Antennas in Microwave Wireless Power Transmission

Xue-Xia Yang*
School of Communication and Information Engineering, Shanghai University, Shanghai, China

Abstract

The transmitting and receiving antenna designs for the microwave wireless power transmission (MPT) systems are illustrated in this chapter. After introducing a brief history, this chapter describes the components of a MPT system and the operation band selections. Several rectennas and arrays with different structures and performances are designed after analyzing the special considerations of the receiving antennas. To obtain the maximum DC-DC (direct current to direct current) system efficiency, the aperture level distributions of the transmitting antenna are investigated with consideration of the receiving rectennas. A MPT system design operating at C-band is explained based on the above discussion and the summary is made finally.

Keywords

Microwave wireless power transmission (MPT); Rectennas; Antennas; Rectifying circuits; Conversion efficiency; Aperture level distribution; Optimization

Introduction

Among several kinds of wireless power transmission (WPT) technologies, the microwave power transmission (MPT) is noticeable for the features of being applied in long-distance and high power transmission. It had been suggested to power helicopter, transfer power to the far-reached areas, and transfer the solar power to the earth by the solar power satellite (SPS). Now the WPT technology has explored its applications in many fields, such as charging portable devices and automobile, powering wireless sensors, telemetry and radio frequency identification (RFID), microwave-driven smart material actuators, and recycling ambient microwave energy. With the development of the wireless communications, radars, and radio astronomy, the techniques of the microwave generators and transmitting antennas have been much developed and could be adopted by the MPT systems. However, the rectennas, which are composed of receiving antennas and rectifying circuits, are unique for the MPT systems. After a brief history and operation principle of MPT technology, the emphasis is put on the designing of the receiving rectennas and the transmitting antennas for the MPT systems.

Section "Introduction" presents the brief history of MPT technology. Section "MPT Technology and System" describes the components of a MPT system and the operation frequency selections. A receiving antenna should be designed to be easily integrated with a rectifying circuit and receives the maximum microwave power, which is detailed in section "Receiving Rectennas Design." Section "Transmitting Antennas Design and *BCE*" shows the transmitting antenna design considering the receiving rectenna to obtain the high system efficiency. Finally, several MPT systems are designed in section "Efficiency Evaluation of C-Band MPT System" and the conclusion is in section "Summary."

Brief History of Wireless Power Transmission and Applications

The gap spark experiment using metal coils made by Heinrich Hertz in 1887 demonstrated the electromagnetic wave propagation in free space. Over 120 years passed, electromagnetic waves have explored many kinds of communications applications including telegraph, broadcast, television, radar, radio astronomy, satellite navigation, and all sorts of mobile communications. Even so, early in 1899, Nikola Tesla suggested transferring power by the electromagnetic wave and did effort to verify the idea. It was said that experiment of transferring power by the resonant radio frequency of 150 kHz using Tesla coil had been carried out at Colorado Springs in 1899. It is a pity that the detailed data had not been recorded. The second famous WPT experiment was performed in the Westinghouse Laboratory by H. V. Noble and was exhibited at the Chicago World's Fair of 1933–1934. Several hundreds of power were transferred by 100 MHz electromagnetic wave. The transmitting and the receiving antennas were dipoles and the distance was 25 ft.

It was not until the end of the 1950s that the microwave WPT technology was noticed again because of the emerging and maturity of the key microwave elements, such as the klystrons and magnetrons that generate the microwave and transistor diodes that rectify efficiently. The microwave generators at the higher radio frequencies and the phased arrays and high-gain antennas in radar systems rapidly developed during World War II make it possible to propagate EM wave by a narrow beam.

The first MPT technology application was microwave platform put forward by Raytheon Company in 1959. The microwave platforms would provide long-endurance operations for communication relay, environment surveillance, space detection, remote sensing, etc. at a high altitude space. Although the microwave platforms were not developed practically, it activated the MPT research work from the beginning of the 1960s. The first MPT experiment in laboratory was performed by Dr. Brown at JPL in 1963 (Brown 1964), in which 400 W microwave power was transmitted and 104 W DC (direct current) power was obtained at the receiver from 7.4 m distance away. It was also reported that a microwave-powered helicopter flew about 10 h at 10 ft height (Brown 1984). In the 1990s and the early 2000s, the concept of microwave platform was investigated further in many plans, such as SHARP plan of Canada (East 1992); MILIX, MILAX, and ETHER plans of Japan (Shinohara 2011; Fujino et al. 1996; Shinohara and Matsumoto 1998); KERI plan of Korea (Youn et al. 1999); and SERT plan of the USA (Strassner and Chang 2003). To verify these plans, some MPT experiments were carried out on the earth from one place to another one or from one point on the earth to the air.

The solar power satellite (SPS) concept introduced by Dr. Peter Glaser in 1968 is the second important MPT technology application (Glaser 1992), which possesses perpetual value as a kind of green energy until now and in the future. The SPS is a power converting station, on which the solar power is transferred to the earth by the microwave beam using its low loss performance in the atmosphere, regardless of day or night. Three steps are included. Firstly, the SPS collects solar power and converts it into DC (direct current) power by the optic-electric converters. Secondly, the microwaves are produced from the DC power by the generators and transmitted to the earth by the transmitting antennas on the SPS. Thirdly, the rectenna arrays on the earth, which are composed of the receiving antennas and the rectifying circuits, receive the microwaves and convert them back to DC power. The conversion efficiency of DC-DC is main parameter concerned by the researchers and the users. As one of the key technologies, MPT research has been strongly inspired by the SPS concept. Some relative areas have been researched, for example, the influences of the microwave beams on the birds, on the soil for growing crops, on the ionosphere, etc. The fractionated spacecraft concept presented by DARPA in 2007 is a good combination of the microwave platforms and SPS. The fractionated spacecraft is a satellite system composed of some modules, one of which obtains energy from the SPS and powered other modules by MPT technology.

MPT technology was also proposed to be applied in powering unmanned aircrafts and transfer power to the faraway districts (Celeste et al. 2004). The microwave beam strength and steering direction can be

DOI 10.1007/978-981-4560-75-7_116-1

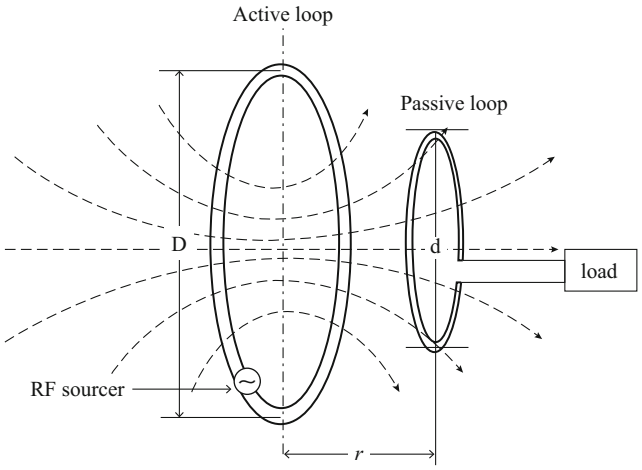

Fig. 1 Near-field magnetic induction

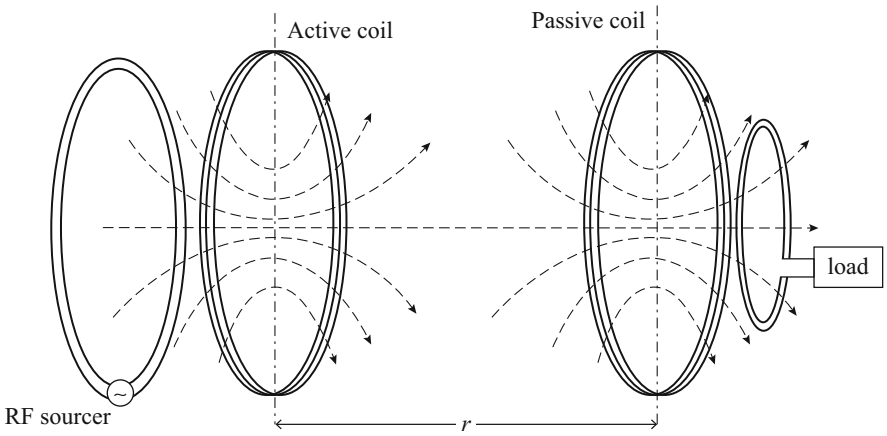

Fig. 2 Strongly coupled magnetic resonance

controlled easily to meet the requirement of safe standards. Now it has explored its applications in low power conditions, such as wireless sensors embedded in concrete bridge or bodies, radio frequency identification (RFID), recycling ambient microwave energy (Zoya et al. 2014), etc.

Remarkably, the planar printed technology developed in the mid-1950s made MPT more practical because the rectennas that receive the microwave beam and convert it into DC power could be very thin and conformal to the DC demanders.

Since the beginning of this century, consumer electronic products have been developed rapidly. It is attractive to recharge electric products wirelessly. Tailless TVs and wireless recharge mobile devices have been shown by the main companies although they have not been widespread in the market. In 2008, the Wireless Power Consortium developed an interface standard for the near-field inductive electrical power transfer, which is named as Qi. The Qi standard is renewed constantly since then (2014). This near-field magnetic induction can wirelessly transfer power to only a centimeter range (Fig. 1). In 2007, strongly coupled magnetic resonances were suggested to transfer much power wirelessly to a little long distance (Kurs et al. 2007). Sixty watts power was collected over 2 m at the efficiency of about 40 % in MIT (Fig. 2).

There are three kinds of wireless power transmission technologies based on different operation principles: magnetic induction, magnetic resonance, and MPT by radiation beam. Generally, the magnetic

DOI 10.1007/978-981-4560-75-7_116-1

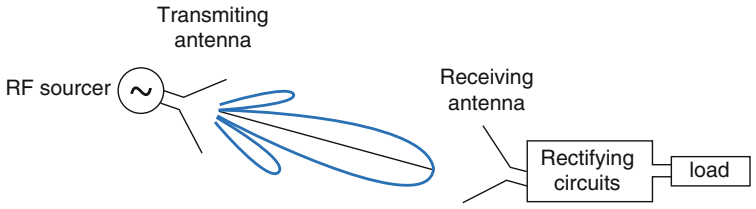

Fig. 3 MPT by radiation beam

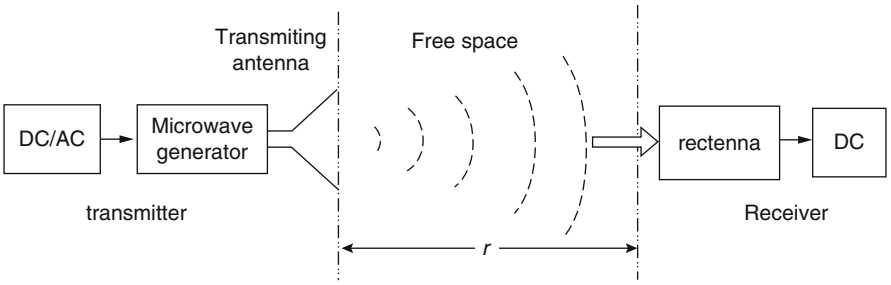

Fig. 4 MPT system

induction and the magnetic resonance manners are based on the near-field theories and the MPT system should be designed by the far-field theory. This chapter put the emphasis on designing the transmitting and receiving antennas for the MPT systems.

MPT by Radiation Beam

It is well known that the losses of microwaves below X-band are low in the atmosphere. The strength and the direction of the microwave beam could be controlled by the transmitting and the receiving antennas as shown in Fig. 3. So it is a feasible manner to transmit power to a far distance on the stage of hundreds of kilometers.

MPT Technology and System

MPT technology has been proposed firstly on the applications of high power and long distance, such as microwave powering high altitude airships and unmanned vehicles, SPS, and transmitting power to the far-reached places. Now MPT has explored the applications to low power density situations of harvesting the ambient electromagnetic wave and recharging the portable electronic devices. Meanwhile, the power density must meet the safety standards for the living environments of human, animals, and plants (IEEE Std 2006).

System Components and Efficiency

A MPT system consists of a transmitter and a receiver as shown in Fig. 4. The microwave transmitted by the transmitter is received and rectified by the receiver after propagating an R distance. The transmitter is composed of a microwave generator and a transmitting antenna or array. The microwave could be excited from a DC or an AC (alternating current) resource. The receiver has a receiving antenna and a rectifying circuit, which is named as a rectenna.

DOI 10.1007/978-981-4560-75-7_116-1

The DC-DC (or AC-DC) efficiency is the key parameter of a MPT system, which is contributed by several factors. The transmitter includes two factors: the efficiency of the microwave generator from DC to mw (microwave) η_g and the transmitting antenna efficiency η_t. The microwave propagation efficiency is indicated as η_p, in which the attenuation in the atmosphere should be considered. The receiver of the rectenna has two factors: the microwave capture efficiency η and the mw-DC conversion efficiency η_r of the rectenna. So the total efficiency of a MPT system is

$$\eta_{sys} = \eta_g \cdot \eta_t \cdot \eta_p \cdot \eta_c \cdot \eta_r \tag{1}$$

To design a MPT system with a high DC-DC efficiency, the transmitting and the receiving antenna apertures must be optimized jointly, which will be detailed in section "Transmitting Antennas Design and *BCE*" where the microwave beam capture efficiency (*BEC*), i.e., η_c, will be investigated. The five efficiency factors in formula (1) are all related to the operation frequency.

Operation Frequency of MPT

The study and applications of MPT technology mainly focus on the ISM (industrial, scientific, and medical) bands of L (915 MHz), S (2.45 GHz), and C (5.8 GHz). With the development of microwave devices, millimeter waves have been applied in MPT technology, such as K- (24.125 GHz), E- (61.25 GHz), and W-bands. The operation frequencies are mainly determined by the application environments.

For the applications of transferring power between a long distance across the atmosphere, such as powering an unmanned vehicle from the earth or an aerostat in the near space, transferring power from one place to another on the ground, and transferring power from the space to the ground (SPS), the losses in the atmosphere must be considered so L-, S- and C- bands should be used. For the applications in the space, where there are nearly no atmosphere losses, the millimeter waves are preferable because of the relatively compact and light generators, transmitting antennas, and rectennas. The lightness and compactness of microwave devices are very important because of the actual load limitation in the space. The millimeter MPT technology is recommended to power the fractionated satellites.

The generator efficiencies of η_g are relative to the operation frequencies. Generally, the generator technique is mature and the efficiencies η_g is higher at the low microwave bands. The propagation efficiency η_p is mainly decreased by the attenuations of the oxygen and water vapor in the atmosphere. Generally, the path losses are very low at the bandwidths below around 10 GHz and can be neglected. However, the losses must be considered when the operation frequencies come to higher. The oxygen molecules resonate at 60 and 118.75 GHz, while the water molecules do at 22.24, 183.31, and 325.5 GHz, which cause serious attenuations. There exist atmospheric windows among these absorbing frequencies, such as 35, 94, 140, and 220 GHz, which can be used to MPT.

The rectennas are generally attached to the surface of a DC power demander so the planar printed process is preferable. As far as the present PCB process level, the printed rectennas at microwave bands are acceptable, while those at millimeter wave bands have high losses and the mw-DC efficiency is relatively low.

With the development of the radar, wireless, and satellite communications, many kinds of high-power microwave antennas and generators have been proposed, which could be utilized in the MPT systems. In this chapter, the emphasis will be put on two items. One is the receiving rectennas and array designs with the high mw-DC efficiency, i.e., η_r. Another is the optimization of the transmitting and the receiving apertures for the high microwave capturing efficiency of *BEC*.

DOI 10.1007/978-981-4560-75-7_116-1

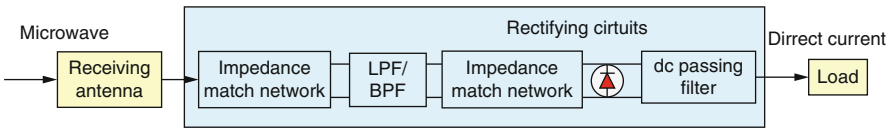

Fig. 5 Components of a rectenna

Receiving Rectenna Design

A rectenna is the integration of a receiving antenna with a rectifying circuit as shown in Fig. 5. The rectifying circuit is composed of a rectifying diode, an input matching network, a bandpass or lowpass filter, a DC-pass filter, and a load. The research on rectenna elements shows that the mw-DC conversion efficiency could reach 80 % when a Schottky diode receives an input power about 100 mW (Strassner and Chang 2003). The common mw-DC efficiencies of rectenna elements are about 75 % at the operation frequencies not higher than X-band (Strassner and Chang 2003; Yang et al. 2008). The mw-DC efficiencies of rectenna arrays would decrease apparently because of the transmission line loss of the circuits, the feedline loss of the antennas, and the nonuniform of the power density on the rectenna elements (Shinohara and Matsumoto 1998).

The antennas should receive enough microwave power to keep the rectifying circuit have a high and constant mw-DC efficiency. Thus, to design a receiving antenna for a rectenna, some factors should be considered, including a high gain, easiness to be integrated with the rectifying circuit, the polarization calibration for the transmitting and the receiving antennas, etc.

Evaluation of mw-DC Conversion Efficiency of Rectennas

The mw-DC conversion efficiency is the most concerned parameter for a rectenna. Supposing the DC voltage on the load R_L is V_{dc}, the mw-DC can be calculated by Eq. 2:

$$\eta_r = \frac{P_{dc}}{P_{in}} = \frac{V_{dc}^2}{R_L P_{in}} \tag{2}$$

where P_{out} and P_{in} are the output DC power and the incident microwave power, respectively. The incident microwave power of the rectenna is calculated by the Friis transmission formula:

$$P_{in} = \left(\frac{\lambda}{4\pi r}\right)^2 P_t G_t G_r \tag{3}$$

where P_t and G_t are the power and the gain of the transmitting antenna, G_r is the receiving antenna gain, and λ is the free space wavelength at the center frequency. Figure 6 illustrates the rectenna efficiency measurement system. The transmitting power P_t can be monitored by a power meter with a little microwave being coupled by a directional coupler.

Considerations for Designing Receiving Antennas

The most commonly used antennas for rectenna systems are the planar antennas, which could be integrated with the rectifying circuits with a minimum loss and be conformal to the electric equipment.

To meet with the rectenna demand of high mw-DC efficiency and engineering applications, the selection of the receiving antenna for a particular application should be based on these considerations: high gain, the same feedline with the transmission lines of the rectifying circuit, necessary bandwidth, and the polarization state.

DOI 10.1007/978-981-4560-75-7_116-1

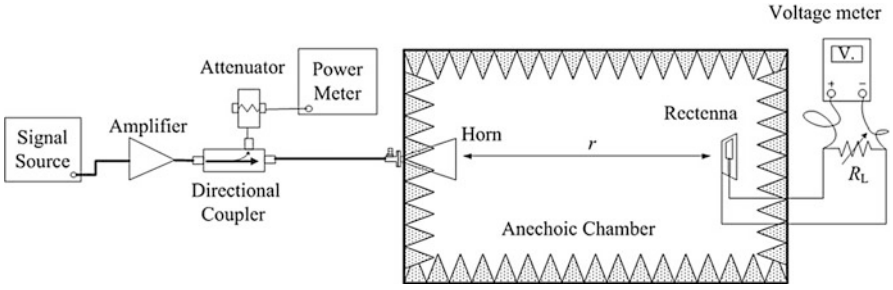

Fig. 6 mw-DC conversion efficiency measurement system of rectennas

High Gain

High-gain demand of the receiving antennas lies on two points. Firstly, on the safety condition of a limited power density, the high-gain antennas can easily obtain enough input microwave power for the rectifying circuits to maintain the high mw-DC conversion efficiency. Secondly, antennas with high gain can reduce the total number of rectenna elements on a given area. Planar printed antennas are preferred to keep low profile and conformal with the DC power demanders.

Matching and Integrating with Rectifying Circuits

Impedance match between the receiving antenna and the rectifying circuit is necessary to transfer the maximum microwave rectifying diode. To minimize the energy lost in the impedance match networks, the feedlines of receiving antennas are the same as the transmission lines of the rectifying circuits. The commonly used planar transmission lines have CPS (coplanar striplines), microstrip lines, and CPW (coplanar waveguides). Generally, to simplify the design process, the input impedances of the antenna and the circuit are all 50 Ω. However, it is better to design the input impedance of the antenna equivalent to that of the diode to make the rectenna compact if the LPF/BPF can be omitted. The design examples of the three different planar transmission lines, including CPS, microstrip line, and CPW, will be introduced in this section.

Bandwidth

Theoretically, MPT can operate on single frequency. Considering the errors of design and manufacture and the frequency uniformity between the receiving antenna and the rectifying circuit, a certain bandwidth is essential. To harvest the ambient electromagnetic energy, a wideband or a multi- band receiving antenna, which covers the microwave bands, is required.

Polarizations

As all know, a linear polarized antenna can receive only half the power of a circularly polarized wave and vice versa. So for the applications of transfer power from one point to another one, the polarization alignment is critical for the receiving and the transmitting antennas with linear polarization operations while only same direction of turning is demanded for the circularly polarized waves. For the MPT applications of one point to multi-point or inverse, circularly polarized rectenna can receive constant microwave at any polarization directions when the transmitted microwaves are linear polarization or the same circular one.

Other Considerations

The functions of the LPF/BPFs in Fig. 9 are used to restrain the high-order harmonic waves excited by the nonlinear diode from being radiated again because re-radiation will decrease the rectenna efficiency.

DOI 10.1007/978-981-4560-75-7_116-1

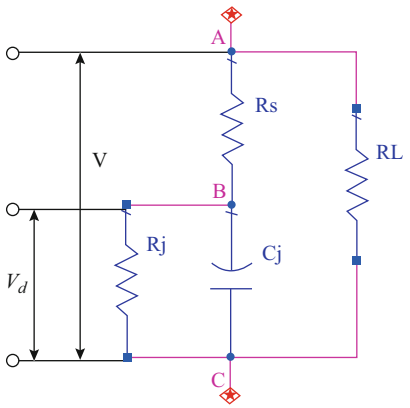

Fig. 7 Equivalent circuit of unpackaged Schottky diode

A receiving antenna with harmonic suppression can avoid the need of the LPF/BPFs and allows for miniaturizing the rectenna.

For the WSN and RFID applications, the electrical devices usually transmit data and obtain power simultaneously. The dual-polarized receiving antenna is a strategy with one polarization for communication and another for MPT. Similarly, a dual-frequency antenna is also an option.

Rectenna Design Examples

CPS Circularly Polarized Rectenna

Dr. Strassner and Chang proposed a kind of CPS circularly polarized rectenna, whose prominent virtues are the high gain of the receiving antenna and the broadband of the antenna and the rectifying circuit (Strassner and Chang 2003). A dual-rhombic loop with a reflecting plane was utilized as the receiving antenna with 10.7 dB gain and 10 % 2:1 VSWR being obtained. The rectifying circuit included a CPS band-reject filter that suppresses the re-radiated harmonics by 20 dB. The rectifying diode was an unpackaged MA4E1317 Schottky diode, whose equivalent circuit is illustrated in Fig. 7. The equivalent circuit parameters are as follows: series resistance $R_S = 4\ \Omega$, zero-bias junction capacitor $C_{j0} = 0.02$ pF, built-in turn-on voltage $V_{bi} = 0.7$ V, and breakdown voltage $V_B = 7$ V. The mw-DC conversion efficiency of approximately 80 % was measured for an input power level of 100 mW on the load of 250 Ω.

A similar rectenna was investigated as shown in Fig. 8, in which a low pass filter (LPF) was used to inhibit the high-order harmonics. According to the formula derived in Strassner and Chang (2003), the input impedance of the MA4E1317 diode was 172 Ω. The input impedance of the antenna and the characteristic impedance of the CPS transmission line could be designed as 172 Ω to omit the impedance match networks in the rectifying circuit. The rectenna was etched on the substrate of 2.55 relative permittivity and 0.8 mm thickness. So the CPS has trace width of 0.6 mm and the slot width of 0.4 mm.

The LPF structure and the S parameter responses are shown in Fig. 9. The main sizes are $L_1 = 5.6$ mm, $L_2 = 3.7$ mm, $L_3 = 3.5$ mm, and $L_4 = 4.3$ mm. $|S_{21}|$ parameters at 5.8, 11.6, and 17.4 GHz are −0.08, −29.45, and −22.9 dB, respectively. The higher-order harmonics have been inhibited effectively.

A dual-rhombic-loop antenna was designed at 5.8 GHz with the reflect plate at the distance of $0.21\lambda_0$. The measured gain is 10 dB and the input impedance was 170 Ω. The antennas and the LPF were simulated together by Designer software and the frequency response of $|S_{11}|$ was shown in Fig. 10. $|S_{11}|$ parameters at the fundamental frequency of 5.8 GHz and the second and third harmonics were −28.8, −1.05, and −1.02 dB, respectively, which illustrated that the harmonics were suppressed successfully. The distance between the diode and the capacitor in Fig. 8 was 9.5 mm and the optimized load was 250 Ω.

DOI 10.1007/978-981-4560-75-7_116-1

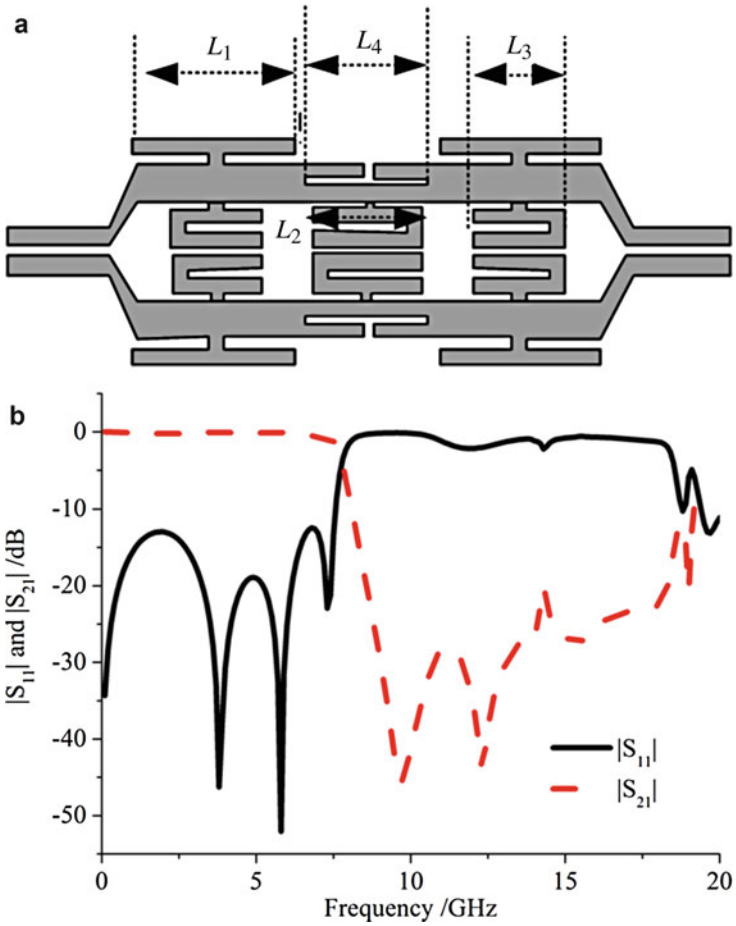

Fig. 9 LPF structure and the S parameter responses. (**a**) LPF structure and (**b**) frequency responses of $|S_{11}|$ and $|S_{21}|$

The experiments had been carried out in a chamber. The maximum mw-DC conversion efficiency was 74 % at 5.95 GHz operation efficiency when the input power was 100 mW. The center frequency shift induced the decrease of the efficiency.

DOI 10.1007/978-981-4560-75-7_116-1

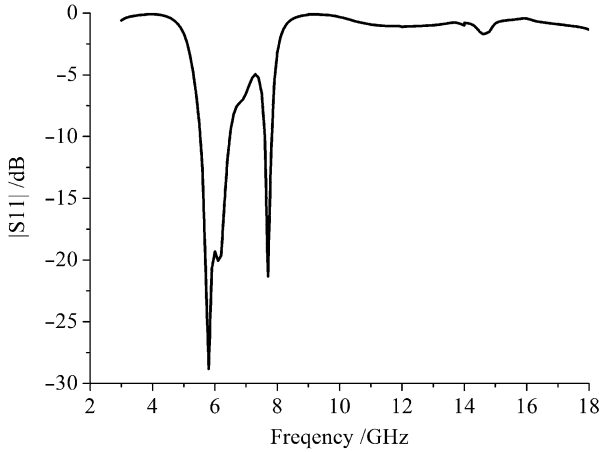

Fig. 10 Simulated $|S_{11}|$ versus frequency of the antenna integrated with the LPF

Circularly Polarized Rectenna with No LPF/BRF

The LPF (or BRF) could be omitted if the receiving antenna has harmonic inhibition function. Itoh et al. proposed a circular-sector antenna with a sector angle of 240° and an inset feeding point at 30° from the edge suppressing effectively the radiations of the second and the third harmonics (Park et al. 2004). Gao et al. designed a circularly polarized patch antenna with DGS (defect ground structure) under the microstrip feedline to avoid the harmonics (Gao et al. 2010). The structure, the simulation, and the measurement performances are illustrated in Fig. 11. The simulation software of HFSS has been used (Ansoft 2011).

The truncated-corner square patch excites the circular polarization wave and the DGS of dual dumbbell below the microstrip line on the ground suppressed the harmonics. The antenna has been etched on a substrate with the thickness of 1.5 mm, the relative dielectric constant ε_r of 2.55, and the tanδ of 0.002. From Fig. 11b, it is obvious that the high-order harmonics are inhibited effectively. The reflection coefficient is −30 dB at 5.8 GHz and about −3 dB at 11.6 GHz. The measured minimum AR is 1.0 dB and the bandwidth of AR less than 3 dB is 60 MHz from 5.78 to 5.84 GHz on the main direction from Fig. 11c. The measured gain is 6.5 dB at 5.8 GHz operating frequency.

The schematic diagram of the rectifying circuit is shown in Fig. 12. The diode used in the circuit was also MA4E1317 and the substrate is the same as the rectenna in Fig. 8. Simulated by ADS software (Agilent 2005), the input impedance of the diode was (230 + j18)Ω. The input impedance match network consists of two $\lambda/4$ microstrip lines and an open stub which is sensible to the operating frequency so the effect of the high harmonics deduced by the diode is low. The output match network is composed of a chip capacitor and a $\lambda/4$ microstrip line, which smoothes the DC voltage and reutilizes harmonics energy. The DC power is collected by a resistive load. This rectifying circuit had the highest simulated mw-DC efficiency of 81.4 % on the load of 320 Ω at 5.8 GHz when the input power was 100 mW.

The receiving antenna and the rectifying circuit were connected by a SMA connector as shown in Fig. 13a. The overall RF-DC conversion efficiency of rectenna versus frequency is illustrated in Fig. 13b. The voltage of 4.34 V was obtained and the highest conversion efficiency reached to 68.4 % on the load of 298 Ω at 5.86 GHz, which was exactly the value of the rectifying circuits. In applications, the antennas and the rectifying can be integrated directly on one substrate by omitting SMA connector. Without the loss of SMAs, the efficiency would be higher.

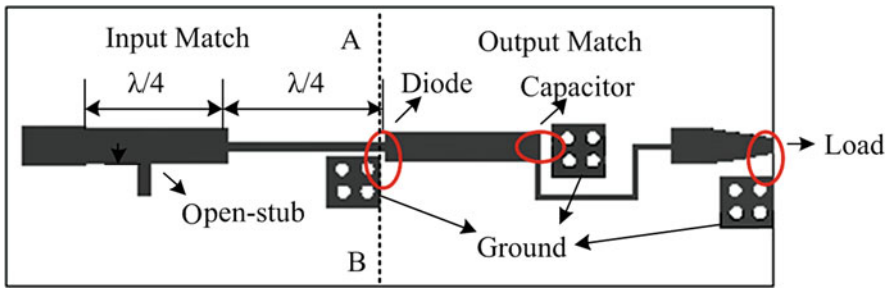

Fig. 12 Schematic diagram of the rectifying circuit

Rectenna with Data Communication Function

Usually, electrical devices obtaining DC power from the microwave also need transmitting and receiving information. A general scheme is designing two antennas, one for communication and another for the rectenna. However, a rectenna with communication function would have two good advantages. First, the RF front end would be compact, which is a critical demand for the most electronic devices. Second, the electromagnetic compatibility could be considered and optimized when designing the antenna for rectenna and communication simultaneously. A triple-band implantable antenna with a rectenna was designed for biotelemetry communication in Huang et al. (2011), in which data telemetry was at 402 MHz, wireless powering transmission at 433 MHz, and wake-up controller at 2.45 GHz. Although the rectifying circuits had a mw-DC conversion efficiency of 86 % at 433 MHz, the rectenna's efficiency

DOI 10.1007/978-981-4560-75-7_116-1

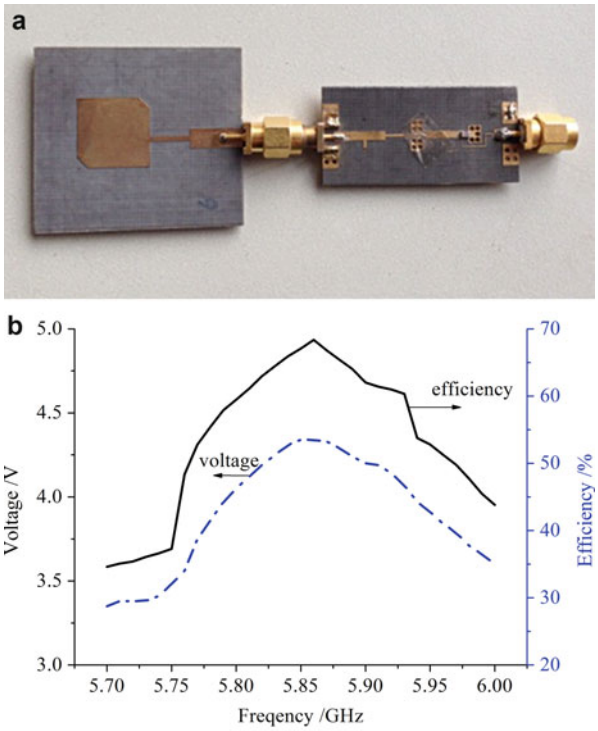

Fig. 13 Rectenna picture and the measured efficiency. (**a**) Picture of rectenna and (**b**) measured voltage and mw-DC efficiency versus frequency

was very low because of the low receiving power capacity of the antenna, which shows that the impedance match is very important for a rectenna design. The example as follow is a rectenna with communication capability (Yang et al. 2013).

Dual-Polarized Antenna Design

The receiving antenna is a dual-polarized square-patch antenna fed by aperture coupling as shown in Fig. 14a. The antenna has two layers of substrate with depths of h_1 and h_2. The square patch is on the top of the upper substrate and the microstrip feedlines are on the bottom plane of the lower substrate. The two orthogonal H-shaped apertures, located in the perfectly conducting plane placed between the two substrates, were used to improve the isolation between the two feed ports. Two orthogonal feed ports V- and H-port excite vertical and horizontal polarization waves, which are used as power supply and data communication, respectively.

The operating frequency f_0 is mainly determined by the side length of the square patch with less influence from the aperture position. This double-layer and aperture coupling fed patch antenna provides higher gain than the single layer and good suppression of harmonic waves so the filter in the rectifying circuit is omitted and the rectenna is compact. The detailed geometrical parameters and the substrate characteristics could be referred to Yang et al. (2013).

The simulated and measured reflection coefficients in terms of $|S_{11}|$ of the V-port, S_{22} of the H-port, and the isolation $|S_{21}|$ versus frequency are displayed in Fig. 14b. For the two polarizations, the measured lowest values of $|S_{11}|$ are -30 and -18 dB at their corresponding center frequencies of 5.8 and 6.1 GHz, respectively, which is mainly caused by the different feed positions and structure. The isolation $|S_{21}|$ is above 25 dB within a broad bandwidth. The V-port, operating at 5.8 GHz, is used as power transformer, while the H-port, operating at 6.1 GHz, is used for communication systems. A wideband simulation shows that the reflection coefficient of the second-order harmonic wave at 11.6 GHz is less than 2 dB. This

DOI 10.1007/978-981-4560-75-7_116-1

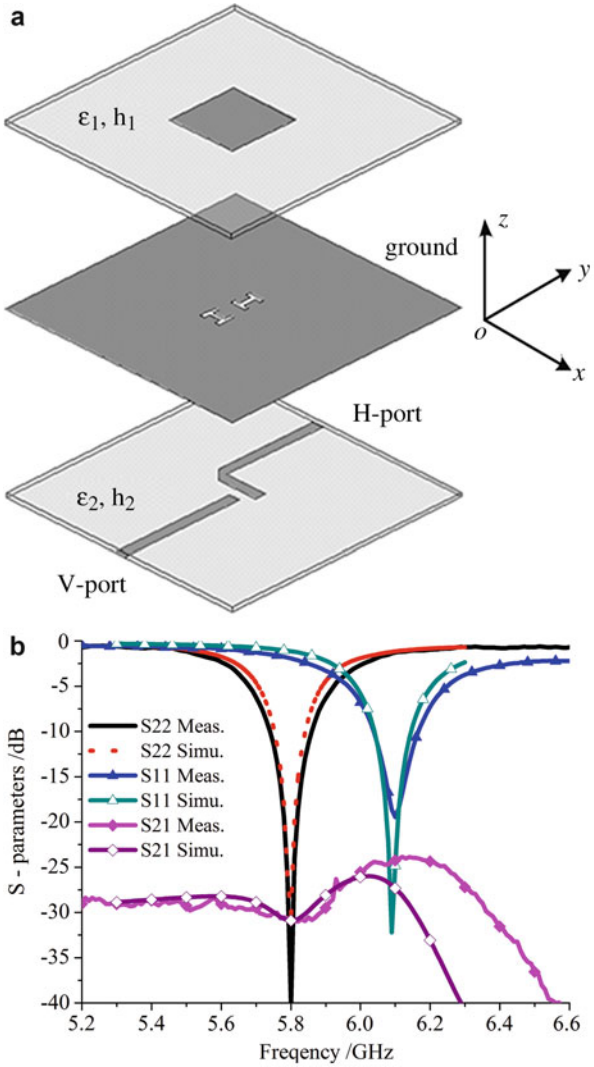

Fig. 14 Configuration of the receiving antenna and S parameter versus frequency. (**a**) Perspective view of the receiving antenna and (**b**) $|S_{11}|$, $|S_{22}|$, and $|S_{21}|$ versus frequency

feature mainly attributes to the antenna symmetry and the aperture coupling feed structure and a special LPF/BRF will not be required for the rectenna. The maximum gains of the H-port for the communication and V-port for the rectifying circuit at their corresponding resonant frequencies are 7.6 and 7.2 dBi, respectively.

Rectifying Circuit Design

The input matching network and the DC-pass filter of the rectifying circuit are designed using microstrip lines as shown in Fig. 15. The substrate is the same as that for the receiving antenna. The open stub of microstrip line 2 and the short stub of microstrip line 3 are used to cancel out the imaginary part of the diode's input impedance Z_{in}, while microstrip line 1 is a $\lambda/4$ impedance transformer to match the impedance to 50 Ω at the input port. Three fan-shaped stubs of different sizes act as a DC-pass filter to smooth the output DC power.

The diode used in the circuit is a packaged Schottky diode of HSMS2860. Apart from the parameters in Fig. 7, the equivalent circuit includes the parasitic inductance L_p and the parasitic capacitance L_c. The equivalent parameters are listed in Table 1. According to ADS simulation, the input impedance Z_{in} of the

DOI 10.1007/978-981-4560-75-7_116-1

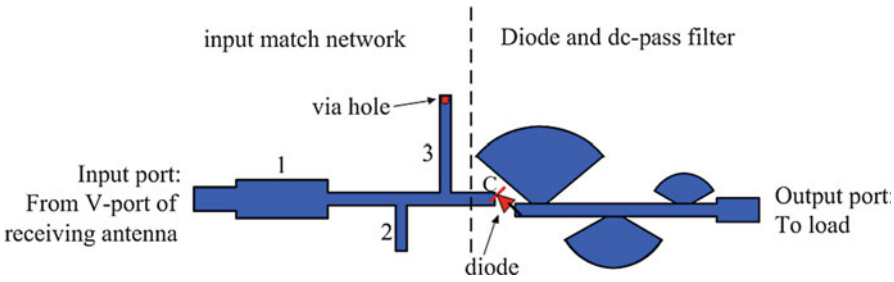

Fig. 15 Structure of the rectifying circuit

Table 1 Equivalent parameters of packaged Schottky diode HSMS2860

V_f Turn-on voltage	V_B Breakdown voltage	L_p Parasitic inductance	C_p Parasitic capacitance	R_s Junction resistance	C_{j0} Junction capacitance
0.3 V	7 V	0.5 nH	0.08 pF	6 Ω	0.18 pF

diode is (22-j55) Ω with 10 mW input power and 1200 Ω load at 5.8 GHz operating frequency to obtain the maximum mw-DC efficiency. Microstrip lines 1, 2, and 3 match the diode input impedance to 50 Ω.

The simulated reflection coefficient at the operation frequency of 5.8 GHz and the second harmonic frequency of 11.6 GHz are −40.2 and −0.13 dB, respectively. So the input port is matched well at the operating frequency and the higher-order harmonics are effectively suppressed. The simulated $|S_{21}|$ of the direct pass filter for the fundamental wave and the second and third harmonics are 50, 25, and 30 dB, respectively, which shows that the fundamental wave and the harmonics are inhibited successfully.

Figure 16 shows the simulated and measured mw-DC efficiency of the whole rectifying circuit. The simulation results show that this rectifying circuit had maximum efficiency of 81 % on the condition of 1200 Ω load and 10 mW input power at 5.8 GHz operating frequency. Experiments showed that the operation frequency with the highest efficiency was 5.78 GHz. The highest conversion efficiencies of 68.7 %, 69.3 %, and 69.9 % were measured on the loads of 1200, 900, and 600 Ω when the input power was 20, 25, and 35 mW, respectively. The differences between the simulations and the experiments lie mainly on several factors: the fabrication errors, the diode model in ADS, and the measurement errors.

The measured optimized condition of 900 Ω load and 5.78 GHz operation frequency would be preferred in the measurements of rectenna in the following section.

Rectenna Performances

The antenna and the rectifying circuit are frequency dependent; hence, a little mismatch would cause large losses. The co-simulation of the receiving antenna and rectifying circuit using HFSS and ADS becomes very important for a high mw-DC conversion efficiency design. To investigate the rectenna performances, the co-simulation by ADS has been carried out. The characteristic of the antenna's input impedance versus frequency could be embedded in the rectifying circuit's input port by S1P file with identical format. The simulated $|S_{11}|$ of the rectenna, receiving antenna, and rectifying circuit versus frequency are then displayed in Fig. 17. Comparing the dash line for the rectifying circuits and the dash dotted line for the receiving antenna reveals that the rectifying circuit has a wider bandwidth than the receiving antenna. From Fig. 17, the simulated power reflection coefficients at 5.8 GHz for the receiving antenna, the rectifying circuit, and the rectenna are −28.1, −40.2, and −27.7 dB, respectively. Thus, a close to perfect impedance match could be assumed and the receiving power of the antenna is considered equal to the

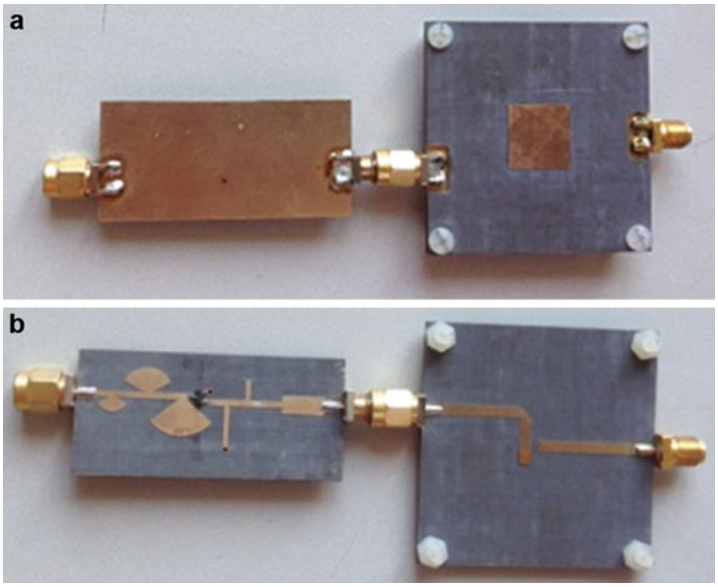

Fig. 18 Photograph of the rectenna: (**a**) front view and (**b**) back view

input power of the diode. The antenna bandwidth is narrower than that of the circuit so the rectenna bandwidth will be mainly decided by that of the antenna.

The receiving antenna and the rectifying circuit were connected by an SMA connector with 50 Ω characteristic impedance as shown in Fig. 18. The mw-DC conversion efficiency was measured by the measurement system shown in Fig. 6. The transmitting horn had a gain of 15.6 dBi and a size of 13.5 × 10 cm. The rectenna was fixed at the distance of 80 cm from the horn, which is in the far-field region. The measured gain of the receiving antenna was 7.0 dBi, which is used to calculate the received RF power of the rectifying circuits.

The output voltage and conversion efficiencies of different loads with the receiving power at 5.78 GHz operation frequency are illustrated in Fig. 19. The rectenna with a higher load achieved the maximum output voltage and conversion efficiency at a relatively low receiving power. The output voltages of the rectenna with various loads approached 4.5 V, which was the breakdown voltage of the diode. The highest conversion efficiency of 63 % was measured on the load of 900 Ω when the receiving power was 25 mW.

Communication Performances

To investigate the communication characteristics of the H-port, the rectenna model shown in Fig. 20 is simulated in HFSS software. The power reflection coefficient $|S_{11}|$ has nearly no change so it is not provided here. The gain patterns for the communication port deteriorate a little, as shown in Fig. 21. Nevertheless, the cross-polarization is still low and is approximately −20 dB in the main radiation direction. The gain decreases to 7.2 dBi from the expected 7.6 dBi because of the rectifying circuit.

When the antenna is connected to the rectifying circuit, the measured reflection coefficient of the communication H-port has nearly no change and is similar to the experimental $|S_{11}|$ curve of Fig. 14b. Figure 22 is the measured patterns of the H-port with and without the circuit. Compared to the simulation results of Fig. 21, the E-plane characteristic is good with −15 dB cross-polarization in the main radiation direction, even though there is an obvious sidelobe in the 120° direction on the H-plane. The measured maximum gain is 7.0 dBi.

The compact size, the ease of fabrication, and the compliance with safety standards are the key advantages of this rectenna.

CPW Rectenna with Broad Operation Band

CPW transmission lines have several advantages, such as the easiness of integration with active and passive elements, high circuit density, low dispersion, low radiation loss, and avoidance of ground vias, which are preferable for rectifying circuits design. Grounded coplanar waveguide (GCPW) is a modification of CPW. It has an additional ground plane on the back of the substrate. Combining CPW and GCPW transmission lines, a broadband CPW rectenna was designed (Nie et al. 2015) and Fig. 23 plots the CPW rectenna.

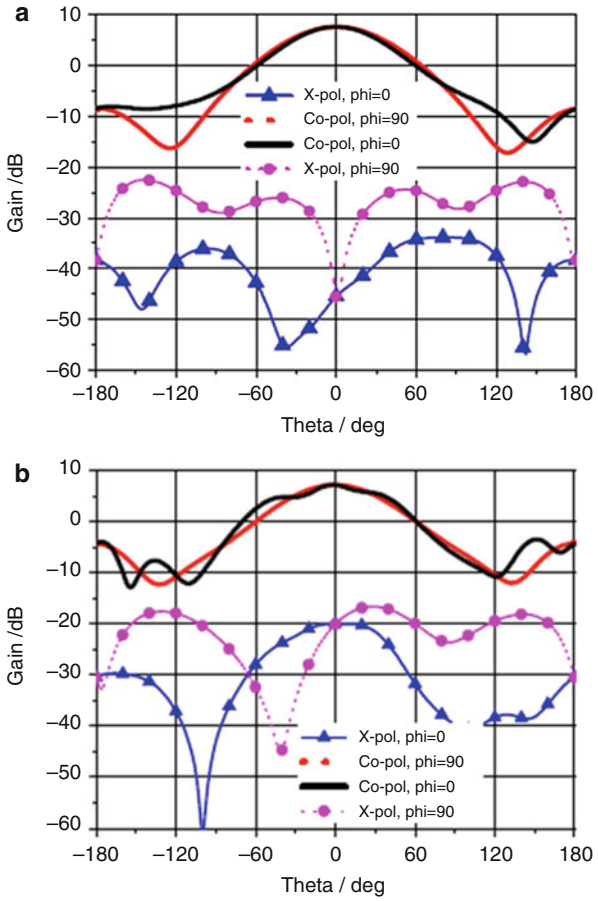

Fig. 21 Pattern comparison with and without rectifying circuit simulated by HFSS. —— E-plane/Co-P, ····· H-plane/Co-P, —+— E-Plane/X-Pol, ··▲·· H-Plane/X-Pol. (**a**) Without rectifying circuit. (**b**) With rectifying circuit

The rectifying circuit consists of a capacitor, a Schottky diode pair, and a DC-pass filter, which are connected in shunt or series on the same front side of the substrate of the GCPW transmission line. The characteristic impedance of the GCPW transmission line is 50 Ω. The input impedance Z_{in} of the diode is (64.2 + j9.8) Ω at 2.45 GHz when the input power is 15 dBm from ADS simulation. Z_{in} is matched to 50 Ω at the input port of the rectifying circuit by designing the input and the output impedance match networks. The input impedance match network is realized by the GCPW sections of L_3 and L_4. The output impedance match network consists of the capacitor pair of C_1 and C_2 and the GCPW section L_5.

In order to match the GCPW rectifying circuit directly, the antenna is fed by the CPW with the length of L_2, while the beginning section is GCPW structure, which could be recognized from Fig. 23b. In order to increase the antenna gain by directing its broadside beam in one direction, a reflecting plane is placed behind the antenna at the distance of $D = 0.18\lambda_0$.

The center frequency is 2.45 GHz when the slot length L_1 is $0.408\lambda_0$. The input impedance of the antenna is well matched to 50 Ω by carefully tuning the length L_1 of the CPW stub. Both the simulated and measured $|S_{11}|$ are found to be better than −30 dB at 2.45 GHz as plotted in Fig. 24a. The measured −10 dB bandwidth is more than 28.6 % (from 2.0 to 2.7 GHz). A good impedance match performance within a broad bandwidth has been achieved. The measured peak gain is 10 dBi at the center frequency of 2.45 GHz, while the simulated one is 10.3 dBi from Fig. 24b. The measured gain is stable and varies between 9.4 and 10 dBi in the bandwidth from 2.0 to 2.5 GHz.

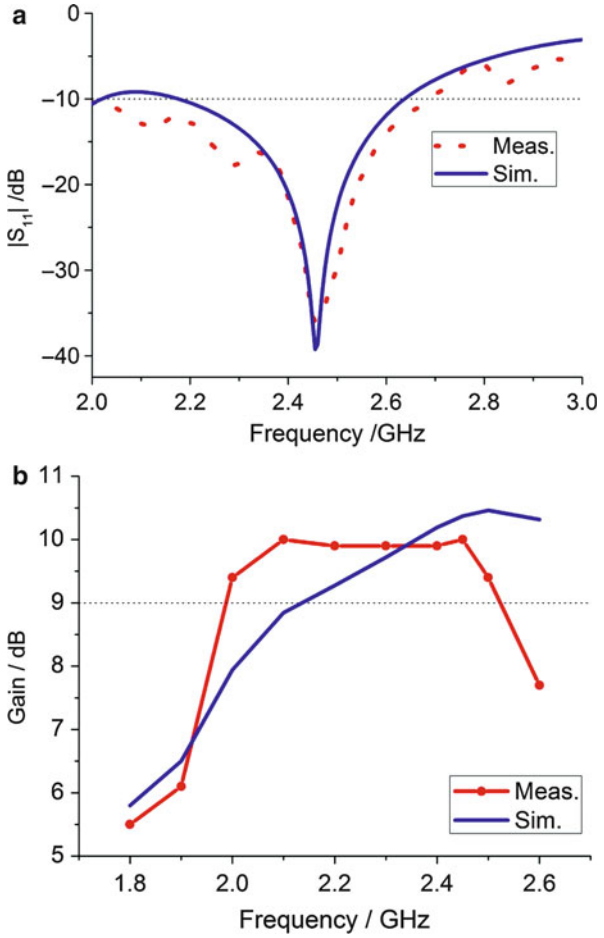

Fig. 24 Simulated and measured $|S_{11}|$ and gain versus frequency of the antenna. (**a**) $|S_{11}|$ and (**b**) gain

The measured conversion efficiencies of the rectenna are shown in Fig. 26. From Fig. 26a, the peak conversion efficiencies for both the rectenna and the rectifying circuit are about 62 % on the same load of 900 Ω, which show good impedance match between the receiving antenna and the rectifying circuit. From Fig. 26b, it can be found that the bandwidth of the efficiencies higher than 50 % is from 2.2 to 2.6 GHz (16.3 %) at 13 dBm received power. This broadband performance benefits from the wide operation bandwidths of the antenna and the rectifying circuit.

