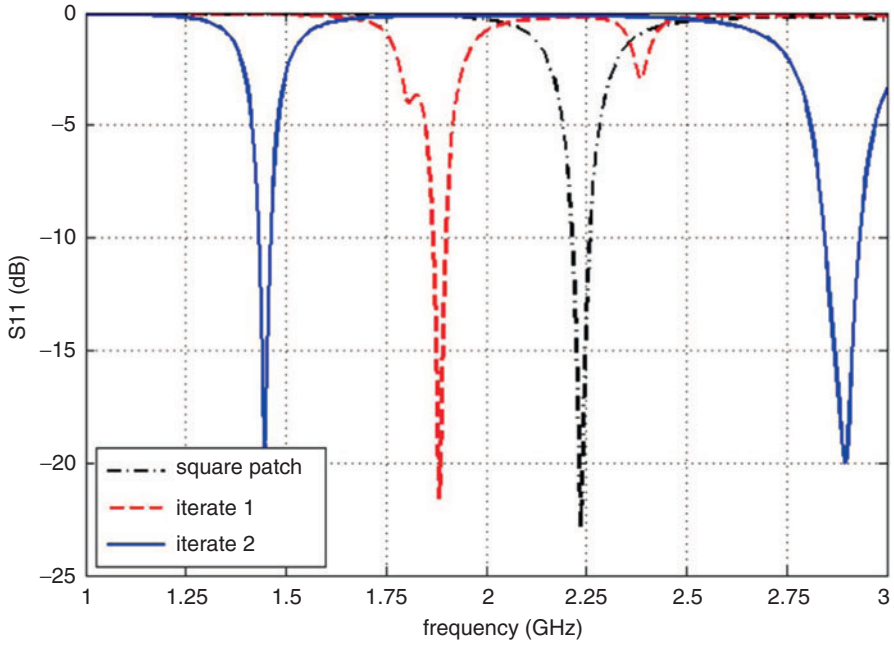

Fig. 39 Simulated S_{11} of the first and second iteration of Peano shape applied to square patch © IEEE 2015

shown in Fig. 38. Simulated reflection coefficient S_{11} for antennas with first and second iteration applied is shown in Fig. 39, in which S_{11} for an antenna of zeroth iteration (square patch) is also provided. The antennas of zeroth and first iteration have only the first-mode resonance frequency, whereas the antenna of second iteration produces the second-mode resonance frequency at 2.9 GHz, by which the antenna may be used for dual-band operation. The resonance frequency of the first-iteration antenna is about 400 MHz lower than that of the square patch, and the second-iteration antenna has about 800 MHz lower resonance frequency. From these results, dimensions of antennas, to which Peano shapes are applied, are made effectively smaller than the square patch, implying that small antennas are achieved by applying Peano shapes.

A Peano-shaped antenna is compared with antennas of other fractal shapes such as triangular Koch, square Koch, tree-type fractal, and Sierpinski fractal (Fig. 40) in terms of resonance frequency, bandwidth, and perimeter, keeping the area constant at 900 mm^2. Table 1 provides a comparison of characteristics of those shapes. Peano shape has the longest perimeter, while the resonance frequency is the lowest, meaning that the Peano shape is the most effective one to realize the smallest antenna compared to other Fractal types.

Use of Metamaterials (MMs)

A very small patch antenna using a MM concept is developed (Ouedraogo et al. 2012). A MM structure is realized by using CSRR (complementary split-ring resonator) (Baena et al. 2005; Lee et al. 2007). Resonance frequency of a patch antenna can be lowered by applying the SRR concept, which increases effective capacitance and inductance depending on the multiple concentric split rings; however, by adopting the concept of duality and complementarity to the SRR, CSRR is composed, and the resonance frequency can be further lowered. The effective permittivity of the medium can be designed to a desirable value when the medium is excited by an electric field polarized along the axis of the CSRR. In a patch antenna, the CSRR medium is placed between the radiating patch and the ground plane as shown by Fig. 41, in which illustrates the side view of, a circular patch antenna is illustrated, where the radiating patch is placed above a circular dielectric substrate backed by a circular ground plane with the same diameter as the substrate. The CSRR is contained in the circular copper disk and the geometry is depicted in Fig. 42. The circular copper disk (CSRR) is placed 0.78 mm below the radiating patch.

The radius of the patch is chosen for patch resonance at 2.45 GHz. Three patches are designed to have radii of 12, 8, and 6 mm, corresponding to size reduction values of 1/2, 1/3, and 1/4 compared to the traditional patch antenna, which does not use the CSRR and has radius of 23.1 mm, resonating at 2.45 GHz. The traditional antenna, which is used for comparison with the CSRR-loaded antenna, has a circular copper patch etched on top of a circular substrate ($\boldsymbol{\varepsilon_r} = 2.33$ and $\tan \boldsymbol{\delta} = 0.0012$) backed by a

ground plane having the same diameter 46.2 mm with the substrate. The geometry of the CSRR within the cavity is optimized to produce an antenna resonance at a frequency well below that of the unloaded antenna. Alternatively, with the resonance frequency fixed, the loaded antenna can be small sized to a desired level of size reduction. Geometry of a proposed antenna, which is shown previously in Fig. 41, is determined in simulation by using in-house GA (genetic algorithm) so that the desired level of the size reduction is appropriate. Parameters of CSRR for each level of small sizing are given in Table 2. The parameters of CSRR are chosen to produce a reflection coefficient lower than 10 dB and the best identical

cost values for each size reduction level. Reflection coefficient of the patch antenna with reduced size reduction of 1/4 (1/16 in terms of the area) is given in Fig. 43, where reflection coefficient of a traditional antenna is also shown as reference. From the figures, bandwidth increase in the CSRR antennas compared to the traditional antenna is observed. However, the radiation efficiency of the CSRR antenna is lower than that of the traditional antenna.

Impedance Matching

It is a common understanding that the minimum achievable Q of an antenna inversely relates to its physical size (Chu 1947). So as the size of an antenna tends smaller, antenna Q values tend higher, imposing a limitation in achievable matching bandwidth for matching of the antenna with lossless passive components. To overcome this problem, the use of active components or non-Foster reactance (−C or L) for the matching is considered as a useful means (Susman-Fort and Rudish 2009; Perry 1973).

Here, an antenna, to which non-Foster reactive elements are embedded inside the antenna (Fig. 44), instead of attached to the antenna terminals, is introduced (Mizaei and Eleftheriades 2013). A non-Foster reactive element does not obey Foster's reactance theorem (Foster 1924) for passive reactive elements. Non-Foster reactive elements can be implemented by using active networks such as NIC (negative impedance converter) or NII (negative impedance inverter) (Sussman-Fort 1998; Kolev et al. 2001). The underlying antenna used here is an ESA (electrically small antenna) with high Q and narrow bandwidth, and the intent is to achieve a wideband antenna by means of integration of NIC into the small antenna structure. An antenna chosen for embedding a non-Foster matching circuit is a frequency reconfigurable antenna, to which tunable reactance elements C_t and L_t are loaded. The tuning behavior of the antenna is given by a curve of $B_t = \boldsymbol{\omega} C_t$ or $X_t = \boldsymbol{\omega} L_t$ with respect to resonance frequency $\boldsymbol{\omega}$. The tuning behavior is simulated by using HFSS for some discrete values of the load capacitance C_t and shown in Fig. 45a for a large bandwidth and (b) tuning susceptance $B_t = \boldsymbol{\omega} C_t$ with respect to $\boldsymbol{\omega}$. The figure shows negative slope due to the non-Foster behavior. In the non-Foster version, C_t is replaced with a parallel combination of $-C_a$ and $-L_a$, while L_t is replaced with a series combination of these elements. The goal is to replace tuning element C_t or L_t with a network that satisfies the resonance condition. As the

DOI 10.1007/978-981-4560-75-7_48-3

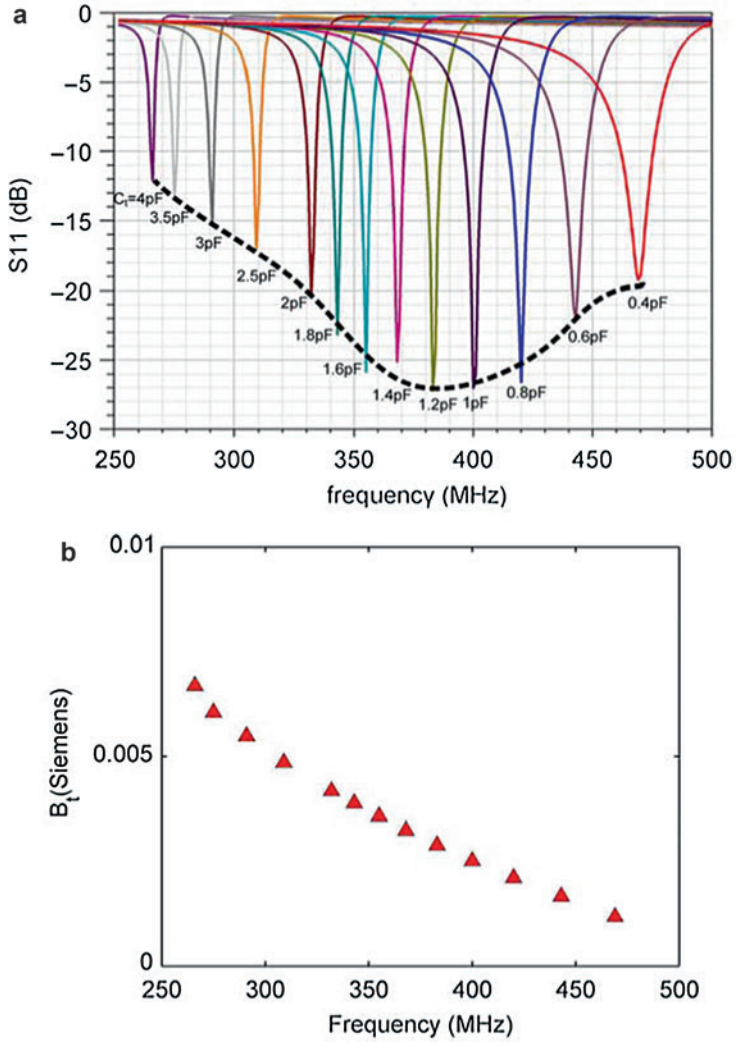

Fig. 45 Simulated tuning behavior of an antenna shown in fig.45; (a) variation with capacitor of S_{11} with C and (b) susceptance Bt vs frequency © IEEE 2015

network to fit the tuning behavior is not unique, different networks can be employed for non-Foster matching or network to be embedded on the antenna. For the antenna under consideration, three reactance functions are considered to fit the antenna tuning behavior shown in Fig. 45b. To select the best function, some factors are analyzed: complexity, values of network elements, and sensitivity. The appropriate function which fits to the tuning behavior should represent synthesizable reactance (susceptance function $B_t(\omega)$ or inductance function $X_t(\omega)$) using a combination of Foster or non-Foster elements. Two Tuning elements C_t or L_t with a network that satisfies the resonance condition in a wide frequency band. Such a network exhibiting behavior shown in Fig. 45b synthesizes a non-Foster reactance of its terminals and can be implemented by the addition of $-C$ or $-L$ elements to the set of the available reactive elements (capacitors or inductors). The antenna is designed in a single layer; however, the circuit uses both sides of the board for fitting the design into the available space. The bottom layer of the board is used mostly for running the DC bias lines all across the NIC circuit and for placing a trimmer capacitor for tuning the NIC circuit. Here the Linvill's NIC circuit scheme (Linvill 1953) is used for the NIC circuit.

Measured results of S_{11} for the fabricated antenna are shown in Fig. 46 for four trimmer states. Then, the results are compared with the tuning data of the passive antenna shown in Fig. 50b, and the results are

DOI 10.1007/978-981-4560-75-7_48-3

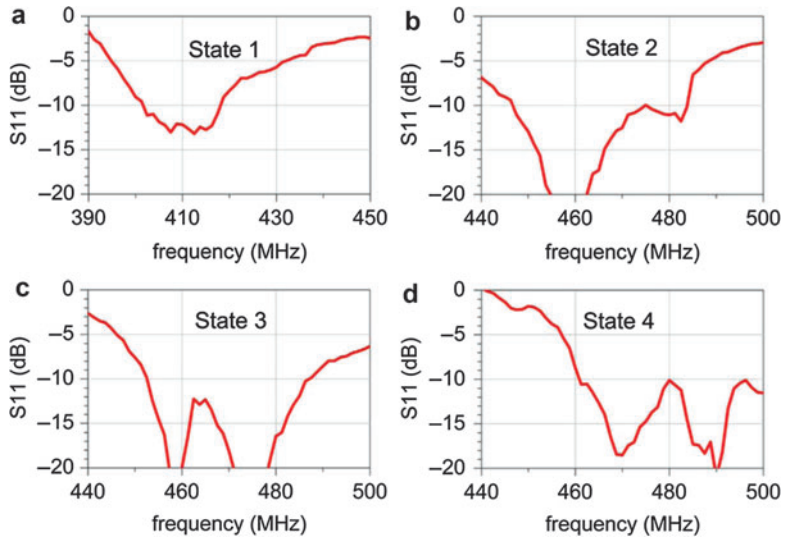

Fig. 46 Measured S_{11} for fabricated antenna for four trimmer states © IEEE 2015

Table 3 Comparison of measures S_{11} for the non-Foster circuit embedded antenna with simulated S_{11} of the associated passive antenna for the four different trimmer status (© IEEE 2015)

	−10 dB S_{11} fractional bandwidth	
Trimmer state	Passive antenna (%)	Non-Foster antenna (%)
State 1	2.0	4.0
State 2	2.9	8.1
State 3	2.9	7.4
State 4	3.0	8.3

provided in Table 3, where −10 dB S_{11} fractional bandwidths for four trimmer states are given. From the table, matching with a non-Foster network obtained a significant improvement in the bandwidth. This increase in the bandwidth is obtained by decreasing the reactive part of the antenna, instead of decreasing the antenna Q by loading with lossy elements. The stability of the embedded matching network is verified by the Nyquist test applied to the loop gain of the NIC circuit.

FSA

UWB (Ultra-wideband) Antennas

(a) Use of self-complementary structure

To obtain a wideband antenna, one of the most useful ways is to use self-complementary structure (SCS) (Mushiake 1996a), which is known to give frequency-independent performance (Rumsey 1957). By using SCS, infinite bandwidth will be realized theoretically if the ground plane is infinite. In practice, however, since the ground plane cannot be infinite, unlimited bandwidth cannot be obtained. Although infinite bandwidth cannot be realized, achieved bandwidths will be still fairly wide while using finite ground planes. How wide a bandwidth is achievable depends on the size of the ground plane when the ground plane is finite. This case is generally called "quasi-self-complementary (QSC)." An example is an

DOI 10.1007/978-981-4560-75-7_48-3

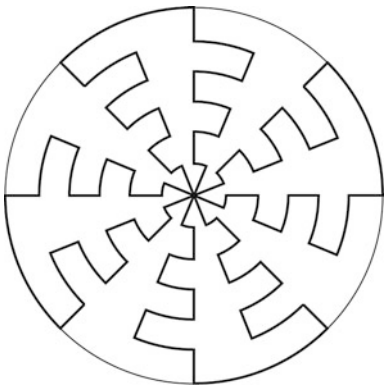

Fig. 47 Example of self-complementary antenna pattern

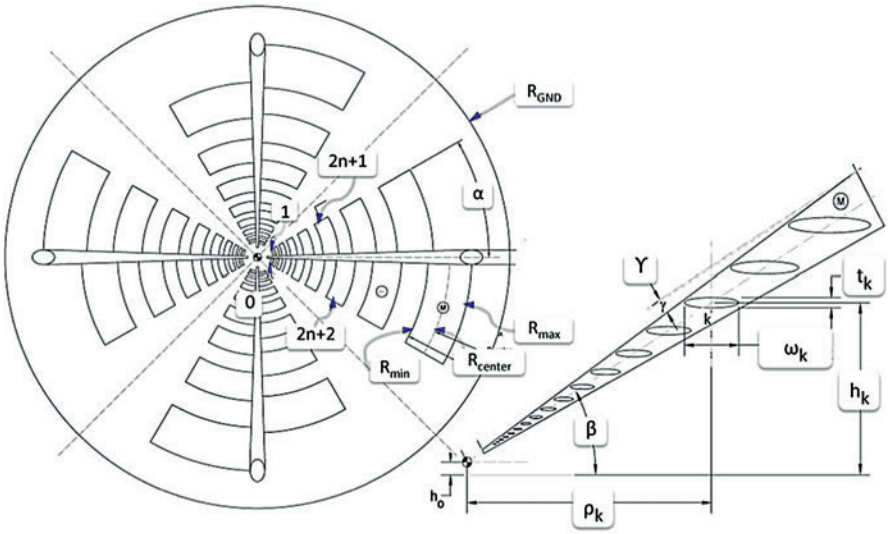

Fig. 48 Geometry of quasi-self-complementary (QSC) antenna and the side view of the one of the four arms © IEEE 2015

antenna pattern shown in Fig. 47, where a log-periodic element is used. The antenna element has log-periodic shape, while the space pattern is self-complementary to the antenna elements.

Here, a nonplanar QSC antenna is introduced (Cortes-Medellin 2011). The QSC antenna geometry is illustrated in Fig. 48, where the left side is top view, showing the projection of the antenna structure, and the right side is side view. As the figure shows, the antenna has four arms, having fourfold azimuth symmetry. The antenna is fed at the center of the structure, in a differential mode between two opposite arms, thus providing dual polarization. Each arm consists of a log-periodic (LP) SC element (it should be noted that LP structure does not always ensure frequency-independent characteristics as SC structure does (Mushiake 1996b)). This QSC antenna has a characteristic of differential VSWR with an input matching level better than a 1.7:1 bandwidth with a 270-ohm normalization, which corresponds to differential input match better than 10 dB from 1 to 20.0 GHz. The VSWR characteristics are shown in Fig. 49. The antenna has low profile, occupying a volume of a pillbox shape having diameter of $1.2\lambda_{min}$ and height of $0.25\lambda_{min}$ (λ_{min} is the wavelength of the lowest frequency for the −10 dB match).

Multiband Antennas

A compact, small-sized seven-band mobile handset antenna is described (Ban et al. 2013). Antenna Geometry and its detailed structure along with optimized dimensions are depicted in Fig. 50. where the

DOI 10.1007/978-981-4560-75-7_48-3

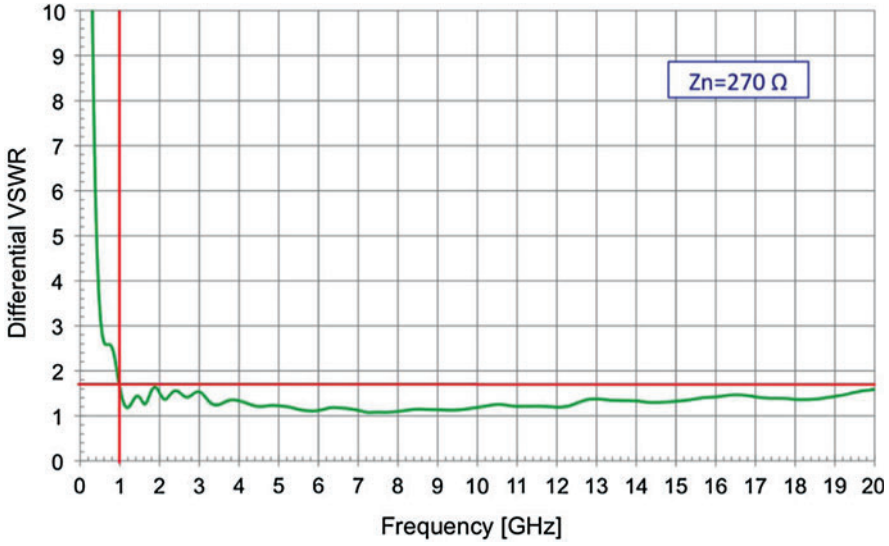

Fig. 49 Calculated differential VSWR, showing ultra-wideband (>10:1): red line indicates −10dB © IEEE 2015

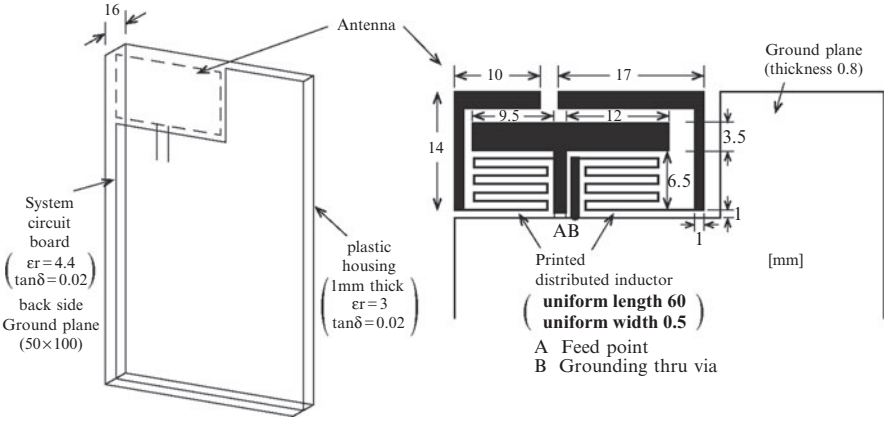

Fig. 50 Configuration of the proposed antenna: geometry of the 7-band antenna, mounted on the mobile phone (in the left) and the antenna structure (on the right)

left side shows the antenna mounted on the one corner of the bottom edge of the system circuit board and the right side expresses detailed dimensions of the metal pattern in the antenna area. The antenna consists of strips; one for feeding and other two (shorter and longer ones) for radiating, and symmetrically printed meandered inductive strips embedded in the shorter radiating strip and longer radiating strip, respectively, to generate dual resonance modes around 810 MHz and 962 MHz. The resonance for the lower band, covering GSM/850/900 (824–960MHz), is achieved by the longer radiating strip (0.25λ at 810 MHz) and the higher bands, covering GSM 850/900/1800/ 1900, UMTS 2100, and LTE 2300/2500 bands, is produced by the shorter radiating strip (0.25λ at 962 MHz). The length of the feeding strip is about 32 mm that supports 0.25λ at about 1800 MHz resonant mode to cover DCS 1800 operation. The shorter and longer radiating strips (total length 90 mm) generate a higher resonance mode at about 2450 MHz. By printing the antenna elements on one corner of the bottom edge of the system circuit board, the SAR (Specific Absorption Rate) values can be decreased. The circuit board uses FR4 substrate with ε_r of 4.4 and tan δ of 0.02, the size of 50 x 150 mm^2, and the thickness of 0.8 mm. There are two printed system ground planes: main ground plane of 50 x 100 mm^2 and a protruded one of 15 x 20 mm^2, leaving a non-ground region of 50 x 30 mm^2 at the top position of the circuit board where the proposed antenna shown in

DOI 10.1007/978-981-4560-75-7_48-3

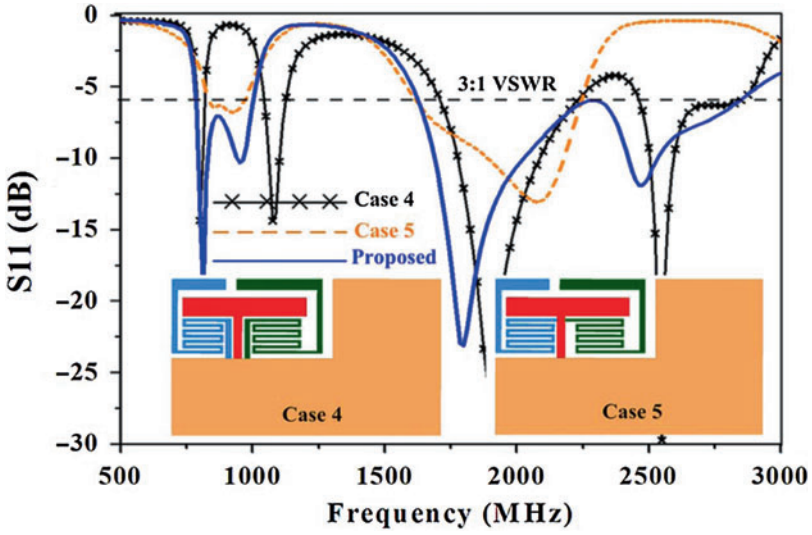

Fig. 51 Simulated S_{11} for the proposed antenna: case 4 and case 5, with the proposed antenna in the inset © IEEE 2015

Fig. 50 is placed. The system circuit board is enclosed by plastic housing with 1-mm-thick slab (ε_r of 4.4 and tan δ of 0.02 and total height of 10 mm) to simulate a practical mobile phone case.

Simulated S_{11} for proposed antennas are shown in Fig. 51, where the antennas of case 4 and case 5 are depicted in the inset. The terms *case 4* and *case 5* mean cases where the feeding method is different; the case 4 is when the shorter and longer strips are fed by coupling, while the case 5 is when those strips are fed directly. Remarkable effect due to the difference in the feeding method is observed in the figure.

By combining a feeding strip with two radiating strips and two symmetrical printed distributed inductors, the proposed antenna can exhibit two wide operating bands for lower frequency regions, 810 and 962 MHz, covering GSM 850/960 bands, and four wide bands for higher frequency regions, 1620–2830 MHz, covering DCS 1800/PCS 1900/UMTS 2100/LTE 2300/2500 operation.

Functional Antenna

A looped bow-tie antenna is designed for RFID tag which operates for a long-range and frequency reconfigurable performance (Lin et al. 2013). Configuration of the antenna is illustrated in Fig. 52, which gives top view with dimensional parameters, side view, and cross-sectional view, respectively. The antenna consists of two non-connected load bars and two bow-tie patches electrically connected to a conducting backplane by four pairs of vias, thus forming a looped bow-tie RFID tag antenna structure. By this structure, the tag antenna is made suitable for mounting on metallic objects. The two load bars are used as integral parts of a metal tag antenna by placing them near the edge so that the effect of the metal on the tag is reduced. The RFID chip is placed across a gap between the two patches and connected to them both. Each pair of vias is equivalent to a single loop, which can be viewed as a single inductor L.

In the RF tag design, four ways to adjust the self-resonance frequency are introduced to obtain the desired complex impedance of the antenna: two for inductances and another two for capacitances by varying dimensions of the antenna and number of vias. Multiple pairs of vias constitute multiple inductors L_i ($i = 1,2,..n$) in a parallel circuit, and a combination of them can yield an equivalent inductor L_a, which is shown in Fig. 53, which provides (a) general circuit model and (b) equivalent circuit. In the figure, C_a and L_a, respectively, are the equivalent capacitance and inductance of the antenna, which determine the antenna self-resonance frequency. Increasing the number of via pairs will lower the inductance, resulting in higher resonance frequency. The capacitances C_g and C_b, respectively, shown in Fig. 53, are capacitances due to the gap of the bow-tie patch elements and that contributed from the load bars with the length

DOI 10.1007/978-981-4560-75-7_48-3

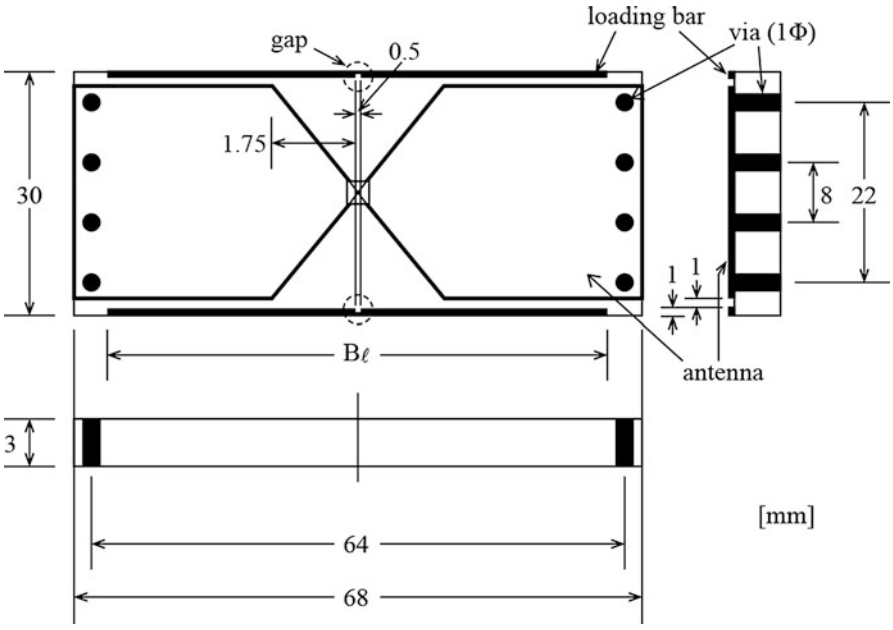

Fig. 52 Configuration of the proposed antenna; ((a) changed to) with dimensional parameters, ("and operating …2015" was changed to) side view (on the right) and cross sectional view (at the bottom) In the figure, dimensional parameters L, BW, Vr, Vd, V1, V2, and H are changed

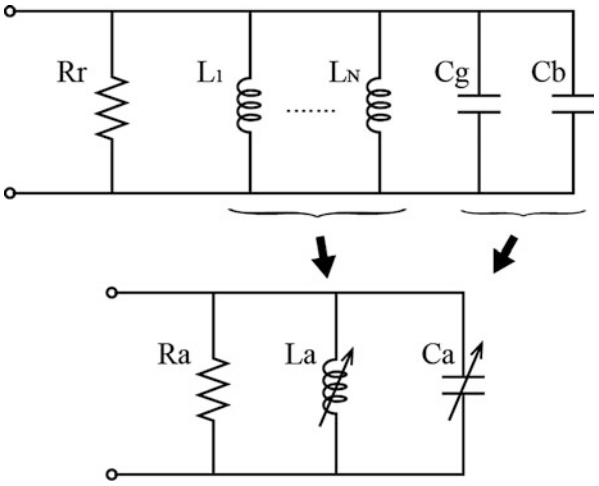

Fig. 53 Circuit model of the proposed antenna; general circuit (upper part) and (b) equivalent circuit (lower part)

of B_ℓ, respectively. Hence, by varying C_g and C_b, respectively, input impedance can be varied, and the resonance frequency can be controlled as well.

In addition, the looped bow tie itself serves as an inductor, which can be controlled by changing the dimensions V_1, V_2, and V_d, between the vias shown in Fig. 52a. By shortening V_d, inductance is decreased, which in turn shifts the resonance frequency higher. Variation of the resonance frequency depending on V_d is shown in Fig. 54. The load bars, each of which has a cutoff point, can be used for reconfiguring the operating frequency of the tag by exciting any one of three frequency modes; hence, the tag can be used for worldwide UHF RFID frequency bands. The experimental tests show that the

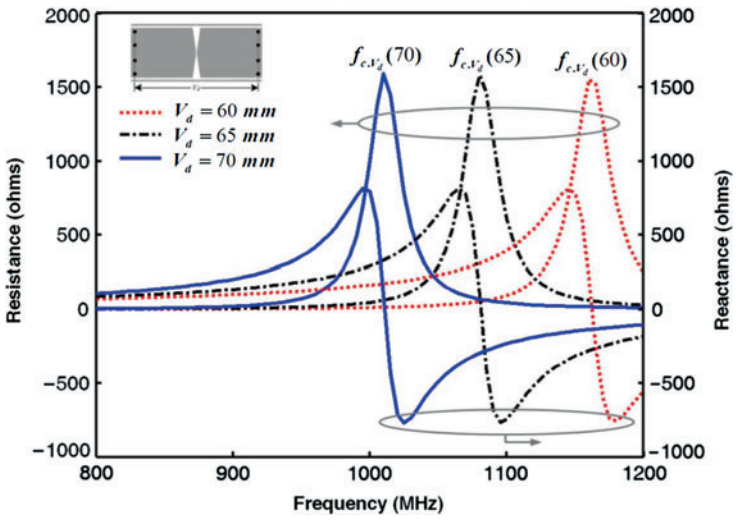

Fig. 54 Simulated input impedance of the proposed antenna for three different Vd's © IEEE 2015

maximum read range, located on a metallic object, was 3.0, 3.2, and 3.3 m for three different operating modes with only 0.4 W EIRP radiation power of the RFID reader.

The overall size of an implemented antenna is 68 x 30 x 3, all in mm.

PCSA

PEC Ground Plane

A printed wide-slot antenna with a parasitic patch in the center of the slot is proposed (Sung 2012). The antenna is designed for the purpose to enhance the bandwidth. Geometry of the proposed antenna is shown in Fig. 55, where a square of the central part shows the printed patch on the substrate and a square outside the central patch shows the etched slot. In the figure, dimensional parameters are also given, and the feed line on the opposite side is shown in dotted lines.

A fabricated antenna is printed on one side of the substrate FR4 ($\boldsymbol{\varepsilon_r} = 4.4$) with the thickness of 1.6 mm. The width of the feed line is 3 mm, by which the characteristic impedance is adjusted to 50 ohms. The distance between the center of the slot and the edge of the feed line is adjusted to obtain good matching.

Simulated and measured reflection coefficient of the proposed antenna is given in Fig. 56. Measured bandwidth (10 dB reflection coefficient) is as large as 3130 MHz (2225–5355 MHz) or 82 % with respect to the center frequency at 3790 MHz. The antenna can be a candidate for 2.4/5.2 GHz WLAN application.

Use of FSS Layers

An EBG (electromagnetic band gap) structure, which is composed by combining two complementary FSS (frequency-selective surface) layers (Munk 2000), is applied to compose a wideband Fabry-Perot resonator antenna (Wang et al. 2014). The EBG structure is illustrated in Fig. 57, which was changed to) antenna is fabricated on a substrate with thickness T and a dielectric constant εr, and the metal patches are on the top side, while the square apertures (metal grids) are on the bottom side. The aperture has complementary shape with the square patch. As the side view shows, the antenna is for the incidence of vertically polarized wave, each horizontal gap between two square patches on the top-side surface acts as a capacitor with capacitance C_p, and inductors are provided by the patch itself with a small inductance value L_p, which is shown in Part B in the equivalent circuit. The square apertures at the bottom shown in

DOI 10.1007/978-981-4560-75-7_48-3

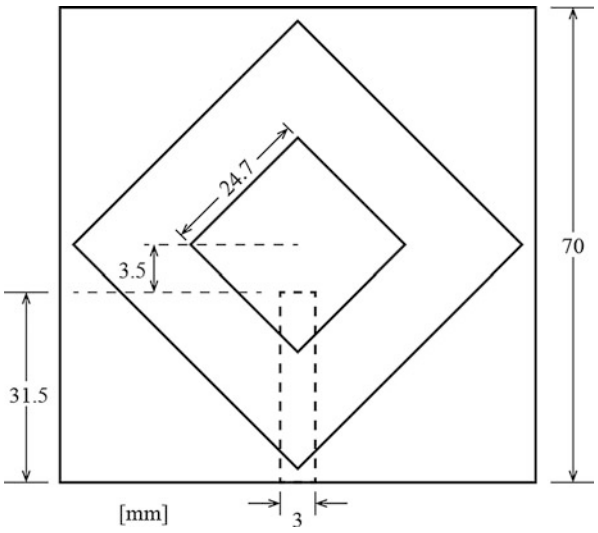

Fig. 55 Geometry of a proposed antenna

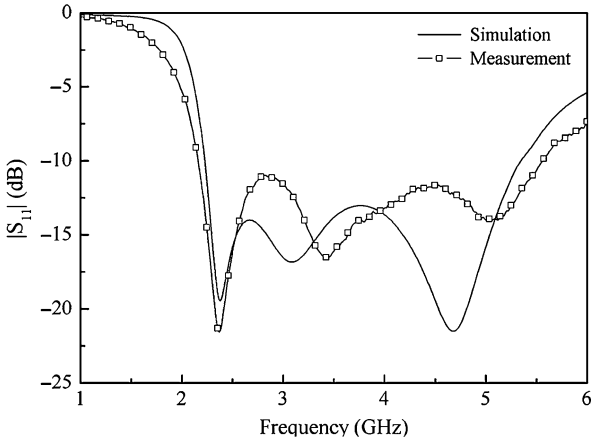

Fig. 56 Simulated reflection coefficient of proposed antenna © IEEE 2015

Fig. 57 are considered to compose long rods which act as inductors, and horizontal bars act as capacitors in parallel with the inductors as shown in Part D in the equivalent circuit given by Fig. 57. The dielectric substrate can be treated as a segment of transmission line with length L_{01} and a characteristic impedance of Z_{01} as shown in Part C in the equivalent circuit shown by Fig. 57. L_{01} is expressed by $T\sqrt{\varepsilon_r}$ and Z_{01} equals to $Z_{air}/\sqrt{\varepsilon_r}$ where Z_{air} is the wave impedance of air, about 377 ohms.

A fabricated Fabry-Perot resonance antenna designed by combining the suspended EBG layer and the feeding antenna is illustrated in Fig. 58, the feeding patch antenna is placed at the center of cavity. The patch antenna is coupled with the feed line through a slot in the ground plane and spaced from the ground plane by an air gap for suppressing the surface wave excitation. The EBG structure has the size 72 x 72 mm^2 and is comprised of 77 unit cells. The dimensions of the unit cell, the patch, and the aperture are designed to be 8 x 8 mm (less than l/3 λ at 10 GHz), 6.3 x 6.3 mm^2 and 5.6 x 5.6 mm^2, respectively.

Metamaterial Application

A compact patch antenna loaded with synthesized metamaterial (MM) is introduced (Dong et al. 2012). The MM is synthesized by using CSRR (complementary split-ring resonator) that is embedded on RIS

(reactive impedance surface) and applied to make the antenna small sized. The CSRR is incorporated on the patch as a shunt LC resonator, which provides low resonance frequency, resulting in making the antenna small. The RIS is realized by using two-dimensional metallic patches printed on a metallic-grounded dielectric. The CSRR structure and its equivalent circuit are shown in Fig. 59. The CSRR is

DOI 10.1007/978-981-4560-75-7_48-3

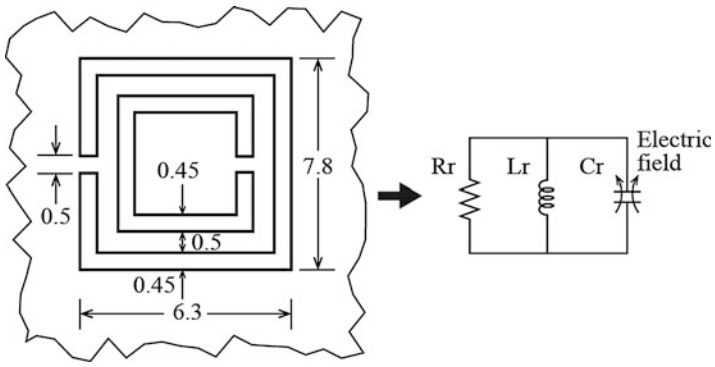

Fig. 59 CSRR structure and the equivalent circuit

modeled by a shunt LC resonator circuit and excited by the orthogonal electric field, so it is understood as an electric dipole placed along the ring axis. The RIS acts to further lower the resonance frequency and can improve the antenna radiation performance. Because it works as an inductor, it can store magnetic energy and increases the inductance value of the patch-type resonance. Then, the resonance frequency of the patch, which is inherently a parallel RLC resonator, is lowered, and the antenna is made small.

Configuration of a proposed antenna is shown in Fig. 60, which gives (a) perspective view, (b) top view, and (c) side view. The antenna consists of two CSRR elements face to back oriented with respect to the direction of the ring split. The antenna is fed by a coaxial probe in the center of the microstrip patch. The RIS is composed of a periodic array of 25 metallic square patches printed on a metal-backed dielectric substrate. As Fig. 60c illustrates, the antenna has three-layer structure, spacing with dielectric having $\varepsilon_r = 4.4$ and $\tan \delta = 0.009$ at 2.4 GHz. By illuminating a single cell by TEM plane wave, PEC (perfect electrically conducting) and PMC (perfect magnetically conducting) boundaries are established around the cell, which can be modeled as a parallel LC circuit, as shown in Fig. 61. The edge coupling of the square patch provides a shunt capacitor C, and the short-circuited dielectric-loaded transmission line can be modeled as a shunt inductor L. The ground size is 34 × 34 mm and the patch size is 12.4 × 19.2 mm.

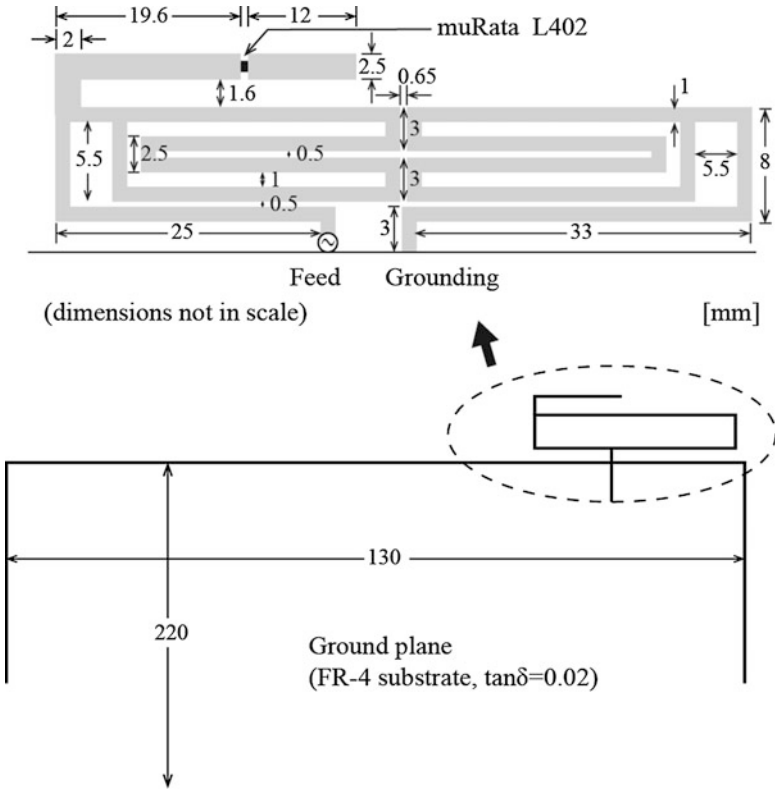

Fig. 63 Geometry of proposed antenna and parametric dimensions

An antenna, which is designed and optimized at 2.4 GHz, is analyzed parametrically. Reflection coefficients, for example, depending on h_2, keeping $h_1 + h_2 = 3$ mm, and on a_1 with $a_2 = 5.68$ mm, are shown in Fig. 62a, b, respectively.

The antenna constructed using results of the analysis is shown to perform specified functions such as circularly polarized radiation, dual- and triple-band operation with the same or different polarizations. The radiation characteristics can be controlled by changing the configurations of the CSRR. The antenna is compact, is simple in structure, and yet can be applied to versatile purposes.

PSA

Physically Small Antenna

(a.) Monopole antenna with closed-loop configuration

A PSA is designed to apply to a tablet and laptop computer (Chang and Liao 2012). It is a monopole type having closed-loop configuration as shown in Fig. 63 where its geometry and dimensions are given. The antenna was evolved from a simple loop to form a broadband antenna composed of two closed-loop elements broken from the simple loop and a folded metal strip line, on which an inductor is placed. The overall footprint of the antenna is 69 × 10 mm with the thickness of 1.6 mm of a dielectric substrate ($\varepsilon_r = 4.4$ and $\tan\delta = 0.02$). The antenna is fabricated by etching on 1.6-mm-thick fiberglass-reinforced epoxy (FR4) substrate. The overall antenna footprint is 0.16λ for

operating capability with broadband in both lower- and higher-frequency bands, this antenna is a candidate as a portable terminal for LTE, both lower and higher band GSM and UMTS systems.

(b) Dipole structure with V shape

This is a UHF RFID tag for sensing applications (Babar et al. 2012). The antenna is a V-shaped dipole (Fig. 65) embedded on multilayer substrates, constituting 0.16-mm-thick FR4, a 0.1-mm-thick vacuumed plastic bag, and a layer of 1-mm-thick paraffin wax (Fig. 66). The paraffin wax acts as the main heat-sensitive layer of the substrates. A variation of the property and characteristics in the paraffin layer is used to detect any structural and physical changes of the substrate materials. Numerical parameters of the antenna geometry shown in Fig. 65 are given in Table 4. IC chips are laid on the terminals ***a*** and antenna feeding lines ***d*** are connected to the two arms of the V dipole. By using a V shape, the current path is made longer, and resonance frequency at the matched condition is lowered to 870 MHz with the help of a shorted line g which gives an additional inductance to make antenna size small along with a T-matching circuit. The overall antenna size is 44×30 mm^2.

The antenna is designed for a heat-sensing tag, detecting the exposure of various goods and products to high-heat environment by detuning the sensor tag. The maximum read range is shown in Fig. 67. The figure shows a frequency shift of about 30 MHz after heating. The paraffin wax acts as the heat-sensitive layer of the substrate, which changes the properties under the high-temperature environments. Change in the paraffin properties affects the dielectric properties of the whole multilayer substrate of the tag that influences the whole substrate, resulting in the change of the impedance and operating frequency of the antenna.

This type of heat-sensing tag is useful in many applications including supply chain operations and transportation of various heat-sensitive drugs and food items.

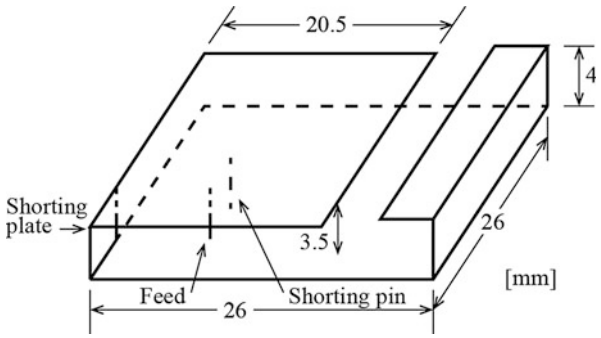

Fig. 68 The proposed antenna structure and its dimensions

(c) Modified PIFA

A compact PIFA operating in ISM band (2.45 GHz) is designed for on-body communication. The antenna (Lin et al. 2012) is composed of the rectangular planar horizontal element (patch) and folded end of the ground plane as the geometry with the dimensional parameters shown in Fig. 68. The horizontal patch (20.5 × 26 mm^2) is grounded by the small shorting plate, and the shorting pin is located near the feeding pin. The antenna size is 26 × 26 × 4 mm^3. The ground plane length ($L_1 + L_2 + L_3$) is 32 mm and the height h is 3.5 mm. With this antenna structure, the resonance frequency is 2.45 GHz. Three kinds of arm phantom are shown in Fig. 69a, while simulated reflection coefficients with those phantoms are given in Fig. 69b. These three arm phantoms are made in forms of rectangular solid, column, and rectangular solid with three layers. The phantoms are comprised of deionized water, agar salt, polyethylene powder, and TX-151. The proposed antenna is placed on a two-third muscle-equivalent phantom (dimensions of 50 × 50 × 400 mm^3, relative permittivity $\varepsilon_r = 35.2$, conductivity $\sigma = 1.16$ S/m). The antenna is put on the arm phantom 70 mm away from its end and takes 2-mm space between the antenna and the phantom. The three-layer phantom is comprised of equivalences of skin ($\varepsilon_r = 42.85$, $\sigma = 1.59$ S/m), fat ($\varepsilon_r = 5.28$, $\sigma = 0.10$ S/m), and

DOI 10.1007/978-981-4560-75-7_48-3

muscle ($\varepsilon_r = 53.59$, $\sigma = 1.81$ S/m). The resonance frequency of the antenna is affected very little when mounted on the human arm.

MW and Higher-Frequency-Range Antennas

(a) Wideband from about 5 to 25 GHz antenna

Hybrid monopole DRAs (dielectric resonator antenna) having hemispherical/conical structure illustrated in Fig. 70. (Guha et al. 2012) are described. The figure shows (a) top view of DRA either structure, (b) side view of monopole loaded with HDRDR (hemispherical dielectric ring resonator),

		Antenna parameters (mm)				
Design freq. f_L-f_H (GHz)	λ_l(cm)	*l*	*s*	*r*	*b*	*a*
#1: 4–16	6.00	15.0	1.35	0.65	2.0	6.8
#2: 5.6–22.4	4.29	10.7	1.3	0.65	1.95	4.8

and (c) side view of a monopole loaded with CoDRR (Conical Dielectric Ring Resonator). Dimensional parameters of the antenna are also given in the figure.

The antenna is designed to have ultra-wideband. The design procedure starts with specifying the operating frequency by using lowest and highest frequencies f_L and f_h, respectively, and they are set to $f_h = 4\ f_L$. Then the the design frequencies used are f_L is 4GHz in the design #1 and 5.6 GHz in the design #2. The parameters of the designed antenna are given in Table 5. In Table 5, parameters ε=10, h=a and d=0.6λ_1 are used, where d is the diameter of the ground plane and h is the height of both HDRR and CoDRR. Simulated S_{11} for HDRR and CoDRR is depicted in Fig. 71a and b, respectively, where the design is identified by #1 and #2.

Parameters	W	$L1$	L_2	L_F	G_1	G_2	H	E_1	E_2	D
Unit (mm)	1.4	0.9	0.4	0.3	0.19	0.11	0.79	0.22	0.15	0.3
λg (guided wavelength)	0.42	0.26	0.12	0.09	0.06	0.03	0.23	0.07	0.04	0.09

The design procedure shown here is useful in producing practical antennas. A considerably compact monopole introduced here has nearly 126 % or 1 to 4 operating bandwidth with average 4 dBi peak gain. The antenna should be applicable in many areas from wide-range EM sensors to UWB communications.

(b) 60-GHz antenna

A planar quarter-wavelength (electric) dipole antenna combined with a quarter-wavelength patch (magnetic) antenna (Ng et al. 2012) is shown in Fig. 72a, while the 3D view and side view are illustrated in Fig. 72b, c, respectively. Practically, the planar dipole element is printed on a ROGERS laminate (RT/duroid 5880, $\varepsilon_r = 2.2$, thickness $h = 0.787$ mm). The quarter-wavelength patch antenna is formed by three metallic vias, fabricated by using plated-through-hole technology, which are located at the inner edge of each half planar dipole and shorted to the ground plane so they effectively form a vertically oriented antenna. Simulated and measured reflection coefficients for the prototype antenna are depicted in Fig. 73. It can be seen in the figure that the antenna has bandwidth as wide as 43 % for −10 dB S_{11} from 48 GHz to 75 GHz. Antenna gain is about 7.5 dB over 5070 GHz. Dimensions of the prototype antenna are given in Table 6.

(c) Antenna in THz and above frequency ranges

An antenna composed of bundled carbon nanotube (BCNT) (Choi and Sarabandi 2011), which is used as a conducting material to fabricate an antenna, is introduced, and its performances are evaluated in THz and above ranges. The performance is compared with the gold film, which is usually used for such antenna fabrication. The macroscopic behavior of BCNT is modeled by an isotropic resistive sheet model which is extracted from the discrete circuit model of a single-wall carbon nanotube (SWNT). By using the method of moment and mixed potential integral equation (MPIE), numerical simulations are performed to quantify radiation efficiency of resonant strip antennas composed of BCNT and gold film.

DOI 10.1007/978-981-4560-75-7_48-3

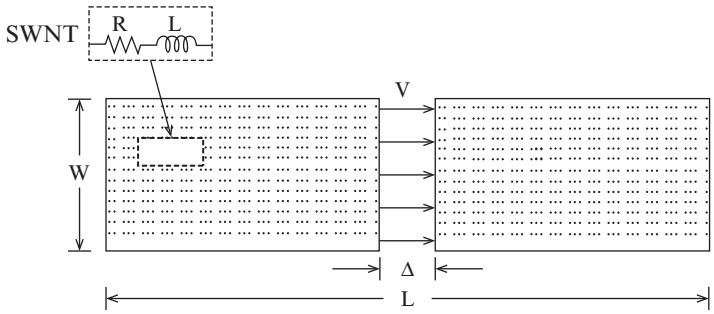

Fig. 74 Strip antenna geometry fed at the center using a thin voltage gap V; with equivalent circuit of SWNT unit

The SWNT has a cylindrical geometry with an extremely high aspect ratio and high resistance per unit length because of its very small radius in the order of nanometers. These properties limit its direct use for microwave application. To overcome this limitation, BCNT is developed to reduce the high intrinsic resistance of SWNT. Here, the performance of the BCNT is investigated as a material for fabricating antennas at THz frequencies and above. Figure 74 illustrates the proposed geometry of a strip dipole antenna constructed from strands of SWNT. In the figure, the macroscopic equivalent circuit model represented by the circuit elements of parallel-connected SWNTs in the bundle structure is given. These strands form an extremely thin conducting layer (about 10 nm), which can support the electric current along the antenna axis. In the bundle, each single nanotube, which is represented by the equivalent circuit model of the SWNT, is assumed to be connected in parallel, and electrons move only along the axis of SWNT; thus, only the electric-field component parallel to the strands can excite the surface currents.

In the THz or optical regions, the Drude model provides the conductivity of a good conductor (copper or gold) as a function of frequency. According to the Drude model, the negative real permittivity of gold at THz frequencies corresponds to an inductive reactance as opposed to the constant permittivity of free space assumed for good conductors at low frequencies.

To evaluate performance of an antenna composed of BCNT or thin gold film, the length L of the strip dipole antenna is varied to obtain fundamental resonance frequency over the range of 1–50 GHz. The antenna (Fig. 74) is excited by a thin voltage gap at the center. The antenna width W is chosen to be L/6 Antenna input impedance and reflection coefficient in terms of 50 Ω are studied to evaluate the performance of the BCNT and gold antennas operating at the same frequencies. Two strip BCNT antennas with density values of 10 and 50 CNTs/μm are considered. The antenna length is chosen to be 150 μm, which corresponds to an ideal dipole antenna operating at 1 THz. Although the density of such values can be realized by current nanofabrication facilities, antenna impedance is rather high in the range of kΩ, and the inductive reactance is also quite large, so matching to the 50-Ω load is difficult to perform. When the input impedance is varied by changing the BCNT density to above 10^3 CNTs/μm, the antenna can easily be matched without an external matching element. It is important to note that the antenna miniaturization effect is achieved by the BCNT antenna. The antenna miniaturization effect is defined by 2 L/λ, which is the normalized antenna length. As the density of BCNT increased from 10^3 to $5{\cdot}10^4$ [CNTs/μm], 2L/λ approaches unity, because the density of BCNT is inversely proportional to the inductance of the bundle and the lower density causes a lower resonance frequency, corresponding to a larger resonance wavelength. Antenna efficiency is compared between BCNT and gold film and given in Fig. 75, where (a) indicates for the densities of BCNT in the range of 10^2 to $5{\cdot}10^4$ [CNTs/μm] and (b) illustrates with magnified scale for the BCNT densities in the range of 10^4 to $5{\cdot}10^4$ [CNTs/μm].

Future Directions and Open Problems

Small antennas are generally applied to numerous wireless systems and further extend to wide areas such as not only communications but also high-rate data and image transmission, radio control, and near-field systems, including RFID, wireless power transmission, body-centric communications, wearable systems, and so forth.

DOI 10.1007/978-981-4560-75-7_48-3

In each era, new systems appeared with advancement of technologies and social needs. Wireless systems were no exception, and neither were small antennas, as antenna technologies also made progress. In turn, it is true that wireless systems have also made progress along with small antennas. Impacts impressed upon wireless systems by small antennas are so great that systems to which small antennas are applied could be of little use without small antennas.

The trend is to extend further the application of small antennas to more sophisticated systems, more compact, small wireless terminals, and so forth. Antenna engineers should always encounter challenges to conquer difficulty in design and development of new small antennas that satisfy requirements of newly deployed systems, even though it might appear to exceed fundamental limitations imposed for small antennas. Integration techniques; application of electromagnetic materials, including metamaterials; and the cutting-edge design technologies expected along with the sophisticated theory will further enhance development and advancement of small antennas, which surely will give rise to a big impact on and contribute endlessly to the significantly wireless world.

SMALL ANTENNAS – BIG IMPACT!

Wideband Magneto-electric Dipole Antennas

Mingjian Li* and Kwai-Man Luk
Department of Electronic Engineering and State Key Laboratory of Millimeter Waves, City University of Hong Kong, Hong Kong SAR, People's Republic of China

Abstract

The magnetoelectric (ME) dipole antenna is a type of complementary antenna. The basic antenna geometry includes a planar electric dipole and a vertical shorted quarter-wave patch antenna. Traditionally, a proximity coupled feed is utilized to excite the antenna which performs as a combination of an electric dipole and a magnetic dipole. As a result, the antenna exhibits a wide impedance bandwidth, a stable gain, and a stable radiation pattern with low cross-polarization and back radiation levels over the operating frequencies. After the discourse of the fundamental magnetoelectric dipole design, several studies are devoted to antenna height reduction and alternative feed methods. And then some research works, focusing on designing magnetoelectric dipoles with different polarizations, are presented. The magnetoelectric dipole antenna is also modified for the fulfillments of various applications, such as UWB and 60-GHz wireless communications. Other than the magnetoelectric dipole, several other types of complementary antennas are also introduced.

Keywords

Magnetoelectric dipole antenna; Electric dipole; Shorted quarter-wave patch; Dual-polarized antenna; Circularly polarized antenna; Diversity antenna; Ultra-wideband antenna; 60-GHz antenna; Complementary antenna

Introduction

In 1954, Clavin proposed a new type of radiating element (Clavin 1954), as shown in Fig. 1. This antenna, consisting of an electric dipole and a coaxial line with an open end, is known as the complementary antenna. Practically, the complementary antenna is a kind of composite antenna, which comprises a pair of complementary sources. If the two sources of equal amplitude are combined in the proper phase, the resulting radiation pattern will be identical in the E- and H-planes, and furthermore, the back radiation will be suppressed. Arising from this concept, several antenna designs were proposed based on a dipole/slot (King and Owyang 1960) or a monopole/slot (Mayes et al. 1972) combination. The slot antenna was used to realize the magnetic dipole when the microstrip patch antenna was not yet developed. Excellent results in radiation patterns and bandwidth were achieved, but the antennas are not suitable for base stations in mobile communications mainly due to their bulky structures.

In 2006, Luk and Wong first utilized a dipole/shorted patch antenna combination to realize a wideband complementary antenna which was designated as the magnetoelectric (ME) dipole, as shown in Fig. 2. It was found that this antenna with excellent performance in all characteristics could be employed to develop wideband base station antennas for mobile communications. In comparison with the conventional

antennas such as the electric dipole antenna and microstrip antenna, the ME dipole can be used in array environment to produce wideband base station antenna with stable performance in gain, beamwidth, and radiation pattern over the operating frequencies. The advantages and disadvantages of the electric dipole, microstrip patch, and ME dipole are listed in Table 1.

Subsequently, the ME dipole antenna was developed into different forms with dual polarizations, circular polarization, or pattern and polarization diversities to fulfill various applications such as mobile, ultra-wideband and millimeter-wave communications.

In this chapter, the theory of complementary antenna is discussed in section "Theory of Complementary Antenna." The basic model of magnetoelectric dipole antenna, methods for height reduction, and other feed mechanisms are the topics of section "Basic Form of Magnetoelectric Dipole Antenna." In section "Magnetoelectric Dipole Antennas with Different Polarizations," examples with dual and circular polarizations are presented. And a magnetoelectric dipole antenna with pattern and polarization diversities is studied. Magnetoelectric dipole antennas for the ultra-wideband and millimeter-wave applications are discussed in sections "Designs for UWB Applications" and "Designs for 60-GHz Applications," respectively. Section "Other Complementary Antenna Designs" presents some other complementary designs. Concluding remarks are given in section "Conclusion."

Table 1 Comparisons between the electric dipole antenna, microstrip patch antenna, and ME dipole antenna

	Advantages	Disadvantages
Electric dipole	Wide impedance bandwidth	High profile Unstable gain over operating frequencies Unstable beamwidth over operating frequencies High cross-polarization and back radiation levels
Microstrip patch	Low profile Conformability to a shaped surface Ease of fabrication	Narrow bandwidth High cross-polarization and back radiation levels
Magnetoelectric dipole	Wide impedance bandwidth Stable gain over operating frequencies Stable beamwidth over operating frequencies Low cross-polarization and back radiation levels	High profile

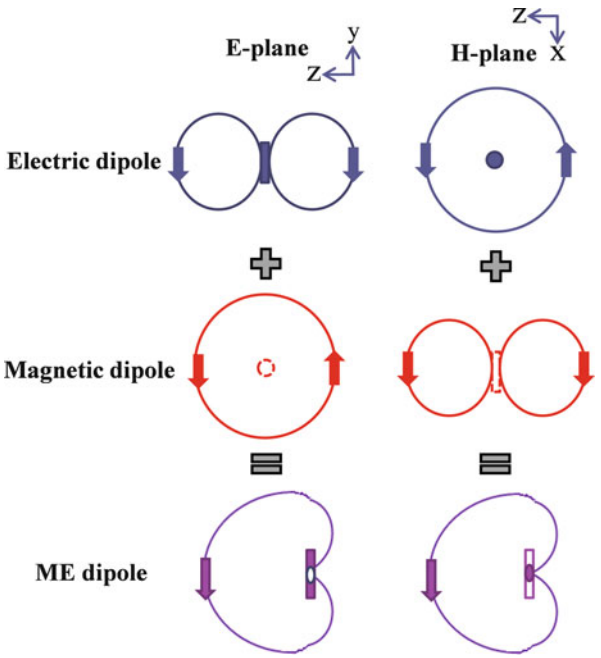

Fig. 3 Radiation mechanism of a complementary antenna

Theory of Complementary Antenna

Radiation Characteristic

Typically, a complementary antenna consists of an electric dipole and a magnetic dipole placed orthogonally and excited simultaneously. The radiation mechanism of a complementary antenna is illustrated in Fig. 3. The radiation pattern of an electric dipole looks like a figure-8 shape in the E-plane and a figure-O shape in the H-plane, whereas the radiation pattern of a magnetic dipole looks like a figure-O shape in the E-plane and a figure-8 shape in the H-plane. When the two sources of equal amplitude are combined in the proper phase, the resulting radiation pattern will have a cardiac shape with identical and symmetrical radiation patterns in the E-plane and the H-plane. More importantly, the back radiation will be zero which is desirable in cellular communications.

DOI 10.1007/978-981-4560-75-7_49-1

Analytically, an electric Hertzian dipole with a length of *dy*, placed along the *y*-axis, can be equivalent to an electric current $I = H_x dx$. Hence, the electric field in the far-field zone can be expressed as

$$\vec{E} = j\frac{Idy}{2\lambda r}\eta\left(e_\theta \cos\theta \quad \sin\varphi + e_\varphi \cos\varphi\right)e^{-jkr}. \tag{1}$$

While a magnetic Hertzian dipole with a length of *dx*, placed along the x-axis, is equivalent to a magnetic current, $I_m = E_y dy$. Hence, the electric field in the far-field zone can be expressed as

$$\vec{E} = \quad -j\frac{I_m dx}{2\lambda r}\left(e_\theta \sin\varphi + e_\varphi \cos\theta \quad \cos\varphi\right)e^{-jkr}. \tag{2}$$

A complementary antenna (or Huygens' source) can be realized by simultaneously exciting the electric Hertzian dipole and magnetic Hertzian dipole with the same magnitude in strength. Hence, the far-field electric field is obtained by adding Eqs. 1 and 2,

$$\vec{E} = j\frac{E_y dxdy}{2\lambda r}\left[e_\theta \sin\varphi(1 + \cos\theta) + e_\varphi \cos\varphi(1 + \cos\theta)\right]e^{-jkr}. \tag{3}$$

Consequently, the normalized radiation patterns in planes of any φ are the same and can be expressed as

$$F(\theta) = \frac{\sqrt{\sin^2\varphi(1 + \cos\theta)^2 + \cos^2\varphi(1 + \cos\theta)^2}}{2} = \frac{(1 + \cos\theta)}{2}. \tag{4}$$

When $\theta = 180°$, $F(\theta) = 0$, indicating that there is no back radiation. Hence, the radiation characteristic of the complementary antenna confirms that this concept can be applied for developing unidirectional antennas.

Impedance Characteristic

The impedance characteristic of complementary antenna is also investigated here. As is known to all, the microstrip patch antenna radiates as a magnetic current source. Hence, different from using the slot antenna in the classical complementary antenna, the patch antenna is employed to realize the magnetic dipole this time. An equivalent circuit of the complementary antenna is shown in Fig. 4. The patch antenna has a fundamental resonant mode which can be represented by a parallel resonant circuit (resistance R_p, capacitance C_p, and inductance L_p), whereas the electric dipole has a fundamental mode which can be represented by a series resonant circuit (resistance R_d, capacitance C_d, and inductance L_d). When the two circuits are connected in parallel, the input admittance is (Luk and Wu 2012)

$$\begin{aligned} Y_{in} &\approx \left[\frac{1}{R_d + j\left(\omega L_d - \frac{1}{\omega C_d}\right)}\right] + \left[\frac{1}{R_p} + j\left(\omega C_p - \frac{1}{\omega L_p}\right)\right] \\ &\approx \left[\frac{1}{R_d} - j\left(\omega L_d - \frac{1}{\omega C_d}\right)\frac{1}{R_d^2}\right] + \left[\frac{1}{R_p} + j\left(\omega C_p - \frac{1}{\omega L_p}\right)\right] \\ &= \left[\frac{1}{R_d} + \frac{1}{R_p}\right] - j\left[\left(\omega L_d - \frac{1}{\omega C_d}\right)\frac{1}{R_d^2} - \left(\omega C_p - \frac{1}{\omega L_p}\right)\right]. \end{aligned} \tag{5}$$

DOI 10.1007/978-981-4560-75-7_49-1

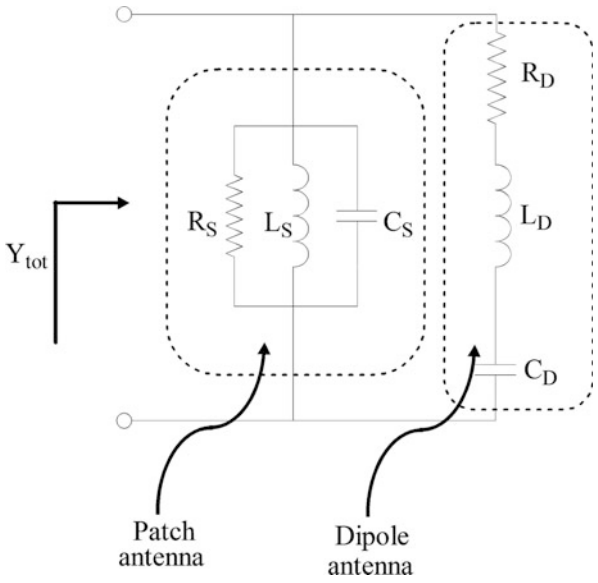

Fig. 4 Equivalent circuit of a complementary antenna

It can be observed that the imaginary part of the input admittance of the complementary antenna can be canceled out if

$$\begin{aligned} C_d L_d &= C_p L_p \\ R_d^2 &= L_d / C_p. \end{aligned} \tag{6}$$

The two equations can be satisfied simultaneously if the electric dipole and the patch antenna have the same resonant frequency, and the input resistance of the electric dipole is adjusted to a value related to the reactive components of the electric dipole and the patch antenna. Although this is not a rigorous proof, the result provides us with the insight that the complementary antenna can be wide in bandwidth if the dimensions of the antenna are selected appropriately.

Basic Form of Magnetoelectric Dipole Antenna

Antenna Configuration

According to the complementary antenna concept studied in the previous section, the magnetoelectric dipole antenna is developed by combining an electric dipole and a magnetic dipole. In the basic form, the electric dipole part is realized by a planar half-wavelength dipole as shown in Fig. 5a. The magnetic dipole part is implemented with the use of a shorted quarter-wavelength patch antenna as shown in Fig. 5b. From the classical cavity model theory, the radiation of a shorted quarter-wave patch antenna is mainly from the open end which radiates as a magnetic current. To combine the two antennas, the planar electric dipole, placed in front of a ground plane with a distance of quarter wavelength, has the inner edges shorted to the ground plane through two vertical metallic walls as shown in Fig. 5c. The metallic walls together with the ground plane between them form a vertical shorted quarter-wave patch antenna with a thickness of approximately 10 % of the operating wavelength. The feed of the antenna is a Γ-shaped probe, consisting of three portions. The first portion incorporated with its adjacent vertical metallic wall performs as an air microstrip line with 50-Ω characteristic impedance. This portion transmits the electric signal from the coaxial launcher to the second portion of the feed which is responsible to couple the electrical energy to

the magnetoelectric dipole. The third portion together with the vertical metallic wall acts as an open circuited microstrip stub which compensates the inductance introduced by the second portion.

Example of a Magnetoelectric Dipole Antenna

In the original study of Luk and Wong (2006), the performance of the antenna was demonstrated experimentally. The dimensions of the ME dipole operating at 2.5 GHz are shown in Table 2. Results for the impedance and radiation characteristics of one such antenna are shown in Figs. 6 and 7. The impedance bandwidth ($S_{11} \leq -10$ dB) is 49.1 % from 1.80 to 2.97 GHz. The antenna gain was approximately 7.9 dBi, varying from 7.54 to 8.14 dBi. The measured radiation patterns were stable across the band. The E-plane and H-plane beamwidths were generally equal. The cross-polarization and back radiation levels were very low across the entire operating bandwidth.

DOI 10.1007/978-981-4560-75-7_49-1

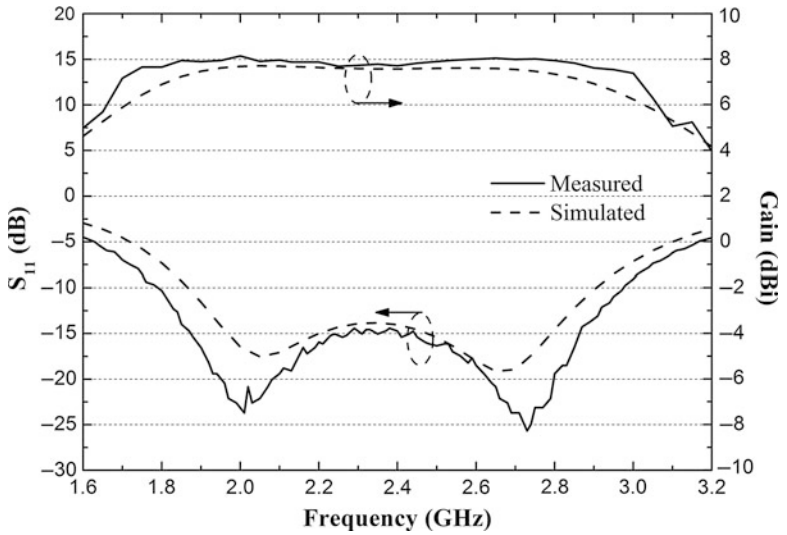

Fig. 6 Simulated and measured SWRs and gains

Magnetic Dipole

Geometrically, there is not much difference between this antenna and the common reflector-backed electric dipole excited by a conventional balun. However, the vertical metallic walls with the Γ-shaped probe make a substantial difference in the performance of the antenna. Three scenarios are studied here as shown in Fig. 8, i.e., ME dipole, planer electric dipole, and electric dipole. The simulations demonstrate that if the width of the vertical wall is reduced to $W_1 = 10$ mm, the beamwidth in H-plane becomes larger than that in E-plane and the back lobe is increased. The reason is that without the help of the magnetic dipole, the antenna works as a reflector-backed electric dipole.

The vertical shorted patch antenna has a height of quarter wavelength. Using the IE3D simulator, the SWR and gain are studied for various heights as shown in Fig. 9. It can be seen that if H is decreased such that the shorted quarter-wave patch antenna is reduced in resonant length, the second resonance is shifted upwards while the first resonance frequency is fixed at 2 GHz. This confirms that the second resonance is controlled by the size of the quarter-wave path antenna.

Electric Dipole

Typically, the planar electric dipole has a length of approximately half wavelength. The SWR and gain are studied for various dipole lengths as shown in Fig. 10. If L is increased such that the electric dipole is enlarged, the first resonance is shifted to a lower frequency, while the second resonance is fixed at 2.7 GHz. This confirms that the first resonance is mainly affected by the electric dipole.

Γ-Shaped Probe

Basically, the Γ-shaped probe performs as an air microstrip line connected to an L-shaped probe. It has a significant effect on the impedance matching of the antenna. The effect of the length of the Γ-shaped probe, **a**, is investigated as shown in Fig. 11. Reducing **a**, the first resonance moves downwards with a fixed second resonance and the in-band SWR is increased. The length of **b** of the Γ-shaped probe is also a crucial parameter on the impedance matching. The result is shown in Fig. 12. When **b** is decreased, the second resonance moves upwards with the first resonance fixed and the impedance matching at lower frequencies deteriorates.

Ground Plane

The ground plane acting as the reflector of the antenna has a significant effect on its performance, so the ground plane size effects have to be studied carefully. One extreme case is that the ME dipole does not have a ground plane. The radiation pattern at the center frequency is shown in Fig. 13a. As the aforementioned complementary antenna concept, the ideal complementary antenna has no back radiation. However, the ME dipole without a ground plane has a back lobe of approximately −7 dB. The reason is that when designing the ME dipole antenna, the antenna and the ground plane should be considered as a

DOI 10.1007/978-981-4560-75-7_49-1

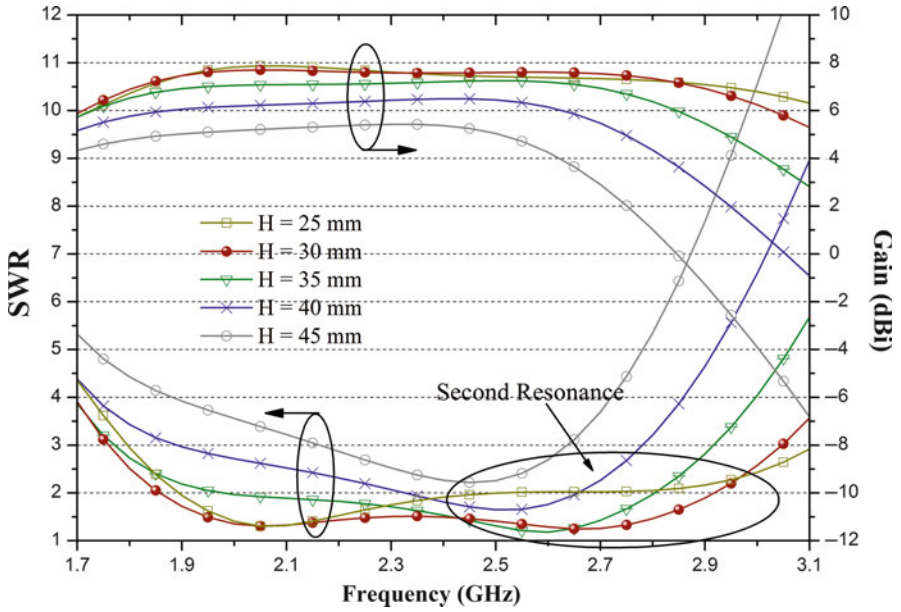

Fig. 9 Effect of the height of antenna H

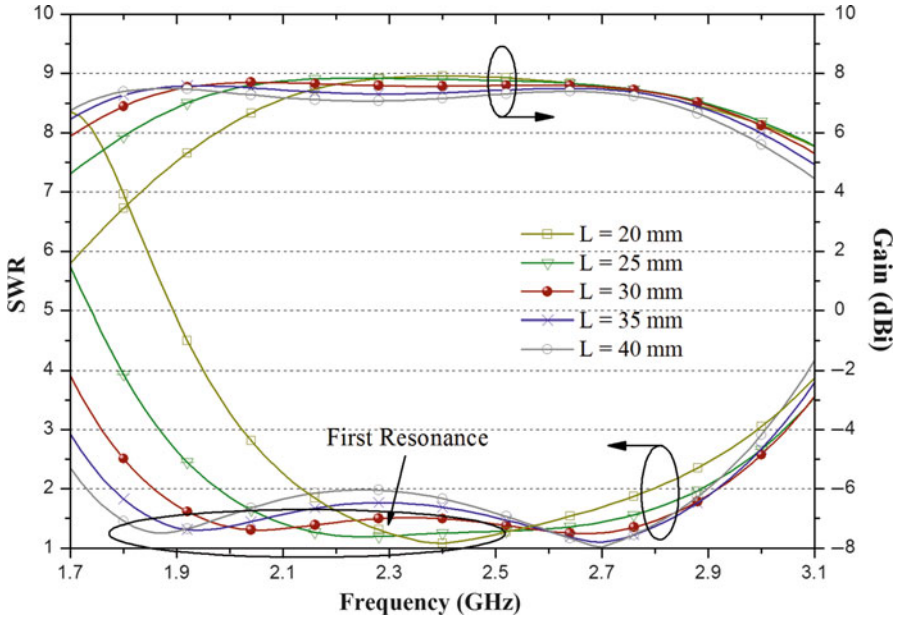

Fig. 10 Effect of the length of the planar electric dipole L

whole. In most cases, the ME dipole antenna cannot be mounted without a ground plane. It has to be noted that the ground plane between the vertical walls is a portion of the quarter-wave patch antenna and cannot be removed. As shown in Fig. 13b, c, and d, the back radiation increases with reducing G. The SWR and gain are also studied with different G, as shown in Fig. 14. The simulations demonstrate that as G is increased, the antenna gain is enhanced. But the ground plane size has no effect on the antenna impedance matching.

Design Guideline

Based on the above study, a design guide is recommended as follows:

Methods of Reducing Height

Compared to microstrip patch antenna, ME dipole antenna has many good electrical characteristics. However, a notable drawback is that the ME dipole has a large height of approximately $0.25\lambda_0$, which may be undesirable for some practical applications. Hence, several methods to reduce the antenna height are introduced below.

Folded Magnetoelectric Dipole

A straightforward approach to the height reduction of ME dipole is to fold the vertical metallic walls as shown in Fig. 15. The folded ME dipole antenna consists of a planar electric dipole, a folded shorted quarter-wave patch antenna, and a folded Γ-shaped probe. The antenna height is $H = 2 \times h_1 + h_3$, whereas the electrical length of the shorted patch antenna is $2 \times h_1 + 2 \times h_2 + h_3$. Hence, this method confirms that the height of the antenna is reduced while keeping the physical length of the shorted patch antenna quarter wavelength. The original Γ-shaped probe is modified. The 50-Ω air microstrip line portion of the probe is folded and placed along the adjacent folded vertical metallic wall. The dimensions of the folded ME dipole operating at 2.95 GHz are shown in Table 3. Experimentally, the antenna with a height of $0.176\lambda_0$ (i.e., 18 mm, $h_1 = h_2 = h_3 = 6$ mm) was constructed and measured. Fig. 16 shows the simulated and measured SWRs and gains. It can be seen that the antenna exhibits a wide impedance bandwidth (SWR $\leq$2) of 46 % from 2.3 to 3.66 GHz and a gain of approximately 7.7 dBi over the operating frequency band. The radiation pattern at 2.8 GHz is shown in Fig. 17. It should be noted that the antenna height can be reduced further by using this method. With the decrease of the antenna height, the operating band is narrowed and shifted upwards. A design guide for this antenna is recommended as follows:

DOI 10.1007/978-981-4560-75-7_49-1

Magnetoelectric Dipole with Dielectric Loading

Another technique for reducing the ME dipole height is to use a higher-permittivity dielectric substrate instead of an air substrate in the shorted quarter-wave patch antenna. Siu et al. (2009) presented experimental study of an ME dipole with dielectric loading. The geometry of the antenna is depicted as shown in Fig. 18. It consists of a planar electric dipole, a dielectric-loaded shorted quarter-wave patch antenna, and a Γ-shaped probe. The region between the two vertical metallic walls is fully filled with the dielectric material with permittivity of 2.65; therefore, the height of the antenna is reduced to $0.16\lambda_0$, and the height can also be reduced further by using a substrate with higher permittivity. The dimensions of the ME dipole with dielectric loading operating at 2.67 GHz are shown in Table 4. As shown in Fig. 19, the antenna exhibits a wide impedance bandwidth ($S_{11} \leq -10$) of 49 % from 2.0 to 3.3 GHz and a gain of approximately 8.1 dBi. The radiation pattern at 2.5 GHz is illustrated in Fig. 20. The cross-polarization level is approximately −18 dB which is quite high in comparison with that of the original ME dipole design, which is probably due to the excitation of higher order modes in the shorted quarter-wave patch antenna.

Using Different Magnetic Dipoles

By using the aforementioned methods, the ME dipole height can be reduced effectively. However, it is obvious that the antenna structure becomes complex and the operating bandwidth is reduced. As a matter of fact, the height of ME dipole is mainly determined by the magnetic dipole which is a shorted quarter-wave patch antenna in the original ME dipole design. By utilizing other types of magnetic dipole, the antenna height can also be reduced while maintaining good electrical characteristics. In this section, two examples of ME dipole antennas employing a loop antenna as the magnetic dipole are presented.

Triangular Loop The triangular loop antenna was first used as a magnetic dipole by Luk and Wu (2012). As shown in Fig. 21, the antenna consists of a planar electric dipole, a triangular loop antenna, and a directly connected feed. The loop antenna is formed by changing the cross-sectional shape of the shorted quarter-wave patch antenna into a triangular shape. For excellent performance, the cross section should have a shape close to an equilateral triangle ($\theta = 60°$) with a total length of approximately $\lambda_0/2$. By using this magnetic dipole, the antenna height is reduced to $0.16\lambda_0$, and the gap between the planar dipole arms is only $0.02\lambda_0$ which allows the feasibility in designing the directly connected feed. This type of feed, including a segment of a coaxial cable and a small patch on the top corner of the triangular loop, will be

than the measured gain. The radiation pattern at 2.4 GHz is depicted in Fig. 23. A design guide for this antenna is recommended as follows:

1. According to the required center frequency of the operating band (λ_0), determine the dimensions of the planar electric dipole antenna with $L = 0.23\lambda_0$ and $W = 0.5\lambda_0$.
2. Determine the dimensions of the triangular loop antenna with $H = 0.16\lambda_0$ and $\theta = 60°$.
3. Choose the ground plane with a proper size ($G \geq \lambda_0$).
4. Design the directly connected feed.

Rectangular Loop Subsequently, Ge and Luk (2012a) utilized a rectangular loop antenna to perform as the magnetic dipole in the ME dipole antenna. Fig. 24 shows the geometry of the antenna. It consists of a planar electric dipole, a rectangular loop antenna, a directly connected feed, and a box-shaped reflector. By using the rectangular loop antenna, the antenna height can be reduced to $0.164\lambda_0$. A box-shaped reflector is employed to further reduce the back lobe and achieve a stable radiation pattern. The directly connected feed includes a segment of coaxial cable and an air microstrip line which extends along one arm

of the dipole, across the gap $S = 0.05\lambda_0$, and then directly connects to the other arm of the dipole. The antenna prototype operating at 2.59 GHz was fabricated with dimensions shown in Table 6. Fig. 25 shows the simulated and measured SWRs and gains. The measured impedance bandwidth is 54.8 % for SWR $\leq$ 1.5 from 1.88 to 3.3 GHz which is much wider than that of the triangular loop ME dipole antenna. The measured gain is approximately 8.6 with 0.8 dBi variation. The radiation pattern at 2.6 GHz is shown in Fig. 26. A design guide for this antenna is recommended as follows:

DOI 10.1007/978-981-4560-75-7_49-1

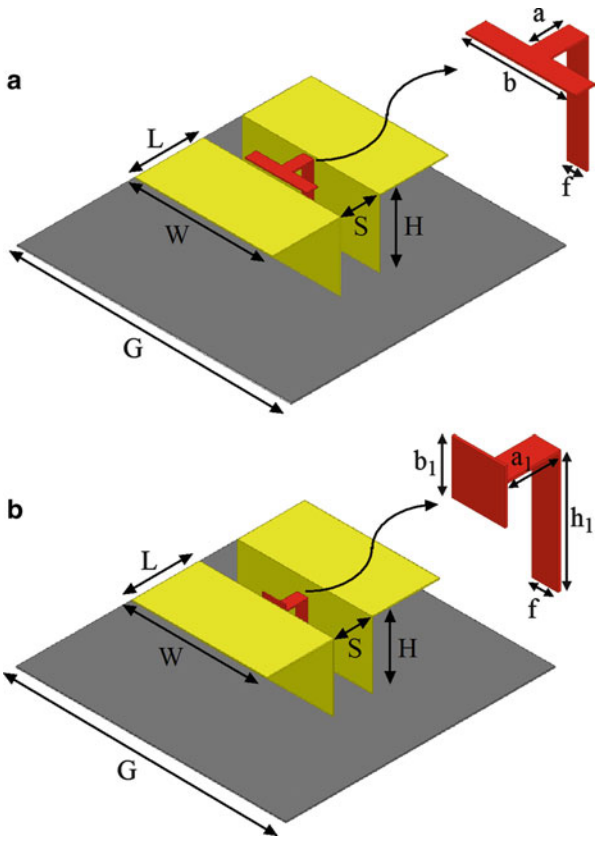

Fig. 27 Other types of ME dipole feeds. (**a**) T-shaped probe, (**b**) square-patch coupled probe

1. According to the required center frequency of the operating band (λ_0), determine the dimensions of the planar electric dipole antenna with $L = 0.259\lambda_0$ and $W = 0.518\lambda_0$.
2. According to the required antenna height, determine M_1 and M_2 by keeping $2 \times (M_1 + M_2) \approx 0.5\lambda_0$.
3. Choose the ground plane with a proper size ($G \geq \lambda_0$).
4. Design a directly connected feed and tune f to achieve a good impedance matching.

Other Feed Mechanisms

In the original ME dipole, a Γ-shaped probe is used to feed the antenna as illustrated in Fig. 5c. In practical use, the third portion of the probe can be deformed into different shapes to compensate the inductive reactance from the second portion. Two types of feeds are shown in Fig. 27, i.e., the T-shaped probe and the square-patch coupled probe. The T-shaped probe shown in Fig. 27a has the third portion of a horizontal patch. This confirms that the design in the millimeter-wave bands can be printed on a single-layer printed circuit board which will be discussed in section "Designs for 60-GHz Applications." The probe shown in Fig. 27b is shorter than the original Γ-shaped probe and has the third portion of a square patch. Although the antenna with either type of feed exhibits a wider impedance bandwidth compared to the case with original Γ-shaped probe, it suffers from higher back radiation and cross-polarization levels.

In addition, the aforementioned types of probes are all coupled proximity feeds and not direct-current (dc) grounded, which therefore cannot fulfill the requirement for lightning protection in outdoor applications. Hence, as studied in section "Methods of Reducing Height," the ME dipole antennas have loop antenna as the magnetic dipole (Luk and Wu 2012; Ge and Luk 2012a; Ge and Luk 2013a). The directly

DOI 10.1007/978-981-4560-75-7_49-1

connected feed is used to excite the antennas. This type of feed together with the loop antenna also functions as a folded balun and provides a wide operating bandwidth. However, because there is no portion compensating the inductance contributed by the portion of the feed across the separation between the dipole arms, it requires the separation to be very small, which definitely increases the complexity of the antenna structure. Moreover, due to the folded balun not working as well as the Γ-shaped probe, the maximum gain cannot occur exactly in the broadside direction at the higher frequencies.

Magnetoelectric Dipole Antennas with Different Polarizations

Dual-Polarized Antenna

General Remarks

The polarization diversity technique has been widely used in mobile communication base stations due to its attractive features and advantages. In real applications, a ± 45° dual-polarized antenna is used to receive and combine two uncorrelated signals to compensate for the signal degradation caused by the multipath-fading phenomena (Vaughan 1990), therefore increasing the signal reliability. Compared to the spatial diversity technique, the polarization diversity technique only requires one antenna for operation, thus reducing the installation cost and space (Turkmani et al. 1995).

In the literature, many dual-polarized antennas were presented based on the slot antenna (Paryani et al. 2010), dipole antenna (Cui et al. 2013), dielectric resonator antenna (Sun and Leung 2013), or microstrip patch antenna (Wong et al. 2004; Lai and Luk 2007; Caso et al. 2010). However, these designs have drawbacks, such as high cross-polarization, high back radiation, or low port isolation. With the rapid development of wireless communications, conventional antennas cannot satisfy the stringent requirements imposed on base station antennas.

Multiple Γ-Shaped Probes

Siu et al. (2009) first developed a dual-polarized ME dipole antenna, based on the linearly polarized design disclosed in the same paper. As shown in Fig. 28, the antenna consists of four square plates which are shorted to the ground plane by vertical metallic walls. The square plates act as planar electric dipoles, while the metallic walls form shorted patch antennas which are fully filled with dielectric substrate to

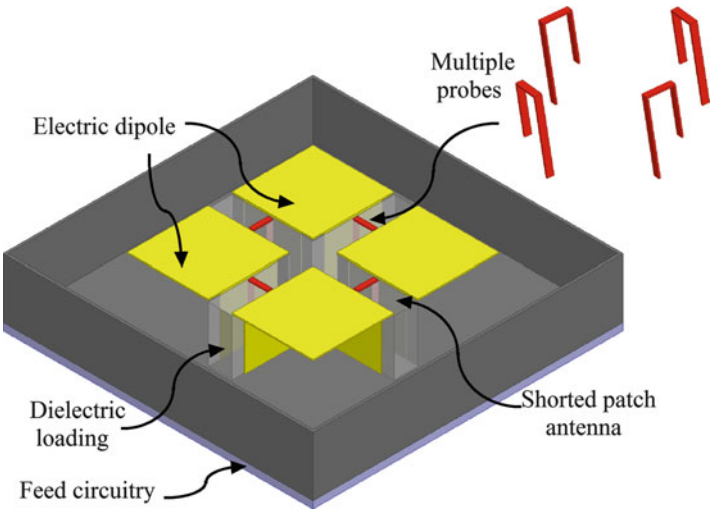

Fig. 28 Geometry of the dual-polarized ME dipole with multiple Γ-shaped probes

DOI 10.1007/978-981-4560-75-7_49-1

reduce the antenna height. Two pairs of Γ-shaped probes are placed between the vertical metallic walls to excite ± 45° polarizations of the antenna. A feed circuitry under the ground plane is needed for this antenna, therefore increasing the fabrication cost. The feed network simply consists of two power dividers. Each power divider splits and transmits the input electrical power to one pair of probes arranged side by side, further exciting one polarization of the antenna. Originally, the impedance bandwidth of the linearly polarized antenna discussed in section "Magnetoelectric Dipole with Dielectric Loading" is 48 %; however, the dual-polarized antenna only exhibits a narrow impedance bandwidth of 24 %, ranging from 1.65 to 2.12 GHz, over which the isolation between the two ports is larger than 29 dB. The average gains for both ports are about 8.2 dBi.

Orthogonal Γ-Shaped Probes

Shortly after the publication of this paper, another dual-polarized ME dipole antenna was introduced by Wu and Luk (2009a). As shown in Fig. 29, the design also consists of four square plates shorted to the ground by the vertical walls, which is very similar to the aforementioned antenna presented in Siu et al. (2009). But this time, only two single Γ-shaped probes are used to excite the ± 45° polarizations, therefore not requiring a feed circuitry. Each Γ-shaped probe consists of three portions. The first portion of the probe together with the adjacent vertical wall forms a tapered air microstrip line and transmits electrical energy from the coaxial cable to the second portion of the probe which comes out from the hole of one dipole arm, across the gap between the arms and enters into the hole of the other dipole arm. It couples the electrical energy to the antenna but introduces inductance which is compensated by the third portion of the probe. It should be noted that the probe is not electrically connected to the antenna.

When one polarization is excited as illustrated in Fig. 29, a pair of orthogonal opposite metallic plates performs as the electric dipole. Each metallic wall together with the adjacent wall and the ground plane between them performs as a shorted quarter-wave patch antenna; therefore, four shorted patch antennas can be formed. Each pair of the shorted patch antennas arranged side by side is equivalent to a magnetic dipole. Thus, the four shorted patch antennas can be equivalent to two magnetic dipoles which have a vector sum perpendicular to the electric dipole. Consequently, the magnetoelectric dipole antenna can be excited.

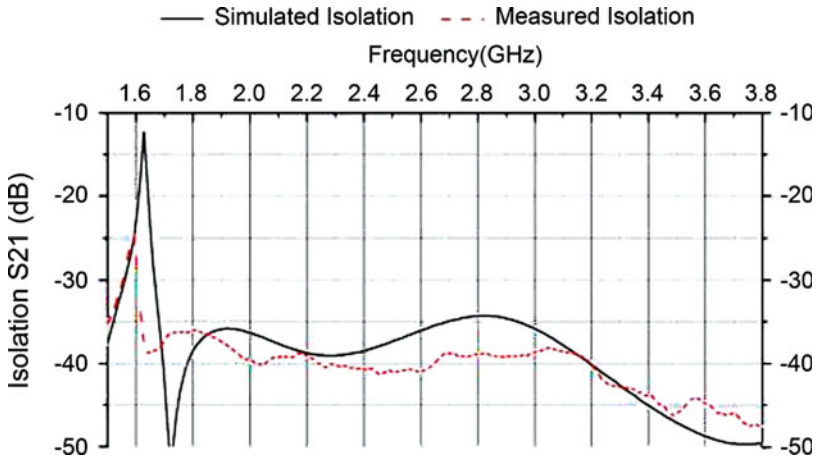

Fig. 31 Simulated and measured isolations (From (Wu and Luk) © 2009a IEEE, Reprinted with permission)

The dimensions of the antenna operating at 2.67 GHz are shown in Table 7. An antenna prototype was fabricated and tested. It can be seen from Fig. 30 that the measured impedance bandwidth (SWR $\leq$2) is 69.7 % and 74.6 % at port 1 and port 2, respectively. The common bandwidth of the two ports is 65.9 %, ranging from 1.7185 to 3.409 GHz, over which the isolation between both ports is more than 36 dB, as illustrated in Fig. 31. The antenna gain is approximately 9 dBi. Fig. 32 shows the measured radiation pattern at 2.701 GHz. It is obvious that, by using the orthogonal Γ-shaped probes, the antenna without the use of a feed circuitry achieves a wider operation bandwidth, compared with the design of Siu et al. (2009). However, the complex feed probes cause difficulties in fabrication and construction.

Simplification of the Orthogonal Γ-Shaped Probes

Subsequently, Li and Luk (2012) considered the simplification of the feeds by placing the two orthogonal Γ-shaped probes between the vertical metallic posts. More recently, Xue et al. (2013) modified the feeds to two pairs of differential feeds for the enhancement of the operating bandwidth and further suppression of the coupling between two polarizations. The antenna achieves a wide impedance bandwidth (SWR $\leq$2) of 68 %, from 0.95 to 1.92 GHz. The differential port-to-port isolation is better than 36 dB. The 3-dB gain bandwidth is 62 % ranging from 1.09 to 2.08 GHz. In what follows, the design with the simplified orthogonal Γ-shaped probes (Li and Luk 2012) is discussed in detail.

Parameter	L	W	S	G	H	a_1	a_2	
Value(mm)	29.2 $0.23\lambda_0$	14 $0.10\lambda_0$	6.2 $0.05\lambda_0$	149.6 $1.28\lambda_0$	28 $0.23\lambda_0$	13.6 $0.12\lambda_0$	13.6 $0.12\lambda_0$	
Parameter	b_1	b_2	f_1	f_2	d_1	d_2	h_1	h_2
Value(mm)	4.5 $0.05\lambda_0$	4.0 $0.03\lambda_0$	2.0 $0.02\lambda_0$	2.0 $0.02\lambda_0$	1.18 $0.01\lambda_0$	1.31 $0.01\lambda_0$	27 $0.23\lambda_0$	21 $0.18\lambda_0$

As shown in Fig. 33, the antenna consists of four metallic plates, four rectangular metallic posts, two orthogonal Γ-shaped probes, and a box-shaped reflector. Each of metallic plate is shorted to the ground through a large metallic post. They are placed uniformly with separation of $S = 0.05\lambda_0$. Two Γ-shaped probes are placed orthogonally in the gaps between the metallic posts. The Γ-shaped probe consists of three portions. For high isolation, the two probes are required to have different heights. In operation, signals are launched to the orthogonal Γ-shaped probes through the two SMA connectors. For each probe, the copper strip, together with the two adjacent shorted metallic posts, forms a modified stripline structure. The surfaces of adjacent metallic posts perform as ground planes, and the middle copper strip transmits the signal. Since the metallic posts are located uniformly with two orthogonal gaps, the portions of horizontal strips in the intersection of two gaps are responsible to couple the electrical energy to the antenna element.

When one polarization is excited as indicated in Fig. 33, a pair of planar electric dipoles and a pair of shorted quarter-wave patch antennas are excited simultaneously. The four metallic plates perform as two planar electric dipoles. Each metallic post, together with an adjacent post and the ground between them, acts as a shorted quarter-wave patch antenna. Every two shorted patch antennas placed side by side can be equivalent to a magnetic dipole that is perpendicular to the electric dipoles. Consequently, the

DOI 10.1007/978-981-4560-75-7_49-1

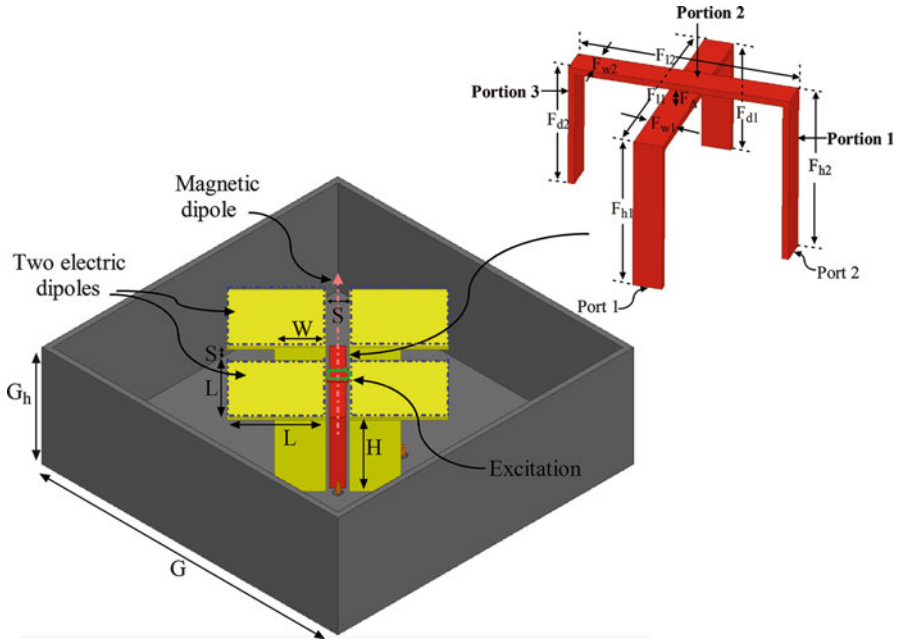

Fig. 33 Geometry of the dual-polarized ME dipole with simplified orthogonal Γ-shaped probes

magnetoelectric dipole antenna can be realized. It should be pointed out that this antenna has the different operation principle compared to the design described in the previous section (Wu and Luk 2009a).

Experimentally, a prototype at 2.2 GHz was fabricated. The antenna operates from 1.69 to 2.83 GHz with a bandwidth of 50 % (SWR $\leq$1.5) and from 1.68 to 2.76 GHz with a bandwidth of 49 % (SWR $\leq$1.5) for ports 1 and 2, respectively. The operating frequency ranges for the two ports are slightly different due to the unequal heights of the two orthogonal probes. The common bandwidth of the two ports is 48 %. Over the operating frequency range, the measured broadside gains for port 1 and port 2 are approximately 8.45 and 8.5 dBi, respectively. Nearly identical antenna gains are obtained for the two ports due to the symmetrical architecture of the proposed antenna design. The measured isolation between the two ports is larger than 30 dB, and the measured front-to-back ratios of the two ports are larger than 29 dB over the operating frequency range. A design guide for this antenna is suggested as follows:

1. According to the required center frequency of the operating band (λ_0), determine the dimensions of the planar electric dipole antenna with $L = 0.20\lambda_0$.
2. Determine the dimensions of the shorted quarter-wave patch antenna (metallic posts) with $H = 0.25\lambda_0$, $W = 0.10\lambda_0$, and $S = 0.05\lambda_0$.
3. Design a box-shaped reflector with dimensions of $G = 0.8\lambda_0$ and $G_h \approx 0.25\lambda_0$.
4. Design a pair of orthogonal Γ-shaped probes and tune f_Δ to achieve a high isolation and a relative acceptable overlapped impedance bandwidth.

The comparison between this antenna and the previous design in Wu and Luk (2009a) is summarized in Table 8. It can be found that the design in Li and Luk (2012) provides a wide operating bandwidth (SWR $\leq$1.5) with lower cross-polarization and back-lobe levels but suffers from an unstable radiation beamwidth and a lower isolation, when compared to the design in Wu and Luk (2009a).

Circularly Polarized Antenna

General Remarks

Circularly polarized (CP) radiation is useful for multipath interference suppression and polarization mismatch reduction. Owing to these features, circular polarization is highly desirable for many applications such as radar, satellite, and millimeter-wave systems. The basic operating principle of a circularly polarized antenna is to radiate two orthogonal field components with equal amplitude and in phase quadrature. Many omnidirectional CP antennas with good performances have been investigated in Pan et al. (2012) and Nakano et al. (2011). However, for some wireless communication systems, unidirectional CP antennas are required because security and efficiency issues should be considered by system designers.

Based on a dual-polarized antenna, a circularly polarized antenna can be realized by adding a feed circuitry. Many types of dual polarized antennas have been investigated in the literature, such as the dual-fed crossed-dipole antenna (Zhang et al. 2013), the quadrature-fed dielectric resonator antenna (Li et al. 2009), and the annular-ring microstrip antenna (Guo et al. 2009). The dual-polarized ME dipole antenna discussed in section "Simplification of the Orthogonal Γ-Shaped Probes" was also developed to a CP antenna (Li and Luk, 2013c). A feed circuitry, consisting of a broadband 90° phase shifter and a Wilkinson power divider, was used. Experimentally, the antenna prototype exhibited a wide impedance bandwidth (SWR ≤2) of 90 % from 1.23 to 3.23 GHz, which covered the whole 3-dB axial-ratio (AR) bandwidth of 82 % from 1.28 to 3.05 GHz. In this operating frequency band, the antenna had a broadside gain of larger than 5dBic above 1.45GHz. Considering the common overlapped bandwidth limited by the impedance, axial ratio, and gain, the antenna provided an effective bandwidth of 71 %.

In comparison with dual-fed CP antenna, single-fed CP antenna does not need feed circuitry and therefore has a simple structure. Thus, Li and Luk (2014) proposed a single-fed circularly polarized ME dipole antenna. In what follows, this design is presented in details.

Single-Fed Design

Fig. 34a shows the single-fed circularly polarized ME dipole antenna. Standing from the dual-polarized ME dipole antenna described in section "Simplification of the Orthogonal Γ-Shaped Probes," one pair of the diagonally opposite metallic plates is truncated at the corners in order to increase its resonant frequency. The other pair is added with hook-shaped strips in order to reduce its resonant frequency. And two of the four gaps are filled with small metallic blocks in order to increase the resonant frequency of the equivalent vertically quarter-wave shorted patch antenna. Thus, the proposed CP antenna consists of a pair of metallic plates with extended strips, a pair of metallic plates with corner truncated, a pair of U-shaped posts, an L-shaped probe feed, and a planar reflector. Fig. 34b depicts the top and side views of the proposed antenna. The metallic plates are direct-current grounded through the U-shaped posts. The

DOI 10.1007/978-981-4560-75-7_49-1

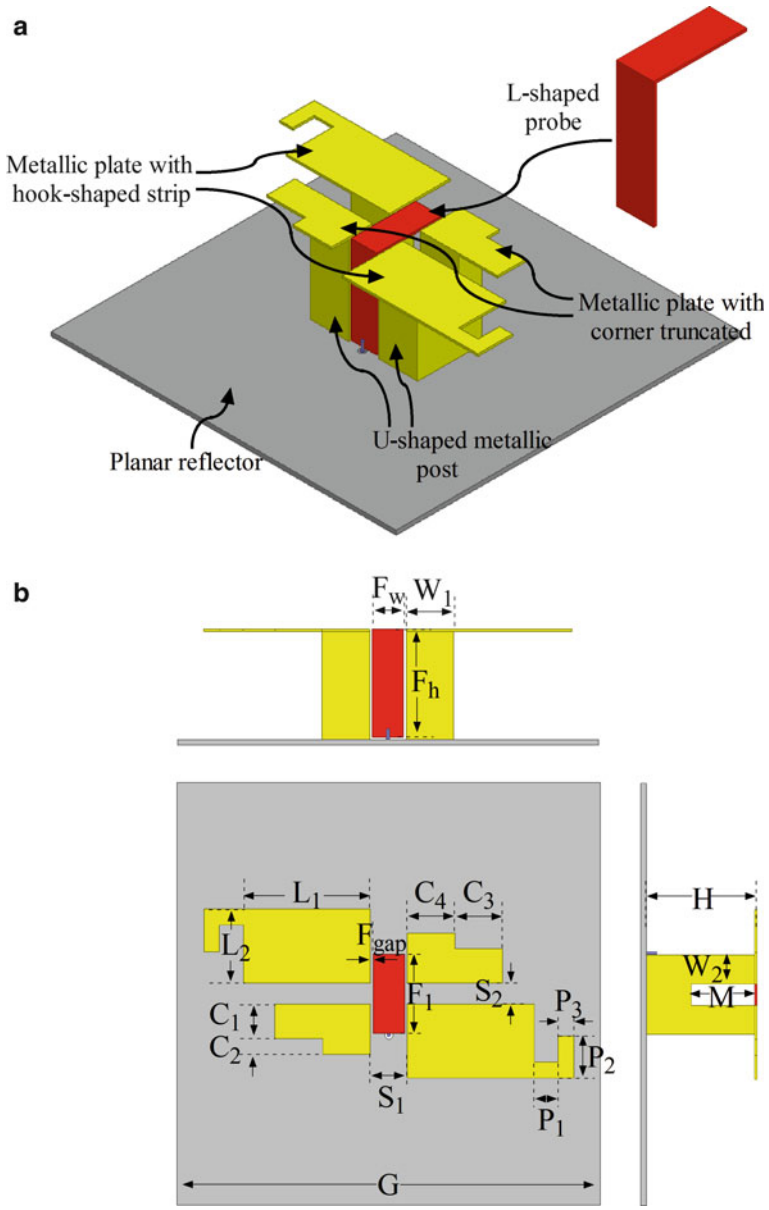

Fig. 34 Geometry of the single-fed circularly polarized ME dipole antenna. (**a**) Perspective view, (**b**) top and side views (From (Li and Luk) © 2014 IEEE, Reprinted with permission)

proposed antenna with the L-shaped probe is mounted on a planar reflector. A SMA connector is placed under the reflector for transmitting signal to the L-shaped probe. Detailed dimensions of the antenna are summarized in Table 9.

Fig. 35 shows simulated and measured SWRs and gains. The simulated impedance bandwidth is 52.3 % with SWR $\leq$1.5 from 1.58 to 2.7 GHz and 60.7 % with SWR $\leq$2 from 1.48 to 2.77 GHz. The measurements indicate that the antenna prototype can achieve a wide impedance bandwidth of 46.6 % (SWR $\leq$1.5) from 1.68 to 2.7 GHz and 73.3 % (SWR $\leq$2) from 1.32 to 2.85 GHz. Within the 1.5:1 SWR band, the antenna broadside gain varies in the range of 5 to 8.6 dBic. Fig. 36 plots the measured and simulated antenna axial ratios. It can be seen that the measured 3-dB AR band is 47.7 % from 1.69 GHz to 2.75 GHz, which is generally covered by the SWR $\leq$1.5 operating band. The measured and simulated radiation patterns at 2.1 GHz are depicted in Fig. 37.

Antenna with Pattern and Polarization Diversities

General Remarks

Recently, diversity antenna has been considered to increase the communication system capability. There are different types of diversity antennas including spatial diversity antenna, frequency diversity antenna, polarization diversity antenna, and pattern diversity antenna (Yang and Luk 2006). As studied in section "Dual-Polarized Antenna," the dual-polarized antennas are two-port antennas with polarization diversity. To further solve multipath-fading effects in complex environments and enhance the performance of a wireless system, a four-port antenna with polarization and pattern diversities is recommended. This type of diversity antenna is capable of radiating and receiving signals through different radiation modes simultaneously and therefore has the advantage of performing higher effective gain while maintaining

DOI 10.1007/978-981-4560-75-7_49-1

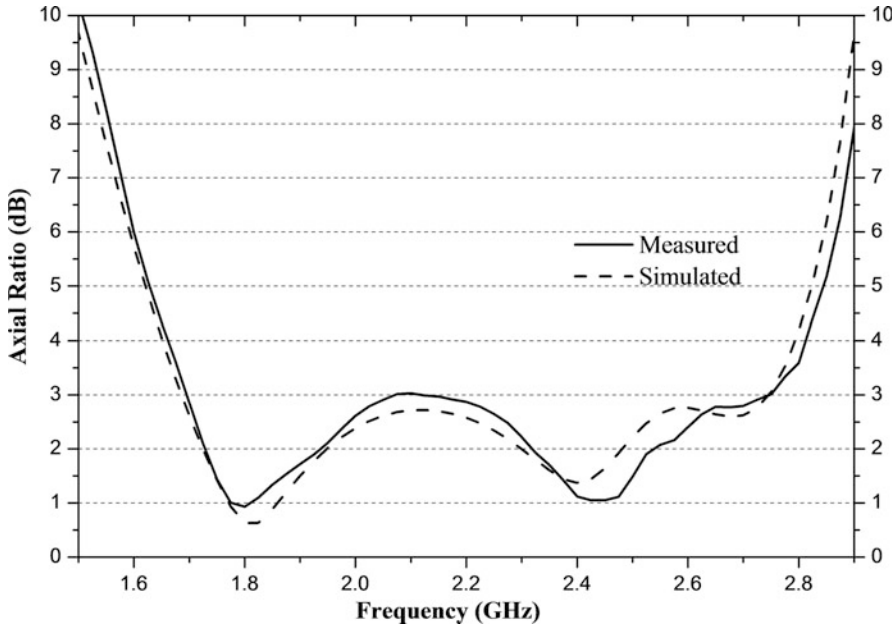

Fig. 36 Simulated and measured ARs of the single-fed CP antenna (From (Li and Luk) © 2014 IEEE, Reprinted with permission)

the same installation space. Yang et al. (2008) first demonstrated that this type of antenna could be realized based on microstrip patch antenna. Unfortunately, the antenna has a drawback of the narrow overlapped bandwidth of the excitation ports. Subsequently, the ME dipole was employed by Wu and Luk (2011a) to develop this kind of diversity antenna with wideband performance. Note that the preliminary work on the design of a magnetic monopole was presented in Wu and Luk (2009c).

Diversity Antenna Design

The geometry of the diversity antenna is shown in Fig. 38. It consists of four ME dipoles arranged in a ring configuration and a wire electric monopole. Each ME dipole is realized by deforming the original ME dipole discussed in section "Antenna Configuration." A pair of sectorial-shape horizontal plates has the inner radius R_1 and outer radius R_2, acting as an electric dipole. The magnetic dipole is performed by a shorted quarter-wave patch antenna realized by two vertical metallic walls and the portion of the ground plane between them. A Γ-shaped probe is employed to excite each ME dipole. Four identical ME dipoles are arranged in a ring configuration and are located at 0°, 90°, 180°, and 270°.

The wire electric monopole is located at the center of the four ME dipoles, radiating a conical beam with vertical polarization (i.e., electric monopole conical mode). As shown in Fig. 39, the feed network, mounted under the ground plane, consists of two hybrid rings and a Wilkinson power divider. Two stages of excitation are used. In the first stage, the output ports of the two hybrid rings are connected to the Γ-shaped probes of the ME dipoles. Two isolated input ports of hybrid rings are used to excite two modes of broadside radiation with horizontal polarization (i.e., ±45° broadside modes). In the second stage, the other input port of each hybrid ring is connected to an output port of a Wilkinson power divider, the input port of which is used to radiate a conical beam with horizontal polarization (i.e., magnetic monopole conical mode). For further understanding the antenna operation, the current distributions of the antenna at $t = 0$ and T/4 are depicted in Fig. 40.

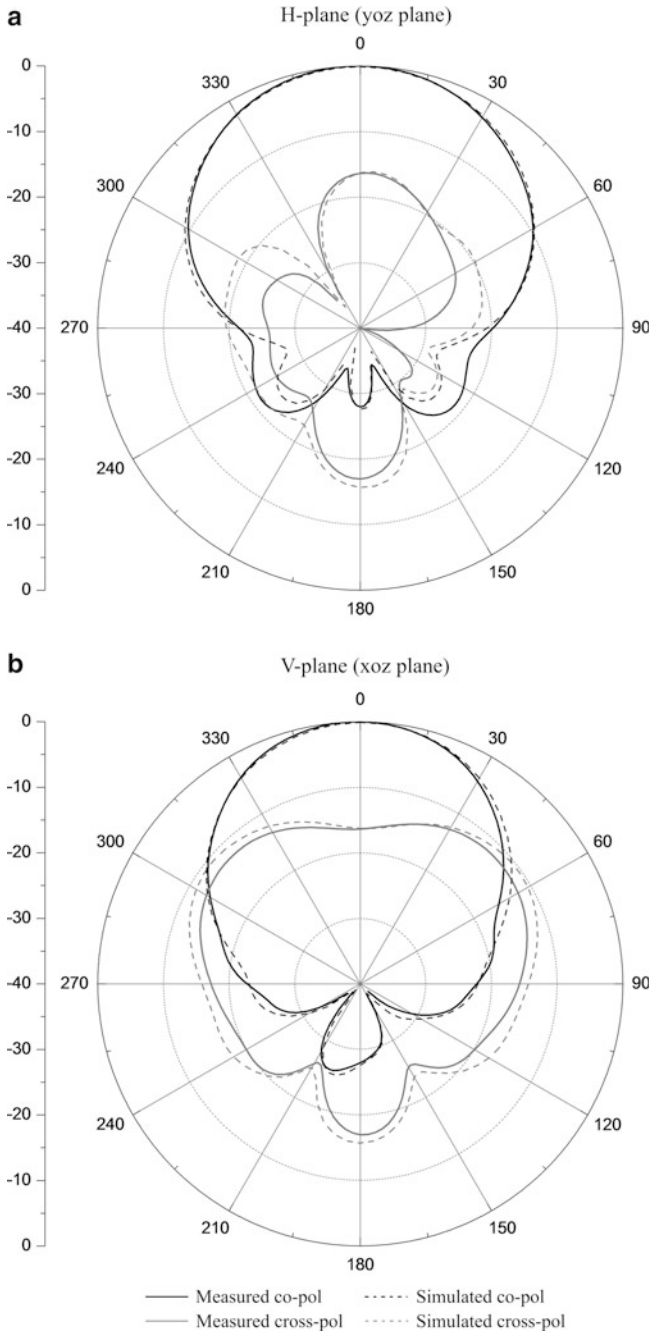

Fig. 37 Simulated and measured radiation pattern at 2.1 GHz (From (Li and Luk) © 2014 IEEE, Reprinted with permission)

Detailed dimensions of the antenna are summarized in Table 10. As shown in Fig. 41, the measured impedance bandwidths (SWR $\leq$2) for electric monopole mode, magnetic monopole mode, +45° broadside mode, and −45° broadside mode are 38.6 % (1.90–2.81 GHz), 22.2 % (2.12–2.66 GHz), 43.1 % (1.87–2.90 GHz), and 39.2 % (1.95–2.90 GHz), respectively. The measured antenna gains for electric and

magnetic monopole modes are approximately 6 dBi and for ±45° broadside modes are approximately 11 dBi. Thus, the overlapped impedance bandwidth is 22.2 % ranging from 2.12 to 2.66 GHz, over which the measured isolation is larger than 26 dB. The measured radiation patterns at 2.4 GHz for different modes are depicted in Fig. 42.

Designs for UWB Applications

Since the Federal Communications Commission (FCC) allocated the 7.5GHz (3.1GHz–10.6GHz) band for unlicensed use, ultra-wideband (UWB) wireless communication technology has attracted much interest. Many applications of UWB technology have been developed including medical imaging systems, ground penetrating radars, and high data rate communication systems.

Typically, the bandwidth of ME dipole antenna is limited to 40–50 % which cannot meet the bandwidth requirement of UWB communication. By deforming antenna structure, the bandwidth can be broadened. Wu and Luk (2009b) first attempted to develop a UWB antenna based on the ME dipole, as shown in Fig. 43. It consists of a pair of trapezoidal plates shorted to the ground plane by right-angle corner walls and a modified box-shaped reflector. A Γ-shaped probe, similar to the probe shown in Fig. 28, is used to excite the antenna. The antenna exhibits a wide impedance bandwidth (SWR $\leq$2) of 91.6 % ranging from 3.05 to 8.2 GHz. The measured average gain is about 9.3 dBi. Unfortunately, the operating band of this antenna cannot cover the whole UWB unlicensed spectrum. Later, a dual-polarized UWB antenna was presented by Wu and Luk (2011b). They utilized a bow-tie antenna and loop antenna as the electric and magnetic dipoles, respectively. The operating bandwidth of this antenna is from 2.4 GHz to 10.6 GHz, which covered the whole UWB frequency band.

After the publication of these papers, another UWB ME dipole antenna was demonstrated by Ge and Luk (2012b). The geometry of the antenna is shown in Fig. 44. It consists of a bow-tie-shaped planar electric dipole and a folded shorted quarter-wave patch antenna. The impedance bandwidth of the antenna (SWR $\leq$2) is 95.2 % from 1.65 to 4.65 GHz. Within the operating frequency band, the antenna gain is about 7.9 dBi with 0.9 dBi variation. Subsequently, this antenna was modified to achieve a wider bandwidth for the coverage of the whole UWB unlicensed band (Ge and Luk 2013b). The modified antenna, as illustrated in Fig. 45, is excited by a printed balun instead of the folded Γ-shaped probe. And a pair of metallic cylindrical posts performs as the magnetic dipole in the new design. The measured impedance bandwidth (SWR $\leq$2) is about 110 % from 3.08 to 10.6 GHz, over which the measured antenna gain varies between 6.8 and 10.6 dBi with 3.8 dBi variation.

Another method for broadening the bandwidth of the ME dipole is to utilize a pair of differentially feeds to excite the antenna. Experimental and parametric studies were presented by Li and Luk (2013a). Fig. 46 shows the geometry of the antenna. Similar to the original ME dipole shown in Fig. 5, this antenna is composed of a planar electric dipole and a shorted patch antenna. Two slots in the electric dipole are

introduced to suppress the high-order mode radiation, further reducing the side-lobe level at the high frequencies. Instead of a planar reflector, the ME dipole is mounted on a rectangular box-shaped reflector which can reduce back radiation and stabilize antenna gain. The antenna provides an impedance bandwidth of 114 % from 2.95 GHz to 10.73 GHz, covering the whole UWB bands. More importantly, the antenna broadside gain is 8.25 dBi with a small variation of ± 1.05 dBi, which is much more stable than other unidirectional UWB antennas.

Designs for 60-GHz Applications

Within the millimeter-wave spectrum, the 60-GHz band is useful for short-range, high-frequency reuse and secure communications because of an oxygen absorption peak occurring in this band. High data rates of multi-gigabits are supported by 60-GHz wireless communications, allowing for many exciting applications, such as a high-definition multimedia interface, uncompressed video streaming, mobile distributed computing, rapid large file transfer, high-speed Internet, sensing, and radar. As a result, the 60-GHz radio technology, representing a valuable opportunity for circuit and antenna engineers, has attracted considerable interest, especially after a global consensus on the 60-GHz band allocation was reached by federal agencies worldwide.

Ng et al. (2012) first proposed a 60-GHz ME dipole antenna on a single-layer printed circuit board. Duroid 5880 substrate with thickness of 0.787 mm, metal thickness of 1/2 oz, $\varepsilon_r = 2.2$, and $\tan\delta = 0.004$ at 60 GHz was chosen for its low loss tangent and approximately $\lambda_g/4$ thickness. The geometry of the antenna is shown in Fig. 47. It can be seen that a planar electric dipole is shorted to the ground by five

DOI 10.1007/978-981-4560-75-7_49-1

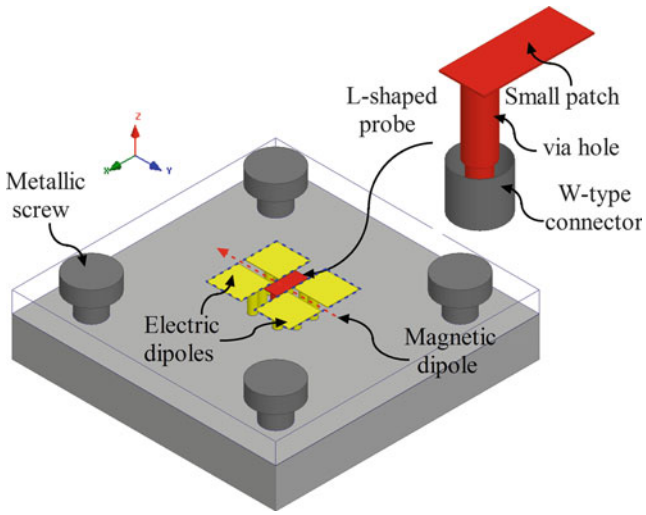

Fig. 48 Geometry of the 60-GHz ME dipole antenna with L-shaped probe

plated via holes. These via holes together with the ground plane between them form a shorted quarter-wave patch antenna. Instead of the Γ-shaped probe of the original model shown in Fig. 5, a T-shaped probe is applied because it can be easily printed on a PCB. As discussed in section "Other Feed Mechanisms," the ME dipole with T-shaped probe suffers from higher back radiation and cross-polarization levels. This antenna exhibits a wide impedance bandwidth ($S_{11} \leq -10$) of 43 % from 48 to 75 GHz, over which the average gain is approximately 7.5 dBi. The radiation pattern is stable and equal in the E- and H-planes. However, the cross-polarization level of the antenna is not as low as that of the original ME dipole, varying between −15 dB and −21 dB across the operating bandwidth from 50 to 70 GHz.

Subsequently, another 60-GHz ME dipole antenna was designed by Luk and Li (2013). This antenna used the same Duroid 5880 substrate of the previous design. Fig. 48 shows the geometry of the antenna which consists of four rectangular metallic patches, four sets of via holes, and an L-shaped probe. The metallic patches perform as two planar electric dipoles. Each set of via holes, consisting of three metallic plated via holes, is located close to the inner corner of a rectangular metallic patch. The via holes together with the ground plane between them form a shorted quarter-wave patch antenna. The L-shaped probe is composed of a plated via hole and a small patch. The via hole, together with the adjacent via holes, accomplishes a transmission line to transmit signals to the small patch. This patch is placed between two planar dipoles which act as its electrical ground. This combination works as a CPW line, the portion of which across the separation between two dipole arms is responsible to couple the electrical energy to the antenna element. Thus, the L-shaped probe can excite the planar dipoles and shorted patch antenna simultaneously. A W-type connector (Anritsu: W1-103 F) is launched underneath the antenna fixture for transmitting signal to the L-shaped probe. Four metallic screws were used to fix the substrate on the antenna fixture. The impedance bandwidth of this antenna is 50.5 % with SWR ≤2 from 41.5 to 69.5 GHz. The antenna gain is about 8 dBi with a variation of about 1.1dBi. Over the entire operating band, the cross-polarization level is less than −20 dB, which is lower than the design that is excited by a T-shaped probe.

Other Complementary Antenna Designs

Apart from ME dipole antenna, many other complementary antennas have been demonstrated in the literature. The combination of an electric dipole and a shorted bow-tie patch antenna resulted in a wideband complementary antenna, as shown in Fig. 49 (Wong et al. 2008). This antenna exhibits an impedance bandwidth of 63 %. It should be pointed out that without the electric dipole, the antenna can also achieve an impedance bandwidth of 62 %. Thus, the addition of an electric dipole can only enhance the gain, suppress the back radiation, and stabilize the frequency response of gain and radiation patterns. Based on this design, a dual-polarized antenna was developed by Mak et al. (2007). The geometry of the antenna is depicted in Fig. 50. This antenna, operated in 1.71–2.17 GHz, has a stable gain of 6.6 dBi, a stable beamwidth of 80°, a large front-to-back ratio of over 19 dB, and a high isolation of over 28 dB. Later, the attempt to reduce the height of this type of antenna was made by Li and Luk (2013b), as shown in Fig. 51. By placing two pairs of electric dipoles next to the shorted bow-tie patch antenna, the antenna height can be reduced to less than $0.1\lambda_0$ which is close to the height level of a wideband microstrip patch antenna. Meanwhile, it maintains all good electrical characteristics of a complementary antenna.

Another kind of the complementary antenna is composed of a printed electric dipole and a printed wire loop. An antenna of this type was investigated by Chan et al. (2007). It radiates unidirectionally without the use of a reflector but suffers from a narrow impedance bandwidth of 7.4 %. When a semiring is placed on a ground plane to perform as the magnetic dipole, instead of the loop antenna, the antenna bandwidth can be broadened (Tang and Xue 2013; Wang et al. 2014).

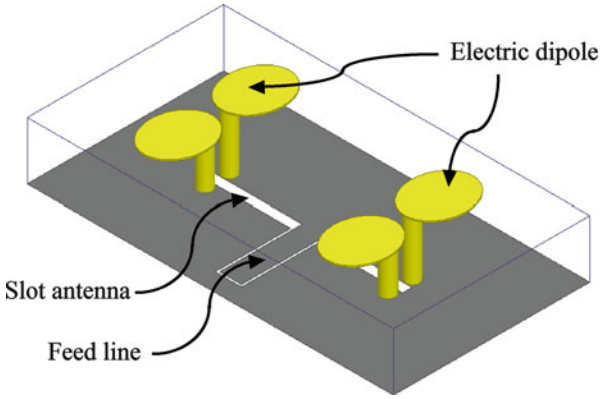

Fig. 52 Geometry of the dipole/slot antenna combination at 60 GHz

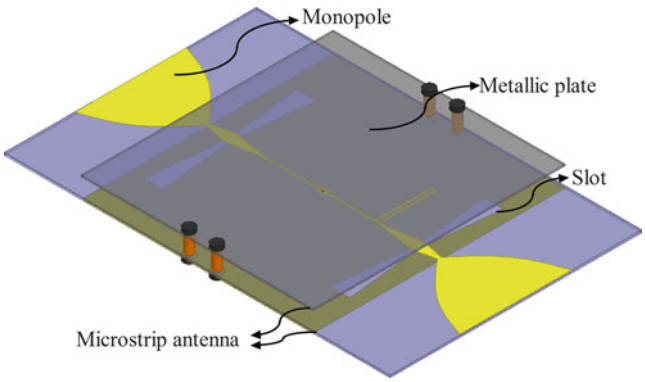

Fig. 53 Geometry of the low-profile monopole/slot/microstrip antenna combination

Subsequently, a 60-GHz complementary antenna was realized by the use of slot antenna and parasitic dipole (Ng et al. 2014). The geometry of the antenna is depicted in Fig. 52. It can be seen that the traditional CPW-fed slot antenna acts as a magnetic source, and a parasitic dipole, located across the slot, acts as an electric source. More recently, a combination of monopole/slot/microstrip antenna was demonstrated by Li and Luk (2015). This design, as shown in Fig. 53, has a low profile of $0.035\lambda_0$ and exhibits a wide impedance bandwidth of over 20 %, a stable broadside gain of 6.11 dBi, and a

DOI 10.1007/978-981-4560-75-7_49-1

unidirectional radiation pattern with low back radiation (< -16 dB) and low cross-polarization (< -25 dB).

Conclusion

This chapter began with discussions on the theory of the complementary antenna, the basic configuration of the magnetoelectric dipole antenna, methods of height reduction, and feed mechanisms. And then some magnetoelectric dipole antennas with dual polarizations, circular polarization, and pattern polarization diversities have been studied in this chapter. These designs can be used to solve multipath-fading effects and enhance the performance of wireless system. The chapter then proceeded to present several antenna solutions for UWB and 60-GHz wireless communications followed by some other types of complementary antennas.

Since the magnetoelectric dipole antenna was created in 2006, there have been many studies in the literature, focusing on the development of the ME dipole antenna to have different polarizations and fulfill various applications. However, a number of challenges remain. For example, most of the designs provide wide bandwidth, while dual-band or multiband ME dipole designs have not been adequately considered. As we know, the mobile base station usually operates in multibands with dual polarizations nowadays, but the design of dual-band or tri-band dual-polarized ME dipole antenna is a big challenge to us. In addition, the research on wideband and low-profile ME dipole antenna is still an active research area. Furthermore, the realization of ME dipoles at higher frequencies, such as 120 GHz or even Terahertz, is an unknown area till now.

Reduced Surface Wave Microstrip Antennas

David R. Jackson*
Department of ECE, Cullen College of Engineering, University of Houston, Houston, TX, USA

Abstract

Reduced surface wave (RSW) microstrip antennas are a class of microstrip antennas that excite much less surface wave fields than do conventional microstrip antennas. Furthermore, they have a greatly reduced amount of lateral (horizontal) radiation that propagates outward from the antenna along the ground plane. This results in less edge diffraction from the edges of the ground plane or supporting structure, which in turn results in smoother front-side patterns and less back radiation. The RSW antennas also exhibit less mutual coupling when the antennas are widely spaced, due to the reduced surface wave field and lateral radiation. This chapter reviews RSW antenna design and the different methods for realizing such antennas, and illustrates their main performance features.

Keywords

Microstrip antenna; Reduced surface wave antenna; Surface waves; Lateral wave; Mutual coupling; Edge diffraction; GPS

Introduction

A common property of most microstrip antennas is that the antenna excites the dominant TM_0 surface wave mode of the grounded substrate, in addition to the fields radiated into space (see Fig. 1). The surface wave is a guided mode with a wavenumber β_{TM0} that spreads out radially in the horizontal plane, decaying slowly as $1/\rho^{1/2}$, where ρ is the distance from the antenna in cylindrical coordinates. Physically, for large distances ρ, the surface wave behaves as a plane wave that bounces up and down inside the substrate beyond the critical angle, decaying exponentially in the air region above (symbolized in Fig. 1 by the horizontal lines of decreasing size), since $\beta_{TM0} > k_0$ (Pozar 1998; Harrington 2001). Because of the slow decay of the surface wave with distance ρ, it can cause coupling and other undesirable effects at a considerable distance from the antenna, if the substrate extends out to large distances. The power launched into the surface wave is power that will eventually be lost, at least for the case of an infinite substrate. For finite-size substrates, the surface wave field will reflect and diffract from the edges of the substrate, resulting in a disturbance of the radiation pattern. Furthermore, the excitation of the TM_0 surface wave also results in increased mutual coupling between distant antenna elements, since the surface wave fields decay more slowly with radial distance than does the space-wave field. For these reasons, the excitation of the surface wave from a microstrip antenna is undesirable. Since the dominant TM_0 surface wave of a grounded dielectric layer has a zero cutoff frequency, a microstrip antenna will usually always excite some surface wave power unless some mitigating technique is used. A reduced surface wave (RSW) microstrip antenna is one that is designed to have a minimum amount of surface wave excitation. This chapter reviews the design and performance of RSW microstrip antennas.

DOI 10.1007/978-981-4560-75-7_50-2

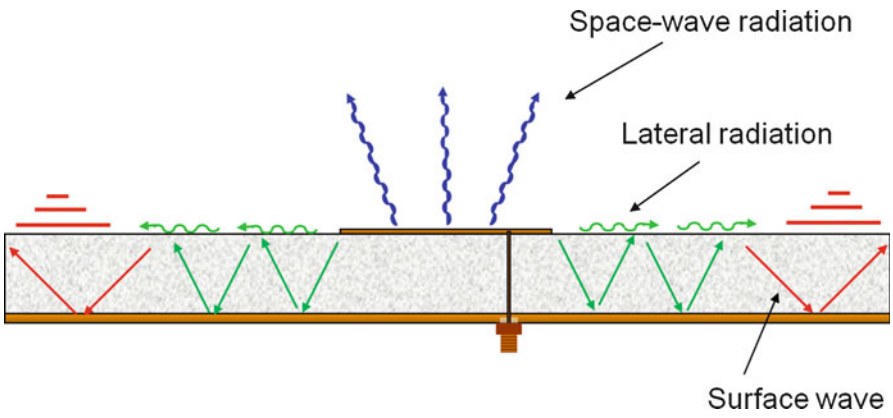

Fig. 1 A sketch showing the different types of waves radiated by a microstrip antenna

In addition to surface wave excitation, microstrip antennas produce lateral radiation, i.e., radiation that propagates outward horizontally (laterally) from the antenna. The lateral radiation exists at the dielectric interface and in the vicinity of the interface in the air region above, with the wavenumber of free space (see Fig. 1). Inside the substrate, for large distances ρ, this field has the character of a plane wave field that bounces between the interface and the ground plane at the critical angle. The lateral radiation initially decays as $1/\rho$, as it would without the substrate. At extreme distances, the lateral radiation field evolves into a "lateral wave" type of field that decays as $1/\rho^2$ due to the interface effect, assuming that the substrate extends out to such extreme distances (King 1992). The lateral-radiation field is often more significant than the surface wave field for small and moderate distances from the antenna, depending on the substrate permittivity and thickness. For example, for a typical microstrip substrate, the lateral-radiation field might be the most significant contributor to the field on the interface out to a distance of about 10 wavelengths, after which the surface wave field becomes dominant. While the space-wave radiation away from the antenna is desirable, as it forms the radiation pattern of the antenna, the lateral radiation along the substrate and ground plane is undesirable. The lateral radiation will diffract from the edges of the ground plane or supporting structure, and this edge diffraction will often cause significant distortion of the radiation pattern, including rippling of the pattern in the forward direction and significant back radiation behind the ground plane. The lateral radiation will also result in significant mutual coupling between antennas and between the antenna and other components.

The same design principles that are used to design RSW antennas can be used (with slight modification) to design reduced lateral wave (RLW) antennas as well. (The term "lateral wave" is used here to denote lateral radiation in general, regardless of the distance from the antenna or whether the substrate is present.) Fortunately, in most practical cases, the wavenumber β_{TM0} of the TM_0 surface wave is fairly close to that of the free-space wavenumber k_0 (unless the substrate is electrically thick). This means that an RSW antenna, designed to greatly reduce the excitation of the TM_0 surface wave, will automatically have a greatly reduced lateral radiation as well.

This chapter will first review the basic design concept of the RSW antenna, based on the "shorted annular ring" (SAR) concept, which is perhaps the simplest way to fabricate an RSW antenna (Jackson et al. 1993). The SAR-RSW antenna design is based on a circular patch of radius b that has a ring of shorting vias located at a radius a in the interior, forming an active annular cavity region $a < \rho < b$. The inner cavity region ($\rho < a$) is a dead region, which can be removed to form an annular ring microstrip antenna structure that is shorted at the inner boundary (and hence the name SAR). Other design variations use a circular patch that has a cylindrical region in the middle of the substrate cored out and replaced by a lower permittivity material, or a circular patch that has the entire substrate inside the cavity region

DOI 10.1007/978-981-4560-75-7_50-2

replaced by an artificial substrate with a lower permittivity than that of the surrounding substrate outside the patch. Results will be presented to demonstrate the improved radiation patterns of the SAR-RSW antennas and the reduced mutual coupling between pairs of such antennas, relative to conventional microstrip antennas on the same substrate (Khayat et al. 2000).

By feeding the SAR-RSW antenna with two 90° feed ports, a circularly polarized (CP) RSW antenna is obtained. One application for CP RSW antennas is for applications that require low levels of lateral radiation and corresponding edge diffraction that would otherwise result in undesirable multipath reception from signals arriving from the back region or at low angles. Conventional antenna systems in applications such as GPS use choke rings to suppress the lateral radiation and reduce the edge diffraction. The RSW antenna is an alternative, being planar and significantly smaller in size (Basilio et al. 2005).

Another design variation of the SAR antenna, called the ISAR ("inverted shorted annular ring") antenna, is also examined. In this design variation, an annular ring microstrip antenna is shorted at the outer boundary, and the inner edge of the annular ring becomes the radiating edge (Basilio et al. 2008). The interior of the annular ring is open space, and other components may be inserted in this region. By inserting an SAR-RSW antenna in this region, a composite SAR/ISAR RSW antenna is obtained. By designing the resonances of the SAR and ISAR antennas to be at different frequencies, a dual-band RSW antenna can be obtained (Basilio et al. 2007). Results will be presented for such a structure.

A general "RSW theorem" is then discussed, which gives a general method for constructing RSW antennas, which do not have to be based on a circular shape as the SAR and ISAR designs are (Komanduri et al. 2013). The theorem states that a microstrip antenna of arbitrary shape will become an RSW antenna if the cavity filling material is chosen to have an effective relative permittivity that is the same as the square of the normalized wavenumber of the TM_0 surface wave, i.e., $\varepsilon_r^{eff} = (\beta_{TM0}/k_0)^2$. This generalizes the design of the RSW antenna to other shapes than those based on a circular geometry.

Although the SAR-RSW antenna has good performance, its main limitation is that its size is larger than that of a convention microstrip antenna. Furthermore, the size of the RSW antenna does not scale with the substrate permittivity, as it does for conventional microstrip antennas. The diameter of the RSW antenna is roughly 0.59 λ_0, independent of the substrate permittivity. Furthermore, the mutual coupling between RSW antennas becomes less than that for conventional microstrip antennas only when the spacing between the antenna centers is larger than about 0.75 λ_0. This means that the RSW antenna is not suitable for phased-array applications that require a large scan range. However, it may be suitable for arrays with limited scan ranges, and the performance of RSW antennas in such arrays is examined here (Chen et al. 2005).

RSW Design Principle

The RSW antennas discussed in the next section are all based on the same principle, namely that a ring of magnetic current inside of a grounded substrate that varies as $\cos\phi$ will not excite the TM_0 surface wave if the radius of the ring is chosen properly. This principle is explained here.

The designs introduced in the next section are all based on a modification of a circular patch, which has a circular radiating edge. If we consider a circular patch antenna operating in the TM_{mn} mode with $m = 1$, the electric field at the edge of the patch varies as $\cos\phi$. The electric field of the resonant mode at the patch edge is given by $E_z = \cos\phi$. In the magnetic current model of the microstrip antenna (Jackson 2007), which is based on the equivalence principle (Harrington 2001), this corresponds to a magnetic surface current at the edge of the patch that is

$$M_{s\phi} = \cos\phi. \tag{1}$$

DOI 10.1007/978-981-4560-75-7_50-2

The surface wave excitation from this sheet of magnetic surface current may be understood by examining the canonical problem of a ring of magnetic current of radius b having a current $K = \cos\phi$ at some height z_0 above the ground plane as shown in Fig. 2, as the sheet of magnetic surface current $M_{s\phi}$ can be thought of as a superposition of such rings. This current ring model is only an approximate model of a circular patch antenna because the aperture is not a perfect magnetic conductor in reality. Furthermore, the simple current function of Eq. 1 neglects all higher-order TM_{mn} modes with $m \neq 1$ that are excited by the feed probe. The approximation of the patch by the magnetic current in Eq. 1 becomes more accurate as the quality factor Q of the patch antenna increases, which means the substrate becomes thinner.

Consider first the radiation from a single infinitesimal (Hertzian) dipole of magnetic current oriented in the x direction, at a height z_0 above the ground plane along the z axis. This infinitesimal dipole will excite a TM_0 surface wave field of the form

$$\psi^{sw} = A(z, z_0)\, H_1^{(2)}(\beta_{TM0}\rho)\, \sin\phi, \tag{2}$$

where ψ denotes the field component of interest, e.g., the field E_z along the ground plane. The wavenumber of the TM_0 surface wave β_{TM0} can be determined numerically once the substrate thickness, permittivity, and operating frequency are specified (for example, using a bisection or secant method search on the real axis between k_0 and k_1). The amplitude factor $A(z,z_0)$ depends on the height of the source and the observation point above the ground plane. This factor can be determined from the residue of the surface wave pole in a spectral-domain solution (Pozar 1982), though the value is not needed for the present discussion. Far away from the dipole, the surface wave field has the approximate form

$$\psi^{sw} = A(z, z_0)\sqrt{\frac{2}{\pi}}\, e^{j3\pi/4}\, \frac{e^{-j\beta_{TM0}\rho}}{\sqrt{\beta_{TM0}\rho}}\, \sin\phi. \tag{3}$$

Next, consider the surface wave excitation from the ring of magnetic current $K = \cos\phi$ shown in Fig. 2. The surface wave field from the ring may be found from the field of the Hertzian dipole, integrating over the ring current. If the observation point is sufficiently far from the ring, a far-field approximation for the phase of the surface wave radiated from each point on the ring may be used. The phase term is then written as

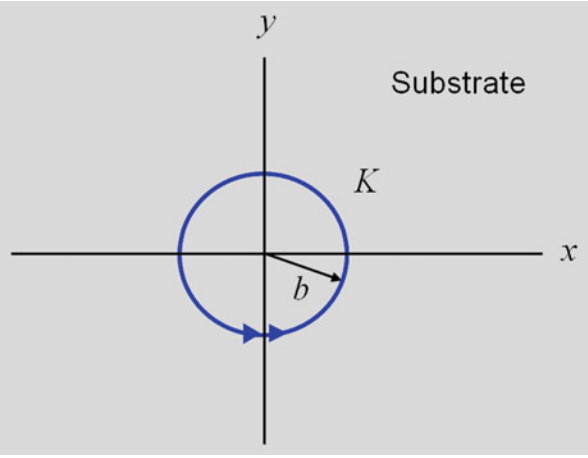

Fig. 2 A ring of magnetic current $K = \cos\phi$ inside of a grounded substrate (*top view*)

DOI 10.1007/978-981-4560-75-7_50-2

$$e^{-j\beta_{\mathrm{TM0}}|\underline{r}-\underline{r}'|} \approx e^{-j\beta_{\mathrm{TM0}}\rho} e^{+j\beta_{\mathrm{TM0}}(x'\cos\phi + y'\sin\phi)} = e^{-j\beta_{\mathrm{TM0}}\rho} e^{+j\beta_{\mathrm{TM0}} b\cos(\phi-\phi')}, \tag{4}$$

where ϕ is the observation angle and ϕ' is the angle of the source point on the ring. The surface wave field excited from the ring is then

$$\begin{aligned}\psi^{sw} = A(z,z_0)\sqrt{\frac{2}{\pi}}\, e^{j3\pi/4}\, \frac{e^{-j\beta_{\mathrm{TM0}}\rho}}{\sqrt{\beta_{\mathrm{TM0}}\rho}} \\ \cdot \int_0^{2\pi} \cos\phi' \sin(\phi - (\phi' + \pi/2)) e^{+j\beta_{\mathrm{TM0}} b\cos(\phi-\phi')} b\, d\phi'.\end{aligned} \tag{5}$$

Using $\alpha = \phi - \phi'$ and shifting the range of integration back to $(0, 2\pi)$, the integration may be written as

$$\begin{aligned}\psi^{sw} = -A(z,z_0)\sqrt{\frac{2}{\pi}}\, e^{j3\pi/4}\, \frac{e^{-j\beta_{\mathrm{TM0}}\rho}}{\sqrt{\beta_{\mathrm{TM0}}\rho}} \\ \cdot \int_0^{2\pi} \left(\cos\phi\cos^2\alpha + \sin\phi\sin\alpha\cos\alpha\right) e^{+j\beta_{\mathrm{TM0}} b\cos\alpha} b\, d\alpha.\end{aligned} \tag{6}$$

To evaluate the integral in Eq. 6, the Jacobi–Anger expansion is used (Abramowitz and Stegun 1970), which is

$$e^{j\beta_{\mathrm{TM0}} b\cos\alpha} = J_0(\beta_{\mathrm{TM0}} b) + 2\sum_{n=1}^{\infty} j^n J_n(\beta_{\mathrm{TM0}} b)\cos(n\alpha). \tag{7}$$

The trigonometric identities

$$\cos^2\alpha = \frac{1+\cos(2\alpha)}{2}, \quad \sin\alpha\cos\alpha = \frac{1}{2}\sin(2\alpha) \tag{8}$$

are then used, and orthogonality then allows us to keep only the $n = 0$ and $n = 2$ terms in Eq. 7. Using the identity

$$J_1'(x) = \frac{1}{2}(J_0(x) - J_2(x)) \tag{9}$$

then allows Eq. 6 to be written as

$$\psi^{sw} = -A(z,z_0)(2\pi b)\sqrt{\frac{2}{\pi}}\, e^{j3\pi/4}\, \frac{e^{-j\beta_{\mathrm{TM0}}\rho}}{\sqrt{\beta_{\mathrm{TM0}}\rho}} \cos\phi J_1'(\beta_{\mathrm{TM0}} b). \tag{10}$$

Equation 10 implies that a ring of magnetic current will not excite the TM_0 surface wave, provided the radius is chosen to satisfy

$$J_1'(\beta_{\mathrm{TM0}} b) = 0, \tag{11}$$

DOI 10.1007/978-981-4560-75-7_50-2

which implies that

$$\beta_{TM0} b = x'_{11} = 1.8412, \tag{12}$$

where x'_{11} denotes the first (smallest) root of the $J_1'(x)$ Bessel function. Any other root x'_{1n} can also be used in Eq. 12, but to have the smallest possible ring, the value $x'_{11} = 1.8412$ is chosen. This corresponds to an SAR-RSW antenna with the smallest possible radius.

A circular patch having a radius chosen according to Eq. 12 will not in general be of resonant size. According to the cavity model, a resonant circular patch operating in the TM_{11} mode will have a radius determined from

$$k_1 b = x'_{11}, \tag{13}$$

where k_1 is the wavenumber of the substrate, which is the same as the wavenumber inside the patch cavity for a conventional circular patch. Since $k_0 < \beta_{TM0} < k_1$, the radius of a circular patch cannot satisfy both Eqs. 12 and 13. A circular patch with a radius chosen from Eq. 12 will be too large to be resonant at the operating frequency (at which β_{TM0} is calculated). Hence, the patch must be modified to make it resonant, while keeping the radius of the radiating edge fixed according to Eq. 12. There are various ways of modifying the resonance frequency of a circular patch, and this leads to several different RSW designs discussed below.

RSW Designs

Shorted Annular Ring (SAR)

The SAR-RSW antenna is shown in Fig. 3. It consists of a circular patch of radius b, with a ring of shorting vias located at radius a, and is fed by a probe at radius ρ_0. The radius b of the antenna is chosen according to Eq. 12. The inner radius a of the shorting vias is then chosen to make the antenna resonant at the operating frequency (the frequency at which β_{TM0} is calculated). The region $\rho < a$ inside the patch cavity is a "dead" region where the fields are zero. Hence, the patch metal can be removed from this circular region, creating an annular ring that is shorted on the inner boundary at $\rho = a$ (and hence the name "shorted annular ring"). The term "shorted annular ring" is used to denote the structure of Fig. 3, regardless of whether or not the interior metal region is present.

A simple cavity model analysis can be used to determine the radius a of the via ring in Fig. 3 to make the SAR-RSW structure resonant. In this approximate analysis, a perfect magnetic conductor (PMC) wall is assumed at the outer radius b, and a perfect short circuit is assumed at the inner radius a. The electric field inside the cavity is assumed to have the form

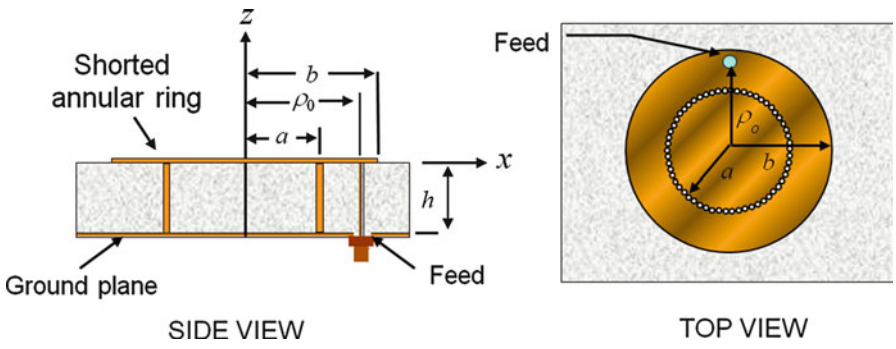

Fig. 3 Geometry of the shorted annular ring reduced surface wave antenna (SAR-RSW)

DOI 10.1007/978-981-4560-75-7_50-2

$$E_z(\rho,\phi) = \cos\phi(AJ_1(k_1\rho) + BY_1(k_1\rho)). \tag{14}$$

Enforcing the boundary conditions at the inner and outer radii, the electric field vanishes at the inner boundary and its normal derivative vanishes at the outer boundary. This yields a transcendental equation for the inner radius a as

$$\frac{J_1(k_1a)}{Y_1(k_1a)} = \frac{J_1'\left(x_{11}'\dfrac{k_1}{\beta_{\mathrm{TM0}}}\right)}{Y_1'\left(x_{11}'\dfrac{k_1}{\beta_{\mathrm{TM0}}}\right)}, \tag{15}$$

which is easily solved numerically. Equation 15 always has one solution for the desired radius a. If the permittivity of the substrate is sufficiently large, a second solution (with a smaller value of a) will also exist as well. This will occur when k_1 is larger than a certain value that corresponds to the solution $a = 0$, so that the argument of the J_1' term in Eq. 15 is at a root of the J_1' function, namely the root x_{12}'. This yields the condition for the second solution to exist as

$$k_1 > \beta_{\mathrm{TM0}}\left(\frac{x_{12}'}{x_{11}'}\right). \tag{16}$$

If the wavenumber of the TM_0 surface wave is approximated as k_0 (this approximation becoming more accurate for thin substrates), then this condition reduces to $\varepsilon_r > 8.38$.

The design procedure for the SAR-RSW antenna is first to calculate the wavenumber β_{TM0} of the TM_0 surface wave from the given substrate thickness, permittivity, and operating frequency chosen. Next, the outer radius b is determined from Eq. 12 and the inner radius a is determined from Eq. 15.

If desired, one can design the SAR structure to be a "reduced lateral wave" (RLW) antenna instead of a reduced surface wave antenna, reducing the lateral radiation that propagates outward horizontally from the antenna with the wavenumber of free space k_0. The design principle of the RLW antenna is very similar to that of the RSW antenna, with k_0 replacing β_{TM0}. To see this, first consider the space-wave field produced by an x-directed magnetic dipole along the z axis at a height z_0 above the ground plane, with no substrate present. The space-wave field has the form

$$\psi^{sp} = B(z,z_0)\frac{e^{-jk_0\rho}}{\rho}\sin\phi, \tag{17}$$

with some amplitude coefficient $B(z, z_0)$. Comparing Eq. 17 with Eq. 3, we see that the forms are similar, with β_{TM0} replaced by k_0. Repeating the same type of deviation above, we find that the ring of radius b in Fig. 2 radiates a space-wave field along the ground plane given by

$$\psi^{sp} = -B(z,z_0)(2\pi b)\frac{e^{-jk_0\rho}}{\rho}\cos\phi J_1'(k_0b). \tag{18}$$

Hence, the outer radius of the SAR-RLW antenna would be chosen as

$$k_0b = x_{11}' = 1.8412. \tag{19}$$

DOI 10.1007/978-981-4560-75-7_50-2

The antenna would then not produce any space-wave field along the ground plane, at least to leading order (a higher-order space-wave field would exist that decays faster than $1/\rho$).

If an infinite substrate were present, the dipole would produce a lateral radiation field where the $1/\rho$ term in Eq. 17 is replaced by a function $F(\rho)$, giving the radial dependence of the lateral radiation. For small and moderate values of ρ, this function would vary as $1/\rho$, and for extreme distances, it would vary as $1/\rho^2$. The lateral radiation field would then be given as

$$\psi^{lw} = -B(z, z_0)(2\pi b)e^{-jk_0\rho}F(\rho)\cos\phi J_1'(k_0 b). \tag{20}$$

In view of Eq. 19, the antenna would not produce any lateral radiation (to leading order) when a substrate is present. The same design, based on Eq. 19, would thus minimize space-wave radiation along the ground plane when no substrate is present and would minimize lateral radiation inside and near the substrate when an infinite substrate layer is present. The inner radius a for the RLW antenna would be chosen according to

$$\frac{J_1(k_1 a)}{Y_1(k_1 a)} = \frac{J_1'\left(x_{11}'\dfrac{k_1}{k_0}\right)}{Y_1'\left(x_{11}'\dfrac{k_1}{k_0}\right)}, \tag{21}$$

which comes from Eq. 15, replacing β_{TM0} with k_0.

Fortunately, for most substrates, the wavenumber β_{TM0} of the TM_0 surface wave is fairly close to that of the free-space wavenumber k_0. Hence, the SAR-RSW and the SAR-RLW designs would be very close to each other. In practice, the SAR-RSW design has both reduced surface wave excitation and a reduced amount of lateral radiation.

Cored Substrate Design

In this design, a cylindrical region of radius a is cored out of the substrate cavity and replaced by a material having a lower relative permittivity ε_{rc}, as shown in Fig. 4 (Jackson et al. 1993). The value of ε_{rc} is chosen to be less than that of the substrate permittivity ε_r, but is otherwise somewhat arbitrary. The core region could be chosen as an air region, in which case $\varepsilon_{rc} = 1$. The lower permittivity of the core region could be obtained by drilling holes in the substrate to create an artificial dielectric in the core region with a lower permittivity than the surrounding substrate (Gauthier et al. 1997; Papapolymerou et al. 1998). The cavity region below the circular patch thus consists of a core region of radius $\rho < a$ and a substrate region with ε_r in the region $a < \rho < b$. The outer radius b is chosen from the basic RSW design Eq. 12, as it is in the SAR design. The inner radius a of the core region is chosen to make the patch resonant at the operating frequency.

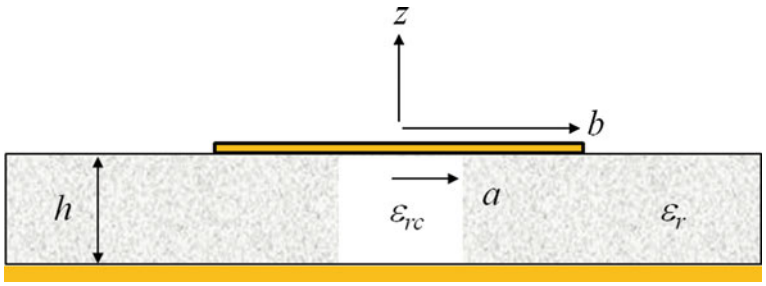

Fig. 4 Geometry of the cored-substrate reduced surface wave antenna

DOI 10.1007/978-981-4560-75-7_50-2

A cavity-model analysis can be used to predict the necessary inner radius a. In the core region, the field is assumed to be

$$E_{z1}(\rho,\phi) = A\cos\phi J_1(k_c\rho), \tag{22}$$

while the field in the substrate region below the patch is assumed to be

$$E_{z2}(\rho,\phi) = \cos\phi(BJ_1(k_1\rho) + CY_1(k_1\rho)). \tag{23}$$

The wavenumbers k_c and k_1 correspond to the core and substrate regions, respectively. Enforcement of the boundary conditions at $\rho = a$ and $\rho = b$ results in the following transcendental equation for determining the inner radius a:

$$\begin{aligned}\frac{\eta_1}{\eta_c}J_1'(k_ca)\left[J_1(k_1a)Y_1'(k_1b) - J_1'(k_1b)Y_1(k_1a)\right] \\ = J_1(k_ca)\left[J_1'(k_1a)Y_1'(k_1b) - J_1'(k_1b)Y_1'(k_1a)\right],\end{aligned} \tag{24}$$

where η_c and η_1 are the intrinsic impedances of the core region and substrate region, respectively. (Alternatively, if the radius a is specified, this becomes a transcendental equation for determining the permittivity ε_{rc} of the core region.)

Patch with Artificial Substrate

This design is similar to that of the cored design in that an artificial substrate is used inside the patch cavity. In this design, the entire substrate within the patch cavity is replaced by an artificial substrate having a relative permittivity of ε_{rp} under the patch, inside the cavity region. The artificial substrate now occupies the entire cavity region $\rho < b$ as shown in Fig. 5. The patch will be resonant when

$$k_pb = x_{11}', \tag{25}$$

with k_p the wavenumber in the patch cavity region. Since we wish for the patch to be an RSW antenna, Eq. 12 is also enforced. Both equations will be satisfied when

$$k_p = \beta_{\mathrm{TM0}}, \tag{26}$$

implying that the filling material of the cavity region must have the same wavenumber as that of the TM_0 surface wave. This means that

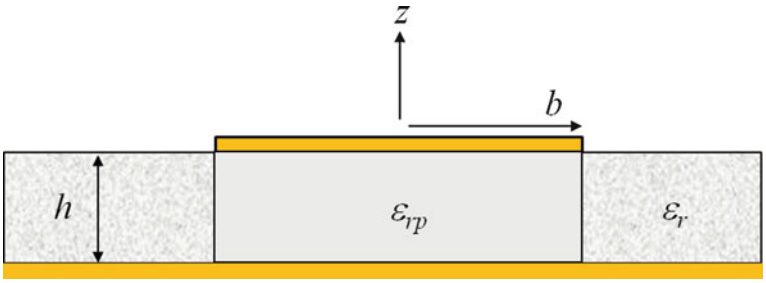

Fig. 5 Geometry of the circular patch with an artificial substrate inside

DOI 10.1007/978-981-4560-75-7_50-2

$$\varepsilon_{rp} = (\beta_{\mathrm{TM0}}/k_0)^2. \tag{27}$$

Since $\beta_{\mathrm{TM0}} < k_1$, it follows that $\varepsilon_{rp} < \varepsilon_r$. This lower permittivity can be realized by drilling holes in the substrate within the patch cavity to lower the permittivity (Gauthier et al. 1997; Papapolymerou et al. 1998), or by adding a dense array of vertical vias inside the patch cavity to create an artificial substrate having a lower effective permittivity (Nikolic et al. 2005).

Inverted Shorted Annular Ring (ISAR)

The previous RSW designs were all based on a circular structure that radiates from the outer edge, with the radius of the outer radiating edge chosen according to Eq. 12. A variation of the design uses a circular structure that radiates from the *inner edge*. The inverted shorted annular ring (ISAR) RSW antenna is based on this design variation (Basilio et al. 2008). The ISAR antenna is shown in Fig. 6 below. It consists of an annular ring structure that is shorted on the outer edge (using shorting vias), with the inner edge being the radiating edge whose radius is chosen according to Eq. 12, with b replaced with a. The outer radius is chosen to make the antenna resonant at the operating frequency. This yields a transcendental design equation for the outer radius b as

$$\frac{J_1(k_1 b)}{Y_1(k_1 b)} = \frac{J_1'(k_1 a)}{Y_1'(k_1 a)}. \tag{28}$$

The ISAR patch is larger than the SAR patch, so for most applications the SAR patch would probably be preferable. However, one advantage of the ISAR patch is that it has a large interior region $\rho < a$ that is empty, into which another RSW antenna can be placed, e.g., an SAR-RSW antenna. The interior SAR-RSW antenna would have to be resonant at a higher frequency than the ISAR antenna, so that the radius of its outer radiating edge is smaller than the inner radius of the ISAR patch. In this way, a dual-band RSW antenna can be realized that is planar. (Stacking RSW antennas of different size would be another way to obtain a dual-band structure.)

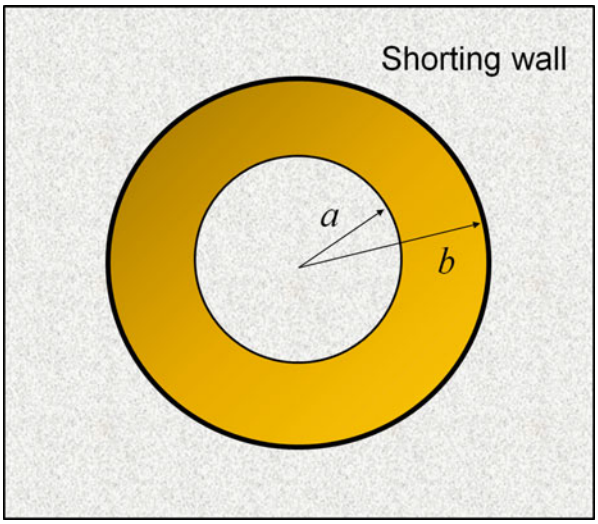

Fig. 6 Geometry of the inverted shorted annular ring (ISAR) patch

DOI 10.1007/978-981-4560-75-7_50-2

Annular Ring

The previous designs were all variations of an annular ring that had one of its edges shorted, either the inner or outer edge. Another design concept is to use an annular ring microstrip antenna with both edges open, and thus radiating from both edges (Hagerty and Popovic 2002). The geometry is the same as that of the ISAR shown in Fig. 6, without the short circuit on the outer boundary. Instead of having a single radiating edge located at a critical radius that does not excite the TM_0 surface wave, the two edges of the annular ring are positioned so that the surface wave field excited by the two edges cancels out. The TM_{12} mode of the annular ring was used in (Hagerty and Popovic 2002). This mode has a $\cos\phi$ variation and an electric field in opposing directions at the two edges, resulting in magnetic currents that are in the same direction (and hence a broadside pattern as for a conventional circular patch).

In view of Eq. 10, the excitation of the TM_0 surface wave field from the two edges can be found from the amplitudes of the magnetic currents at the edges, given by

$$K(\phi) = \pm E_z(\phi)h, \tag{29}$$

where E_z is the electric field at the corresponding edge, with the "+" sign being for the outer edge and the "−" sign being for the inner edge. The surface wave field is then given by

$$\psi^{sw} = -A(z,z_0)(2\pi h)\sqrt{\frac{2}{\pi}}e^{j3\pi/4}\frac{e^{-j\beta_{TM0}\rho}}{\sqrt{\beta_{TM0}\rho}}\cos\phi\left(-aE_z(a)J_1'(\beta_{TM0}a) + bE_z(b)J_1'(\beta_{TM0}b)\right). \tag{30}$$

The electric field inside the patch is given by Eq. 14. Enforcing a zero radial derivative at the two edges (assuming an approximate open circuit or PMC boundary), the field inside the patch is described by

$$E_z = \cos\phi\left(J_1(k_1\rho)Y_1'(k_1a) - Y_1(k_1\rho)J_1'(k_1a)\right), \tag{31}$$

where

$$J_1'(k_1b)Y_1'(k_1a) - Y_1'(k_1b)J_1'(k_1a) = 0. \tag{32}$$

At a given frequency, if the inner radius a is chosen, Eq. 32 gives the corresponding outer radius b for the ring to be resonant. In order for the ring to not excite the TM_0 surface wave, Eq. 30 implies that the inner radius must be chosen to satisfy

$$-aE_z(a)J_1'(\beta_{TM0}a) + bE_z(b)J_1'(\beta_{TM0}b) = 0. \tag{33}$$

Hence, substituting from Eq. 31, it follows that

$$\begin{aligned} -a\left(J_1(k_1a)Y_1'(k_1a) - Y_1(k_1a)J_1'(k_1a)\right)J_1'(\beta_{TM0}a) \\ + b\left(J_1(k_1b)Y_1'(k_1a) - Y_1(k_1b)J_1'(k_1a)\right)J_1'(\beta_{TM0}b) = 0. \end{aligned} \tag{34}$$

For a given value of the inner radius a, the outer radius b is found from Eq. 32, so that b is a function of a. Hence, Eq. 34 may be viewed as a transcendental equation for the unknown inner radius a.

Note that if the inner or outer radius of the ring is short-circuited, Eq. 33 reduces to the design equation of the SAR or ISAR design equation for the radius of the radiating edge.

Because the interior of the annular ring is open substrate space, components can be placed there. In (Hagerty and Popovic 2002) an X-band oscillator using a class-E amplifier was inserted inside the ring to

DOI 10.1007/978-981-4560-75-7_50-2

make a radiating element for spatial power combining. Similarly, components can be placed inside the ISAR antenna as well. (Components can also be placed inside the SAR antenna, though the inner radius is short-circuited so care must be taken if the components are to be connected to the antenna.)

Non-circular Designs

Other designs of RSW antennas, based on geometries that are not circular in shape, have also been explored in addition to the ones reviewed above that were based on circular geometries. In Hickey et al. (2001), a twin-arc slot design was introduced. This design uses two opposing slots that lie along arcs of a circle, with the slots lying in the ground plane of a grounded substrate. The diameter of the circle and the slot lengths are allowed to vary independently in order to minimize surface wave excitation while maintaining resonance. Although the surface wave excitation is not completely eliminated, it is greatly reduced. The slots were fed by coplanar waveguide and the substrate was electrical thick, about a quarter-wavelength in the dielectric of the substrate. The design greatly reduced the surface wave excitation, which would have otherwise been quite serious for such a thick substrate. The twin-arc slot design is a useful alternative to the patch antenna when it is desired to implement a slot antenna.

In Amendola et al. (2005), a modification of the SAR was introduced, in which the inner and outer edges of the annular ring have elliptical boundaries instead of circular boundaries. The antenna is called the shorted annular elliptical patch (SAEP). The use of elliptical boundaries allows for dual-band operation. As the ellipticity increases, the separation between the two bands increases. The surface wave excitation cannot be eliminated exactly at both frequency bands, so a compromise must be made between the band separation and the amount of surface wave reduction. As long as the band separation is not large, the surface wave excitation is minimal at both bands.

It is also possible to design a rectangular patch that has reduced surface wave excitation. If the two radiating edges of the rectangular patch are spaced apart by a distance L (the resonant length of the patch) then the surface wave excitation will be eliminated in the E-plane provided $\beta_{\mathrm{TM0}} L = \pi$, so that the surface wave excitation from the two edges cancels in the E-plane direction. The surface wave excitation will also be zero in the H plane, since the TM-surface wave field pattern from the magnetic currents on the radiating edges will have a null in this direction. The surface wave field excitation pattern thus has the shape of a four-leaf clover, being zero in the E and H planes and maximum approximately in the four diagonal-plane directions. Although the surface wave excitation is not eliminated, it is greatly reduced. The patch will not be resonant (unless the substrate permittivity satisfies Eq. 27) so the interior of the patch must be modified to make the patch resonant, and this can be done in a variety of ways. In Papapolymerou et al. (1995), a cored substrate inside the rectangular patch was used. In Boccia et al. (2005), shorting pins were used to create an inner rectangular-shaped shorted cavity region, similar to the circular-shorted cavity region ($\rho < a$) of the SAR design.

RSW Theorem

The previous RSW antennas were all circular in shape and were based on the basic design condition of Eq. 12. It is possible to design more general RSW antennas of arbitrary shape, provided the cavity region inside the patch antenna is chosen properly. An "RSW theorem" was introduced in (Komanduri et al. 2013) that allows for such designs. The RSW theorem applies to a planar microstrip patch antenna of arbitrary shape, whose cavity region below the patch has been replaced by an artificial material having a relative permittivity ε_{rp} that is given by Eq. 27. The general patch configuration is shown in Fig. 7.

DOI 10.1007/978-981-4560-75-7_50-2

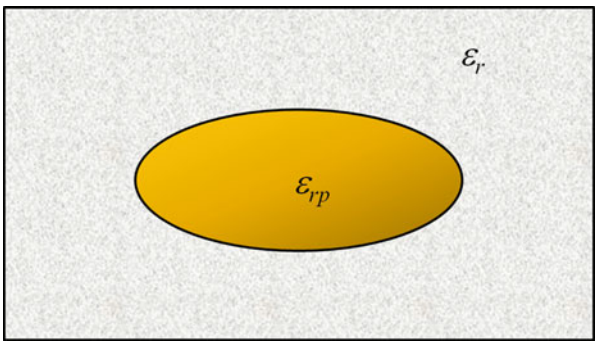

Fig. 7 Geometry of an arbitrary patch having a cavity that is filled with a material having a relative permittivity ε_{rp}

Note that this design generalizes the circular patch filled with an artificial material, shown in Fig. 5. The RSW theorem indicates that any patch shape can be used, and the patch will not excite the TM_0 surface wave when the corresponding cavity is filled with the relative permittivity specified by Eq. 27.

A proof of the RSW theorem is based on the fact that the radiation from the patch can be found from the magnetic current model, modeling the patch by a sheet of magnetic surface current at the boundary of the patch. For simplicity, a single ring of magnetic current varying as $K(\phi')$ inside the substrate, flowing around the boundary C of the patch, is considered. The surface wave field at some z coordinate (e.g., at $z = 0$) launched by such a ring has an amplitude given by

$$\psi^{sw} = A_1 \left(\frac{e^{-j\beta_{\mathrm{TM0}}\rho}}{\sqrt{\rho}} \right) I, \tag{35}$$

where

$$I = \int_C K(\ell')\, e^{j\beta_{\mathrm{TM0}}\left(\underline{\rho}'\cdot\underline{\hat{\rho}}\right)} \sin\left(\phi - \alpha(l')\right) dl', \tag{36}$$

with α being the local tilt angle of the magnetic current in the ring with respect to the x axis, and A_1 being a constant. We wish to prove that the integral I in Eq. 36 is zero when condition Eq. 27 is satisfied. To do this, we consider a scenario when the entire half-space space above the ground plane (both inside the patch cavity and outside of it) is filled with a material having an effective relative permittivity ε_{rp}. According to the cavity model, the patch in this scenario has (approximately) the same fields inside the cavity and the same resonance frequency as the actual patch structure does (which has the material ε_{rp} inside the patch cavity and a substrate with ε_r and thickness h outside the patch cavity). The space wave field ($1/\rho$ field along the ground plane) produced by the same magnetic current ring (now modeling the patch in this new half-space scenario) has the form

$$\psi^{sp} = A_2 \left(\frac{e^{-j\beta_{\mathrm{TM0}}\rho}}{\rho} \right) I, \tag{37}$$

where A_2 is another constant.

The space wave field from the patch in the new scenario can also be calculated using the electric current model, in which a planar surface current radiates at a height h above a ground plane, when the entire medium above the ground plane is a homogeneous one having $\varepsilon_r = \varepsilon_{rp}$. It can be shown by image theory that a horizontal electric current radiating above an infinite ground plane in a homogenous medium will

DOI 10.1007/978-981-4560-75-7_50-2

have a space wave field along the ground plane that falls off with distance faster than $1/\rho$. Therefore, the integral I appearing in Eq. 37 must be zero. Since this is the same I term appearing in Eq. 36, then it must be true that I in Eq. 36 is also zero, and hence that ψ^{sw} is zero. This completes the proof.

As a variation of the RSW theorem, an "RLW theorem" can also be stated. For a patch of arbitrary shape, if the patch cavity is filled with air, then the patch will operate as a reduced lateral wave antenna, with minimal lateral radiation along the substrate and ground plane. The proof of this parallels the preceding proof of the RSW theorem. The lateral-radiation field ψ^{lw} along the substrate or ground plane has the form

$$\psi^{lw} = B_1 e^{-jk_0\rho} F(\rho) I \tag{38}$$

where

$$I = \int_C K(\ell')\, e^{jk_0\left(\underline{\rho}'\cdot\underline{\hat{\rho}}\right)} \sin\left(\phi - \alpha(l')\right) dl'. \tag{39}$$

The term $F(\rho)$ transitions from a $1/\rho$ behavior to a $1/\rho^2$ behavior at extreme distances (if the substrate is infinite). In the proof, we now consider a new scenario where there is free space above the ground plane, both inside and outside the patch, instead of a half-space of material. The space wave radiation along the ground plane in this new scenario is predicted by

$$\psi^{sp} = B_2 \left(\frac{e^{-jk_0\rho}}{\rho}\right) I. \tag{40}$$

The space wave radiation in this scenario falls off with distance faster than $1/\rho$ because of the homogenous (air) region above the ground plane, so the integral term I in Eq. 40 must be zero. The same integral term in Eq. 38 is therefore zero. Hence, the original patch filled with an air cavity will have a lateral radiation field along the substrate or ground plane that is zero to leading order, meaning that the lateral radiation field is a weaker, higher-order field compared to that produced by a conventional microstrip antenna.

The fact that a patch of arbitrary shape filled with an air cavity will not produce lateral radiation along the ground plane was first observed in Nikolic et al. (2005), where the authors demonstrated reduced mutual coupling from the corresponding RLW antennas. For a thin substrate, an RLW antenna should also be an RSW antenna, since β_{TM0} is close to k_0. For thicker and higher-permittivity substrates where β_{TM0} is not very close to k_0, it is worthwhile to distinguish between the two designs. In this case, it may be desirable to design the antenna as an RSW antenna if the goal is to reduce mutual coupling for widely separated antennas, since the surface wave may be more dominant than the lateral radiation. This would depend on the separation between the antennas, however.

Results for RSW Antennas

In this section results are presented for different types of RSW antennas, both for the single element and for the mutual coupling between a pair of elements. Results are also shown for an array of RSW antennas.

DOI 10.1007/978-981-4560-75-7_50-2

Patterns of SAR-RSW Antenna

Figures 8 and 9 compare the E-plane patterns of two microstrip patch antennas that are designed for 2.0 GHz: a conventional circular patch antenna (Fig. 8) and the SAR-RSW antenna (Fig. 9) (Khayat et al. 2000). The patches are on a substrate of thickness 0.1524 cm with a relative permittivity of 2.94 and a loss tangent of 0.0012. The conductivity of the copper patch and ground plane was chosen as 3.0×10^7 S/m in the simulations. The conventional patch has a radius of 2.66 cm. The SAR-RSW patch has an inner radius of 2.42 cm and an outer radius of 4.39 cm. Both antennas are fed by a standard 50 Ω SMA connector on the *x* axis. For each patch, the feed was positioned to give a 50 Ω match, giving a radial feed location of 0.61 cm for the conventional patch and 2.95 cm for the SAR-RSW antenna. The patterns were measured on a 1-m diameter circular ground plane. The measured patterns are also compared with the theoretical patterns that assume an infinite ground plane.

DOI 10.1007/978-981-4560-75-7_50-2

The E-plane pattern of the conventional patch in Fig. 8a shows significant back radiation and scalloping (rippling) of the pattern in the forward direction. Both of these effects are due to edge diffraction from the space wave radiated by the patch when it hits the edge of the ground plane. According to the geometrical theory of diffraction (GTD) (Mcnamara 1990; Balanis 2005), the E-plane pattern consists of the pattern of the antenna on an infinite ground plane together with the pattern due to two diffraction points at the E-plane edges of the ground plane (i.e., at $\phi = 0°$ and 180°, assuming a probe feed along the x axis). These two diffraction points act as sources that radiate, and this radiation produces the back radiation as well as the radiation that interferes with the main pattern of the antenna (the pattern of the antenna on an infinite ground plane) in the forward region.

It is seen from Fig. 9a that the E-plane pattern of the SAR-RSW antenna has much less back radiation as well as a greatly reduced scalloping of the forward pattern. Because of the greatly reduced edge diffraction, the measured pattern also agrees much better with the theoretical pattern than for the conventional patch. The E-plane beamwidth of the SAR-RSW antenna is smaller than that of the conventional patch. This is due to the larger size of the SAR-RSW patch, which introduces an array-factor effect. This array factor almost has a null at the horizon ($\theta = 90°$) since the outer patch radius approximately satisfies Eq. 19, since $\beta_{TM0} \approx k_0$. The SAR-RSW antenna therefore also has a larger directivity than a conventional circular patch, being about 10 dBi for the SAR-RSW antenna compared to about 7 dBi for the conventional circular patch. The radiation efficiency was found to be very similar to that of the conventional circular patch, around 75 %. (Although the SAR antenna produces only a very small amount of surface wave power, the overall efficiency is dominated by the conductor and dielectric loss, which is about the same as for the conventional patch.) The gain of the SAR-RSW antenna (about 9 dBi) was therefore about 3 dB higher than that of the conventional circular patch (about 6 dBi). The bandwidth was also found to be similar between the two antennas (about 1 %, based on an SWR < 2 definition).

Figures 8b and 9b show the H-plane patterns of the same two patches. According to GTD, the two diffraction points that determine the H-plane pattern are located at the edge of the ground plane along the H plane. Since the far-field radiation pattern component E_θ varies as $\cos\phi$, this component has a null in the H plane. Therefore, there is minimal diffraction in the H plane, even for the conventional patch. Hence, the H plane pattern of the conventional patch (Fig. 8b) shows little back radiation and forward scalloping. Two exceptional points are at $\theta = 0°$ and 180°; in these directions the E and H planes coincide. A fairly significant back radiation occurs at $\theta = 180°$, while a bump is observed at $\theta = 0°$. These effects are removed in the H-plane pattern of the SAR-RSW patch (Fig. 9b).

One interesting observation is that the E and H plane patterns of the SAR-RSW patch are nearly equal, with the E-plane pattern being slightly narrower. The SAR-RSW patch has nearly the same H plane pattern as does the conventional patch, while the E plane pattern is narrower, making the two planes of the SAR-RSW patch more nearly equal than for the conventional patch. This makes it possible to obtain a circularly polarized patch with a good axial ratio over a fairly wide angle range, as will be shown below.

Mutual Coupling Between SAR-RSW Antennas

Figure 10 shows the geometry for the mutual coupling between a pair of antennas. For E-plane coupling, $\Delta y = 0$, while for H-plane coupling $\Delta x = 0$.

Figure 11 shows the mutual coupling parameter S_{21} in the E plane between a pair of conventional circular patches and a pair of SAR-RSW antennas, with the antennas being the same as in Figs. 8 and 9. The coupling is shown versus the normalized center-to-center separation $\Delta x/\lambda_0$. Measured and calculated values are shown, and the measured results are seen to agree well with the calculated values (Khayat et al. 2000). The E-plane coupling between conventional patches falls off with separation approximately as $1/\rho$, while for SAR-RSW patches the E-plane coupling falls off as $1/\rho^3$, so it becomes very weak as the

DOI 10.1007/978-981-4560-75-7_50-2

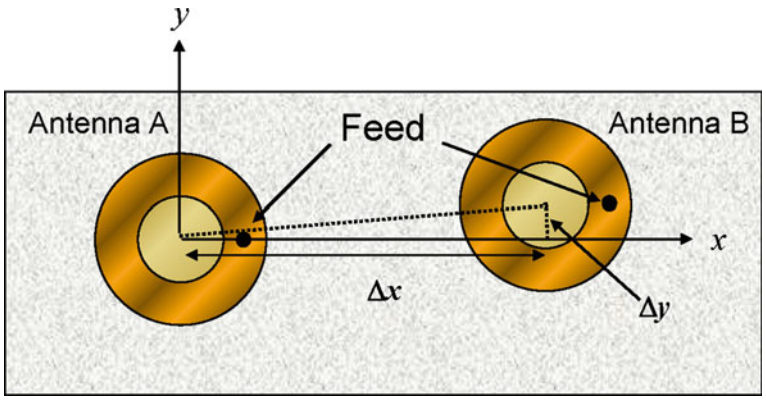

Fig. 10 Geometry setup for mutual coupling between either a pair of conventional or SAR-RSW antennas (SAR-RSW antennas are shown here)

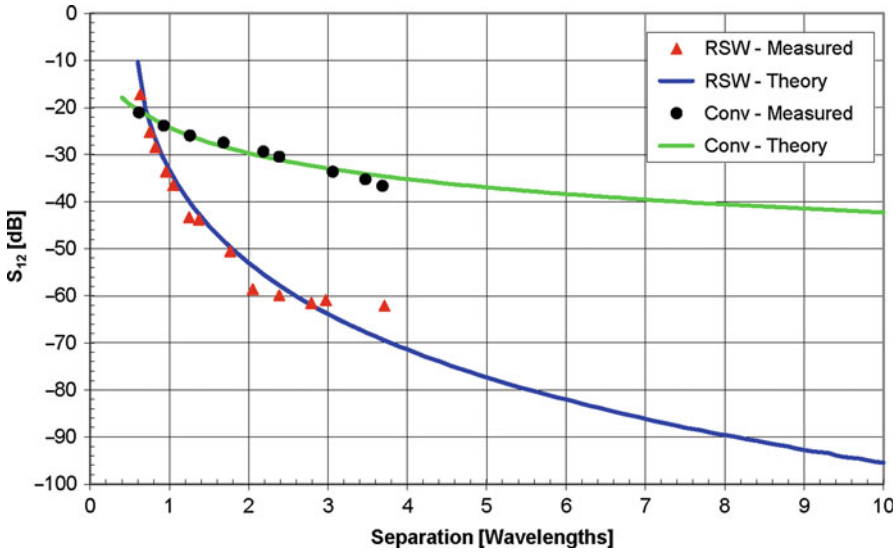

Fig. 11 Comparison of E-plane mutual coupling between a pair of conventional circular patches and a pair of SAR-RSW patches at 2.0 GHz. The patches are the same as in Figs. 8 and 9

separation increases (Khayat et al. 2000). The mutual coupling between the SAR-RSW antennas becomes less than that between conventional circular patches when the separation between the centers exceeds roughly 0.75 λ_0.

Figure 12 shows the calculated mutual coupling between conventional and SAR-RSW patches in both the E and H planes. Figure 12 shows that the mutual coupling between conventional patches falls off much slower in the E plane than the H plane as expected (Pozar 1982), since the E_θ component of the radiation field varies as $\cos\phi$ along the ground plane far away from each antenna. The E-plane coupling between conventional patches therefore falls off as $1/\rho$, while the H-plane coupling falls off as $1/\rho^2$. The H-plane coupling between the SAR-RSW antennas is only slightly lower than that between the conventional antennas, and also falls off as $1/\rho^2$. The E-plane coupling between the SAR-RSW antennas is the lowest of all the couplings for large separations, falling off as $1/\rho^3$.

Figure 13 shows the calculated E-plane mutual coupling between the pair of conventional circular patch antennas decomposed into its constituent components, including the surface wave component, the lateral-radiation component (called the “lateral wave”) and the total (the complex sum of the two)

DOI 10.1007/978-981-4560-75-7_50-2

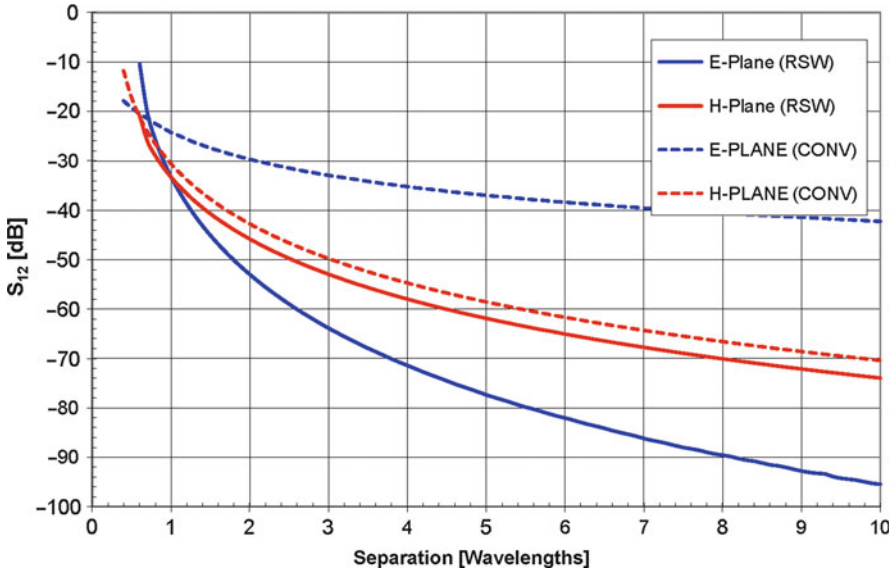

Fig. 12 Comparison of mutual coupling between a pair of conventional circular patches and a pair of SAR-RSW patches at 2.0 GHz, in different planes. The patches are the same as in Figs. 8 and 9

(Khayat et al. 2000). It is seen that for this typical substrate ($\varepsilon_r = 2.94$, $h/\lambda_0 = 0.010$), the lateral-radiation field is the dominant coupling mechanism out to a separation of about 9.5 λ_0. Beyond this separation, the surface wave field becomes the dominant coupling mechanism. This confirms that for separations that are not too large, it is more important to reduce the lateral radiation than the surface wave.

Circularly Polarized SAR-RSW Antenna

The SAR-RSW antenna can be made into a circularly polarized (CP) antenna by feeding at two orthogonal feed ports spaced 90° apart, with a 90° phase difference between the two feed ports. A RHCP version of the SAR-RSW antenna was designed for the GPS L1 frequency of 1.575 GHz using a substrate of

DOI 10.1007/978-981-4560-75-7_50-2

thickness 0.1524 cm with a relative permittivity of 2.94 and a loss tangent of 0.0012. The SAR-RSW patch has an inner radius of 3.03 cm and an outer radius of 5.58 cm. The short-circuit inner boundary of the SAR-RSW was realized using vias that were spaced 10 mils (0.0254 cm) apart (from edge to edge) and were each 25 mils (0.0635 cm) in diameter. This is sufficient to ensure a good short circuit boundary at the inner radius. Both antennas are fed by a standard 50 Ω SMA connector at each feed port. For each antenna, the feed was positioned to give a 50 Ω match, corresponding to a radial feed location of 3.70 cm from the center of the patch. A standard 90° quadrature hybrid was used to feed the patch at the two orthogonal feed points.

Figure 14 shows the RHCP and LHCP far-field radiation components of the antenna, measured on a 1 m diameter circular ground plane. There is little back radiation, and the LHCP cross-pol level is lower than −30 dB. The low level of back radiation and the null in the pattern at the horizon reduce the susceptibility of the antenna to low-angle multipath and multipath arising from reflections from the ground.

Because of the low level of lateral radiation, the ground plane size can be reduced relative to that of a conventional microstrip antenna, while maintaining an acceptable pattern. Figure 15 shows the patterns for the same antenna in Fig. 14 when mounted on a smaller ground plane. In Fig. 15a, the antenna is mounted on a circular ground plane that is 35.5 cm (14 in.) in diameter. In Fig. 15b, the antenna is mounted on a square ground plane that is 12.7 cm (5 in.) on a side. In both cases, the pattern degradation due to the smaller ground plane is minimal, though in Fig. 15b the back radiation has now exceeded −20 dB.

Dual-Band SAR/ISAR-RSW Antenna

As mentioned in the Introduction, the SAR and ISAR designs can be combined to form a dual-band RSW antenna, with the SAR inside of the ISAR. The inner SAR antenna resonates at the lower frequency, while the outer ISAR antenna resonates at the upper frequency. The design procedures for the SAR and ISAR are given in sections "Shorted Annular Ring (SAR)" and "Inverted Shorted Annular Ring (ISAR)", respectively. As was discussed in the previous section, a quadrature hybrid can also be used together with two feed ports on each patch to obtain circular polarization. The design is shown in Fig. 16.

As an application, a dual-band RHCP antenna was designed for the L1 (1.575) and L2 (1.227 GHz) bands. The substrate had a thickness of 0.1524 cm with a relative permittivity of 2.94 and a loss tangent of

0.0012. The SAR antenna had the same dimensions as in the previous section, while the ISAR had an inner radius of 5.577 cm and an outer radius of 8.727 cm. The inner radius of the SAR and the outer radius of the ISAR were short-circuited using vias that were spaced 10 mils (0.0254 cm) apart (from edge to edge) and were each 25 mils (0.0635 cm) in diameter.

Figure 17 shows the measured patterns at the L1 and L2 frequencies. As seen, the patterns are good at both frequencies, almost as good as those for the single CP SAR antenna of the previous section.

Antennas Based on the RSW Theorem

The RSW theorem of section "RSW Theorem" indicates that a general method for constructing an RSW antenna is to fill the cavity region of the patch with an artificial material having an effective permittivity that is chosen according to Eq. 27. The patch itself may have an arbitrary shape. To test this, both a rectangular patch and a circular patch were designed using a three-layer structure as shown in Fig. 18a (Komanduri et al. 2013). Note that the upper layer is an electrically thick ($h_3 = 0.062\ \lambda_0$) high-permittivity layer ($\varepsilon_{r3} = 9.8$), which would tend to create a significant surface wave excitation when excited by a microstrip source. However, a bottom layer is introduced and a second air spacer layer is placed on top of the bottom layer, below the patch. The thickness of the air spacer layer is chosen so that the effective

DOI 10.1007/978-981-4560-75-7_50-2

permittivity inside the patch cavity (based on a simple series capacitor type of calculation) satisfies Eq. 27. The wavenumber of the TM_0 surface wave on the three-layer structure is $\beta_{TM0} = 1.180\, k_0$, found from a numerical solution of the appropriate transcendental equation for the wavenumber on the three-layer structure (details omitted here). This corresponds to an effective relative permittivity inside the patch cavity (the region below the patch) of $\varepsilon_{rp} = 1.393$. For comparison purposes, Fig. 18b shows a patch design that has the same upper superstrate and maintains the same composite thickness below the patch. However, the lower substrate has been replaced with air. This patch design is referred to as the "non-RSW" design. In both cases the patches are resonant at 4 GHz and are fed at the 50 Ω match points.

Figure 19a shows the E-plane coupling between the two RSW patches (rectangular and circular) and the non-RSW rectangular patches. It is seen that the E-plane coupling for both of the RSW antennas is much less than that of the non-RSW rectangular patches for larger separations, verifying that the RSW patches are operating with reduced surface wave excitation, and that the RSW property is independent of the patch shape. Figure 19b shows that the H-plane coupling is about the same for the RSW and non-RSW antennas, which is consistent with the trends observed with the SAR-RSW antenna, as seen in Fig. 12.

If a patch antenna is printed on a single substrate layer, as opposed to using multiple layers, then an artificial substrate must be used in order to fill the patch cavity with a material satisfying Eq. 27, where the filling material has a lower permittivity than the surrounding substrate. One way to lower the effective permittivity of a substrate region is to drill holes in it (Gauthier et al. 1997; Papapolymerou et al. 1998). Another way is to add shorting vias inside the patch cavity. Shorting vias behave as inductors at

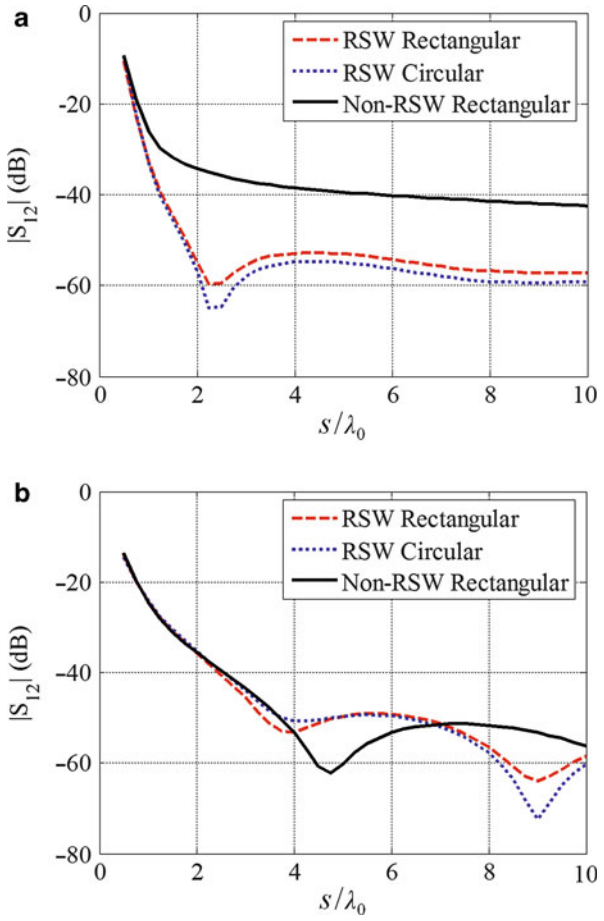

Fig. 19 Mutual coupling versus the normalized separation s/λ_0 between the patch centers for the antennas shown in Fig. 18. (**a**) E-plane coupling. (**b**) H-plane coupling

DOI 10.1007/978-981-4560-75-7_50-2

microwave frequencies, so that when they are added inside of a parallel capacitor region they lower the effective capacitance of the capacitor. (If the vias become very close together, they can also be used to create a short-circuit wall, as was done for the SAR and ISAR designs.) From another point of view, the inductive current on the vias partially cancels the capacitive polarization currents set up by the electric field inside the dielectric material (Nikolic et al. 2005). If the vias are chosen so that the artificial substrate below the patch has a permittivity satisfying Eq. 27, the patch will be an RSW antenna. If the artificial substrate has a free-space permittivity, the patch will be an RLW antenna.

Figure 20 shows a rectangular RSW antenna that has an array of vias (Komanduri et al. 2013). The patch is on an electrically thick substrate with $\varepsilon_r = 9.2$, and $\tan\delta = 0.002$, and a thickness $h = 3.25$ mm. The substrate has an electrical thickness (in terms of wavelength in the dielectric) of $h/\lambda_d = 0.073$ at a resonance frequency of 2.14 GHz. The dimensions are $r_1 = 0.3$ mm, $s_1 = 3$ mm, $s_2 = 6$ mm, $s_3 = 5.5$ mm, $d_1 = 22$ mm, $d_2 = 27$ mm, and $d3 = 32$ mm. The radius of the shorting vias was $r_1 = 0.3$ mm. The radius of the two SMA feed probes was 0.635 mm. Because of the electrically thick substrate, the SMA feed probe radiation is significant, so a balanced two-probe feed system was used to minimize probe radiation, consisting of two SMA feeds 180° out of phase, symmetrically located 5.5 mm from the center of the patch.

In the design process, the wavenumber β_{TM0} was first calculated, and from this the effective relative permittivity of the patch cavity was calculated using Eq. 27. Based on this permittivity, the length of the patch was calculated to make the patch resonant at the design frequency. Vias were then added into the patch until the simulated resonance frequency was the desired design frequency. The vias were kept away from the feed probes to avoid unwanted interaction with the probes. The length of the patch (resonant dimension) was 63 mm and the width was 45 mm.

For comparison, conventional rectangular patches on the same substrate were simulated as well, having a length (resonant dimension) of 22.4 mm and a width of 13.75 mm. The conventional antenna was also designed to resonate at 2.14 GHz and was also fed with a balanced SMA probe feed.

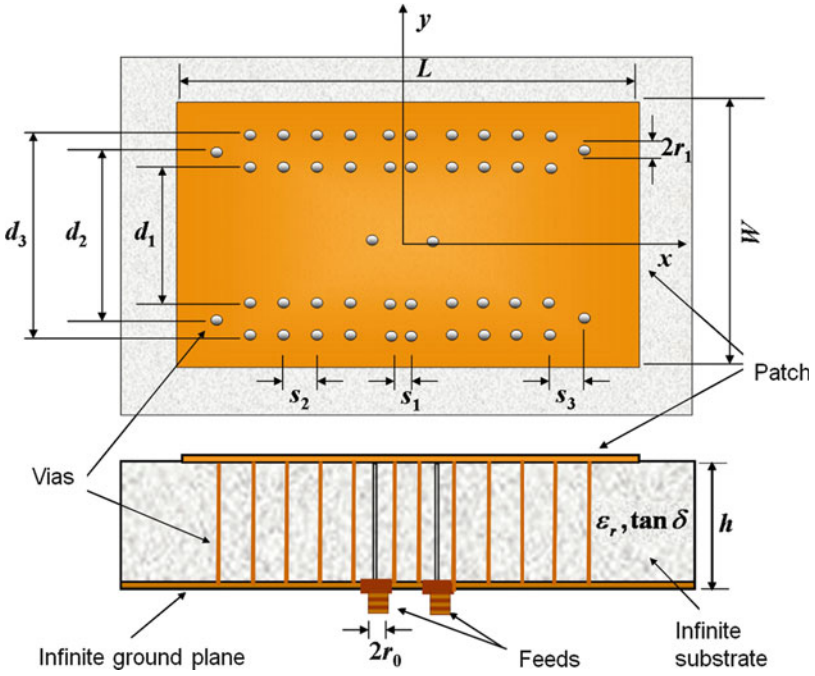

Fig. 20 Rectangular patch loaded with vias. The patch is on an electrically thick substrate with vias added. A balanced two-probe feed system (using two probes that are 180° out of phase) is used to improve symmetry

DOI 10.1007/978-981-4560-75-7_50-2

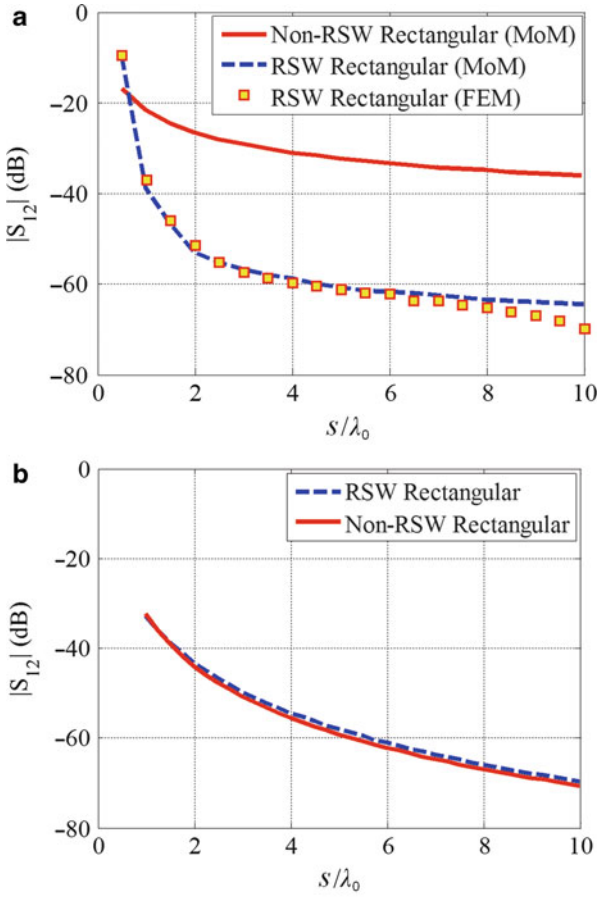

Fig. 21 Mutual coupling between two via-loaded rectangular patches and between two conventional rectangular patches versus the separation between centers. (**a**) E-plane. (**b**) H-plane

Figure 21 shows the simulated mutual coupling between a pair of the via-loaded RSW antennas and a pair of the conventional rectangular patch antennas, versus the separation between the patch centers. The simulation is done using a method of moments (MoM) simulation, using Ansys Designer. For the E-plane coupling (Fig. 21a), a finite element method (FEM) simulation was also used (Ansys HFSS) for validation. The E-plane coupling is much lower with the RSW antennas than with the conventional antennas as the separation increases. The H-plane coupling was approximately the same for both antennas, consistent with the mutual coupling results seen for the SAR-RSW antenna (Fig. 12).

Array of RSW Antennas

The mutual coupling between RSW antennas becomes small when the separation between the antennas increases, as seen in previous results. This is because of the greatly reduced surface wave excitation as well as the reduced lateral radiation along the ground plane. Because of this, there may be an advantage to using an array of RSW antenna to reduce scan blindness, which occurs due to the coherent buildup of the surface wave field from microstrip antennas in an array, adding constructively from one element to the next (Pozar and Schaubert 1984). The scan blindness is most serious in the E plane of an array, since the surface wave is excited the strongest in this direction. However, one limitation of using RSW antennas in an array is the larger size relative to a conventional microstrip antenna. The diameter of the SAR-RSW antenna is about 0.59 λ_0, which is the same size as a conventional circular patch on an air substrate. The interelement spacing between SAR-RSW elements in an array must therefore be larger than 0.59 λ_0, and in

DOI 10.1007/978-981-4560-75-7_50-2

practice larger than about 0.75 λ_0 in order to avoid having too strong of a coupling between nearest neighbors. This large separation will set a limit to the scan range of an array before grating lobes occur (Balanis 2005). For a 0.75 λ_0 separation, the scan range in the E plane will be limited to about 20°, assuming a square lattice element layout. Results are presented below to compare an array of SAR-RSW antennas with an array of conventional circular patches (Deshpande and Bailey 1989).

Figure 22 shows the broadside scan impedance of the center element of a two-dimensional array of antenna elements. The center element is assumed to be matched to the feed line (zero reflection coefficient) when the center element is isolated, with no other elements present. All antennas are fed equally and in phase. The total number of elements in the array is varied (an odd number since the elements are symmetric about the center) with the separation between the centers of the elements being 0.75 λ_0. Results are shown for SAR-RSW elements and conventional circular microstrip antennas. The substrate has a relative permittivity of $\varepsilon_r = 2.94$ and a loss tangent $\tan\delta = 0.0012$, and a thickness of $h = 0.1524$ cm.

For the SAR-RSW antennas, the inner radius is 2.39 cm and the outer radius is 4.38 cm. Each antenna is fed at a radius $\rho_0 = 2.91$ cm, which gives a 50 Ω match when the antenna is isolated. The SAR-RSW antennas resonate at 1.99 GHz. The conventional circular patches have a radius of 2.64 cm and are fed at a radius of $\rho_0 = 0.63$ cm, which gives a 50 Ω match when the antenna is isolated. The conventional circular patch antennas resonate at 1.88 GHz. All antennas are constructed from copper, with a conductivity of $\sigma = 3.0 \times 10^7$ S/m assumed in the simulations. In both cases, the interelement spacing is 0.75 λ_0 at the frequency of operation.

From Fig. 22 it is seen that for the array of SAR-RSW antennas the scan impedance stabilizes quickly, after the array size is only about three elements on a side (nine total elements). This is because the mutual coupling falls off fast enough that it has a negligible effect for elements that are more than one unit cell away. The converged value for the infinite array is about $40 + j10$ Ω, which is not greatly different from the

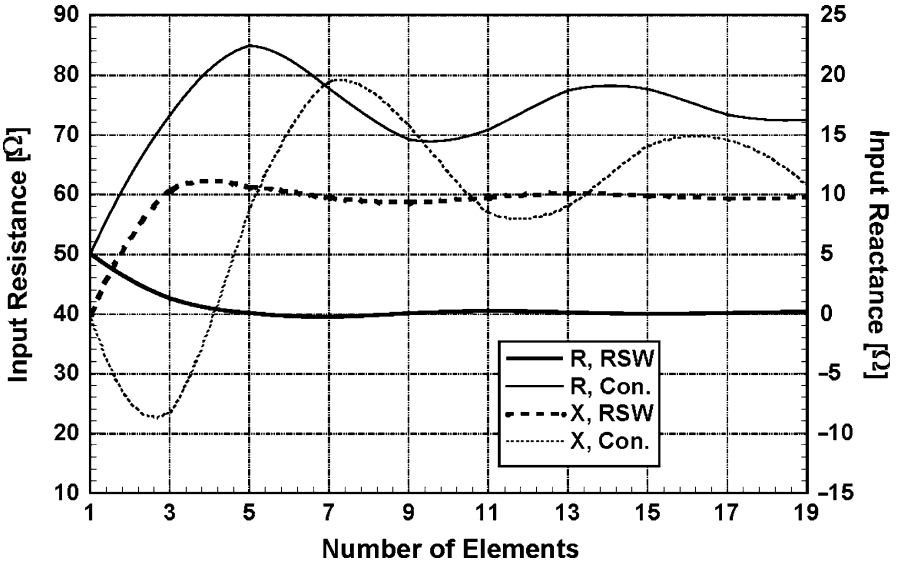

Fig. 22 Broadside scan impedance versus the number of elements N on each side of a two-dimensional $N \times N$ array with an element separation of 0.75 λ_0. The real and imaginary parts of the scan impedance are shown for an array of conventional circular patches and an array of SAR-RSW antennas

DOI 10.1007/978-981-4560-75-7_50-2

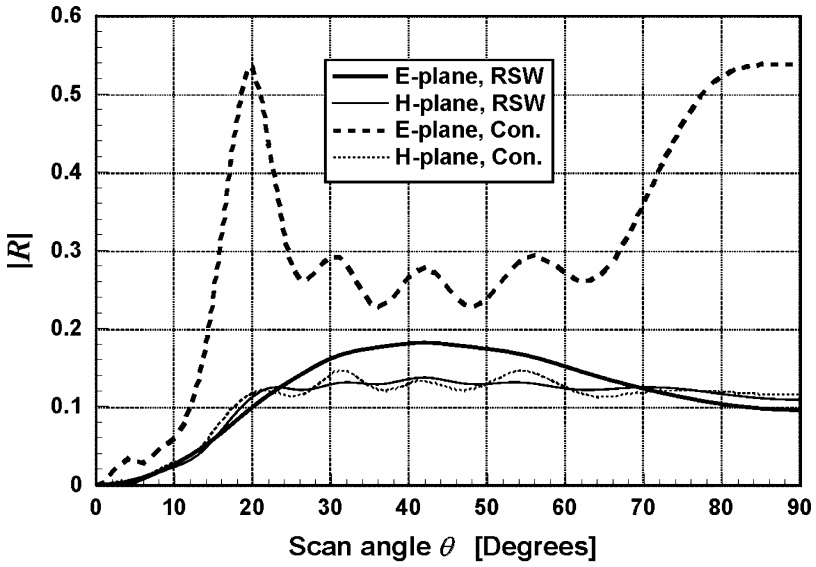

Fig. 23 Magnitude of the reflection coefficient versus the scan angle for a two-dimensional 19 × 19 array with an element separation of 0.75 λ_0. The reflection coefficient is shown for an array of conventional circular patches and an array of SAR-RSW antennas

isolated value of $50 + j0\ \Omega$ for the single patch. The array of conventional circular patches shows a very large variation in the scan impedance as the number of elements increases, and even for an array of 19 × 19 elements, convergence has not yet been obtained. The converged value appears to be around $75 + j12\ \Omega$, which is significantly different from the isolated input impedance of the single patch, namely $50 + j0\ \Omega$.

Figure 23 shows the magnitude of the reflection coefficient for the same array with 19 × 19 elements, as the scan angle is varied by changing the interelement phase shift in either the E plane or the H plane. Because of the large separation between elements, a scan blindness occurs in the E plane for the array of conventional patches, at about 20°. At this scan angle, the magnitude of the reflection coefficient rises to slightly more than 0.5, due to the TM_0 surface wave fields of the patches adding coherently in phase with the $n = -1$ space harmonic (Floquet wave) of the guided wave on the periodic structure. As the size of the patch array increases, the magnitude of the reflection coefficient would rise even higher (Pozar 1986). For the array of SAR-RSW antennas, no visible scan blindness occurs, due to the very small amount of surface wave field being excited by each antenna element. The H-plane for the array of conventional circular patches does not show a scan blindness, since the TM_0 surface wave is not excited in the H plane direction for a ring of magnetic current varying as $\cos\phi$, far away from the current. This can be seen from Eq. 10. The H-plane scan impedances of the SAR-RSW and conventional antennas are almost identical, consistent with the fact that the H-plane mutual coupling between conventional and RSW antennas due to lateral radiation both fall off with distance y in the H plane as $1/y^2$ (Khayat et al. 2000).

Of course, the scan blindness problem with the array of conventional patches can be avoided by simply choosing a smaller element spacing, such as 0.5 λ_0. One cannot use this smaller spacing for the array of SAR-RSW antennas, due to their larger size. However, if one wishes to have a larger array spacing such as 0.75 λ_0, e.g., to keep the number of elements in the array to a minimum, the use of SAR-RSW elements offers an opportunity to avoid the scan blindness problem. In this case, the array scan angle is not limited by the scan blindness effect, but by the onset of grating lobes. For an array spacing of 0.75 λ_0, grating

DOI 10.1007/978-981-4560-75-7_50-2

lobes will appear when the array is scanned in either the E plane or the H plane beyond about 19.5°. Therefore, the use of SAR-RSW antennas in a phased array is limited to applications requiring only a small scan range. The use of a hexagonal lattice will allow the scan range to increase to approximately 30° before the onset of grating lobes, for this same element spacing.

Conclusion

A reduced surface wave (RSW) microstrip antenna is a type of microstrip antenna that excites much less surface wave field than does a conventional microstrip antenna on the same substrate. The antenna is designed so that the TM_0 surface wave field is not excited by the magnetic current that models the dominant patch cavity mode, and hence the amount of surface wave excitation is very small and is mainly due to higher-order effects such as the higher-order modes of the patch. The same concepts used to design an RSW antenna can also be used to design a reduced lateral wave (RLW) antenna, in which case the lateral radiation (horizontally propagating radiation along the substrate and ground plane) is reduced instead of the TM_0 surface wave. In most practical cases where the substrate is relatively thin compared to a wavelength, the wavenumber β_{TM0} of the TM_0 surface wave is fairly close to the wavenumber k_0 of free space. This implies that an antenna designed to reduce the TM_0 surface will also greatly reduce the lateral radiation.

One class of RSW antennas is based on the concept that a ring of magnetic current inside of a grounded substrate that varies as $\cos\phi$ will not excite the TM_0 surface wave if the radius b of the ring is chosen correctly, according to $\beta_{TM0}b = x_{11}{}' = 1.8411$, where $x_{11}{}'$ is the first root of the $J_1{}'$ Bessel function. Various designs can be implemented based on this concept, which are all variations of a circular patch and are circularly symmetric with a dominant mode field that varies as $\cos\phi$. The designs all have a circular radiating edge that has the appropriate critical radius b.

One design is the shorted annular-ring RSW (SAR-RSW) antenna. This design consists of an annular-ring microstrip antenna that is shorted-circuited at the inner radius $\rho = a$, using shorting vias. The outer radius $\rho = b$ is selected to reduce the surface wave excitation, while the inner radius is chosen to make the antenna resonant at the operating frequency. Another design variation starts with a circular patch having the critical radius b and cores out a circular region inside the patch cavity of radius a and replaces it with material having a lower permittivity, whose value is chosen according to the radius a. Another design variation starts with a circular patch having the critical radius b and fills the patch cavity with an effective permittivity selected so that $\varepsilon_r^{eff} = (\beta_{TM0}/k_0)^2$. Another design variation, called the inverted shorted annular ring RSW (ISAR-RSW) antenna, uses a shorted annular ring that is short circuited at the outer radius $\rho = b$ with radiation coming from the inner edge at $\rho = a$. The inner radius now satisfies $\beta_{TM0}a = x_{11}{}' = 1.8411$ and the outer edge at $\rho = b$ is selected to make the antenna resonant. A dual-band RSW antenna can be constructed by placing an SAR-RSW antenna inside of an ISAR-RSW antenna, with the SAR-RSW antenna operating at the lower frequency.

Another class of RSW antennas is based on an "RSW theorem" that states that a resonant planar microstrip antenna of arbitrary shape will not excite the TM_0 surface wave if the patch cavity is filled with a material having an effective permittivity chosen according to $\varepsilon_r^{eff} = (\beta_{TM0}/k_0)^2$. (Alternatively, the antenna will minimize lateral radiation if the filling material is selected to be air.) The circular patch filled with such an effective permittivity is thus a special case of this more general class of RSW antennas.

The advantages of RSW antennas include improved radiation patterns due to less edge diffraction from the supporting ground plane and less mutual coupling between antenna elements (or between the antenna and other circuit components) that are widely separated. The radiation patterns of the RSW antenna are also slightly more directive than for conventional microstrip antennas (due to the larger size). The E and

DOI 10.1007/978-981-4560-75-7_50-2

H plane patterns are more similar for the RSW antenna than for conventional microstrip antennas (which have a broader E plane pattern). This allows for a good axial ratio to be obtained over a fairly large range of angles when using a circularly polarized version of the RSW antenna (using two feeds 90° out of phase).

The main disadvantage of the RSW antennas is that they are larger than conventional microstrip antennas. The SAR-RSW antenna has a diameter of about 0.59 λ_0 and the size cannot be made smaller by increasing the permittivity of the substrate, as it can for a conventional microstrip antenna.

Results show that the SAR-RSW antenna has an E-plane radiation pattern that has much less scalloping on the front side and much less total radiation on the back side, due to less diffraction from the edges of the supporting ground plane. The E-plane mutual coupling between SAR-RSW antennas is also much less than for conventional microstrip antennas when the antennas are widely separated. This is because of the reduced surface wave excitation, and also because of the reduced lateral radiation, since the lateral-radiation field falls off with separation distance x in the E plane as $1/x^3$ for the SAR-RSW antenna, while only falling off as $1/x$ for the conventional microstrip antenna. The H plane lateral-radiation field falls off as $1/y^2$ for both the SAR-RSW and the conventional microstrip antennas. The mutual coupling between SAR-RSW antennas starts to become less than that for conventional microstrip antennas when the element spacing becomes larger than about 0.75 λ_0.

Because the RSW antenna excites very little surface wave field, an array of such antennas will not exhibit scan blindness, which is an effect that arises due to surface wave excitation. However, due to the larger size of the RSW antennas, the interelement spacing in the array also needs to be larger than what is allowable for conventional microstrip antennas. This limits the scan range before grating lobes occur. For example, with an interelement spacing of 0.75 λ_0, the scan range is limited to about 20° from broadside when using a square lattice of elements. For such limited scan applications, RSW antennas may be beneficial.

Waveguide Slot Array Antennas

Jiro Hirokawa* and Miao Zhang
Tokyo Institute of Technology, Tokyo, Japan

Abstract

At first, the history on studies on waveguide slot antennas and arrays is described briefly. Then the components for the waveguide slot antennas are explained. Various configurations of the waveguide slot antenna are described, and the equivalent circuits for some configurations are given. The procedure to design a waveguide slot array antenna is explained, and also the analysis model to design the element is discussed as well as the scattering matrix in connecting the equivalent circuit with a transmission line. Finally, the design examples for one-dimensional and two-dimensional arrays of the waveguide slot antennas are explained.

Slot antenna; Waveguide; Array; Equivalent circuit; Longitudinal slot antenna; Inclined slot antenna; Edge-slot antenna; Reflection-canceling slot antenna; Standing-wave excitation; Traveling-wave excitation; Series feed

Introduction

A waveguide slot antenna is a radiating slot antenna cut on a waveguide. This chapter focuses on slot antennas and their arrays on rectangular waveguide(s) of metal. Typically, the waveguide is hollow but sometimes it is filled with dielectric to reduce the guided wavelength. The waveguide slot antenna has features of low loss and high-power capability. It is mainly used for communication and radar systems in the microwave band and higher.

The theories for the analyses and the designs on the waveguide slot antennas and their arrays have been developed well for a long time by using knowledge on mathematics. Recently, electromagnetic wave simulators have also been developed well, and they are used to analyze and design the waveguide slot antennas and their arrays. This chapter pays attention to the analysis and the design of using them.

History on Waveguide Slot Antennas and Arrays

Watson investigated experimentally at first (Watson 1946, 1947). A slot cut on a waveguide wall interrupts the current flow and couples a power from the waveguide modal field into free space. Stevenson formulated firstly the theoretical analysis as a boundary value problem (Stevenson 1948). He found that an aperture electric field of a resonant slot had sinusoidal distribution in the first approximation. Expressions for the normalized conductance and resistance were derived for various resonant slots. Oliner derived an equivalent impedance of a slot on a transmission line model by the variational method (Oliner 1957). His

*Email: jiro@antenna.ee.titech.ac.jp

DOI 10.1007/978-981-4560-75-7_51-1

expression for the conductance was depended on both the offset and length of the slot, but the susceptance was not depended the offset. He also included the effects of the waveguide wall thickness to verify the theoretical results with experimental ones. Oliner's variational solution was extended to include the effects of the offset by Yee (1974). Stegen measured carefully a set of data and facilitated the slot array design by making plots for the conductance and susceptance of longitudinal slot antennas cut on the broad wall of a rectangular waveguide as a function of slot length normalized to its resonant length (Stegen 1971). Khac and Carson solved the slot analysis problem numerically at first, using moment method (Khac and Carson 1973). They used pulse basis functions and point matching to solve for the unknown electric fields on the slot apertures. Lyon and Sangster used entire basis sinusoidal functions and concluded two bases functions are sufficient to get accurate solutions (Lyon and Sangster 1981). Stern and Elliott used piecewise sinusoidal functions in Galerkin's method (Stern and Elliott 1985). Seki and Goto analyzed a circularly polarized slot pair by taking into the mutual coupling between the two slots on the narrow wall of a rectangular waveguide together with the wall thickness effect (Seki and Goto 1981). Josefsson and Rangarajan analyzed accurately longitudinal and compounded slots on the broad wall of a rectangular waveguide, respectively (Josefsson 1987; Rangarajan 1989). Elliott presented a design theory of linear or planar arrays of waveguide-fed slots, including the effects of external mutual coupling (Elliott and Kurtz 1978; Elliott 1983).

Components

Slot Antenna

Figure 1 shows the typical structure of a slot antenna. It is a narrow straight rectangular aperture on a flat metal plate. The length is about a half wavelength for the slot antenna to resonate. The width is much smaller than the length and the wavelength.

The slot antenna is excited by an electric current crossing with it (equivalently a magnetic field along it). The excitation is controlled by the intensity of the current. It is also controlled by the crossing angle of the current. When the current is perpendicular to the slot antenna (the magnetic field is parallel to the slot antenna), the excitation is the maximum. When the current is parallel to the slot antenna (the magnetic field is perpendicular to the slot antenna), the excitation is zero. Also, the length is smaller than a half wavelength; the excitation becomes weaker.

The polarization of the slot antenna (the electric field on the slot antenna) is oriented along the width. The amplitude of the electric field is sinusoidal along the length and zero at the edges. It is diverged at the edges along the width. The radiation pattern in the E-plane is uniform. It is a figure of eight in the H-plane. The radiation is the maximum in the boresight and null along the length.

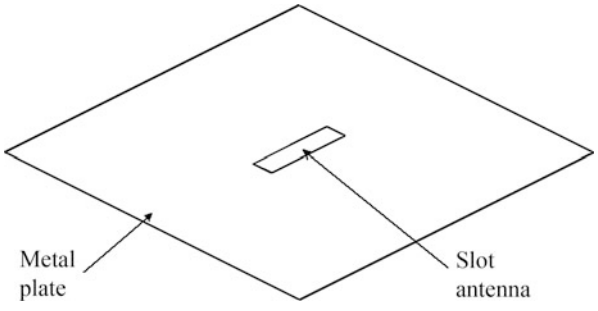

Fig. 1 Slot antenna

DOI 10.1007/978-981-4560-75-7_51-1

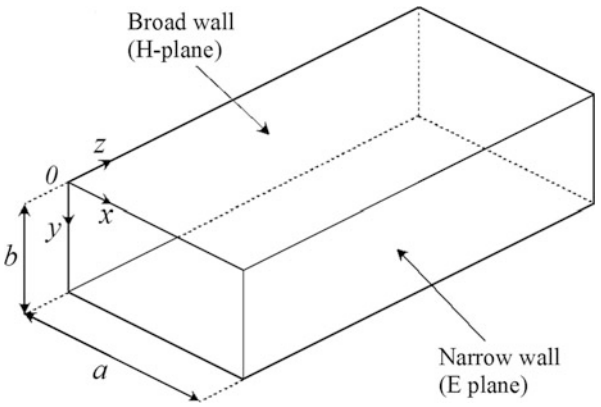

Fig. 2 Rectangular waveguide

Rectangular Waveguide

Figure 2 shows the structure of a rectangular waveguide. The broad-wall width a should be in a range from a half wavelength to one wavelength, and the narrow-wall width b should be less than a half wavelength to propagate only a dominant TE_{10} mode. The broad wall is called as the H-plane because the magnetic field of the TE_{10} mode is parallel to the broad wall. Similarly, the narrow wall is called as the E-plane because the electric field of the TE_{10} mode is parallel to the narrow wall. The field components of the $+z$-directed TE_{10} mode are given by

$$H_z = A\cos\frac{\pi x}{a}\exp(-j\beta z)$$

$$H_x = \frac{j\beta}{k_c}A\sin\frac{\pi x}{a}\exp(-j\beta z)$$

$$E_y = -jAZ_h\frac{\beta}{k_c}\sin\frac{\pi x}{a}\exp(-j\beta z)$$

$$E_z = E_x = H_y = 0$$

where k_c, β, and Z_h are the cutoff wave number, the propagation constant, and the characteristic impedance, respectively. They are given by

$$k_c = \frac{\pi}{a}$$

$$\beta = \sqrt{k_0^2 - \left(\frac{\pi}{a}\right)^2}$$

$$Z_h = -\frac{E_y}{H_x} = \frac{k_0}{\beta}Z_0$$

where k_0 and Z_0 are the wave number and the wave impedance in the free space, respectively. They are given by

DOI 10.1007/978-981-4560-75-7_51-1

$$k_0 = \frac{2\pi}{\lambda_0}$$

$$Z_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} = 120\pi$$

where λ_0, ε_0, and μ_0 are the wavelength, the permittivity, and the permeability in the free space, respectively.

The transverse component of the electric current (the longitudinal component H_z of the magnetic field) on the broad wall is sinusoidal, which is the maximum at the edges and zero at the center along the broad-wall width. The longitudinal component of the electric current (the transverse component H_x of the magnetic field) on the broad wall is sinusoidal, which is the maximum at the center and zero at the edges along the broad-wall width. The electric current on the narrow walls has the component along height (the magnetic field has only the longitudinal component). The components of the fields and the current are uniform along the narrow wall.

The guided wavelength λ_g of a hollow rectangular waveguide is given as follows.

$$\lambda_g = \frac{2\pi}{\beta} = \frac{\lambda_0}{\sqrt{1 - \left(\frac{\lambda_0}{2a}\right)^2}}$$

It is longer than the free-space wavelength. When slot antennas are arrayed with a spacing of one guided wavelength for inphase excitation on a hollow rectangular waveguide, undesired grating lobes are observed. To suppress the grating lobes, the spacing should be a half guided wavelength which is shorter than the free-space wavelength. Or slow-wave structure such as filling dielectric should be placed in the waveguide.

Elements

Longitudinal Slot Antenna

Figure 3 shows the structure of a longitudinal slot antenna. It is cut in parallel to the waveguide with an offset d from the center on the broad wall. The polarization is perpendicular to the waveguide. The

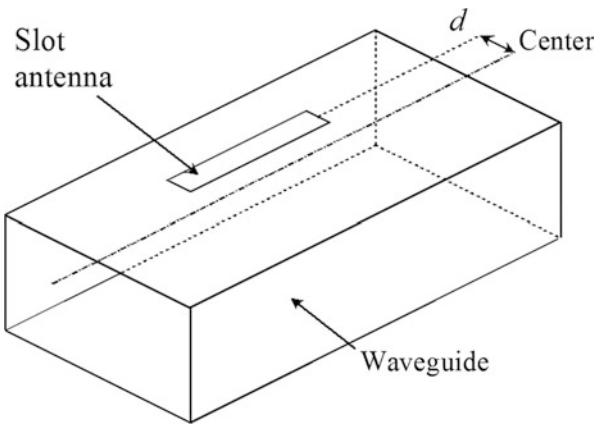

Fig. 3 Longitudinal slot antenna

DOI 10.1007/978-981-4560-75-7_51-1

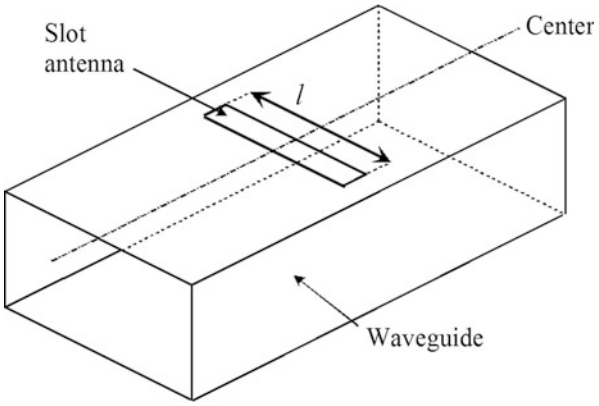

Fig. 4 Transverse slot antenna

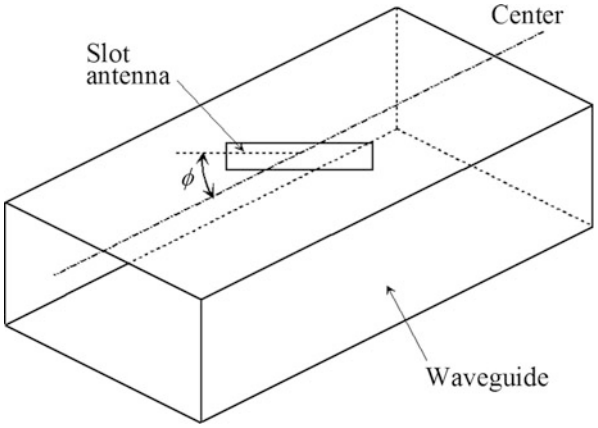

Fig. 5 Inclined slot antenna

excitation is controlled mainly by the offset. It is the maximum at the edges and zero at the center. The equivalent circuit on a transmission line is a parallel admittance because the longitudinal slot antenna is excited by the transverse component of the current flowing between the upper and the bottom broad walls through the narrow wall.

When the longitudinal slot antenna is resonant, the equivalent circuit for the design becomes a parallel conductance. In order to radiate in the boresight, the longitudinal slot antennas are arrayed by a spacing of a half guided wavelength, and the offset direction is opposite among the adjacent slots.

Transverse Slot Antenna

Figure 4 shows the structure of a transverse slot antenna. It is cut perpendicularly to the waveguide on the broad wall. It is placed at the center. The polarization is parallel to the waveguide. The excitation is mainly controlled by the length l. In order to radiate in the boresight, the transverse slots should be arrayed by a spacing of one guided wavelength, and the slow-wave structure such as filling dielectric should be placed in the waveguide.

Inclined Slot Antenna

Figure 5 shows the structure of an inclined slot antenna. It is cut with a tilting angle from the center axis on the broad wall. The excitation is controlled by the tilting angle ϕ. It becomes stronger for a larger tilting angle, and it is zero for 0°. The equivalent circuit on a transmission line is a series impedance because the

DOI 10.1007/978-981-4560-75-7_51-1

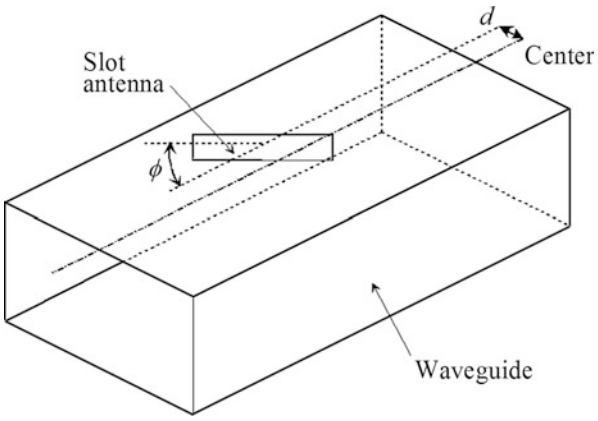

Fig. 6 Compound slot antenna

inclined slot antenna is excited by the longitudinal component of the current flowing along the center of the broad wall. When the inclined slot antenna is resonant, the equivalent circuit becomes a series resistance.

In order to radiate in the boresight, the inclined slot antennas are arrayed with a spacing of a half guided wavelength, and the inclining direction is opposite among the adjacent slots. The main polarization is perpendicular to the waveguide axis. Undesired cross polarization is observed in tilted directions with the angle θ from the boresight given by $\sin^{-1}\frac{\lambda_0}{\lambda_g}$. Its level is higher for a larger tilting angle of the slot.

The inclined slots are often used to feed radiating waveguides in a two-dimensional waveguide slot array antenna.

Compound Slot Antenna

Figure 6 shows the structure of a compound slot antenna (Maxum 1960). The compound slot antenna has both the offset and the tilting angle from the waveguide center axis on the broad wall. For a resonant length, it can arbitrarily control the phase of the excitation, while the longitudinal or the inclined slot antennas have the fixed phase of the excitation. The inclination makes the cross polarization.

Edge-Slot Antenna

Figure 7 shows the structure of an edge-slot antenna. The edge-slot antenna is cut with a tilting angle from the waveguide center axis on the narrow wall. In order to get a resonant length of a half wavelength, the edges are often cut on the broad wall. The excitation is controlled by the tilting angle ϕ. It becomes smaller for a larger tilting angle, and it is zero for 0°. The equivalent circuit on a transmission line is a parallel admittance because the edge-slot antenna is excited by the transverse component of the current flowing on the narrow wall between its top and its bottom. When the edge-slot antenna is resonant, the equivalent circuit becomes a parallel conductance.

In order to radiate in the boresight, the edge-slot antennas are arrayed with a spacing of a half guided wavelength, and the tilting direction is opposite among the adjacent slots. The main polarization is parallel to the waveguide axis. Undesired cross polarization is observed in tilted directions with the angle θ from the boresight given by $\sin^{-1}\frac{\lambda_0}{\lambda_g}$. Its level is higher for a small tilting angle of the slot.

Reflection-Canceling Slot Antenna

Each of the abovementioned slot antennas gives reflection. In an array of these slot antennas, the reflections can make the operation and the design complicate. In order to avoid the complexity, the

DOI 10.1007/978-981-4560-75-7_51-1

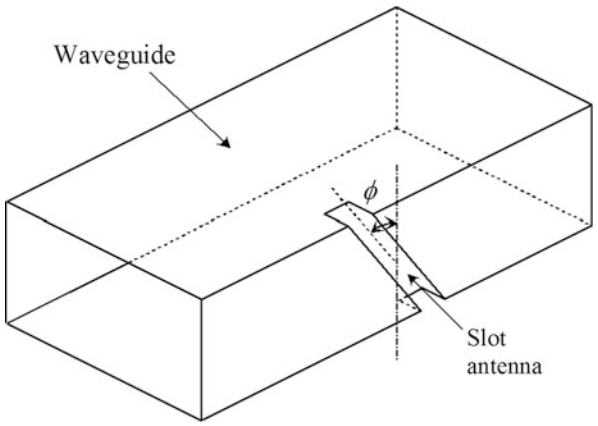

Fig. 7 Edge-slot antenna

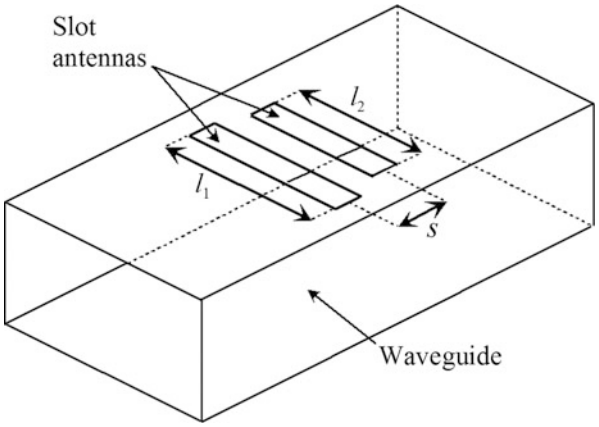

Fig. 8 Transverse slot antenna pair

reflection-canceling slot antennas were introduced. Figure 8 shows the structure of a transverse slot antenna pair on the broad wall (Sakakibara et al. 1994). The two slot antennas in a pair have a spacing of about a quarter guided wavelength. The spacing is smaller than a quarter guided wavelength due to the mutual coupling between the two slot antennas. The reflected waves from the two slot antennas have an effective path length difference of a half guided wavelength so that they are canceled out. The length of one slot antenna is used to control the amplitude of the excitation. The length of the other slot antenna and the spacing between the two slot antennas are used to suppress the reflection. Another example of the reflection-canceling slot antenna is the configuration consisting of a slot antenna with a post or a wall (Park et al. 2003). In an array of the reflection-canceling slot antennas, the phase of the excitation among the adjacent elements can be easily controlled by the spacing of the elements.

A circularly polarized element on a rectangular waveguide has generally small reflection. It consists of orthogonal two slot antennas excited by 90-degree phase difference. The reflected waves from the two slot antennas have 180-degree phase difference so that they are canceled out.

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_51-1

Design Procedure for a Waveguide Slot Array Antenna

The design procedure for a waveguide slot array antenna is as follows.

1. Design of the excitation distribution of the elements
2. Design of the elements for their desired excitations
3. Design modification of the elements by analyzing the overall array antenna

For a two-dimensional slot array antenna, the array of slot antennas on the radiating waveguide and that on the feed waveguide should be designed separately. Each step in the above procedure is explained below.

Design of the Excitation Distribution of the Elements

The excitation distribution of the elements in the array should be designed to have a desired radiation pattern using pattern synthesis technique with the consideration of the element pattern.

Design of the Elements for Their Desired Excitations

The dimensions in each element should be designed to have the desired excitation. In other words, they should be designed to have the desired value of the parallel admittance or the series impedance in the equivalent circuit or the desired coupling in the reflection-canceling element. Figure 9 shows the analysis model of a longitudinal slot antenna as an example. A ground plane is typically embedded in the external region. Its size is infinite or finite depending on the analysis method for an isolated slot antenna. In many cases, such as using an electromagnetic wave simulator, the ground plane is finite, and the external region is truncated as a radiation box. The truncation of the ground plane affects the radiation pattern and the coupling. The faces of the box are assumed to be radiation boundaries except the ground plane. For an example, the size of the radiation box is chosen as $1\lambda_0(x) \times 1\lambda_0(y) \times 0.5\lambda_0(z)$ not to affect the coupling very much. The consideration of the mutual coupling in the infinite array with uniform excitation could give better initial values of the dimensions of the slot antenna. For a one-dimensional array, two faces parallel to the *xy*-plane in the radiation box should be replaced with periodic boundary walls. The spacing of the two faces in the *z*-direction should be equal to the element spacing. For a two-dimensional array, not only two faces parallel to the *xy*-plane but also those parallel to the *yz*-plane should be replaced with

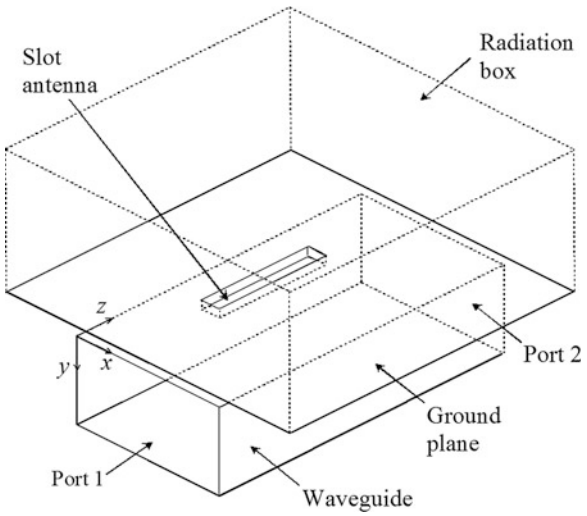

Fig. 9 Analysis model of a longitudinal slot antenna

DOI 10.1007/978-981-4560-75-7_51-1

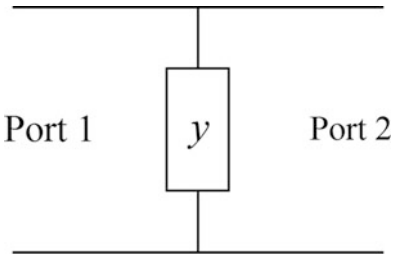

Fig. 10 Parallel admittance

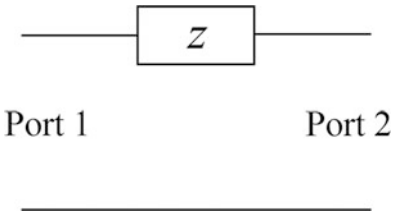

Fig. 11 Series impedance

periodic boundary walls. The spacing of the two faces in the *x*-direction should be equal to the broad-wall width plus the wall thickness of the waveguide. The wall thickness as well as the shape (sometimes rounded from the fabrication point of view) of the edges in the slot antenna should be included because it could affect the frequency dependence of the excitation.

Ports should be placed at both ends of the waveguide. The distance between the port and the center of the slot is large enough to attenuate high modes. For example, it is chosen to be a half guided wavelength. Once the scattering matrix of a waveguide slot antenna is obtained by analyzing it, the parameter of the equivalent circuit can be derived. When the equivalent circuit is a parallel admittance as shown in Fig. 10, the value y which normalized the characteristic admittance of the transmission line is given by the components of the 2-port scattering matrix as follows.

$$y = -2\frac{S_{11}}{1+S_{11}} = 2\frac{1-S_{21}}{S_{21}}$$

Similarly, when the equivalent circuit is a series impedance as shown in Fig. 11, the value z which normalized the characteristic impedance of the transmission line is given as follows.

$$z = 2\frac{S_{11}}{1-S_{11}} = 2\frac{1-S_{21}}{S_{21}}$$

Note that $S_{12} = S_{21}$ is satisfied because of the reciprocity, and $S_{22} = S_{11}$ is satisfied because of the symmetry of the circuit.

Design Modification of the Elements by Analyzing the Overall Array Antenna

The dimensions in each element should be modified by analyzing the overall structure of the waveguide slot antenna to have the desired excitation.

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_51-1

One-Dimensional Slot Array Antennas

Standing-Wave Excitation

Figure 12 shows the structure of a one-dimensional array of resonant longitudinal slot antennas with standing-wave excitation. The number of the slot antennas is N. The array antenna is fed with the end feed. It is fed from one end of the waveguide and is terminated by a short circuit at the other end. The spacing between the short circuit and the last slot antenna is a quarter guided wavelength at the design frequency. The short circuit makes a standing wave in the waveguide, which excites the slot antennas. The longitudinal slot antennas are spaced with a half guided wavelength at the design frequency with the offsets opposite among the adjacent elements. The main beam is oriented to the broadside.

Figure 13 shows the equivalent circuit of the array antenna with the standing-wave excitation. The designed excitation amplitude of the n-th slot is given as α_n. The normalized conductance to be determined of the n-th slot is g_n. The n-th slot is excited by a constant voltage V. The radiation power of the n-th slot is $g_n V^2$, which is proportional to a_n^2. Therefore, $g_n = Ca_n^2$ where C is a constant. For others to match at the feed, $\sum_{n=1}^{N} g_n = C\sum_{n=1}^{N} a_n^2 = 1$ should be satisfied. From this equation, C is determined, and then g_n is specified. The parameters for the n-th slot are determined for g_n.

Another way to feed the one-dimensional array is the center feed where it is fed from the center of the waveguide and is terminated by short circuits at both ends. In this way, the matching condition at the feed becomes $\sum_{n=1}^{N} g_n = C\sum_{n=1}^{N} a_n = 2$.

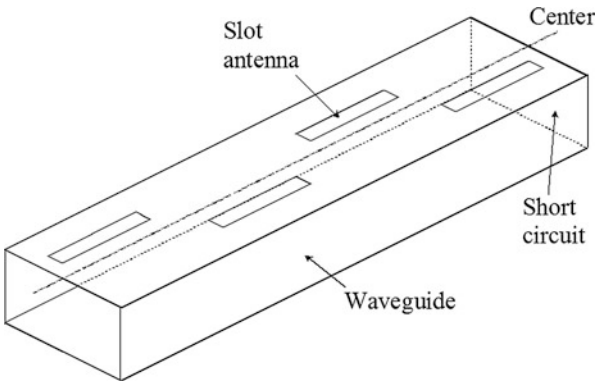

Fig. 12 One-dimensional array of resonant longitudinal slot antennas with standing-wave excitation

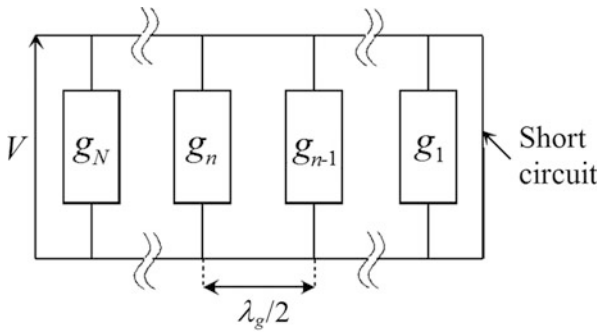

Fig. 13 Equivalent circuit of the resonant longitudinal slot array antenna with the standing-wave excitation

DOI 10.1007/978-981-4560-75-7_51-1

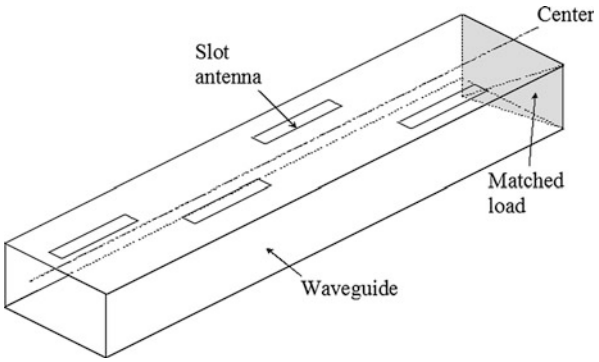

Fig. 14 One-dimensional array of resonant longitudinal slot antennas with traveling-wave excitation

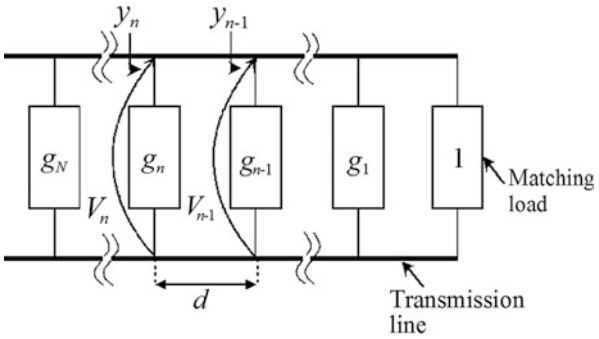

Fig. 15 Equivalent circuit of the resonant longitudinal slot array antenna with the traveling-wave excitation

Traveling-Wave Excitation

Figure 14 shows the structure of a one-dimensional array of resonant longitudinal slot antennas with traveling-wave excitation. The number of the slot antennas is N. The array antenna is fed with the end feed. It is terminated by a matching load. The matching load could be replaced with a matching element that radiates all the residual power at the end. No reflected wave from the end makes a traveling wave in the waveguide, which excites the slot antennas. The longitudinal slot antennas are spaced with other than a half guided wavelength at the design frequency with the offsets opposite among the adjacent elements. The main beam is tilted from the broadside.

Figure 15 shows the equivalent circuit of the array antenna with the traveling-wave excitation. The slot antennas are numbered from the end to the feed. The designed excitation amplitude of the n-th slot is given as a_n. The normalized conductance to be determined of the n-th slot is g_n. The spacing is set to be constant d, and the propagation constant in the waveguide is β. At the n-th slot, the total admittance looking to the matched load and the voltage are y_n and V_n. They satisfy the following recurrence relations.

$$y_n = g_n + \frac{y_{n-1}\cos\beta d + j\sin\beta d}{\cos\beta d + jy_{n-1}\sin\beta d}$$

$$V_n = V_{n-1}(\cos\beta d + jy_{n-1}\sin\beta d)$$

The radiating power of the n-th slot is $g_n|V_n|^2$, which is proportional to a_n^2. Therefore, $g_n|V_n|^2 = Ca_n^2$ where C is a constant. According to the above recurrence relations, g_n is specified.

DOI 10.1007/978-981-4560-75-7_51-1

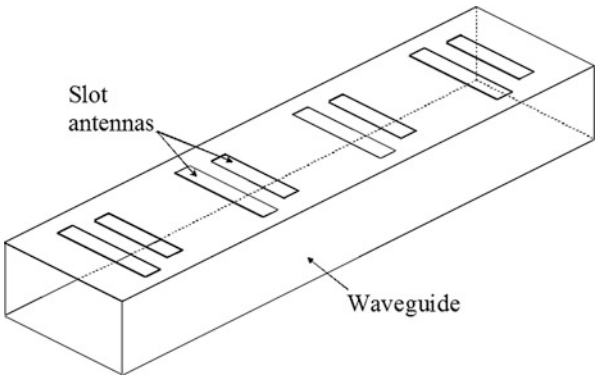

Fig. 16 One-dimensional array of transverse slot antenna pairs

When the number of the slot antennas is large, the reflections among them are negligible, and all the slots are excited uniformly; the design can be simplified. The constant spacing d is determined to suppress the overall reflection at the feed.

$$d = \left(\frac{1}{2} \pm \frac{1}{2N}\right)\lambda_g$$

The beam-tilting angle θ toward the end is given as

$$\sin\theta = \lambda_0\left(\frac{1}{\lambda_g} - \frac{1}{2d}\right)$$

where λ_0 is the free-space wavelength, and λ_g is the guided wavelength. The parameters for the n-th slot are determined for the conductance g_n given similarly to the standing-wave excitation.

Reflection-Canceling Slot Array Antennas

Figure 16 shows the structure of a one-dimensional array of transverse slot antenna pairs. Each transverse slot antenna pair is designed to suppress the reflection. The number of the slot antenna pairs is N. The array antenna is fed with the end feed. It is terminated by a matching element that radiates all the residual power at the end.

The slot antenna pairs are numbered from the end to the feed. The designed excitation amplitude and phase in degrees of the n-th slot antenna pair are given as a_n and P_n, respectively. The coupling c_n of the n-th slot antenna pair is determined as

$$c_n = \frac{a_n^2}{\sum_{m=1}^{n} a_m^2}$$

where the coupling is defined as the ratio of the radiating power over the incident power. The dimensions or the n-th slot are determined for c_n. The transmission phase p_{21n} and the radiation phase p_{31n} in degrees are also estimated for c_n. Figure 17 shows the phase relation in the array antenna. The element spacing d_n between the elements $n + 1$ and n is derived by the following equation.

DOI 10.1007/978-981-4560-75-7_51-1

$$p_{n+1} - p_{31n+1} + p_{21n+1} - 360\frac{d_n}{\lambda_g} + p_{31n} = p_n - 360$$

Two-Dimensional Slot Array Antennas

Structure

Figure 18 shows a typical structure of a two-dimensional array of longitudinal slot antennas. Radiating waveguides are arrayed on the upper layer. A feed waveguide is placed at the lower layer. The feed waveguide is typically located at the center of the radiating waveguides. It is fed in phase toward both directions by a longitudinal feed slot antenna at its center. Inclined coupling slot antennas are cut to couple between the radiating and the feed waveguides as shown. They are spaced with a half guided wavelength in the feed waveguide and have opposite orientation among the adjacent slot antennas to excite them in phase at the design frequency. Figure 19 shows the structure of the inclined coupling slot antenna. The radiating and the feed waveguides are designed separately. Mutual coupling among the radiating slot antennas in the external region should be included in the design, while mutual coupling among the coupling slot antennas outside the feed waveguide does not need to be included in the design.

Series Feed and Corporate Feed

In the series-feed array antennas excited in phase at the design frequency, when the frequency is away from the design one, the slot antennas are not excited in phase anymore due to the change of the guided

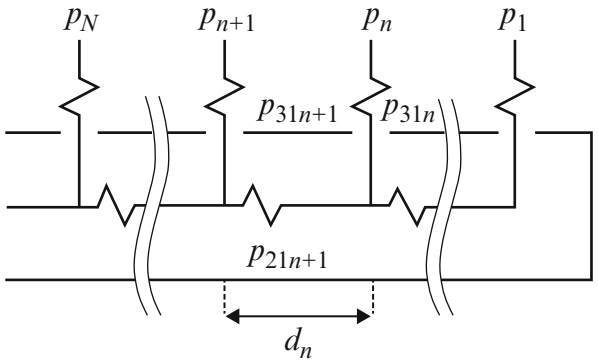

Fig. 17 Phase relation in the transverse slot antenna pair array

DOI 10.1007/978-981-4560-75-7_51-1

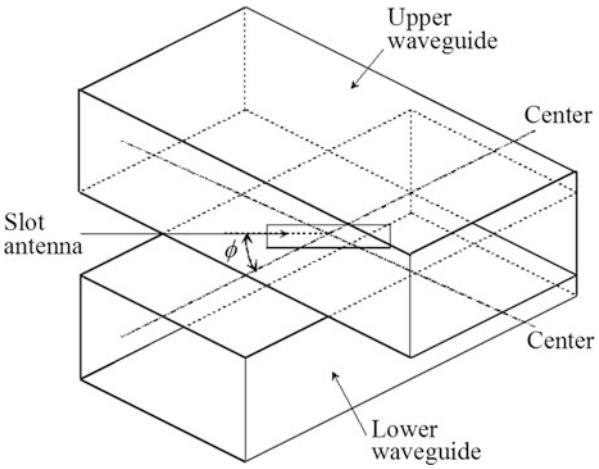

Fig. 19 Inclined coupling slot antenna

wavelength, and the directivity is degraded. On the other hand, in the corporate-feed array antennas, even when the frequency is away from the design one and the guided wavelength is changed, the slot antennas are kept to excite in phase, and the directivity is not degraded. The bandwidth of the corporate-feed array antenna is dependent on those of the elements in the radiating and the feed waveguides.

Design Examples

Alternating-Phase Fed Single-Layer 18 × 18-Element Waveguide Slot Array

An alternating-phase fed single-layer (Sakakibara et al. 1997) 18 × 18-element array with uniform distribution is designed at 25.3 GHz. There are 18 radiating waveguides connected with a feeding circuit at one end. Eighteen slots cut in each radiating waveguide are fed in series. The dimensions of the radiating waveguide are 7.9 mm in width and 3.0 mm in height. On the other hand, the thickness of waveguide sidewall and that of slot thickness are 1.5 and 0.2 mm, respectively. In order to suppress the reflection from the slots as well as to decrease the slot spacing below a half guided wavelength, backward beam-tilting technique is adopted in the design of the slot array. The slot spacing calculated from the equation $d = (1/2 + m/18)\lambda_g$ is fixed at 7.96 mm in common for $m = -1$, and the main beam is tilted at -4.7° from boresight to the feed.

Step 1: To realize a uniform aperture distribution as well as a maximum antenna gain, the targeted values of slot admittances are determined from the equivalent circuit model first. A matching slot that radiates all the residual power is adopted at the end. The normalized conductance and susceptance in a one-dimensional array are summarized in Fig. 20. Since an array of resonant slots is assumed to be realized, the susceptance will be zero for each element. Additionally, the total reflection at the waveguide input is estimated at −19.9 dB from its equivalent circuit mode as well.

Step 2: To obtain the design chart as well as the initial slot parameters, a single resonant slot located in a uniformly excited infinite two-dimensional array is simulated. Here, one pair of periodic boundary walls in the longitudinal direction and the other pair of PEC (perfect electric conductor) walls in the transverse direction are assumed in the external region of slot array as illustrated in Fig. 21. These PEC walls will be replaced by periodic boundary walls for an inphase fed array instead of an alternating-phase fed one. The slot length and offset for a resonant slot as a function of normalized conductance are

DOI 10.1007/978-981-4560-75-7_51-1

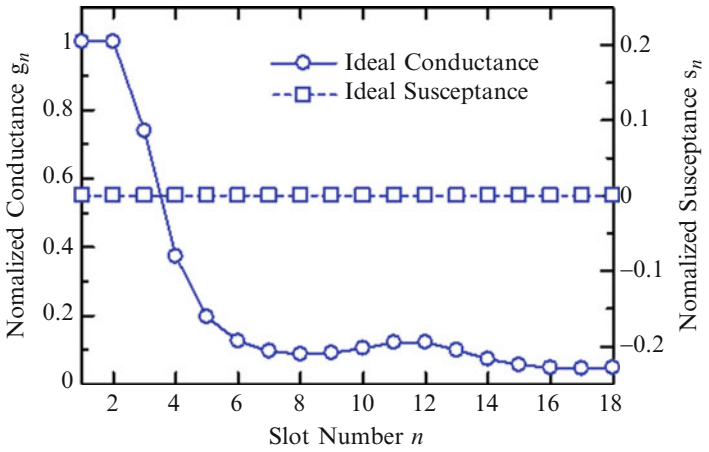

Fig. 20 Normalized conductance and susceptance determined in an equivalent circuit 2-D array

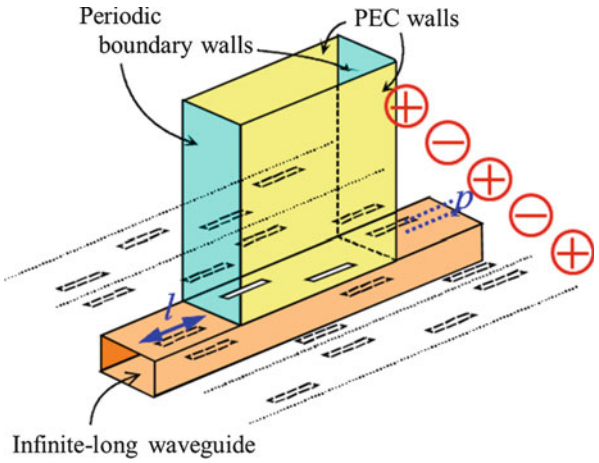

Fig. 21 Single-slot analysis model with periodic boundary walls in the external region

summarized in Fig. 22 which is used in the design chart. The initial slot parameters shown in Fig. 23 are determined to realize the slot admittances in Fig. 20.

Step 3: The one-dimensional array with slot parameters designed above is analyzed with the effects of mutual coupling taken into account. Here, either a method of moment (MoM) analysis (Sakakibara et al. 1996) or an electromagnetic (EM) field simulator adopting periodic boundary walls in the transverse direction can help us to evaluate the external mutual coupling. It is a good approximation for an actual two-dimensional 18 × 18-element array and has the feature of short computation time. The slot parameters will be iteratively designed for further improvement, and the optimized slot parameters are also summarized in Fig. 23 for comparison.

Step 4: After the design of slots, a feed circuit consisting of a series of T-junctions will be designed to excite the radiating waveguides in identical amplitude and alternating phase with a difference of 180°. The full-structure analysis can be conducted by applying a full-wave MoM code (Zhang et al. 2011) or by just an EM field simulator to confirm the antenna performances. The excitation coefficients obtained from the MoM analysis are shown in Fig. 24. The nonuniformities in amplitude and phase are 5 dB and ± 25°, respectively. The simulated antenna gain is 32.3 dBi with an aperture efficiency of 79 %.

DOI 10.1007/978-981-4560-75-7_51-1

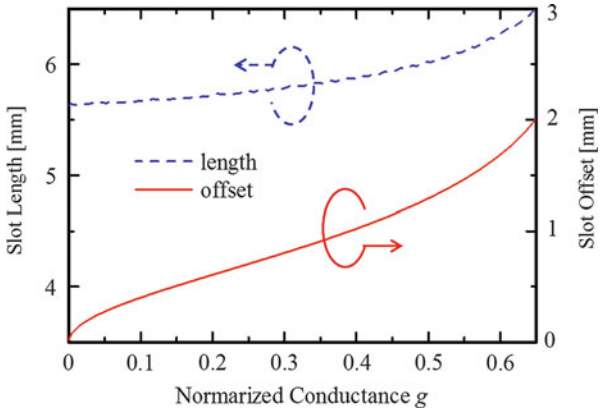

Fig. 22 Slot length and offset as a function normalized conductance obtained in an infinite ground plane

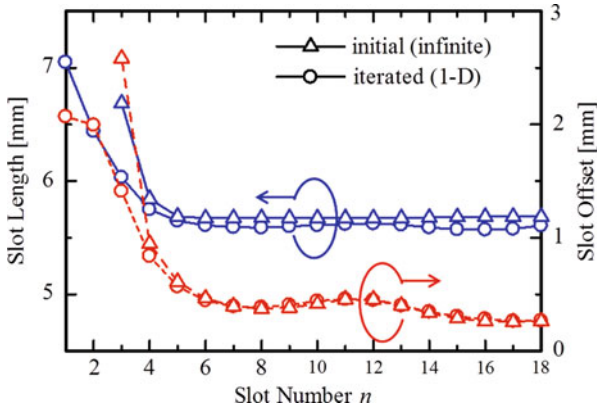

Fig. 23 Initial and iterated values of slot length and offset

By the way, an advanced design technique has been developed (Zhang et al. 2011) to improve the reflection as well as uniformity furthermore. Firstly, with the explicit restraint of input matching, the admittance and element spacing are determined in the equivalent circuit from antenna input toward the termination. At the same time, a significant deviation in the excitation phase as shown in the y direction of Fig. 24b can be compensated by changing the slot spacing d_n or by tuning the admittance y_n off resonance. Secondly, to realize the admittance specified above, the slot length and offset are determined by iterative use of the full-wave MoM analysis of the finite two-dimensional waveguide slot array. Hence, the uniformity in both x and y directions as well as the aperture efficiency can be further improved.

Partially Corporate-Feed Double-Layer 20 × 20-Element Waveguide Slot Array

A 20 × 20-element double-layer antenna with uniform excitation is to be designed at 38.7 GHz. The widths of the radiating and feeding waveguides are 5.0 and 5.4 mm, respectively. The waveguide heights are 2.0 mm in common, and the thickness of sidewalls are 1.0 mm. The widths and thicknesses of both the radiating and coupling slots are 1.0 and 0.4 mm, respectively. By introducing a partially corporate-feed structure as illustrated in Fig. 25, the whole antenna is decomposed into 2 × 2 sub-arrays. Those four sub-arrays are fed in same amplitude and phase without frequency dependence in theory. In addition, the inphase fed array adopted in this paper has regular slot arrangement and the advantage of suppressing the second-order beam (Kurtz and Yee 1957). That is, all radiating waveguides are fed in phase through slot

couplers. Generally, it is enough to design only five elements in both the feeding and radiating parts, because the 20 × 20-element array is simplified into 2 × 2 sub-arrays according to the partially corporate feed.

In the center-feed and partially corporate-feed arrays, it is necessary to maintain the main beam radiation of the sub-array at the boresight. In addition, the number of elements in series is only five. Instead of beam-tilting technique, inductive walls are introduced to all the radiating slots to realize reflection suppression as well as traveling-wave excitation. The main design parameters for slot and wall are illustrated in Fig. 26. It should be noted that the slot shape treated in this design has round edges at both ends. Similar to the procedure illustrated in the previous design example, a MoM analysis or an EM field simulator is applied in the element design and the one-dimensional array analysis. Since the number of elements is only five, it is not necessary to make a design chart. Each element can be designed individually with a coupling $c_n = 1/n$, where n is the slot number. The slot parameter length and offset are summarized in Fig. 27 as a function of coupling c_n. The positions of inductive walls as illustrated in Fig. 26 are optimized to suppress the reflection locally, and their parameters are summarized in Fig. 28. By the way, the first slot called matching slot can be matched by itself without the assistance from an inductive wall. Since an array of resonant slots is adopted here, the radiation phase p_{31n} is simply assumed to have identical value for all n. The slot spacing d_n is increased from a half guided wavelength to compensate the phase enhancement p_{21n} due to the introduction of inductive wall. The values of spacing and phase are summarized in Fig. 29. The frequency characteristics of reflection for each element are summarized in Fig. 30. It is easily observed that in an array with traveling-wave excitation, the slot closer to the end has stronger coupling and shows narrower bandwidth in reflection. In addition, the reflection of the five-element sub-array is also included in Fig. 30 and is well suppressed below −30 dB at the center frequency. The first sidelobe level is −12.8 dB, and a relative good uniformity in excitation is also predicted.

[b]National University of Singapore, Singapore, Singapore

Abstract

An omnidirectional antenna which radiates electromagnetic wave uniformly in a specific plane (often in the azimuth plane) is one of the most popularly used antennas in wireless applications. This chapter illustrates the basic principles and recent development of the omnidirectional antennas. The discussion is carried out based on a category of polarization of the omnidirectional antennas. The polarizations of the omnidirectional antennas include linear polarizations of vertical polarization and horizontal polarization, dual linear polarization, and circular polarization. A brief literature review about omnidirectional antennas is also presented along with state-of-the-art designs.

Keywords

Omnidirectional antenna; Vertically polarized omnidirectional antenna; Horizontally polarized omnidirectional antenna; Dual polarized omnidirectional antenna; Circularly polarized omnidirectional antenna; Dipole antenna; Monopole antenna; Loop antenna; Slot antenna; Dielectric resonator antenna

Introduction

Antennas are essential components of all wireless systems. An antenna consisting of an arrangement of metallic conductors (elements) is used with either a wireless transmitter or a wireless receiver. An oscillating current of electrons forced through the antenna by a transmitter will create an oscillating magnetic field around the antenna elements, while the charge of the electrons also creates an oscillating electric field along the elements. These time-varying fields radiate away from the antenna into space as a moving transverse electromagnetic field wave. Conversely, during reception, the oscillating electric and magnetic fields of an incoming electromagnetic wave exert the force on the electrons in the antenna elements, causing them to move back and forth, creating oscillating currents in the antenna.

The tremendous numbers of antennas have been designed and applied in various systems since 1888 when Heinrich Hertz carried out his pioneering experiments to prove the existence of electromagnetic waves. Generally, the antennas can be classified on the basis of:

- Frequency: very-low-frequency (VLF) antenna, low-frequency (LF) antenna, high-frequency (HF) antenna, very-high-frequency (VHF) antenna, ultrahigh-frequency (UHF) antenna, microwave antenna, millimeter/submillimeter (mmW) antenna, Terahertz antenna, and optical antenna.
- Aperture: wire antenna, reflector antenna, microstrip patch antenna, slot antenna, and so on.
- Polarization: linearly (vertically/horizontally) polarized antenna, dual linearly polarized antenna, and circularly polarized antenna.

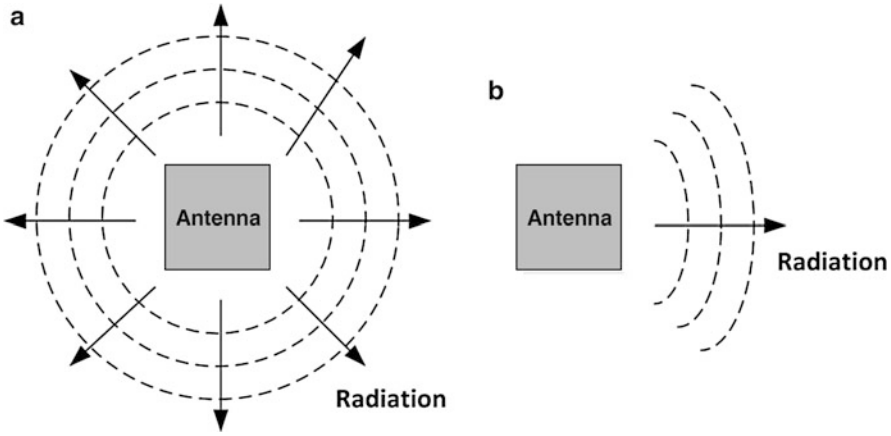

Fig. 1 Omnidirectional antenna versus directional antenna; (**a**) radiation from omnidirectional antenna and (**b**) radiation from directional antenna

- Radiation: isotropic antenna, omnidirectional antenna, and directional antenna.

As shown in Fig. 1, an omnidirectional antenna is able to radiate radio wave uniformly in all directions and offers a 360° coverage in a specific plane (normally in Azimuth plane), which make it very suitable to communicate multiple users. Omnidirectional antennas are widely used for radio broadcasting, satellite, global positioning system (GPS), access point of wireless local area network (WALN), and mobile devices such as cell phone, cordless phone, FM radio, laptop, and so on (Riblet 1947; Croswell and Cockrell 1969).

The first omnidirectional antenna dates back to very early days, a simple dipole or monopole antenna generates vertically polarized omnidirectional radiation in a specific plane. Generally, the omnidirectional radiation is achieved either by the circularly symmetrical current distribution on the radiating element such as monopole antennas and dipole antennas or by combining the radiation of cylindrically positioned multiple directional radiating elements such as microstrip patches and slot antennas. This chapter is organized to concisely summarize the fundamentals of omnidirectional antennas first. Various types of omnidirectional antennas are then reviewed; some of recently developed technologies such as metamaterial-based omnidirectional antennas are also discussed.

Omnidirectional Radiation Pattern

Based on the IEEE Standard Definitions of Terms for Antennas (IEEE Standard 145–1983), the relevant definitions regarding the antenna radiation are as follows:

Isotropic antenna: a hypothetical, lossless antenna having equal radiation intensity in all directions
Omnidirectional antenna: an antenna having an essentially nondirectional pattern in a given plane of the antenna and a directional pattern in any orthogonal plane
Directional antenna: an antenna having the property of radiating or receiving electromagnetic waves more effectively in some directions than others

An isotropic antenna radiates its energy equally in all directions with a spherical radiation pattern, namely, it exhibits omnidirectional radiation pattern in any plane. However, an isotropic antenna never physically exits; it is used as the reference antenna to compare the characteristics of actual antennas. An omnidirectional antenna radiates radio wave power uniformly in all directions in one plane, with the

DOI 10.1007/978-981-4560-75-7_52-1

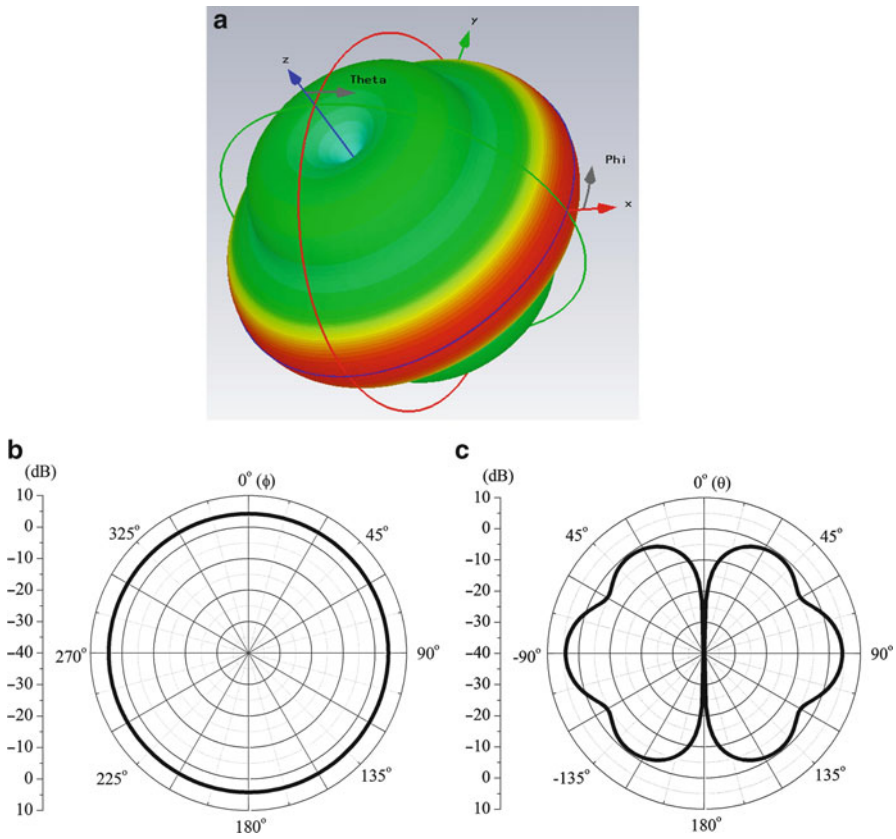

Fig. 2 Typical radiation patterns of an omnidirectional antenna, (**a**) three-dimensional pattern, (**b**) omnidirectional pattern in the azimuth plane (*x-y plane*), and (**c**) pattern in the elevation plane (*x-z* plane)

radiated power decreasing against elevation angles above or below the plane, dropping to zero on the antenna's axis, and producing a "doughnut-shaped" radiation pattern, as shown in Fig. 2.

Directivity of Omnidirectional Antenna

The directivity of an isotropic antenna is unity since its power is radiated equally in all directions. For all other antennas, the maximum directivity will always be greater than unity, and it is a relative "figure of merit" which gives an indication of the directional properties of the antenna as compared with those of an isotropic antenna. It is known that the directivity of a directional antenna can be estimated accurately using the half-power beamwidth (HFBW) of the antenna in the two main planes (Balanis 1997). However, such a formula is not valid for the omnidirectional antenna because the HFBW definition is not applicable in the plane with omnidirectional radiation.

The radiation pattern of an omnidirectional antenna in the elevation plane can be approximated by

$$U = |\sin^{n}(\theta)|, 0 \leq \theta \leq \pi, 0\,\phi \leq 2\pi \tag{1}$$

where n can be integer or non-integer values. The directivity of an antenna with pattern represented by Eq. 1 can be determined in a closed form using the definition with known n. However, an approximate formula for directivity calculation using HFBW will be more convenient for practical design.

McDonald (1978) derived a formula of antenna directivity based on the array factor of a broadside collinear array; it is given by

DOI 10.1007/978-981-4560-75-7_52-1

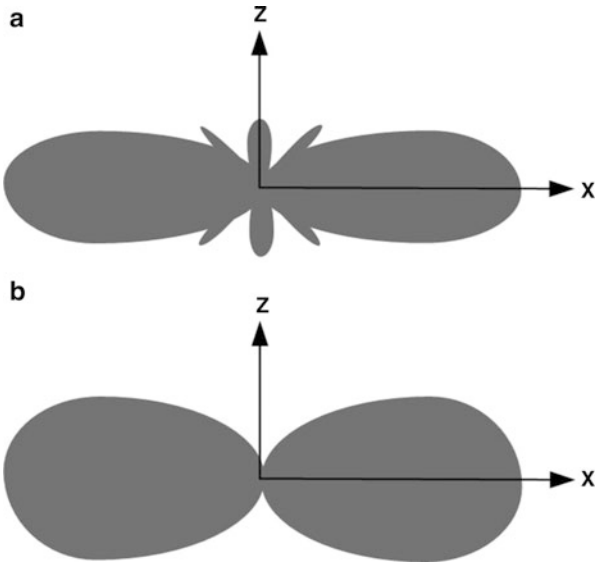

Fig. 3 Omnidirectional patterns with/without minor lobes; (**a**) with minor lobes and (**b**) without minor lobes

$$D_0 \cong \frac{101}{HPBW(\text{degrees}) - 0.0027[HPBW(\text{degrees})]^2} \tag{2}$$

Pozar (1993) derived the formula of antenna directivity based on the exact values obtained using Eq. 1 and then represented the data in a closed form using curve fitting, and it is expressed as

$$D_0 \cong -172.4 + 191\sqrt{0.818 + 1/HPBW(\text{degrees})} \tag{3}$$

In general, the formula Eq. 3 should be more accurate for omnidirectional patterns with minor side lobes of very low intensity (ideally no minor lobes), while Eq. 2 should be more accurate for omnidirectional patterns without minor side lobes, as shown in Fig. 3a, b respectively.

Omnidirectionality

An omnidirectional radiation pattern of a circle can never be achieved for practical antenna designs. As shown in Fig. 4, the omnidirectional radiation pattern of a practical antenna generally exhibits asymmetry or ripples which caused by the asymmetrical radiating structure, the fabrication tolerance, the undesired antenna assembly, the measurement error, and so on.

Omnidirectionality, or roundness, an engineering term, is not defined by the IEEE Standard Definitions of Terms for Antennas but widely used in practical applications. It is a parameter to characterize the uniformity of the omnidirectional radiation in each direction and quantified by the ratio of the maximum to minimum gain of the antenna. An ideal omnidirectional antenna radiation pattern should be a circle with consistent amplitude at any direction so that the omnidirectionality or the roundness is zero dB since the gain of the antenna keeps unchanged along the angles. The engineering requirement of omnidirectionality for an omnidirectional antenna is typically from 6 dB (or ± 3 dB) to 2 dB (or ± 1.0 dB) or even 1 dB (or ± 0.5 dB) for specific applications. Figure 4 demonstrates an omnidirectional pattern where an omnidirectionality of 5 dB is exhibited.

DOI 10.1007/978-981-4560-75-7_52-1

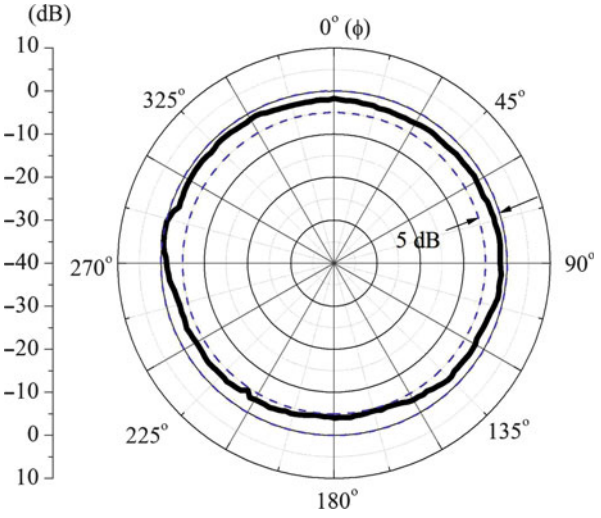

Fig. 4 The definition of the omnidirectionality

Configurations of Omnidirectional Antennas

Figure 5 shows the typical omnidirectional antenna configurations. The simplest way to realize omnidirectional radiation is to utilize a radiator with circularly symmetrically distributed current. A straight dipole is with such a current distribution and able to generate the omnidirectional radiation in the plane perpendicular to the radiator. An electrically small loop antenna exhibits similar performance wherein the current flows along the circular loop and produces omnidirectional radiation in the plane accordance with the loop.

Alternatively, the omnidirectional radiation can be realized by using multiple directional radiators. These directional radiating elements are normally positioned on the surface of a cylindrical structure or along a circle in a planar manner to generate a combined omnidirectional pattern (Knudsen 1956; Chu 1959; Jayakumar et al. 1986; Herscovici et al. 2001; Li et al. 2003; Wang et al. 2012). For multiple antenna element configurations, the positioning of the elements is the key factor for achieving a desired omnidirectional radiation pattern. In general, the omnidirectional antennas with one circularly symmetrical radiating element have better omnidirectionality than those with multiple radiating elements.

Design Considerations for Omnidirectional Antennas

The same as any other antennas, a desired omnidirectional antenna should be with specific radiating characteristics with size and cost constraints. Among the factors, the issues as following should be more important for an omnidirectional antenna design.

Polarization: The polarization is the first factor to be considered for omnidirectional antenna design, which is the starting point of the antenna configuration. A vertically positioned dipole is able to generate vertically polarized but horizontally polarized omnidirectional radiation, namely, a dipole can only produce the omnidirectional radiation pattern in *H*-planes instead of *E*-planes. To achieve horizontally polarized omnidirectional radiation, the electrically small loop antenna or multiple radiators have to be applied with proper arrangements. For dual linearly polarized or circularly polarized omnidirectional antenna, the configuration is more complicated so that orthogonal field components as well as phase delay should be considered.

Omnidirectionality: The omnidirectionality is somehow the most critical parameter for engineering applications. From a design point of view, a single radiator with circular symmetry is able to achieve desired omnidirectionality more easily than the multiple elements with combined omnidirectional radiation.