This CPW rectenna has a wide operation bandwidth. The receiving antenna has a high gain and a wide half-power beamwidth, which lessens the demand of the strict direction alignment. The rectifying circuit is designed by the GCPW transmission line, which avoids the use of ground vias and it is easy for the diodes and capacitors to be connected.

Rectenna Arrays

The power capacity of a Schottky diode is limited, so rectenna array design is necessary to obtain higher DC output power for most applications. A rectenna element can be equivalent to the series connection of a voltage source E and a load R_L. R_L, which is relative to the input mw power to the diode, is the optimized load with the aim of obtaining the highest mw-DC conversion efficiency. Rectenna arrays have three kinds of connections: series, parallel, and series/parallel mixed connections.

The rectenna element with communication function in section "Rectenna with Data Communication Function" will be referred to investigate the operation laws of rectenna arrays. The Schottky diodes used

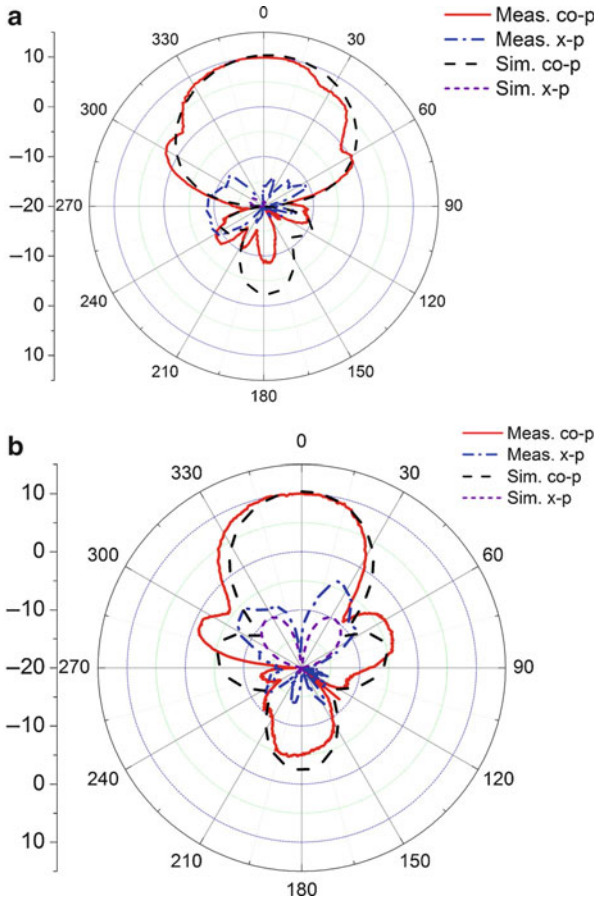

Fig. 25 Simulated and measured gain pattern at 2.45 GHz of the antenna in (**a**) E-plane (*xoz*-plane) and (**b**) H-plane (*yoz*-plane)

in the circuits are also the packaged Schottky diode of HSMS2860, whose equivalent circuit parameters are listed in Table 1.

Parallel Connection of Rectenna Arrays

Figure 27 schematically shows the parallel connection of n rectenna elements, which has the output DC power of nE^2/R_L. Based on the equivalent circuit principle, this parallel connection can be simplified as the series connection of a source of E and a resistor of $R_L./n$, whose equivalent load R_p and equivalent current I_p are

$$R_p = R_L/n \tag{4}$$

$$I_p = nE/R_L \tag{5}$$

Two-element parallel array is simulated by ADS software. The output DC power and mw-DC conversion efficiency versus the load are shown in Fig. 28. Apparently, the output current is two times of that of the element when the load is lower than 600 Ω, while the output voltage moves to the saturation of 3.2 V when the load becomes higher. The optimized loads of the element and the two-element array are 1200 Ω and 600 Ω, respectively, which meet with formulas (4) and (5) of the equivalent model. It can be seen that the maximum mw-DC efficiencies for the element and the two-element array are all about 81 %.

DOI 10.1007/978-981-4560-75-7_116-1

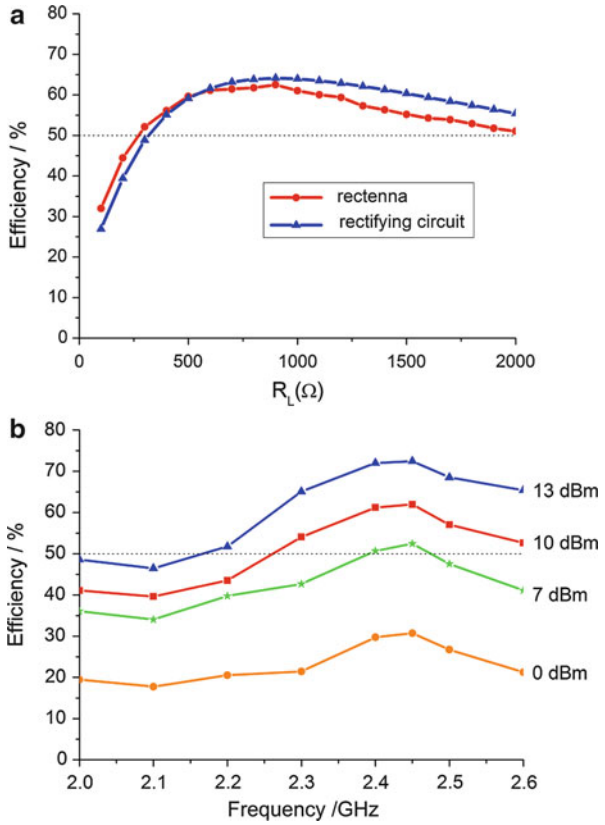

Fig. 26 Measured efficiency of the rectenna. (**a**) Efficiency versus load. (**b**) Efficiency versus frequency

Figure 29 gives the picture of the two-element array, the measured output voltage, and the mw-DC

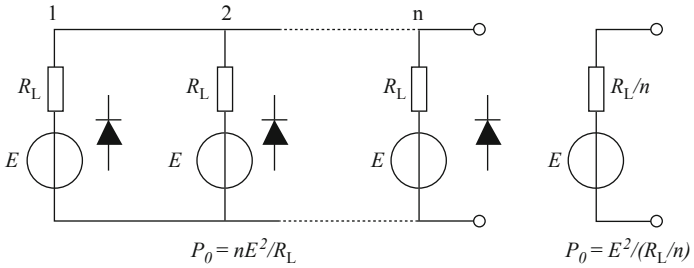

Fig. 27 Equivalent circuit model and its simplified model of parallel connection of n rectenna elements

efficiency versus the load with the element results being compared. The trends also accord with formulas (4) and (5). The maximum mw-DC efficiency of two-element array is about 60 %, which is lower than that of the element of 65 %. The difference between the simulated and measured results has been analyzed previously.

Series Connection of Rectenna Arrays

The series connection of n rectenna elements and the corresponding simplified equivalent circuits are illustrated in Fig. 30. The output DC power is also nE^2/r. The equivalent load R_S and equivalent voltage U_S are as follows:

DOI 10.1007/978-981-4560-75-7_116-1

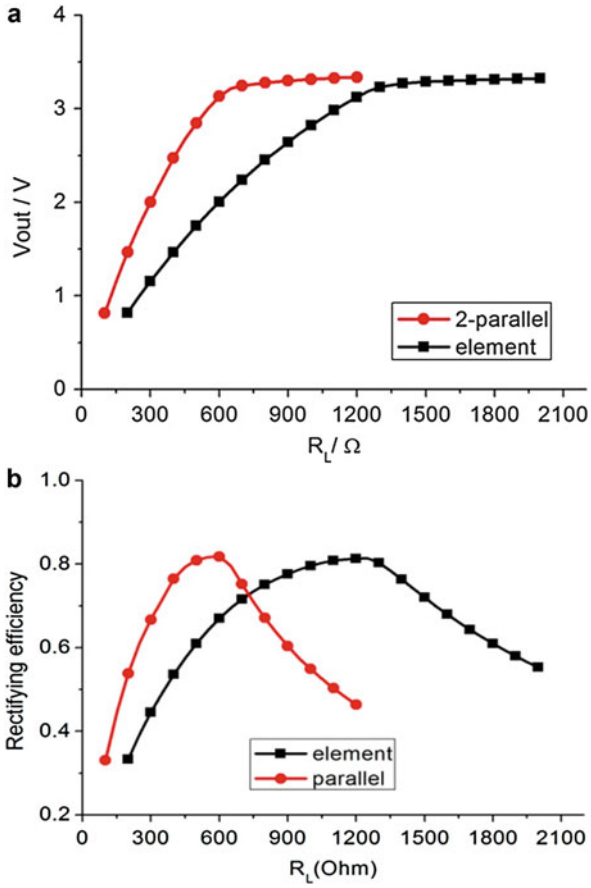

Fig. 28 ADS simulated output voltage and efficiency of element and two-element parallel array. (**a**) Output voltage versus load. (**b**) mw-DC efficiency versus load

$$R_s = nR_L \tag{6}$$

$$U_s = nE \tag{7}$$

The picture of the two-element series array and the measured output voltage and mw-DC efficiency are illustrated in Fig. 31 with the measured results of the element being plotted for comparing. When the load is less than 500 Ω, the diodes are not saturated, so the current on the loads of the element and the array are the same. The optimized loads of the element and the series array are 800 Ω and 1600 Ω, with the corresponding mw-DC efficiencies of 64.3 % and 62.1 %, respectively. Formulas (6) and (7) are validated.

So the conclusions can be drawn as follows. The array design accords with the general circuit theory of series and parallel connections when a rectenna element is equivalent to the series connection of a voltage source E and a load R_L. The optimized load of a series array is n times that of the element, while the current is the same if the diodes are not saturated. The optimized load of a parallel array is 1/n times that of the element and the output voltage is the same. At the same time, the minimum distance between two elements must comply with the principle of antenna array design. Extra narrow distance between two rectenna elements will decrease the receiving efficiency of the antennas, while extra wide one will enlarge unnecessarily the rectenna array area.

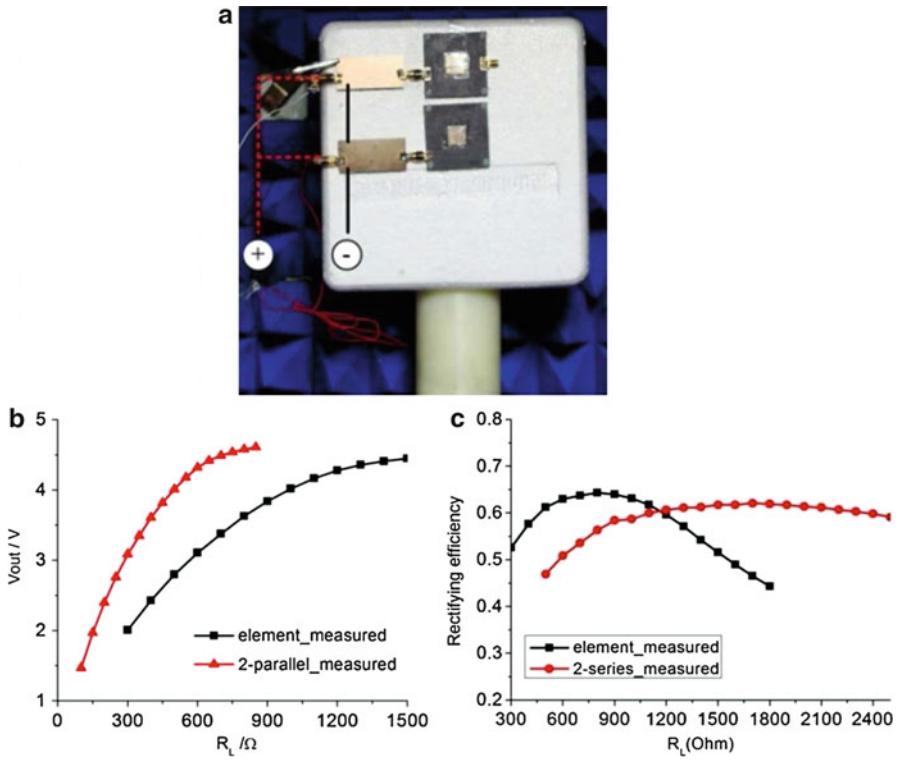

Fig. 29 Two-element parallel array and measured output voltage and efficiency. (**a**) Array picture. (**b**) Output voltage versus load. (**c**) mw-DC efficiency versus load

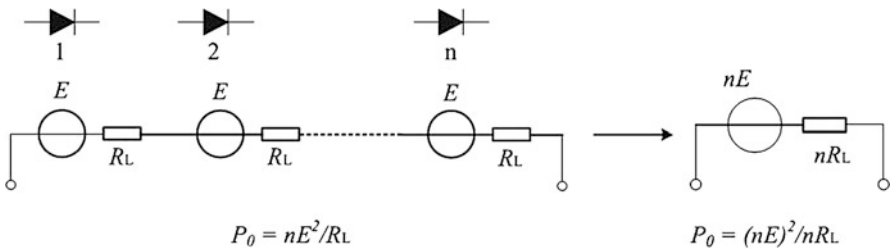

Fig. 30 Equivalent circuit model and its simplified model of series connection of *n* rectenna elements

Series/Parallel Mixed Connections of Rectenna Arrays

Generally, the load is given for an actual application so the array design should be carried out to get the maximum mw-DC efficiency after a rectenna element has been optimized. Two kinds of six-element rectenna arrays are shown in Fig. 32. Figure 32a is two branches in parallel connection after three elements in series, whose load is $3R_L/2$. Figure 32b is three branches in parallel after two elements in series, whose load is $2R_L/3$. Two arrays have the same output DC power of $P = 6E^2/R_L$ and different optimal loads.

Thus, if an array has n branches in parallel and every branch has n elements in series connection, the optimized load of the array is the same as that of the element of R_L.

A circularly polarized rectenna element in Fig. 33 is used as the array design. The quasi-square patch fed by aperture coupling is used as the circularly polarized receiving antenna. The rectifying circuit is on the same layer with the microstrip feedline of the antenna. This double-layer structure not only minimizes

DOI 10.1007/978-981-4560-75-7_116-1

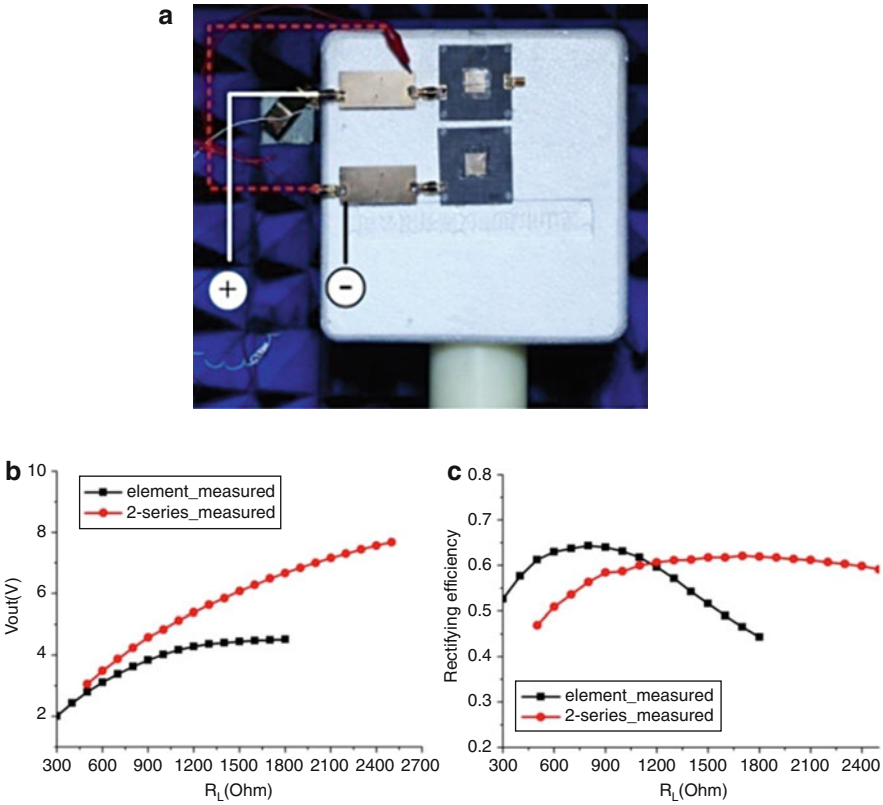

Fig. 31 Picture of two-element series array and measured output voltage and efficiency. (**a**) Picture. (**b**) Output voltage versus load. (**c**) mw-DC efficiency versus load

the size of the rectenna but also decreases the effects of the circuits on the antenna. To make the rectenna array compact, several microstrip lines are bended, so the rectifying circuit is just below the antenna.

The rectenna operates at C-band. The measured mw-DC efficiencies versus the loads on different input microwave powers are plotted in Fig. 34. From Fig. 34a, a maximum mw-DC efficiency of 63 % is measured when the input power is about 85 mW and the optimized load is 250 Ω. From Fig. 34b, the mw-DC efficiency on the 45° direction is only lower 8 % than that of the 0° direction, which shows a preferable circular polarization performance.

DOI 10.1007/978-981-4560-75-7_116-1

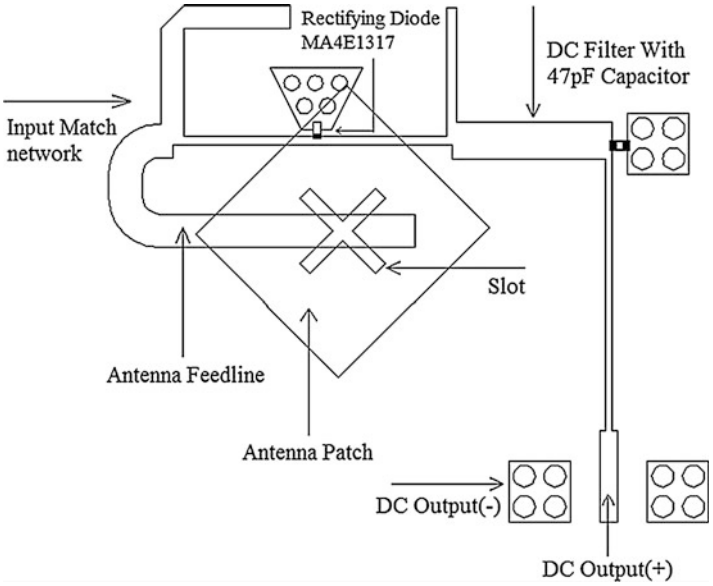

Fig. 33 Circularly polarized rectenna element

A rectenna array of 3 × 3-element with three branches in parallel and every branch having three elements in series connection is designed as illustrated in Fig. 35. The measured output DC voltage and the mw-DC efficiency versus loads are shown in Fig. 36 with the element results being plotted for comparing. When the input mw power P_{in} for every rectenna element is 81.1 mW, the measured maximum mw-DC efficiency for the array is 63 %, while the optimal loads for the array and the element are the same with the values of 250 Ω from Fig. 36a. The center frequency is 6.04 GHz and the maximum efficiency direction is at 45°. The output DC voltages of the array are about nine times by those of the element from Fig. 36b. The output DC power is about 461 mW on the load of 250 Ω with the receiving aperture of 12 × 10 cm.

The measured maximum efficiencies of the rectenna element and the 3 × 3-element array both occurred at 6.04 GHz while the designed center frequency had been 5.8 GHz, which was the main factor that decreased the efficiency. Another factor was that the input microwave power was 84.9 mW in the experiment. The mw-DC efficiency could be improved in some degree until the breakdown voltage of 4.5 V is reached, on which the input mw power is about 100 mW. So the mw-DC conversion efficiency of this sub-array could be expected to improve to 75 % after a careful design. Considering the rectenna array losses, the mw-DC efficiency is estimated to be 65 % for a large array. Under this assumption of 100 mW input mw power and 65 % conversion efficiency, 585 mW DC power could be expected on the rectenna array size of 12 × 10 cm.

Transmitting Antennas Design and *BCE*

The most concerned performance for a point-to-point MPT system is the DC-DC efficiency. Early in 1964, Degenford et al. studied level distribution of Gaussian function on the transmitting antenna aperture and verified experimentally on a reflecting beam waveguide with near 100 % *BCE* (beam capture efficiency) being obtained (Degenford et al. 1964). However, the reflecting beam waveguide propagation path model is impractical for the applications of long-distance microwave transmission. 10 dB Gauss amplitude tapered beam has been verified to be efficiently transferring the power from the transmitting

DOI 10.1007/978-981-4560-75-7_116-1

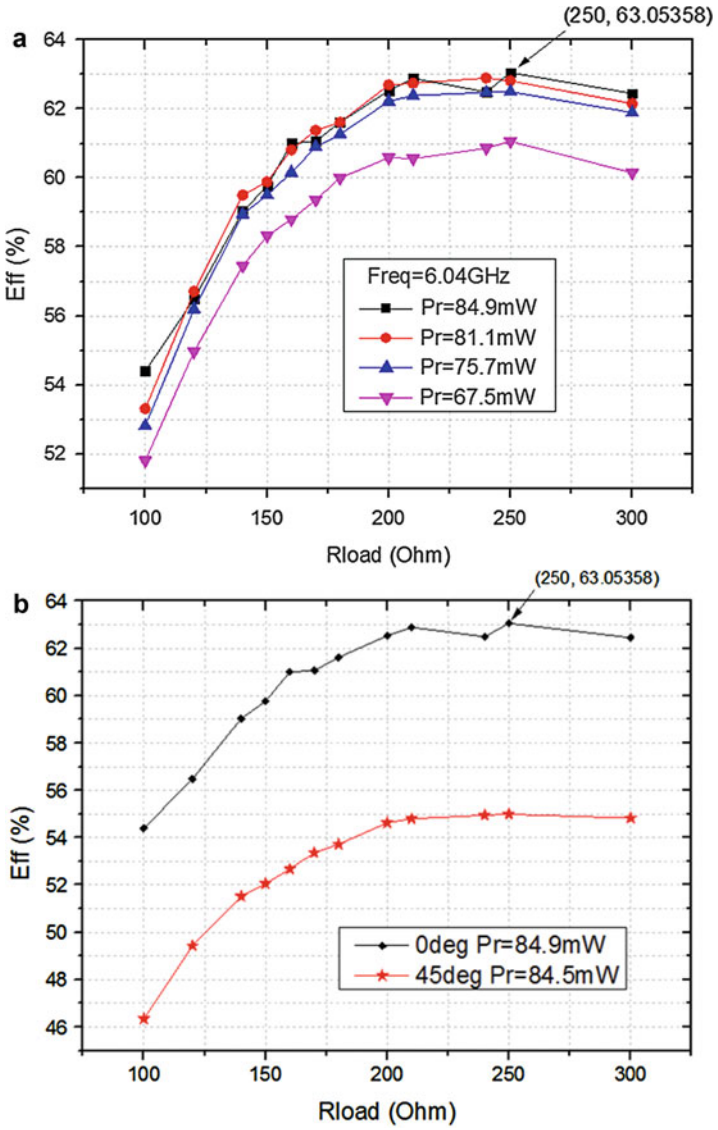

Fig. 34 Measured mw-DC efficiency of the rectenna element versus load. (**a**) Different input mw power. (**b**) Different receiving directions

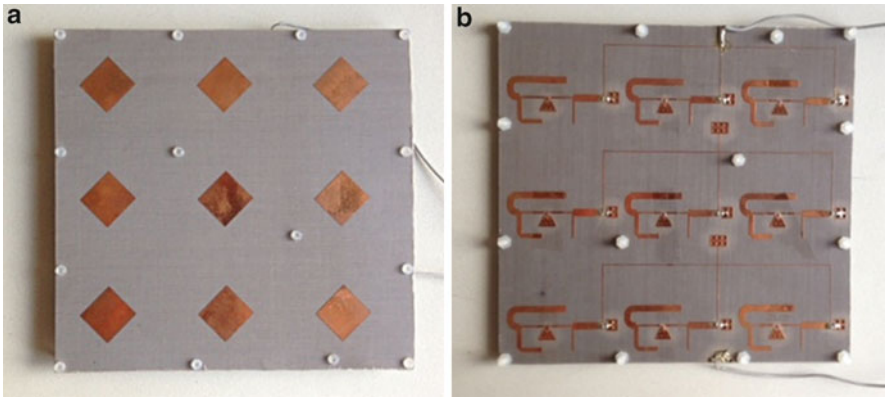

Fig. 35 Pictures of the 3 × 3-element array: (**a**) front view and (**b**) back view

DOI 10.1007/978-981-4560-75-7_116-1

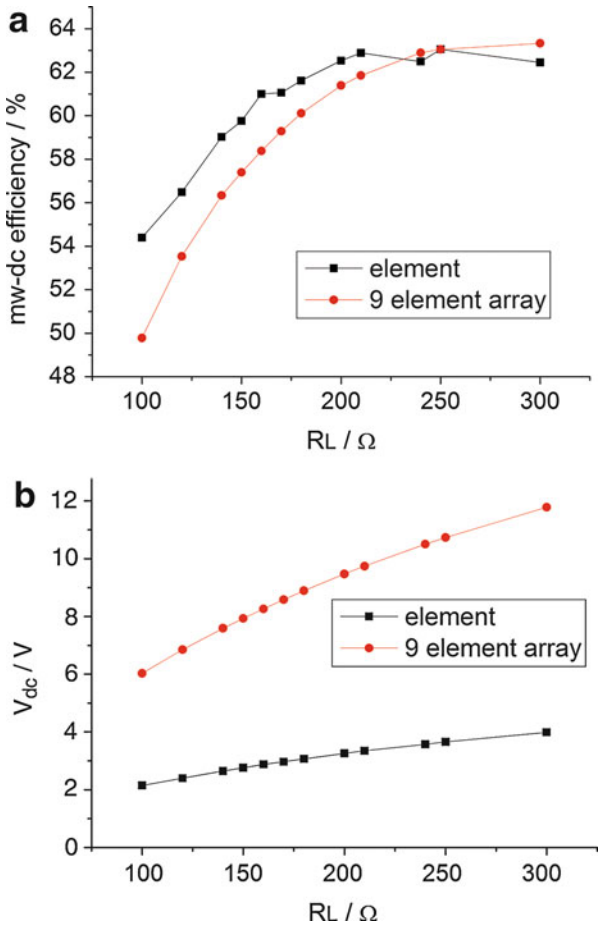

Fig. 36 Measured mw-DC efficiency and DC voltages versus loads of 3 × 3 array and element. (**a**) mw-DC efficiency and (**b**) DC voltage

aperture to the receiving rectenna array (Murao 2000). The high level at the center of the transmitting and the receiving apertures easily damages the center microwave devices so the 10 dB Gauss tapered beam is limited in some practical applications. Some kinds of truncated taper beams were studied in Zepeda et al. (2003). In 2013, Oliveri et al. investigated the maximum *BCE* optimization by using eigenvalue method (Oliveri et al. 2013). It was concluded that near 100 % *BCE* for any shape of transmitting and receiving apertures could be obtained only if the apertures are large enough. Normally, the transmitting antenna and the receiving rectenna have square apertures, which are convenient to be manufactured and fixed. The circular apertures of the transmitting and the receiving antennas can capture more microwave beam at a low budget on the concept that every element of the transmitting antenna operates efficiently (Zhou and Yang 2014).

This section mainly discusses two schemes for the maximum *BCE* of MPT systems. One is the topological models of square, truncated square, and circle for the transmitting apertures. Another is the various level distributions on the transmitting apertures.

Topological Models of Transmitting Antenna

The transmitting antenna aperture is composed of N radiating elements, numbered as 0, 1, 2. . .$N-1$ as shown in Fig. 37. The nth element is located at (x_n, y_n), $n = 0, 1, 2. . .N-1$, with the normalized element weights w_n. Considering the directivity of the transmitting antenna, the receiving rectenna in the far-field

DOI 10.1007/978-981-4560-75-7_116-1

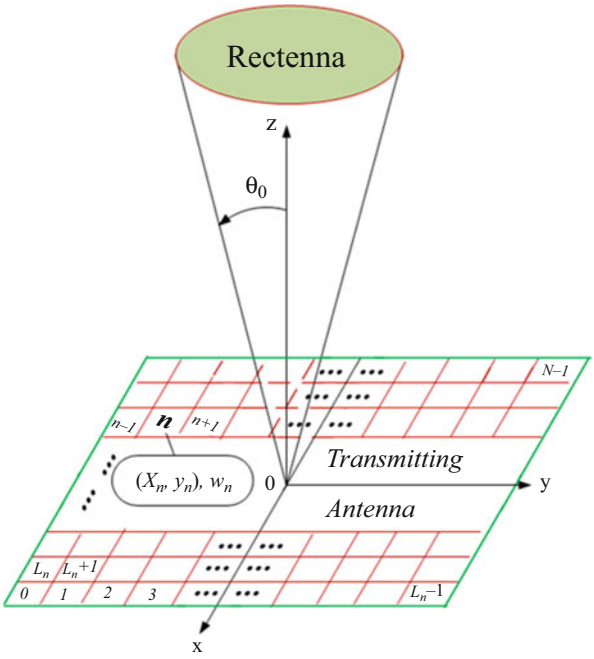

Fig. 37 Transmitting and receiving apertures of a MPT

region is supposed to have a circular aperture. The distance between the transmitter and the receiver is r and the receiving angle of the rectenna aperture is θ_0.

Every element of the transmitting aperture is equivalent to a square Huygens element and is a source with identical amplitude E_n and inphase angle. The electrical field strength in the radiation field is

$$E = \frac{C_0}{r} f_e \sum_{n=0}^{N-1} w_n e^{jk(ux_n + vy_n)} \tag{8}$$

where parameters u and v are $u = \sin\theta\cos\varphi$ and $v = \sin\theta\sin\varphi$, respectively. f_e is the normalized pattern of the Huygens element and C_0 is the coefficient as follows:

$$f_e = \frac{1 + \cos\theta}{2} \operatorname{sinc}\left(\frac{kau}{2}\right) \operatorname{sinc}\left(\frac{kbv}{2}\right) \tag{9}$$

$$C_0 = \frac{jk}{2\pi} e^{-jkr} E_n ab \tag{10}$$

Supposing the level distribution is symmetrical to the center, E of the radiation field could be calculated as

$$E = \frac{C_0}{R} f_e \left[\sum_{\substack{x_n>0 \\ y_n>0}} 4w_n \cos(kux_n) + \sum_{\substack{x_n=0 \\ y_n\geq 0}} 2w_n \cos(kvy_n) + \sum_{\substack{x_n\geq 0 \\ y_n=0}} 2w_n \cos(kux_n) + w_n = y_n = 0 \right] \tag{11}$$

DOI 10.1007/978-981-4560-75-7_116-1

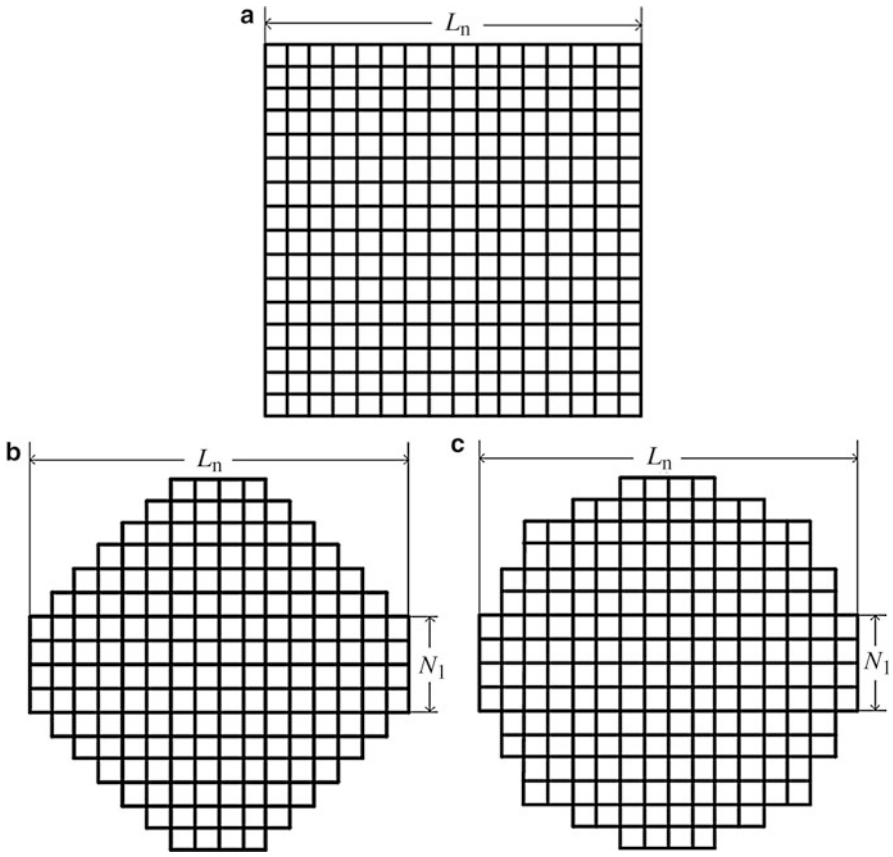

Fig. 38 Typical examples of three topological models: (**a**) SQ, (**b**) TQR, and (**c**) CR

The power density at the radiation field is

$$S = \frac{|C_0|^2}{2\eta R^2} f_e^2 \left| \sum_{n=0}^{N-1} w_n e^{jk(ux_n + vy_n)} \right|^2 \tag{12}$$

The total transmitting power is the integral of power density S from $\theta = 0$ to $\theta = \pi$ and the receiving power is from $\theta = 0$ to $\theta = \theta_0$. So the beam capture efficiency can be calculated as

$$BCE = \frac{P_r}{P_t} = \frac{\int_0^{2\pi} \int_0^{\theta_0} f_e^2 \left| \sum_{n=0}^{N-1} w_n e^{jk(ux_n + vy_n)} \right|^2 \sin\theta d\theta d\phi}{\int_0^{2\pi} \int_0^{\pi} f_e^2 \left| \sum_{n=0}^{N-1} w_n e^{jk(ux_n + vy_n)} \right|^2 \sin\theta d\theta d\phi} \tag{13}$$

The square model (SQ) for the transmitting antenna aperture plotted in Fig. 38a is the most used one, which has the total element number N, the column and row number L_n, and the element number N_1 of the first column. The topological models of truncated square (TSQ) and circle (CR) have the same L_n as SQ model, as shown in Fig. 38b, c. The total N numbers of the three topological models are different when the row (or column) L_n numbers are the same.

DOI 10.1007/978-981-4560-75-7_116-1

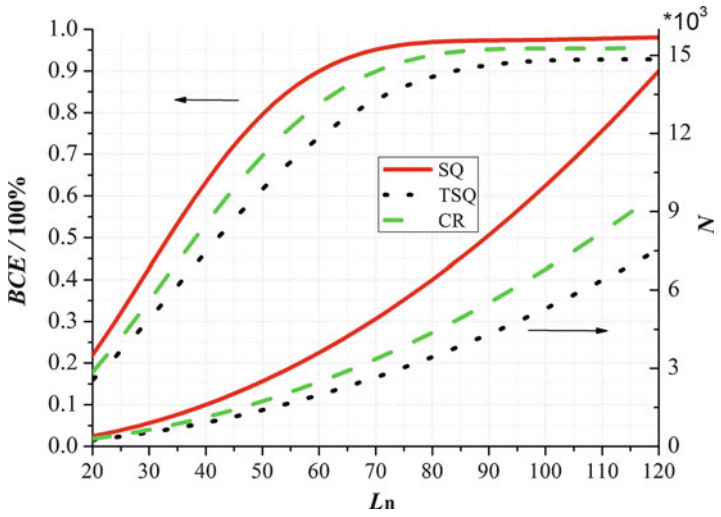

Fig. 39 Total element number N and BCE of three models versus column number L_n

Assuming element aperture a is $\lambda/2$ in Eq. 10, and the transmitting antenna aperture being normalized to wavelength λ, the weight of every element for 10 dB Gaussian taper distribution on the transmitting aperture can be calculated by

$$w_n = e^{-1.1513\rho_n^2} \tag{14}$$

$$\rho_n = \begin{cases} \dfrac{4\sqrt{(|x_n| - 0.25)^2 + (|y_n| - 0.25)^2}}{L_n}, \text{ for even } L_n; \\ \dfrac{4\sqrt{x_n^2 + y_n^2}}{L_n}, \text{ for odd } L_n. \end{cases} \tag{15}$$

For long-distance MPT systems, given the receiving angle θ_0 of the rectenna as 0.03, the three topological models are compared subsequently.

Figure 39 shows the total number N and BCE versus column number L_n for the three topological models. When L_n is 80, BCEs of SQ, TSQ, and CR models are 96.9 %, 88.6 %, and 93.8 %, and the corresponding total element N are 6400, 3436, and 4372, respectively. CR model saves transmitting elements 31.7 % at the cost of losing 3.1 % BCE compared with the SQ model.

Figure 40 shows the transmitting power P_t and BCE of the three models versus total element number N. It should be noticed that the actual transmitting power P_t is the product of the value in Fig. 41 by the factor of $|C_0|^2/2\eta$.

BCEs of three models are very near to each other if the total transmitting elements are the same. When N is less than about 4500, BCEs of the CR and SQ models are higher than that of the TSQ model. The transmitting power P_t of the TSQ and CR models is obviously higher than that of the SQ model.

Several conclusions can be drawn from above analysis. For the same column number L_n, CR and TSQ models can save much more array elements than SQ one with a little BEC being lost. For the same total element number N, CR and TSQ models can obtain higher BCE than SQ when N is lesser than a certain number and transfer much more power. CR model has a relative higher BEC than other two at any total element number N. So CR topological model for the transmitting antenna aperture is efficient for any scale of MPT systems.

DOI 10.1007/978-981-4560-75-7_116-1

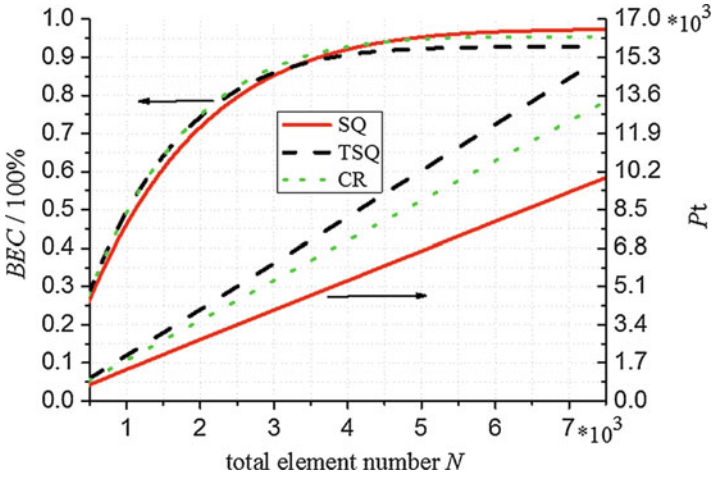

Fig. 40 Transmitting power P_t and *BCE* of three models versus total element number N

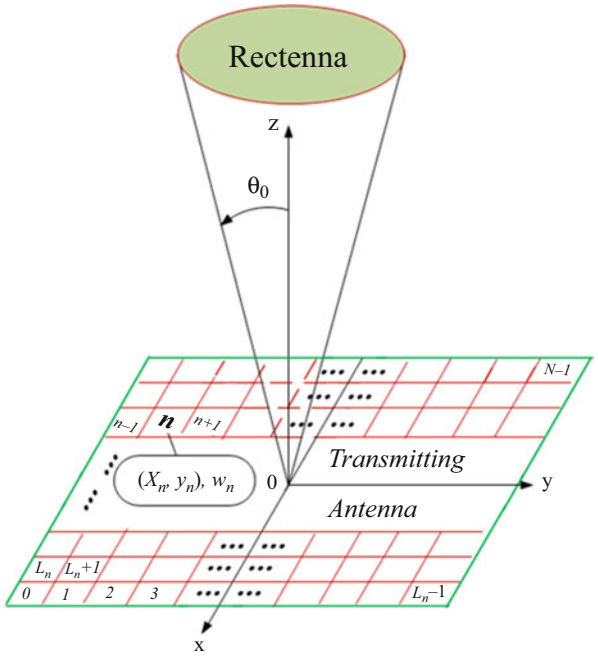

Fig. 41 Transmitting and receiving apertures of a MPT

Level Distributions on Transmitting Antenna Apertures

Considering trade-off between *BCE* and the operation efficiency of all the transmitting elements, the MPT system has circular transmitting and receiving apertures as shown in Fig. 41. The transmission distance is R, while the radii of the transmitting and the receiving aperture are R_t and R_r, respectively. The receiving angle of the rectenna aperture is θ_0.

The aperture level distribution of 10 dB Gauss pulse is verified having high *BCE* but the high power density at the center makes the microwave devices easy to be damaged. The *BCE* and sidelobe level of the truncated taper function of SC (Split Circle) will be investigated and compared with those of the 10 dB Gauss in formulas (14) and (15). SC function expression is as follows:

DOI 10.1007/978-981-4560-75-7_116-1

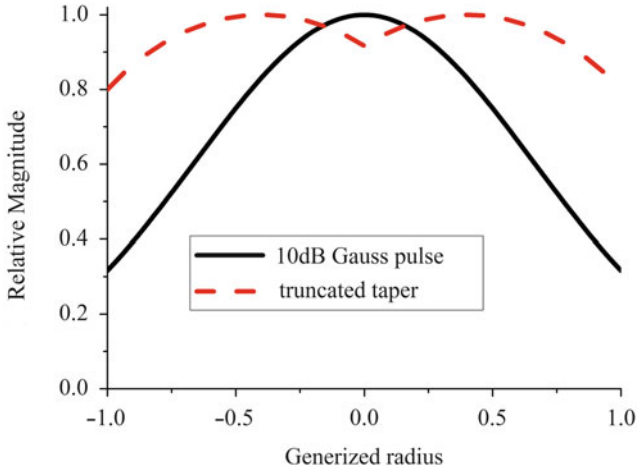

Fig. 42 10dB Gauss pulse and truncated taper functions

$$f(x) = \begin{cases} \sqrt{1-(x-0.4)^2} & x > 0 \\ \sqrt{1-(x+0.4)^2} & x < 0 \end{cases} \tag{16}$$

The curves of 10 dB Gauss pulse and the SC truncated taper functions are shown in Fig. 42 Resembling the 10 dB Gauss pulse and using the topological model of CR in Fig. 38, the weight of every element for SC function distribution on the transmitting aperture can be calculated by

$$w_n = \sqrt{1-[a(\rho_n - b)]^2} \tag{17}$$

where $a = 1.0$, $b = 0.4$, and

$$\rho_n = \begin{cases} \dfrac{4\sqrt{(|x_n|-0.25)^2+(|y_n|-0.25)^2}}{L_n}, \text{ for even } L_n; \\ \dfrac{4\sqrt{x_n^2+y_n^2}}{L_n} \qquad\qquad \text{, for odd } L_n. \end{cases}$$

Given the receiving angle θ_0 of the rectenna as 0.03 for a long-distance MPT system, Fig. 43 shows the total number N and microwave beam capture efficiency BEC versus column number L_n for SC level distribution. It could be seen that BEC increases fast with the number of L_n until L_n is greater than 60 while the total number N increases continuously. Considering the cost of MPT system, L_n is chosen as 74. On this condition, the total element number N is 3748, BEC is 85.2 %.

The weight coefficient distribution for $L_n = 74$ and $N_1 = 4$ is illustrated in Fig. 44. A relative constant level distribution from 0.8 to 1.0 could be found. Figure 45 shows the power density distribution in the radiation field of the transmitting antenna. It could be seen that the first sidelobe is lower −25 dB than the main beam and 85.2 % power could be captured by the receiving aperture with $\theta_0 = 0.03$ rad.

Efficiency Evaluation of C-Band MPT System

For a MPT system in Fig. 4, the available microwave generators mainly include the magnetic amplifiers, the klystron, and the solid state amplifiers. Magnetrons have high power handling capability and have the maximum DC-mw efficiency η_g of 70 ~ 80 % at the microwave bands of S-, C-, and X- bands.

A magnetron with 80 % of DC-mw conversion efficiency η_g at 5.8 GHz is supposed to be applied as the microwave generator. A parabolic antenna or a waveguide slot array antenna has high transmitting efficiency η_t of about 80 %, which can be used as the transmitting antenna element. Considering the array losses for the generators and the transmitting antennas composed of large array to obtain the demanded level distribution, the efficiencies are evaluated as 70 % for both η_t and η_t.

The microwave power capture efficiency *BEC* has been optimized to be 85.2 % in the above section. In section "Series/Parallel Mixed Connections of Rectenna Array," based on the experiment of a 3 × 3-element rectenna array and the reasonable analysis of the results, 585 mW DC power could be obtained on the receiving aperture of 12 × 10 cm and a large rectenna array is estimated to have 65 % mw-DC efficiency at 5.8 GHz. From Eq. 1, the DC-DC system efficiency is evaluated about 27 %.

From Fig. 38c, the diameter of the transmitting aperture is 1.91 m at 5.8 GHz when the column number L_n is 74. The diameter of the receiving aperture is 8.4 m at the far-field distance of 140 m when the receiving angle is 0.03 radial. About 2700 W DC power will be obtained on this receiving rectenna array aperture.

It should be noticed that the results are obtained in an inaccurate evaluation instead of a strict calculation. The power density at the 140 m far field may not be uniform, which will decrease the mw-DC conversion efficiency obviously. The rectifying circuit losses for a large rectenna array may be high. So the optimization method of the transmitting antenna and the receiving rectenna array is the breakthrough that should be investigated further in the near future.

Summary

MPT is a challenging technology in long-distance applications. At the present level with the transmitter of DC-mw and transmitting antenna efficiencies of both 70 %, the beam capture efficiency of 85.2 %, and the rectenna array of 65 % mw-DC efficiency, the DC-DC system efficiency of 27 % can be probably achieved. To further improve the MPT efficiency, some key techniques should be overcome. Firstly, the rectifying Schottky diodes should be specially developed to increase the mw-DC efficiency of the rectifying circuits. The diodes should have lower series resistance R_S, low zero-bias junction capacitor C_{j0}, and higher breakdown voltage V_B. On the applications of low power density, the lower built-in turn-on voltages V_{bi} are required. Secondly, the beam capture efficiency can be increased by optimizing the level distribution on the transmitting aperture. Thirdly, to maintain 70 % DC-mw of the generators and 70 % transmitting efficiency of the transmitting antenna array for the optimized level distribution, the transmitter design is a challenging topic.

Near-Field Antenna Measurement Techniques

Flaminio Ferrara, Claudio Gennarelli* and Rocco Guerriero
Dipartimento di Ingegneria Industriale, Università di Salerno, Fisciano (Salerno), Italy

Abstract

A complete description of the near-field antenna measurement techniques is provided in this chapter. After a discussion of the state of the art, the key steps of the classical near-field–far-field (NF-FF) transformations with plane-rectangular, cylindrical, and spherical scannings, in their probe-uncompensated and probe-compensated versions, are summarized, by also providing some analytical details on the wave expansions commonly adopted to represent the antenna radiated field. The nonredundant sampling representations of electromagnetic field are then introduced and applied to drastically reduce the number of required NF data and related measurement time with respect to the classical NF-FF transformations. At last, the NF-FF transformations with innovative spiral scannings, allowing a further measurement time saving, are described.

Keywords

Antenna measurements; Near-field – far-field transformation techniques; Plane wave expansion; Cylindrical wave expansion; Spherical wave expansion; Probe compensation; Nonredundant sampling representations of electromagnetic fields; Spiral scannings

Introduction

When dealing with electrically large antennas, far-field (FF) range size limitations, transportation, and mounting problems make it absolutely impractical or impossible to measure their radiation patterns on a conventional FF range. On the other hand, the increasing use of high-performance antennas, as those employed in radar and satellite systems, requires an accurate measure of their radiating characteristics. For instance, satellite antennas are designed to transmit or receive over long distances, and accordingly the requirements to beam pointing may be severe; thus a high measurement accuracy is mandatory to verify that the antenna fulfills all the specifications. As a consequence, the problem of the determination of the antenna FF pattern from near-field (NF) measurements has attracted considerable attention in the last 50 years (Appel-Hansen et al. 1982; Yaghjian 1986; Gillespie 1988; Hald et al. 1988; Gennarelli et al. 2004; Gregson et al. 2007; Francis and Wittmann 2008; Gennarelli et al. 2012; Francis 2012).

NF measurements may be performed in a controlled environment, as an indoor shielded anechoic chamber, which allows one to overcome those drawbacks that, due to weather conditions (rain, snow, etc.), electromagnetic (EM) interference, and other, cannot be eliminated in FF measurements. In addition, NF scanning techniques are the better choice when complete pattern and polarization measurements are required. Moreover, they provide the necessary information to determine the field at

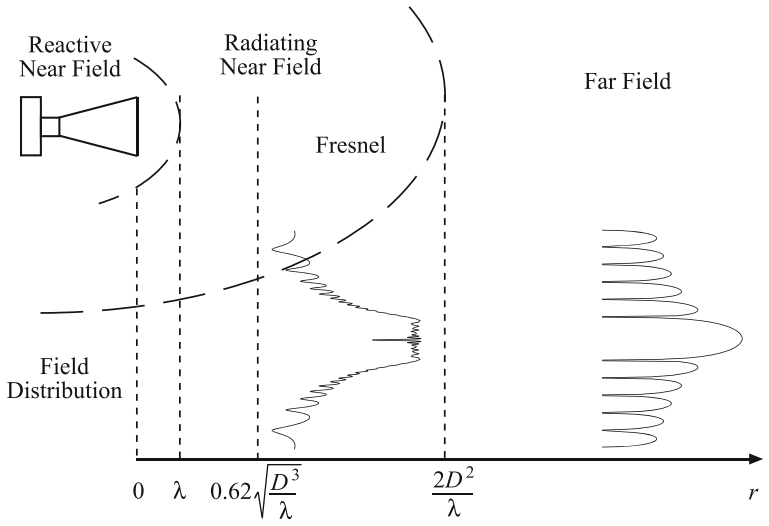

Fig. 1 Field regions of an electrically large antenna

the surface of the antenna. Such an information can be properly employed for the diagnostics of surface errors in a reflector antenna or of faulty elements in an array (microwave holographic diagnostics (Yaccarino et al. 1994)).

Another advantage of NF measurements stems from the fact that the reflected signal will be weaker than in a FF measurement facility because it is transmitted and received through far-out sidelobes. Moreover, the absorbers will work more efficiently than in a FF range, where they are employed close to the grazing incidence condition.

It is the authors' opinion that a comprehensive chapter on the NF-FF transformation techniques cannot begin without a preliminary discussion which highlights the field behavior when the distance from the antenna increases. The free space surrounding an antenna is usually subdivided into three regions: the reactive near-field, the radiating near-field, and the far-field region (see Fig. 1). Although no abrupt change in the field behavior can be observed when their boundaries are crossed, the field configuration is quite different in them. For an antenna focused at infinity, the optical term *Fraunhofer region* can be used synonymously with far-field region. For such an antenna, the optical term *Fresnel region* can be also employed to denote a subregion of the radiating near-field zone. The reactive near-field region is the zone immediately surrounding the antenna wherein the reactive field predominates. It extends up to a distance of about $\lambda/2\pi$ from the antenna surface, λ being the wavelength. However, experience with NF measurements indicates that λ is a more reasonable limiting distance for such a region. Outside this zone the reactive field decays rapidly and can be neglected at a distance of a few wavelengths from the antenna surface. The radiating near-field region is the intermediate zone between the reactive near-field and the far-field regions. In such a region the radiation fields predominate, but the angular distribution of the field is dependent on the distance from the antenna, and the field does not exhibit the dependence $e^{-j\beta r}/r$ typical of the antenna far field, β being the wavenumber. It is worthy to note that a time dependence $e^{j\omega t}$ has been implicitly assumed. It will be assumed and suppressed throughout the chapter. The Fresnel region is the radiating near-field subregion wherein a quadratic phase approximation can be used in the vector potential integral. The far-field region is the zone of the free space where the relative angular field distribution is independent of the distance from the antenna and the electric and magnetic fields vary according to the $e^{-j\beta r}/r$ dependence. Commonly, for electrically large antennas, the inner boundaries of the Fraunhofer and Fresnel regions are set at $2D^2/\lambda$ and $0.62\sqrt{D^3/\lambda}$, respectively, where D is the maximum dimension of

DOI 10.1007/978-981-4560-75-7_117-1

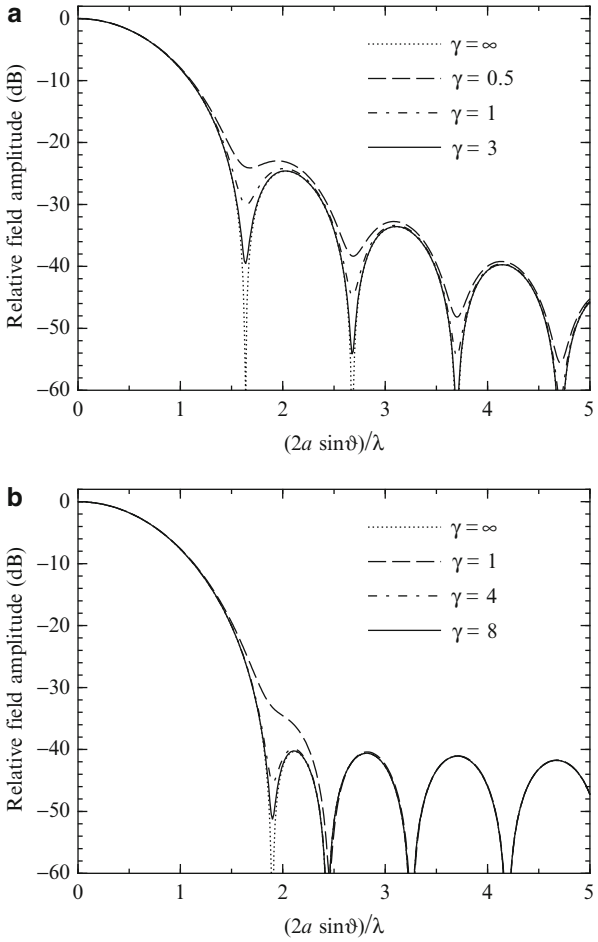

Fig. 2 Pattern behavior referred to the normalized distance $\gamma = r/(2D^2/\lambda)$: (**a**) for a circular aperture with $f(\rho) = (1 - \rho^2)$, (**b**) for a circular Taylor aperture distribution

the antenna. These boundaries are determined by assuming acceptable a maximum phase error of $\pi/8$, when a linear or quadratic phase approximation is used in the expression of the vector potential integral.

It has been recognized that distance requirements depend both on first sidelobe level of the antenna and on the desired accuracy (Silver 1984; Hollis et al. 1972). The widely used Rayleigh $2D^2/\lambda$ distance criterion gives rise to negligible pattern errors only for antennas with moderate sidelobe level (−25 dB). When measuring antennas having low (−30 to −40 dB) and ultralow (below −40 dB) sidelobe levels, a distance far larger than $2D^2/\lambda$ is needed (Hansen 1984; Corona et al. 1989). As shown in Fig. 2, particularly for antennas having low sidelobes, a significant increase in the sidelobe level and a more considerable raising of the null between it and the main lobe occur. As a conclusion, the distance requirements for measuring in a FF range the near-in sidelobes, which are below −30 dB, are very severe (Hansen 1984; Corona et al. 1989). For example, a distance of at least $6D^2/\lambda$ is required to measure, within a 1 dB accuracy, the first sidelobe of a Taylor antenna with sidelobe ratio (SLR) = 50 dB.

Usually, the NF antenna characterization can exploit complex field data or phaseless field data, the first choice being the most commonly used in practice.

In a NF facility processing complex field data, the probe, located near the antenna under test (AUT), is moved through a surface (scanning surface) which can be planar, cylindrical, or spherical (see Fig. 3). It collects complex voltage samples which are stored together with their positions. From these amplitude and phase data, measured for two different orientations of the probe (the probe is rotated by 90° around its

DOI 10.1007/978-981-4560-75-7_117-1

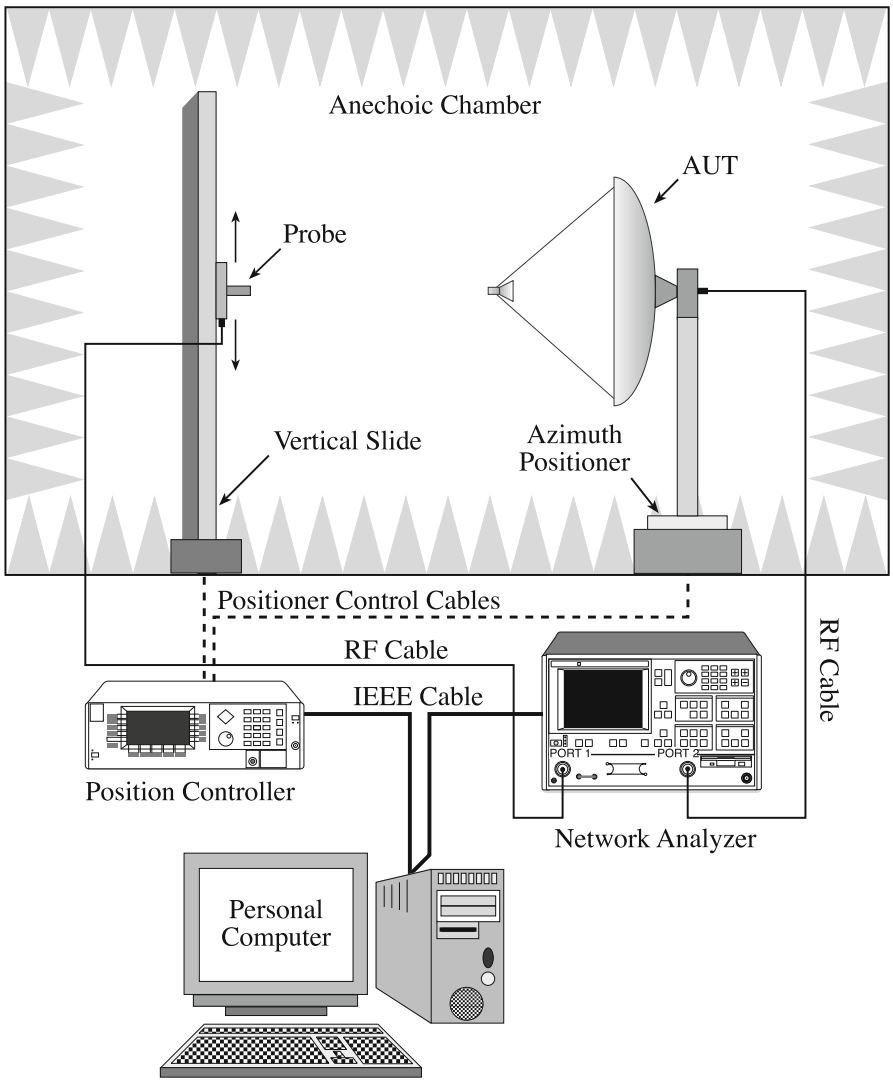

Fig. 3 NF measurement system: cylindrical scanning

axis in the second set), and taking into account the probe effects, one can compute the antenna FF pattern. It is worth noting that both the copolar and cross-polar components of the antenna far field can be recovered. Moreover, during the NF data acquisition, no information on the AUT polarization is needed. Nevertheless, such an information can be accurately determined by properly processing the reconstructed far field. The probe and its mounting structure should introduce minimum disturbance into the field to be measured, and its characteristics must be stable with time, environmental conditions, and orientations (Francis 2012). Commonly, the measured NF data are transformed into FF patterns by using an expansion of the AUT field in terms of modes, namely, a complete set of solutions of the vector wave equation in the region outside the antenna. Plane, cylindrical, or spherical waves are generally used. The type of modal expansion employed for representing the field determines the kind of the NF scanning surface, which accordingly will be a plane, a cylinder, or a sphere. The orthogonality properties of the modes on such surfaces are then exploited to obtain the modal expansion coefficients, which allow the reconstruction of the AUT far field. The development and the spreading of NF-FF transformation techniques employing planar, cylindrical, or spherical scanning systems is justified from the fact that each approach has its own particular advantages, depending on the AUT and the measurement requirements. The complexity of the

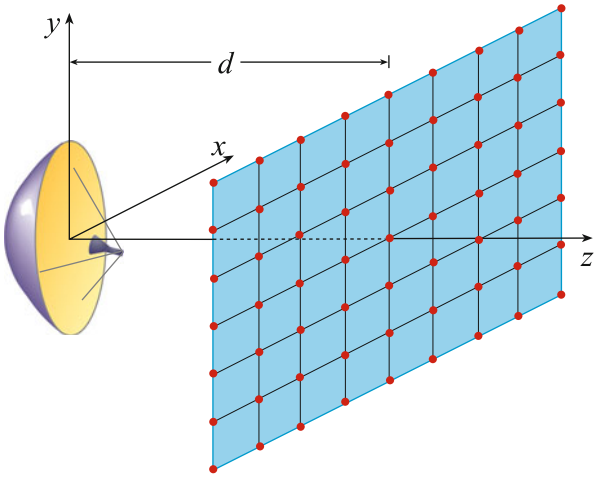

Fig. 4 Plane-rectangular scanning

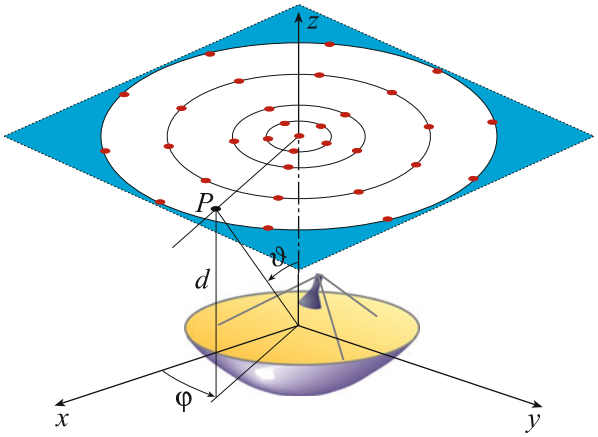

Fig. 5 Plane-polar scanning

analytical transformation increases from the planar to the cylindrical and from the cylindrical to the spherical surfaces.

The NF-FF transformations using a planar scanning are the most simple and efficient ones from the analytical and computational viewpoint. Their main disadvantage is that the pattern can be reconstructed only in a cone with an apex angle less than 180° without repeating the measurements. Accordingly, they are particularly suitable for highly directive antennas which radiate pencil beam patterns. There are quite different ways to realize a planar scanning: plane-rectangular (Kerns 1970, 1981; Joy and Paris 1972; Paris et al. 1978; Joy et al. 1978) (see Fig. 4), plane-polar (Rahmat-Samii et al. 1980; Gatti and Rahmat-Samii 1988; Yaghjian and Woodworth 1996; Bucci et al. 1991a, 1998a, 2000; Fig. 5), and bipolar (Yaccarino et al. 1994; Williams et al. 1994; D'Agostino et al. 2003; Fig. 6).

At the cost of a modest increase in the analytical and computational complication with respect to the planar scannings, the NF-FF transformation with cylindrical scanning (Joy et al. 1978; Leach and Paris 1973; Yaghjian 1977; Appel-Hansen 1980; Bucci et al. 1998b; D'Agostino et al. 2002, 2012a; Qureshi et al. 2013) (see Fig. 7) allows one to reconstruct, from a single set of NF measurements, the AUT complete radiation pattern save for the zones surrounding the spherical polar angles. Such a scanning is particularly attractive when considering antennas that concentrate the EM radiation in an angular region centered on the horizontal plane, as the radiating systems for radio base stations.

DOI 10.1007/978-981-4560-75-7_117-1

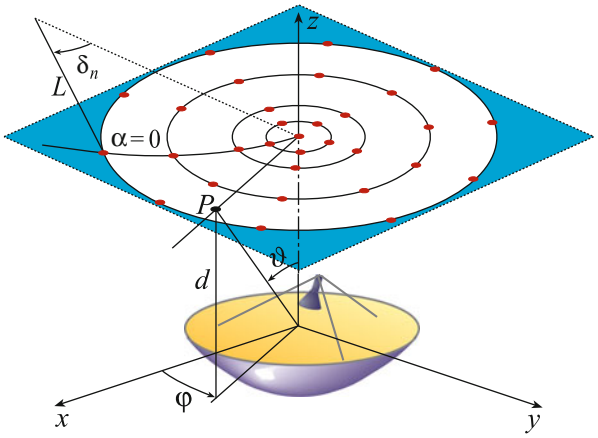

Fig. 6 Bipolar scanning

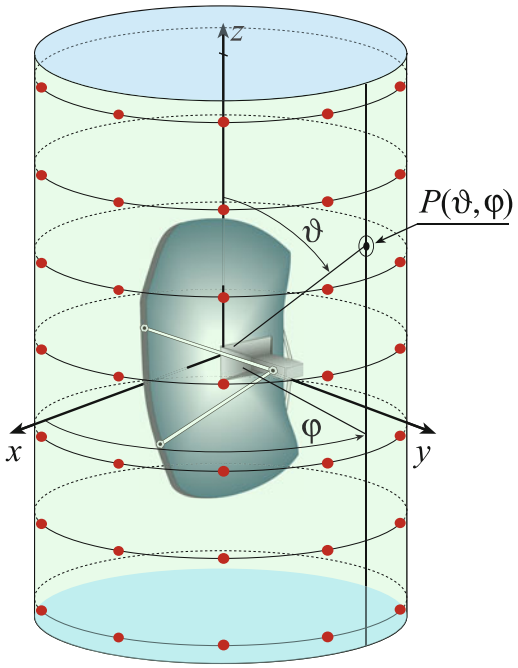

Fig. 7 Cylindrical scanning

The NF-FF transformation with spherical scanning (Hald et al. 1988; Qureshi et al. 2013; Wacker 1975; Larsen 1980; Yaghjian and Wittmann 1985; Hansen 2011; Bucci et al. 2001a; D'Agostino et al. 2011, 2013a) (see Fig. 8) allows one to reconstruct, from a single set of NF measurements, the complete radiation pattern of the AUT. However, the data processing to get the far field is considerably more complicated than that needed by planar and cylindrical facilities. The NF spherical scanning is, obviously, particularly tailored to measure low-gain and omnidirectional antennas.

In recent years, NF-FF transformations techniques based on the reconstruction of a proper set of equivalent currents have been developed (Petre and Sarkar 1992; Taaghol and Sarkar 1996; Sarkar and Taaghol 1999; Las-Heras and Sarkar 2002; Las-Heras et al. 2006; Alvarez et al. 2008). These (unknown) equivalent currents, lying on a selected surface enclosing the antenna, are evaluated by solving a set of integral equations relating them to the NF data acquired on the scanning surface. Once these equivalent

DOI 10.1007/978-981-4560-75-7_117-1

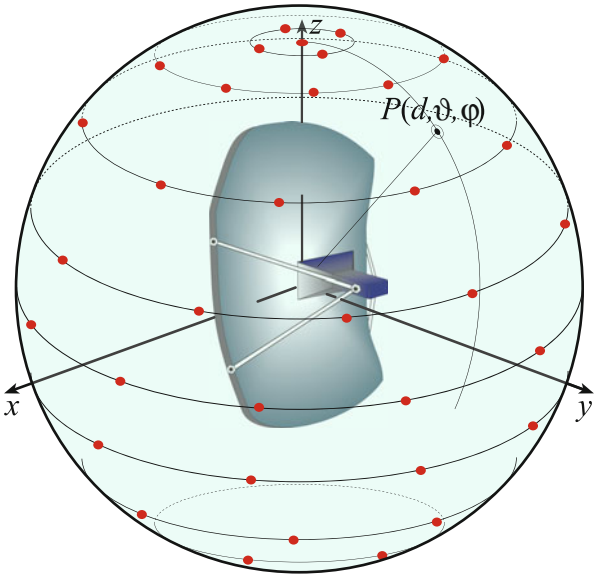

Fig. 8 Spherical scanning

currents have been determined, according to Love's equivalence theorem, it is possible to obtain the field at any point outside the equivalent source domain and, then, to evaluate the FF pattern. Unlike the NF-FF transformations using the modal expansion approach, they do not require the use of canonical scanning surfaces (plane, cylinder, sphere) but can be applied to an arbitrary measurement surface. On the other hand, their main drawback is the remarkably increased computational cost. As a matter of fact, the solution of a system equation (eventually ill-conditioned) with several thousands of unknowns is usually required. It is worthy to note that, for these NF-FF transformations too, it is possible to correct the distortion due to the nonisotropic radiation pattern of the employed probe. The probe correction is obtained by considering the antenna pattern of the probe as a weighting function in the integral equations relating the fields and the equivalent sources (Alvarez et al. 2008).

As already stressed, near-field techniques usually require the measurement of both the amplitude and phase of the antenna near field. Nevertheless, phaseless NF measurements have recently attracted a considerable interest, due to the less expensive measurement facilities required and to the increasing difficulty to perform accurate phase measurements in the millimeter and submillimeter frequency range. Over the years, several techniques have been proposed to determine the antenna far field from only amplitude NF measurements. A first possibility is the use of interferometric techniques (Bennett et al. 1976), which require an additional reference antenna whose transmitted signal, interfering with that transmitted by the AUT, allows to recover the lacking phase information. Other approaches exploit the functional relationship existing between two sets of only amplitude NF data collected by a probe on two scanning surfaces (Bucci et al. 1990, 1999; Isernia et al. 1996; Yaccarino and Rahmat-Samii 1999) or by two probes on the same scanning surface (Pierri et al. 1999) to retrieve the phase. A basically interferometric approach, avoiding the use of a reference antenna and using two identical probes and a simple microstrip circuit, has been also proposed to retrieve the phase information (Costanzo and Di Massa 2002; Costanzo et al. 2005).

Each member of the antenna measurement techniques community can profit today by about 50 years of research activity on NF data acquisition and related NF-FF transformations. Over these years, many solutions have been proposed to meet the demands of the various applications. In this framework, significant improvements in the performance of NF measurements have been recently achieved.

DOI 10.1007/978-981-4560-75-7_117-1

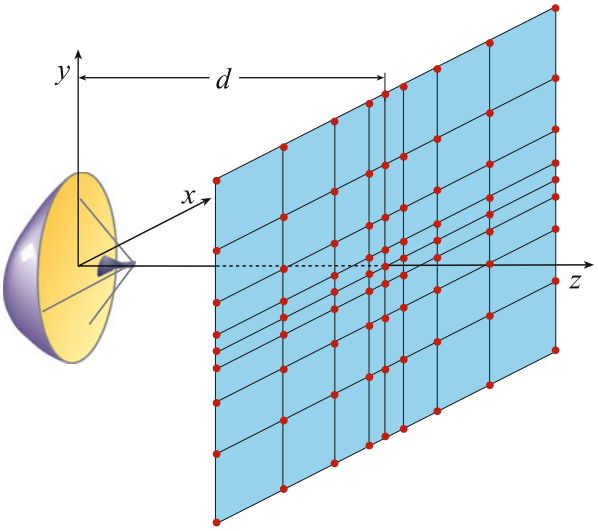

Fig. 9 Planar wide-mesh scanning

They are based on the spatial band limitation properties of radiated EM fields (Bucci and Franceschetti 1987, 1989), on their nonredundant sampling representations (Bucci et al. 1998c; Bucci and Gennarelli 2012), and on the optimal sampling interpolation (OSI) expansions of central type (Bucci et al. 1991a, b; Gennarelli et al. 1994). In particular, a significant reduction of the number of required NF data (and, as a consequence, of the corresponding measurement time) has been obtained for all the conventional scannings (see (Bucci et al. 1991a, 1998a, 2000) for the plane-polar, (D'Agostino et al. 2003) for the bipolar, (Bucci et al. 1998b; D'Agostino et al. 2002, 2012a) for the cylindrical, and (Bucci et al. 2001a; D'Agostino et al. 2011, 2013a) for the spherical scanning). In fact, the NF data needed by the corresponding traditional NF-FF transformation technique are accurately recovered by interpolating a minimum set of measurements via OSI expansions. A remarkable measurement time saving can be so obtained making these nonredundant transformations more and more appealing, since nowadays such a time is very much greater than the computational one. The mathematical justification for these results relies on the abovementioned band limitation properties and nonredundant sampling representations of EM fields. In fact, the EM fields radiated by antennas, enclosed in a convex domain bounded by a rotational surface Σ and observed on surface $\mathcal{M}$ with the same rotational symmetry, can be very well approximated by spatially band-limited functions when a proper phase factor is singled out from the field expression and proper parameterizations are used to describe $\mathcal{M}$ (Bucci et al. 1998c). Since the voltage acquired by a nondirective probe has the same effective spatial bandwidth of the AUT field, these representations can be, obviously, applied to the voltage too. The application of these nonredundant sampling representations has allowed also the development of an innovative and efficient planar NF-FF transformation using the planar wide-mesh scanning (PWMS) (Ferrara et al. 2007; D'Agostino et al. 2014a). Such a nonconventional plane-rectangular scanning technique is so named, since the sample grid is characterized by meshes wider and wider when going away from the center of the scanning region (see Fig. 9).

The use of the modulated scattering technique employing arrays of scattering probes, which allows a very fast electronic scanning, has been also proposed in (Bolomey et al. 1988) to reduce the time required for the acquisition of the NF data. However, apart from measurement precision issues, antenna testing facilities based on such a technique are not very flexible. Anyway, exploitation of the nonredundant sampling representations could allow to reduce the number of needed probes.

DOI 10.1007/978-981-4560-75-7_117-1

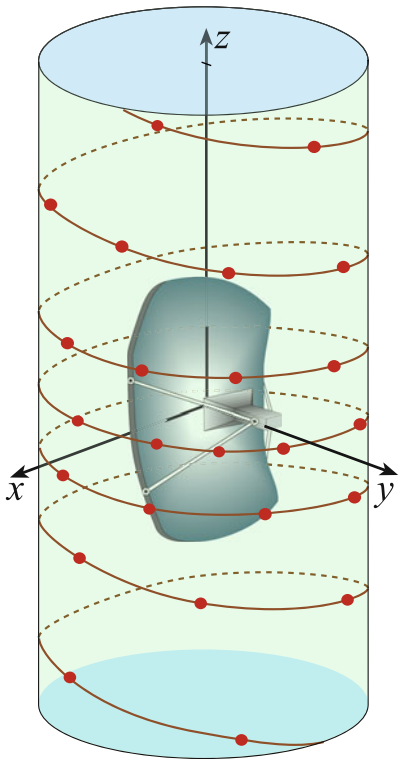

Fig. 10 Helicoidal scanning

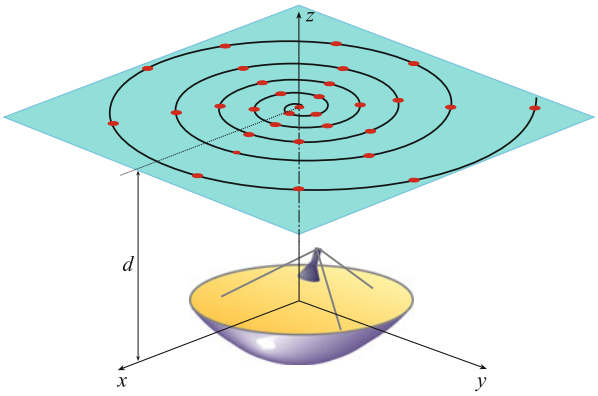

Fig. 11 Planar spiral scanning

A more viable way to reduce the time required for the NF data acquisition is the employment of innovative spiral scanning techniques. They have been implemented, as suggested in (Yaccarino et al. 1996), by means of continuous and synchronized movements of the positioning systems of the probe and AUT. Accurate, stable, and efficient NF-FF transformations with helicoidal (Bucci et al. 2001b; D'Agostino et al. 2008a, 2009a, b, 2012b) (see Fig. 10), planar (Bucci et al. 2002; D'Agostino et al. 2008b; Fig. 11), and spherical (Bucci et al. 2003; D'Agostino et al. 2009c, 2012c, 2013b, 2014b; Fig. 12) spiral scanning have been developed in the last years. They rely on nonredundant sampling representations and reconstruct the NF data needed by the classical NF-FF transformation corresponding to the adopted scanning surface, by interpolating, via appropriate OSI formulas, the nonredundant

DOI 10.1007/978-981-4560-75-7_117-1

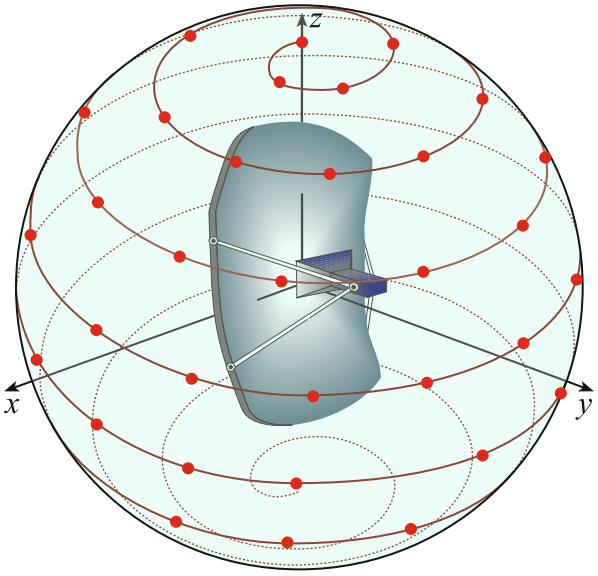

Fig. 12 Spherical spiral scanning

samples acquired by the measurement probe on the considered curve (helix or spiral). Other NF-FF transformation techniques with spiral scannings have been also proposed (Yaccarino et al. 1996; Costanzo and Di Massa 2004, 2007). However, since these approaches do not exploit the nonredundant representations of EM fields, they need a useless large amount of NF measurements.

The chapter is organized as follows. The classical NF-FF transformations with plane-rectangular, cylindrical, and spherical scannings, in their probe-uncompensated and probe-compensated versions, are summarized in section "Classical NF-FF Transformation Techniques." The nonredundant sampling representations of the electromagnetic fields are introduced in section "Nonredundant NF-FF Transformation Techniques," highlighting the role of the optimal parameterization and phase factor. In the same section, the application of these representations to the NF-FF transformations with conventional scannings, allowing a drastic measurement time saving, is also described. The theoretical foundations of the NF-FF transformations with spiral scanning for both quasispherical antennas (D'Agostino et al. 2006, 2009d) and those having two dimensions very different from the third one (D'Agostino et al. 2009e; Cicchetti et al. 2014) are presented in the subsequent section "NF-FF Transformation Techniques with Spiral Scannings" by providing an efficient sampling representation, which allows the reconstruction of the EM field (probe voltage) on a quite arbitrary rotational surface from a nonredundant number of its samples collected on a spiral wrapping it.

Classical NF-FF Transformation Techniques

NF-FF Transformation with Plane-Rectangular Scanning

The NF-FF transformation with plane-rectangular scanning (see Fig. 4) is without doubt the most simple and efficient one from the analytical and computational viewpoints. Its main drawback is that the antenna far field can be reconstructed only in a cone with an apex angle less than 180°. Therefore, it can be conveniently employed for highly directive antennas which radiate pencil beam patterns well within the solid angle specified by the edges of the AUT and those of the scanning area. In the plane-rectangular scanning, the probe is mounted on a $x - y$ positioner so that it can acquire the NF amplitude and phase data

DOI 10.1007/978-981-4560-75-7_117-1

on the wanted plane-rectangular grid. From these data, measured for two different orientations of the probe, one can compute the FF pattern of the AUT (Kerns 1970, 1981; Joy and Paris 1972; Paris et al. 1978; Joy et al. 1978).

In the first part of this subsection, the use of an ideal probe able to measure in its two orientations the tangential components E_x, E_y of the AUT electric field on the scanning plane is assumed and NF-FF transformation formulas derived. Then, such a hypothesis is removed and probe-corrected formulas given.

The starting point is the plane wave spectrum representation of EM fields (Clemmow 1966), summarized in the paragraph "Plane Wave Expansion" for readers' convenience. As shown in it, the tangential components E_x, E_y of the electric field radiated by the AUT can be represented on the scan plane at $z = d$ as a superposition of elementary plane waves, i.e.,

$$E_{x,y}(x,y,d) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \left[\hat{E}_{x,y}(k_x,k_y)\mathrm{e}^{-\mathrm{j}\,k_z d}\right]\mathrm{e}^{-\mathrm{j}\left(k_x x + k_y y\right)}\mathrm{d}k_x\mathrm{d}k_y \tag{1}$$

By Fourier inverse transforming, it results

$$\hat{E}_{x,y}(k_x,k_y) = \frac{1}{4\pi^2}\mathrm{e}^{\mathrm{j}k_z d}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} E_{x,y}(x,y,d)\mathrm{e}^{\mathrm{j}\left(k_x x + k_y y\right)}\mathrm{d}x\mathrm{d}y \tag{2}$$

Accordingly, by assuming that the tangential components of the electric field are zero out of the measurement region on the scanning plane, it is possible to obtain the x and y components of the plane wave spectrum by a two-dimensional fast Fourier transform (FFT) algorithm. The other component of the spectrum can be determined by means of Eq. 75.

As shown in (Joy and Paris 1972), the sample spacings of the NF data are

$$\Delta x \le \lambda/2; \quad \Delta y \le \lambda/2 \tag{3}$$

In fact, if the scanning plane is located in a region of space where the EM field does not contain evanescent waves, then the plane wave spectrum is zero for $|k_x| > 2\pi/\lambda$ and $|k_y| > 2\pi/\lambda$. As a consequence of the two-dimensional Nyquist sampling theorem (Papoulis 1987), the EM field on the plane $z = d$ can be reconstructed from the knowledge of its samples at a rectangular lattice of points separated by grid spacings satisfying Eq. 3.

Once the plane wave spectrum has been determined, the FF components of the electric field in the spherical coordinate system (r, ϑ, φ) can be evaluated (see paragraph "Plane Wave Expansion") by using the relations

$$E_\vartheta(r,\vartheta,\varphi) = \mathrm{j}2\pi\beta\cos\vartheta\,\hat{E}_\vartheta(\beta\sin\vartheta\cos\varphi, \beta\sin\vartheta\sin\varphi)\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r} \tag{4}$$

$$E_\varphi(r,\vartheta,\varphi) = \mathrm{j}2\pi\beta\cos\vartheta\,\hat{E}_\varphi(\beta\sin\vartheta\cos\varphi, \beta\sin\vartheta\sin\varphi)\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r} \tag{5}$$

where $\hat{E}_\vartheta$, $\hat{E}_\varphi$ are related to $\hat{E}_x$ and $\hat{E}_y$ by

DOI 10.1007/978-981-4560-75-7_117-1

$$\hat{E}_{\varphi} = -\hat{E}_x \sin\varphi + \hat{E}_y \cos\varphi \tag{6}$$

$$\hat{E}_{\vartheta} = \left(\hat{E}_x \cos\varphi + \hat{E}_y \sin\varphi\right)/\cos\vartheta \tag{7}$$

As a matter of fact,

$$\hat{E}_{\vartheta} = \hat{E}_x \cos\vartheta\cos\varphi + \hat{E}_y \cos\vartheta \sin\varphi - \hat{E}_z \sin\vartheta$$

from which, by taking into account Eq. 75, Eq. 7 is easily obtained.

It is convenient to describe the employment of the FFT algorithm for computing the two-dimensional Fourier transforms in Eq. 2 from the knowledge of the acquired NF data. It can be useful to remember (Brigham 1974) that the discrete Fourier transform (DFT) is defined by

$$G\left(\frac{n}{NT}\right) = \sum_{i=0}^{N-1} g(iT)\mathrm{e}^{-\mathrm{j}2\pi ni/N} \quad n = 0, 1, \ldots, N-1 \tag{8}$$

whereas the inverse discrete Fourier transform (IDFT) is given by

$$g(iT) = \frac{1}{N}\sum_{n=0}^{N-1} G\left(\frac{n}{NT}\right)\mathrm{e}^{\,\mathrm{j}2\pi ni/N} \quad i = 0, 1, \ldots, N-1 \tag{9}$$

As well known, Eqs. 8 and 9 can be efficiently computed via the FFT algorithm. Moreover, they require both the functions to be periodic, namely,

$$G\left(\frac{n+pN}{NT}\right) = G\left(\frac{n}{NT}\right) \quad p = 0, \pm 1, \pm 2, \ldots \tag{10}$$

$$g[(i+pN)T] = g(iT) \quad p = 0, \pm 1, \pm 2, \ldots \tag{11}$$

The integration along x in Eq. 2 is now considered. By taking into account explicitly the truncation due to the finite size $2L_x \times 2L_y$ of the scanning plane and applying a straightforward approximation, it results

$$G(k_x) = \int_{-L_x}^{L_x} g(x)\mathrm{e}^{\mathrm{j}k_x x}\mathrm{d}x \approx \Delta x \sum_{n=0}^{N_x-1} g(x_n)\mathrm{e}^{\mathrm{j}k_x(n-N_x/2)\Delta x} \tag{12}$$

where $x_n = (n - N_x/2)\Delta x$, $N_x = 2L_x/\Delta x$ is the number of the measurement points along x (the overall number of measurement points is N_xN_y). When evaluating $G(k_x)$ at $k_{x_i} = i\Delta k_x = 2\pi i/(N_x\Delta x)$, it results

$$G(k_{x_i}) \approx \frac{2L_x}{N_x}\mathrm{e}^{-\mathrm{j}\pi i}\sum_{n=0}^{N_x-1} g(x_n)\mathrm{e}^{\mathrm{j}2\pi ni/N_x} \tag{13}$$

Accordingly, the integration over x in Eq. 2 can be efficiently performed via an inverse FFT algorithm, provided that the so obtained results are multiplied by the factor $2L_x\mathrm{e}^{-\mathrm{j}\pi i}$. The same considerations can be, obviously, applied to the integration over y.

DOI 10.1007/978-981-4560-75-7_117-1

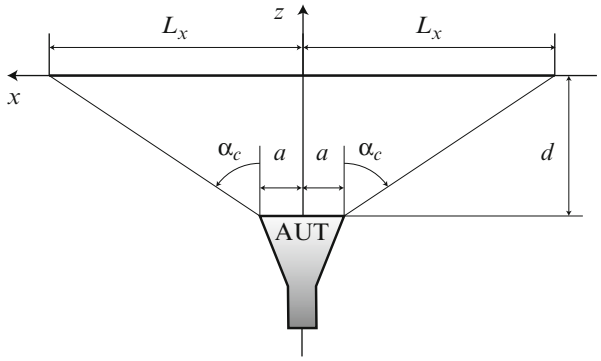

Fig. 13 Relevant to the evaluation of the validity angle

Summing up, for the evaluation of each of the Cartesian components $\hat{E}_x$ and $\hat{E}_y$ of the spectrum are needed N_y one-dimensional FFTs of size N_x and N_x FFTs of size N_y. This allows to obtain the FF components at the values of k_x and k_y given by $k_{x_i} = 2\pi i/(N_x \Delta x)$ and $k_{y_p} = 2\pi p/\left(N_y \Delta y\right)$. Note that the k_x and k_y vales such that $k_x^2 + k_y^2 > \beta^2$ must not be considered since the corresponding plane waves (called evanescent waves) do not contribute to the far field and represent NF reactive power storage.

To obtain the FF components with a greater resolution, it is sufficient "zero-filling" the NF data. Namely, to increase the number of output k_x values from N_x to N_x', the NF data must be increased with a proper number of zeros corresponding to fictitious $\left(N_x' - N_x\right)/2$ measurement points both before and after the effective ones. Similarly, to increase the number of output k_y values from N_y to N_y', $\left(N_y' - N_y\right)/2$ zeros must be added before and after the measured ones.

Since the measurement region is truncated in the plane-rectangular scanning, the reconstructed far field is affected by an inevitable truncation error, whose amount depends on the level of the neglected NF data external to the scanning area. In the following, the effect of the truncation due to the finite extension of the scanning plane along the x direction is analyzed. Quite analogous results hold also for that relevant to the y direction. When considering a scanning plane at distance d from the AUT, whose dimension along x is $2a$ (see Fig. 13), a convenient rule of thumb to predict the angular region of validity of the recovered FF pattern is given (Newell 1988) by

$$-\alpha_c \leqslant \vartheta \leqslant \alpha_c \tag{14}$$

where

$$\alpha_c = \tan^{-1}\left(\frac{L_x - a}{d}\right) \tag{15}$$

Such a validity angular region criterion was developed empirically from extensive NF measurements involving a large number of antenna and probe combinations (Yaghjian 1975) and derived using a theoretical analysis (Newell and Crawford 1974). Moreover, a ripple caused by the discontinuity of the near field at the edges of the scanning plane can appear even in the region of validity (Newell 1988).

It can be easily recognized that the NF tangential components E_x, E_y cannot be acquired when performing the measurement by means of a real, not ideal, probe. In fact, the probe sees the AUT center under different directions when moving on the scanning plane. Moreover, also at a fixed position, it sees each portion of the AUT under a different direction. As a consequence, the antenna far field cannot be

DOI 10.1007/978-981-4560-75-7_117-1

accurately recovered from the measured NF data by employing the previously described uncompensated NF-FF transformation.

The basic theory of probe-compensated NF measurements on a plane as proposed in (Paris et al. 1978; Joy et al. 1978) is based on the application of the Lorentz reciprocity theorem. The key relations in the here adopted reference system are

$$E_{\vartheta}(\vartheta,\varphi) = \left(I_H E'_{\varphi_V}(\vartheta,\ -\varphi) - I_V E'_{\varphi_H}(\vartheta,\ -\varphi)\right)/\Delta \tag{16}$$

$$E_{\varphi}(\vartheta,\varphi) = \left(I_H E'_{\vartheta_V}(\vartheta,\ -\varphi) - I_V E'_{\vartheta_H}(\vartheta,\ -\varphi)\right)/\Delta \tag{17}$$

where

$$\Delta = E'_{\vartheta H}(\vartheta,\ -\varphi)E'_{\varphi_V}(\vartheta,\ -\varphi) - E'_{\vartheta_V}(\vartheta,\ -\varphi)E'_{\varphi_H}(\vartheta,\ -\varphi) \tag{18}$$

and

$$I_{V,H} = A\cos\vartheta\ \ \mathrm{e}^{\,\mathrm{j}\beta d\cos\vartheta}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} V_{V,H}(x,y)\mathrm{e}^{\,\mathrm{j}\beta x\sin\vartheta\cos\varphi}\mathrm{e}^{\,\mathrm{j}\beta y\sin\vartheta\sin\varphi}\mathrm{d}x\ \ \mathrm{d}y \tag{19}$$

A being a proper constant. Namely, the antenna far field is related to (i) the two-dimensional Fourier transforms of the output voltages V_V and V_H of the probe for two independent sets of measurements (the probe is rotated by 90° in the second set); (ii) the FF components E'_{ϑ_V}, E'_{φ_V} and E'_{ϑ_H}, E'_{φ_H} radiated by the probe and the rotated probe when used as transmitting antennas.

In the following, a simple demonstration of the probe-compensated NF-FF transformation with plane-rectangular scanning is given. It is valid in the hypothesis that the mutual coupling effects be negligible and the AUT and probe be reciprocal. By expressing the electric field radiated by the AUT and impinging on the probe as superposition of elementary plane waves (see Eq. 80) and taking into account the relations between the AUT and the probe coordinate systems (see Fig. 14), it can be easily verified that the open circuit voltage at the probe terminals is given by

$$V(\underline{r}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \underline{\hat{E}}(k_x,k_y)\cdot\underline{h}(k_x,\ -k_y)\mathrm{e}^{-\mathrm{j}\underline{k}\cdot\underline{r}}\mathrm{d}k_x\mathrm{d}k_y \tag{20}$$

where $\underline{h}$ is the receiving effective length of the probe and the symbol $(\cdot)$ denotes the inner product. By Fourier inverse transforming Eq. 20, it results

$$\underline{\hat{E}}(k_x,k_y)\cdot\underline{h}(k_x,\ -k_y) = \frac{1}{4\pi^2}\mathrm{e}^{\mathrm{j}k_z d}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} V(x,y)\mathrm{e}^{\mathrm{j}\left(k_x x+k_y y\right)}\mathrm{d}x\mathrm{d}y \tag{21}$$

For a reciprocal antenna the receiving and transmitting effective lengths coincide, and thus, by expressing the electric field $\underline{E}'$ radiated by the probe in the FF region as function of probe effective length (Franceschetti 1997)

DOI 10.1007/978-981-4560-75-7_117-1

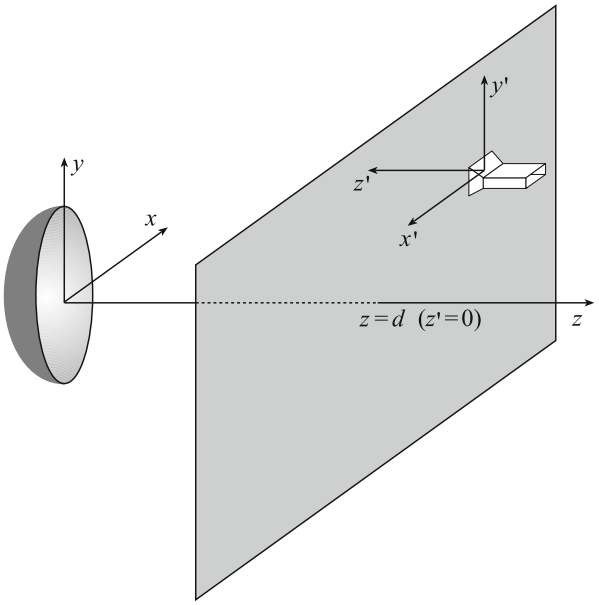

Fig. 14 Geometry relevant to the probe compensation

$$\underline{E}' = \mathrm{j}\frac{\zeta}{2\lambda r} I_0 \mathrm{e}^{-\mathrm{j}\beta r}\underline{h} \tag{22}$$

where ζ is the free-space impedance and I_0 is the antenna input current, it results

$$\hat{\underline{E}}(k_x, k_y)\cdot\underline{E}'(k_x, -k_y) = \frac{\mathrm{j}\zeta I_0 \mathrm{e}^{-\mathrm{j}\beta r}}{2\lambda r}\frac{\mathrm{e}^{\mathrm{j}k_z d}}{4\pi^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} V(x,y)\mathrm{e}^{\mathrm{j}\left(k_x x + k_y y\right)}\mathrm{d}x\mathrm{d}y \tag{23}$$

This last, by taking into account Eq. 81, becomes

$$\underline{E}(\vartheta,\varphi)\cdot\underline{E}'(\vartheta, -\varphi) = -\frac{2\pi\beta\zeta I_0 \mathrm{e}^{-\mathrm{j}2\beta r}}{2\lambda r^2}\frac{\mathrm{e}^{\mathrm{j}\beta d\cos\vartheta}}{4\pi^2}\cos\vartheta\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} V(x,y)\mathrm{e}^{\mathrm{j}\left(k_x x + k_y y\right)}\mathrm{d}x\mathrm{d}y \tag{24}$$

This last can be rewritten in a more convenient form by considering that the following relations between the AUT and the probe reference systems (see Fig. 14) hold:

$$\vartheta' = \vartheta; \quad \varphi' = -\varphi; \quad \hat{\vartheta}' = -\hat{\vartheta}; \quad \hat{\varphi}' = \hat{\varphi} \tag{25}$$

By properly taking into account these last, it is possible to rewrite Eq. 24 in terms of the spherical components of the field quantities, thus getting

$$\begin{aligned} &E_\vartheta(\vartheta,\varphi)E'_\vartheta(\vartheta, -\varphi) - E_\varphi(\vartheta,\varphi)E'_\varphi(\vartheta, -\varphi) \\ &= A\cos\vartheta\ \ \mathrm{e}^{\mathrm{j}\beta d\cos\vartheta}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} V(x,y)\ \ \mathrm{e}^{\mathrm{j}\beta x\sin\vartheta\cos\varphi}\mathrm{e}^{\mathrm{j}\beta y\sin\vartheta\sin\varphi}\mathrm{d}x\mathrm{d}y \end{aligned} \tag{26}$$

DOI 10.1007/978-981-4560-75-7_117-1

where

$$A = \frac{1}{4\pi^2}\frac{2\pi\beta\zeta I_0 \mathrm{e}^{-\mathrm{j}2\beta r}}{2\lambda r^2}$$

From Eq. 26, by assuming to perform two independent sets of measurements (the probe is rotated by 90° around its axis z' in the second set), the following linear system is obtained:

$$E_\vartheta(\vartheta,\varphi)E'_{\vartheta_V}(\vartheta,\ -\varphi) - E_\varphi(\vartheta,\varphi)E'_{\varphi_V}(\vartheta,\ -\varphi) = I_V \tag{27}$$

$$E_\vartheta(\vartheta,\varphi)E'_{\vartheta_H}(\vartheta,\ -\varphi) - E_\varphi(\vartheta,\varphi)E'_{\varphi_H}(\vartheta,\ -\varphi) = I_H \tag{28}$$

By solving such a system, Eqs. 16 and 17 are finally got.

NF-FF Transformation with Cylindrical Scanning

The NF-FF transformation with cylindrical scanning (see Fig. 7) allows one to reconstruct, from a single set of NF measurements, the antenna complete radiation pattern save for the zones surrounding the spherical polar angles and, accordingly, is particularly tailored for antennas that radiate mainly in an angular region centered on the horizontal plane. This, however, is obtained at the cost of a moderate increase in the analytical and computational complication with respect to that using the plane-rectangular scanning. In a cylindrical scanning facility, the AUT is mounted on a rotating table, whereas the probe moves along a line parallel to the rotation axis of the table. By properly matching these movements, the probe can acquire the NF amplitude and phase data on the wanted cylindrical grid. From these data, measured for two different orientations of the probe and accounting for the probe effects, the FF pattern can be evaluated (Joy et al. 1978; Leach and Paris 1973; Yaghjian 1977). As done in the plane-rectangular case, probe-uncorrected NF-FF transformation formulas, valid in the ideal probe assumption, are initially derived. Then, such an assumption is removed and probe-compensated formulas given.

As well known, in the cylindrical coordinate system (ρ, φ, z), the tangential components of the electric field radiated by the AUT can be represented (Leach and Paris 1973) on the scanning cylinder as a superposition of elementary cylindrical waves (see paragraph "Cylindrical Wave Expansion"), namely,

$$E_z(\varphi,z) = \sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty} b_v(\eta)\frac{\Lambda^2}{\beta}H_v^{(2)}(\Lambda d)\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}\mathrm{d}\eta \tag{29}$$

$$E_\varphi(\varphi,z) = \sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[b_v(\eta)\frac{v\eta}{\beta d}H_v^{(2)}(\Lambda d) - a_v(\eta)\frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\Big|_{\rho=d}\right]\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}\mathrm{d}\eta \tag{30}$$

where d is the cylinder radius, a_v and b_v are the modal expansion coefficients, $H_v^{(2)}(\cdot)$ is the Hankel function of second kind of order ν, and $\Lambda = (\beta^2 - \eta^2)^{1/2}$.

The modal coefficients are determined by Fourier inverse transforming Eqs. 29 and 30, thus obtaining

DOI 10.1007/978-981-4560-75-7_117-1

$$b_v(\eta)\frac{\Lambda^2}{\beta}H_v^{(2)}(\Lambda d)=\frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\pi}^{\pi}E_z(\varphi,z)\mathrm{e}^{-\mathrm{j}v\varphi}\mathrm{e}^{\mathrm{j}\eta z}\mathrm{d}\varphi\,\mathrm{d}z \tag{31}$$

$$b_v(\eta)\frac{v\eta}{\beta d}H_v^{(2)}(\Lambda d)-a_v(\eta)\frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\bigg|_{\rho=d}=\frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\pi}^{\pi}E_\varphi(\varphi,z)\mathrm{e}^{-\mathrm{j}v\varphi}\mathrm{e}^{\mathrm{j}\eta z}\mathrm{d}\varphi\mathrm{d}z \tag{32}$$

In the classical approach (Leach and Paris 1973), the FFT is employed to evaluate the modal coefficients in an efficient way, and the sample spacings of the NF data are

$$\Delta z\leqslant\lambda/2;\quad \Delta\varphi\leqslant\pi/(\beta a')=\lambda/(2a') \tag{33}$$

where a' is the radius of the smallest cylinder enclosing the AUT. In fact, if the scanning cylinder is located in a region of space where the EM field does not contain evanescent waves, then the cylindrical wave coefficients are zero for $|\eta|>\beta$ and $|v|>\beta a'$. As a consequence of the two-dimensional Nyquist sampling theorem (Papoulis 1987), the EM field on the cylinder at $\rho=d$ can be reconstructed from the knowledge of its samples at a regular lattice of points separated by grid spacings satisfying Eq. 33.

Once the modal coefficients are determined, the FF components of the electric field in the spherical coordinate system (r,ϑ,φ) can be evaluated (see paragraph "Cylindrical Wave Expansion") by

$$E_\vartheta(r,\vartheta,\varphi)=-\mathrm{j}2\beta\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r}\sin\vartheta\sum_{v=-\infty}^{\infty}\mathrm{j}^v b_v(\beta\cos\vartheta)\mathrm{e}^{\mathrm{j}v\varphi} \tag{34}$$

$$E_\varphi(r,\vartheta,\varphi)=-2\beta\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r}\sin\vartheta\sum_{v=-\infty}^{\infty}\mathrm{j}^v a_v(\beta\cos\vartheta)\mathrm{e}^{\mathrm{j}v\varphi} \tag{35}$$

It is worth noting that the summations in the above equations can be efficiently performed via the FFT.

The use of the FFT for the efficient evaluation of the two-dimensional Fourier transforms in Eqs. 31 and 32 is now briefly described. As regards the integration with respect to φ, by a straightforward approximation, it results

$$F_v=\int_0^{2\pi}f(\varphi)\mathrm{e}^{-\mathrm{j}v\varphi}\mathrm{d}\varphi\approx\frac{2\pi}{N}\sum_{m=0}^{N-1}f\left(\frac{2\pi m}{N}\right)\mathrm{e}^{-\mathrm{j}2\pi vm/N} \tag{36}$$

where $N=2M_1$, $M_1=\pi/\Delta\varphi$ is the highest order v of the angular harmonics. Accordingly, save for the factor $2\pi/N$, such an integration can be efficiently performed via a direct FFT algorithm. The integration over z can be tackled in the same way as that along x or y of the plane-rectangular case. Accordingly, by taking into account the truncation due to the finite height $2h$ of the measurement cylinder, it results

$$G(\eta_i)=G\left(\frac{2\pi i}{N_1\Delta z}\right)\approx\frac{2h}{N_1}\mathrm{e}^{-\mathrm{j}\pi i}\sum_{n=0}^{N_1-1}g(z_n)\mathrm{e}^{\mathrm{j}2\pi ni/N_1} \tag{37}$$

where $N_1=2h/\Delta z$ is the number of the measurement rings. Thus, the integration over z can be efficiently

DOI 10.1007/978-981-4560-75-7_117-1

performed via an inverse FFT algorithm, provided that the so obtained results are multiplied by the factor $2he^{-j\pi i}$.

By summing up, the two-dimensional Fourier transforms of the tangential components of the electric field can be efficiently computed through the following steps: (i) on each measurement ring, the NF data are directly transformed via FFT and then multiplied by the factor $2\pi/N$; (ii) for each index v, the so obtained data are inversely transformed via FFT and then multiplied by $2he^{-j\pi i}$.

Note that the evaluation of the Fourier transform integrals in Eqs. 31 and 32 via the FFT allows one to get the modal expansion coefficients a_v and b_v and, as a consequence, the FF components, at the values of ϑ given by

$$\vartheta_i = \cos^{-1}(\eta_i/\beta) = \cos^{-1}(i\lambda/(N_1\Delta z)) \tag{38}$$

To obtain the FF components with a greater resolution in ϑ, it is sufficient "zero-filling" the NF data. Namely, to get the FF components at the values $\vartheta_i = \cos^{-1}(i\lambda/(N_2\Delta z))$, the NF data must be increased with a proper number of zeros corresponding to fictitious $(N_2 - N_1)/2$ rings at both the ends of the scanning cylinder. In a similar way, to obtain the FF components at $2M_2$ values of φ, the positive and negative angular harmonics must be both augmented with $M_2 - M_1$ zeros before performing the summations in Eqs. 34 and 35 via the FFT.

Since the height of the scanning cylinder is obviously finite, an inevitable truncation error occurs, whose amount depends on the level of the neglected NF data. The angular region wherein the recovered FF pattern is accurate can be determined as in the plane-rectangular case. The truncation error arising when the scanning along φ does not cover a whole 2π range can be handled (Francis 2012) as that occurring in a truncated spherical scan (Hald et al. 1988).

It can be easily recognized that the NF tangential components E_z and E_φ cannot be acquired when performing the measurement by means of a real probe. In fact, it sees the AUT center under different directions when moving on the cylinder. Moreover, also at a fixed position, the probe sees each portion of the AUT under a different direction. As a consequence, the antenna far field cannot be accurately recovered from the measured NF data by employing the uncompensated NF-FF transformation.