DOI 10.1007/978-981-4560-75-7_52-1

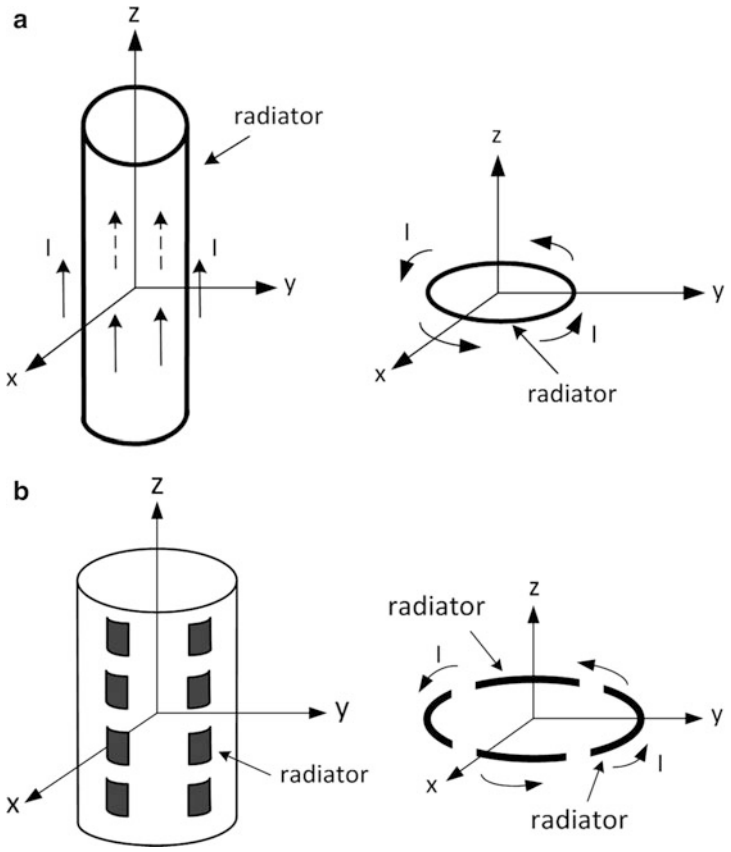

Fig. 5 Omnidirectional antenna configurations; (**a**) single radiator with circular symmetrical current distribution and (**b**) multiple radiators for omnidirectional radiation

Bandwidth: The bandwidth is another key factor for omnidirectional antennas, which can be extremely large for modern wireless systems for ultra-wideband or multiband operation. For example, an omnidirectional antenna for ultra-wideband radios is required to cover the frequency range of 3.1–10.6 GHz (109.5 %). The antenna for Long-Term Evolution (LTE) indoor access point is required to operate at a frequency band of 670 MHz to 2,690 MHz with a fractal bandwidth of 122.7 %. It is a big challenge to design such broadband antennas with constraints of omnidirectional radiation and polarization. Usually, a broadband vertically polarized omnidirectional antenna can be realized by enlarging the volume of a radiator. For a horizontally polarized omnidirectional antenna, the broadband operation can be achieved using specially configured radiator or multiple broadband elements such as tapered slots and log-period antennas.

Gain: Compared to a directional antenna, an omnidirectional antenna is normally with lower gain. To have omnidirectional antenna with higher gain, an antenna array is the most direct solution. For example, a dipole antenna exhibits gain of 2.15 dBi, while a 1×4 dipole antenna array is able to achieve gain of 6−7 dBi. In addition, using some specific configurations is able to achieve high gain as well; the omnidirectional antenna with a dual-shaped reflector exhibits the gain of more than 10 dBi.

Vertically Polarized Omnidirectional Antenna

This section discusses a variety of vertically polarized omnidirectional antennas. When the antenna is positioned to generate vertically polarized omnidirectional radiation in a horizontal plane, or *H*-plane, the vertically polarized omnidirectional antenna is also named as an *H*-plane omnidirectional antenna.

Dipole-Based Omnidirectional Antennas

Straight Dipole

Dipoles are one of the fundamental classes of antennas that are evolved through many years. In fact, Hertz employed a dipole antenna on his spark-gap generator during the historical experiment in 1888. Being one of the fundamental types of radiators, it generates omnidirectional radiation because of the inherent circular symmetrical structure. The analysis and design principle of the dipole antenna have been fully carried out (Kraus and Marhefka 2008) and are not repeated here. It is worth to note that the shorter dipole antenna (overall length of the dipole is less than one operating wavelength) is with a main lobe only and maximum radiation in the horizontal plane ($\theta = 90^\circ$), while a longer dipole (overall length of the dipole is larger than one operating wavelength) is with multiple beams, as shown in Fig. 6.

Coaxial Collinear Dipole Antenna (CoCo Antenna)

The coaxial collinear (CoCo) antenna, introduced by H. A. Wheeler (1956), is a kind of high-gain omnidirectional antennas (Balsley and Ecklund 1972; Judasz and Balsley 1989). It radiates as a collinear array of wire dipoles driven in phase and provides a narrow broadside beam and an omnidirectional pattern in the plane perpendicular to the antenna axis. It is used both as an isolated antenna element and in large arrays. For its simple structure and easy fabrication, it has been used over the past few decades mostly in radar and communication systems.

As illustrated in Fig. 7, the CoCo antenna consists of a sequence of collinear sections of a coaxial cable that are half-wave long (in terms of the guided wavelength, λ_g), where the inner conductor of one coaxial cable section is electrically connected to the outer conductor of the adjacent one. The intent is to have the excitation voltages across all the slots in phase and equal in magnitude, so that a strong in-phase current distribution can be driven on the outer surface of the coaxial cable to obtain a high gain in the broadside direction. Therefore, every coaxial cable section acts as not only a transmission line but also a radiator.

Besides the coaxial line configuration, a microstrip version of the collinear dipole antenna was introduced by R. Bancroft and B. Bateman (2004). The geometry of the antenna is shown in Fig. 8, it consists of two metallic strips on the opposite sides of a printed circuit board (PCB). The strip on the top layer starts with a wide trace of width (W_1) and follows a narrow trace (W_2); the strips are with the same length, L. The strips alternate between a narrow section and a wide section until a wide section terminates the antenna on the bottom of the PCB. The strip on the bottom layer begins with a narrow strip and alternates from narrow to wide for complementing the wide to narrow variation of the strip on the top layer. The first and last strips on the bottom are shorted to the center of the corresponding wide strips on the top layer. The width (W_2) of the narrow strip is chosen such that it forms a 50-Ω microstrip line with the wide strip on the opposite side viewed as a ground plane. The width of the wide strip sections (W_1) is approximately five times of the narrow strip. The length L of each section is selected to be approximately $\lambda_g/2$, which is determined by the operating frequency, the dielectric constant, and the thickness of the PCB. The four-section antenna design example at 2.4 GHz band exhibits a simulated maximum gain of 6.4 dBi (measured gain of 4.6 dBi), side lobe levels of 11 dB, and VSWR ≤ 2 over a frequency band of 15.5 %.

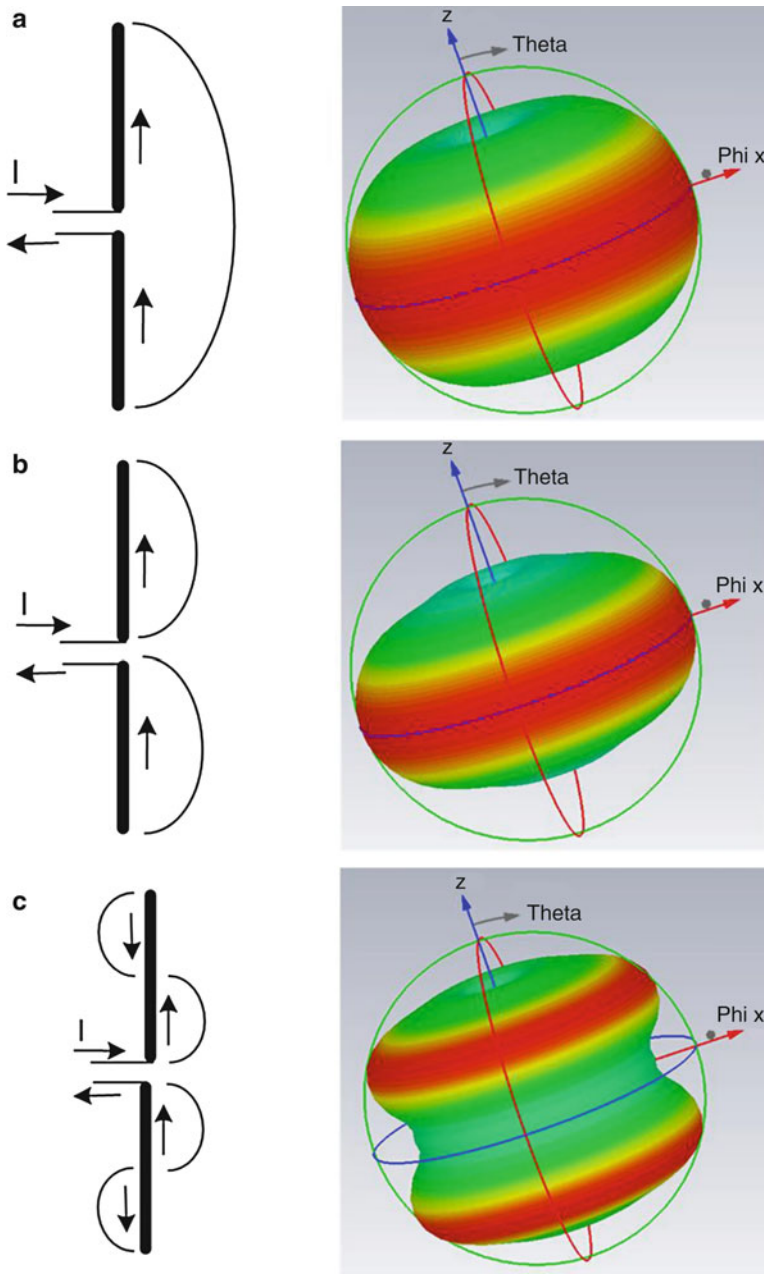

Fig. 6 Current distributions of the dipole antennas and three-dimensional radiation patterns; (**a**) half-wave dipole, (**b**) full-wave dipole, and (**c**) two-wave dipole

Biconical Antenna

Biconical antennas feature dipole-like characteristics, e.g., omnidirectional radiation in the *H*-plane, "eight figure"-shaped patterns in the *E*-plane, fixed phase center, and comparable gain, with an enormous wide bandwidth achieved by double cone elements. During the last decades, many biconical antennas have been developed with the frequency range from MHz to GHz and above with bandwidths of three or more octaves.

As shown in Fig. 9, a biconical antenna is formed by placing two metallic cones that extend opposite one another. It is typically hourglass shaped, as both the cones have a common axis. It can be thought to be a uniformly tapered transmission line (Barrow et al. 1939; Nagasawa and Matsuzuka 1988).

DOI 10.1007/978-981-4560-75-7_52-1

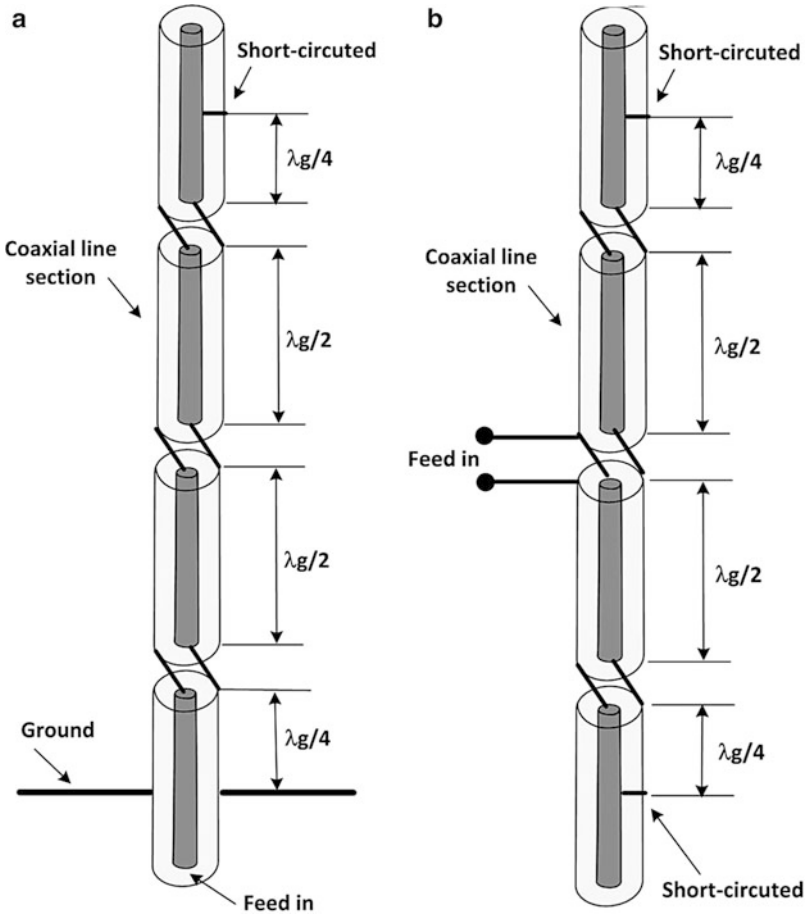

Fig. 7 Coaxial collinear dipole antennas: (**a**) bottom feed and (**b**) central feed

The input impedance of the infinite biconical antenna, Z_{in}, can be written as

$$Z_{in} = 120 \ln\left[\cot\left(\frac{\alpha}{4}\right)\right] \tag{4}$$

which is a pure resistance where α is a cone angle. For small cone angles α, Z_{in} can be expressed as

$$Z_{in} = \frac{\eta}{\pi} \ln\left[\cot\left(\frac{\alpha}{4}\right)\right] = \frac{\eta}{\pi} \ln\left[\frac{1}{\tan(\alpha/4)}\right] \cong \frac{\eta}{\pi} \ln\left[\frac{4}{\alpha}\right] \tag{5}$$

The input impedance of the biconical antenna is reasonably constant over a wide frequency range. The biconical antennas with small angles are not very practical (small α offers large Z_{in} so that the antenna may not matched with feed line easily), but wide-angle configurations ($30^\circ < \alpha/2 < 60^\circ$) are often used. Besides the cone angle, another key factor in practical antenna design is the spacing between the cones, in particular at higher frequencies. At microwave frequencies, it is a common practice to support the cones using a spacer; the property of the spacer may affect the impedance of the antenna as well. Fortunately, for practical antenna design, we do not need to calculate the impedance by all these formula; with aid of powerful electromagnetic simulation software, designers will optimize a reasonable cone angle for antennas.

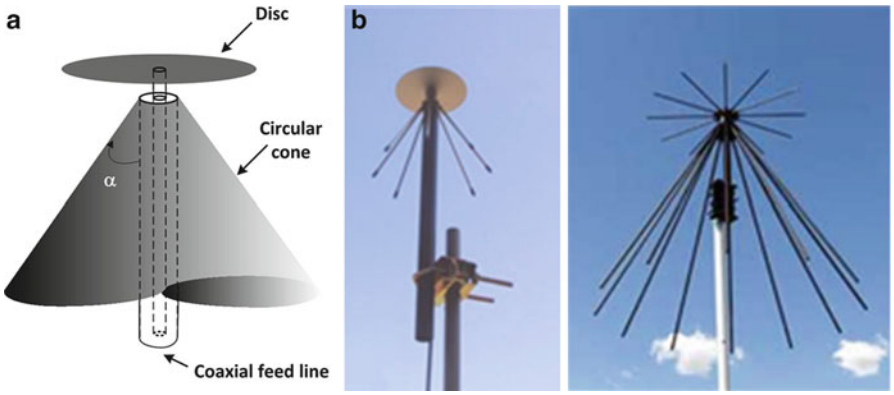

Fig. 11 Discone antenna; (**a**) antenna geometry and (**b**) practical discone antennas

The biconical antenna can be fed by a coaxial line directly or with a balun for bandwidth enhancement. Some practical biconical antennas are shown in Fig. 10; the cones can be formed by wires, the shape of the cone can be pyramid shaped, and the length of the cones can be different as well.

Discone Antenna

The discone antenna is a vertically polarized omnidirectional antenna with multi-octave bandwidth (Nagasawa and Matsuzuka 1988; Bergmann 2003; Kim et al. 2005; Qing et al. 2005; Chen et al. 2011). As illustrated in Fig. 11, a discone antenna is formed by a disk and a cone – that is where the name "discone" comes from – where the disk is on the top of the cone and perpendicular to the cone's axis. The discone antenna is easy to be fed by a coaxial line, the disk is attached to the inner conductor of the coaxial cable, and the cone is connected at its apex to the outer shield of the coaxial cable. The input impedance of the discone antenna is strongly dependent on the apex angle, as long as the cone is longer than about a quarter wavelength and the apex angle is relatively large. In general, the performance of discone antenna as a function of frequency is similar to a high-pass filter. Below a cutoff frequency, it becomes inefficient, and it produces severe standing waves in the feed line. At cutoff frequency, the slant height of the cone is approximately one quarter wavelength.

A discone antenna for ultra-wideband (UWB) applications is shown in Fig. 12 (Qing et al. 2005), and the performance of the antenna is exhibited in Fig. 13. The $|S_{11}|$ of less than -10 dB and gain of about 2 dBi (at $\theta = 90°$, $\phi = 0°$) are achieved over the frequency range of 3.0–11.0 GHz. The measured radiation patterns are shown in Fig. 13c; good omnidirectional patterns are observed in the *x*-*y* plane with the omnidirectionality of 3 dB.

DOI 10.1007/978-981-4560-75-7_52-1

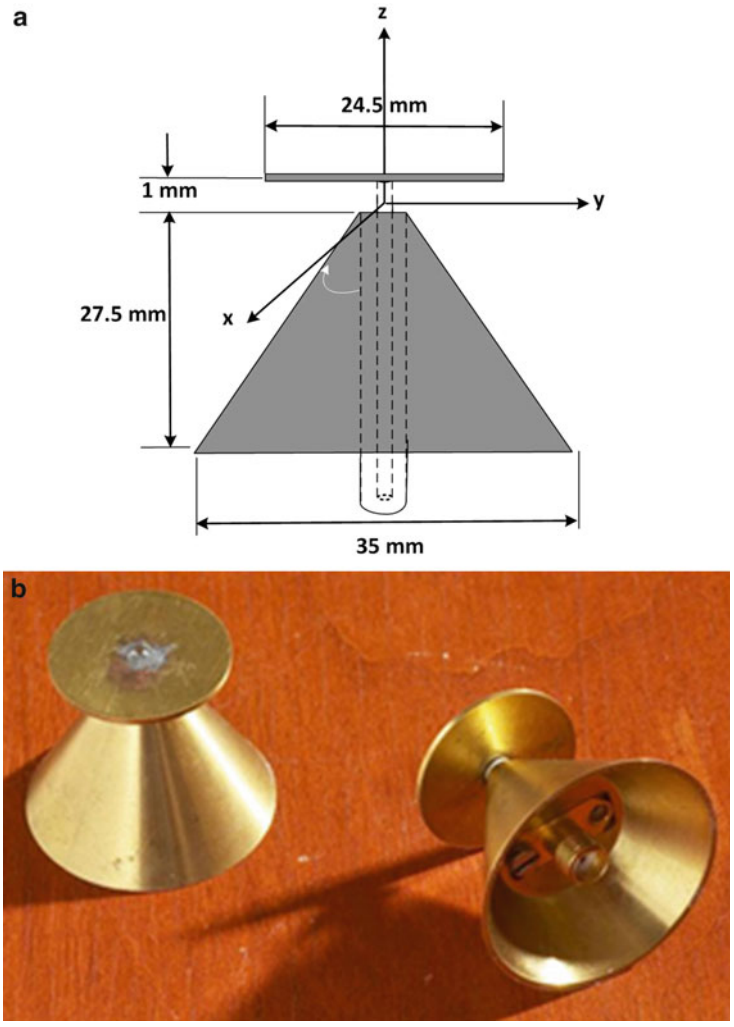

Fig. 12 Discone antenna for UWB applications; (**a**) detailed dimensions of the antenna and (**b**) antenna prototypes

Monopole-Based Omnidirectional Antenna

A conventional monopole antenna consists of a straight rod-shaped conductor, almost always mounted perpendicularly above some sort of ground planes. The monopole antenna was invented in 1895 by Guglielmo Marconi, who discovered if he attached one terminal of his transmitter to a long wire suspended in the air and the other to the Earth, he could transmit radio waves for longer distances. For this reason, it is sometimes called a *Marconi antenna*, although Alexander Popov independently invented it at nearly the same time.

As shown in Fig. 14, a monopole antenna can be visualized as being formed by replacing the bottom half of a vertical dipole antenna with a ground plane at right angle to the remaining half. From image theory, it is known that the radiation pattern of a monopole antenna with a perfectly conducting, infinite ground plane is identical to the top half of the pattern of a dipole with double length. Monopole antennas up to quarter wavelength long have a single "lobe," with field strength declining monotonically from a maximum in the horizontal direction, but longer monopoles have more complicated patterns with several conical "lobes" (radiation maxima) directed at angles into the sky. Because it radiates only into the space above the ground plane, or half the space of a dipole antenna, a monopole antenna will have a directivity of twice (3 dB over) the directivity of a full dipole antenna. In addition, the input impedance of the monopole antenna is one half of that of a full dipole antenna. For example, for a quarter-wave monopole

DOI 10.1007/978-981-4560-75-7_52-1

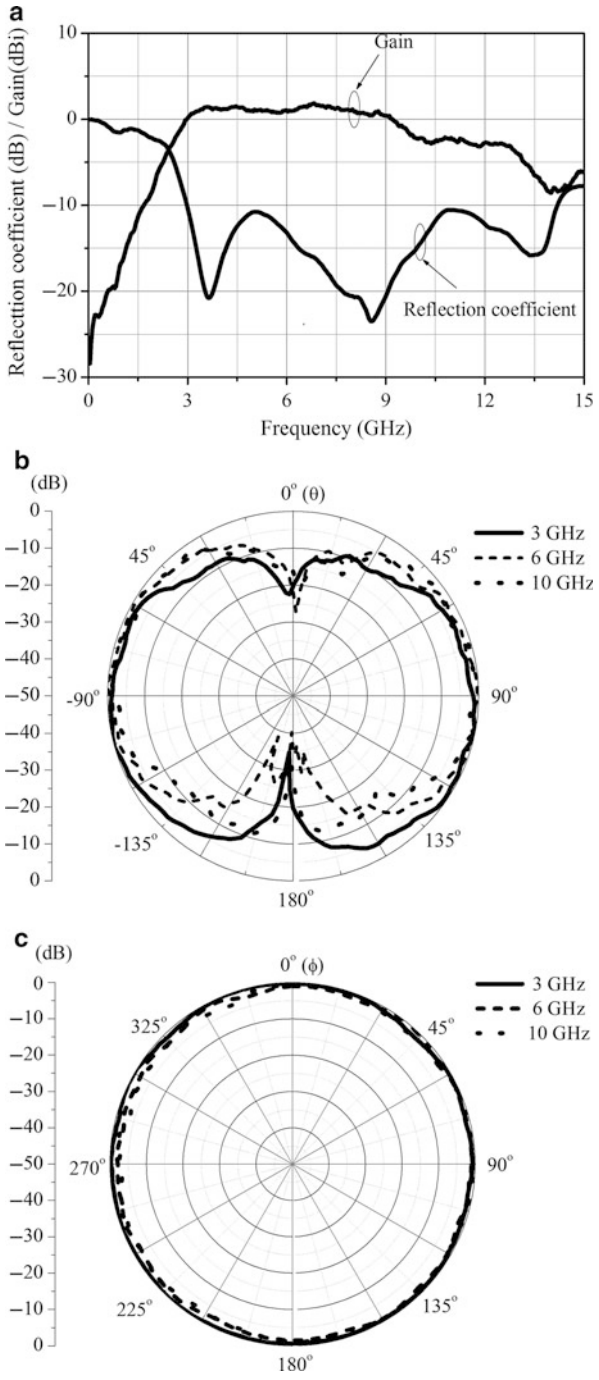

Fig. 13 Measured results of the UWB discone antenna; (**a**) reflection coefficient and gain, (**b**) normalized radiation pattern in the *x-z* plane, and (**c**) normalized radiation pattern in the *x-y* plane

antenna ($L = 0.25\lambda$) with an ideal infinite ground plane, its directivity will be 5.15 dBi and input impedance $Z_{in} = 36.5 + j21.25$ Ohms.

The ground plane used with a monopole may be the actual earth; in this case, the antenna is mounted on the ground, and one side of the feed line is connected to an earth ground at the base of the antenna. Such a design is used for the mast radiator antennas employed in radio broadcasting at low frequencies. At VHF and UHF frequencies, the physical size of the ground plane needed is smaller, so metallic plane is used to

DOI 10.1007/978-981-4560-75-7_52-1

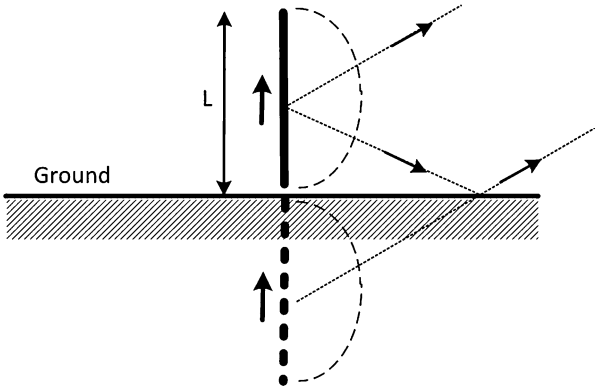

Fig. 14 Monopole analysis using image theory

allow the antenna to be mounted above it; the examples of such surfaces are the roof of a car or airplane body.

The general effect of the electrically small ground plane as well as imperfectly conducting earth ground on the performance of the monopole antenna is to tilt the direction of maximum radiation up to higher elevation angles. Figure 15 compares the radiation patterns of a quarter-wave monopole with different ground sizes.

Three-Dimensional Monopole Antennas

Unlike a dipole antenna, the monopole antenna is an unbalanced antenna so that it is very convenient to be fed using a coaxial cable. As shown in Fig. 16, the inner conductor of the coaxial connector such as subminiature version A (SMA) is connected to the lower end of the monopole and the other conductor of the SMA attached to the ground plane. Besides the basic rod shape, the radiator of the monopole antenna can be with different configurations, for example, conical cone, tapered cone, cross plate, parallel plate, and rolled plate. The radiator with larger volume exhibits the broader bandwidth over the rod-shaped one, wherein the tapered structure will provide better impedance matching (Taniguchi and Kobayashi 2002; Wong et al. 2005; Wong and Su 2005; Chen 2005). Note that all the configurations are able to offer broadband impedance matching, while only those antennas with circular symmetrical radiator can generate the desired omnidirectional radiation.

Printed Planar Monopole Antennas

A number of printed omnidirectional antennas have been reported, wherein the planar monopole and the ground are etched on a PCB. As exhibited in Fig. 17, such an antenna is composed of a radiator and a small ground plane and fed by a microstrip line or a coplanar waveguide (CPW). For microstrip-fed antenna, the radiator and the microstrip feed line are positioned on one side of the PCB while the ground plane is on the other side. For CPW-fed configuration, both the radiator and the CPW are on the same side of the PCB. The antennas are able to provide broad impedance and gain bandwidth while desired omnidirectional radiation, in particular, at high frequencies, wherein a bidirectional instead of an omnidirectional pattern is achieved. Changing the shape of the radiator is helpful to adjust the bandwidth of the antenna and realize some specific characteristic such as band-notch performance.

Slot Array Antenna

The vertically polarized omnidirectional radiation can be achieved by cutting transverse slot on the circular waveguide or coaxial line. Normally, a slot array instead of a single slot is applied for higher gain, where the slot elements are positioned with a spacing of guided wavelength (λ_g) to achieve the in-phase

DOI 10.1007/978-981-4560-75-7_52-1

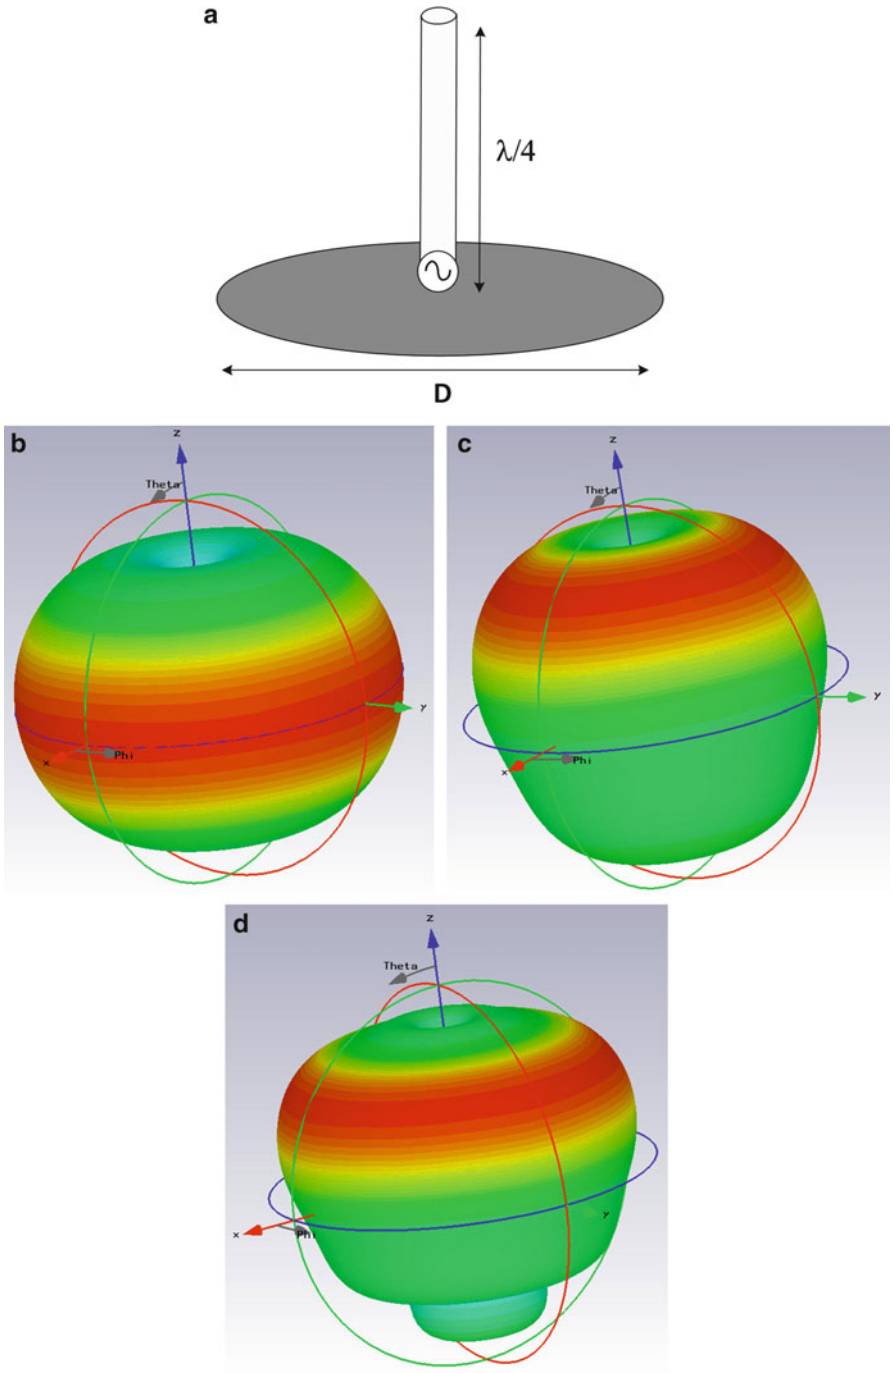

Fig. 15 Radiation patterns of a quarter-wave monopole with different sizes of ground planes; (**a**) antenna configuration, (**b**) $D = 0.25\lambda$, (**c**) $D = 1\lambda$, and (**d**) $D = 2\lambda$

excitation. A circular waveguide carrying the TM_{01} mode is suitable for implementing the slot array for omnidirectional radiation because of the circular symmetrical current distribution along the wall of the waveguide. One point to be noted is that the λ_g of a hollow circular waveguide carrying TM_{01} mode is larger than the free space wavelength (λ_0); the slot antenna array will have grating lobes. To avoid the grating lobes, λ_g should be less than λ_0. Filling dielectric into the hollow circular waveguide or utilization of the slow wave structure is suggested.

DOI 10.1007/978-981-4560-75-7_52-1

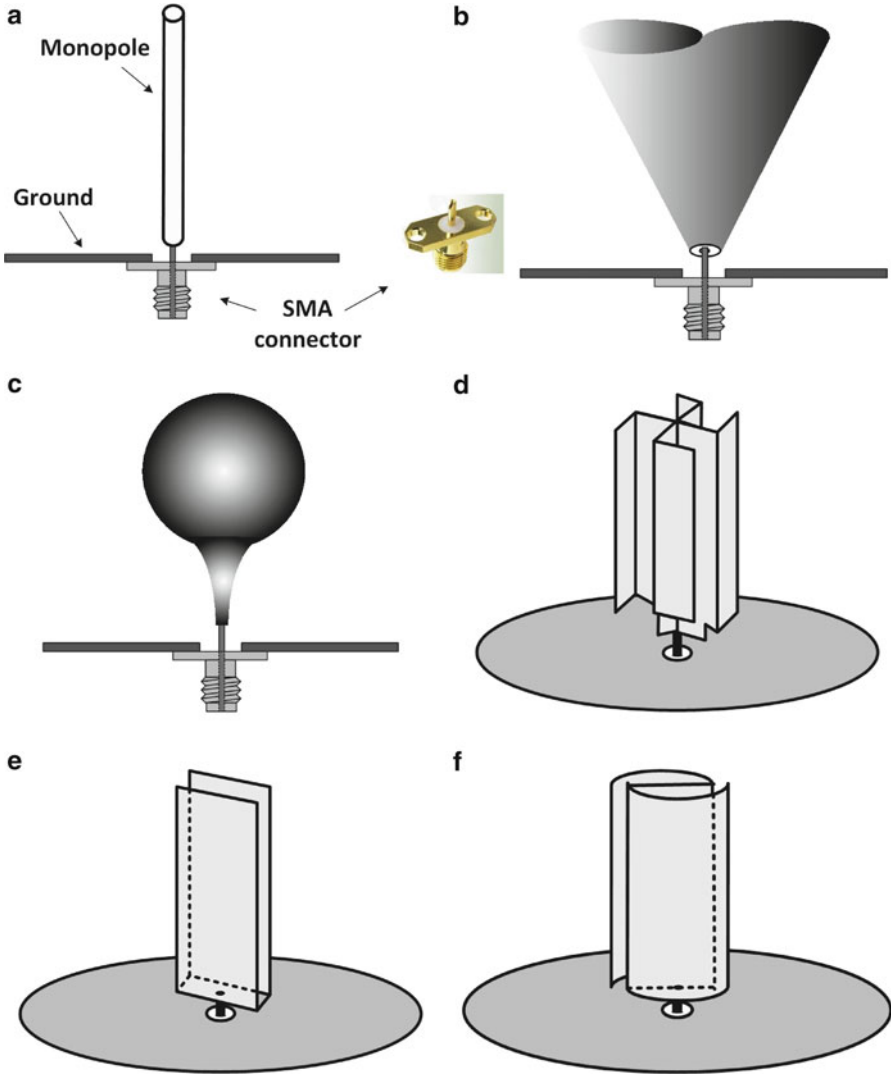

Fig. 16 Coaxial line fed monopole antenna and different three-dimensional radiator configurations; (**a**) rod-shape, (**b**) cone-shape, (**c**) taper-shape, (**d**) crossed plates, (**e**) parallel plates, and (**f**) rolled plates

Coaxial line is also suitable for omnidirectional slot array implementation. Baumer and Landstorfer (1990) demonstrated a slot array antenna as shown in Fig. 18. A slow wave structure is used as the inner conductor of the coaxial line; the diameter of the outer conductor is about a quarter of the free space wavelength at the center frequency. For implementation convenience, the nonresonant transverse slots are a little bit less than 360°. The eight-element slot array antenna is able to achieve desired omnidirectional radiation patterns in azimuth planes with the measured directivity of 10 dBi.

Chen et al. proposed a planar omnidirectional slot array antenna as shown in Fig. 19 (Chen et al. 2011). The antenna consists of a central conductor and two metal ground planes. The central conductor is embedded in a PCB and sandwiched in between two parallel ground planes to form a strip line, and one end of the central conductor is connected to the feeding coaxial cable and the other end open. A series of rectangular loop slots are etched on the top and bottom metal grounds. It is found that a nonuniform array with uneven loop slots having unequal distances between them is able to provide greater flexibility in antenna design and might achieve better performance compared to one with equal spaced slots with uniform size. The antenna is easily implemented using low-cost and precise planar printed technique. An antenna with eight back-to-back slots exhibits impedance bandwidth of 4.6 % ($|S_{11}| < -10$ dB) with

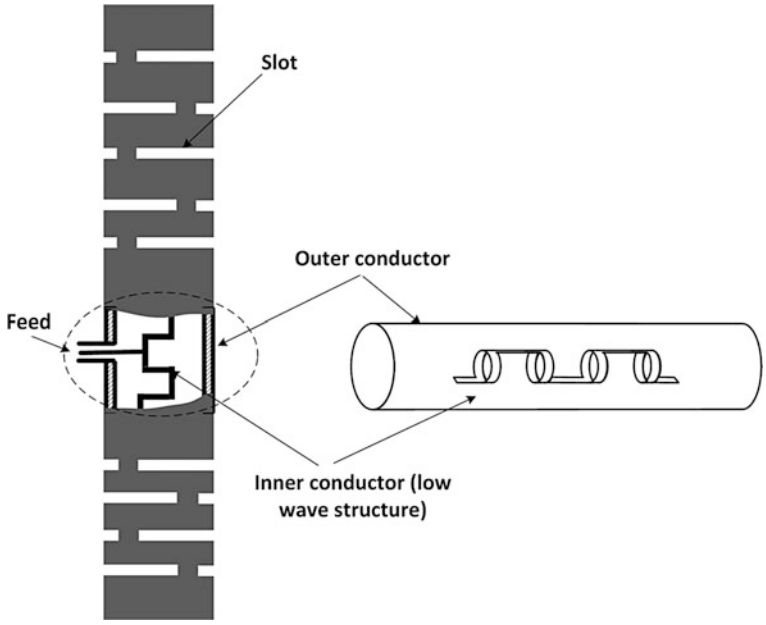

Fig. 18 Slot antenna array on coaxial line for vertically polarized omnidirectional radiation

center frequency of 5.8 GHz; it has a well-formed omnidirectional pattern with omnidirectionality of 0.5 dB in the horizontal plane, a gain of 10 dBi, side lobe levels of 10 dB below the main lobe, and no beam squint.

Dual-Reflector Omnidirectional Antenna

The coming generation of communication systems is expected to provide services through high-data-rate wireless channels. They will operate at millimeter-wave band up to 60 GHz, which requests the antenna offering the absolute operating frequency bandwidth of several gigahertz. The conventional rod-shaped dipole antenna and monopole antenna usually suffer from narrow operating bandwidth. The biconical

DOI 10.1007/978-981-4560-75-7_52-1

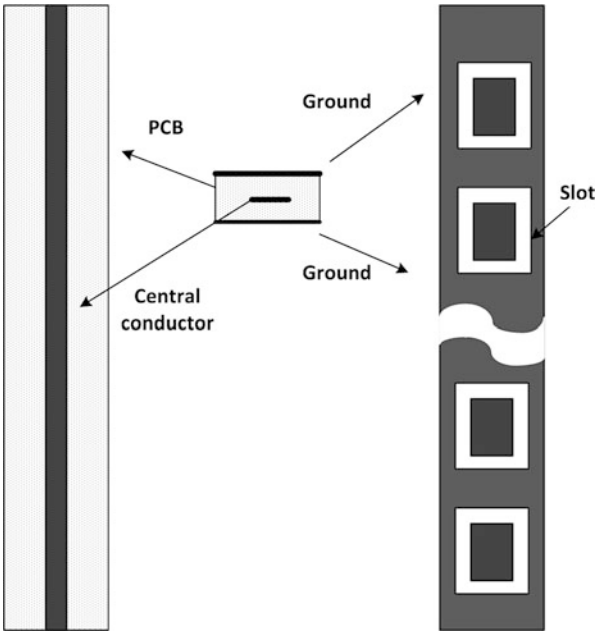

Fig. 19 Slot antenna array on strip line for vertically polarized omnidirectional radiation

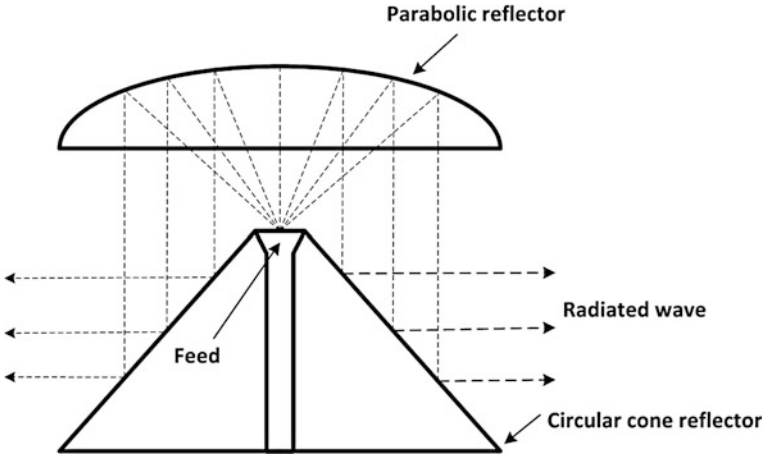

Fig. 20 Schematic diagram of dual-reflector omnidirectional antenna

antenna and discone antenna can offer broader operating bandwidths but lower gain and difficult implementation at millimeter frequencies.

The dual-reflector antenna (Willoughby and Heider 1959; Orefice and Pirinoli 1993) is a desired candidate for vertically polarized omnidirectional coverage at higher frequencies up to millimeter-wave bands. As shown in Fig. 20, an omnidirectional dual-reflector antenna is composed of two circularly symmetric reflectors with a common symmetry axis and fed by coaxial horn. The feed is located in the focus of the sub-reflector, a paraboloid. The field is firstly reflected by the paraboloid and then directed towards the main conical reflector; the plane wave is therefore eventually reflected in all the directions of the horizontal plane. The conical reflector can be shaped in order to point the maximum radiation to a specific elevation angle.

DOI 10.1007/978-981-4560-75-7_52-1

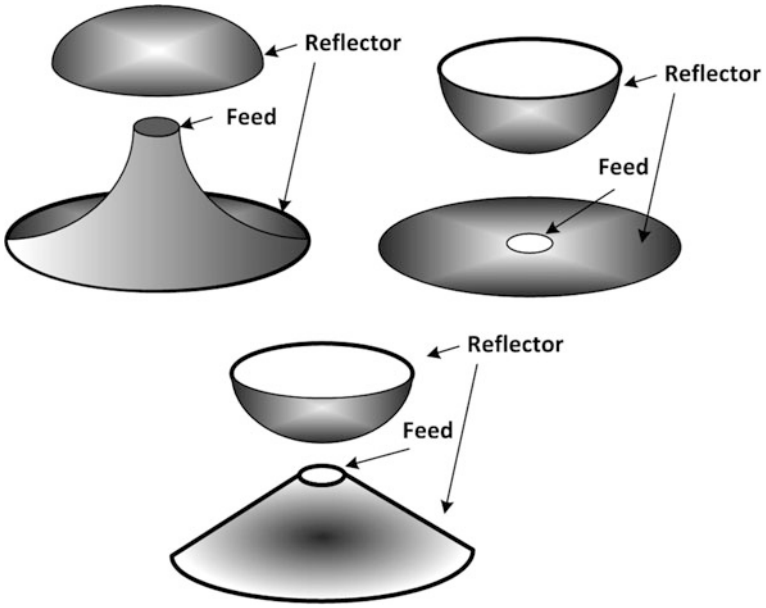

Fig. 21 Variations of the shape of the reflectors

A key feature of the antenna is the use of an unconventional feed for obtaining the vertical polarization. The feed is requested to radiate a field with only a θ-directed component and a null on the axis. A pure radial-mode aperture such as a coaxial horn or a TM_{01} excited conical horn is suitable for the antenna feed.

The configuration of the reflectors can be with different shapes as illustrated in Fig. 21, where the azimuth omnidirectional radiation is kept unchanged while the shape of the *E*-elevation radiation pattern as well as the title angle of the maximum radiation can be controlled by the profile of the reflectors (Pino et al. 2000; Bergmann and Moreira 2004; Silva and Bergmann 2005; Zang and Bergmann 2013).

Low-Profile Omnidirectional Antenna

A conventional monopole antenna with a quarter wavelength height is undesirable for today's wireless systems such as LTE and TV white space radios, where the operating frequency starts from a few hundred megahertz. Meanwhile, a low-profile antenna is always preferable, in particular, for indoor systems. The vertical height of a monopole antenna can also be reduced through antenna loading techniques using dielectric, inductive loading, and capacitive loading (Delaveaud et al. 1998; Foltz et al. 1998; Mclean et al. 1999; Liu et al. 2004; Heydari et al. 2009). Apart from the miniaturized monopole-type antennas, the other low-profile vertically polarized antennas with monopole-like omnidirectional radiation patterns include Goubau antenna (Goubau et al. 1982), a multielement antenna consisting of four electrically small vertical conductors, each one terminated in a conductive plate; quadripod kettle antenna (QKA) (Tokumaru 1976), comprising of multiple metallic plates; the spiral-mode microstrip (SMM) antenna (Wang et al. 2011), a traveling wave-based broadband antenna; and so on. These antennas are with a small antenna height of a twentieth operating wavelength.

Multielement Low-Profile Omnidirectional Antenna

A multi-plate omnidirectional antenna, namely, quadripod kettle antenna (QKA) as shown in Fig. 22, was presented by Shinobu Tokumaru in 1976 (Tokumaru 1976). The QKA is a self-standing purely multi-plate metallic structure that consists of a ground plane, a fed lower plate, and an upper plate. The lower metallic plate, in the form of cross with a central small square or circular patch, is fed by a probe at the center and shorted to the ground at the ends. The upper plate in the shape of a square or octagon/circle is connected to

DOI 10.1007/978-981-4560-75-7_52-1

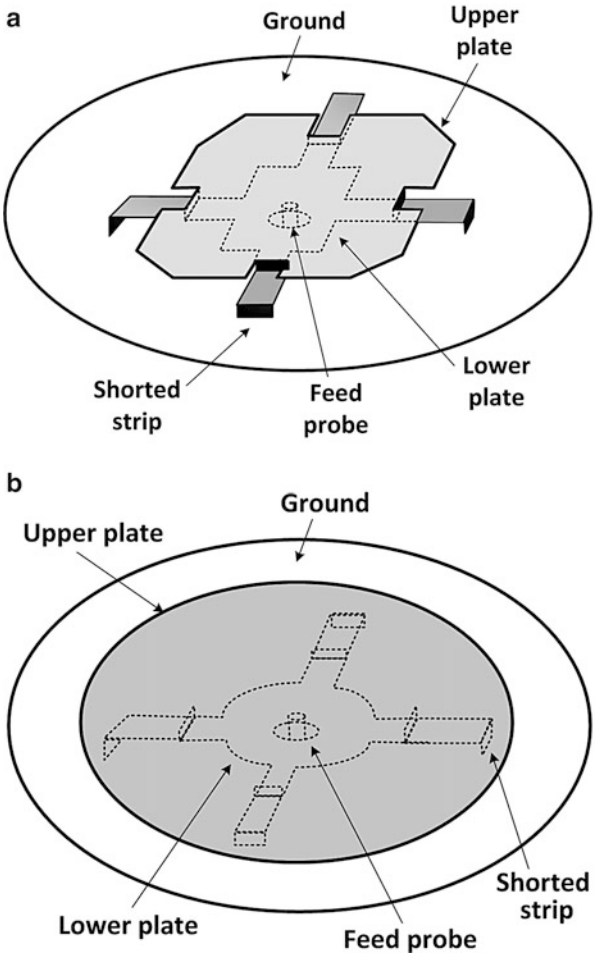

Fig. 22 Schematic diagram of quadripod kettle antenna (*QKA*), (**a**) octagon structure and (**b**) circular structure

the lower plate by means of another four pods at the edge. The antenna can be fed by a coaxial cable conveniently by connecting the external conductor of the coaxial cable to the ground plane and extending the inner conductor of the coaxial cable to the lower plate. The length of cross arms of the lower plate determines the lowest operating frequency, while the shape of the upper plate determines the impedance matching characteristic over the bandwidth. The QKA is an axially symmetrical antenna which is able to generate vertically polarized radiation similar to a monopole antenna with antenna height of less than 0.05 wavelength and bandwidth of more than 50 %.

Besides the quadripod configuration, the multi-plate antenna can be configured with tripod, hexapod, or octopod. Zurcher proposed a tripod kettle antenna (TKA) (Zurcher 2013), as shown in Fig. 23. The antenna designed at center frequency of 7.5 GHz exhibits an impedance bandwidth of 94 % ($|S_{11}| < -10$ dB) with an antenna height of 5.9 mm (0.079λ at lower edge frequency).

Another multielement low-profile vertically polarized omnidirectional antenna is shown in Fig. 24. The antenna features less than λ/20 in height and λ/5 or smaller in lateral dimension. Similar to the QTA antenna, the antenna is composed of a ground plane, a lower metallic structure with four ground ends and an upper metallic structure. Different from the QTA, the metallic plates are replaced by strips, and the upper plate is center fed by the probe together with the lower strips. Furthermore, the upper strips are open ended. The lateral dimension of the antenna is able to be miniaturized by meandering and turning the strips into form of a multi-arm spiral. The antenna is able to be matched to a 50-Ω coaxial line without the

DOI 10.1007/978-981-4560-75-7_52-1

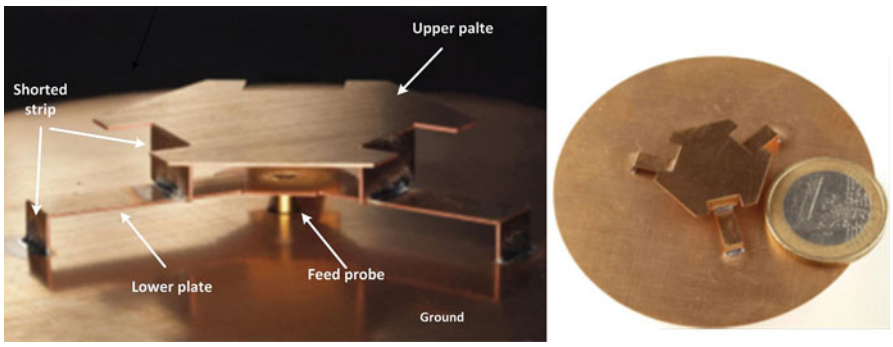

Fig. 23 Tripod kettle antenna

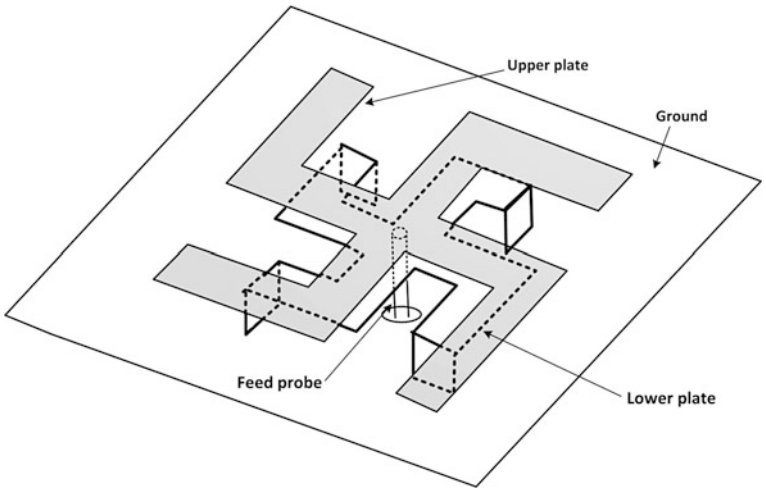

Fig. 24 Schematic diagram of miniaturized multielement monopole antennas (Hong and Sarabandi 2009)

need for external matching. The meandering between the short-circuited end and the feed point also facilitates the impedance matching.

Metamaterial-Based Low-Profile Omnidirectional Antenna

The artificial metamaterial structures can also be applied for omnidirectional antenna design. A low-profile omnidirectional zeroth-order resonator (ZOR) antenna using mushroom structures is exhibited in Fig. 25. The mushroom structure as a transmission line has negative, zero, and positive propagation constant depending on its operation frequency. Zeroth-order resonance, of which length is independent of the physical length, is naturally presented. In particular, mushroom ZOR antenna generates a uniform vertical electric field against a ground plane. The vertical electric field of mushroom ZOR is similar to that of short monopole antenna on a flat metal ground plane, so that it is able to generate the vertically polarized omnidirectional radiation in a horizontal plane. The resonant frequency of the mushroom ZOR and the number of unit cell can be determined from its dispersion curve.

Lee (Lee and Lee 2007) demonstrated an omnidirectional ZOR antenna at 7.8 GHz. The antenna is designed on a 1.57-mm thick RT/duroid 5880 PCB with dielectric constant of 2.2. The 3×2 mushroom array is with a unit cell size of 4.8×4.8 mm (patch), gap of 0.2 mm, and diameter of via of 0.3 mm. The low-profile antenna with a height of 0.04λ achieves the gain of 3.1 dBi and reflection coefficient of -15 dB at 7.8 GHz. Desired omnidirectional radiation pattern is achieved with the omnidirectionality of 2 dB.

DOI 10.1007/978-981-4560-75-7_52-1

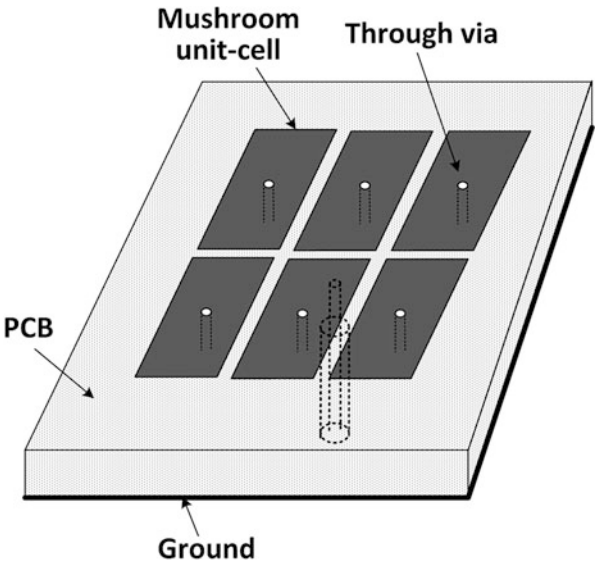

Fig. 25 ZOR antenna with coaxial probe feed

Horizontally Polarized Omnidirectional Antenna

In urban or indoor wireless environments, the polarization of propagating radio waves may change significantly because of the complicated multiple reflections or scatterings. Although vertically polarized antennas are used in many current wireless systems, it has been reported that using horizontally polarized antennas with both the transmitter and receiver can achieve a 10-dB improvement in terms of system gain as compared to vertically polarized antennas at both the ends of the link (Chizhik et al. 1998). In a third-generation (3G) network, the horizontally polarized omnidirectional antennas are often used together with vertically polarized omnidirectional antennas to form a multiple-input–multiple-output (MIMO) antenna system that provides polarization diversity in substitution for space diversity. Polarization diversity can be used to improve the reliability of a communication link, where the orthogonal polarization allows the frequency to be reused and isolation to be increased between the independent local area networks.

In contrast to the vertically polarized omnidirectional antenna which radiates equally in the plane aligning the *H*-field, the design of horizontally polarized omnidirectional antenna is more challenging since it is required to radiate equally in the plane aligning the *E*-field. The key consideration of such an antenna design is to form a structure with uniform and in-phase current distribution along a circle in the azimuth plane, either by using single loop or multielement configurations.

Loop-Based Omnidirectional Antenna

Electrically Small Loop Antenna

An electrically small solid-line loop is able to generate horizontally polarized omnidirectional radiation because of the current flowing along it features single direction and uniform distribution. However, such electrically small solid-line loop antenna has a very small radiation resistance and a large reactance, which makes the antenna very difficult to match with the excitation source. A solid-line loop antenna with perimeter comparable to one wavelength has a reasonable radiation resistance and reactance for impedance matching, while there is no longer omnidirectional radiation since the current flowing along the loop features phase inversion. In general, the small loop antenna having a circumference of less than a tenth wavelength is with uniform and in-phase current distribution. Figure 26 exhibits the radiation patterns of

DOI 10.1007/978-981-4560-75-7_52-1

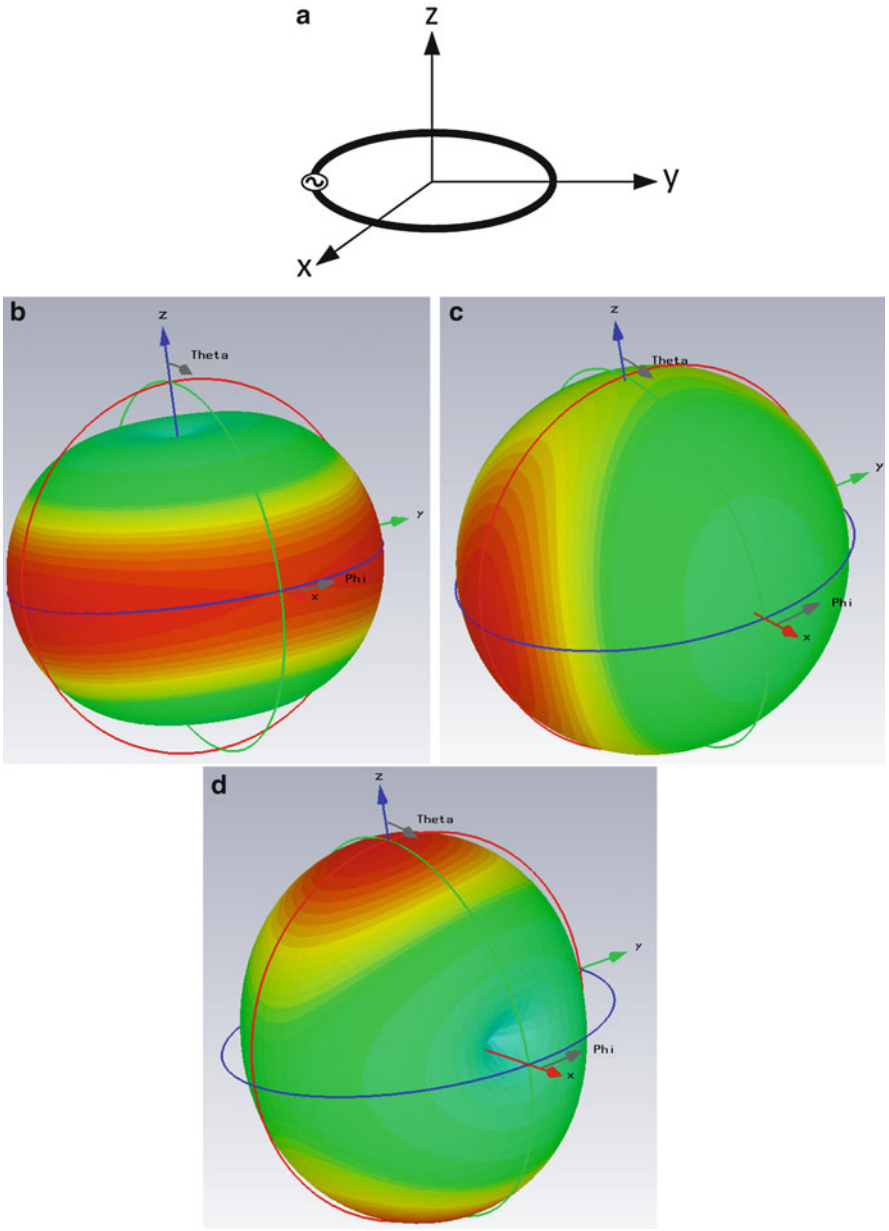

Fig. 26 Three-dimensional radiation patterns of the loop antenna with different circumference, (**a**) loop antenna with coordinate, (**b**–**d**) pattern with circumference of 0.1λ, 0.5λ, and 1λ, respectively

the loop antenna with different circumferences. It is observed that the loop antenna is able to achieve desired omnidirectional radiation when the circumference of the loop is less than 0.1λ. The loop antenna exhibits a bidirectional radiation when its circumference becomes electrically larger.

Alford Loop Antenna

The Alford loop antenna was presented by Alford and Kandoian in 1940 (Alford and Kandoian 1940). As exhibited in Fig. 27, it is composed of two Z-shaped metallic wires/strips, which are crossly positioned to form a square outline. The antenna is fed at the central portion of (K, K'); due to the symmetric structure, the current flowing on the wire sections AB and CD will have the same magnitude but opposite direction, which is the same as wire sections BC and AD. Furthermore, since the wire sections BB', DD', and AC

DOI 10.1007/978-981-4560-75-7_52-1

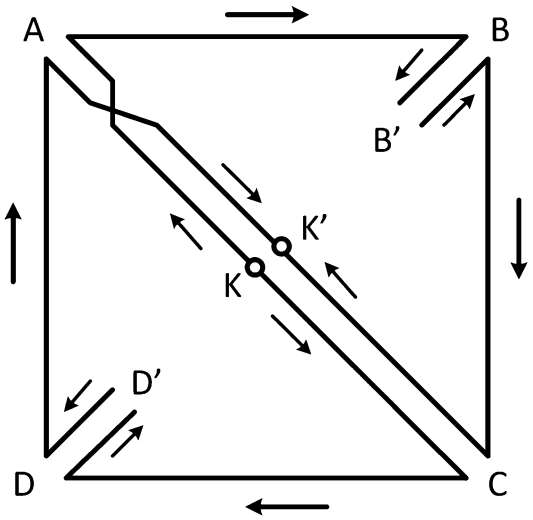

Fig. 27 Alford loop

are positioned very close to each other, the radiation from the opposite-directed current flowing along these sections cancel out each other. Therefore, the currents along the outline of the Alford loop form a square "loop"-type current distribution and achieve horizontally polarized omnidirectional radiation. In practical design, a circular instead of a square loop configuration is applied for better omnidirectional radiation performance. The circumference of the outline can be about one wavelength so that it is suitable for applications up to gigahertz with convenient implementation. A number of variations have been reported for different applications; some design examples are discussed in the following sections.

Printed Alford Loop Antenna

A printed Alford loop antenna as shown in Fig. 28a (Lin et al. 2006) was proposed for the integration with an external interface card, such as the personal computer memory card international association (PCMCIA) card and WLAN card for a laptop PC. The antenna consists of two Z-shaped strips printed on the top and bottom sides of a PCB. The bottom strip is arranged in such a manner that the "arm" is mapped to that of the top strip through the PCB substrate. A coaxial connector is used to connect the central feed point of the top and bottom strips. The "wing" length of the Alford loop is of the order of a quarter wavelength. Due to structure symmetry, the antenna current distribution on the two strips will have the same magnitude but opposite flowing directions. Since the thickness of the PCB substrate is very small, the radiation of the antenna current along the "arm" will cancel out each other. The antenna currents on the two "wings" of each Z-shaped strip establish a square "loop"-type current distribution and generate horizontally polarized omnidirectional radiation.

A windmill-shaped loop antenna (Kim et al. 2007) is exhibited in Fig. 28b. The antenna consists of two crossed Z-shaped strip lines etched on the opposite sides of a PCB. Each strip line has four arms with arc-shaped outer section which is of about one eighth wavelength. The arc-shaped outer sections on the upper side of the PCB are the mirror images of those on the bottom sides of the PCB or vice versa. Such an arrangement configures a combined loop antenna which consists of eight arc-shaped sections with a circumference of one wavelength. Feeding from the center of the antenna, the currents flowing on cross-shaped parallel strips are with opposite directions, while the currents flowing along the combined loop are with the same magnitude and single direction. Therefore, omnidirectional radiation is generated in the *E*-plane (*x*-*y* plane). An antenna using RT/duroid 5880 PCB with the dielectric constant of 2.2 mm and

DOI 10.1007/978-981-4560-75-7_52-1

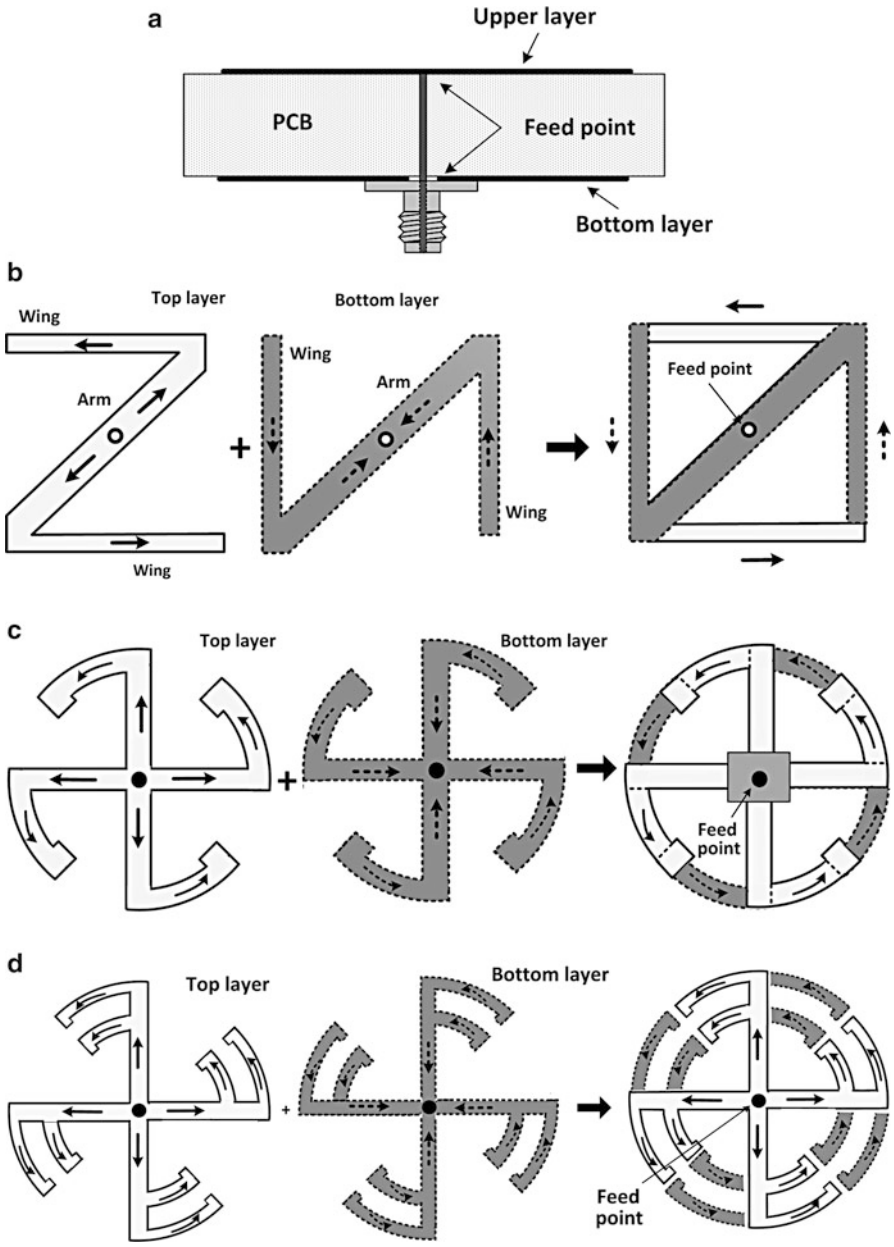

Fig. 28 Printed Alford loops, (**a**) PCB configuration, (**b**) square-shaped loop, (**c**) windmill-shaped loop, and (**d**) dual-band windmill-shaped loop

height of 1.6 mm operates at 2.6 GHz and achieves an impedance bandwidth of 6 % ($|S_{11}| < -10$ dB) and antenna gain of 1.5 dBi.

A dual-band windmill-shaped Alford loop antenna (Ahn et al. 2009) can be configured by adding one more set arc-shaped strips, as shown in Fig. 28d. The antenna is composed of two combined loops with different diameters, which resonant at different frequencies. The dual-frequency operation is achieved without any extra matching circuits or parasitic components. An antenna design has been exemplified at dual bands with the center frequencies of 2.45 and 3.9 GHz, respectively.

DOI 10.1007/978-981-4560-75-7_52-1

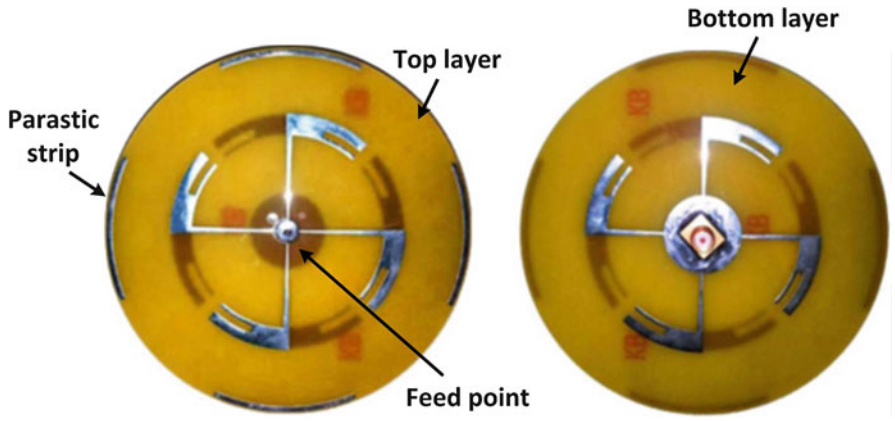

Fig. 29 Wideband Alford loop antenna for 4G LTE applications

Broadband Alford Loop Antenna

The traditional wire-type Alford loop antenna or printed strip-type Alford loop antenna is with limited bandwidth of less than 10 %, which is unable to meet the 4G LTE system requirements of high data throughput and long link range, where a peak speed of 100 Mb/s for high-mobility communication and 1 Gb/s for low-mobility communication is required.

Figure 29 shows a broadband Alford loop antenna (Yu et al. 2013). Similar to a conventional printed Alford loop antenna, the multiple arc-shaped strips on the opposite sides of a PCB are used to form the combined loop for horizontally polarized omnidirectional radiation. For bandwidth enhancement, tapered strip lines, parasitic strips, and a balun are applied.

The antenna consists of two pairs of arc-shaped radiators and a circular patch on the top and bottom sides of a PCB, respectively, as well as four parasitical strips on the top side. The four arc-shaped strips on the top layer are connected to a small circular conducting patch located at the center through four tapered strip lines, respectively. The end of the arc-shaped strip is notched to create two resonances that are close to each other. Four parasitical stripes are also printed on the top layer of the substrate to suppress the reactance of the antenna for bandwidth enhancement. The arrangement of the radiators on the bottom layer is similar to those on the top side, while the arc-shaped strips are positioned in a counter clockwise manner and connected to a larger circular conducting patch located at the center. The circular patches along with the tapered feeding lines constitute a balun for the coax feeding to the antenna. When excited, the quasi-TEM waves between two circular patches are guided to four pairs of arc-shaped radiators through the tapered strip lines. Due to the opposite-directed currents flowing on the straight strips on the opposite sides, the currents on the arc-shaped strips flow synchronously in clockwise or counterclockwise and form a circular combined loop and generate omnidirectional radiation. A practical antenna is able to operate from 1.76 to 2.68 GHz with a return loss greater than or equal to 10 dB, peak gain of 3.6–4.2 dBi, an average radiation efficiency of 83 %, and very good omnidirectional radiation pattern in *E*-plane over the entire impedance bandwidth.

Metamaterial-Based Zero-Phase-Shift Line Loop Antenna

The metamaterial-based zero-phase-shift line loop antennas have been attracted more attention recently for horizontally polarized omnidirectional antenna design. A transmission line with zero-phase-shift is ideal to configure an electrically large loop antenna for horizontally polarized omnidirectional since a uniform current distribution without phase inversion can be easily achieved. Two types of metamaterial-based transmission line, namely, the composite right-/left-handed transmission line (CRLH-TL)

DOI 10.1007/978-981-4560-75-7_52-1

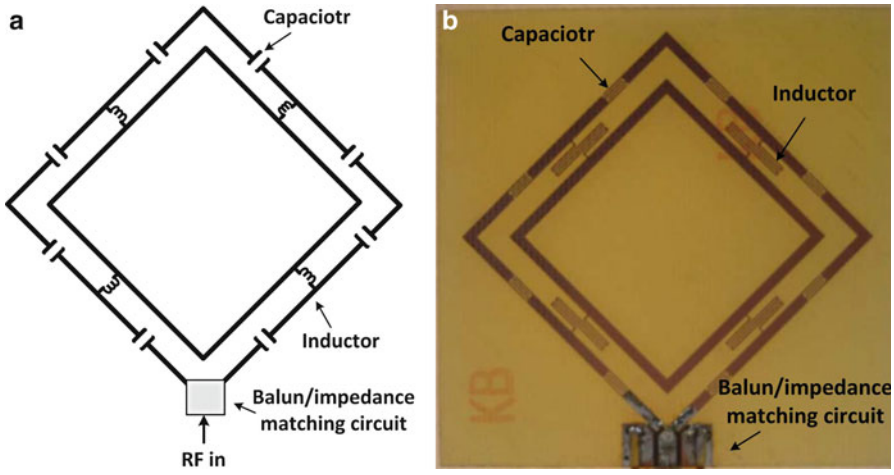

Fig. 30 CRLH line loop antennas, (**a**) antenna design with lumped components and (**b**) printed version

[16]–[18] and mu-negative transmission line (MNG-TL), have been utilized for designing the loop-type antennas for omnidirectional radiation in *E*-plane.

CRLH Line Loop Antenna

CRLH lines have been widely used for improving the performance of microwave devices (Sanada et al. 2003; Caloz et al. 2004) and leak wave antenna (Liu et al. 2002). These metamaterial-based transmission lines are characterized by the existence of three different spectral regions: the left-handed region at lower frequencies supporting a backward wave wherein a negative propagation constant β is observed ($\beta < 0$), right-handed region at higher frequencies supporting a forward wave wherein the propagation constant β is positive ($\beta > 0$), and a transition point wherein $\beta = 0$. The unique property of the zero propagation constant with nonzero group velocity at the zeroth-order resonance makes the CRLH lines suitable to form a loop antenna with omnidirectional radiation. Figure 30a exhibits a CRLH line loop antenna where surface-mounted lumped inductors and capacitors are used (Borja et al. 2007). The antenna exhibits *E*-plane omnidirectional radiation patterns but a low gain of 0.3 dBi at 500 MHz. The low gain attributes to the utilization of the lossy lumped components for CLRH line implementation. Figure 30b shows a revised design (Locatelli et al. 2012), where all the lumped components have been replaced by printed ones. The antenna demonstrates an omnidirectionality of 0.4 dB for *E*-plane pattern and maximum gain of 1.35 dBi at 2.4 GHz.

Segmented Line Loop Antenna

Segmented loop antennas have been investigated firstly for UHF radio-frequency identification (RFID) applications, where the reader antenna is required to generate strong and even magnetic field over a large interrogation zone while the conventional solid-line loop antenna cannot make it. Dobkin et al. firstly presented the segmented magnetic antenna consisting of a number of segments, and each segment is composed of a metal line and a series lumped capacitor (Dobkin et al. 2007). In this structure, segmenting and combining the parasitic inductance of each section with a lumped capacitor make the electrically large loop keeping the uniform current flowing in the same direction and generating strong magnetic field. Based on the method, several segmented loop antennas (Qing et al. 2009; Ong et al. 2010) have been presented; the lumped capacitor is replaced by either couple lines or distributed capacitors as shown in Fig. 31.

Since the electrically large segmented line loop supports the uniform and uni-directed current distribution, it has been applied to design the horizontally polarized omnidirectional antenna for 2.4 GHz and

DOI 10.1007/978-981-4560-75-7_52-1

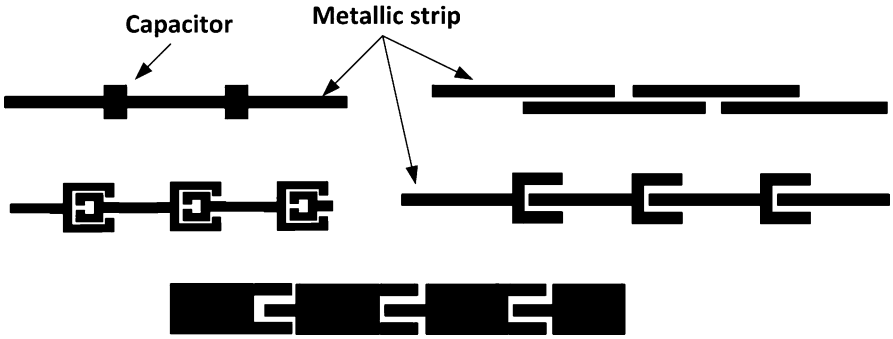

Fig. 31 Configurations of the segmented lines

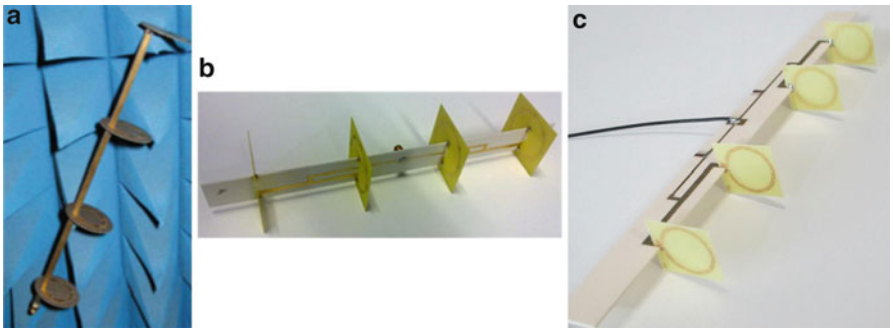

Fig. 32 Segmented line loop antenna arrays; (**a**) 2.4-GHz four-element series-fed MNT-TL loop antenna array (Wei et al. 2012), (**b**) 2.4-GHz four-element corporate-fed segmented line loop antenna array (Qing and Chen 2013), and (**c**) 5-GHz four-element corporate-fed segmented line loop antenna array (Qing and Chen 2014)

5 GHz WLANs (Qing and Chen 2012; Hasse et al. 2012; Wei et al. 2012). Wei et al. propose a circuit model to analyze the segmented line with periodically loaded parallel-plate lines (Wei et al. 2012). It is found that the effective permeability of the segmented line-based unit cell is negative, zero, and positive. When the transmission line operates at the mu-zero frequency, it has a unique property that supports a zero propagation constant with nonzero group velocity. At the zeroth-order resonance, there is no phase shift across the resonator so that the current distribution along the loop remains in phase and could yield a desired horizontally polarized omnidirectional pattern. Note that the general theoretical analysis of the segmented line is still a challenge till today since no valid transmission line mode can be applied to a single line, so that such an antenna design is mainly carried out with the help of simulation tools.

Compared to Alford loop antennas which must be fed from the center of the antenna, the side fed segmented line loop antenna is more convent to configure an antenna array for higher gain. Figure 32 shows some horizontally polarized omnidirectional segmented line loop arrays for the WLAN applications at 2.4 GHz and 5 GHz bands with series feeding or corporate feeding network.

Figures 33 and 34 demonstrate the detailed configuration and performance of the antenna array shown in Fig. 32c. The four-element antenna array is designed for 5-GHz WALN applications. The segmented line loop is printed onto a piece of FR4 PCB slab ($\varepsilon_r = 4.4$, $\tan\delta = 0.02$) with thickness of 0.5 mm. The four elements are connected to the outputs of the parallel-line feeding network, respectively. The parallel-line feeding network is etched on the opposite sides of a 0.8-mm thick RO4003 PCB ($\varepsilon_r = 3.38$, $\tan\delta = 0.0023$). Two open-circuited stubs are used to enhance the impedance matching of the antenna array. The antenna array exhibits wideband characteristics: reflection coefficient of less than −10 dB, gain

of greater than 5 dBi, omnidirectional *E*-plane radiation patterns with omnidirectionality of less than 5 dB over the frequency range of 5.05–5.9 GHz, which is desired for WALN mesh networks.

Waveguide Slot Array Antenna

Similar to vertically polarized omnidirectional slot antennas, the waveguide slot array is able to achieve the horizontally polarized omnidirectional radiation as well. A circular waveguide carrying rotationally symmetric mode TM_{01} or coaxial line with TEM mode is suitable to configure such antennas. Figure 35 shows the basic configuration of the horizontally polarized omnidirectional antenna using circular waveguide and rectangular waveguide (Sangster and Wang 1995; Grabherr and Huder 1999; Kyouichi and Tanaka 2000).

Generally, the antenna contains a number of rows of slots in its axial direction. Each row consists of several equally spaced identical half-wave slots arranged on the circumference of the waveguide. It has been found that eight slots are adequate to achieve the desired omnidirectional radiation in the azimuth planes. Because the currents on the wall of the circular waveguide carrying TM_{01} mode are axially directed, the slots must be inclined with a certain angle for efficient coupling from the waveguide to free space. The radiation pattern in the elevation plane is determined by the number and distance of the rows of slots as well as by the shape and the inclination angle of the slots themselves. Succeeding rows are generally positioned with a distance of half wavelength of the TM_{01} mode that propagates in the circular waveguide. To realize a stable broadside omnidirectional radiation, the waveguide is short circuited at quarter wavelength behind the last row of slots, which makes the antenna to be a resonant array. The inner diameter of the circular waveguide has to be chosen sufficiently small in order to allow the propagation of the TM_{01} mode, but below the cutoff for the next higher TM_{11} mode. On the other hand, the wavelength of

DOI 10.1007/978-981-4560-75-7_52-1

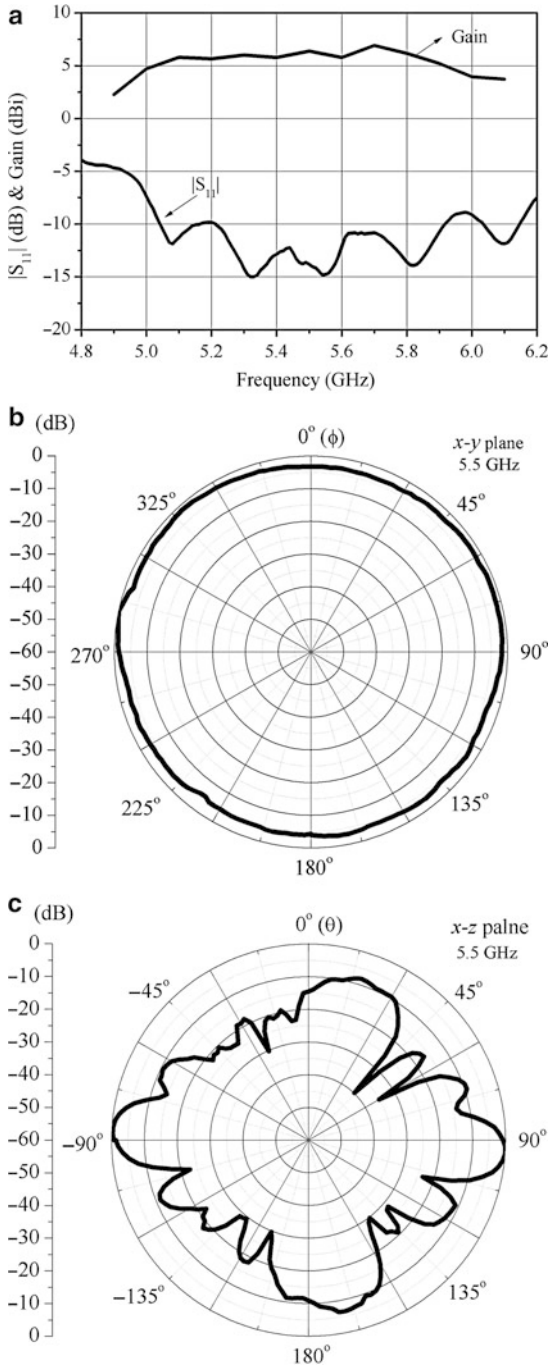

Fig. 34 Measured results of the 5-GHz segmented line loop array; (**a**) $|S_{11}|$ and gain, (**b**) normalized radiation pattern in *E*-plane, and (**c**) normalized radiation pattern in *H*-plane

the TM_{01} mode in the waveguide and the distance of successive rows of slots increase with decreasing its inner diameter. To avoid grating lobes in the radiation pattern of the elevation plane, the distance of the rows must be smaller than one free space wavelength. In general, the minimum inner diameter of the circular waveguide can be selected to be one wavelength in free space at the central operating frequency. For the slot array on the circular waveguide carrying TE_{11} mode, the slots are not needed to be inclined because the currents on the wall of the circular waveguide are ϕ directed.

DOI 10.1007/978-981-4560-75-7_52-1

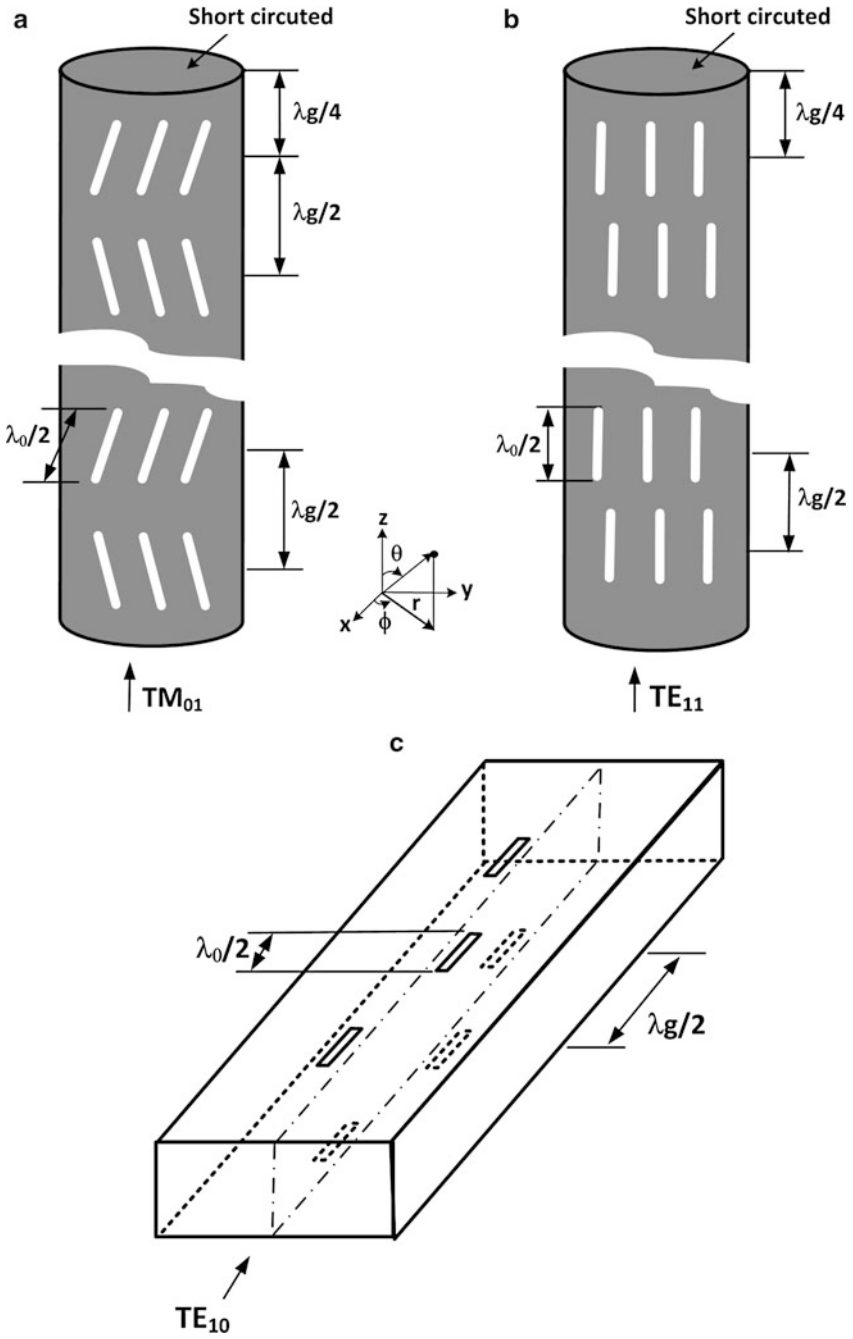

Fig. 35 Waveguide slot arrays, (**a**) slot array on circular waveguide carrying TM_{01} mode, (**b**) slot array on circular waveguide carrying TE_{11} mode, and (**c**) slot array on rectangular waveguide carrying TE_{10} mode

The rectangular waveguide carrying TE_{10} mode can be used to configure the slot array for horizontally polarized radiation as well. Furthermore, the longitudinal slot array features very low cross-polarization levels. As shown in Fig. 35c, the longitudinal slots are cut on both the broad walls of the waveguide to achieve desired omnidirectional radiation. The resonant slots are positioned at the opposite side of the central line of the waveguide alternatively with half a guided wavelength of the TE_{10} mode in the waveguide. Such an arrangement counteracts the 180° phase shift of the waveguide mode at each half-guided wavelength and ensures the slots with in-phase excitation.

DOI 10.1007/978-981-4560-75-7_52-1

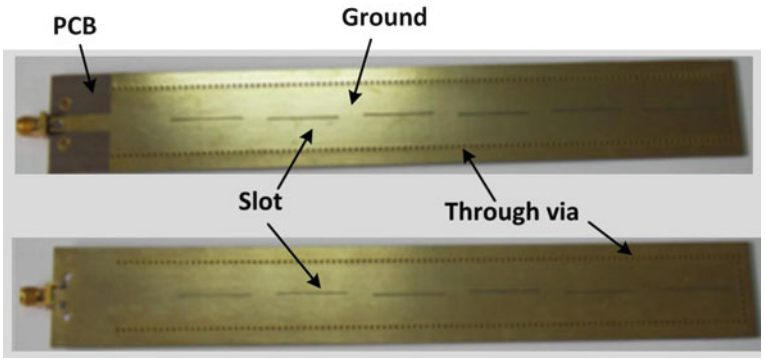

Fig. 36 SIW slot array antenna

The conventional metallic rectangular waveguide slot array antennas have been widely used in radar, navigation, and the communication systems for years. However, the volume, weight, and cost of these antennas are often puzzled for some applications. With the development of the substrate integrated waveguide (SIW) technology, it is possible to design a fully printed slot array antenna with horizontally polarized omnidirectional radiation, which is desired for WALN applications owing to the merits of small size, light weight, low manufacture cost. The SIW is a planar-guided wave structure which supports the similar TE-modes as in a conventional metallic rectangular waveguide. It can easily be integrated into microwave and millimeter-wave integrated circuits and has been extensively investigated for designing filters, couplers, power dividers, antennas, and even a passive front end (Takenoshita and Fujii 1998; Deslandes and Wu 2001; Yan et al. 2004; Hao et al. 2005).

A horizontally polarized omnidirectional SIW slot array is exemplified in Fig. 36 (Hua et al. 2008). The antenna is designed using a normal PCB ($\varepsilon_r = 2.2$, $\tan\delta = 0.003$, thickness = 1.5 mm) and fabricated with a standard PCB process, wherein longitudinal slots are etched on the upper and bottom grounds of the SIW. The antenna designed at 6GHz shows a bandwidth (VSWR $\leq$ 1.5) of 3 % and very good *E*-plane omnidirectional radiation patterns.

Apart from the waveguide slot antenna array, the horizontally polarized omnidirectional antennas based on microstrip slot configuration have been reported as well (Qing et al. 2012).

Planar Antenna Array

Consider a group of antenna elements arranged in a ring formation as shown in Fig. 37a, where N antenna elements are uniformly positioned along a circle with a radius of *r*. Assuming the antenna elements are equally excited with dominant electric current components in the direction of increasing ϕ, horizontally polarized omnidirectional radiation is expected to be generated by selecting suitable N and *r* (McEwan et al. 2003). The antenna configuration features the null radiation at zenith while varied maximum radiation at a specific elevation angle. For example, the maximum radiation will occur at θ of 90° if dipoles are used as the element; the maximum radiation will be directed to a certain elevation angle when the antenna elements are with the ground plane (such as a microstrip antenna), wherein the omnidirectional radiation with a conical beam is generated.

One antenna design is demonstrated in Fig. 38, where four broadband T-dipole elements (Sabatier 2003) are used to achieve *E*-plane omnidirectional radiation. The antenna is implemented on a circular PCB such as RF4; the T-dipoles are etched on the upper side of the PCB and are interconnected by a metallic square, which is also the ground plane for the microstrip line on the opposite side. The feed is located at the center of the antenna. The ground of the coaxial cable is connected to the ground plane of the antenna, and the inner conductor of the coaxial cable is connected to the microstrip line through the substrate. A proper impedance matching can be achieved using two stubs: a parallel stub located between

DOI 10.1007/978-981-4560-75-7_52-1

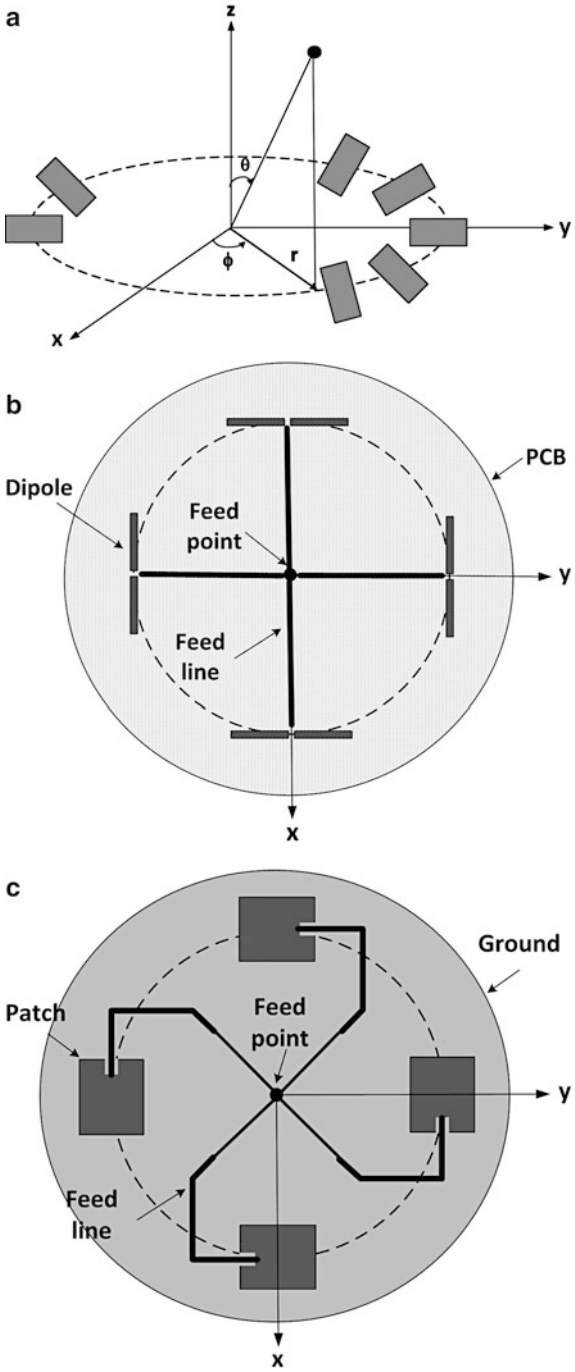

Fig. 37 Planar antenna array, (**a**) basic configuration, (**b**) antenna array with four dipole antennas, and (**c**) antenna array with four microstrip patch antennas

the two horizontal aims of the T-dipole and a serial stub at the end of the microstrip line. The four-element T-dipole antenna array (Ma and Wu 2006) achieves an impedance bandwidth of 80 % (3–7 GHz) for the reflection coefficient of less than −9 dB and gain of about 0 dBi. Good *E*-plane omnidirectional radiation patterns are achieved from 3 to 5.4 GHz with omnidirectionality of 3 dB.

Using more antenna elements may benefit the enhancement of the omnidirectionality while making the antenna configuration more complicated (Wu et al. 2007). In addition, applying broadband antenna

DOI 10.1007/978-981-4560-75-7_52-1

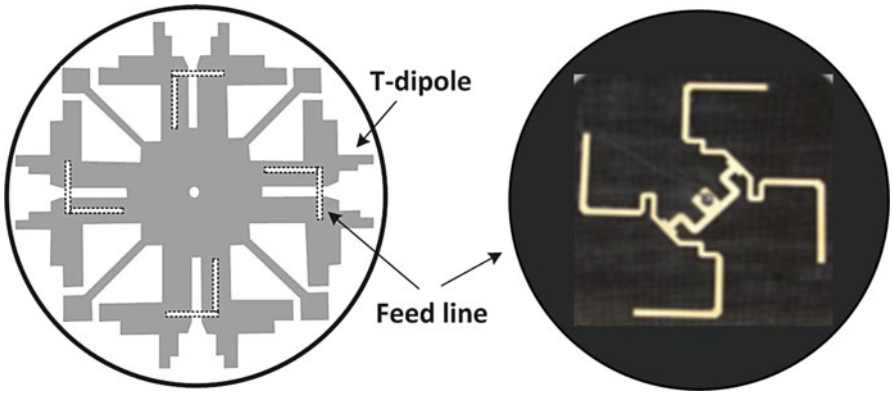

Fig. 38 Horizontally polarized omnidirectional antennas with four T-dipoles

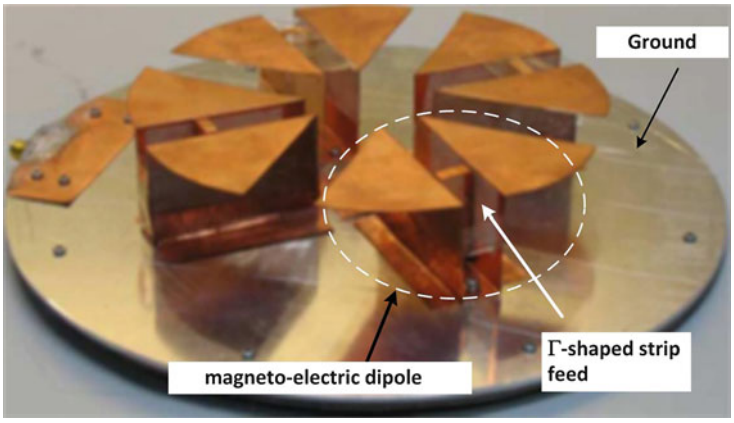

Fig. 39 Broadband omnidirectional antenna with conical beam using magnetoelectric dipoles

elements such as log-periodic antenna or tapered slot is helpful to improve the bandwidth of the antenna array (Fu and Hu 2008).

For the ceiling mounted indoor WLAN base station antennas, omnidirectional radiation with conical beam is preferable, where the antenna offers omnidirectional pattern in azimuth plane with a null at zenith but peak radiation at specific elevation angle (such as 60°). Monopole-type antennas are widely used for such purpose while they radiate vertically polarized wave and normally with high profile. Figure 39 shows a broadband horizontally polarized omnidirectional antenna with conical beam (Wu and Luk 2009). The four magnetoelectric dipoles are excited by an in-phase tapered power divider located below the ground plane. The configuration of each magnetoelectric dipole is a combination of an electric dipole and a magnetic dipole. The upper part of the antenna, which is an electric dipole, is constructed by a pair of sectorial-shape horizontal plates. The electric dipole is connected to the lower part of antenna, which is equivalent to a folded magnetic dipole. The magnetic dipole is due to a pair of vertically oriented shorted patch antennas, coupled by a Γ-shaped strip feed to produce a magnetic current along the edge of the two vertical walls. The low-profile antenna (height of $0.1867\lambda_0$) achieves an impedance bandwidth of 38 % (1.61–2.38 GHz) and average antenna gain of 5 dBi. Stable conical beam patterns are achieved across the operating band.

DOI 10.1007/978-981-4560-75-7_52-1

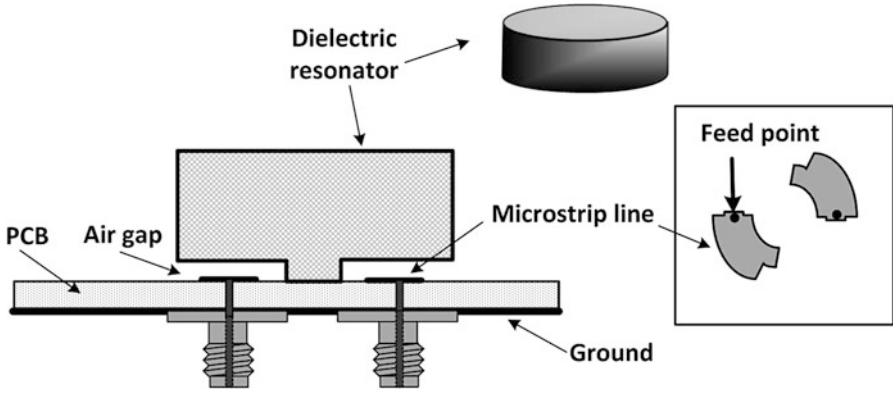

Fig. 40 Dielectric resonator antenna with $TE_{01\delta}$ mode for horizontally polarized omnidirectional radiation

Dielectric Resonator Antenna

Besides the patch array and magnetoelectric dipole array, a dielectric resonator antenna is able to generate horizontally polarized omnidirectional radiation with a conical beam as well. Regarding the first three fundamental modes in a cylindrical dielectric resonator (DR), $TM_{01\delta}$, $HEM_{01\delta}$, and $TE_{01\delta}$, the first two modes have been extensively studied for the vertically polarized omnidirectional radiation with broadside radiation patterns, respectively. In contrast, the $TE_{01\delta}$ mode is usually used as a filter because of its high-quality (Q) factor. Recently, it was reported that the $TE_{01\delta}$ mode in a cylindrical DR is able to be utilized to produce horizontally polarized omnidirectional radiation with conical beam patterns.

A design example is illustrated in Fig. 40 (Zuo and Fumeaux 2011). A cylindrical DR with ε_r of 10, diameter of 40 mm, and height of 6.62 mm is mounted on a Rogers Ultralam PCB (ε_r of 2.5 and thickness of 1.524 mm) with metalized bottom side. The $TE_{01\delta}$ mode is excited by two curved microstrip lines with identical sizes printed onto the top side of the substrate. Two SMA connectors, located at the back of the substrate, are utilized to connect the two microstrip lines to a splitter. The measured impedance bandwidth ($|S_{11}| < -10$ dB) covers a frequency range from 3.84 to 4.06 GHz. The antenna gain is above 4 dBi with a maximum of 5.2 dBi. Compared to other types of *E*-plane omnidirectional antennas, the DR antenna is attractive for its simplicity, low profile, and relatively high gain.

Dual Linearly Polarized Omnidirectional Antenna

Antennas with dual polarization are widely studied and applied in wireless communication systems because of the improved channel capacity and mitigated multipath fading. The polarization diversity that combines pairs of antennas with orthogonal polarizations has been widely used in mobile communications. For the polarization diversity scheme with a 360° full coverage, dual-polarized (vertically/horizontally) omnidirectional antennas are needed for base stations. Therefore, the design of dual-polarized omnidirectional antennas has become an interesting topic in wireless communications nowadays.

It is well known that the antenna configurations with vertically polarized omnidirectional radiation are distinct from those with horizontally polarized omnidirectional radiation. It is almost impossible to generate the orthogonal polarized omnidirectional radiation using one radiator; the most applicable solution is to combine the vertically and the horizontally polarized omnidirectional antenna elements together for achieving the dual-polarized omnidirectional radiation. An exception is the dual-polarized omnidirectional DR antenna, where different modes in one radiator are used to generate the orthogonal polarized omnidirectional radiation.

DOI 10.1007/978-981-4560-75-7_52-1

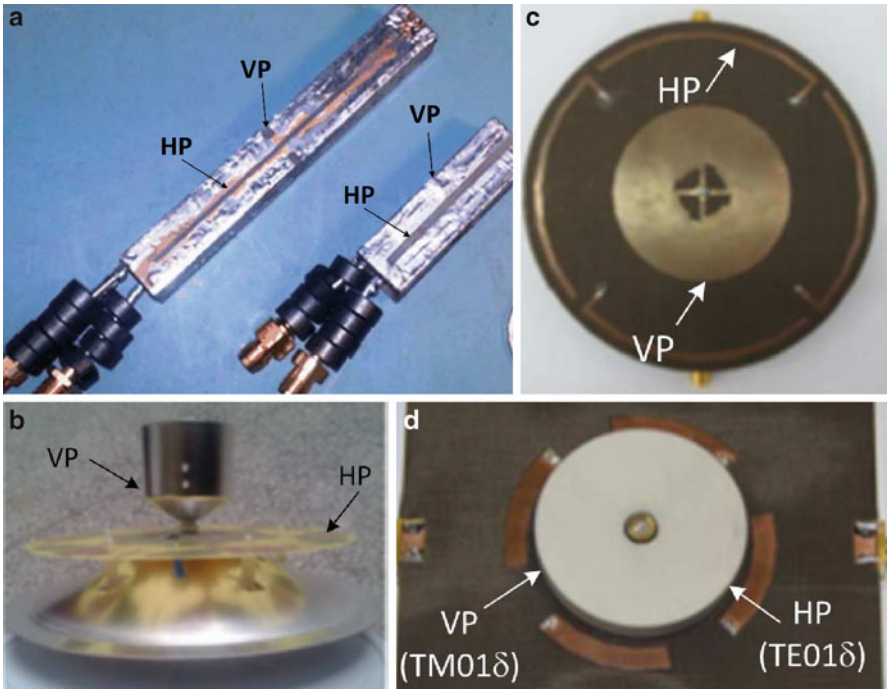

Fig. 41 Dual linearly polarized omnidirectional antennas; (**a**) compact slot antennas in slender column (Li et al. 2012, 2014), (**b**) multiband/wideband antenna (Dai et al. 2013), (**c**) low-profile antenna (Deng et al. 2012), and (**d**) dielectric resonator antenna (Zou et al. 2012)

Figure 41 illustrates some dual linearly polarized omnidirectional antennas. In Fig. 41a (Li et al. 2012, 2014), the dual polarizations are achieved by positioning two orthogonal slots cut onto the walls of a slender columnar cuboid. The antenna design at the WLAN band of 2.4–2.48 GHz achieves gains of greater than 3.17 dBi and 1.19 dBi for vertical and horizontal polarizations, respectively, and port isolation of higher than 33.5 dB with an antenna size of $0.664\lambda_0 \times 0.088\lambda_0 \times 0.088\lambda_0$. A compact design with reduced size was reported (Li et al. 2014), where a cavity-backed notch is applied for the horizontal omnidirectional polarization and a folded slot for the vertical omnidirectional polarization. With the antenna size of $0.336\lambda_0 \times 0.096\lambda_0 \times 0.096\lambda_0$, the antenna achieves isolation of higher than 32.5 dB and a maximum gain of 2.78 dBi and 1.35 dBi for vertical and horizontal polarization, respectively, from 2.4 to 2.48 GHz. The radiation patterns at 2.44 GHz show an omnidirectionality of 4.5 dB for vertical polarization and 2.4 dB for horizontal polarization.

Figure 41b exhibits a multiband/wideband dual linearly polarized antenna (Dai et al. 2013). The antenna is able to cover the frequency ranges of 806–960 MHz (17.4 %) and 1,880–2,700 MHz (35 %) for vertical polarization and 1,880–2,700 MHz (35 %) for horizontal polarization, which makes it suitable for GSM900, CDMA800, GSM1800, GSM 1990, PCS, UMTS, and LTE communication systems. The antenna is a combination of a modified asymmetric biconical antenna for the vertical polarization and six printed dipoles with concentric placement for the horizontal polarization. The element for vertical polarization consists of two modified cones with different diameters, designed to work in the multiband. The printed dipoles for horizontal polarization are fed by a six-way power splitter printed on a PCB. The horizontal polarized element is positioned between two cones of the vertical polarized element, forming a compact structure. The antenna exhibits desired performance with gain of 1.4–2.2 dBi for vertical polarization at lower band, and about 4.5 dBi for both polarizations at higher band; an isolation of greater than 25 dB; cross-polarization levels of lower than −15 dB in the azimuth plane for both polarizations; and desired omnidirectional patterns with omnidirectionality of 1.5 dB.

DOI 10.1007/978-981-4560-75-7_52-1

A low-profile broadband dual linearly polarized antenna as shown in Fig. 41c was designed to operate at 2-GHz band for the based-station applications (Deng et al. 2012). The antenna is a combination of a modified low-profile monopole for the vertical polarization and a circular planar loop for the horizontal polarization. The modified low-profile monopole is a circular folded patch shorted by four tubes, while the circular loop consists of four half-wavelength arc dipoles. The antenna achieves a bandwidth of 25 % (1.7–2.2 GHz) with an isolation of around 40 dB and omnidirectionality of 2.5 dB and 1.5 dB for the vertical and horizontal polarizations, respectively.

In contrast to the conventional dual linearly polarized antenna designs employing different radiating elements to generate the orthogonal polarized radiations, a DR antenna is able to generate dual linearly polarized radiation with single radiator. Figure 41d shows an omnidirectional cylindrical DR antenna simultaneously realizing the horizontally and vertically polarized omnidirectional radiation with low cross coupling (Zou et al. 2012). The horizontally and vertically polarized radiations are achieved by exciting the orthogonal $TE_{01\delta}$ and $TM_{01\delta}$ modes in a single cylindrical dielectric resonator. The $TE_{01\delta}$ mode corresponding to horizontally polarized radiation is with higher Q-factor so that the bandwidth of horizontal polarization is smaller than that of the vertically polarized radiation generated by the $TM_{01\delta}$ mode. To increase the bandwidth of the $TE_{01\delta}$ mode and suppress the influence of higher-order modes, two groups of four radially arranged microstrip feeding lines with two different lengths are utilized, and a dual-polarized omnidirectional radiation is realized at the overlapping operating band of the modes with a bandwidth of 7.4 % (3.78–4.07 GHz).

The other dual linearly polarized omnidirectional antenna designs are reported with different configurations; the combinations include notched disk antenna and wire antenna, planar conical cone antenna and circular loop antenna, collinear array antenna and slotted cylinder antenna, and so on. For convenience, a comparison of some antennas is tabulated in Table 1.

Circularly Polarized Omnidirectional Antenna

A linearly polarized antenna radiates wholly in one plane containing the direction of propagation. An antenna is vertically or horizontally polarized when its electric field is perpendicular or parallel to the Earth's surface. For a circularly polarized antenna, the plane of the polarization rotates in a corkscrew pattern, making one complete revolution in each wavelength. The electric field of the circularly polarized antenna lies in both the vertical and horizontal planes as well as all the planes in between in a rotating manner. Compared to linearly polarized antenna, a circularly polarized antenna features the unique advantage as follows:

- Able to establish a reliable signal link regardless of the orientation of the antennas.
- More effective to suppress the multipath interferences.
- More resistant to signal degradation due to inclement weather conditions.
- The circularly polarized wave is more effective be propagated through wall and can achieve an overall better reach throughout the building.

Circularly polarized omnidirectional antennas have been widely used in television broadcasts; mobile satellites; space vehicles such as airplanes, missiles, rockets, and spacecraft; mobile communication; and WLANs.

A circularly polarized radiation can be obtained by generating two orthogonal field components with 90° phase difference. To design a circularly polarized omnidirectional antenna is more complicated than that of the linearly polarized one since the designer has to consider the spatial orthogonal field components

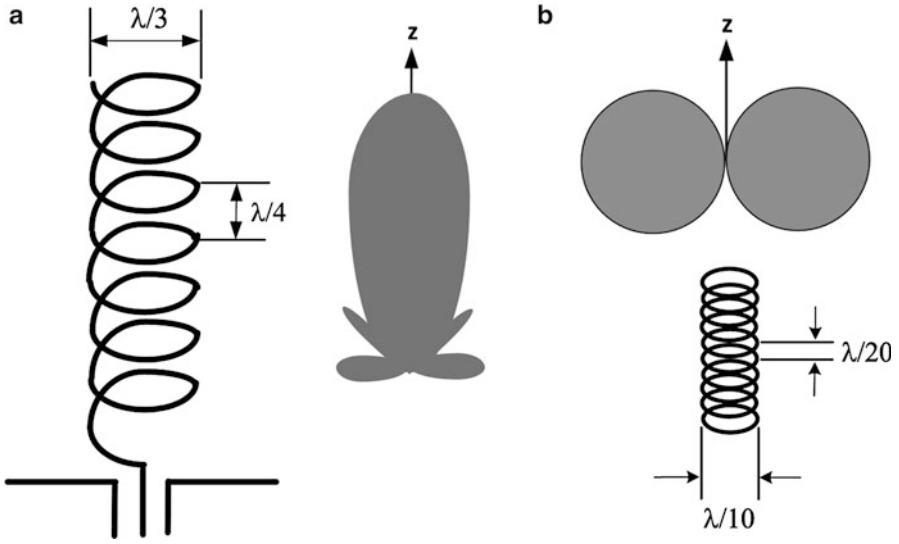

Fig. 42 Field patterns of the axial and normal radiation modes of the helical antenna; (**a**) normal mode and (**b**) axial mode

and the proper phase delay of the field components over a specific bandwidth at desired directions. The studies of circularly polarized omnidirectional antenna can be dated back to 1940s (Wheeler 1947; Lindenblad 1941; Brown and Woodward 1947). Over the last few decades, a number of circularly polarized omnidirectional antennas have been developed; the configurations can be categorized as follows:

- Single radiator
- Conformal array with circularly polarized radiator
- Combination of linear polarized radiator

Circularly Polarized Omnidirectional Antennas with Single Radiator

Helical Antenna

Helical antenna is well known for its circularly polarized radiation characteristics. When the circumference of a helical antenna is approximately one wavelength, the axial mode of radiation is dominant; when the circumference is much smaller the one wavelength, the normal mode is dominant, as shown in Fig. 42.

As illustrated in Fig. 43, the far field of a helix may be described by two components of the electric field, E_ϕ and E_θ, which are contributed by the small loop and the short dipole, respectively. For a small helix, the current is assumed to be uniform in magnitude and in phase over the entire length of the helix. The far field of the small loop has only an E_ϕ component as below (Kraus and Marhefka 2008):

$$E_\phi = \frac{120\pi^2[I]\sin\theta}{r}\frac{A}{\lambda^2} \tag{6}$$

where A is the area of the loop, $A = \pi r D^2/4$

The far field of the short dipole has only an E_θ; it can be expressed as

$$E_\theta = j\frac{60\pi[I]\sin\theta}{r}\frac{S}{\lambda} \tag{7}$$

DOI 10.1007/978-981-4560-75-7_52-1

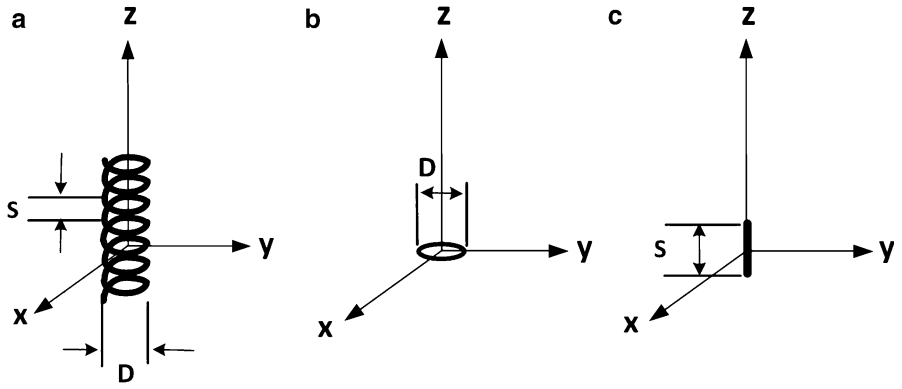

Fig. 43 Small helix for normal mode calculation; (**a**) helix, (**b**) small loop, and (**c**) short dipole

Comparing Eqs. 6 and 7, the j operator in Eq. 7 and its absence in Eq. 6 indicate that E_ϕ and E_θ are in-phase quadrature. The ratio of the magnitudes of Eqs. 6 and 7 then gives the axial ratio of the polarization ellipse of the far field

$$AR = \frac{|E_\theta|}{|E_\phi|} = \frac{S\lambda}{2\pi A} = \frac{2S\lambda}{\pi^2 D^2} = \frac{2S_\lambda}{C_\lambda^2} \tag{8}$$

where S_λ and C_λ are the pitch and circumference of the helix in wavelength, respectively.

A circularly polarized radiation can be achieved when AR is a unit; from Eq. 8, we have

$$\pi D = \sqrt{2S\lambda} \text{ or } C_\lambda = \sqrt{2S_\lambda} \text{ or } A = \frac{\lambda}{2\pi} S \tag{9}$$

The relation was first presented by Wheeler (1947) so that such antenna is also called "Wheeler coil." A monofilar normal-mode helix is a resonant and narrowband circularly polarized omnidirectional antenna. To enhance the bandwidth, the bifilar configuration can be applied (Amin et al. 2013).

Dipole-/Monopole-Type Antenna with Polarizer

It is known that a pair of 45° tilted dipole antennas with a λ/4 spacing, in orthogonal crossed disposition, radiates circularly polarized wave in both directions of the array axe if current distribution on the dipoles is identical. Figure 44 exhibits the schematic view of a dipole antenna with a polarizer for circularly polarized omnidirectional radiation; where the polarizer is formed by a concentric array of 45° tilted parasitic elements, the spacing between the dipole and the parasitic elements is set to $R = \lambda/4$. The radiation field from the vertical dipole can be divided into two orthogonally crossed electric fields (parallel and perpendicular components to the parasitic strip elements); each tilted element is excited by the parallel component of the field accordingly. Because of the λ/4 separation between the dipole and the parasitic elements, the reflection of the perpendicular component is canceled. The 90° phase difference between the two radiated field components is achieved by the interaction between the parasitic elements and the parallel component.

Generally, the parasitic elements are uniformly spaced approximately λ/2 apart. The length of the elements is around 0.5λ and the width of each element about λ/10. In practical design, the parasitic elements are normally implemented with a supporting material such as a piece of foam or PCB; the dimensions as well as the spacing between the dipole antenna and the parasitic elements are required to be adjusted for optimal performance.

DOI 10.1007/978-981-4560-75-7_52-1

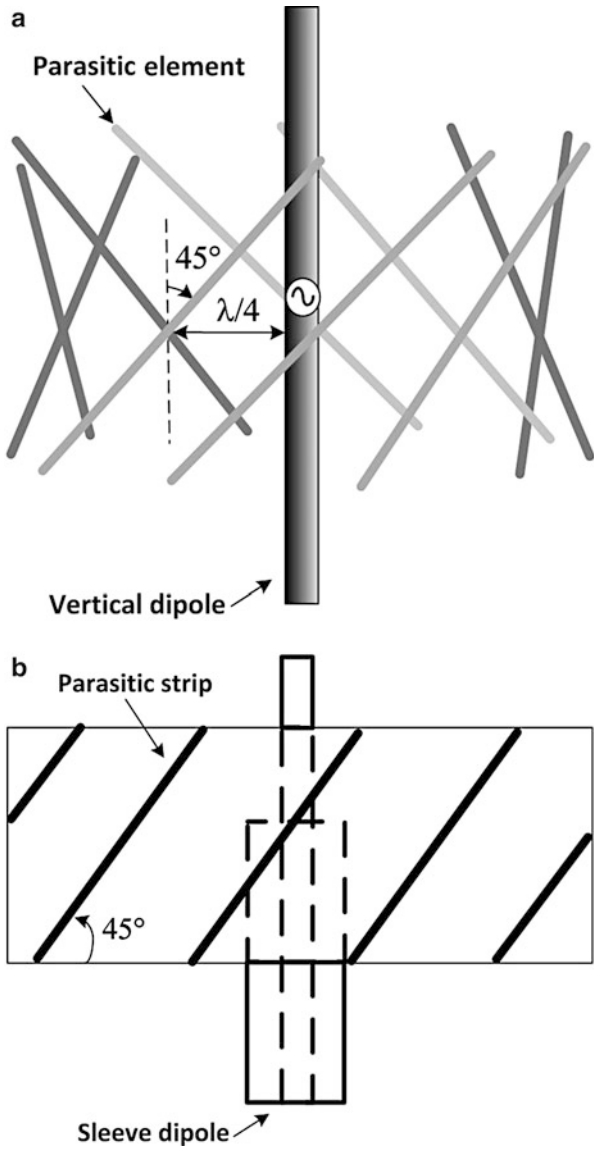

Fig. 44 Dipole/sleeve antenna with a conformal array of 45° tilted parasitic elements; (**a**) dipole configuration and (**b**) sleeve dipole configuration

Based on the basic configuration, a number of variation of the polarizer have been reported for generating circularly polarized omnidirectional radiation, where biconical cones, sleeve dipole, and a conical skirt monopole are used as the radiators while multilayer parasitic elements are applied (Kelleher and Morrow 1955; Goatley and Green 1956; Sakaguchi and Hasebe 1993; Fernandez et al. 2007).

Circularly Polarized Omnidirectional Antennas with Multiple Circularly Polarized Radiators

Conformal Cylindrical Array

The arbitrarily oriented satellites and space vehicles such as missiles and rockets require a circularly polarized omnidirectional antenna to reliably maintain a communication link with a central receiving link. A low-profile conformal cylindrical omnidirectional antenna array is desirable for such applications (Galindo and Green 1965; Wu 1995). To configure such antenna arrays, the most convenient way is to

DOI 10.1007/978-981-4560-75-7_52-1

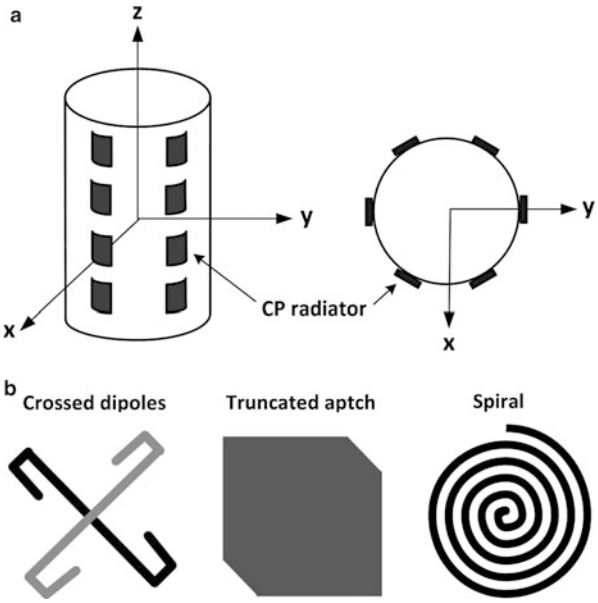

Fig. 45 Conformal cylindrical array; (**a**) basic configuration and (**b**) CP elements

position a certain number of circularly polarized radiators with equidistant intervals on the surface of a cylindrical surface. Desired omnidirectional radiation is able to be achieved by arranging adequate number of radiators on the cylindrical surface properly. A variety of low-profile radiators such as cross dipoles, truncated microstrip patch, spiral, slots, and so on can be utilized as the array elements (Dubost et al. 1979; Nakayama et al. 1999) as exhibited in Fig. 45.

Cutting slots directly on the surface of a circular waveguide is able to achieve circularly polarized omnidirectional radiation as well. Such an antenna configuration may be more preferable from a system point of view because of the merits of simplicity, robustness, and lightweight. Figure 46 shows a slot array design (Masa-Campos et al. 2007), where the conformal slot array is designed at the millimeter-wave band of 36.7–37 GHz; the eight slot pairs are symmetrically positioned on the wall of a circular waveguide carrying TM_{01} mode. Each slot pair consists of two resonant slots with a length of $\lambda_0/2$ and a separation of $\lambda g/4$ (λg is the guided wavelength of the propagated TM_{01} mode).

The conformal cylindrical antenna arrays with traditional circularly polarized radiator are with limited bandwidth for impedance matching, in particular, the circular polarization characteristic of axial ratio, which makes the antennas not suitable for modern mobile communications. For example, the second- and third-generation mobile communication systems require a base-station antenna covering the frequency range from 1.71 to 2.17 GHz; a bandwidth of at least 25 % is needed. Recently, Quan et al. (2013) presented a broadband conformal circularly polarized omnidirectional antenna as shown in Fig. 47. The four rectangular loop elements are first printed on a flexible thin dielectric substrate and then rolled into a hollow cylinder. A conducting cylinder is added inside the hollow cylinder for achieving desired omnidirectional circularly polarized performance. The antenna exhibits a bandwidth of 41 % (1.65–2.5 GHz) for axial ratio of less than 3 dB and omnidirectionality of 1 dB and 45 % (1.58–2.5 GHz) for return loss greater than 10 dB.

Back-to-Back Patches

To simplify the complicated feeding network of the conformal cylindrical array, the back-to-back coupled patch antennas are investigated for circularly polarized omnidirectional radiation; H. lwasaki and Chiba reported a coplanar waveguide (CPW) fed back-to-back patch antenna (lwasaki and Chiba 1999) as

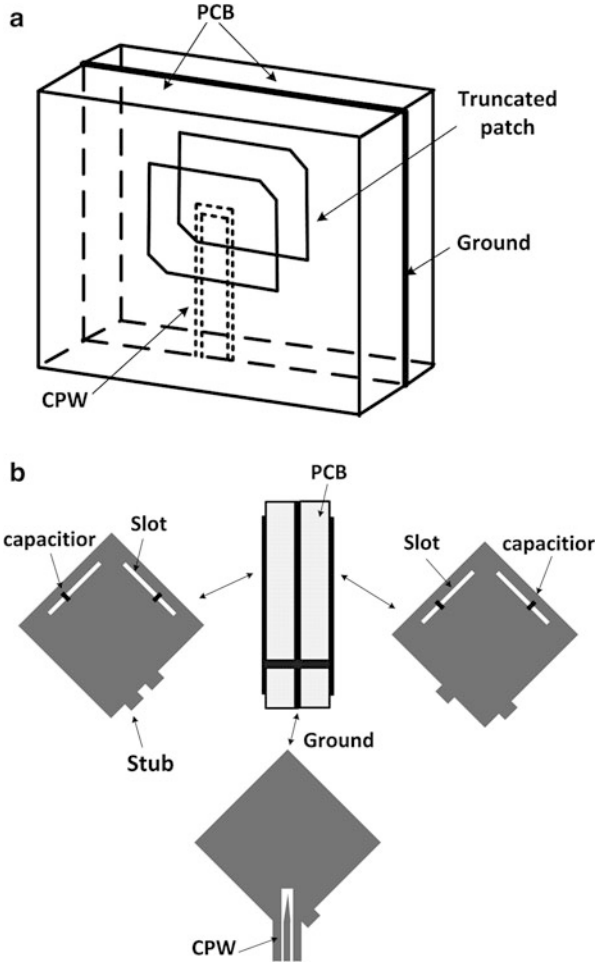

Fig. 48 Circularly polarized omnidirectional antennas with back-to-back patches, (**a**) truncated patches and (**b**) slotted patched

shown in Fig. 48a, where two truncated microstrip patch elements are positioned on the opposite sides of a PCB slab and a CPW feed line is sandwiched in between. The antenna exhibits narrow impedance bandwidth of 13 % (VSWR < 2) and axial ratio of less than 4 dB in the azimuth plane.

Narbudowicz et al. (2013) proposed a dual-band circularly polarized omnidirectional antenna using back-to-back slotted patch configuration. As illustrated in Fig. 48b, the antenna consists of two layers of substrate with three layers of metallization. The inner metallization forms the ground plane and comprises the coplanar waveguide (CPW) feeding structure, whereas the outer ones form two patches. The patches are additionally connected together by a thin copper strip. The radiators are electromagnetically coupled to the 50-Ω CPW located along the diagonal of the patches. The two slots of slightly different lengths with a lumped capacitor connected across the center are utilized to provide dual-band circularly polarized radiation. The conducting strip connected the patches, and a reduced ground plane size allows better impedance matching and reduced overall size. The dual-band antenna radiates right-handed circular polarization at both the lower and upper frequencies of 1.329 and 1.565 GHz with bandwidth of about 20 MHz, respectively. The axial ratio in the omnidirectional plane varies from 0.4 to 3.8 dB for the lower band and from 0.6 to 4.8 dB for the upper band. The omnidirectionality in the omnidirectional plane is 3.3 dB for the lower band and 3.8 dB for the upper band.

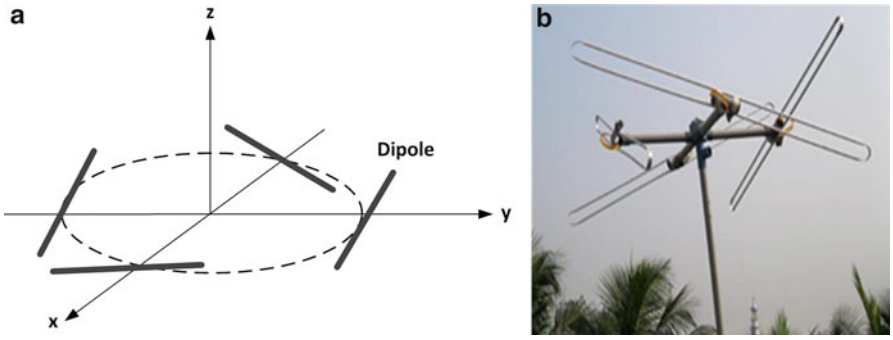

Fig. 49 Lindenblad antenna, (**a**) antenna configuration and (**b**) practical antenna design

In short, the back-to-back patch design features simple configuration with limited bandwidth and radiation performance. Furthermore, it is difficult to achieve desired omnidirectionality and axial ratio, in particular, at the directions apart from the boresight.

Circularly Polarized Omnidirectional Antennas with Combined Linearly Polarized Radiators

Lindenblad Antenna

The circularly polarized omnidirectional radiation can be realized by positioning multiple linearly polarized radiators properly. The Lindenblad antenna might be the first circularly polarized omnidirectional antenna with such a configuration (Lindenblad 1941). As shown in Fig. 49, a Lindenblad antenna uses four dipole elements that are fed in phase to create an omnidirectional circularly polarized radiation pattern. The dipoles are canted at 30° from horizontal and positioned equally around a circle of about λ/3 diameter. For easy impedance matching with a 50-Ω feed line, folded dipole instead of straight dipole is most used in practical designs. Seventy years after the invention, this antenna is still widely used in broadcasting stations, satellite communications, and amateur radios.

Monopole and Loop Combination

A dipole or monopole antenna is desired for vertically polarized omnidirectional radiation, and a loop antenna with a uniform current flowing in a single direction is able to generate horizontally polarized omnidirectional radiation. The combination of the dipole and loop antennas with an adequate arrangement to provide a 90° phase difference between the currents on the orthogonal radiators features the possibility to produce a circularly polarized omnidirectional radiation.

As shown in Fig. 50, considering the combination of the short dipole of length L and a loop with a radius of a, the dipole is positioned coincidently with the z-axis and with its center at the origin. The far field generated by the short dipole is expressed as (Kraus and Marhefka 2008)

$$E = j\frac{[I]L\omega\mu_0}{4\pi r}\sin\theta\hat{\theta} \tag{10}$$

where $[I]$ is the current on the short dipole, ω is the angular frequency, μ_0 is the permeability of the free space, and r is the distance between the origin and observation point.

The loop is placed in the x-y plane with its center at the origin; its axis is along the z-axis. The current on the loop is assumed to be the same with the dipole, which is uniform and in phase along the loop. The far field of the loop can be written as [16]

DOI 10.1007/978-981-4560-75-7_52-1

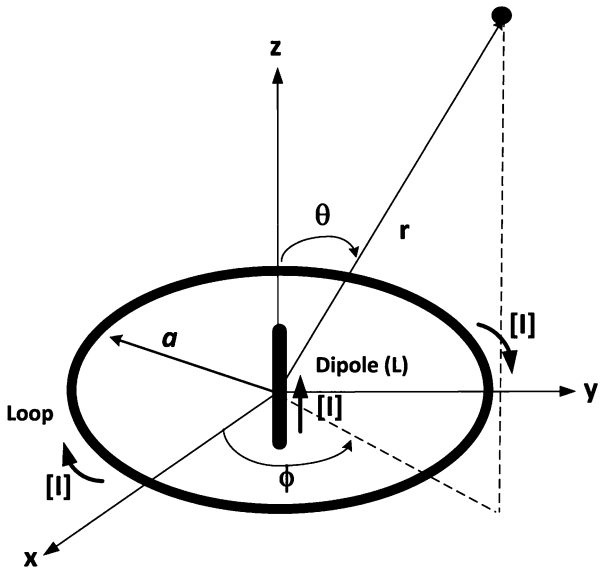

Fig. 50 Configuration of an ideal omnidirectional circularly polarized antenna combining a short dipole with the height of L and a small loop with the radius of a

$$E = \frac{[I]a\omega\mu_0}{2r} J_1(\beta a \sin\theta)\hat{\phi} \tag{11}$$

where J_1 is the Bessel function of the first order and of argument ($\beta\alpha\sin\theta$).

By superposing the far fields of the dipole and the loop, the far field of the combining dipole/loop antenna is given by

$$E = j\frac{[I]L\omega\mu_0}{4\pi r}\sin\theta\hat{\theta} + \frac{[I]\alpha\omega\mu_0}{2r} J_1(\beta a \sin\theta)\hat{\phi} \tag{12}$$

Then, the axial ratio of the combining antenna can be given by

$$AR = \left|20\log_{10}\left(\left|\frac{L}{2\pi a}\frac{\sin\theta}{J_1(\beta a\sin\theta)}\right|\right)\right| \tag{13}$$

The circularly polarized omnidirectional antenna is required to achieve good axial ratio in the azimuth plane (x-y plane). Considering $\theta = 90°$, Eq. 13 can be written as

$$AR = \left|20\log_{10}\left(\left|\frac{L}{2\pi a}\frac{1}{J_1(\beta a)}\right|\right)\right| \tag{14}$$

The AR equals 0 dB when

$$\left|\frac{L}{2\pi a}\frac{1}{J_1(\beta a)}\right| = 1 \tag{15}$$

From the above equation, it can be found that, by choosing a suitable value of L and a in Eq. 15, the axial ratio can equal 0 dB, and thus the antenna can achieve a perfect circularly polarized radiation.

DOI 10.1007/978-981-4560-75-7_52-1

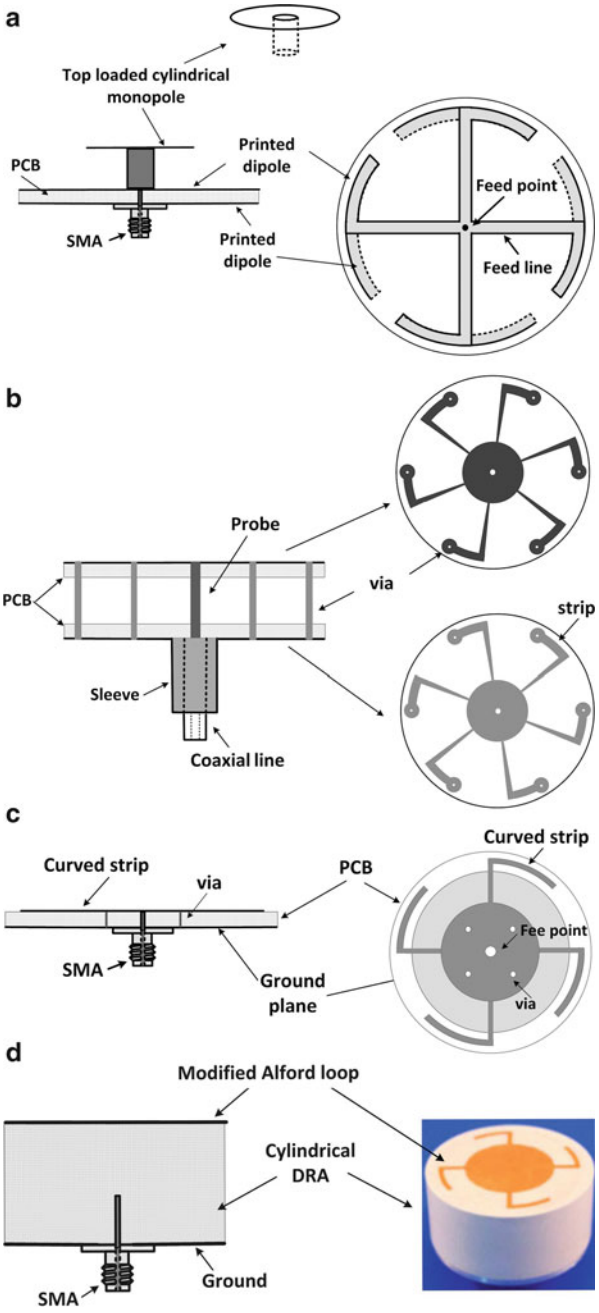

Fig. 51 CP antenna designs with combining radiators, (**a**) top-loaded monopole plus arc-shaped dipoles and (**b**) sleeve antenna plus printed spoke-like strips, (**c**) zeroth- and first-order resonance modes epsilon-negative transmission line plus curved strips, and (**d**) dielectric resonator antenna plus modified Alford loop

One of the antenna examples as shown in Fig. 51a is designed for 2.4-GHz WLAN applications, where a top-loaded cylindrical monopole generates vertically polarized omnidirectional radiation; four printed identical arc-shaped dipoles form a virtual loop to produce horizontally polarized omnidirectional radiation (Hisao and Wong 2005). The 90° phase difference between the two orthogonal components is achieved through tuning the length of the feed lines for the arc-shaped dipoles, thereby resulting in circularly polarized omnidirectional radiation. Figure 51b exhibits another example, where a metal sleeve acts as a monopole and the printed spoke-like metal strips fabricated onto two pieces of substrate function

DOI 10.1007/978-981-4560-75-7_52-1

as a loop (Li et al. 2013). Figure 51c demonstrates a metamaterial-based dual-band circularly polarized omnidirectional antenna comprising a circular mushroom structure with curved branches. The dual-band vertically polarized radiation is achieved by using the zeroth- and the first-order resonance modes of the epsilon-negative (ENG) transmission line, and the horizontally polarized omnidirectional radiation is realized by the curved branches (Park and Lee 2012).

A compact omnidirectional circularly polarized antenna combining cylindrical DR antenna and a top-loaded modified Alford loop is exhibited in Fig. 51d (Li and Leung 2013). Fed by an axial probe, the DR antenna operates in its $TM_{01\delta}$ mode, which radiates like a vertically polarized electric monopole. The modified Alford loop comprising a central circular patch and four curved branches is placed on the top of the dielectric resonator antenna and provides an equivalent horizontally polarized magnetic dipole mode. Omnidirectional circularly polarized radiation can be obtained when the two orthogonally polarized fields are equal in amplitude but 90° different in phase.