The basic theory of probe-compensated NF measurements over a cylinder was developed by Leach and Paris (1973) and is based on an application of the Lorentz reciprocity theorem. They demonstrated rigorously that the modal coefficients a_v and b_v of the cylindrical wave expansion of the field radiated by the AUT are related to (i) the two-dimensional Fourier transform of the probe voltage for two independent sets of measurements (the probe is rotated 90° about its longitudinal axis in the second set); (ii) the coefficients of the cylindrical wave expansion of the field radiated by the probe and the rotated probe, when used as transmitting antennas. The key relations to obtain the modal expansion coefficients are

$$a_v(\eta) = \frac{\beta^2}{\Lambda^2\Delta_v(\eta)}\left[I_v(\eta)\sum_{m=-\infty}^{\infty} d'_m(-\eta)H^{(2)}_{v+m}(\Lambda d) - I'_v(\eta)\sum_{m=-\infty}^{\infty} d_m(-\eta)H^{(2)}_{v+m}(\Lambda d)\right] \tag{39}$$

$$b_v(\eta) = \frac{\beta^2}{\Lambda^2\Delta_v(\eta)}\left[I'_v(\eta)\sum_{m=-\infty}^{\infty} c_m(-\eta)H^{(2)}_{v+m}(\Lambda d) - I_v(\eta)\sum_{m=-\infty}^{\infty} c'_m(-\eta)H^{(2)}_{v+m}(\Lambda d)\right] \tag{40}$$

DOI 10.1007/978-981-4560-75-7_117-1

$$I_v(\eta) = \int_{-\infty}^{\infty}\int_{-\pi}^{\pi} V(\varphi, z)\ \mathrm{e}^{-\mathrm{j}v\varphi}\mathrm{e}^{\mathrm{j}\eta z}\mathrm{d}\varphi\mathrm{d}z; \quad I'_v(\eta) = \int_{-\infty}^{\infty}\int_{-\pi}^{\pi} V'(\varphi, z)\ \mathrm{e}^{-\mathrm{j}v\varphi}\mathrm{e}^{\mathrm{j}\eta z}\mathrm{d}\varphi\mathrm{d}z \tag{41}$$

$$\begin{aligned}\Delta_v(\eta) = &\sum_{m=-\infty}^{\infty} c_m(-\eta)H_{v+m}^{(2)}(\Lambda d)\sum_{m=-\infty}^{\infty} d'_m(-\eta)H_{v+m}^{(2)}(\Lambda d) + \\ &- \sum_{m=-\infty}^{\infty} c'_m(-\eta)H_{v+m}^{(2)}(\Lambda d)\sum_{m=-\infty}^{\infty} d_m(-\eta)H_{v+m}^{(2)}(\Lambda d)\end{aligned} \tag{42}$$

where V and V' are the voltages measured by the probe and the rotated probe at the point (d, φ, z). Quite analogous results have been obtained (Yaghjian 1977) by using the source scattering matrix formulation. In fact, as shown in (Appel-Hansen 1980), this last formulation leads, except for a normalization constant, to the same expressions.

The integrals I_v and I'_v are again efficiently evaluated via FFT and the NF data are spaced according to Eq. 33. The modal coefficients of the probe (c_m, d_m) and the rotated probe (c'_m, d'_m) can be evaluated from the measured amplitude and phase of the FF components radiated by them (Leach and Paris 1973). Once a_v and b_v have been determined, the FF components of the electric field in the spherical coordinate system (r, ϑ, φ) can be evaluated by means of Eqs. 34 and 35.

NF-FF Transformation with Spherical Scanning

The NF-FF transformation with spherical scanning (see Fig. 8) gives the full antenna pattern coverage, even though the data processing is considerably more complicated than that required by planar and cylindrical NF facilities. A tangible amount of work has been done in the past years for formulating and solving the problem of the FF reconstruction from the NF data acquired on a spherical scanning surface (Hald et al. 1988; Wacker 1975; Larsen 1980; Yaghjian and Wittmann 1985). In this framework, a comprehensive book (Hald et al. 1988), which deals with the theoretical as well as the practical aspects of the spherical NF scanning, was published by J.E. Hansen.

There are several ways to perform the scanning in a spherical NF facility (Hald et al. 1988). The most commonly adopted one is the roll-over-azimuth configuration (see Figs. 15 and 16). In such a configuration, the probe stays fixed, whereas the AUT is mounted on a roll positioner (φ axis), which is anchored by means of an L-shaped bracket to an azimuth rotating table (ϑ axis). In the elevation-over-azimuth configuration, the probe stays fixed and the AUT is mounted on an elevation positioner (φ axis), which is mounted on an azimuth rotating table (ϑ axis). On the contrary, in the azimuth-over-elevation setup, the AUT is anchored to an azimuth rotator (φ axis), mounted on an elevation positioner (ϑ axis). Another possibility is to mount the AUT on an azimuth rotating table for selecting the scanning meridian and to move the probe along an arc to perform the scanning along it.

Whatever the configuration has been chosen, the probe can acquire the NF amplitude and phase data on the wanted spherical grid. From these data, measured for two different orientations of the probe and accounting for the probe effects, the FF pattern can be evaluated (Hald et al. 1988). As done in the plane-rectangular and cylindrical scanning cases, probe-uncorrected NF-FF transformation formulas, valid in the ideal probe assumption, are initially derived. Then, such an assumption is removed and probe-compensated formulas given.

As well known, in the spherical coordinate system (r, ϑ, φ), the transverse electric field radiated by an AUT can be expressed on a sphere of radius $r = d$ containing it as a superposition of elementary spherical waves (see paragraph "Spherical Wave Expansion"), namely,

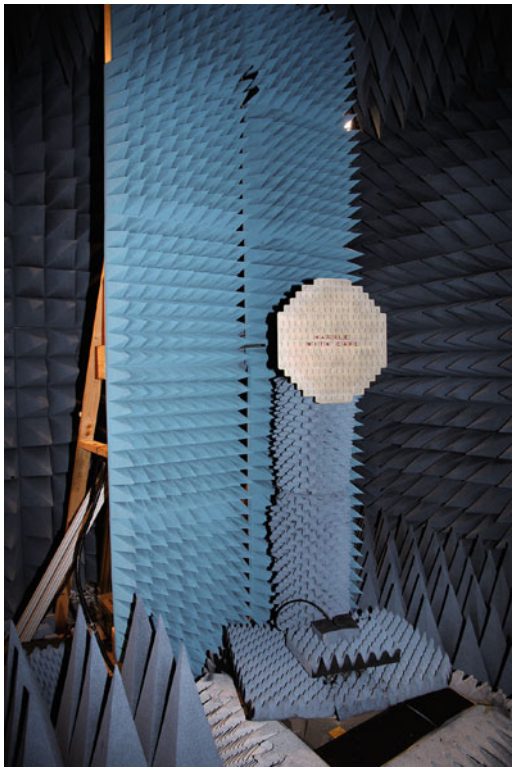

Fig. 16 Photo of the versatile NF system at the UNISA antenna characterization LAB: roll-over-azimuth spherical setup

DOI 10.1007/978-981-4560-75-7_117-1

$$\underline{E}_t(d,\vartheta,\varphi) = \beta \sum_{n=1}^{N_{\max}} \sum_{m=-n}^{n} \left[a_{1nm} g_{1n}(\beta d) \underline{F}_{1nm}(\vartheta,\varphi) + a_{2nm} g_{2n}(\beta d) \underline{F}_{2nm}(\vartheta,\varphi) \right] \tag{43}$$

where a_{1nm}, a_{2nm} are the spherical wave expansion coefficients,

$$\underline{F}_{1nm}(\vartheta,\varphi) = \underline{f}_{1nm}(\vartheta) \mathrm{e}^{\mathrm{j}m\varphi};\ \underline{F}_{2nm}(\vartheta,\varphi) = \underline{f}_{2nm}(\vartheta) \mathrm{e}^{\mathrm{j}m\varphi} \tag{44}$$

$$\underline{f}_{1nm}(\vartheta) = \left(\frac{-m}{|m|}\right)^m \frac{1}{\sqrt{2\pi n(n+1)}} \left[\frac{\mathrm{j}m}{\sin\vartheta} \overline{P}_n^{|m|}(\cos\vartheta)\hat{\vartheta} - \frac{\mathrm{d}}{\mathrm{d}\vartheta} \overline{P}_n^{|m|}(\cos\vartheta)\hat{\varphi} \right] \tag{45}$$

$$\underline{f}_{2nm}(\vartheta) = \left(\frac{-m}{|m|}\right)^m \frac{1}{\sqrt{2\pi n(n+1)}} \left[\frac{\mathrm{d}}{\mathrm{d}\vartheta} \overline{P}_n^{|m|}(\cos\vartheta)\hat{\vartheta} + \frac{\mathrm{j}m}{\sin\vartheta} \overline{P}_n^{|m|}(\cos\vartheta)\hat{\varphi} \right] \tag{46}$$

$$g_{1n}(\beta d) = h_n^{(2)}(\beta d);\quad g_{2n}(\beta d) = \frac{1}{\beta d} \frac{\mathrm{d}}{\mathrm{d}(\beta r)} \left(\beta r h_n^{(2)}(\beta r) \right) \Big|_{r=d} \tag{47}$$

$h_n^{(2)}(x)$ being the spherical Hankel function of second kind and order n.

In the classical approach (Hald et al. 1988), the choice of the highest spherical wave is usually determined according to the following rule of thumb:

$$N_{\max} = \mathrm{Int}(\beta a) + 10 \tag{48}$$

where a is the radius of the smallest sphere enclosing the AUT. In the approach (Bucci et al. 2001a), it is rigorously fixed by the spatial band limitation properties of the radiated EM fields (Bucci and Franceschetti 1987) and it results

$$N_{\max} = \mathrm{Int}(\chi' \beta a) + 1 \tag{49}$$

where χ' is an enlargement bandwidth factor slightly larger than unity for electrically large antennas (Bucci and Franceschetti 1987).

In Eqs. 45 and 46, $\overline{P}_n^{|m|}(x)$ (see Eq. 107) is the normalized associated Legendre function as defined by Belousov (1962).

The expansion coefficients a_{1nm}, a_{2nm} can be evaluated from the knowledge of the tangential electric field on the scanning sphere by taking into account that the spherical vector wave functions $\underline{F}_{1,2nm}(\vartheta,\varphi)$ are orthonormal. As a matter of fact, from Eq. 43 it results

$$\left\langle \underline{E}_t, \underline{F}_{1,2nm} \right\rangle = \int_0^{2\pi} \int_0^{\pi} \underline{E}_t(d,\vartheta,\varphi) \cdot \underline{F}^*_{1,2nm}(\vartheta,\varphi) \sin\vartheta \mathrm{d}\vartheta \mathrm{d}\varphi = \beta a_{1,2nm}\, g_{1,2n}(\beta d) \tag{50}$$

where the asterisk (*) indicates the complex conjugation, and therefore

$$a_{1,2nm} = \frac{1}{\beta g_{1,2n}(\beta d)} \int_0^{2\pi} \int_0^{\pi} \underline{E}_t(d,\vartheta,\varphi) \cdot \underline{f}^*_{1,2nm}(\vartheta) \mathrm{e}^{-\mathrm{j}m\varphi} \sin\vartheta \mathrm{d}\vartheta d\varphi \tag{51}$$

DOI 10.1007/978-981-4560-75-7_117-1

Once the spherical wave expansion coefficients have been determined, the transverse electric field radiated by the AUT in the FF region can be evaluated (see paragraph "Spherical Wave Expansion") by the FF spherical wave expansion:

$$\underline{E}_t(r,\vartheta,\varphi) = \frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r}\sum_{n=1}^{N_{\max}}\sum_{m=-n}^{n}\left[\mathrm{j}^{n+1}a_{1nm}\,\underline{f}_{1nm}(\vartheta) + \mathrm{j}^{n}a_{2nm}\,\underline{f}_{2nm}(\vartheta)\right]\mathrm{e}^{\mathrm{j}m\varphi} \tag{52}$$

As will be shown in the following, the FFT is used to evaluate the modal coefficients in an efficient way, and the sample spacings of the NF data in the classical approach (Hald et al. 1988) are

$$\Delta\vartheta \leqslant 2\pi/(2N_{\max}+1); \quad \Delta\varphi = \Delta\vartheta \tag{53}$$

The number of NF data along φ can be reduced if the radius a' of the smallest cylinder enclosing the AUT and having its axis coincident with the z one is smaller than the radius a of the minimum sphere. In such a case, it results (Hald et al. 1988)

$$\Delta\varphi \leqslant 2\pi/(2M+1) \tag{54}$$

where $M = \mathrm{Int}\,(\beta a') + 10$.

In the approach (Bucci et al. 2001a), the sample spacings are rigorously fixed by the spatial band limitation properties of the radiated EM fields (Bucci and Franceschetti 1987) and, accordingly, $N_{\max}$ is now given by Eq. 49, whereas $\Delta\varphi$ is given by Eq. 54, where M decreases when moving from the sampling parallels near the equator to those near the poles according to the law

$$M = \mathrm{Int}(\chi^{*}\beta a \sin\vartheta) + 1 \tag{55}$$

In this last relation,

$$\chi^{*} = \chi^{*}(\vartheta) = 1 + (\chi' - 1)[\sin\vartheta]^{-2/3} \tag{56}$$

is the azimuthal enlargement bandwidth factor.

The efficient evaluation of Eq. 51 is now briefly described. By expanding the tangential electric field components on the measurement sphere in Fourier series with respect to φ, namely,

$$\underline{E}_t(d,\vartheta,\varphi) = \sum_{k=-M}^{M}\underline{G}_k(\vartheta)\mathrm{e}^{\mathrm{j}k\varphi} \tag{57}$$

the coefficients can be rewritten as follows:

$$a_{1,2nm} = \frac{2\pi}{\beta g_{1,2n}(\beta d)}\int_0^{\pi}\underline{G}_m(\vartheta)\cdot\underline{f}^{*}_{1,2nm}(\vartheta)\sin\vartheta\,\mathrm{d}\vartheta \tag{58}$$

The integration over ϑ in Eq. 58 can be efficiently carried out by expanding in Fourier series the components of $\underline{G}_m(\vartheta)$ and $\underline{f}_{1,2nm}(\vartheta)$ via FFT. Accordingly, it results

DOI 10.1007/978-981-4560-75-7_117-1

$$a_{1,2nm} = \frac{2\pi}{\beta g_{1,2n}(\beta d)} \sum_{\ell=-N_{\max}}^{N_{\max}} \sum_{i=-N_{\max}}^{N_{\max}} \underline{G}_{m\ell} \cdot \underline{f}^{*}_{1,2nmi} \int_0^{\pi} \mathrm{e}^{\mathrm{j}(\ell-i)\vartheta} \sin\vartheta \, \mathrm{d}\vartheta \tag{59}$$

The integral in Eq. 58 is so transformed in a double summation, of indexes ℓ and i, involving the Fourier series coefficients (in ϑ) of the components of $\underline{G}_m(\vartheta)$ and $\underline{f}_{1,2nm}(\vartheta)$, and the integrals

$$\int_0^{\pi} \mathrm{e}^{\mathrm{j}(\ell-i)\vartheta} \sin\vartheta \, \mathrm{d}\vartheta$$

Note that, in order to evaluate the Fourier series coefficients of the components of $\underline{G}_m(\vartheta)$ and $\underline{f}_{1,2nm}(\vartheta)$, it is necessary to extend the components of $\underline{G}_m(\vartheta)$ and $\underline{f}_{1,2nm}(\vartheta)$, from $[0, \pi]$ on the range $[0, 2\pi]$. This can be easily done by taking into account that (i) the components of $\underline{f}_{1,2nm}(\vartheta)$ are even about $\vartheta = \pi$ when m is odd, and vice versa; (ii) the components of $\underline{G}_m(\vartheta)$ have the same parity as those of $\underline{f}_{1,2nm}(\vartheta)$.

To take advantage of the numerical efficiency of the standard FFT algorithm, the number of NF parallels to be considered in the NF-FF transformation and the number of samples on them must be the first power of two greater or equal to $N_{\max}$ and $2M$, respectively.

Moreover, by inverting the summation order in Eq. 52, it can be rewritten in the form

$$\underline{E}_t(r,\vartheta,\varphi) = \frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r} \sum_{m=-M}^{M} \sum_{\substack{n=|m| \\ (n\neq 0)}}^{N_{\max}} \left[\mathrm{j}^{n+1} a_{1nm} \underline{f}_{1nm}(\vartheta) + \mathrm{j}^{n} a_{2nm} \underline{f}_{2nm}(\vartheta)\right] \mathrm{e}^{\mathrm{j}m\varphi} \tag{60}$$

which allows an efficient evaluation of the antenna far field at the considered elevation angle ϑ by performing the summation via FFT.

It can be easily recognized that the NF tangential components E_ϑ and E_φ cannot be acquired when performing the measurement with a real probe. In fact, it sees each portion of the AUT under a different direction. As a consequence, the antenna far field cannot be accurately recovered from the measured NF data by using the uncompensated NF-FF transformation.

The probe-compensated NF-FF transformation with spherical scanning has been developed by using the source scattering matrix formulation. As shown in (Hald et al. 1988), when using a probe with a first-order azimuthal dependence FF pattern (e.g., an open-ended circular waveguide), the modal expansion coefficients can be determined from the knowledge of the voltages V and V' measured by the probe and rotated probe, respectively, and are given by

$$a_{1nm} = \frac{2n+1}{16\pi} \frac{\int_0^{\pi}\int_0^{2\pi} [I_1(\vartheta)V - \mathrm{j}\, I_2(\vartheta)V']\mathrm{e}^{-\mathrm{j}m\varphi} \sin\vartheta \;\; \mathrm{d}\varphi \, \mathrm{d}\vartheta}{\sum_{\nu=1}^{\nu_{\max}} \left[a'_{1\nu 1} A^{n}_{\nu 1}(\beta d) - a'_{2\nu 1} B^{n}_{\nu 1}(\beta d)\right]} \tag{61}$$

DOI 10.1007/978-981-4560-75-7_117-1

$$a_{2nm} = \frac{2n+1}{16\pi} \frac{\int_0^{\pi}\int_0^{2\pi} [I_2(\vartheta)V - \mathrm{j}\ I_1(\vartheta)V']\mathrm{e}^{-\mathrm{j}m\varphi} \sin\vartheta\ \ \mathrm{d}\varphi\ \mathrm{d}\vartheta}{\sum_{v=1}^{v_{\max}} \left[a'_{1v1}B^n_{v1}(\beta d) - a'_{2v1}A^n_{v1}(\beta d)\right]} \tag{62}$$

where $v_{\max}$ is the highest spherical wave of the probe, $a'_{1,2v1}$ are its expansion coefficients,

$$I_1(\vartheta) = \left[d^n_{1m}(\vartheta) - d^n_{-1m}(\vartheta)\right]; \quad I_2(\vartheta) = \left[d^n_{1m}(\vartheta) + d^n_{-1m}(\vartheta)\right] \tag{63}$$

and

$$d^n_{\mu m}(\vartheta) = \sqrt{\frac{(n+\mu)!(n-\mu)!}{(n+m)!(n-m)!}} \sum_{\sigma} \binom{n+m}{n-\mu-\sigma} \binom{n-m}{\sigma} (-1)^{n-\mu-\sigma} \cdot \left(\cos\tfrac{\vartheta}{2}\right)^{2\sigma+\mu+m} \left(\sin\tfrac{\vartheta}{2}\right)^{2n-2\sigma-\mu-m} \tag{64}$$

are the rotation coefficients (Hald et al. 1988; Edmonds 1974), the summation over σ involving all terms in which the binomial coefficients do not lead to negative arguments for the factorials. Moreover,

$$A^n_{v\mu}(\beta d) = \sqrt{\frac{(2n+1)\,(2v+1)}{n(n+1)v(v+1)}} \sqrt{\frac{(v+\mu)!(n-\mu)!}{(v-\mu)!(n+\mu)!}} (-1)^{\mu} \frac{1}{2} \mathrm{j}^{n-v} \cdot \sum_{p=|n-v|}^{n+v} \left\{\mathrm{j}^{-p}[n(n+1) + v(v+1) - p(p+1)]\ \tau\ (\mu, n, -\mu, v, p)\ h^{(2)}_p(\beta d)\right\} \tag{65}$$

$$B^n_{v\mu}(\beta d) = \sqrt{\frac{(2n+1)\,(2v+1)}{n(n+1)v(v+1)}} \sqrt{\frac{(v+\mu)!(n-\mu)!}{(v-\mu)!(n+\mu)!}} (-1)^{\mu} \frac{1}{2} \mathrm{j}^{n-v} \cdot \sum_{p=|n-v|}^{n+v} \left[\mathrm{j}^{-p}(2\mathrm{j}\mu\beta d)\ \tau\ (\mu, n, -\mu, v, p)\ h^{(2)}_p(\beta d)\right] \tag{66}$$

are the translation coefficients (Hald et al. 1988; Larsen 1980; Bruning and Lo 1971), wherein $\tau\ (\mu, n, -\mu, v, p)$ are the linearization coefficients defined by the expansion of the product of two unnormalized associated Legendre functions

$$P^{\mu}_n(x)P^{-\mu}_v(x) = \sum_{p=|n-v|}^{n+v} \tau(\mu, n, -\mu, v, p)P_p(x) \tag{67}$$

The probe expansion coefficients $a'_{1,2v1}$ in Eqs. 61, 62 can be evaluated from the knowledge of its tangential electric field $\underline{E}'_t$ on a scanning sphere when it is used as transmitting antenna

DOI 10.1007/978-981-4560-75-7_117-1

$$a'_{1,2v1} = \frac{1}{\beta g_{1,2v}(\beta d)} \int_0^{2\pi} \int_0^{\pi} \underline{E}'_t(d,\vartheta,\varphi) \cdot \underline{f}^*_{1,2v1}(\vartheta) \mathrm{e}^{-\mathrm{j}\varphi} \sin\vartheta \, \mathrm{d}\vartheta \, \mathrm{d}\varphi \tag{68}$$

Classical Wave Expansions of the Field Radiated by an Antenna

Some analytical details on the wave expansions commonly employed to represent the antenna field in the region external to it are collected in this paragraph. In any case, its reading is not strictly necessary for the comprehension of the Chapter and its aim is to enable the interested reader to achieve a more in-depth knowledge of the topic.

Plane Wave Expansion

As well known, in a linear, homogeneous, and isotropic medium, an EM field

$$\underline{E} = \underline{\hat{E}} \mathrm{e}^{-\mathrm{j}\underline{k}\cdot\underline{r}}; \; \underline{H} = \underline{\hat{H}} \mathrm{e}^{-\mathrm{j}\underline{k}\cdot\underline{r}} \tag{69}$$

represents a time-harmonic plane wave whose direction of propagation is specified by the vector $\underline{k} = k_x\hat{x} + k_y\hat{y} + k_z\hat{z}$.

Since the operator ∇ transforms into $-\mathrm{j}\underline{k}$ for such a field, Maxwell's equations in a region free of sources become

$$\underline{k} \times \underline{\hat{E}} = \omega\mu\underline{\hat{H}} \tag{70}$$

$$\underline{k} \times \underline{\hat{H}} = -\omega\varepsilon\underline{\hat{E}} \tag{71}$$

$$\underline{k} \cdot \underline{\hat{E}} = 0 \tag{72}$$

$$\underline{k} \cdot \underline{\hat{H}} = 0 \tag{73}$$

From Eqs. 70 and 71, it results that $\underline{\hat{E}}$ and $\underline{\hat{H}}$ cannot be chosen independently, for instance, $\underline{\hat{H}}$ is related to $\underline{\hat{E}}$ by

$$\underline{\hat{H}} = \frac{1}{\omega\mu}\underline{k} \times \underline{\hat{E}} \tag{74}$$

From Eq. 72, it results that, for any k_x, k_y, and k_z, only two components of $\underline{\hat{E}}(\underline{k})$ are independent. Let these be $\hat{E}_x$ and $\hat{E}_y$, then

$$\hat{E}_z = -\left(\hat{E}_x k_x + \hat{E}_y k_y\right)/k_z \tag{75}$$

From Eq. 70, it results that

$$\underline{k} \times \left(\underline{k} \times \underline{\hat{E}}\right) = \omega\mu\underline{k} \times \underline{\hat{H}} \tag{76}$$

Such a relation, taking into account Eqs. 71, 72 and the vector identity $\underline{a} \times (\underline{b} \times \underline{c}) = \underline{b}(\underline{a} \cdot \underline{c}) - \underline{c}(\underline{a} \cdot \underline{b})$, becomes

DOI 10.1007/978-981-4560-75-7_117-1

$$\underline{\hat{E}}\left[(\underline{k}\cdot\underline{k})-\omega^2\varepsilon\mu\right]=0 \tag{77}$$

In order that such an equation have a solution different from the trivial one $\underline{\hat{E}}=0$, it is necessary that

$$\underline{k}\cdot\underline{k}=k_x^2+k_y^2+k_z^2=\omega^2\varepsilon\mu=\beta^2 \tag{78}$$

Thus, at a fixed frequency, only two of the components of $\underline{k}$ can be independently specified. Let these be k_x and k_y, then the third component is related to them via the relation

$$k_z=\begin{cases}\left(\beta^2-k_x^2-k_y^2\right)^{1/2}, & \text{if } k_x^2+k_y^2\leqslant\beta^2\\ -\mathrm{j}\left(k_x^2+k_y^2-\beta^2\right)^{1/2}, & \text{if } k_x^2+k_y^2>\beta^2\end{cases} \tag{79}$$

The negative sign in the second of Eq. 79 is chosen in order to ensure that the plane wave Eq. 69 is bounded at infinity.

Since the medium is linear as well as the field equations, the general solution for $\underline{E}$ and $\underline{H}$ can be constructed as linear combination over all k_x and k_y:

$$\underline{E}(\underline{r})=\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\underline{\hat{E}}(\underline{k})\mathrm{e}^{-\mathrm{j}\underline{k}\cdot\underline{r}}\,\mathrm{d}k_x\mathrm{d}k_y;\ \underline{H}(\underline{r})=\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\frac{1}{\omega\mu}\underline{k}\times\underline{\hat{E}}(\underline{k})\mathrm{e}^{-\mathrm{j}\underline{k}\cdot\underline{r}}\,\mathrm{d}k_x\mathrm{d}k_y \tag{80}$$

Namely, any arbitrary monochromatic wave can be represented as a superposition of plane waves with different amplitudes and propagating in different directions. The amplitude function $\underline{\hat{E}}(\underline{k})$ is called the plane wave spectrum of the field. It is worthy to note that the dimensions of $\underline{\hat{E}}$ in Eqs. 69 and 80 are different although the same notation has been used.

In general, the evaluation of the double integral in Eq. 80 is difficult. However, it can be shown (Franceschetti 1997; Balanis 1997), by applying the stationary phase method, that in the far-field region such an integral can be represented by the asymptotic expansion

$$\underline{E}(r,\vartheta,\varphi)=\mathrm{j}2\pi k_z\underline{\hat{E}}(k_x,k_y)\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{r} \tag{81}$$

where

$$k_x=\beta\sin\vartheta\cos\varphi;\quad k_y=\beta\sin\vartheta\sin\varphi;\quad k_z=\beta\cos\vartheta \tag{82}$$

Cylindrical Wave Expansion

In the cylindrical wave expansion (CWE), the field is represented as superposition of transverse electric (TE) and transverse magnetic (TM) cylindrical modes (Stratton 1941), which are elementary solutions of the homogeneous wave equation in the cylindrical coordinates (ρ, φ, z). In fact, an arbitrary field in a homogeneous source-free region can be always expressed as the sum of a TE field and a TM field (Harrington 1961). The expression for these modes can be easily derived by using the auxiliary vector potentials $\underline{A}$ and $\underline{F}$, which, in such a hypothesis, are solutions of the homogeneous vector Helmoltz equations:

DOI 10.1007/978-981-4560-75-7_117-1

$$\nabla^2 \underline{A} + \beta^2 \underline{A} = 0;\ \nabla^2 \underline{F} + \beta^2 \underline{F} = 0 \tag{83}$$

As well known, the fields $\underline{E}$ and $\underline{H}$ are related to them by

$$\underline{E} = -\mathrm{j}\omega \underline{A} + \frac{\nabla\nabla \cdot \underline{A}}{\mathrm{j}\omega\varepsilon\mu} - \frac{1}{\varepsilon}\nabla \times \underline{F};\quad \underline{H} = -\mathrm{j}\omega \underline{F} + \frac{\nabla\nabla \cdot \underline{F}}{\mathrm{j}\omega\varepsilon\mu} + \frac{1}{\mu}\nabla \times \underline{A} \tag{84}$$

From Eq. 84, it can be easily recognized that, to derive the field expressions that are TE to z, it is sufficient to assume (Balanis 1989)

$$\underline{A} = 0;\ \underline{F} = \hat{z}F(\rho, \varphi, z) \tag{85}$$

whereas

$$\underline{A} = \hat{z}A(\rho, \varphi, z);\ \underline{F} = 0 \tag{86}$$

for the TM to z modes (Balanis 1989). In both the cases, the vector Helmoltz equations reduce to the scalar ones. Their elementary solution is obtainable by using the separation of variables method (Balanis 1989) and, in the considered case of observation region external to smallest cylinder enclosing the AUT, is given by $H_v^{(2)}(\Lambda\rho)\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}$, where v is an integer, η is a real number, $\Lambda = \left(\beta^2 - \eta^2\right)^{1/2}$, and $H_v^{(2)}(\Lambda\rho)$ is the Hankel function of second kind and order v.

By substituting such an elementary solution in Eq. 84, it results

$$\underline{E} = (-1/\varepsilon)\underline{M}_{v\eta} \tag{87}$$

for the TE case and

$$\underline{E} = (\beta/\mathrm{j}\omega\varepsilon\mu)\underline{N}_{v\eta} \tag{88}$$

for the TM one, wherein

$$\underline{M}_{v\eta}(\rho, \varphi, z) = \left(\frac{\mathrm{j}v}{\rho}H_v^{(2)}(\Lambda\rho)\hat{\rho} - \frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\hat{\varphi}\right)\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z} \tag{89}$$

$$\underline{N}_{v\eta}(\rho, \varphi, z) = \left(-\frac{\mathrm{j}\eta}{\beta}\frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\hat{\rho} + \frac{v\eta}{\beta\rho}H_v^{(2)}(\Lambda\rho)\hat{\varphi} + \frac{\Lambda^2}{\beta}H_v^{(2)}(\Lambda\rho)\hat{z}\right)\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z} \tag{90}$$

Accordingly, the electric field radiated by the AUT at a point external to the smallest cylinder enclosing it can be represented (Stratton 1941) as a linear combination of the elementary fields Eqs. 87 and 88 involving an integral over all η values, and a sum over all v:

$$\underline{E}(\rho, \varphi, z) = \sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[a_v(\eta)\underline{M}_{v\eta}(\rho, \varphi, z) + b_\eta(\eta)\underline{N}_{v\eta}(\rho, \varphi, z)\right]\mathrm{d}\eta \tag{91}$$

therefore

DOI 10.1007/978-981-4560-75-7_117-1

$$E_\rho(\rho,\varphi,z)=\sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[a_v(\eta)\frac{\mathrm{j}v}{\rho}H_v^{(2)}(\Lambda\rho)-\frac{\mathrm{j}\eta}{\beta}b_v(\eta)\frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\right]\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}\mathrm{d}\eta \tag{92}$$

$$E_\varphi(\rho,\varphi,z)=\sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[b_v(\eta)\frac{v\eta}{\beta\rho}H_v^{(2)}(\Lambda\rho)-a_v(\eta)\frac{\partial}{\partial\rho}H_v^{(2)}(\Lambda\rho)\right]\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}\mathrm{d}\eta \tag{93}$$

$$E_z(\rho,\varphi,z)=\sum_{v=-\infty}^{\infty}\int_{-\infty}^{\infty}b_v(\eta)\frac{\Lambda^2}{\beta}H_v^{(2)}(\Lambda\rho)\mathrm{e}^{\mathrm{j}v\varphi}\mathrm{e}^{-\mathrm{j}\eta z}\mathrm{d}\eta \tag{94}$$

The evaluations of the FF components of the electric field in the spherical coordinate system (r, ϑ, φ) from the above expressions involve the following steps. The first step is to replace in the CWE the Hankel function and its first derivative by their asymptotic expansions

$$H_v^{(2)}(x)\underset{x\to\infty}{\approx}\sqrt{\frac{2\mathrm{j}}{\pi x}}\mathrm{j}^v\mathrm{e}^{-\mathrm{j}x};\quad\frac{\mathrm{d}}{\mathrm{d}x}H_v^{(2)}(\alpha x)\underset{x\to\infty}{\approx}\sqrt{\frac{2\mathrm{j}\alpha}{\pi x}}\mathrm{j}^{v-1}\mathrm{e}^{-\mathrm{j}\alpha x} \tag{95}$$

The obtained expressions are then rewritten in terms of the spherical coordinates r, ϑ, φ. The next step is the asymptotic evaluation of the integrals over η by means of the method of the stationary phase (James 1980). At last, the FF components of the electric field in the cylindrical coordinate system are transformed in the spherical ones, thus obtaining Eqs. 34 and 35.

Spherical Wave Expansion

In the spherical wave expansion (SWE), the field is represented as superposition of transverse electric (to the radial direction) spherical modes (TE^r) and transverse magnetic ones (TM^r) (Stratton 1941), which are elementary solutions of the homogeneous wave equation in the spherical coordinates (r, ϑ, φ). In fact, an arbitrary field in a homogeneous source-free region can be expressed as the sum of a TE field and a TM field (Harrington 1961). The expression for these modes can be determined by using the auxiliary vector potentials $\underline{A}$ and $\underline{F}$. In particular, to derive the field expressions that are TE to r, it is sufficient to assume (Balanis 1989)

$$\underline{A}=0;\quad\underline{F}=\hat{r}F(r,\vartheta,\varphi) \tag{96}$$

whereas

$$\underline{A}=\hat{r}A(r,\vartheta,\varphi);\quad\underline{F}=0 \tag{97}$$

for the TM to r modes (Balanis 1989).

It must be stressed that, unlike the cylindrical scanning case, it is not convenient now to determine the auxiliary potentials by means of the vector Helmholtz equations (Eq. 83), valid in a source-free region when assuming that the vector potentials $\underline{A}$, $\underline{F}$ and the scalar ones Φ, Ψ satisfy the Lorentz conditions:

$$\nabla\cdot\underline{A}+\mathrm{j}\omega\varepsilon\mu\Phi=0;\quad\nabla\cdot\underline{F}+\mathrm{j}\omega\varepsilon\mu\Psi=0 \tag{98}$$

DOI 10.1007/978-981-4560-75-7_117-1

In fact, since $\nabla^2(\hat{r}G) \neq \hat{r}\nabla^2 G$, the vector Helmholtz equations (Eq. 83) do not reduce any longer to the corresponding scalar ones. Obviously, in such a case, also the expressions (Eq. 84), relating the fields to the auxiliary potentials, are no longer valid. Different relations for the fields and potentials that are not based on Lorentz conditions are now derived.

The TE^r case ($\underline{A} = 0, \underline{F} = \hat{r}F(r, \vartheta, \varphi)$) is first considered. It can be easily recognized that

$$\underline{E} = -\frac{1}{\varepsilon}\nabla \times \underline{F}; \quad \underline{H} = \frac{1}{\mathrm{j}\omega\varepsilon\mu}\nabla \times \nabla \times \underline{F} \tag{99}$$

By substituting the former of Eq. 99 in the second of Maxwell's equations, it results

$$\nabla \times (\underline{H} + \mathrm{j}\omega\underline{F}) = 0 \tag{100}$$

and, accordingly,

$$\underline{H} = -\mathrm{j}\omega\underline{F} - \nabla\Psi \tag{101}$$

By substituting Eq. 101 into the latter of Eq. 99, it is obtained

$$\nabla \times \nabla \times \underline{F} - \beta^2\underline{F} = -\mathrm{j}\omega\varepsilon\mu\nabla\Psi \tag{102}$$

By expanding Eq. 102 in spherical coordinates and imposing that $\Psi = (-1/\mathrm{j}\omega\varepsilon\mu)\ \partial F/\partial r$, it can be shown (Balanis 1989) that F can be determined by solving the scalar Helmholtz equation

$$\nabla^2\psi + \beta^2\psi = 0 \tag{103}$$

where

$$\psi(r, \vartheta, \varphi) = F(r, \vartheta, \varphi)/r \tag{104}$$

The elementary solution to Eq. 103 can be obtained by using the separation of variables method (Balanis 1989) and, in the considered case of an observation region external to the smallest sphere enclosing the AUT, it is given by

$$\psi(r, \vartheta, \varphi) = h_n^{(2)}(\beta r)\overline{P}_n^{|m|}(\cos\vartheta)\mathrm{e}^{\mathrm{j}m\varphi} \tag{105}$$

where n and m are integers, $\overline{P}_n^m(x)$ is the normalized associated Legendre function as defined by Belousov (1962), and $h_n^{(2)}(x)$ is the spherical Hankel function of second kind and order n, which is related to the ordinary Hankel function of second kind by

$$h_n^{(2)}(x) = \sqrt{\frac{\pi}{2x}}H_{n+1/2}^{(2)}(x) \tag{106}$$

The normalized associated Legendre function $\overline{P}_n^m(x)$ is related to the associated Legendre function $P_n^m(x)$ (solution of the associated Legendre differential equation (Balanis 1989)) by

DOI 10.1007/978-981-4560-75-7_117-1

$$\overline{P}_n^m(x) = \sqrt{\frac{2n+1}{2}\frac{(n-m)!}{(n+m)!}}P_n^m(x) \tag{107}$$

A similar procedure can be applied in the TM^r case ($\underline{A} = \hat{r}A(r,\vartheta,\varphi), \underline{F} = 0$), thus obtaining

$$\underline{H} = \frac{1}{\mu}\nabla \times \underline{A}; \quad \underline{E} = \frac{1}{\mathrm{j}\omega\varepsilon\mu}\nabla \times \nabla \times \underline{A} \tag{108}$$

and

$$\nabla \times \nabla \times \underline{A} - \beta^2 \underline{A} = -\mathrm{j}\omega\varepsilon\mu\nabla\Phi \tag{109}$$

By expanding Eq. 109 in spherical coordinates and imposing that $\Phi = (-1/\mathrm{j}\omega\varepsilon\mu)\ \partial A/\partial r$, it can be shown (Balanis 1989) that A can be determined by solving the scalar Helmholtz equation (Eq. 103), wherein now

$$\psi(r,\vartheta,\varphi) = A(r,\vartheta,\varphi)/r \tag{110}$$

The transverse electric field $\underline{E}_t$ related to an elementary spherical TE^r wave can be easily found from the former of Eq. 99, by expanding $\nabla \times \underline{F}$ in spherical coordinates and taking into account Eqs. 104 and 105, thus obtaining

$$\underline{E}_t = -\frac{1}{\varepsilon}g_{1n}(\beta r)\widetilde{\underline{F}}_{1nm}(\vartheta,\varphi) = -\frac{1}{\varepsilon}g_{1n}(\beta r)\widetilde{\underline{f}}_{1nm}(\vartheta)\mathrm{e}^{\mathrm{j}m\varphi} \tag{111}$$

where

$$g_{1n}(\beta r) = h_n^{(2)}(\beta r); \quad \widetilde{\underline{f}}_{1nm}(\vartheta) = \frac{\mathrm{j}m}{\sin\vartheta}\overline{P}_n^{|m|}(\cos\vartheta)\hat{\vartheta} - \frac{\mathrm{d}}{\mathrm{d}\vartheta}\overline{P}_n^{|m|}(\cos\vartheta)\hat{\varphi} \tag{112}$$

In a similar way, the transverse electric field related to an elementary spherical TM^r wave can be determined from the latter of Eq. 108, by expanding $\nabla \times \nabla \times \underline{A}$ in spherical coordinates and taking into account relations Eqs. 105 and 110, thus getting

$$\underline{E}_t = \frac{\beta}{\mathrm{j}\omega\varepsilon\mu}g_{2n}(\beta r)\widetilde{\underline{F}}_{2nm}(\vartheta,\varphi) = \frac{\beta}{\mathrm{j}\omega\varepsilon\mu}g_{2n}(\beta r)\widetilde{\underline{f}}_{2nm}(\vartheta)\mathrm{e}^{\mathrm{j}m\varphi} \tag{113}$$

where

$$g_{2n}(\beta r) = \frac{1}{\beta r}\frac{\mathrm{d}}{\mathrm{d}(\beta r)}\left(\beta r h_n^{(2)}(\beta r)\right); \quad \widetilde{\underline{f}}_{2nm}(\vartheta) = \frac{\mathrm{d}}{\mathrm{d}\vartheta}\overline{P}_n^{|m|}(\cos\vartheta)\hat{\vartheta} + \frac{\mathrm{j}m}{\sin\vartheta}\overline{P}_n^{|m|}(\cos\vartheta)\hat{\varphi} \tag{114}$$

By expressing the transverse electric field radiated by the AUT on a sphere of radius r containing it as a superposition of elementary TE^r and TM^r spherical waves, it results

$$\underline{E}_t = \sum_{n=1}^{N_{\max}}\sum_{m=-n}^{n}\left[\tilde{a}_{1nm}g_{1n}(\beta r)\widetilde{\underline{F}}_{1nm}(\vartheta,\varphi) + \tilde{a}_{2nm}g_{2n}(\beta r)\widetilde{\underline{F}}_{2nm}(\vartheta,\varphi)\right] \tag{115}$$

DOI 10.1007/978-981-4560-75-7_117-1

where $N_{\max}$ is the index of the highest spherical wave to be considered. It is worth noting that the summation on m extends from $-n$ to n, since $\overline{P}_n^{|m|}(\cos\vartheta)$ vanishes for $|m| > n$, whereas that on n starts from 1, since $\underline{\widetilde{F}}_{100}$ and $\underline{\widetilde{F}}_{200}$ are both null (Hald et al. 1988).

It can be shown (Hald et al. 1988) that

$$\left\langle \underline{\widetilde{F}}_{1nm}, \underline{\widetilde{F}}_{2\overline{nm}} \right\rangle = \int_0^{2\pi}\int_0^{\pi} \underline{\widetilde{F}}_{1nm}(\vartheta,\varphi)\cdot \underline{\widetilde{F}}^{*}_{2\overline{nm}}(\vartheta,\varphi)\sin\vartheta \mathrm{d}\vartheta\mathrm{d}\varphi = 0 \tag{116}$$

According to Eq. 116, the spherical wave functions $\underline{\widetilde{F}}_{1nm}$ and $\underline{\widetilde{F}}_{2\overline{nm}}$ are always orthogonal on the sphere even when $\overline{n} = n$ and $\overline{m} = m$. Moreover, it can be shown (Hald et al. 1988) that

$$\left\langle \underline{\widetilde{F}}_{1nm}, \underline{\widetilde{F}}_{1\overline{nm}} \right\rangle = \left\langle \underline{\widetilde{F}}_{2nm}, \underline{\widetilde{F}}_{2\overline{nm}} \right\rangle = 2\pi n(n+1)\delta_{m\overline{m}}\delta_{n\overline{n}} \tag{117}$$

where

$$\delta_{m\overline{m}} = \begin{cases} 1 & \text{for} \quad \overline{m} = m \\ 0 & \text{for} \quad \overline{m} \neq m \end{cases} \tag{118}$$

is the Kronecker delta.

In order to have orthonormal spherical wave functions and power-normalized spherical waves, it is convenient to introduce the new functions

$$\underline{F}_{1nm}(\vartheta,\varphi) = \left(\frac{-m}{|m|}\right)^m \frac{1}{\sqrt{2\pi n(n+1)}} \underline{\widetilde{F}}_{1nm}(\vartheta,\varphi) \tag{119}$$

$$\underline{F}_{2nm}(\vartheta,\varphi) = \left(\frac{-m}{|m|}\right)^m \frac{1}{\sqrt{2\pi n(n+1)}} \underline{\widetilde{F}}_{2nm}(\vartheta,\varphi) \tag{120}$$

The factor $(-m/|m|)^m$ ensures that the phase of the modes follows the phase of the spherical harmonics as defined by Edmonds (1974).

The transverse electric field radiated by the AUT on a sphere of radius r can be then rewritten in the form

$$\underline{E}_t = \beta \sum_{n=1}^{N_{\max}} \sum_{m=-n}^{n} \left[a_{1nm}\, g_{1n}(\beta r)\underline{F}_{1nm}(\vartheta,\varphi) + a_{2nm}\, g_{2n}(\beta r)\underline{F}_{2nm}(\vartheta,\varphi) \right] \tag{121}$$

The expression of the transverse electric field radiated by the AUT in its far-field region can be easily obtained from Eq. 121 by taking into account that

$$h_n^{(2)}(\beta r) \underset{\beta r\to\infty}{\approx} \mathrm{j}^{n+1}\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{\beta r}; \quad \frac{1}{\beta r}\frac{\mathrm{d}}{\mathrm{d}(\beta r)}\left(\beta r h_n^{(2)}(\beta r)\right) \underset{\beta r\to\infty}{\approx} \mathrm{j}^{n}\frac{\mathrm{e}^{-\mathrm{j}\beta r}}{\beta r} \tag{122}$$

thus obtaining Eq. 52.

DOI 10.1007/978-981-4560-75-7_117-1

It is worth noting that, according to the Sommerfeld radiation conditions, in the far-field region the longitudinal electric field component E_r must vanish. Indeed, this is the case. As a matter of fact, each elementary TE^r spherical wave has no longitudinal component, whereas that relevant to a TM^r one decreases asymptotically as $1/r^2$ (Hald et al. 1988).

Nonredundant NF-FF Transformation Techniques

Nonredundant Sampling Representations of EM Fields

The main theoretical results concerning the nonredundant sampling representations of EM fields (Bucci et al. 1998c; Bucci and Gennarelli 2012) are summarized in this section. To this end, the field radiated by an arbitrary finite-size source enclosed in a convex domain $\mathcal{D}$, bounded by a surface Σ with rotational symmetry and observed on a regular surface $\mathcal{M}$ external to $\mathcal{D}$ and having the same symmetry, is considered. Due to its rotational symmetry, the surface $\mathcal{M}$ can be described by meridian curves and azimuthal circumferences, so that the field representation over a regular curve $\mathcal{C}$ described by a proper analytical parameterization $\underline{r} = \underline{r}(\xi)$ is considered in the following. Moreover, according to (Bucci et al. 1998c), it is convenient to define the reduced electric field

$$\underline{F}(\xi) = \underline{E}(\xi)\ e^{j\gamma(\xi)} \tag{123}$$

where $\gamma(\xi)$ is a proper analytical phase function to be determined. As shown in (Bucci and Franceschetti 1987; Bucci et al. 1998c), the "band limitation" error, occurring when the reduced field $\underline{F}(\xi)$ is approximated by a spatially band-limited function, becomes negligible as the bandwidth exceeds the critical value

$$W_\xi = \max_\xi [w(\xi)] = \max_\xi \left[\max_{\underline{r}'} \left| \frac{d\gamma(\xi)}{d\xi} - \beta \frac{\partial R(\xi, \underline{r}')}{\partial \xi} \right| \right] \tag{124}$$

where $\underline{r}'$ denotes the source point and $R = \left| \underline{r}(\xi) - \underline{r}' \right|$. As a matter of fact, for large sources and observation domains not too near them, such an error exhibits a step-like behavior, decreasing more than exponentially as the bandwidth exceeds W_ξ (Bucci and Franceschetti 1987; Bucci et al. 1998c). As a consequence, it can be effectively controlled by choosing the bandwidth of the approximating function equal to $\chi' W_\xi$, where χ' is an enlargement bandwidth factor (slightly greater than unity for electrically large antennas).

In order to obtain a nonredundant representation, namely, a representation requiring a minimum number of samples, first of all, the "local" bandwidth $w(\xi)$ must be minimized for each ξ. This is accomplished by choosing γ such that its derivative is given by

$$\frac{d\gamma}{d\xi} = \frac{\beta}{2} \left[\max_{\underline{r}'} \frac{\partial R}{\partial s} + \min_{\underline{r}'} \frac{\partial R}{\partial s} \right] \frac{ds}{d\xi} = \frac{\beta}{2} \left[\max_{\underline{r}'} \hat{R} \cdot \hat{t} + \min_{\underline{r}'} \hat{R} \cdot \hat{t} \right] \frac{ds}{d\xi} \tag{125}$$

namely, $d\gamma/d\xi$ is the average between the maximum and minimum value of $\beta \partial R/\partial \xi$, when $\underline{r}'$ varies in the source domain $\mathcal{D}$. In Eq. 125, s is the curvilinear abscissa on $\mathcal{C}$, $\hat{t}$ is the unit vector tangent to $\mathcal{C}$ at the observation point P, and $\hat{R}$ is the unit vector pointing from the source point to P. Accordingly, the optimal phase factor to be used is given by

DOI 10.1007/978-981-4560-75-7_117-1

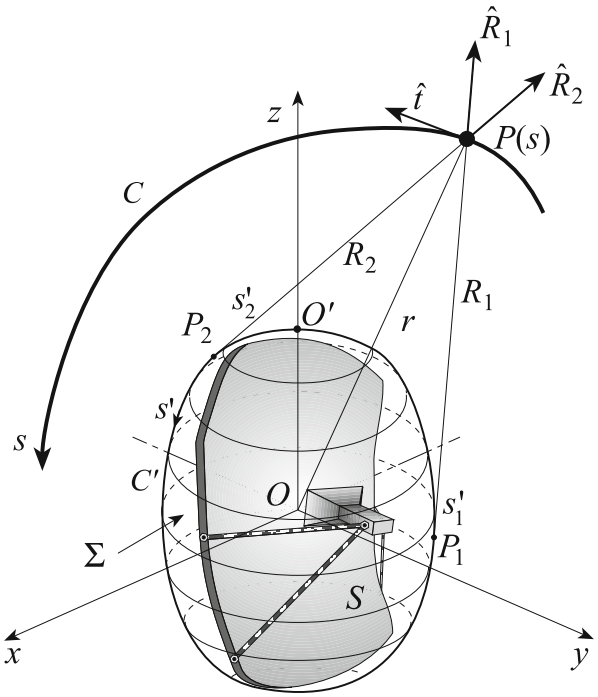

Fig. 17 Relevant to a meridian curve

$$\gamma(\xi) = \frac{\beta}{2} \int_0^{s(\xi)} \left[\max_{\underline{r}'} \frac{\partial R}{\partial s} + \min_{\underline{r}'} \frac{\partial R}{\partial s} \right] \mathrm{d}s = \frac{\beta}{2} \int_0^{s} \left[\max_{\underline{r}'} \hat{R} \cdot \hat{t} + \min_{\underline{r}'} \hat{R} \cdot \hat{t} \right] \mathrm{d}s \tag{126}$$

It can be easily verified that, by choosing $\mathrm{d}\gamma/\mathrm{d}\xi$ according to Eq. 125, it results

$$w(\xi) = \frac{\beta}{2} \left[\max_{\underline{r}'} \frac{\partial R}{\partial s} - \min_{\underline{r}'} \frac{\partial R}{\partial s} \right] \frac{\mathrm{d}s}{\mathrm{d}\xi} = \frac{\beta}{2} \left[\max_{\underline{r}'} \hat{R} \cdot \hat{t} - \min_{\underline{r}'} \hat{R} \cdot \hat{t} \right] \frac{\mathrm{d}s}{\mathrm{d}\xi} \tag{127}$$

With reference to the parameter ξ, for avoiding redundancy, it must be determined by requiring that the local bandwidth is constant. In fact, if $w(\xi)$ is variable with ξ, the sample spacing, which is dictated by the bandwidth W_ξ, becomes unnecessarily small in the zones wherein $w(\xi)$ is smaller than its maximum value, giving rise to redundancy in the sampling representation. Accordingly, by imposing that $w(\xi)$ is constant and equal to W_ξ, it results

$$\xi = \frac{\beta}{2W_\xi} \int_0^{s} \left[\max_{\underline{r}'} \frac{\partial R}{\partial s} - \min_{\underline{r}'} \frac{\partial R}{\partial s} \right] \mathrm{d}s = \frac{\beta}{2W_\xi} \int_0^{s} \left[\max_{\underline{r}'} \hat{R} \cdot \hat{t} - \min_{\underline{r}'} \hat{R} \cdot \hat{t} \right] \mathrm{d}s \tag{128}$$

When $\mathcal{C}$ is a meridian curve (Fig. 17) and $\hat{t}$ is external to the cone of vertex P, tangent to Σ, the extreme values of $\hat{R} \cdot \hat{t}$ occur at the two tangency points $P_{1,2}$ on $\mathcal{C}'$ (intersection curve between the meridian plane and Σ). By taking into account that in such a case (Bucci et al. 1998c)

DOI 10.1007/978-981-4560-75-7_117-1

$$\left.\frac{\partial R}{\partial s}\right|_{s'_{1,2}} = \frac{\mathrm{d}R_{1,2}}{\mathrm{d}s} \pm \frac{\mathrm{d}s'_{1,2}}{\mathrm{d}s} \tag{129}$$

where $s'_{1,2}$ are the arclength coordinates of $P_{1,2}$ and $R_{1,2}$ the distances from P to $P_{1,2}$ (Fig. 17) and choosing $W_\xi = \beta\ell'/2\pi$ (ℓ' being the length of C'), it results

$$\gamma = \frac{\beta}{2}\left[R_1 + R_2 + s'_1 - s'_2\right] \tag{130}$$

$$\xi = \frac{\pi}{\ell'}\left[R_1 - R_2 + s'_1 + s'_2\right] \tag{131}$$

Note that the angular-like parameter ξ covers a 2π range when P encircles the source once and the number of samples at Nyquist spacing ($\Delta\xi = \pi/W_\xi$) on a closed meridian curve $\mathcal{C}$ (also unbounded) is always finite and equal to $N_\xi = 2\pi/\Delta\xi = 2\ell'/\lambda$.

It can be shown (Bucci et al. 1998c) that in any meridian plane the curves $\gamma = \text{const}$ and $\xi = \text{const}$ are orthogonal.