Conclusion

Omnidirectional antennas are essential for modern wireless communication systems, in particular for base-station applications for providing a wide coverage. Over the last several decades, many omnidirectional antennas have been developed for various applications. In general, the omnidirectional radiation can be achieved by using single radiator with circularly symmetrically distributed current or multiple radiators with a combined circular current distribution. This chapter has outlined the classic omnidirectional antenna configurations based on the antenna polarizations and discussed a number of antenna design examples for each topic. The relevant literature review is believed to benefit the antenna researchers, engineers, and students to further understand the omnidirectional antennas.

Abstract

Recently, multiple-input multiple-output (MIMO) technology and diversity have attracted much attention both in industry and academia due to high data rate and high spectrum efficiency. By increasing the number of antennas at the transmitter and/or the receiver side of the wireless link, the diversity/MIMO techniques can increase wireless channel capacity without the need of additional power or spectrum in rich scattering environments. However, due to limited space of small mobile devices, the correlation coefficients between MIMO antenna elements are usually very high, and the total efficiencies of MIMO elements would be degraded severely due to mutual couplings. In addition, the human body causes high losses on electromagnetic waves. In real applications, the presence of users may result in significant reduction of total antenna efficiencies, and the correlations of MIMO antenna systems are also highly affected. In this chapter, the performance of some basic MIMO antennas as well as recent technologies to improve MIMO antenna performance of portable devices and mobile terminals are reviewed. The interactions between MIMO antennas and human body are also addressed particularly in mobile terminals application.

Introduction

Antenna diversity techniques have been introduced in communication systems for many years since 1960 (Pierce and Stein 1960; Schwartz et al. 1965; Jakes 1974). In the late 1970s, the diversity technique was used to overcome the performance of degradation due to fading environments by using multiantenna systems (Taga 1990; Pedersen and Andersen 1999; Ogawa et al. 2001). Multiantenna systems usually require low mutual coupling loss and low pattern correlation between radiating elements in order to realize good diversity performance. Independent fading signals (diversity branches) are not only achieved by spaced receiving antennas, *space diversity*, but also attained by other techniques such as *frequency diversity, angle-of-arrival diversity, polarization diversity, time diversity, and multipath diversity.* An overall diversity performance of a system is usually a combined result of various diversity mechanisms.

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_53-1

Since 1985, mobile communication systems have been rapidly evolved from analog system (1G: first-generation system) to digital system (2G: second-generation system) and later to third-generation system (3G), which can support multimedia transmission. To further increase the data transmission rate, MIMO technology has become an important feature in LTE wireless communication systems (4G: fourth-generation system). As a great achievement in wireless communications during the last decade, MIMO can linearly increase channel capacity with an increase in number of antennas and by using space multiplexing, without requiring additional frequency spectrum or power. Moreover, most popular wireless communication systems typically operate in a rich scattering environment such as fourth-generation LTE cell phones and IEEE 802.11n, ac WiFi, in which MIMO exploits to achieve the aforesaid large performance gain.

A multiantenna system can operate as diversity or MIMO scheme depending on the signal-to-noise ratio (SNR) level under a rich scattering circumstance in a latest modern smartphone. The phone also supports multiband and multimode operations. Due to limited space of the small-size mobile terminal, the correlation coefficient between multiple antenna elements could be very high and so the corresponding bandwidths and total efficiencies would be degraded severely.

Furthermore, the human body causes high losses on electromagnetic wave energy. In practical applications, the presence of users usually results in a significant reduction on total antenna efficiency and a change of correlation in a MIMO antenna system. Mobile terminals need to fulfill different standards and requirements. For instance, the RF OTA performance of mobile phones with users' impact has been required by many telecommunication operators. In addition, SAR of a mobile terminal shows the amount of RF radiation emitted by a radio to a human body. SAR values of mobile terminals are strictly limited by governments' regulations. It is a fact that MIMO technology is able to enhance the channel capacity of a system but the complexity of SAR issue will be increased accordingly.

In this chapter, the antenna design for diversity and MIMO applications in mobile terminals will be discussed. In the section "Performance Characterization of Diversity and MIMO Antennas," general terminologies for diversity and MIMO antennas in mobile terminals will be described, such as different diversity schemes, diversity gain, correlation coefficient of multiple antennas, MIMO capacity, and multiplexing efficiency. Then, the fundamental MIMO antenna performances will be analyzed and presented in the section "Performances of certain Fundamental MIMO Antennas." In the section "Decoupling Techniques of Compact MIMO Antenna Designs," various techniques to decouple closely spaced MIMO antennas will be described. The section "Antenna Designs in LTE MIMO Applications" will provide several compact MIMO antenna designs for WiFi and LTE high and low bands in mobile terminals. Lastly, the section "Multi-Antenna SAR and OTA Performance, Field Trial" will present SAR and body loss of a MIMO terminal with different antenna arrangements, as well as some field trial data by using MIMO antennas in a 700 MHz-band LTE network.

Performance Characterization of Diversity and MIMO Antennas

Diversity Technology in Mobile Communications

Space Diversity

The most common and probably the simplest mechanism for achieving diversity branches is space or spatial diversity. Using two antennas separated at a distance, the phase delay lets signals arriving at the antenna elements differ in fading. The minimum spacing between antenna elements at a mobile terminal is usually about 0.5 wavelength, calculated using zero-order Bessel function, in order to acquire sufficient low correlation between fading signals. This does not include the effects of mutual couplings which could

DOI 10.1007/978-981-4560-75-7_53-1

be significant to the system. Antenna spacing smaller than 0.5 wavelength should incorporate other diversity mechanisms. Recently, as operating frequency of mobile systems is getting higher, space diversity has redrawn researchers' attention again.

Frequency Diversity
Frequency diversity is described as the transmission of a signal at two or more different frequency carriers, such that different versions of signals with various independent fading can be achieved. It is a costly mechanism because of the complexity to generate several transmitted signals and to combine signals at the receiver at several different frequencies.

Angle Diversity
Signals arriving at antennas are coming from different angles or directions. Being independent in their fading variations, these signals can be used for angle or angular diversity. At a mobile terminal, angle diversity can be achieved by using two omnidirectional antennas which are acting as parasitic elements to each other. The radiation patterns can be switched in order to manage the reception of signals at different angles.

Time and Multipath Diversities
Time and multipath diversities are related mechanisms which are most likely applied in the digital transmission. Time diversity is achieved by transmitting a single bit of information repetitively at different time intervals. Fading variations for these different repetitions of signal will become independent. Multipath diversity is using time diversity in multipath environments. Repetitive signals will be transmitted to the receiver at different traveling paths.

Polarization Diversity
Transmission of one polarization (depolarized by the propagation medium) gives the possibility of receiving two orthogonal polarizations with fading variations uncorrelated. This diversity mechanism is relatively practical because much smaller size of antennas can be used. It is also the mechanism that is mostly combined with spaced diversity.

MIMO in Wireless Communications

In a conventional wireless system, there is one transmitter and one receiver, which are called single-input single-output (SISO) system. In a condition of narrow band and static environment (frequency and time invariant), the scalar signal mode can be given as

$$\boldsymbol{y} = \boldsymbol{h}\boldsymbol{x} + \boldsymbol{n}, \tag{1}$$

where y is the received signal, x is the transmitted signal, and n is characterized by additive white Gaussian noise (AWGN) with zero mean and variance. For the bandwidth of 1 Hz, the channel capacity of SISO is upper bounded by Shannon (1948)and Winters (1987):

$$\boldsymbol{C} = \log_2\left(1 + \frac{\boldsymbol{E_s}}{\boldsymbol{N_0}}|\boldsymbol{h}|^2\right) \tag{2}$$

where E_s and $|\boldsymbol{h}|^2$ are the total transmit power and the power gain of the scalar channel, respectively. It is noted that the channel capacity of a SISO system is increased logarithmically with an increase in transmit power.

DOI 10.1007/978-981-4560-75-7_53-1

In a MIMO system, it allows to apply several antennas at both transmitting and receiving ends. Several pioneering works (Winters 1987; Foschini and Gans 1998; Telatar 1999) have been carried out on MIMO systems. The channel response is now described by a channel matrix H and can be expressed as

$$\begin{bmatrix} \boldsymbol{h}_{11} & \cdots & \boldsymbol{h}_{1M_R} \\ \vdots & \ddots & \vdots \\ \boldsymbol{h}_{M_T1} & \cdots & \boldsymbol{h}_{M_TM_R} \end{bmatrix} \tag{3}$$

where $\boldsymbol{h_{mn}}$ is the complex transmission coefficient from the element n at Transmitter to the element m at Receiver. In this case, the sampled vector signal model is given as

$$Y = HX + n \tag{4}$$

where Y is the received signal vector at the M_R receive antennas, X is the transmitted signal vector for the M_T transmit antennas, and n is the AWGN vector at the MR receive antennas. Without the channel state information (CSI) at the transmitter, the channel capacity of MIMO systems can be expressed by Winters (1987)

$$\boldsymbol{C} = \sum_{\boldsymbol{i}=1}^{r} \mathbf{log}_2 \left(1 + \frac{\boldsymbol{E_s}}{\boldsymbol{N_0 M_T}} \boldsymbol{\lambda_i} \right) \tag{5}$$

where r is the number of orthogonal subchannels (i.e., rank) and $\boldsymbol{\lambda_i}$s are the eigenvalues of the matrix HH^H (if $M_T < M_R$) or H^HH (if $M_T > M_R$). $(\bullet)^H$ denotes the conjugate transpose (or Hermitian) operator. Eq. 5 can reveal that the high data rate signal of a MIMO system is achieved by providing multiple streams between transmitters and receivers with the same operating frequency channel.

Multiple-Antenna Performance Evaluation

A multiple-antenna system can operate in diversity or MIMO schemes according to the SNR level in a rich scattering circumstance. If the SNR is low, the diversity can be applied to combat the fading. All antennas at the transmitter (or receiver) will send (or receive) the same signals over the same channel. Since the transmitting (or receiving) antennas are not correlated, the possibility for all antennas suffering to the fading deep would be low. So the reliability in the wireless link can be improved. In the high SNR region, the multiple antennas system will work as a MIMO scheme and utilize the fading to provide several uncorrelated channels. The different data can be simultaneously transmitted over different channels within the same operating frequency. As a result, the maximum data rate can be achieved. In this chapter, the figure of metrics for multiple-antenna systems will be addressed. This helps to evaluate the diversity and MIMO performances. Details of parameters for a single antenna (impedance bandwidth, gain, radiation pattern, efficiency, etc.) will not be discussed here but can be found in Balanis (2005).

Diversity Performance

Balanced Branch Power–Mean Effective Gain (MEG)

The imbalanced power of diversity branches will result in a diversity loss which is proportional to the imbalanced level (Plicanic et al. 2009). This imbalance will be affected by the total antenna efficiency. However, since the diversity will be used in any possible circumstances, so the antenna-channel mismatch also plays an important role. Therefore, the mean effective gain (MEG) is more desirable, in which it can

DOI 10.1007/978-981-4560-75-7_53-1

account for all effects of the total antenna efficiency, antenna gain, as well as wireless environment. MEG can be expressed by the following formula (Taga 1990):

$$\boldsymbol{MEG} = \oint\left(\frac{\boldsymbol{XPR}}{\boldsymbol{XPR}+1}\boldsymbol{G_\theta}(\Omega)\boldsymbol{P_\theta}(\Omega) + \frac{1}{\boldsymbol{XPR}+1}\boldsymbol{G_\phi}(\Omega)\boldsymbol{P_\phi}(\Omega)\right)\boldsymbol{d\Omega} \tag{6}$$

where $\boldsymbol{d\Omega} = \sin\boldsymbol{\theta d\theta d\phi}$, $\boldsymbol{G_\theta(\Omega)}$, and $\boldsymbol{G_\phi(\Omega)}$ are the $\boldsymbol{\theta}$ and ϕ components of the realized antenna gain pattern, respectively. It is noted that MEG should be normalized by antenna gains (Ogawa et al. 2001):

$$\oint\left(\boldsymbol{G_\theta}(\Omega) + \boldsymbol{G_\phi}(\Omega)\right)\boldsymbol{d\Omega} = 4\boldsymbol{\pi} \tag{7}$$

The statistical propagation properties of both vertically and horizontally polarized incident radio waves can be represented by $\boldsymbol{P_\theta(\Omega)}$ and $\boldsymbol{P_\phi(\Omega)}$. If $\boldsymbol{P_\theta(\Omega)}$ and $\boldsymbol{P_\phi(\Omega)}$ are separable in elevation and azimuth, they can be described as follows (Pedersen and Andersen 1999):

$$\boldsymbol{P_\theta}(\Omega) = \boldsymbol{P_\theta}(\boldsymbol{\theta},\phi) = \boldsymbol{P_\theta}(\boldsymbol{\theta})\boldsymbol{P_\theta}(\phi) \tag{8}$$

$$\boldsymbol{P_\phi}(\Omega) = \boldsymbol{P_\phi}(\boldsymbol{\theta},\phi) = \boldsymbol{P_\phi}(\boldsymbol{\theta})\boldsymbol{P_\phi}(\phi) \tag{9}$$

Also they satisfy the normalization relations

$$\oint\left(\boldsymbol{P_\theta}(\Omega)\right)\boldsymbol{d\Omega} = \oint\left(\boldsymbol{P_\phi}(\Omega)\right)\boldsymbol{d\Omega} = 1 \tag{10}$$

XPR (cross-polarization ratio) is the ratio of time average vertical $\boldsymbol{P_\theta(\Omega)}$ power to time average horizontal $\boldsymbol{P_\phi(\Omega)}$ power (Knudsen 2001):

$$\boldsymbol{XPR} = \frac{\boldsymbol{P_\theta}(\Omega)}{\boldsymbol{P_\phi}(\Omega)} \tag{11}$$

In an isotropic environment, it can be characterized by $XPR = 1$, $\boldsymbol{P_\theta}(\Omega) = \boldsymbol{P_\phi}(\Omega) = \frac{1}{4\boldsymbol{\pi}}$ (Kildal and Rosengren 2004), and $MEG = \boldsymbol{\eta}/2$, where $\boldsymbol{\eta}$ is the total antenna efficiency (Glazunov et al. 2009).

In order to obtain a good diversity performance, the multiple-antenna system should have balanced

$$MEG_{\text{antenna1}} \approx MEG_{\text{antenna2}} \tag{12}$$

Correlation

Correlation Coefficient Calculation from Radiation Pattern

The correlation of a multiple-antenna system is used to describe how independent across different antenna ports. The complex correlation coefficient has been given in Vaughan and Andersen (2003):

$$\boldsymbol{\rho_c} = \frac{\oint\left(\boldsymbol{XPR}\cdot\boldsymbol{E_{\theta X}}\boldsymbol{E^*_{\theta Y}}\boldsymbol{P_\theta} + \boldsymbol{E_{\phi X}}\boldsymbol{E^*_{\phi Y}}\boldsymbol{P_\phi}\right)\boldsymbol{d\Omega}}{\sqrt{\oint\left(\boldsymbol{XPR}\cdot\boldsymbol{E_{\theta X}}\boldsymbol{E^*_{\theta X}}\boldsymbol{P_\theta} + \boldsymbol{E_{\phi X}}\boldsymbol{E^*_{\phi X}}\boldsymbol{P_\phi}\right)\boldsymbol{d\Omega}\oint\left(\boldsymbol{XPR}\cdot\boldsymbol{E_{\theta Y}}\boldsymbol{E^*_{\theta Y}}\boldsymbol{P_\theta} + \boldsymbol{E_{\phi Y}}\boldsymbol{E^*_{\phi Y}}\boldsymbol{P_\phi}\right)\boldsymbol{d\Omega}}} \tag{13}$$

DOI 10.1007/978-981-4560-75-7_53-1

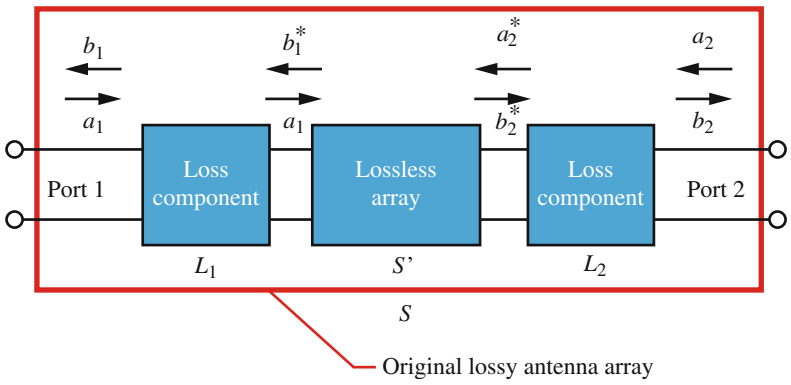

Fig. 1 Correlation coefficient calculation from S-parameters and radiation efficiency

where $\boldsymbol{E}_{\boldsymbol{\theta},\phi\mathbf{X}}$ and $\boldsymbol{E}_{\boldsymbol{\theta},\phi\boldsymbol{Y}}$ are the embedded, polarized complex electric field patterns of two antennas X and Y in a multiple-antenna system. In Rayleigh fading, the envelope correlation coefficient becomes $\boldsymbol{\rho_e} \approx |\boldsymbol{\rho_c}|^2$. The rule of thumb for good diversity/MIMO performance is $\boldsymbol{\rho_e} < 0.5$. From Eq. 13, it is shown that the correlation is also a parameter over certain wireless circumstances. In a real multiple-antenna system, the correlation can be affected by antenna element distance, directivity of antennas, ground plane (or chassis), Q factors, etc.

Correlation Coefficient Calculation from S-Parameters and Radiation Efficiency

In a lossless MIMO antenna system, the correlation coefficient can also be estimated from S-parameters (Blanch et al. 2003). Taking the radiation efficiency into account, the upper bound of the correlation can be calculated (Hallbjorner 2005) (Eq. 14). The authors in Li et al. (2013) use an equivalent circuit-based method to calculate correlation in lossy antenna arrays. The equivalent circuit is shown in Fig. 1, where a lossy component is introduced to simulate the loss. A more accurate estimation of the correlation can be obtained compared with the methods in Hallbjorner (2005) and Li et al. (2013).

$$|\rho_{ij}|_{\max} = \left| \frac{-S_{ii}^* S_{ij} - S_{ji}^* S_{jj}}{\sqrt{\left(1 - |S_{ii}|^2 - |S_{ji}|^2\right)\left(1 - |S_{jj}|^2 - |S_{ij}|^2\right)\eta_i \eta_j}} \right| + \sqrt{\left(\frac{1}{\eta_i} - 1\right)\left(\frac{1}{\eta_j} - 1\right)} \tag{14}$$

Diversity Gain

Diversity gain can be used to describe the gain enhancement of a multiple-antenna system in a combined signal over time-averaged SNR. The best antenna branch is selected as a reference antenna (Vaughan and Andersen 2003; Plicanic 2011), and then the diversity gain (DG) at the possibility $\boldsymbol{P}(\boldsymbol{r_c})$ can be expressed by Vaughan and Andersen (2003):

$$DG = \left. \frac{\left(\frac{\boldsymbol{r_c}}{\boldsymbol{\Gamma_c}}\right)}{\left(\frac{\boldsymbol{r}}{\boldsymbol{\Gamma}}\right)_{\text{Best branch}}} \right|_{\boldsymbol{P}(\boldsymbol{r_c})} \tag{15}$$

DOI 10.1007/978-981-4560-75-7_53-1

where r and r_c are instantaneous SNRs and Γ and Γ_c are mean SNRs for the combined and best antenna branch signals, respectively. Typically, the possibility $P(r_c)$ is 1 % or 50 %.

In general, the total efficiency of the best antenna branch in a compact multiple-antenna system is lower than that of a single-antenna system due to the mismatch, mutual coupling, and additional ohm loss. Effective diversity gain (EDG) is also commonly utilized to make the result more comprehensive (Kildal and Rosengren 2004):

$$EDG = \left.\frac{\left(\frac{r_c}{\Gamma_c}\right)}{\left(\frac{r}{\Gamma}\right)_{\text{Best branch}}}\right|_{P(r_c)} \cdot \eta_{\text{Best branch}} \tag{16}$$

where $\eta_{\text{Best branch}}$ is the total efficiency of the best antenna branch in a compact multiple-antenna system.

As DG and EDG give two extreme values, another parameter called actual diversity gain (ADG) is introduced to provide additional information in which it uses a real single-antenna system as reference (Plicanic 2011; Kildal and Rosengren 2004):

$$DG = \left.\frac{\left(\frac{r_c}{\Gamma_c}\right)}{\left(\frac{r}{\Gamma}\right)_{\text{Single antenna solution}}}\right|_{P(r_c)} \tag{17}$$

MIMO Performance

MIMO Capacity

In the section MIMO in Wireless Communications, it has already been discussed that without the channel state information (CSI) at the transmitter, the power will be equally allocated to the transmitter, and the channel capacity of MIMO systems can be expressed by Winters (1987):

$$\mathbf{C}_{\textbf{equal power}} = \sum_{\mathbf{i}=1}^{\mathbf{r}} \mathbf{log}_2\left(1 + \frac{E_s}{N_0 M_T}\lambda_i\right) \tag{18}$$

where r is the number of orthogonal subchannels (i.e., rank) and λ_is are the eigenvalues of the matrix HH^H (if $M_T < M_R$) or HH^H (if $M_T > M_R$). $(\bullet)^H$ denotes the conjugate transpose (or Hermitian) operator. If the CSI is available at the transmitter, the power allocation can be optimized by a water filling algorithm to the stronger subchannels rather than the weaker ones (Vaughan and Andersen 2003):

$$C_{\text{water filling}} = \sum_{i=1}^{r} \log_2(\lambda_i \cdot D) \tag{19}$$

and

$$D = \frac{1}{\lambda_i} + p_i \tag{20}$$

where D is the "water level" for each of the subchannels to be filled up to and $p_i = \mathbf{SNR}_i/\lambda_i$ is the input power to the i-th subchannel.

DOI 10.1007/978-981-4560-75-7_53-1

Multiplexing Efficiency

In order to evaluate the MIMO performance in a simple way, the multiplexing efficiency (ME) or $\eta_{\mathbf{mux}}$ is introduced according to Tian et al. (2011). *ME* is defined as the power penalty of a realistic multiple-antenna system in achieving a given capacity, compared to an ideal antenna system with 100 % total efficiency and zero correlation (Tian et al. 2011).

With the assumption of high SNR and isotropic environment (i.e., equal likelihood of impinging waves from any directions), *ME* can be expressed by Tian et al. (2011):

$$\eta_{\text{mux}} = \sqrt{\boldsymbol{\eta}_1 \boldsymbol{\eta}_2 \left(1 - |\boldsymbol{\rho}_c|^2\right)}, \tag{21}$$

where η_1 and η_2 are the total efficiencies of the MIMO antenna elements.

In a propagation channel with Gaussian distribution of the angle of arrival (AoA) given by Eq. 9 in Tian et al. (2011), the MIMO multiplexing efficiency can also be evaluated with the following assumptions: The mean incidence direction is denoted by ϕ_0 and $\boldsymbol{\theta}_0$ (as opposed to the isotropic channel, the likelihood of impinging waves is not the same in all directions but has a maximum at AoA ϕ_0 and $\boldsymbol{\theta}_0$). It is assumed that the angular spread is the same in both elevation and azimuth and approximately equal to 30°. The analysis is further restricted to channels with balanced polarizations, i.e., with cross-polarization ratio $XPR = 1$. For reference, two ideal cross-polarized antennas will give a zero correlation. Following the above conditions, the multiplexing efficiency is a function of the mean incidence direction:

$$\eta_{\text{mux}}(\phi_0, \boldsymbol{\theta}_0) = \sqrt{4\, \boldsymbol{MEG}_1(\boldsymbol{\theta}_0, \phi_0) \boldsymbol{MEG}_2(\boldsymbol{\theta}_0, \phi_0) \left(1 - |\boldsymbol{\rho}_c(\boldsymbol{\theta}_0, \phi_0)|^2\right)} \tag{22}$$

where $\boldsymbol{MEG}_1(\boldsymbol{\theta}_0, \phi_0)$ and $\boldsymbol{MEG}_2(\boldsymbol{\theta}_0, \phi_0)$ are the mean effective gains of each antenna port (Tian et al. 2012) and $\boldsymbol{\rho}_c(\phi_0, \boldsymbol{\theta}_0)$ is the complex envelope correlation of the received signal. This definition could be useful for evaluation of MIMO performance in massive MIMO and millimeter wave systems in the new-generation mobile system (Bentsson et al. 2015).

Discussion

From the introduction and analysis of metrics for multiple-antenna systems, it is found that the total efficiencies of antennas and the correlation between multiple antenna elements will affect both the diversity and MIMO performance. If the propagation channel environment is determined and the multiple antenna elements are symmetrical in a compact mobile terminal, a good diversity/MIMO performance can be achieved with high total antenna efficiencies and low correlation. In addition, multiple and wide impedance bandwidths of diversity/MIMO antenna elements are also important to make the compact terminal satisfy various standards and functions.

In a multiport antenna system, when only one port is fed and the others are terminated with 50-Ω load, the total efficiency can be evaluated by the following equations:

$$\boldsymbol{\eta}_{\text{total}} = \boldsymbol{\eta}_{\text{radiation}} \boldsymbol{\eta}_{\text{mismatching+coupling}} \tag{23}$$

$$\boldsymbol{\eta}_{\text{mismatching+coupling}} = 1 - |\boldsymbol{S_{ii}}|^2 - \sum_{\boldsymbol{j \neq i}} |\boldsymbol{S_{ji}}|^2 \tag{24}$$

where $\boldsymbol{\eta}_{\text{total}}$, $\boldsymbol{\eta}_{\text{radiation}}$, and $\boldsymbol{\eta}_{\text{mismatching+coupling}}$ are the total efficiency, radiation efficiency, and mismatch + mutual coupling efficiency, respectively. Subscripts *i, j* represent the working and terminated ports,

DOI 10.1007/978-981-4560-75-7_53-1

respectively. Mutual coupling ($\sum_{j\neq i}|S_{ji}|^2$) will also decrease total efficiency. Therefore, high efficiency and low correlation can be achieved by reducing mutual coupling between diversity/MIMO elements (Zhang et al. 2013a; Zhao et al. 2014). Typically, this method is effective when multiple antennas are operating at high frequencies (higher than 1700 MHz).

If the radiation efficiency is low in a multiple-antenna system, high losses in various forms are expected. Lower mutual coupling between antenna elements will not help to increase total efficiency. Mobile terminal MIMO/diversity antennas operating at low frequencies (less than 960 MHz) belong to this situation. In addition, the wavelength at low frequency band (700–960 MHz) is comparable with the mobile chassis size. The ground plane will become an effective radiator and make all MIMO/diversity elements have similar radiation patterns. This would degrade the multiple-antenna performance eventually. It is also noted that the low mutual coupling does not reflect the low correlation and high efficiencies in this situation.

In compact MIMO antenna design, the bandwidth requirement is one of key concerns. In fact, all antenna parameters such as antenna impedance matching, antenna efficiency, envelope correlation between antennas, diversity gain, and multiplexing efficiency have their own bandwidths. The single-antenna element bandwidth is mainly affected by the fundamental small antenna limits such as size, material loading, and Q value. However, in multiple-antenna cases, the operation bandwidth will also be affected by the size of the antenna system, antenna imbalance, and mutual coupling between the antenna elements. In the section "Performances of Certain Fundamental MIMO Antennas," the performance of several basic MIMO antennas will be discussed.

In addition, the interactions between multiple antennas and users will reduce the total efficiency of antennas by shifting resonant frequencies, and some of the radiated/received power is absorbed. The presence of human body will highly affect the correlations and efficiency in different situations (talking mode, data mode, or reading mode). More details will be discussed in the section "Multi-Antenna SAR and OTA Performance, Field Trial".

Performances of Certain Fundamental MIMO Antennas

Parallel Dipoles

Two dipole elements are placed parallel to each other and the resonant frequency set to be 850 MHz, The distance between two elements is 0.1λ, and the lengths of dipole antennas are $\lambda/6$, $\lambda/3$, and $\lambda/2$ (Fig. 2). The typically resonant length of a dipole antenna is $\lambda/2$, and thus matching networks have been added on $\lambda/3$ and $\lambda/6$ MIMO dipoles to adjust their resonant frequencies to 850 MHz.

Performances of parallel MIMO dipoles are shown in Fig. 3. Four different parameters including S-parameters, efficiencies (the radiation efficiency (RE) and the total efficiency (TE)), envelope correlation coefficient (ECC), and multiplex efficiency (MUX) are used to evaluate MIMO antenna performances. The impedance bandwidth of an antenna is generally defined with reflection coefficient S11 smaller than −6 dB. However, for MIMO applications, it is also needed to consider the bandwidth of total efficiency that the efficiency is larger than −4 dB, and the bandwidth of envelope correlation coefficient that the coefficient is smaller than 0.5. From Fig. 3a, it can be observed that larger antenna volumes are able to generate larger S11 bandwidths. Also, mutual couplings (S21) in larger antenna volumes are lower in general.

In Fig. 3b, smaller MIMO dipole antennas also have lower antenna efficiency; this is a combined effect from the strong mutual coupling and the matching network. Consequently, the total efficiency of $\lambda/6$ is always lower than −4 dB, and thus its efficiency bandwidth becomes zero.

DOI 10.1007/978-981-4560-75-7_53-1

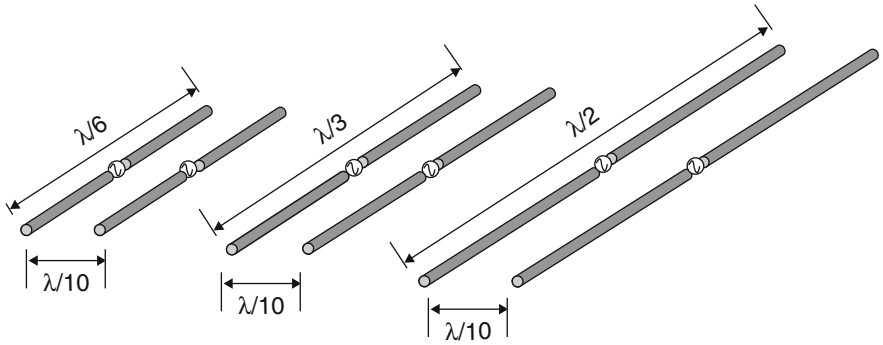

Fig. 2 Structures of fundamental MIMO dipole antennas

It is also noticed that smaller-volume MIMO dipoles have smaller ECC bandwidths. However, the smaller antenna volume leads to a lower ECC at center frequency (Fig. 3c). This is because a smaller-volume antenna always has higher Q value, which can increase the mutual scatter effect to decrease the ECC (Zhang et al. 2013a). Comparing to $\lambda/2$ MIMO dipoles, the MUX is also lower for $\lambda/3$ MIMO dipoles and $\lambda/6$ MIMO dipoles.

When the correlation of MIMO antennas is close to 1, dual-element MIMO antennas can be seen as a single antenna with a double volume. As a result, the efficiency of the antenna could be increased but the MUX remains low due to the high correlation. This phenomenon can be observed at 860 MHz of the $\lambda/6$ MIMO dipoles.

In Zhao et al. (2014) a comprehensive parameter to evaluate MIMO performance has been defined as the overlapping part of S11 bandwidth, TE bandwidth, and ECC bandwidth. The effective bandwidth is similar to MUX bandwidth but with stricter standards in general. Effective bandwidths of proposed MIMO dipole antennas are shown in Table 1. It is easy to notice that smaller-volume MIMO antennas (e.g., $\lambda/3$ MIMO dipoles and $\lambda/6$ MIMO dipoles) are able to achieve better performance at center frequency of certain parameters, but the effective bandwidth is always smaller than large-volume MIMO antennas (e.g., $\lambda/2$ MIMO dipoles). The trend of effective bandwidth coincides with MUX bandwidth but always smaller.

Cross Dipoles, Three Dipoles

Cross Dipoles

Two dipole elements are placed orthogonal to each other and their performances with different antenna volumes shown in Figs. 4 and 5, respectively.

The orthogonal MIMO dipole antennas can perform much better than the parallel dipole antennas. Results of S21 and ECC are omitted here as the two antenna elements are theoretically decoupled with each other and the value of S21 and ECC is too low. Therefore, the dual elements can be seen as two independent single antennas, and this antenna configuration can achieve a high diversity gain and large MIMO channel capacity.

As a result, the MUX bandwidth and the effective bandwidth of orthogonal arranged MIMO dipoles are much larger than parallel cases, which are shown in Table 2. These MIMO antennas perform like two single antennas because of the orthogonality. Their radiation efficiencies are high, but envelope correlation coefficients are extremely low. The effective bandwidth is mainly limited by the antenna volume.

Table 1 The effective bandwidth of parallel MIMO dipoles with matching networks

	λ/2 MIMO dipoles	λ/3 MIMO dipoles	λ/6 MIMO dipoles
S11 bandwidth (<−6 dB)	800–920 MHz	840–870 MHz	840–860 MHz
TE bandwidth (>−4 dB)	770–950 MHz	850–890 MHz	Null
ECC bandwidth (<0.5)	> 800 MHz	830–860 MHz	837–850 MHz
Effective bandwidth	800–920 MHz	850–860 MHz	Null

Three Dipoles

It has been suggested by Andrews et al. (2001) that, with three orthogonal components of electric fields and magnetic fields, it is possible to obtain six independent channels at a single point with full angular spread of paths over a sphere.

In Chiu et al. (2007a), it is reported that three-port orthogonally polarized antennas can be realized with dipoles or half-slot antennas. For example, tripolarized dipoles can be constructed by integrating three dipoles in which antenna elements are fabricated on FR4 epoxy boards. The overall size of each board is 51 mm × 51 mm × 1.6 mm. It should be noted that one of the dipoles needs to be offset from the intersecting point of other two dipoles, so that a slot can be cut for assembling (Fig. 6a).

The experiment results of the tripolarized dipoles show that all antennas are able to resonate at similar frequency of 2.5 GHz. The average mutual coupling between antenna elements is below −25 dB, except mutual coupling between *P*ort 2 and *P*ort 3 which is −18 dB. This is because dipole 2 and dipole 3 are constructed on the same FR4 board on the opposite side and there is a small overlap between the two dipoles in fabrication (balun is not shown in the figure).

Three Half-Slot Antennas

A half-slot antenna is shown in Fig. 7a in which it is fabricated on an FR4 epoxy board with an overall size of 22 mm × 27 mm × 1.6 mm. The half-slot antenna is evolved from a standard slot antenna with half-wavelength resonant length. For a standard slot antenna, its midpoint appears electrically open after being transformed by quarter-wavelength from the feed. Therefore, a half-slot antenna can be formed to operate at the same frequency as a normal slot antenna but with its length reduced by half. Tripolarized antennas can then be formed by integrating three of these half-slot antennas orthogonally, as illustrated in Fig. 7b.

DOI 10.1007/978-981-4560-75-7_53-1

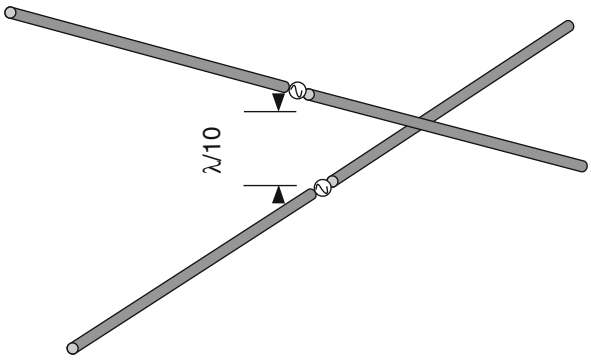

Fig. 4 The structure of orthogonal MIMO dipole antennas

Experimental results show that the worst-case mutual coupling at 2.58 GHz is −21 dB, although three antenna elements are closely packed together.

A system would have an ideal diversity performance if the signal correlation coefficients were zero and the mean received signal-to-noise ratios (SNRs) were equal (Vaughan and Anderson 1987). In case of a practical system using maximum ratio combining at the receiver, a condition for good diversity action is $\rho < 0.8$, where ρ is the signal correlation coefficient (Norklit et al. 2001). For practical antennas with nonideal radiation efficiency, the upper bound of the signal correlation coefficient can be obtained from Hallbjorner (2005), where $|\rho_{eij}|_{\max}$ is the upper bound of the signal correlation coefficient between antenna i and antenna j and η_i and η_j are the radiation efficiencies of antenna i and antenna j, respectively. From the previous expression, the maximum values of the signal correlation coefficients of the proposed antennas are computed using the measured data and the results summarized in Table 3. As seen from the table, the upper bounds of the correlation coefficients of the proposed antennas satisfy the criteria given in Norklit et al. (2001). Therefore, it can be concluded that both of the proposed antennas exhibit a good diversity performance.

Coground Monopoles

Monopole-type antennas are more popular in mobile terminal than dipole antennas because of its smaller resonant length and simple feeding structure. In this part, the MIMO performance of ideal dual-element $\lambda/4$ MIMO monopoles with center frequency around 850 MHz is studied. Radiating elements are mounted on a large round ground plane with radius larger than 2λ and the separation distance around 0.1λ, which are shown in Fig. 8.

The S-parameter, total efficiency, and envelope correlation coefficient of coground monopoles are plotted in Fig. 9. Due to the close placement, the mutual coupling is fairly high with this antenna configuration, and the total efficiency is less than −2 dB at the resonant frequency. Similar to those of parallel MIMO dipole antennas, the envelope correlation coefficient is mainly impacted by mutual scatter effects (Zhang et al. 2013a).

The effective bandwidth of illustrated MIMO monopoles is from 810 to 960 MHz, which is better than that of $\lambda/2$ parallel MIMO dipoles but worse than $\lambda/2$ orthogonal MIMO dipoles.

Decoupling Techniques of Compact MIMO Antenna Designs

In the sections "Neutralization Line," "Coupler Design," "Matching Network," and "Scatter Decoupling," coground dual-element $\lambda/4$ MIMO monopoles with different decoupling methods are

studied. The designed center frequency is around 850 MHz. A raw monopole structure has been presented in Fig. 9 for reference.

Neutralization Line

Neutralization line is a metal strip that connects two antennas at some points of radiating elements or feeding lines. The idea was first proposed for PIFAs in Chebihi et al. (2008). The use of neutralization line is to compensate the coupling between two elements. If the neutralization line is positioned in an appropriate way, it is possible to achieve good decoupling bandwidth while keeping the antennas matched. In this study, a strip is used to connect two monopole antennas and antenna structures illustrated in Fig. 10.

DOI 10.1007/978-981-4560-75-7_53-1

Table 3 Calculated signal correlation coefficient of tri-polarized dipoles and half-slot antennas

Port		Dipole	Half-slot
i	j	ρ_{eij}	ρ_{eij}
1	2	0.48	0.36
1	3	0.41	0.38
2	3	0.56	0.46

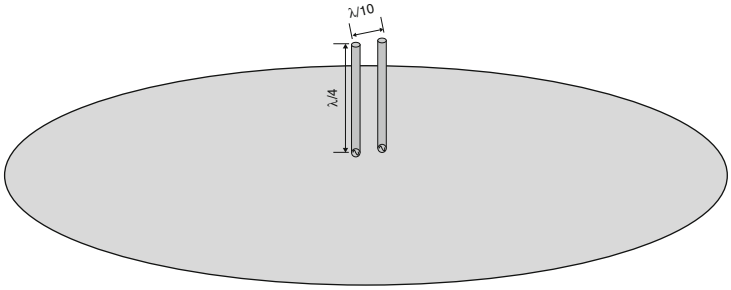

Fig. 8 The co-ground monopole antennas

As the decoupling element has to be inserted between two antennas, the separation of two radiating elements cannot be too small. However, the neutralization line can also be relocated from inner edges to outer edges of PIFAs as demonstrated in Diallo et al. (2008), such that antenna separation can be further reduced. The neutralization line method is also suitable for dual-band MIMO Wi-Fi antennas which are shown in Fig. 11. By changing the length of neutralization line, a proper decoupling frequency can be obtained. The simulation results which include a matching network are presented in Fig. 12.

Coupler Design

Hybrid coupler is a microwave component that divides power from one input to two outputs. There is a fourth port called isolated port which has no power to be delivered theoretically. The way of using hybrid coupler to decouple antennas is to connect antennas to the coupler's input and isolated ports, such that no coupling between two antennas is found ideally. In this example, a 90° hybrid coupler has been designed for operating at 859 MHz with 50 Ω characteristic impedance. The layout of the coupler and the corresponding antennas' S-parameters are shown in Fig. 13a, b, respectively.

Apart from 90° coupler, people can also use 180° coupler for antenna decoupling (Volmer et al. 2008). The 180° coupler can decompose a feeding signal into two orthogonal signals, normally referred to as "even" and "odd" modes, and thus generate a very deep and wideband decoupling. In fact, the coupler can be operated in two different ways. First, signals can be applied to either the sum port or the difference port, according to Fig. 14a. This will result in two equal parts appearing at ports 2 and 3 in phase or separated by 180°. The fourth port will then act as an isolated port. A second way of operating the coupler is to feed two separate signals into ports 2 and 3, in which signals will be adding up at the sum port and subtracting at the difference port. Decoupling antennas can be realized with the second way.

According to Fig. 14b, the coupling is relatively low, almost consistently below −20 dB for the entire simulated frequency span. This is also a direct consequence of the mode decomposition as two ports become orthogonal. The two signals will not influence each other in theory. Although perfect isolation is only strictly true for the center frequency, the decoupling effect is also achieved over a relatively large bandwidth.

DOI 10.1007/978-981-4560-75-7_53-1

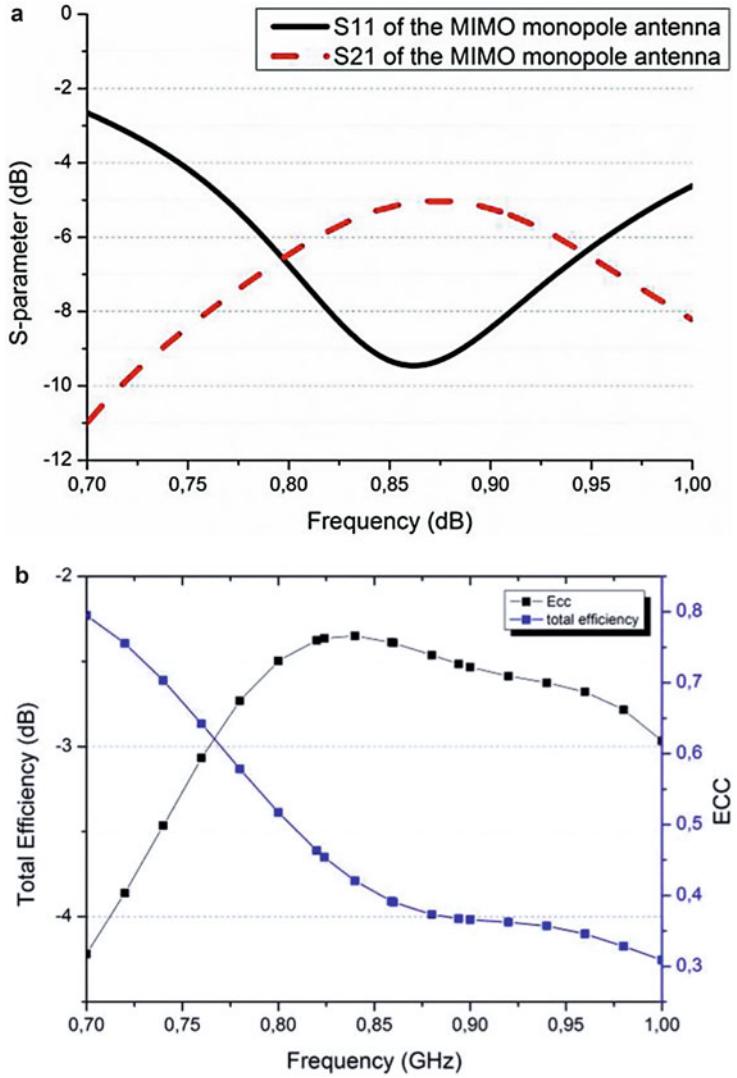

Fig. 9 (**a**) The S-parameters and (**b**) the total efficiency and envelope correlation coefficient of co-ground monopoles

Matching Network

In Pozar (2005), lumped component equivalent circuits for the 90° and 180° hybrid couplers are presented. Since these are much more compact than their distributed counterparts, it is interesting to see how well they would perform. The optimizations are carried out for both full bandwidth (824–894 MHz) and for the center frequency (859 MHz). However, only optimization for the center frequency could be found. The associated layout and S-parameters of the lumped component 90° hybrid coupler are found in Fig. 15a, b, respectively. For the 180° lumped component hybrid coupler, the layout and S-parameters are presented in Fig. 16a, b, respectively.

Scatter Decoupling

Implementing parasitic elements between two antennas is another way to reduce the mutual coupling and the correlation coefficient. The parasitic elements can act as a scatter and be formalized by chokes, parasitic stubs. In order to further reduce the mutual coupling, a new resonant mode was excited in Zhang et al. (2009a, 2010a). In Zhang et al. (2012a) a quarter-wavelength slot is excited by utilizing the edges of

DOI 10.1007/978-981-4560-75-7_53-1

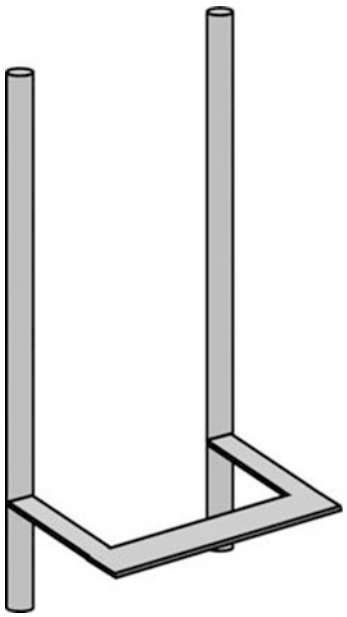

Fig. 10 The structure of neutralization line

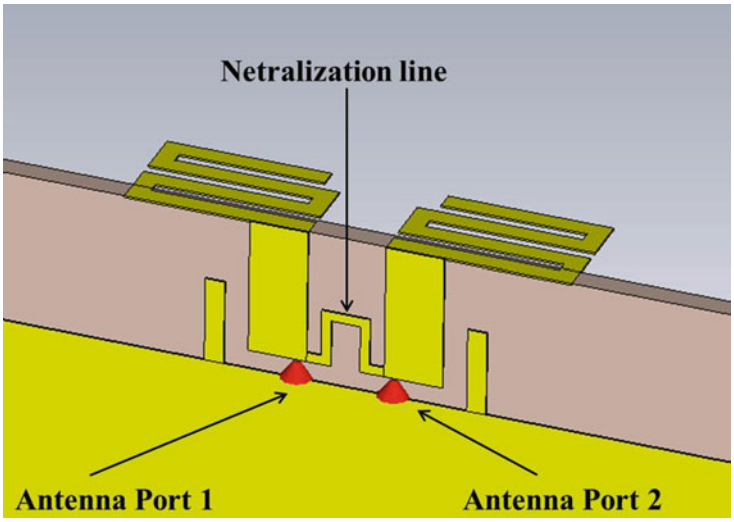

Fig. 11 The dual/multi band Wi-Fi antenna design with the decoupling neutralization line

two PIFAs. Another slot is cut on the ground plane in Ogawa et al. (2001) to form a half-wavelength U-shape slot in between. Apart from trapping the displacement coupling current between the antennas, the new mode in Zhang et al. (2010a) also traps the coupling current on the ground plane in the U-shape slot. Thus, the resonant mechanism of the slot effectively cuts off all coupling currents and allows an isolation of above 40 dB (in simulation) for an inter-PIFA spacing of 0.0016 wavelength. However, the methods in Zhang et al. (2009a, 2010b) cannot be utilized for a ground plane with arbitrary size and shape, (e.g., that of a mobile phone), because it may not be possible to match well enough the decoupling slots in these cases in order to excite them successfully. In Zhang et al. (2012a) a matching stub is added to make naturally formed decoupling slot matched on any kind of size and shape of the ground plane, as shown in

DOI 10.1007/978-981-4560-75-7_53-1

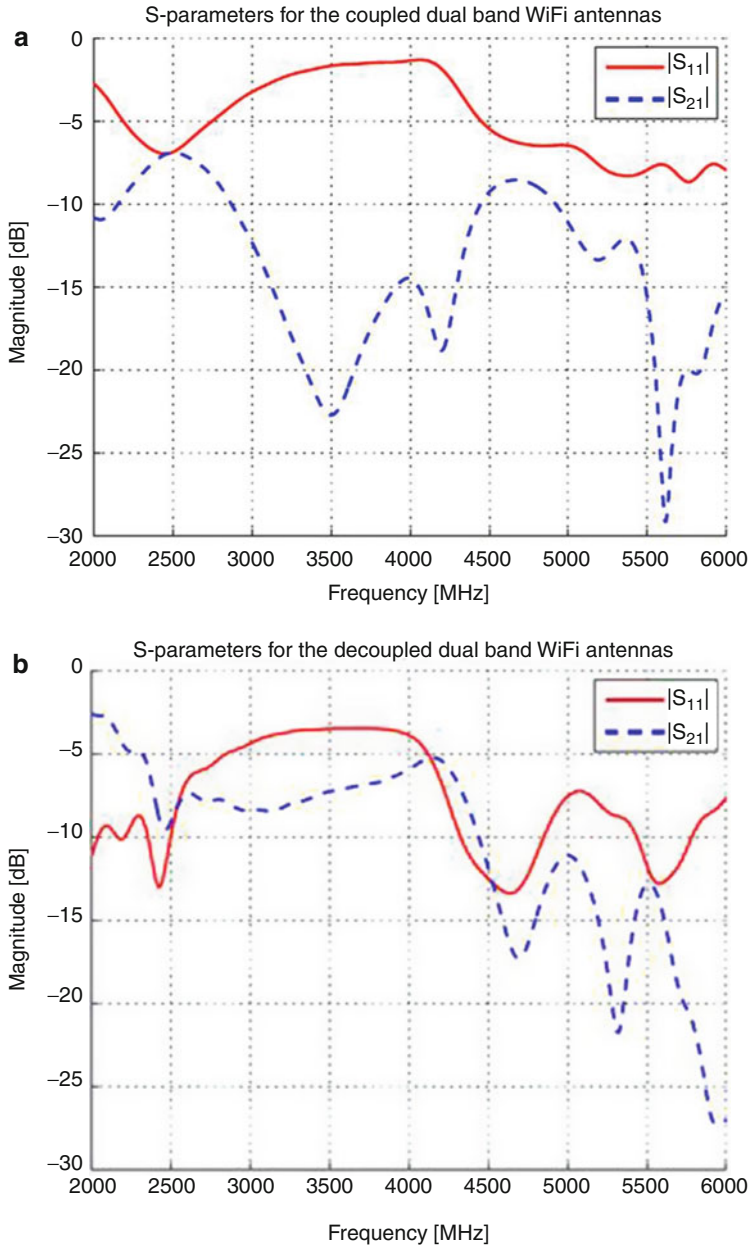

Fig. 12 (**a**) Coupled antennas S-parameters.and (**b**) decoupled antennas S-parameters

Fig. 17. In Chiu et al. (2013), a pair of parasitic stubs is added on sides of a mobile phone chassis to reduce mutual coupling of main and subcellular antenna, which is shown in Fig. 18. Furthermore, the decoupling element technique can also be used in UWB MIMO antennas in a USB dongle (Zhang et al. 2009b).

Ground Plane Modification

The previous technique was also combined with another method which consists in etching one or several thin slits in the PCB, not necessarily between radiators (Chiu et al. 2007b; Zhang et al. 2009) (Fig. 19). This technique can also be viewed as a modification to the shape of PCB ground plane. This physical modification forces the currents circulating on PCB to flow around the slits. In this way, the signal from one antenna port to another arrives with a suitable phase for overall signal cancellation. The same technique was used in Mavridis et al. (2006), Shin and Park (2007), and Chae et al. (2008) to address a

DOI 10.1007/978-981-4560-75-7_53-1

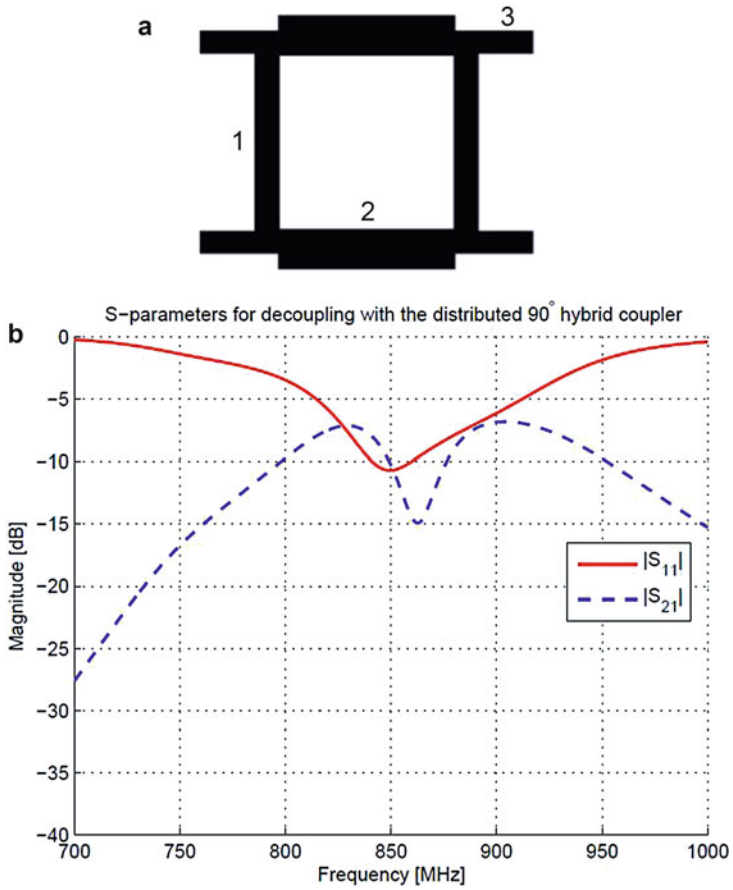

Fig. 13 The 90° hybrid couplers: (**a**) geometric layout, (**b**) S-parameters

dual-band 2.5/5 GHz case. Depending on the shape of the slot, this technique can be described in terms of N-section resonators (Kim and Ahn 2007). The authors of Chi et al. (2005) have made a protruding T-shape extension as a modification to the shape of PCB. Different and complicated extensions of PCB were presented in Liu et al. (2008)and Ding et al. (2007) to enhance the isolation between two or four monopole antennas for UMTS mobile phones. In some structures, the etched slots were even named (by the authors from RIM Blackberry and Sony-Ericsson) as the main radiators (Bolin et al. 2005; Rao and Wang 2009). Unfortunately, although the ground plane modification can achieve impressive broadband isolation enhancement between antenna elements, it may not be suitable for all real applications as every single square millimeter of PCB in smartphones nowadays is used for electronic component accommodation.

Orthogonal Mode Decoupling

Different polarizations have been applied in Tian et al. (2010) to design a very compact three-port dielectric resonant antenna (DRA) (see Fig. 20). The polarization and pattern diversity method was utilized in Zhang et al. (2009b) to realize wideband isolation for UWB MIMO antennas in a USB dongle. The designed MIMO antennas cover the UWB lower band of 3.1–5 GHz with isolation higher than 20 dB.

Another example is a pair of half-wavelength slot and narrow patch antennas stacked together to form a set of nearly collocated antennas with low mutual couplings which is shown in Fig. 21. In Chiu et al. (2009), it is reported that the antenna pair with an overall volume of $40 \times 30 \times 6.6$ mm^3 can exhibit mutual coupling better than -17 dB at around 2.5 GHz. The low mutual coupling between two

DOI 10.1007/978-981-4560-75-7_53-1

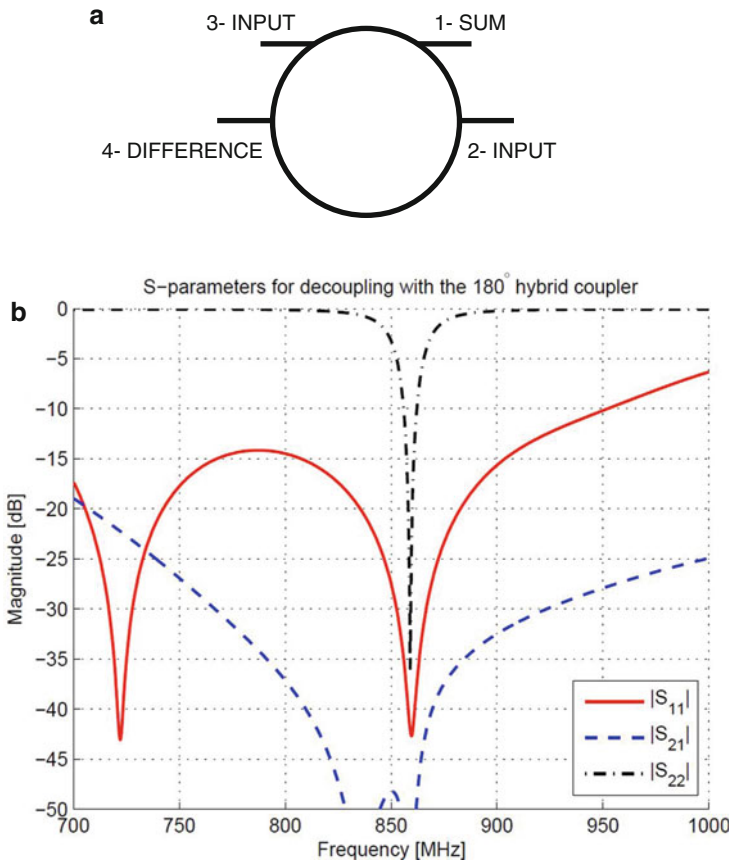

Fig. 14 The 180° hybrid coupler: (**a**) geometric layout, (**b**) S-parameters

closely packed antenna elements is due to orthogonal electric E- and magnetic H-fields received simultaneously. In fact, the idea can be further extended to exploit polarization diversity on each coordinate axis in which three pairs of half-wavelength slot and PIFA antennas are packed at a point in x, y, and z directions. This provides an example of how to realize a compact six-port antenna in which six radiating elements are at a point and are angularly spaced in the Cartesian directions.

Antenna Designs in LTE MIMO Applications

In current and future wireless telecommunication systems, such as LTE and LTE Advanced, MIMO systems are an integral part at mobile terminals. In the LTE standards, several new channels are allocated to the lower frequency bands of 700–960 MHz. As mentioned in the section "Decoupling Techniques of Compact MIMO Antenna Designs," the elements in a MIMO antenna system should have a low correlation and a high total efficiency in order to guarantee a good multiplexing MIMO performance. Unlike the higher frequency bands, the mobile handset MIMO antenna system operating at the lower frequencies will not focus on the reduction of mutual coupling but rather on the improvement of the correlation and efficiency explicitly due to the low radiation efficiency (Li et al. 2013). The wavelengths in the lower frequencies are much longer than those in the higher bands, and this poses some new challenges on the practical realization of having good MIMO performance in mobile terminals: (1) each MIMO antenna element has to be redesigned to obtain a compact structure fitting in the device; (2) the structures for decorrelation have to be small enough and still working well; (3) the MIMO elements and the

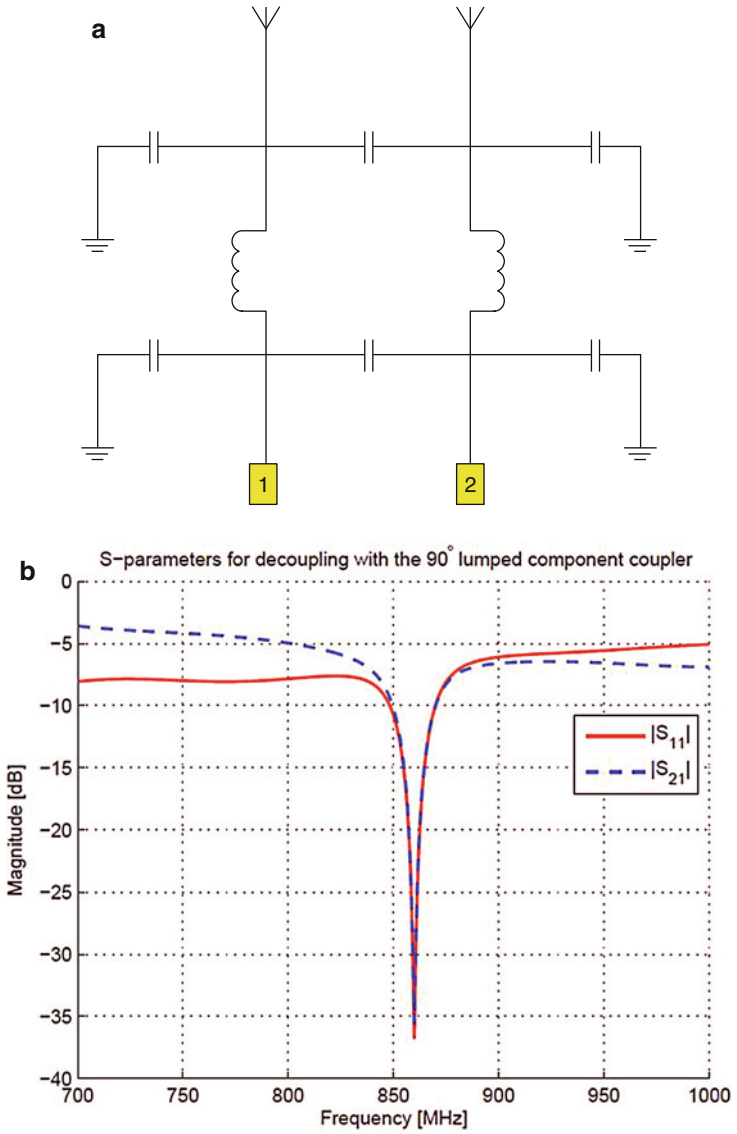

Fig. 15 (**a**) Antennas decoupled with the 90° hybrid coupler lumped component equivalent, (**b**) S-parameters

decorrelating structures are more closely positioned which cause high correlation and low efficiencies; and (4) the chassis mode will be efficiently excited, which makes the radiation pattern of each MIMO element quite similar leading to a very high correlation. An envelope correlation coefficient less than 0.5 and a total efficiency higher than 40 % are reference values for cellular LTE MIMO antennas in the lower bands according to industry researches, including field trials and mock-ups (Ying 2012). Recently, several studies have been done to solve these problems such as to use neutralization line for single-band LTE MIMO antennas in Bae et al. (2010), and Park et al. (2009) or to use decoupling networks for the lower bands in Park et al. (2011), Kim et al. (2011), andLau and Andersen (2012). However, these methods can only be used for very narrow band operations and will cause a large radiation efficiency reduction in practice. In the following, more technologies for correlation reduction and total efficiency improvement in low frequency bands will be reviewed (less than 1 GHz).

Chassis Mode and Orthogonal Chassis Mode MIMO Antennas

In Li et al. (2012b), the interactions between MIMO antennas and mobile chassis have been studied. The *E*-fields and *H*-fields of the fundamental mobile chassis characteristic mode are given in Fig. 22. The results reveal that the characteristic modes play an important role in determining the optimal placement of antennas. For example, if two electric antennas are put at the two ends of the mobile chassis, a very high mutual coupling between two antennas is expected.

In mobile terminals, the orthogonal mode MIMO antennas can be realized by combining an electrical antenna (dipole) and a magnetic antenna (slot, loop) (Li et al. 2012a), based on the analysis in Li et al. (2012a). The prototype of the designed orthogonal mode MIMO antennas is presented in Fig. 23 (Li et al. 2012a). A very low mutual coupling (<-20 dB) has been achieved in a narrow band of lower frequencies.

Localized Mode

In some cases, when two electrical MIMO antenna elements are used in a mobile terminal, a good diversity and decoupling performance can be achieved by exciting different modes for different antennas. For example, Antenna 1 is exciting in chassis mode, whereas Antenna 2 is exciting in localized mode (Li et al. 2011). Typical directive antennas like patch, notch, and balanced dipoles are good candidates to be excited in localized mode. In Fig. 24, it shows the current distributions of a PIFA with different dielectric permittivity. With a higher dielectric permittivity, the current distribution on the PIFA is more localized. The radiation patterns of localized mode antenna will be different compared to the chassis mode

DOI 10.1007/978-981-4560-75-7_53-1

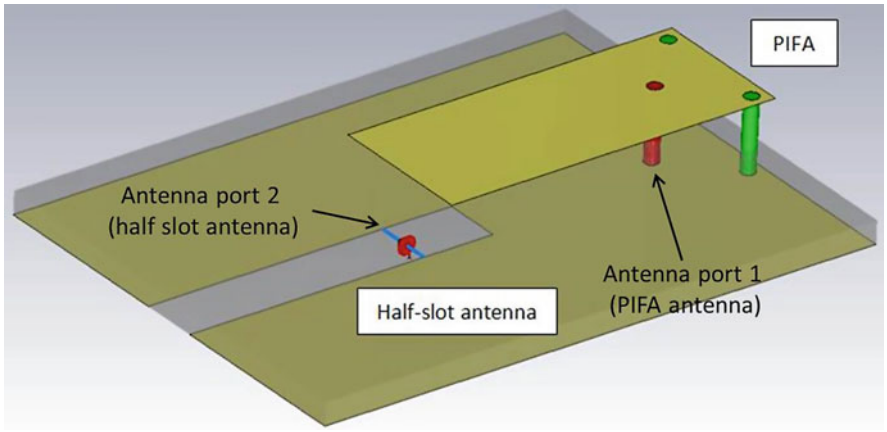

Fig. 21 Geometry of half-wavelength slot and PIFA antenna pair

antenna, thus the envelope correlation between the two antennas could be reduced. The trade-off of this design would be imbalanced MIMO antenna structures. In Li et al. (2011), current distribution with different permittivity of a MIMO antenna configuration has been given, and the impact of localized mode on MIMO performance have also been presented.

Mutual Scattering Mode and Diagonal Antenna-Chassis Mode for MIMO Bandwidth Enhancement

In order to realize a correlation less than 0.5 and total efficiency higher than −4 dB in a wideband operation of low frequency bands, mutual scattering mode (Zhang et al. 2012b, 2013a) and diagonal

DOI 10.1007/978-981-4560-75-7_53-1

antenna-chassis mode (Zhang et al. 2012c, 2013b, 2015a) were proposed for MIMO bandwidth enhancement.

For closely located MIMO antennas, the strong mutual scattering effect can be used to reduce correlation coefficient of the MIMO antenna effectively (Zhang et al. 2012a, b). In general, MIMO antennas with high Q values will have strong mutual scattering effect, in which this can be realized by optimizing impedance matching with lumped elements. In Fig. 25, it is revealed that when two antennas are put in the same end of the mobile terminal, higher Q factor could provide a lower correlation with an improved total efficiency. In addition, a MIMO reference antenna based on the mutual scattering mode had been proposed in Zhang et al. (2013b) for OTA applications.

To combine with a diagonal chassis mode, a better pattern diversity can be achieved in the low LTE band (less than 1 GHz) (Zhang et al. 2012c, 2013b, 2015a). When a terminal antenna operates at low frequency, the antenna element and the ground plane can be seen as two arms of a dipole antenna. Thus, the direction of the radiation pattern of this dipole antenna will be mainly determined by the current distribution on the ground plane. This can be concluded as a fact that the volume of ground plane is much larger than the antenna element. The diagonal chassis mode can be realized by putting the two antenna ports of dual-element MIMO antennas to different corners of the ground plane. As a result, the two MIMO elements can form two orthogonal dipole-like radiation patterns. In Figs. 26 and 27, it can be seen that colocated MIMO antennas have almost opposite patterns due to the effect of diagonal chassis mode.

Decorrelation Scatterer Design

Another common practice of realizing two cellular antennas in an LTE terminal is that a main antenna situates at the bottom, whereas a subantenna locates at the top of the phone. In Zhang et al. (2014), it is reported that envelope correlation can be reduced from 0.7 to 0.2 at 750 MHz after inserting scatterers. Dual-frequency operations are also possible if two scatterers are introduced on different sides of a phone chassis as depicted in Fig. 28. The associated resonant frequencies can be adjusted independently. In general, the two conformal scatterers could be printed either outside or inside of phone housing with groundings to the main PCB. It should be noted that as the scatterer can be thought as a kind of radiator, the far more away from ground plane helps enhance operating frequency bandwidth. However, hand effects are also needed to be considered in real applications.

Inserting a scatterer between two closely packed antennas can improve the isolation because an additional coupling path has been artificially created in which field cancellation occurs and consequently lowers the corresponding envelope correlation. In addition, it should be noted that according to Booker's relation (Chiu et al. 2013), dipole and slot antenna are complementary elements in terms of electromagnetism. Therefore, the scatterer design is also suitable for metallic chassis phone to lower envelope correlation in such a way that a similar slot structure is etched on the housing.

Ring Antenna and Less Body Sensitive Antenna

In Zhao et al. (2015), as the human body is insensitive to magnetic fields, the author proposed a novel mobile terminal antenna named as double-ring antenna, which is mainly working on magnetic loop mode (Fig. 29). The loop mode is enclosed by the ground plane in which ring 1 is going along the grounding element and the feed line of port 1 (follow the black line in Fig. 30a). As port 2 uses C-fed, the current is not cut off by the feeding line but is enclosed between two groundings (follow the black line in Fig. 30b). Furthermore, it can be seen that loop modes are enclosed by grounding elements, which are as isolators between the two cellular antennas. Based on this method, it is possible to integrate even more ports with a larger perimeter of a metal ring. Another advantage of using ring antenna for MIMO is the low correlation between two slot antennas.

DOI 10.1007/978-981-4560-75-7_53-1

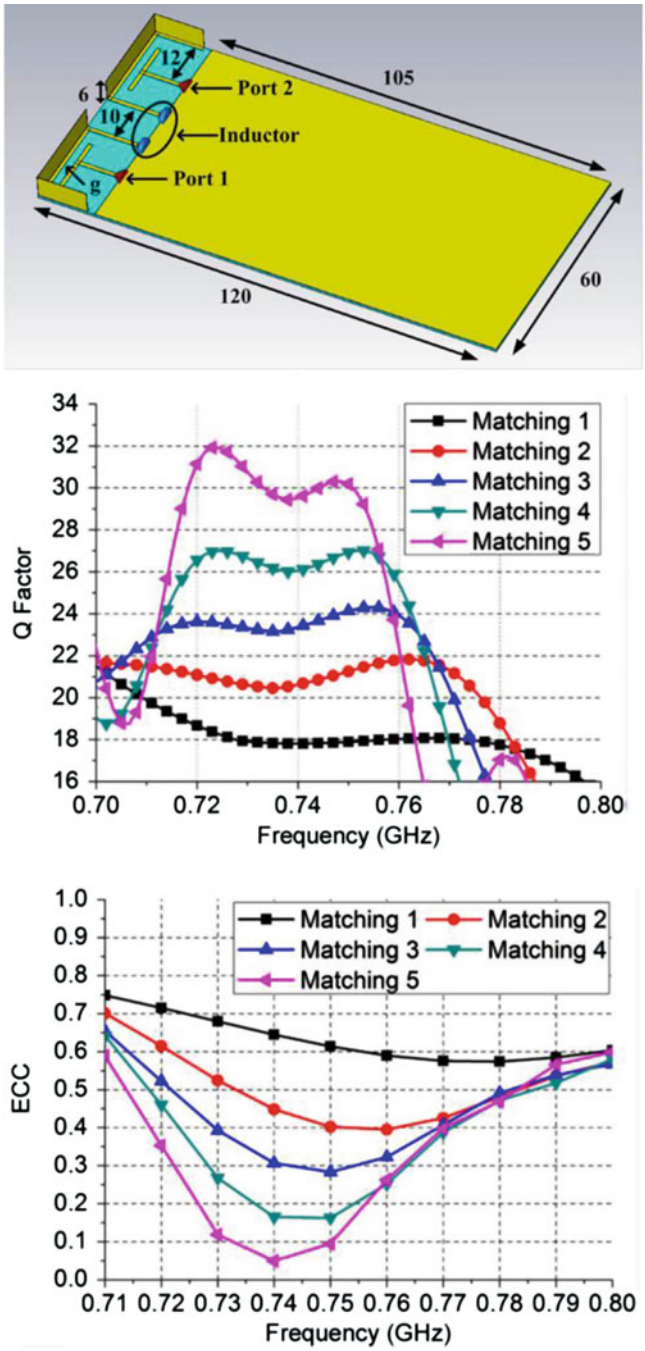

Fig. 25 Mutual scattering mode in mobile terminals

The double-ring antennas are measured with a real human (see Fig. 31a). The comparison of single hand effects on S-parameters between the double-ring antenna and a conventional design are shown in Fig. 31b. The average total efficiency loss on the single hand is presented in Table 4. All results show that the double-ring antenna is able to maintain relatively high total efficiencies in user case when compared to other conventional MIMO antennas in mobile terminals.

Multiantenna SAR and OTA Performance, Field Trial

Body Effects on Compact MIMO Antennas in Mobile Terminals

The radiation performance of MIMO antennas in mobile terminals including user effects is another important issue. Test regulations for mobile terminals in the user case have been developed or are ongoing. The Cellular Telecommunications and Internet Association (CTIA)/The Wireless Association is a United States-based international organization that serves the interests of the wireless industry by lobbying government agencies and assists with regulation settings (CTIA 2011). Up to date, two user cases have been defined by CTIA in the OTA test of mobile terminals, which are the talking mode (head + hand) and the data mode (single hand) shown in Fig. 32.

For user case, both correlation coefficient and total efficiencies of MIMO terminal antennas are low in general. The substantial loss of total efficiency is mainly due to the mismatching and reduction of the radiation efficiency of the antenna (body absorption). The mismatching can be solved by tuning the operating frequency of the antenna with lumped elements, but the drop of the radiation efficiency is not easy to be compromised. Generally, the efficiency loss is related to the antenna volume, antenna type, and terminal volume. Larger antenna and terminal volume will be helpful to reduce the efficiency loss, and magnetic antennas (loop, slot) suffer less efficiency loss than electric antennas (IFA, PIFA, etc.).

DOI 10.1007/978-981-4560-75-7_53-1

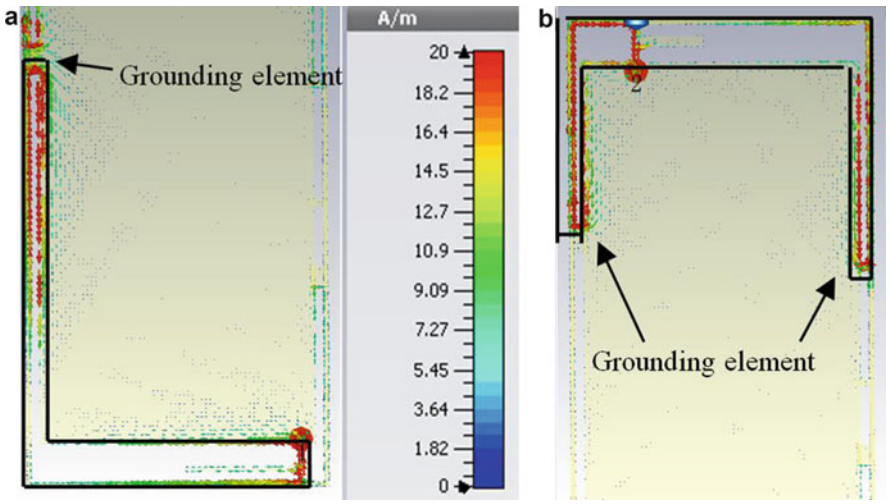

Fig. 30 Current distribution of (**a**) Port 1 at 880 MHz and (**b**) Port 2 at 880 MHz

The correlation coefficient becomes low due to body scattering and shadowing. For a good MIMO reception, the body effect to antenna performance is a main concern.

The efficiency loss of MIMO terminal antennas depends on several factors, including antenna locations, operation frequencies, phone size, etc. (Zhao et al. 2013a; Zhang et al. 2013c, 2015b), as shown in Fig. 33. Several methods have been proposed against the body loss in MIMO terminal antennas. In Zhao et al. (2013), by introducing a small space between human body and antenna, the hand-effect body loss for LTE mobile antenna can be reduced significantly in CTIA talking and data modes. In Zhang et al. (2015b), an adaptive quad element MIMO antenna array is designed (Fig. 34). The body loss can be optimized and the MIMO performance enhanced by selecting the best two elements out of four when the terminal is held by users.

Multitransmitter SAR Problem

Due to the extensive spread of mobile handsets, the radiation of mobile phones has rapidly been given increased attention. The radiation can be evaluated by SAR, which represents the time rate of microwave energy absorption inside the tissue.

$$\mathrm{SAR} = \frac{\sigma}{2\rho} E^2 \tag{25}$$

where σ and ρ are the electrical conductivity (S/m) and mass density (kg/m^3) of the tissue, respectively, and E is the internal induced electrical field (V/m). The SAR value of a mobile terminal is strictly limited by governments, which makes this parameter important to mobile antenna designs. There are two standards of SAR: In Europe, the limitation of SAR is set to be 2.0 W/kg over a 10-g cube by International Commission on Non-Ionizing Radiation Protection (ICNIRP) (ICNRP 1998); in the United States, the Federal Communication Commission (2008) set the limitation to be 1.6 W/kg over a 1-g cube (FCC 2008). The SAR value needs to be measured on Specific Anthropomorphic Mannequin (SAM) head phantom and flat phantom (Fig. 34), for the talking case and the body worn case, respectively.

For MIMO antennas, the evaluation of SAR becomes more complicated. Only the stand-alone SAR is not sufficient to evaluate SAR performances of MIMO antennas. The simultaneous SAR is required when multiple antennas are transmitting simultaneously, which needs to add up SAR fields of the two ports and calculate the combined peak SAR value.

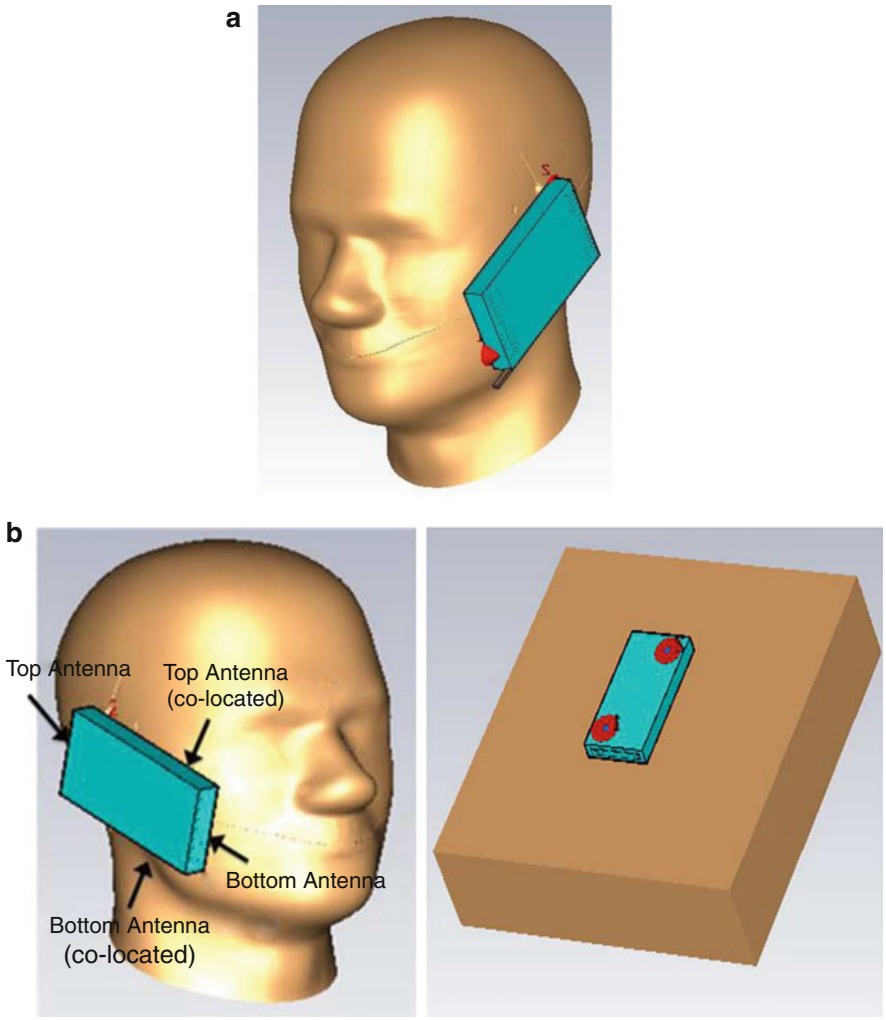

Fig. 34 SAR test positions: (**a**) SAM head phantom and (**b**) flat phantom

In order to simplify the SAR evaluation of MIMO antenna in mobile terminal, the value of SAR to PEAK location spacing ratio (SPLSR) is defined by FCC (2008):

$$\mathrm{SPLSR} = \frac{(\mathrm{SAR1} + \mathrm{SAR2})}{D} \tag{26}$$

where SAR1 and SAR2 are SAR values (W/kg) of elements 1 and 2, respectively, and D is the separation distance (cm) of the two SAR peaks, as illustrated in Fig. 35.

Subject to FCC standard, simultaneous SAR measurement of a phone is not necessary if the SPLSR is smaller than 1.6 (FCC 2008). From Eq. 26, it is clear that the length of ground plane plays an important role for simultaneous SAR. On the one hand, a proper ground plane length can excite the chassis mode, which will reduce the peak value of stand-alone SAR; on the other hand, the strong chassis mode could reduce the separation distance between the two SAR peaks due to the peak position of SAR moving the center of the ground plane, which could enhance simultaneous SAR (FCC 2008). Apart from the ground plane length, antenna types also have great impacts on SAR value, as shown in Fig. 36. From the engineering point of view, a ground free antenna is always (with high SAR) located at the bottom of the phone, whereas an on-ground antenna (with low SAR) will be put to the top of the phone to reduce

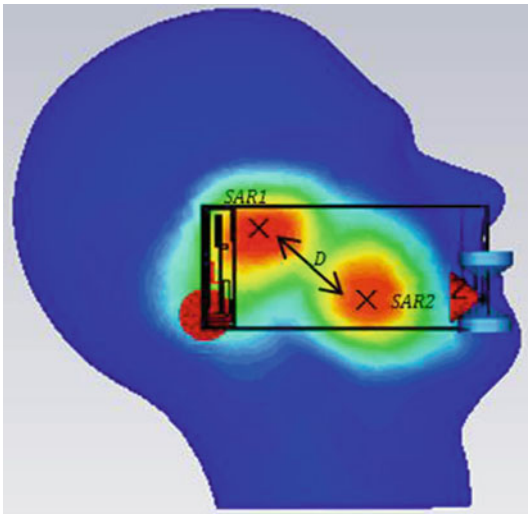

Fig. 35 The illustration of the value of SAR to PEAK location spacing ratio (SPLSR)

correlation. The head phantom can be measured through DASY system and a flat phantom SAR can be measured with iSAR system in Fig. 37. The comparison between simulated and measured SAR (dB) distribution (dB) for semi-ground-free PIFA at 10 mm above the flat phantom is presented in Fig. 38 (Zhao et al. 2013b).

LTE Field Trial at 700 MHz Band with Different MIMO Antenna Designs

For an LTE MIMO terminal, both mean effective gain and correlation will determine the MIMO throughput performance. In a typical smartphone, antennas usually have relatively low correlation for frequency bands around 2 GHz and above. So the main effort to realize a good MIMO performance is to design high efficient antennas with less coupling loss at those frequency ranges which have been discussed in the section "Decoupling Techniques of Compact MIMO Antenna Designs." However, it is quite a big challenge to design low-correlation and low-coupling MIMO antennas at low frequency bands, especially at 700 MHz band. Some detailed mock-ups in different correlation level were built and tested in Sony Mobile research laboratory and field trial with Ericsson Research. Figure 39 shows four different MIMO antenna designs for typical smartphones at 700 MHz band. Design (a) has two monopoles at top and bottom ends; the chassis mode is strong and thus the correlation is relatively high. Design (b) composes a monopole and a notch in which the two antennas are orthogonally arranged to each other. So the correlation is low in this case. Design (c) has colocated loop antenna, where one antenna element is fed by two ports. This is on-purpose design to have a very high correlation. Design (d) consists of one chassis mode monopole and one localized mode patch antenna, and it is found that the correlation is extremely low. The mock-ups were tested and characterized in Sony Mobile laboratory; the performances are summarized in Table 5 (Fig. 40).

Compared to the performance of reference antennas (separated orthogonal dipoles), it is found that a compact MIMO antenna arrangement could also have a fairly good MIMO performance. The envelope correlation can be less than 0.5 even at 700 MHz band. Good antenna efficiency of both antennas is essential to cover larger service area of LTE with good data communication quality (Hagerman et al. 2011). In user case, the human body loading and absorption are the main impacts on the mean effective gain which determine the good data rate coverage service area; the correlation are generally low in user cases (Hagerman et al. 2011; Derneryd and Ying 2010).

Summary

In this chapter, certain basic parameters characterizing the diversity and MIMO antennas have been discussed. Several fundamental MIMO antennas' performance and useful decoupling techniques were presented. In addition, recent advanced technologies for compact MIMO antennas particularly for portable devices and mobile terminals were also reviewed. The interactions between MIMO antennas and human body and the multiple radio SAR problems are important for mobile industry. It is demonstrated that the antenna impact could be addressed in an LTE MIMO field trial at 700 MHz.

Abstract

This chapter provides a broad discussion on the progress in low-profile antenna design and their applications. The antennas are divided broadly into dipole-based antenna designs, slot antennas, loop antennas, and microstrip patch antennas. In addition to the basic concepts, a literature review that outlines state-of-the-art designs along with recent trends in this field is incorporated. The objective of these discussions is to enrich the readers with conceptual knowledge in this marvelous field of engineering.

Keywords

Dipole antenna; Low-profile antenna; Compact antenna; PIFA; Loop antenna; Microstrip antenna; Printed strip dipole; Slot fed antenna; Open sleeve dipole

Introduction

In this modern era, the world is experiencing a huge technological wisdom in almost every phase of life. The developments in interdisciplinary areas of science and engineering have synergistically produced powerful tools for various applications. The magnificent field of wireless communications is not an exception; it has undergone drastic developments that resulted in a broad line of products ranging from a wireless keyboard to complex space shuttles with sophisticated communication modules. One of the outstanding revolutions in this century is the advancements in the field of wireless communication, introducing smart phones and tablet computers which are integrated with plenty of services. These handheld devices incorporate various wireless communication components that are manyfold complex in design compared to their one-decade-ago versions. The thrust of human civilization to exchange data without boundaries made further progress in this amazing field of technology. This has led most of the information technology industries to invest in wireless communication systems. For example, Apple Inc. and Google Inc. opened several research and development centers for hardware development. These advancements have resulted in huge expansion of the world of wireless communication, where most devices we meet in our day-to-day life are equipped with one or other form of wireless communication units.

In an antenna engineer's perspective, the antenna design strategies have considerably changed for the last three decades. The huge expansion of the wireless communication sector produced modern systems which require advanced low-profile antennas for newly evolved systems. One of the key differentiating facts is the integration of various communication segments to the modern mobile phones. This made them more advanced than the traditional voice communication systems. This requires careful integration of

multiple low-profile antennas in contrast to the single RF module design in the old-generation handsets. For example, the antennas employed in current smartphones and tablet computers, such as Apple iPhone® or Google Nexus®, are manyfold advanced compared to the sleeve dipole antenna used in the first commercial handheld cellular phone, Motorola Dyna TAC 8000×, introduced in 1983 (Motorola DynaTAC). Apart from smartphones, the wireless communication sector has been enriched with numerous types of systems. Some of them are smartwatches, near-field communication (NFC) devices, chipless RFID, wearable systems, medical sensors, and so forth. These complex systems introduce a broad range of low-profile antenna design challenges that need to be solved without degrading the overall system performance. For example, modern communication units need to comply with rigorous specifications, such as specific absorption ratio (SAR), in order to pass the regulations put by various governing authorities. This chapter address four important categories of low-profile antennas, based on their fundamental working concepts, state-of-the-art designs, and recent trends. This includes dipole-based designs, slot antenna designs, loop antennas, and microstrip patch-based low-profile antennas (Fig. 1).

The Terminologies: Low-Profile Antennas and Electrically Small Antennas

- **Low-Profile Antennas:** The Oxford Dictionary defines the word profile as "a vertical cross section of a structure." Thus, it is quite straightforward to define the low-profile antenna as the one with relatively small vertical cross section. One of the earlier definitions for low-profile antennas is found in Stutzman and Davis (1998) defines as "Antennas of small physical thickness." This terminology has evolved through many years and is used to represent antennas with relatively small physical cross-sectional area with respect to the wavelength (λ) in which it operates. Some of the well-known low-profile antennas

DOI 10.1007/978-981-4560-75-7_55-1

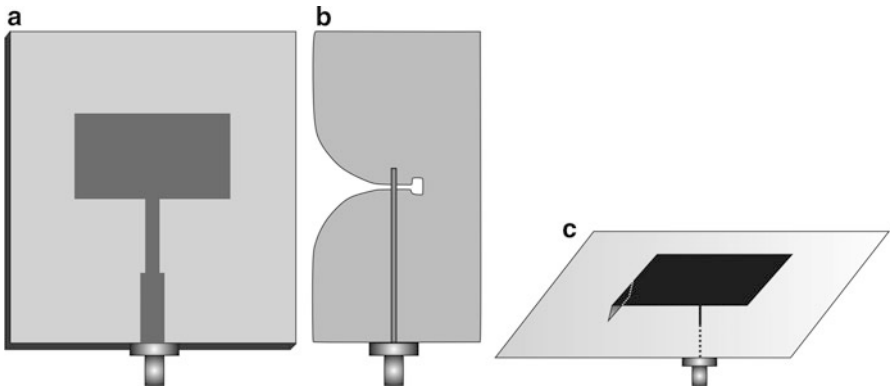

Fig. 2 Classical low-profile antennas (**a**) Microstrip patch antenna, (**b**) Tapered slot antenna (**c**) Planar Inverted F Antenna (PIFA)

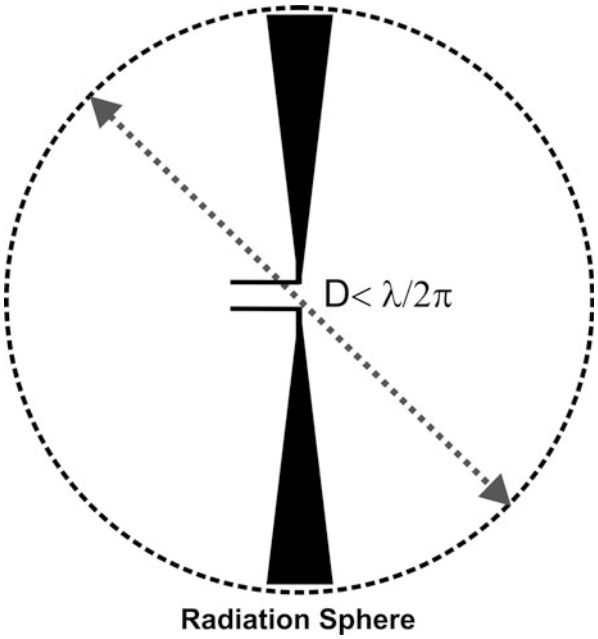

Fig. 3 Electrically small antenna definition based on Wheeler (1947)

are microstrip patch antennas, planar inverted-F antennas (PIFA), slot antennas, and loop antennas. Some classical low-profile antennas are illustrated in Fig. 2.

- **Electrically Small Antennas (ESAs):** The electrically small antennas (ESAs) were often being confused with low-profile antennas. Even though there are low-profile antennas that are electrically small, all low-profile antennas do not come under the definition of electrically small antennas. A widely adopted definition is by Harold Wheeler in his 1947 paper (Wheeler 1947). This defines ESA as an antenna that could be enclosed within a sphere of radius $r = \lambda/2\pi = 0.0796\lambda$ called the radiation sphere as shown in Fig. 3. The IEEEE standard definition of terms for antennas ("IEEE Standard Definitions of Terms for Antennas" 1993) defines electrically small antenna as "An antenna whose dimensions are such that it can be contained within a sphere whose diameter is small compared to a wavelength at the frequency of operation." These definitions indicate that electrically small antennas are not necessarily physically small. In fact, some of the historical antennas used by Marconi in the early stages of wireless

DOI 10.1007/978-981-4560-75-7_55-1

communication (1890s) were electrically small. The classical ESA is a variant of reactively loaded dipoles, loop antennas fabricated on special core material, and dielectric resonator antennas.

As a concluding remark about the terminologies, it is important to note that "low-profile" is a comparative term and the boundary between electrically small antennas and low-profile antennas is quite tough to draw. On the other hand, the electrically small antennas are clearly defined as the ones that are smaller than a radian sphere. Thus, all low-profile antennas are not necessarily electrically small antennas. This chapter discusses various low-profile antennas in which some of them can meet the standard definition of electrically small antennas as well.

Why Low-Profile Antennas Are Important?

Historical Perspective: The significance of low-profile antennas is recognized from the very beginning of the communication era, where antennas were one of the huge structures that needs to be deployed in a limited space. The invention of vacuum tubes and other relatively high power sources enabled earlier researchers to extend the technology by developing more compact antenna systems. Around the 1930s various techniques, such as magnetic material loaded antennas and slot antennas, were implemented and available for practical use. This resulted in the invention of various electrically small antennas, such as helical antennas, and microstrip patch antennas. The decades following this period, several antenna designs attracted various researchers around the globe who are working on the development of low-profile antennas and electrically small antennas (Fujimoto 1987). Some of the initial applications of this technology were the radio communication systems installed in vehicles traveling on the ground. The special situations during World Wars I and II accelerated the research in the development of antennas that are more compact and low profile. The end of the twentieth century witnessed extreme developments in the field of mobile communication which further made progress in the development of low-profile antennas. In this era, the severe increase in the demand for small and low-profile antennas was mainly because of advancements in various interdisciplinary areas of science and engineering that resulted in a system-level shrinking for almost every type of wireless communication devices. Few of the key examples include wireless communication systems such as tablet computers and smartphones. Today, consumer market also provides various wireless communication accessories for these new-generation communication devices.

Importance and design challenges: The integrated circuits inside a wireless communication equipment become highly dense in accordance with Moore's law; meanwhile the reduction in antenna size is relatively less (Schaller 1997). This is due to the fact that the size of electronic chips is based on fabrication techniques; meanwhile, the antenna size is based on the fundamental principles of physics. One of the immediate consequences of reducing the antenna size is the drop in system efficiency or bandwidth. Thus, the quest of industries to produce electrically small antennas despite this fundamental barrier makes this research field highly challenging and significantly attractive.

Design Fundamentals and Limitations

In this section, typical design strategies of various low-profile antennas are outlined along with few fundamental limitations of implementing them.

Miniaturization Techniques

Various miniaturization techniques have been employed in antenna design to develop low-profile and electrically small antennas. Most of these techniques focus on exciting fundamental resonant mode by

DOI 10.1007/978-981-4560-75-7_55-1

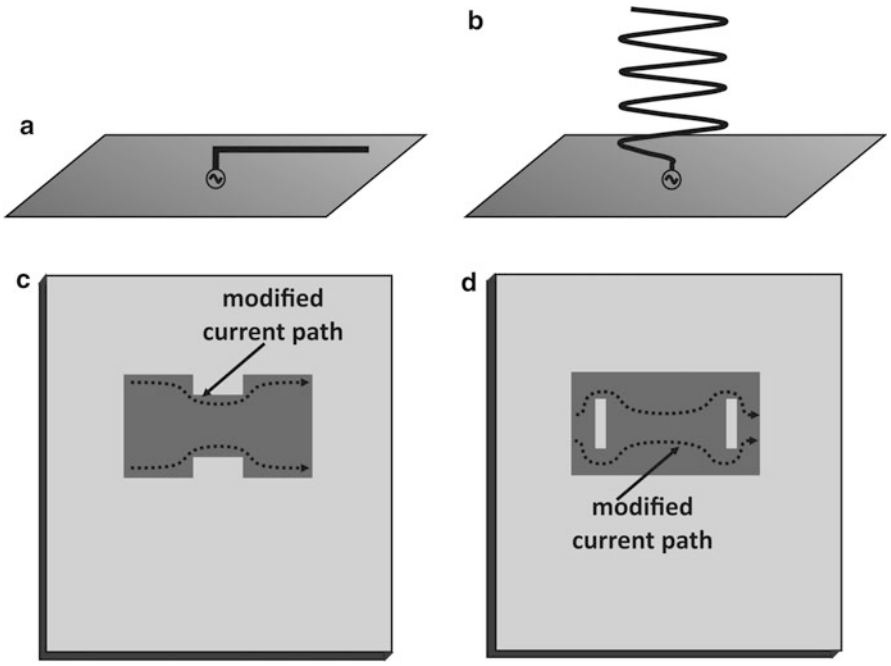

Fig. 4 Modification of resonant length in classical antennas for miniaturization (**a**) inverted L antenna (**b**) helical antenna (**c**–**d**) microstrip patch loaded with slots

incorporating some elements that help to overcome some of the structural limitations of classical antennas such as dipoles and microstrip patch antennas.

- ***Modification of Resonant Length***: This is one of the commonly employed miniaturization techniques to modify the antenna profile. In this technique, the current path is altered in such a way that it is longer than the direct distance between two points that conform the antenna structure. Design examples include inverted-L antenna, helical antenna, and slot loaded microstrip patch, as depicted in Fig. 4. Even though this provides miniaturization, extreme care must be taken during the design process to avoid cancellation of fields due to the surface currents in the opposite direction, which otherwise results in extreme reduction of radiation efficiency.
- ***Employing materials with high dielectric permittivity***: As a general design rule, an antenna structure can be excited to operate in different modes. The mode corresponding to the lowest frequency is called the dominant mode. Each resonant mode provides radiation at different frequencies with its own radiation characteristics. The antenna topologies require a resonant length of approximately $\lambda_g/2$, where $\lambda_g = \lambda_0/\sqrt{\varepsilon_{\text{eff}}}$; λ_0 is the free space wavelength, and ε_{eff} is the effective dielectric constant of the antenna material. The above relation indicates that the wavelength through the medium is inversely proportional to the effective dielectric constant of the material. This indicates that the overall antenna size can be reduced by using high permittivity substrates. For example, the dielectric resonator antennas can be realized with high-permittivity material resulting in antenna dimension reduction as small as $\lambda_0/20$. However, increasing dielectric permittivity of the antenna materials does have consequences such as reduction in the bandwidth because of the high value of the antenna quality factor (Q). It also increases the dielectric loss in the material. In practical scenarios, antenna designers find a trade-off solution between the bandwidth and the overall antenna size.
- **Reactive Loading:** This is one of the commonly adapted techniques to reduce the antenna size in mobile communication handsets. The concept is to add a capacitive or inductive effect to the resonant

DOI 10.1007/978-981-4560-75-7_55-1

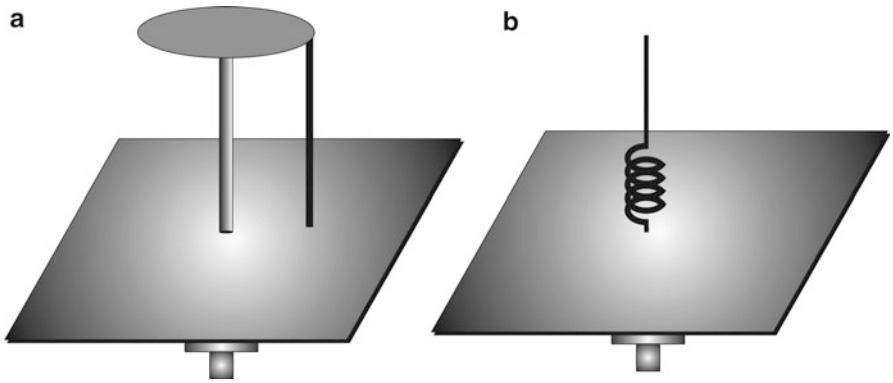

Fig. 5 Reactive loading technique to reduce the overall antenna size (**a**) capacitive loading (**b**) inductive loading

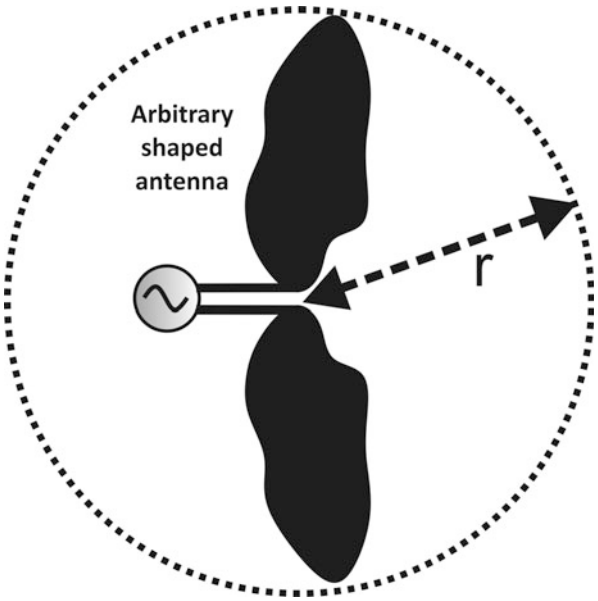

Fig. 6 The smallest sphere encloses the electrically small antenna (ESA)

structure of the antenna, which will lower the operational frequency and thus makes the antenna electrically smaller. In earlier days, the general preference was to modify the antenna structure to facilitate a reactive loading. However, with the recent technological advancements in the manufacturing of lumped reactive components, it is reliable to use lumped elements without much degradation of the overall system efficiency. For example, top-hat loading of a vertical monopole antenna and inductive loading in whip antenna shown in Fig. 5 are two of the conventional methods used for developing low-profile antennas.

Fundamental Limitations

As technology advances there is growing interest in shrinking the size of mobile communication systems. However, there are a few fundamental limitations that need to be respected while designing low-profile antennas. The concepts outlined below help antenna designers to reach a trade-off between the size and the antenna characteristics.

Chu Limit: Chu limit helps to estimate the maximum possible normalized bandwidth of an electrically small antenna from its physical size at a specific frequency. According to Chu's formula (Chu 1948), the

DOI 10.1007/978-981-4560-75-7_55-1

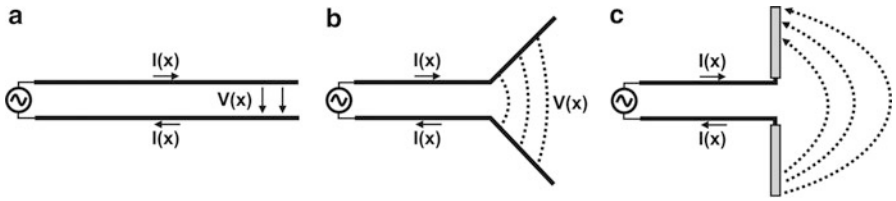

Fig. 7 Formation of a dipole antenna from a two-wire transmission line

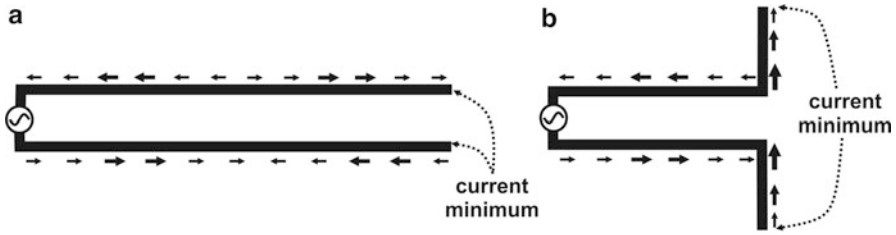

Fig. 8 Current representation in (**a**) balanced transmission line (**b**) dipole antenna

lowest quality factor (Q) of an electrically small antenna is r/λ, where r is the radius of a sphere enclosing the antenna as shown in Fig. 6. In the initial Chu's paper (Chu 1948), the radiation boundary given by Chu was based on a model without much detailed theoretical considerations so as to fit various scenarios. This is modified by other prominent scientists (Geyi 2003; McLean 1996; Wheeler 1947). The approximate value of normalized bandwidth for $Q \gg 1$ of a resonant antenna can be evaluated from (Hansen 1981)

$$\mathrm{Q-factor} = \frac{\mathrm{upper\ \ frequency\,(fu)} - \mathrm{lower\ \ frequency\,(fL)}}{\mathrm{center\ \ frequency\,(fc)}} \tag{1}$$

In practical situations, one of the challenges faced by the antenna designer would be the calculation of the minimal sphere radius. For example, in the case of an antenna mounted on a tablet computer system ground, there are chances that some part of the ground will contribute in the radiation. In that case, considering only the antenna element will result in an error in the calculation.

Types of Low-Profile Antennas

Dipole-Based Designs

Dipoles are one of the fundamental class of antennas that evolved through many years. In fact, Hertz used a dipole antenna on his spark-gap generator during the historical demonstration of electromagnetic wave propagation in 1888. Being one of the fundamental type of radiator, various designs based on a dipole have been proposed for different applications. It is true that the clear understanding of the dipole antenna concepts is necessary for further understanding various dipole-based antennas in the modern era. As shown in Fig. 7, the dipole antenna is a natural extension of a two-wire transmission line into an efficient radiator. The transmission line, shown in Fig. 7a, can be made as an antenna by bending it perpendicular to the axis of the transmission line, as indicated in Fig. 7b–c. This makes two parallel wires which when excited with an alternative signal oscillate the charges across the pair of conductors, which produces alternating electric and magnetic fields. Based on the physical dimensions of these conductors, a portion of the signal power will be radiated into space as a traveling electromagnetic wave.

Table 1 Characteristics of different dipole configurations

		Short dipole	Half-wave dipole	Full-wave dipole
Directivity, dB		1.76	2.15	3.8
Input impedance	Real	Very small	≅73 Ω	Very high
	Imaginary	Highly capacitive	≅0	≅0
Half-power beamwidth (HPBW)		∼90°	∼78°	∼47°
Polarization		Linear	Linear	Linear
Radiation pattern				
- **Why dipoles are called so:** This can be better understood by observing the current distribution in the transmission line and of a dipole, as shown in Fig. 8. In an open-circuit transmission line, as illustrated in Fig. 8a, the current at the end of the transmission line is zero (minimum). When we bend the transmission line to form a dipole, at a specific frequency, the current distribution will self-arrange as depicted in Fig. 8b. It is observed from the current directions in Fig. 8b that at a specific instant of time, the current is flowing from the bottom to the top of the dipole. This leads to an assumption that negative charges will be accumulated at the bottom end, while positive charges will be accumulated at the top end of the bended transmission line (dipole). This is in turn observed as two charges or poles (positive and negative) separated by a distance, and therefore it is a di-pole.
- **Basic classifications:** Based on the total length of the radiator(L), the dipole antennas can be classified as short dipole, half-wave dipole, or full-wave dipole as illustrated in Fig. 9. This classification is based on how much longer or shorter the dipole length (L) is with respect to the wavelength (λ) of the signal fed to the antenna. The characteristics of various dipole configurations are outlined in Table 1.
- **Input Impedance:** Impedance (z) is a concept that relates voltage (v) to the current (I) at the input of an antenna terminal. The real part of the impedance is a representation of the part of energy that is either

DOI 10.1007/978-981-4560-75-7_55-1

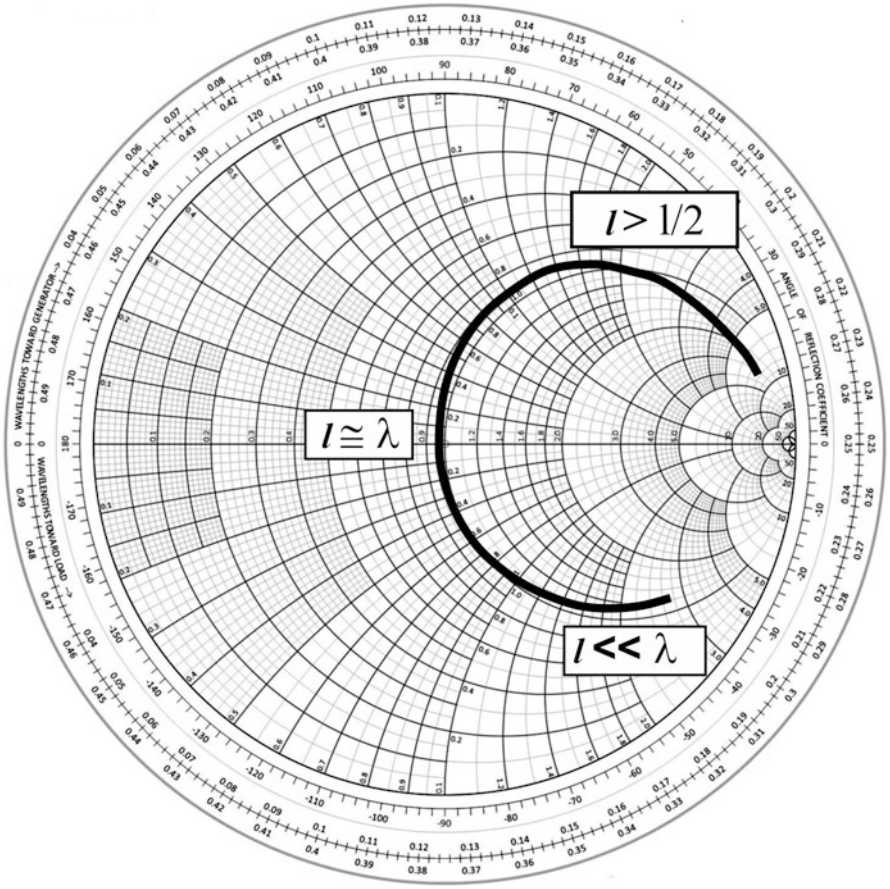

Fig. 10 Smith chart of a dipole antenna

radiated or absorbed by the antenna, while the imaginary part is a function of the energy stored in the field in the close surroundings of the antenna (near-field). An antenna can be made resonant when the antenna impedance is purely real (zero imaginary part). A Smith chart (invented by Philip H. Smith) is a powerful tool to analyze multiple antenna parameters including input impedance. A closer look at the Smith chart shown in Fig. 10 provides a clear view of the input impedance as function of dipole length (L).

It is interesting to note that when the length of the dipole is equal to half the wavelength, the antenna is at its natural resonance, meaning the imaginary part of the impedance is equal to zero. At its natural resonance, the real part of the impedance for a half-wave dipole is approximately 73 Ω. The dipole behaves like a lossy capacitor as the lengths of the poles become very small; this can be understood from the fact that the shorter the dipole, the more it acts as an open-ended transmission line, which is highly capacitive. As the dipole length (L) increases beyond half-wave length, the impedance increases and reaches an antiresonance when L reaches around λ with very high input impedance. When L = ½ λ, the input impedance is independent of the conductor thickness whereas for all other cases, the input reactance is highly sensitive to the diameter of the dipole wire. This makes the half-wave dipole one of the most popular antenna configurations.

- **Current Distribution:** The approximate current distribution on a thin dipole antenna can be mathematically expressed as

DOI 10.1007/978-981-4560-75-7_55-1

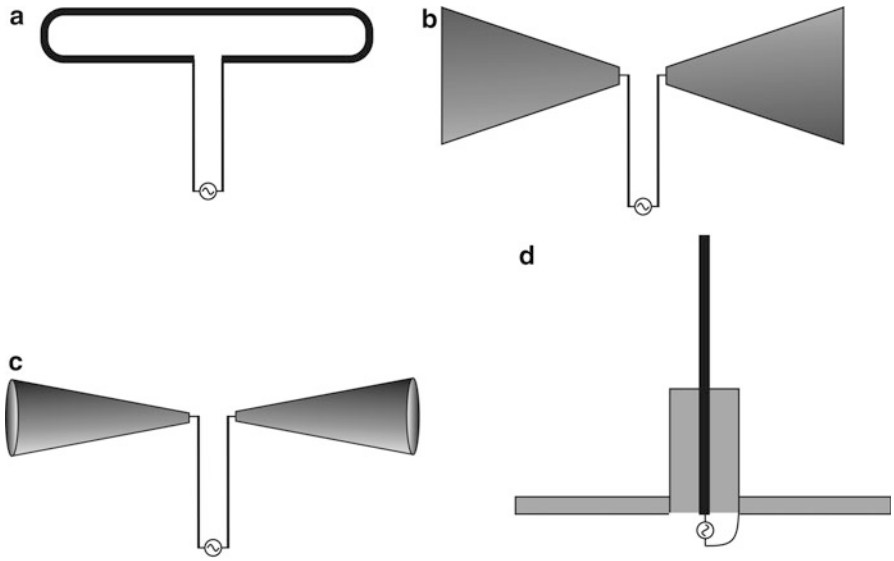

Fig. 11 Design variations of dipole antenna

$$I(z) = I_0 \sin(\beta(l - Z)) \quad \text{for} \quad 0 \le Z \le l \tag{2}$$

$$I(z) = I_0 \sin(\beta(l + Z)) \quad \text{for} \quad -l \le Z \le 0 \tag{3}$$

where I_0 is the peak current on the wire forming the dipole, which is obviously different from the current at the feed point. It reveals that the current at the ends of the dipole always approaches zero. As it can be seen from the equations, the current distribution is also a periodic distribution of one wavelength.

The key features of the half-wave dipole are

- Omnidirectional radiation pattern, which is suitable for most wireless communication scenarios.
- Relatively good directivity suitable for broad coverage in the horizontal plane.
- The input impedance is around 73 Ω with zero reactive part, which is in a reasonable range relatively easy to match with standard impedance matching techniques.
- The reactive impedance is insensitive to the wire diameter, which gives more flexibility and design freedom.

Popular design variations of dipole antennas are outlined in Fig. 11, including a biconical, bow-tie, half-wave, folded, and coaxial sleeve dipole.

State-of-the-Art Low-Profile Dipole Antennas: The advancements in the area of printed circuit technology have provided researchers a good platform to develop various printed antennas. Many antenna designs, including the printed dipole antennas, have evolved from its basic wire antenna counterpart. Table 2 lists some of the state-of-the-art designs in this field. There are various design strategies that have been used for implementing low-profile antennas, such as printing dipole elements on either side of a high-frequency laminate. The thickness can be kept in the range of $0.003\ \lambda_0 < h < 0.012$, while maintaining impedance bandwidths up to 109 % in dipole-based printed antenna designs. The artificially engineered materials have been extensively utilized for enhancing the overall performance of antennas. For example, the zeroth-order resonator (ZOR) can be embedded into multiband low-profile monopole

DOI 10.1007/978-981-4560-75-7_55-1

antennas to reduce the overall size up to 60 % (Mehdipour et al. 2014a). Another interesting design approach is to integrate electromagnetic bandgap structures (EBG) in the ground plane of the patch antenna. This approach provides size reduction while improving the impedance bandwidth and gain (Siya and Yee Hui 2013). Examples of dipole-based low-profile designs are shown in Fig. 12.

Recent Trends: Being one of the popular antenna design, dipole-based antennas are still an interesting design strategy for many researchers around the world. Some of the recent works are outlined in Table 3,

DOI 10.1007/978-981-4560-75-7_55-1

There are numerous applications which require antennas with equal beamwidth in principal radiation planes. Recent reports have indicated that very low-profile dipole-based directive antennas with thickness of 0.017 λ_0 have been proposed. These antennas provide an average gain up to 21 dB for a corrugated microstrip dipole antenna with integrated reflector (Qudrat-E-Maula et al. 2014). Some of the recent examples of dipole-based designs are shown in Fig. 13. The recent approaches also include effective

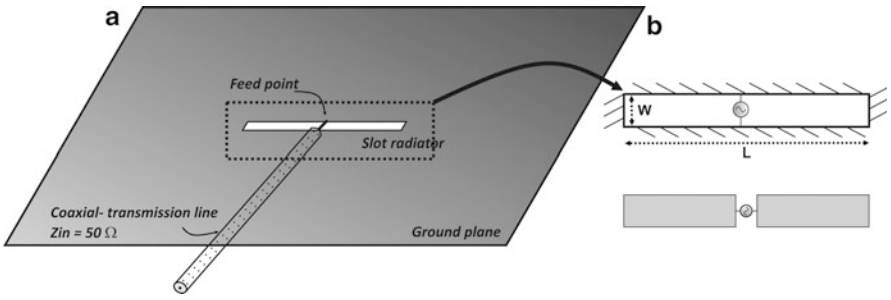

Fig. 14 Structure of a slot antenna (**a**) Slot antenna (**b**) Complementary dipole

utilization of artificially engineered materials for reconfiguring dipole antennas. In a recent work (Zarghooni et al. 2014), a dipole antenna operating at 3.3 GHz with reconfigurable radiation pattern has been reported. This novel approach uses a combination of double-split-ring resonator and spiral resonator as a metamaterial media to facilitate beam steering of 35° in the E-plane. Modified printed dipole antennas are suitable for mobile phone applications. One of the design variants is monopole based, in which one half of a dipole is mounted above the system ground plane. In addition, another attractive design using a uniplanar folded monopole antenna has been proposed (Augustin et al. 2014b). In this design two folded monopole elements and a capacitively coupled **parasiti**c element are integrated to a footprint of 22 × 34 × 0.8 mm^3. The single metal layer design provides three resonant bands, which are broad enough to cover major LTE/GSM/UMTS/WiFi bands.

Slot Antenna Designs

Slot antennas are another canonical design widely considered for the realization of low-profile antennas. It comes under a broad category of "aperture antennas," which are typically used in a wide frequency spectrum from 200 MHz to more than 25 GHz. As the name implies, slot antennas are formed by making a cutout in a relatively large aperture such as the system ground plane. The key design features are

- Ability to form low-profile, conformal antennas
- Ability to form linear/circular polarization
- Nearly omnidirectional radiation patterns

The structure of a slot antenna is outlined in Fig. 14, which shows a slot created in a plain metal sheet. This can be made on one wall of a waveguide or in a printed circuit board. The slot can be excited through various methods, including electromagnetic coupling and coaxial feed lines. The structural parameters that influence the radiation characteristics are

1. Shape of the slot
2. Material for fabrication (e.g., the dielectric constant of the high-frequency laminate)
3. Dimensions of the slot

- **Babinet's Principle:** Babinet's principle in optics states that a source of light behind a complementary thin conducting sheet produces lit regions on the source-free side that when superposed will give a completely lit region, just the same as that would exist without the sheet. In this perspective, the complementary structure of a slot antenna is shown in Fig. 14b, which is a dipole. An extension of this principle from optical to low frequency can be applied to calculate the input impedance of complementary antennas (Lang 1973). Thus, for a self-complementary antenna,

DOI 10.1007/978-981-4560-75-7_55-1

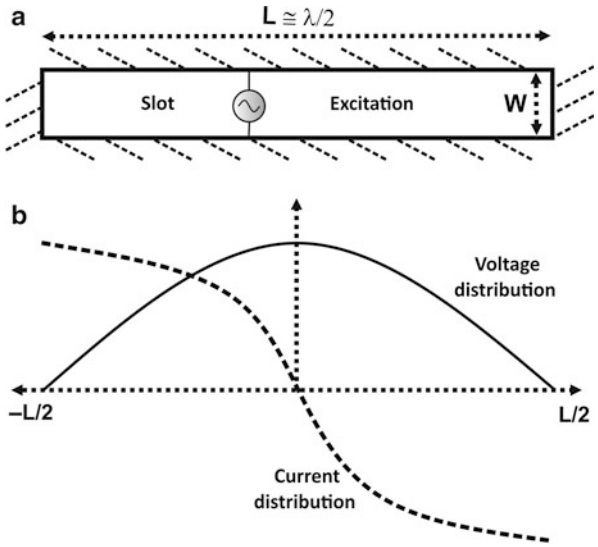

Fig. 15 Voltage and current distribution on a half-wavelength slot antenna

$$Z_{metal}Z_{air} = \frac{\eta^2}{4} \tag{4}$$

where Z_{metal} is the impedance when metal is present, Z_{air} is the impedance when air is present, and η is the intrinsic impedance of the medium, which is 377 Ω for air, and is also given by $\sqrt{\mu_0/\varepsilon_0}$. This implies that, based on the concept of self-complementary structure, a slot antenna will behave as a dipole antenna with electric and magnetic fields interchanged. This will result in interchanging the polarization of the slot antenna compared to a dipole. This means, if a dipole is horizontally polarized, its complementary slot antenna will be vertically polarized.

Half-wave slot antenna: A half-wave (λ/2) slot antenna is shown in Fig. 15a. The antenna is fed from one side of the slot to the other side, and the feed point will be slightly offset from the center in order to have relatively low input impedance. As evident from the voltage (V) and current (I) profile of the antenna, if the slot is fed at the center, a high impedance will result ($I \rightarrow 0$; $V/I \rightarrow \alpha$). It is important to note that the radiation in a slot antenna is due to the time-varying electric fields across the slot which is in contrast to the current variation in a wire dipole. When the antenna is excited, the currents flow in the metal sheet and spread out to the entire sheet. This is complementary to a wire dipole in which the current is more confined. The current vectors around the slot in a slot antenna are equal in magnitude but opposite in phase, therefore they cancel each other. This reveals the fact that, compared to a slot antenna, relatively higher amount of current flow is required in a wire dipole to produce a given wattage of radiation. The slot antenna can take different shapes ranging from simple square to an exponential curve. The shape of the slot influences the radiation characteristics of the antenna. Examples of various slot antenna structures are outlined with their key merits in Table 4.

- **State-of-the-art slot antennas:**
  There are various low-profile slot antenna designs that were quite popular during the last few decades. This includes various slot shapes with different excitation mechanisms. The progress in low-cost printed circuit board materials along with modern fabrication techniques has facilitated extreme growth in this sector. Some examples of low-profile slot antenna designs along with their

including the ground plane and feeding, range from 0.5 to 2.89 λ_0 in these designs. The geometries of these designs are outlined in Fig. 16.

- **Recent Trends:**

  The ability of slot antennas to use a broad surface made them popular for various applications. The recent technological advancements in the field of wireless communication demand conformal antennas for various communication modules. Some of the designs such as tapered slot/elliptical slots facilitate simultaneous excitation of various modes in slot antenna designs. This feature makes them popular for antenna designs that require a broad VSWR bandwidth. Some of the recent slot antenna designs are listed in Table 6.

DOI 10.1007/978-981-4560-75-7_55-1

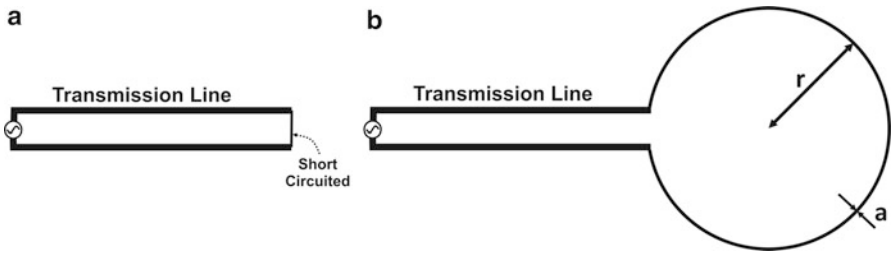

Fig. 18 Short-circuit transmission line and a loop antenna

The classical shapes such as annular ring and bow tie are still attractive candidates for many researchers due to their key design characteristics. The recent developments in very thin-profile slot antenna design indicate that there are designs with thickness as low as 0.005 λ_0, which has an overall maximum antenna dimension of 0.85 λ_0. Some interesting slot antenna shapes have recently been developed and are outlined in Fig. 17. The slot antenna topology also provides a good platform for developing dual-port integrated antennas. For example, in Augustin and Denidni (2012), a coplanar waveguide-fed slot antenna is integrated at a space between two tapered slots. This dual-port (ultrawideband/narrowband) design provides a single metallic-layer antenna structure with good interport isolation without degrading the frequency- and time-domain characteristics of the ultrawideband antenna. Another feature is the easy integration of RF circuits for antenna reconfigurability. An interesting application of this method is in cognitive radios (Augustin et al. 2014a; Chacko et al. 2015), in which the communication system can electronically change its transmitter parameters by detecting the environment. Another exciting application of dual-port slot antenna is for enhancing the diversity performance of multiple-input-multiple-output (MIMO) wireless communication systems (Ayatollahi et al. 2012). An orthogonal feeding in a modified annular slot can provide good polarization diversity with low envelope correlation coefficient and nearly omnidirectional radiation pattern (Chacko et al. 2013). The above reports indicate that the slot antennas provide attractive features that have potential applications in modern wireless communication systems.

Loop Antennas

The historical root of loop antennas goes back to Hertz's radio system, where a dipole antenna was employed in the transmitter and a loop antenna in the receiver module. In contrast to the dipole antenna, which is evolved from an open-circuit transmission line, the loop antenna can be seen as developed from a

DOI 10.1007/978-981-4560-75-7_55-1

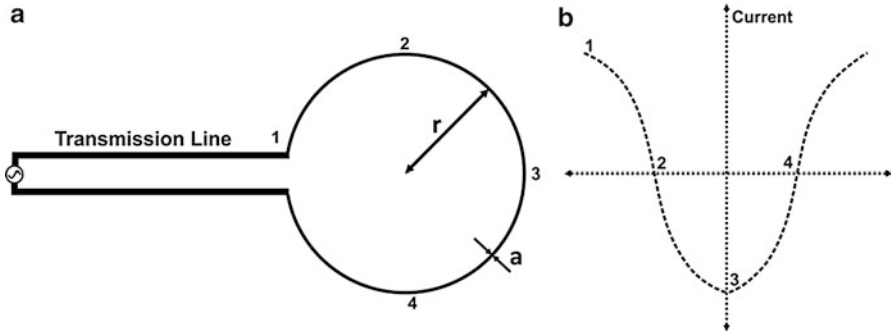

Fig. 19 Current in a resonant loop

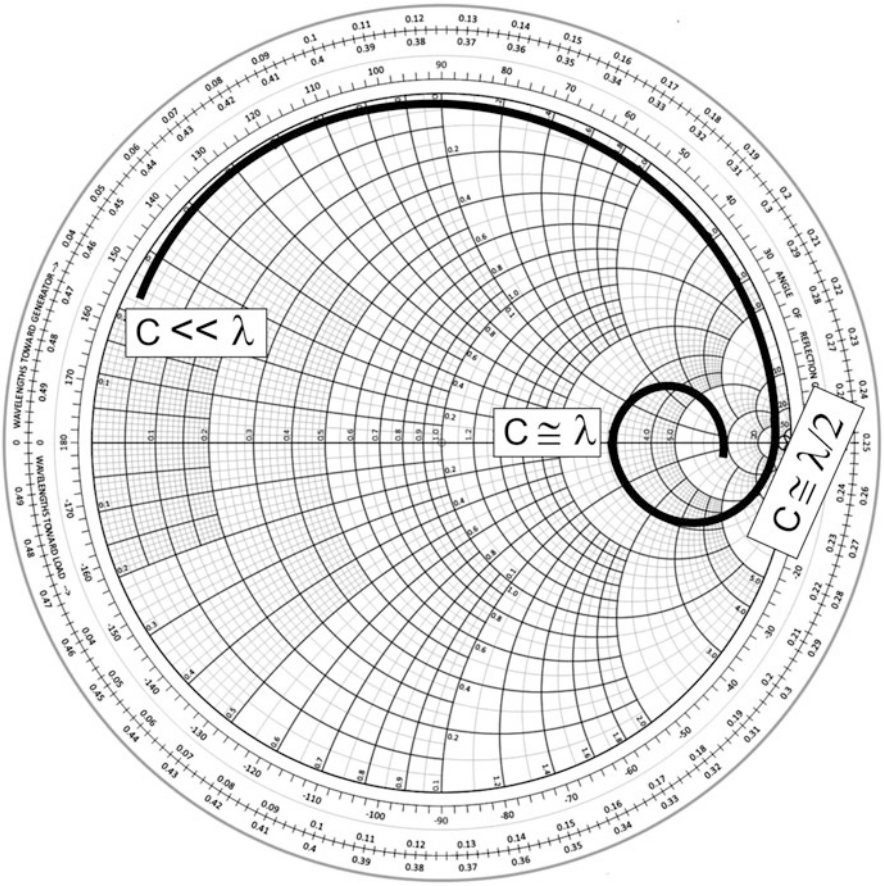

Fig. 20 Smith chart of a loop antenna demonstrating impedance characteristics at different loop circumferences

short-circuit transmission line, as illustrated in Fig. 18. In its simple form, the loop antenna consists of a balanced transmission line feeding a single or multiple loop(s) of electrical conductor. The loop antenna becomes resonant (imaginary part of the impedance approaches zero), when its circumference approaches one wavelength. For example, an IEEE 802.11 b/g WiFi antenna, operating at 2.4 GHz, will only need to be 12.5 cm circumference. It also can form different shapes such as circular, triangular, square, elliptical, and so forth. This structural flexibility makes them capable of becoming electrically small as well as electrically large with loop circumference ranges from 0.1 to 1.0 λ. Another important design parameter is the number of loops, which is directly proportional to the radiation resistance. This infers that electrically

1.5	1	Circular	0.89	0.064	74.67	7	2	(Nakano et al. 2000)

small loops with a single turn have relatively small radiation resistance. For example, if the circumference of the loop is smaller than $\lambda/3$, the current around the loop is much higher than the voltage across the loop. This results in smaller values of the input impedance, which is quite difficult to match with the transmitter. However, the antenna designer needs to choose the shapes in such a way that it will not result in the cancellation of current and thereby reduction in the antenna efficiency and bandwidth. For example, a widely used technique of meandering can introduce capacitance of the loop and cause the currents to cancel.

Duality – Loop and Dipole: Dipole antenna is considered as the "dual" of the loop antenna because it is possible to predict the electric/magnetic field of the other by knowing the field of either one of the antennas. Based on the duality theorem, if the basic principle behind radiation in one antenna is magnetic current then the other's would be electric current. This implies that the electric far field of a loop antenna is identical to the magnetic far field of the dipole antenna. Thus both dipole and loop antennas have identical donut-shaped radiation patterns, but the nulls in the dipoles are in the direction of the wire in the dipole, while the nulls in the loop are aligned perpendicular to the plane of the loop. It is also important to note that being a modified short-circuit transmission line, the loop antennas can induce high current in the coil. This is in contrast with the dipole antennas, which are modified open-ended transmission lines. In fact, the current in a resonant loop antenna is a cosine function as illustrated in Fig. 19. However, the overall efficiency of a loop antenna depends on the relative values of the dissipation resistance and radiation resistance.

Radiation resistance: The radiation resistance of a an electrically small loop antenna is relatively smaller than that of a short dipole. This reduces the efficiency of these antennas and limits them for those applications, where the overall system efficiency is the critical design criterion. The radiation resistance of a small loop antenna is given as

$$R_r = 20\pi^2 \left(\frac{C}{\lambda}\right)^4 \tag{5}$$

where C is the circumference of the loop and λ is the free-space wavelength. The Smith chart representation of the input impedance of a loop antenna is illustrated in Fig. 20. At lower frequencies (loop circumference $<< \lambda$), the loop behaves almost like a short circuit, meaning as frequency increases, the inductive impedance of the loop increases, which leads to increased radiation resistance. When the loop

circumference is close to half wavelength, the trace crosses the real axis on Smith chart (reflection coefficient close to 1). The resonance condition occurs when C is approximately a wavelength long.

Loop antennas and human body: It is well known that the human body tends to be conductive and possesses high permittivity (Salonen et al. 2004). This makes antennas that have strong electric field in the close vicinity (near field) highly sensitive when they are placed near a human body. For example, a dipole antenna is not a good selection for body-centric wireless communication systems because permittivity acts on electric field and in turn tunes the radiation characteristics. On the other hand, a human body is relatively less magnetic. In addition, the magnetic fields are stronger than the electric fields in the near field of a loop antenna. This implies that the loop antennas are highly robust since they are relatively insusceptible to the human body. Hence loop antennas are frequently used in wearable systems such as a hearing aid implant or smartwatch. Some of the key benefits of the loop antennas are outlined below:

- Possibility of low-profile structural design
- Omnidirectional/directional radiation pattern
- Design flexibility for unbalanced or balanced feeding
- Linear/circular polarization
- Robust design for wearable antenna applications

DOI 10.1007/978-981-4560-75-7_55-1

- **Popular Loop Antenna Designs:**
  There are various design modifications of low-profile loop antennas. They are very promising candidates for various applications, including mobile communication handsets (Denidni et al. 2005; Wang et al. 2008). For this purpose, various designs have been proposed to operate as full-wavelength structures. For instance, some popular low-profile antennas are outlined in Table 7. A vast majority of the literature focuses on the development of low-profile loop antennas for various commercial applications. For example, most of the designs outlined in Table 7 use loop shapes such as meander line, square, and circular above a system ground plane. These designs are prototyped on a very thin FR4 laminate (Lee et al. 2008; Wong and Chen 2009; Wong and Huang 2008). Another attractive strategy is a coplanar waveguide-fed design (Denidni et al. 2005) that demonstrates a wideband impedance bandwidth (1.68–2.68 GHz) without degrading the radiation efficiency (Fig. 21).

Microstrip Patch/Planar Inverted F Antenna

Microstrip patch antennas are one of the most popular low-profile designs commercially available today. The initial concepts were introduced in the early 1950s (Deschamps 1953). These ideas faced some challenges for experimental realization due to the unavailability of low-cost standard dielectric material. The technological advancements during the mid-1970s made significant progress to these concepts. This attracted large numbers of researchers who were focused on the development of patch antennas for various wireless communication applications. In the modern era, cutting-edge technology allows the patch antennas to be printed directly on a circuit board. The key attractions include ease of fabrication and low cost.

- **Basic Concepts:**
  As shown in Fig. 22a the patch antenna in its basic form consists of a piece of metal plate over a large ground plane. The antenna structure incorporates a cavity with a dielectric material or air. The center frequency of the patch antenna can be approximately calculated as

$$F_c \cong \frac{C}{2L\sqrt{\varepsilon_r}} \tag{6}$$

  When excited with an alternating signal, the voltage measured across the patch and the ground plane and its relation to the current over the patch for a half-wavelength patch are shown in Fig. 22c. On the other hand, the current on the patch adds up in phase, but equal and opposite currents over the patch and

Table 8 Various feeding mechanisms

Feed type	Illustration	Comments
Insert feed		The insert length controls the input impedance which is a function of cos(πD/L), where D is the insert length
Stepped impedance txn line		The concept is to match impedance using a stepped impedance transformer
Probe feed		In this method, the feed has more freedom to alter the feed position and in turn to control the impedance
Capacitively coupled feed		The capacitive gap introduces an extra degree of design flexibility by providing a reactive element
Aperture coupled feed		The key benefit is that the transmission line is shielded by the ground plane and in turn avoids spurious radiation from the microstrip line

ground plane cancel each other. Thus a microstrip patch antenna is a voltage radiation in which the radiation arises from the fringing fields as illustrated in Fig. 22b. This is in contrast to the wire antennas which are current radiators. The radiation pattern of a patch antenna can be expressed as

$$E\theta = \frac{\sin\left(\frac{kW\sin\theta\sin\varphi}{2}\right)}{\frac{kW\sin\theta\sin\varphi}{2}}\cos\left(\frac{kL}{2}\sin\theta\cos\varphi\right)\cos\varphi \tag{7}$$

DOI 10.1007/978-981-4560-75-7_55-1

Table 9 Design parameters and influence on various antenna characteristics

Parameter	Influence
L	Mainly controls the resonant frequency $F_c \cong \frac{C}{2L\sqrt{\varepsilon_r}}$
W	Controls the input impedance (in general, the wider the patch, the lower the input impedance) Influence on radiation pattern
h	Influences the bandwidth (higher the height, the broader the bandwidth)
ε_r	It controls the fringing of the fields and thereby the radiation pattern. Lower the dielectric constant, wider the fringing and broader the radiation pattern The input impedance increases with higher permittivity Higher the permittivity, the smaller the patch size (it is evident from the basic equation for Fc that increasing ε_r four times results in size reduction by two times)

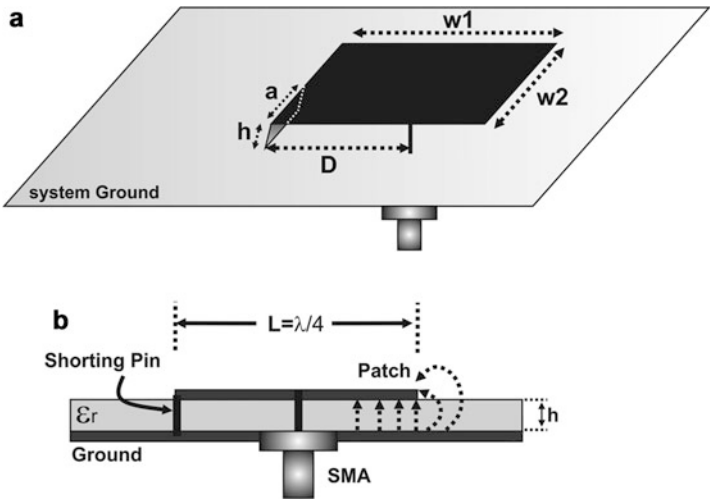

Fig. 24 Planar inverted F antenna (**a**) perspective view (**b**) side view

$$E\varphi = -\frac{\sin\left(\frac{kW\sin\theta\sin\varphi}{2}\right)}{\frac{kW\sin\theta\sin\varphi}{2}}\cos\left(\frac{kL}{2}\sin\theta\cos\varphi\right)\cos\theta\sin\varphi \tag{8}$$

where k = free space wave number = $2\pi/\lambda$. The radiation pattern in two principal planes are depicted in Fig. 23.

- **Feeding Techniques and Design Parameters:**

The excitation techniques of microstrip antennas are outlined in Table 8. This design flexibility of having broad range of feeding options is one of the reasons for their popularity in the industrial sector. On the other hand, the structural parameters of the antenna have strong influence on their radiation characteristics. For example, the dielectric constant does have an impact on how bowed the fringing of the field is, which means the higher the dielectric constant, the less bowed the fields become. The width of the patch antenna controls the input impedance and bandwidth. For example, in a square patch, the input impedance is approximately 300 Ω. However, by increasing the width, the input impedance can be reduced. Table 9 summarize structural parameters of a microstrip patch along with their influence on various antenna characteristics.

DOI 10.1007/978-981-4560-75-7_55-1

The basic concept behind a planar inverted F antenna has originated from an effort to further reduce the size of a microstrip patch antenna. At the center of a half-wave patch antenna, the current peaks and an additional short will reduce the overall size of the patch by half, while maintaining the same current voltage distribution. This can be obtained by short-circuiting a half-wave patch at the center as shown in Fig. 24.

The shorting distance, D, controls the input impedance of the PIFA. The closer the feed to the shorting pin the smaller will be the input impedance. Therefore, distance D acts as a tuning parameter for the PIFA. The resonant frequency of the PIFA also depends on the sorting pin dimension "a." An approximate relation that determines the frequency of a PIFA is given by Eq. 9,

$$F_{\mathrm{GHz}} = \frac{30}{4 \cdot [W_{1\ \mathrm{cm}} + W_{2\ \mathrm{cm}} - a_{\mathrm{cm}}]} \tag{9}$$

As depicted in Fig. 24b, this results in the disappearance of fringing fields at one end of the patch due to the shorting to the ground. Meanwhile, the fringing on the other end of the patch remains the same and contributes to the radiation. This provides the benefit of overall size reduction up to 50 % while maintaining the basic properties of the patch antenna. However, one of the immediate consequences is the reduction in the gain.

State-of-the-Art Designs

There are various microstrip antenna designs that become conceptual foundations for various modern antenna designs. The present technology enables us to prototype these printed low-profile designs through various techniques including laser-based techniques. Some of the fundamental microstrip/PIFA antennas are tabulated in Table 10.

Most of these designs that evolved from the basic patch antenna design do have various patch shapes such as "E" shape, rectangular, circular, etc. The overall patch dimensions vary from 0.11 to 0.68 λ_0 with thickness ranges from 0.007 to 0.12 λ_0. It is interesting to note that most of these foundational designs do have bandwidth limitations. Some designs such as Yang et al. (2001)and Cabedo et al. (2009) employed bandwidth enhancement techniques such as slot loading or L-probe feeding. Patch antennas also provide electronic reconfigurability by tuning the surface current path using RF switching diodes. One of the simple methods is to load a square microstrip patch with a hexagonal slot and switch between resonant modes TM_{10} and TM_{01} with a PIN diode (Shynu et al. 2005, 2006). The recent technological advancements in the field of microelectromechanical systems (MEMS) are also utilized to develop reasonably efficient patch antennas with improved reconfigurability (Rajagopalan et al. 2014). The design simplicity of the patch antennas makes them easily adaptable to broad range of applications. For instance, the reinforced continuous carbon fiber composite (RCCFC) materials are widely used in aviation industry because of their outstanding mechanical and chemical properties (Mehdipour et al. 2013). The patch antenna design can be made reconfigurable by loading RCCFC composite which makes them an excellent candidate for military applications (Mehdipour et al. 2014b). Despite their attractive features of simple design and low-cost fabrication, they suffer from relatively low gain. One of the conventional techniques is to form an antenna array at the cost of large size and complex feed network. The use of artificially engineered materials is a modern technique to resolve this issue (Augustin et al. 2013; Chacko et al. 2014; Niroo-Jazi et al. 2013).

Conclusion

This chapter has outlined low-profile antenna designs that evolved through the last few decades. The fundamental low-profile antenna designs have been outlined that include dipole antennas, slot antennas, loop antennas, microstrip patches, and planar inverted F antennas. The objective of this chapter is to help the early-stage antenna designers with fundamental concepts along with recent updates of this magnificent field of antenna engineering.

On-Chip Antennas

Tianwei Deng[a]* and Yue Ping Zhang[b]
[a]Temasek Laboratories, National University of Singapore, Singapore, Singapore
[b]School of Electrical and Electronics Engineering, Nanyang Technological University, Singapore, Singapore

Abstract

On-chip antennas feature the integration of antennas with other front-end circuits on the same chip in mainstream silicon technologies such as CMOS and SiGe. This chapter describes the basics, technology, and applications of on-chip antennas with particular emphasis on their circuit modeling, radiation efficiency, and integration as well as their crosstalk mechanisms with other circuit elements.

Keywords

On-chip antenna; CMOS technology; RF circuit; Radiation efficiency; Communication

Introduction

Silicon technology sustains the prosperous development of semiconductor and integrated circuits industries, providing the possibility of integrating an entire system on a single chip. A key issue, or an ultimate wish, for a radio-frequency (RF) system-on-chip, is the integration of antennas with other circuits. In 2002, Floyd et al. demonstrated on-chip dipole antennas with integrated transmitter and receiver in a standard 0.18-μm CMOS technology for intra-chip wireless interconnect at 15 GHz (Floyd et al. 2002). In 2003, Chan et al. characterized an on-chip monopole antenna fabricated on silicon wafer with an optimized proton implantation process over 100 GHz (Chan et al. 2003). In 2005, Zhang et al. reported the impedance and radiation characteristics of on-chip inverted-F and quasi-Yagi antennas at 60 GHz (Zhang et al. 2005). Meanwhile, the propagation mechanisms and communication performances between on-chip antennas have received attention. Kim et al. observed that the transmission between on-chip antennas improves with the frequency over an intra-chip channel (Kim and Kenneth 1998; Kim et al. 2001). Zhang et al. found that a frequency window for better transmission exists and that the guided propagation of surface waves plays an important role over the intra-chip channel (Zhang et al. 2007). Zhang also analyzed the bit-error-rate performance of a wireless interconnect between on-chip antennas over intra-chip channels (Zhang 2004). Lin et al. showed wireless communication between on-chip antennas over free space (Lin et al. 2004). The abovementioned and other studies revealed that the key problem of on-chip antennas is poor radiation efficiency (Cheema and Shamim 2013; Zhang and Liu 2009). Hence, new techniques were devised to enhance the radiation efficiency, such as proton implantation (Chan et al. 2003), micromachining (Chu et al. 2012), and the use of artificial magnetic conductors (Kang et al. 2010) and superstrates (Ou and Rebeiz 2012). Recently, much effort has been paid to on-chip antennas for applications in the bands of millimeter and terahertz frequencies (Uzunkol et al. 2013; Ojefors et al. 2009).

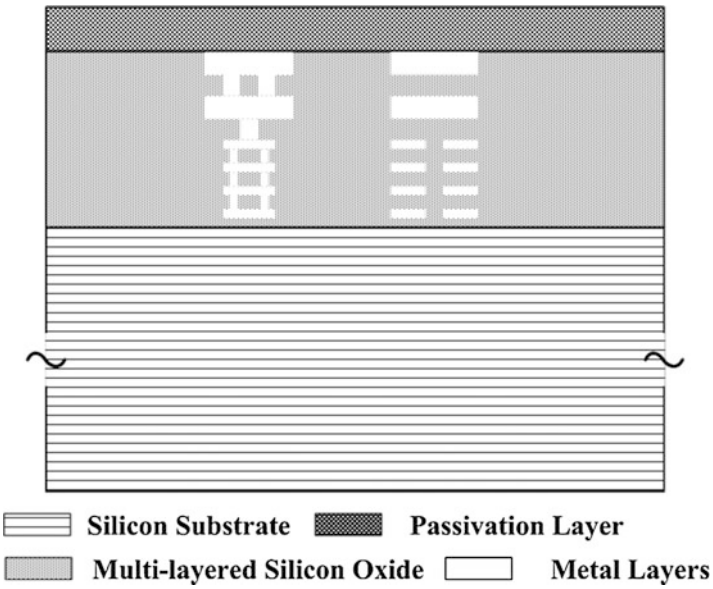

Fig. 2 The multiple-layered structure of standard CMOS chip

On-Chip Antenna Technology

The sophisticated integration of circuits/systems in CMOS technology brings new challenges to antenna designs. These challenges come from the complexity of integrated chip and co-design with circuits compared with single antenna structure optimization. Figure 1 shows a typical RF front-end of a direct-conversion transceiver suitable for a single-chip solution. The transceiver uses an antenna by incorporating a T/R switch to connect with the low-noise amplifier (LNA) or power amplifier (PA). In addition, it should be mentioned that a differential architecture that helps improve the signal-to-noise ratio (SNR) is extensively adopted in RF-integrated transceivers. In such cases, a differential antenna is required.

The standard CMOS process involves multiple metal and dielectric layers as shown in Fig. 2. The silicon substrate has thickness $t_s = 250 \sim 700$ μm, dielectric constant $\varepsilon_{rs} = 11.9$, and low resistivity $\rho_s = 10\Omega$.cm. Transistors are constructed at the top region of the silicon substrate by doping this area to be N- or P-well. Above the silicon substrate, there are layers of silicon oxide, or its variations, with layer thickness $t_i = 0.2 \sim 1.5$ μm and dielectric constant $\varepsilon_{ri} = 2.2 \sim 4.2$. The silicon oxide layers act as the insulators between metal layers. Currently, the number of metal layers is $4 \sim 8$, and the separation from

DOI 10.1007/978-981-4560-75-7_56-1

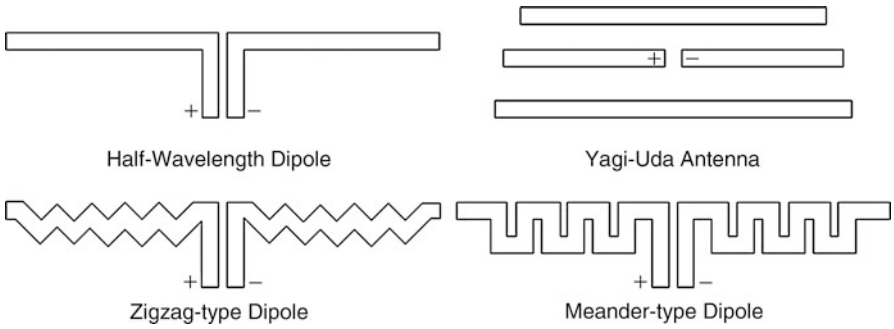

Fig. 3 Illustration of on-chip dipoles

the top to the bottom metal layers rarely exceeds 15 μm. Between metal layers, metal via can be used to connect them. These metal layers are used for interconnect or passive components, such as inductors and capacitors. The on-chip antennas are usually realized using the top metal (copper) layer with thickness $t_{\mathrm{d}} = 1 \sim 4$ μm and conductivity $\sigma_d = 5.8 \times 10^6$S/m. At the top of the chip, the passivation layer is silicon nitride with thickness $t_{\mathrm{p}} = 1 \sim 5$ μm and dielectric constant $\varepsilon_{rp} = 4.2 \sim 8.1$.

Design rule checking (DRC) is the most significant process before fabrication. Basically, there are four rules that impact the passive components design, especially for on-chip antennas. First, the metal layer design rules define the maximum width (w_{mi}), minimum separation space (w_{msi}), and minimum diagonal length of enclosed area (l_{mei}) of metal line/patch. Here, the subscript "*i*" denotes the layer number. The requirements vary for different layers. Generally, the maximum width (w_{mi}) of metal lines is less than 20 μm, which limits the antenna design greatly. Second, the metal via design rules describe the maximum width (w_{vi}), minimum separation space (w_{vsi}), and minimum enclosure width (w_{vei}) of the metal via array. Third, the metal density design rules provide restrict requirements on the metal density at each metal layer and in every checking window region. Rectangle metal fills are recommended by foundries to enlarge the physical metal density. The metal fills accordingly increase the dielectric loss of the silicon oxide layers and induce other design concerns for those cases in which the fills are placed near or under/above the passive components. Fourth, the off-chip connection rules require a connection window in the passivation layer and a connection pad on the aluminum cap above the top metal layer. Bonding wires and bump bolder, which are conductive and bulky, are used for off-chip connection. The impact of off-chip connection on on-chip antennas should be studied.

The dipole is a popular on-chip antenna structure. Generally, a half-wavelength dipole with a width of only several micrometers is used. Hence, it occupies a quite small area and is easy to be arranged with other circuit elements. To further reduce its size, a dipole can have a zigzag or meander shape, as shown in Fig. 3. A Yagi-Uda antenna is often used to increase the directivity of a normal dipole at the cost of larger antenna size.

Figure 4 shows the configuration of on-chip loop antennas. A loop antenna takes up a larger area compared with a dipole. It is usually placed around circuits for easy integration (Shamim et al. 2007; Huang and Wentzloff 2011; Ojefors et al. 2007). However, the passive components, such as the inductors of a low-noise amplifier, have a relatively large size. Thus, their layout inside the loop antenna needs to be carefully planned.

The microstrip antenna is another popular candidate for on-chip antennas. When this type of antenna is adopted for on-chip systems, two concerns should be considered. First, the typical microstrip patch is nearly a half-wavelength long, which is much larger than the requirement in the metal layer design rules. Designers have to slot the patch to meet the rules, as shown in Fig. 5 (Seok et al. 2008). Second, the ground plane should be kept as far as possible from the patch.

DOI 10.1007/978-981-4560-75-7_56-1

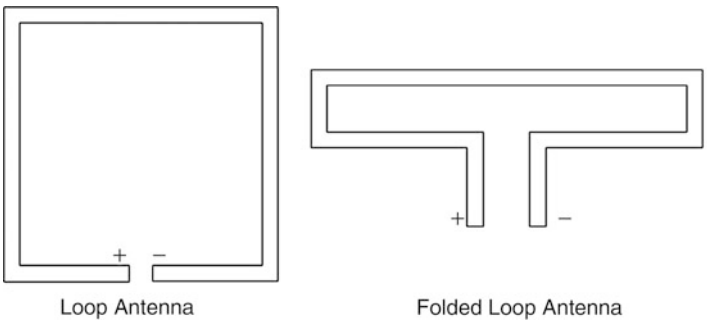

Fig. 4 Illustration of on-chip loop antennas

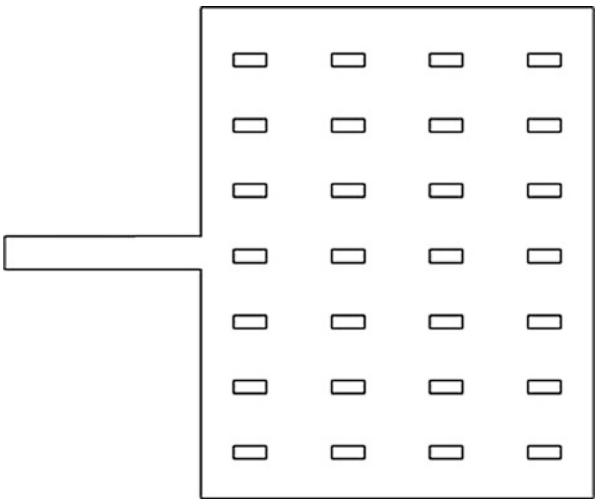

Fig. 5 Illustration of on-chip microstrip antenna

The slot antenna is also used in on-chip antenna designs (Jiang et al. 2006). Normally, a dielectric resonator or superstrate layer is placed above the slot antenna to increase the radiation efficiency (Edwards and Rebeiz 2012). Monopole and inverted-F antennas also find applications in on-chip antenna designs (Chan et al. 2003; Zhang et al. 2005). Table 1 lists key data of some reported on-chip antennas.

On-Chip Antenna Compact Circuit Model and Radiation Efficiency

The design of on-chip antennas relies heavily on numerical field simulators (e.g., HFSS or CST), which unfortunately require large computation power. Upon integration of antennas on a chip with circuits, co-design of antennas and circuits is necessary to evaluate the impact of impedance matching and mutual coupling on each other. However, the field simulators cannot be easily incorporated with circuit simulators (e.g., Cadence or Mentor Graphics). Designers need compact circuit models of on-chip antennas to obtain not only reduced computation power and time but also rapid circuit optimization. As previously mentioned, the dipole is widely used in the design of on-chip antennas. Figure 6 shows a compact circuit model of an on-chip dipole. The compact circuit model is divided into two parts: the shunt branch estimates the effect of the silicon substrate and the silicon oxide layer, and the series branch evaluates the radiation performance and the losses of the antenna. In the model, the series branch comprises R_r, R_c, R_{sur}, L_d, and C_d. The resistances R_r, R_c, and R_{sur} account for the radiation, conductor, and surface-wave losses

of the dipole, respectively. L_d and C_d are the inductance and capacitance of the dipole, respectively. The shunt branch consists of C_{ox}, C_{sub}, and R_{sub}. C_{ox} represents the oxide capacitance between the dipole and the silicon substrate. C_{sub} and R_{sub} are the silicon substrate capacitance and resistance, respectively. Regarding other on-chip antenna structures, the compact circuit models are similar. The differences that should be revised are that the shunted resonance tank (L_d and C_d) is used for the shunted resonance antenna and the oxide capacitance, C_{ox}, is shorted to ground without the silicon substrate capacitance and resistance C_{sub} and R_{sub}, respectively, when on-chip ground is applied.

DOI 10.1007/978-981-4560-75-7_56-1

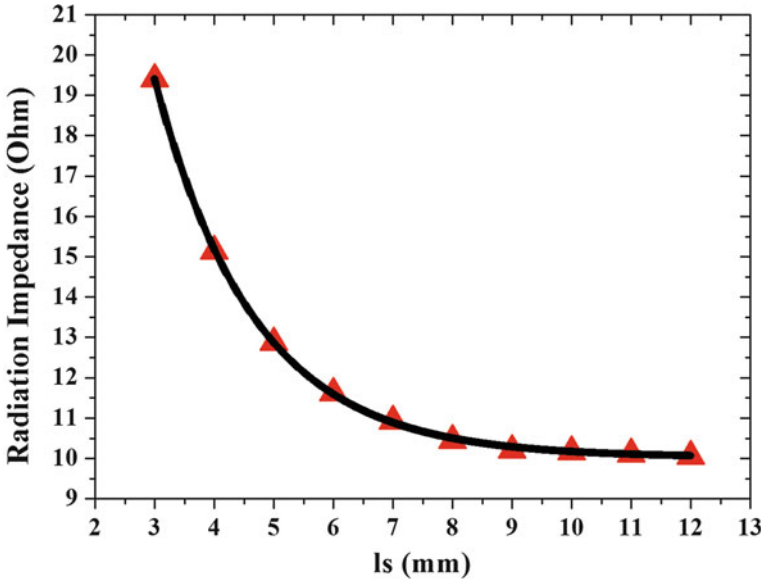

Fig. 7 The radiation resistance of on-chip dipole versus the side length of the chip (*ls*)

For an on-chip dipole with a multilayered substrate, the radiation resistance R_r is sensitive to the properties of the substrate layers. This can be expressed approximately similar to that of a microstrip dipole (Perlmutter et al. 1985):

$$R_r = \frac{120}{\pi}\varepsilon_{eff}\int_0^{\pi/2}\int_0^{2\pi}\frac{\cos^2\left(\pi\sin\theta\cos\phi/\left(2\sqrt{\varepsilon_{eff}}\right)\right)}{\left(\sin^2\theta\cos^2\phi-\varepsilon_{eff}\right)^2}\times\left[\frac{\cos^2\theta\sin^2\phi}{\left(\varepsilon_{eq}-\sin^2\theta\right)\cot^2\left(hk_0\sqrt{\varepsilon_{eq}-\sin^2\theta}\right)+\cos^2\theta}\right.$$
$$\left.+\frac{\cos^2\theta\cos^2\phi\left(\varepsilon_{eq}-\sin^2\theta\right)}{\left(\varepsilon_{eq}-\sin^2\theta\right)+\varepsilon_{eq}^2\cos^2\theta\cot^2\left(hk_0\sqrt{\varepsilon_{eq}-\sin^2\theta}\right)}\right]\times\sin c^2\left(w_dk_0\sin\theta\sin\phi/2\right)\sin\theta\cdot d\theta d\phi \tag{1}$$

where h, w_d, and k_0 denote the total thickness of the substrate, the width of the microstrip dipole, and the free space wave vector, respectively. ε_{eq} is the equivalent permittivity of the multilayered substrate (Yoon and Kim 2000). ε_{eff} is the effective permittivity of the multilayered substrate, which can be derived as the well-known equation:

$$\varepsilon_{eff} = \frac{\varepsilon_{eq}+1}{2}+\frac{\varepsilon_{eq}-1}{2\sqrt{1+10h/w_d}} \tag{2}$$

A particular concern is the chip size, which is usually less than 5 mm × 5 mm. Considering the possibility of integrating more circuits such as the baseband processor on the same chip, one can expect that the chip size may increase to 10 mm × 10 mm. However, the dimensions are not electrically large to ignore its influence on the radiation resistance (Gutierrez et al. 2009). For example, Fig. 7 shows that the radiation resistance R_r of an on-chip dipole will decrease from 19.5 to 10.5 Ω when the chip side length increases from 3 to 10 mm at 60 GHz; this is due to the surface-wave radiation at the edge of the chip (Deng et al. 2011).

DOI 10.1007/978-981-4560-75-7_56-1

The conductor loss of the microstrip antenna is usually negligible at low frequency but significant in the millimeter wave region. The thickness of the available metal layer on the chip is very thin, possible less than 5 μm. The eddy current incorporates an inevitable conductor loss R_c. The skin depth δ of the metal layer can be given as

$$\delta = \sqrt{\frac{R_{sh} \cdot t_d}{\pi \cdot \mu_0 \cdot f}} \tag{3}$$

where R_{sh} and t_d denote the sheet resistance and the thickness of the metal layer, respectively, and f is the frequency. The conductor resistance R_c of a rectangular metal patch with length l_d and equivalent radius w_{eff} can be expressed as

$$R_c = \frac{l_d}{w_{eff}} \sqrt{\frac{\mu_0 \cdot f \cdot R_{sh} \cdot t_d}{\pi \cdot \exp\left(-\frac{t_d}{\delta}\right)}} \tag{4}$$

For example, at 60 GHz, when the sheet resistance $R_{sh} = 25$ mohm/sq, the thickness $t_d = 2$ μm, and the ratio of $l_d/w_{eff} = 60$, the conductivity is $\sigma_d \approx 2.35 \times 10^6$, and the conductor resistance is $R_c \approx 15.3\Omega$.

The surface-wave resistance R_{sur} denotes the losses of surface waves, which varies with different silicon substrate thicknesses ($t_s = 300 \sim 700$ μm) and operation frequencies. The surface-wave power p_{sw} of the basic TM_0 mode is given by (Pozar 1990)

$$P_{sur} = 30\pi k_0^2 \frac{\varepsilon_{eq}\left(\chi_0^2 - 1\right)}{\varepsilon_{eq}\left[\frac{1}{\sqrt{\chi_0^2 - 1}} + \frac{\sqrt{\chi_0^2 - 1}}{\varepsilon_{eq} - \chi_0^2}\right] + \left[1 + \frac{\varepsilon_{eq}^2\left(\chi_0^2 - 1\right)}{\varepsilon_{eq} - \chi_0^2}\right] k_0(t_s + t_i)} \tag{5}$$

where $\beta_0 = x_0 \cdot k_0$ is the TM_0 surface-wave propagation constant and k_0 is the wave number of air. The result of p_{sw} is exact if x_0 is exact. For a high-dielectric-constant substrate, x_0 can be given as

$$x_0 = 1 + \frac{-\varepsilon_{eq}^2 + \alpha_0\alpha_1 + \varepsilon_{eq}\sqrt{\varepsilon_{eq}^2 - 2\alpha_0\alpha_1 + \alpha_0^2}}{\varepsilon_{eq}^2 - \alpha_1^2} \tag{6}$$

where

$$\alpha_0 = \sqrt{\varepsilon_{eq} - 1}\tan\left(k_0 t_s\right)$$
$$\alpha_1 = \frac{-1}{\sqrt{\varepsilon_{eq} - 1}}\left[\tan\left(k_0 t_s\right) + \frac{k_0 t_s}{\cos^2(k_0 t_s)}\right]$$

With the surface-wave power p_{sw}, the surface-wave resistance R_{sur} can be expressed as

$$R_{sur} = \frac{Z_0^2}{2P_{sur}} \tag{7}$$

DOI 10.1007/978-981-4560-75-7_56-1

The silicon substrate resistance R_{sub} denotes the losses in the low-resistive silicon substrate, which are further enlarged because $C_{ox} << C_{sub}$. Floating metal-shielding structures were designed and placed between the metal layer and silicon substrate (Kim et al. 2001), which increases the value of C_{ox} and blocks EM waves propagated into the silicon substrate. However, this results in the disadvantage of induced losses on the metal-shielding structures.

The main concern regarding on-chip antennas is their poor radiation efficiency. This is due to the combined effect of the low resistivity and high permittivity of the silicon substrate (Zhang and Liu 2009). The low resistivity causes loss due to heating in the presence of an electric field in the substrate, and the high permittivity causes loss due to power trapped in surface-wave modes in the substrate. The radiation efficiency of on-chip antennas is the key factor in evaluating their radiation performance, which could be expressed as

$$\eta = \frac{R_r}{\mathrm{Re}[Z_{in}(j\omega_d)]} \tag{8}$$

where $Re[Z_{in}(j\omega_d)]$ is the real part of the input impedance of the on-chip antenna at the resonant angular frequency ω_d. The radiation resistance is actually quite low, and the other resistances are large, leading to low radiation efficiency. There are several effective methods of improving the radiation efficiency of on-chip antennas.

Modifying the Silicon Substrate

Silicon substrate has low resistivity, which causes large substrate loss and is a key reason for the low radiation efficiency of on-chip antennas. A proton implantation process has been developed to increase the resistivity from 10 to 10^6 Ω cm. To avoid the latch-up issue, the implantation is done only in certain selected areas underneath the antenna (Chan et al. 2003). A micromachining technique has also been developed to remove silicon substrate and create an air cavity under the on-chip antennas. It has been shown that the radiation efficiency of a single on-chip monopole can be increased to 93.9 % (Chu et al. 2012). A thick silicon substrate supports more surface-wave modes and results in high surface-wave loss. Substrate thinning is beneficial to radiation efficiency.

Implementing Artificial Magnetic Conductor

Because the losses are mostly from the silicon substrate, designers can place an on-chip ground at the bottom metal layer to block the propagation of electric field into the silicon substrate and to reduce the surface-wave power. However, the closely placed on-chip ground induces an image current to diminish the radiation of the antenna. Usually, the distance between on-chip ground and antenna is less than 10 μm. At THz frequencies, the on-chip ground is effective and widely used in on-chip antenna design (Seok et al. 2008). At millimeter frequencies, artificial magnetic conductor (AMC) can be implemented to avoid the impact of the image current (Kang et al. 2010; Kuo et al. 2013; Jiang et al. 2012; Bao et al. 2012; Takahagi and Sano 2011). This provides an in-phase reflection of electromagnetic waves as a perfect magnetic conductor (PMC). The radiation is enhanced rather than canceled. An efficiency improvement from 5 % to 10 % was achieved by implementing an AMC structure under a Yagi-Uda antenna.

Adding Superstrate and Dielectric Resonator

Adding a superstrate above an antenna can improve the radiation efficiency (Alexopoulos and Jackson 1984). For instance, a slot-coupled antenna achieves 30 % radiation efficiency with a quartz superstrate,

DOI 10.1007/978-981-4560-75-7_56-1

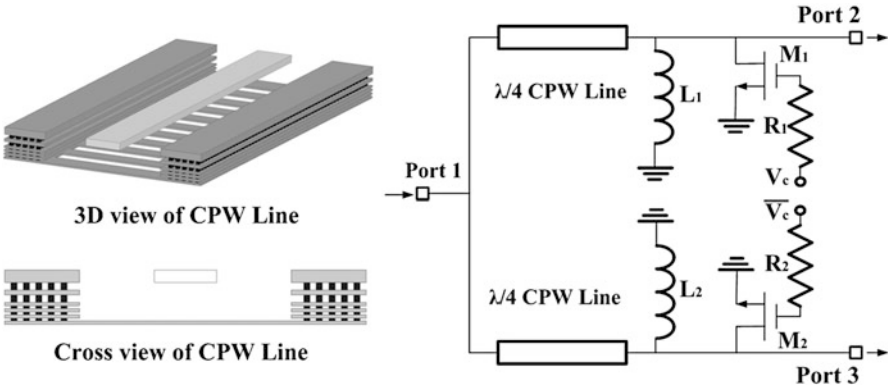

Fig. 8 Schematic of the SPDT switch with the CPW line (Uzunkol and Rebeiz 2010)

compared with 6 % radiation efficiency without the superstrate (Edwards and Rebeiz 2012). The use of on-chip dielectric resonator antenna (DRA) is another approach. The radiation efficiency of DRAs can be very high because the silicon substrate is isolated by an on-chip ground, and there is no image current issue to cancel out the antenna radiation. However, one concern is that adding the DRA on a chip with high precision is difficult.

Using Substrate Lens

A hemispherical silicon lens with a matching layer can convert the surface-wave power to a useful radiated power. Therefore, such lens is used to increase the radiation efficiency and directivity of on-chip antennas (Babakhani et al. 2006). Usually, the bottom metal layers are used for the antennas, and the silicon substrate is thinned to minimize the path length through which the radiated wave travels inside the low-resistivity silicon substrate.

On-Chip Antennas and Circuits

This section introduces the integration of an antenna with circuits on the same chip and discusses the crosstalk mechanisms and effects between the antenna and passive circuit components.

Integration of Antennas with Circuits

For a single transmitter or a receiver, an on-chip antenna is directly integrated with a PA or LNA (Uzunkol et al. 2013; Babakhani et al. 2006). For a transceiver, the antenna is usually integrated with a single-pole double-throw (SPDT) switch. At higher frequencies, the SPDT switch topology shown in Fig. 8 is often adopted. This has three ports, with port 2 to the PA, port 3 to the LNA, and port 1 to the antenna. When Vc is high, transistor M_1 is on, and transistor M_2 is off, the signal picked up by the antenna is fed to the LNA. When Vc is low, transistor M_1 is off, and transistor M_2 is on, the signal from the PA is fed to the antenna. Two quarter-wavelength transmission line sections are used for impedance matching and two shorted transmission line stubs acting as two inductors are used to tune out the capacitances of the transistors (Uzunkol and Rebeiz 2010).

Figure 9 shows the 3D view of a slot-folded dipole antenna with a CPW feed line used in the integration (Chen et al. 2012). The folded-slot structure is favored because it provides a wide bandwidth, a CPW-friendly interface, low metallic loss, and high isolation.

DOI 10.1007/978-981-4560-75-7_56-1

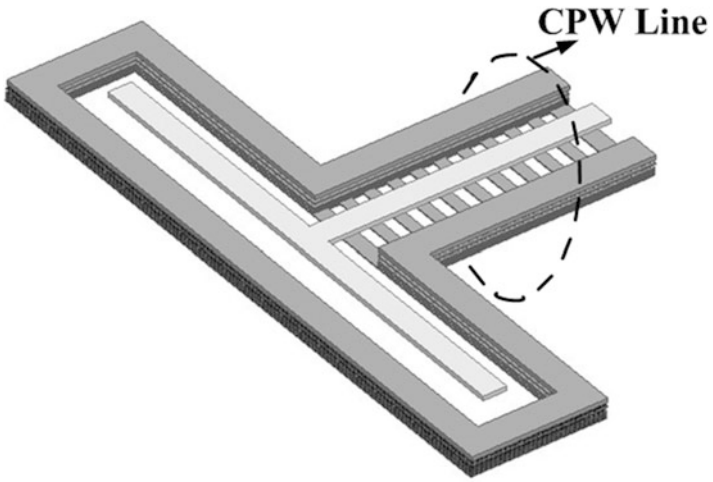

Fig. 9 3D view of slot-folded dipole antenna (Chen et al. 2012)

Crosstalk Between On-Chip Antennas and Circuits

A major concern with on-chip antennas is the risk of crosstalk with the on-chip circuits such as an LNA and a voltage-controlled oscillator (VCO) (Deng et al. 2013). The noise currents are injected from the on-chip antennas into the substrate and coupled to the active region of the on-chip circuits through the substrate medium (Briaire and Krisch 2000). Figure 10 shows the crosstalk from an on-chip antenna to active region of the on-chip circuits. The crosstalk between on-chip antenna and MOS transistor may become significant at high frequencies due to the drain and source junction capacitances and at low frequencies due to the body effect. Higher-resistivity doping on silicon substrate can obtain lower substrate noise coupling (Soens et al. 2006). Besides, isolation via and guard rings show good noise-isolation properties (Chu et al. 2012; Kang et al. 2010; Uemura et al. 2012). Correspondingly, thermal and switching noise currents generated by transistors flow from the substrate to the on-chip antennas. These are common mode in nature and could be adequately rejected by applying differential antennas instead of single-ended ones.

The passive elements are more susceptible to crosstalk from the on-chip antennas than are the active devices. This is because the sizes of passive elements, such as inductors, capacitors, and transmission lines, are much bigger than those of active devices, such as transistors in the LNA and varactors in the VCO circuits. Normally, the crosstalk between on-chip antenna and passive elements involves different mechanisms, depending on the frequency of operation and the distance of separation. It also considers that on-chip antenna and passive elements are placed in the near-field region. Figure 11 shows the equivalent circuit of an on-chip monopole with an inductor. C_{ant}, L_{ant}, and R_{ant} are the capacitance, inductance, and resistance of the monopole, respectively. L_{ind} and R_{ind} are the inductance and resistance of the inductor, respectively. C_{oxi_ant} (or C_{oxi_ind}) is the oxide capacitance between the monopole (or the inductor) and silicon substrate. R_{sil_ant} and C_{sil_ant} (or R_{sil_ind} and C_{sil_ind}) represent the silicon substrate resistance and capacitance, respectively, of the monopole (or the inductor). C_m and R_m denote, respectively, the capacitance and resistance between the monopole and the inductor. The magnetic coupling coefficient K_m estimates the magnetic coupling between the monopole and inductor.

The discussion of the crosstalk mechanism between the monopole and inductor is conveniently classified as electric coupling, magnetic coupling, and resistive coupling. The electric coupling through the mutual capacitance (C_m) is dominant at low frequency, which shows a high-pass frequency response; the magnetic coupling from the magnetic coupling coefficient K_m varies with the different shapes and

DOI 10.1007/978-981-4560-75-7_56-1

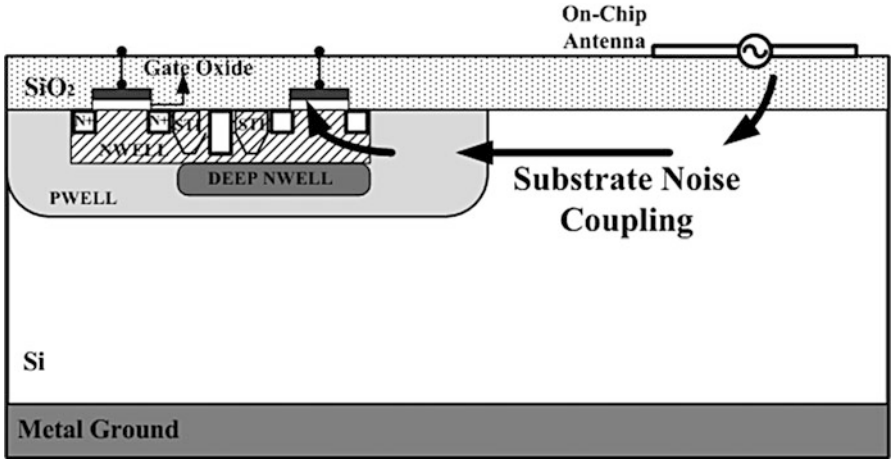

Fig. 10 The substrate crosstalk is due to electrical fluctuations propagated in substrate medium

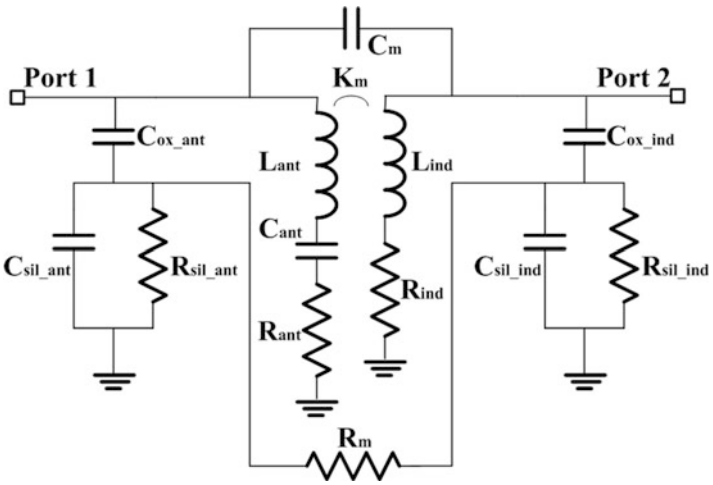

Fig. 11 The equivalent circuit of crosstalk between on-chip antenna and inductor

arrangements of inductors; and the resistive coupling through the substrate due to R_m is inevitable, the level of which is invariable versus the frequency. However, the resistive coupling is weak compared with the EM coupling. There is a resonance due to the combined effect of the magnetic (inductive due to the monopole and inductor, i.e., L_{ant}, L_{ind}, and K_m) and electric (capacitive C_m) coupling. The response frequency is given from the equivalent circuit:

$$f_{dip} = \frac{1}{2\pi\sqrt{L_{eq}C_{eq}}} \approx \frac{1}{2\pi\sqrt{\left(\frac{L_1L_2}{L_3} + L_1 + L_2\right)C_m}} \tag{9}$$

where

$L_1 = L_{ant} - L_m, L_2 = L_{ind} - L_m, L_m = K_m\sqrt{L_{ind}L_{ant}}$

DOI 10.1007/978-981-4560-75-7_56-1

$$L_3 = L_m - \frac{R_{ind}^2}{\omega^2 C_{ant}\left[(R_{ant} + R_{ind})^2 + 1/\omega^2 C_{ant}^2\right]} \approx L_m$$

Equation 9 predicts a low mutual coupling null/window. The response frequency of this null/window shifts with the different shielding and guide structures placed around or under the inductor. In addition, the oxide and substrate capacitances (C_{oxi_ant}, C_{sil_ant}, C_{oxi_ind}, and C_{sil_ind}) might decrease the coupling level with increasing frequencies, because the signal is shorted to substrate or ground from the oxide and substrate capacitances, rather than coupled to another port. Regarding the crosstalk between antennas and transmission lines, the coupling mechanism is similar at these frequencies. Note that coplanar waveguide (CPW) lines have ground lines adjacent to the signal line. The coupling drops because the oxide and substrate capacitances do not occur in this case.

Crosstalk effects are important to optimize the layout of circuits with antennas. The passive elements, including inductors, capacitors, and transmission lines, act as parasitic patches in on-chip antennas for the case they are placed near each other. Normally, the electric field is terminated at the off-chip ground through the silicon substrate. When passive elements are placed, they tend to interact with the monopole to induce observation of asymmetric electric field distribution and terminate the electric field instead of the off-chip ground.

The far-field patterns of the monopole shown in Fig. 12 verify this. The nearby inductor or CPW line shifts the maximum radiation direction of the monopole to $10^\circ \sim 20^\circ$ in the H plane. The passive elements can be used as parasitic reflectors similarly to that in Yagi-Uda antennas. However, they increase the cross-polarization at least 20 dB in the E plane, which decreases the radiation performance of the monopole. The on-chip monopole has limited influence on the passive elements, especially when floating shielding structures are added to protect these elements.

Examples of On-Chip Antenna Application

Wireless interconnect has been proposed to communicate among cores within a chip for ultra large-scale integration (ULSI) or system-on-chip (SoC). On-chip antennas are used to construct the intra-chip communication systems, and the signal coupling between on-chip antennas is based on the propagation of radio waves rather than R-C coupling. Figure 13 shows a wireless interconnect for delivering a global clock signal on a chip at 15 GHz (Floyd et al. 2002). As seen in the figure, one clock transmitter and one clock receiver are placed on different locations on the chip. On-chip dipole antennas are used in both the transmitter and receiver, and a 1.875-GHz local clock signal from the clock transmitter can be detected by a clock receiver over a 5.6-mm distance.

Conventional wireless communication systems that use on-chip antennas have also been shown. For example, the wireless communication range between a single-chip radio with the on-chip antenna and a 20-dBi gain horn antenna can be as far as 95 m at 24 GHz (Cao et al. 2008). The wireless communication range between another single-chip radio on a high-resistivity substrate and an 11-dBi gain patch antenna can achieve 100-kb/s data transmission at 5.8 GHz over a separation distance of 310 m (Lin et al. 2007).

On-chip antennas are also used in highly integrated radars and imagers. In a range-sensing radar (Khanh et al. 2013); a 180-nm CMOS transceiver with on-chip antennas is implemented with a 9–11-GHz damping-pulse transmitter and a receiver including a mixer and a three-stage LNA. The transmitter and receiver antennas are the same and placed in an orthogonal direction to minimize crosstalk. Besides, a

focal-plane array for room-temperature detection of 0.65-THz radiation fully integrated into a low-cost 0.25-μm CMOS process technology. The circuit architecture is based on the principle of distributed resistive self-mixing and facilitates broadband direct detection well beyond the cutoff frequency of the technology. The 3 × 5-pixel array consists differential on-chip patch antennas, NMOS direct detectors, and integrated 43-dB voltage amplifiers. At 0.65 THz the FPA achieves a 80-kV/W responsibility and a noise equivalent power of 300 pW/sqrt(Hz) (Ojefors et al. 2009).

Summary

Driven by the development of the RF system-on-chip, there have been some attempts to implement on-chip antennas in mainstream silicon technologies. In this chapter, the basics, technology, and applications of on-chip antennas are described, with emphasis on their circuit modeling, radiation efficiency, and integration, as well as their crosstalk mechanisms with other circuit elements. Future studies should focus on the challenges of fast simulation and optimization of on-chip antennas and co-design of on-chip antennas with other circuits. Also, how to test on-chip antennas at THz frequencies, particularly, their radiation efficiencies should be made? Furthermore, an effective solution to improve radiation efficiency is always the main concern in on-chip antenna design.

Substrate Integrated Waveguide Antennas

Tarek Djerafi*, Ali Doghri and Ke Wu
Poly-Grames Research Center, École Polytechnique de Montréal, Montreal, QC, Canada

Abstract

Research and development progress in the area of millimeter-wave antennas has been associated since recent years with substrate integrate waveguide (SIW). SIW was proposed and studied as a class of efficient integrated transmission lines compatible with planar technologies, offering incomparable self-consistent shielding and high-quality factor performances. SIW can be designed as open wave-guiding structures and energy leakage will take place when the uniformity of those guides is perturbed or they are not excited in an appropriate mode. This leakage effects may be used positively for the design of antennas by deliberately introducing perturbations in these guides so that they radiate in a controlled fashion. With the advantages of broadband, efficiency, and high gain, a specific benefit of such antennas is their compatibility with SIW from which they are derived, thus facilitating an integrated design. In this chapter, H-plane horns, leaky-wave structures (long and periodic) and tapered slot antennas are presented. Special attention is given for tapered slot antennas and arrays with their application in the design of passive imaging systems.

Antenna array; Antipodal structure; Imaging system; Horn antenna; Leaky-wave; Millimeter-wave; Polarization; Slot antenna; Rod antenna; Substrate integrated waveguides (SIW); Tapered slot antenna; Twist; Directional coupler; Vivaldi antenna

Introduction

The frequency range from 30 to 300 GHz is generally defined as millimeter waves or extremely high-frequency waves. Wavelengths over this frequency band are ranged from 10 to 1 mm, thus naming it the millimeter-wave band or simply millimeter-wave (MMW or mmW). Compared to lower frequency bands, electromagnetic waves in this band are subject to high atmospheric attenuations and they are absorbed by atmospheric gases. Beyond this millimeter-wave range, electromagnetic radiation is referred to as terahertz (THz) radiation. Millimeter-wave bands offer exciting opportunities for various bandwidth-demanding and spectrum-sensitive applications such as short-range communications in the 60 GHz band and automotive radar and imaging systems in the frequency windows of 77 and 94 GHz (Meinel 1995; Solbach and Schneider 1999; Schoebel and Herrero 2010). Since a number of years, emerging applications are being reported such as imaging sensors for security and biomedical applications (Salmon 2004). There is also a great deal of interest in millimeter imaging arrays for other applications such as remote sensing, radioastronomy, and plasma measurement (Nanzer 2012).

In commercial system developments, low-cost, mass-producible, high-performance and high-yield microwave, and millimeter-wave technologies are critical for developing successful and sustainable

DOI 10.1007/978-981-4560-75-7_57-1

commercial broadband systems, in particular, front end and antenna modules. Specifications of antenna components and systems for those applications should satisfy not only desired electrical performances as gain, low side lobe level (SLL), and low cross-polarization, but also stringent mechanical criteria of size, weight, and shielding. The integrability with other active and passive system elements is also considered as a main key criterion, which generally defines the ultimate cost and consequently the commercial success. The millimeter-wave bands are useful for enabling the design of densely packed systems integrated with high-gain antenna arrays.

Antennas in standard technology or in SIW can be classified as either resonant or nonresonant types. Resonant antennas, such as microstrip patches and dipoles, resonate at discrete frequencies. Nonresonant antennas or traveling-wave antennas do not resonate but rather leak energy out along their wave propagating path, thereby producing more efficient broadband structures. The resonant structures do not provide an easy-to-accept performance in the millimeter-wave range. This is because of very high conductor losses arising from immense current densities (singularities) at the strip edges, especially in the feeding network. The substrate becomes electrically thicker at higher frequency and more surface wave modes (parasitic modes) may exist. This can be deleterious for standard microstrip antennas with radiation efficiency reduction and radiation pattern perturbations, which result from the diffraction of surface waves at the edges of the antenna structure in an uncontrolled manner (Pozar 1983).

In this chapter, different constraints and limits of SIW antennas are examined with focus on no-resonance structures. At millimeter-wave, the energy is much easier to radiate out from open transmission lines. As such, a number of leaky-wave or surface-wave antennas can be synthesized and developed. They include tapered slot antenna (TSA), printed Yagi-Uda antenna or log-periodic dipole array, dielectric rod antenna, long slot leaky-wave, partially reflective surface-based antenna, etc. For more background information and development history, readers are referred to (Walter 1965; Oliner et al. 2007; Suntinjo et al. 2008; Caloz et al. 2011). Tapered slot antenna (TSA), also known as flared notch or Vivaldi antenna, is among the most promising candidates satisfying all the requirements described above (radiation, mechanical, integrabilty, and cost). TSA has some unique characteristics of symmetrical patterns in two planes, high gain in addition to having wide bandwidth characteristics in terms of radiation performance and impedance characteristics. TSA has proved to be of particular interest due to its potential as effective radiating elements in an array, and the possibility of using it at very high frequencies.

The integration of structure is a crucial issue for front-end and antenna system developments. The conservative waveguide solutions, which have been widely deployed for numerous applications, present a number of challenging problems in connection with size, cost, weight, and fabrication complexity of feed networks and antenna systems. Various discontinuities and lossy structures within the feed networks should be avoided or reduced or used with caution since noise emitted or interference created by such components into the receiver could affect the overall performance. Substrate integrated waveguide (SIW) with the advantages of self-consistent field shielding, low cost, and light weight is an excellent candidate to substitute the traditional solutions for antenna array design as well for whole system development (Djerafi and Wu 2013).

This chapter presents an overview and a summary of recent developments for leaky-wave antennas (LWAs). An LWA makes use of a guiding structure that supports wave propagation along the length of the structure with the wave radiating or “leaking” continuously along the structure. Such antennas may be uniform, quasi uniform, or periodic in topology. After reviewing the basic physics and operating principles behind, a summary of some recent advances for those types of structure is given and discussed. Horn antenna based on SIW presents some constraint in connection with thickness. Recent advances on SIW horn antenna will be presented.

The performance of TSAs with three different profiles will be compared over the Ka-band and corrugation effects will be detailed. Mutual coupling effects are critical on the performance of antenna

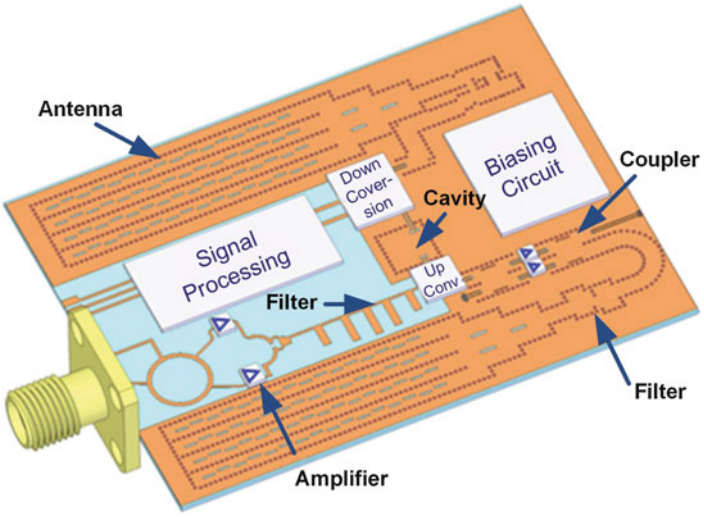

Fig. 1 A potential SIW-based platform in which SIW antennas, couplers, cavities, filters are all combined with active and DSP circuits on the same substrate or master board

arrays. The coupling in H and E-plane arrangement of two TSAs is studied as well as 90° configuration. This configuration is useful to build up antenna arrays with dual or circular polarization capabilities.

Substrate Integrated Waveguide

A new generation of high-frequency integrated circuits called "substrate integrated circuits – SICs" was proposed and demonstrated many years ago (Wu 2001). This disruptive concept has unified the hybrid and monolithic integrations of various planar and nonplanar circuits that are made in single substrate and/or multilayer platforms. Basically, any nonplanar structures can be made or synthesized in planar form, which presents the foundation of SICs. Being synthesized on a planar substrate, the substrate integrated image guide (SIIG), for example, can be combined in a hybrid way with the SIW and the Substrate Integrated Nonradiative Dielectric guide (SINRD) on the same substrate, operating with different modes and/or different frequency ranges. These guides can also be combined with standard waveguide, microstrip, Coplanar waveguide (CPW) or slotline, leading to attractive hybrid schemes of planar and nonplanar structures. In fact, an easy-to-handle low-cost hybrid design strategy is of critical importance for the development of high-volume millimeter-wave ICs and systems as illustrated in Fig. 1. These technologies have well been studied in the millimeter wave range. Since the transmission line technology is instrumental for developing high-frequency electromagnetic hardware, the choice of an appropriate waveguide or line structure is critical for millimeter-wave developments and applications. The transmission lines of choice should allow high-density integration and mass-production scheme at low cost. Rectangular waveguides have widely been used in the development of microwave- and millimeter-wave components and systems with their salient features such as low insertion loss, high quality factor (Q-factor) and high power capability, etc. However, they are also characterized by their bulky size, stringent manufacturing precision and nonplanar geometry. Therefore, it is impossible to design and develop microwave and millimeter-wave integrated circuits with this technological platform. Benefiting from the properties of low profile, easy fabrication, and low cost, microstrip-like circuits including coplanar waveguides (CPW) and strip lines are presently the principal choices of integration for the development of microwave and millimeter wave circuits. Unfortunately, such printed circuits suffer

DOI 10.1007/978-981-4560-75-7_57-1

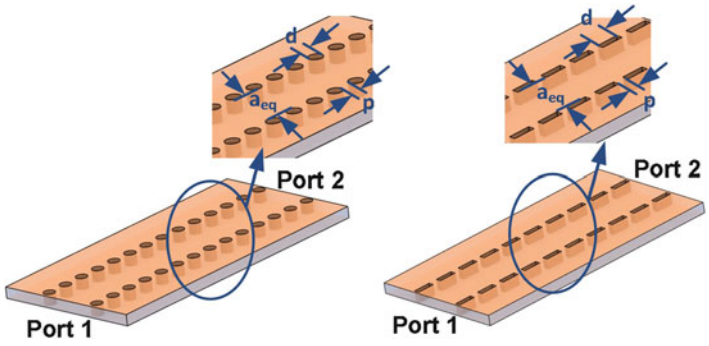

Fig. 2 The topology of a typical single-layered SIW. Metalized via and slot arrays for creating equivalent metallic fence or wall configurations with: (**a**) cylindrical via arrays, (**b**) long slot trenches

from significant losses and packaging problems. In fact, the performances of microstrip-like circuits are fundamentally limited by physical properties such as field or current singularities occurring at the stripline (Zhu and Wu 2002).

SIW structure preserves most of the advantages associated with conventional metallic waveguides, namely high Q-factor (low loss) and high power-handling capability with self-consistent electromagnetic shielding. The most significant advantage of SIW technology is its capacity of enabling a possible complete integration of all the components on the same substrate, including passive components, active elements, and even antennas as presented in Wu et al. (2003, 2012), Deslandes and Wu (2006), Bozzi et al. (2011). SIW techniques can be used to solve a series of headache problems, which renders it hugely popular in the community today (Vye 2011). A remarkable problem arising at high frequency is the appearance (trapping) of surface waves that generally decrease the antenna efficiency. The SIW can effectively control this phenomenon. Since SIW components are bounded by conducting surfaces on both sides of the substrate, they exhibit the merits of extremely low (completely negligible) radiation/leakage loss and insensitive to outer interferences. The SIW technology has already experienced a rapid development over more than one decade. This development allows the demonstration and applications of innovative passive and active circuits, antennas, and systems at microwave and millimeter-wave frequencies covering a very broad frequency range from subgegahertz to subterahertz. In addition, the SIW technique can be combined with other SICs platforms to create multiformat and multifunction devices and systems.

SIW Techniques and Design Basics

The SIW (also known as postwall waveguide or a laminated waveguide (Uchimura et al. 1998)) is a rectangular waveguide-like structure in an integrated planar form, which can be synthesized and fabricated by using two rows of conducting cylinders, vias or slots embedded in a dielectric substrate that is electrically sandwiched by two parallel metal plates as illustrated in Fig. 2.

The operating frequency range is delimited by the monomode propagation of quasi-TE_{10} wave as its cut-off frequency is only related to equivalent width a_{eq} of the synthesized waveguide as long as the substrate thickness or waveguide height is smaller than this width. This equivalent width will be discussed in the following section.

Via Configurations

Round metalized via holes are used to create the electric sidewalls or fences of SIW through two parallel via arrays. The discontinued current flow along the via- or slot-synthesized metalized sidewalls does not allow the propagation of TM modes. In addition, a large width-to-height ratio of SIW supports the

DOI 10.1007/978-981-4560-75-7_57-1

propagation of TE_{m0} modes. Since these techniques are amenable to arbitrarily shaped perforations, the limitation of circular via shapes is no longer mandatory. Rectangular slot trenches were found to be advantageous for lower leakage and better definition of the SIW sidewalls. This is important for some designs such as those iris and window coupling geometries found in the filter design. Rounded corners increase the overall mechanical stability, allowing for a better metallization, which often cannot be avoided in the fabrication process due to the finite diameter of laser beams in the case of using a laser-based micromachining process. Figure 2 shows two different slot trench (SIW) configurations: (a) cylindrical via arrays and (b) longer slots for SIW operation between the first and second stop bands. Note that the SIW structure is a periodic geometry, which is subject to the guided-wave phenomena of all periodic waveguides such as bandgap (stopband) effects. Such stopbands, caused by the distributed Bragg reflection, occur around frequencies at which the periodic spacing p is equal to a multiple of half a guided wavelength (Patrovsky et al. 2007).

SIW Propagation Modes

A three-dimensional view of the SIW is illustrated in Fig. 2. The PCB's ground planes form the broad walls of the SIW and a linear array of metalized via holes is used for the narrow walls. Since only vertically oriented currents can flow on the via-hole walls, this structure is capable of containing mode patterns with only vertical components of the electric field vector. Mode patterns with horizontal components of the electric field vector have horizontal components of the current distribution on the via hole walls, which will radiate. The SIW is thus ideally suited for containing the dominant mode pattern in a rectangular waveguide. The thickness h of waveguide does not have an effect on the propagation constant. This gives the designer certain degree of freedom in the choice of the SIW substrate.

The cut-off frequency of modes TE_{m0} can be derived using:

$$f_{c_{m0}} = \frac{m}{2a_{eq}\sqrt{\mu\varepsilon}} \tag{1}$$

and the corresponded guided wavelength is:

$$\lambda_g = \frac{\lambda_0}{\sqrt{\varepsilon_r\left(1 - \left(\frac{f_c}{f}\right)^2\right)}} \tag{2}$$

This expression gives a good approximation of the field propagation in the SIW. This equation shows that there are two important parameters: ε that represents the dielectric constant inside the waveguide and a the width of the metallic waveguide that is not defined here in the case of the SIW.

The modeling and design of SIW interconnects and circuits can be made on full-wave analysis tools, either general purpose commercial packages or specialized numerical codes. Among the most common techniques adopted for the design of SIW structures, there are the Finite-Difference Time Domain (FDTD) method or the Finite-Difference Frequency Domain (FDFD) (Xu et al. 2003), the Boundary Integral-Resonant Mode Expansion (BI-RME) method (Cassivi et al. 2002), the Method of Lines (MoL) (Yan et al. 2005), and the Transverse Resonance Method (Deslandes and Wu 2006).

Using those different numerical methods, the propagating parameters of the dominant mode, like wavenumber k or complex propagation constant γ can be derived.

The SIW propagation constant of the mode TE_{10} can be obtained using a simulation software like HFSS or CST or using measurement. To characterize the propagation and attenuation constants of the SIW line,

DOI 10.1007/978-981-4560-75-7_57-1

simulations are conducted using the HFSS software. The permittivity and height of the substrate used are respectively 2.94 and 0.762 mm in the calculations. The width of the line is 3.75 mm, $p = 0.4$ mm, and $d = 0.4$ mm according to Fig. 2.

By considering two SIW lines with different length l_2 and l_1, and after generating simulated S-parameters, phase constant β and attenuation constant α are calculated using:

$$\beta = \frac{\left|\angle\left(S_{21,l_2}\right) - \angle\left(S_{21,l_1}\right)\right|}{\Delta l} \tag{3}$$

and

$$\alpha = -\frac{ln\left|\left(S_{21,l_1}\right) / \left(S_{21,l_2}\right)\right|}{\Delta l} \tag{4}$$

and

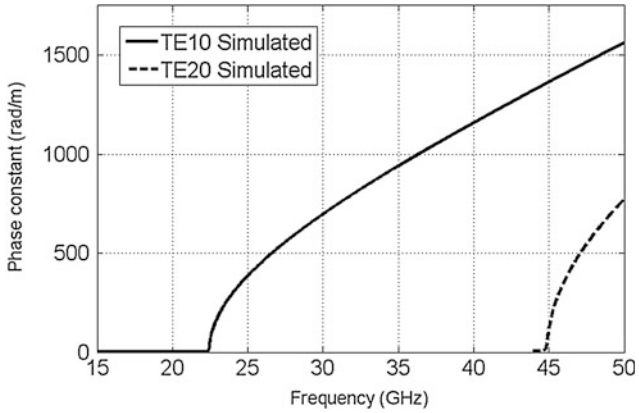

Fig. 3 Phase constants of TE_{01} and TE_{20} modes simulated using a full wave simulator

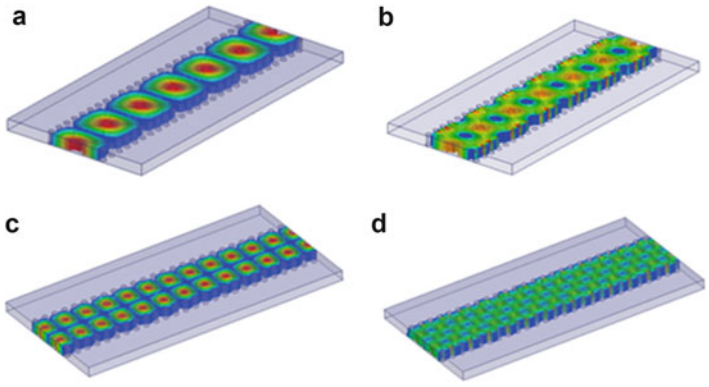

Fig. 4 (**a**) E-field distribution of the first mode, (**b**) H-field distribution of the first mode, (**c**) E-field distribution of the second mode, and (**d**) H-field distribution of the second mode

DOI 10.1007/978-981-4560-75-7_57-1

$$\gamma = \alpha + i\beta \tag{5}$$

Figure 3 shows the phase constant for the first and second modes; the second mode's cut-off frequency is twice that of the first mode just like the standard rectangular waveguide. The corresponding E and H field distributions are illustrated in Fig. 4.

Equivalent Width

The SIW can be modeled by a conventional rectangular waveguide (RW) through the so-called equivalent width a_{eq}. This parameter is calculated such that the resulting dielectric-filled rectangular waveguide has the same cut-off frequency of the fundamental TE_{10} mode as its corresponding SIW structure. This determines the propagation characteristics of the TE_{10} mode. Physical parameters of via-holes d and p are set to minimize the radiation (or leakage) loss as well as the return loss (Deslandes and Wu 2003). The equivalent rectangular waveguide width can be approximated according to the geometrical parameters illustrated in Fig. 2a as follows:

$$a_{eq} = a_{SIW} - \frac{d^2}{0.95p} \tag{6}$$

The cut-off frequency of the first mode is defined by:

$$f_c(\mathrm{TE}_{10}) = \frac{\mathrm{c}}{2 \cdot \sqrt{\varepsilon_r}} \cdot \left(a_{SIW} - \frac{d^2}{0.95p} \right)^{-1} \tag{7}$$

And for the second mode by:

$$f_c(\mathrm{TE}_{20}) = \frac{\mathrm{c}}{\sqrt{\varepsilon_r}} \cdot \left(a_{SIW} - \frac{d^2}{1.1p} - \frac{d^3}{6.6p^2} \right)^{-1} \tag{8}$$

Loss Considerations

The energy in transmission may be lost or dissipated through different physical mechanisms including dielectric losses, conductor losses, and radiation losses. Since the inner part of SIW is filled with a dielectric material, an adequate choice of dielectric material and conductor quality can reduce the contribution of the first two loss mechanisms (Bozzi et al. 2014).

- Attenuation because of the dielectric losses is related to tanδ of the dielectric substrate:

$$\alpha_d = \frac{k^2 \tan\delta}{2\beta} \tag{9}$$

- Attenuation because of the conductive loss:

$$\alpha_c = \frac{R_s}{a^3 b \beta k \eta} \left(2b\pi^2 + a^3 k^2 \right) \tag{10}$$

with:

DOI 10.1007/978-981-4560-75-7_57-1

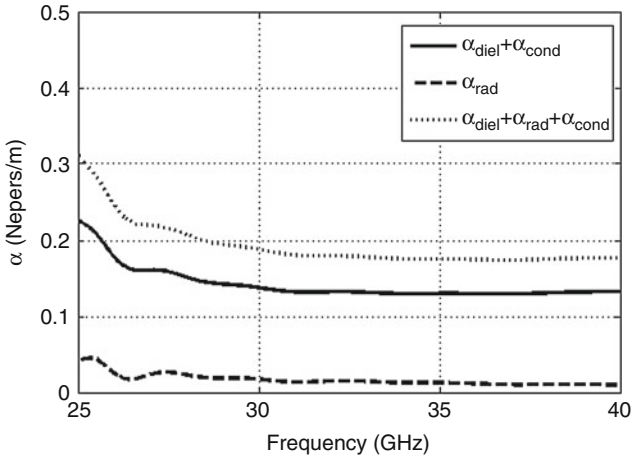

Fig. 5 Attenuation constant versus frequency for an SIW structure

$$R_s = \sqrt{\frac{\omega\mu_0}{2\sigma}} \text{ (surface resistance)} \tag{11}$$

The radiation leakage is caused by the gaps between the metalized via and slots. Radiation or leakage leads to two consequences, namely additional signal losses and undesired interferences.

$$\alpha_R = \frac{\frac{1}{a_{SIW}}\left(\frac{d}{a_{SIW}}\right)^{2.84}\left(\frac{p}{d}-1\right)^{6.28}}{4.85\sqrt{\left(\frac{2a_{SIW}}{\lambda_g}\right)^2-1}}\left[\frac{dB}{m}\right] \tag{12}$$

In order to ensure that the synthesized waveguide section becomes radiationless or free from leakage loss, parametric effects of p and d were studied on those issues (Deslandes and Wu 2003). To simplify the analysis, dielectric and conductor losses are not considered, the loss solely comes from radiation. It is found that the following requirements can be put forward to minimize the return and leakage losses, that is, the diameter of hole should satisfy some geometric constraints:

$$d < \frac{\lambda_g}{5} \tag{13}$$

$$p \leq 2d \tag{14}$$

At millimeter and submillimeter frequencies, planar circuits usually suffer from radiation originating at bends and discontinuities. 90° SIW and microstrip bend losses were analyzed (Djerafi and Wu 2012a) in the 77 GHz band. The major part of losses in microstrip is related to the radiation compared to an insignificant radiation loss in SIW bend.

Using Eq. 5 and the same lines used to estimate the phase propagation constant below, Fig. 5 shows the attenuation versus frequency with only the contribution of the radiation loss and with the metallic and dielectric loss. The dielectric loss represents the major part of the losses. The attenuation constant decreases when frequency increases, especially the radiation loss.

Principal SIW Parameters

Substrate Materials

Low-loss material is the foundation for developing high-performance integrated circuits and systems. This becomes more critical for power budget as frequency increases to the millimeter-wave ranges and beyond. This is because it is relatively difficult to amplify over those ranges. Thermal effect, dielectric nonuniformity and metallic surface roughness may have to be taken into account for better and accurate design. This is especially important for antenna developments. The SIW can theoretically be constructed with any available substrate. The most used ones are Rogers RT/duroid®5880 glass microfiber reinforced PTFE composite and RT/duroid®6002 for conventional PCB processing, which are easily sheared with laser and machined to the required shape. The holes can easily be drilled mechanically into these machinable materials compared to ceramics which can only be processed by the laser perforation and other special techniques. All these materials have an excellent dimensional stability. Of course, a good thermal stability of the material of choice should also be considered in the design. These selections will not just affect the performances but also defines power handling capabilities (Cheng et al. 2008).

SIW Line Configurations

The SIW structures can be arranged in different configurations. Depending on applications in term of allowed space, integrability, task and performance, one of them can specially be preferred. Table 1 summarizes some attention-grabbing configurations. The H-to E-plane interconnection shown in (b) is very useful in the design of multipolarization antenna feeding. To realize the corner, a vertical line is inserted into a horizontal line. The vertical and horizontal layers making up the corner were fabricated using a conventional printed circuit board (PCB) process, before manually introducing the vertical layer in the horizontal one (Djerafi et al. 2012a).

Comparing to other types of planar transmission lines, a large form factor of SIW is a bottleneck for its integration with other conventional integrated circuits. Miniaturization techniques for SIW therefore become very crucial in some designs (Ding and Wu 2008; Djerafi et al. 2012b). The proposed structures present transversely folded waveguides in different shape, namely, C-type, T-type, and L-type. In 2005, a 2-layered T-type structure was proposed for the miniaturization of an SIW for the first time with SIW in

DOI 10.1007/978-981-4560-75-7_57-1

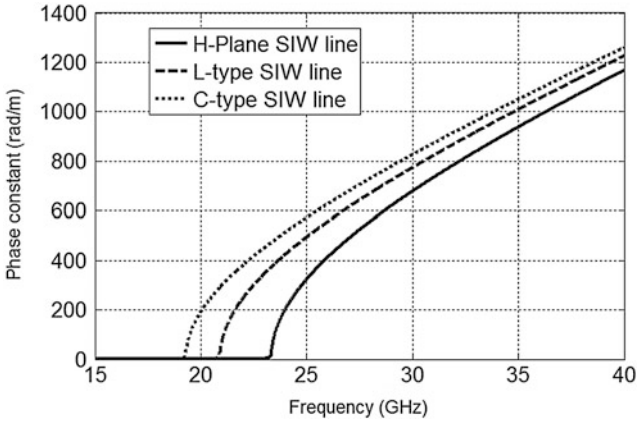

Fig. 6 Dispersion characteristics of different SIW lines

multilayered substrates (Grigoropoulos and Young 2004). Subsequently, C-type folding approaches as described in column (b) were also implemented with SIW in multilayered substrates (Grigoropoulos et al. 2005). L-FSIW was proposed (Doghri et al. 2013) to build a series of couplers. The cross section of the L-FSIW is equivalent to 2-D transmission line with a shunt capacitance that models the effect of the corner region.

For the C-type SIW line, the propagation constant is obtained by solving:

$$\tan(s+d)k_x + \tan(a-s-d)k_x = 0 \tag{15}$$

and for L-type SIW line by:

$$\beta_{10}^{f} = \sqrt{(2\pi f\sqrt{\mu\varepsilon})^2 - \beta'^2} \tag{16}$$

where

$$\beta'_{10} = \frac{2}{a'}cot^{-1}\left[8a'tf^2\mu\varepsilon\ln\left(\frac{2*\left(1-\frac{\sqrt{2}t}{a'}\right)}{\sqrt{2}C_f}\right)\right] \tag{17}$$

In Fig. 6, dispersion characteristics of the dominant mode in the two types of folded waveguide are compared with that of the conventional version of the original unfolded SIW (Ding and Wu).

All three lines have the same substrate filling. It is clearly observed that the cut-off frequencies of the L-type SIW line and C-type SIW line are lower than the classic SIW line. The shift in frequency is due to the effect added by the corners.

Characteristic Impedance

The impedance is an important characteristic especially when the SIW is connected to other planar and nonplaner structures. One definition of impedance in a rectangular waveguide is the wave impedance. This impedance, however, does not take into account the geometry of the transmission line. Another impedance definition more often employed in the design of matching networks is the characteristic

DOI 10.1007/978-981-4560-75-7_57-1

impedance. The characteristic impedance in a transmission line supporting a TEM wave can be defined in one of the three following ways (D'Orazio 2004):

$$Z_{PV} = \frac{VV^*}{2P_t} \tag{18}$$

$$Z_{PI} = \frac{2P_t}{II^*} \tag{19}$$

$$Z_{VI} = \frac{V}{I} \tag{20}$$

In a rectangular waveguide, however, the choice of voltage and current is not unique and these definitions do not produce the same results. The choice of which definition is more suitable depends on the targeted applications in question. The three definitions of characteristic impedance in an SIW are given by:

$$Z_{PV} = \frac{2h}{a_{eq}} Z_{TE} \tag{21}$$

$$Z_{PI} = \frac{\pi^2 h}{8a_{eq}} Z_{TE} \tag{22}$$

$$Z_{VI} = \frac{\pi h}{2a_{eq}} Z_{TE} \tag{23}$$

where Z_{TE} is the wave impedance of the TE mode.

SIW Transitions

Transitions from SIW to microstrip or coplanar waveguide or from SIW to air-filled rectangular waveguide are necessary to couple high-Q waveguide components to active planar ones. In addition, these transitions are necessary to be able to experimentally characterize the SIW components. They should have the following properties, namely broadband, low loss, and minimum VSWR.

Although the design of transitions is specific to a particular geometry, some basic guidelines can be appreciated. The design of broadband transitions, in general, requires that the level of the characteristic impedances be similar (impedance matching) and that the field distributions of the coupling structures be similarly oriented (field matching). The design of transitions between two dissimilar structures is complicated by the excitation of higher order modes at the discontinuity.

Different waveguide-to-SIW transitions are detailed in the literature. Most of these transitions are based on waveguide-to-microstrip or to-CPW (Cassivi et al. 2002; Deslandes 2010).

Microstrip/CPW-to-SIW Transition

The microstrip-to-SIW transition shown in Fig. 7 is based on the quarter-wave transformer principle. The main parameters of this transition are the width of the SIW (a_{eq}), the width of the microstrip taper (w) and the taper length (l). a_{eq} can be computed using Eq. 6. For each substrate having thickness h and permittivity ε_r, an optimum taper width is obtained by solving this equation (Deslandes 2010):

DOI 10.1007/978-981-4560-75-7_57-1

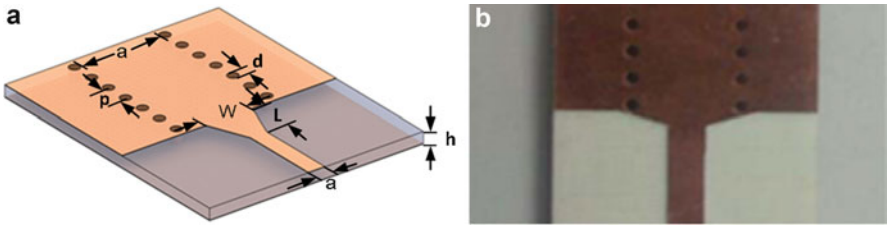

Fig. 7 Microstrip-to-SIW transition: (**a**) configuration and (**b**) example of a fabricated prototype

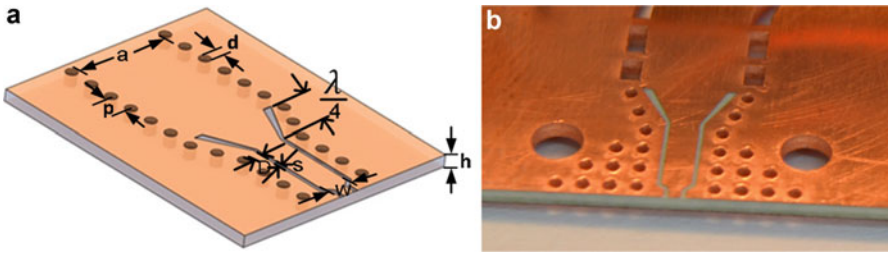

Fig. 8 GCPW-to-SIW transition: (**a**) configuration and (**b**) example of a fabricated prototype

$$\frac{1}{w_e} = \begin{cases} \dfrac{60}{\eta h}\ln\left(8\dfrac{h}{w} + 0.25\dfrac{w}{h}\right); & \dfrac{w}{h} < 1 \\ \dfrac{120\pi}{\eta h[w/h + 1.393 + 0.667\ln(w/h + 1.444)]}; & \dfrac{w}{h} > 1 \end{cases} \tag{24}$$

$$\frac{1}{w_e} = \frac{4.38}{a_{eq}} e^{-0.627\frac{\varepsilon_r}{\frac{\varepsilon_r+1}{2}+\frac{\varepsilon_r-1}{2}\frac{1}{\sqrt{1+12h/w}}}} \tag{25}$$

For a given substrate (h and ε_r) and SIW width (a_{eq}), to find w, Eqs. 24 and 25 are equalized, which yields the optimum taper width.

l is optimized to minimize the return loss over the full bandwidth, this length can be computed using some analytical equations described in Lu (1997).

Patrovsky et al. (2007) proposed a CPWG-to-SIW transition using an E-field coupling. The coupling slots are cut on the top surface of the SIW and placed next to the short circuit termination of the SIW. The coupling slots act like a magnetic dipole antenna with a strong E-field across the slot in the center but weaker at the end of the slot. In Li et al. (2009) Fig. 8, the sidewalls of the SIW are tapered along the triangle-shaped coupling slot in such a way that the direction of the electric field on the coupling slot is always perpendicular to the SIW sidewalls. This allows for a smooth transition. The tapered coupling slot also serves as an impedance transformer to transform any arbitrary impedance line in SIW to the CPWG port impedance exactly as the microstrip transition does.

To assure a single mode operation in the CPW, the following condition must be satisfied:

$$W + 2S + 2D < \frac{c}{2f_{\max}\sqrt{\varepsilon_r}} \tag{26}$$

W, S, and D are defined in Deslandes and Wu (2003), $f_{\max}$ is the maximum frequency of operation. The optimal taper length is $\frac{\lambda}{4}$ which gives a wider bandwidth.

Rectangular Waveguide-to-SIW Transition

In (Xia et al. 2006), a radial probe extended from an SIW inserted into a height-tapered waveguide is used, losses of about 2.5 dB are achieved at 33 GHz. In order to design the transition to a rectangular waveguide, two step transformers are used in Moldovan et al. (2006) with parallelepiped alumina probe to improve the scattering parameter, more than 3 dB of loss is measured in W band. In Li et al. (2009), a longitudinal slot window etched on the broad wall of SIW couples the energy between SIW and rectangular waveguide. This transition shows a return loss of less than 15 dB over a frequency range of 800 MHz at 35 GHz with loss of 2.5 dB in measurement and more than 1 dB in the simulation. In Li et al. (2010), a novel transition structure is realized by using a finline probe inserted into a WR-28 waveguide with an insertion loss of 1.4 dB. To measure this transition, two parts of the waveguide sandwich the substrate, which normally increases the width of the metallic waveguide. In Djerafi et al. (2012c), a WR-28-to-SIW transition based on ALTSA (Antipodal Linearly Tapered Slot Antenna) as illustrated in Fig. 9 is presented. A design constraint was to make the transition without any modification on the waveguide. A back-to-back transition has been fabricated, and measured results confirm performances of this transition. In Djerafi et al. (2013), a transition from the WR10 waveguide to SIW structure has been designed and fabricated. The proposed transition consists of a multistep impedance transformer milled into an aluminum block. The transition is illustrated in Fig. 10 where the parameters to be optimized in this transition are the aspect ratios and lengths of the steps.

Nonresonant SIW Antenna

The SICs and related antennas technologies converge toward the development of system-on-substrate (SoS) technology that allows for a complete and seamless integration of antennas and circuits. SIW supports the design of different antennas involving various elements and feeds as detailed in Wu et al. (2012). The more adaptable and popular antenna elements: slot (Wei et al. 2013) and patch backed by cavity. To miniaturize the size of antennas, different techniques can be used in the design of slot array antennas (Ding and Wu 2009, 2010). Printed antennas such as the microstrip patch, which might fulfill design requirements in the microwave range, do not provide sufficient performances in the millimeter-wave range. This is because of very high conductor losses arising from immense current densities (singularities) at the strip edges, especially in resonant structures. Disadvantages of resonant elements include also, the fact that it is usually narrowband, with bandwidths of a few percent being typical. Also, the radiation efficiency of the microstrip antenna tends to be lower than some other types of antennas, with efficiencies less than 70 % being typical.

An antenna operating in a traveling-wave configuration could provide the bandwidth and the efficiencies needed. Traveling-wave antennas are a class of antennas that use a traveling wave on a guiding structure as the main radiating mechanism. On the other hand, leakage can also be generated with enclosed waveguide structures with carefully designed geometrical asymmetry, open apertures, or slots. Therefore, leaky-wave or surface-wave antennas can be developed for millimeter-wave applications including tapered slot antenna (TSA), printed Yagi–Uda antenna or log-periodic dipole array, dielectric rod antenna, long-slot leaky-wave antenna. SIW supports the design of different antennas involving various elements and feeds as detailed in Wu et al. (2012). Over the last decade, various nonresonant antennas in SIW technique have been studied, which will be presented in the following section.

Horn Antenna

Horns provide high gain, relatively wide bandwidth, and they are not difficult to make. There are three basic types of rectangular horns. The rectangular horns are ideally suited for rectangular waveguide feeders. The horn acts as a gradual transition from a waveguide mode to a free-space mode of electromagnetic waves. The radiation fields from aperture antennas, such as slots, open-ended waveguides, horns, reflector and lens antennas, are determined from the knowledge of the fields over the aperture of the antenna. The theory of waveguide aperture antennas is generally used to study the horns. However, phase error occurs due to the difference between the lengths from the center of the feeder to the center of the horn aperture and the horn edge.

Horn antennas are now commonly used for many applications including microwave communications, feeds for reflector antennas, and radar elements. In Li and Wu (2004), an integrated *H*-plane horn antenna

DOI 10.1007/978-981-4560-75-7_57-1

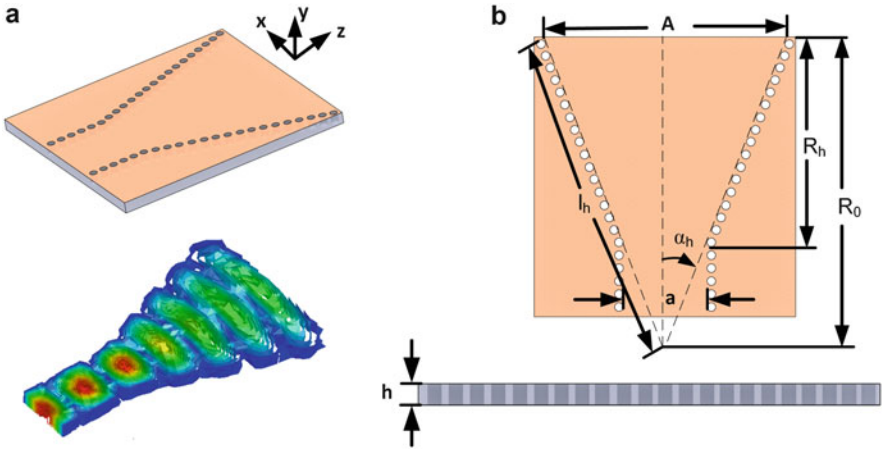

Fig. 12 (**a**) Geometry of H-plane SIW horn, (**b**) electric field distribution simulated at 35 GHz, (**c**) and (**d**) the parameters used in the analysis

was proposed. In Wang et al. (2010), a dielectric load was added to the SIW H-plane horn antenna in order to have a narrow beamwidth in both E-plane and H-plane. In Wong et al. (2008), a broadside horn antenna was implemented by the SIW technology.

E-Plane SIW Horn (Waveguide Transition)

The design of an appropriate SIW-waveguide transition passes through the design of a multiple stepped waveguide quarter-wave impedance transformer. The transformer makes use of a multiple reflection scheme. This transition can be used for designing a surface mountable horn antenna feed by SIW line. The waveguide port of the transition is flared into a large opening and forms an E-plane horn.

The proposed transition consists of a multistep impedance transformer milled into an aluminum block. The transition is illustrated in Fig. 11. The parameters to be optimized for this transition are the aspect ratios and lengths of the steps. The detail of the design has been well established (Pozar 2011).

The impedance in each section of the quarter-wave transformer is defined by:

$$Z_i = \frac{\pi^2 h_i \sqrt{\frac{\mu}{\varepsilon}}}{8a\sqrt{1-\left(\frac{\lambda_0}{2a}\right)^2}} \tag{27}$$

where h_i is the height of each section. The input impedance is defined by SIW line.

Since most of microwave integrated circuit modules need a metal housing, this structure can be installed as part of an external housing. A prototype presented by Li and Wu (2004) has an HPBW of 15° in H-plane and 27° in E-plane and a cross polarization below 30 dB.

H-Plane SIW Horns

The horn antenna integrated into substrate is a waveguide aperture flared into a large opening on the H-plane by keeping the perpendicular dimension constant. The radiation is focused in the H-plane. The geometry is shown in Fig. 12.

DOI 10.1007/978-981-4560-75-7_57-1

$$l_h{}^2 = R_0 + \left(\frac{A}{2}\right)^2, \tag{28}$$

$$\alpha_h = \arctan\left(\frac{A}{2R_0}\right), \tag{29}$$

$$R_h = \left(A - a_{eq}\right)\sqrt{\left(\frac{l_h}{A}\right) - \frac{1}{4}}, \tag{30}$$

To have a single mode excitation, the width and height of the SIW line must satisfy:

$$\frac{\lambda_0}{2\sqrt{\varepsilon_r}} < a_{eq} < \frac{\lambda_0}{2\sqrt{\varepsilon_r}} \tag{31}$$

and

$$h < \frac{\lambda_0}{2\sqrt{\varepsilon_r}} \tag{32}$$

where λ_0 is wavelength in free space.

The design rules follow the same principles of the conventional horn. The corresponding pattern can be computed using:

$$F_H(\theta, \varphi = 0^\circ) = \frac{1 + \cos(\theta)}{2} \frac{\mathrm{I}\left(\theta, \varphi = 0^\circ\right)}{\mathrm{I}(\theta = 0^\circ, \varphi = 0^\circ)} (\mathrm{H} - \text{plane pattern}) \tag{33}$$

$$F_E(\theta, \varphi = 90^\circ) = \frac{1 + \cos(\theta)}{2} \frac{\sin\left[\left(\frac{\beta b}{2}\right)\sin\theta\sin\varphi\right]}{\left(\frac{\beta b}{2}\right)\sin\theta\sin\varphi} (\mathrm{E} - \text{plane pattern}) \tag{34}$$

where

$$\begin{aligned} I(\theta, \varphi) = {} & e^{j\left(\frac{R_1}{2\beta}\right)\left(\beta\sin\theta\cos\varphi + \frac{\pi}{A}\right)^2}\left[C\left(S_2'\right) - jS\left(S_2'\right) - C\left(S_1'\right) - jS\left(S_1'\right)\right] \\ & + e^{j\left(\frac{R_1}{2\beta}\right)\left(\beta\sin\theta\cos\varphi - \frac{\pi}{A}\right)^2}\left[C\left(t_2'\right) - jS\left(t_2'\right) - C\left(t_1'\right) + jS\left(t_1'\right)\right] \end{aligned} \tag{35}$$

$$S_1' = \sqrt{\frac{1}{\pi\beta R_1}}\left(-\frac{\beta A}{2} - R_1\beta\sin\theta\cos\varphi - \frac{\pi R_1}{A}\right) \tag{36}$$

$$S_2' = \sqrt{\frac{1}{\pi\beta R_1}\left(\frac{\beta A}{2} - R_1\beta\sin\theta\cos\varphi - \frac{\pi R_1}{A}\right)} \tag{37}$$

DOI 10.1007/978-981-4560-75-7_57-1

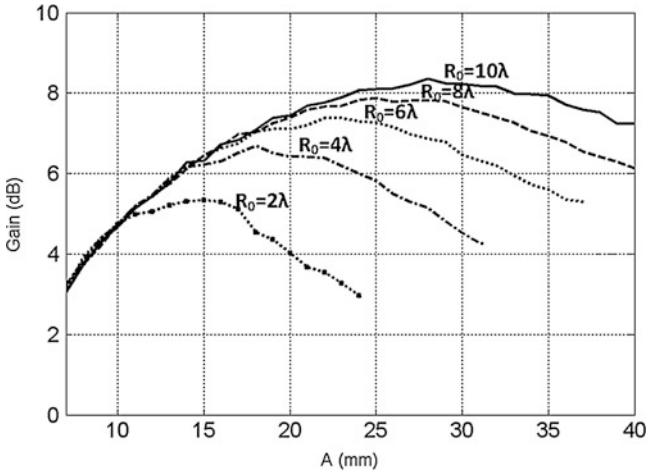

Fig. 13 Optimal gain for different lengths and apertures

$$t_1' = \sqrt{\frac{1}{\pi\beta R_1}\left(-\frac{\beta A}{2} - R_1\beta\sin\theta\cos\varphi + \frac{\pi R_1}{A}\right)} \tag{38}$$

$$t_2' = \sqrt{\frac{1}{\pi\beta R_1}\left(\frac{\beta A}{2} - R_1\beta\sin\theta\cos\varphi + \frac{\pi R_1}{A}\right)} \tag{39}$$

$C(x)$ and $S(x)$ are Fresnel integrals, which are defined as

$$C(x) = \int_0^x \cos\left(\tfrac{\pi}{2}\tau^2\right)d\tau \text{ and } S(x) = \int_0^x \sin\left(\tfrac{\pi}{2}\tau^2\right)d\tau$$

The directivity is calculated by

$$D = \frac{4\pi}{\lambda^2}\varepsilon_t\varepsilon_{ph}^H(Ah) \tag{40}$$

where

$$\varepsilon_t = \frac{8}{\pi^2}$$

$$\varepsilon_{ph}^H = \frac{\pi^2}{64t}\left((C(p_1) - C(p_2))^2 + (S(p_1) - S(p_1))^2\right)$$

$$p_1 = 2\sqrt{t}\left(1 + \frac{1}{8t}\right)$$

$$p_2 = 2\sqrt{t}\left(-1 + \frac{1}{8t}\right)$$

DOI 10.1007/978-981-4560-75-7_57-1

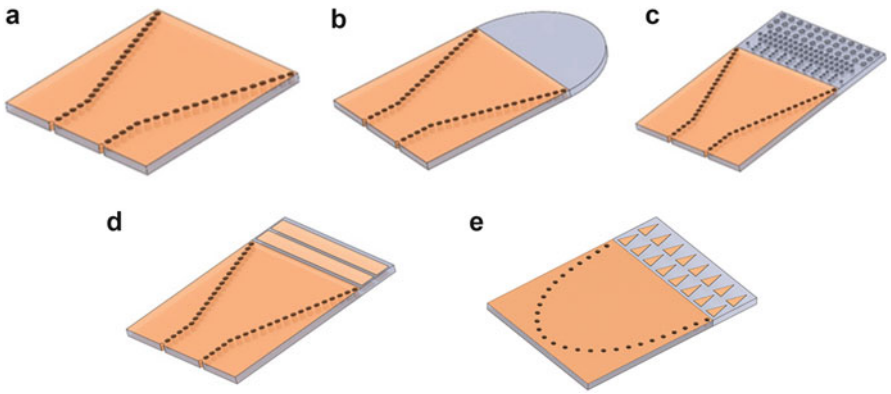

Fig. 14 SIW horn antennas (**a**) standard, (**b**) SIW horn with a dielectric lens (the lens has a constant permittivity, (**c**) SIW horn antenna with dielectric lens (the lens has different permittivity), (**d**) SIW horn with a 2 block printed transition to the air, (**e**) SIW horn antenna with a triangular grated transition and a superelliptical taper

$$t = \frac{1}{8}\left(\frac{A}{\lambda}\right)^2 \frac{\lambda}{R_0}$$

Figure 13 shows an example of the gain obtained using HFSS for different lengths (R_0) and apertures A. The substrate used has a dielectric constant of 2.94 and a thickness of 2 mm ($a_{eq}/2$)

For each length, there is an optimal aperture that gives the maximum gain. The figure demonstrates that by increasing the length, the gain enhancement is less and less significant.

For a very thin substrate thickness with respect to propagation wavelength, the electromagnetic waves will be confined within the substrate instead of radiating. The mismatch between the SIW horn and the air increases which results in a poor bandwidth.

Matching Bandwidth and Radiation Improvements

One of the solutions to improve the horn performance is the insertion of lens in front of the radiating aperture. Generally, dielectric lenses are constructed by extending the same dielectric used to build the horn. In the lens-corrected horn, the lens acts as a focusing element, which increases the front to back ratio and reduces the front phase error. When the substrate becomes thinner, generally below $\frac{\lambda_0}{6}$, the lens effects become less relevant. The different developed topologies in the literature are shown in Fig. 14 as well as the fabricated counterpart in Fig. 15.

SIW H-plane sectorial horn antenna is given in Fig. 15a. The rectangular waveguide and sectorial horn antenna are integrated by using the same single substrate based on the SIW technology in Wang et al. (2010). A reasonable length of 15 mm was determined to obtain an acceptable quadratic phase error and single mode on the aperture. The simulated gain and side lobe level are 6.73 dBi and −12.08, respectively; the simulated beamwidths of the E-plane and the H -plane are 180° and 48°, respectively. Efforts for improving the impedance matching of planar horn antenna have been reported in recent papers. Solutions based on integrated dielectric lens (Fig. 14b, c) or printed transition for SIW were proposed (Fig. 14d, e).

In Wang et al. (2010) a dielectric slab is placed in front of the aperture of the horn. This slab serves as the dielectric guiding structure in the H-plane. In the H-plane, for a horn with maximum gain, the aperture phase distribution along the H-plane is nearly uniform without the dielectric loading. This antenna is loaded by a dielectric elliptical slab with a length of 1.4 mm. In this case, the dielectric loading serves as the phase corrector in the H-plane to compensate the quadratic phase error caused from the shortened length. The gain is 5.75 dBi, the back sidelobe level is 11.78 dB and the beamwidths of the E- and H-plane

DOI 10.1007/978-981-4560-75-7_57-1

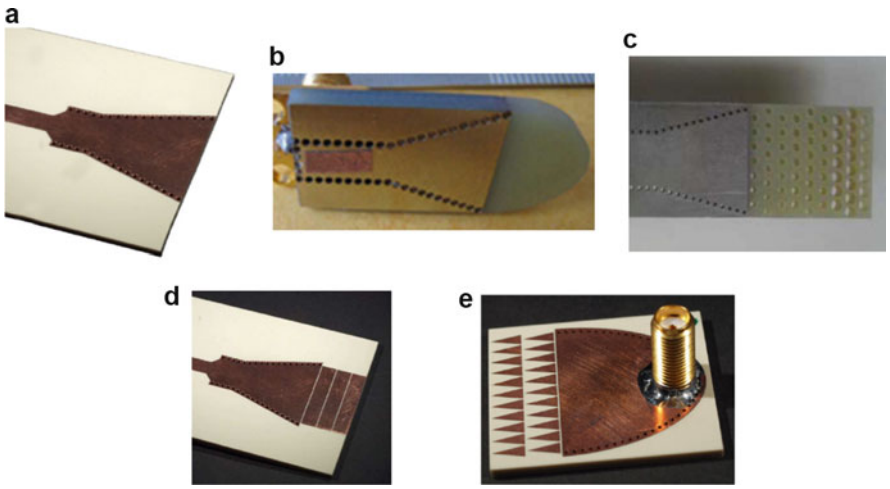

Fig. 15 Example of the fabricated horn antennas according to Fig. 14

are 178° and 63°, respectively. Different shapes of dielectric loading can be used (ellipse, rectangle, hyperbola, and parabola). In Cao et al. (2014) a planar SIW horn antenna with a modified dielectric lens was proposed, by drilling air vias in the substrate, different effective dielectric constants can be realized by adjusting via diameter. Therefore, the SIW horn antenna loaded by a dielectric slab with gradually decreasing dielectric constant is designed.

The presented solution in Esquius-Morote et al. (2013a) is focused on improving the reflection coefficient of H-plane SIW horn antennas with additional parallel plate block. The horn aperture practically behaves as a slot in an infinite ground plane with a front-to-back ratio (FTBR) close to unity. The proposed printed transition does not significantly modify the radiation characteristics of a conventional SIW horn. The main radiating element of an SIW horn with the proposed transition is indeed the open-ended termination of the last parallel plates waveguide. Therefore, the differences in radiation performances are mainly due to diffraction effects at the transition edges. Modifications of the transition geometry have been presented in Esquius-Morote et al. (2013b) to improve the radiation performances of SIW horn antennas (Figs. 14d and 15d).

The tapered ridge was proposed in Mallahzadeh and Esfandiarpour (2012), consisting of a simple arrangement of vias on the side flared wall within the multilayer substrate. VSWR below 2.5 for the whole frequency range of 18–40 GHz was realized by simulation.

Leaky-Wave Antenna

Leaky-wave antennas (LWA) are nonresonant, consisting of a series of perturbations on a metallic or dielectric waveguide in question. The perturbations produce radiation since they cause energy to leak away along the waveguide. Leaky-wave antennas have been studied for more than four decades, exhibiting interesting features due to their traveling-wave nonresonant nature. Leaky-wave antennas have the inherent property that the beam scans with frequency. For scanning applications, this is an important advantage. Most of the early leaky-wave antennas were based on enclosed rectangular or NRD waveguides, in which some kind of cuts or holes were introduced in order to produce the leakage of power along the length of the waveguide. In the last two decades, the research was focused in the millimeter-wave band, where new LWA designs have been proposed to overcome the technological problems associated to these higher frequencies.

Leaky-wave antennas support a fast wave on the guiding structure, where phase constant β is less than free-space wavenumber k_0. The leaky-wave is therefore fundamentally a radiating type of wave, which

DOI 10.1007/978-981-4560-75-7_57-1

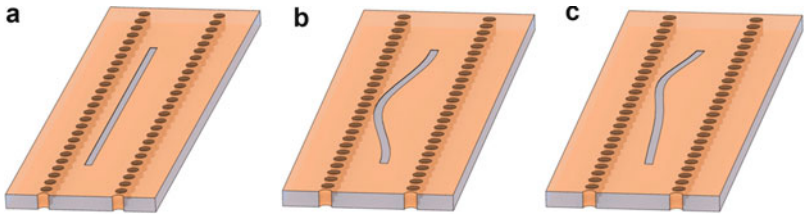

Fig. 16 Leaky-wave long slot antenna: (**a**) straight longitudinal slot, (**b**) sine squared meander pattern, and (**c**) Taylor power distribution meander pattern

radiates or "leaks" power continuously as it propagates on the guiding structure (and hence the name of the antenna). The operation is therefore quite different from a slow-wave or surface-wave type of antenna, where radiation mainly takes place at the end of the antenna.

Depending upon their architecture, leaky-wave antenna can be categorized as either uniform or periodic or quasi uniform periodic. Uniform antennas are homogeneous along the length of the guiding structure. Periodic structure has regular perturbations along their length. They both are derived from specific guided-wave counterparts and follow the same rules of formation of leaky wave. These two types can be constructed on the top wall (broad wall) or lateral wall (narrow wall). Another distinction that can be made is between a one-dimensional (1D) leaky-wave antenna and a two-dimensional (2D) leaky-wave antenna.

Uniform Leaky-Wave Structure

Long Slot Leaky-Wave Antenna

Figure 16 shows different configurations of SIW uniform leaky-wave structure. Usually, a fast wave ($b < k_0$) travels in enclosed guided-wave structures such as rectangular metallic waveguide and SIW. A physical cut that disturbs the guided wave along the longitudinal propagation direction will produce a leaky wave because the condition of forming a leaky wave has been fulfilled in this case. The long slot on the broadside of waveguide has to be precisely machined with a specific meandering profile in order to synthesize the desired radiation properties. Cheng et al. (2011) introduces a design process of SIW long slot leaky-wave antenna.

Using substrate with permittivity ε_r, the beam direction θ at the operation frequency is defined as:

$$\theta = \arcsin\frac{\lambda_0}{\lambda_g} = \arcsin\sqrt{\varepsilon_{r-}\left(\frac{c}{2a_{eq}f}\right)^2} \tag{41}$$

a_{eq}, the SIW equivalent width is generally selected to ensure the monomode operation.

As shown in Fig. 17, the scanning range of uniform leaky-wave antennas using a standard air-filled waveguide is about 12° with 4 GHz of frequency sweep around 35 GHz. The variation of pointing angle in the same bandwidth increases when the SIW line is used, with permittivity of 3. The scanning angle is three times in SIW compared to the hollow waveguide. In Cao et al. (2014) planar beam scanning substrate integrated waveguide (SIW) slot leaky-wave antenna (LWA) is proposed for enhancing scanning range and gain flatness using a modified composite right/left-handed transmission line (CRLH TL) structure.

It is assumed that the leaky-wave antenna is terminated with load which absorbs a fraction R of input power. Generally, the length L is considered equivalent to 20 wavelength to ensure efficiency of 95 % ($R = 0.05$). The slot width should be around 0.08 λ_g.

DOI 10.1007/978-981-4560-75-7_57-1

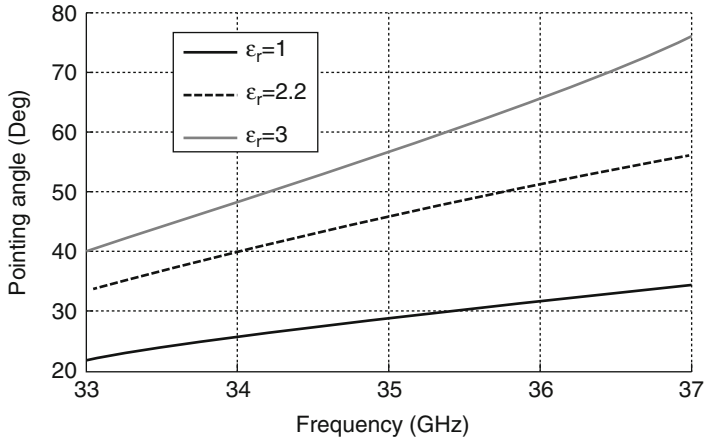

Fig. 17 Scanning range of uniform slot with different permittivity

Different meander contour can be considered other than the straight longitudinal slot; sine squared plotted in Fig.16b is defined by in Whetten and Balanis (1991)

$$x = \left(0.5 + 0.2sin^2\left(\frac{\pi}{L}z\right)\right)a \tag{42}$$

The slot starts at waveguide center ($x = 0.5\ a$ at $z = 0$) and returns at the center at the end of the slot. Different contours can be defined regarding the distribution of the radiated power. This type of meander contour provides the necessary aperture field taper for superior antenna far-field amplitude performance. Since the power within the waveguide is continuously lost along the slot, the ideal meander pattern must account for both the amount of power to be radiated at a given point along the slot, and the amount of power remaining in the guide. Thus, at the leading edge of the slot (nearest to the generator), the slot can remain near the centerline of the guide and still radiate sufficient power. Farther along the slot, as the power level decreases within the guide, the slot must meander closer to the sidewall in order to radiate the desired power level. The exact meander contour is usually very difficult to determine. Starting from the required amplitude distribution (Taylor (shown in Fig. 17c), Tchebechev, sinusoidal, etc.), the radiation per unit length α is defined by:

$$\alpha(z) = \frac{\frac{1}{2}|A(z)|^2}{\frac{1}{1-R}\int_0^L A(\zeta)^2 d\zeta - \int_0^z A(\zeta)^2 d\zeta} \tag{43}$$

Then the relation between offset x, and radiation per unit length α should be determined. Most of previous works determined the radiation properties of a long slot leaky-wave antenna by a numerical analysis of the fields in the slot. In Cheng et al. (2011), Ansoft HFSS was used to determine radiation per unit length, and normalized phase propagation per unit length, according to different offset. In Scharp (1982) the relation is defined as:

DOI 10.1007/978-981-4560-75-7_57-1

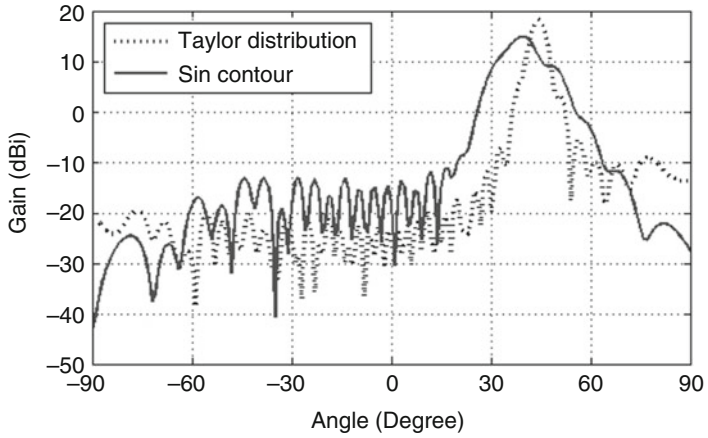

Fig. 18 Simulated patterns of leaky-wave antenna

$$x(z) = \frac{a}{\pi} arcsin \sqrt{\frac{h}{2d}\frac{\lambda_c^3}{\lambda\lambda_g L}\frac{\alpha\left(\frac{z}{L}\right)}{1-\int_0^{\frac{z}{L}}\alpha(y)dy}} \tag{44}$$

d for the width of the slot and h is the substrate thickness, the illumination being a function of the distance z divided by the length L.

Figure 18 gives simulated radiation patterns for an LWA antenna with Sin contour and Tayler distribution. Dielectric with 2.2 of permittivity and 0.5 mm of thickness with length of 115 mm (20 λ_g at 35 GHz) is used in the two designs. The antenna with Taylor distribution shows higher gain, narrower 3-dB beam-width and better sidelobe levels. However, the sin contour slot is very simple to design and in general its performance is still acceptable.

Lateral Slot Leaky-Wave Antenna

Using its half-mode (HM) version, the SIW structure offers another advantage when used in the design of leaky wave structures. When only the mode TE10 is propagating in SIW waveguide, the maximum value of E-field is located at the vertical center plane along the propagating direction and the center plane can be considered as an equivalent magnetic wall. As a result, the half-mode substrate integrated waveguide (HMSIW) can be simply achieved by dividing the SIW into two equal parts. HMSIW was proposed by Hong et al. (2006). In an SIW structure, the ratio of width a to height b is usually very large when an SIW is cut into two half waveguides along the center plane, the resulting open aperture between the top and bottom planes is thus very close to a magnetic wall. The dominant mode in such a structure is just like one half of the dominant mode TE_{10} in a complete SIW. In the area close to the aperture, the field is out-diffused a little bit to satisfy its boundary conditions. On the other hand, an HMSIW can also be regarded as a half of microstrip line, which is terminated by a short-circuited plane in the middle. The first higher order mode of the microstrip line has been demonstrated to be an efficient leaky-wave line source. Usually an electric wall is inserted in the middle plane of a microstrip line to suppress the dominate mode (quasi-TEM mode). Interestingly, the working mechanism of a half microstrip line excited by its first high-order mode is exactly the same as that of an HMSIW. Since the leaky-mode is the fundamental mode in the HMLWA, the excitation becomes easier, and complicated feeding structures are not needed anymore. A leaky-wave antenna based on the HMSIW technique was proposed and investigated in Xu

et al. (2008). The antenna is characterized by many attractive advantages, including compact size, easy fabrication, low cost, low loss, wide bandwidth, and direct integration with planar circuits.

The proposed LWA topology is shown in Fig. 19, to improve the return loss, a section of HMSIW with gradually tapered width from W_2 to W_1 is adopted. L is the antenna length, b is the thickness of substrate and the dielectric constant of the used substrate is 2.2, W_2 is the width between the metal via holes and leakage aperture (also called aperture depth when seen from antenna angle), and W_0 is the width between the metal via holes and the other edge of waveguide (input HMSIW lines). The width of additional dielectric is designed less than $\lambda/4$ to avoid the undesired channel modes.

The far-field radiation pattern of this antenna indicates a quasi omnidirectional characteristic, which is a hollow cone centered on the axis. The beam will then be in the form of a conical beam that opens along the negative z axis at an angle θ that increases with frequency, approaching a donut-shaped pattern at broadside. The angle of the cone can be controlled using the thickness as shown in Fig. 20. As the used substrate is thicker as the aperture of the cone is smaller.

Periodic Structures

This type of leaky-wave antenna consists of a slow-wave structure that has been modified by periodically modulating the structure in some fashion. A typical example is a rectangular waveguide that is loaded with a dielectric material (so that the TE_{10} mode is a slow wave) and then modulated with a periodic set of holes or slots, as shown in Fig. 21. Many of the features common to 1D periodic leaky-wave antennas may be appreciated by consideration of this simple (but practical) structure. The antenna can be designed to radiate from backward to forward. In rectangular waveguide, (Hyneman 1959) shows a closely spaced slotted traveling wave array. All slots have the same length, the waveguide does not taper, and the

DOI 10.1007/978-981-4560-75-7_57-1

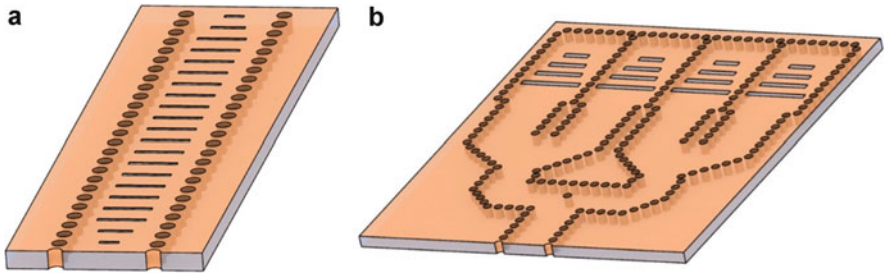

Fig. 21 (**a**) Configuration of periodic slot LWA, (**b**) example of array architecture

waveguide is filled with air. Dion (1958) describes relationships among parameters within nonresonant slotted arrays.

It is assumed that the relative permittivity of the filling material is sufficiently high so that the TE_{10} mode is a slow wave over the frequency region of interest. This will be the case provided

$$\varepsilon_r > 1 + \left(\frac{\pi}{k_0 a_{eq}}\right)^2 \tag{45}$$

According to Floquet's theorem, the infinite numbers of space harmonics of guided mode inside the periodic LWA are related to,

$$\beta_n = \beta_0 + 2n\pi/p \tag{46}$$

The first kind of leaky-wave antennas provides radiation into the forward quadrant and can yield scanning from broadside to forward end-fire directions. The scanning range for periodic leaky-wave antennas reaches from backward end-fire through broadside directions into a part of the forward quadrant. The dominant mode on the former type represents a fast wave, while the latter type is a slow wave structure. As a result, the dominant mode on periodic leaky-wave antennas does not radiate and radiation is achieved by using one of its space harmonics.

The first higher-order radiating harmonic β_{-1} inside the dielectric-filled rectangular waveguide for which $(\beta_n/k_0) \leq 1$ is related as:

$$\frac{\beta_{-1}}{k_0} = \sqrt{\varepsilon_r}\sqrt{1 - \left(\frac{c}{2af\sqrt{\varepsilon_r}}\right)^2} - \frac{n\lambda_0}{d} \tag{47}$$

Dispersion behavior inside the LWA is explained through the attenuation constant α and the propagation constant β. An angle of radiation ϕ_0 is a function of space harmonic β_n. If $\beta_{-1} < 0$, antenna radiates in the backward direction, as frequency is increasing $\beta_{-1} > 0$, antenna radiates in the forward direction.

$$\phi_0 = sin^{-1}\left(\frac{\sqrt{\varepsilon_r}\beta_{-1}}{k_0}\right) \tag{48}$$

The distance d_0 corresponding to this condition is

$$d_0 = \frac{\lambda}{1 + |cos\,\phi_0|}\pi r^2 \tag{49}$$

DOI 10.1007/978-981-4560-75-7_57-1

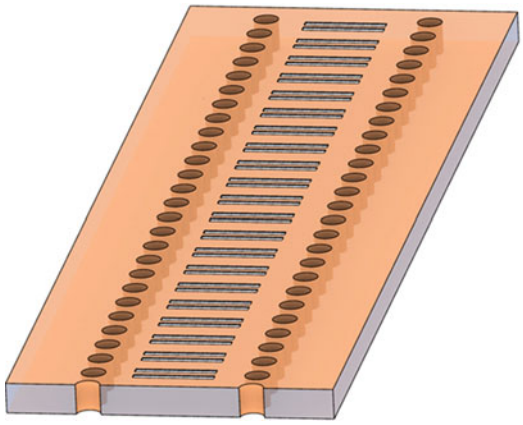

Fig. 22 The reflection cancelation forward-wave LWA

Since the slots cause a perturbation to the TE mode of the SIW, to suppress the reflection, the slot lengths are tapered linearly at both ends as shown in Fig. 21. The slot length is transformed from zero to slot length and keep the other parameters of the slots constant. To enhance the bandwidth, the SIW width can be tapered as a cosine function at both ends.

The periodic frequency scanning antenna generally has a poor radiation efficiency around broad side due to the existence of open stop band in the narrow frequency band. The reason is that the constructive addition of all series or shunt admittances along the transmission line forces input impedance to become zero. The addition of reflection cancelation stub at the distance of $\lambda_g/4$ from excitation slot avoids the undesired open stopband. The dual slot structure was proposed in Yamamoto et al. (2002), but the structure is of broadside nature only. The periodic array of eight radiating transverse slots is embedded on the broad wall of the guiding structure. The distance (S_1) between the excitation slot and reflection cancelation slot is approximately one quarter of a guided wavelength (λ_g) as shown in Fig. 22. The total phase shift between the two slots is approximately 180°. Hence, the reflected waves from the two slots are added in out-of-phase resulting in a very low reflection coefficient at the input. The slot pairs are periodically spaced at 1 λ_g, hence progressive phase is multiple of 2π, resulting in the fact that all the slot pairs are added in phase.

One-port LWA, steering from backward to forward directions including the broad side, is studied and implemented in the SIW technology. The azimuth plane scanning of multibeam antenna (MBA) is obtained through the phase control of array of nine 1-D elevation plane frequency scanning LWAs, each fed through the vertical corner on the array port contour of a Rotman lens. The complete antenna prototype fabricated on single Rogers RT/Duriod 6002 substrate with $\varepsilon_r = 2.94$ and 0.508 mm thickness is simulated through Ansoft HFSS.

The periodic frequency scanning antenna has poor radiation efficiency because of the existence of an open stopband around broad side in the narrow frequency band. In Guntupalli (2014), SIW LWA using the concept of reflection cancelation was developed. Directional pattern characteristics were studied and demonstrated from −37° to +18° by changing frequency from 58 to 78 GHz at an interval of 1 GHz. A matched termination was designed, validated and integrated to realize single port LWA. A 2-D scanning multibeam conformal array was realized by utilizing a Rotman lens BFN feeding nine LWAs in the azimuth plane for E-plane steering and natural frequency scanning property of 1 × 8 LWA for H-plane steering. The whole 3-D circuit is constructed after fabricating nine LWAs and then inserted into the slots made on the Rotman lens BFN (Fig. 23). The antenna array has seven inputs for beam switching, four dummy ports for sidewall absorption and nine LWAs on the contour of the Rotman lens. The lens is

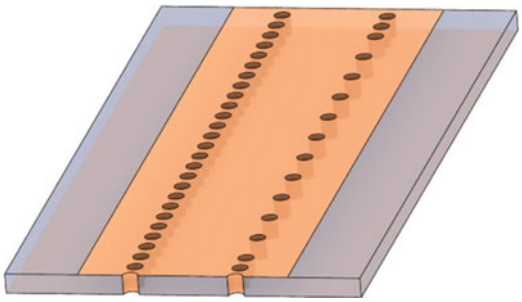

Fig. 24 Open periodic waveguides

synthesized to distribute the desired amplitude to the radiating elements located on the output ports of the Rotman lens contour.

Laterally Open Periodic Waveguides

The scheme of a lateral periodic open SIW LWA is shown in Fig. 24. This configuration is similar to the HMLWA with the addition of a second row of conducting vias separated a distance P, which behaves as an inductive partially reflective surface (PRS) (Martinez-Ros et al. 2010) and allows the propagation of the fundamental mode in an SIW. In the SIW LWA introduced by Deslandes and Wu (2005), there is a lateral wave that radiates from the open end of the truncated substrate. The radiation mechanism was the basis for identifying additional limitations originating from Snell's law at the dielectric-air interface. In general case, the periodic modulation of the conductors that gives the periodic LWA a larger scanning range and a more flexible design scheme than the uniform leaky-wave antenna. The lateral LWA radiates in the form of a space leaky-wave created in the discontinuity between the grounded microstrip lateral edge and the extended dielectric-filled ground plane as any periodic LWA.

Antipodal Tapered TSA

TSA

The Tapered Slot Antenna (TSA) consists of a tapered slot cut in a thin film of metal with or without an electrically thin substrate on one side of the film as shown in Fig. 25. The slot is narrow toward one end (s) for efficient coupling to devices such as mixer diodes. Away from this region (L_{ant}), the slot is tapered and

DOI 10.1007/978-981-4560-75-7_57-1

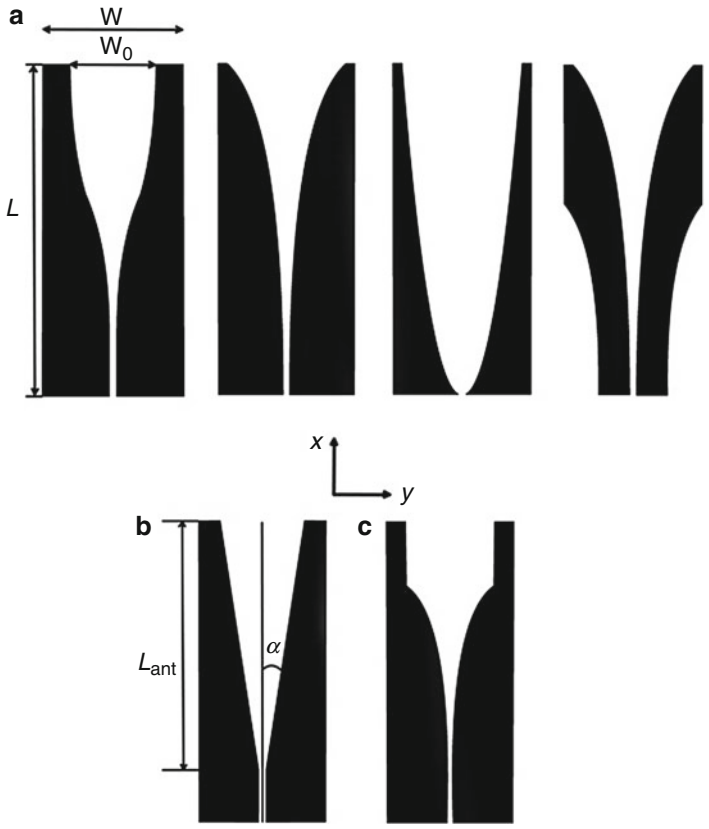

Fig. 25 Differently shaped tapered-slot antennas: (**a**) Nonlinear: Exponential (Vivaldi, *ETSA*), Fermi, Parabolic (*PTSA*), Dual Exponentially (*DETSA*), (**b**) Linear (*LTSA*) and (**c**) Constant Width Slot

a traveling wave propagating along the slot radiates in the end-fire direction (w_0). Antenna is in principle a transition from a guided wave to an unbounded wave or vice versa. Looking at typical TSA, this definition is quite intuitive. As the width of the slot increases, the characteristic impedance increases as well providing smooth transition to the free space characteristic impedance of $120\pi\ \Omega$. The antenna was first proposed by Lewis et al. (1974). Prasad and Mahapatra (1979) first introduced the linearly tapered slot antenna (LTSA) in 1979. Their antenna of about one free space wavelength long was etched on a piece of 25-mil alumina substrate. In the same year, Gibson (1979) reported a TSA with exponentially tapered profile, also known as – Vivaldi antenna, which demonstrated a bandwidth of 8–40 GHz.

An SIW-based antipodal LTSA was demonstrated in Hao et al. (2005) and width corrugated version in Djerafi and Wu (2012b). In the antipodal version of the TSA, the metallization on either side of the substrate is flared in opposite directions to form the tapered slot. When the SIW waveguide is used to feed the antipodal TSA, the bandwidth limitation caused by balun can be removed and, thus, wideband characteristics are indeed obtainable. The SIW TSAs have many advantages such as low profile, low weight, wideband characteristics, and they are easy to integrate with other planar devices. The TSA's antennas are very sensitive to the thickness and the permittivity of their supporting substrate. They can exhibit higher cross-polarized lobes in the (E or H)-plane and sidelobe in the H-plane. This is not only very critical in element design but affects considerably the array performances. The different material, antenna shape, as well as mutual coupling have been widely studied for one side TSAs unlike the SIW antipodal version (Fig. 26).

In the antipodal version, a balanced microstrip feed is used in a double-sided arrangement for the antenna. When SIW is used to feed the antipodal TSA (Fig. 27), the bandwidth limitation caused by balun

DOI 10.1007/978-981-4560-75-7_57-1

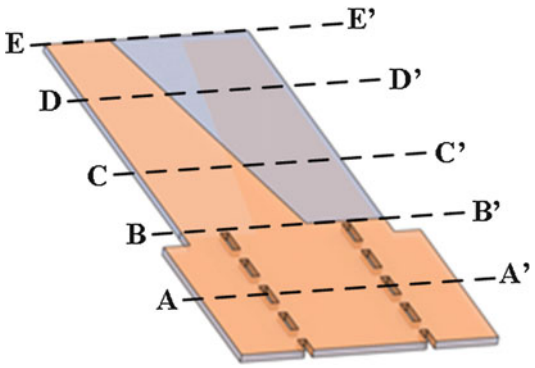

Fig. 26 SIW TSA

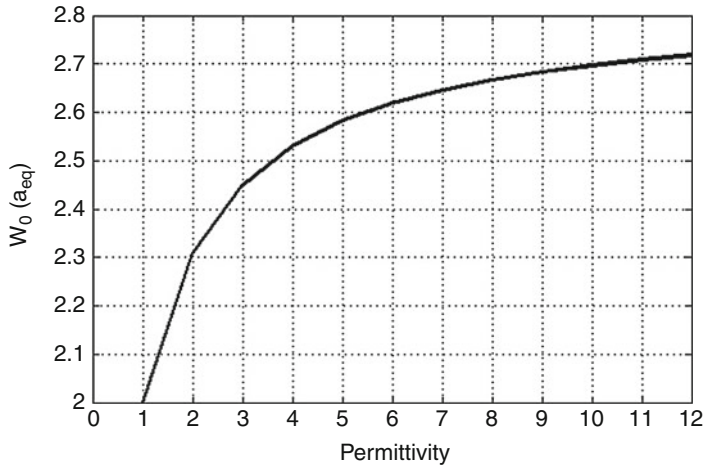

Fig. 27 SIW TSA end-fire slot width (w_0) versus the used material permittivity

can be removed. The performance of the antenna is determined both by its geometry and by the thickness and permittivity of the supporting dielectric substrate.

Slot-line field components are not confined to the substrate alone. They extend into the air regions above the slot and below the substrate also. Therefore, the energy is distributed between the substrate and the air regions. Consequently, the effective dielectric constant for a slot-line (ε_{re}) is less than the substrate permittivity ε_r. Galejs (1962) has shown that the zeroth-order value of ε_r for a slot on an infinitely thick substrate is the average dielectric constant of the two media, that is, the aperture can be calculated using the following equation

$$w_0 = \frac{c}{f_{low}\sqrt{(\varepsilon_r + 1)/2}} \tag{50}$$

To cover the entire monomode bandwidth, the lower frequency is equal to the SIW first mode cut-off, which gives

$$w_0 = \frac{2a_{eq}\sqrt{\varepsilon_r}}{\sqrt{(\varepsilon_r + 1)/2}} \tag{51}$$

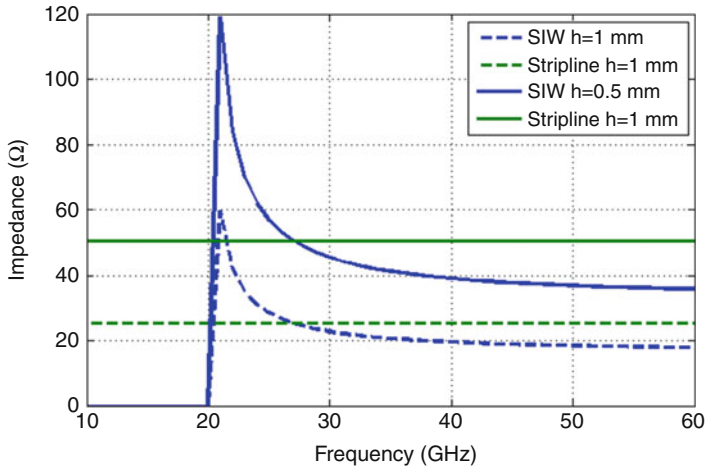

Fig. 29 SIW and stripline impedance

Figure 27 shows that it is possible to reduce the width of the antenna efficiently using dielectric with permittivity lower than 4.

Balun

The tapered antipodal finline smoothly transforms the incident TE_{10} (Fig. 26 cut A) waveguide mode to a quasi microstrip mode which is propagating in the area of overlapping antipodal fins of the transition (Fig. 26 cuts B and C). E field in the transition area concentrates and rotates by almost 90° until waveguide mode transforms to quasi slot mode (Fig. 26 cut D). The E field transformation process in different cut planes of the transition is shown in Fig. 28. Smooth transformation of the field mode allows the transition to operate in a wide frequency band. The region II (plane BB' to CC') act as balun and impedance transformer. In addition, region II transforms the impedance of the TE_{10} waveguide mode to high impedance of slot line component.

Figure 29 shows the SIW waveguide impedance according to the Eq. 21 and the impedance of the overlapping fins at Cut BB' considered as parallel plat line. When the thickness of SIW changes, the cut-off frequency remains the same and the impedance changes. The parallel plat impedance is higher than its SIW counterpart, when the overlapping section diminishes, the impedance increases ensuring a wideband operation. The limit of width of the overlapping section is the half of the SIW width..

DOI 10.1007/978-981-4560-75-7_57-1

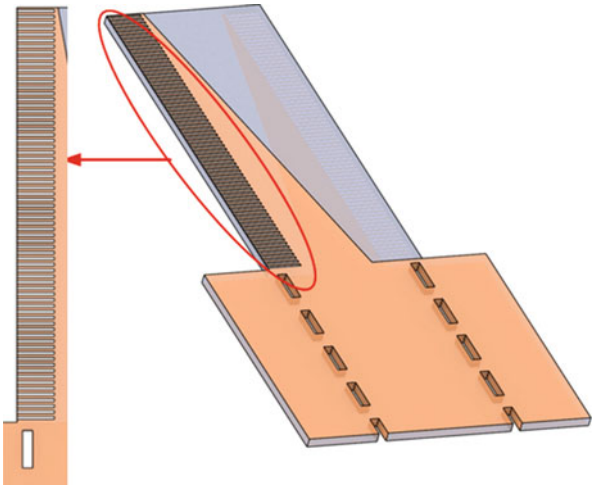

Fig. 30 TSA antenna with corrugation

Corrugation

TSA width w should be larger than 2λ. A degradation of radiation pattern has been observed for a narrower TSA width (Schaubert 1993). This degradation in the radiation pattern is a significant problem for the effective design of compact TSAs. Pattern improvement for a narrow width antenna can be achieved by using a corrugation structure, which makes this technique suitable for the formation of antenna arrays where a small spacing between antenna elements is needed. A Fermi TSA antenna with a corrugation was proposed in Sugawara et al. (1998) and in Sato et al. (2003). This technique was verified with SIW in Djerafi and Wu (2012b). It has been successfully demonstrated that the use of corrugations along the sides as shown in Fig. 30 can reduce the antenna width and improve the VSWR over a wide frequency range, as well as suppress the side lobe levels. The corrugation structure is used to alter the phase of currents flowing along the outer edge of the substrate, changing the orientation of the electric field at the edge of the antenna substrate.

To explain this improvement, simulated E-field distributions along the antipodal LTSA structures with and without corrugation are shown in Fig. 31. The E-field counterparts in the transverse plane over the radiation region are described. In the case without corrugation, the electrical field orientation at the edge of the antenna substrate is opposite to that in the antenna aperture. Some reference claims that the alternation of strips and slots behaves like a slow-wave structure that increases effective aperture size resulting in lower reflection of the radiated wave. As observed in Fig. 31 this phenomenon is not observed. The current distribution illustrated in Fig. 32 clearly shows that the energy is more confined in the central region and radiation from the side is limited.

The effective antenna aperture is thus increased by the presence of the corrugation, which ensures a plane wave phase front over the antenna aperture. In standard antenna, the antipodal nature of the antenna gives rise to very high levels of cross-polarization, particularly at high frequencies because the skew in the slot fields is close to the throat of the flare. As shown in the field distribution in the transverse view in Fig. 31, the field in the center region is more highlighted in the structure without corrugation. Out of this perturbed region, the field is parallel to the two sides of the substrate compared to the one in the antenna without corrugation which is arranged in an arc.

Physical dimension of the slot corrugation is constrained by the fabrication process. In fact, the smallest possible slot width, feasible under this process, is 236 um in this work. The slot lengths are selected to be around $\lambda_r/4$, where λ_r is the wavelength in the dielectric substrate. The SIW antipodal LTSA is optimized

around 28 GHz. Substrate RT/Duroid 6002 with thickness h of 508 um and dielectric constant of $\varepsilon_r = 2.94$ is used.

Figure 33 shows simulated pattern results of antennas with and without corrugation. Without corrugation, the E-plane pattern beamwidth is excessively large and the SLL in H-plane is 12 dB. Once the corrugation is used, a noticeable decreasing of 3 dB beamwidth can be observed in the E-plane, while the

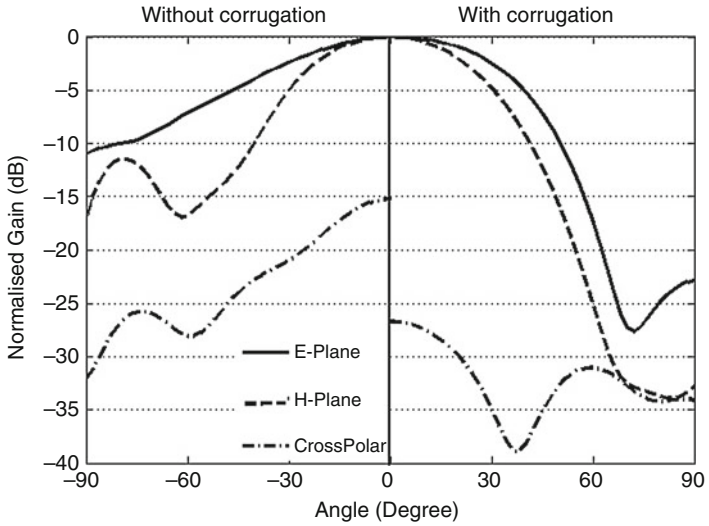

Fig. 33 Simulated radiation patterns with and without corrugation obtained by HFSS at 28GHz

Table 2 Typical properties of end fire traveling antenna

Type	Maximum gain	Low sidelobes
Directivity (dB)	$10\ \log\left(10\frac{L}{\lambda_0}\right)$	$10\ \log\left(4\frac{L}{\lambda_0}\right)$
Beamwidth	$55/\sqrt{\frac{L}{\lambda_0}}$	$77/\sqrt{\frac{L}{\lambda_0}}$

beamwidth in the H-plane increases. The sidelobe in the H-plane for this antenna is 23 and 33 dB in the E-plane. The cross-polarization level with corrugation is found to be better than 27 dB at the frequency of design and without corrugation is 15 dB.

The impact of the slot width is verified for its dimensional variation from 6 to 12 mil. A small effect on the SLL level is observed without gain degradation. For the slot depth, the variation affects the gain of the antenna by changing the effective aperture. It is possible to optimize the corrugation slot to achieve the same beamwidth in both E- and H- planes.

Maximal Gain Versus Length

Generally, directivity increases as the length, L, of a TSA is increased. For lengths between three and eight wavelengths, the increase is linear according to Formula in Table 2 defined in Yngvesson et al. (1985). In this table, the tapered dielectric rod antennas are classified by Zucker as low sidelobes traveling wave.

Figure 34 shows the studied linear and constant with TSA antennas. The CWTSA is a kind of tapered slot antenna for which the width of the radiating slot is constant over the antenna length. Since the slot line that feeds the antenna is generally narrow, there should be a tapering section between the feeding slot and the radiating slot in order to achieve a better impedance matching. If such a transition is not used, there could be a high return loss due to the abrupt change in the characteristic impedance.

Figures 35 and 36 show the gain variation with antenna length. In the LTSA version the gain increases linearly between 1 λ_0 and 3 λ_0 and saturates after 14 dBi. The real constraint with this version is the angle α (according to Fig. 25). The taper angle in the case of the LTSA version is: $5° \leq 2\alpha \leq 15°$. If the length increases, the antenna will be out of the acceptable angle range after a specific value. The linear dependence of the gain on L/λ_0 is an important characteristic of all end-fire traveling-wave antenna. For

DOI 10.1007/978-981-4560-75-7_57-1

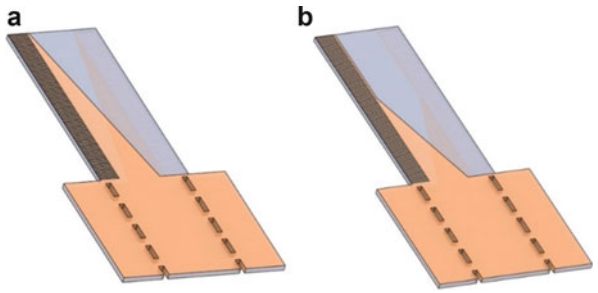

Fig. 34 (**a**) Linear taper, (**b**) CWTSA with linear taper

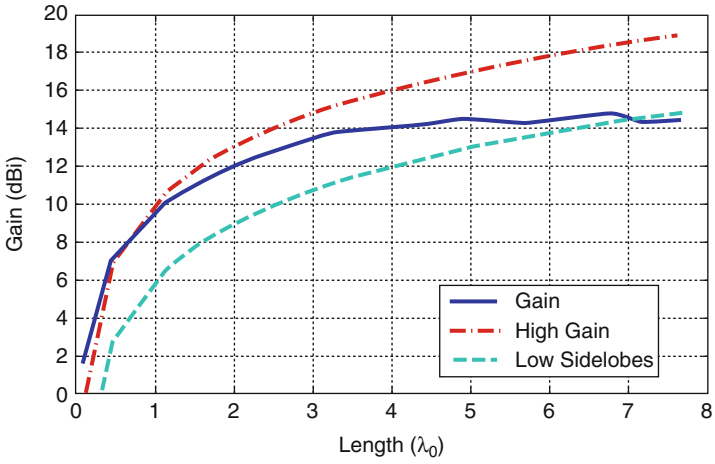

Fig. 35 Effect of antenna length variations on gain of LTSA

CWTSA, the typical numbers are gain of 12–18 dBi with length of the antenna L in the range of 3 λ_0 to 8 λ_0. For longer antennas, the coefficient multiplying L/λ_0 decreases somewhat.

Figures 37 and 38 show the effect of length variations on E- and H-plane patterns for LTSA and CWTSA. The CTWSA shows that the beam width and gain essentially following the high gain standard curve for length below 5 λ_0. In the TSA, the E-plane beam with curve has a very steep slope for length of 4–5 λ_0, exactly as standard curves. After 3 λ_0, the beamwidth in the E- and H-plane follow the low side lobe curve. While TSA elements have many features in common with the general class of traveling-wave antenna, there are some differences, for example, the beamwidth often follows $(1/\sqrt{L})$ while the E-plane varies more slowly with L. The E- and H- bandwidths follow the low side lobe type curve in the case of LTSA and high gain curve for the CWTSA version.

Substrate Thickness

There is a trade-off in substrate thickness; a too "thick" substrate launches surface modes, which degrade the antenna performance, whereas a too "thin" substrate yields higher cross-polarizations and less symmetrical beam patterns. The optimum substrate thickness h has experimentally been defined by Yngvesson et al. (1985) as a function of factor, t_{eff}:

$$t_{eff} = b(\sqrt{\varepsilon_r} - 1)/\lambda_0 \tag{52}$$

DOI 10.1007/978-981-4560-75-7_57-1

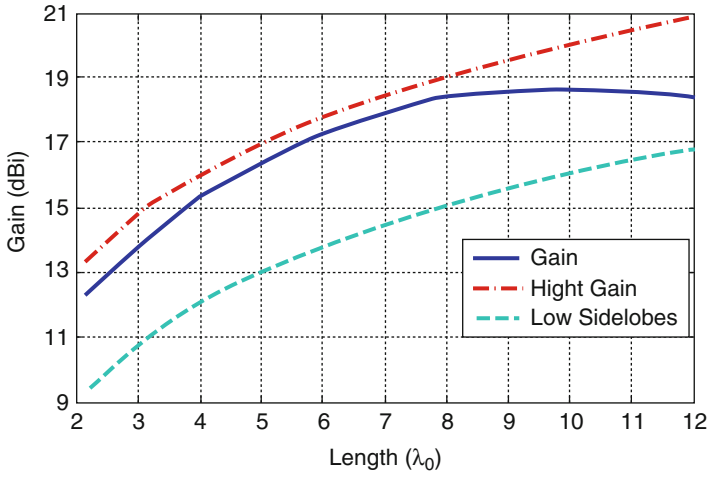

Fig. 36 Effect of antenna length variations on gain of CWTSA

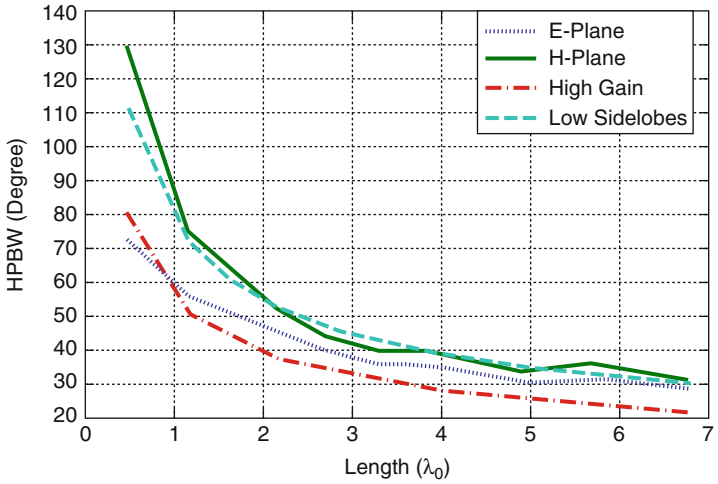

Fig. 37 Effect of antenna length variations on E- and H-plane patterns for LTSA

An acceptable range of t_{eff} for a good TSA opeacceptable range of t_{eff} for a good TSA operation is ration is determined to be between 0.005 and 0.03.