When $\mathcal{C}$ is an azimuthal circumference of radius ρ, the extreme values of $\hat{R}\cdot\hat{t}$ are opposite and constant along it. It follows from Eqs. 126 and 128 that γ is constant and any parameter proportional to the arclength is optimal. As a consequence, it is convenient to use the azimuthal angle φ as parameter and to choose for γ the value relevant to any meridian curve passing through the observation point on $\mathcal{C}$. The corresponding bandwidth is (Bucci et al. 1998c)

$$W_\varphi = \frac{\beta}{2}\max_{z'}\left(R^+ - R^-\right) = \frac{\beta}{2}\max_{z'}\left(\sqrt{(z-z')^2 + (\rho+\rho'(z'))^2} - \sqrt{(z-z')^2 + (\rho-\rho'(z'))^2}\right) \tag{132}$$

where R^+ and R^- are the maximum and minimum distance, respectively, from each circumference describing the surface Σ to the observation point P and $\rho'(z')$ is the equation of Σ in cylindrical coordinates. As shown in (Bucci et al. 1998c), the maximum is attained on that zone of the surface Σ lying on the same side of the observation circumference with respect to the maximum transverse circle of Σ. When the radius of the observation circle goes to infinity, it results $R^+ = R^- + 2\rho'\sin\vartheta$ and, accordingly,

$$W_\varphi = \beta\rho'_{\max}\sin\vartheta \tag{133}$$

ϑ being the polar angle of the circle points and $\rho'_{\max}$ the maximum transverse radius of Σ.

It can be shown (Bucci et al. 1998c) that the number of samples N_s at Nyquist spacing on any closed observation surface (also unbounded) surrounding the source is

$$N_s \cong (\text{area of } \Sigma)/(\lambda/2)^2 \tag{134}$$

Any finite-size source can be always considered as enclosed in a spherical surface. Accordingly, by choosing Σ coincident with a sphere of radius a, for any meridian curve, it results

$$R_1 = R_2 = \sqrt{r^2 - a^2} \tag{135}$$

$$s'_1 = (\vartheta - \alpha)a; \quad s'_2 = (\vartheta + \alpha)a; \quad \alpha = \cos^{-1}(a/r) \tag{136}$$

DOI 10.1007/978-981-4560-75-7_117-1

Accordingly, since $\ell' = 2\pi a$, it results $W_\xi = \beta a$ and

$$\gamma = \beta\sqrt{r^2 - a^2} - \beta a \cos^{-1}(a/r); \quad \xi = \vartheta \tag{137}$$

When considering an azimuthal circumference, by putting $z' = a \cos \vartheta'$ and $\rho' = a \sin \vartheta'$, it can be shown (Bucci et al. 1998c) that the maximum in Eq. 132 is attained at $\vartheta' = \cos^{-1}(a \cos \vartheta/r)$ and, accordingly,

$$W_\varphi = \beta a \sin \vartheta \tag{138}$$

Eq. 134 highlights the role that the source modeling plays in minimizing the overall number of samples: the surface Σ must fit very well the antenna geometry, moreover it must be analytically regular and such that the corresponding phase factor and parameterization are simple to be determined. To this end, ellipsoidal geometries (oblate and prolate) are considered in the following.

An effective modeling for elongated antennas is obtained by choosing the surface Σ coincident with a rotational prolate ellipsoid, having major and minor semiaxes equal to a and b (Fig. 18), whereas a rotational oblate ellipsoid is an appropriate modeling for quasiplanar sources. In both the cases, it can be shown (Bucci et al. 1998c) that in any meridian plane the curves $\gamma = \text{const}$ and $\xi = \text{const}$ are respectively ellipses and hyperbolas confocal to $\mathcal{C}'$. This implies that ξ and γ are functions of the elliptic coordinates $u = (r_1 - r_2)/2f$ and $v = (r_1 + r_2)/2a$, respectively, where $r_{1,2}$ are the distances from the observation point P on the meridian plane to the foci of $\mathcal{C}'$ and $2f$ is the focal distance. By taking into account that the length of the ellipse $\mathcal{C}'$ is $\ell' = 4aE(\pi/2|\varepsilon^2)$, the bandwidth W_ξ becomes

$$W_\xi = (4a/\lambda)E\left(\pi/2|\varepsilon^2\right) \tag{139}$$

where $E(\cdot|\cdot)$ denotes the elliptic integral of second kind and $\varepsilon = f/a$ is the eccentricity of $\mathcal{C}'$.

The evaluation of γ at P can be simplified by considering the intersection point between the confocal ellipse through P and the symmetry axis, instead of P itself, since the same value of γ corresponds to all points lying on a confocal ellipse. By straightforward but lengthy computations, from Eq. 130, it results (Bucci et al. 1998c)

$$\gamma = \beta a \left[v\sqrt{\frac{v^2 - 1}{v^2 - \varepsilon^2}} - E\left(\cos^{-1}\sqrt{\frac{1 - \varepsilon^2}{v^2 - \varepsilon^2}}|\varepsilon^2 \right) \right] \tag{140}$$

With reference to ξ, since the same value corresponds to all points on the confocal hyperbola branch passing through P, it can be convenient to consider, instead of P itself, the intersection point P_0 between the considered hyperbola branch and $\mathcal{C}'$. Accordingly from Eq. 131, it results $\xi = 2\pi s_0'/\ell'$, s_0' being the curvilinear abscissa of P_0. By straightforward computations, the following expression is finally obtained (Bucci et al. 1998c):

$$\xi = \frac{\pi}{2} \begin{cases} E(\sin^{-1}u|\varepsilon^2)/E(\pi/2|\varepsilon^2) + 1 & \text{prolate ellipsoid} \\ E(\sin^{-1}u|\varepsilon^2)/E(\pi/2|\varepsilon^2) & \text{oblate ellipsoid} \end{cases} \tag{141}$$

Such a relation is valid when the angle ϑ corresponding to P belongs to the range $[0, \pi/2]$. The case in which ϑ belongs to $[\pi/2, \pi]$ can be easily handled by determining the value ξ' corresponding to the point specified by the angle $\pi - \vartheta$ and then putting $\xi = \pi - \xi'$.

DOI 10.1007/978-981-4560-75-7_117-1

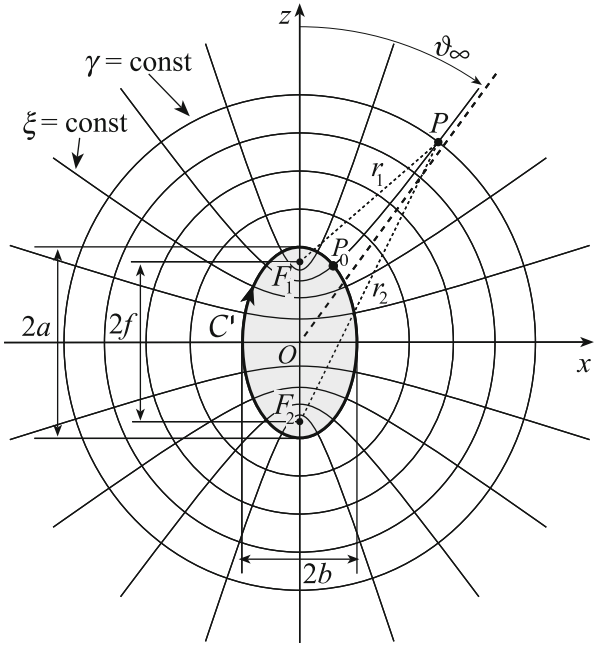

Fig. 18 Ellipsoidal source modeling: prolate case

Since all transverse circles belonging to the hyperboloid of rotation fixed by a value of ξ are characterized by the same value of W_φ (Bucci et al. 1998c), the bandwidth value corresponding to an azimuthal circumference can be evaluated by moving such a circle to infinity along the hyperbola $\xi = \text{const}$. Accordingly, by taking Eq. 133 into account, it results

$$W_\varphi(\xi) = \begin{cases} \beta b \sin \vartheta_\infty(\xi) & \text{prolate ellipsoid} \\ \beta a \sin \vartheta_\infty(\xi) & \text{oblate ellipsoid} \end{cases} \tag{142}$$

where

$$\vartheta_\infty = \begin{cases} \sin^{-1} u + \pi/2 & \text{prolate ellipsoid} \\ \sin^{-1} u & \text{oblate ellipsoid} \end{cases} \tag{143}$$

is the polar angle of the asymptote to the hyperbola through P (see Fig. 18).

It can be easily shown (Bucci et al. 1998c) that the spherical modeling can be obtained from the prolate or oblate ellipsoidal one by considering an ellipsoid with eccentricity $\varepsilon = 0$.

Another effective source modeling for long antennas is obtained by choosing the surface Σ coincident with a rounded cylinder (Fig. 19), namely, a cylinder of height h' ended in two half-spheres of radius a' (Bucci et al. 1998b; D'Agostino et al. 2011). Such a modeling is quite general and contains the spherical one as particular case. When considering quasiplanar antennas, a convenient alternative to the oblate ellipsoidal modeling is the two-bowls one (Fig. 20), wherein Σ is a surface formed by two circular bowls with the same aperture diameter, but with bending radii c and c' of the upper and lower arcs eventually different to fit better the actual AUT geometry (Bucci et al. 1998a; D'Agostino et al. 2011). It can be easily recognized that the surface Σ coincides with a sphere if $c = c' = a$, it becomes a half-sphere if $c = 0$ and $c' = a$, and it reduces to a circular dish for $c = c' = 0$.

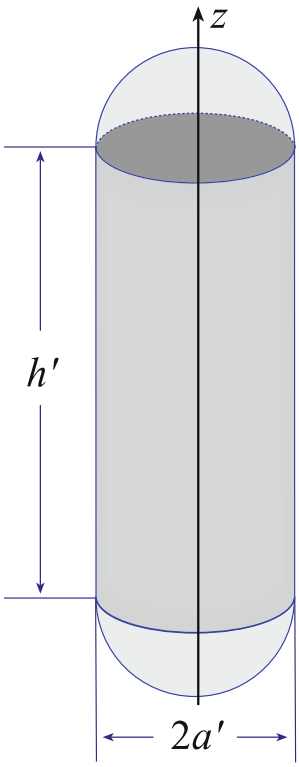

Fig. 19 Rounded cylinder modeling

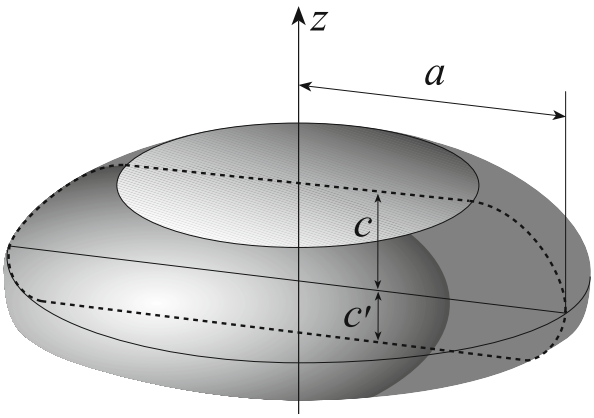

Fig. 20 Two-bowls modeling

The real part of the electric field and reduced electric field y-component radiated by an antenna along a line is reported in Fig. 21 to show the effect of multiplying the field by the factor $e^{j\gamma(\xi)}$. The considered antenna is a uniform planar circular array with radius equal to 20λ, lying in the plane $z = 0$, and has been modeled by an oblate ellipsoid with $2a = 40\lambda$ and $2b = 5\lambda$. The array elements, radially and azimuthally spaced of 0.8λ, are elementary Huygens sources linearly polarized along the y axis. The considered straight line is the x-directed line at $y = 0$, lying in a plane at distance $d = 12\lambda$ from the AUT center. As can be seen, the spatial variations of the reduced field component are slower than the electric field ones, since the local bandwidth has been minimized. Quite analogous results are obtained for the imaginary part.

DOI 10.1007/978-981-4560-75-7_117-1

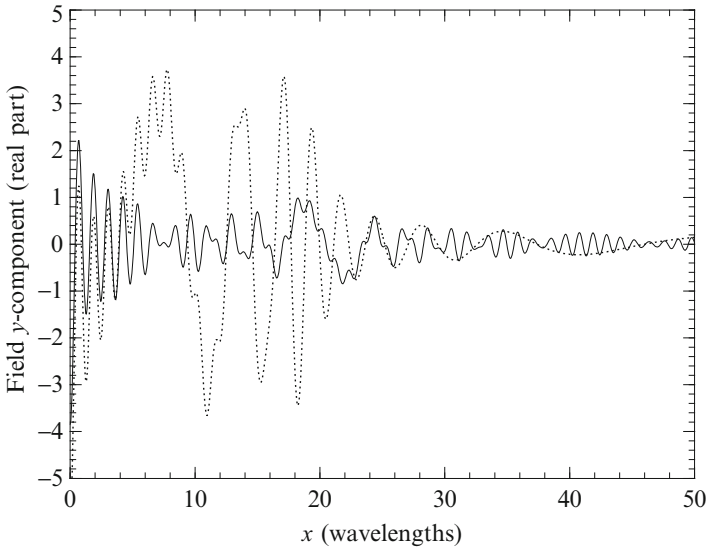

Fig. 21 Real part of the NF *y*-component on the given line. *Solid line*: electric field. *Dashed line*: reduced field

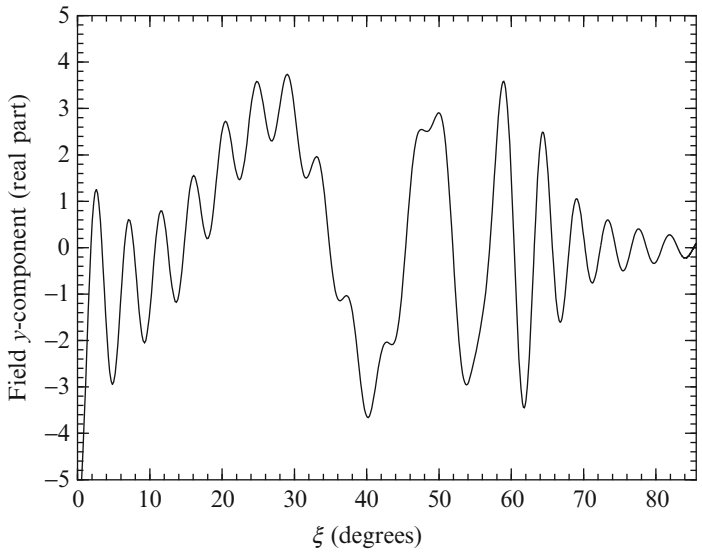

Fig. 22 Real part of the reduced electric field *y*-component on the given line as function of the optimal parameter ξ

In order to highlight the role of the optimal parameter for a convenient representation of the reduced field on the observation curve, the real part of the reduced electric field *y*-component along the same straight line is plotted as function of ξ in Fig. 22.

As can be seen, when using the optimal parameter, the regions wherein the reduced field exhibits fast changes are represented in an enlarged scale, whereas those characterized by slow variations are shown in a reduced scale. As a consequence, a uniform sampling in ξ gives rise to a denser sample distribution where the local bandwidth w is greater and to a sparser one in the zones characterized by smaller values of w (see Fig. 23).

Application of the Nonredundant Sampling Representations to the NF-FF Transformations

Let an antenna be considered as enclosed in a convex domain bounded by a rotational surface Σ, and the surface scanned by a nondirective probe be obtained by rotating a meridian curve always external to the cone of vertex at the observation point P and tangent to Σ. Since the voltage V measured by such a kind of probe has practically the same effective spatial bandwidth of the AUT field (Bucci et al. 1998d), the above described nonredundant sampling representations of EM fields can be applied to it and, accordingly, it is convenient to introduce the reduced voltage $\tilde{V}(\xi) = V(\xi)e^{j\gamma(\xi)}$.

Therefore, the use of cardinal series (CS) expansions (Whittaker 1915) springs out naturally as an appropriate tool to conveniently represent it. However, the use of the CS representation, while completely satisfactory from the accuracy point of view, has the drawback that all samples (or, at least, all the relevant ones) must be considered in evaluating the voltage at each output point, otherwise a relatively large truncation error is introduced, due to the slow decay of the sampling functions. As a consequence, its use would lead to unacceptably large computational times. Such a slow decay leads to a further, subtler difficulty, if it is taken into account that, in any practical instance, the measured data are inaccurate. Provided that their values are well above the noise level, the measured results are usually affected by an (approximately) constant relative, not absolute, error, so that the absolute error corresponding to the highest voltage values can be relatively large. This error is spread out by the sampling functions without a severe attenuation, and this gives rise to a remarkable relative error in the zones where the voltage level is low (Bucci et al. 1991b). These difficulties have been overcome by resorting to an OSI expansion (Bucci et al. 1991a, b), in which only relatively few samples in the neighborhood of the output point are used in the reconstruction. These algorithms minimize the truncation error for a given number of retained samples and are more stable than the CS expansions with respect to random errors affecting the data.

In the light of the above discussion, the voltage at P $(\xi(\vartheta), \varphi)$ on the meridian curve fixed by φ can be efficiently evaluated via the OSI expansion (Bucci et al. 1998c; Bucci and Gennarelli 2012):

DOI 10.1007/978-981-4560-75-7_117-1

$$V(\xi(\vartheta),\varphi)=\mathrm{e}^{-\mathrm{j}\gamma(\xi)}\tilde{V}(\xi,\varphi)=\mathrm{e}^{-\mathrm{j}\gamma(\xi)}\sum_{m=m_0-q+1}^{m_0+q}\tilde{V}(\xi_m,\varphi)\Omega_M\left(\xi-\xi_m,\overline{\xi}\right)D_{M''}(\xi-\xi_m) \tag{144}$$

where $m_0=\mathrm{Int}(\xi/\Delta\xi)$ is the index of sample nearest (on the left) to P, $2q$ is the number of the retained intermediate samples $\tilde{V}(\xi_m,\varphi)$, namely, the reduced voltages at the intersection points between the sampling azimuthal circumferences and the meridian curve, $\overline{\xi}=q\Delta\xi$, $M=M''-M'$, and

$$\xi_m=m\Delta\xi=2\pi m/(2M''+1);\quad M''=\mathrm{Int}(\chi M')+1;\quad M'=\mathrm{Int}(\chi' W_\xi)+1 \tag{145}$$

χ being an oversampling factor required to control the truncation error (Bucci et al. 1991a, 1998c), and $\mathrm{Int}(x)$ denoting the integer part of x. Moreover,

$$D_{M''}(\xi)=\frac{\sin\left[(2M''+1)\xi/2\right]}{(2M''+1)\sin(\xi/2)};\quad \Omega_M\left(\xi,\overline{\xi}\right)=\frac{T_M\left[2\cos^2(\xi/2)/\cos^2\left(\overline{\xi}/2\right)-1\right]}{T_M\left[2/\cos^2\left(\overline{\xi}/2\right)-1\right]} \tag{146}$$

are the Dirichlet and Tschebyscheff sampling functions, respectively, $T_M(\cdot)$ being the Tschebyscheff polynomial of degree M.

It is worth noting that the weight function $\Omega_M(\cdot,\cdot)$ has been obtained in (Bucci et al. 1991a, b) by paralleling the properties of the so-called sampling window function introduced by Knab (1983), which (in the square norm) represents the practically optimal weight function for the case of an indefinite observation domain, where the kernel of the CS expansion is the $\sin(x)/x$ function instead of the Dirichlet one.

The intermediate samples $\tilde{V}(\xi_m,\varphi)$ can be determined by means of the OSI formula:

$$\tilde{V}(\xi_m,\varphi)=\sum_{n=n_0-p+1}^{n_0+p}\tilde{V}\left(\xi_m,\varphi_{n,m}\right)\Omega_{N_m}\left(\varphi-\varphi_{n,m},\overline{\varphi}\right)D_{N''_m}\left(\varphi-\varphi_{n,m}\right) \tag{147}$$

where $n_0=\mathrm{Int}(\varphi/\Delta\varphi_m)$, $\tilde{V}(\xi_m,\varphi_{n,m})$ are the reduced samples on the azimuthal circumference fixed by ξ_m, $2p$ is the retained samples number, and

$$\varphi_{n,m}=n\Delta\varphi_m=2\pi n/\left(2N''_m+1\right);\quad N''_m=\mathrm{Int}\left(\chi N'_m\right)+1;\quad N'_m=\mathrm{Int}\left[\chi^* W_\varphi(\xi_m)\right]+1 \tag{148}$$

$$\overline{\varphi}=p\Delta\varphi_m;\quad N_m=N''_m-N'_m;\quad \chi^*=1+(\chi'-1)\left[\sin\vartheta(\xi_m)\right]^{-2/3} \tag{149}$$

The variation of the azimuthal enlargement bandwidth factor χ^* with ξ is required to ensure a band limitation error constant with respect to ξ (Bucci and Franceschetti 1987).

By properly matching Eqs. 144 and 147, the two-dimensional OSI expansion is obtained:

$$\begin{aligned}V(\xi(\vartheta),\varphi)=\mathrm{e}^{-\mathrm{j}\gamma(\xi)}\sum_{m=m_0-q+1}^{m_0+q}&\left\{\Omega_M\left(\xi-\xi_m,\overline{\xi}\right)D_{M''}(\xi-\xi_m)\right.\\&\left.\cdot\sum_{n=n_0-p+1}^{n_0+p}\tilde{V}\left(\xi_m,\varphi_{n,m}\right)\Omega_{N_m}\left(\varphi-\varphi_{n,m},\overline{\varphi}\right)D_{N''_m}\left(\varphi-\varphi_{n,m}\right)\right\}\end{aligned} \tag{150}$$

DOI 10.1007/978-981-4560-75-7_117-1

which makes possible to reconstruct efficiently and accurately the NF data needed to carry out the traditional NF-FF transformation corresponding to the considered scanning geometry from a nonredundant, i.e., minimum, number of NF measurements.

Efficient and accurate NF-FF transformation techniques with plane-polar (Bucci et al. 1998a, 2000), bipolar (D'Agostino et al. 2003), cylindrical (Bucci et al. 1998b; D'Agostino et al. 2002), and spherical (Bucci et al. 2001a; D'Agostino et al. 2011, 2013a) scannings have been so developed. In all the cases, a remarkable reduction of the number of the required NF data and of the related measurement time has been achieved.

The effectiveness of the OSI algorithms depends on the choice of the following parameters: the enlargement bandwidth factor, the oversampling factor, and the retained samples number. The enlargement bandwidth factor χ' allows to control the aliasing error and values slightly greater than unity are enough to ensure small errors in the case of electrically large antennas (Bucci and Franceschetti 1987, 1989). A numerical procedure to properly select the χ' value is described in (Gennarelli et al. 1994). As regards the choice of the parameters controlling the truncation error, namely, the oversampling factor χ, and the numbers p, q of the retained nearest samples, it can be numerically made as in (Bucci et al. 1998c). Note that such an error can be decreased on increasing p, q, and/or χ. An increase of p, q implies a growth of the interpolation time, whereas an increase of χ reflects in a growth of the required NF data and, as a consequence, of the measurement time. In practice, the choice of the above parameters is done in such a way that the error related to the interpolation (aliasing plus truncation) must be smaller than the measurement one (background noise plus measurement uncertainties). It must stressed that, due to the filtering properties of the interpolation functions, it is possible also to cut away the spatial harmonics relevant to the noise sources outside the AUT spatial bandwidth.

NF-FF Transformation Techniques with Spiral Scannings

The scanning of a nondirective probe along a proper spiral wrapping an arbitrary rotational surface $\mathcal{M}$, obtained by rotating a meridian curve always external to the cone having the vertex at P and tangent to the rotational surface Σ enclosing the AUT, is considered in the following. The Cartesian coordinates of a generic point on such a spiral are

$$\begin{cases} x = r(\theta)\sin\theta\cos\phi \\ y = r(\theta)\sin\theta\sin\phi \\ z = r(\theta)\cos\theta \end{cases} \tag{151}$$

where $r(\theta)$ is specified by the meridian curve generating the surface $\mathcal{M}$, ϕ is the angular parameter describing the spiral, and the angle θ is a monotonic increasing function of ϕ. It can be easily verified that $r(\theta) = d/\cos\theta$ in the case of a planar spiral lying on a plane at distance d, $r(\theta) = d/\sin\theta$ for a helix wrapping a cylinder of radius d, whereas $r(\theta) = d$ when a spherical spiral is considered. It is worth noting that the angle θ, unlike the zenithal angle ϑ, can assume negative values. As a matter of fact, when the spiral describes a complete round on the surface $\mathcal{M}$, moving from the south pole to the north pole and then returning to the south one, θ varies in the range $[-\pi, \pi]$. Moreover, ϕ is always continuous, whereas, according to Eq. 151, the azimuthal angle φ displays a discontinuity jump of π when the spiral crosses the poles.

In order to obtain a nonredundant sampling representation of the probe voltage on the surface $\mathcal{M}$ from its samples collected along the spiral, it is necessary (D'Agostino et al. 2009e; Cicchetti et al. 2014):

DOI 10.1007/978-981-4560-75-7_117-1

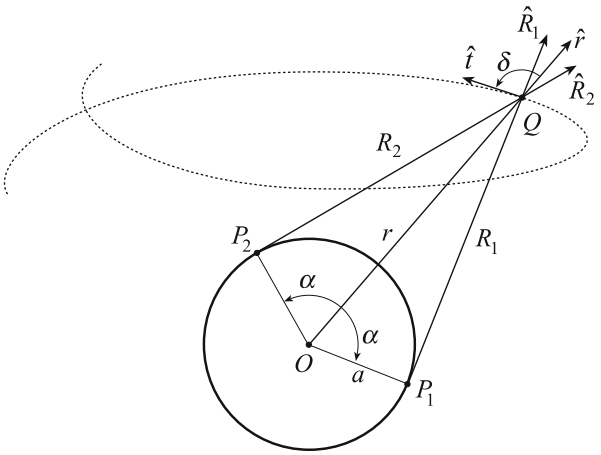

Fig. 24 Geometry of the problem in the plane $\hat{t}$, $\hat{r}$

(a) to choose the spiral in such a way that its pitch, specified by two consecutive intersections (at ϕ and $\phi + 2\pi$) with a meridian curve, be equal to the sample spacing needed for the interpolation along this curve;
(b) to develop a nonredundant sampling representation along the spiral.

According to condition (a), the optimal parameter ξ relevant to the meridian curve and the angular one ϕ describing the spiral are related by

$$\xi = k\phi \tag{152}$$

where k must be such that the interval $\Delta\xi = 2\pi k$, corresponding to the spiral pitch, is equal to the required sample spacing $\Delta\xi = 2\pi/(2\,M'' + 1)$ (see Eq. 145). Accordingly, $k = 1/(2\,M'' + 1)$. The scanning spiral can be so viewed as the projection on the surface $\mathcal{M}$, via the curves at $\xi = \text{const}$, of the corresponding spiral wrapping with the same pitch the modeling surface Σ.

The development of a nonredundant sampling representation of the voltage along the spiral is a more complex task, which has been heuristically solved in (D'Agostino et al. 2009e) by paralleling the rigorous procedure (D'Agostino et al. 2006) valid when the antenna is modeled by a spherical surface. Therefore, the main results of the unified theory of spiral scannings for antennas enclosed in a spherical surface (D'Agostino et al. 2006) are reviewed in the following.

In such a case, the optimal parameter to describe a meridian curve is the angle θ (which coincides in the range $[0, \pi]$ with the zenithal one ϑ) and the related bandwidth is βa. Moreover, the optimal phase factor ψ and parameter η to obtain a nonredundant representation along the spiral can be obtained from Eqs. 126 and 128 by observing that the extreme values of $\hat{R} \cdot \hat{t}$ occur (D'Agostino et al. 2006) at the two tangency points $P_{1,2}$ (Fig. 24) between the sphere modeling the AUT and the straight lines passing through the point Q on the spiral and belonging to the plane specified by the unit vectors $\hat{t}$ (tangent to the spiral at Q) and $\hat{r}$ (pointing from the origin to Q). Denoting by $\hat{R}_{1,2}$ the related unit vectors and by δ the angle between $\hat{r}$ and $\hat{t}$ (see Fig. 24), it results (D'Agostino et al. 2006)

$$\left(\hat{R}_1 + \hat{R}_2\right)/2 = \hat{r}\sin\alpha = \hat{r}\sqrt{1 - a^2/r^2} \tag{153}$$

$$\left(\hat{R}_1 - \hat{R}_2\right)/2 = \hat{n}\cos\alpha \tag{154}$$

where $\hat{n}$ is the unit vector parallel to the plane $\hat{r}$, $\hat{t}$ and orthogonal to $\hat{r}$. Accordingly

$$\left(\hat{R}_1 - \hat{R}_2\right) \cdot \hat{t}/2 = (\hat{n} \cdot \hat{t})\,(a/r) = (a/r)\sin\delta \tag{155}$$

By substituting Eq. 153 in Eq. 126 and taking into account that $\mathrm{d}r = \hat{r} \cdot \hat{t}\,\mathrm{d}s$, it results

$$\psi = \beta \int_0^r \sqrt{1 - a^2/r^2}\,\mathrm{d}r = \beta\sqrt{r^2 - a^2} - \beta a \cos^{-1}(a/r) \tag{156}$$

Namely, the phase function ψ relevant to the sampling representation along the spiral coincides with that γ related to the representation on a meridian curve.

By differentiating Eq. 151, it can be easily verified that

$$\mathrm{d}s = \sqrt{r^2 \sin^2\theta + k^2 r^2 + k^2 \dot{r}^2}\,\mathrm{d}\phi \tag{157}$$

where $\dot{r} = \mathrm{d}r/\mathrm{d}\theta$. Moreover,

$$\hat{r} \cdot \hat{t} = \frac{\mathrm{d}r}{\mathrm{d}s} = \frac{\mathrm{d}r}{\mathrm{d}\phi}\frac{\mathrm{d}\phi}{\mathrm{d}s} = \left[\frac{\mathrm{d}r}{\mathrm{d}\theta}\frac{\mathrm{d}\theta}{\mathrm{d}\phi}\right]\frac{\mathrm{d}\phi}{\mathrm{d}s} = k\dot{r}\frac{\mathrm{d}\phi}{\mathrm{d}s} = \frac{k\dot{r}}{\sqrt{r^2 \sin^2\theta + k^2 r^2 + k^2 \dot{r}^2}} \tag{158}$$

and, accordingly,

$$\sin\delta = \sqrt{1 - (\hat{r} \cdot \hat{t})^2} = \sqrt{\frac{r^2 \sin^2\theta + k^2 r^2}{r^2 \sin^2\theta + k^2 r^2 + k^2 \dot{r}^2}} \tag{159}$$

By substituting Eqs. 155 and 157 in Eq. 128 and taking into account Eq. 159, it results

$$\eta = \frac{\beta a}{W_\eta} \int_0^\phi \sqrt{k^2 + \sin^2 k\phi}\;\mathrm{d}\phi \tag{160}$$

that is, the optimal parameter η for describing the spiral is β/W_η times the arclength of the projecting point that lies on the spiral wrapping the sphere Σ. Since such a spiral is a closed curve, it is convenient to choose the bandwidth W_η in such a way that the angular-like parameter η covers a 2π range when the entire projecting spiral is described. Therefore,

$$W_\eta = \frac{\beta a}{\pi} \int_0^{(2M''+1)\pi} \sqrt{k^2 + \sin^2 k\phi}\;\mathrm{d}\phi \tag{161}$$

namely, the bandwidth W_η is β/π times the length of the spiral which wraps from pole to pole the sphere Σ.

The more general case wherein the AUT is no longer modeled as enclosed in a sphere is now considered. The parameterization η for describing the scanning spiral, the related phase factor ψ, and bandwidth W_η can be heuristically obtained (D'Agostino et al. 2009e) by generalizing the corresponding ones for the spherical modeling case (see Eqs. 160, 156, and 161). In particular, η is β/W_η times the

DOI 10.1007/978-981-4560-75-7_117-1

arclength of the projecting point that lies on the spiral wrapping the surface Σ (the projection is obtained by the curves at $\xi = \text{const}$ that, in such a case, take the role of the radial lines of the spherical modeling), ψ coincides with the phase function γ for a meridian curve, and the bandwidth W_η is β/π times the length of the spiral wrapping Σ from pole to pole. In other words, the spiral, ψ, and η coincide with those relevant to the spherical modeling when the surface Σ approaches a sphere.

In the light of the above results, the reduced voltage at any point Q of the spiral can be reconstructed by the following OSI expansion (D'Agostino et al. 2006, 2009e; Cicchetti et al. 2014):

$$\tilde{V}(\eta) = \sum_{n=n_0-p+1}^{n_0+p} \tilde{V}(\eta_n)\Omega_N(\eta - \eta_n, \overline{\eta})D_{N''}(\eta - \eta_n) \tag{162}$$

where $2p$ is the number of retained samples $\tilde{V}(\eta_n)$, $n_0 = \text{Int}(\eta/\Delta\eta)$ is the index of the sample nearest (on the left) to the point Q, $\overline{\eta} = p\Delta\eta$, $N = N'' - N'$, and

$$\eta_n = n\Delta\eta = 2\pi n/(2N'' + 1); \quad N'' = \text{Int}(\chi N') + 1; \quad N' = \text{Int}\left(\chi' W_\eta\right) + 1 \tag{163}$$

It must be stressed that small variations of η correspond to very large changes of ϕ in the neighborhood of the poles ($\vartheta = 0$ and $\vartheta = \pi$), so that, when interpolating the voltage in these zones, the enlargement bandwidth factor χ' must be properly increased to avoid a significant growth of the band limitation error.

The expansion (Eq. 162) can be used to determine the "intermediate samples," namely, the reduced voltage values at the intersection points between the meridian curve passing through the observation point P and the spiral. Once they have been determined, the voltage at the point P can be recovered by means of the following OSI expansion:

$$V(\xi(\vartheta), \varphi) = \mathrm{e}^{-\mathrm{j}\gamma(\xi)} \sum_{m=m_0-q+1}^{m_0+q} \tilde{V}(\xi_m)\Omega_M\left(\xi - \xi_m, \overline{\xi}\right)D_{M''}(\xi - \xi_m) \tag{164}$$

where $2q$ is the number of retained intermediate samples $\tilde{V}(\xi_m)$, $m_0 = \text{Int}\,[(\xi - \xi_0)/\Delta\xi]$ is the index of the sample nearest (on the left) to the point P, $M = M'' - M'$, $\overline{\xi} = q\Delta\xi$, and

$$\xi_m = \xi_m(\varphi) = k\varphi + m\Delta\xi = \xi_0 + m\Delta\xi \tag{165}$$

Summary

The aim of this chapter is to provide a complete description of the NF antenna measurement techniques to students, junior engineers, researchers, and physicists that wish to tackle such a topic. To this end, a wide introduction resumes the state of the art by supplying also a rich and updated bibliography. Then, the classical NF-FF transformations with plane-rectangular, cylindrical, and spherical scannings, in their probe-uncompensated and probe-compensated versions, are summarized by pointing out their advantages and drawbacks. Moreover, some analytical details on the wave expansions commonly employed to represent the antenna field in the region external to it are reported in order to enable the interested reader to achieve a more in-depth knowledge of the topic. The nonredundant sampling representations of the electromagnetic fields are then introduced, highlighting how their application to the NF-FF transformations with conventional scannings allows a drastic measurement time reduction with respect to the classical ones, without any loss in accuracy of the FF reconstruction. At last, the NF-FF transformations

DOI 10.1007/978-981-4560-75-7_117-1

using innovative spiral scannings, which allow a further measurement time saving by exploiting continuous and synchronized movements of the positioning systems, are described. They employ efficient sampling representations to accurately reconstruct the probe voltage on a quite arbitrary rotational surface from a nonredundant number of its samples collected on a proper spiral wrapping it.

Reconfigurable Antennas for Wireless Communications

Y. Jay Guo* and Pei-Yuan Qin
University of Technology, Sydney, Australia

Abstract

With the capability to dynamically change their radiation characteristics, reconfigurable antennas will become indispensable parts for the next-generation wireless communications and sensing systems where the RF front-ends are required to be cognitive in nature. Compared to traditional antennas whose characteristics are fixed, reconfigurable antennas pose new challenges to antenna researchers and designers, such as tuning the operating frequency of an antenna whilst maintaining its radiation pattern. In the last two decades, substantial progress has been made in the development of reconfigurable antennas from both academia and industry. This chapter provides an overview of the state-of-the-art of reconfigurable antennas by elaborating the basic concepts of different reconfigurable antennas and practical techniques to realize them. It is focused on both reconfigurable antenna elements and arrays, and outlines some directions for future research.

Keywords

Reconfigurable antennas; Frequency reconfigurable antennas; Polarisation reconfigurable antennas; Pattern reconfigurable antennas; Leaky wave antennas; Phase shifters; Arrays

Introduction

Owing to the rapid proliferation of wireless communications systems, the limited electromagnetic spectrum has become more and more congested. To address this challenge, future wireless communications systems need to be cognitive and reconfigurable. They will have the intelligence and capacity to adopt the most appropriate communications strategy based on the feedback from channel sensing activities and signal quality assessment, including the operating frequency, the main beam direction and modulation schemes. In order to achieve these flexibilities, reconfigurable antennas (RAs) with adaptive radiation characteristics are required instead of traditional antennas whose structures are tailored to fit particular applications. RAs can also be used to avoid interference, save energy, enhance security, and mitigate signal quality deterioration caused by multipath fading.

Typical parameters of an antenna that can be reconfigured include frequency, polarization, radiation pattern, or a combination of the above. Depending on the reconfiguration mechanisms, RAs can also be classified into three main groups, namely, those using electrical devices, such as PIN diodes, varactor diodes and radio frequency micro electromechanical system (RF-MEMS), and those using mechanical changes and using material changes. Although this topic is a relatively new one, there are several books (Bernhard 2005; Bernhard and Volakis 2007) dedicated to it and a large number of papers reported

*Email: jay.guo@uts.edu.au

DOI 10.1007/978-981-4560-75-7_119-1

(Christodoulou et al. 2012). This chapter presents recent progress of RAs using electrical methods to achieve reconfiguration. Regarding those RAs using mechanical changes, readers can refer to (Tawk et al. 2011; Bernhard et al. 2001) for frequency RAs, (Barrera and Huff 2014) for polarization RAs and (Rodrigo et al. 2012; Sievenpiper et al. 2002) for pattern RAs.

The remainder of the chapter is organised as follows. Sections "Frequency Reconfigurable Antennas (RAs)," "Polarization Reconfigurable Antenna (RA)," "Pattern Reconfigurable Antenna (RA)," and "Compound Reconfigurable Antennas (RAs)" review the designs of frequency RAs, polarization RAs, pattern RAs and combined frequency and polarization RAs, respectively. Section "Reconfigurable Phase Shifter and Its Application in Beamforming Antennas" describes a novel phase shifter based on reconfigurable defected microstrip structure and its application in a beam-scanning antenna arrays. Section "Reconfigurable Leaky Wave Antennas" presents some designs of reconfigurable leaky wave antennas. Section "Summary" summarizes this chapter and gives some directions for future research.

Frequency Reconfigurable Antennas (RAs)

Frequency RAs can change the antenna operating frequency while keeping the polarization and radiation pattern stable across the entire frequency tuning range. Currently, it is a common practice for a single radio device to handle several services over a wide range of frequencies. For example, smart mobile phones or laptops may be required to support different standards, such as wireless local area network (WLAN), Worldwide Interoperability for Microwave Access (WiMAX), Bluetooth, Global Positioning System (GPS), 3G and 4G. To this end, the antennas need to cover multiple frequency bands. From the antenna perspective, multiband, wideband and frequency RAs are three potential candidates to be employed in systems requiring multiple operating bands. However, if only a portion of these operating bands is required at any given time, then frequency RAs would be the most appropriate choice. Compared to multiband and wideband antennas, one of the merits of frequency RAs is that the antenna can provide noise rejection in the bands that are not in use, so that the filter requirements of the front-end circuits can be greatly reduced. Furthermore, compared to multiband or wideband antennas, frequency RAs can be made much more compact.

Frequency RAs can be classified according to the basic antenna elements employed including microstrip antennas, dipole antennas, planar inverted F antennas (PIFA) and slot antennas. Alternatively, frequency RAs can also be classified into two types, namely, frequency continuous tuning and discrete tuning. The following introduction will be presented based on this classification.

Continuous Tuning

Varactor diodes are usually employed to achieve continuous frequency tuning. Initial work in this regard employed a method to load the radiating edges of patch antennas with varactor diodes to realize frequency agility (Bhartia and Bahl 1982; Waterhouse and Shuley 1994). By changing the bias voltages of the varactor diodes, the effective electrical size of the patch can be varied, which can produce a 1.1–1.2 frequency tuning ratio. Hum et al. proposed a differentially-fed frequency-agile microstrip patch antenna (Hum and Xiong 2010), as shown in Fig. 1. By loading three pairs of varactor diodes on the microstrip patches, the antenna can achieve a 2.0 frequency tuning ratio. Microstrip slot antennas also serve as good candidates for frequency RA designs. By using varactor diodes to change the length of the slot, the frequency of the antenna can be tuned. Generally speaking, slot frequency RAs can accomplish a wider tuning ratio, such as 3.52 (Li et al. 2010a), but they have the drawbacks of lower gain and efficiency.

Owing to the advantages of high gain, wide impedance bandwidth and ease of integration with microstrip-based monolithic-microwave integrated-circuits (MMIC), frequency reconfigurable printed

DOI 10.1007/978-981-4560-75-7_119-1

Fig. 2 Photo of the frequency reconfigurable UHF antenna (with a 60 cm long metallic ruler)

quasi-Yagi dipole antennas have attracted significant attention (Deal et al. 2000). Compared to a broadband printed dipole antenna with fixed frequency response, a frequency reconfigurable design offers frequency selective functionality which can reduce the adverse effects of co-site interference and jamming. The mechanism of frequency reconfiguration is to change the electrical length of the dipole arms by using varactor diodes or switches. In (Cai et al. 2012), a frequency reconfigurable high-gain quasi-Yagi dipole antenna operating over the 478–741 MHz UHF TV band was proposed for cognitive radio applications. The antenna consists of two main parts: a printed Yagi antenna with varactor-loaded dipole elements and a metallic corner reflector combined with a metallic hollow box for mechanical support, as shown in Fig. 2. The antenna metallization is etched on both sides of a Rogers RO3035 printed circuit board (PCB) with dimensions of 745 mm $\times$ 360 mm. The thickness of the substrate is 1.524 mm and the dielectric constant is 3.55. The top metallization consists of a driven dipole element, four parasitic directors, a broadband microstrip-to-coplanar stripline (CPS) transition and resistive biasing lines. The bottom side is a truncated microstrip ground, which serves as the reflector element for the antenna. Two varactor diodes are placed in each arm of the driven dipole and in each director. As the capacitance of the varactor diodes in the driven dipole is varied, the effective length of the dipole is changed, thereby altering the antenna resonant frequency. In the meantime, the varactor diodes in the directors are tuned to maximise the gain and to realize an acceptable impedance match for each operating frequency. A simulated and measured frequency tuning range from 478 to 741 MHz is achieved, which is shown

DOI 10.1007/978-981-4560-75-7_119-1

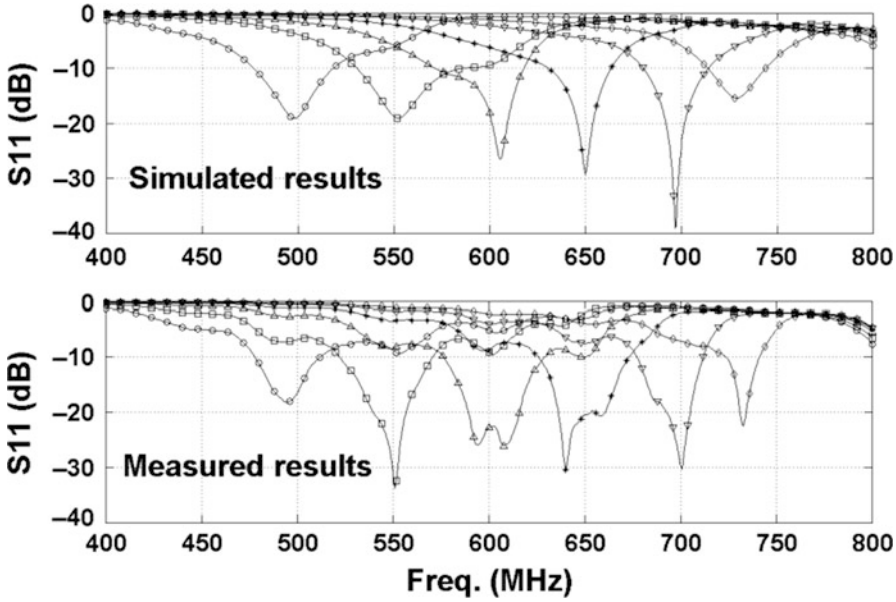

Fig. 3 Simulated and measured reflection coefficients in the six tuning sub-bands

in Fig. 3. In order to bias the diodes embedded in the driver and directors that are located on the ungrounded substrate, a low-cost and effective resistive biasing circuitry is employed, in which thin (1 mm width) but long metallic strip lines are broken down in short sections. The gaps between the metallic sections are bridged with high value surface mount resistors. The resistive nature of the biasing circuitry chokes high frequency currents effectively.

Discrete Tuning

PIN diode and MEMS switches are usually employed to realize discrete frequency tuning. A typical example is the compact frequency-agile microstrip patch antenna presented in (Genovesi et al. 2014). The antenna consists of a central patch connected to four different peripheral elements using PIN diodes. Each one of the four peripheral elements operates at a certain frequency independent from the others that can be designed according to the specifications. The patch antenna can achieve an overall of $2^4 = 16$ different states within a wide frequency range from 0.8 to 3.0 GHz.

In addition, a frequency reconfigurable folded dipole quasi-Yagi antenna was presented in (Qin et al. 2010b). The antenna is printed on two sides of a RO4003 substrate (0.813 mm thick and dielectric constant 3.55). The configuration of the antenna is shown in Fig. 4. The top side of the substrate consists of a microstrip feed, a broad-band microstrip-to-CPS balun, a folded dipole driver element fed by the CPS and a dipole parasitic director element. The bottom side is a truncated microstrip ground serving as the reflector element for the antenna. The combination of the parasitic director and reflector element directs the radiation of the antenna towards the end-fire direction. The folded dipole driver element is printed with six 0.5 mm gaps. Six PIN diodes are mounted across the gaps using electrically conductive silver epoxy. The length of the folded dipole element can be changed by switching between the different states of the diodes. When diodes 1 and 2 are on and all the other diodes are off, the length of the folded dipole is L_7. In this case, the length of the folded dipole is short and the proposed antenna resonates at a high operating frequency (denoted as State I). Changing the polarity of the dc voltage turns diodes 1 and 2 off and all the other diodes on. In this case, the length of the folded dipole is increased to $L_7 + 2\,W_{10} + 2\,L_{10}$ and the antenna resonates at a lower frequency (denoted as State II). Figure 5 shows the simulated and measured reflection coefficients versus frequency for State I and State II. From State II to State I, the

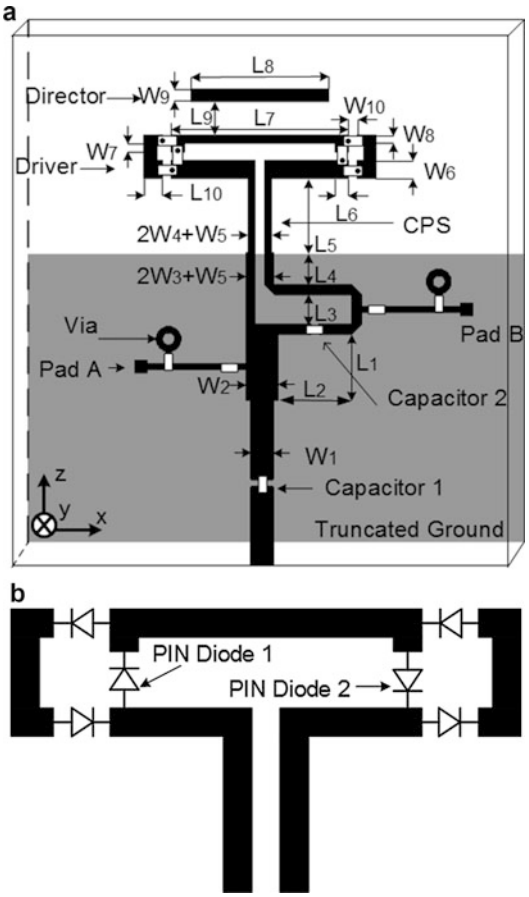

Fig. 4 (**a**) Configuration of the reconfigurable quasi-Yagi folded dipole Antenna. (**b**) Orientation of the PIN diodes in the folded dipole

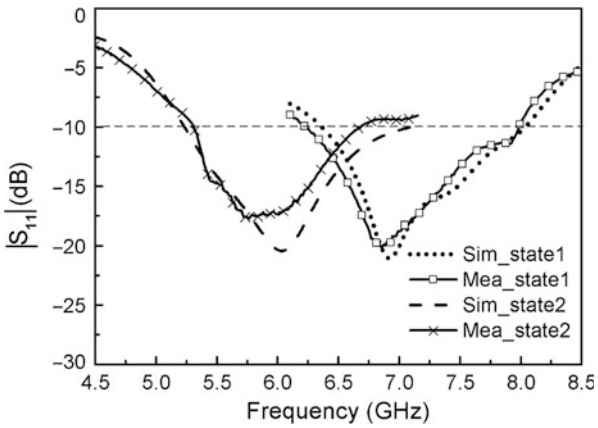

Fig. 5 Simulated and measured input reflection coefficients for the different states of Antenna

resonant frequency shifts from 5.95 to 7.2 GHz, corresponding to a frequency ratio of 1.21. The dc bias voltages are applied to the diodes through the metallization of the balun, CPS and folded dipole. It can be noted that, by using a folded dipole, a closed dc circuit is formed, thereby eliminating the need for extra biasing lines to be attached to the folded dipole. This, in turn, helps maintain the radiation pattern across the frequency tuning range.

Polarization Reconfigurable Antenna (RA)

Polarization reconfiguration can take place in the form of changing angles of linear polarizations, or switching between left-hand circular polarization (LHCP) and right-hand circular polarization (RHCP), as well as between linear and circular polarizations. Such antennas can provide polarization diversity to mitigate signal fading in multipath propagation environments. Moreover, polarization diversity can be employed to increase the capacity of a multiple-input-multiple-output (MIMO) system (Qin et al. 2010a, b). The main challenge in achieving polarization agility is that it must be accomplished without significant changes in the antenna input impedance characteristics. As a result, it is challenging to design a polarization RA that can switch between linear and circular polarizations because it is difficult to simultaneously realize a good impedance match for these two polarizations. The reason is that circular polarization (CP) is typically generated by two degenerate orthogonal linear modes, and its input impedance is significantly different from that of the one resonant mode used to generate linear polarization (LP). Furthermore, it is even more difficult to design a dual-band or a multi-band polarization RA as the interdependence between the frequency response and the polarization characteristic is much stronger than that of a single-band antenna. In other words, it is more challenging to change the polarization states for the dual/multiple bands simultaneously while keeping the frequency response stable. In this section, some novel techniques are presented that can realize polarization switching between linear and circular senses and dual-band polarization RAs.

Single Band Polarization RA

Several interesting polarization RA designs have been proposed to switch between circular and linear polarizations. In (Sung et al. 2004), four pin-diodes were used on a corner-truncated square patch to produce LP and CP radiation with a small impedance bandwidth (2.5 %). A perturbed square-ring slot antenna using four pin diodes was designed that allows operation in both CP and LP modes (Dorsey and Zaghloul 2009). Unfortunately, the authors did not introduce the physical biasing and control circuits. In (Chen and Row 2008), a ring-slot-coupled microstrip circular patch antenna, as shown in Fig. 6, was proposed that can switch between linear and circular polarizations with an overlapped impedance bandwidth of 2.2 %. It was fabricated on two single FR4 substrates separated by a piece of foam, thus it may be difficult to integrate the antenna into a compact wireless device due to its large volume.

Another example is the design of a microstrip U-slot patch antenna that can switch between linear and circular polarizations (Qin et al. 2010c). The configuration of the proposed antenna is shown in Fig. 7. A U-slot is inserted into a rectangular patch which is printed on a 3.175-mm-thick RT/duroid 5880 substrate (dielectric constant 2.2). It should be noted that in the antenna prototype, another thinner slot is cut on the top of the U-slot, which separates the patch into two parts to ensure dc isolation. Three 30 pF capacitors are placed across this thinner slot to maintain RF continuity. The outer part of the patch is dc grounded by a shorting pin through an inductor used as an RF choke. Both the dc bias voltage and the RF signal are simultaneously fed through the coaxial probe by using a bias-tee. Beam lead PIN diodes are used as switching elements in the U-slot. The length of the U-slot arm can be changed by changing between the different states of the diodes. When the left diode is on and the right diode is off, the RF current can flow across the left arm of the U-slot. In this case, the left arm of the U-slot is shorter than the right arm. The asymmetrical U-slot can excite two orthogonal modes in the patch. Adjusting the location of the PIN diodes can make the two modes have the same magnitude and a phase difference of 90° at a given frequency, thus enabling the antenna to generate CP radiation with an acceptable axial ratio.