Considering the criteria of 3 dB gain bandwidth, the CWTSA gain is still in this bandwidth from t_{eff} of 0.015–0.053 as shown in Fig. 39. The width of the bandwidth is still in the same order of Yngvesson range (in this simulation ε_r is fixed and thickness modified). With a smaller length, the LTSA gain variation shows a larger t_{eff} range (Fig. 40). This condition is not applicable to antipodal SIW TSAs, which is less subject to substrate mode. LTSA is designed using substrate with 2.94 of relative permittivity and 0.508 mm of thickness, which is equivalent to $t_{eff} = 0.034$ at 28 GHz. Obviously, this value is out of the Yngvesson range. The designed antenna still works adequately in both simulation and measurement. To examine the possibility of using material out of the defined range, two different thicknesses are tested here: $t = 0.05$ mm and $t = 1.25$ mm. This is equivalent to t_{eff} of 0.0034 and 0.101, respectively. Figure 41 illustrates E-plane radiation patterns of the two selected structures. For the two substrate, SLL is still low and an acceptable gain is achieved. These results demonstrate the possibility to design the antipodal

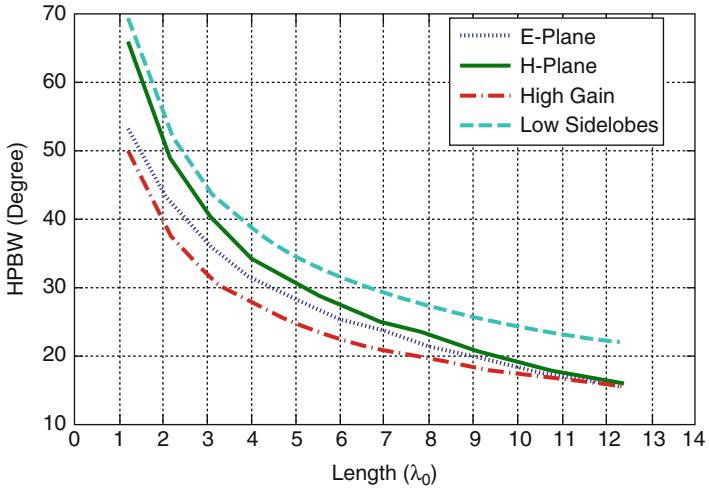

Fig. 38 Effect of antenna length variations on E- and H-plane pattern for CWSA

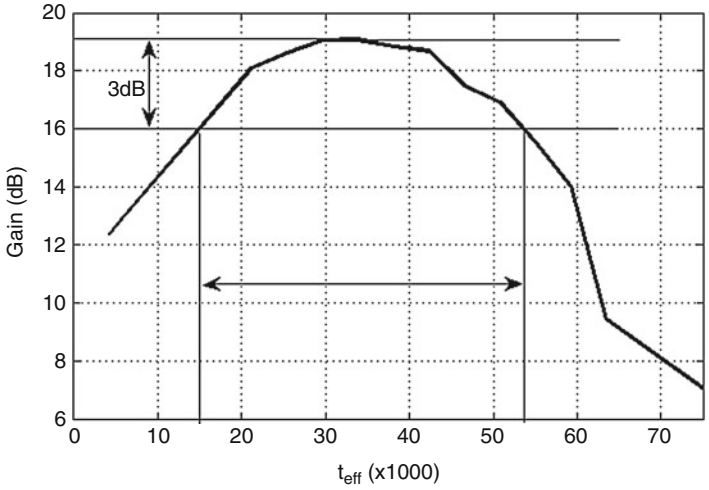

Fig. 39 Simulated gain obtained by HFSS for CWTSA at 28 GHz versus substrate thickness

corrugated TSA with materials out of Yngvesson's range. In this chapter, new criteria will be established for the SIW antipodal version.

Prototypes

Several TSA designs have been reported; as shown in Fig. 25. The tapered slot section which constitutes the radiating region can take on any of three geometric profiles:

- Nonlinear taper (Vivaldi, tangential or parabolic),
- Linear taper (LTSA),
- Constant width (CWTSA).

Vivaldi

The Vivaldi antenna has been studied since its first appearance. It undergoes many improvements in the last three decades, including introducing corrugated edges to form a better radiation pattern (Sugawara

DOI 10.1007/978-981-4560-75-7_57-1

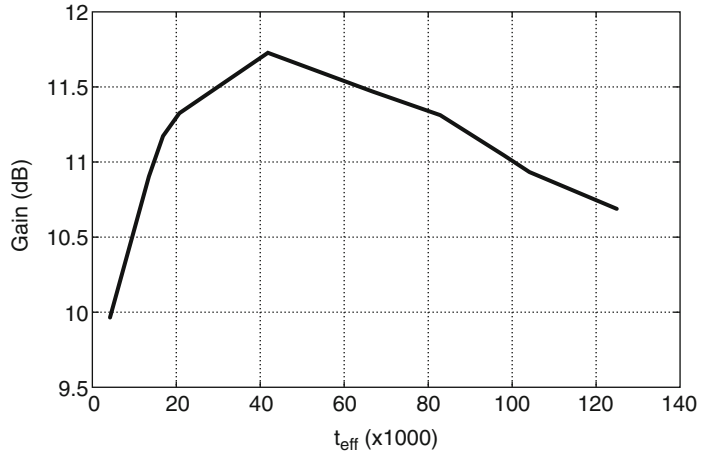

Fig. 40 Simulated gain obtained by HFSS for LTSA at 28 GHz as a function of substrate thickness

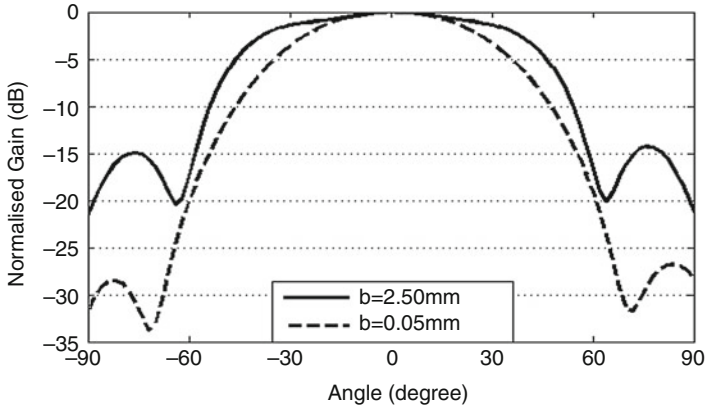

Fig. 41 Simulated radiation pattern obtained by HFSS at 28 GHz in connection with substrate thickness of 0.05 and 2.5 mm

et al. 1998), or changing its beam width by changing the shape, length, dielectric constant, and dielectric thickness. As one of the improvements, antipode Vivaldi antenna was proposed (Kim and Chang 2004).

The exponential taper profile is defined by the following equation:

$$y(x) = Ae^{Rx} + y_0 \tag{53}$$

where R specifies how the slot is widening, parameter A is determined by the length L and also the width w_0 of the taper and parameters y_0 is equal to L-L_{ant}. Very wide band performance can be acquired using an antipodal Vivaldi antenna with its easy wideband transition from microstrip line to radiation part of the antenna (Yang 2008).

Dual Exponentially Tapered Slot Antenna (DETSA), also known as Bunny-Ear Antenna (BEA), is an end-fire traveling wave antenna used for UWB applications. This antenna is a special form of Tapered Slot Antenna (TSA). It is created by tapering the outside edge of the slotline conductor of a Vivaldi antenna. The outer slot taper of the DETSA is described by an exponential function. This adds additional antenna design degrees of freedom.

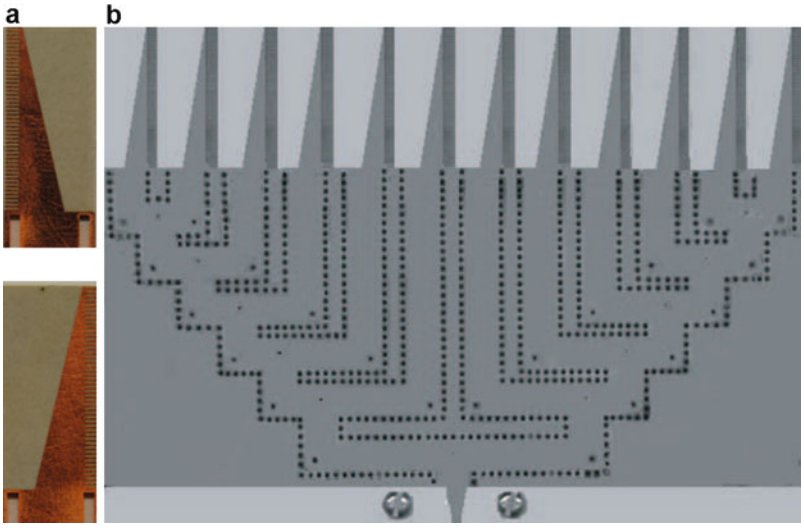

Fig. 42 (**a**) *Top* and *bottom* photograph of the fabricated SIW corrugated antipodal LTSA ($L = 25.6$ mm, $a_{eq} = 5$ mm, $w = 8.44$ mm), (**b**) example of array using LTSA

Fermi

The designed feed antennas are based on the TSA concept of Sugawara et al. with a Fermi taper. It provides symmetric radiation patterns and low side lobe level in both E-and H plane, The Fermi-TSA opens out the shortest while the Vivaldi opens out with the longest extension and the linear TSA is in the middle. The Fermi-TSA profile is defined by the following:

$$y(x) = \frac{w_0}{1 + e^{-R(x-b)}} \tag{54}$$

where R and b are variable. The antipodal version was suggested first in Gazit (1988).

The Parabolic

The inner side is shaped as a parabola

$$y(x) = Ax^2 + y_0 \tag{55}$$

The parabolic type opens out the shortest while the Vivaldi opens out with the longest extension and the Fermi-TSA linear is in the middle. Consequently, the beamwidth is narrowest for the PTSA and wide for the FTSA and widest for Vivaldi (Wang et al. 2009).

LTSA

The linearly tapered slot antennas (LTSA) have been reported for years (Simons et al. 1992; Yngvesson et al. 1985, 1989; Nesic 1991; Wu et al. 1998). Due to their salient features such as narrow beam width, high element gain, wide bandwidth, and small transverse spacing between elements in arrays, it attracts lots of interests in many applications. Practically, the performance of the LTSA is mainly determined by the feeding system. The angle of the aperture should be lower than 15°.

In this section, different types of the SIW TSA antenna are fabricated and tested.

DOI 10.1007/978-981-4560-75-7_57-1

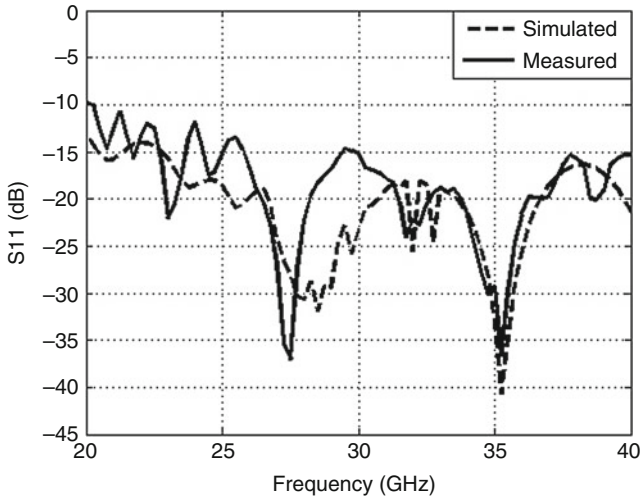

Fig. 43 Measured and simulated return losses

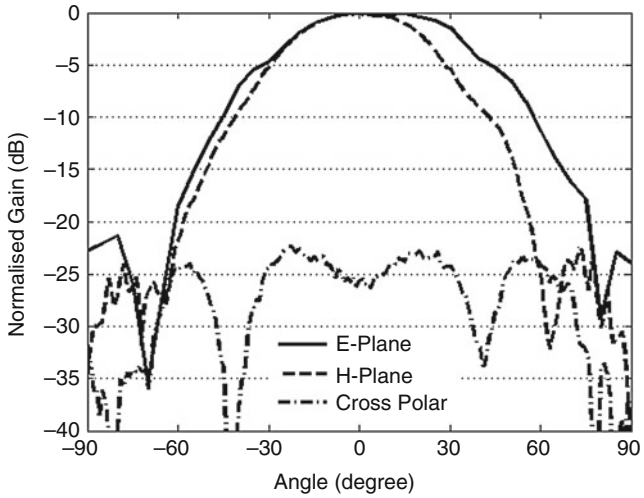

Fig. 44 Measured radiation patterns at 28 GHz

LTSA

SIW antipodal LTSA is optimized to work around 28 GHz for LMDS or future 5G systems. Substrate RT/Duroid 6002 with thickness b of 0.508 mm and dielectric constant of $\varepsilon_r = 2.94$ is used. Parameters of the optimized structure are shown in Fig. 42. Simulated and measured return losses of the proposed antenna are shown in Fig. 43. The return losses are greater than 15 and 10 dB in the simulation and measurement, respectively. Such an observed degradation is probably caused by the mismatch effect of transitions.

E-plane and H-plane patterns of the antenna as well as the cross-polarizations at 28GHz are measured and shown in Fig. 44. The achieved gain is 12.2 dBi against the simulated 11.9 dBi. This difference is within the calibration-related tolerance range of the antenna reference in used anechoic chamber. The 3 dB beamwidth is 59° in the E-plane and 48° in the H-plane and the first primary side lobe is located at −22 dB. It can be seen that the measured results are in good agreement with the simulated ones. The cross-polarization level shows a 4 dB degradation compared to the simulated counterpart.

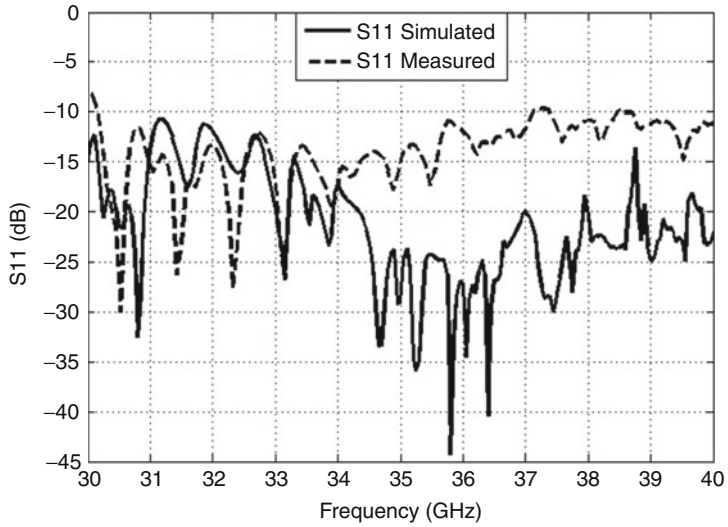

Fig. 46 Simulated and measured S-parameter characteristics of the SIW corrugated Fermi-TSA

Corrugated Fermi

A single corrugated antipodal Fermi-TSA has been designed to cover the band of interest around 35 GHz for imaging array applications. Substrate RT/Duroid 6002 with thickness of 0.508 mm and dielectric constant of $\varepsilon_r = 2.94$ is used. To realize the desired gain, antenna length L_1 has been increased to reach the value of 8 λ_0. The antenna width has been slightly modified due to the restrictions related to the design of antenna arrays where the width of the antenna is 0.79 λ_0. The photograph of the fabricated SIW corrugated Fermi-TSA (top and bottom) is shown in Fig. 45.

Simulated and measured reflection coefficients versus frequency are presented in Fig. 46. It can be noticed that the antenna bandwidth covers the entire considered frequency band of 28.57 % at 35 GHz for both measured and simulated results that are obtained by the use of HFSS.

Figure 47 presents simulated and measured copolar E-plane and H-plane radiation patterns. From these results, it can be seen that there is a good agreement between the measured and simulated radiation patterns. The 3 dB beam widths are approximately 25.33° and 28° for both E-plane and H-plane patterns, respectively. The side lobes are lower in the E-plane compared to the H-plane. At 35 GHz, the antenna gain is about 19.4 dBi based on simulations and almost 18.4 dBi is obtained in practice according to measured results. The cross-polarization level is found to be better than 20 dB thanks to the overlapped flaring metal in the SIW version. The excellent radiation properties and compact size of this antenna make it ideal as either a standalone antenna with a broad pattern or as an array element.

Corrugated SIW Planar and Folded Antipodal Parabolic Tapered Slot Antenna

A folded tapered slot antenna is presented in Doghri et al. (2013), this antenna represents a three dimensional version of Parabolic Tapered Slot Antenna. The PTSA is folded along its longitudinal center line which gives the possibility to have 45° and −45° polarizations.

Planar PTSA

To design an L-folded TSA, the first step is to design a planar TSA with respect to the required half power beamwidth, side lobe level, gain, etc. over all the desired operating frequency bandwidth. The geometrical parameters such as width, dielectric thickness, taper profile, length, and so on are optimized to meet requirements. Several TSA designs have been reported. For the demonstration purpose of the L-folded TSA PTSA (Parabolic Tapered Slot Antenna) is used in this design to obtain an optimal matching and bandwidth. The corrugation is also used for effectively reducing the width of the TSAs without degrading the antenna performances. The fabricated planar prototype is shown in Fig. 48, radiation and matching performances in Figs. 49 and 50 successively.

Folded SIW Line

An SIW line folded along its longitudinal center line is used to properly feed the L-folded TSA (LFSIW). Figure 51 illustrates a cross-sectorial view of SIW and LFSIW with the transverse electric and magnetic field lines of the fundamental TE_{10} mode. The junction acts as a tapered matching section between the two

waveguide types. The taper is optimized to achieve the minimum reflection coefficient. The optimized length of the L-Junction is about 1.41 λ_g at the center frequency. The back-to-back structure layout is illustrated in Fig. 52 with the taper shape. The back-to-back configuration is used to measure performances of the junction. The fabricated prototype is shown in Fig. 52b. The fabrication processes involve laser micromachining permitting arbitrarily shaped perforations, long and large rectangular vias with rounded corners that define SIW walls. After machining the structure, vias are electroplated. A back-to-back configuration is used to measure the performance of the junction because it was not possible to measure directly the L-shaped SIW line.

Figure 52a shows the measured reflection and transmission coefficients. The back-to-back junction achieves a return loss of better than 28 dB and an insertion loss of better than −0.9 dB over the 30–40 GHz bandwidth. The quality of the design is demonstrated by the E-field distribution inset in Fig. 52.

Folded PTSA

The third design step consists in folding the planar TSA. The previously introduced L-junction is used to feed the L folded PTSA. The main geometrical parameters are not altered by the folding step. The fabrication of this antenna involves two PCBs that are illustrated with dimensions in Fig. 53. The fabricated prototype is shown in Fig. 48b. Two posts are used for alignment purposes. When assembled, the two corners are metalized for a proper electrical connection between the two PCBs.

Similar performances are observed when the proposed L-folded antenna is compared with the nonfolded counterpart. Figure 54 shows the measured and simulated radiation patterns in the E and H-planes, corresponding to the 45° and −45° planes. The measured gain is 11 dBi while the simulated gain is 13 dBi. The 3 dB beamwidth is 38° in the E and H-planes. The cross polarization is 10.7 dB in simulation and 8.1 dB in measurement. The folded version has a better symmetry in the E and H-planes. However, the gain and the cross polarization are reduced.

Coupling

Mutual coupling between elements is an important issue in designing antenna arrays. It modifies impedance, radiation pattern, beamwidth, and directivity of an array, and even degrades the performance. Therefore, it is a parameter that must be taken into account during the design process. The previously described antenna topology has been studied.

Using HFSS simulations to evaluate the isolation levels between two adjacent elements (Fig. 55). The isolation is about 13 dB between the elements aligned along their *E*-plane and separated by 0.68 λ_0. The dielectric is subtracted in the central region and the isolation between the two elements is 3 dB lower. To explain the coupling effect and a possible improvement, simulated E-field distributions are shown in Fig. 56 along the antipodal Fermi-TSA structures with and without the substrate removal. The effective antenna aperture is thus increased by such a removal, which ensures a plane wave phase front over the

antenna aperture. As shown in the transverse view of the field distribution in Fig. 56, the field in the center region is more highlighted in the structure without the subtraction. In the modified antenna, the field is more spread along the transverse section. In fact, the air gap creates discontinuities and the field is confined along the air gap. When used in the two element array, the air slotted version gives more than 1 dB of improvement. The gain of one simulated Fermi-TSA element in the presence of a second passive element is 2 dB lower than that of an isolated element. In the H-plane, as the field is confined around the material, the coupling is very small between two elements disposed in the parallel arrangement.

Circular polarization can be ensured in wide bandwidth with high gain performances based on LTSA and sequential rotation. This element can then be integrated into a subarray cell to determine the optimal geometry. The four elements are physically rotated relative to each other and the feed phase is individually adjusted for each arrangement as shown in Fig. 57. In the figure, the field distribution in the transverse view when just one port is excited is illustrated. The mutual coupling effect changes with configuration, the first cell shows a better gain performance. The coupling is very high between two elements disposed in the parallel arrangement as in V configuration and directly affect the center of the parallel element. The total gain is in the same level of one element. The 3rd case is the complement of the first one to build a larger antenna array. The field distribution in the three cases gives some idea about the expected asymmetrical radiation pattern.

Application to Imaging

Passive millimeter-wave radiometer for imaging has found applications primarily in the security and defense industries. It is desired because of its ability to image through typical obscurants such as smoke, dust, and materials like plastic and textile, in certain frequency ranges. Certain frequency windows present low atmospheric losses (centered at 35, 94, 135, and 220 GHz). Many designers typically build passive sensors to operate within these windows in order to exploit low atmospheric attenuation and increased image contrast compared to lower frequencies.

DOI 10.1007/978-981-4560-75-7_57-1

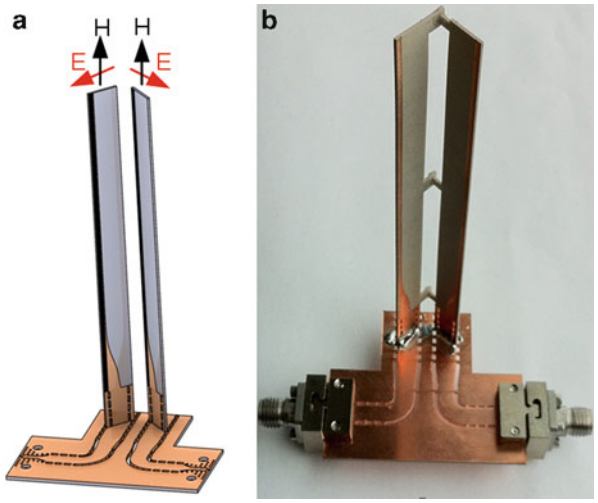

Fig. 58 (**a**) Topology of the SIW dual polarization system, (**b**) photograph of the fabricated SIW dual polarization system

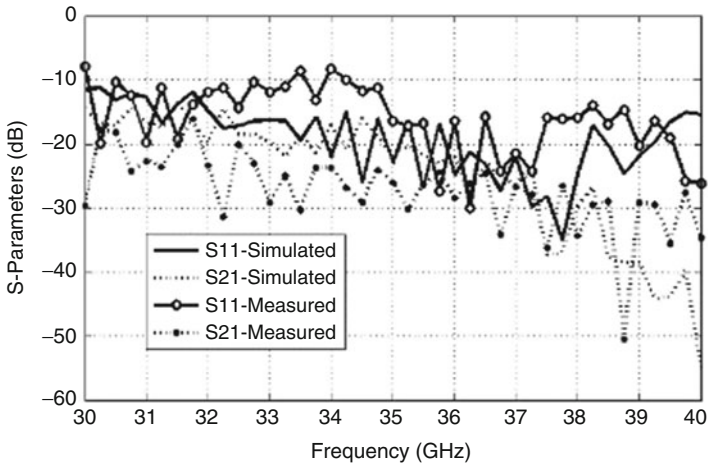

Fig. 59 S-parameter characteristics of the prototyped antennas

The antenna architecture for imaging application should satisfy defined conditions in term of high gain and low side lobe level (SLL). In addition, low cost and light weight characteristics are always required for highly integrated, reliable and portable systems. In fact those systems are generally duplicated to achieve a better resolution, which increase the weight and total volume.

Thanks to the intrinsic shielding of the proposed SIW feeding, a compact feed can be obtained without resorting to any coupling in the feeding network that would deteriorate isolation and therefore increase cross-polarization. Different antennas based on TSA element with orthogonal polarization are presented in the following. An array of 128 elements shows low SLL and height gain with just 200 g of the total weight is used to build image.

Dual-Polarized end-Fire Antenna

Progressive plane wave can be decomposed into two linearly polarized waves formed orthogonal vectors; which are also orthogonal to the direction of propagation. In the case of the radiometry these orthogonal components are referred to as the vertical and horizontal polarization. The natural radiation emitted by the human is unpolarised, but after interaction with certain objects around it becomes polarized. One of the

challenging issues in utilizing such full polarimetry is the need of a good discrimination between the H- and V- polarization, which finally leads to an accurate imaging synthesis. Therefore, achieving good isolation between the H- and V- polarization port, along with the important antenna parameters including antenna gain, impedance matching, co- and cross- polarization discrimination, etc., is crucial. Three different configurations for building dual polarization TSA are presented in this section.

A Dual Polarization Fermi Tapered Slot Antenna Setup Using E-Plane Corner

Compared to other types of tapered slot antennas, the corrugated Fermi-ATSA provides almost the same E-plane and H-plane patterns, presenting at the same time low side lobe levels. Two 45° and −45° vertical arm rotated E-plane bends are arranged to feed two Fermi antennas in posture of 90°, as illustrated in Fig. 58a. The photograph of the fabricated prototype is shown in Fig. 58b.

Measured and simulated S-parameters of the dual polarization setup are shown in Fig. 59 (El Khatib et al. 2012a). The isolation between the two ports is almost better than 20 dB in simulation over the entire 32–40 GHz band and in the measured one. The measured performance matches well with the simulation. Figure 60 presents measured copolar (E-plane) radiation patterns of the design at the 0°, 90° planes angle, the two ports are fed in phase simultaneously. The E field amplitude in the 0° plane is the geometrical

addition of the E field in the two planes. In counterpart, the 90° plane is the subtraction of the two. The radiation curves show some little dissymmetry due to the presence of the other element. Difference between the E field at 0° and 90° plane is 22 dB in the broadside direction.

A Dual Polarization Fermi Tapered Slot Antenna Setup Using Twist

In the second configuration, two PTSAs are disposed perpendicular to each other which give us the vertical and horizontal polarization. To bring the signal of the vertical antenna to the horizontal an SIW 90° twist is used (Doghri et al. 2013).

The SIW 90° twist consists of a progressive deformation of an L-Shaped SIW line shown in Fig. 61. The width is progressively decreasing in one plane and increasing in the other. The signal from the horizontal plane will move to the vertical one and vice versa. To validate the proposed device, a prototype operating over the *Ka*-band (26.5–40 GHz) was designed based on RT/Duroid 6002 substrate with dielectric constant of $\varepsilon_r = 2.94$ and substrate thickness of 0.76 mm. The fabricated prototype involving two LEGO-like interconnected PCBs is shown in Fig. 61b, c. Figure 61a illustrates the measured

DOI 10.1007/978-981-4560-75-7_57-1

performance of the proposed twist, a reflection coefficient of less than −18 dB and an insertion loss better than 1 dB over the *Ka*-band is achieved.

Two high gain and broadband corrugated PTSAs are used as radiating elements. Some slots and holes are used for alignment purposes. The fabricated prototype is shown in Fig. 62, two K connectors are added to feed the access. The measured and simulated return losses and isolations are shows in Fig. 63. The structure achieves a return loss better than −10 dB and an isolation higher than 32 dB from 32 to 38 GHz (22 % bandwidth centered at 35 GHz). Due to the shielding of the structure, the interference in the feeder is minimized to a negligible level.

Simulated and measured radiation characteristics of this dual-polarized antenna when one port is excited while the other port is matched are shown in Fig. 64. The vertically polarized antenna fed by the twist achieves a gain of 14.44 dBi at 35 GHz while the horizontally polarized antenna achieves a gain of 14.28 dBi. The two patterns have a cross-polarization of better than 27 dB in the 0° direction. A small asymmetry is observed in the co- and cross-polarization patterns because of the presence of the other elements. This solution shows a better isolation than the first solution with corner.

Four Elements Dual-Polarized end-Fire Antenna

Compared to two-element configuration, four elements will give a better symmetry between the two vertical and horizontal planes. The horizontal polarization is obtained thanks to the use of 3-port E-plane junction. Figure 65 illustrates the proposed E-plane junction. The proposed E-plane junction consists of a progressive deformation of a T-shaped junction to rectangular waveguide with TE_{20}. The resulting mode is then divided in two arms to feed two TE_{10} mode SIW lines with equal amplitude and 180 phase difference.

As depicted in Fig. 65, the E-plane junction divides and rotates the mode signal of the input SIW line in H-plane to the mode signal of the two output SIW lines in E-plane. An experimental prototype operating over the frequency range of 30–40 GHz was designed using RT/Duroid 6002 substrate from Rogers Corporation, having substrate thickness of 0.76 mm. The equivalent synthesized bilateral walls of the SIW are rectangular metalized slot arrays with width 0.762 mm (the minimum is defined by the metallization process, in presented case 0.254 mm).

The photograph of the fabricated prototype is shown in Fig. 66a. The prototype was measured using a vector network analyzer and a Line-Reflect-Line (LRL) calibration to de-embed the connectors, transitions and 90 bend effects. As shown in Fig. 66b, c, return loss and insertion loss of, respectively, less than

16 and 0.46 dB, are observed from 30 to 40 GHz. In addition, as shown in Fig. 66d, the E-plane junction provides a 180 phase difference with phase imbalance of less than $\pm 3^\circ$ over all the frequency range.

The proposed junction is used to feed four PTSA elements. The prototype shown in Fig. 67 involves three Lego-style PCB blocks accurately aligned using posts and slots.

Figure 68 shows the measured and simulated return losses and isolations. In this case, ports 1 and 2 correspond to the vertical and horizontal ports, respectively. The structure achieves a return loss better than 10.6 dB and isolation better than −26 dB from 30 to 40 GHz (28 % bandwidth). Figure 69 compares simulated and measured radiation patterns of the horizontally and vertically arranged arrays, respectively. The horizontally polarized array achieves a gain of 14.6 dBi at 35 GHz while the vertically polarized array fed by the E-plane junction achieves a gain of 14 dBi. Thanks to the symmetry of the array arrangement, a good symmetry of the radiation patterns is observed.

Fermi Tapered Slot Antenna Array for Imaging Applications

A Villeneuve distribution is used for sidelobe control in the proposed 8 by 16 array (El Khatib et al. 2012b). Figure 70a shows the 1/16 power divider, the 4-stage H-plane SIW power divider makes use of an equal and unequal-split T-junction power divider to achieve the required aperture distribution. H-plane bends are used to compensate different delays generated by the imbalanced power splitting. The equal power division in the fourth stage of the power divider represents a compromise that is needed due to the tight dimensions that are dictated by the element spacing. All transmission coefficients fluctuate around the ideal coupling factor in the band of 30–40 GHz. Similar to the previous 1/16 power divider, an 8-way T-junction power divider is designed in order to accommodate the feeding for eight samples of the above mentioned 1×16 linear array, thus forming the proposed integrated 8×16 planar antenna array.

DOI 10.1007/978-981-4560-75-7_57-1

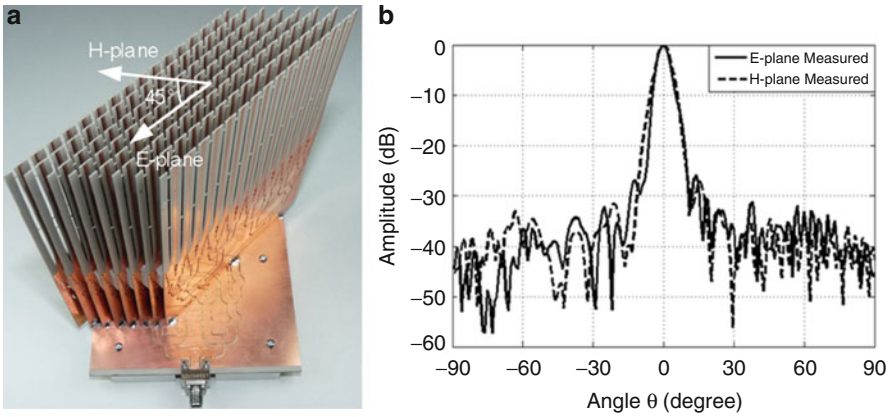

Fig. 71 (**a**) Photograph of the proposed three-dimensional architecture of 128 element antenna array, (**b**) E-plane and H-plane radiation pattern performances of the 8 × 16 SIW corrugated Fermi-TSA planar array at 35 GHz

Fermi element described in the SIW TSA section is selected to ensure initial high gain and broadband characteristics for the array. At 35 GHz, the simulated gain is about 19.4 and 18.4 dBi is obtained in measurement. The mutual coupling between the elements of antenna arrays must be taken into account during the design process. The previously described antenna topology has been studied to evaluate the isolation levels between two adjacent elements along their *E*-plane.

The isolation is about 13 dB between the elements aligned and separated by 0.68 λ_0. The dielectric is subtracted in the central region and the isolation between the two elements is 3 dB lower. In the modified antenna, the field is more spread along the transverse section. In fact, the air gap creates discontinuities and the field is confined along the air gap. When used in the two element array, the air slotted version gives more than 1 dB of improvement. The gain of one simulated Fermi-TSA element in the presence of a second passive element is 2 dB lower than that of a single element. The coupling is very small between two elements disposed in the parallel arrangement.

Figure 71 illustrates this novel planar array composed of 8 × 16 antenna elements of corrugated antipodal Fermi-TSA, and fed with an SIW power divider. A 45° rotated E-to-H-plane interconnect ensures, with eight 1 × 16 and one 1 × 8 power dividers, the construction of one block feeding network for 128 antenna element array. The whole antenna is fabricated with standard PCB process (7 PCB plaques). The gain of the planar array is 27 dBi, and the SLL is better than 26 dB in both E-plane and H-plane as shown in Fig. 71b, the beamwidth is about 5.15° in the E-plane and 6.20° in the H-plane. The total weight of the array is less than 200 g, showing an important advantage of SIW technology in payload's design efficiency.

Imaging System

There is a number of different ways to obtain a passive radiometric image from a scene (Goldsmith et al. 1993). Phased arrays have been limited in their success at millimeter wavelengths due to difficulties designing efficient phase shifter as well as relatively large feed system. Mechanically scanned systems have been employed for different imaging applications in the millimeter range, but suffer the very major handicaps of expensive, relatively unreliable mechanical systems together with low data rate from the single receivers utilized. Another way of acquiring an image is to implement a FPA (Focal Plane Array), which uses an array of independent detector elements in the focal surface of an imaging lens or reflector. Recently, moderate-cost systems using small FPAs combined to mechanical scanning have been built allowing real-time imaging (Doghri et al. 2011).

DOI 10.1007/978-981-4560-75-7_57-1

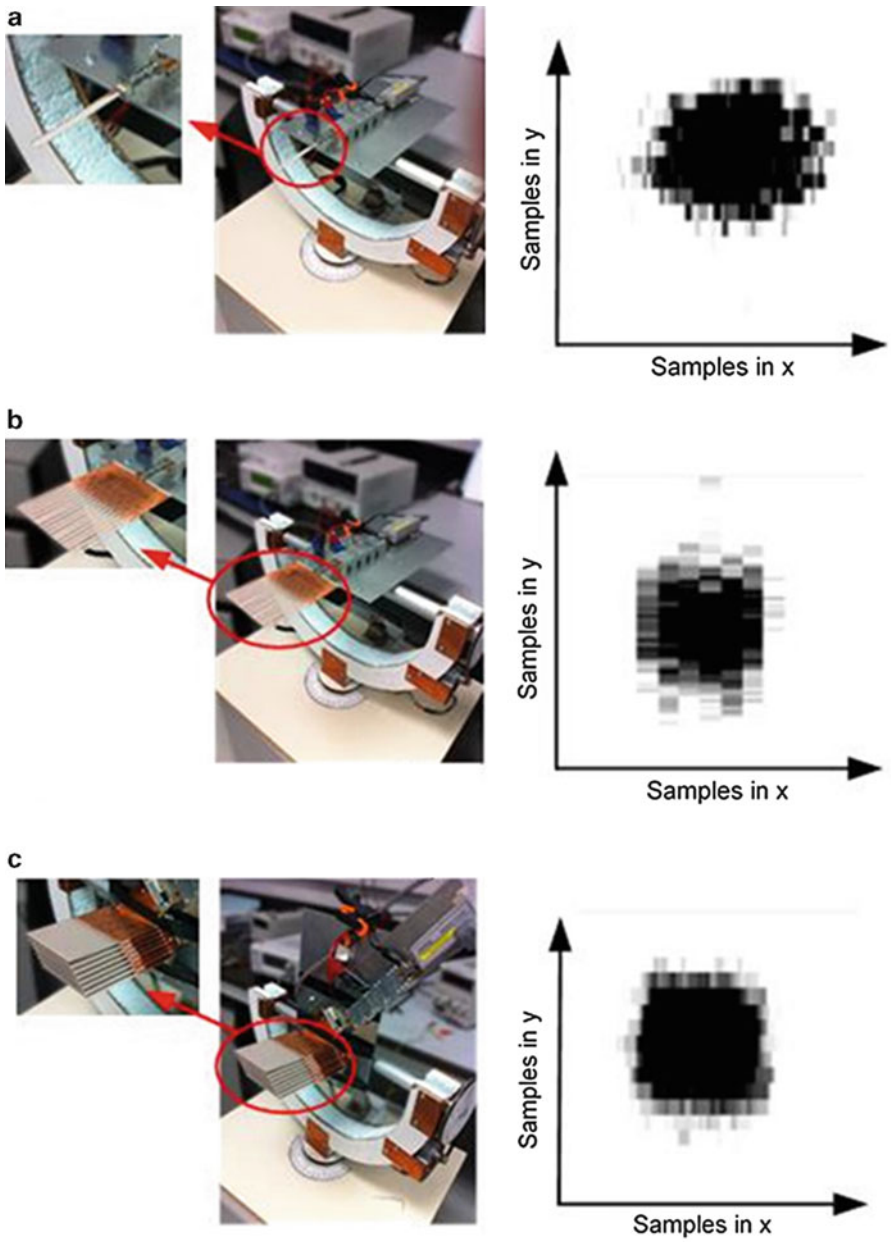

Fig. 72 Heated square object imaged by three different antenna configurations with: (**a**) single element, (**b**) linear array, (**c**) planar array

For passive imaging system, the antenna is used together with a very sensitive receiver to detect and provides measurements of the electromagnetic radiation intensity received within a solid angle subtended by the antenna beam. It is necessary to accommodate the antenna in this system design with high gain, low side lobe level and low cross-polarization. Array antenna schemes can be used to accomplish these goals. However, they present a number of problems in connection with cost, weight, and fabrication complexity of the feed networks. Various discontinuities within a feed network should be avoided or used with caution since noise emitted or interference created by such components into the receiver could desensitize and confound the radiometric measurement. Images issued from a simple receiver composed of a front-end circuit, which has two prime tasks, namely, the input frequency-band selection and the amplification of the received signal into a proper level for the detector. A novel SIW prototyping approach was used to

DOI 10.1007/978-981-4560-75-7_57-1

build up the receiver. This approach consists of SIW subcircuits realizing simple functions and interconnects as LEGO building blocks to build up a complex function out of basic elements. Putting the SIW transmission lines in front of each other with sufficient pressure passes the electromagnetic wave through with a negligible loss.

The signal from the detector is fed to the analog to digital (A/D) input of the microcontroller and then sent to the computer through a USB port and processed by the data acquisition software developed on the Matlab platform.

The tests were done using respectively one element, a planar array composed by 16 elements and a 2D array composed by 128 elements shown in Fig. 71 shows the three images corresponding to the three scenarios. By increasing the antenna gain, the resolution is increased as shown in Fig. 72. The 2D array gives a closer image of the square as it presents a higher gain and a better beam symmetry in the two planes compared to one element and the planar array. The image resolution can be further improved by increasing the number of array elements or by increasing the gain of each element.

Conclusion

It is well recognized that the antenna is one of the most important system components that limit or enhance system performance, depending on the design of such a component. Generally, antenna elements cannot be conveniently integrated in chip-set because either they are too large or the required performance such as efficiency cannot be achieved by integrated components. In some cases, they could simply be considered as part of the package that embeds the chip-set, which may be of importance for millimeter-wave system design. In most high-gain antenna applications, array geometries are always required that involve both radiating elements and feed network. Special feed networks in the form of beam-forming networks present the engine for the development of multibeam, beam-scanning and beam-agile systems. In this chapter, nonresonant SIW antenna structures well suited for a wide range of applications over millimeter-wave and terahertz frequency bands are presented and discussed.

Different dielectric loaded H–plane SIW horn antennas are presented. Through a proper choice of the structure and parameters, the maximum gain for the given size or the minimum size for a given gain may be achieved.

Two different kinds of leaky-wave structures have been discussed in this chapter. One is related to uniform guided-wave structures while the other consists of an array of periodic guided-wave structures. They share common features but also exhibit many interesting differences in connection with electrical and mechanical aspects. They exhibit low losses, very flexible radiation characteristics, and excellent mechanical simplicity. Tapered slot antennas based on SIW feed with different shapes are presented with simulation and measurement results. Configurations which ensure dual polarization and applications of an array on imaging system are detailed. Other type of SIW-based nonresonant antenna can be fed by SIW or integrated to the SIW antenna like Yagi, Lenses, Rod.

Advances in thick film technology have been made such as photoimageable and photoetchable conductor pastes, which have enabled system-in-package (SiP) techniques to be demonstrated well into the up-millimeter-wave frequency range (500 GHz, for example). LTCC technology has been known to well synergize with SIW techniques since it offers multilayered 3D passive integration. Proposed LEGO-style blocks fabricated and assembled with easy-to-connect and manipulate PCB pieces have been studied and demonstrated in different components as well as for imaging system. This technique will play a critical role with LTCC and PCB fabrication processes.

Abstract

The focus of UWB antenna research activity has matured in recent years and currently mainly concentrates on applications such as biomedicine and security. Early UWB antenna designs were driven by the FCC allocation of spectrum in 2002 and focussed on obtaining wide impedance bandwidths with reasonable group delay characteristics. Many of these were simple planar monopoles antennas with canonical geometries. The emergence of new applications channelled the emphasis towards miniaturisation and integration into devices. This required optimisation of the antenna geometries to ensure that good system performance is achieved from the integrated antenna. Many optimisation techniques are available including the spline technique to generate the outline of the antenna element and ground plane. Simple methods based on genetic algorithms are employed and evolutionary algorithms which are capable of optimising for multiple goals are beneficial when multiple antenna parameters are simultaneously investigated. These techniques have proven advantageous especially when time-domain performance is critical and provide solutions for both single-ended and differential feed arrangements. The main applications using UWB channels in the 3.1 GHz −10.6 GHz spectrum are localization and tracking applications, mainly employing impulse radio UWB imaging, and generally using linear polarization. However circularly-polarized UWB antennas have been developed, both directional and omnidirectional and are being investigated across various systems.

Planar monopole antennas; Splines; Optimisation; Time domain performance; Impulse response; Asset tracking antennas; Imaging antennas; Vivaldi antennas; Circular polarisation; Dipole antennas; Miniaturisation; Slot antennas; Radio tags

Introduction

In 1897, Guglielmo Marconi sent the first wireless communication over open sea using a spark-gap transmitter and in 1901, performed the first transatlantic communication from Poldhu, England to St. John's, Newfoundland (Balanis 2005). Because of the spark-gap transmitter, the signal used by Marconi was inherently wideband. Since then the evolution of radio technology has greatly increased. For many of the following decades, radio technology advancements focussed mainly on narrow band transmission, due to the congestion in the electromagnetic spectrum. However in the late 1960's, researchers started to study Ultra Wide Band (UWB) technology. Between 1977 and 1989 the United State Air Force (USAF) had a program on the UWB system (Barret 2001) and some universities focused

*Email: max.ammann@dit.ie

DOI 10.1007/978-981-4560-75-7_59-1

on the interaction of short pulses with matter. In 1994 T.E. McEwan invented the Micropower Impulse Radar (MIR) which proved to be the first compact, inexpensive and low power radar, which consumes only microwatts from batteries (Azevedo and McEwan 1996).

In 2002, the Federal Communication Commission (FCC) allocated the 3.1–10.6 GHz for UWB unlicensed use and standardisation began. It limited the maximum Equivalent Isotropic Radiated Power (EIRP) for UWB radio to −41.3 dBm/MHz (74 nW/MHz) and specified that a UWB signal must have, at any point in time, a fractional bandwidth equal to or greater than 20 % or have a 500 MHz bandwidth regardless of the fractional bandwidth (Allen et al. 2007). The high-data rate UWB standard was prepared by the IEEE 802.15.3a task group (Mandke et al. 2003), but ceased in early 2006. However, a high data rate Multi-Band OFDM scheme was standardized by the ECMA-368 standard. In 2004, the IEEE 802.15.4a task group was established for low rate UWB systems which chose to use two approaches for the physical layer, the Direct Sequence UWB (DS-UWB) and the Chirp Spread Spectrum (CSS) (IEEE 2011). The IEEE since published the IEEE 802.15.6 standard for Body-Area-Networks, which provides for UWB channels. Because of their very wide bandwidth, UWB signals have a high temporal resolution (typically less than 1 ns), making this technology particularly suitable for Wireless Sensor Network (WSN) and Real Time Location System (RTLS).

Some of the most popular antennas employed in modern wideband wireless communications systems are the dipole and monopole family. These elements exhibit broad impedance bandwidths which can be extended by increasing the radius of the cylindrical element. This is true up to a point where the stepped radius from the feed probe to the cylindrical element becomes abrupt. Tapering this transition is beneficial and used in wideband elements such as biconical dipoles, but cost limits these to laboratory applications. However, it has been shown that replacing the cylindrical element of a monopole or dipole with planar elements provide a wider impedance bandwidth, and with some simple adjustment, UWB bandwidth. The first mention of the planar monopole antenna was in a textbook in 1968 by Meinke and Gundlach (1968), who describe it as a variant of the cylindrical and conical monopole. Dubost and Zisler provided more detail about the wide impedance characteristics of this antenna in 1976 (Dubost and Zisler 1976). A disc-shaped planar monopole antenna was subsequently reported in 1991 by Honda et al. (1992), who proposed this antenna for the Japanese television band (90–770 MHz). In 1992 he reported one which had a 10 dB impedance bandwidth ratio in excess of 10:1 (Honda et al. 1991). A model for determining the value of the input impedance of the circular disc-shaped monopole was reported in 1993 by Hammoud et al. (1993) based on the Method of Moments. Circular and elliptical disc monopoles were also studied in 1998 by Agrawall et al. (1998), who proposed a formula for predicting the frequency corresponding to the lower edge of the impedance bandwidth. Since then a plethora of canonical shapes were reported to provide UWB impedance bandwidth. These include square, rectangular, elliptical, circular, trapezoidal and triangular (Ammann 1999; Evans and Ammann 1999). The use of triangular and bow-tie geometries for the planar element were also investigated by Chen (2000). Furthermore, bevelling of the shapes and feed asymmetry was introduced to further widen the impedance bandwidths and very wide impedance bandwidth ratios were realised (Ammann 2001; Ammann and Chen 2003a, b).

At the time, these elements were studied when placed above a classical ground plane and in many cases, only the impedance properties were reported. As time moved on, many of the geometries migrated to printed antennas geometries where the ground planes are printed on the same PCB (Kuo and Wong 2002; Go and Jung 2004; Liang et al. 2004). The ground planes, which were often excluded from any design rules, were populated with components and modules, which is particularly attractive for portable terminal devices (Fig. 1).

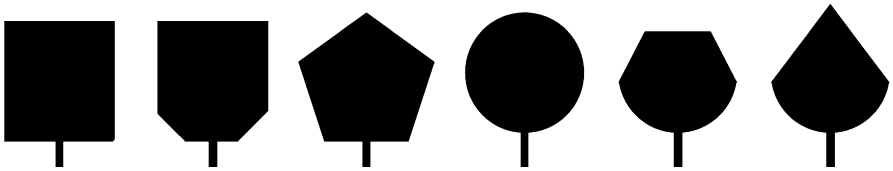

Fig. 1 A selection of planar monopole shapes including square, tapered square, pentagonal, circular and combinations of these

Optimised UWB Antennas

Geometries of recent UWB antennas are based on simple geometric elements, such as rectangles (Chen et al. 2006a), circles (Liang et al. 2005) or ellipsis (Angelopoulos et al. 2006), or a combination of these (Griffiths et al. 2005). Examples for combining multiple elements are a combination of rectangles, triangles and circles in (Karacolak and Topsakal 2006) or polygons, circles and exponential curves in (Chen et al. 2006b).

To optimise a specific antenna design, a number of optimisation methods are available ranging from simple interpolation methods to evolutionary algorithms capable of optimising for multiple goals. There is a large number of publications available dealing with electromagnetic optimisation. Evolutionary methods include genetic algorithm (GA) (Johnson and Rahmat-Samii 1997; Haupt 2007; John and Ammann 2007) and particle swarm optimisation (PSO) (Jin and Rahmat-Samii 2005; Donelli and Massa 2005). Today, a variety of methods are available in commercial EM software such as CST, Feko or HFSS. In the following example the GA in CST Microwave Studio is used.

This section analyses antenna geometries based on quadratic Bézier spline curves (Foley et al. 1993; Bartels et al. 1996). Splines are curves generated by quadratic interpolation between control points. This spline is used to outline the radiating element and/or ground plane of an antenna. The benefit of this technique is an inherently rounded shape of the radiating element and a straight forward way of assigning parameters to the control points. The design methodology overcomes the geometrical constraints of a circular or elliptical disk and the need of combining simple geometric elements.

Spline Theory

A spline is a function defined by polynomials. In mathematics, splines are used for interpolation and smoothing problems. In computer graphics, the term spline refers to a piecewise polynomial parametric curve used to illustrate complex shapes (Bartels et al. 1996). Splines are classified by the degree of the polynomial, such as linear, quadratic, cubic or higher order splines. In computer graphics and CAD programs, quadratic and cubic splines are most common (Foley et al. 1993). Bézier curves are named after Dr. Pierre Bézier who used these curves to design automobile bodies for Renault in the 1960s.

The electromagnetic simulator CST Microwave Studio (MWS) uses the quadratic form of these curves. One curve segment of a quadratic Bézier spline is the path traced by the function B(t)

$$B(t) = (1-t)^2 P_0 + 2t(1-t)P_1 + t^2 P_2; t \in [0,1], \quad (1)$$

when t is swept from 0 to 1. The points P_n are defined by their x- and y-coordinates in a two dimensional plane.

Figure 2 shows this path for various *t*. It can be seen that, as *t* is varied in five steps from 0 to 1, the '×' (green) traces a quadratic curve (red). To create more complex shapes, an arbitrary number of Bézier curves can be attached together in a chain.

DOI 10.1007/978-981-4560-75-7_59-1

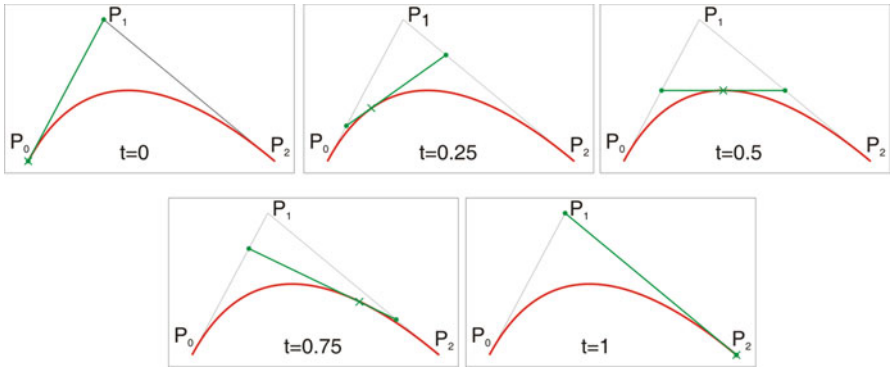

Fig. 2 Quadratic Bézier curve for various t

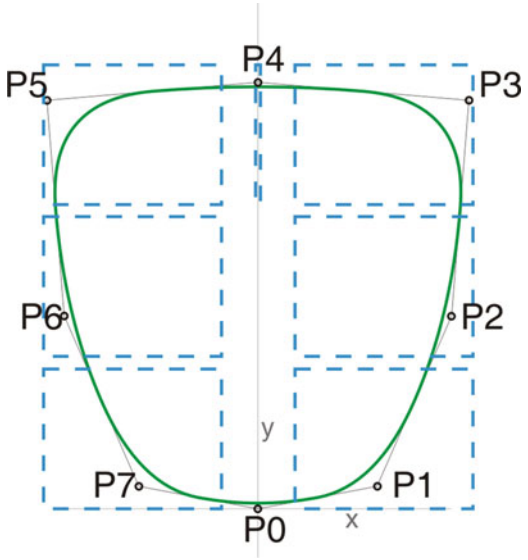

Fig. 3 Control points and bounds for spline geometry

Example of a Spline Based Antenna Geometry

As an example a quadratic Bézier spline is used to describe the outline of the radiating element of a printed monopole antenna in the following way. The spline curve is defined by 8 control points P0–P7. Figure 3 shows the outline curve and its control points. Point P0 is fixed at (0,0), this is where the antenna is fed by a 50 Ω microstrip line. Points P1–P3 are defined their by x and y-coordinates, which are variable parameters. Point P4 is fixed at $y = 0$ and can only be moved along the x-axis. Points P5–P7 are derived from points P1–P3 by mirroring them along the x-axis. In order to achieve a closed curve, the curve ends again in point P0. This creates a symmetrical radiator with the intention of achieving an omnidirectional radiation pattern. The resulting curve can be used as the outline of a radiating element of a printed monopole antenna. It is placed on the substrate with a partial ground plane on the rear, the enclosed area filled with copper and connected to a microstrip feedline.

The coordinates of the control points are used as parameters for optimisation by the genetic algorithm in the CST Studio Suite. Bounds are defined for the coordinates of each point, they are shown in Fig. 3 by blue rectangles. These bounds serve two purposes. Firstly, they constrain the size of the design to be

DOI 10.1007/978-981-4560-75-7_59-1

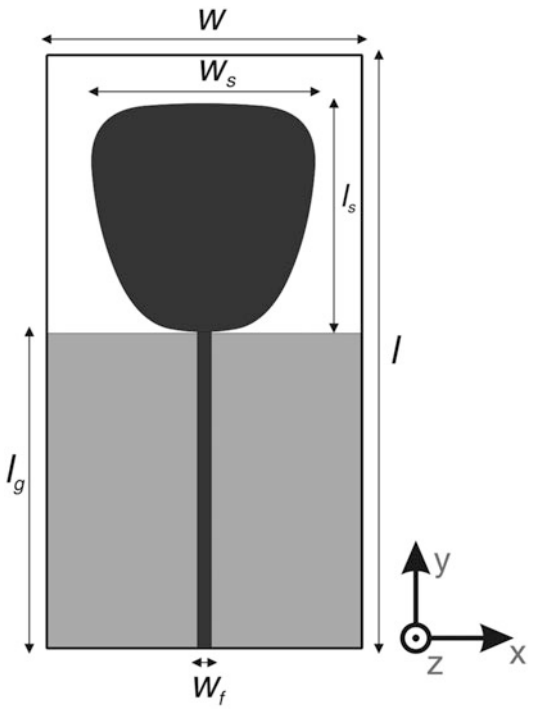

Fig. 4 Geometry of the optimised spline based monopole

within the limits defined by the substrate size. This ensures that the radiating patch does not extend over the side of the substrate. Secondly, the bounds ensure that the resulting spline does not form a loop.

Due to the wide operating bandwidth anticipated from this design, Rogers RO4350B was used as the RF substrate. The substrate size was w = 45 mm and l = 85 mm with the 45 mm square ground plane located on the rear side. A 2.4 mm wide 50 Ω microstrip feedline is used to feed the antenna. The complete geometry is shown in Fig. 4. It is the result of a GA optimisation with a population size of 30 which was evolved over 20 generations. The fitness function was set to maximise the −10 dB S11 bandwidth within the 0–20 GHz simulation bandwidth. In the resulting geometry, it can be seen that the radiating element curves smoothly away from the feedpoint. The maximal possible height is exploited as point P4 is placed at the maximum of its bound. The dimensions of the spline based radiating element are l_s = 33 mm by w_s = 32 mm.

Bandwidth

The simulated and measured S11 are shown in Fig. 5. It can be seen that the measured S11 is better than −10 dB from 1.44 GHz to 14.7 GHz. This corresponds to an impedance bandwidth ratio of 10.2:1, which is very wide for a printed monopole.

Surface Currents

The surface currents in the metallised parts of the antenna have been computed for various frequencies. They are show in Fig. 6. For the lowest frequency of 2 GHz (Fig. 6a), the plot indicates a first order resonance. Animation of a series of plots at this frequency for different phases shows that this mode has a standing wave current pattern. Higher modes at 8 GHz or 16 GHz (Fig. 6c and d) show more complex current patterns. An animation of these plots in a phase sweep shows that the current is travelling along the edge of the radiating element. It is concluded that this antenna is working in a hybrid mode (Chen 2007) of operation between a standing wave and a travelling wave antenna.

DOI 10.1007/978-981-4560-75-7_59-1

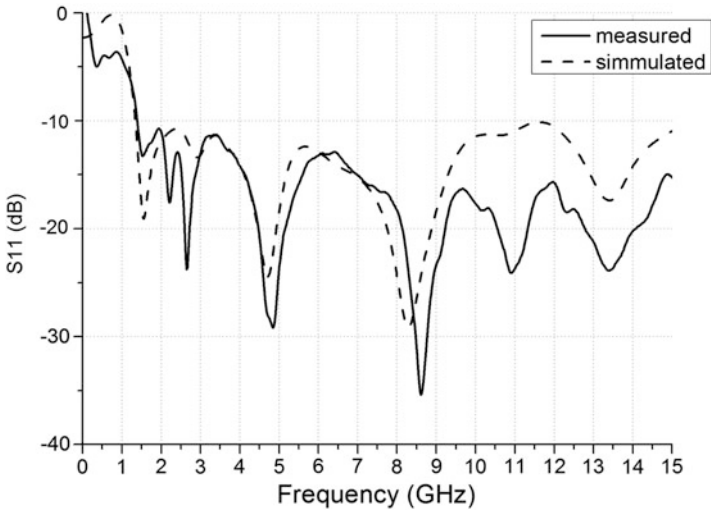

Fig. 5 Simulated and measured S11 of the spline based monopole

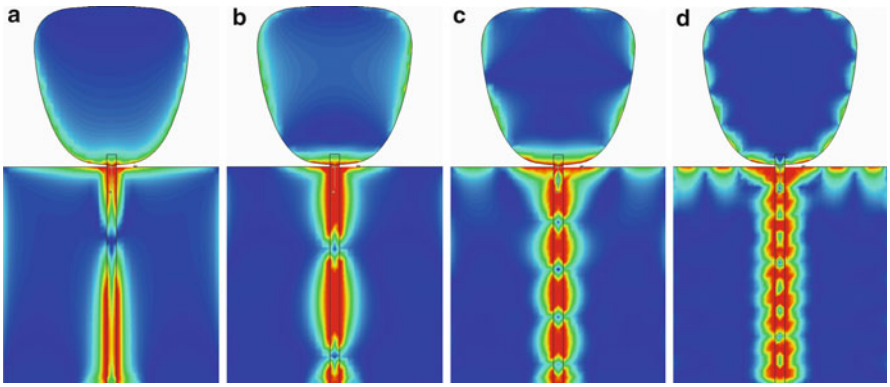

Fig. 6 surface current in the spline based monopole at 2, 4, 8, and 16 GHz

Radiation Pattern

The measured radiation patterns are shown in Fig. 7. The H-plane patterns are found to be omnidirectional up to about 8 GHz. The measured gain is 2.8 dBi at 2 GHz, 4.3 dBi at 6 GHz, 4.8 dBi at 10 GHz and 5.3 dBi at 14 GHz. The simulated radiation efficiency at these frequencies is 91, 96, 92 and 89 % respectively.

Group Delay

Group delay was measured in three orientations of the antennas, front-front, front-side and side-side. Measurement results are shown in Fig. 8. In the UWB band from 3.1 GHz to 10.6 GHz, the group delay variation is below 0.5 ns. Group delay is the derivative of the pulse response of the S21 between the two antennas. A linear phase response is required for low group delay variation. There was no explicit optimisation goal for a linear phase response in this example. A linear phase response is inherent in the spline geometry as the current path is very smooth around the outside of the radiating element. Hence the spline based design methodology is suitable for designing antennas for communication applications where low pulse distortion is required.

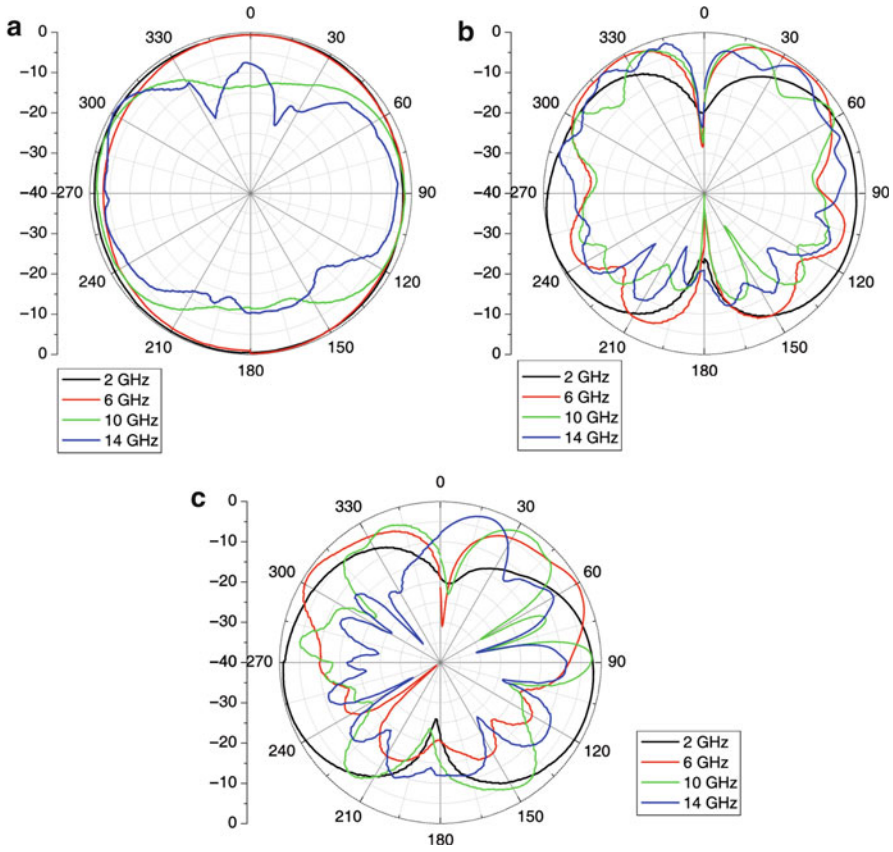

Fig. 7 Measured radiation patterns for the spline based monopole antenna in x-z, x-y and y-z planes

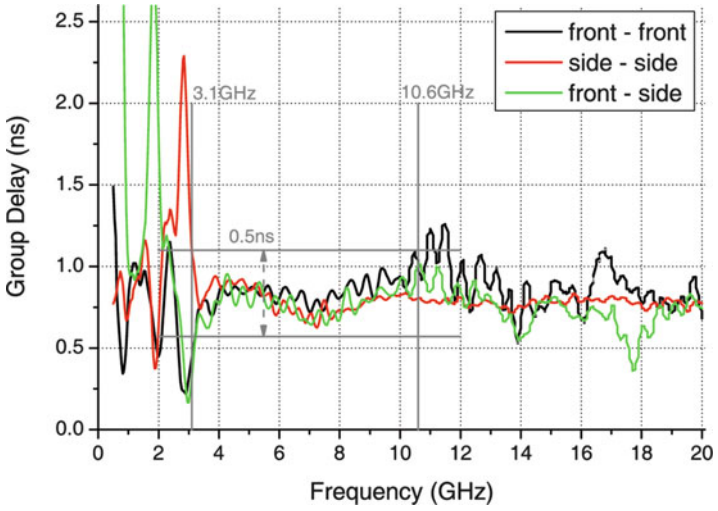

Fig. 8 Measured group delay for a pair of spline based monopole antennas in three orientations

This spline based optimisation technique can be easily adopted to design antennas of constrained size. Figure 9 shows a 40 × 30 mm monopole operating in the 3.1–10.6 GHz band with the ground plane shape also optimised (John and Ammann 2009).

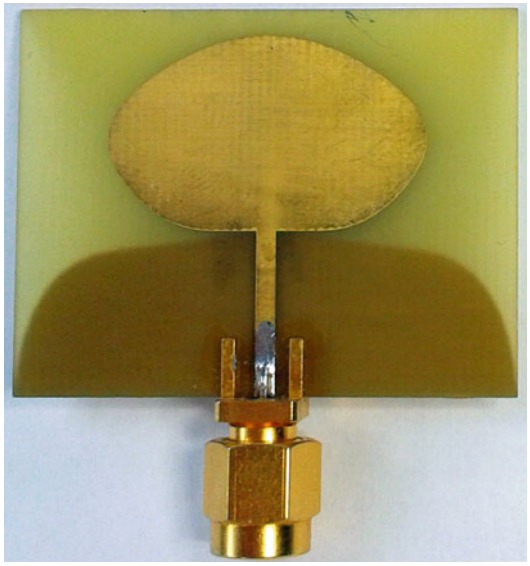

Fig. 9 Small UWB antenna developed at the Dublin Institute of Technology

UWB Antennas Optimised for Time Domain Applications

Impulse radio Ultra Wide Band (IR-UWB) systems use very short pulses (typically less than 1 ns) to achieve very broad bandwidth for low powered communications. The short pulses can be used for UWB Real Time Location System (RTLS) for proximity ranging or localization with centimeter precision. Earlier publications consider and analyse time domain performance of UWB antennas (Schantz and Fullerton 2001; Kwon 2006), but do not optimize for it. Schantz, in (2004) gives general rules on how to minimize dispersion in UWB antennas. Recent publications synthesize UWB antennas from a time-domain perspective by optimizing antenna geometries depending on the pulse shape they radiate (Telzhensky and Leviatan 2006; Dumoulin et al. 2012; Lizzi et al. 2012).

UWB Pulse Shapes

UWB antenna literature predominantly reports Gaussian and Rayleigh pulses, and their derivatives, for antenna excitation (Chen et al. 2004; Lizzi et al. 2009; Chen et al. 2005; Guo et al. 2007). Their characteristics include very low level side lobes in the frequency-domain and fast energy damping in the time-domain. However, the energy distribution across the frequency range is typically bell-shaped and antennas that are optimized with these pulse profiles do not have the bandwidth for an efficient fit to the 802.15.4a spectrum mask (Chen et al. 2005), (Chamaani et al. 2011), (Cerny and Mazanek 2007). While a series of modulated Gaussian pulses can be sequenced (IEEE 2007) to cover the entire UWB mask, the approach increases the duration of the excitation pulse. It extends antenna simulation run-times and adds complexity to the time-domain analysis of the models.

Alternatively, an SRRC pulse overcomes the limitations. The analytical form of the SRRC pulse is shown in Eq.2 (Zhang et al. 2003).

DOI 10.1007/978-981-4560-75-7_59-1

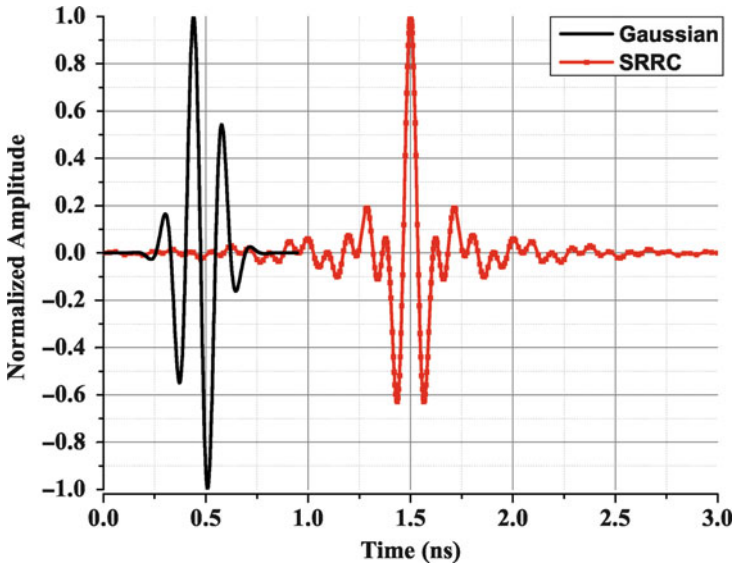

Fig. 10 Modulated Gaussian and Square Root Raised Cosine pulses with respective peak values normalized to unity

$$F_{SRRC}(t) = \left[\frac{2\beta}{\pi\sqrt{T_s}} \times \frac{\cos\left[(1+\beta)\pi\frac{t}{T_s}\right] + \frac{\sin\left[(1-\beta)\pi\frac{t}{T_s}\right]}{4\beta\frac{t}{T_s}}}{\left[1-\left(4\beta\frac{t}{T_s}\right)^2\right]} \right] \tag{2}$$

where t is the time, $T_S = 1/R_S$, R_S being the symbol rate and β is a dimensionless roll-off factor for bandwidth control.

Figure 10 shows an amplitude modulated Gaussian pulse and an amplitude modulated SRRC pulse (roll-off factor of 0.1 and symbol rate of 7.1 GHz); both centred at 6.85 GHz and with the respective peak values normalized to unity. Figure 11 shows the corresponding Power Spectrum Density (PSD) plots with the 802.11.4a UWB indoor use spectrum mask.

The evenly contoured power spectrum of the SRRC pulse, compared to that of the Gaussian pulse, conveys a broader bandwidth at a higher energy level. Although many UWB systems only operate using channels with bandwidths in range 500–1300 MHz, different channels can be used in different jurisdictions and hence it is beneficial to optimise over the full UWB range. The design goal is to create antennas that can support pulses of increased bandwidths across the spectrum profile of the SRRC.

Differentially Fed UWB Antennas

While monopole antennas are suitable for most applications, they need a balanced to unbalanced transformer (BALUN), when connected to a differential IC output. The introduction of the balun incurs losses and dispersion in both transmission and reception mode, impairing the accuracy and range of the overall system. Balanced antennas, such as dipoles or slot antennas can be differentially fed making their integration into the system more straightforward.

DOI 10.1007/978-981-4560-75-7_59-1

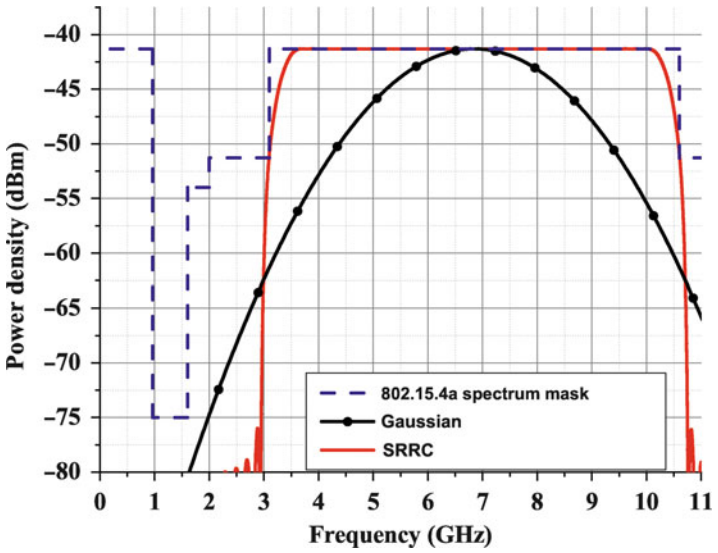

Fig. 11 802.15.4a indoor use spectrum mask with power spectrum density of Gaussian and SRRC pulses; respective peak values normalized to −41.3 dBm

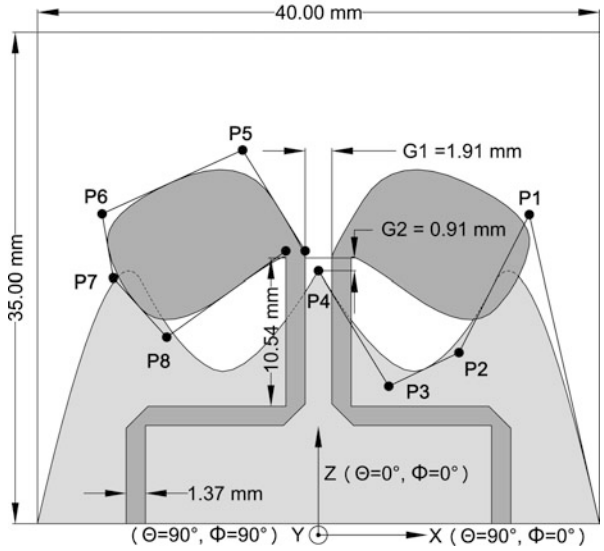

Fig. 12 Gaussian Dipole (GD) geometry

In this example a differentially fed balanced dipole is examined. The dipole geometry is optimised using both a SRRC excitation and a modulated Gaussian like excitation signal. Spectral and time-domain performances of the resulting antennas are compared.

The dipole antennas were optimised for wide-band performance and pulse fidelity, using a SRRC excitation signal for the SRRC dipole (SD) and a modulated Gaussian like excitation signal for the Gaussian dipole (GD) shown in Figs. 10 and 11. Antennas GD and SD, shown in Figs. 12 and 13, are planar dipole-like with a balanced microstrip feed arrangement which requires a small ground plane. They consist of two identical dipole arms (defined by 4 spline points) fed with 50 Ω dual mitred microstrip lines and a mirrored splined ground plane (4 points). The spline points for the radiators have two degrees of

DOI 10.1007/978-981-4560-75-7_59-1

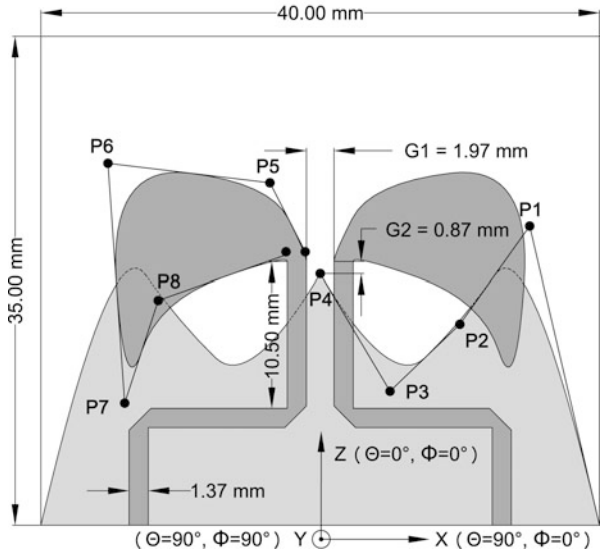

Fig. 13 SRRC Dipole (SD) geometry

freedom (X and Z-axis), while the spline points for the ground plane are restricted to one degree of freedom (Z-axis) in order to limit the complexity of the problem.

Both antennas were fabricated on a 40 × 40 × 0.7 mm FR4 double-sided laminate with a dielectric constant $\varepsilon_r = 4.3$ and loss tangent = 0.02. The antennas were initially performance-optimized without SMA connectors but the simulation model included the connectors to allow a fair comparison between measurement and simulation. The dimensional constraints of the antenna, defined in millimetres, are shown below.

- $P_{1,2,3,4}\ (z) = 5 < z < 26$
- $P_5\ (x) = 0 < x < 4$
- $P_5\ (z) = P_4 < z < 40$
- $P_{6,7,8}\ (x) = 10 < x < 20$
- $P_{6,7,8}\ (z) = P_5 < z < 40$
- $G_1 = 1 < x < 5$
- $G_2 = 0 < z < 5$

Optimisation

The antennas were optimised for best fidelity factor between the excitation signal derivative and the radiated signal. For time-domain optimization, E-field-probes were located 30 cm from the dipoles in the azimuth plane. Simulation time was halved by using field symmetry in the H-plane and by limiting probes to [$\varphi = 90°$, $-90° \leq \theta \leq 90°$ in 5° steps].

A weighted cost function was post-processed for the design iterations using Eq.3.

$$Cost = -0.3 \times \frac{\Gamma}{\alpha} - 0.7 \times \frac{\sum FF}{\gamma}, \text{for } \Gamma < \alpha \tag{3}$$

$$Cost = -0.3 - \left(0.7 \times \frac{\sum FF}{\gamma}\right), \text{for } \Gamma \geq \alpha$$

DOI 10.1007/978-981-4560-75-7_59-1

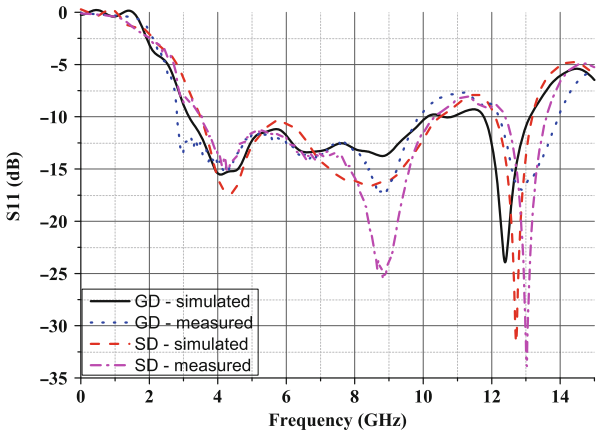

Fig. 14 Simulated and measure S11 for the GD and SD dipoles

where Γ is the least matched magnitude in the S11, α is the S11 match target, *FF* is the fidelity factor (Chen et al. 2005) (field probes relative to the derivative of the excitation pulse) at each angle and γ is the number of FF values. The empirically selected coefficient weightings were chosen to provide a balance between optimization time and accuracy.

Additionally, a subroutine was used to skip simulations of non-realistic structures or re-simulation of identical structures (Guo et al. 2007), more of which occur as the algorithm converges on the optimum range of possible solutions. These significantly reduce the optimization time with minimum effect on the GA behavior. The algorithm also uses an intermediate crossover, the roulette wheel selection, and stops after 30 population iterations (maximum antenna simulations $\leq$ 8085).

Frequency-Domain Results

The simulated and measured S11 for the two Dipoles *GD* and *SD* are illustrated in Fig. 14. The dipoles exhibit an 8 dB return loss across 2.75–10.6 GHz and 2.9–13.8 GHz, respectively. The antennas have good impedance matching for the 3.1–10.7 GHz band, with good agreement between simulations and measurements.

The dipole radiation patterns were similarly measured in the H-plane (Z-Y plane). Figures 15 and 16 show good stability in the radiation pattern across 3.1–10.6 GHz. The dipoles achieve an average realized gain of -0.27 dBi (std. dev. = 2.45) and 0.8 dBi (std. dev. = 2.47) respectively. *Dipole GD* has a maximum gain of 6.4 dBi (θ, $\varphi = 90°$, 55°) at 8.88 GHz, while *Dipole SD* has a maximum gain of 6.87 dBi (θ, $\varphi = 90°$, 60°) at 9.4 GHz.

Time Domain Measurement and Results

To quantify the time-domain performance of an antenna, or a system of two antennas, the most common metric is the Fidelity Factor (FF). The FF is established by the maximum absolute value of the cross-correlation coefficient of the two normalized pulses. It is a useful measure of how much time-domain dispersion an antenna will add to a pulse being transmitted through it.

The antenna and its operating mode determine if the radiated pulse will be radically different to the source pulse. It has been shown that the transient response of an antenna in transmitting mode is proportional to the time derivative of the impulse response of the same antenna in receiving mode (Kanda 1986; Ghosh et al. 2006; Rambabu et al. 2009). Researchers have demonstrated that radiation of UWB pulses involve fields that are time-delayed time-derivatives of the signal currents from the various parts of the transmitting antenna (Siwiak and McKeown 2004). Hence, the simulated radiated pulses have to be cross-correlated with the 1st-order derivative of the excitation pulse.

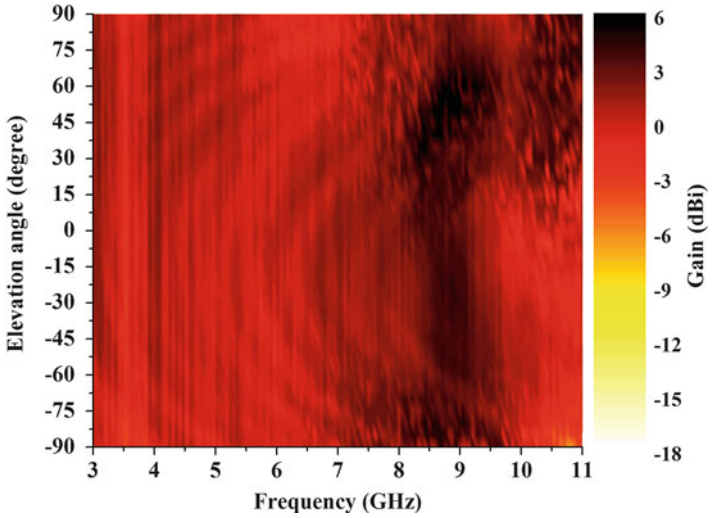

Fig. 15 Measured Dipole GD radiation pattern in the $\varphi = 90^\circ$ plane

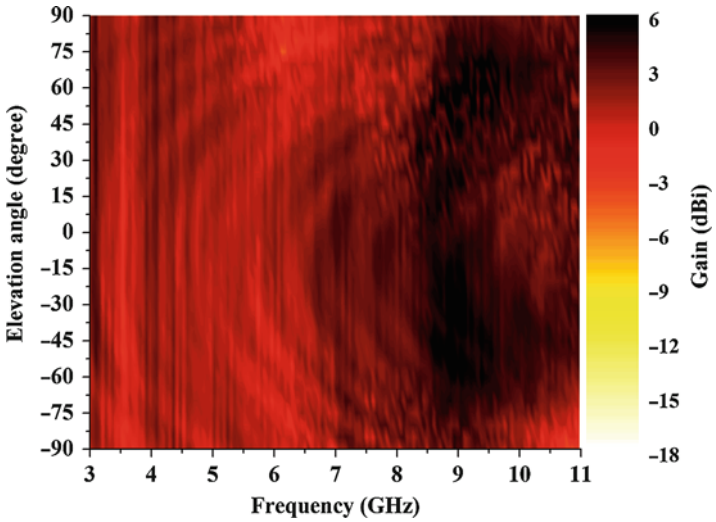

Fig. 16 Measured Dipole SD radiation pattern in the $\varphi = 90^\circ$ plane

Measurement Setup To generate the SRRC UWB pulse, a digital sampled waveform was exported to a Tektronix AWG 7122C Arbitrary Waveform Generator (AWG). Due to its output voltage limitation, the AWG output signal was amplified with a Picosecond Pulse Labs wideband amplifier (Model 5865) and fed to the antenna under test. Also, in order to accurately measure the radiated pulse, the receiving antenna should not be dispersive. Consequently a directional tapered slot antenna was designed and its geometry is shown in Fig. 17. Using the SRRC pulse (see Fig. 10) as an incident signal instead of excitation signal, it was optimised for optimal time-domain performance on bore-sight in receiving mode. In this operating mode, the antenna has a simulated pulse fidelity factor of 98.6 % at the bore-sight. This result indicates that the received signal at the antenna's port is nearly identical to the replica of the incident signal.

A distance of 20 cm was chosen between the transmitting and receiving antenna to maintain the farfield measurement while achieving an adequate signal to noise ratio (SNR) because from a distance of 50 cm, the SNR dropped to an unacceptable level, impairing the time-domain measurement. Figure 18, depicts the time-domain measurement setup.

DOI 10.1007/978-981-4560-75-7_59-1

Pulse Equalisation

Because of the imperfect impulse response of the transmit network components, the AWG generated SRRC pulse fed at the AUT's input port suffers from impaired frequency- and time-domain characteristics. If such a signal is fed to the transmit antenna, the measured pulse fidelity will not represent the full transient performance of the AUT.

Figure 19 illustrates the AWG input waveform *in(t)* with the pulse *out(t)* offered to the transmit antenna. To subdue the component losses, the input signal was compensated using Eq.4, where the Inverse Fast

DOI 10.1007/978-981-4560-75-7_59-1

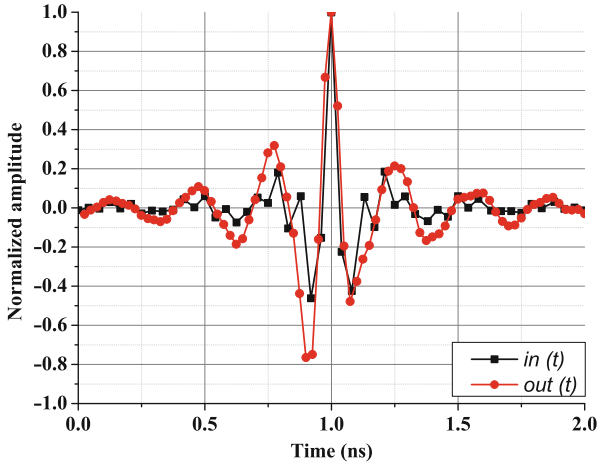

Fig. 19 *in(t)* waveform to AWG and *out(t)* pulse

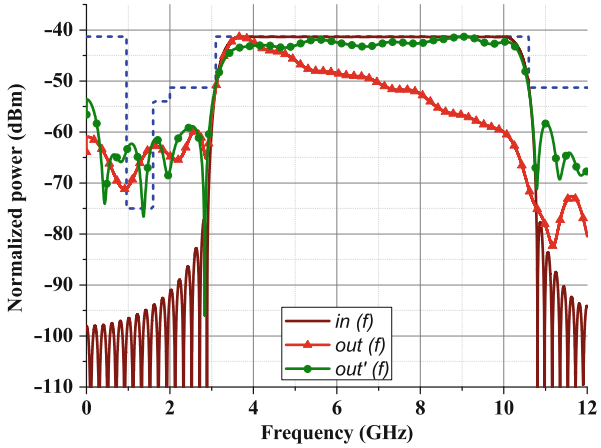

Fig. 20 Input, output and output equalized pulse Power Spectrum

Fourier Transform (IFFT) and the Fast Fourier Transform (FFT) are used to manipulate the pulse in frequency- and time-domain. In Fig. 20, the power spectrum density of the compensated signal *out'(t)*, the input signal *in(t)* and the initial output signal *out(t)* are shown.

$$in'(t) = IFFT\left[FFT(in(t)) / FFT(out(t))\right] \tag{4}$$

Compared to the original SRRC signal *in(t)*, the compensated signal *out'(t)* energy distribution level share many characteristics in the UWB band, demonstrating that the transmit network impulse response was equalised. Hence, the *out'(t)* signal was fed at the transmitting antenna port allowing an accurate time-domain characterisation of the AUT.

Antenna Impulse Response De-embedding

In the last section, an equalisation method was presented, suppressing the transmit network impulse response from the measurement. However, in order to get an accurate measure of the radiated signal, the receive network impulse response, which includes the one from the receiving antenna, should also be removed.

DOI 10.1007/978-981-4560-75-7_59-1

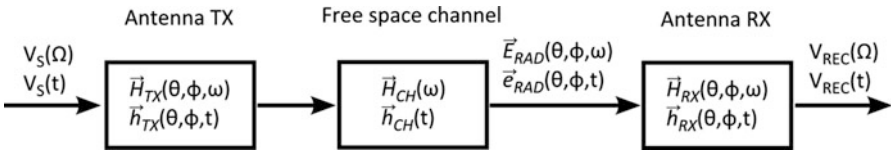

Fig. 21 UWB channel model

Using two identical antennas, in an antenna system configuration, and by using the method described by (Duroc et al. 2007), it is possible to estimate the transient and frequency response of the AUT. Indeed, the UWB channel model can be decomposed in three different blocks, consisting of the transmitting antenna, the free space channel, and the receiving antenna. Each block can be described by a transfer function such as, $\vec{H}_{TX}(\theta,\varphi,\omega), H_{CH}(\ \Omega)$and $\vec{H}_{RX}(\theta,\varphi,\omega)$, as shown on Fig. 21.

Hence the UWB channel can be completely described in both frequency- and time-domain as shown in Eqs.5 and 6 (Kanda 1986).

$$\frac{V_{REC}\ (\omega)}{V_S\ (\omega)} = \vec{H}_{TX}(\theta,\varphi,\omega) \times H_{CH}(\omega)\ \times\ \vec{H}_{RX}(\theta,\varphi,\omega) \tag{5}$$

$$V_{REC}(t) = \vec{h}_{TX}(\theta,\varphi,t) * h_{CH}(t)\ *\ \vec{h}_{RX}(\theta,\varphi,t) * V_S(t) \tag{6}$$

where Ω is the angular frequency, and the symbol $*$ is the convolution symbol. The free space channel transfer function can be defined using Eq.7, where c is the speed of light in free space, d is the antenna separation and λ is the wavelength.

$$H_{CH}(\omega) = \frac{\lambda}{2d}\exp\left(-j\omega\frac{d}{c}\right) \tag{7}$$

Then, by measuring the vectorial S21 of two identical antennas with same orientation, it is possible to deduce the transfer function of the antenna in transmitting and receiving mode as shown in Eqs. 8 and 9.

$$\vec{H}_{TX}(\theta,\varphi,\omega) = \sqrt{\left(\frac{\vec{S}_{21}\ (\theta,\varphi,\omega)}{H_{CH}(\omega)}\ \frac{j}{\lambda}\right)} \tag{8}$$

$$\vec{H}_{RX}(\theta,\varphi,\omega) = \sqrt{\left(\frac{\vec{S}_{21}\ (\theta,\varphi,\omega)}{H_{CH}(\omega)}\ \frac{\lambda}{j}\right)} \tag{9}$$

By knowing the transfer function of the receiving antenna, the free space channel and the antenna system's S_{21}, the transfer function of the unknown transmitting antenna can be calculated has shown on Eq.10.

$$\vec{H}_{TX}\ (\theta,\varphi,\omega) = \frac{\vec{S}_{21}(\theta,\varphi,\omega)}{H_{CH}(\omega)\ \times\ \vec{H}_{RX}(\theta,\varphi,\omega)} \tag{10}$$

DOI 10.1007/978-981-4560-75-7_59-1

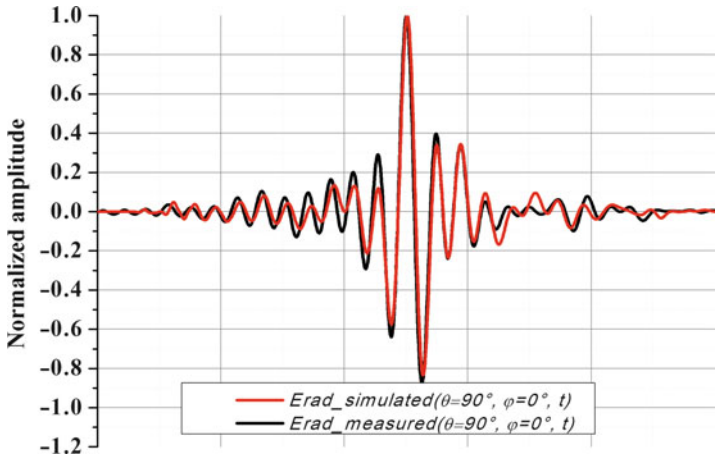

Fig. 22 Simulated and measured radiated pulse

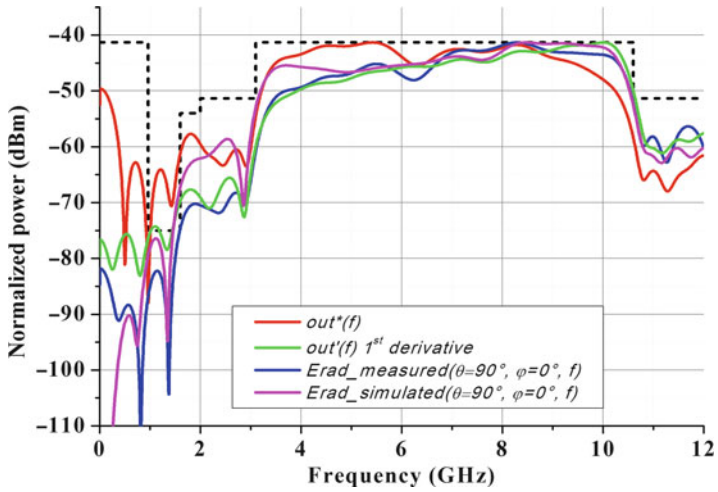

Fig. 23 Received output signal *out*(t)*, 1st derivative pulse *out'(t)*, simulated radiated signal $\vec{e}_{RAD\_simulated}(\theta = 90°, \varphi = 0°, t)$, measured radiated signal $\vec{e}_{RAD\_measured}(\theta = 90°, \varphi = 0°, t)$, normalised power spectrum density

Hence the incident radiated pulse $\vec{e}_{RAD}(\theta, \varphi, t)$ at the receiving antenna can be deduced by using Eq.11

$$\vec{e}_{RAD}(\theta, \varphi, t) = \vec{h}_{RX}(t) \overline{*} \left[IFFT \left(\vec{S}_{21}(\theta, \varphi, \omega) \right) \right] \tag{11}$$

where the symbol $\overline{*}$ stands for the deconvolution. Using this method, the measured radiated pulse from the transmitting antenna can be compared with the simulated radiated field captured from the virtual probe in the simulation model. It is seen that the measured radiated signal $\vec{e}_{RAD\_measured}(\theta = 90°, \varphi = 0°, t)$ is in good agreement with the simulated radiated signal $\vec{e}_{RAD\_simulated}(\theta = 90°, \varphi = 0°, t)$ as seen in Fig. 22. Figure 23 demonstrates that the signal $\vec{E}_{RAD\_measured}(\theta = 90°, \varphi = 0°, f)$ energy distribution shares similarities, in the UWB frequency range, with the energy spectrum of the $\vec{E}_{RAD\_simulated}(\theta = 90°, \varphi = 0°, f)$ and the 1st order derivative of the reference signal *out'(f)*,

DOI 10.1007/978-981-4560-75-7_59-1

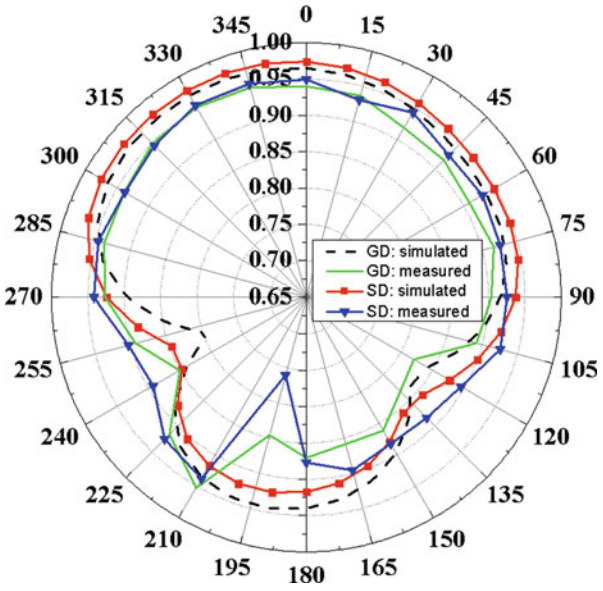

Fig. 24 Measured and simulated FF for an antenna system for Dipole GD and Dipole SD with an equalized modulated SRRC excitation pulse

demonstrating that the transmitting antenna tends to radiate a signal that is approximately proportional to the reference signal derivative at $\theta = 90°$, $\varphi = 0°$.

The transmitting antenna was rotated through 15° angle steps in the radiation plane. The oscilloscope was set to 64-sweep averaging to mitigate spurious sampling artefacts in the measured waveforms. Separate equalization eliminated the dispersive effects due to the cables between the reference antenna and the oscilloscope. The resultant measurement data for the antenna under test was then equivalent to the simulated field-probe data.

The FF was computed by correlating the post-processed received pulse waveforms with the 1st order derivative of the AWG output pulse out'(t). Figure 24 shows the measured FF polar plot for Dipole GD and Dipole SD alongside the simulated results from a modulated SRRC excitation pulse. Good agreement between simulation and measurement is achieved. Furthermore, the measurements validate that an antenna optimized for the full SRRC UWB pulse (Dipole SD) has better time-domain performance for the full UWB range than an antenna optimized with a pulse that does not fit to the FCC UWB spectral mask (Dipole GD).

UWB Localization and Tracking Applications

Impulse Radio UWB (IR-UWB) technology addresses one of the most topical frontiers of emerging wireless communication: precise indoor location and tracking. It allows both accurate measurement of time and data communications to occur simultaneously and so enable a wide variety of applications by developers of real-time location and indoor positioning systems, location-based services, Internet of Things and Wireless Sensor Networks. In healthcare applications doctors and equipment can be located to within centimetres, or children and elderly people can be monitored for their safety and security. In the automotive sector motorists can open and start their cars by simply approaching them. Defence and security can take advantage of weapons that are programmed to respond only to the licensed holder, and military personnel in the field can be tracked. IR-UWB radio devices are currently commercialised (DecaWave, TimeDomain, Zebra Technologies to cite a few) and overcome the intrinsic problems of

DOI 10.1007/978-981-4560-75-7_59-1

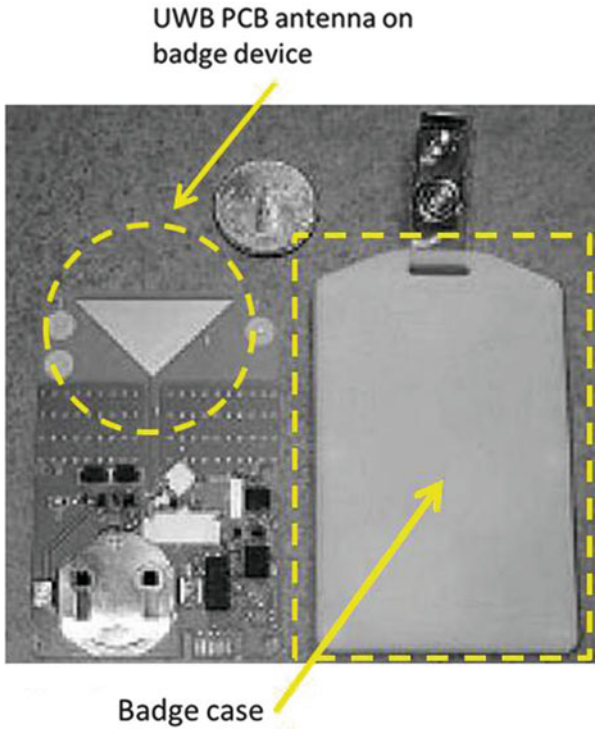

Fig. 25 Tag for IR-UWB personnel tracking (Zebra Technologies DartTag Badge device)

narrowband radio schemes such as high power consumption and poor performance in multipath environments. IR-UWB technology allows longer battery operation and it also enables higher degrees of flexibility in the deployment of wireless networks and sensor positioning, together with increased communication reliability.

Real Time Location Systems are used to track and identify asset tags in real time generally using simple, inexpensive nodes (i.e., badges or tags) attached to or embedded in assets. These tags transmit wireless signals to devices called anchors or readers which employ the wireless signals to determine their location. Current commercial products provide a precision of 10 cm at a distance of up to 300 m in Line-of-Sight (LOS) mode even when devices are moving at speed. High node density is also supported with the accurate location of up to 11,000 items to such precision in a 20 m radius.

Dedicated antenna design is required to deliver this performance. On the tag side, omni-directionality and high compactness are desirable together with pulse fidelity and performance resilience in diverse operating configurations (i.e., close to human body or attached to different materials). But also easy antenna integration on the tag PCB is a required characteristic enabling further miniaturization. Monopole and dipole antennas are a convenient compromise in terms of operating bandwidth, omnidirectional radiation pattern and compactness when integrated on PCB.

In Fig. 25 a commercial product from Zebra Technologies Ltd. for personnel tracking is shown (Online http://www.zebra.com/us/en/products-services/location-solutions/dart-uwb/dart-tag.html). By printing the triangular monopole on the PCB, good compactness and cost reduction are achieved. The tag is approximately the size of a credit card (ID-1 format, 85.60 × 53.98 mm).

Figure 26 shows a tag where a ceramic UWB antenna is integrated on the PCB with the chip. The chip itself together with the metallized board acts as ground for the bevelled monopole (Online http://www.decawave.com/products/dwm1000-module).

While larger antenna solutions are afforded on the anchor device, the requirement for high gain and minimum group delay variation across frequency and angular beamwidth makes the design very

DOI 10.1007/978-981-4560-75-7_59-1

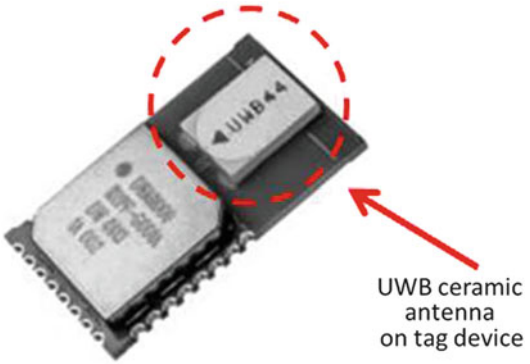

Fig. 26 Tag for IR-UWB radio localization and tracking (DecaWave DWM1000 Module)

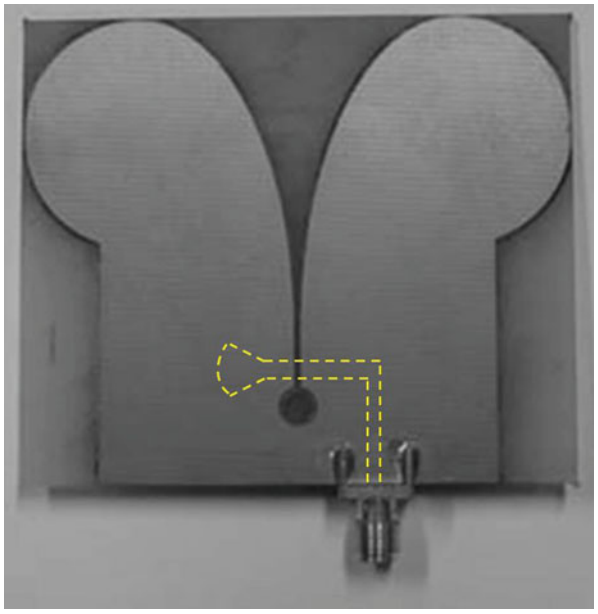

Fig. 27 Modified Vivaldi antenna developed at Queen Mary, University of London

challenging. More directive antennas at the anchor station enable the coverage of larger operating areas. Printed Vivaldi antennas are good candidate for this application due to their large operating bandwidth and directivity.

This antenna with an exponentially tapered slot enables a good trade-off between bandwidth and minimal length. Figure 27 shows a variation of a printed Vivaldi antenna, developed at Queen Mary College, University of London (Valderas et al. 2011). The edge of both arms was rounded to further improve the bandwidth and minimize distortion from the arm-extremities. The antenna is fed through a microstrip to a slot line transformer. The direction of maximum radiation in the Vivaldi antenna corresponds to the aperture between the two arms. In order to reduce the total length of printed tapered slot antennas, variations in the arm profiles were proposed. For instance, the bunny ear antenna (Fig. 28) combines an exponentially tapered aperture with a slot line which is designed to match the 50 Ω input impedance. The element is symmetrically printed on both sides of the substrate and can be easily integrated into a dual-polarized antenna with two centrally intersected PCB slabs (Lee and Livingston 1993).

DOI 10.1007/978-981-4560-75-7_59-1

Fig. 28 Bunny-ear antenna

In their stand-alone conventional configuration, dipole antennas have omnidirectional radiation patterns in the H-plane. The presence of a reflector restricts the operating frequency range of the antenna as it must be placed at a quarter-wavelength distance from the dipole. However, several reported dipole-based antennas have been recently proposed to combine UWB performance, low-profile design and directional radiation patterns (Fig. 29). Examples of band enhancement techniques include the integration of composite reflectors such as E- and H-type corrugated reflectors to support surface currents across a large frequency range (Wu et al. 2010) and minimize destructive current images. In (Wang et al. 2012) a reversed T-match dipole with a flat ground plane was introduced achieving a 77 % operating bandwidth. Small variation input impedance, large bandwidth and stable radiation patterns were reported in (Qu et al. 2009) using a cavity-backed folded triangular bowtie antenna with a rimmed circular reflector.

Circularly Polarized (CP) antennas have been used in a number of radar, communication and navigation systems for many years to mitigate polarization mismatch and reduce orientation constraints between the transmitting and receiving antennas. Recently, systems capable of transmitting and receiving circularly polarized UWB waves were proposed for accurate radio-localization. The objective is to combine the natural immunity of CP transmit/receive systems to arbitrary polarisation alignment with high spatial and temporal resolutions provided by UWB short pulse signals (Shlivinski 2009). But this creates two significant challenges for the antenna engineer: increasing circular polarization across a large operating bandwidth while satisfactory time-domain performance is provided. In Qing et al. (2007) use a three-stub hybrid coupler to provide controlled power division to two orthogonal UWB slot antennas over the frequency range 2.8–5.2 GHz, shown in Fig 30.

The investigation is carried out in terms of typical frequency-domain parameters to characterize CP antennas (i.e., impedance matching, gain, axial ratio, radiation patterns) with further analysis in the time-domain in terms of pulse-distortion, group delay variation and fidelity.

The same operating principle of directing equal signals to two orthogonal UWB antennas is also adopted by Narbudowicz et al. in (2012) but applied to directive antipodal Vivaldi antennas. The input signal is split using a 3-stage Wilkinson divider to provide smooth transmission with minimal variation between antenna feeds. The desired 90° phase shift between the antenna feeds is obtained in two stages by

coupling the signal through the elliptical slot in the ground plane to a microstip line located on the rear side of the dielectric (Fig. 31). Although the mismatch of the two phase centers generates a small tilt in the main beam, this can be mitigated by placing the antennas as close as possible.

Biomedical UWB Imaging

Microwaves and millimeter waves have been widely used as a successful and low-cost imaging method for dielectric structures. In this spectrum, electromagnetic waves have wavelengths ranging from a millimeter to a meter and can penetrate into several optically opaque media. In particular, when UWB radar technology is used, target detection can be achieved with high accuracy. Compared to narrowband systems, UWB radar offers greater imaging resolution and improved target characterization. Recently, UWB radar technology has been successfully proposed in biomedical diagnostics.

UWB microwave imaging techniques for biomedical scenarios are based on the transmission of low-power short microwave pulses (tens picoseconds to nanoseconds) into the body and the consequent detection of the differentiated scattering due to the dielectric contrast between the target and healthy tissues. The advantage of using short pulses is due to easier identification of the target contribution in the received scattered signal. This consists of the incident signal together with a large number of delayed and attenuated replicas from dielectric discontinuities inside human tissue. Narrowband antennas would generate larger pulses and overlapping signal replicas which can hide the informative signals coming from the target. The short pulses are advantageous in detecting a target in human tissue, but the UWB antenna design presents several challenges.

Human tissue such as skin, muscle, fat, brain, and many others present very different electrical properties from those of air. Starting with the skin layer with a relative permittivity around 30 and a specific conductivity of about 3 S/m in the low GHz range, deeper layers of fat, muscle, fibro-glandular and connective tissues contribute to the rejection of the microwave power due to reflection and dissipation. Moreover, the electrical properties of tissue exhibit strong dispersion with frequency in the RF and microwave spectra. In this difficult propagation scenario the electromagnetic signal is subjected to strong attenuation and distortion. Moreover, the attenuation between incident and penetrated signal challenges the dynamic range of the measurement setup and the UWB signal distortion can make the imaging formation process extremely difficult, resulting in clutter which masks the signal scattered by the target. The attenuation and distortion limitations tolerable by the imaging system translate into the following requirements for a successful diagnostic procedure:

- The system must provide appropriate penetration into the body area under assessment;
- The coupling mechanism between sources, sensors and the body must be stable across the operating bandwidth and screening configurations.

The design of the UWB antenna plays a vital role. The first consideration comes from the strong rejection of electromagnetic signals by skin and deeper layers for frequencies above 10 GHz. A few

DOI 10.1007/978-981-4560-75-7_59-1

centimeters of tissue along the direction of propagation can attenuate a 10 GHz signal by more than 80 dB. Good signal penetration can be achieved at lower frequencies (i.e., below 1 GHz). However, the allocation of the operating bandwidth is compromised by the requirement for compact antennas. The diagnostic device design involves the integration of small antennas to facilitate manoeuvrability or array integration. Size reduction is often achieved by immersing the antenna into a liquid solution with a dielectric constant similar to that of tissue. This medium provides an impedance transformation between the antenna and the body, improving tissue coupling.

Another important constraint for the designer is to provide resilience of antenna performance under all operating configurations. In particular, adequate impedance matching must be maintained with the antenna in close proximity to different body areas and for different antenna-skin separation. Suitable antenna designs should be capable of screening interference by backscatter from undesired directions.

Frequency-domain characterization of antennas is not appropriate for biomedical imaging applications where near-field conditions occur. Parameters such as gain, radiation efficiency, phase center and radiation pattern refer to far-field conditions and are not suitable in scenarios where the body strongly couples to reactive fields. These parameters rapidly change when the antenna is in close proximity to the body as in typical medical imaging configurations. The dramatic dependence of the antenna behaviour on scanning position and the body area necessitates alternative quality figures. This is validated by numerical tools which simulate the complex electromagnetic problems in the presence of highly detailed voxel models which reproduce the morphology and the electrical dispersion of benign and malignant tissues. But tissue-mimicking phantoms can also enable ad-hoc antenna characterization at the experimental stage.

Although in realistic scenarios tissue morphology changes from patient to patient with consequent variations in antenna response, specific parameters of merit were introduced to characterize antennas in biomedical imaging applications. For this purpose, standard testing configurations were proposed to combine the requirement of approximating a realistic operating situation in a controlled environment (Fig. 32). The following parameters are able to characterize the antenna in terms of properties which are useful for a near-field UWB radar imaging application.

Fidelity Factor: calculated as the maximum magnitude of the cross correlation between the normalized transmitted and the normalized received response across tissue-mimicking multi-layer structures.

Pulse duration: For radar-based breast cancer detection it is important that pulses produced by the antenna are as short as possible with minimal late-time ringing (Gibbins et al. 2010). Therefore pulse duration is a good indication of the ability of the antenna to effectively transmit UWB signals into the medium. The time taken for 99 % of the energy of these pulses to be received can be calculated for different antenna polarizations and across a defined angular beamwidth.

Half Energy Beam (HEB) and *Half Energy Beamwidth (HEBW)*: The HEB and HEBW are based on the Energy Flux Density (EFD) which is calculated by summing time samples of the instantaneous Poynting vector over the duration of the simulation time (Bourqui et al. 2010). In the near-field, the HEB is defined on a plane which is orthogonal to the main radiation beam and situated at a given distance from the antenna aperture as shown in Fig. 33. The HEB describes the region over which the energy is greater than half of the maximum value on the selected plane. Accordingly, the HEBW is defined by the angular width of this region.

Among different screening typologies under investigation, breast cancer imaging has advanced faster and is currently at a clinical trial stages. Hagness et al. pioneered this imaging modality by proposing small UWB microwave radar systems to detect malignant tumors in the breast (Hagness et al. 1998). Encouraging outcomes and the critical necessity for developing early-stage breast cancer screening tools with high sensitivity and specificity prompted significant research efforts which have grown into a well-established microwave application (Hagness et al. 2012). Microwave imaging of breast cancer is either

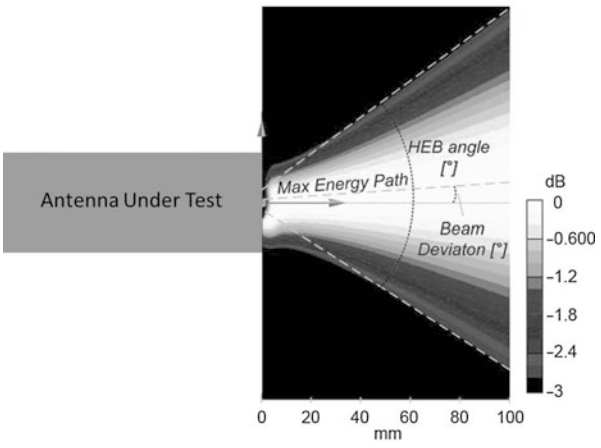

Fig. 33 Half energy area in one plane and HEB representation

based on mapping the permittivity and conductivity distributions as functions of position or the simple detection of malignant tissues. With both approaches measured data are collected by antennas in specific positions and then processed in search of scatterers, i.e., objects with properties which differ from those in the normal or healthy state of the imaged body region. Accordingly, the more electrically similar a tumor is to its surrounding benign tissues, the more challenging it is to detect it. The dielectric contrast between malignant and benign tissues is generally defined as the ratio, often in percentage, of the permittivities (or the conductivities) of the scatterer and the host medium. Recent studies (Sha et al. 2002; Lazebnik et al. 2007a, b; Meaney et al. 2007; Poplack et al. 2007; Halter et al. 2009) indicate that while contrasts

between malignant and adipose breast tissue may be as large as 10, those between malignant and healthy fibroglandular tissues can be as low as 1.1 in both permittivity and conductivity.

Both mono- and multi-static radar architectures have been proposed for microwave breast cancer imaging (Fig. 34). Whether the antenna is a fixed array element displaced around the body area or the antenna moves across different screening positions, its performance must be stable for all configurations.

Numerous antenna designs for radar-based UWB microwave breast imaging have been proposed over the past 15 years. A wide slot antenna with interesting features for UWB cancer detection was developed at the University of Bristol (Gibbins et al. 2010) (Fig. 35). This antenna is surface-mounted on a hemispherical bowl to form a 31-element array and function as a multi-static system with 465 independent measurements (Klemm et al. 2011). The imaging system operates in the full UWB frequency range, between 3 and 10 GHz. Both these antennas mainly consist of printed dielectric substrates with a relative permittivity of 10.2. The geometry was optimized to operate with the antenna face immersed in a matching medium with dielectric properties that mimics that of human breast tissue, in order to reduce reflections by eliminating the air/skin interface (Sill and Fear 2005). The matching medium used is mainly a solution made of paraffin oil and distilled water. This mixture has a relative permittivity of between 9 and 10 in the 2–10 GHz region and an attenuation of 2 dB/cm at 8 GHz. The wide-slot antenna developed at

DOI 10.1007/978-981-4560-75-7_59-1

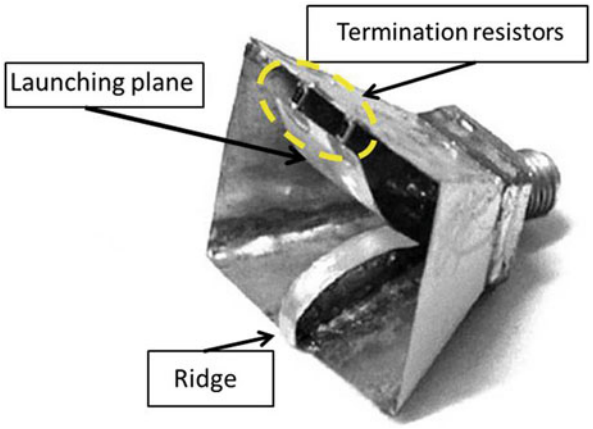

Fig. 36 Modified ridged pyramidal horn antenna with curved launching plane developed at the University of Wisconsin

the University of Bristol consists of an approximately square slot cut out from a ground plane which is printed on one side of a substrate with relative permittivity of 10.2. The slot is fed by a forked microstrip feed that splits just below the slot from a 50 Ω feed into two 100 Ω sections. The fork feed excites multiple resonances with a consequent increase of the impedance matching bandwidth.

A cavity is attached to the antenna on the side where the microstrip feed is located. This small cavity prevents any radiation from the antenna rear side (opposite to skin interface) coupling with other elements in the array. The cavity is absorber lined and also stops interference from spurious radiation on the imaging formation process. The antenna provides suitable bandwidth for use in UWB detection systems. In consideration of the complex array architecture where the antenna operates, inter-element transmission properties were also investigated. The wide-slot antenna presents a stable transfer function over a large angular range across bore-sight direction. This results in a fidelity factor better than 90 % for angles up to 60° from boresight and reduced late-time ringing and distortion of transmitted signals.

For monostatic data collection more voluminous three-dimensional antenna designs may be suitable. A ridged pyramidal horn antenna (Li et al. 2003) was reported by the University of Wisconsin, and resistively loaded dipole, tapered slot, transverse electromagnetic horn, and balanced antipodal Vivaldi antennas have been presented by the University of Calgary (Bourqui et al. 2009). Li et al. proposed a modified ridged pyramidal horn antenna with a curved launching plane (Fig. 36). The bandwidth of horn antennas can be increased significantly by adding metallic ridges to the waveguide and flared sections (Walton and Sundberg 1964). In Li's antenna one of the two ridges is replaced by a curved metallic plane terminated by two 100-Ω resistors that suppress reflections from the end of the launching plane (Fig. 36). The waveguide section was eliminated to reduce size. The pyramidal horn has a depth of 13 mm with a 25 mm × 20 mm aperture and is connected to the outer conductor of the coaxial feed and serves as the ground plane, providing a current return path. The maximum width of the tapered launching plane is 12 mm, whereas the thickness of the ridge is 2 mm. The antenna is made of brass and fed by an SMA connector. Thickness, curvature and shape of the launching plane critically control the input impedance of the antenna. But its tapered profile prevents reflections which can distort the pulse.

In 2010 Bourqui et al. proposed a modified balanced antipodal Vivaldi antenna (BAVA) which includes a profiled high dielectric section placed in the antenna aperture (Bourqui et al. 2010). The BAVA provides a more compact profile combined with near-field focusing of the energy in the endfire direction. This antenna was designed to operate in a monostatic scanner immersed in canola oil. From 1 to 14 GHz, the permittivity and conductivity of this coupling medium varies from 2.55 to 2.35 and 0.01–0.04 S/m, respectively. The antenna consists of three copper layers; the two external layers are the ground planes and the central layer is the conductor (Fig. 37). The copper layers are printed on two dielectric substrates

DOI 10.1007/978-981-4560-75-7_59-1

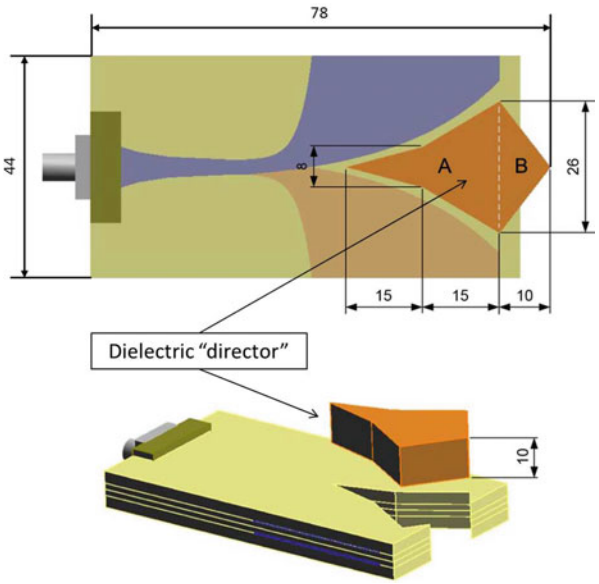

Fig. 37 BAVA including a higher dielectric permittivity director developed at the University of Calgary. All dimensions are in mm

(supportive substrates) and two additional dielectric layers are stacked on each side of the antenna (stacking substrates) to balance the dielectric loading between the conductor and ground planes. As a result of this solution, the usual beam squint observed across frequency in this type of antenna (Langley et al. 1996) is considerably reduced. Moreover, for this application, the energy coupling is improved since contact between the lossy canola oil and the external copper layer is avoided. The director is made of Eccostock HIK material with a relative permittivity of 6. The shape of the director is designed to prevent reflections from its extremities and to enhance near-field focusing. The effect of such narrower beamwidth was verified with the transmitted energy between two antennas being significantly greater in the presence of the director. Furthermore, it was demonstrated that the presence of the director in the aperture of the BAVA increases the backscatter energy from an object placed in front of the antenna, such as a tumor embedded in the breast.

Selective illumination of the breast may assist in tumor localization. In the context of microwave imaging applications, a more focused beam illuminates a smaller volume which can increase the tumor-to-clutter ratio. Ruvio et al. compared three antennas with different coupling mechanisms and focusing capability for a UWB mono-static radar illumination of a tumor embedded in a 2-D multi-layer breast-mimicking phantom (Ruvio et al. 2014). In particular, an antipodal Vivaldi antenna shown in Fig. 38 was optimized by means of a ParEGO algorithm to provide a stable transfer function over the operating

DOI 10.1007/978-981-4560-75-7_59-1

bandwidth ranging from 1 to 3 GHz when immersed in a coupling medium with permittivity of 12. Both numerical and experimental results show the antipodal Vivaldi antenna outperforms a coplanar and a semi-folded monopole as it enables more pronounced clutter mitigation in reconstructions.

Future Directions and Open Problems

The main research activity on UWB antennas is currently driven by emerging applications in biomedicine and security. Since UWB imaging provides low-cost, high resolution imaging, good target recognition and robust immunity to passive jamming, it has the potential to replace or complement the ionizing radiation used in conventional non-invasive imaging applications. Emerging biomedical applications include UWB microwave impedance spectroscopy (non-invasive measurement of glucose and cholesterol levels in blood) and vital signs detection. Security applications include a low-cost alternative detection of concealed metal objects, as well as through-the-wall imaging, body-area networks and asset-tracking. Automotive applications include vehicle entry systems and relay attack avoidance. In the agricultural sector, livestock tracking and feed control methods using UWB are evolving.

Some of the main challenges facing UWB antenna design relate to the environment. For example, close proximity to the body realises dielectric loading which is highly sensitive to proximity distance. There is demand for antennas which are resilient to this loading across all applications. New parameters are required to describe UWB antennas when in close proximity with media which are not known a priori (on-body networks, ground penetrating radar, through-the-wall imaging, microwave breast cancer imaging. . .). These parameters would describe antenna resilience to proximity of these media.

In communications applications, UWB antennas may also be employed in multi-band or cognitive radio applications. Of course, UWB antennas are not confined to 3.1–10.6 GHz with activity below (ground penetrating radar) and above this band. High rate communications in the 57–66 GHz band is the focus of research on UWB antennas on-chip packaging (→On-chip Antennas).

Beam-Scanning Leaky-Wave Antennas

Jun H. Choi[a,b]* and Tatsuo Itoh[a]
[a]Department of Electrical Engineering, University of California, Los Angeles, Los Angeles, CA, USA
[b]Department of Electrical Engineering and Computer Science, Center for Science and Technology, Syracuse University, Syracuse, NY, USA

Abstract

This chapter presents the basic principles and recent developments of beam-scanning leaky-wave antennas. The single radiating element is realized by modifying waveguides to leak along the structure producing radiated beams that scan as the operating frequency is varied. This unique characteristic distinguishes leaky-wave antennas from other types of antenna. Leaky-wave antennas are broadly classified into three classes: uniform, periodic, and quasiperiodic. In the following sections, each class will be explained and compared. Samples of novel design techniques and potential applications are also highlighted.

Keywords

Beam scanning; Dispersion diagram; Frequency scanning; Leaky-wave antenna; Metamaterial; Periodic structure

Introduction

Leaky-wave antennas exhibit radiated beams that scan as a function of frequency. The unique frequency-scanning feature is realized by engineering the waveguiding structure to leak energy as the wave propagates down the waveguide. Therefore, leaky-wave antennas are considered traveling wave-type antennas. Since leaky-wave antennas are generally realized by utilizing or modifying conventional waveguiding structures, the key in designing such antennas lies in producing and controlling the leakage. As will be shown in the following sections, leakage may be produced by operating the waveguide in a higher-order propagating mode or spatial harmonics or utilizing unconventional waveguide structures that permit the fundamental mode to radiate. The latter approach includes the use of a relatively new waveguide technology based on the metamaterial concept.

If the field traveling inside the waveguide structure leaks energy, the complex propagation wavenumber of the guided field is expressed by leakage constant α and propagation constant β. The frequency-dependent propagation constant $\beta(\omega)$ mainly dictates the beam-scanning angles and α shapes the amplitude distribution of the antenna. The length of the antenna is usually designed such that most of the energy is leaked out of the antenna by the time the wave reaches to the opposite end, where the leakage constant can be judiciously engineered to meet design-specific requirements. For example, if the antenna dimension is relatively short, large α is preferred to radiate the energy quickly to make the antennas more

*Email: jhcho100@syr.edu
*Email: choijh@ucla.edu

DOI 10.1007/978-981-4560-75-7_60-1

efficient. On the other hand, if a longer antenna dimension is allowed, α can be relaxed to spread the amplitude distribution thereby increasing the radiated directivity of the antenna.

The very first leaky-wave antenna dates back to 1940, when rectangular waveguides were the dominant type of microwave guiding medium (Hansen 1940). Radiation was achieved by opening a narrow slit along the side of the waveguide. As the wave propagated through the medium, partial energy coupled to free space through the narrow slits. The concept was then extended to various structural forms using different waveguide technologies (Hessel 1969; Tamir 1969; Menzel 1979; Oliner and Jackson 2007; Jackson and Oliner 2008; Sutinjo et al. 2008; Caloz et al. 2011; Jackson et al. 2012; Jackson 2013; Menzel 2013). Elaborate details in the theory and analysis of leaky-wave antennas can be found in these book chapters and review articles, which are highly recommended for readers seeking for more in-depth understanding. This chapter is organized to concisely summarize the core fundamentals of leaky-wave antennas. The second half of the chapter highlights samples of recent techniques in designing leaky-wave antennas with specific radiating characteristics. Practical applications will also be presented at the end of the chapter.

Leaky-Wave Antenna Physics and Classifications

A large number of design techniques are available to control and enhance the radiated beam characteristics of leaky-wave antennas. But before considering various improvement options or adding particular features, the antenna has to first properly leak energy. The primary requirement in designing a leaky-wave antenna is therefore to ensure the waveguiding structure is operated in the fast-wave region ($\beta/k_o < 1$). This condition allows the propagation constant of outward pointing wavenumber vector at the interface between the antenna and open boundary to be real, which translates to radiation. To better understand the radiating mechanism, this section discusses the fundamental operating principles of leaky-wave antennas. Then, different realization options will be briefly introduced.

Leaky-Wave Antenna Fundamentals

For a general understanding of the radiating mechanism, consider a lossless two-dimensional waveguide structure with the source located at $z \ll 0$ (Fig. 1). When designing a simple planar antenna radiating toward the upper hemisphere, the lower boundary of the waveguide (at $x = -h$) is assigned with a perfect

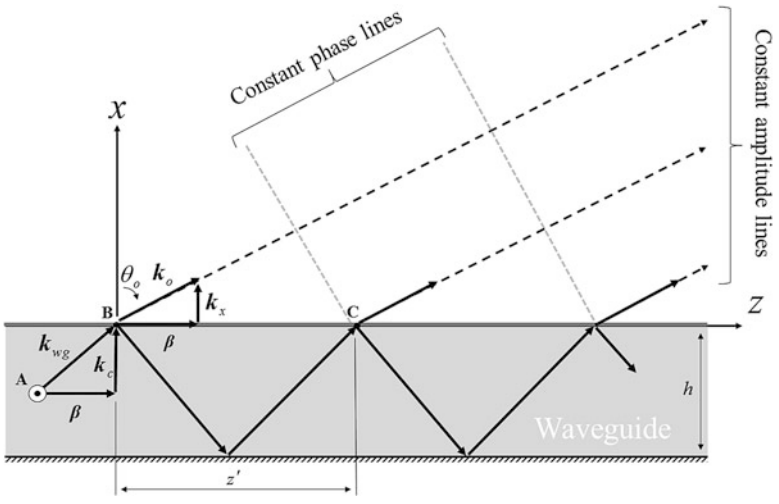

Fig. 1 Side view of an arbitrary two-dimensional leaky-wave antenna

DOI 10.1007/978-981-4560-75-7_60-1

reflecting layer such as a perfect electric conductor (PEC) or perfect magnetic conductor (PMC). To accommodate radiation, the upper boundary of the waveguide (at $x = 0$) should however be a slightly imperfect reflecting boundary (partially leaking boundary) that minimally disturbs the guided field. Although this is a generalized example, the main concept can be applied in understanding the fundamental working mechanisms of leaky-wave antennas. The partially reflective interface can take various forms, such as the interface between different material layers, narrow slots, periodic array of apertures or slots, array of parallel wires, etc. (Oliner and Jackson 2007).

Consider a y-oriented field propagating along the z-direction with the propagation constant $\beta(\omega)$. The magnitude of $\boldsymbol{k}_{wg}$ may vary depending on the material enclosed by the waveguide structure. For example, k_{wg} equals free-space wavenumber (k_o) if the guiding structure is filled with air but becomes larger than k_o if the guiding structure encloses dielectric materials. In this example, lossless condition also results k_{wg} to be real. The cutoff wavenumber k_c is determined by the waveguide dimensions and the propagation mode. If the antenna permits partial energy leakage only at the interface between the antenna and air (in our case at $x = 0$), the reflected field amplitude is reduced in proportion to the leakage amount, α. Starting with the initial field expression at point A,

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o e^{-j(k_c x+\beta z)}, \tag{1}$$

where A_o is the initial amplitude of an arbitrary field. Assuming the antenna interface generates negligible reactive near-field energy storage, partial leakage produces

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o e^{-j(\mathrm{k}_o\cdot\mathrm{r})} = \hat{y}A_o T e^{-j(k_x x+\beta z)} \quad \text{for } x = 0^+, \tag{2a}$$

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o e^{-j\left(\mathrm{k}_{wg}\cdot\mathrm{r}\right)} = \hat{y}A_o \Gamma e^{-j(-k_c x+\beta z)} \text{ for } x = 0^-, \tag{2b}$$

just above and below the interface point B between the antenna and air, respectively. Here, the transmission coefficient (T) and reflection coefficient (Γ) are not strictly due to material discontinuity but are also due to the radiating structure. The coefficients are dictated by impedance mismatch at the interface. Also, the phase-matching condition at the interface requires $\beta(\omega)$ to be continuous for lossless case. Continuing along the propagation path, the fields just above and below the interface at the second interface point C can be treated in a similar manner,

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o T\Gamma e^{-j(k_x x+\beta z)} \text{ for } x = 0^+, \tag{3a}$$

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o \Gamma\Gamma e^{-j(-k_c x+\beta z)} \text{ for } x = 0^-. \tag{3b}$$

The field inside the antenna will continue propagating down the waveguiding structure transversely bouncing back and forth in a zigzag manner until either all the energy is leaked out or the wave is terminated with a matched load. As the wave travels over a unit distance z', the field amplitude is reduced by $\Gamma = \exp(-\alpha z')$. Thus, the field amplitude is exponentially reduced by a unit attenuation constant (α) as the guided field encounters each field-emanating interface. Consequently, the field just above the interface can be expressed as

$$\boldsymbol{\psi}(x,z) = \hat{y}A_o T e^{-\alpha z} e^{-j(k_x x+\beta z)}. \tag{4}$$

The dispersion relation directly above the interface (or aperture) of the antenna is given by

DOI 10.1007/978-981-4560-75-7_60-1

$$k_x = \sqrt{k_o^2 - \beta^2}. \tag{5}$$

To support wave propagation away from the interface, the antenna has to operate in the fast-wave regime where $\beta(\omega) < k_o$. The term "fast wave" describes the faster phase velocity of the wave traveling down the propagating direction (z-direction) relative to that of the speed of light:

$$v_p = \frac{\omega}{\beta(\omega)} > c = \frac{\omega}{k_o}. \tag{6}$$

If $\beta(\omega) > k_o$ (slow wave), k_x becomes imaginary which translates to an evanescent wave along the positive x-direction. Under the latter condition the structure will no longer behave as a leaky-wave antenna. The main beam angle θ_o of the leaky-wave antenna operating under the fast-wave condition is determined by the ratio between $\beta(\omega)$ and k_o as

$$\theta_o(\omega) = \sin^{-1}\left[\frac{\beta(\omega)}{k_o}\right]. \tag{7}$$

The length of the antenna (L) is generally adjusted to radiate about 90 % of its power. An initial length satisfying this condition can be estimated by taking the ratio of the power leaving through the opposite end of the antenna structure over the input power and then equating the ratio to 10 %:

$$L \approx \frac{0.18(\lambda_o)}{(\alpha/k_o)}. \tag{8}$$

Designing leaky-wave antennas with near 100 % efficiency is generally considered impractical because the aperture dimension has to be extremely large.

Leaky-Wave Antenna Classifications

Leaky-wave antennas are classified as uniform, periodic, or quasiperiodic. When choosing the class, it is up to the designer to evaluate the design trade-offs. For example, leaky-wave antennas based on uniform structures are relatively easy to design and fabricate, but usually provide limited frequency-scanning capability. Periodic-type leaky-wave antennas demand a relatively relaxed fabrication requirement in comparison to the quasi-uniform types, but require special design technique to circumvent undesired radiated gain reduction near broadside direction. Quasi-uniform structures can be systematically designed to provide full-frequency-scanning capability, but are comprised of relatively complex structural forms. Although numerous variations are currently available in realizing each class of leaky-wave antennas, the following sections will use single-conductor rectangular waveguides and multiconductor planar waveguides to illustrate the subtle differences between classes.

Leaky-Wave Antenna Designs

In this section, three classes of leaky-wave antennas will be explained using dispersion diagrams (commonly known as k-β diagram). Samples of novel design techniques are also outlined in the second half of the section. A dispersion diagram provides graphical interpretation of the dispersion relations of forward and backward propagating waves in the waveguide. $k_o d$ and βd represents spatial phase-shift quantity per unit distance (d) along the unbound and bound propagating directions, respectively. The dash

DOI 10.1007/978-981-4560-75-7_60-1

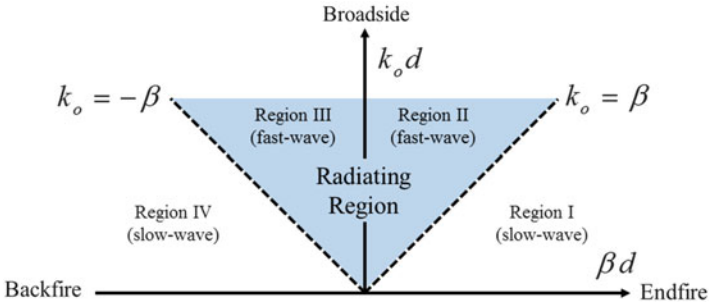

Fig. 2 Dispersion diagram of a 1-D leaky-wave antenna

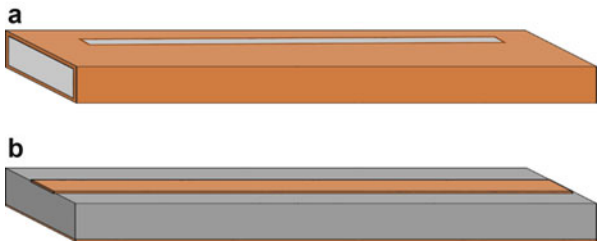

Fig. 3 Sketch of uniform leaky-wave antennas based on (**a**) single-conductor waveguide with a narrow open slot and (**b**) multiconductor microstrip line

line is called the airline or transverse electromagnetic (TEM) line that delineates the radiation (fast-wave) region and guided (slow-wave) region (Fig. 2). The dispersion diagram presents a graphical reference to quickly determine if a given waveguide structure is radiative. For example, even if the structure is not completely shielded and permits radiation, the fields will be confined within the structure when operating in the slow-wave region (regions I and IV). On the other hand, if the same structure is operated inside the fast-wave region (regions II and III), the same waveguiding structure behaves as an antenna and radiates with a main beam direction given by Eq. 7. The plot has been primarily utilized to analyze the dispersion characteristics of periodic structures. But in this chapter it is also used to explain the uniform-type leaky-wave antennas to provide a more consistent comparison between the three leaky-wave antenna classes. When plotting the dispersion diagram for the uniform case, the structure is assumed to be infinitely long with $d \ll \lambda_g$.

Uniform Structure

The fundamental mode of a conventional single-conductor rectangular waveguide shown in Fig. 3a exhibits a dispersion that originates inside the fast-wave region and asymptotically approaches the airline as the frequency (proportional to $k_o d$) increases (Fig. 4a). Therefore, a leaky-wave antenna can be realized by partially opening the closed structure to allow the fundamental mode to couple energy to the surrounding unbound environment. The latter condition assumes the energy coupling aperture or interface minimally perturbs the guided wave. A unidirectionally fed uniform leaky-wave antenna scans the beam from near broadside direction toward the endfire direction as the frequency increases. As shown in Fig. 4a, asymptotic behavior of the dispersion curve for an air-filled waveguide ($\varepsilon_r = 1$) requires relatively wide frequency bandwidth to tilt the radiated beam to near endfire direction. However, if the waveguide is loaded with high dielectric materials ($\varepsilon_r > 1$), the dispersion curve asymptotically approaches the dielectric-loaded line (dashed line). The dispersion curve slope and hence leaky-wave bandwidth can therefore be engineered. Engineering flexibility provides relaxed design criteria for practical systems with

DOI 10.1007/978-981-4560-75-7_60-1

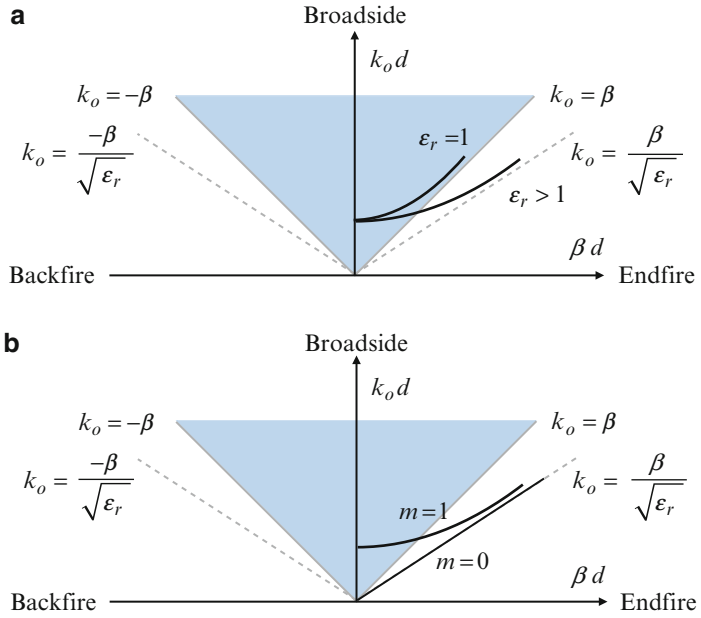

Fig. 4 Dispersion diagrams of uniform leaky-wave antennas based on (**a**) single-conductor waveguide and (**b**) multiconductor microstrip line

limited frequency bandwidth needing to scan the beam from near broadside to endfire. In addition to the fundamental propagating mode, an infinite number of higher-order propagating modes are also generated as the frequency is increased. However, since leaky-wave antennas usually operate in the lower propagation modes, only the dispersion relations for the frequency band corresponding to the lower modes are shown throughout the chapter.