DOI 10.1007/978-981-4560-75-7_119-1

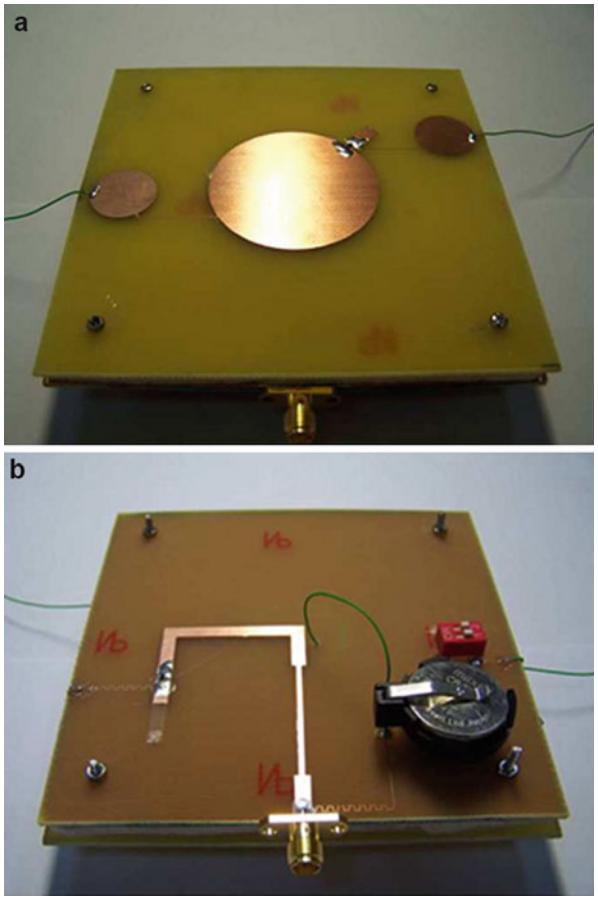

Fig. 6 Circular patch polarization reconfigurable antenna: (**a**) Top layer; (**b**) Bottom layer

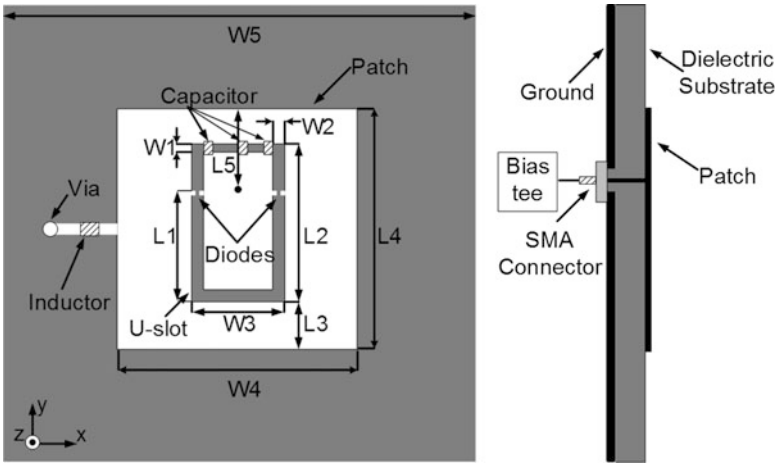

Fig. 7 Schematics of the reconfigurable U-slot antenna

The antenna radiates LHCP when the left arm of the U-slot is longer than the right arm. RHCP can be achieved if the right arm is longer than the left arm. The U-slot becomes symmetrical when both of the diodes are on or off, which enables the antenna to radiate linear polarization. In this case, the electric field polarization is parallel to the y-axis in Fig. 7.

DOI 10.1007/978-981-4560-75-7_119-1

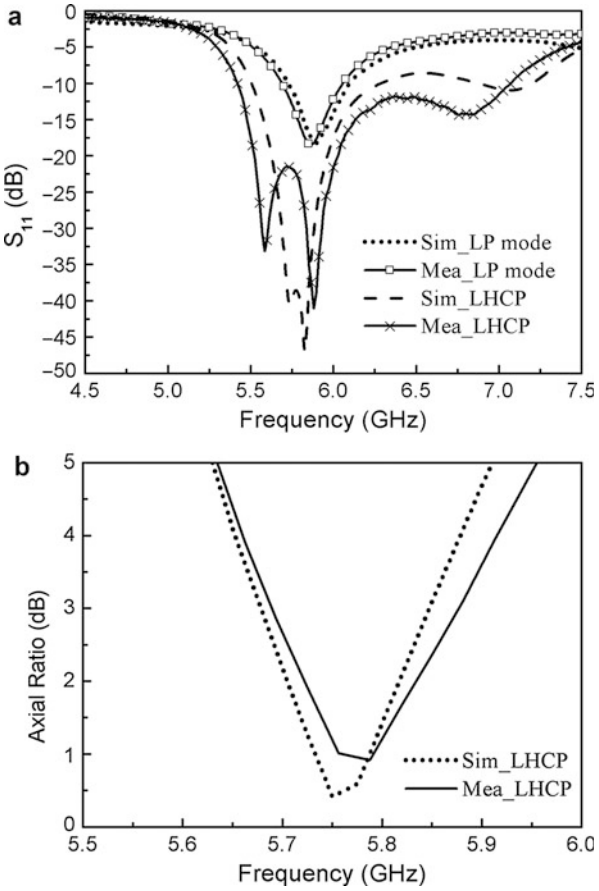

Fig. 8 Simulated and measured (**a**) input reflection coefficients for the LP and CP modes (**b**) axial ratio for the CP mode

Simulated and measured input reflection coefficients versus frequency for the CP and LP modes are shown in Fig. 8a. Simulated and measured axial ratios at boresight for the CP mode are given in Fig. 8b. From the experimental results, it is observed that the impedance bandwidths for the LP and CP modes are 6.1 % and 13.5 %, respectively, with almost the same center frequency of 5.9 GHz, which can cover the entire 5.725–5.85 GHz wireless local area network (WLAN) band. The measured 3 dB axial ratio bandwidth at boresight extends from 5.7 to 5.86 GHz (2.8 %).

Dual-band Polarization RA

Recently, many single-band polarization reconfigurable antennas have been developed for WLAN systems. Hsu et al. designed a polarization reconfigurable microstrip antenna using piezoelectric transducers (PETs) (Hsu and Chang 2007). Either RHCP or LHCP can be obtained by changing the bias voltage of two PETs at 5.8 GHz. An E-shaped patch antenna was studied in (Khidre et al. 2013), which is capable of radiating either RHCP or LHCP targeting the 2.4 GHz band. Li et al. described a microstrip square slot antenna with a coplanar waveguide-to-slot line transition (Li et al. 2010b). It can switch between horizontal and vertical polarizations at 2.4 GHz. For the above reported designs, the antennas can reconfigure their polarizations at only one frequency band of the WLAN standards. Since dual-band operation is commonplace for today's WLAN devices, a polarization reconfigurable antenna operating at both 2.4 and 5.8 GHz bands is highly desirable. To meet this requirement, Qin et al. proposed a single-aperture-fed polarization reconfigurable antenna enabling the switch between horizontal, vertical, and 45° linear polarizations in both 2.4 and 5.8 GHz bands (Qin et al. 2013a).

DOI 10.1007/978-981-4560-75-7_119-1

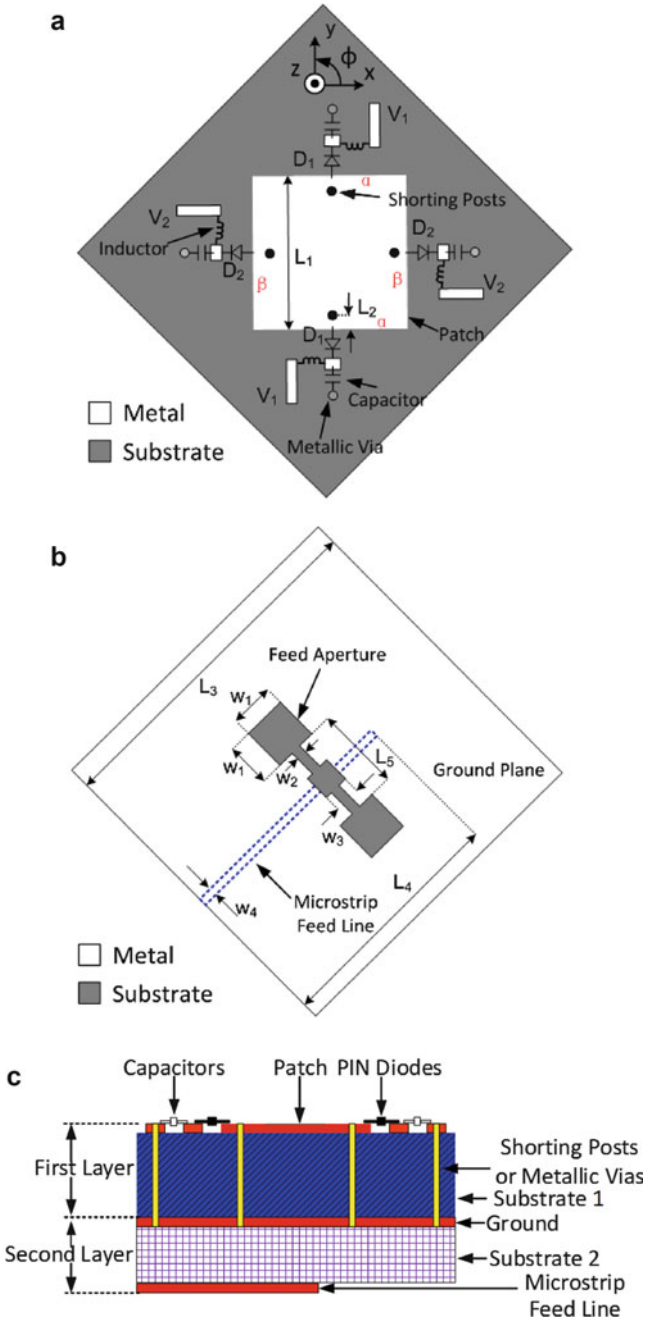

Fig. 9 Schematics of the proposed antenna: (**a**) First layer; (**b**) Second layer; (**c**) Side view

The configuration of the proposed antenna is shown in Fig. 9. The antenna consists of two substrate layers as shown in Fig. 9a, b, respectively. A side view of the antenna structure is given in Fig. 9c. The first layer is a 4.75-mm-thick RT/Duriod 5880 substrate (dielectric constant 2.2). A square patch inserted with four shorting posts is printed on the top side of this layer. There is no metallization on the bottom side of this layer. The TM_{10} and TM_{30} modes of the microstrip patch are selected to make the antenna operate in the 2.4 and 5.8 GHz bands, respectively. Generally speaking, the resonant frequency of TM_{30} mode is three times as high as that of TM_{10} mode. In order for the frequency ratio of the two modes to meet the WLAN dual-band (2.4 and 5.8 GHz) requirement, shorting posts are inserted at the nulls of the electric field of the TM_{30} mode. The shorting posts have a significant effect on the resonant frequency of TM_{10}

DOI 10.1007/978-981-4560-75-7_119-1

mode whilst having little effect on the TM_{30} mode. In this way, the frequency gap between the two modes is reduced.

The second layer is a 1.524-mm-thick RO4003C substrate (dielectric constant 3.55) with metallization on both sides. On the top side, a modified H-shaped feed aperture consisting of an ordinary H-shaped slot and a smaller centrally located square slot are etched in the ground plane (see Fig. 9b). The patch is coupled to the microstrip feed line through this aperture. The dimensions of the modified H-shaped aperture are optimized to achieve good impedance match for each polarization state of the dual bands. A 50-Ω-microstrip feed line (blue dashed line in Fig. 9b) is printed on the bottom side of this layer.

As the microstrip feed line is located along the diagonal line of the patch, both the *x* - and *y*- polarized modes with the same resonant frequency are excited for both TM_{10} and TM_{30} modes. By connecting the middle of the patch edges α (Fig. 9a) to the ground through metallic vias, the resonant frequency of the *y*-polarized mode is changed without affecting the *x*-polarized mode. This is because edges α are the radiating edges for the *y*-polarized mode. Similarly, by shorting the middle of the patch edges β to the ground, the resonant frequency of the *x*-polarized mode is changed without affecting the *y*-polarized mode. Therefore, a single mode (*x*- or *y*- polarized) can be selected by shifting the resonant frequency of another mode away from targeted bands. For the proposed antenna, PIN diodes are placed between the vias and the middle of each patch edge so that the connection between the patch edges and ground can be controlled. According to the orientation of the PIN diodes in Fig. 9a, the edges α of the patch are shorted to the ground when PIN diodes D1 are turned on and D2 are turned off. In this case, the frequency of *y*-polarized mode is shifted to above the *x*-polarized one. The *x*-polarized one is chosen as the antenna operating mode (State I). When PIN diodes D1 are turned off and D2 are turned on, the *y*-polarized mode is chosen as the antenna operating mode (State II). When all the diodes are turned off, the antenna radiates 45° linear polarization (State III) that is parallel to the feed line. When all the diodes are switched on, it is found that the input reflection coefficient of the antenna is too high to be acceptable for WLAN applications.

Figures 10, 11 and 12 show the simulated and measured input reflection coefficients versus frequency for States I, II and III, respectively. It can be observed that for States I and II two bands are found at 2.4 and 5.8 GHz. As discussed in last paragraph, the mechanism of the polarization reconfiguration is to separate the *x*- and *y*-polarized modes by moving the resonant frequency of one mode away from the targeted bands. As a result, in Figs. 10 and 11, it can be seen that the undesired modes are around 2.7 GHz. In addition, for the three polarization states, there is a parasitic resonance around 3.8 GHz, which is caused by the feed aperture. In practice, filters would be employed in a wireless communications system to reject the interference signals from the unwanted frequency bands.

Pattern Reconfigurable Antenna (RA)

Pattern RAs have the capability to change the main-beam shape or provide main-beam scanning. They have the potential to reduce interference by altering the null positions, to save energy by directing the signal toward intended users and to provide large coverage by steering the main beam. In addition, pattern diversity provided by pattern reconfigurable antennas can be exploited by the multiple-input-multiple-output (MIMO) systems to increase the system capacity and/or link quality.

The frequency characteristic should be maintained nearly unchanged for the different radiation patterns of the antenna. Since the currents on the antenna structure directly determine the antenna radiation pattern, the reconfigurability of the radiation pattern is usually realized by manipulating the current distribution. However, as the current distribution also has a strong impact on the antenna frequency response, it is very challenging to deliver pattern reconfigurability without significant changes in the operating frequency. Several methods have been employed to overcome this challenge. One of them is to use specific antenna structures, such as reflector antennas or parasitically coupled antennas, so that the input feed port can be almost independent from the reconfigured part of the structure, allowing frequency characteristics to remain almost stable. Another measure is to compensate for the changes in the antenna input impedance by using some additional structures or matching circuits.

DOI 10.1007/978-981-4560-75-7_119-1

Change of Main-Beam Shape

An example is a wideband circular patch antenna that can switch between boresight and conical radiation patterns by using dual L-probe feeds (Yang and Luk 2006). TM_{11} mode for boresight radiation and TM_{01} for conical radiation are excited by the two feeds, respectively. Four shorting posts are added to the patch to reduce mainly the resonant frequency of the conical pattern mode, thereby enlarging the overlapped operating frequency of the two modes. In order to reconfigure the radiation pattern electronically, an integrated matching network consisting of switches is required. In (Wu and Ma 2008; Li et al. 2011), wideband bow-tie pattern reconfigurable antennas with tunable coplanar waveguide (CPW)-to-Slotline transition feed were presented. PIN diodes are used to reconfigure the feed mode between CPW mode, left slotline (LS) mode, and right slotline (RS) mode. The CPW feed mode can generate an almost omni-directional pattern while the LS mode and the RS mode can excite two end-fire patterns whose main beams are directed to exactly opposite directions.

Another example is a pattern reconfigurable U-slot antenna that is shown in Fig. 13 (Qin et al. 2012). A U-slot is inserted into a square patch of dimensions $L1 \times L1$ on a 3.175-mm-thick RT/Duroid 5880 substrate (dielectric constant 2.2). Each side of the patch is connected with two shorting posts via PIN diodes. The orientation of the diodes is also shown in Fig. 13. As all PIN diodes are mounted across the ground and the center patch, only a bias tee attached to the SMA connector is needed to control the PIN diodes. When the bias voltage is supplied from the coaxial probe, opposite bias conditions are applied to diodes in group A and B due to their reversed orientation. When the dc voltage is zero, all diodes are turned off. In this case, the antenna operates in the normal patch mode and radiates a boresight pattern (State I). When the dc voltage is negative, diodes in group B are on, and the other diodes are off. In this case, the antenna has four shorting posts connected and can be regarded as a monopolar patch antenna, which radiates a conical pattern with the maximum power level in the *z*-*y* plane (State II). Changing the

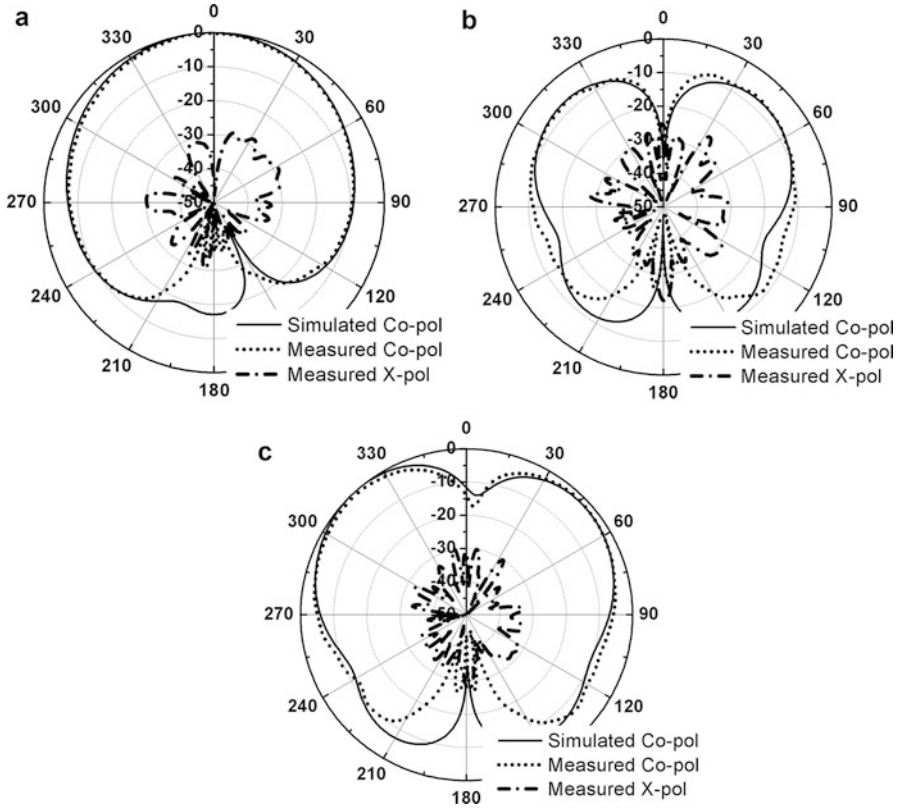

Fig. 14 Measured and simulated *z-x* plane normalized radiation patterns of the proposed antenna at 5.3 GHz (**a**) State I (**b**) State II (**c**) State III

polarity of the dc voltage from negative to positive, diodes in group A are on, and all the other diodes are off. In this case, a similar conical pattern can be observed with the maximum power level in the *z-x* plane (State III). Two shorting posts are used at each side of the patch instead of one in order to realize good impedance match for all operating states.

Simulated and measured normalized radiation patterns at 5.3GHz for the *z-x* and *z-y* planes are displayed in Figs. 14 and 15, respectively. For State I, boresight radiation patterns with a maximum cross-polarization level of −20 dB are shown in Figs. 14a and 15a. For State II, a symmetrical conical pattern with the maximum power level in the *z-y* plane directed at (elevation angle) 44° is plotted in Figs. 14b and 15b. For State III, an asymmetrical conical pattern with the maximum power level in the *z-x* plane directed at (elevation angle) 45° is drawn in Figs. 14c and 15c. It can be seen from Fig. 14c that the pattern is asymmetrical and there is 1 dB difference between the left and right maximum power level of the conical pattern. This is due to the position of the probe feed. Simulation results show that if the probe feed is located at the center of the patch, the difference between the left and right maximum power level in Fig. 14c will become smaller. However, in that case the overlapped impedance bandwidth of the two modes will be reduced. This can be viewed as a compromise for the antenna to provide good overlapped impedance bandwidth and radiation patterns.

Main Beam Scanning

Various antennas have been proposed to steer the main beam to predefined directions by using electronic switches, such as PIN diodes, to activate one or several elements out of a few radiators. Lai et al. proposed a four-element L-shaped antenna array that can achieve beam steering over 360^0 in the azimuth plane with

a gain around −0.5–2.1 dBi (Lai et al. 2008). The configuration of the antenna is shown in Fig. 16. It is composed of four L-shaped quarter-wavelength slot antenna elements which are arranged towards 0^0, 90^0, 180^0, and 270^0, respectively. The maximum radiation direction is toward near the direction of the open

DOI 10.1007/978-981-4560-75-7_119-1

end of the slot. As a result, by using PIN diodes to enable one or more L-shaped slot antennas, several switchable patterns can be achieved. Also, spiral structure was employed to change the main beam direction by altering the length of the spiral. In (Jung et al. 2006; Huff et al. 2003; Nair and Ammann 2007), rectangular single-arm spiral antennas were designed to change the main beam over five directions, three directions and four directions, respectively. The gains of the antennas in (Jung et al. 2006; Huff et al.2003; Nair and Ammann 2007) are between 3–6 dBi, 4 dBi, and 1.1–4.6 dBi, respectively. In addition, work has gone into developing beam-steering antennas based on Yagi-Uda type array. Usually, such antennas have one driven element and several parasitic elements integrated with switches. By controlling the switches, the directive and reflective roles of the parasitic elements can be changed, thereby changing the main beam direction. The driven element can be either a microstrip dipole (Zhang et al. 2004), a microstrip patch (Yang et al. 2007; Donelli et al. 2007), or a wire antenna (Lim and Ling 2007). While there have been substantial advances in the design of beam-steering pattern reconfigurable antennas, it is found that most of the reported antennas suffer from low realized gain, which may significantly limit their applications.

In (Qin et al. 2013b), a high gain beam-switching pattern reconfigurable quasi-Yagi dipole antenna was proposed. It is capable of directing the E-plane main beam direction towards either 20^0, -20^0, or 0^0 with a realized gain between 7.5 and 10 dBi. The antenna was etched on a 1.27-mm-thick Rogers 6010 substrate (dielectric constant 10.9), as shown in Fig. 17. As shown in Fig. 17a, the top side of the substrate consists of a microstrip feed, an impedance transformer, a broad-band microstrip-to-coplanar stripline (CPS) balun, a dipole driver fed by the CPS, and two tilted rows of directive strips. The bottom side is a truncated ground, serving as the reflector. Usually, a design for maximizing the gain of a Yagi-Uda antenna requires a non-uniform director length and spacing. In this work, the directive strips are of the same length and the spacing between two adjacent strips is identical in order to reduce the design complexity.

The microstrip-to-CPS balun is used to introduce a phase difference for the currents on the two arms of the dipole. Details of the balun are shown in Fig. 17b. It can be seen that the balun is a symmetrical structure with respect to the line AA′. Therefore, only the balun above the line AA′ is described. The right-hand part of the balun is split into three sections with lengths of L_1, L_2, L_3, respectively, and the left-hand part is split into two sections with lengths of L_1 and L_4, respectively. The gap between each section is connected by PIN diodes. The width of the gap for the PIN diodes is W_{PIN}. In addition, the second section of the right-hand part of the balun with the length of L_2 is split into two smaller sections by a capacitor with a gap W_c. This capacitor is used for biasing purpose.

Conventionally, the directors of a quasi-Yagi dipole antenna are placed horizontally (parallel to the dipole driver) to direct the maximum beam towards the end-fire direction ($\varphi = 0^0$). However, it is found that when the beam is steered away from the end-fire direction, the original horizontally located directors can reduce the beam scanning range and the antenna gain. This is because the directors are not parallel to the titled beam direction any more. In order to increase the beam steering range and maintain the antenna gain, two tilted rows of metal strips are placed in front of the dipole driver with 6 strips on each row, which is shown in Fig 17a. To a certain extent, the tilted angle of the directive strips determines the maximum steering range. In this work, it is made to be close to the desired antenna beam tilted angle. Furthermore, a small gap is etched on each strip to split it into two short parts with PIN diodes inserted into the gaps. When the PIN diodes are switched on, the two short strips are connected to perform as a director. When the PIN diodes are switched off, the two short strips are disconnected and they do not serve as directors, thereby having little effect on the far-field radiation pattern. In this way, the PIN diodes can be used to choose the proper directors for a certain main beam direction. To be specific, when the PIN diodes *L* are switched on and the diodes *R* are switched off, only the left-hand row of strips perform as directors and they facilitate the beam tilt towards the left-hand side with respect to the end-fire direction. Similarly, when the PIN diodes *R* are switched on and diodes *L* are switched off, the beam tilt towards the right-hand

DOI 10.1007/978-981-4560-75-7_119-1

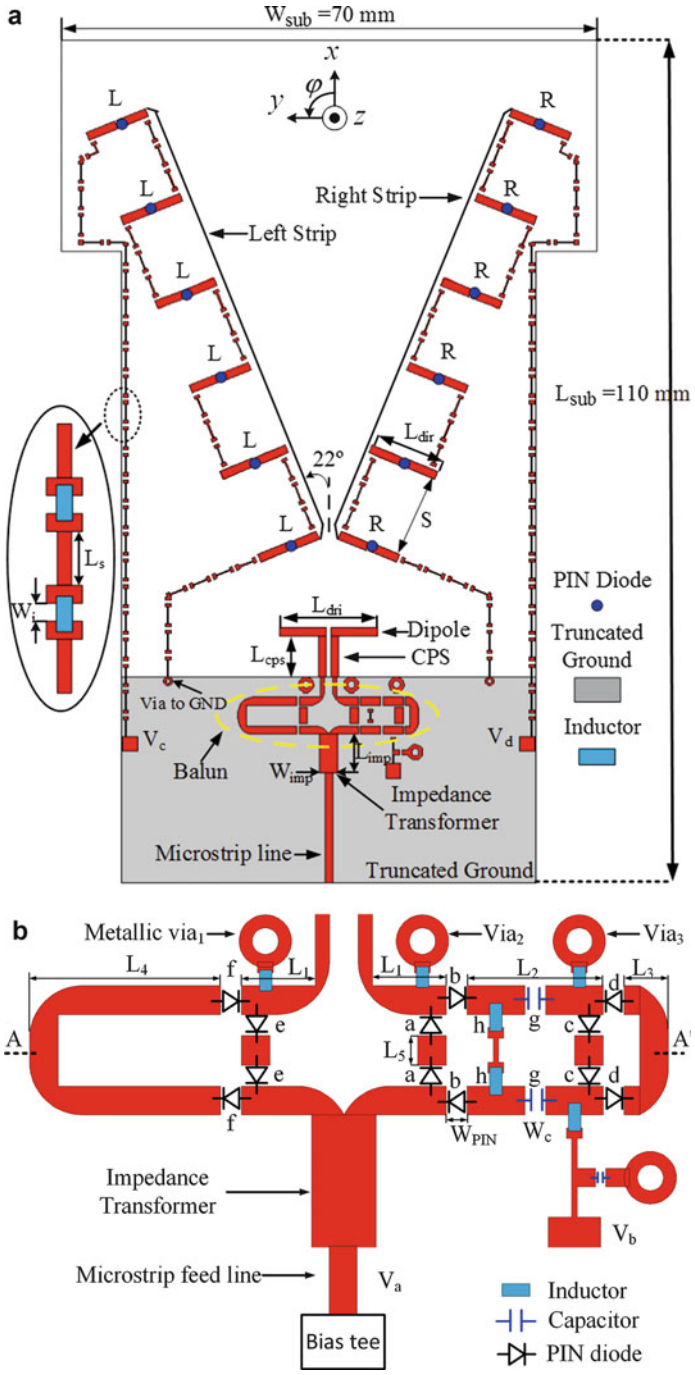

Fig. 17 Schematics of the proposed antenna: (**a**) Whole structure; (**b**) Balun of the antenna

side is enhanced. When both sides of the diodes are switched on, two rows of directors maintain the beam towards the end-fire direction.

By switching between the different states of the PIN diodes on the balun, the lengths of the current path on the right-hand and left-hand parts of the balun can be changed, thereby altering the phase difference of the currents on the dipole arms. According to the PIN diodes orientation shown in Fig. 17b, the antenna can operate in three states. For State I, diodes *e*, *b*, *c* and the diodes on the two rows of directive strips (diodes *L* and *R*) are switched on, and all the others are switched off. In this case, the maximum beam directs at $\varphi = 0^\circ$ (end-fire direction). For State II, diodes *e*, *b*, *d* and the diode group *L* are on, and all the

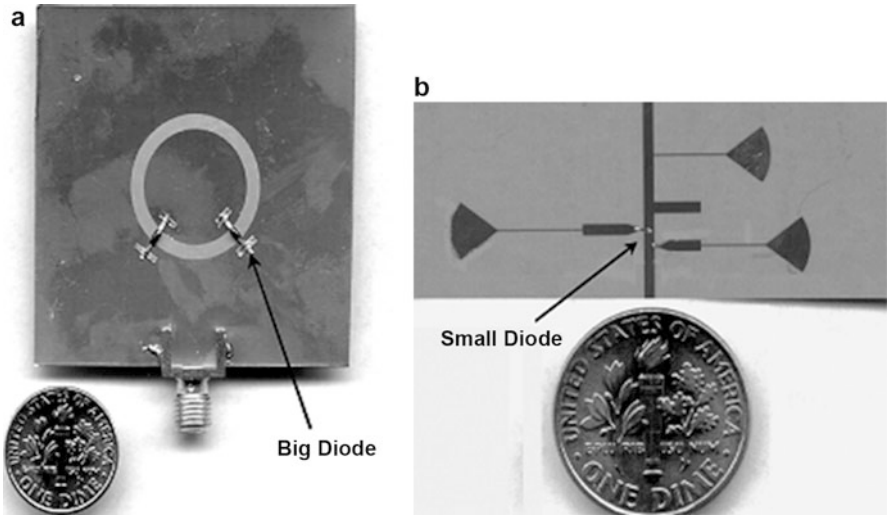

Fig. 19 (**a**) Front side of the annular slot antenna; (**b**) Back side, the impedance matching network

others are off. In this case, the maximum beam in E plane (*x*-*y* plane) radiate towards $\varphi = 20^\circ$ direction. For State III, diodes *f*, *a*, and diode group *R* are on, and all the others are off. For this state, the maximum beam direction can be directed towards $\varphi = -20^\circ$. Figure 18 shows the simulated and measured far-field radiation patterns at 5.2 GHz. As seen from the figure, the measured main beam for State I is pointed at end fire direction, while it is steered to 19^0 and -20^0 for State II and State III, respectively.

Compound Reconfigurable Antennas (RAs)

Compound RAs have the ability to independently change the operating frequency, polarization, and radiation pattern of an antenna, which is the ultimate goal of reconfigurable antenna design. Since a compound RA can deliver more flexibility and diversity than a single characteristic reconfigurable antenna, it can bring significant benefits to wireless communication systems. Recently, Nikolaou et al. have achieved combined frequency and radiation pattern reconfigurability (Nikolaou et al. 2006). Figure 19 shows the antenna configuration. By loading PIN diodes across the slot at specific locations

DOI 10.1007/978-981-4560-75-7_119-1

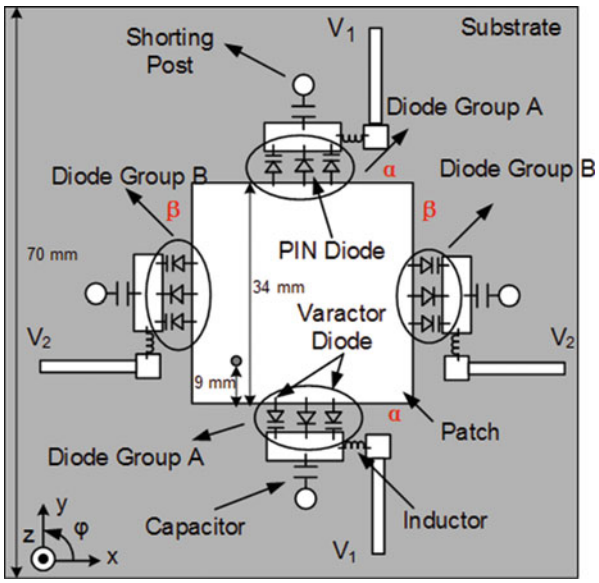

Fig. 20 Schematics of the proposed reconfigurable antenna

(Fig. 19a), the direction of the null of the radiation pattern can be changed. In addition, by reconfiguring the matching network shown in Fig. 19b, the operating frequency of the antenna can also be tuned.

In addition, Qin et al. proposed a single-fed combined frequency and polarization reconfigurable microstrip patch antenna with a maximum 1.67 frequency tuning ratio (Qin et al. 2011). The antenna can radiate one of the three linear polarizations (horizontal, vertical, and 45^0 linear polarizations) with a wide independent frequency tuning range for each polarization. The layout of the antenna is shown in Fig. 20. The lengths of the square substrate and the patch are 70 mm and 34 mm, respectively. The feed point is located 9 mm from the bottom of the patch edge along the diagonal line. The centre of each edge of the patch is connected to a shorting post via a PIN diode. Two varactor diodes (with a 0.1–1.0 pF junction capacitance tuning range for a corresponding voltage from 20 to 2 V) are located beside the PIN diode at each edge.

A square patch antenna fed along the diagonal line without any connection to the ground radiates *x*- and *y*- oriented modes, which have the same resonant frequency. By adding shorting posts in the middle of the patch edges α (Fig. 20), the resonant frequency of the *y*-oriented mode is increased without affecting the *x*-oriented mode. This is because edges α are the radiating edges for the *y*-oriented mode. By attaching shorting posts which can be represented by inductors, the resonant frequency of the *y*-oriented mode is increased. But the *x*-oriented mode will not be affected since its radiating edges are β. Similarly, by adding shorting posts in the middle of the patch edges β, the resonant frequency of the *x*-oriented mode is raised without affecting the *y*-oriented mode. Therefore, a single mode (*x*- or *y*- oriented) can be selected by shifting the resonant frequency of the undesired mode away from that of the desired one. For each mode, two varactor diodes are mounted along the corresponding radiating edges to change the resonant frequency.

Another recent design with full polarization diversity and frequency agility was presented in (Ho and Rebeiz 2014). MEMS switches are integrated into a feed network to provide four states of polarization control: vertical, horizontal, left-hand circular polarization, and right-hand circular polarization. Hyper-abrupt silicon junction tuning diodes are used to tune the antenna center frequency for each polarization. The tuning ranges are from 0.9 to 1.55 GHz and 1.1–1.5 GHz for linear and circular polarizations, respectively.

Reconfigurable Phase Shifter and Its Application in Beamforming Antennas

Phase Shifter Design Based on Reconfigurable Defected Microstrip Structure (RDMS)

Phased array antennas can achieve analogue beamforming with high gains and are extensively utilized in satellite communications, radar systems, and other military applications (Parker and Zimmermann 2002). Usually, a large number of phase shifters are employed in a phased array antenna, and thus their cost, size, and integration method are of great concerns (Hansen 1998). The most popular phase shifters used in phased array antennas are diode ones (White 1974; Davis 1975) and ferrite phase shifters (Whicker 1973). Diode phase shifters have fast switching time, a low weight, a low cost but a high insertion loss, whereas ferrite phase shifters are relatively bulky and heavy, and require significant switching power compared with diode ones.

Recently, phase shifters based on defected ground structure (DGS) are developed (Patil et al. 2012; Han et al. 2005; Shafai et al. 2004). For most of the designs, multi-layer structures and micro electromechanical systems (MEMS) are used. Therefore, they suffer from a high cost and high fabrication complexity, and they are difficult to be integrated into microstrip systems, which substantially limits their applications. As a dual structure of DGS, the defected microstrip structure (DMS) also has the potential to provide a phase shift. In (Ye et al. 2012), C-shaped slots are etched on microstrip lines in the feed network for phase alignment. However, each slot only has a fixed phase delay of 3^0 at 12.5 GHz. In order to have controllable phase shift, Can et al. proposed compact phase shifters using reconfigurable defected microstrip structure (RDMS) for phased array antennas (Ding et al. 2014; Ding et al. 2015).

Figure 21 shows the structure of the RDMS unit based on a 50-Ω microstrip line for the phase shifter design. As depicted in the figure, a rectangular slot with a size of $W_{slot} \times L_{slot}$ is etched on the microstrip line to introduce a defect. PIN diodes are inserted into the edges of the slot area, which enables structural reconfiguration and results in a RDMS unit. Capacitors and metal stubs used for capacitor mounting are placed in the middle of the slot to achieve RF continuity as well as to provide DC isolation. The RDMS unit has two working states, the "All-on" and "All-off" states, when the diodes are turned "on" and "off," respectively. In the All-on state, both the diodes and capacitors allow the currents to go through them with minor losses. Numerical simulations find that the RDMS unit behaves like a uniform microstrip line in this state. In the All-off state, the currents across the diodes are blocked, resulting in a different current distribution as shown in Fig. 21b. It is noted that in the All-off state, the current path is longer than that in the All-on state, which produces a phase shift. The phase shift value is in proportional to the difference of the electrical length of the current path in the two states, which is affected by W_{slot} and L_{slot}. An RDMS

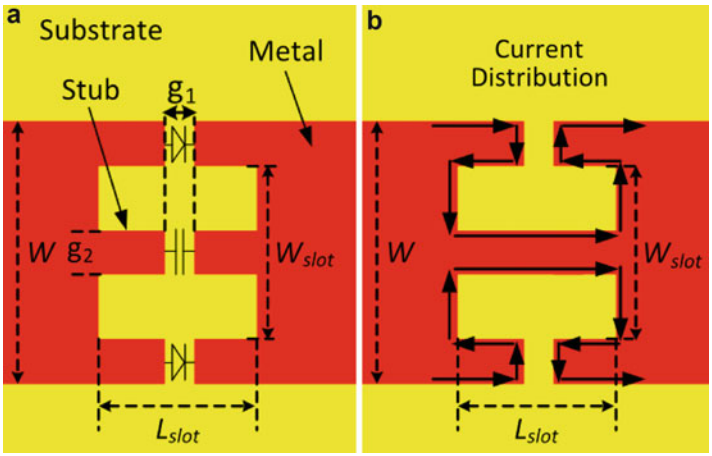

Fig. 21 (**a**) Structure of the RDMS unit. (**b**) All-off state current distribution

DOI 10.1007/978-981-4560-75-7_119-1

unit with $\{W_{slot}, L_{slot}\} = \{2\text{ mm}, 3.3\text{ mm}\}$ was fabricated as an example. Figure 22a, b, and c shows the picture of the fabricated RDMS unit, the measured insertion losses, and phase shifts, respectively. According to the measured results, the fabricated RDMS unit produces a phase shift of 20^0 with an insertion loss of 1.1 dB at 5.2 GHz.

Larger phase shift values can be achieved by cascading several RDMS units described above. A 2-RDMS phase shifter cascading two RDMS units is shown in Fig. 23a, which can realize a 40^0 phase shift. Furthermore, a phase shifter cascading four RDMS units is shown in Fig. 23b. By using two biasing voltages, phase shifts of 44° and 88° can be obtained at 5.2 GHz.

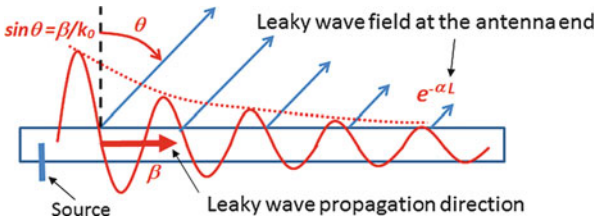

Fig. 26 Scheme of a leaky wave antenna

the H plane. In this design, 3 Wilkinson power dividers are employed to split the power while 8 phase shifters are integrated in the feed network to realize 50° progressive phase differences between the array elements at 5.2 GHz. Each phase shifter is composed of two RDMS units with $W_{slot} = 2\ mm$ and $L_{slot} = 3.6\ mm$. For the first-level power divider, there are 2 phase shifters at each of the 2 branches. For the second-level, there is 1 phase shifter at each of the 4 branches. Two bias DC voltages labelled by *V1* and *V2* are employed to control the phase shifters. There are 4 different working states of the phased array. When voltages *V1* and *V2* are "+,+," "–,–," "+,–," and "–,+," the phased array can work in the "All-on," "All-off," "left-on-right-off," and "Left-off-right-on" states. In the All-on and All-off states, the array elements are in phase so that the beam is not tilted. In the left-on-right-off and Left-off-right-on states, phase advances and delays of 50^0 between the array elements are obtained, respectively. Therefore, beam tilts of -15^0 and 15^0 are realized. The measured far-field pattern of the array is given in Fig. 25.

Reconfigurable Leaky Wave Antennas

Introduction

Leaky wave antennas can be regarded as transmission lines that gradually leak the energy out into free space. The direction in which the energy is radiated from a leaky wave antenna, θ, is determined by the phase constant β, of the leaky wave along the transmission line (Goldstone and Oliner 1959), as shown in Fig. 26. The beamwidth of a leaky wave antenna is determined by the length of the leaky aperture, which must be illuminated by proper control over the leakage rate α (Goldstone and Oliner 1959).

The concept of leaky-wave antennas has been around for decades (Horn et al. 1980). Compared with reflector and lens antennas, it has the advantage that no protruding feed is needed so the antenna can have

DOI 10.1007/978-981-4560-75-7_119-1

a very low profile. Compared with array antennas, it does not need a feed network which can become very lossy for large arrays. The phase constant of a leaky wave antenna is typically a function of the operating frequency, and this fact can be used to steer the beam direction by sweeping the operating frequency.

In the last decade, the fastest growth of the wireless communications industry and a multitude of wireless communications system standards have been witnessed. Wireless communication systems normally operate in a given frequency band defined by the spectrum regulators. Therefore, the inherent frequency scanning nature of leaky wave antennas has very limited use. To this end, there is a great need to develop pattern reconfigurable (beam-steering) leaky wave antennas which can be used to exploit the complexity of the propagation channel. Furthermore, leaky wave antennas have relatively narrow bandwidth, typically of only a few percent. However, given that wireless communications systems do not need a simultaneous wide bandwidth, a frequency reconfigurable (tunable) leaky wave antenna would serve as a good candidate for many applications.

The frequency-dependent nature of leaky wave antennas has limited their applications in modern communication systems, which generally require fixed frequency operation for effective channelization. In the past, significant efforts have been directed toward developing frequency-independent leaky wave antennas. Horn et al. (Horn et al. 1980) used PIN diodes as switches and electrically changed the radiation angle by controlling the guided wavelength. In their approach, however, only two discrete radiation angles were present because diodes have only two states, namely biased and unbiased. Maheri et al. (Maheri et al. 1988) reported a magnetically scannable leaky-wave antenna built on a ferrite slab structure, in which the radiation angle is scanned by tuning the DC magnetic field. In (Huang et al. 2000), Huang et al. applied PIN diodes as switches to control the period of the structure, and the reconfigurability was limited to two discrete radiation angles.

In (Sievenpiper 2005), Sievenpiper employed a high impedance surface which called a textured surface to develop a leaky wave antenna which can scan from backward to forward directions from -50^0 to 50^0. In the design, varactor diodes incorporated into the structure allow electronic control of the reflection phase and the surface wave properties. This tunable textured surface is then used as an electronically steerable leaky wave antenna by coupling energy into a leaky wave band using a flared notch antenna. The textured surface consists of a periodic lattice of small mushroom-shaped protrusions made of square metal plates, connected to a common ground plane by vertical metal pins. These pins are alternatively connected to and protruded through the ground-plane to allow the controlling voltage to be applied. The square plates are all connected to each other with varactor diodes. By exploiting multiple degrees of freedom which the surface geometry provided, the author achieved independent control of the magnitude and phase of the surface wave radiation, so the antenna can be programmed to have a large effective aperture over the entire scan range.

Left-handed (LH) materials characterised by simultaneously negative permittivity and permeability were introduced theoretically by Veselago (Veselago 1968) and investigated experimentally by Shelby et al. (Shelby et al. 2001). The propagation constant of a left-handed material is negative, representing a phase advance, whereas that of a right handed material is positive, representing a phase lag. Combining structures with LH and RH contributions results in a composite RH-LH (CRLH) structure, which can be used to realize both forward and backward scanning. This concept was first introduced using a transmission line structure in (Liu et al. 2002). In (Lim et al. 2005), a metamaterial-based electronically controlled transmission line structure incorporating varactor diodes was proposed as a leaky-wave antenna with tunable radiation angle and beamwidth functionalities. This structure is, in essence, a CRLH microstrip structure incorporating varactor diodes for fixed-frequency voltage-controlled operation. Angle scanning at a fixed frequency is achieved by modulating the capacitances of the structure by adjusting a uniform bias voltage applied to the varactors. Beamwidth tuning is obtained by making the structure non-uniform by the application of a non-uniform bias voltage distribution of the varactors. A 30-cell leaky wave

antenna structure, incorporating both series and shunt varactors for optimal impedance matching and maximal tuning range, was designed. This prototype exhibits continuous scanning capability from $+50^0$ to -49^0 by tuning the bias voltages from 0 to 21 V at 3.33 GHz. A maximum gain of 18 dBi at broadside is achieved, but the gain variation with scan angle is large. In addition, it provides half-power beamwidth variation of up to 200 % with comparison to the case of uniform biasing.

Employing tunable partially reflective surfaces and high impedance surfaces in Fabry-Pérot structures proved to be another way of achieving frequency reconfigurability and pattern reconfigurability in leaky wave antennas effectively. The authors of this chapter have conducted a systematic study in this regard in recent years which will be presented in the following sections.

Frequency Reconfigurable Fabry Pérot Antenna

Fabry-Pérot leaky wave antennas have the advantages of low profile, simple construction and high directivity. They are created by placing a partially reflective surface (PRS) around half a wavelength above a ground plane containing a low directivity source antenna (Trentini 1956; Feresidis and Vardaxoglou 2001; Feresidis et al. 2005; Wang et al. 2006; Weily et al. 2008). The PRS is usually a periodic array of dipoles, patches or slots on a dielectric substrate. If the ground plane is replaced with a high impedance surface (HIS), the profile of the antenna can be significantly reduced (Feresidis et al. 2005; Wang et al. 2006). A significant drawback of the Fabry-Pérot leaky wave antenna is the narrow operating bandwidth, due to the high Q factor of the Fabry Pérot cavity. However, the utility can be improved by making the operating frequency reconfigurable, through the use of a tunable HIS on the lower surface of the cavity where each cell of the HIS is tuned through the voltage applied to a pair of varactor diodes (Hum et al. 2005; Hum et al. 2007).

The geometry of the Fabry-Pérot leaky wave antenna, comprising a PRS, tunable HIS and stacked patch feed antenna, is shown in Fig. 27 (Weily et al. 2008). Its operating frequency was designed to be tuned from 5.2 to 5.775 GHz to enable use in WLAN applications. Referring to Fig. 28, the cavity height Lr can be expressed in terms of the operating wavelength λ_0, and the reflection phase of the PRS φ_1 and tunable HIS φ_2 as follows (Wang et al. 2006).

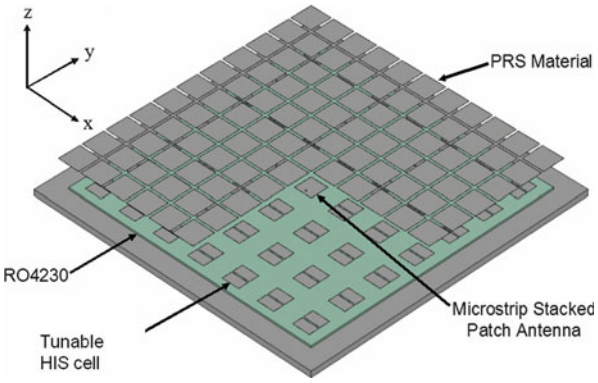

Fig. 27 Geometry of the frequency reconfigurable FP LWA

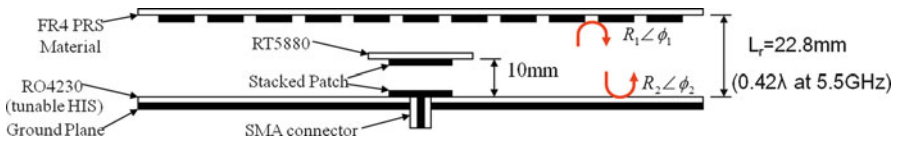

Fig. 28 Schematic of the frequency reconfigurable FP LWA showing reflection coefficients of the PRS and HIS

DOI 10.1007/978-981-4560-75-7_119-1

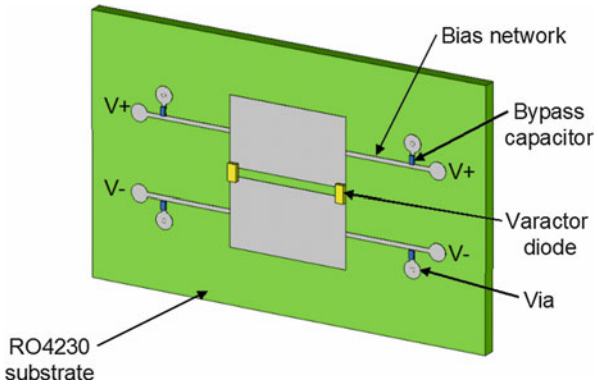

Fig. 29 Geometry of the tunable HIS unit cell

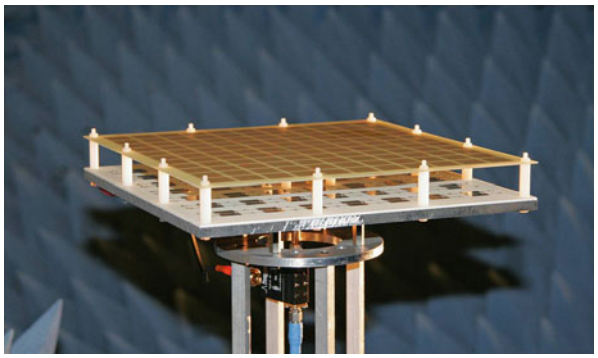

Fig. 30 Photograph of the frequency reconfigurable FP LWA prototype

$$L_r = \left(\frac{\varphi_1 + \varphi_2}{\pi}\right)\frac{\lambda_0}{4} + \frac{\lambda_0}{2} \tag{1}$$

Since φ_2 is a function of the varactor tuning voltage, it is possible to reconfigure the operating frequency of the antenna. Increasing the tuning voltage gives an increase in the antenna resonant frequency, while lowering the voltage reduces the resonant frequency. In this implementation the PRS is made from 18 mm $\times$ 18 mm square metallic patches placed on a 0.8 mm thick FR4 substrate ($\varepsilon_r = 4.4$, $tan\delta = 0.018$), with a periodicity of 20 mm in both x- and y-directions. A total of 48 tunable HIS cells are used on a 1.524 mm thick Rogers RO4230 substrate ($\varepsilon_r = 3.0$, $tan\delta = 0.0023$). Patch dimensions are 14 mm by 17 mm, with a 1 mm air gap between its two halves for placement of the varactor diode pair. Both substrates have lateral dimensions of 240 mm by 240 mm. A stacked probe-fed patch was chosen for the source because simulations showed it gave better matching as the HIS surface was tuned, compared to a single patch.

Figure 29 depicts the geometry of the tunable HIS cell used in the antenna, and includes the bias network which consists of 0.5 mm wide high impedance lines, 2.2 pF bypass capacitors and vias. The tunable HIS cell is based on a design from (Hum et al. 2005), used in a reconfigurable reflectarray (Hum et al. 2007). However, it has been modified to include a distributed element bias network to allow simultaneous biasing of a complete row of tunable HIS cells. A photograph of the fabricated prototype antenna is shown in Fig. 30. Various nylon spacers have been used to position the PRS above the tunable HIS, and the coupled patch above the driven patch. A low-loss bias tee, which may be observed behind the antenna, is used to provide the bias voltage to the tunable HIS cells, and thus reconfigure the antenna's operating frequency. The varactor diodes used in the prototype were also "matched" by the manufacturer

to ensure variations between the devices were as small as possible. The measured directivity versus frequency is plotted in Fig. 31 for six different bias voltages, which correspond to six different junction capacitances of the varactor diode. It is clear from Fig. 31 that the measured operating frequency tunes from 5.2 to 5.95 GHz. The measured reflection coefficient of the antenna is shown in Fig. 32 and tracks the directivity peaks of Fig. 31 for the corresponding six bias voltages.

Pattern Reconfigurable Leaky Wave Antennas

As mentioned earlier, one of the disadvantages of leaky wave antennas is that the radiation beam typically scans with the operating frequency. This is often problematic as, for many applications, it is required to have a fixed frequency band when the antenna beam is scanned. With one dimensional leaky wave antennas, this can be done by electronically reconfiguring the leaky-line boundary condition. Using active

DOI 10.1007/978-981-4560-75-7_119-1

devices such as varactor diodes or MEMS, the leaky-mode complex propagation constant can be altered, thus producing the desired control of the scanning beam. Using the Fabry-Pérot structure, a number of techniques have been developed to scan the beam of a leaky-wave antenna at a fixed frequency.