A slightly different approach is required to operate a multiconductor uniform waveguide structure such as a microstrip line shown in Fig. 3b as a radiating structure. A microstrip line is not a completely shielded structure, but the fundamental quasi-TEM mode ($m = 0$) is bounded as shown in Fig. 4b. If however the structure is operating in the first higher-order mode ($m = 1$), radiation occurs in the frequency regions above the first higher-order mode cutoff frequency and within the leaky-wave region. The radiation takes place from open side boundaries of the microstrip line. This antenna was first proposed by Menzel (Fig. 3b) and then extensively analyzed by Oliner (Menzel 1979; Oliner and Lee 1986).

Among the three classes of leaky-wave antennas, uniform leaky-wave antennas have a relatively simpler form factor. However, one of the major drawbacks is the limited beam-scanning range since this class of antennas can only direct the beam toward the endfire direction. Full-frequency beam scanning from backfire to endfire requires additional design techniques such as using more exotic ferrite materials. Detailed explanations of this method will be discussed in section "Ferrite Loaded Leaky-Wave Antenna."

Periodic Structure

Periodic structures can be analyzed in the spatial frequency domain using spatial Fourier expansion or more commonly known as Floquet spatial harmonic expansion (Hessel 1969; Collin 1991; Pozar 1998). For an arbitrary one-dimensional periodic waveguide structure (Fig. 5), the time-harmonic field reacting to the structure can be described by

$$\boldsymbol{\psi}(x, y, z + d) = e^{-jk_{z0}d}\boldsymbol{\psi}(x, y, z). \tag{9}$$

DOI 10.1007/978-981-4560-75-7_60-1

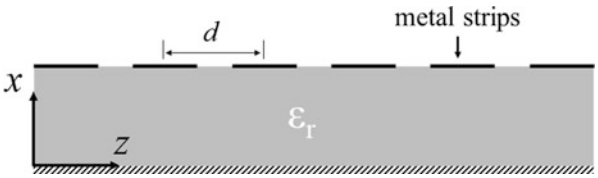

Fig. 5 Example of a periodic waveguide (dielectric waveguide with periodic perturbation along the propagating axis)

The neighboring field at a distance d away only differs by the zero space harmonic complex phase-shift amount of $k_{z0}d = (\beta - j\alpha)d$. The above equation can be expressed in terms of a periodic vector function $\boldsymbol{P}(x, y, z) = \boldsymbol{P}(x, y, z + d)$ as follows:

$$\boldsymbol{\psi}(x, y, z) = e^{-jk_{z0}z}\boldsymbol{P}(x, y, z). \tag{10}$$

Moreover, the periodic function may be expanded in a Fourier series,

$$\mathrm{P}(x, y, z) = \sum_{n=-\infty}^{\infty} \boldsymbol{a}_n(x, y)e^{-j\frac{2\pi}{d}nz}, \tag{11}$$

where $\boldsymbol{a_n}$ is a function describing the spatial harmonic field variation in the x and y directions. Plugging Eq. 11 into Eq. 10 results in

$$\boldsymbol{\psi}(x, y, z) = \sum_{n=-\infty}^{\infty} \boldsymbol{a}_n(x, y)e^{-jk_{zn}z}, \tag{12}$$

where

$$k_{zn} = k_{z0} + \frac{2\pi}{d}n,\ n = 0,\ \pm 1,\ \pm 2,\ \geq \cdots. \tag{13}$$

The corresponding propagation constants of outward pointing wavenumber vectors at the field-emanating interface are

$$k_{xn} = \sqrt{k_o^2 - k_{zn}^2}, \tag{14}$$

which simplifies to

$$k_{xn} = \sqrt{k_o^2 - \beta_n^2} \tag{15}$$

for the lossless case. Radiation conditions are satisfied for all n^{th} spatial harmonics located inside the fast-wave region. This relation can be visualized by plotting the dispersion diagrams of spatial harmonics that repeats in βd with period 2π (Hessel 1969).

Two examples of periodic leaky-wave antennas are shown in Fig. 6. The first antenna is realized by opening periodic slots on the top metallic layer of an air-filled rectangular waveguide. The second example is a planar microstrip line with periodic open stubs etched on a grounded low dielectric substrate. Although a realistic dispersion diagram takes a much more complicated form, a simplified version of an antenna with unidirectional feeding can be drawn assuming the perturbation due to the periodic loading is

DOI 10.1007/978-981-4560-75-7_60-1

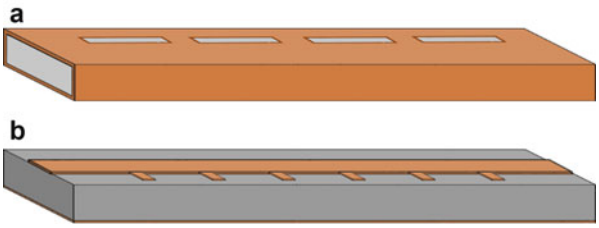

Fig. 6 Sketch of periodic leaky-wave antennas based on (**a**) single-conductor waveguide and (**b**) multiconductor combline structure

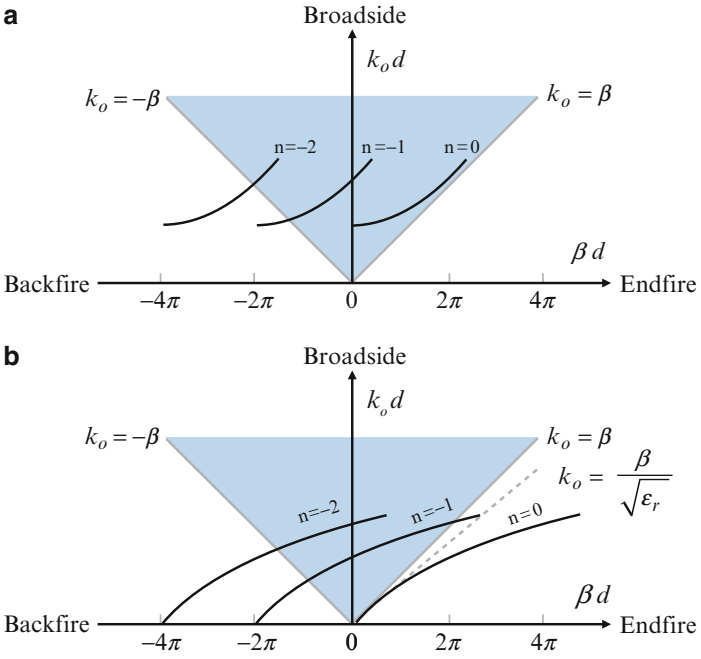

Fig. 7 Dispersion diagrams of periodic leaky-wave antennas based on (**a**) single-conductor waveguide and (**b**) multiconductor combline structure

negligibly small (Fig. 7). Furthermore, plotting only the first few spatial harmonics near $n = 0$ is sufficient to understand the basic properties of the periodic leaky-wave antennas. In the first case, the fundamental mode will appear above the cutoff frequency of the waveguide and asymptotically approach the airline. All other space harmonics have the same dispersion curve but are shifted by $\pm 2\pi$ along the βd axis. Figure 7 shows first three $n \leq 0$ space harmonics that lie within the fast-wave region. For the combed microstrip line structure, the $n = 0$ mode starts at DC ($k_o d = 0$) and then becomes a slow wave as the frequency is increased. Since the fundamental mode never enters the fast-wave region, $n < 0$ modes are used for radiation.

For both structures shown in Fig. 6, additional design schemes are needed if single beam scanning from backfire to endfire direction is desired. For the combline structure, a simple method is to use high dielectric constant material and limit the periodicity to less than $\lambda_o/2$ (Jackson and Oliner 2008). Sketch of the modified dispersion diagram of high dielectric-loaded combline leaky-wave antenna is shown in Fig. 8. Within the highlighted operating bandwidth, single spatial harmonic ($n = -1$) scans the beam from backfire toward endfire directions. For different waveguide technologies, alternate options including the phase-reversal technique (which will be discussed in section "Phase-Reversal Technique") are also available to ensure single-mode radiation.

DOI 10.1007/978-981-4560-75-7_60-1

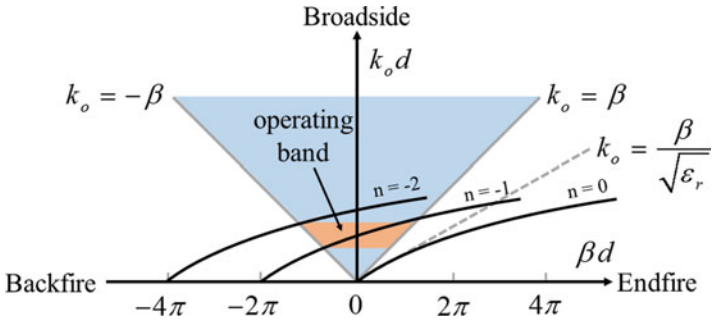

Fig. 8 Dispersion diagram of a periodic leaky-wave antenna based on the combline structure with high dielectric loading

The simplified dispersion curves shown above serve well in illustrating the basic radiating characteristics for periodic-type leaky-wave antennas. However, to be more precise, the partial reflections at each periodic discontinuity cannot be completely disregarded, especially at frequencies where each reflected wave all superimposes constructively creating a stopband region within the desired operational bandwidth. For full-frequency-scanning antennas, the stopband that occurs near $\beta = 0$ point has negative effect on the radiated gain stability. At this point, the traveling waves become a standing wave and excite all the loading elements simultaneously. As an example, consider the periodic combline structure in Fig. 6b operating at the broadside direction. All the stubs are excited in phase with $\beta_{-1} = 0$, and the admittance of individual loading add together, resulting in a short-circuit condition at the location of each stub. The field within the unit cell between adjacent stubs becomes a perfect standing wave instead of a traveling wave. From a practical implementation perspective, the antenna becomes difficult to match since the input impedance would be equivalent to a short circuit, resulting in complete reflection (Jackson and Oliner 2008; Caloz et al. 2011). Therefore, bandgap circumventing techniques such as integrating matching networks between the unit cells (which will be discussed in section "Stopband Countering Technique Near the Transition Frequency") are required to minimize the undesired stopband near $\beta = 0$ point.

Metamaterial (Quasi-uniform) Structure

Recent introduction of metamaterial concepts in the microwave field has revitalized leaky-wave antenna research (Liu et al. 2000; Grbic and Eleftheriades 2002; Lai et al. 2004; Caloz and Itoh 2005; Eleftheriades and Balmain 2006; Engheta and Ziolkowski 2006). Metamaterial based leaky-wave antennas are considered quasi-uniform because the periodicity is substantially smaller than the guided wavelength ($d \ll \lambda_g$), which macroscopically behaves as a uniform homogeneous structure. These antennas can perform frequency scanning from backfire to endfire including broadside direction while operating in the fundamental mode. One of the important achievements in the development of metamaterial-based leaky-wave antenna is the systematic design approach based on equivalent circuit models (Caloz and Itoh 2005). In addition to the dispersion diagrams, circuit analysis provides a very straightforward design procedure in obtaining initial geometrical parameters of the antennas. Samples of metamaterial-based leaky-wave antennas are shown in Fig. 9. Since planar structures have an easier fabrication process and a lower form factor profile, the substrate integrated waveguide (SIW)-based metamaterial leaky-wave antenna is chosen for the first example. SIW is a rectangular waveguide integrated inside the dielectric substrate with closely spaced vias forming the effective side metallic walls (Hirokawa and Ando 1998; Wu et al. 2003; Bozzi et al. 2011). Similar to the uniform and periodic type of rectangular waveguide leaky-wave antenna, SIW metamaterial leaky-wave antennas operate in the fundamental TE_{10} mode (Dong and Itoh 2011). A composite right/left-handed (CRLH) transmission-line (TL)-based leaky-wave antenna shown in Fig. 9b is one of the first microwave metamaterial structures developed in the early 2000s.

DOI 10.1007/978-981-4560-75-7_60-1

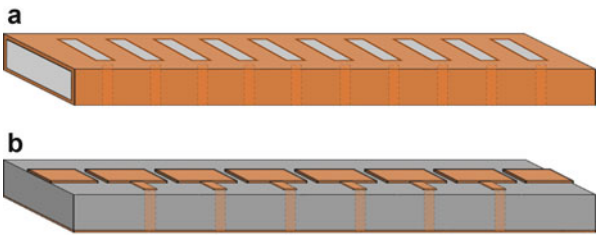

Fig. 9 Sketch of metamaterial leaky-wave antennas based on (**a**) substrate integrated waveguide and (**b**) multiconductor transmission line structure

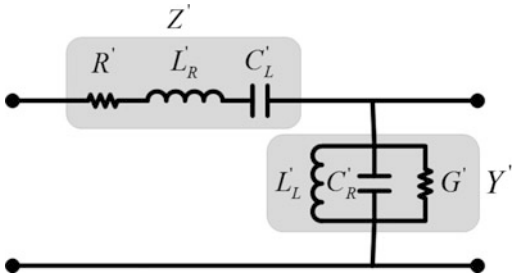

Fig. 10 Metamaterial leaky-wave antenna unit cell

The unit cell of a CRLH metamaterial structure is comprised of both conventional right-handed (series inductance L_R and shunt capacitance C_R) reactive elements and their dual left-handed (series capacitance C_L and shunt L_L) counterparts (Fig. 10). Per-unit-length series impedance and shunt admittance including dissipation and radiation losses are denoted with the constituent unit elements as follows:

$$Z' = R' + j\omega L'_R - j\frac{1}{\omega C'_L}, \tag{16a}$$

$$Y' = G' + j\omega C'_R - j\frac{1}{\omega L'_L}. \tag{16b}$$

The complex propagation constant and characteristic impedance can be obtained from the generalized telegrapher's equations as

$$k'_z = \sqrt{Z'Y'}, \tag{17a}$$

$$Z'_c = \sqrt{\frac{Z'}{Y'}}, \tag{17b}$$

respectively. The dispersion diagram of CRLH structures is bounded by low-frequency and high-frequency stopbands, and typically an interband bandgap is also generated between the series and shunt resonant frequencies. $(k_o d)_{se}$ and $(k_o d)_{sh}$ related to the series and shunt resonant frequencies, respectively, are defined as

DOI 10.1007/978-981-4560-75-7_60-1

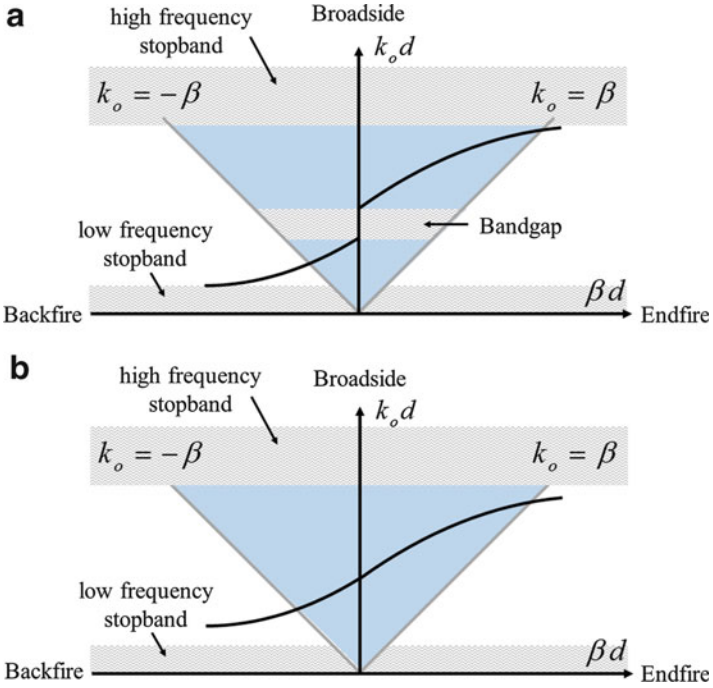

Fig. 11 Dispersion diagrams of metamaterial leaky-wave antenna under the (**a**) unbalanced and (**b**) balanced condition

$$(k_o d)_{se} = \frac{d}{c\sqrt{L'_R C'_L}}, \tag{18a}$$

$$(k_o d)_{sh} = \frac{d}{c\sqrt{L'_L C'_R}}, \tag{18b}$$

where c is the speed of light. Under the balanced condition where the following condition is satisfied:

$$(k_o d)_{se} = (k_o d)_{sh}, \tag{19}$$

a continuous dispersion curve can be obtained, eliminating an undesired bandgap near the transition frequency (Fig. 11). Therefore, a constant gain can be maintained when the scanning beam approaches broadside direction. Also, the characteristic impedance of the periodic structure becomes independent of frequency:

$$Z_c = \sqrt{\frac{L'_R}{C'_R}} = \sqrt{\frac{L'_L}{C'_L}}. \tag{20}$$

This enables a more relaxed antenna feed matching requirement and supports efficient frequency scanning over the entire spatial angle.

Design Techniques

The frequency-scanning property of leaky-wave antennas is a unique and attractive feature. However, additional radiation properties such as gain, side lobe level, polarization, etc., should also be carefully

DOI 10.1007/978-981-4560-75-7_60-1

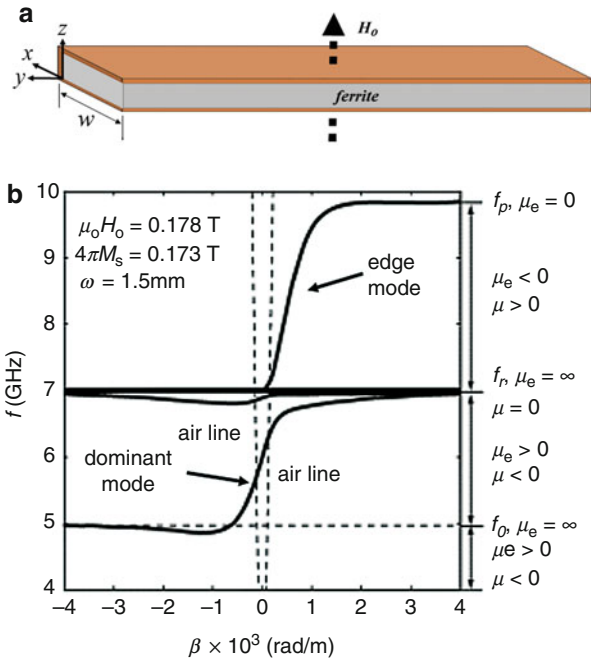

Fig. 12 (**a**) Sketch of a uniform ferrite-loaded leaky-wave antenna and (**b**) its dispersion diagram (Kodera and Caloz 2009, © IEEE)

examined when designing practical antennas. In this section, design examples are collected to highlight novel techniques in controlling and improving the radiated properties of leaky-wave antennas.

Ferrite-Loaded Leaky-Wave Antenna

A drawback of the uniform type of leaky-wave antennas is the limited beam-scanning range. As discussed in section "Uniform Structure," single-conductor-based leaky-wave antennas generally steer the beam toward the endfire direction. However, if the uniform type of leaky-wave antenna is filled with ferrite material and externally biased by a DC magnetic field, full scanning capability from backfire to endfire can be achieved (Baccarelli et al. 1997). A simplified sketch of the ferrite-loaded open waveguide leaky-wave antenna with the magnetic biasing field (H_o) and the corresponding dispersion diagram of the first two modes are shown in Fig. 12. A similar structure was originally developed as a magnetic isolator (Araki et al. 1975). However, it operated as an edge-mode located inside the slow-wave region to prevent radiation (Fig. 12b). If the structure is operated in the lower frequency band, the structure radiates with the dispersion characteristics that resemble that of CRLH leaky-wave antennas (Kodera and Caloz 2009). This fundamental mode provides full-frequency scanning from backward to endfire direction without the bandgap at the transition frequency ($\beta = 0$). The dispersion relation that takes the form of the transcendental equation can be derived using the transverse resonance technique (Baccarelli et al. 1997; Kodera and Caloz 2009).

Phase-Reversal Technique

Periodic leaky-wave antennas normally suffer from multiple spatial harmonic radiations. For example, in Fig. 7a, full-frequency-scanning bandwidth of any radiating mode will always be shared by one or more leaky space harmonics. Phase-reversal technique can be applied to generate a single radiated beam that can scan the entire backfire-to-endfire spatial angle. In this technique, an additional π phase shift per period is provided through structural modifications resulting in an effective phase delay per cell of $\beta_o d + \pi$ instead of $\beta_o d$ (Hessel 1969). The technique was originally utilized for broadside radiating arrays to

DOI 10.1007/978-981-4560-75-7_60-1

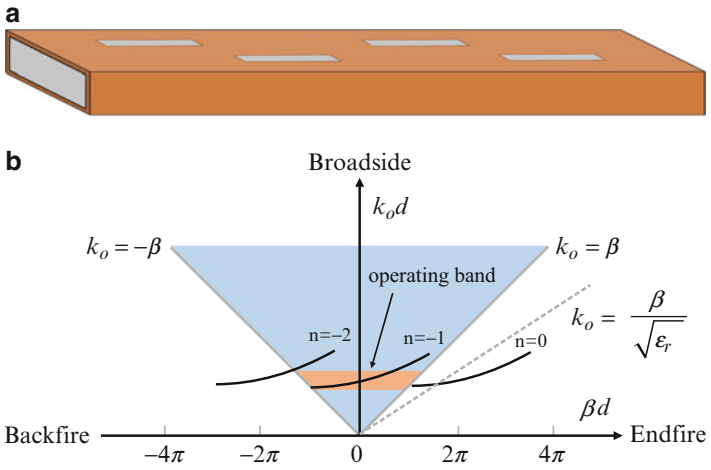

Fig. 13 (**a**) Sketch of a single-conductor periodic leaky-wave antennas with phase-reversal technique and (**b**) corresponding dispersion diagram

suppress the grating lobes without using high dielectric materials or structurally complex corrugated lines (Silver 1949). But the same concept is also adapted in leaky-wave antenna design to ensure single-mode radiation. A waveguide-based phase-reversal leaky-wave antenna is shown in Fig. 13a, where multimode radiation is suppressed by shifting the dispersion curves along the βd-axis, thereby pushing $n = 0$ mode outside the $n = -1$ radiation band (Fig. 13b). Examples of phase-reversal leaky-wave antennas applied in different structural forms including waveguide and planar structures can also be found in Hessel (1969) and Yang et al. (2009).

Stopband Countering Technique Near the Transition Frequency

Another downside of periodic-type leaky-wave antennas is the difficulty in providing efficient radiation toward the broadside direction (Caloz et al. 2011; Burghignoli et al. 2006; Jackson et al. 2012). Figure 14 shows a conventional planar combline leaky-wave antenna. Without any treatment for the transition frequency ($\beta = 0$), the radiated gain drops drastically as the beam approaches broadside direction (Fig. 14b). A simple yet effective approach in countering the stopband at the broadside direction is by incorporating impedance transforming networks composed of a delay line and a quarter-wave transformers or a matching stub between the junctions of unit cells (Paulotto et al. 2009). These internal matching networks minimize the abrupt impedance discontinuities between the unit cells in periodic-type leaky-wave antennas. Figure 15 shows an example of a combline leaky-wave antenna where a section of delay line of length d_1 followed by a quarter-wave transformer is inserted between the unit cells. The impedance looking into the quarter-wave transformer at each unit cell can be matched to the port impedance of Z_o if the delay line length is adjusted so that the impedance looking into the delay line is real-valued and the transformer impedance is designed to

$$Z_{\text{in}_{\lambda/4}} = \sqrt{Z_o \cdot Z_{\text{in}_{\text{delay\_line}}}}. \tag{21}$$

Sinusoidally Modulated Reactance Surface-Based Leaky-Wave Antenna

In section "Periodic Structure," periodic-type leaky-wave antennas are explained using grating-like structures. However, space harmonic generation and corresponding dispersion behavior can also be obtained by periodically modulating the impedance surface. The advantage of this technique is the independent control of the leakage and phase constants along the surface, thereby providing better design

DOI 10.1007/978-981-4560-75-7_60-1

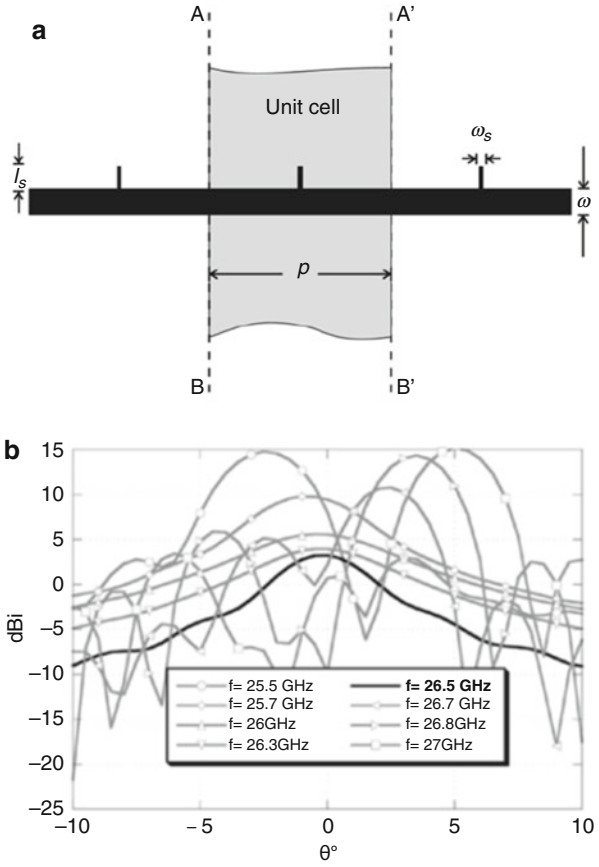

Fig. 14 (**a**) 1-D microstrip combline leaky-wave antenna and (**b**) simulated gain patterns near broadside direction for various operating frequencies (Paulotto et al. 2009, © IEEE)

control of the radiated beamwidth, side lobe level, and scan angle (Patel and Grbic 2011). Theoretical investigation of sinusoidally modulated reactance surface (SMRS) was first reported by A. Oliner in 1959 (Oliner and Hessel 1959). SMRS can be designed to take the following form (Oliner and Hessel 1959; Patel and Grbic 2007, 2011):

$$\eta_{\text{surf}}(z) = j\eta_o X' \left[1 + M\cos\left(\frac{2\pi z}{a}\right)\right], \tag{22}$$

where X' is the average surface reactance normalized by the free-space wave impedance ($X' = X/\eta_o$), M is modulation factor, z is wave propagation direction, and a is periodicity of the sinusoid. Based on this concept, printed leaky-wave antenna is realized by etching metallic strips separated by varying gaps on the top surface of a back-metallized dielectric substrate (Fig. 16). The proposed antenna is designed to radiate via the $n = -1$ space harmonic (Patel and Grbic 2007, 2011). In addition to frequency-scanning capability, this antenna can also be systematically designed to direct a particular frequency beam to a desired elevation angle:

$$\theta_{n=-1} \approx \sin^{-1}\left(\sqrt{1 + X'^2} - \frac{2\pi}{k_o a}\right). \tag{23}$$

DOI 10.1007/978-981-4560-75-7_60-1

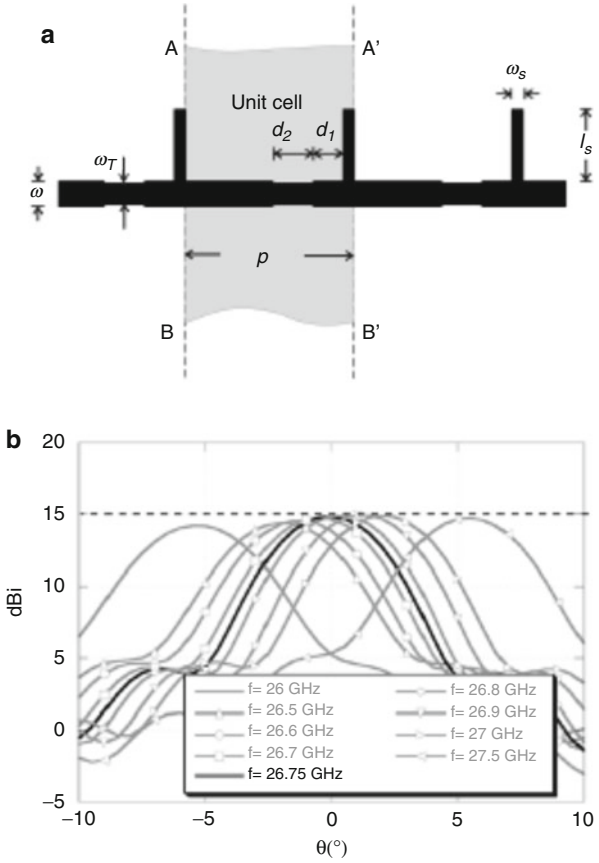

Fig. 15 (**a**) 1-D microstrip combline leaky-wave antenna with matching circuits and (**b**) simulated gain patterns near broadside direction for various operating frequencies (Paulotto et al. 2009, © IEEE)

Fig. 16 Photograph of a 1-D leaky-wave antenna based on sinusoidally modulated reactance surface (Patel and Grbic 2011, © IEEE)

The far-field beamwidth can be independently controlled by changing the modulation factor, which mainly alters the attenuation constant (α) (Patel and Grbic 2007).

Polarization Control

Polarization type and orientation have to be well defined and controlled to maximize the signal transfer. However, for some leaky-wave antennas such as the CRLH type shown in Fig. 9b, the radiation takes place from both interdigital capacitors and stub inductors resulting in an ambiguous polarization orientation (Liu et al. 2000). This section illustrates design approaches that enable better control of the polarization properties. In the first example (Fig. 17), orientation of a linearly polarized field is controlled by placing two CRLH-based leaky-wave antennas side-by-side and driving the antenna with either common-mode or differential-mode excitations (Hashemi and Itoh 2010). If the common-mode excitation is applied, fields radiated by the interdigital capacitors add in phase, whereas the fields radiated by the subinductors add destructively in the far-field. Therefore, electrical polarization is oriented parallel to the antenna scanning plane. The effects are reversed if the coupled CRLH-based leaky-wave antennas are driven with differential feeding, radiating linearly polarized wave oriented along the cross-plane with respect to the antenna scanning plane. In both cases, measured results show the cross-pol level is maintained below 15 dB throughout the observed scan range (around $-30^\circ < \theta_o < +30^\circ$). A simple polarization-orienting mechanism can be realized by adding a rat-race coupler to the input of the antenna and switching the input excitation to either the sum or difference port of the coupler.

Several techniques have been proposed to generate circularly or elliptically polarized fields (Dong and Itoh 2012; Kitatani et al. 2012; Ishii and Fukusako 2012; Lee et al. 2014a, b). Figure 18 shows a recent example based on single radiator SIW-based circularly polarized leaky-wave antenna. This SIW CRLH leaky-wave antenna-inspired structure is a periodic type of leaky-wave antenna where each unit cell is composed of a pair of orthogonally oriented radiating slots with $\pi/2$ phase-shifting separation to generate circular polarization (Lee et al. 2014a). A broadside enhancement technique discussed in section

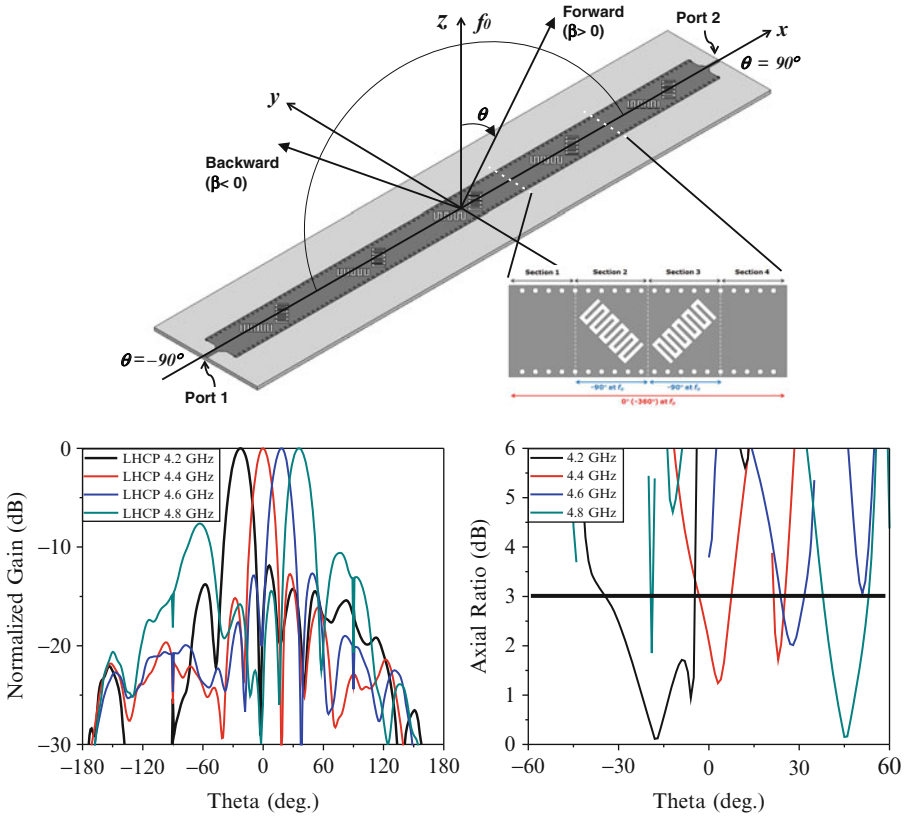

Fig. 18 (**a**) Perspective view of a single-conductor SIW-based circularly polarized leaky-wave antenna, (**b**) measured normalized radiation patterns versus frequency, and (**c**) measured axial ratio versus frequency (Lee et al. 2014a, © IEEE)

"Stopband Countering Technique Near the Transition Frequency" is also incorporated to maintain high gain value throughout the entire scanning angle (Lee et al. 2014b). The measured results for the radiated $n = -1$ space harmonic exhibit wide space angle frequency scanning without gain fluctuation while maintaining an axial ratio under 3 dB throughout the entire operating bandwidth.

Amplitude Control

Far-field radiation patterns are governed by the Fourier relation of the current amplitude distribution on the radiating aperture (Balanis 1997; Stutzman and Thiele 1998). For a given antenna size, the highest directivity is obtained when the radiating aperture is excited with uniform amplitude distribution; however, it suffers from high side lobe levels since the first side lobe is over 4 % of the peak intensity. If the side lobe level is a more critical design requirement, the aperture amplitude distribution can be properly tapered to suppress side lobes. As discussed in section "Leaky-Wave Antenna Fundamentals," leaky-wave antennas normally have exponentially decaying amplitude distribution. However, leakage distribution along the aperture can be varied through structural modifications (Whetten and Balanis 1991; Wu et al. 2009; Siragusa et al. 2012). In Whetten and Balanis (1991) far-field patterns of leaky-wave antennas with different long slot configurations are analyzed. Figure 19 shows three example configurations and their corresponding far-field radiation patterns. All three antennas are 20 λ long and 0.08 λ wide. The first antenna is a straight longitudinal slot with an offset of $x_o = 0.75\ a$, where a is the width of the waveguide. The second antenna is a sine squared curvature antenna with the meander contour of

$$x = \left[0.5 + 0.2\sin^2\left(\frac{\pi}{L}z\right)\right]a \tag{24}$$

DOI 10.1007/978-981-4560-75-7_60-1

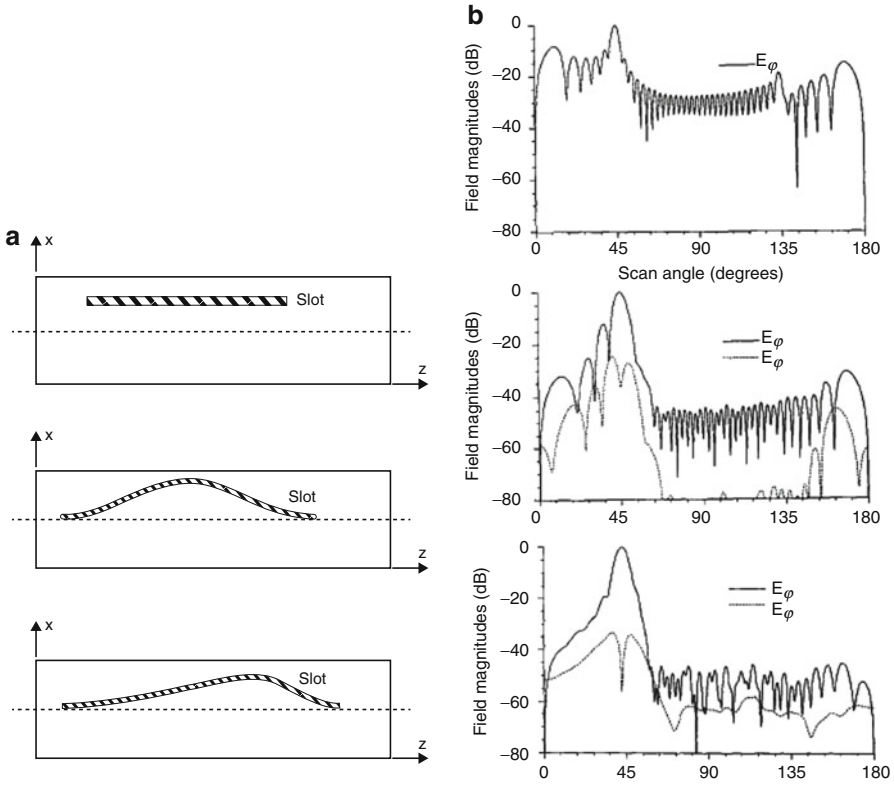

Fig. 19 (**a**) Leaky-wave long slot antennas with different meander patterns and (**b**) corresponding radiation patterns (Whetten and Balanis 1991, © IEEE)

The third antenna is contoured to compensate the exponentially decaying field distribution so that the radiated power has sinusoidal distribution. The antenna with sine squared curvature (second configuration) produces side lobe levels that are lower compared to that of the straight line case. In the last configuration, the side lobes are further reduced where all side lobe levels except for a small shoulder on the main beam are suppressed below 40 dB.

Multiband Leaky-Wave Antennas

Metamaterial-based leaky-wave antennas for multiband applications have been recently proposed and analyzed in Rennings et al. (2006) and Eleftheriades (2007). Figure 20a shows the equivalent circuit model of a unit cell for generalized negative-refractive-index transmission line (also known as extended composite right/left-handed transmission line) that supports dual-band operation. In a lossless symmetric T-model, the propagation constant is

$$\beta d = \cos^{-1}(1 + Z_h Y_v) \tag{25}$$

where Z_h and Y_v are series impedance and shunt admittance, respectively. To close the undesired bandgap at the transition frequencies and obtain continuous beam scanning in both bands, the following condition has to be satisfied (Eleftheriades 2007):

$$L_{hs} C_{hp} = L_{vs} C_{vp}. \tag{26}$$

The dual-band balanced dispersion diagram is shown in Fig. 20b. The Bloch impedance can be approximated to

DOI 10.1007/978-981-4560-75-7_60-1

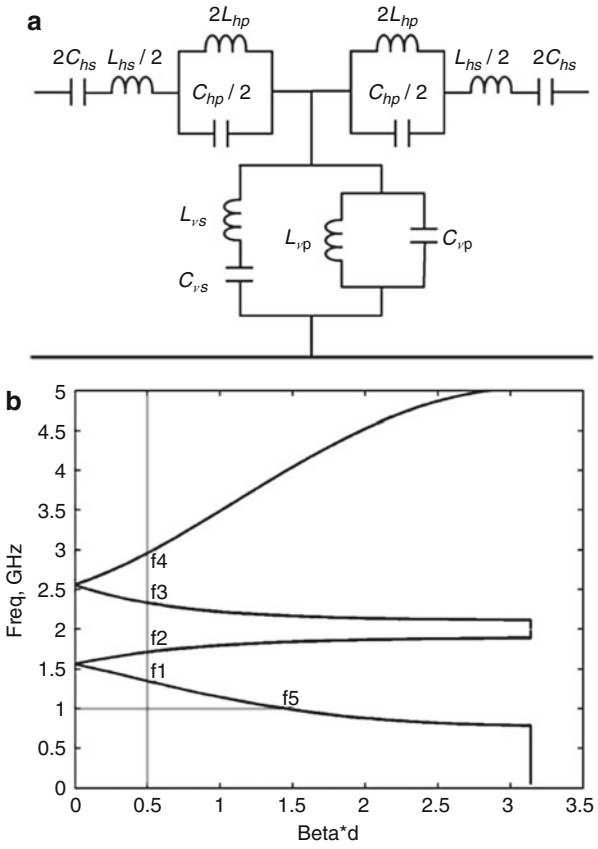

Fig. 20 (**a**) Circuit diagram of an NRI-TL unit cell and (**b**) corresponding dual-band dispersion diagram (Eleftheriades 2007, © IEEE)

$$Z_B \approx \sqrt{\frac{2Z_s}{Y_p}} \tag{27}$$

if the unit-cell dimension is electrically small ($\beta d \ll 1$). Based on the above concept, dual-band leaky-wave antennas have been realized in planar and SIW forms (Ryan and Eleftheriades 2010; Machac and Polivka 2012; Duran-Sindreu et al. 2013). Figure 21 shows an SIW-based dual-band leaky-wave antenna. This antenna provides continuous frequency scanning in the two operating bands, 3.5–4.2 GHz and 5.164–5.6 GHz (Duran-Sindreu et al. 2013).

Power Recycling

Leaky-wave antennas are generally designed to radiate about 90 % of the energy by the time waves reach the opposite end of the antenna structure. To obtain this high level of efficiency, leaky-wave antennas are usually elongated to around 8–10 λ_o. But antennas with such large electrical dimension may be problematic for applications with size constraints. To maintain high efficiency of leaky-wave antennas in a more compact size, unradiated energy of the traveling wave can be recycled and fed back to the antenna through a power combining rat-race coupler as shown in (Fig. 22) (Nguyen et al. 2010). The coupler is designed to constructively add the recycled power (port 3) to the input signal of the system (port 1) through the sum port (port 4). For a lossless system where dielectric and metallic losses are assumed to be zero, the radiated efficiency (η_s) can reach 100 % if the scattering matrix of the power recycling system becomes unitary. Given the scattering matrix of the rat-race coupler

DOI 10.1007/978-981-4560-75-7_60-1

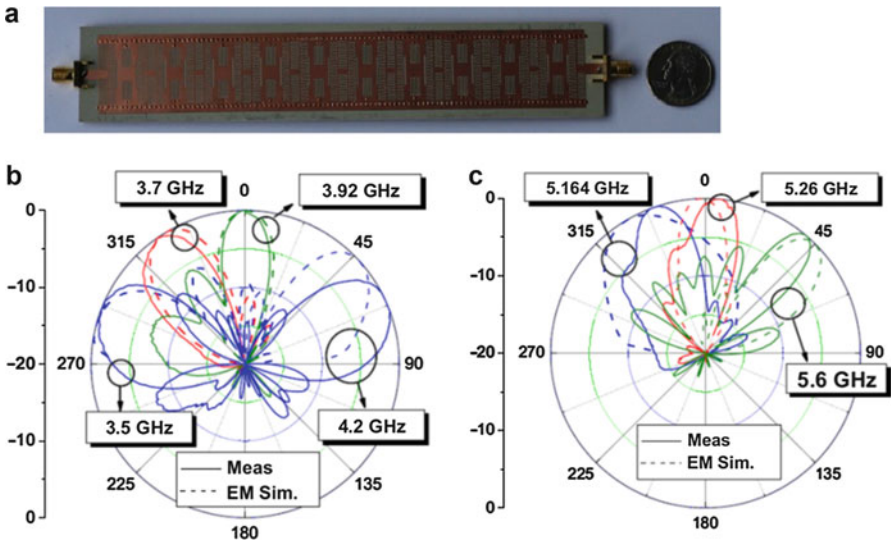

Fig. 21 (**a**) Photograph of a fabricated SIW metamaterial based dual-band leaky-wave antenna, (**b**) normalized simulated and measured radiation patterns for the lower radiation bands, and (**c**) normalized simulated and measured radiation patterns for the upper radiation bands (Duran-Sindreu et al. 2013, © IEEE)

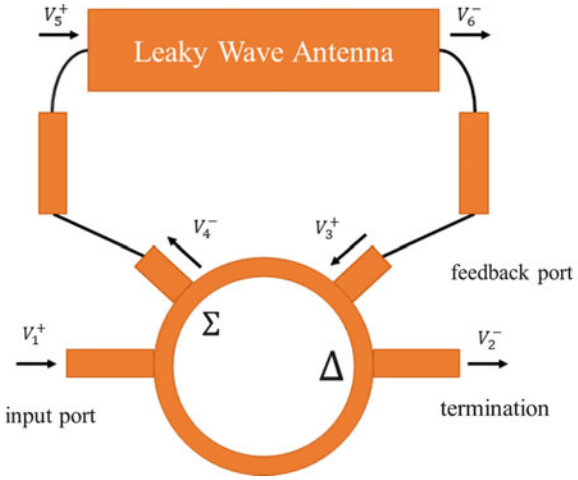

Fig. 22 Sketch of a power recycling leaky-wave antenna using rat-race coupler

$$\begin{bmatrix} V_1^- \\ V_2^- \\ V_3^- \\ V_4^- \end{bmatrix} = \begin{bmatrix} 0 & ja & 0 & -jb \\ ja & 0 & -jb & 0 \\ 0 & -jb & 0 & -ja \\ -jb & 0 & -ja & 0 \end{bmatrix} \begin{bmatrix} V_1^+ \\ V_2^+ \\ V_3^+ \\ V_4^+ \end{bmatrix}, \tag{28}$$

the required conditions to achieve system efficiency of 100 % for the power recycled leaky-wave antenna are as follows:

$$a = \sqrt{1 - \eta_0} \tag{29a}$$

DOI 10.1007/978-981-4560-75-7_60-1

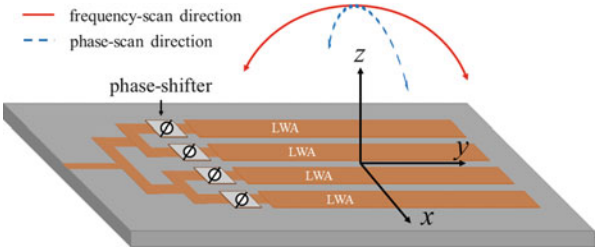

Fig. 23 Sketch of a 2-D leaky-wave antenna in an array arrangement

$$b = \sqrt{\eta_0} \tag{29b}$$

$$\theta = -\frac{\phi}{2} + \frac{3\pi}{4} + m\pi,\ m \in N, \tag{29c}$$

where η_o is the radiated efficiency of isolated leaky-wave antenna without the feedback circuit, θ is the electrical length of the delay lines connecting the rat-race coupler to the leaky-wave antenna, and ϕ is the total phase shift across the antenna. Experimental results for power recycled leaky-wave antenna with $\eta_o = 38$ % accounting all the mismatch and absorptive losses show the system radiated efficiency enhancement by a factor of 1.8 (Nguyen et al. 2010).

Two-Dimensional Leaky-Wave Antennas

In 1-D leaky-wave antennas, radiated directivity along the scanning plane can be simply controlled by varying the aperture length of the antenna. But since the transverse dimension (width) of the antenna is usually narrow and fixed, 1-D leaky-wave antennas produce a fan-beam radiation pattern with narrow beamwidth along the beam-scanning plane but wide beamwidth along its cross-plane. Therefore, 1-D leaky-wave antennas have poor spatial resolution in the plane orthogonal to the scanning plane. For applications requiring high spatial resolution in both dimensions, a pencil beam pattern can be obtained by placing 1-D leaky-wave antennas in an array arrangement (Fig. 23). If phase shifters are added at the input of each leaky-wave antenna, a fixed-frequency beam can be scanned in Z-X plane in addition to the frequency scanning along Z-Y plane (Oliner and Jackson 2007).

When an all passive 2-D periodic structure is operated as a leaky-wave antenna, a unique frequency-scanning conical beam pattern can be generated. An example of 2-D leaky-wave antenna based on the mushroom structure (Sievenpiper et al. 1999) is shown in Fig. 24 (Allen et al. 2004). If the 2-D periodic mushroom structure is fed at the center, radially propagating waves produce a frequency-scanning conical beam pattern with a radiation null at the broadside direction. This null in the pattern is due to destructive interferences of the far-fields generated by radially traveling waves in a 2-D symmetric structure.

Applications

Several interesting applications and devices exploiting the frequency-scanning capability of leaky-wave antennas can be found in Shelley et al. (1991), Tospann et al. (1995), Sato et al. (2007), and Menzel and Moebius (2012). This section presents sample of systems and applications that may benefit from this unique beam-scanning property. Examples of leaky-wave antenna systems that are covered in this section include automotive radar sensor and direction-of-arrival systems. Various fixed-frequency beam-scanning antennas based on the leaky-wave antenna are also presented. In comparison to fixed-frequency beam-scanning phased-array systems that rely on a large number of antenna elements, complex feed network,

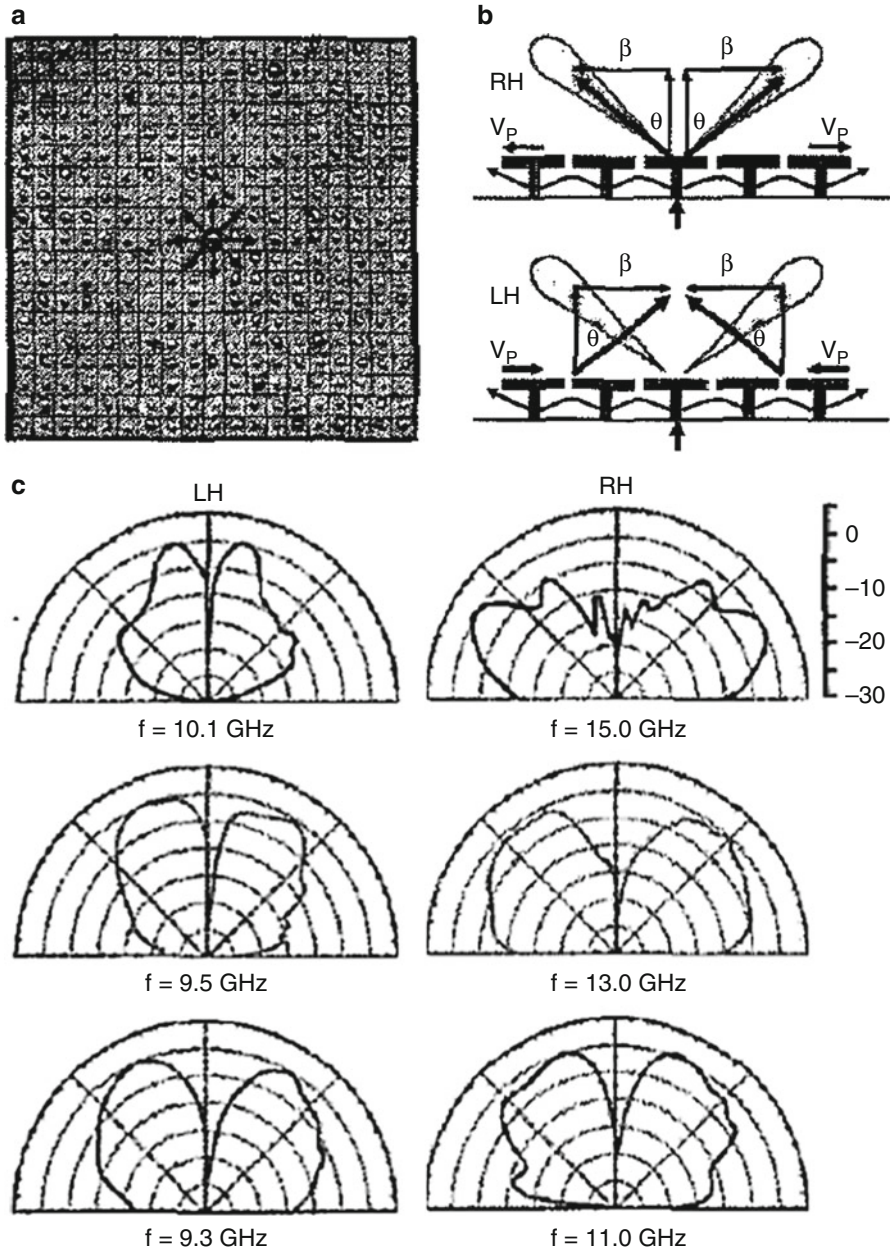

Fig. 24 (**a**) *Top* view of a 2-D leaky-wave antenna based on periodic mushroom structure, (**b**) side view of the antenna illustrating the RH and LH radiation, (**c**) radiation patterns for different operating frequencies (Allen et al. 2004, © IEEE)

and costly/bulky phase shifters, leaky-wave antennas provide an attractive alternative design solution using single radiating element and low-cost tuning schemes without a complex feed network.

Leaky-Wave Antenna-Based Radar Sensor

Beam-scanning leaky-wave antennas spread the radiated beams to different spatial angles with respect to the frequency. However, for single-frequency or narrowband operation, highly directive fixed-frequency beam-scanning antennas can also be realized using leaky-wave antennas. In 2009, Continental ADC commercialized a radar sensor based on a leaky-wave antenna for automobile applications. Beam scanning is achieved by placing a dielectric waveguide close to a rotating drum with periodic metallic ridges (Menzel and Moebius 2012). The wave traveling inside the dielectric waveguide encounters

DOI 10.1007/978-981-4560-75-7_60-1

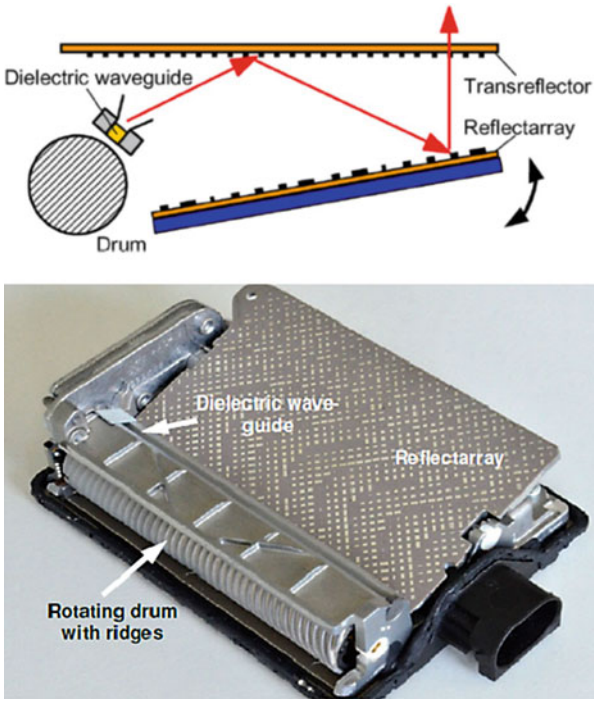

Fig. 25 (**a**) Sketch of ARS300 antenna, (**b**) photograph of ARS300 antenna with the cover removed (Menzel and Moebius 2012, © IEEE)

periodic perturbations from the ridges, leading to leaky radiation. The periodicity of the metallic ridges is varied by rotating the drum, thereby scanning the radiated beam along the azimuth direction (Manasson et al. 1996). Narrow beamwidth along the elevation angles is obtained by adjusting the phase angles of the reflectarray. The elevation angle of the final radiated beam leaving the radar sensor can also be adjusted by mechanically controlling the reflectarray angle. In this design, the transreflector not only serves as a polarizer to direct the radiated waves from the dielectric waveguide to the reflectarray but also works as a transparent cover to the waves leaving and entering the sensor. The sketch of the sensor and a photograph of the actual sensor with the cover removed are also shown in Fig. 25.

Phase-Shifter Less Electronically or Magnetically Scanning Leaky-Wave Antennas

In the previous section, single-frequency beam scanning is achieved through mechanical actuation. An alternate nonmechanical solution to generate fixed-frequency beam-scanning patterns can be realized using either electrically or magnetically controlled leaky-wave antennas (Baccarelli et al. 1997; Huang et al. 2000; Lim et al. 2004; Sato et al. 2006; Kodera and Caloz 2009; Ueda et al. 2012). In comparison to the conventional phased arrays, these techniques do not require bulky and costly voltage-controlled phase shifters to obtain fixed-frequency beam scanning. In the first example (Fig. 26), varactors are added in each unit cell to electrically tune series-capacitance and shunt-inductance values (Lim et al. 2004). An ideal electrically controlled leaky-wave antenna can shift the dispersion curve along the frequency axis by varying applied reverse bias voltages of the varactors. As a result, the propagation constant at a fixed operating frequency becomes a function of applied DC bias voltage, $\beta(V)|_{\omega o}$. Measured beam patterns of a 30-unit-cell electronically controlled leaky-wave antenna operating at 3.33 GHz with various biasing voltages ($V = 1.5$–18 V) are shown in Fig. 26.

A second example of a fixed-frequency beam-scanning antenna is realized by varying the external magnetic field of a ferrite-loaded asymmetrical CRLH antenna. The antenna is composed of a finite length CRLH TL terminated at both ends with either a short or open circuit. Once the energy is coupled to the

DOI 10.1007/978-981-4560-75-7_60-1

antenna, the wave travels down the waveguide and returns after reflecting back from the boundary. When an external magnetic field is applied perpendicular to the ground plane of a ferrite slab, field displacement occurs where the RF energy tends to be concentrated at one side of the transmission line (Hines 1971; Tsutsumi and Ueda 2004; Ueda et al. 2009). Therefore, nonreciprocal phase shift can be obtained by asymmetrical reactive loading. In (Ueda et al. 2012), CRLH structure is periodically loaded to one side of the transmission line and designed so that the propagation constant value has the same magnitude but opposite sign with respect to the case without the loading. Therefore, the radiated beams caused by the wave traveling in opposite directions will add in phase in the far-field. Without the external magnetic field, the ferrite material will behave as dielectric material and the radiated beam points to the broadside. But the dispersion diagram can be shifted along the βd-axis, depending on the magnitude and direction of the externally applied magnetic field as shown in Fig. 27b. The antenna was designed at around 6 GHz to

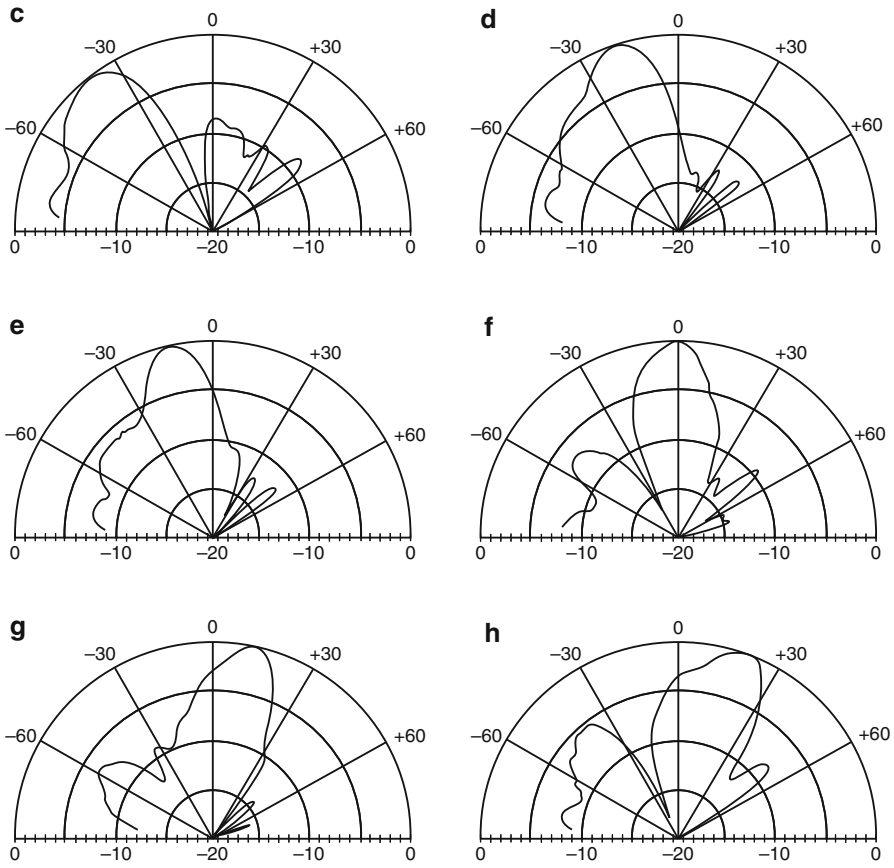

Fig. 26 (**a**) Photograph of an electronically controlled CRLH leaky-wave antenna, (**b**) ideal dispersion diagram illustrating the vertical dispersion shifting concept and measured normalized radiation patterns for various reverse biased voltages: V = (**c**) 18, (**d**) 10, (**e**) 8, (**f**) 3.5, (**g**) 2, and (**h**) 1.5 V (Lim et al. 2004, © IEEE)

avoid large magnetic loss below 4.5 GHz. The realized antenna demonstrated continuous backfire-to-endfire beam steering with more than 40° with almost constant 5 dBi gain.

Direction-of-Arrival Estimation Using Leaky-Wave Antenna

A simple direction-of-arrival (DoA) estimating system can be designed when an electronically scanning leaky-wave antenna is operated in the receiving mode. Although full-range ($-90^\circ \leq \theta_i \leq +90^\circ$) estimation can ideally be achieved using only one power meter attached to either end of the antenna, power detectors are attached at each end of the antenna in Abielmona et al. (2011) to relax the required dynamic range of the varactors. In this scheme, DoA is estimated by measuring the difference of power at the two detectors. Full-range estimation can be obtained by operating the system in either V_F-only mode or V_B-only mode, as illustrated in Fig. 28b. When the angle of the incident wave (θ_i) is aligned to the scan angle (θ_p) of the leaky-wave antenna, the received power at one of the detectors reaches a maximum value. θ_p is varied by changing the applied reverse biasing voltage of the varactors. A leaky-wave antenna-based DoA estimator provides an alternative cost-effective solution in a planar and compact form.

Terahertz Leaky-Wave Antenna

Terahertz (THz) frequencies accommodate larger communication bandwidth and provide high spatial resolution in comparison to microwave frequencies. Since the band is located just below the infrared

DOI 10.1007/978-981-4560-75-7_60-1

band, the nonionizing property is also less harmful to human tissues especially for medical imaging or security scanning applications. Despite these attractive features, realization of practical devices such as THz transceivers and sensors has been partially hampered by the antennas. Recently, leaky-wave antennas have been considered as a candidate for THz applications since directive beam patterns can be obtained in a relatively simple and compact form without a complex feed network. But designing THz antenna systems is nontrivial due to high material loss and difficulty of scaling solid-state electronic devices. In

this section, recent achievements of THz leaky-wave antennas that utilize clever techniques that overcome the previously mentioned challenges are highlighted.

The first example shown in Fig. 29 is a leaky-wave antenna with distributed photonic gain excited by a quantum cascade laser (QC-laser) (Tavallaee et al. 2011). The structure resembles that of Menzel's

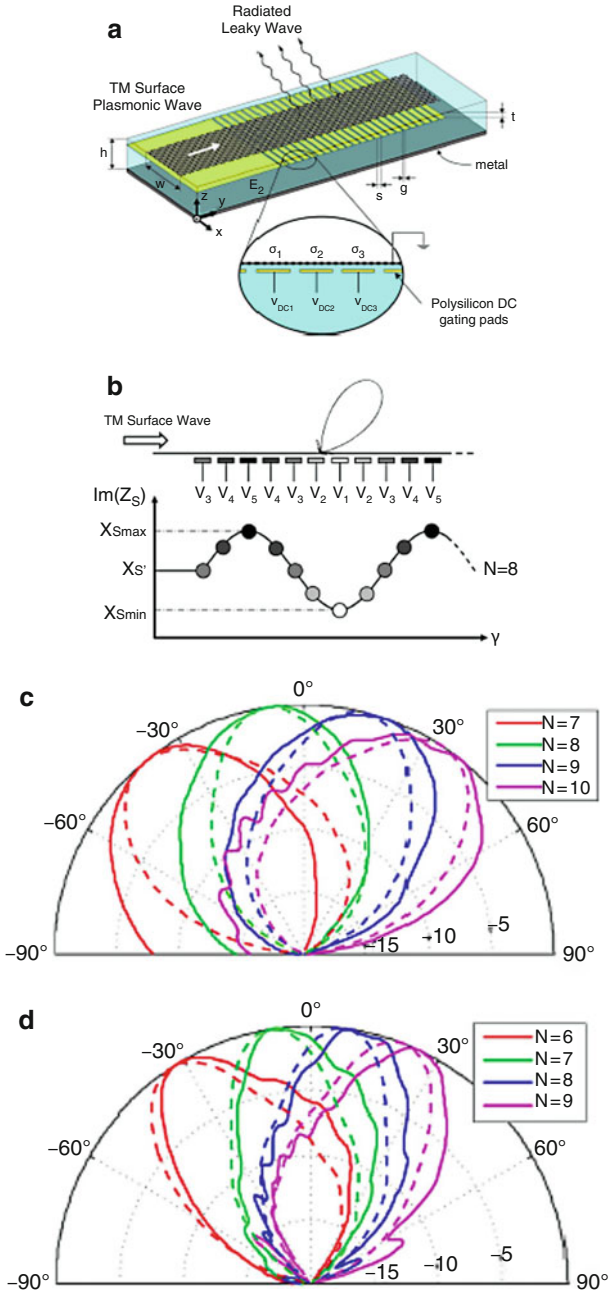

Fig. 30 (**a**) Terahertz leaky-wave antenna based on sinusoidally modulated reactance graphene surface, (**b**) sketch illustrating the relationship between the biasing DC voltage and corresponding graphene reactance profile, (**c**) radiation patterns versus N [parameters used: electron relaxation time (τ) = 1 ps, temperature (T) = 300 K, f_o = 2 THz, V_{DC} = 6.5–45 V, ε_r = 3.8, pad length (s) = 4.8 μm, gap between pads (g) = 0.2 μm], (**d**) normalized radiation patterns versus N using τ = 1 ps, T = 300 K, f_o = 2 THz, V_{DC} = 6.5–45 V, ε_r = 3.8, s = 4.8 μm, and g = 0.2 μm (Esquius-Morote et al. 2014, © IEEE)

antenna (Menzel 1979) and functions in a similar manner, where first higher-order mode is forced to radiate. GaAs/AlGaAs multiple quantum wells comprise the dielectric layer of the antenna and, when biased, provide amplification via stimulated emission of photons due to intersubband THz radiative transition. To provide independent biasing of the antenna, the antenna is proximity coupled to a metal-metal QC-laser cavity. The fabricated antenna provides directive patterns with full width at half maximum of around 15° and a frequency scanning toward endfire direction was also demonstrated around 2.7 THz.

DOI 10.1007/978-981-4560-75-7_60-1

The second example extends on the concept of a sinusoidally modulated surface described in section "Sinusoidally Modulated Reactance Surface-Based Leaky-Wave Antenna" (Oliner and Hessel 1959; Patel and Grbic 2007, 2011) to design a fixed-frequency beam-scanning leaky-wave antenna operating in the THz spectrum. The proposed antenna can be realized by transferring graphene sheet just above a set of polysilicon DC grating pads arranged on a grounded dielectric substrate (Fig. 30). The graphene sheet supports the propagation of transverse-magnetic surface plasmon polaritons, which can be manipulated by applying DC voltage to different pads that alter the complex conductivity σ (or surface impedance $1/\sigma$) of the graphene sheet (Esquius-Morote et al. 2014). In this design, one modulation period p is sampled in N points according to the number of grating pads used. For fixed pad length and distance between the pads, p can be dynamically controlled according to the periodicity imposed by the different V_{DC}. The simulated results validate fixed-frequency beam scanning at 2 THz when varying the sampling points (Fig. 30).

Summary

Beam-scanning leaky-wave antennas have been steadily improving ever since it was first introduced by W. W. Hansen in 1940 (Hansen 1940). With the addition of metamaterial concepts, novel leaky-wave antennas and unique design techniques have recently flourished in both research and industrial communities. As the general supporting technologies improve each year, leaky-wave antennas are expected to mature with improved fabrication technologies, novel realization methods, new exotic materials, etc., delivering yet more unique beam-scanning features with newer functionalities and enhanced radiation characteristics. With the ongoing advancements, leaky-wave antennas will continue to serve as a competitive design solution for applications requiring beam scanning, high directivity, and fabrication simplicity.

Abstract

In this chapter, a summary of the various components, categorization, and design process of reconfigurable antennas is presented. The various applications where reconfigurable antennas have been implemented and the association of various antenna properties with new communication applications are discussed. The chapter takes into consideration new and evolving applications and associate novel antenna designs with these applications. The control, modeling, and optimization of reconfigurable antennas are also detailed and multiple mechanisms are presented. Finally this chapter emphasizes on the development of reconfigurable antennas to service futuristic and evolving practical wireless communication applications and propose optimal solutions for more efficient and holistic designs.

Introduction

New emerging applications in wireless communications require advanced antenna systems that are able to satisfy the needs of such applications. Reconfigurable antennas appear to offer a solution that allows the integration of multiple radios into a single platform. The integration of multiple radios with reconfigurable antennas maximizes connectivity without resorting to multiple antenna components. The ability of reconfigurable antennas to change their functionality on demand allows them to dynamically cater for multiple wireless services without increasing the real estate required to accommodate multiple antennas.

Designing any antenna requires the understanding of its fundamental characteristics such as gain, impedance matching, and radiation properties. For a reconfigurable antenna, these characteristics become tight constraints, especially when an antenna designer is trying to come up with a reliable design that is predictable for every state of its reconfiguration. Reconfiguring an antenna is achieved by rearranging the antenna currents or reconfiguring its radiating edges (Bernhard 2007; Balanis 2011; Christodoulou et al. 2012; Costantine et al. 2013c). The change in the antenna functionality allows it to be used for multiple wireless communications applications.

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_61-2

An antenna design can be made reconfigurable by utilizing various reconfiguration techniques such as switches or mechanical actuators. The most widely reconfigured antenna type is the microstrip antenna, where the integration of reconfiguring components into the antenna structure becomes part of the antenna design process. Typically, a reconfigurable patch antenna consists of a number of separate metalized regions that lie on a plane and are connected together using tuning components (Costantine et al. 2013c). By dynamically controlling the state of the tuning components, the different metalized sections can be activated in a very selective way, thus altering the radiation performance of the total antenna.

In general, every reconfigurable antenna design starts with a predetermined objective that aims to satisfy the existing technical constraints. However, every antenna engineer targets a certain antenna property to reconfigure. An example of such property can be frequency of operation, radiation pattern, and/or polarization. Once this property is determined, the designer works to achieve this objective by rearranging the different antenna components correspondingly.

In this chapter, the different methods of designing reconfigurable antennas that do not resort to redundant components while maintaining an optimal performance are discussed. The applications of reconfigurable antennas in practical wireless communication applications are presented. This chapter also discusses the modeling, control, and optimization of reconfigurable antenna structures.

How to Design Reconfigurable Antennas?

The different methods adopted in the design of reconfigurable antennas are based on the reconfiguration techniques as well as the properties of each reconfiguration. Reconfigurable antennas can be assembled into various groups based on the properties of each reconfiguration (Costantine et al. 2013c). These groups are shown in Fig. 1 (Costantine et al. 2013c) and are arranged as follows:

- *Group 1: Frequency reconfigurable antennas*
  Antennas under this group can change their frequency of operation based on the user's demand. They reconfigure their operation to function in multiple frequency bands. Such antennas are widely useful in wireless communication applications that require a change in operating frequencies and to switch from one channel into another. Cognitive radio is an example application for this antenna group.
- *Group 2: Radiation pattern reconfigurable antennas*
  Antennas under this group can change their radiation pattern while maintaining a fixed frequency of operation. These antennas reshape their radiation patterns to block a signal or to allow radiation in a certain predetermined direction. Mobile antenna systems can be proposed as examples of such antenna group.
- *Group 3: Antennas with reconfigurable polarization*
  Antennas under this group can change their polarization type while maintaining their fixed frequency and radiation pattern. These antennas reshape their radiation characteristics to exhibit multiple

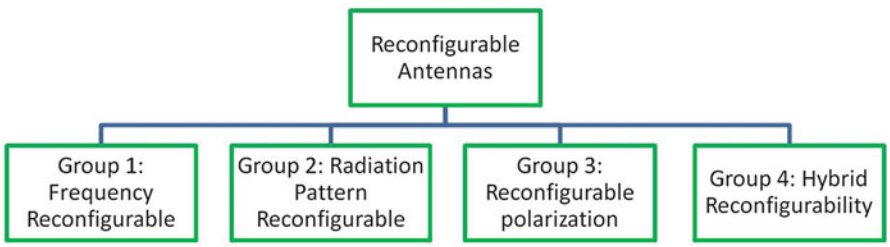

Fig. 1 Categorization of reconfigurable antennas (Costantine et al. 2013c)

DOI 10.1007/978-981-4560-75-7_61-2

polarization schemes. MIMO (multiple input multiple output) channels are application examples of such antenna group.

– *Group 4: Antennas with hybrid reconfiguration techniques*

  Antennas under this group can simultaneously change multiple characteristics in their operation. These antennas can, for example, change their operating frequency as well as their polarization scheme for each frequency of interest. They can also reshape their radiation pattern while changing their operating frequencies or polarizations.

Achieving the required reconfiguration functionality requires an appropriate selection of the reconfiguration mechanism that will achieve the desired functionality or property. A reconfiguration mechanism is selected to satisfy imposed constraints while completing the antenna design task efficiently. There are numerous reconfiguration techniques that can be incorporated into the antenna design in order to redistribute its currents. The reconfiguration techniques are also divided into multiple categories as shown in Fig. 2 (Costantine et al. 2013c; Christodoulou et al. 2012).

Electrical reconfiguration techniques are based on the use of switches to connect and disconnect antenna parts as well as to redistribute the antenna currents. Radio-frequency microelectromechanical systems (RF MEMS) have been proposed for integration into reconfigurable antennas since 1998 (Brown 1998). Many designs have resorted to RF MEMS to reconfigure their performance (Huff and Bernhard 2006; Erdil et al. 2007; Nikolaou et al. 2009; Cetiner et al. 2010; Grau et al. 2010; Yang et al. 2011; Zohur et al. 2013). RF MEMS-based reconfigurable antennas rely on the mechanical movement of these switches to achieve reconfiguration. The isolation of RF MEMS is very high, and they require minimal power consumption. The switching speed of RF MEMS is in the range of 1–200 μsec which may be considered low for some applications (Christodoulou et al. 2012).

Faster electrical reconfiguration techniques lead to PIN diodes or varactors. These types of switches are faster and more compact alternatives to RF MEMS. The switching speed of a PIN diode is in the range of 1–100 nsec (Christodoulou et al. 2012). Reconfigurable antennas resorting to PIN diodes (Chen et al. 2007; Chen and Row 2008; Kim et al. 2008; Wu and Ma 2008; Sarrazin et al. 2009; Shelley

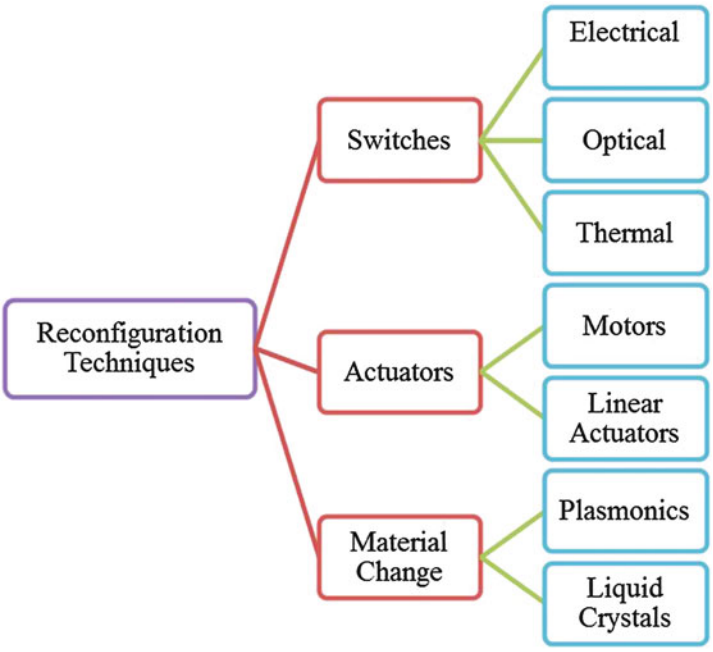

Fig. 2 Different reconfiguration techniques

DOI 10.1007/978-981-4560-75-7_61-2

et al. 2010; Perruisseau-Carrier et al. 2010; Piazza et al. 2010; Qin et al. 2010b; Quin et al 2012; Hinsz and Braaten 2014) have a more dynamic reconfiguration capability. Other reconfigurable antennas resort to the use of varactors (Daviu et al. 2007; Jeong et al. 2008; Yang et al. 2008; Jiang et al. 2009; Oh et al. 2010; Tawk et al. 2012a; Bai et al. 2013; Onodera et al. 2013; Ramadan et al. 2014) where varying the biasing voltage can result in varying the capacitance of the corresponding varactor. Such antennas enjoy a wide tuning ability that is based on integrating a variable capacitance into the antenna structure. It is important to indicate that while electrical switching components may present an efficient reconfiguration mechanism, they require an appropriate design of their biasing networks.

The integration of photoconductive switches into antenna structures allow the use of optical switching mechanisms. Photoconductive switches incorporated into an antenna structure become conductive once they are subjected to a laser beam (Tawk et al. 2010, 2012b; Jin et al. 2011; Sathi et al. 2012; Patron et al. 2014; Pendharker et al. 2014). The laser beam originates from integrated laser diodes (Tawk et al. 2012b). The integration of all these components into compact antenna structures, while taking into consideration power consumption issues, constitutes challenges of such reconfiguration techniques. Thermal switches (Jiang and Yang 2013) have also been proposed as candidates for antenna reconfiguration. Other reconfiguration techniques are based on graphene plasmonics (Perruisseau-Carrier et al. 2013), liquid crystals (Liu and Langley 2008), and mechanical reconfiguration techniques (Rodrigo et al. 2012; Liyakath et al. 2013; Mehdipour et al. 2013; Costantine et al. 2014).

As a summary, an antenna designer applies a reconfiguration technique to any antenna structure and thus transforms it into a reconfigurable antenna. The application of an appropriate reconfiguration technique allows the implementation of the corresponding antenna in a practical wireless communication application that requires an adaptive RF front-end. The cost of adding reconfigurability to the antenna behavior can be determined as a function of multiple factors (Christodoulou et al. 2012) as discussed below:

(a) Factor 1: A complexity is added to the antenna structure due to the presence of biasing networks that are required to control the state of the reconfiguration components.
(b) Factor 2: The incorporation of active components results in increased power consumption.
(c) Factor 3: Undesired effects such as generation of harmonics due to the addition of nonlinear active components.
(d) Factor 4: The speed of the reconfiguration leading to the required functionality.

Why Design Reconfigurable Antennas?

The new era of antenna design must generate antennas that are cognitive and adjust to the environment and ever-changing surrounding conditions. Also, there is a need for antennas that can overcome failures and swiftly respond to new developments. Cognitive radio, multiple input multiple output (MIMO) channels, on-body networks, satellites, and space communication platforms are all possible applications for the integration of highly versatile, reliable, and efficient reconfigurable antennas. In this section, the design of reconfigurable antennas that are proposed to service different practical wireless communication applications is discussed.

Reconfigurable Antennas for MIMO Communication Systems

A MIMO communication system is based on the need for multiple antennas that are installed at both sides of the communication channel. The purpose of such installation is to enable the communication channel to transmit and receive multiple signals at the same time. This ability increases the spectral efficiency and

DOI 10.1007/978-981-4560-75-7_61-2

capacity, thus overcoming issues such as multipath and fading. On the other hand, a large improvement over the channel capacity can be achieved by incorporating reconfigurable antennas that exhibit a reconfiguration in their radiation patterns and polarizations (Cetiner et al. 2004; Piazza et al. 2008; Li et al. 2009; Grau et al. 2010; Qin et al. 2010a; Christodoulou et al. 2012).

As an example, an antenna shown in Fig. 3 (Quin et al 2012) exhibits a reconfigurable radiation pattern. The antenna is a microstrip U-slot patch antenna that uses eight PIN diodes to achieve pattern reconfiguration. Eight shorting posts are implemented around the patch to change the operating mode of the antenna from monopolar patch mode to normal patch mode (Quin et al 2012). The two modes of operation are designed to operate in similar frequency ranges.

The proposed antenna can electrically reconfigure the radiation pattern between conical and bore-sight patterns with an overlapping impedance bandwidth. Four antenna elements with the same design concept are then employed in a 2 × 2 MIMO-OFDM prototype. The capacity results are compared with omnidirectional antennas, and channel capacity enhancements are witnessed in both line-of-sight and non-line-of-sight indoor environments (Quin et al 2012).

Another example of an antenna designed for MIMO channels is an electronically steerable passive array radiator (ESPAR). This antenna shown in Fig. 4 (Zhou et al. 2014) consists of one driven monopole in the center surrounded by a ring of six uniformly spaced (quarter wavelength spacing) parasitic monopoles. Each parasitic element is terminated with a load that consists of a 0.3 nH inductor and a PIN diode. This load is essential to provide the reactance required to either make the monopole a director when it is inductive or a reflector when it is capacitive (Zhou et al. 2014). If three adjacent passive elements were configured as directors and the remaining three as reflectors, the antenna system would be able to generate a directive beam at a chosen direction. Shifting the configuration circularly by one element each time allows ESPAR to generate six patterns with the beam angles 60° apart in azimuth. Two prototypes are fabricated and are optimized to maximize pattern flexibility.

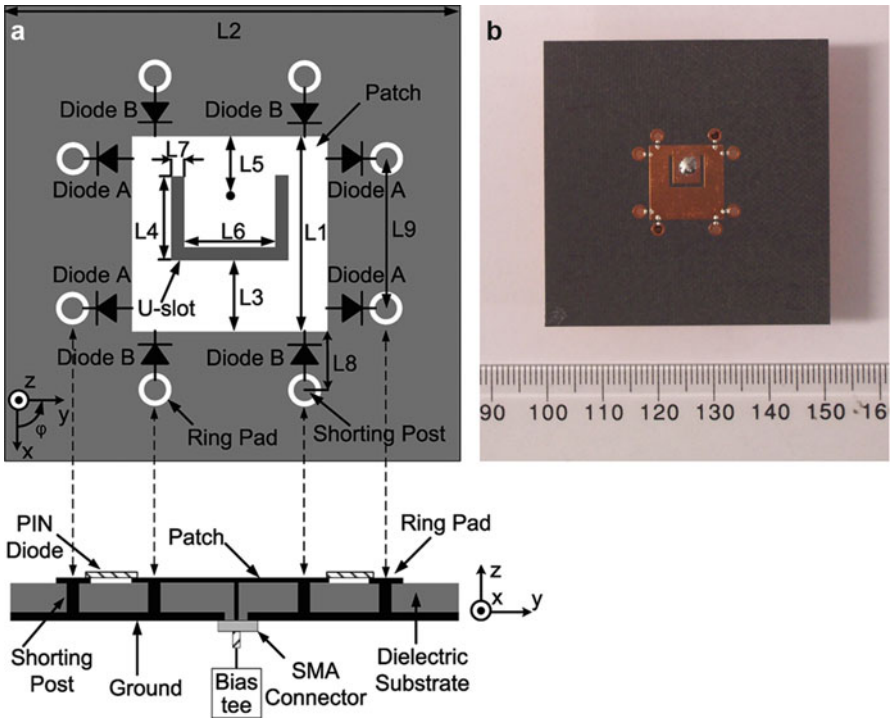

Fig. 3 Antenna with reconfigurable radiation pattern (Quin et al. 2012)

DOI 10.1007/978-981-4560-75-7_61-2

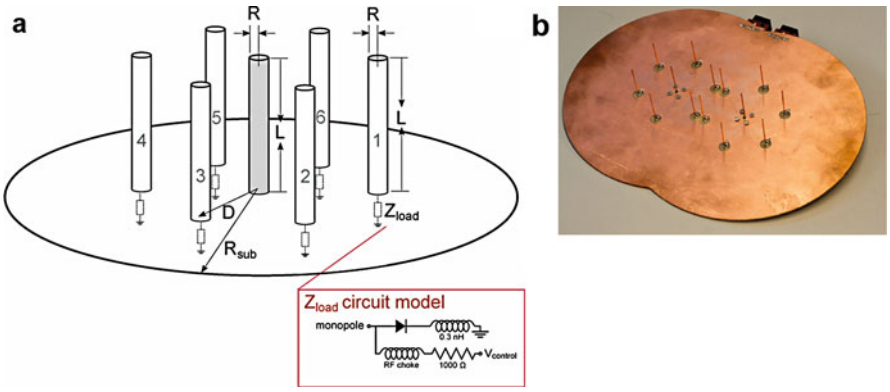

Fig. 4 Proposed and fabricated ESPAR for MIMO communications (Zhou et al. 2014)

Multiple techniques and algorithms are also discussed in literature to facilitate the reconfigurable antennas state selections allowing a smoother reconfiguration transition. For example, spatial correlation and average signal-to-noise ratio (SNR) information are utilized in Piazza et al. (2009) to select the antenna radiation pattern at the receiver. It is shown that the approach proposed (Piazza et al. 2009) achieves capacity gain in a multielement reconfigurable antenna system without changing the data frame of a conventional MIMO system (Piazza et al. 2009).

Reconfigurable Antennas for Mobile Terminals

Mobile terminals such as smartphones, GPS receivers, laptops, or other compact devices make use of multiband antennas to operate over multiple wireless protocols. Newly adopted smartphone platforms allow users to jump from one operational protocol to another with ease and fast selection ability. This multi-standards operation requires the integration of antennas that are able to reconfigure their operations swiftly and dynamically. Thus, reconfigurable antennas are proposed as suitable candidates for this application.

Multiple experiments have been carried out to prove the advantages of using a reconfigurable antenna setting over multiple antennas in mobile terminals. For example, in Yang et al. (2009) a GPS receiver is exposed to a jamming signal when the receiver is using either a multiband antenna or a reconfigurable antenna. The multiband antenna used in this experiment operates over both the GPS and wireless LAN frequencies, while the reconfigurable antenna can selectively change its operation from GPS to WLAN (Yang et al. 2009). It is found that, in the case where the reconfigurable antenna is used, no degradation in the signal quality is noticed. However, the multiband antenna showed a poor out-of-band rejection. Additional filtering would be required for the multiband antenna to attain better noise rejection (Yang et al. 2009). In general, frequency reconfigurable antennas possess inherent band-pass characteristics and generally have excellent out-of-band rejection without filters (Yang et al. 2009). Their higher-order resonances are typically far away from the operating band and can be removed with much less selective filters and at a lower cost (Yang et al. 2009).

The antenna shown in Fig. 5 (Li et al. 2012) is an example of a frequency reconfigurable antenna designed for mobile phones. The antenna design is composed of a folded loop that is reconfigured using one PIN diode and a tuning pad. A matching bridge is also incorporated for increased bandwidth. The PIN diode switches allow the antenna to be transformed from a folded loop into an inverted "F" antenna (IFA) (Li et al. 2012). As a result, hepta-band coverage is achieved in a compact volume. This reconfigurable antenna structure allows operation over GSM 850, GSM 900, GPS, DCS, PCS, UMTS, and WLAN (Li et al. 2012).

DOI 10.1007/978-981-4560-75-7_61-2

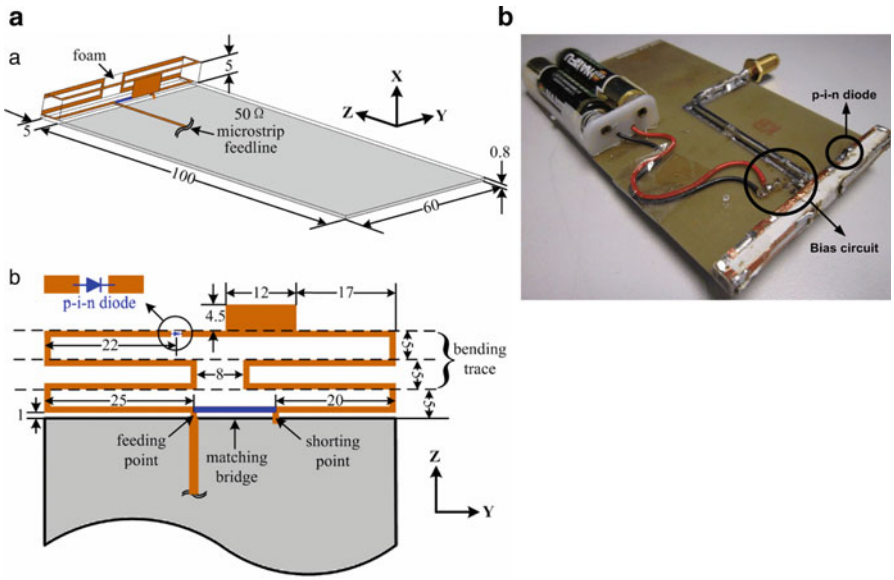

Fig. 5 Simulated and fabricated antenna system as proposed in Li et al. (2012)

Another antenna proposed as a suitable candidate for smartphones is a folded coupled-fed narrow-frame antenna for hepta-band WLAN/LTE (Ban et al. 2014). The antenna shown in Fig. 6 (Ban et al. 2014) is reconfigured using one PIN diode that changes its resonant mode by modifying the electrical length of the lower band in two working states (Ban et al. 2014). The antenna is proven to operate over GSM 850/900/1800/1900/UMTS/LTE2300/2500 (Ban et al. 2014).

Reconfigurable Antennas for Cognitive Radio Applications

A cognitive radio requires antenna systems that have the ability to identify changes in a communication setting and be able to react accordingly. Cognitive radio is based on the concept of monitoring a channel and searching for unused spaces in the spectrum. Once unused spaces are identified, a reconfigurable antenna is activated to tune its operation to broadcast, thus increasing the communication efficiency (Tawk et al. 2014a).

Channel sensing can be achieved through a wideband antenna or a reconfigurable narrowband antenna. The communication process on the other hand requires a reconfigurable antenna to be able to change its operation in order to manage the dynamically discovered white spaces in the spectrum. A cognitive radio device's operation is based on a cycle that is shown in Fig. 7 (Tawk et al. 2014a). This cycle starts by observing the channel activity, which is achieved by a sensing (wideband) antenna. In the second step of the cycle, a cognitive processor decides which part of the spectrum is suitable for communication. The processor next activates the communicating antenna to achieve the required mode of communication. In the last step, the processor achieves cognition by learning from previous channel activities. This cycle allows the cognitive radio device to self-decide and optimally self-reconfigure its hardware in order to realize the selected mode of communication (Jayaweera and Christodoulou 2011; Tawk et al. 2014a).

Multiple reconfigurable antenna designs are presented in literature for implementation on a cognitive radio platform. An example of such antennas is the one shown in Fig. 8 (Rajagopalan et al. 2014). The antenna presented is a frequency reconfigurable E-shaped patch antenna that provides wideband frequency switching using MEMS. The antenna is proposed for applications on cognitive radio platforms with large terminals such as laptops or as an array element (Rajagopalan et al. 2014). The presented E-shaped patch offers a simple single-layer, single-feed structure with a wide instantaneous bandwidth (Rajagopalan et al. 2014).

DOI 10.1007/978-981-4560-75-7_61-2

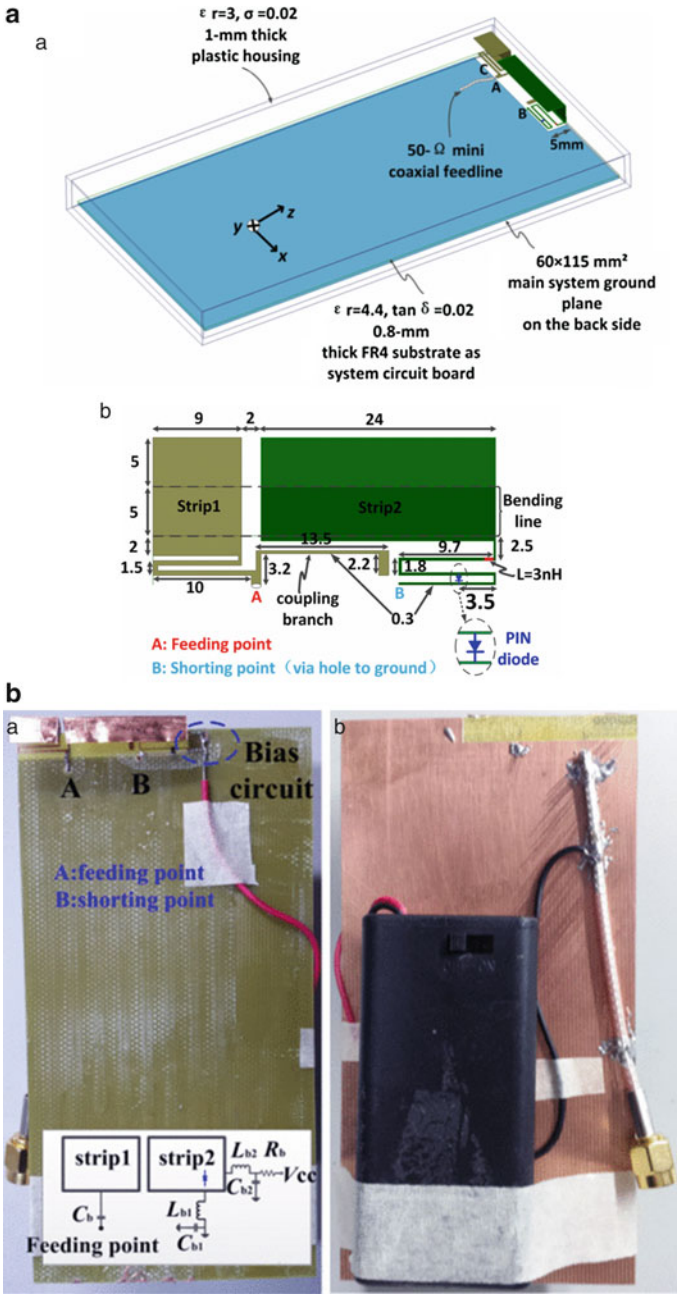

Fig. 6 Narrow-frame reconfigurable antenna proposed in Ban et al. (2014)

A reconfigurable antenna design that is based on switching between wide- and narrowband frequency operation is shown in Fig. 9 (Augustin et al. 2014). The antenna is a single-port antenna design that achieves switching between wideband and narrowband operation by resorting to a slot-based resonator filter. The filter consists of two quarter wavelength resonators that generate two stop bands far spread out to form a passband. Two PIN diodes are embedded across the slot entrance from the CPW. In addition to that, on either side of the CPW, two 0.2 mm slots incorporated with capacitors are introduced. The antenna design also resorts to an elliptically curved slot to reduce back-lobe radiation as well as to enhance the cross-polar level of the antenna (Augustin et al. 2014). An antenna based on the same design concept of using a slot resonator filter is also proposed in Chacko et al. (2015) with an added feature of polarization diversity.

DOI 10.1007/978-981-4560-75-7_61-2

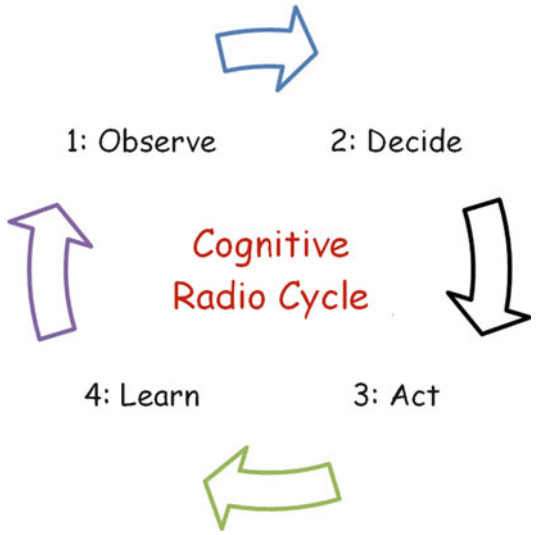

Fig. 7 The cognitive radio cycle (Tawk et al. 2014a)

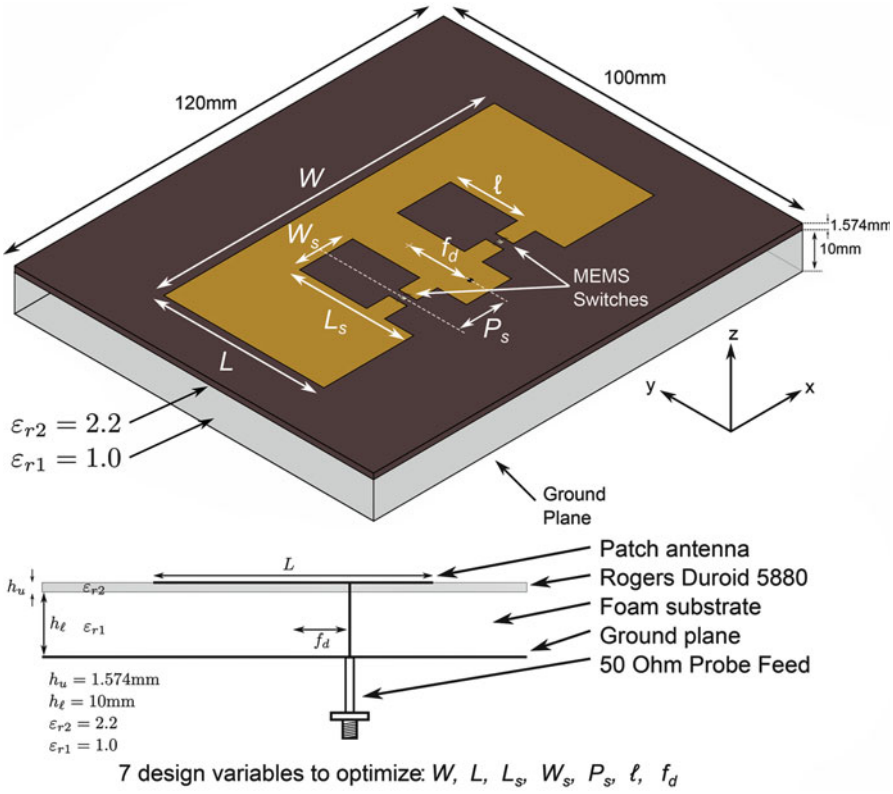

Fig. 8 Reconfigurable E-shaped patch (Rajagopalan et al. 2014)

Another antenna system proposed for cognitive radio applications is based on the integration of band-pass and band-stop filters in either the ground plane of the antenna or the feeding line. The antenna proposed is shown in Fig. 10 (Mansoul et al. 2014). It is composed of a radiating element in the form of an inverted U, fed by a microstrip line on its upper side. In order to achieve the frequency reconfiguration, four horizontal slots with integrated switches are disposed in three rows and incorporated onto the antenna ground plane. The upper and bottom slots are used as stop-band filters in order to suppress the whole

DOI 10.1007/978-981-4560-75-7_61-2

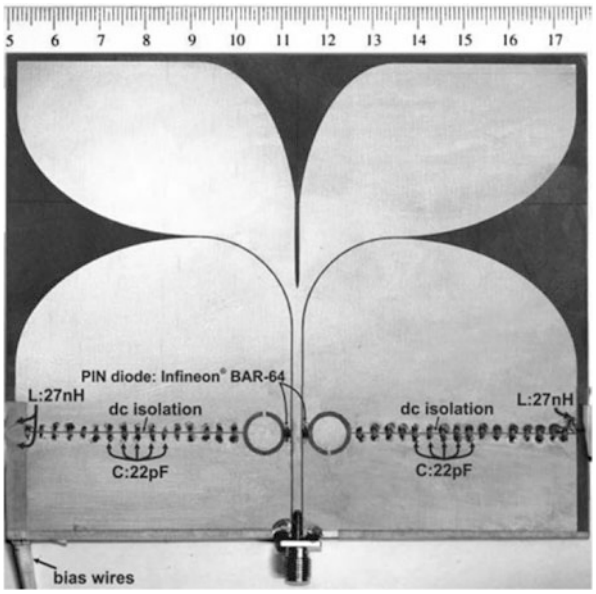

Fig. 9 Cognitive radio reconfigurable antenna proposed in Augustin et al. (2014)

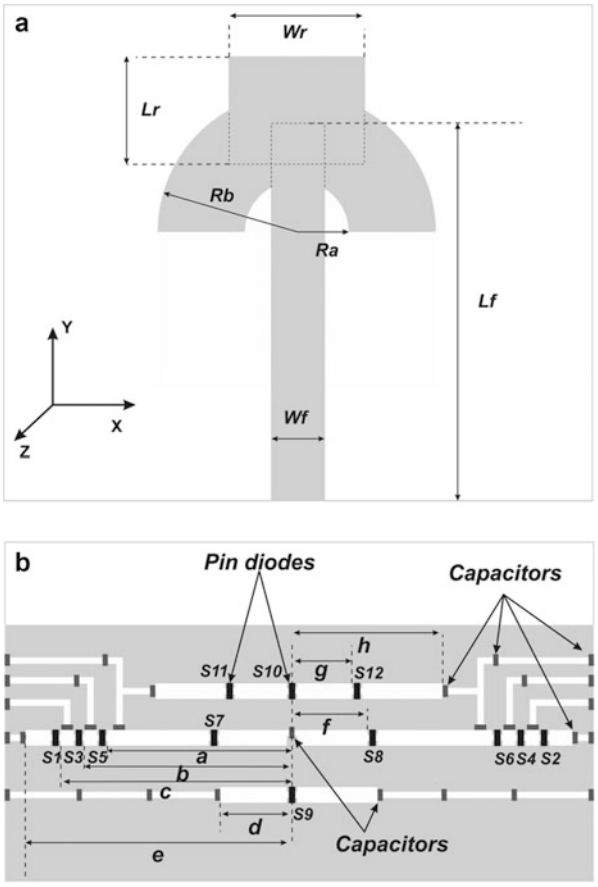

Fig. 10 (**a**) *Front* view, (**b**) *back* view of the proposed antenna (Mansoul et al. 2014)

considered band. The upper slot attenuates the lower frequencies in the band, while the bottom one suppresses the high frequencies (Mansoul et al. 2014). Once the considered band is suppressed, the

DOI 10.1007/978-981-4560-75-7_61-2

introduction of the middle slots in the antenna's ground plane creates a high operating band whose frequency depends on its length. Thus, by controlling the slot length by means of switches, the antenna's operating band can be tuned accordingly (Mansoul et al. 2014).

Reconfigurable Antennas for MIMO-Based Cognitive Radio Applications

Various antenna systems can be proposed for cognitive radio applications (Tawk et al. 2014b). However, it is critical to understand that adding cognition to antenna systems and allowing them to communicate over unused frequency gaps do not solve all other issues in the spectrum. Hence, it is important to design antennas that address spectrum concerns such as fading or multipath in a cognitive radio setup. A MIMO-based antenna can be proposed for cognitive radio applications as shown in Fig. 11 (Tawk et al. 2014b). The reason behind adopting a MIMO-based antenna for cognitive radio is to combat fading, ensure reliable communication between the end users, and improve spectrum usage efficiency.

The MIMO-based cognitive radio antenna system shown in Fig. 11 consists of two sensing antennas as well as two reconfigurable "filtennas" packed all together on the same substrate (Tawk et al. 2014b). The reconfigurable antennas resort to PIN diodes to tune their frequency band-pass operation. A reconfigurable antenna, in a cognitive radio setting, is able to react to the observations of the wideband sensing antenna, based on the recommendations of the cognitive processor as described in Fig. 7. The evaluation of the performance of the proposed antenna systems in mitigating fading in a rich multipath environment is done by observing the values of the envelope correlation coefficient ρ_e and the mean effective gain (MEG) (Vaughan and Andersen 1987; Tawk et al. 2014b).

Another MIMO-based reconfigurable cognitive radio antenna is shown in Fig. 12 (Hussain and Sharawi 2015). The antenna system design is based on a compact meandered line planar reconfigurable two-element MIMO system. The antenna system is made tunable in different bands using PIN and varactor diodes. The antenna operates at lower frequency bands starting from 580 to 680 MHz and from 834 to 1,120 MHz. The important feature of the proposed design is that the reference ground plane of the reconfigurable antenna is optimized to work as a sensing antenna to scan the frequency spectrum while operating as a ground plane for the reconfigurable antenna during the communication stage (Hussain and Sharawi 2015).

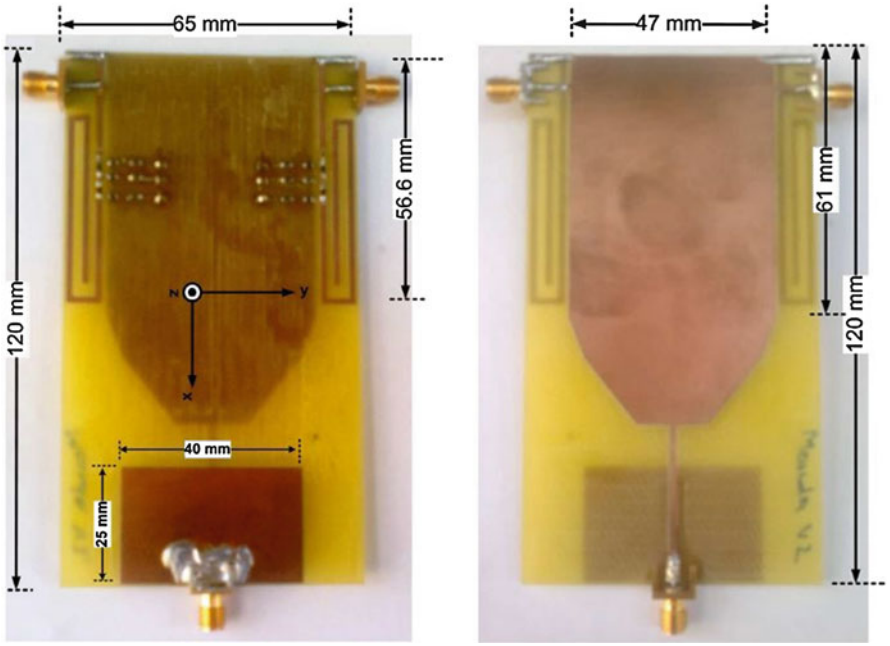

Fig. 12 *Front* and *back* view of the proposed MIMO-based reconfigurable cognitive radio antenna system (Hussain and Sharawi 2015)

Reconfigurable Antennas with Wireless Local Area Network (WLAN) Band Rejection

A very common problem is the interference that occurs between existing ultra-wideband (UWB) antennas and signals from WLAN communication networks. Since UWB antennas possess a large bandwidth, their in-band interference is usually a result of increased traffic over 802.11 n usage or from WLANs that allocate different channels in their upper operational band (5.15–5.825 GHz) (Federal Communications Commission 2002; Anagnostou et al. 2014). The problem of interference between WLAN and UWB nearby signals can be solved by proposing UWB antennas with permanent WLAN band rejection. The problem arises when rejection is not permanently needed and, in this case, dynamic or reconfigurable rejection becomes a necessity (Anagnostou et al. 2014).

An example of a reconfigurable antenna that achieves WLAN rejection is shown in Fig. 13 (Anagnostou et al. 2014). This UWB antenna uses microelectromechanical switches (MEMS) to reconfigure its band rejection on demand in the 5.15–5.825 GHz 802.11 a/n WLAN bands. The antenna design is a planar disc-shaped UWB monopole. The antenna design lacks a backside ground plane which makes it ideal for monolithically integrated MEMS. A quartz substrate is used for the antenna and the high-resistive bias lines. This led to the monolithic on-wafer integration of the whole system (Anagnostou et al. 2014).

Reconfigurable Antennas for Wireless Sensing

Wireless sensing can be applied in applications such as industrial process control, battlefield surveillance, habitat monitoring, and implantable medical telemetries (Jiang and Yang 2013), to mention a few. An example of a reconfigurable antenna that has been proposed for wireless sensing is shown in Fig. 14 (Jiang and Yang 2013). The antenna is a conventional printed dipole with a T-matching network. The antenna's impedance is conjugate matched with an RFID integrated chip (IC) as shown in Fig. 14. The antenna system is printed on an FR4 substrate. The realized gain of the tag antenna and the sensitivity of the IC determine the read range of the tag antenna. The RFID microchip is a nonlinear load whose complex

DOI 10.1007/978-981-4560-75-7_61-2

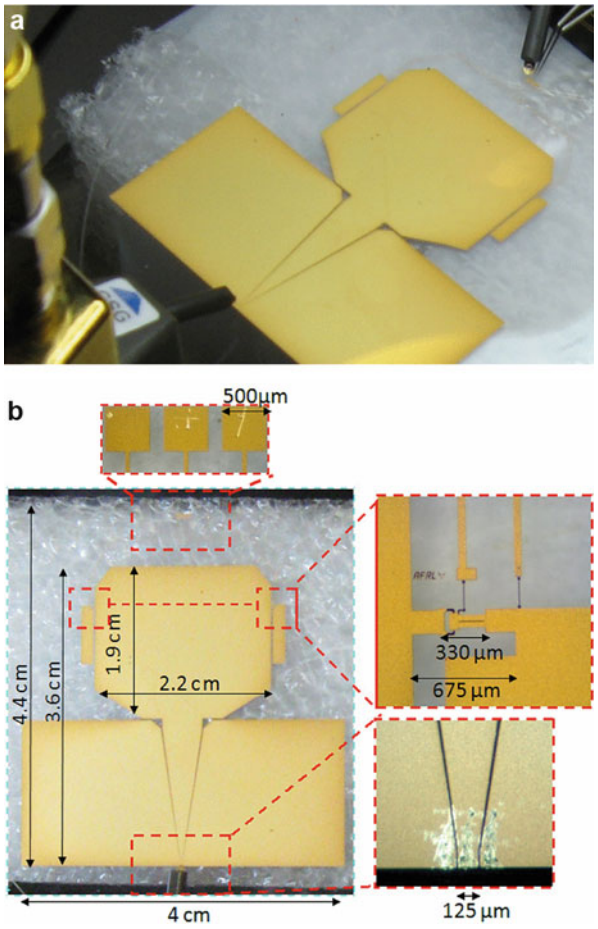

Fig. 13 Antenna with WLAN band rejection discussed in Anagnostou et al. (2014)

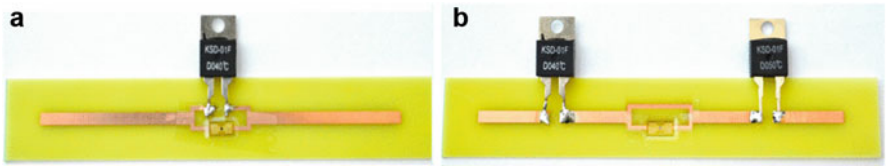

Fig. 14 The proposed reconfigurable sensing antenna with a thermal switch at the center of the dipole (Jiang and Yang 2013)

impedance varies with the frequency and the input power (Jiang and Yang 2013). The reconfigurable antenna can monitor the temperature of the surrounding environment by integrating thermal switches in series or parallel. When the temperature exceeds the specific threshold, the switch will change its status, which leads to a significant change in the antenna performance (Jiang and Yang 2013).

Reconfigurable Antennas for Terahertz (THz) Communication Applications

Communication at THz frequencies has attracted the attention of many antenna researchers especially after the rise of graphene as an antenna design material. The ability of graphene to support slow surface plasmonic modes at THz frequencies, allows the miniaturization of various communication devices for communication and sensing purposes (Tamagnone et al. 2013). The behavior of the surface conductivity of graphene in the THz region enables the creation of plasmonic modes in radiating structures

DOI 10.1007/978-981-4560-75-7_61-2

(Tamagnone et al. 2013). The design of antennas using graphene provides a good total efficiency, good matching, high miniaturization, and inherent reconfiguration capabilities. The antenna structures take advantage of resonant plasmonic modes propagating on graphene sheets to implement actual radiators, able to couple electromagnetic energy from small THz sources to free space (Tamagnone et al. 2013). An example of the use of graphene for reconfigurable antenna design over THz frequencies is shown in Fig. 15 where two self-biasing stacked graphene layers (patches) are designed to achieve dynamical tuning (Tamagnone et al. 2013). The two graphene layers considered are separated by a thin film of Al_2O_3. A DC voltage is applied between the two graphene sheets into the thin insulating layer. With this geometry, the magnetic permeability can be tuned dynamically by varying the voltage between the graphene layers.

A graphene-based leaky-wave antenna has also been proposed based on the graphene modes of operation for THz applications (Perruisseau-Carrier et al. 2013). The antenna can be composed of a graphene sheet deposited on a dielectric substrate with several independent polysilicon DC grating pads beneath it (Perruisseau-Carrier et al. 2013). The desired graphene surface reactance profile is achieved by applying different bias voltages to the different pads to create the periodic reactance modulation. By modifying the modulation period, the pointing angle of the radiated beam can be controlled (Perruisseau-Carrier et al. 2013). The aforementioned work is also extended to the design of a reconfigurable beam reflect-array antenna (Carrasco et al. 2013). The complex conductivity of graphene can be varied when an electric field is applied allowing the control of the phase of the reflected wave at each element of the reflect-array. The proposed patches support plasmonic slow-wave propagation at THz frequencies, drastically reducing the physical dimensions of the cell (Carrasco et al. 2013).

Reconfigurable Antennas for Millimeter-Wave Communication Applications

Communication between 30 and 300 GHz is defined as communication over millimeter (mm)-wave frequencies. The mmWave spectrum has become of high interest for many system designers for its many benefits that are mainly focused on its wide bandwidths (Federal Communications Commission 1997). Such wide bandwidths are useful and practical when it comes to high speed data transmission and video distribution. The propagation characteristics of mmWaves are very particular in the sense that mmWave signals can only travel a few miles or less. These waves do not penetrate solid materials very well and are heavily affected by environmental factors such as raindrops and fog (Federal Communications Commission 1997).

Many reconfigurable antennas have been developed for operation over mmWave frequencies. An example of such antennas is the one shown in Fig. 16 (Lafond et al. 2013). This antenna is composed of

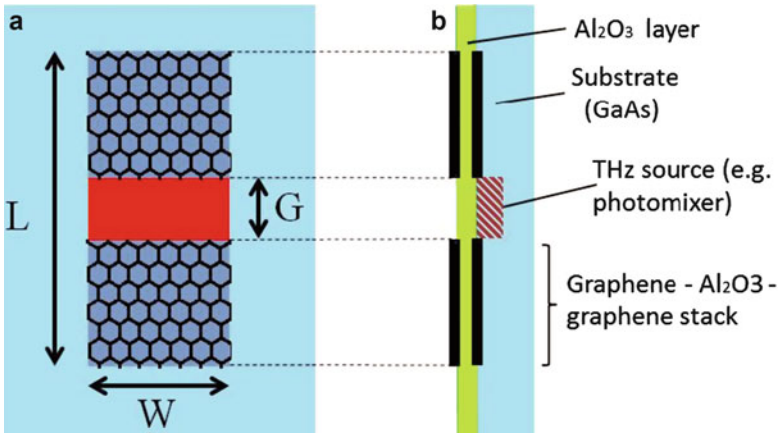

Fig. 15 The proposed double-layered graphene antenna. (**a**) *Top* view. (**b**) Cross section (Tamagnone et al. 2013)

DOI 10.1007/978-981-4560-75-7_61-2

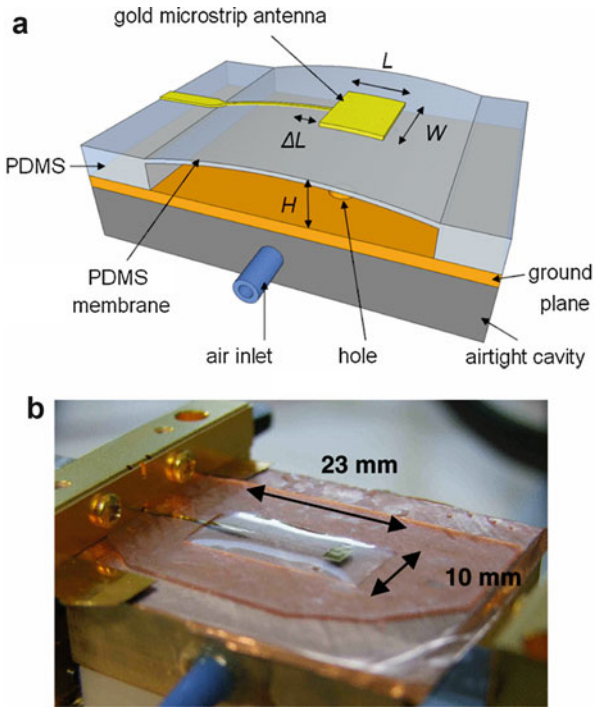

Fig. 17 PDMS antenna proposed in Hage-Ali et al. (2010)

16 different patches that are fed by a corporate feeding network. The different patches are placed in a semicircle manner with 10° apart from each other. The patches are fed by ridged source waveguides and are matched by using monolithic microwave integrated chip (MMIC) power amplifiers. The whole system is then connected to a lens that is illuminated by the various patch sources. The lens is a plate Luneburg lens that is defined as an inhomogeneous lens with infinity focus points. Once a patch illuminates the lens, the other patches are loaded with 50 Ω (Lafond et al. 2013).

Reconfigurable antennas for mmWaves' applications can also be designed using liquid crystals (Hu et al. 2008) or mechanical reconfiguration techniques similar to the one shown in Fig. 17 (Hage-Ali et al. 2010). The antenna presented (Hage-Ali et al. 2010) is a millimeter-wave frequency-agile

DOI 10.1007/978-981-4560-75-7_61-2

microstrip antenna that is printed on an ultrasoft elastomeric polydimethylsiloxane (PDMS) substrate. The microstrip patch antenna is supported by a PDMS membrane suspended over an air cavity. The distance between the patch and the ground plane is tuned using pneumatic actuation, taking advantage of the extreme softness of the PDMS membrane. The tuning of the antenna height results in tuning of the antenna's operating frequency. A continuous frequency shift varying from 55.35 to 51 GHz has been obtained for a tuning range of height between 200 and 575 μm. In all configurations, the antenna remains matched and its radiation characteristics are stable (Hage-Ali et al. 2010).

Reconfigurable Antennas for Space Communication Applications

Space communication is based on deployable antennas that are packed during launch and then deployed once in space. Many types of deployable antennas have been used on orbit. Reflector types constitute the widest category (Tadashi et al. 2004). Other deployable structures made with folded hoops or ribs are also used for space communications (Zheng et al. 2008). Some researchers have also resorted to tape springs and neutrally stable material to design their structures (Murphey and Pellegrino 2004). Helical antennas (Balanis 2012) are also a popular choice of satellite antennas due to their natural circular polarization and wide bandwidth (King and Wong 1980).

Traditional deployable antennas present valid options for space communication. However, the rise of small satellites' development and the launch of clusters of CubeSats have increased the need for more agile antennas. Currently dipole antenna arrays in various configurations constitute the most common antennas deployed on CubeSats (Muri et al. 2010). The merging of reconfigurable and deployable antennas appears to be a solution to the increased demand for communication agility in space.

Mechanical antenna reconfiguration techniques merged with deployment techniques seem to present an answer to reconfigurability in space. Other electrical reconfiguration techniques can also be explored especially with the advancement in satellite power handling technology. Mechanical reconfiguration mechanisms for deployable antennas are based on the nature of the antennas, their composite material, and their deployment mechanism. For example, the reconfiguration of deployable antennas that are designed with bistable composite tape springs can be achieved using one-way linear or rotary actuator (Murphey et al. 2010; Jeon and Murphey 2011; Costantine et al. 2012b). Antennas made with neutrally elastic mechanism (NEM) tape springs require two-way actuators to be reconfigured (Murphey et al. 2010; Jeon and Murphey 2011; Costantine et al. 2012b).

Another reconfiguration technique can be based on deploying in progression. For example, a helical antenna shown in Fig. 18 (Costantine et al. 2013a) deploys in stages by using actuators. The sequential deployment tunes the antenna's operating frequency. The concept is based on the fact that only the part of the antenna that is above the deployed ground plane radiates (Costantine et al. 2013a). In general,

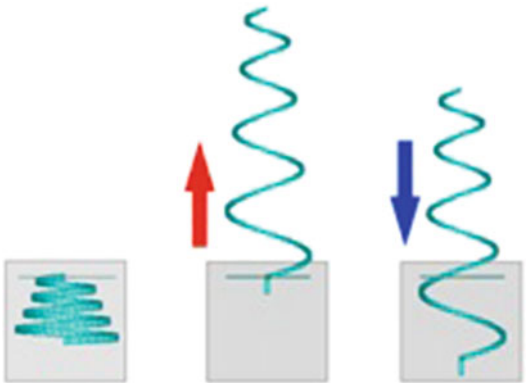

Fig. 18 Helical antenna deployed in progression (Costantine et al. 2013a)

DOI 10.1007/978-981-4560-75-7_61-2

reconfiguring antennas for space communications is a difficult task with many constraints, such as maintaining antenna performance without draining existing power and reducing reliability. However, space communications agility is a great addition that constitutes a major advancement in available communication technology.

Reconfigurable Antennas for Multiple Wireless Communication Applications

Several reconfigurable antenna concepts have been proposed in literature for multiple wireless communication applications. An example of such antennas is the one shown in Fig. 19 (Hinsz and Braaten 2014). The reconfigurable antenna shown is an autonomously controlled frequency reconfigurable antenna. The presented antenna does not require external and separate control signals to achieve reconfiguration. The antenna design concept consists of a power divider, band-pass filter, voltage doubling circuitry, and reconfigurable antenna controlled with voltage. The system is based on the concept that once RF power is provided to the summing junction of the power divider, part of it is sent to the reconfigurable antenna and the band-pass filter. If the signal is in the passband of the filter, RF power is provided to the voltage doubling circuit and converted to a positive DC voltage proportional to the input RF power (Hinsz and Braaten 2014). As a result, the antenna can then be reconfigured based on this output voltage. If the RF signal driving the antenna is not in the passband of the filter, then it gets rejected and the antenna will not be reconfigured.

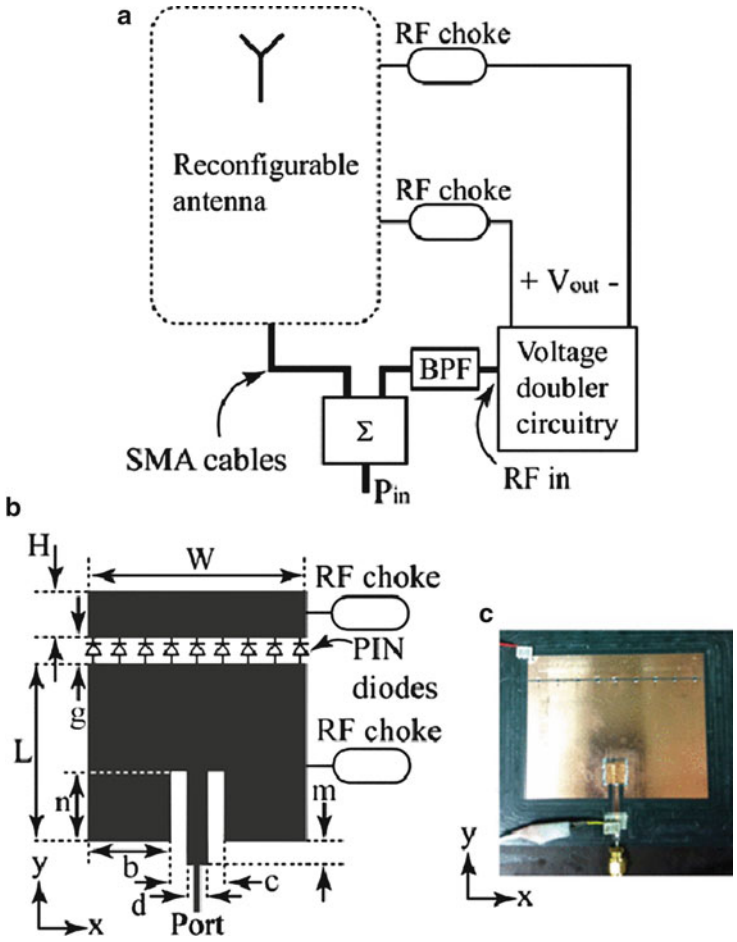

Fig. 19 Layout of the autonomously reconfigured antenna (Mazlouman et al. 2011)

DOI 10.1007/978-981-4560-75-7_61-2

Mechanically reconfigurable antennas are also proposed for various applications that can tolerate these systems. Antennas with electroactive polymers (Mazlouman et al. 2011), shape-memory alloys (Mazlouman et al. 2011), or actuators (Costantine et al. 2014) are mainly proposed as techniques that are alternative to switching reconfiguration methods for multi-application reconfigurable antennas.

Modeling, Control, and Optimization of Reconfigurable Antennas

Reconfigurable antennas are required to transition from one state into another to cater for varying communication channels requirements. To that aspect, antenna designers have resorted to various optimization algorithms to smooth the state transition in a reconfigurable antenna's operation. Genetic algorithms, simulated annealing, ant-colony optimization, self-organized maps, particle swarm optimization, the cross-entropy method, and the self-adaptive-induced mutation algorithm are proposed to smooth transitions between various states of a reconfigurable antenna (Coleman et al. 2004; Min et al. 2004; Bossard et al. 2005; Akdagli et al. 2007; Jin and Rahmat-Samii 2007; Connor 2008; Skinner et al. 2009; Song and Murch 2014; Cao et al. 2014). These algorithms also minimize the negative effect of any reconfiguration technique on the antenna performance. A comparison between these optimization techniques shows that a particular optimization algorithm cannot be separated from the rest as the best fit, before selecting a specific reconfigurable scheme (Langoni et al. 2009).

Additionally, the complexity of some large reconfigurable antenna designs is another aspect that requires consideration. An increased complexity results in unwanted costs and losses (Costantine et al. 2013c). Several approaches have been proposed to reduce the complexity without affecting the reliability of any reconfigurable antenna system (Mehmood and Wallace 2010; Obeidat et al. 2010; Costantine et al. 2011a, 2012a, c; Mehmood et al. 2014). Most of these approaches are based on applying on antenna structures various techniques or models that are already known in other fields of study (Costantine et al. 2013c). Learning state selection approaches can be used to learn the antenna behavior for various reconfiguration states and then regenerate them on demand (Gulati and Dandekar 2013). Neural networks constitute a great example of such learning approaches. Neural networks can be used as an antenna behavioral predictor that allows the generation of various antenna states based on previous learning experience (Patnaik et al. 2005). The merging of neural networks and graph models has resulted in computational reduction and optimal antenna regeneration (Costantine et al. 2011b).

Graph Modeling Reconfigurable Antennas

Graphs are used as models that help automate and optimize the antenna performance. The user controlling the reconfiguration process of an antenna resorts to software to control the tuning of the antenna (Costantine et al. 2013c). In fact, the rise of reconfigurable antennas is based on the fact that these antennas are software controlled and can be automated easily. Graph models (Cormen et al. 2001) have been used to improve the software control process of reconfigurable antennas and to allow the employment of various algorithms into the antennas' automation and optimization process (Costantine et al. 2013c).

Graphs are mathematical illustrations of various systems. They are symbolic representations of relationships between different points in a system. A graph can also be a description of a communication protocol. In particular, a suitably designed graph can precisely describe and direct the changing network topology of a self-organizing system (Klavins et al. 2004; Klavins 2006; Napp et al. 2006; Klavins 2007) such as a reconfigurable antenna.

A graph is a collection of vertices that are connected by lines called edges (Costantine et al. 2011a). Each vertex can represent a part of an antenna or an endpoint of a switch (Costantine et al. 2013c). The

DOI 10.1007/978-981-4560-75-7_61-2

connection between the different antenna parts or the activation of the switch is represented by the presence of an edge connecting the corresponding vertices (Costantine et al. 2013c). Several rules are introduced to model reconfigurable antennas (Costantine et al. 2013c). These rules allow the designer to relate each possible topology to a corresponding electromagnetic performance. Once a graph is drawn, an adjacency matrix can be formed based on this graph. Thus, the graph has transformed an antenna into a matrix where various algorithms can be applied.

Graph models can also be used to investigate the presence of redundant components in an antenna structure. An element is defined as redundant if its presence gives the antenna more functions than required and its removal does not affect the antenna's performance (Costantine et al. 2011a). A redundancy reduction approach is proposed in Costantine et al. (2011a) to eliminate redundant components from reconfigurable antenna structures for more efficient designs. Removing redundant components from an antenna structure reduces its complexity and allows for a more efficient antenna reconfiguration. For example, reducing the number of switches used to reconfigure an antenna reduces the nonlinearity effects and the interference from the corresponding switching components' biasing lines. The planar antenna shown in Fig. 20 (Costantine et al. 2011a) is built out of a hexagonal main patch and six trapezoidal parts placed around it. Each trapezoidal part is connected to the main patch by a switch. Thus, this antenna originally utilizes six switches to tune its frequency operation. The graph model of this antenna shown in Fig. 20a is composed of six vertices (P_1, P_2, P_3, P_4 P_5, P_6) representing the trapezoidal

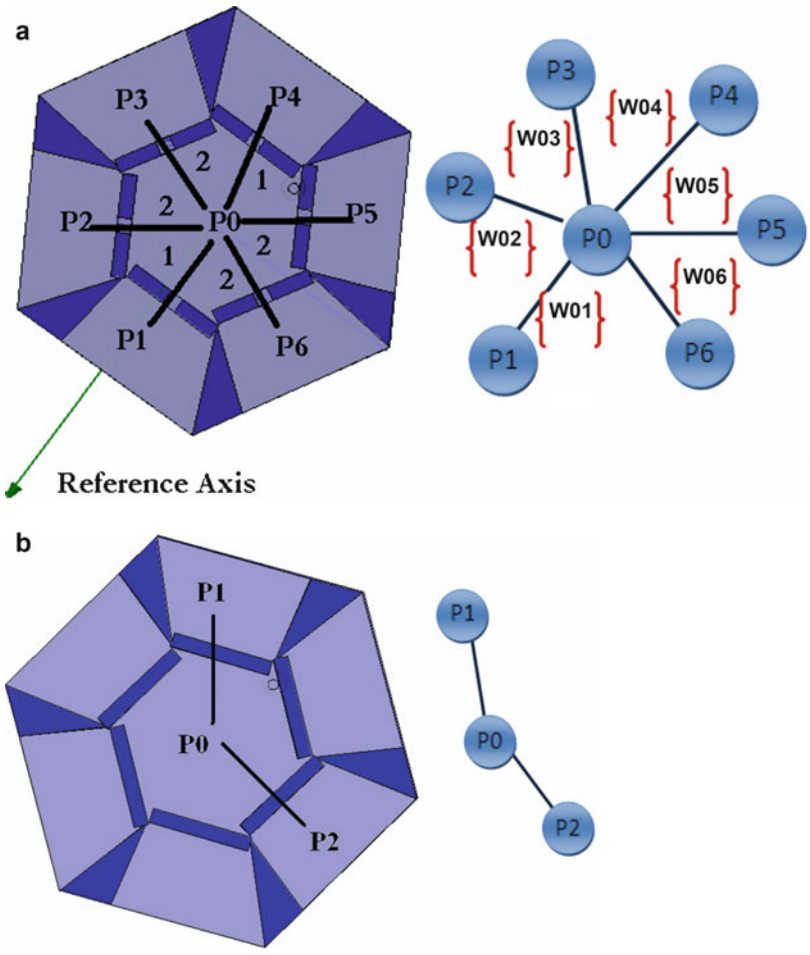

Fig. 20 (**a**) Reconfigurable antenna before the redundancy reduction approach, (**b**) reconfigurable antenna after the redundancy reduction approach (Costantine et al. 2011a)

DOI 10.1007/978-981-4560-75-7_61-2

parts connected by six edges to the seventh vertex (P_0) that represents the main patch (Costantine et al. 2011a). After the application of the graph-based redundancy reduction approach, the number of used switches is transformed from six to two as shown in Fig. 20b. It is important to note that the functioning of the antenna is preserved and its optimized response is compared with the original redundant antenna response (Costantine et al. 2011a). The redundancy reduction approach is also tested on antennas with a larger number of switches, and as a result, more efficient designs are created for an easier system control and integration (Costantine et al. 2011a).

Reconfigurable antennas can achieve the operation at one frequency with multiple switch configurations. These configurations are defined as "equivalent configurations" (Costantine et al. 2012c). Reducing redundant components and eliminating unwanted switches reduce the antenna's general complexity and also reduce the number of equivalent configurations. On the other hand, it is important to address the effect of switch failure on the antenna's reliability, after eliminating the redundant switching components from the antenna structure. It is shown that while the physical antenna redundancy is reduced, the equivalent configurations present are sufficient to maintain acceptable antenna reliability (Costantine et al. 2012c).

The reliability of a reconfigurable antenna mainly depends on the number of antenna configurations at a certain frequency and the probability to achieve them. However, it is inversely proportional to the number of edges needed. The solution is to design reconfigurable antennas with several equivalent configurations but only with a small number of connections. Thus, the reliability of a reconfigurable antenna can be calculated as in Eq.1 (Costantine et al. 2012c). On the other hand, an antenna's general complexity is represented by the total number of edges in a graph as shown in Eq. 2 (Costantine et al. 2012c). Antenna's frequency-dependent complexity is the measure of the maximum number of edges in a particular configuration as defined in Eq. 3 (Costantine et al. 2012c). It can be deduced from these equations that the reliability of a reconfigurable antenna is inversely proportional to its frequency-dependent complexity (Costantine et al. 2012c). This conclusion affects the design process of an antenna researcher that looks to maximize the reliability of its design while reducing its complexity.

$$R(f) = \frac{\sum_{i=1}^{Nc(f)} \sum_{j=1}^{NE_i(f)} P(E_{ij})}{\sum_{i=1}^{Nc(f)} NE_i(f)} \times 100 \tag{1}$$

where:

$R(f)$ = the reconfigurable antenna reliability at a particular frequency f.
$NC(f)$ = the number of configurations achieving the frequency f.
$NE(f)$ = the number of edges for different configurations at the frequency f.
$P(E)$ = probability of achieving the edge $E = 1 - P$ (a switch failing).

$$C = NE \tag{2}$$

where NE represents the total number of edges in a graph for all possible connections.

$$C(f) = \underset{i=1, NC(f)}{\text{Max}} (NE_i(f)) \tag{3}$$

DOI 10.1007/978-981-4560-75-7_61-2

where:

$C(f)$ represents the complexity of the antenna system at a frequency f.
$NC(f)$ represents the number of equivalent configurations at a frequency f.
$NE_i(f)$ represents the number of edges at the configuration i for a frequency f.

The graph-based analysis can also be extended to reconfigurable antenna arrays where their complexity, reliability, and switch failure correction techniques are correlated and analyzed (Costantine et al. 2012a).

The importance of the graph-based analysis is that it gives the antenna designer a strong tool to use at the initial design process of reconfigurable antennas. It is executed so that optimal reconfigurable antenna designs are created with less redundancy. Reducing redundant components while maintaining reliability creates systems that have less loss and fewer costs and are efficient and easier to control and automate.

Software Control of Reconfigurable Antennas

Many tools can be used to automate the software control of reconfigurable antennas. The use of field-programmable gate arrays (FPGA), a simple microcontroller, or an Arduino board (Arduino 2013) constitutes valid approaches that have been used in the past. For example, the antenna discussed in Shelley et al. (2010) uses an FPGA to activate and deactivate PIN diodes that connect different parts of its structure as shown in Fig. 21 (Costantine et al. 2013c). The use of an FPGA in such a system allows the antenna user to control the operation of this antenna through simple commands. In another example, LabVIEW and an NPN Darlington array control the rotation mechanism of a stepper motor that is used to reconfigure an antenna structure (Tawk et al. 2011). The simplicity of such an approach makes the software-controlled reconfiguration process a task that can be executed by any antenna designer without very complicated programming skills.