Half-space scanning 1D Fabry-Pérot leaky wave antenna

As the first step, a one-dimensional half-space scanning leaky wave antenna is designed, as shown in Fig.33a. This structure is inspired by the passive 1D Fabry-Pérot leaky wave antenna presented in (García-Vigueras et al. 2011), where a Fabry-Pérot cavity made of a top partially reflective surface (PRS) and a bottom high impedance surface (HIS) enables control of the leakage rate (α) and the phase constant (β) of the leaky mode through design of the physical length of the resonant patches. In this case, the structure provides electronic scanning of the main beam in the forward quadrant, at a fixed operating frequency (Guzmán-Quirós et al. 2012a), by replacing the passive HIS of (García-Vigueras et al. 2011) by a bottom

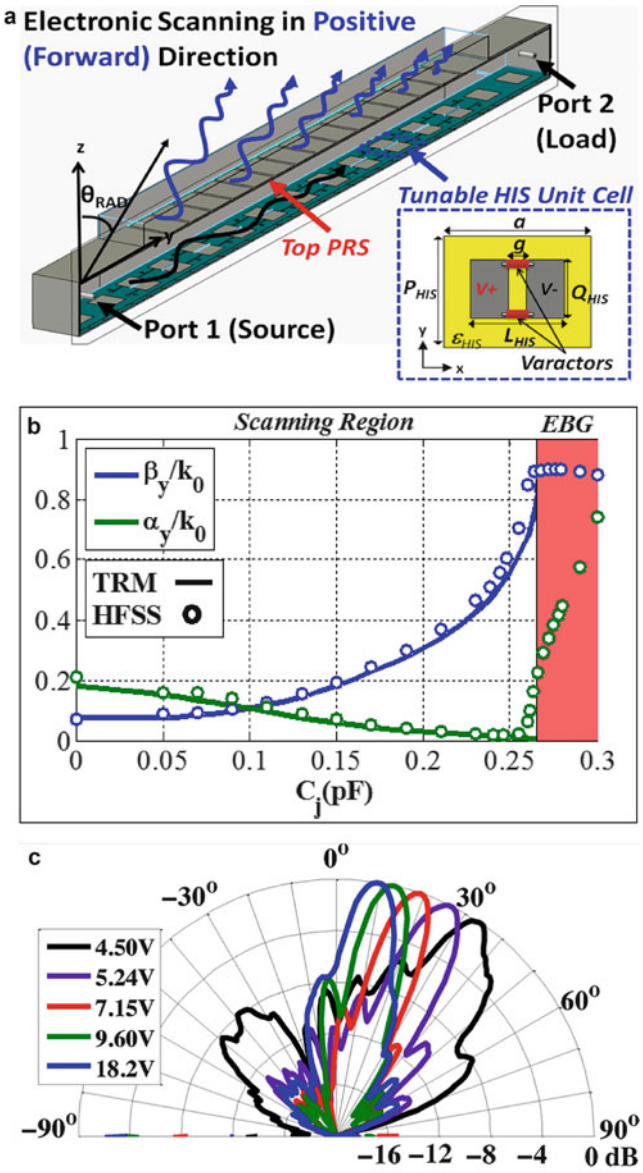

Fig. 33 (**a**) Scheme of a half-space scanning 1D FP LWA (**b**) Dispersion curves versus Cj and (**c**) Measured radiation patterns (H-plane) for different V_R at 5.5 GHz

DOI 10.1007/978-981-4560-75-7_119-1

tunable high impedance surface (HIS) loaded with varactor diodes (Guzmán-Quirós et al. 2012a). Now, the β of the leaky wave antenna can be controlled electronically as a function of the tunable junction capacitance (C_j) introduced by the varactor diodes which load the HIS patches (Fig. 33a) (Weily et al. 2008; Hum et al. 2005; Hum et al. 2007). This C_j is tuned by the DC bias voltage (V_R) applied to the diodes.

The control of the LM dispersion with C_j is demonstrated in Fig. 33b, showing the normalized phase (β/k_0) and leakage (α/k_0) rates as a function of C_j for a fixed operating frequency of 5.5 GHz, where k_0 is the free-space wave number in air. It is shown how the LM phase constant increases with C_j in the scanning region defined in the range $C_j = [0\text{ pF},0.27\text{ pF}]$. As β/k_0 is related with the main beam radiation angle θ_{RAD} by $sin(\theta_{RAD}) \approx \beta/k_0$ (Goldstone and Oliner 1959), a half-space electronic scanning of the fan beam direction with V_R is obtained in the positive quadrant from $\theta_{RAD} = +9°$ to $\theta_{RAD} = +34°$, as experimentally confirmed by the measured radiation patterns shown in Fig. 33c.

Full-space scanning 1D Fabry-Pérot leaky wave antennas

The structure of a symmetrically-fed 1D Fabry-Pérot leaky wave antenna is depicted in Fig. 34a. This antenna is conceived to extend the half-space scanning range obtained from the previous 1D Fabry-Pérot leaky wave antenna design, to a full-space scanning range. This is achieved by taking advantage of the electromagnetic band-gap (EBG) property that is presented in the Fabry-Pérot cavity for low values of the tuning voltage V_R (Guzmán-Quirós et al. 2012b). As shown in Fig. 34b, an EBG zone extends beyond the scanning region for $C_j = [0.27\text{ pF}, 0.3\text{ pF}]$. LM propagation along the FP waveguide is prevented in this zone. A central coaxial probe feed divides the original antenna in to two symmetric leaky lines: LWA_{LEFT} and $\text{LWA}_{\text{RIGHT}}$. Each one is separately biased by V_L or V_R. Therefore, two leaky waves which are oppositely launched by the central coaxial feed yield two radiation patterns whose main beam pointing angles can be independently controlled based on the dispersion properties of the 1D Fabry-Pérot leaky wave antenna (Guzmán-Quirós et al. 2012a).

Using the scanning and EBG properties of the HIS-loaded Fabry-Pérot cavity, the leaky wave antenna can be electronically tuned to propagate/radiate energy or to serve as a reflector, depending on the electronic tuning of the HIS. Hence, the symmetrically-fed 1D Fabry-Pérot leaky wave antenna can be electronically tuned to operate in three different regimes:

(1) Backward scanning regime ($\theta_{RAD} < 0°$): LWA_{LEFT} must be tuned inside the scanning region ($C_{jL} < 0.27$ pF) while $\text{LWA}_{\text{RIGHT}}$ is fixed at EBG region ($C_{jR} = 0.3$ pF). In this way the input signal is guided to the left side of the LWA (no energy travels to the right side), providing scan at negative angles.
(2) Forward scanning regime ($\theta_{RAD} > 0°$): This is the symmetrical case. LWA_{LEFT} is operated in the EBG region ($C_{jL} = 0.3$ pF) and $\text{LWA}_{\text{RIGHT}}$ is tuned in the scanning region to provide beam steering at positive angles (with $C_{jR} < 0.27$ pF).
(3) Broadside radiation ($\theta_{RAD} = 0°$): Radiation at boresight can be obtained by launching two oppositely-directed leaky waves. To this end, LWA_{LEFT} and $\text{LWA}_{\text{RIGHT}}$ are tuned at the same operating point inside the scanning region at or below the splitting condition $\beta = \alpha$ (Lovat et al. 2006) (which is obtained for $C_{jR} = C_{jL} = 0.1$ pF in this case), so that the fields on the two sides of the antenna merge to form a single beam radiating at $\theta_{RAD} = 0°$.

DOI 10.1007/978-981-4560-75-7_119-1

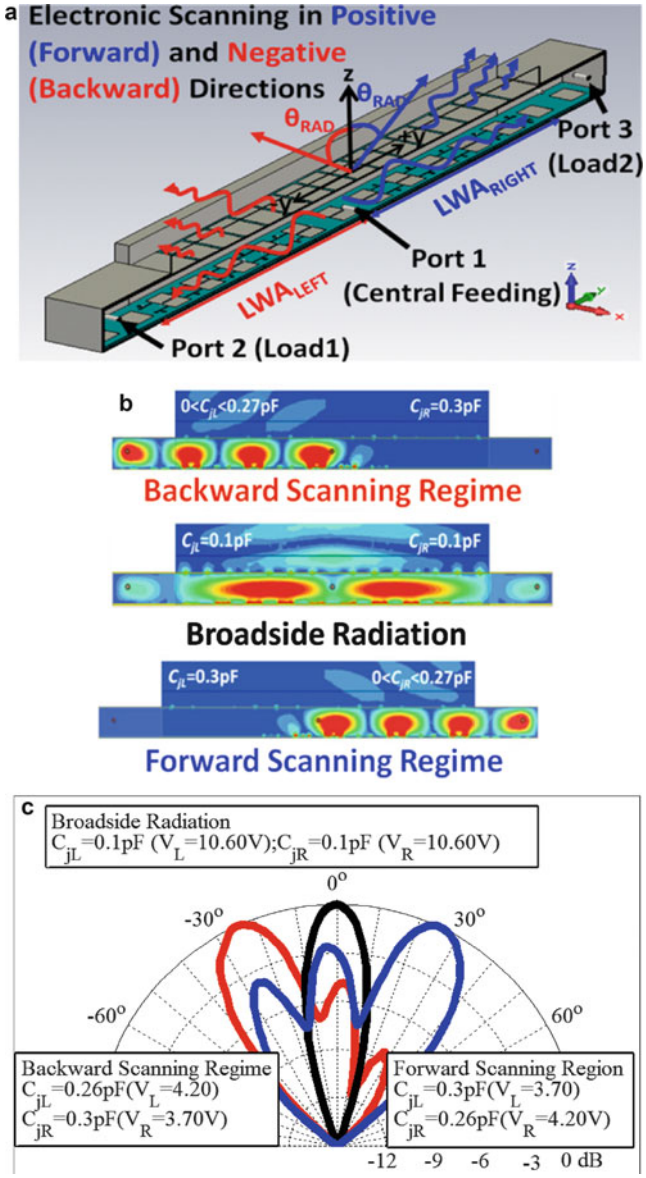

Fig. 34 (**a**) Scheme of full-space scanning 1D FP LWA (**b**) Electric field distribution along the 1D FP LWA structure and (**c**) Measured normalized radiation patterns (H-plane) at different operating regions (5.5 GHz)

For a better physical insight, the electric field distribution inside the Fabry-Pérot cavity is depicted in Fig. 34b for the three operating configurations, showing how the input energy can be routed to the right or left directions depending on the tuning voltage of the varactor diodes. Finally, measured radiation patterns of a fabricated prototype are shown in Fig. 34c, confirming full-space electronic scanning from −25° to +25° at 5.5 GHz.

Full-Space scanning 2D Fabry-Pérot leaky wave antennas

The EBG routing and scanning concepts described earlier can be extended from 1D to 2D Fabry-Pérot leaky wave antennas, so that 2D electronic scanning (azimuth and elevation) is obtained without using phased-arrays (Debogovic and Perruisseau-Carrier 2014). As a proof of the concept, a 2D Fabry-Pérot antenna was designed using a 2D PRS at the top and 2D tunable HIS at the bottom. The varactors have been arranged into four independently biased azimuthal sectors (SA to SD, as shown in the scheme of

DOI 10.1007/978-981-4560-75-7_119-1

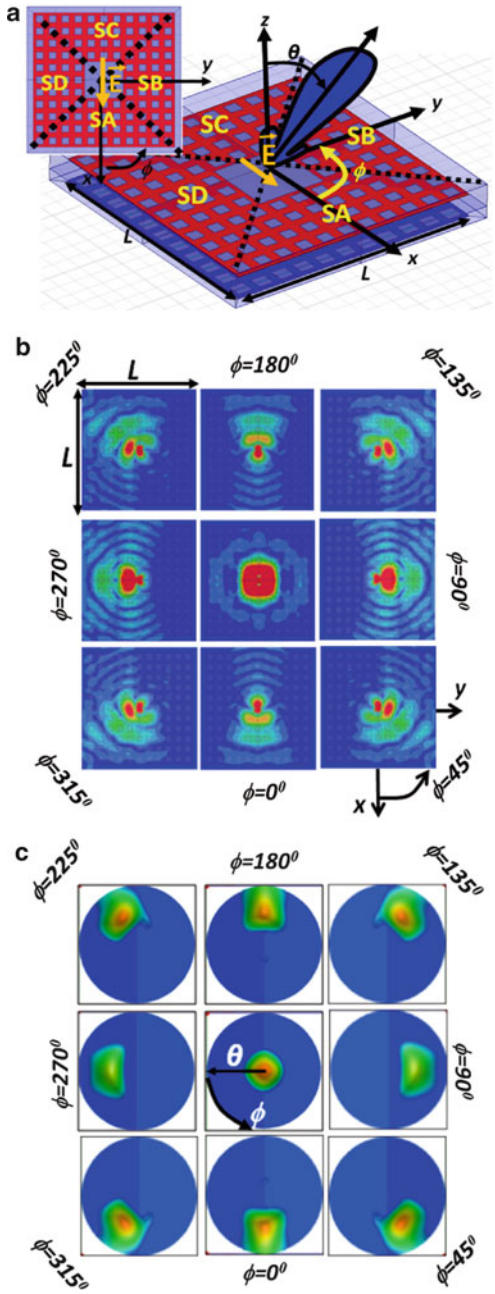

Fig. 35 Extension of the EBG routing mechanism for full-space electronic scanning in 2D FP LWAs: (**a**) HFSS 3D model of the tunable 2D FP ($A = 5.4\lambda_0 \times 5.4\lambda_0$), (**b**) Near fields inside the 2D FP cavity for several configurations of the sectors and (**c**) Radiation pattern in U-V coordinates (θ range represented [0°,45°])

Fig. 35a). In this case, a cylindrical LM is excited at the centre of the 2D Fabry-Pérot cavity by a horizontal dipole oriented along the *x* axis (Fig. 35a). This cylindrical LM is thus TM-polarized in sectors SA and SC (*x*-axis), TE-polarized in sectors SB and SD (*y*-axis), and a hybrid TE/TM LM for other directions (Ip and Jackson 1990). As in the 1D case, the LM will be routed towards a given sector by tuning it into the scanning region while the rest of the sectors are tuned to the EBG region.

Therefore, pencil beams which are scanned in the elevation plane (θ_{RAD}) can be created for discrete azimuthal (ϕ_{RAD}) angles defined by the four sectors. As a result, four radiation regions can be defined according to the direction of propagation of the wave:

DOI 10.1007/978-981-4560-75-7_119-1

(1) Radiation by TM LM propagating along the $\pm x$ axis. SA or SC is active (tuned at the scanning region) while all other sectors are inactive (tuned at EBG region).
(2) Radiation by TE LM propagating along the $\pm y$ axis. SB or SD is active and all other sectors are inactive.
(3) Radiation by hybrid TE/TM LM propagating along the oblique directions when two adjacent sectors are active (configurations SA&SB, SB&SC, SC&SD or SD&SA) and the other two are tuned to the EBG region.
(4) Broadside radiation. Optimal directive pencil beam radiating at boresight can be obtained when all the sectors are active and tuned at or below the splitting condition (Lovat et al. 2006).

Four different configurations of the sectors are illustrated in Fig. 35b, c), showing the simulated near fields inside the 2D Fabry-Pérot cavity and their respective radiation patterns. From the guided fields depicted in Fig. 35b, it is observed how the antenna aperture illumination can be modified by changing the activation of the azimuthal sectors. These illuminations lead to the synthesis of radiated pencil beams which can be steered to discrete azimuthal angles $\phi_{RAD} = [0°, 45°, 90°, 135°, 180°, 225°, 270°, 315°]$. This is demonstrated by the position of the pencil beam in the radiation patterns obtained in Fig. 35c for each sector configuration. Moreover, for any constant azimuthal angle ϕ_{RAD}, tuning of the elevation scanning angle in the range $\theta_{RAD} = [5°, 25°]$ can be obtained, by properly tuning the active sector inside the scanning range. Finally, the broadside case is also obtained when the four sectors are tuned to (or below) the splitting condition, resulting in a cylindrical LM covering all sectors (Fig. 35b) and a pencil beam pointing at boresight (Fig. 35c).

From these results, it is demonstrated that continuous elevation scanning and discrete azimuthal sectorization can be electronically obtained. This requires accurate control of the dispersion properties of TE, TM and hybrid TE/TM cylindrical LMs.

Reconfigurable 1D SIW LWA

Reconfigurable LWAs can also be realized in substrate integrated waveguide (SIW), taking advantage of the planar, low cost, low loss, easy integration with planar circuits, and simple excitation properties of this technology (Xu and Wu 2005). Several reconfigurable LWAs have been proposed in the last decade using metamaterial CRLH microstrip leaky lines (Liu et al. 2002; Lim et al. 2005) in order to obtain electronic beam steering (Liu et al. 2002) or even beamshaping (Lim et al. 2005). In this section, two structures are presented to operate at ISM frequency band (5.5 GHz). The first one is a reconfigurable 1D antenna in SIW technology (1D SIW LWA), which is based on the non-reconfigurable static design presented in (Martínez-Ros et al. 2012a). This design is modified to provide full reconfiguration of its radiation pattern (radiation angle and beamwidth) using two control lines. It must be highlighted that it is the first time that it is demonstrated simultaneous electronic reconfiguration over the scanning angle and the beamwidth, without using complicated metamaterial unit-cells (Lim et al. 2005). The second structure is a radial array of SIW LWAs as originally proposed in (Martínez-Ros et al. 2012b). The introduction of electronic reconfiguration in the 2D LWA provides electronic elevation scanning and azimuth sectorization (as in the 2D FP LWA studied in the previous section), as well as electronic shaping of the pencil beam.

A schematic of the proposed full-reconfigurable 1D SIW LWA is presented in Fig. 36. The antenna consists of a double-layer structure with a ground plane in between. The top layer holds the SIW, which is loaded with a tunable PRS and a tunable HIS in substrate integrated technology. Both PRS and HIS are SIW versions of the Fabry-Pérot sheets. They are made of arrays of metallic posts periodically arranged at a certain distance (called PRS posts and HIS posts in Fig. 36). The PEC plane needed for the HIS is made of a dense arrangement of via-holes at a certain distance D from the HIS posts. Each post is connected by a through via to a varactor diode loaded in a microstrip stub, which is etched to the second layer (the control

DOI 10.1007/978-981-4560-75-7_119-1

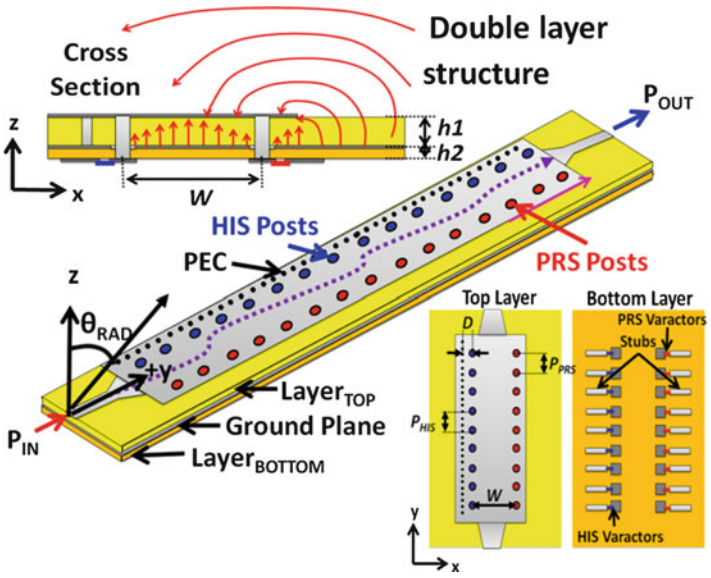

Fig. 36 Schematic of full-reconfigurable 1D SIW LWA: 3D model, cross section and front and rear views of the structure

layer). Teflon substrates with $\varepsilon_r = 2.2$ and thicknesses $h_1 = 3.17$ mm and $h_2 = 0.127$ mm are used for the radiation and control layers, respectively.

The PRS and HIS are separated by a distance W, comprising a resonant cavity that is analogous to the FP air-filled cavities of the antennas presented in the previous section, but in a substrate integrated technology. It is interesting to note that the radiation mechanism of this 1D SIW LWA is quite similar to the previous 1D FP LWA; according to the defined coordinate system, the FP antennas resonate between the PRS-HIS cavity, so the resonance is produced along the z-axis, whereas in the 1D SIW LWA case, this resonance arises along the x-axis. Moreover, in this case the PRS is also a tunable structure, so that it allows electronic control of the leakage rate (α) of the LM which is related to the half-power beamwidth and directivity (Goldstone and Oliner 1959). On the other hand, the tunable HIS controls the scanning angle by altering the LM phase constant (β), as described for the previous FP antennas. Both SIW PRS and HIS are independently biased, to enable independent and simultaneous electronic control of the radiation angle and beamwidth of the scanned fan beam.

A 1D SIW LWA has been simulated at a fixed frequency of 5.5 GHz in order to demonstrate the concept. The antenna length is $L_A = 3\lambda_0$, and it is terminated with a short-circuit load in order to estimate the variations in the leakage rate from the reflected lobe. The tuning parameters which reconfigure the antenna are the varactors' junction capacitances introduced at the HIS and the PRS circuits, C_{jHIS} and C_{jPRS}, respectively. Simulated radiation patterns at 5.5 GHz for six different configurations are presented in Fig. 37. The values of the scanning angle (θ_{RAD}), the normalized attenuation constants (α/k_0), and associated -3 dB beamwidth ($\Delta\theta$), are listed in Table 1 for each case. It is demonstrated that the scanning angle and the beamwidth can be simultaneously controlled by properly adjusting the two independently tunable parameters, namely C_{jHIS} and C_{jPRS}. Particularly, cases 1 and 2 show a beam scanned at $\theta_{RAD} \approx 15°$ with variable beamwidths $\Delta\theta = 11°$ and $\Delta\theta = 36°$, as it can be seen in the radiation patterns of Fig. 37a. The synthesis of narrow and broad beams is repeated for other scanning angles, namely $\theta_{RAD} \approx 24°$ and $\theta_{RAD} \approx 34°$, for cases 3–4 and 5–6, respectively. The normalized leakage rate is estimated for each case, by measuring the level between the main lobe and the mirrored reflected lobe (Goldstone and Oliner 1959). As expected, narrow beams correspond to low leakage rates, while broader beams arise

from increased leakage rate. A one-order-of-magnitude variation in α/k_0 is obtained for all scanning angles. To conclude, these preliminary simulations verify that the proposed tunable 1D SIW LWA allows flexible electronic tuning of the scanning angle and the directivity at a fixed frequency of 5.5 GHz. Future work will provide a more detailed study of the dispersion curves of the antenna with C_{jPRS} and C_{jHIS}, and the optimal design and fabrication of a full prototype.

Summary

In the last decade, substantial achievements on reconfigurable antennas (RAs) have been made and several inherent challenges have been successfully overcome, including the design of dual-band polarization RAs and high-gain beam-steering pattern RAs. Furthermore, the authors of this chapter have employed novel reconfiguration techniques to achieve low-cost, low-loss phase shifters and reconfigurable leaky wave antennas. The reconfigurable defected microstrip structure (RDMS) based phase shifter has demonstrated its capability to realize a compact phased antenna array for beamforming applications. The reconfigurable leaky wave antennas are capable of solving two disadvantages of traditional leaky wave antennas, including the narrow impedance bandwidth and frequency dependent beam scanning. This, in turn, makes the leaky wave antenna more promising for today's wireless communications systems.

Future work in this field includes the design of a RA that can deliver full reconfiguration of the three characteristics of the antenna. Such a RA can bring considerable benefits to many wireless communication systems. However, the strong linkage between an antenna's frequency response and its radiation characteristics makes it extremely challenging to independently control of operating frequency, polarization and radiation pattern. Therefore, new and effective techniques are needed to break the linkage in order to achieve full reconfiguration of an antenna. Another significant direction for future work is the reconfiguration of the entire radio frequency (RF) front-end as well as the signal processing in the physical layer. It is well known that antennas are only one part of the entire transmitter and receiver sub-systems. If reconfigurable antennas are incorporated in wireless communications systems, the other parts of the system should also be capable of reconfiguring their characteristics in order to utilize the diversity derived from antenna agility. As research on these two topics progresses, RAs may play a major role to enhance the performance of the next-generation communications systems significantly.

Abstract

The objective of this chapter is to illustrate that an electromagnetic macro model can accurately predict the dominant component of the propagation path loss for a cellular wireless communication. The reason a macro model can provide accurate results that agree with experiments is because the trees, buildings, and other man-made obstacles contribute second-order effects to the propagation path loss as the dominant component that affects propagation is the free-space propagation of the signal and the effect of the earth over which the signal is propagating. It is demonstrated using both measurements and an analytical theoretical model that the propagation path loss inside a cellular communication cell is first 30 dB per decade of distance, and later on, usually outside the cell, it is 40 dB per decade of the electrical distance between the transmitter and the receiver irrespective of their heights from the ground. This implies that the electric field decays first at a rate of $\rho^{-1.5}$ inside the cell and later on, usually outside the cell, as ρ^{-2}, where ρ stands for the distance between the transmitter and the receiver. This appears to be independent of the frequency of operation in the band of interest and the parameters of the ground. It is also illustrated that the so-called slow fading is due to the interference between the direct wave and the ground wave as introduced by Sommerfeld over 100 years ago. All these statements can be derived from the approximate integration of the Sommerfeld integrals using a modified path for the steepest descent method and also using a purely numerical methodology. Finally, an optical analog is described based on the image theory developed by Van der Pol to illustrate the mechanism of radio wave propagation in a cellular wireless communication system.

developed mainly along mathematical lines, taking for granted the physical significance of the quantities which are fundamental in its formalism. But communication is the transmission of physical effects from one system to another. Hence communication theory should be considered as a branch of physics.

This illustrates that to visualize the physics of the propagation mechanism in cellular wireless communication systems, it is necessary to apply the basic principles of electromagnetic theory as a statistical model is incapable of capturing the fundamentals of propagation with a field decay of $\rho^{-1.5}$ with distance ρ inside the cell. To illustrate this point, various experimental data are presented first. Then an analytical model (Abdallah et al. 2014; Sarkar et al. 2012a, b) is derived from the Sommerfeld integrals to reproduce the experimental data of Okumura et al. (1968) as this is one of the few papers which clearly state the nature of the transmitting and receiving antennas used and in which environment they were operating, thus making it possible for an interested reader to completely duplicate the experiment. Comparison is also made with other experimental data to illustrate the accuracy of the prediction carried out using an electromagnetic macro model based on available computational electromagnetic codes. Thus, it is shown that these electromagnetic analysis codes can provide path loss models which are as good as carrying out real-time path loss measurements using a van and other accompanying equipment which are both very expensive and time consuming. Finally, an optical analog is provided to visualize the actual mode of propagation for the nature of the wave propagation in a cellular environment (Abdallah et al. 2014; Sarkar et al. 2012a, b; De et al. 2010).

Description and Analysis of Measured Data

Figure 12 of Okumura et al.'s classic paper (Okumura et al. 1968), which is presented here as Fig. 1, illustrates quite clearly that for most practical heights of the base station antenna, the decay of the electric field strength is at a rate of $\rho^{-1.5}$ where ρ stands for the distance from the transmitting antenna. As described by Okumura et al. in Fig. 1, it is seen that the decay of the electric field strength inside the cell is at a rate of $\rho^{-1.5}$ or equivalently the power decays as ρ^{-3}, where ρ represents the distance from the transmitter. This translates into a propagation path loss of 30 dB per decade of distance traveled. This conclusion appears to be independent of the frequency of operation.

In Fig. 2, the data from Ericsson for an in-building path loss model is presented. This was shown in chapter 3 of *Mobile Antenna Systems Handbook* (Fujimoto 2008). Figure 2 shows that for the distance between 1 m and 10 m, the path loss is typically 30 dB at 900 MHz, the same value stated earlier by

authors of this article but by the authors of that chapter). If one goes from 100 m to 1000 m, it is seen that the path loss is again 30 dB for the best fit line at 900 MHz as presented in Fujimoto (2008) even though the parameters of the experiment are different from that of Fig. 3.

In 1937, C. R. Burrows from Bell Labs (Burrows 1937) carried out the measurements over Seneca Lake, New York, USA, to find the nature of electromagnetic wave propagation over water at 150 MHz. The transmitting and receiving antennas were placed on two different boats as seen in Fig. 4a. The measured propagation path loss is illustrated in Fig. 4b. Again, it is seen that as one moves from 10 m to 100 m, the path loss is 30 dB and forms 100 m to 1000 m, away from the transmitter, the path loss is 40 dB as mentioned before but this time at 150 MHz.

Next, results are presented displaying actual measurements carried out at different frequencies for three base stations located in dense urban, urban, and suburban environments. The special feature of the data taken in an urban environment was that the houses were not uniformly spaced. First, the results are presented for data taken at the carrier signals of 1800-MHz GSM base station transmitters located in the dense urban/urban environments of New Delhi area belonging to *Idea Cellular Network* which have been monitored with Nokia GSM receiver (model 6150) generally used as a drive-in tool for planning cellular

DOI 10.1007/978-981-4560-75-7_120-1

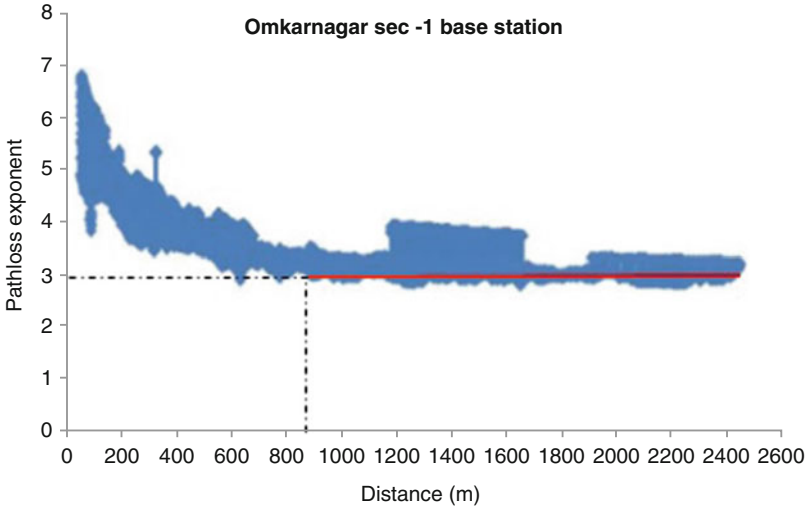

Fig. 5 Variation of path loss exponent with distance for OM-1 base station (1800 MHz). Base station height 24 m

networks along with a GPS receiver to know the latitude and longitude of the mobile. The sensitivity of the receiver is –102 dBm. The transmitting powers of all the base stations are +43 dBm. The receiving equipment was installed in a vehicle along with the data acquisition system. The vehicle moved on a normal road at a permissible speed in the traffic and the downlink signal strength was monitored by the receiver. The observed signal levels were converted into path loss values based on the received signal level, the transmitter power, and the transmitting and receiving antenna gains for further analysis. The gain of the transmitting antenna was 18 dBi. The estimated measurement rms (root mean square) error is around 1.5 dB. The height of the mobile receiving antenna was 1.5 m from the ground.

For the case of the 900-MHz results, the experiment is carried out with the help of *Aircom International Limited*, a UK company based in India. The transmitting power for all the base stations used in this study was 43.8 dBm, and the transmitting antenna gain was 2 dBi for all the base stations. The gain of the receiving antenna was 0 dBi and the height from the ground was 1.5 m. The receiver is a standard Nokia equipment used in drive-in tools used for field trials. For all the measurements, the position of the mobile is determined from the GPS (global positioning system) receiver, and this information with the coordinates of the base station was utilized to deduce the distance traveled by the mobile from the base station. The signal strength information recorded in dBm was converted into path loss values utilizing the gains of the antenna. The data was recorded with 512 samples in one second on a laptop computer, and the number of samples collected for each site varied from 1×10^5 to 2×10^5. Measured rms error was around 1.5 dB. The data was averaged over a conventional range of 40 $\mathscr{W}^o$ where $\mathscr{W}^o$ represents the wavelength.

The first base station operating at 1800 MHz called OM-1 was located in a dense urban environment in the Indian capital city of Delhi, and the height of the transmitting base station antenna was at 24 m from the ground. The variation of the path loss is shown in Fig. 5. It is seen that inside the cell, the path loss has settled down approximately to a factor of 3.

Next, the data at 900 MHz for the base station UA located in a medium urban environment of the Indian capital city of Delhi is shown. The base station antenna is located at a height of 24 m. From Fig. 6, it appears that the path loss exponent factor in the cell has settled down to a value of 3 at around $\frac{4H_{TX}H_{RX}}{\mathscr{W}^o} = \frac{4\times24\times1.5}{1/3} = 432$ m as predicted by the theory (H_{TR} represents the height of the transmitting antenna over the ground, H_{RX} represents height of the receiving antenna over the ground, and $\mathscr{W}^o$ is the wavelength of operation) (De et al. 2010).

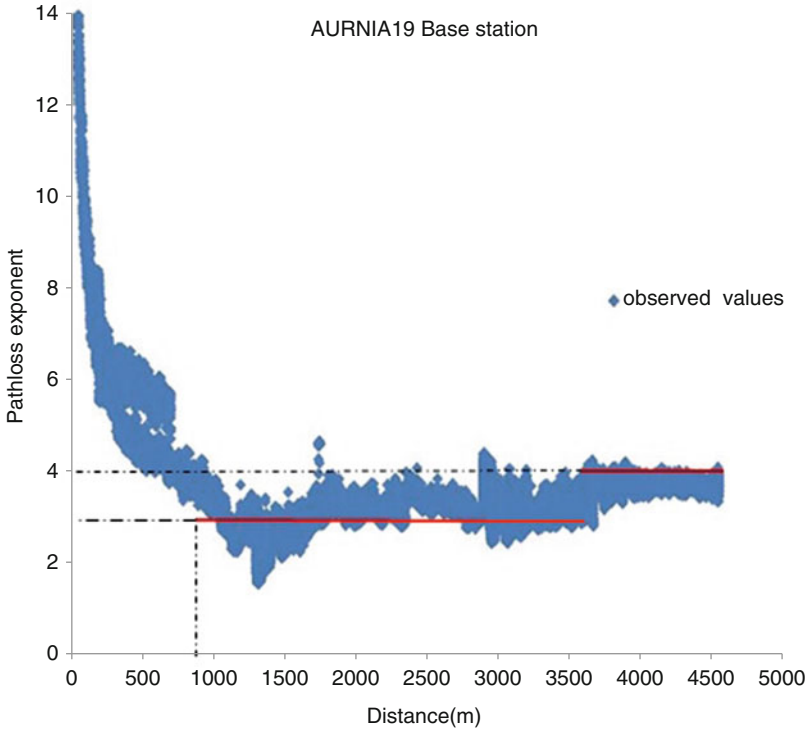

Fig. 7 Variation of path loss exponent with distance for AURNIA 19 base station (900 MHz). Base station height 50 m. Near the transmitter, the path loss exponent has a value of 3 and changing to 4 as one moves further away from the base station

Figure 7 shows the variation of the path loss exponent from the base station AURNIA 19. This station is located in an industrial area in the city of Aurangabad, in the Maharashtra state of western India. The transmitter height was 50 m from the ground and was operating at 900 MHz. The path loss exponent is expected to start at 3 at approximately a distance of $\frac{4H_{TX}H_{RX}}{\mathcal{W}^{\circ}} = \frac{4\times50\times1.5}{1/3} = 900\,\text{m}$ (De et al. 2010) as the operating frequency was 900 MHz. This region starts where the slow fading region ends as illustrated in

DOI 10.1007/978-981-4560-75-7_120-1

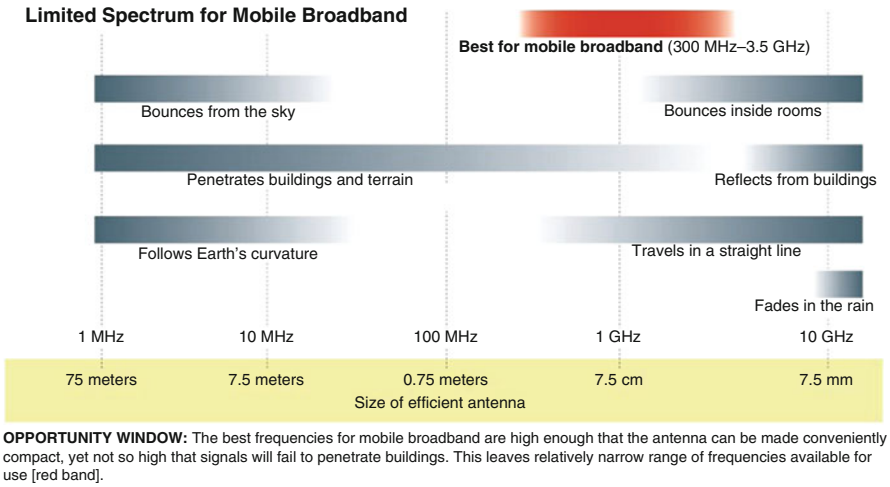

Fig. 8 Suitable bands for mobile communications in the electromagnetic spectrum (Lazarus 2010)

De et al. (2010). After some distance, the path loss exponent gradually increases to 4 in the far-field region, as predicted by theory (De et al. 2010).

All three measurements show that in an intermediate region from the base station antenna, the propagation path loss exponent is 3. Outside that region and far away from the transmitter, the path loss exponent is 4. This is independent of the frequency of operation and also of the ground parameters. This implies that the electric field varies as $\rho^{-1.5}$ inside the cell and in the far-field region, usually outside the cell as ρ^{-2}. Another observation to be made is that at 1000 m from the transmitter, the path loss due to the decay of the free-space fields propagating over earth is 10 $\log_{10}$ ρ^{-3} which is equal to −90 dB. This is quite a large value. Also, the large variation in the experimental data reveals that due to buildings, trees, and so on, the curve is not smooth but has the variability in the path loss exponent as illustrated in the measured data. This variation due to environments is approximately of the order of 30–40 dB. Hence, it is clear that the path loss due to the free-space propagation which is of ~90 dB is of prime importance and the effects of the buildings and the nature of the terrain are secondary as they are ~30–40 dB. Also, the path loss exponent seems to be insensitive to the nature of the ground, be it an urban and suburban grounds or propagation over water. It is also insensitive to the height of the transmitting antenna.

From the above data, it is now asserted that a physics-based electromagnetic macro model can provide accurate predictions for the path loss exponent in a cellular network using electromagnetic simulation tools that depend only on some physical parameters of the macro model and primarily those related to the antennas and the electrical parameters of the ground. In a macro model, one needs to include only the electrical parameters of the environment without including the clutter-effect factors such as buildings, trees, and so on.

Furthermore as illustrated in Lazarus (2010) and displayed in Fig. 8, the reason that the 0.8–2.1-GHz cellular band was chosen for mobile broadband is that the reflection from buildings is negligible, and yet the signals can penetrate buildings and do not significantly bounce inside the rooms. Furthermore in Fig. 9, the one-way attenuation through common building materials illustrates that at the cellular band, signals can penetrate buildings very easily McMillan (2006). Hence, the clutter effects generated by buildings or trees are considered to be second-order effects, as the primary factor influencing propagation is the effect of the imperfectly conducting ground which however is seldom accounted for in any propagation model. Information in Figs. 8 and 9 makes it clear that the use of an electromagnetic macro model for the analysis of the propagation path loss in mobile communication using physical parameters like height, gain, and tilt of an antenna over an imperfect ground can accurately duplicate

DOI 10.1007/978-981-4560-75-7_120-1

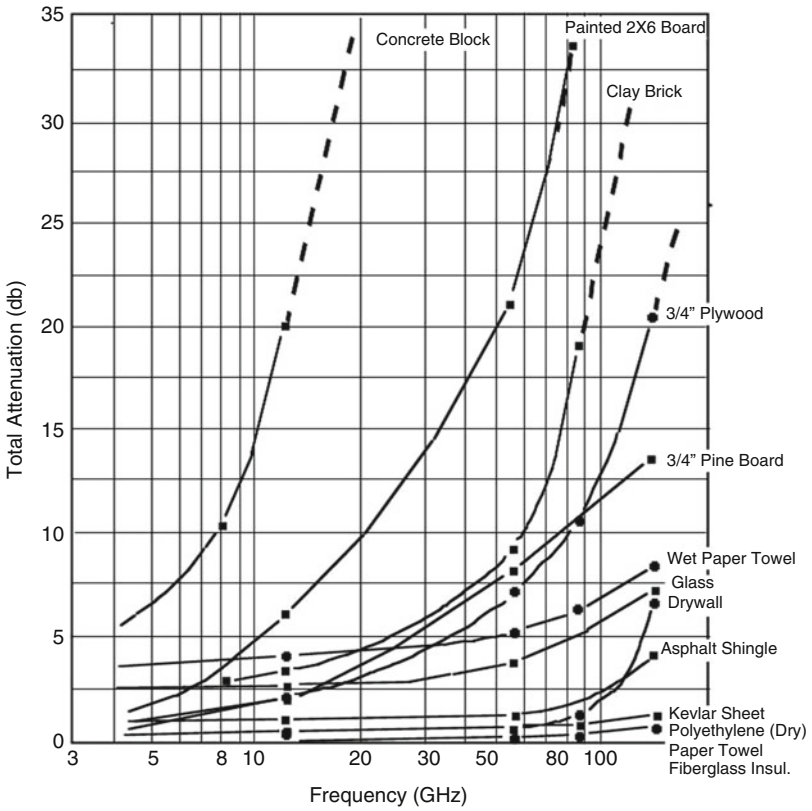

Fig. 9 One-way attenuation through common building materials as a function of frequency (McMillan 2006)

experimental data taken in a real environment. The nonplanar nature of the real ground is deemed not to be a show stopper for the propagation analysis using a macro model as illustrated in Abdallah et al. (2014), Sarkar et al. (2012a, b), and De et al. (2010). It is primarily because of the preponderance of physical evidence that wireless signals penetrate through buildings and do not get reflected significantly from them that an electromagnetic macro model has been proposed based on fundamental physics replacing the statistical models which do not address the underlying electromagnetics, namely, the effect of the propagation over earth!

Typically, in the current state of the art, the drive test data are fit in a least-squares fashion to a statistical model or a ray-tracing scenario is used. The fact of the matter is that current propagation modeling tools cannot capture the fundamental physics, namely, inside a cell, the path loss is typically 30 dB per decade (Abdallah et al. 2014; Sarkar et al. 2012a, b) or equivalently, the electric field strength varies as $\rho^{-1.5}$ with the distance from the antenna ρ, and outside the cell, the propagation path loss is approximately 40 dB per decade or equivalently, the electric field strength varies as ρ^{-2}. Thus, statistical-based models do not capture the basic physics as they are generally devoid of basic physics. Furthermore, it does not make sense to have the path loss exponent tied to a value of a reference distance in the current state-of-the-art ad hoc models which is quite meaningless from a scientific point of view as the propagation effects should be dependent on the physical parameters of the system. In addition, the value of the reference distance should be such that it is located in the far field of the transmitting antenna. But seldom is this ad hoc rule of thumb respected!

Next, the electromagnetic macro model that is going to predict the path loss exponents is presented.

DOI 10.1007/978-981-4560-75-7_120-1

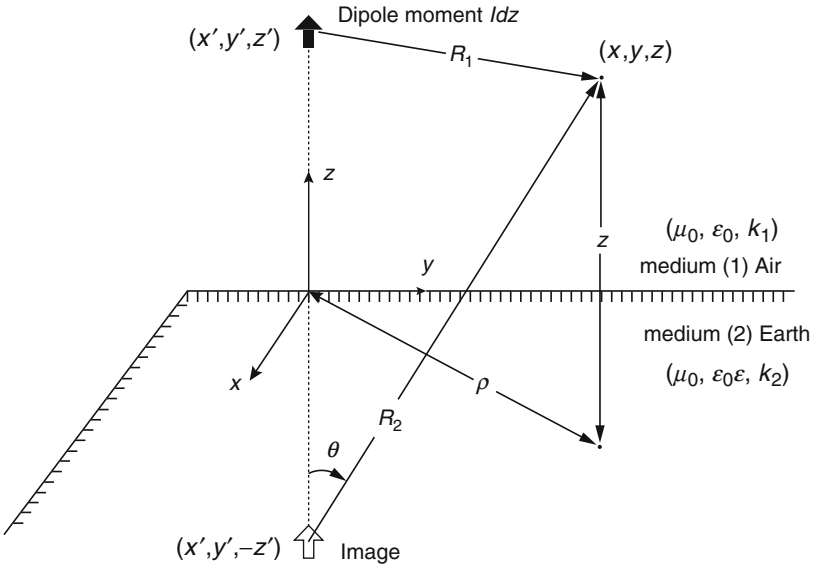

Fig. 10 A vertical dipole over a horizontal imperfect ground plane

Theoretical Analysis of Propagation over Earth

To simulate the electromagnetic propagation path loss in a cellular environment accurately using the physical parameters related to the environment, a method of moment code based on Sommerfeld Green's function to treat the imperfectly conducting planar ground has been used (Sommerfeld 1909; Sarkar 1977; Djordjevic et al. 2002; Dyab et al. 2013; Sarkar et al. 2014). However, an approximate analytical formulation based on integrating the semi-infinite integrals by a modified method of steepest descent is also going to be used in addition to an accurate numerical evaluation which also reaches the same conclusion.

In the original Sommerfeld formulation, one considers an elementary dipole of moment *Idz* oriented along the *z*-direction and located at (x', y', z'). The dipole is situated over an imperfect ground plane characterized by a complex relative dielectric constant ε as seen in Fig. 10. The complex relative dielectric constant is given by $\varepsilon = \varepsilon_r - \frac{j\sigma}{\omega \varepsilon_0}$ where ε_r represents the relative permittivity of the medium, ε_0 is the permittivity of vacuum, σ is the conductivity of the medium, ω stands for the angular frequency, and j is the imaginary unit, i.e., $j = \sqrt{-1}$. It is possible to formulate a solution to the problem of radiation from the dipole operating in the presence of the imperfect ground in terms of a single Hertzian vector potential $\hat{u}_z \Pi_z$ of the electric type, where $\hat{u}_z$ stands for the unit vector in the positive *z*-direction. A time variation of exp ($j\,\omega\,t$) is assumed throughout the analysis, where t is the time variable. The Hertzian vector potential $\hat{u}_z \Pi_z$ in this case satisfies the wave equation

$$\left(\nabla^2 + k_1^2\right)\Pi_{1z} = \frac{-I\,dz}{j\omega\,\varepsilon_0}\,\delta(x - x')\delta(y - y')\delta(z - z') \tag{1}$$

$$\left(\nabla^2 + k_2^2\right)\Pi_{2z} = 0 \tag{2}$$

where

$$k_1^2 = \omega^2 \mu_0 \varepsilon_0 \tag{3}$$

$$k_2^2 = \omega^2 \mu_0 \varepsilon_0 \varepsilon \tag{4}$$

and δ represents the delta function. The primed and unprimed coordinates are for the source and field points, respectively. The subscript 1 denotes the upper half space which is air, and the subscript 2 denotes the lower half space which is the imperfectly conducting earth characterized by a complex relative dielectric constant ε. The electric and the magnetic field vectors are derived from the Hertzian vector potential using

$$\vec{E}_i = \vec{\nabla}\left(\vec{\nabla} \bullet \vec{\Pi}_i\right) + k_i^2 \overrightarrow{\Pi_i} \tag{5}$$

and

$$\vec{H}_i = j\omega\varepsilon_0\varepsilon_i\left(\vec{\nabla} \times \overrightarrow{\Pi_i}\right) \tag{6}$$

respectively, with $i = 1, 2$.

In medium 1, $\varepsilon_1 = 1$, and for medium 2, $\varepsilon_2 = \varepsilon$. So that the propagation constants in mediums 1 and 2, called k_1 and k_2, respectively, are related by $\frac{k_2}{k_1} = \sqrt{\varepsilon}$. At the interface $z = 0$, the tangential electric and magnetic field components must be continuous, conditions which in terms of the Hertzian vector potential components can be written as

$$\frac{\partial \Pi_{1z}}{\partial y} = \varepsilon \frac{\partial \Pi_{2z}}{\partial y} \tag{7a}$$

$$\frac{\partial \Pi_{1z}}{\partial x} = \varepsilon \frac{\partial \Pi_{2z}}{\partial x} \tag{7b}$$

$$\frac{\partial}{\partial y}\left(\frac{\partial \Pi_{1z}}{\partial z}\right) = \frac{\partial}{\partial y}\left(\frac{\partial \Pi_{2z}}{\partial z}\right) \tag{7c}$$

$$\frac{\partial}{\partial x}\left(\frac{\partial \Pi_{1z}}{\partial z}\right) = \frac{\partial}{\partial x}\left(\frac{\partial \Pi_{2z}}{\partial z}\right) \tag{7d}$$

Since all the boundary conditions must hold at $z = 0$ for all x and y, the x and y dependence of the fields on either side of the interface must be the same. Therefore,

$$\Pi_{1z} = \varepsilon \Pi_{2z} \tag{8a}$$

$$\frac{\partial \Pi_{1z}}{\partial z} = \frac{\partial \Pi_{2z}}{\partial z} \tag{8b}$$

The complete solutions for the Hertz vector potentials satisfying the wave Eqs. 1 and 2 and the boundary conditions (8) have been derived by many researchers over the last century. An incomplete partial list (Sommerfeld 1909; Sarkar 1977; Djordjevic et al. 2002; Dyab et al. 2013; Sarkar et al. 2014) that will be

DOI 10.1007/978-981-4560-75-7_120-1

important to our discussions is provided starting with Sommerfeld. The solutions of the Hertz potentials are

$$\Pi_{1z} = P\left[\left[\frac{\exp(-jk_1R_1)}{R_1} + \int_0^\infty \frac{J_0(\lambda\rho)}{\sqrt{\lambda^2 - {k_1}^2}} \frac{\varepsilon\sqrt{\lambda^2 - {k_1}^2} - \sqrt{\lambda^2 - {k_2}^2}}{\varepsilon\sqrt{\lambda^2 - {k_1}^2} + \sqrt{\lambda^2 - {k_2}^2}} \exp\left(-\sqrt{\lambda^2 - {k_1}^2}(z+z')\right)\lambda\, d\lambda\right]\right] \tag{9}$$

and

$$\Pi_{2z} = 2P\int_0^\infty \frac{J_0(\lambda\rho)\exp\left(\sqrt{\lambda^2 - {k_2}^2}z - \sqrt{\lambda^2 - {k_1}^2}z'\right)}{\varepsilon\sqrt{\lambda^2 - {k_1}^2} + \sqrt{\lambda^2 - {k_2}^2}}\lambda\, d\lambda \tag{10}$$

for Real $\left[\sqrt{\lambda^2 - k_{1,2}^2}\right] > 0$. Here,

$$P = \frac{I\, dz}{j\omega 4\pi\varepsilon_0} \tag{11}$$

$$\rho = \sqrt{(x-x')^2 + (y-y')^2} \tag{12}$$

$$R_1 = \sqrt{\rho^2 + (z-z')^2} \tag{13}$$

and λ is the variable of integration. For Π_{1z}, the first term inside the brackets can be interpreted as the particular solution or the direct line-of-sight (LOS) contribution from the dipole antenna source, i.e., a spherical wave or a direct wave originating from the source and reaching to the observation point, and the second term can be interpreted as the complementary solution or a reflection term (reflection from the imperfect ground plane). This second term in the potential, Π_{1z}, is responsible for the fields of the *ground wave*, as per IEEE Standard Definitions of Terms for Radio Wave Propagation (Standards 1998). Observe in Eq. 9 that the second term of this potential is the strongest one near the surface of the earth and exponentially decays as one goes away from the interface.