Arduino boards also allow antenna designers to program their antenna systems, control and automate them in a compact setting as discussed in Costantine et al. (2014). The user in such systems controls the operation of the antenna and decides when and how to change its function. In other cases, detection of surrounding activities is needed to change an antenna's operation. An example of such system is one where a change in temperature triggers thermal switches installed onto the antenna structure (Jiang and

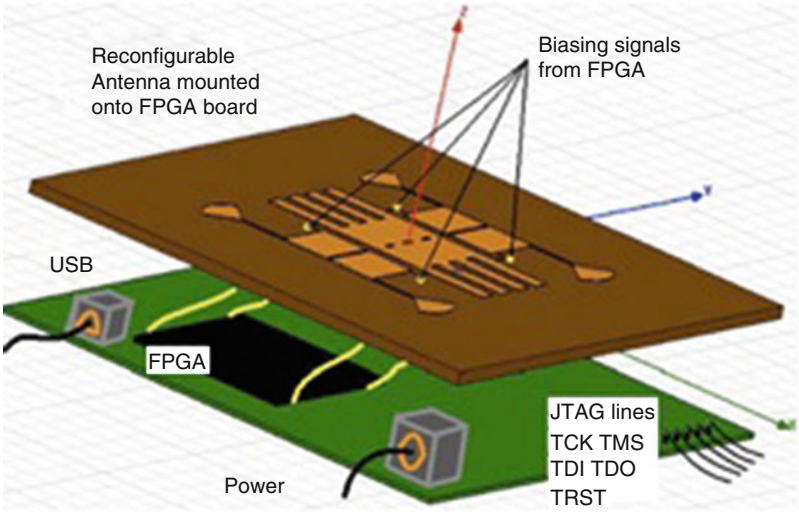

Fig. 21 FPGA controlling a PIN diode frequency reconfigurable antenna (Costantine et al. 2013c)

DOI 10.1007/978-981-4560-75-7_61-2

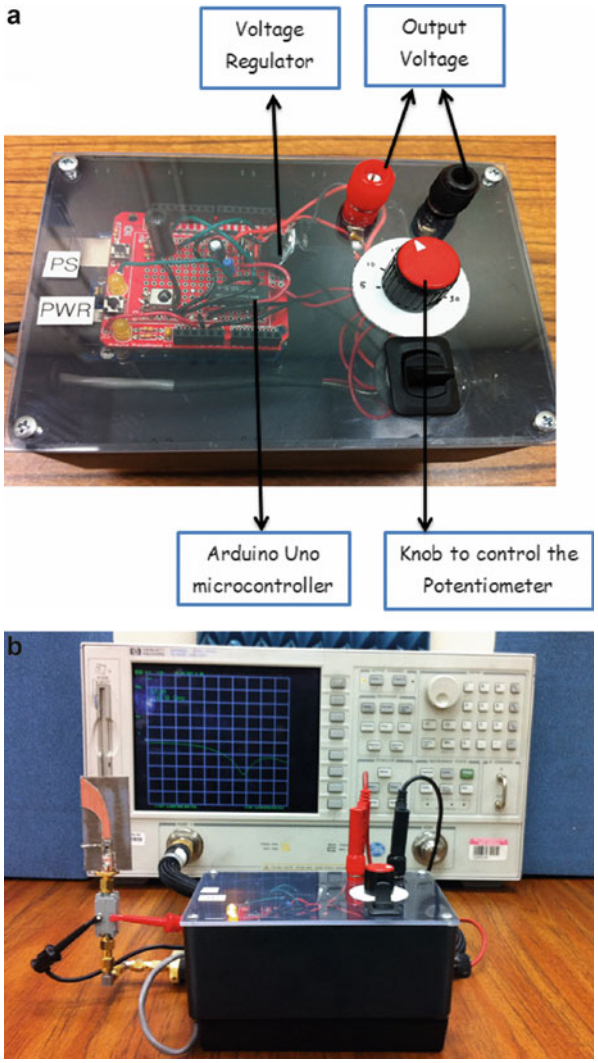

Fig. 22 The motion detection circuit connected to the varactor-based reconfigurable "filtenna" (Costantine et al. 2013b)

Yang 2013). Motion detection is also a trigger mechanism that can be used to bias and tune a reconfiguring component. An infrared (IR) motion detection sensor is connected to the biasing network of a varactor, incorporated onto a reconfigurable antenna as shown in Fig. 22 (Costantine et al. 2013b). Once a movement is detected in a predetermined area, the biasing circuit changes voltage levels. This action results in antenna frequency tuning (Costantine et al. 2013b).

Graph models also help in the software control process by minimizing redundant components and allowing the application of graph algorithms to optimize performance. For example, a shortest path algorithm (Costantine et al. 2013c) applied to a mechanically reconfigurable antenna expedites its performance by always searching for the shortest path. This results in the fastest reconfiguration process possible with the reconfiguration technique (Costantine et al. 2013c).

Neural Networks Applied to Reconfigurable Antennas

The use of software to control reconfigurable antennas has encouraged antenna researchers to employ neural networks (NNs) to control their antennas through FPGAs. NNs are used on reconfigurable antennas as antenna synthesizers. A NN is trained to associate all the different configurations of a reconfigurable antenna with its different operating frequencies (Costantine et al. 2011b). NN can be

DOI 10.1007/978-981-4560-75-7_61-2

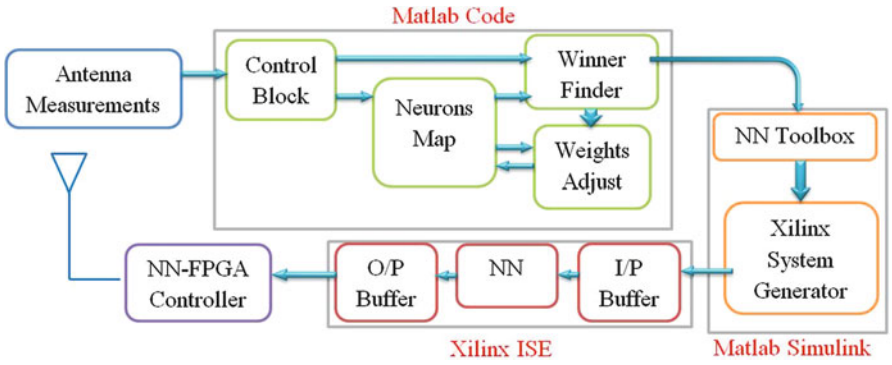

Fig. 23 Block diagram of the NN operation (Costantine et al. 2011b)

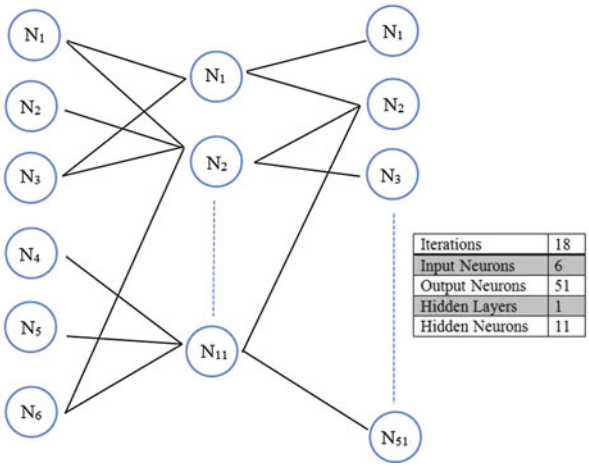

Fig. 24 The NN structure of the antenna in Fig. 21a (Costantine et al. 2011b)

designed using a standard back-propagation technique, which provides meaningful cues that steer the design to convergence (Lyke 2002). Applying NNs to reconfigurable antennas results in the association of different antenna configurations with different frequency responses called clusters. The association of such frequency clusters with corresponding antenna configurations trains the NN to be able to configure the antenna and regenerate frequency responses on demand.

The NN architecture has three layers: input layer, hidden layer, and output layer. The input layer represents, in the case of a switch-reconfigured antenna, the number of switches existing in that antenna. The number of hidden neurons in the hidden layer represents the accuracy needed to regenerate the frequency response of the antenna in question. The number of output layer neurons is determined depending on the number of points required to recreate, up to an acceptable accuracy the return loss of the antenna (Zuraiqi 2012).

The application of neural networks requires a lot of data training and software handling. The general methodology is summarized in the block diagram of Fig. 23 (Costantine et al. 2011b). A neural network is built and trained in MATLAB Simulink. Training the NN requires adjusting the connection weights and specifying the number of hidden neurons. Error back-propagation (BP) is used to train the NN in this case. BP compares neural networks' output to the measured antenna response and calculates an error adjustment for each of the nodes in the network. The neural network adjusts the connection weights according to the error values assigned to each node (Zuraiqi 2012). After the weight adjustment process, a Xilinx system generator creates the NN VHDL code to be used to control an FPGA (Zuraiqi 2012).

DOI 10.1007/978-981-4560-75-7_61-2

As an example, applying neural networks to a reconfigurable antenna with six switches such as the one shown in Fig. 20a results in six input neurons, 11 hidden neurons, and 51 output neurons. The NN structure for this antenna is shown in Fig. 24. After removing the redundant components from this antenna as shown in Fig. 20b, the input layer of the neural network shrinks from six to two and the number of hidden neurons will have to shrink from 11 to 8 (Costantine et al. 2011b). As a result the training process requires less time and the regeneration of antenna states based on NN is faster and more efficient.

Summary

In this chapter, the questions that any antenna designer asks in regards to reconfigurable antenna design are addressed. The chapter addresses the need to design such antenna structures and presents the reader with a plethora of applications in which reconfigurable antennas are proposed as potential solutions. Reconfigurable antennas constitute a major part of future communication systems. They are the basis for many novel applications that are based on cognition and reaction to evolving/changing conditions in any RF or communication environment. A static communication system that relies on one or more fixed antennas no longer caters for the evolving needs of today's communication technology.

A reconfigurable antenna that is used for any wireless communication application is not complete without the possibility of its software control and automation. The learning of communication activities and the application of previously learned experiences into future action allow the reconfigurable antenna to leap from a simple RF front-end in a communication device into a real cognitive structure.

Future terrestrial and space communications will be based on antennas that adapt and learn. The adoption of reconfigurable antennas into commercial devices will increase with the progression of available technology. Therefore, it is crucial to understand these structures and optimize their behavior for a more efficient futuristic wireless communication protocols.

Radial Line Slot Antennas

Hiroyuki Arai*
Yokohama National University, Yokohama, Kanagawa, Japan

Abstract

This chapter presents the development history of radial line slot antenna. The antennas are used for circular polarized high-gain antenna in microwave and millimeter wave bands. Linearly polarized arrays are also provided by changing slot array arrangement. The feeding structures are given by a coaxial probe and cavity resonators, which is presented in detail. The applications of radial line slot antennas are satellite communication antenna, plasma etching, and high power use. This chapter also describes these applications.

Keywords

Radial line; Slot antenna; Circular polarization; Linear polarization; Direct broadcast satellite; Plasma etching

History of Radial Line Slot Antenna

Radial line is an infinite parallel plate waveguide excited by a feeding probe at the center. The propagating outward cylindrical wave is multimode in azimuth direction, and antenna elements on the top plate are arrayed to control the radiation pattern and polarization. The first application of radial line antenna was designed as the planar circularly polarized slot array which generates sum or difference far-field patterns for monopulse tracking. The antenna is a concentric slot array designed to radiate right-hand circular polarization in the frequency range 10.2–10.8 GHz (Kelly and Goebels 1964), and difference patterns are obtained by a phasing circuit of circular waveguide (Subbarao and Fusco 2003).

A radial line slot antenna (RLSA) is a circularly polarized high efficiency planar array. Two types of RLSAs, a single-layered and a double-layered one, were released commercially for 12 GHz band direct broadcast satellite (DBS) reception. The former adopts nonuniform slots excited by a radially outward traveling wave, while the latter has uniform ones excited by an inward traveling wave. The RLSA was initially developed as a double-layered folded waveguide for the uniform aperture distribution not disturbed by slot array near the feeding probe. A radially inward traveling transverse electromagnetic (TEM) mode is propagating inside the upper waveguide, excited by the outer rim of a twofold radial waveguide fed by a coaxial probe at the center of lower waveguide. Slots are arrayed in spirally on the top plate to radiate a circularly polarized broadside beam in X band (Ando et al. 1985). The measured performance of an antenna with a diameter of 0.6 m is gain of 35 dBi, axial ratio of 1 dB, and the aperture efficiency of 57 % at 12.2 GHz (Ando et al. 1986). For the compact antenna design, a single-layered radial line slot antenna (RLSA) utilizes a radially outward traveling wave, and the slot length is varied to synthesize uniform aperture illumination. The DBS reception antenna consists of back plate, foam, slotted plate, and radome as shown in Fig. 1. The radial line is terminated by a matching spiral, in place of a

Fig. 1 Radial line slot antenna (Courtesy of Tokyo Tech)

dummy load. It suppresses reflection and radiates all the residual power in circular polarization. For a model antenna of 600-mm diameter, the efficiency of 65 % was obtained (Takahashi et al. 1991, 1992). Merging the single-layered RLSA in the double-layered one, dual circularly polarized RLSA was proposed for DBS antenna at 12 GHz. A double coaxial waveguide provides an outward traveling wave in upper layer and an inward wave transferred from lower waveguide. Polarization isolation is more than 20 dB in DBS frequency band (Takahashi et al. 1995). A lightweight portable planar slot array antenna at X band for fixed satellite communications is composed of two RLSAs: one for reception band with left-handed circular polarization (LHCP) and the other one for transmission band with right-handed circular polarization (RHCP). A lightweight two-layered dielectric structure is used to achieve and optimize the RLSA weight. A radiation efficiency of more than 70 % is achieved due to the low dielectric constant substrate (Gonzalez et al. 2011).

Linear polarization is given by another slot array for RLSA; however, its concentric slot arrangement increases reflection from radiating elements at the feed point due to in-phase condition. The poor input S11 response is typical for waveguide broadside arrays and is suppressed by tilting the beam from the boresight (Ando et al. 1988; Takada et al. 1992). This effect is also suppressed by reflection-canceling slots; four slots form one slot set as a unit radiator of linear polarization. The antenna input reflection of S11 is improved from −2 to −10 dB, and antenna efficiencies of 48 and 54 % are measured for 400- and 600-mm-diameter antennas, respectively (Davis et al. 1997, 1999). A circularly polarized conical beam is also provided by another slot arrangement of RLSA (Takada et al. 1994). A dual linearly polarized single-layered RLSA is given by the slots arrayed in concentric ellipses and feeding the structure with two ports at the ellipses foci. Antenna ports are accessed through a 180° hybrid ring to obtain the dual behavior (Pla et al. 2006).

For a concentric array radial line slot antenna (CA-RLSA), a rotating mode should be excited. A pair of slots should have the same excitation amplitude by setting two slots with the same inclined angle to radial direction. This constraint is not applied to arbitrary polarization angle, i.e., the arbitrary phase, for slot pairs on the radial waveguide. The spiral arrangement of slot pairs is used to control its phase for the RLSA. By exciting a rotating mode inside the radial waveguide, the concentric slot arrangement can be used. Feeding circuits for the rotating mode excitation are a cum-shaped phase shifter and a cavity resonator at the feeding point (Sumiyoshi et al. 1993; Arai and Goto 1995). Another feeding circuit consists of a coplanar waveguide (CPW), ring slot, and cavity, which is planar and suitable for integrating and minimizing even in a millimeter-wave band. The experimental results agree well with the simulation (Sudo et al. 2007; Ronghong et al. 2001). Matching slots are also used for small aperture CA-RLSA. In contrast to large aperture RLSAs based upon continuous source model, the parameters of discrete slots in

DOI 10.1007/978-981-4560-75-7_62-1

the finite aperture are directly determined for uniform excitation. A very high efficiency of 85 %, and 82 %, is measured for 24-cm and 16-cm-diameter antennas, respectively (Akiyama et al. 1988).

The design of slot arrangement was investigated by a measurement-based method (Sasazawa et al. 1988), and then the slot coupling to the radial waveguide was approximated as a parallel plate waveguide with a periodic boundary condition to simulate a sectoral region of the circular aperture in an RLSA. A set of integral equations for the fields in the slot is derived, based on the field equivalence theorem, and is solved numerically by Galerkin's method. Theoretical results effectively express the measured effects of the various antenna design parameters on the slot coupling (Hirokawa et al. 1990). Using the wall impedance approach, the analysis of a single-layered RLSA is divided into two separate problems of the cavity and its external environment. A field matching method is described to analyze a recessed circular cavity radiating into a radial waveguide. This analysis was developed for linearly polarized RLSA (Bialkowski et al. 2002). The full-wave analysis and design of RLSAs was given by MoM-based software (Takada et al. 1997; Albani et al. 2006, 2009). The linearly polarized RLSAs are also applied to full-wave analysis for beam-tilting pattern (Herranz et al. 2010). Although slot antennas are usually modeled as perfectly electric conductors, for accurate antenna design and optimization, ohmic loss effects cannot be neglected. This is especially true in millimeter- and submillimeter-wave applications; Green's functions accounting for the finite conductivity of metals are derived analytically and used in the MoM admittance matrix expressions. Several RLSA realizations are analyzed to investigate the effect of ohmic losses in a practical antenna design (Mazzinghi et al. 2010; Albani et al. 2011).

The RLSA has been developed for DBS applications; however, the other is the antennas in millimeter wave bands. The conventional structure is composed of three separate parts, two conducting disks, and a foaming dielectric material, while another is a PTFE substrate for mass production. The antenna characteristics are measured in the 60-GHz band, and an excellent efficiency of 50 % at 33 dBi is obtained (Akiyama et al. 2000). A single-layered RLSA etched on a substrate and fed by a rectangular waveguide is also presented in the 60-GHz band. The antenna has rectangular waveguide feed structure using a rectangular waveguide-to-radial line transition. The prototype antenna of 10-cm diameter was tested and the gain of 30 dBi was measured at 60 GHz (Kim et al. 2002). At a 270-GHz band, the RLSA is integrated in low-temperature co-fired ceramic (LTCC). The impedance matching is enhanced by loading each radiating slot individually with a strip pair and employing an integrated feeding transition to an external standard waveguide in measurement. The antenna prototype exhibits boresight gain of 27.6 dBi with a 3-dB gain bandwidth of 9.8 GHz (Junfeng et al. 2013). Lightweight RLSAs with honeycomb-type parallel plate are also designed and demonstrated for a satellite on board antenna with a diameter of 900 mm, weight of 1.16 kg, and high gain of 44.6 dBi at 32 GHz (Nguyen et al. 2013).

Array Design

The radiation pattern of RLSA is designed by slot arrangement on the radial waveguide. Amplitude and phase of each slot are adjusted to obtain a required pattern and polarization. A popular application of high-gain circular polarization is given by a pair of nonresonant slots cut on the radial axis with orthogonal angles and quarter guided wavelength ($\lambda_g/4$) spacing as shown in Fig. 2. The λ_g is larger than the wavelength in free space not to excite grating lobes, and a slow-wave structure is inserted between the top and bottom plate. The nonresonant slot is used to control its excitation coefficient in wide range and the orthogonal slot and $\lambda_g/4$ spacing is determined to excite circular polarization. The $\lambda_g/4$ spacing also satisfies the reflection cancelation by the reflected waves from both slots with out of phase. A slot pair on the axis ρ is cut with the angle of $\pm 45^\circ$, and the directions of radiating electric fields are denoted as E_1 and E_2. The phase of E_2 delayed in $\pi/4$ gives the clockwise polarization location, while a slot pair on the axis ρ'

DOI 10.1007/978-981-4560-75-7_62-1

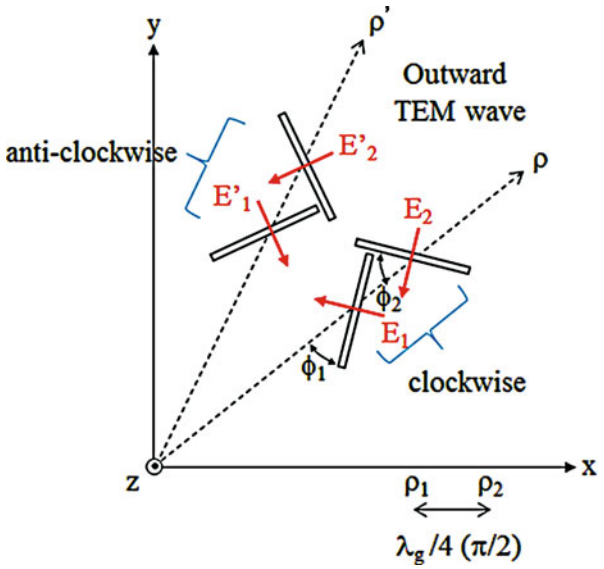

Fig. 2 Geometry of slot arrangement

is for the anticlockwise one. As shown in Fig. 2, the angle of slot cut, ϕ_1 and ϕ_2, determines the right- or left-handed circular polarization.

The coupling factor of the slot depends on the magnetic field strength parallel to the slot propagating inside the radial waveguide. A large number of slot pairs for a pencil boresight beam give very small difference in their amplitude excitation coefficient for a quarter wavelength distance along the radial direction, and then a pair of slots is designed as the same length. The array parameter S_φ and S_ρ are less than λ_g not to excite grating lobes. The slot pairs are placed on a spiral to provide the phase difference between adjacent ones to keep rotational phase angle for the circular polarization. The direction of TEM wave propagating inside radial waveguide changes the right- or left-handed circular polarization. The slot arrangement in Fig. 3 gives right-handed circular polarization for outward propagation wave. The spiral arrangement parameter is given by the position of slot pair along the ρ axis to satisfy the condition of $(\rho'_1 - \rho_1)/\lambda_g = (\Phi_2 - \Phi_1)/2\pi$ for the circular polarization as shown in Fig. 4.

The aperture distribution is designed based on the traveling-wave excitation inside radial waveguide. The amplitude of nonresonant slot pair is controlled by the length, which causes phase shift by the radiation from slots and requires the phase control for uniform phase distribution. The phase between adjacent slot pairs is controlled by its spacing. A theory of the slot design for uniform aperture distribution proposed in (Takahashi et al. 1991) is given in the following procedure. As the first step, a unit slot pair is characterized by a parallel plate waveguide with periodic side wall conditions. Assuming of no reflections from slot pairs, an incident unit power is split into the slot radiation $1-\exp(-2\alpha S_\rho)$ and the transmission $\exp(-2\alpha S_\rho)$, where α and S_ρ are a coupling factor and a spacing between slot pairs along the ρ axis, respectively. The phases of the radiated and transmitted field are denoted as Φ and $-k_o S_\rho/\zeta$ by expressing the slow-wave factor as ζ. The coupling factor α for desired aperture distribution is derived as a function of slot location ρ as shown in Fig. 5a, where the antenna radius of 0.3 m and the power dissipation of 15 % at the termination are assumed at 12 GHz. This curve is determined not to disturb the rotational symmetry of the field excessively. The slot length and position are determined by nonuniform array designs, assuming the variation of these parameters is very small (Hirokawa et al. 1992). Once the slot position ρ_s is set, the coupling factor $\alpha(\rho_s)$ (m) is given by the solid curve denoted as (i) in Fig. 5a; the slot length L_s/λ_o is chosen by the dashed curve as (ii). The slow wave factor ζ and the phase Φ of the radiated field are obtained in Fig. 5b. This procedure is repeated by the end slot. As the last adjustment, all the slot pairs are

DOI 10.1007/978-981-4560-75-7_62-1

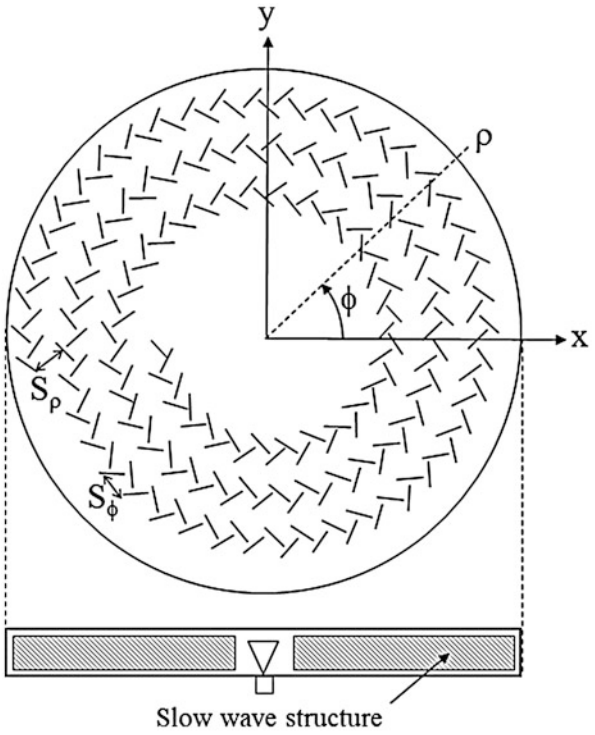

Fig. 3 Spiral slot array for circularly polarization

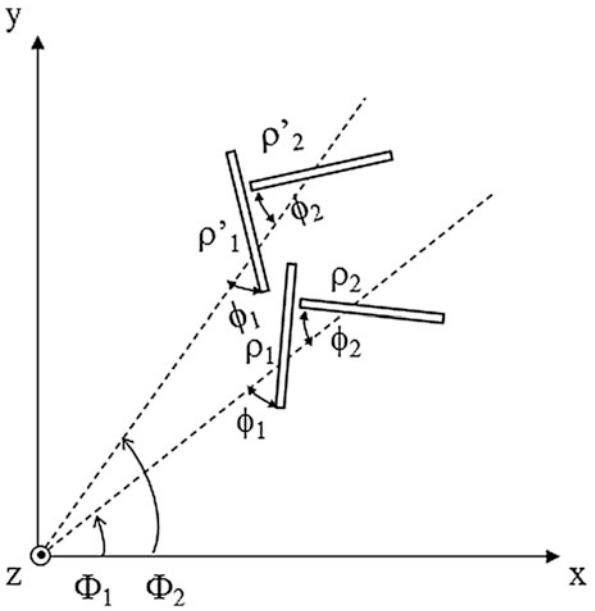

Fig. 4 Slot parameters for circularly polarization

shifted to compensate the phase Φ to obtain uniform phase distribution. This procedure is also applied to a Taylor distribution to suppress the sidelobes (Takahashi et al. 1997; Hirokawa and Ando 2000).

Small-sized aperture antennas have a problem to obtain uniform amplitude distribution by strong excitation of slots near the waveguide center. Another slot arrangement is given by concentric array as

DOI 10.1007/978-981-4560-75-7_62-1

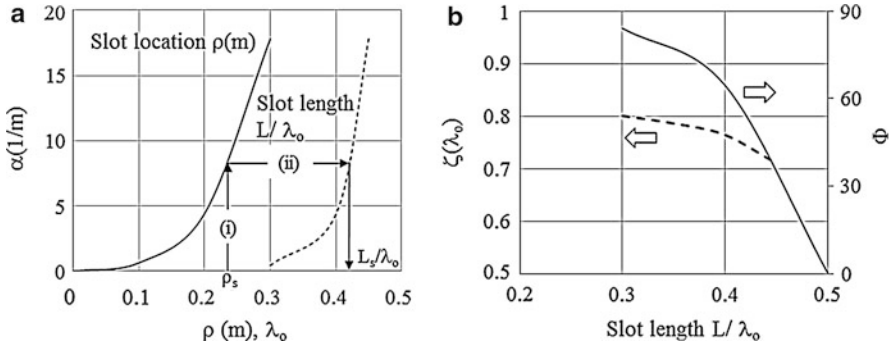

Fig. 5 Slot design parameters, (**a**) coupling factor, (**b**) slow-wave factor

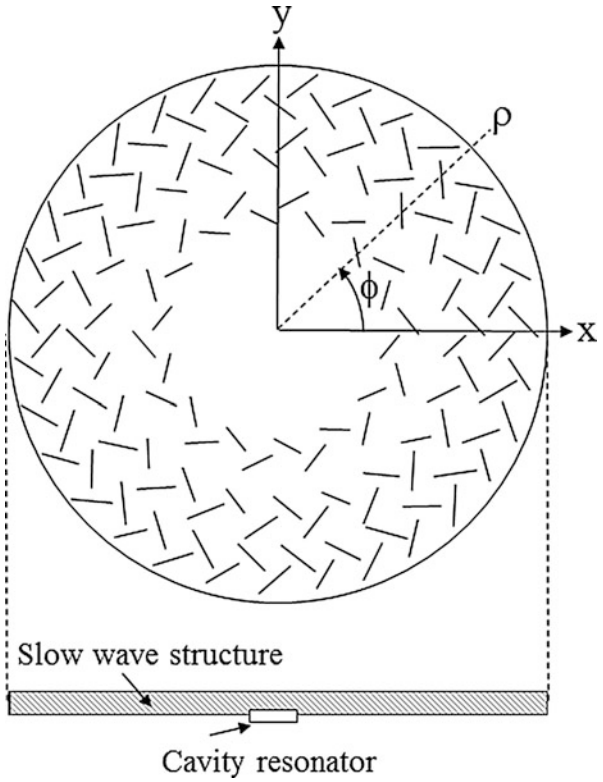

Fig. 6 Concentric slot array

shown in Fig. 6. The slot pairs are arrayed on concentric rings to keep the rotational symmetry and uniform aperture distribution along radial direction. This array needs feed circuits to excite rotating mode in azimuth direction. The feeding structures for this mode excitation are a cavity resonator (Arai and Goto 1995) and a ring or crossed slot cut on the bottom plate (Kigure et al. 1998; Sudo et al. 2002). The concentric array provides a conical beam by the TEM wave excitation inside waveguide. A probe feed at the waveguide center same as the spiral arrangement array is also used.

A linear polarized RLSA is given by the slot arrangement as shown in Fig. 7 (Ando et al. 1988). A slot pair is placed with $\lambda_g/2$ spacing to make the x-directed linear polarization given as the sum of E_1 and E_2. Slots on the x axis parallel to x direction are not coupled to propagating wave, and only y-directed ones radiate in the boresight. The $\lambda_g/2$ spacing of slot pairs degrades input impedance matching at the feed due to reflection waves from the slot in phase, and then reflection-canceling slots, a slot pair with $\lambda_g/4$ spacing,

are introduced to improve input reflection performance (Takada et al. 1992). A tilted beam is also effective to suppress the reflections (Takada et al. 1988).

Other radiating elements for radial waveguide are a helical and a microstrip antenna for circular polarization (Nakano et al. 1992; Shibata et al. 1993). Each antenna element is excited by different length probe for amplitude control, and the phase is changed by its rotation angle. Figure 8 shows RLSA with microstrip antenna radiating elements. The fine-tuning of aperture distributions is easy by adjusting two excitation parameters.

DOI 10.1007/978-981-4560-75-7_62-1

RLSA Applications

RLSAs were introduced for high-density plasma sources of the electron cyclotron resonance (ECR) plasma system, providing low-profile antenna structure, high-power handling capability, and uniform aperture field distribution (Takahashi et al. 1993). The RLSA system eliminates a uniform and strong magnetic field generated by a coil outside the vacuum chamber which has been used for horn antenna systems to improve the uniformity of the plasma on a wafer. The RLSA in a cylindrical vacuum chamber was used in the plasma process (Ohmi 1997). Microwave energy is radiated into the vacuum chamber through a quartz glass. The measured electron density is raised more than 10^{12} cm^{-3}. The plasma is excited by the surface of the glass wafer plate and diffuses towards the electrode. The electron density below the quartz glass surface is far beyond the cutoff density. Microwave incident on the plasma is completely dissipated by high-density plasma near the quartz plate.

The radial line slot antenna provides high-density plasma system at a temperature of 400 °C as an advanced gate dielectric film, resulting in low density of interface trap and bulk charge, lower leakage current than jet vapor deposition silicon nitride, and thermally grown silicon oxide with same equivalent oxide thickness. It raised breakdown field intensity with no stress-induced leakage current, very little trap generation even in high-field stress, and excellent resistance to boron penetration and oxidation (Sekine et al. 2000).

For high-power microwave applications, RLSA is fed from a double-layered radial line waveguide to realize the directional radiation with high efficiency. A reflection-canceling slot is added to improve the antenna impedance matching. An antenna operating at 9.42 GHz was designed with a length of 15 cm and an aperture radius of 27 cm; the high-power experiment proves that this antenna has a power-handling capacity of more than 1 GW (Cheng et al. 2013).

For an application of near-field focusing, the RLSA is designed to control the side lobe level and beamwidth of the normal component of the electric field with respect to the radiating aperture. The requirements on the near-field pattern are provided over a focusing plane at a given distance from the radiating aperture. A set theoretic approach is then used to derive the aperture field distribution fitting the requirements over the near field. Then, the aperture field distribution is synthesized by accurately placing and sizing the slots of the antenna. The spillover efficiency is maximized during the design process. The antenna is centrally fed by a simple coaxial probe. The antenna design is validated by a prototype and measurements at 12.5 GHz (Ettorre et al. 2014).

Summary

This chapter described the development history, the theory, and application of RLSAs. The unique features of RLSA are a simple feeding circuit and hundreds of radiating elements. The array parameters are designed by several approximate methods and also by full-wave analysis to control precisely. The low transmission loss waveguide is the advantage of this antenna, which provides high-gain antennas in high-frequency range and expands the application in wide areas.

Millimeter-Wave Antennas and Arrays

Wonbin Hong*
Samsung Electronics, Suwon, Republic of Korea

Abstract

The growing interest associated with exploiting the millimeter-wave spectrum for future wireless communication devices and networks has rendered the ensuing need for in-depth research and development of advanced millimeter-wave antennas. This chapter provides an overview of the background and motivation of ultrafast, low-latency millimeter-wave wireless applications as well as key characteristics of the spectrum. Major antenna design considerations and techniques are introduced and discussed in detail. The discussion is followed with state-of-the-art millimeter-wave antenna design techniques applicable to next-generation wireless devices. The chapter is concluded with discussions of future directions.

Keywords

Millimeter waves; Planar antennas; Beam steering; Phased array; 60 GHz; 5G communications

Introduction

Millimeter waves (mmWaves) are collectively defined as frequency spectrums in which the free-space wavelength can be described using millimeter units. Formally denoted as an extremely high frequency (EHF) by the International Telecommunications Unit (ITU), the spectrum ranges from 30 to 300 GHz. The very concept of mmWave radio technology commands over a century-long history with early applications in radio astronomy and military applications half a century ago. However, to the majority of the demographic, mmWave remained a distant, obscure terminology until recent years.

It was not until the relatively recent remarkable technological advancements in silicon and compound semiconductors, coupled with the relentless demand for sophisticated wireless data infrastructure, that mmWave technologies gained traction among diverse technology circles. As of present, potentially disruptive technologies, such as extreme high-data-rate low-latency wireless communication (Chen and Niknejad 2011; Emami et al. 2011; Ghosh et al. 2014; Roh et al. 2014; Talwar et al. 2014), advanced resolution radar imaging (Valdes-Garcia et al. 2013), and inter- and intra-chip communication networks (Baek and Hong 2013), are primary examples of how mmWave radio and radars are reshaping the paradigm of wireless technologies. For each of these applications, increasing the operating frequency by several orders of magnitude is a viable and an effective solution to the current worldwide frequency spectrum overcrowding issues below 6 GHz. Moreover, the channel capacity denoted in bits per seconds established in the classical work by Shannon and Hartley (Shannon 1948) is directly proportional to the channel bandwidth. For instance, the short-range, high-data-rate IEEE 802.11ad WiGig standard can achieve PHY (physical layer) rates that are ten times or more higher than conventional Wi-Fi by utilizing more than 2 GHz of channel bandwidth centered around the unlicensed 60 GHz IMS (industrial, medical, scientific) band. The latest 4G Long-Term Evolution (LTE) cellular technology continues to become

*Email: wonbin.hong@samsung.com

DOI 10.1007/978-981-4560-75-7_64-1

increasingly sophisticated and efficient using innovative technologies such as carrier aggregation (CA), single-user and multiuser multiple-input multiple-output (SU-MIMO/MU-MIMO), and heterogeneous networks (HetNets) using macro and small cells. Encouraged by notable advancements in cost-efficient mmWave RFIC technologies (Natarajan et al. 2009; Cohen et al. 2013; Tsukizawa et al. 2013; Kong et al. 2013; Bereka et al. 2014; Okada et al. 2014), ultra-wideband mmWave wireless communication technologies that can augment LTE networks are being actively researched and experimented by numerous research institutions and private sectors (Sun et al. 2014; Taori and Sridharan 2014; Chin et al. 2014; Hong et al. 2014a). By exploiting the large available bandwidth at mmWave, low real-time latency access and backhaul networks with more than 10 Gbps peak data rates are projected to be the backbone of future fifth-generation wireless communications.

The benefits of mmWave technologies do not come without challenges. The inherent difference at mmWave compared to frequencies below 10 GHz demands unique design considerations in hardware circuitry. The antenna is one of the most critical elements that affect the overall performance of mmWave radios. In this chapter, section "Theory" will first discuss and understand the unique nature of mmWave spectrum and major factors that must be taken into consideration during the antenna design. Afterward, key mmWave design techniques and schematics will be presented in detail in section "Key mmWave Antenna Design Techniques". Section "Notable mmWave Antenna Applications" will exemplify notable mmWave antenna topologies currently employed in high-volume applications such as consumer electronics and will discuss the top-down design process. Section "Conclusion" presents a number of important future trends in mmWave antenna technology, and the chapter is concluded.

Theory

Key Properties of mmWaves

At mmWave spectrum, there are several notable loss factors that will significantly affect the behavior of radio transmission and reception. A number of key propagation loss factors that affect radio signal transmission and reception in the following will be first identified and discussed.

Free-Space Propagation Loss

Free-space propagation loss is defined as the propagation loss that is dependent on the distance and operating frequency of two isotropic transmit and receive antennas. Equation 1 describes the free-space propagation loss in closed-form expression,

$$\text{Free} - \text{Space}\ \ \text{Propagation}\ \ \text{Loss} = \left(\frac{4\pi R}{\lambda}\right)^2 \tag{1}$$

where R is the distance between transmit and receive antennas and lambda is the free-space wavelength at the operating frequency. Equation 1 can be rewritten in dB scale and frequency for better understanding as shown in Eq. 2:

$$\text{Free} - \text{Space Propagation Loss}\ (\text{dB}) = \ 20\log F + 20\log R + 92.4 \tag{2}$$

where frequency F is expressed in GHz and distance R is expressed in kilometers (km). It can be intuitively interpreted that the free-space path loss will increase in logarithmic scale of the operating frequency. The effect of free-space propagation loss on the radio link budget can be visualized using the following Eq. 3, where P_{RX} is defined to be the receiving power (dB) and P_{TX} is defined to be the transmitting power (dB):

DOI 10.1007/978-981-4560-75-7_64-1

$$P_{RX} = P_{TX}\left(\frac{\lambda}{4\pi R}\right)^2 \tag{3}$$

Precipitation Loss

At mmWave frequencies, the sizes of the raindrops are typically within several multitudes of the free-space wavelength. This causes noticeable scattering during radio signal transmission in the presence of rain. Figure 1 presents the radio signal attenuation per kilometer (*km*) as a function of rain rate and rain intensity. As it can be observed, radio signals below 10 GHz generally experience limited levels of attenuation as a function of rain rate. In contrast for mmWave radio transmission, the specific region and the yearly rain rate must be taken into account from the beginning of the signal link budgeting and the antenna design as this is one of the major factors that account for signal fading.

Atmospheric Absorption and Gaseous Loss

Atmospheric constituents tend to absorb radio signals at much higher rates at mmWave frequencies compared to lower microwave frequencies. This tendency is loosely proportional to signal frequency, and a number of notable attenuation peaks can be observed as presented in Fig. 2. This can be explained by the natural mechanical resonance behaviors of oxygen (O_2) molecules and water (H_2O) molecules at certain mmWave frequencies. For example, the oxygen absorption rates at 30 and 60 GHz are 0.02 and 15 dB/km, respectively. The O_2 molecules reach maximum absorptions around 60.3 GHz. The inherent nature of severe gaseous losses at certain mmWave frequencies are the primary factors behind majority of the devised close-range communication scenarios. Otherwise, spectral regions within the mmWave frequency bands with limited gaseous losses commonly denoted as "atmospheric windows" are utilized for transmissions requiring midrange and above scenarios.

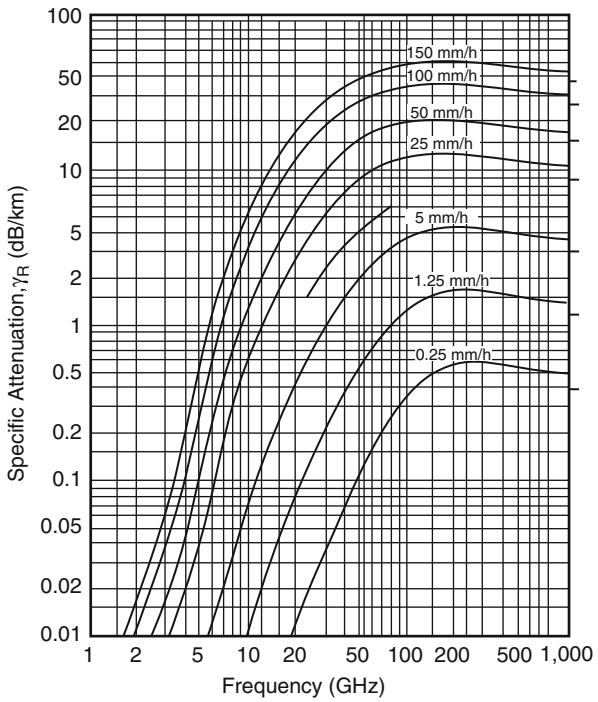

Fig. 1 Precipitation loss as a function of rain rate (Marcus and Pattan 2005)

DOI 10.1007/978-981-4560-75-7_64-1

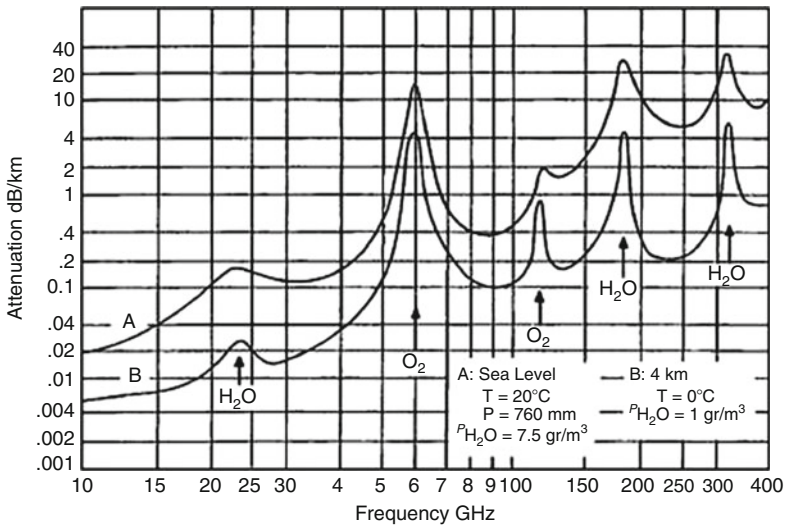

Fig. 2 Atmospheric absorption (Marcus and Pattan 2005)

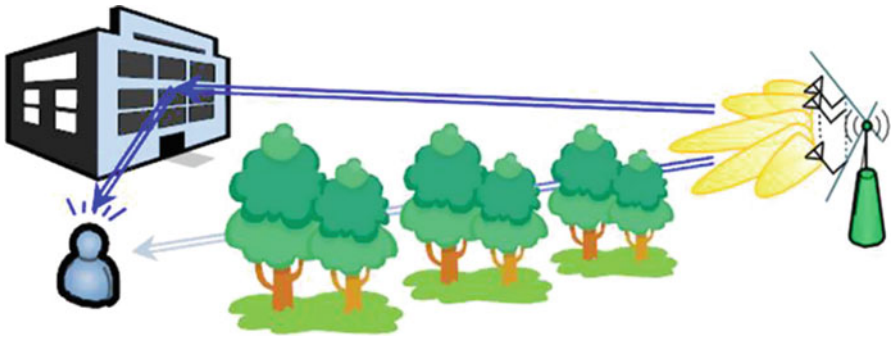

Fig. 3 Illustration of foliage loss

Foliage Loss

Losses incurred by foliage can significantly affect long-term fading of the mmWave channel. Foliage loss illustrated in Fig. 3 is dependent on the density of the foliage, the tree species, humidity, etc., and non-negligible (Marcus and Pattan 2005). The empirical foliage loss can be expressed as Eq. 4 as follows where f is defined as the operating frequency in MHz and D is denoted as the depth of foliage transverse in meters when $D < 400$ m:

$$L_{foliage} = 0.2f^{0.3}D^{0.6} \text{ dB} \tag{4}$$

Material Loss

It is imperative to carefully consider signal attenuation loss incurred by various materials during the design stage. With few exceptions, radio signals beyond 5 GHz are subject to an exponential increase in attenuation as the signal waves propagate through the stated material. This tendency is presented in Fig. 4. Consequently, proper material selection becomes one of the most critical design aspects for mmWave antennas as the material composition of the antenna substrate, the radome, and the connectors is closely linked to the radiation efficiency. Furthermore, the importance of low-loss interconnects and antenna feeding and packaging technologies is emphasized to minimize attenuations of hard-fought mmWave

DOI 10.1007/978-981-4560-75-7_64-1

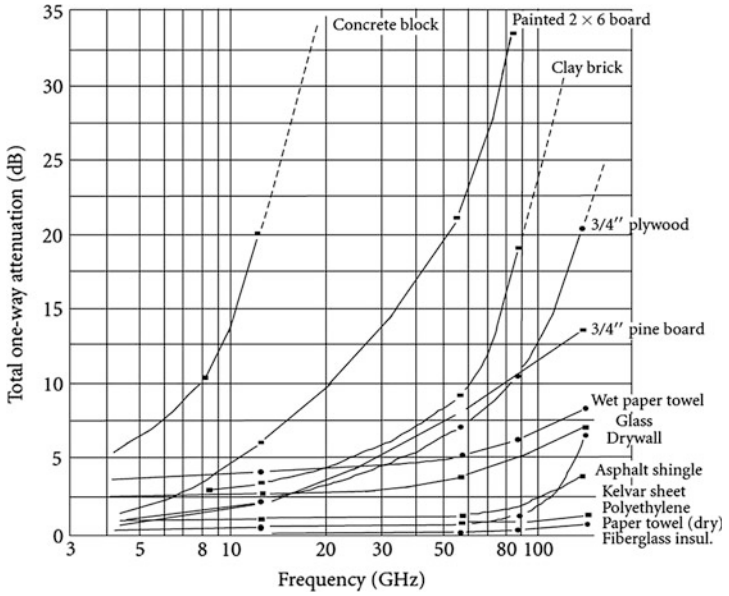

Fig. 4 One-way signal attenuation as a function of frequency

signals that were received and generated by the antenna and the RFIC, respectively. It is imperative that antenna and mmWave radio link designers must be accurately aware of the loss tangent properties of materials that the radio waves are likely to encounter during propagation scenarios. As it is not common for majority of the material vendors and manufacturers to possess material properties beyond 10 GHz, permittivity and loss tangent extraction and calculation techniques (El Sabbagh et al. 2004; Fratticcioli et al. 2004; Fang et al. 2004) must be considered and selectively applied for each design scenario.

Antenna Gain

As it can be observed from the previous subsection, notable levels of signal attenuation from numerous factors are one of the most compelling properties at the mmWave frequency spectrum. In order to establish successful radio transmission, the collective signal attenuation must be less than the radio link budget. The radio link budget can be expressed as described in Eq. 5 below:

$$\text{Radio Link Budget (dB)} = \text{PTX} + \text{GTX} + \text{GRX} - R_{\text{sensitivity}}\ \text{(dB)} \tag{5}$$

$R_{\text{sensitivity}}$ is defined as the minimum received power that is detectable for the specified bit error ratio (BER) or packet error ratio (PER). $R_{\text{sensitivity}}$ incorporates the various signal attenuation loss factors described earlier. The term should not be confused with the receiver noise figure or the signal-to-noise ratio (SNR) as these terms are also inclusive of the $R_{\text{sensitivity}}$ calculation. The designing of the mmWave RX antenna is closely related to $R_{\text{sensitivity}}$ as the signal attenuation loss in the antenna feedlines degrades the noise figure of the receiver. PTX is defined as the transmit power and can be understood as either the total power transmitted at the TX antenna port or the total power generated by the power amplifier. In general, the amplitudes of the two tend to be different as internal signal losses such as routing losses between the power amplifier and the TX antenna or switch and duplexer losses tend to be non-negligible at mmWave frequencies. Conclusively speaking, maximizing the radio link budget (dB) is the principal priority in mmWave radio system design.

DOI 10.1007/978-981-4560-75-7_64-1

Based on Eq. 5, increasing P_{TX} is an intuitive method in achieving the desired radio link budget and mmWave radio signal coverage. However, it remains an extremely difficult technical challenge to achieve an ideal balance between permissible levels of power consumption and power-added efficiency (PAE) using present-day semiconductor technologies. The scarcity of available power consumption capacity is evidently rampant particularly in the consumer electronics arena. For example, the recent design trend featuring continuously improved hardware capacity for slimmer smartphones results in significant strain on realizing improved battery life for mobile and wearable devices. Utilizing III–V compound semiconductor technologies in conjunction with CMOS processing for better RF output power and efficiency at mmWave can potentially alleviate this constraint. However, identifying cost-effective fabrication and packaging schematics remains a pertinent issue at present.

The significant power constraints related to PTX exemplifies the importance of antenna gain at mmWave frequencies. For better understanding of the effect of the antenna gain, Eq. 3 can be reorganized to be function of the antenna aperture as presented in Eq. 6:

$$P_{RX} = P_{TX}\left(\frac{1}{4\pi R^2}\right)\left(\frac{\lambda^2}{4\pi}\right) \tag{6}$$

For resonant antennas, the apertures of mmWave antennas are within the sub-mm and mm range, which are typically a fraction of low-microwave-frequency antenna apertures. This decrease in antenna aperture at mmWave naturally results in smaller captured energy at the receiver side which explains the inverse relationship between P_{RX} and antenna operating frequency. Employing omnidirectional antennas similar to those that are typically used for Wi-Fi and cellular communications, the relatively small antenna gain combined with signal attenuation loss at mmWave can potentially reduce received signal power levels in the orders of 20log$F$ where F is operating frequency in GHz. For example, for identical P_{TX}, the P_{RX} at 30 GHz will be 20 dB less than that at 3 GHz. Consequently, these design parameters become significant limiting factors in transmitting and receiving radio signals beyond very close range, line-of-sight (LoS) distance. This phenomenon justifies many of the mmWave applications designated for reactive and Fresnel zones for which the antenna design aspects will be discussed later in this chapter. Evidently, the mmWave antenna aperture becomes an ever-important piece in the puzzle. As antenna aperture is directly linked to its directivity and gain, Eq. 6 can be rewritten in the form of Friis transmission formula as shown in Eq. 7:

$$P_{RX} = P_{TX}G_{TX}G_{RX}\left(\frac{\lambda}{4\pi R}\right)^2 \tag{7}$$

G_{TX} and G_{RX} are denoted as the respective antenna gain for transmit and receive antennas. Furthermore, Eq. 7 can be reorganized to illustrate how transmit and receive antenna apertures affect P_{RX} as shown in Eq. 8 where $A_{e,\,Tx}$ and $A_{e,\,Rx}$ are defined as the effective antenna aperture for transmit and receive antennas, respectively:

$$\begin{aligned} P_{RX} &= P_{TX}\left(\frac{4\pi A_{e,Tx}}{\lambda^2}\right)\left(\frac{4\pi A_{e,Rx}}{\lambda^2}\right)\left(\frac{1}{4\pi R^2}\right)\left(\frac{\lambda^2}{4\pi}\right) \\ &= P_{TX}A_{e,Tx}A_{e,Rx}\left(\frac{1}{\lambda^2 R^2}\right) \end{aligned} \tag{8}$$

DOI 10.1007/978-981-4560-75-7_64-1

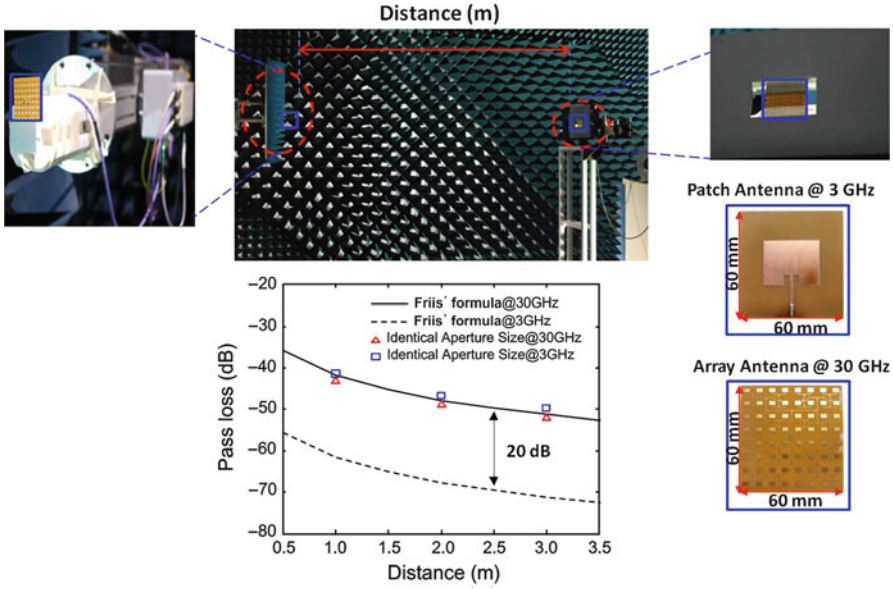

Fig. 5 Demonstrating the effectiveness of increasing the antenna aperture

From Eq. 8, P_{RX} can be interpreted as the product of the effective apertures of the two antennas and is inversely proportional to the square of the operating frequency and communication distance. Figure 5 illustrates a simple demonstration of the effectiveness of increasing the antenna aperture at mmWave. As an example, a rudimentary patch antenna at 3 GHz is designed. When applying an identical patch antenna topology at 30 GHz, the antenna aperture would decrease in accordance to the square of the antenna scaling factor, eventually resulting in a 20 dB difference in P_{RX}. However, by designing an antenna topology at 30 GHz which features an antenna aperture size that is identical to that at 3 GHz, the consequent antenna gain enhancement compensates for the inherent path loss difference associated within $R_{\text{sensitivity}}$ as described earlier. This demonstration underlines the critical importance of exploiting numerous antenna gain improvement design methodologies for mmWave communications. It also explains why majority of mmWave antenna designs employ various aperture and phased-array antenna design schematics. At mmWave frequencies, losses within the antenna substrate material interconnect insertion losses and polarization mismatch can be mostly attributed to the reduction in antenna gain.

Antenna Radiation Characteristics

The antenna gain is inherently dependent on the directivity of the antenna. The antenna directivity is defined to be the ratio of the radiation intensity in a given direction (θ,φ) in the far-field region to the radiation intensity value which is averaged over a surface area of sphere. Resonant-type or electrically small antennas tend to radiate equally in all directions and effectively have very low directivity which is close to 1 in amplitude or 0 dBi. For applications where the antennas mostly operate within the near-field or very close range, the directivity of mmWave antennas is less of a design priority. In contrast for scenarios where the mmWave transmitter and receiver are separated by more than a few meters in distance, the directivity of the antenna plays a substantial role in establishing a radio link. It is possible to categorize how the antenna radiation characteristics affect the overall quality of mmWave radios based on the deployments of the transmitter and receiver.

DOI 10.1007/978-981-4560-75-7_64-1

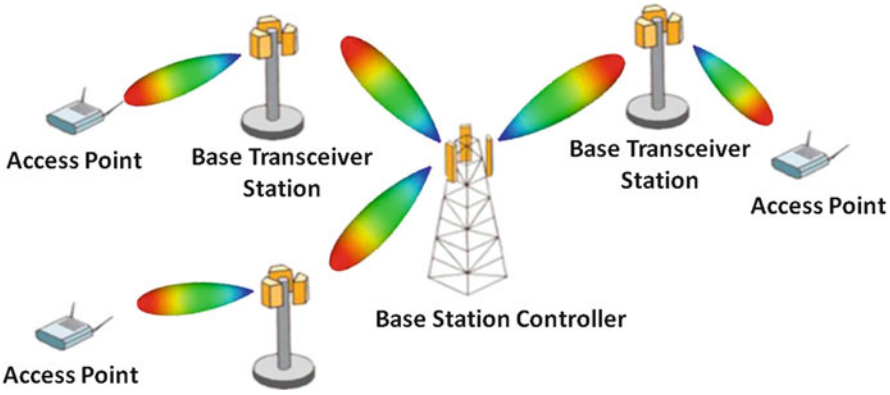

Fig. 6 Example of a mmWave fixed-beam application

Fixed-Beam Applications (Point to Point)

The RX and TX antennas are respectively configured based on careful radio link estimations using SNR, effective isotropic radiated power (EIRP), and received signal strength indication (RSSI). The deployments of the mmWave transmitter and receiver are carefully devised often using iterative ray tracing and channel propagation modeling and eventually set at stationary positions. Such deployment schematics are often used for close- and midrange network architectures such as mmWave backhaul/fronthaul as well as very close-range applications such as chip-to-chip (C2C) or board-to-board communication scenarios. An exemplary user scenario is illustrated in Fig. 6.

The beamwidth and directivity of the stationary mmWave antennas must be carefully designed to suppress unexpected misalignment between the transmitter and receiver. The sensitivity of the antenna misalignment for LOS communications becomes a greater issue as the communication range increases and the antennas become more directive. This becomes an important design consideration in particular due to the fact that majority of point-to-point mmWave communications are designed for outdoor environments where anything as subtle as wind, snow, birds, and any other expected environmental distractions can offset the antenna alignments by a few millimeters. The beamwidths of the mmWave antennas must be designed to withstand such degradations to preserve the quality of service (QoS). Some of the recent mmWave antenna designs for point-to-point communication circumnavigate this issue by employing precise mechanical beam steering. Electrical beam steering methods such as phased array are also being researched in recent years. However, interconnect losses between the antenna elements and the radio-frequency front end become increasingly problematic as the number of antenna elements increases.

Antenna Beamforming Applications Using Beam Steering

For situations where LOS environment propagation environments or point-to-point communication conditions cannot be guaranteed, it is essential to able to redirect the mmWave signals in order to search and reestablish a connection link within a very short time. Widely referred as to antenna beamforming technology, mmWave signals with narrow beamwidths generated by directive antennas are steered across the elevation and azimuth angle to transmit and receive radio signals using the most efficient propagation path. Antenna beamforming is highly effective for indoor environments where there tends to be limited wall penetrations, high absorptions, and various multipaths due to signal reflecting off furniture, ceiling, humans, etc., at mmWave spectrum. Compared to frequencies commonly used for present-day cellular and Wi-Fi applications (below 6 GHz), radio waves and mmWave frequencies rely on reflection when establishing links for NLOS propagation conditions as illustrated in Fig. 7. Antenna beamforming is also a

DOI 10.1007/978-981-4560-75-7_64-1

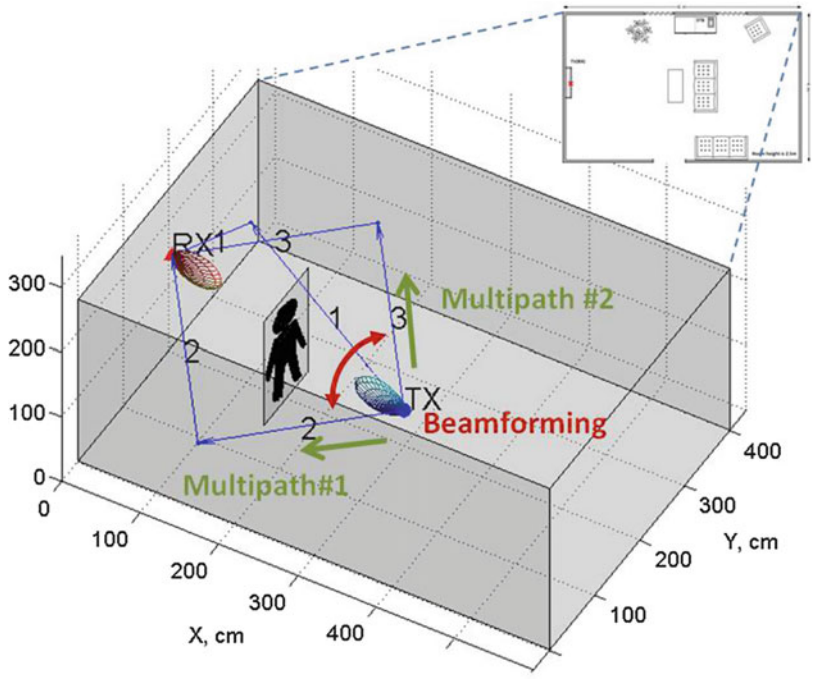

Fig. 7 Indoor mmWave beam steering scenario

critical and useful methodology for outdoor and indoor-to-outdoor applications. Obstacles such as pedestrians, vehicles, lightning posts, and foliage can instigate double knife-edge diffractions (Vogler 1982) causing "point of failures" in fronthaul, backhaul, and access networks. By spatially reusing the atmosphere, mmWave outdoor communication systems can not only circumvent signal blockage but also significantly enhance the network capacity and data rates.

Encouraged by the advancements of silicon technology and antenna packaging techniques, electrical beam steering has been increasingly favored over conventional mechanical beam steering at mmWave spectrum due to advantage in form factor, economic cost, and accuracy. Electrical beam steering can be broadly categorized into two techniques as follows:

Switched Beam Steering Switched beam steering techniques combine the radio wave signals in the array using a fixed set of weight vectors and time or phase delays. This is widely used for access points and cellular base stations where the direction of arrival (DoA) is well understood. Each antenna element must be designed to the radiation within a predefined "sector of coverage" and oftentimes utilize active RF components, such as switches, MEMS, combiners, etc., for real-time beam steering. Due to the small antenna aperture at mmWave frequencies, the overall antenna dimension employing switched beam steering can be advantageous for maximized far-field radiation coverage as illustrated in an example in Fig. 8. mmWave sub-array schematics can be employed to enhance the directivity targeted for each sector. Similar to point-to-point communication applications, the directivity of the mmWave antenna must be carefully designed to avoid unexpected nulls in the combined far-field radiation patterns. This is especially the case for military and space applications where design tolerances are usually very tight. However, for commercial mmWave applications, such as mmWave access points and sensors, the antenna pattern requirements are typically lower. Low cost, design complexity, ease of manufacturing, and form factor must be carefully considered. An antenna array with simplified corporate feeding networks (Pozar 1992), sub-array overlapping, or interleaved array arrangements (Abbaspour-Tamijani

DOI 10.1007/978-981-4560-75-7_64-1

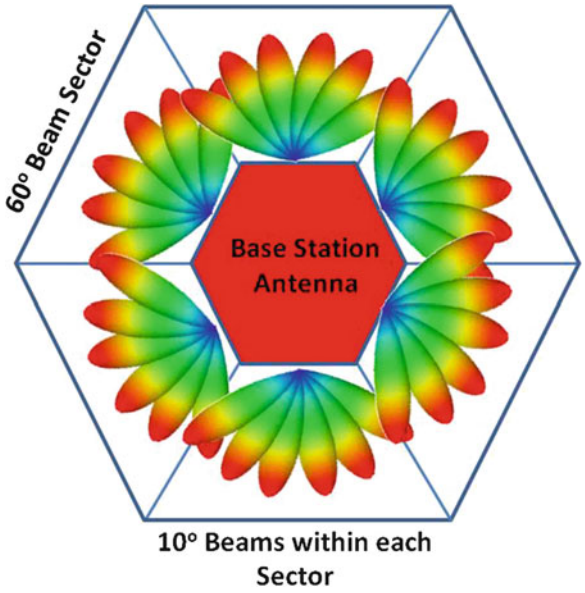

Fig. 8 Sectorized switched beam steering

and Sarabandi 2003) can be very instrumental in reducing the number of active RF components. For interleaved mmWave array, the mutual loading between adjacent antenna elements is dependent on the state of the antenna beam and methods to mitigate the mutual coupling effects must be taken into consideration. Furthermore, fixed beam steering techniques can be applied in conjunction with adaptive beam steering for mmWave applications requiring beyond long-distance coverage and wide beam steering range.

Adaptive Beam Steering Initially developed in the 1960s for military applications such as sonar and radar, adaptive beam steering was initially devised to mitigate the effect of signal jamming. The concept has continued to evolve over the decades and is now commonly defined as a technique to automatically adopt in real time based on predefined criterion to constructively combine the signals in a direction exhibiting the least amount of propagation attenuation.

A line array consisting of N number of identical point sources that are uniformly spaced as a function of d is represented in Fig. 9. Assuming that the array is receiving an incoming signal $S_n(t)$ at the strongest direction θ, the slanted angle θ introduces a delay in the time of arrival of the signal between the reference signal point source $P_0(t)$ and $P_m(t)$ denoted as τ where $\tau_n = n\tau$. τ is defined as

$$\tau = \frac{d \sin \theta}{c} \tag{9}$$

The received signals can be superimposed in a constructive manner in the direction of θ by subsequently adding true-time delays so that the signals arrive in a coherent manner. Then $S_n(t)$ can be expressed as follows in Eq. 10:

$$S_n(t) = S\left(t - \tau_n - \tau_{\text{shift},n}\right) \cos\left(\omega_{RF}\left(t - \tau_{\text{shift},n}\right)\right) \tag{10}$$

Majority of mmWave communication applications fit the model of narrowband conditions in which the frequency bandwidth is a fraction of the center frequency ω_{RF}. In such cases, the true-time delay can be approximated with a constant phase shift instead. Denoted as phased array (Natarajan 2007), Eq. 10 can

DOI 10.1007/978-981-4560-75-7_64-1

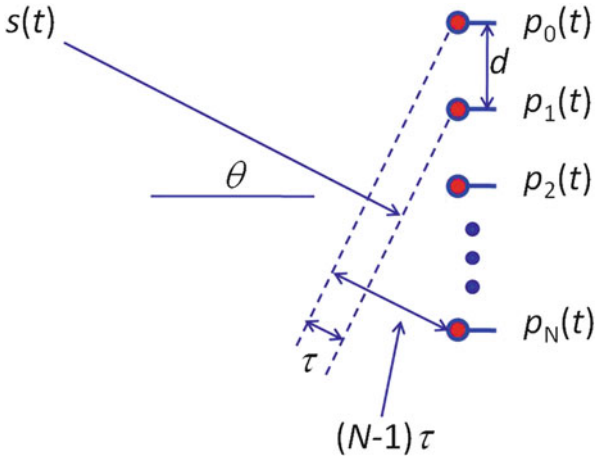

Fig. 9 An illustration of a uniformly spaced lined array

then be reorganized in the frequency domain and can replace the true-time delay with phase shifts φ_n at each point source. Then $S_n(t)$ can be expressed as follows in Eq. 11:

$$S_n(t) = S(t - \tau_n)\cos\left(\omega_{RF}(t - \tau_n) - \phi_n\right) \tag{11}$$

where φ is

$\phi_n = (N - n)\phi$

The total received signal of the phased array in the direction of θ can be expressed as the summation of $S_n(t)$ as follows in Eq. 12:

$$\begin{aligned} S_{\text{array}}(t) &= \sum_{n=0}^{N-1} S(t - \tau_n)\cos\left(\omega_{RF}(t - \tau_n) - \phi_n\right) \\ &= \sum_{n=0}^{N-1} S(t - n\tau)\cos\left(\omega_{RF}t - n\omega_{RF}\tau - (N - n)\phi\right) \end{aligned} \tag{12}$$

Assuming narrowband conditions,

$$S(t) \approx S(t - n\tau) \approx S(t - \tau) = S_0(t)$$

It is possible to rewrite S_{array} *(t)* as the following:

$$\left|S_{\text{array}}(t)\right| = \left|\frac{\sin\dfrac{N(\omega_{RF}\tau - \phi)}{2}}{\sin\dfrac{\omega_{RF}\tau - \phi}{2}} S_0(t)\right| \tag{13}$$

Equation 13 infers that for planar antenna arrays where $d > \lambda/2$, the far-field radiation pattern of the phased array will be subject to grating lobes. Phased-array antennas where $d << \lambda/2$ can potentially result in excessive mutual coupling and introduce nonlinear terms in Eq. 13. Hence, it is generally the rule of thumb to approximately configure $d = \lambda/2$. The 3 dB beamwidth is dependent on N and θ and be approximated as in Eq. 14. Based on the rules of antenna reciprocity, the beam steering behavior remains identical during transmission mode:

DOI 10.1007/978-981-4560-75-7_64-1

$$BW_{3\text{dB}} = \frac{0.87\lambda}{Nd\cos(\theta)} \tag{14}$$

The derivation of the phased-array antenna pattern demonstrates that each phase shifter located at respective point sources must be variable from 0 to 2π to scan the main beam of the antenna array across the hemisphere (i.e., $-\pi/2 \leq \theta \leq \pi/2$). For practical use cases, the scanning angle of the main beam is reduced due to the rise in side lobes and can be detrimental in distinguishing the most coherent propagation path for beamforming algorithms using the maximum power criterion. The effect of antenna beam steering range and the beamwidth on mmWave beamforming protocols can be understood in a qualitative manner.

Figure 10 exemplifies a set of beamforming protocols for the 60 GHz-based IEEE 802.11ad standard which is devised for uncompressed high-definition (HD) video streaming and high-speed data transfer. Understanding the specifics of the protocol is beyond the scope of this handbook, and the readers are referred to Jo et al. (2014) for details. The basic principle of concept can be described as below:

- To define a set of antenna steering directions θ for **a spherical sector coverage**
  - To cover the given spherical sector with minimum antenna gain
  - To minimize the number of antenna positions used
- Then, the generated set of the antenna positions is applied at both TX and RX sides, and *an iteration over all mutual TX and RX antenna positions* from this set is used to define a combination giving the maximum transmission power.

The radiation patterns during the quasi-omnidirectional antenna configuration and directional TX/RX antenna configuration are highly correlated to the efficiency of the adaptive beam steering algorithm illustrated in Fig. 10. Oftentimes, it is necessary to introduce variations in the antenna beamwidth between the sector level sweep (SLS) and the beam refinement protocol (BRP) frame. A main beam of an $N \times M$ phased-array antenna can be characterized by its respective beamwidth BW_{ev} and BW_{az} in the elevation and azimuth plan as shown in Fig. 11. During the adaptive beamforming optimization process, the SLS frame initiates link detection by selectively training the TX and RX antenna. Antenna array configurations with predefined BW_{ev} and BW_{az} are used in search of the best sector. The BRP frame uses an iterative procedure to "train" the RX and TX antenna in identifying the optimal propagation path in that certain sector and oftentimes employ identical BW_{ev} and BW_{az} used during the SLS . In situations where the received power levels fall beyond the dynamic range of the wireless link budget, the protocol reverts back to the SLS frame using a refined main beam exhibiting different BW_{ev} and BW_{az}. The dynamic scalability of BW_{ev} and BW_{az} is correlated to the efficiencies of the SLS and BRP frames.

The steering angle θ must be designed to cover the maximum physically allowable range while minimizing the beam steering iterations for a timely transmit and receive training field (TRN-T/TRN-R). The resolution of the antenna array beam steering is a function of antenna spacing d and the angular resolution (or the number of maximum allowable bits) of the corresponding phase shifters. Pencil-beam and fan-beam antenna patterns are commonly preferred for mmWave-based adaptive beam steering for this matter. The final decision will be made based on the specific application.

Key mmWave Antenna Design Techniques

This section discusses a number of antenna design parameters and ensuing techniques that are particularly critical at mmWave frequencies. For wireless communication applications, low-profile antenna topologies

Table 1 Summarized comparison of mmWave antenna types

Antenna type	Ease of fabrication	Real estate	Gain	Bandwidth
Planar and printed antenna	Feasible	Small	Moderate	Narrow
Dielectric resonator antenna	Moderate	Moderate	Moderate	Low
Substrate-integrated waveguide antenna	Moderate	Moderate	Moderate	Large
Reflector antenna	Difficult	Large	High	Moderate
Slot antenna	Feasible	Moderate	Low	Moderate
Lens antenna	Difficult	Large	High	Narrow

are preferred due to its ease of fabrication, assembly, and integration with the rest of the wireless system. Oftentimes, the reduction of the antenna topology is realized at the cost of important antenna characteristics such as directivity, gain, and bandwidth. Therefore it becomes imperative to clarify the advantages and disadvantages of each antenna designs when faced with specific allowable antenna real estate. Fabrication and assembly cost is another important design consideration in consumer electronics and automobile industry and this is closely correlated to the selection and lamination of the antenna material and type of the antenna. To assist in designing the appropriate type of antenna for a specific application, several mmWave antenna types that are frequently used are illustrated and summarized in Table 1.

The aforementioned antenna types can be used independently or in a combination in the form of multipurpose antenna arrays. The design procedure can be collectively characterized as listed below:

1. Identify the target frequency of operation and required antenna bandwidth.
2. Determine the antenna gain utilizing the wireless link budget for a target communication distance and coverage.
3. Estimate the optimal directivity, radiation pattern, and polarization based on the environment encompassing the antenna.
4. Assess the maximum allowable antenna real estate and determine the best placement within the wireless device.
5. Assess the antenna feeding mechanism and calculate the feedline loss.
6. Select the type of antenna to be used for the specific application.
7. Choose the antenna substrate material, methods of packaging, fabrication, and integration with the mmWave RFIC.
8. Devise methods of antenna performance evaluation and identify design parameters for occasional fine-tuning.

DOI 10.1007/978-981-4560-75-7_64-1

In-depth discussions on the design procedure will be presented in the following subsections.

mmWave Antenna Packaging and Integration

Antenna Packaging

Methods of integrating the antenna with the rest of the wireless module are one of the most distinguishable differences between mmWave RF front ends and those designed at microwave frequencies (typically below 10 GHz). Antennas for preexisting wireless communications such as 3G/4G or legacy Wi-Fi are regarded as an independent design block within the entire wireless architecture. The antenna, RFIC, digital IC, and the subsequent interconnects are separately designed based on predefined and oftentimes standardized hardware interfaces. The antenna and RFIC are typically connected via industry standard interconnects such as coaxial RF connectors, surface-mount (SMT) contact clips, printed circuit board (PCB) lines, and RF switches that are frequently used in conjunction with external microwave matching networks. The major contributors to the insertion loss between the antenna and RFIC are input reflection coefficient properties and the dielectric loss of interconnect and the matching networks. However, this composition becomes problematic when the target operating frequency is located at mmWave spectrum as the insertion loss is increased dramatically compared to the microwave spectrum. Emphasis on containing the insertion loss of the interconnects between the antenna port and the RFIC pad becomes one of the primary concerns for mmWave antenna design. Hence, the basic rule of thumb for mmWave antennas is to minimize the physical distance between the antenna port and the RFIC pad.

In general, there are two major philosophies for mmWave antenna packaging – the system on chip (SoC) and the system in package (SiP). SoC antenna packaging is realized in the form of on-chip antennas which are directly incorporated within multilayer metals using silicon technologies such as CMOS or III–V semiconductors. An on-chip antenna configuration using 130 μm CMOS technology is exemplified in Fig. 12. CMOS implementations are advantageous over III–V technologies for its scalability, higher levels of integration with the rest of the microwave integrated circuits (MMIC), and lower cost. On the other hand, III–V technologies are superior in terms of higher electron mobility, power handling capacity, and lower substrate loss. The low resistivity of the substrate used for on-chip antennas is the primary attribution to its poor antenna gain and high insertion loss across the antenna feeding networks. The resistivity is in the orders of 10 Ω-cm for high-volume CMOS technologies and approximately in the orders of 10^7–10^9 Ω-cm for III–V technologies. mmWave antennas designed using low-resistivity

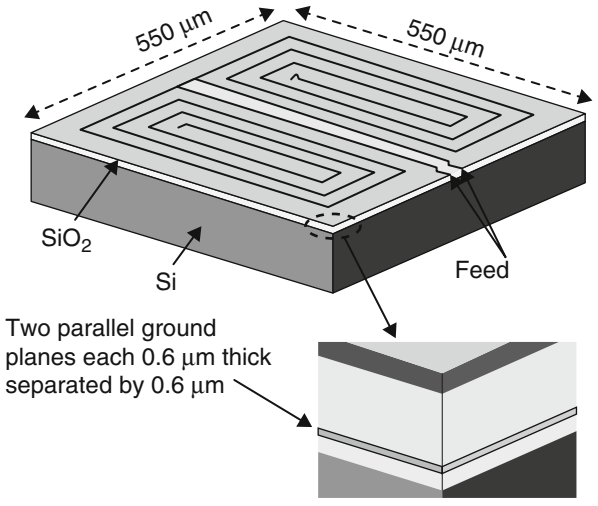

Fig. 12 Design example of an on-chip slot antenna (Behdad et al. 2007)

DOI 10.1007/978-981-4560-75-7_64-1

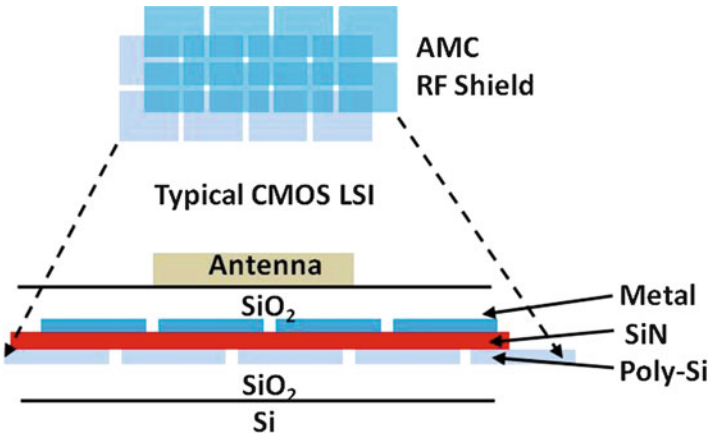

Fig. 13 SoC antenna implemented on an artificial magnetic surface (AMC)

substrates are subject to severe signal attenuation and this is exacerbated by the thin metallic layers incorporated using standard foundry processes. The thickness of the metallic layers is fractions of the skin depth at mmWave frequencies and the antenna topology is further penalized with substantial substrate losses. On-chip antennas employing high-resistivity silicon substrates are effective methods in reducing the signal attenuation constant. However, the high fabrication cost remains an obstacle for mass market applications such as consumer electronics. In recent years, periodic electromagnetic bandgaps in the form of metamaterial surface or artificial magnetic conductor (AMC) surfaces have been postulated for on-chip antennas as presented in Fig. 13 (Lin and Ooi 2009; Chu et al. 2009).

The main motivation behind SoC antenna packaging is to realize the entire RF front-end architecture in a completely monolithic fashion. As previously explained, the reduced physical distance between the mmWave antenna element and the rest of the MMIC does not always warrant improved antenna feedline losses. For applications where multiple number of antenna elements are required, SoC antenna may not be justifiable in the sense of engineering and economics. For example, in 60 GHz phased-array applications, the increased area incurred by the inclusion of multiple on-chip antenna elements within a silicon RFIC die will dramatically drive the unit price of the RFIC die upward. Attributed to these trade-off relations, SoC antenna packaging schematics are better suited for mmWave spectrum beyond 90 GHz or for very close-range mmWave wireless communication scenarios.

Another efficient method is to directly integrate the antenna with the rest of the wireless module. Defined as system in package (SiP), the packaging methodology is illustrated in Fig. 14 using multilayer lamination topologies.

The lateral integration schematic presented in Fig. 14a is suitable for applications where an end-fire radiation mode is advantageous. The mmWave antenna element is designed and placed in very close distance to the RFIC using microstrip, stripline, or coplanar waveguide (CPW)-based antenna feeding networks. This topology is especially compatible with dielectric resonators antennas (DRA), Yagi-Uda antennas, and horizontal dipole antenna types. Oftentimes, an additional transition such as a balun or a matching subnetwork is required to fine-tune the characteristic input impedance of the antenna port. High-permittivity substrates such as ceramic, high-end organic materials, and polymers are selected for the chosen antenna designs such as DRA and subsequently integrated with the surface of the mmWave carrier board using surface-mount technology. For planar antenna types such as Yagi-Uda antennas and horizontal dipole antennas, utilizing the top surface of the PCB carrier board is more advantageous in terms of design simplicity, cost, and overall aperture of the mmWave antenna module. Figure 15 shows a unique antenna packaging method – for mmWave frequencies where the profile of the resonant antenna is small

DOI 10.1007/978-981-4560-75-7_64-1

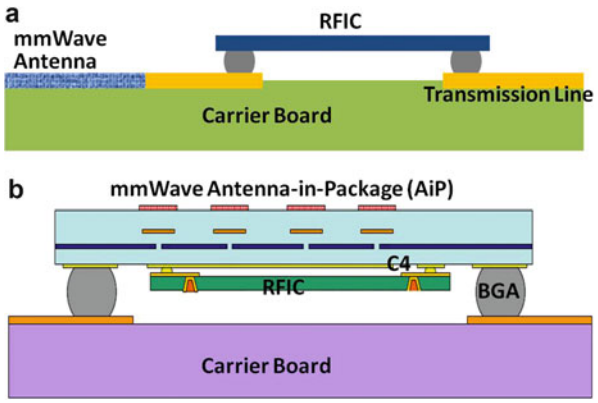

Fig. 14 SiP mmWave antenna integration schematic. (**a**) Lateral integration. (**b**) Vertical integration

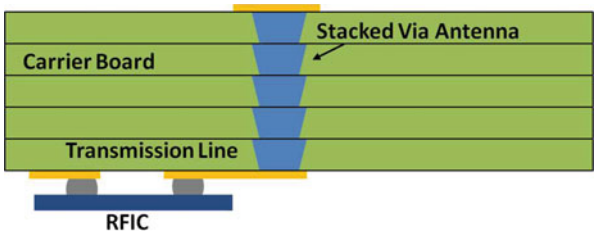

Fig. 15 The end-fire monopole antenna realized using stacked vias

enough to be fully embedded *within* the antenna carrier board. Using multilayer lamination technology, the antenna element is constructed using vertical interconnects such as stacked vias, through vias, and buried vias. The antenna element topology is equivalent to a vertically oriented monopole antenna and will radiate in the end-fire direction.

The effectiveness of the lateral integration schematic tends to degrade as the number of antenna elements increases. This is primarily attributed to the increased complexity and physical length of the antenna feeding networks as the antenna elements must be mutually separated at a predefined minimum pitch. Consequently, the lateral integration schematics are commonly used for mmWave wireless communication scenarios where the total number of RF paths and the antenna element is relatively small.

Figure 14b illustrates a vertical integration schematic. This type of antenna packaging configuration offers a wider range of antenna type selections compared to the lateral integration schematic. The antenna elements and the RFIC are typically located on opposite faces of the antenna module substrate for two distinctive reasons: (1) minimized interconnection insertion loss due to the employment of vias and (2) minimized antenna array footprint and antenna module dimension. Assembling the RFIC with the antenna module in an inverted manner is denoted as flip-chip bonding, also known as controlled collapse chip connection, or C4. The solder bumps are deposited on the top side of the RFIC during the final wafer processing process constructing RF ball pads. The RFIC is eventually inverted or "flipped" over so that the solder bumps come in direct contact with the signals pads of the antenna module. Subsequently solder is reflowed to construct the interconnect. At mmWave spectrum, flip-chip bonding tends to be preferred over conventional wire bonding attributed to superior rigidity and parasitic effects. The parasitic inductance of bond wires at mmWave frequencies is approximately 1 nH per 1 mm bond wire length. This amount of parasitic is sufficient to cause detrimental detuning of the antenna impedance matching. The limited controllability on the exact wire bonding procedure is another challenge when the RFIC die requires large number of bonding connections with the carrier board.

DOI 10.1007/978-981-4560-75-7_64-1

Planar antennas with broadside pattern properties such as patch antennas and slot antennas are particularly advantageous with the vertical integration schematic. The die size of mmWave RFICs is within the range of a few mm^2, while the mmWave antenna array topology tends to be much larger. Therefore, in addition to the vertical interconnects, lateral antenna feedlines such as microstrip, striplines, or CPW transmission lines are used to route the RF signals and align the ball pads of the RFIC to the corresponding antenna element ports. Likewise, the insertion loss attributed by the antenna feeding network is proportional to the number of RF paths and antenna elements.

Antenna Material

The substrate material for the mmWave antenna modules is a critical design parameter in terms of cost-effectiveness, design flexibility, and antenna performance. Advanced antenna materials such as low/high-temperature co-fired ceramics (LTCC/HTCC) and organic printed circuit boards represented by liquid crystal polymers (LCP) feature scalable permittivity and low loss tangent values at high RF frequencies. For such reasons, they are preferred over high-volume PCBs such as FR-4 for high-performance mmWave antenna designs. In addition, the fabrication and lamination processes using advanced antenna materials oftentimes exhibit more precise and sophisticated design rules such as smaller producible line widths and finer via pad diameters compared to FR-4. These advantages collectively grant mmWave antenna engineers enhanced degrees of freedom during the design stage. Ease of integration with various lumped components or ICs (die) is another important criterion in selecting among available antenna materials. The designed antenna aperture must feature minimum warpage to avoid damaging surface-mount lump components. Warpage can be quantitatively characterized using parameters such as the Young's modulus (Wang et al. 2003). Thermal stability and rigidity is another important design consideration. The excessive heat created by the MMIC circuit is typically harnessed or funneled using thermal vias or external heat sinks. In cases where the mmWave antenna modules are extremely small in dimension, the antenna material is exposed to higher heat temperatures and can result in unexpected mechanical deformation. Such thermal expansions of the antenna material can lead to damages or cracks in the solder balls between the antenna pads and the IC. Antenna materials with coefficient of thermal expansion (CTE) values that are closer to that of the IC lessen the probability of such incidents from occurring.

In terms of scales of economy, the material and fabrication cost of advanced antenna materials can frequently be several times higher than that of FR-4. The lamination can be simplified by reducing the number of layers or the total antenna module dimension for further cost savings.

mmWave Wireless Module Integration

mmWave wireless modules can be in large classified into three major components – the antenna module, RFIC, and the digital IC. The three components are ultimately integrated together on a carrier board which contains external peripheral components such as peripheral component interconnect express (PCIe) or universal serial bus (USB) interfaces. Extensive interconnections transporting numerous signals and reference in the form of RF, IF (intermediate frequency), reference clocks, IC power supply voltage, and reference signal ground coexist within wireless communication modules. The complexity of the interconnections and RF architecture must be taken into account in devising an appropriate method of integration. Three distinctive methods of mmWave wireless module integration are illustrated in Fig. 16.

The key differentiating features between the wireless module integration technique presented in Fig. 16a compared with Fig. 16b and c are the composition of the wireless module and the ensuing assembly procedure. This type of wireless module topology is preferred when the different material substrates are used for the antenna module and the carrier board, respectively. The antenna module entails a vertical integration schematic oftentimes using advanced multilayer laminations such as LTCC, HTCC,

DOI 10.1007/978-981-4560-75-7_64-1

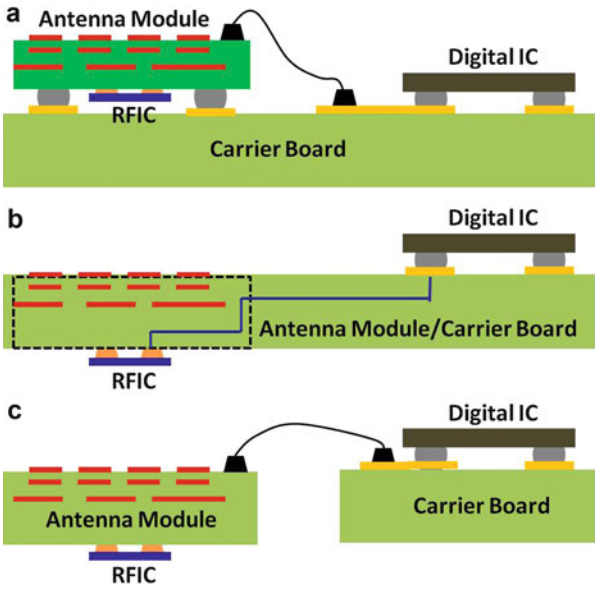

Fig. 16 mmWave wireless module integration techniques

or organic PCBs. The three major components identified as the antenna module, RFIC, and the carrier boards are subsequently assembled to realize an integrated wireless module using the following three-step assembly procedure:

1. Flip-chip attach the RFIC to the antenna module.
2. Surface mount the antenna module containing the RFIC with the carrier board using grid-array assembly technologies such as ball grid array (BGA) or land grid array (LGA).
3. Surface mount external peripherals such as connectors and lumped components on to the carrier board.

The finalized wireless module is connected with the digital IC either via a microwave transmission line or coaxial-type transmission line depending on the physical separation distance between the two. Within the wireless module, the IF signals, reference clock, power supply voltage, and the signal ground reference are interconnected from the digital IC via the antenna module and the carrier board. The flip-chip solder balls must be meticulously designed to minimize RF reflections and impedance mismatches. The electrical properties of the vertical interconnect represented by the flip-chip solder ball can be modeled using numerical electromagnetic computations based on computer-aided design (CAD) renderings. Figure 17 illustrates a flip-chip solder ball transition between the antenna module and the RFIC pad. The reactance of the transition tends to be inductive (several nH) and this can be compensated using passive matching networks such as shunt stubs which are attached to the antenna feedlines. The solder ball layout constructed on the bottom of the antenna module must be identically mirrored on the top surface of the RFIC die. For mmWave antenna modules, optimizing the solder ball layout is one of the most critical design stages out of the entire process. The following key design parameters are affected by the solder ball layout:

– The RFIC die size and front-end architecture
– Antenna material, manufacturer, and fabrication method
– Characteristic impedance of the vertical interconnect at the target operating frequency

DOI 10.1007/978-981-4560-75-7_64-1

Fig. 17 Layer view of the flip-chip solder ball transition

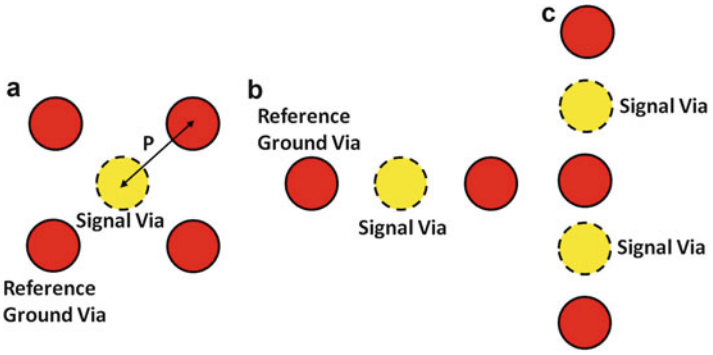

Fig. 18 Topologies of the solder ball layout. (**a**) Quasi-TEM mode. (**b**) CPW mode. (**c**) Multiple signal bump layout

Accurate characterization of the solder ball transition is extremely critical as the cascaded LNA, PA, and switches which will most likely not feature purely resistive 50 Ω input impedance. It is imperative to implement reactive matching networks on the solder ball layout. The topology of the solder ball layout must be devised so that each signal pad remains balanced and operate in the quasi-TEM mode. Each signal pad must be encompassed by a minimum of four reference ground pads as illustrated in Fig. 18a. Closely resembling a coaxial topology, the pitch *P* between the signal pad and the reference ground pad determines the characteristic impedance of the vertical interconnect as well as the permittivity of the solder balls, encapsulation, underfill, and antenna material. The minimum allowable pitch *P* is frequently limited by the fabrication accuracy and resolution of the PCB lamination technology involved. In situations where permissible real estate of the RFIC or the antenna module cannot afford four reference ground pads, the solder ball layout can be further simplified to a CPW configuration as illustrated in Fig. 18b. This rule of thumb can be further expanded for solder ball layouts containing multiple signal pads as shown in Fig. 18c. Failure to properly shield the signal pads with sufficient number of reference ground pads will pick up stray electric fields and induce unwanted noise in the antenna feeding network.

As discussed previously, the mechanical rigidity of the flip-chip solder balls are affected by the specific substrate material of the antenna module and heat generated by the RFIC. The flip-chip solder balls can be significantly enhanced mechanically, owing to recent advances in flip-chip underfill materials and processes.

mmWave antenna modules using the three-step configuration generally require several hundreds of grid-array assemblies to construct an electrical, mechanical, and thermal passage between the RFIC and the carrier board via the antenna module. Needless to say, any minor damaging of the grid arrays can potentially be related to a direct failure of the entire mmWave module. The importance and the sensitivity of the grid array result frequently require extensive levels of quality assurance inspections involving time-consuming and costly testing such as X-ray scanning. Compounded with the usage of advance antenna materials, the fabrication cost incurred by the ball grid arrays may exceed target price ranges for selected high-volume applications.

DOI 10.1007/978-981-4560-75-7_64-1

Figure 16b presents a wireless module integration technique which can be instrumental in resolving cost-related issues discussed in the three-step configuration. As opposed to a separate antenna module and carrier board configuration, the stated topology fully embeds and integrates the antenna module inside the carrier board. This approach eliminates the need for a discrete antenna module and the entire lamination can be realized monolithically. The overall assembly process of the wireless module is simplified compared to the three-step configuration as described in the following:

1. Flip-chip attach the RFIC to the monolithic antenna module/carrier board.
2. Surface mount external peripherals such as connectors and lumped components.

It should be noted that the specific sequence between the two assembly procedures can be interchanged depending the feasibility of applying the stencils for the flip-chip assembly process with or without surface-mount components. As it can be observed, the two-step wireless module configuration entirely eliminates the need for any grid-array assemblies. Consequently, the overall time and cost of the wireless module integration is noticeably reduced, translating to a more competitive unit cost for high-volume applications. Bypassing the grid-array assembly enables integration flexibility with the rest of the wireless communication hardware. This integration technique enables a multilayer mmWave antenna design to be realized within a wireless device hardware without any additional discrete material cost and assembly process. The whole motherboard and the wireless module can be integrated as one, simultaneously designed and fabricated monolithically. Figure 16b is extremely advantageous for scenarios where the characteristics of the selected mmWave antenna design, the antenna material, its specific user scenario, and the antenna placement are well established. One notable limitation comes with the need to implement the digital IC in close proximity to the antenna for super heterodyne wireless architectures. In addition, in situations where a faulty mmWave RFIC die or an error within the antenna module is identified, the entire carrier board must be replaced as opposed to just replacing the antenna module in Fig. 16a. Figure 16c mitigates this issue with a stand-alone antenna module.

The two-step wireless module configuration is valid under the precondition that the antenna module, carrier board, and occasionally the motherboard use identical or very similar substrate materials, laminations, and design rules. This can be rephrased to state that the antenna material is dependent on the material composition of the carrier board and the motherboard. Few exceptions withstanding, conventional high-volume PCB materials such as FR-4 are likely to be used in consumer electronics, telecommunications, and automobile industries. As the material loss tangent for conventional PCBs can be in the orders of 0.005 and higher, it is imperative to devise methods in reducing the insertion loss incurred by the antenna feeding networks within the antenna module/carrier board. Utilizing the CPW topologies as opposed to microstrip topologies and efficient antenna feedline routing and layout are effective methods.

Hybrid mmWave Antenna Packaging Technologies

It becomes possible to apply hybrid packaging and integration approach for mmWave frequencies that are high enough for resonant-type antenna elements to be deduced to extremely small form factors.

Figure 19 illustrates a mmWave wire bonding antenna topology. The inductive reactance and the capacitive reactance respectively derived from the wire bond and the signal pad on the PCB carrier board are utilized at a target resonant frequency. As the antenna geometry is quite fragile, additional encapsulation such as a polymer-based casing is required to protect the mmWave wire bond antenna from unexpected deformation. The mmWave wire bond antenna is instrumental especially when dealing with a limited number of end-fire radiation mode antenna elements typically at frequencies beyond 80 GHz. The design flexibility is relatively limited as the wire bonding process is subject to few variations.

DOI 10.1007/978-981-4560-75-7_64-1

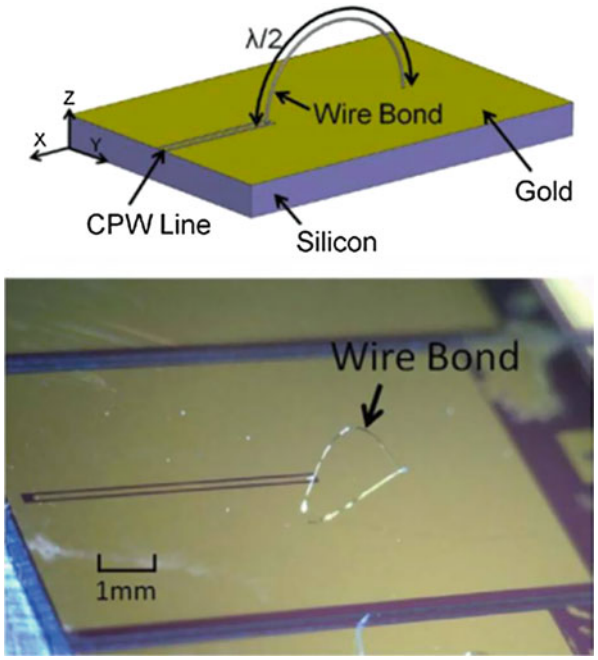

Fig. 19 Diagram of the mmWave wire bond antenna and its fabricated prototype (Willmot et al. 2009)

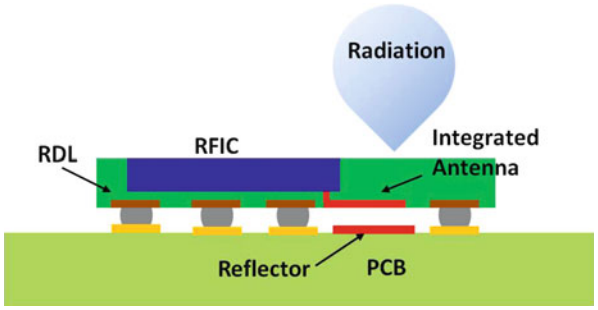

Fig. 20 Illustration of the mmWave eWLB antenna

Another notable hybrid packaging and integration technique is described as the embedded wafer-level ball grid array (eWLB). This approach is derived by introducing fan-out regions inside a conventional wafer-level package (WLP) as illustrated in Fig. 20. This is especially beneficial for multi-chip packaging applications such as high-power communications in the automobile and telecommunication arena. The concept of the eWLB antenna is to devise a planar antenna topology inside the fan-out region of the package by utilizing the redistribution layer (RDL) (Al Henawy and Schneider 2011). This type of packaging technique is best fit for broadside antenna modes. The degree of freedom becomes somewhat limited when designing antenna array geometries as the topology must be devised with the antenna elements encompassing the IC situated at the center. Nonetheless, the eWLB antennas are one of the most effective methodologies for close- and midrange mmWave communications beyond V-band frequencies.

Wideband mmWave Antenna Design

The acute disparity between the available spectrum below 10 GHz and the required frequency bandwidth for multi-Gbps wireless communication underlines the need of facilitating mmWave frequencies. In accordance to the classical Shannon-Hartley information theory, one of the most notable methods of

DOI 10.1007/978-981-4560-75-7_64-1

significantly enhancing the wireless capacity at mmWave frequencies lies in the expansion of the frequency bandwidth. Bandwidth enhancement techniques that are relatively well understood and frequently applied at microwave frequencies can also be incorporated in mmWave frequencies. Additional design considerations which are unique to mmWave applications such as the aforementioned packaging and integration design parameters must be further taken into account. The laminations and multilayer package topologies can be capitalized in devising a robust, efficient, and broadband antenna design topology. Single-layer mmWave antennas such as dipole antennas, Yagi-Uda antennas, and traveling wave antenna types can also be designed to be compatible with the rest of the antenna module package at the cost of increased lateral dimension.

Generally speaking, there are two ways of achieving broadband multilayer antennas at mmWave frequencies. The first approach involves the employment of low-permittivity antenna substrate materials. Antenna designs based on low-permittivity dielectrics feature lower Q which translates to a more usable antenna bandwidth. The second approach involves increasing the thickness of the dielectric (Katehi and Alexopoulos 1983). However, this tends to induce surface-wave excitations which are especially detrimental for planar antenna geometries. For TE and TM mode surface waves, the cutoff frequencies can be expressed as follows in Eq. 15 (Harrington 1961):

$$f_c = \frac{nc}{4h\left(\sqrt{\varepsilon_r} - 1\right)} \tag{15}$$

where c is the speed of light and n is an integer number for the corresponding TE and TM surface modes. Parameter h is defined as the height of the dielectric substrate of the antenna. More surface modes can exist as n increases. In addition, the increase in height of the dielectric substrate enables lower-order surface modes to couple easier. In majority of situations, the dimension of the mmWave antenna module can be regarded as a finite-size dielectric substrate. In such cases, the excitation of surface-wave modes causes undesired diffractions which are difficult to characterize. The edge diffractions eventually result in radiation nulls in the main lobe, rise of side lobes, and deteriorated gain and polarization. The effect of surface modes on the far-field behavior for mmWave antennas is analyzed in Liu et al. (2009). The trade-off related to increasing the thickness of the dielectric substrate for bandwidth enhancement can be circumvented to a certain extent by slowly varying the excitation across the designed mmWave antenna element. As a rule of thumb, antenna substrate profiles with $h < 0.01\lambda$ are recommended for planar antenna type topologies.

Selection of the optimum permittivity of the antenna material substrate and its height is succeeded by the designing of the mmWave antenna geometry. For rudimentary planar antennas such as patch antennas, achieving more than 10 % bandwidth may be technically challenging. Generating multiple numbers of closely spaced antenna mode resonances by carefully controlling the parasitic capacitance is an effective technique for multilayer laminations. Figure 21 illustrates variations of mmWave planar antenna schematics based on parasitic capacitance coupling methods. Figure 21a is described as the vertically stacked antenna geometry and is among the most effective methods for broadband applications requiring more than 15 % bandwidth. The ensuing design consists of multiple parallel RLC circuits, respectively represented by patch antennas. The combined RLC circuit is excited by series capacitance coupling which is predominantly dependent on the separation gap between the patch antennas. In reality, this separation gap is highly correlated to the specific antenna substrate material, the available substrate height, and the lamination and fabrication method. Therefore the fine-tuning range of the separation gap is typically discrete. Figure 21b illustrates a horizontally coupled antenna configuration. As the name indicates, the electric field generated by the parasitic capacitive coupling is contained in the horizontal plane. As a result, this type of antenna configuration is especially suitable for linearly polarized antennas

DOI 10.1007/978-981-4560-75-7_64-1

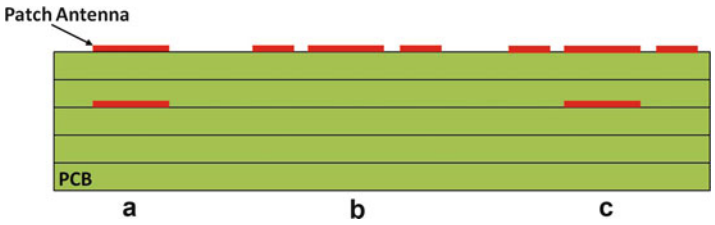

Fig. 21 Bandwidth enhancement techniques for mmWave multilayer antennas

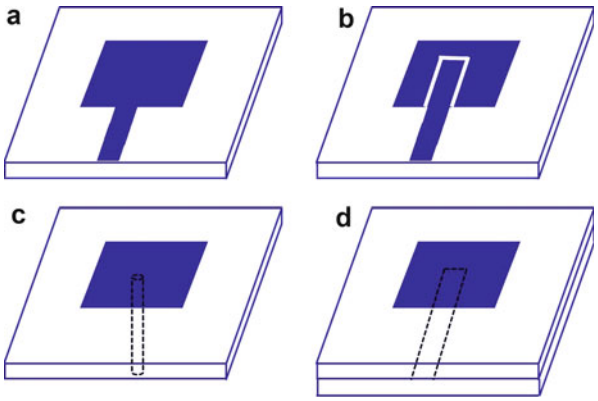

Fig. 22 Illustrations of planar antenna feeding techniques. (**a**) Microstrip edge feed. (**b**) CPW feed. (**c**) Probe feed. (**d**) Capacitive feed

having the E-plane located in the direction that is transverse to the horizontal separation gap. This type of bandwidth enhancement is useful for mmWave antennas requiring thin antenna substrates or limited layers of lamination. The drawback compared to the vertically stacked antenna geometry is the increased dimension in the horizontal plane. Additional antenna miniaturization techniques may be required for antenna array applications. The vertically stacked antenna and the horizontally coupled antenna technique can be used in conjunction as described in Fig. 21c. This configuration further enhances the antenna aperture efficiency and can be very effective for planar antenna designs at mmWave spectrum that require more than 20 % bandwidth. The trade-off is the increased complexity in the design which can lead to possible degradation of the fabrication yield. When applying conventional, high-volume PCB technology, the fabrication tolerance is oftentimes in the range of tens of microns, and this can result in detuning the parasitic capacitive coupling by more than 30 %. One way to stabilize the fabrication process and avoid costly fine-tuning the antenna design is to first design and fully characterize the vertically stacked antenna and the horizontally coupled antenna geometry respectively and separately. Consequently the two methods can be used in conjunction once the dominant design parameters that affect the antenna bandwidth are well analyzed.

The antenna feeding is another critical consideration for broadband mmWave antennas. It can be largely classified into uniplanar and multilayer antenna feeding techniques as categorized in Fig. 22. Figure 22a represents a microstrip edge feed method which is compatible for patch antennas and planar monopole antennas. The microstrip feed is characterized as a series inductive feed and this method is favored for its simplicity as both the antenna and feedline geometry can be fabricated in simultaneously. The drawback is the design inflexibility incurred by the limited number of available design parameters and the increasing far-field radiation contribution of the microstrip feed as the footprint of the mmWave antenna becomes smaller. Therefore it is important to limit the length of the microstrip feed at mmWave spectrum. Figure 22b complements the restrictions and the limitations of the microstrip feed by utilizing a

DOI 10.1007/978-981-4560-75-7_64-1

CPW feed technique. Similar to the Fig. 22a, the antenna feedline is situated on the same plane which contains the antenna. Compared to the microstrip feeding method, the CPW method offers more design flexibility and reduced erratic far-field radiation by the antenna feedlines. The uniplanar antenna techniques illustrated collectively suffer from drawbacks related to increase in the lateral real estate. For mmWave phased-array applications, the complexity of the antenna feeding networks is alleviated by devising sub-array topologies using corporate and serial feedings. In addition, the inductive nature of the antenna feedline typically limits the antenna bandwidth to less than 10 %. Figure 22c represents a probe feed method. For mmWave multilayer laminations, the probe is realized using signal through-hole vias. Quasi-TEM mode can be realized by encircling the signal via with multiple numbers of ground vias to closely emulate a coaxial vertical transition. This method benefits from negligible antenna feed radiation and extremely small profile. The input impedance matching of the antenna element to the probe is controlled by adjusting the contact location of the probe in the lateral direction. However, the bandwidth remains relatively narrowband. A capacitive antenna feeding method is illustrated in Fig. 22d. The antenna element is excited via electromagnetic coupling and feature enhanced design flexibility. Shielded microstrip or slot lines can be designed for the antenna feed transmission line. Using this method, it is possible to excite dual antenna resonance by adjusting the antenna feed geometry and is one useful way of enhancing the bandwidth. Figure 23 is denoted as the aperture-coupled feed (Pozar 1985). As one of the most favored and widely used mmWave antenna feeding techniques, the feeding structure consists of a transmission line and an aperture. The antenna element located at the top of the multilayer lamination is excited due to the electromagnetic coupling between the apertures. The dimension of the aperture can be carefully designed so that it contributes constructively in the main direction of the mmWave antenna element. Naturally this method is preferred for broadside antenna modes and is best fit for patch antenna types. The input impedance of the antenna can be matched by adjusting the location where the

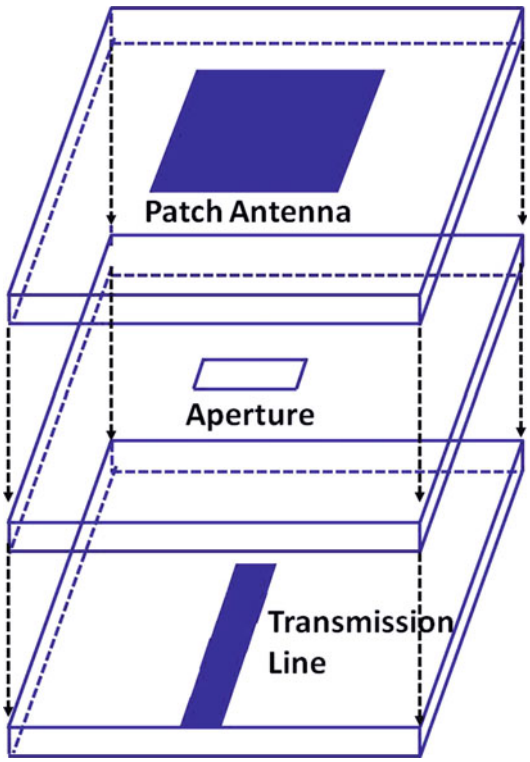

Fig. 23 Diagram of the aperture-coupled feed

DOI 10.1007/978-981-4560-75-7_64-1

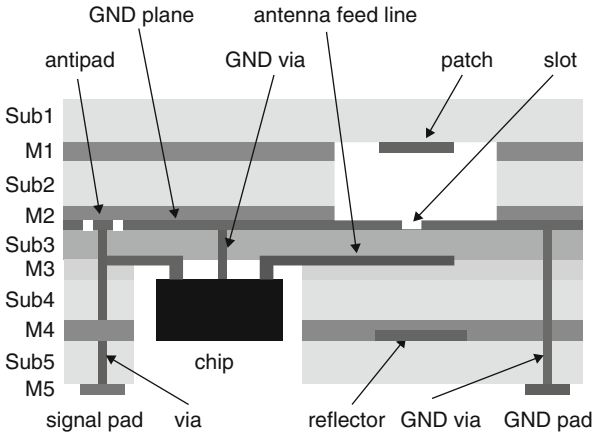

Fig. 24 Cross-sectional view of the integrated mmWave antenna using aperture-coupled patch antenna (Liu et al 2011)

transmission line and the aperture intersect on the horizontal plane. As multiple numbers of antenna resonances can be realized through the aperture and the antenna element, the aperture-coupled feed can be a very powerful technique in realizing broadband characteristics.

In order to better understand how the antenna design topologies and the feeding methods are used in practical scenarios, one of the most notable state-of-the-art broadband antennas designed for mmWave communications (Liu et al 2011) will be investigated. Figure 24 illustrates a cross-sectional view of an integrated mmWave antenna based on a five-layer PCB lamination. The antenna substrate material for the third layer denoted as Sub3 is chosen to feature dielectric permittivity which is approximately 12 % lower than the rest of the antenna substrate materials. This enables the antenna feedline designed on the 3rd layer (M3) of featuring an adequate width-to-height ratio for improved impedance matching. To further improve the antenna feedline efficiency, low-loss adhesives are applied on Sub3, whereas relatively lossy adhesives are applied elsewhere to reduce the overall cost and enhance manufacturability. As it can be observed, portions of Sub4 and Sub5 are removed to form an open cavity. The form factor of the open cavity is designed so that the RFIC can be completely inserted inside the mmWave antenna module. This configuration eliminates the need for vertical signal transitions using via holes and also eliminates requirement of associated matching networks. Signal pads and reference ground pads are implemented on the bottom layer M5 for ball-grid-array assembly to the carrier board.

The presented mmWave antenna renders an aperture-coupled feed technique to achieve broadband performance. The mmWave patch antenna element is designed and implemented on the M1 layer. A sealed air cavity is created by removing portions of Sub2. This essentially lowers the effective permittivity of the patch antenna resulting in lower Q. The ground plane located in M2 functions as the reference ground for the patch antenna and also is an effective way of shielding erratic radiation and signal cross talk within the antenna module. The aperture located on the M2 layer is designed based on a set of resonant, half-wavelength slots as shown in Fig. 25. By merging the two antenna resonance modes, more than 15 % 2:1 VSWR bandwidth can be achieved. The slots are designed to have slightly different resonant frequencies in comparison to the patch antenna. The exact position of the two slots are determined so that the surface waves generated by the slots and the patch antenna are destructively added. As a result, the antenna gain can be further improved. The slots are fed using a set of transmission lines situated in M3. The metallic pattern located in M4 functions as the reflector for the slots since a slot antenna is inherently bidirectional.

mmWave Antennas Design Technologies for Directional and Reconfigurable Radiation Patterns

The applicability of classical omnidirectional antennas is greatly limited to very close-range mmWave communication scenarios due to numerous propagation loss factors discussed in detail in section "Theory." In addition mmWave omnidirectional antennas are prone to receiving undesired incoming stray signals across a diverse range of angle of arrivals (AoA), which can significantly affect the noise figure of the receiver circuitry. This phenomenon, denoted as desense, can degrade the sensitivity of the wireless architecture by up to 10 dB or more under real-life propagation environments and is one of the primary concerns during the design phase. Spatial diversity techniques in the form of antenna beam steering are instrumental in circumventing the influence of interferers especially for multipath propagation environments. Given ideal antenna design conditions, a beam steering antenna such as in the form of a phased array featuring a complete spherical radiation pattern coverage and fine angular resolution would be the most effective solution. Unfortunately in most realistic antenna design conditions, such topologies cannot be realized due to constraints associated with dimension, economical, and technical costs. One practical approach involves enabling mmWave antenna elements featuring sectorized radiation patterns. This technique is particularly useful in propagation environments where the angles of arrival and departure can be estimated based on statistical spatial channel models. Directional mmWave antenna elements can be largely classified into broadside and end-fire topologies and will be discussed in detail as follows.

mmWave Broadside Antenna

For planar mmWave antennas exhibiting broadside antenna mode, the main radiation lobe is situated along the axis that is approximately perpendicular to the plane which contains the antenna geometry. Broadside antenna mode is instrumental when the transmitting and the receiving planar antenna topologies are configured to be facing one another. In another scenario, which is confined to indoor propagation environments, the two broadside antennas can be implemented adjacent to one another and establish a NLOS wireless link through utilizing the ceiling as an effective reflector. When multiple broadside antenna elements are employed to devise antenna arrays, the accuracy of the mmWave NLO antenna beam steering is affected by the relative surface roughness of the ceiling at the operating carrier frequency.

Conventional planar patch antennas are one of most widely used broadside antennas at mmWave. The antenna gain is typically in the range of 3–5 dBi for each patch antenna element under the precondition

DOI 10.1007/978-981-4560-75-7_64-1

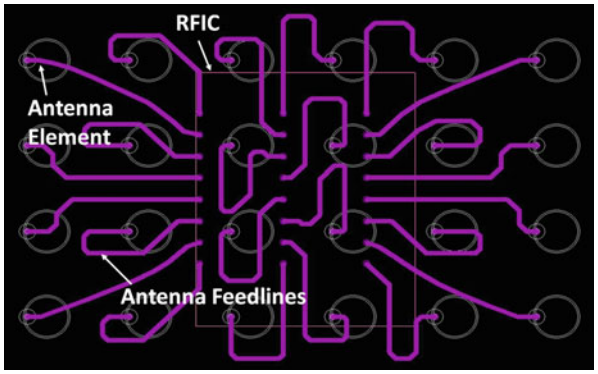

Fig. 26 Layout of a mmWave broadside antenna array and the ensuing antenna feedlines

that relatively low-loss antenna substrate materials are used. mmWave patch antennas can be further expanded into a two-dimensional array in order to attain greater antenna directivity and gain in the broadside direction. In accordance to the well-understood phased-array theory, the array factor is proportional to the logarithmic value of the total number of antenna elements. This relation infers that it is possible to continue enhancing the antenna gain and directivity in the broadside direction through the addition of antenna elements. However, in reality, the effectiveness of this method is eroded beyond a certain number of antenna elements. This is due to the growing disparity between the footprint of the mmWave RFIC die and the broadside antenna array. As illustrated in Fig. 26, the physical lengths of the antenna feedlines which route the mmWave signals between the RFIC signal pads and the respective antenna element ports are proportional to the total number of antenna elements comprising the broadside antenna array. The cumulative insertion loss incurred in the antenna feedline network continues to rise until a certain threshold where it equals the array factor as presented in Fig. 27. Beyond this threshold, the gain of the broadside antenna array starts to decrease as the insertion loss of the antenna array becomes greater than the antenna array factor. Increasing the mmWave RFIC die introduces complicated problems associated with extremely expensive unit costs and unexpected warpage as is deemed unrealistic. Due to this limitation, it becomes difficult to attain an antenna gain beyond 30 dBi using mmWave patch antenna arrays.

In situations where the antenna gain and the directivity need to be enhanced further, an additional dielectric lens can be implemented with the original antenna geometry. This design consists of a mmWave broadside patch antenna situated on the upper layers of the PCB lamination. Illustrated in Fig. 28, a dielectric lens featuring an elliptical or quasi-elliptical shape having a radius R is integrated with a cylindrical-shaped dielectric with an extension height denoted as h The curvature of the dielectric functions as a plano-convex lens, introducing true-time delays (TTD) to form a highly directional antenna radiation pattern. The variations of extension height h modify the elliptical shape of the lens, leading to different broadside directivity. Optimization of the integrated lens antenna is performed by modifying extension height h to control the antenna directivity and antenna array beam steering range. The loss tangent of the dielectric lens and the internal signal reflections in the dielectric lens body are the two primary factors that degrade the antenna gain. The broadside antenna element which is feeding the integrated lens is typically placed at the integrated lens focus to mitigate internal reflections. A fully fabricated mmWave integrated lens prototype and variations of dielectric lens are respectively presented in Fig. 29.

For mmWave access points, backhauls, and compact mobile terminals, the volumetric convex integrated lens solution can be potentially problematic. Designs based on spatial true-time-delay units employing bandpass filter technologies can be effective flat lens design techniques. Also denoted as

mmWave transmit array, the topology comprises of single or multilayer quasiperiodic resonant elements arranged to locally compensate the phase delay associated with different path lengths. An illustrative concept depicting the transmit array is presented in Fig. 30. The resonant elements constituting the transmit array layers rephrase the incoming spherical waves and retransmit the mmWave signals in the form of plane waves. The required phase adjustments are dependent on the distance the signal has traveled from the broadside antenna to each of the resonant elements. R_i denoted in Fig. 30 is defined as the vector of *i*th element from the phase center of the broadside antenna. r_i is denoted as the position vector to the *i*th

DOI 10.1007/978-981-4560-75-7_64-1

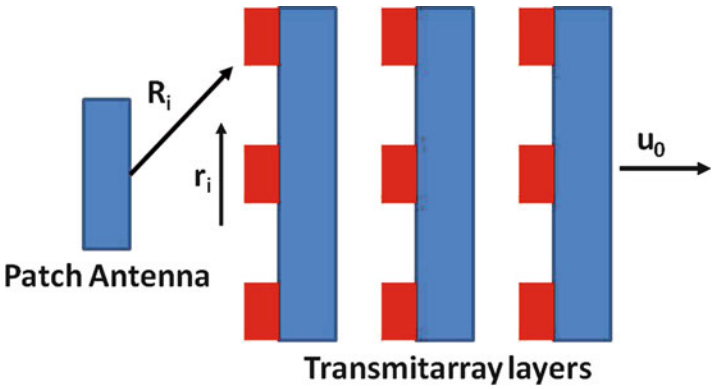

Fig. 30 Transmit array antenna (Ryan et al. 2010)

resonant element from the center of the transmit array lens and u_o is the direction of the transmitted main beam of the antenna. k is denoted as the propagation constant. Defined in Black and Wiltse (1987), Hristov and Herben (1995), and Ryan et al. (2010), the required phase compensation ϕ_i at each resonant element can be expressed as Eq. 16 below:

$$\phi_i + k(R_i + r_i \cdot u_o) = 2\pi n \quad \text{where n} = 0, 1, 2, 3 \ldots \tag{16}$$

Transmit array lenses offer the benefits of reduced profile and wide beam steering scanning ranges. However, due to the RLC circuitry of the resonant elements, they are commonly narrowband and may require extensive multilayer fabrication procedures. The gain enhancement effect is highly sensitive to the physical alignment of the transmit array lens and the broadside antenna, so additional efforts focused on eliminating mechanical jitters and vibrations may be required.

mmWave End-Fire Antenna

End-fire antenna modes are effective solutions for mmWave device-to-device (D2) communications such as file transfers or ultrahigh definition (UHD) seamless video streaming scenarios. The axis of the main lobe is parallel to the plane containing the planar mmWave antenna geometry. The mmWave Vivaldi antennas, (Yngvesson et al. 1989) which are classified as traveling wave antennas, are advantageous when the number of available layers within a mmWave antenna module is limited. This type of antenna geometry is most compatible with the lateral integration schematic described in the previous subsection and widely used when the mmWave RFIC in implemented on the same plane of the carrier board. The antenna gain is proportional to its length which is usually a multiple of the wavelength. For resonant-type end-fire antenna designs, the mmWave Yagi-Uda and the planar dipole antennas respectively illustrated in Fig. 31a and b are by far the most preferred topologies for low-profile applications (Alhalabi and Rebeiz 2009). The mmWave Yagi-Uda antenna largely consists of three discrete sub-elements. The driven element consists of a planar dipole antenna topology which employs a half-wavelength balun on one of the two branches. The balun enables a 180° phase shift and drives the dipole into the desired antenna mode. The driver element electromagnetically couples to the driven element and enhances the directivity in the boresight angle of the Yagi-Uda. The reflector suppresses the back radiation of the driven element which is induced by the inherent nature of bidirectional planar dipoles and redirects the radiating field in the boresight direction. This design is particularly favored for its relatively wide bandwidth and monolithic fabrication. The planar dipole antenna topology illustrated in Fig. 31b is typically applied in applications where an end-fire antenna mode featuring low height profile and wide beamwidth in the elevation plan ("fan-beam patterns" are preferred. Conventional planar dipole antennas feature antenna

DOI 10.1007/978-981-4560-75-7_64-1

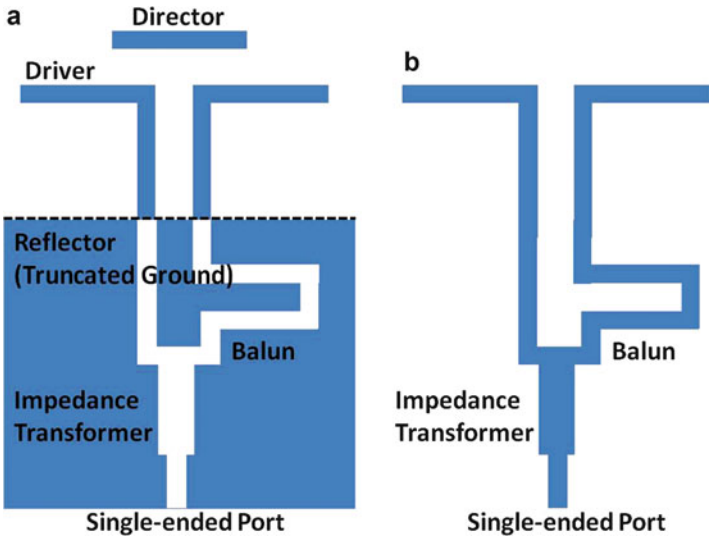

Fig. 31 (**a**) Yagi-Uda antenna. (**b**) Planar dipole antenna

gain values of less than 2 dBi which in turn results in relatively low EIRP for mmWave communications. The EIRP can be doubled when the mmWave planar dipole antenna is used in conjunction with a multi-RF chain phased-array transceiver IC. The half-wavelength balun is completely eliminated and each branch of the planar dipole antenna is respectively connected to each RFIC signal port. Assuming sufficient angular resolution is available by the RF phase shifter, a 180° phase difference between the two RF signals can be fed to each branch. The phase difference drives the planar dipole antenna topology into an antenna mode with a 3 dB enhancement in the radiated power.

Despite the numerous benefits, Yagi-Uda and planar dipole antennas are often subject to performance degradations in real-life mmWave applications. One of the most notable issues can be attributed various metallic layers which may be implemented underneath the antenna module. For compact mobile terminals such as smartphones and wearable devices, the footprint of the wireless module is extremely limited and the ensuing circuitries are densely spaced. The end-fire mmWave antenna will have to be placed in very close proximity to other signal tracelines and metallic layers for reference ground and heat sink. Yagi-Uda and planar dipole antennas inherently require the removal of metallic layers beneath the antenna topology in order to operate in the end-fire radiation mode. In the presence of a metallic ground underneath the mmWave Yagi-Uda and planar dipole antenna, the far-field radiation patterns may experience severe distortions as illustrated in Fig. 32. Methods of mitigating this issue will be discussed in detail in section "Notable mmWave Antenna Applications."

Pattern-Reconfigurable mmWave Antennas

With the advent of durable, efficient active components such as phase shifters, switches, PIN diodes, and microelectromechanical systems (MEMS), reconfigurable antennas are increasingly becoming a practical solution for mmWave communications. In Yang et al. (2005), the patch antenna is composed of two orthogonal quasi-Yagi-Uda antennas printed on the antenna substrate material. Electromagnetic bandgap (EBG) structures are controlled and modified depending on the state of the MEMS switches.

Another state-of-the-art pattern-reconfigurable technique proposed in Marnat et al. (2013) controls the antenna pattern by reorienting the antenna geometry as illustrated in Fig. 33. A broadside antenna mode is enabled when the mmWave bow-tie antenna is placed in parallel to the antenna substrate material. By controlling the buckled cantilever plate (BCP), the designed antenna can be mechanically rotated by 90° to transform into an end-fire antenna mode. For low-latency Gbps communications, the relatively slow

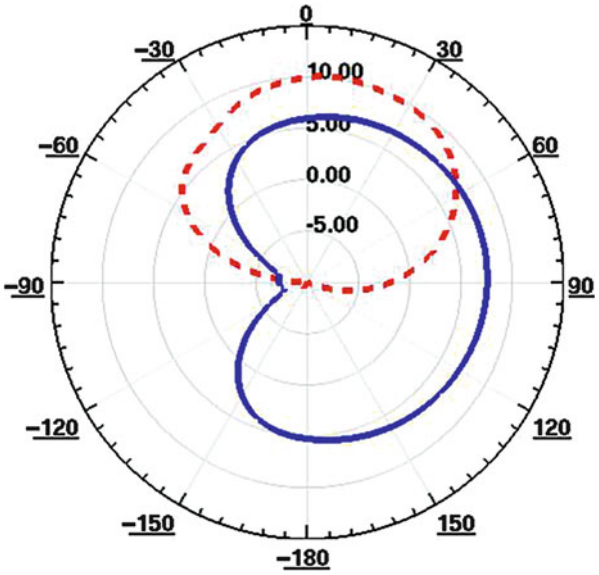

Fig. 32 End-fire pattern distortion when implementing Yagi-Uda and planar dipole antennas above a metallic surface. *Solid line*: elevation pattern in free space. *Dotted lines*: elevation pattern with the inclusion of the metallic surface

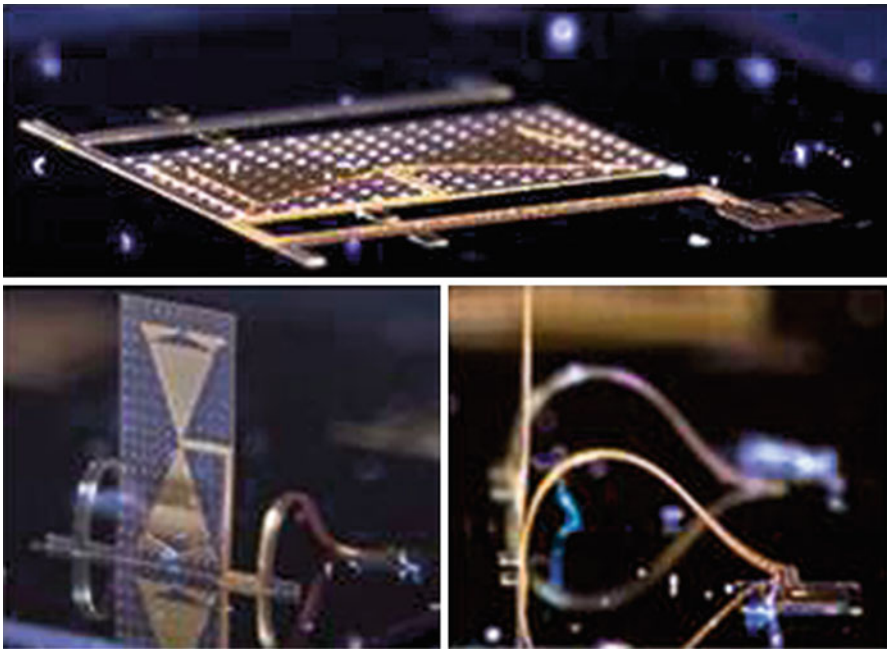

Fig. 33 Photographs of the pattern-reconfigurable mmWave bow-tie antenna (Marnat et al. 2013)

switching speed needs to be further researched as well as addressing the fragility of the entire topology. For high-volume applications, it is imperative for pattern-reconfigurable antennas to feature a small real estate and efficient packaging schematics. Consequently, future active components required for mmWave pattern-reconfigurable antennas will most likely need to be integrated inside the RFIC as opposed to majority of the present-day solutions which are based on discrete, off-chip active components. It is imperative that the mmWave antenna topology must be conceived concurrently with the entire RF front-end architecture.

Notable mmWave Antenna Applications

This section will present two mmWave antenna designs in detail which are respectively applied to ongoing progress of Gbps mmWave communication applications in the global wireless and consumer electronics industry. Many of the antenna designs introduced in this section have either been incorporated or are projected to be applied to present and upcoming wireless mobile terminals. The readers are recommended to refer to Hong et al. (2012, 2013, 2014b) for further detail.

Phased-Array Antenna for 60GHz WiGig/IEEE 802.11ad

Introduction and Background

The explosive proliferation of wireless local area networks (WLAN) and high-quality multimedia data demands Gbps wireless data communication with extremely latencies less than 1 ums. Among numerous IEEE wireless standards, the WiGig/IEEE 802.11ad specializes in ultrafast data transfer and seamless streaming of audio and video files at close-range communication scenarios using the unlicensed 60 GHz frequency band.

The concept and notion of utilizing 60 GHz has been perceived more than two decades ago among research institutions and universities and have been followed with rigorous proof-of-concept (PoC) research and investigations. Over the years, 60 GHz antennas have continued to advance at an unprecedented pace. Consequently, as antenna element technology begins to mature, the main focus of research and development efforts has shifted to the realization of low-profile, high-performance 60 GHz antenna modules. Articulating the balance between performance and cost competitiveness is increasingly crucial.

Antenna Module Configuration

To mitigate the high cost associated with advanced antenna materials and ball-grid-array (BGA) assemblies, the state-of-the-art 60 GHz antenna design employs a two-step wireless module integration schematic introduced in section "Key mmWave Antenna Design Techniques." Figure 34 illustrates the lamination configuration. The 60-GHz array antenna package is wholly designed using HDI FR-4 PCB substrates. Consequently, the antenna module is homogeneously embedded within the 12 layer FR-4 carrier board, enabling a simplified, monolithic fabrication and assembly. The 60-GHz RFIC is flip-chip attached to the bottom layer M12 of the antenna module while lumped elements are implemented through SMT. The sequence between the two assembly processes is interchangeable. The lamination of the

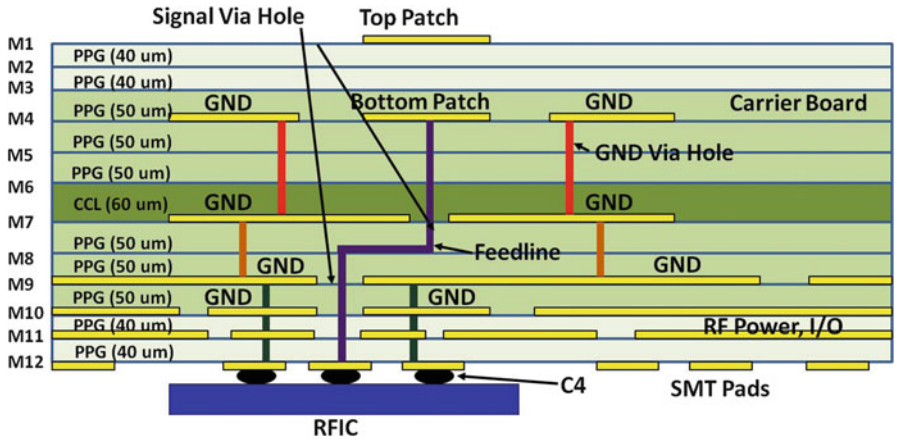

Fig. 34 Lamination configuration of the 60 GHz AiP (Hong et al. 2013)

DOI 10.1007/978-981-4560-75-7_64-1

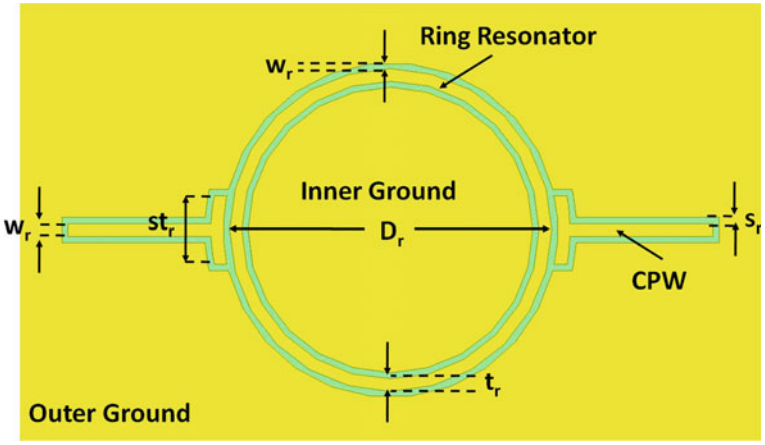

Fig. 35 Topology of the microstrip ring resonator (Hong et al. 2013)

antenna module consists of one substrate core and the prepregs. The substrate core is situated at the center of the lamination. Five prepregs are adhesively bonded together using 0.254 mm thick epoxy resins and stacked above the substrate core. Similarly, another five prepregs are adhesively bonded underneath the substrate core. Metal layers from M2 to M11 are implemented using 20 m thick copper. Metal layers M1 and M12 are each composed of 25 m thick Au plating and finished with 20 m thick solder resist. Laser and mechanical micromachining processes are utilized for the construction of through, buried, and stacked via holes for each substrate prior to lamination.

It is rarity for PCB vendors to characterize the electrical properties of the antenna substrate material beyond 10 GHz. The inherent frequency-dependent nature of pertinent material properties such as permittivity and dielectric loss tangent must be well defined prior to the 60 GHz antenna design process. The deviations in the electrical characteristics between the core substrate and prepregs are reported by the FR-4 supplier to be well less than 1 % up to 10 GHz. Therefore for brevity, the FR-4 PCB substrate is modeled as a homogeneous, isotropic material up to 60 GHz in this subsection. A number of weakly coupled, coplanar waveguide (CPW)-fed microstrip ring resonators are designed to extract the permittivity of the FR-4 substrate. The top view of the ring resonator layout situated on M1 is visualized in Fig. 35. Design parameters are optimized to be $w_r = 0.2$ mm, $s_r = 0.1$, $t_r = 0.2$ mm, $s_{tr} = 1.1$ mm, and $D_r = 5.18$ mm. The bottom ground is implemented on M4. One such measured and simulated S21 amplitudes are presented in Fig. 36. Measurement results indicate the calculated average permittivity $\varepsilon_r = 3.92 \pm 0.13$ among three identical ring resonator samples at 58.3 GHz. Calculation of the loss tangent at 60 GHz is difficult due to limitations in accurate extraction of conductor and radiation loss. As a result, the simulated loss tangent is iteratively matched to the measured results of various transmission lines. The loss tangent is confirmed to be $tan\delta = 0.027 \pm 0.07$ at 60 GHz.

The antenna module is largely classified into three distinct portions based on functionality. The antennas are allocated in the upper portion of the module to avoid interference with the RFIC, occupying layers from M1 to M7. The antenna feedlines which route the 60-GHz signal paths from each of the RFIC ports to the corresponding antenna elements are situated in the mid-portion of the antenna module, ranging from M7 to M9. Lastly, power distributed networks (PDN), control lines, low-speed and high-speed interfaces for the RFIC, and digital blocks are located on the bottom portion of the antenna module occupying layers at M10 and M11. The antenna ports which are each electrically connected to corresponding RFIC ports through flip-chip assembly are designed on M12. M7 and M9 are designated as RF grounds to maximally isolate the antennas and antenna feedlines from unexpected spurious modes and cross talks that may occur in the bottom portion of the antenna module after integration with the RFIC.

60 GHz Antenna Element Design

A circular stacked patch antenna model discussed in section "Key mmWave Antenna Design Techniques" is devised to achieve the required −10 dB S11 bandwidth from 57 to 66 GHz and broadside radiation characteristic while keeping the lateral footprint to be minimal. Figure 37 illustrates the detailed topology. Two separate circular patches are designed and implemented on M1 and M4 and denoted as the top and bottom patch, respectively. The top and bottom patches are vertically aligned in a way that their center coordinates are identical in the xy plane. A probe-fed mechanism is realized for the bottom patch by connecting a signal via hole at a certain distance d_p from the center of the bottom patch. As a result, a first

resonance is triggered by the bottom patch. The top patch is implemented above the bottom patch with the distance that equals the combined thickness prepreg substrates between M1 and M4. The two patches are not physically in contact with one another. The configuration produces a secondary parasitic resonance that is primarily controlled by the top patch antenna dimension. In comparison to advanced antenna materials such as LTCC or LCP, FR-4 PCB is relatively more prone to substrate thickness variations during the lamination process due to its inferior mechanical and thermal properties such as Young's modulus and CTE (coefficient of thermal expansion). Any unexpected variations and especially reduction in the combined thickness of the prepreg substrates during the fabrication process will have a direct effect on the coupling capacitance between the top and bottom patches. Therefore a parametric study regarding the location of the signal via hole (d_p) and the radii of the top and bottom patches r_{top} and r_{bottom} is performed using numerical simulators to find the optimal design parameter combination for situations where the combined prepreg substrates change within the range of ± 30 um. Minimum bandwidth buffers are incorporated into the target design specification in preparation of any frequency deviations caused by various possible scenarios such as fabrication error, measurement discrepancies, and numerical errors. The finalized design parameters of the circular stacked patch antenna are $d_p = 0.42$ mm, $r_{\text{top}} = 0.61$ mm, and $r_{\text{bottom}} = 0.64$ mm.