Similarly, the solution for Π_{2z} can be interpreted as a partial transmission of the wave from medium 1 into medium 2. With these thoughts in mind, the potential Π_{1z} can be split up into two terms or equivalently the potentials responsible for the direct and the ground wave as

$$\Pi_{1z} = \Pi_{1z}^{\text{direct}} + \Pi_{1z}^{\text{reflected}} = P(g_0 + g_s) \tag{14}$$

where

$$\Pi_{1z}^{\text{direct}} = P\exp(-jk_1R_1)/R_1 = Pg_0 \tag{15}$$

$$\Pi_{1z}^{\text{reflected}} = P\int_0^\infty \left(\frac{\varepsilon\sqrt{\lambda^2 - {k_1}^2} - \sqrt{\lambda^2 - {k_2}^2}}{\varepsilon\sqrt{\lambda^2 - {k_1}^2} + \sqrt{\lambda^2 - {k_2}^2}}\right)\frac{J_0(\lambda\rho)\exp\left[-\sqrt{\lambda^2 - {k_1}^2}(z+z')\right]}{\sqrt{\lambda^2 - {k_1}^2}}\lambda\, d\lambda = Pg_s \tag{16}$$

DOI 10.1007/978-981-4560-75-7_120-1

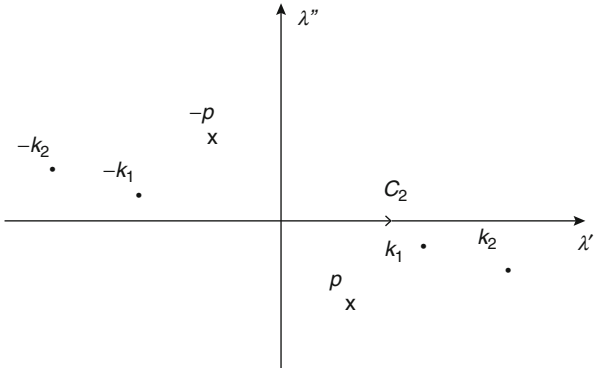

Fig. 11 The contour of integration along the real axis from 0 to ∞ in the complex λ-plane

The path of integration for the semi-infinite integral is labeled C_2 along the positive real axis and is depicted in Fig. 11 along with the singularities of the multivalued function, two branch points at k_1 and k_2 and a pole p arising from the ratio of two functions placed inside brackets in Eq. 16. A physical explanation to the two components of the Hertz potential Π_{1z} can now be given. The first one Π_{1z}^{direct} can be explained as a spherical wave originating from the source dipole. This term is easy to deal with. The difficult problem lies in the evaluation of $\Pi_{1z}^{\text{reflected}}$. Therefore, $\Pi_{1z}^{\text{reflected}}$ is interpreted as a superposition of plane waves resulting from the reflection of the various plane waves into which a spherical wave from the image point can be expanded. This arises from the identity

$$\frac{\exp(-jk_1R_2)}{R_2} = \int_0^\infty \frac{J_0(\lambda\rho)\exp\left[-\sqrt{\lambda^2 - {k_1}^2}(z+z')\right]}{\sqrt{\lambda^2 - {k_1}^2}}\lambda\, d\lambda \tag{17}$$

and

$$R_2 = \sqrt{\rho^2 + (z+z')^2} \tag{18}$$

The term under the integral sign in Eq. 17 can be recognized as a multiple plane-wave decomposition of the spherical wave source. Upon reflection of the plane waves from the dipole source as expressed in $\Pi_{1z}^{\text{reflected}}$, the amplitude of each wave must be multiplied by the reflection coefficient $\Gamma(\lambda)$. The complex reflection coefficient $\Gamma(\lambda)$ takes into account the phase change as the wave travels from the source (x', y', z') to the boundary and then to the point of observation (x, y, z). The reflection coefficient $\Gamma(\lambda)$ is then defined as the term inside the brackets in Eq. 16 as

$$\Gamma(\lambda) = \frac{\varepsilon\sqrt{\lambda^2 - {k_1}^2} - \sqrt{\lambda^2 - {k_2}^2}}{\varepsilon\sqrt{\lambda^2 - {k_1}^2} + \sqrt{\lambda^2 - {k_2}^2}} \tag{19}$$

where the semi-infinite integral over λ in $\Pi_{1z}^{\text{reflected}}$ takes into account all the possible plane waves. As $\varepsilon \to \infty$, i.e., a perfect conductor for the earth, then g_s of Eq. 16 reduces to Eq. 17 and represents a simple spherical wave originating at the image point. The reflection coefficient takes into account the effects of the ground plane in all the waves' decomposition of the spherical wave and sums it up as a ray originating from the image of the source dipole but multiplied by a specular reflection coefficient $\Gamma(\theta)$, where $\Gamma(\theta) = \frac{\cos\theta - \sqrt{\varepsilon - \sin^2\theta}}{\cos\theta - \sqrt{\varepsilon - \sin^2\theta}}$ and θ is illustrated in Fig. 10.

DOI 10.1007/978-981-4560-75-7_120-1

It is now important to point out that there are two forms of $\Pi_{1z}^{\text{reflected}}$ that may be used interchangeably as the two expressions are mathematically identical in nature (but have different asymptotic properties as will be illustrated).

The first one is defined as

$$\Pi_{1z}^{\text{reflected}} = P\left[\frac{\exp(-jk_1R_2)}{R_2} - 2\int_0^\infty \frac{\sqrt{\lambda^2-k_2{}^2}}{\sqrt{\lambda^2-k_1{}^2}} \frac{J_0(\lambda\rho)\exp\left[-\sqrt{\lambda^2-k_1{}^2}(z+z')\right]}{\varepsilon\sqrt{\lambda^2-k_1{}^2}+\sqrt{\lambda^2-k_2{}^2}}\lambda\, d\lambda\right] \underline{\Delta}\, P[g_1 - g_{sV}] \tag{20}$$

where g_1 represents the spherical wave originating from the image of the source and g_{sV} represents the correction factor to accurately characterize the effects of the ground.

Equivalently, one can rewrite the same expression as

$$\Pi_{1z}^{\text{reflected}} = P\left[-\frac{\exp(-jk_1R_2)}{R_2} + 2\varepsilon\int_0^\infty \frac{J_0(\lambda\rho)\exp\left[-\sqrt{\lambda^2-k_1{}^2}(z+z')\right]}{\varepsilon\sqrt{\lambda^2-k_1{}^2}+\sqrt{\lambda^2-k_2{}^2}}\lambda\, d\lambda\right] \underline{\Delta}\, P[-g_1 + G_{sV}] \tag{21}$$

Now, the image from the source has a negative sign along with the correction factor. This expansion is useful when both the transmitter and the receiver are close to the ground, since the reflection coefficient $\Gamma(\theta)$, is -1 for grazing angle of incidence where $\theta \approx \pi/2$. Then the direct term g_0 cancels the image term g_1 leaving only the correction factor G_{sv}.

In Sommerfeld's 1909 paper, he changed the limits of the integration from 0 to ∞ in Eq. 20 to an integral from $-\infty$ to $+\infty$ by transforming the Bessel function of the first kind and zeroth order to a combination of Hankel functions of the first and second kinds and zeroth order through the use of the following identity

$$J_0(x) = \frac{1}{2}\left[\mathrm{H}_0{}^{(1)}(x) + \mathrm{H}_0{}^{(2)}(x)\right] \tag{22}$$

and also utilizing

$$\mathrm{H}_0{}^{(1)}\left(xe^{j\pi}\right) = -\mathrm{H}_0{}^{(2)}(x) \tag{23}$$

where $H_0{}^{(1)}$ and $H_0{}^{(2)}$ are the Hankel functions of zeroth order and of first and second kinds, respectively. Thus, Sommerfeld closed the path integral C_2 of Fig. 11 by using the contour as shown in Fig. 12 where he also plotted the locations of the branch points k_0 and k_1, and the pole p for the term $\Pi_{1z}^{\text{reflected}}$. Also shown in Fig. 12 are the two appropriate branch cuts and a path encircling the pole.

The crux of the problem lies in the characterization of the various branch points and singularities associated with Eq. 19. The first point to observe is that the second term of the Hertz potential denoted by a complex integral and particularly $\Gamma(\lambda)$ has four branch points located at $\pm k_1$ and $\pm k_2$. Associated with these branch points are four branch cuts and this gives rise to four Riemann sheets. On the four Riemann sheets, the following conditions are satisfied:

Sheet 1: Real $(\sqrt{\lambda^2-k_1{}^2}) > 0$ and Real $(\sqrt{\lambda^2-k_2{}^2}) > 0$
Sheet 2: Real $(\sqrt{\lambda^2-k_1{}^2}) < 0$ and Real $(\sqrt{\lambda^2-k_2{}^2}) > 0$

DOI 10.1007/978-981-4560-75-7_120-1

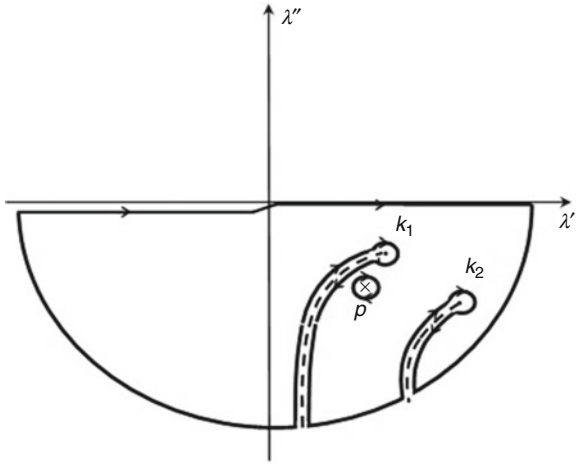

Fig. 12 Actual location of the pole in the lower complex λ-plane

Sheet 3: Real $(\sqrt{\lambda^2 - {k_1}^2}) > 0$ and Real $(\sqrt{\lambda^2 - {k_2}^2}) < 0$
Sheet 4: Real $(\sqrt{\lambda^2 - {k_1}^2}) < 0$ and Real $(\sqrt{\lambda^2 - {k_2}^2}) < 0$

Sheet 1 is the proper Riemann sheet. Now, the function described in Eq. 19 has two zeros corresponding to the zeros of the numerator, usually called Brewster zeros, and two poles corresponding to the zeros of the denominator, usually called the surface wave poles. The zeros and poles occur exactly at the same location $\lambda_S = \pm \frac{k_1 k_2}{\sqrt{k_1^2 + k_2^2}}$. However, on some Riemann sheets, they appear as poles and on other Riemann sheets as zeros. So, the four poles and zeros are distributed on the four Riemann sheets. The most confusing stuff is that on the proper Riemann sheet whether it will be a pole or zero depends on the value of the dielectric constant ε. For example, examining the denominator of $\Gamma(\lambda)$, one can observe that for real values of ε on the proper Riemann sheet, there is a zero at λ_s. Whereas for a complex value of the dielectric constant ε, that zero becomes a pole on the proper Riemann sheet. Therefore, unless one specifies the values for the dielectric constant and chooses the proper Riemann sheet, it is difficult to know whether the pole will occur or not on the proper Riemann sheet in the presentation of Eq. 19.

The zero of the reflection coefficient in Eq. 19 illustrates the Brewster's phenomenon (i.e., the wave goes into the second medium for a particular angle of incidence without reflecting any energy), and a pole for the reflection coefficient illustrates the presence of a surface wave (i.e., a wave propagating close to the interface). Also, in general, it is difficult to distinguish between a Zenneck wave and a surface wave as both decay exponentially as one moves away from the planar interface and the wave propagates with a low loss along the radial direction (Sarkar et al. 2014). In addition, it is well known that the Brewster's angle which illustrates that a wave will penetrate into the second medium without reflection is independent of frequency, whereas the surface wave phenomenon is highly dependent on frequency. As the frequency increases, the fields of the wave are more confined to the planar boundary. In addition, a surface wave does not radiate, whereas a Zenneck wave does. These points have been illustrated in Sarkar et al. (2014).

In the original Sommerfeld formulation (Sommerfeld 1909), there was no error in the sign, but the presentation by Sommerfeld was not complete. First, of all Sommerfeld demonstrated in his expression, there was a pole, and he wrote the partial solution – the contribution from the pole and associated with that some physical properties. However, as has been pointed out in Abdallah et al. (2014), Sarkar et al. (2012a, b, 2014), and Dyab et al. (2013) and illustrated in Fig. 12 that when $\varepsilon_r > 0$, the pole should lie within the circle defined by the locus whose center is at $\lambda = 0$ and of radius k_1. In addition, when the integration along

DOI 10.1007/978-981-4560-75-7_120-1

the branch cut is evaluated using the saddle point method, part of this branch cut integral actually cancels the contribution from the pole, and so in the final solution, the effect of the pole is not seen! This has been explicitly demonstrated in Collin (2004), and so the conjecture that there was an error in sign in Sommerfeld's formulation as initially intimated by Norton is a myth! The fact that the pole does not contribute to the total solution makes sense as in some cases the poles may not exist on the proper Riemann sheet, as can be demonstrated particularly for real values of the dielectric constant. Also, when the hyperbolic branch cuts in the Sommerfeld's solution are replaced by vertical branch cuts, the poles migrate into a different Riemann sheet and are not relevant (Ishimaru 1991; Baños 1966)!

The integral in Eq. 20 can be simplified by making the following substitutions (Sarkar et al. 2012a, b, 2014):

$$\lambda = k_1 \sin\beta \tag{24}$$

$$\rho = R_2 \sin\theta \tag{25}$$

$$z + z' = R_2 \cos\theta \tag{26}$$

The interpretation of the angle θ is shown in Fig. 10. Hence, the application of Eqs. 23, 24, 25, and 26 to 19 yields

$$g_{sV} \approx \int_{\Gamma_1} \left[\frac{2k_1 \sin\beta}{\pi R_2 \sin\theta}\right]^{1/2} \frac{\sqrt{\varepsilon - \sin^2\beta}}{\varepsilon\cos\beta + \sqrt{\varepsilon - \sin^2\beta}} \cdot \exp[j\{\{-\pi/4 - k_1 R_2 \cos(\beta - \theta)\}\}]d\beta \tag{27}$$

where Γ_1 is a path in the complex β plane as shown in Fig. 13. The application of Eqs. 24 to 26 to 29 yields

$$g_{sV} \approx \int_{\Gamma_1} e^{-j\pi/4} \sqrt{\frac{2k_1 \sin\beta}{\pi R_2 \sin\theta}} \frac{\sqrt{\varepsilon - \sin^2\beta}}{\varepsilon\cos\beta + \sqrt{\varepsilon - \sin^2\beta}} \exp[-jk_1 R_2 \cos(\beta - \theta)]d\beta \tag{28}$$

where Γ_1 is a path in the complex β plane as shown in Fig. 13. The path of steepest descent never crosses any of the poles.

In order to solve for the total field near the interface, a modified saddle point method as explained in Sarkar et al. (2012a, b) is applied to take into account the effect of the pole β_P near the saddle point. In the expression of both g_{sV} and G_{sV} in Eqs. 20 and 21, there is a pole β_P, resulting in

$$\frac{1}{\left[\varepsilon\cos\beta + \sqrt{\varepsilon - \sin^2\beta}\right]} = \frac{1}{\varepsilon^2 - 1} \frac{\sqrt{\varepsilon - \sin^2\beta} - \varepsilon\cos\beta}{\sin(\beta + \beta_P)\sin(\beta - \beta_P)} \tag{29}$$

where $\varepsilon\cos\beta_P + \sqrt{\varepsilon - \sin^2\beta_P} = 0$ with $\sin\beta_P = \pm\sqrt{\frac{\varepsilon}{\varepsilon+1}}$ and $\cos\beta_P = -\sqrt{\frac{1}{\varepsilon+1}}$. One obtains for G_{sV}, applying a modified saddle point integration (Sarkar et al. 2012a, b) to obtain

DOI 10.1007/978-981-4560-75-7_120-1

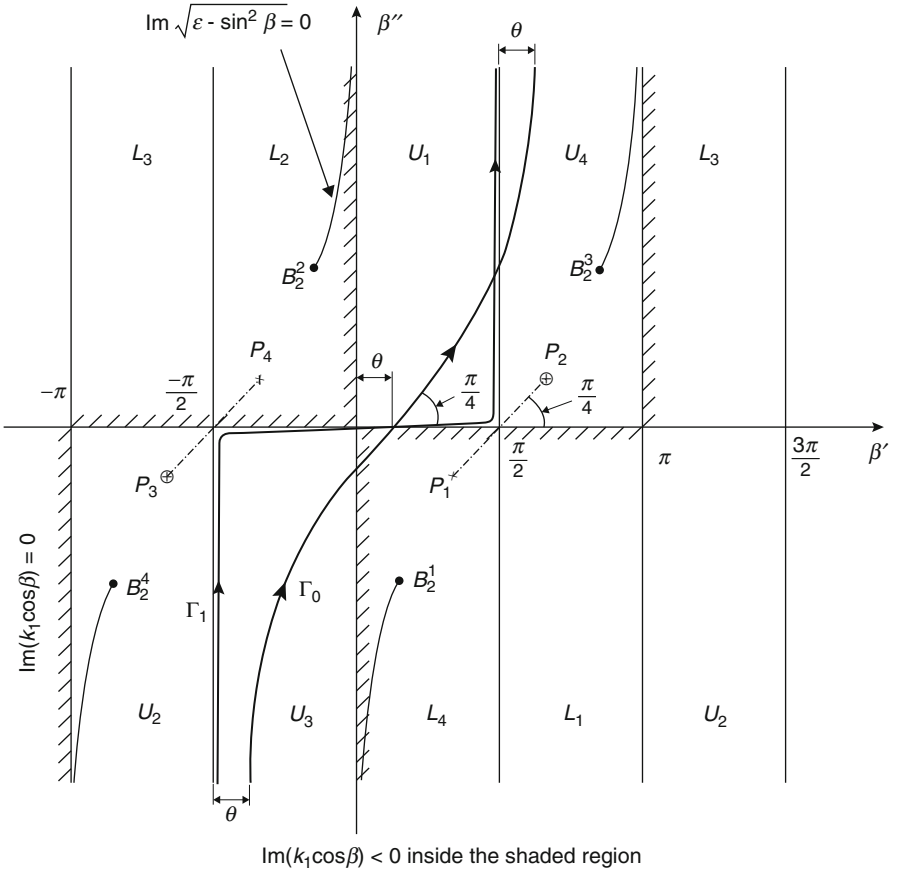

Fig. 13 The complex β plane showing possible branch points, branch cuts, poles, and the path of steepest descent for an imperfect ground plane with the material parameters $\varepsilon = \varepsilon'(1-j)^2$ and $|\varepsilon| >> 1$

$$G_{sV} = \varepsilon \exp\left(-j\tfrac{\pi}{4}\right) \int_{\Gamma_1} \left(\frac{2k_1 \sin\beta}{\pi R_2 \sin\theta}\right)^{1/2} \frac{\exp[-jk_1R_2\cos(\beta-\theta)]\cos\beta}{\varepsilon\cos\beta + \sqrt{\varepsilon - \sin^2\beta}}\, d\beta$$
$$\approx \varepsilon\sqrt{\frac{4\pi k_1 j}{R_2}}\, \frac{\cos\theta}{\cos\theta - \dfrac{1}{\sqrt{\varepsilon+1}}}\, \frac{\sqrt{\varepsilon - \sin^2\theta} - \varepsilon\cos\theta}{\varepsilon^2 - 1}\, \frac{\exp\left[-jk_1R_2 - W^2\right] erfc(jW)}{\sqrt{1 + \dfrac{\cos\theta}{\sqrt{\varepsilon+1}} + \dfrac{\sqrt{\varepsilon}\sin\theta}{\sqrt{\varepsilon+1}}}} \tag{30}$$

where

$$W^2 = -jk_1R_2\, 2\sin^2\left(\frac{\theta - \beta_P}{2}\right) = -jk_1R_2\left[1 + \frac{\cos\theta}{\sqrt{\varepsilon+1}} - \frac{\sqrt{\varepsilon}\sin\theta}{\sqrt{\varepsilon+1}}\right] \tag{31}$$

Here, W was termed by Sommerfeld (1909) the numerical distance. If $|\varepsilon| >> 1$, $\theta \approx \pi/2$, and W is very small, then one obtains $\exp\left[-W^2\right] erfc(jW) \approx 1$. Under this assumption, a simplified expression for G_{sV} can be obtained and is given by Sarkar et al. (2012a)

$$G_{sV} \approx -\sqrt{\frac{2\pi k_1 j}{R_2}} \exp[-jk_1R_2]\, \frac{(z+z')}{R_2}\, \frac{\varepsilon}{\sqrt{\varepsilon^2 - 1}} \approx -\sqrt{2\pi k_1 j}\, \frac{(z+z')\exp[-jk_1R_2]}{R_2^{1.5}}. \tag{32}$$

DOI 10.1007/978-981-4560-75-7_120-1

Equation 32 thus illustrates that when $\theta \approx \pi/2$, the dominant term of the potential $\Pi_{1z} \propto {R_2}^{-1.5}$ and therefore the leading term for the fields will also be varying approximately as $\rho^{-1.5}$, if $(z + z')$ is small compared to ρ in Eq. 32. It is interesting to observe that Eq. 32 is not a function of the ground parameters nor of the frequency of operation. So under these conditions, the path loss exponent factor should be 3 near the ground, as the field varies as $\rho^{-1.5}$. Also, the reflection coefficient method is not applicable, under those circumstances. This is the situation corresponding to cellular communication systems. These results are in accordance with the case of an imperfectly conducting ground as mentioned by Stratton (1941) since the reflection coefficient is approximately +1 for a perfectly conducting ground when the fields are observed far from the ground and it transforms to -1 when the fields are observed near the ground, i.e., for $\theta \approx \pi/2$. This particular variation of the field near an imperfect ground will be verified by an accurate numerical analysis and experimental data in the next sections.

The previous results are valid for small values of W. However, as W becomes large, then

$$\exp\left[-W^2\right] erfc(jW) \approx \frac{-j}{W\sqrt{\pi}}\left[1 + \frac{1}{2\,W^2}\right] \tag{33}$$

for

$$|W| \to \infty \tag{33}$$

and

$$|\arg\, W| < \frac{3\pi}{4} \tag{33}$$

and for $|\varepsilon| >> 1$, $W^2 \approx \frac{-j\,k_1 R_2}{2\,\varepsilon}$. Under this condition,

$$G_{sV} \approx 2\sqrt{\varepsilon}\exp[-jk_1R_2]\,\frac{(z+z')}{R_2^2}\left[1 - \frac{\varepsilon}{j\,k_1R_2}\right] \tag{34}$$

Thus, the total Hertz potential in medium 1, which is valid near the interface, for $|\varepsilon| >> 1$ and $\theta \approx \pi/2$ becomes

$$\Pi_{1z} \approx \begin{cases} P\left[\dfrac{\exp(-jk_1R_1)}{R_1} - \dfrac{\exp(-jk_1R_2)}{R_2} - \sqrt{j2\pi k_1}(z+z')\dfrac{\exp(-jk_1R_2)}{{R_2}^{1.5}}\right], & W < 1 \\ P\left[\dfrac{\exp(-jk_1R_1)}{R_1} - \dfrac{\exp(-jk_1R_2)}{R_2} + 2\sqrt{\varepsilon}(z+z')\dfrac{\exp(-jk_1R_2)}{{R_2}^2}\left[1 - \dfrac{\varepsilon}{jk_1R_2}\right]\right], & W > 1 \end{cases}$$

Next, one can observe that as one moves further away from the source (i.e., for $W > 1$), the dominant term of the field near the interface decays asymptotically as $1/R^2$ as the first two terms cancel each other. A wave with such a decay can be recognized as a Norton surface wave. It is important to note that the third term for $W > 1$, i.e., the Norton surface wave term, shows up only in the far-field region. Note also that it provides the so-called height gain for the transmitting and receiving antennas and that, consequently, this height gain only applies to the intermediate and in the far-field regions. Also, in the far field, the ground parameters do influence the result. Finally, it can also be seen that there is a higher-order term which decays as $1/R^3$, which also shows the height gain and the influence of the ground parameters.

As mentioned before, in the intermediate region, i.e., the region before the far-field region, the fields decay as approximately $\rho^{-1.5}$ (when the height of the antenna is small compared to the distance from the antenna). Also, for $W < 1$, the above expression is independent of the ground parameters and of the

DOI 10.1007/978-981-4560-75-7_120-1

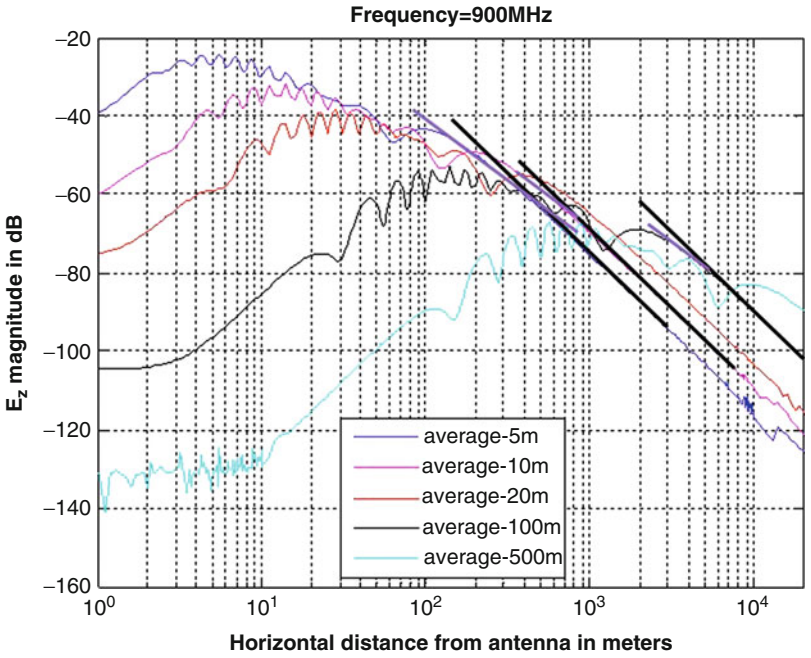

Fig. 14 Magnitude of the z-component of the electric field in dB radiated from a half-wave dipole antenna over an average imperfect ground $\varepsilon_r = 15$ and $\sigma = 0.005$ mhos/m, different curves belong to different heights above the imperfect ground, and the frequency of operation is 900 MHz

frequency of operation. This is the reason why for all the measurements carried out for a cellular wireless system the propagation path loss is 30 dB per decade as illustrated in section "Description and Analysis of Measured Data," irrespective of whether the system is located in an urban, suburban, or rural area, and this holds even when the transmit/receive system is located over water.

Next, the exact Green's function in Eq. 14 is calculated accurately using a computational electromagnetic code evaluating the semi-infinite integral in Eq. 9 in an essentially exact way. This is carried out by using the commercially available code AWAS (Djordjevic et al. 2002). As an example, consider a vertically oriented half-wave dipole located at different heights over an average ground with parameters for the permittivity $\varepsilon_r = 15$ and $\sigma = 0.005$ mhos/m, where the ground parameters were taken from De et al. (2010). The frequency of operation was 900 MHz. Figure 14 plots the field strength as a function of the radial distance for different heights of the antenna above the ground. In this figure, it is seen that near the transmitting antenna, there is the interference between the direct space wave and the field from the image produced by the imperfect ground, providing variation of the total field strength. This is often labeled as fading. This interference pattern stops at an approximate distance of $\frac{4H_{TR}H_{RX}}{\mathcal{W}^o}$, and a monotonic decay of the fields occurs with a slope of 30 dB per decade and continues approximately to a distance of $\frac{8H_{TR}H_{RX}}{\mathcal{W}^o}$ from where the far field of the antenna starts and the slope becomes roughly 40 dB per decade (De et al. 2010). In Fig. 14, the slope of 30 dB per decade is marked by a thick purple straight line, and the slope of 40 dB per decade is marked by a thick black straight line. Observations seem to verify this prediction carried out by the electromagnetic macro model (De et al. 2010). There is a height gain in the far field of the antenna, but in the near field which is of importance in cellular communication, there is actually a height loss. Hence, it is proposed that a better solution will then be to deploy the transmitting antenna closer to the ground. In that case, the region of the variation in the field strength would be quite small, and the field strength will decay monotonically inside the remainder of the cell minimizing fading. Since there will not be any interference pattern and thus no slow fading, then it is possible to reduce the transmitting power at least by a factor of 10 (say) providing a better safe and cheaper system as in most

DOI 10.1007/978-981-4560-75-7_120-1

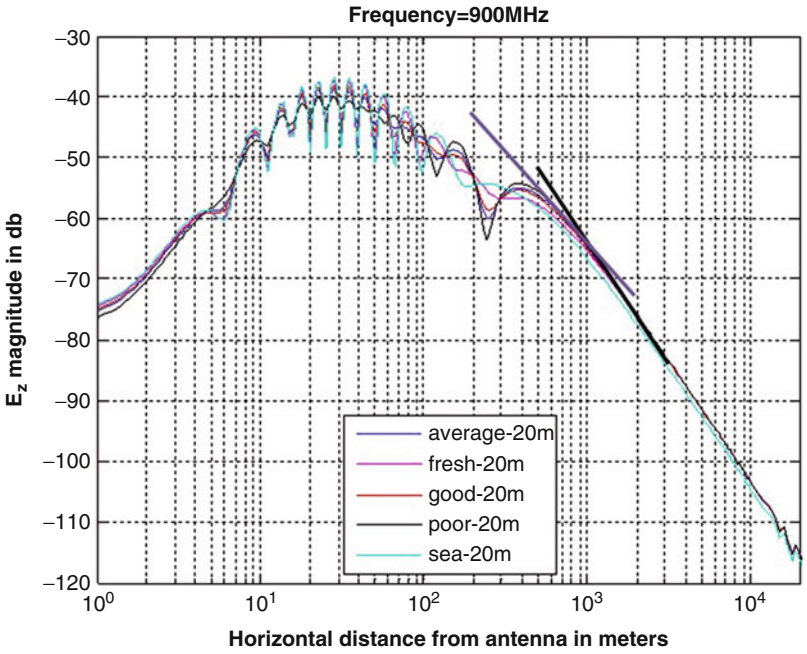

Fig. 15 Magnitude of the z-component of the electric field in dB radiated from a half-wave dipole antenna over different imperfect grounds, height of the antenna is 20 m, different curves belong to different imperfect grounds, and the frequency of operation is 900 MHz

cases the tower costs more than the antenna system. However, one could deploy more base stations as the transmitting power for each antenna is significantly reduced. An interesting scenario of this can be seen perhaps in some South American cities where Wi-Fi is delivered to individual houses by deploying base station antennas on every lamp post. Such a discussion is quite relevant as there is a second channel from the mobile to the base station in which there is no height gain as the mobile is near the ground and the mobile is transmitting a fraction of the power of the base station. Moreover, the antenna on the mobile can be oriented in any direction, and hence, one should question the validity of the state-of-the-art rules of thumb developed for deploying base station antennas as they do not consider the environment of the second mobile channel which is quite important and which does not satisfy any of the rules of thumb associated with the deployment of base stations!

Figure 15 shows another simulation result for a vertical half-wave dipole located 20 m above different types of imperfect grounds. The frequency of operation was 900 MHz. The ground parameters chosen were for the poor ground with a dielectric permittivity and a conductivity of $\varepsilon_r = 4$ and $\sigma = 0.001$ mhos/m, for the average ground, $\varepsilon_r = 15$ and $\sigma = 0.005$ mhos/m, for the good ground $\varepsilon_r = 25$ and $\sigma = 0.02$ mhos/m, for the sea water $\varepsilon_r = 81$ and $\sigma = 5$ mhos/m, and for the fresh water $\varepsilon_r = 81$ and $\sigma = 0.01$ mhos/m. The ground parameters were taken from De et al. (2010). By observing the plots in Fig. 15, it is seen that within the cell, the electrical properties of the ground have very little effects as for a fixed height of the transmitting antenna radiating over an imperfect ground, the ground parameters do not change the nature of the distant fields, whereas near the antenna, the shape of the interference pattern can be slightly different. In Fig. 15, the slope of 30 dB per decade is marked by a thick purple straight line, and the slope of 40 dB per decade is marked by a thick black straight line. This implies that whether we consider propagation in urban, suburban, industrial, rural, or over water, the results for the fields should not differ too much from each other, and furthermore, an electromagnetic macro model can accurately make such predictions!

Experimental Validation of the Theoretical Analysis of Sommerfeld Using Okumura et al.'s Measurement Data

The analysis presented is now used for the analysis of the propagation data measured by Okumura et al. (1968) in their classic propagation measurements in the city of Tokyo. Okumura et al. placed a transmitting antenna at different heights. The specific height that will be chosen for the simulation for comparison with experimental data is 140 m. The signal is received by another vertically polarized antenna located on top of a van 3 m above the ground. The receiving antenna had a gain of 1.5 dB. The transmitting antenna was a 5-element Yagi having a gain of approximately 11 dB and radiating 150 W of power. The van was then driven in the city of Tokyo from 1 km to 100 km from the transmitting antenna. Here, the measurements are carried out at 453 MHz. Since the 5-element Yagi was an antenna composed of wires, in the current simulations, an optimized 5-element Yagi antenna array which had a gain of 11 dB was used. In this analysis, the Yagi antenna was synthesized and was used in the computations. First, the integral equation using the Green's function was used to solve for the current distribution on the transmitting antenna, and then these currents were used to compute the radiating fields (Sarkar 1977). The radiating fields are calculated using the new Green's function (Schelkunoff formulation) (Dyab et al. 2013) instead of using the classical Sommerfeld Green's function in a code that has been already developed for the analysis of radiation over imperfect ground planes based on Sommerfeld integrals. An example for such a code is AWAS (Djordjevic et al. 2002). The parameters for the urban ground were relative permittivity of $\varepsilon_r = 4$ and $\sigma = 2 \times 10^{-4}$ mhos/m (De et al. 2010). However, since one did not know how Okumura et al. matched their antennas and how it was exactly fed, and with not knowing how much power was being radiated by their antenna, first, a simple 1 V excitation was applied to the Yagi antenna for the simulation. Then all of the computed filed points were scaled up simultaneously by adding a constant value of decibels (98 dB) to the computed results, so that the two different plots (the simulated and the measurement) exactly matched at one point at 7 km as shown in Fig. 16a. Then the various plots are overlaid without any further massaging of the data and all the plots of the theoretical predictions by both the new Schelkunoff formulation (Sarkar et al. 2014) and the classical Sommerfeld formulation (Djordjevic et al. 2002), all scaled up by the value of 98 dB, and plotted along with Okumura et al.'s experimental data. The plots show remarkable similarity. It is interesting to note that the simulation using the Schelkunoff Green's function provided a more stable qualitative plot of the field from 1 km to 100 km from the base station antenna. The results were computed for this analysis by using the commercially available computer code called *analysis of wire antennas and scatterers* (AWAS) (Djordjevic et al. 2002) using the Sommerfeld formulation and the new Schelkunoff formulation (Sarkar et al. 2014). In summary, the three plots in Fig. 16 compare between the experimental (Okumura et al. 1968) and theoretical predictions (Schelkunoff and Sommerfeld formulations) computed through a macro model for predicting propagation path loss in an urban environment at (a) 453 MHz, (b) 922 MHz, and (c) 1920 MHz. In AWAS, the results for the fields became somewhat unstable when the horizontal distance from the transmitting antenna becomes quite large, say greater than 10 km. This is due to the Sommerfeld integral tail problem which is totally eliminated in the new formulation (Dyab et al. 2013). It is also important to point out that for both the theoretical and experimental data, the slope for the path loss exponent between 1 km and 10 km is about 30 dB per decade, which was expected from the theoretical analysis using the saddle point method in Sarkar et al. (2012a, b). The slope between 10 km and 100 km is 40 dB per decade, as predicted by the Norton ground wave for the far field. This illustrates that an accurate electromagnetic macro modeling of the environment is sufficient to predict the path loss as evidenced by the comparison between theory and experiment. To compare with the experimental data, a power adjustment was made to the theoretical graphs to compensate for the different input power levels. In Fig. 16b, 130 dB is added to the theoretically computed data, and in Fig. 16c, 125 dB is added to the theoretically computed data to

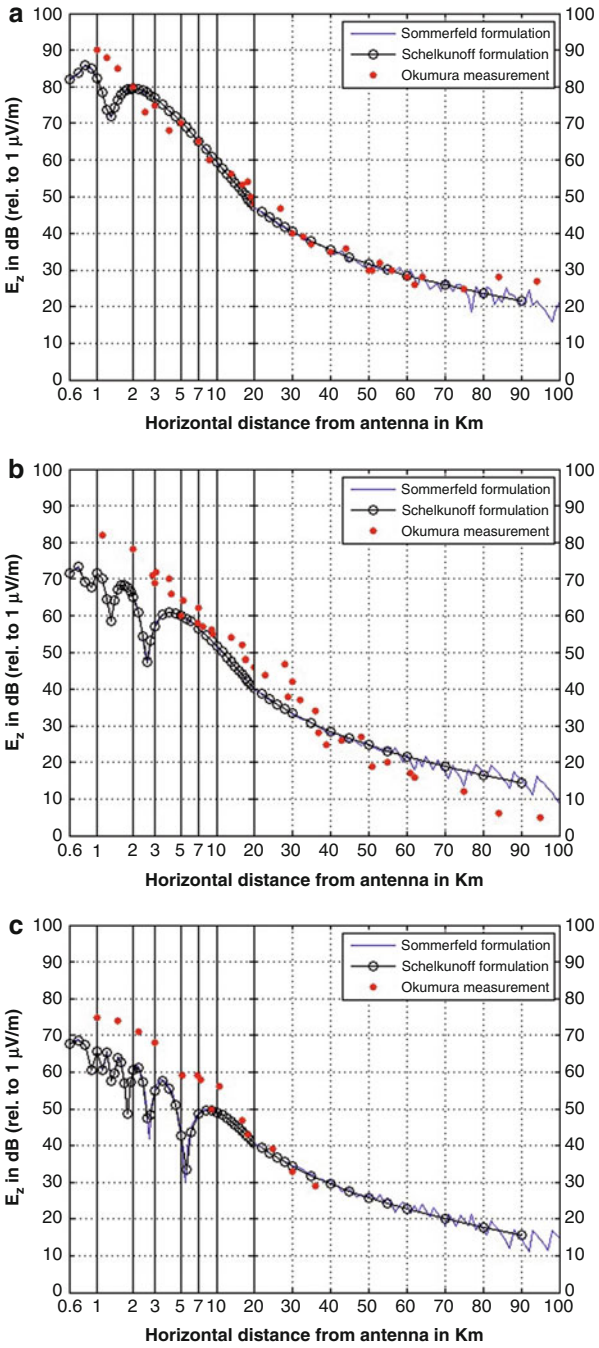

Fig. 16 Comparison between the experimental (Okumura et al. 1968) and theoretical predictions (Schelkunoff and Sommerfeld formulations) computed through a macro model for predicting propagation path loss in an urban environment at (**a**) 453 MHz, (**b**) 922 MHz, and (**c**) 1920 MHz

compare with the experimental data. It is important to note that those numbers include the adjustment of the reference field from 1 V/m to 1 μV/m. For the last two frequencies, the plots in Fig. 16b and c are not in perfect match with the experiment because in the simulations, at these two frequencies, a simple half-wave dipole antenna was used as the transmitter, whereas Okumura et al. (1968) used a highly directive antenna like a parabolic reflector whose dimensions were not reported in their paper.

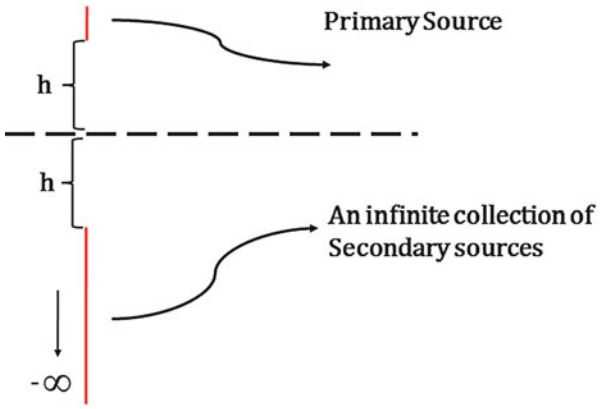

Fig. 19 Equivalent image sources that generate the desired radiation fields at the interface

Next, the nature of the mechanism of radio wave propagation over a single boundary layer generated by two dissimilar mediums on each side is illustrated.

Visualization of the Propagation Mechanism

How does the signal actually propagate over a single boundary generated by two different mediums can be visualized by inspecting the path of each of the waves represented by the integrands in Eq. 9, for example, especially those waves represented by the main part of the contour going from 0 to k_1. Those waves when they hit the ground, which is imperfectly conducting, they suffer from different reflection coefficients which depend on their different angles of incidence. On reflection, the rays diverge forming a semi-infinite image. The rays will never converge to form a perfect image of the same size as the source except in case that the second medium is perfectly conducting and perfectly smooth. This fact was predicted in 1935 by Van der Pol (1935) which explains the elongated image of the sun or moon on a clear day on a wavy lake.

Van der Pol (1935) points out that the results of Sommerfeld (1926) and Weyl (1919) were, as a rule, not very transparent on account of the fact that the approximations or developments used were more of a mathematical nature. This leads Van der Pol to recast the same problem without any approximation whatsoever which leads to a solution in the form of a simple space integral which allows a direct physical interpretation. The integration related to the source of the fields from a transmitting dipole located over an imperfect ground extends over the part of space occupied by the second medium below the geometrical image of the source. This scenario is seen in Fig. 19, which is similar to Fig. 10 in many respects. It is shown that the field in the first medium where the dipole is located, apart from the direct radiation from an elementary dipole, can be described as due to a secondary wave originating in the integration space extending from its image from $-h$ to $-\infty$. In other words, the image of a source over an imperfect ground consists of a line source starting from its image and continuing to $-\infty$ as shown in Fig. 19. The amplitude of the wave from the image is determined by the amplitude of the primary wave. It can be considered to spread from the geometrical image of the point source with the propagation constant and absorption of the second medium. The higher the conductivity of this second medium, the more the primary wave is concentrated near the image of the point source until, for infinite conductivity, it is wholly concentrated at the image itself.

This result that the fields produced by a dipole over an imperfect ground plane are due to the direct contribution from the source plus the effect of the ground represented by an equivalent image which consists of a line source that extends from $-h$ to $-\infty$ has been used by other researchers. In fact, the same

DOI 10.1007/978-981-4560-75-7_120-1

physical picture is available in Booker and Clemmow (Booker and Clemmow 1950). Sommerfeld also writes a similar expression (Sommerfeld 1909, Eq. 10d on p. 250). The detailed derivation is available in Van der Pol's work (1935), and one obtains for the Hertz potential due to a normalized point source located at a height z_a, while the observation point is located at z_b, the following expression:

$$\Pi_{1z} \approx \frac{\exp(-jk_1R_1)}{R_1} + \frac{\exp(-jk_1R_2)}{R_2} - \frac{2jk_1^2}{k_2}\exp[-a(z_a+z_b)] \int_{\zeta=z_a+z_b}^{\zeta=z_a+z_b+\varepsilon\times\infty} \frac{\exp\left(-jk_1\sqrt{\rho^2+\zeta^2}\right)}{\sqrt{\rho^2+\zeta^2}}\exp(a\zeta)\,d\zeta \tag{35}$$

where

$$a = -\frac{jk_1^2}{k_2}$$

and

$$\zeta = z_a + z_b + \varepsilon z$$

As stated by Van der Pol, the third term in Eq. 35 can be interpreted as a wave spreading from the geometrical image of the point source while all points of the second medium below the level of the geometrical image, apparently, send secondary waves to the observer. When $\varepsilon \gg 1$, the distance from an arbitrary point in the second medium to the observer, as given in the exponent of the third term, contains z multiplied by ε, i.e., to the observer, the vertical part of the distance below the image of the point source is multiplied by ε. The wave originating from the image will therefore be observed as elongated vertically, like the vertically very elongated image of the sun over a wind-rippled lake, as shown in Fig. 17 (Van der Pol 1935; Sarkar et al. 2014).

Next, consider a rainy night, when the ground is wet representing a partially reflective surface, and then try to observe how the city lights are stretched along the ground by waves propagating over the surface. Compare such a view as shown in Fig. 18 to the situation as described by Van der Pol in Eq. 35. Imagine that the existence of the green traffic light is the information to be transmitted by the source, and now notice how a wet ground helps to transfer the information to a point where there is no line-of-sight path. In fact, in cellular systems, the ground is always an imperfect reflecting surface, and the way light propagates in Fig. 19 is what we should expect as a propagation mechanism in a cellular system. In other words, the transmitting antennas (usually down tilted to the ground) excite a radiating field in the cell, which in the intermediate region behaves as a radiating field from a line source and in the far-field region behaves as a Norton surface wave. This wave then represents one of the main dominant means by which the base station antenna communicates with the mobile device. This mechanism of propagation is shown in Figs. 17, 18, and 19. Hence, the stretching of the lights in Figs. 17 and 18 essentially represents the image of the primary source.

Figures 17, 18, and 19 provide a physical insight into how waves propagate in mobile communications systems and thus illustrates why smart antennas and beamforming are not very successful in cellular communications till now despite all of the research efforts done in those fields. If the real scenario of propagation is something similar to what is seen in Figs. 17, 18, and 19, then one should change their outlook at the implementation of multiple antennas and adaptive arrays in cellular systems. The important point is that the effect of the ground plays a dominant role. This equivalent line source formed from the images generates a field in the air which decays as 30 dB per decade. The decay of the fields as 30 dB per

decade with distance is generated in the intermediate region approximately where the slow fading region ends which is approximately at a distance of about $\frac{4H_{TX}H_{RX}}{\mathscr{W}^{o}}$ (De et al. 2010) from the base station antenna. Here, H_{TX} and H_{RX} represent the height of the transmitting and the receiving antennas over the ground, and $\mathscr{W}^{o}$ λ is the wavelength of operation.

A Note on the Conventional Propagation Models

Typically, in the current state of the art, the drive test data are fit in a least-squares fashion to a statistical model or an empirical-based ray-tracing scenario is often used. The fact of the matter is that current propagation modeling tools cannot capture the fundamental physics, namely, inside a cell, the path loss is typically 30 dB per decade (Abdallah et al. 2014) or equivalently the electric field strength varies as $\rho^{-1.5}$ with the distance ρ from the antenna inside the cell, and outside the cell, the propagation path loss is approximately 40 dB per decade or equivalently the electric field strength varies as ρ^{-2} as a consequence of the addition of the direct wave from the source and the infinite image that has been discussed. Thus, statistical-based models do not capture the basic physics.

Conventionally, in wireless communications textbooks, such as Goldsmith (2005), this problem of propagation modeling is tackled first by explaining the two-ray model over a flat perfectly conducting earth. In the two-ray model – the incident and the reflected rays – the reflection coefficient is taken to be -1 and θ (the angle of incidence) is always $\frac{\pi}{2} = 90^{\circ}$ (i.e., perfect reflecting earth is considered). However, the two-ray model illustrates the intermediate path loss to be 20 dB per decade since the field decays ρ^{-1} for free-space propagation. This is in contrast to the path loss of 30 dB per decade as has been presented in this chapter. After explaining the two-ray model, empirical models are usually presented, such as the well-known Okumura-Hata model (Fujimoto 2008). Although empirical models (Ji et al. 2001, 2002) have been extensively applied with good results, they suffer from some disadvantages. The main disadvantage is that empirical models provide no physical insight into the mechanism by which propagation occurs. In addition, these models are limited to the specific environments and parameters used in the measurements.

Next, a brief description of the Hata model (an example for the empirical models) is provided and that of the two-ray model. Then one can make a comparison between the proposed macro model described in this chapter and these two empirical models.

Hata model is an empirical formulation of the graphical path loss data provided by Okumura's model. The formula for the median path loss in urban areas is given by

$$L(\text{urban})(\text{dB}) \;=\; 69.55 + 26.16\log f_c - 13.82\log h_{te} - a(h_{re}) + (44.9 - 6.55\log h_{te})\log d \qquad (36)$$

where f_c is the frequency in MHz and varies from 150 to 1500 MHz, h_{te} and h_{re} are the effective heights of the base station and the mobile antennas (in meters), respectively, d is the distance from the base station to the mobile antenna in kilometers, and $a(h_{re})$ is the correction factor for the effective antenna height of the mobile which is a function of the size of the area of coverage. For small- to medium-sized cities, the mobile antenna correction factor is given by

$$a(h_{re}) = (1.1\log f_c - 0.7)h_{re} - (1.56\log f_c - 0.8)\ \text{dB} \qquad (37)$$

For a large city, it is given by

DOI 10.1007/978-981-4560-75-7_120-1

$$a(h_{re}) = 8.29(\log 1.54h_{re})^2 - 1.1 \text{ dB for } f_c \leq 300\,\text{MHz} \tag{38}$$

$$a(h_{re}) = 3.2(\log 11.75h_{re})^2 - 4.97\,\text{dB for } f_c \geq 300\,\text{MHz} \tag{39}$$

To obtain the path loss in a suburban area, the standard Hata formula is modified as

$$L(\text{dB}) = L(\text{urban}) - 2\left[\log(f_c/28)\right]^2 - 5.4 \tag{40}$$

The path loss in open rural areas is expressed through

$$L(\text{dB}) = L(\text{urban}) - 4.78(\log f_c)^2 - 18.33\log f_c - 35.94 \tag{41}$$

If one is interested in calculating the received power instead of the path loss, then one can use the following formula to calculate the received power in dBm knowing the path loss L(dB), the transmitted power P_t (dBm), and the gain G_t (dB) through

$$P_r(d) = P_t + G_t - L \tag{42}$$

This model is quite suitable for large cell mobile systems, but not for personal communications systems, which cover a circular area of approximately a few kilometers in radius (Goldsmith 2005; Ji et al. 2001, 2002; Sarkar et al. 2003).

The two-ray model is based on ray-tracing techniques. In the two-ray model, one only considers the direct ray and the ray reflected off the plane of the earth. In the model, the reflection coefficient is considered to be –1 which is that of a perfect conductor. The formula for the two-ray model is given by

$$P_r(d) = P_t G_t \left[\frac{\lambda}{4\pi}\right]^2 \left| \frac{1}{\sqrt{(h_t - h_r)^2 + d^2}} - \frac{e^{-j2\pi\left(\sqrt{(h_t+h_r)^2+d^2} - \sqrt{(h_t-h_r)^2+d^2}\right)}}{\sqrt{(h_t + h_r)^2 + d^2}} \right|^2 \tag{43}$$

where P_t is the transmitted power, G_t is the transmitting antenna gain, λ is the wavelength, h_t is the transmitting antenna height in meters, h_r is the receiver antenna height in meters, and d is the horizontal distance from the transmitting antenna in meters.

Figure 20 plots the results for the electromagnetic macro model generated by AWAS for a vertical half-wave dipole over an urban ground at a height of 20 m above the ground assuming that the receiving antenna is located at 1.5 m above the ground. The frequency is 900 MHz. In Fig. 20, in addition to the results generated by the electromagnetic macro model, the results for the two-ray model and that from the Hata model for the same transmitting and receiving antenna locations are also presented. One can clearly see that neither the two-ray model nor the Hata model predicts a decay of 30 dB per decade. Furthermore, the nulls in the two-ray model are much sharper than the AWAS results, and this is due to the assumption of a perfect ground for the earth used in the two-ray model. In fact, if one assumes a vertical half-wave dipole over a perfect ground using the electromagnetic analysis code AWAS, one will obtain a slope of 20 dB per decade in the path loss of the far field as the two-ray model suggests and not the usual 40 dB per decade which physics predicts! Again, this is because in the two-ray model, one assumes that the reflection coefficient is –1, while the truth is that the reflection coefficient is +1 for a vertical dipole radiating on top of a perfect ground and it is –1 for a horizontal dipole operating over a perfect ground. In

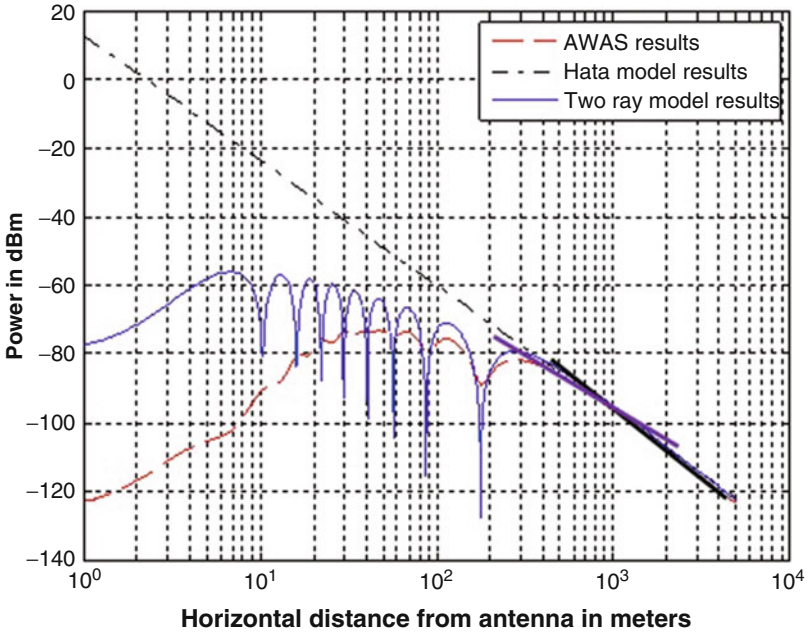

Fig. 20 The *dashed red curve* is the received power of a vertical half-wave dipole at 20 m above an urban ground using AWAS. The *dashed black curve* is the results from the Hata model for the same setup as in the AWAS simulation. The *blue curve* is the results for the two-ray model for the same setup as in the AWAS simulation

Fig. 20, the purple thick line represents the slope of 30 dB per decade and the black thick line represents the slope of 40 dB per decade.

So, to find more satisfactory models, researchers usually follow one of the two paths. Either they choose more sophisticated physical models which encounter other propagation mechanisms such as diffraction, scattering, and ray tracing (Fujimoto 2008; Ji et al. 2001, 2002; Sarkar et al. 2003) or they delve into statistical modeling (Goldsmith 2005). It is quite interesting to read the following conclusion from Fujimoto (2008):

> Although the plane earth model has a path loss exponent close to that observed in actual measurements (i.e., 4), the simple physical situation it describes is rarely applicable in practice. The mobile is always almost operated (at least in macro cells) in situations where it does not have a line-of-sight path to either the base station or to the ground reflection point, so the two-ray situation on which the plane earth model relies is hardly ever applicable. To find a more satisfactory physical propagation model, we examine diffraction as a potential mechanism.

Instead of examining diffraction as a potential mechanism or going to statistical modeling, the work presented in this chapter provides a rigorous mathematical solution based on the exact Sommerfeld formulation of the two-ray model but with imperfectly reflecting earth taken into consideration. This approach directly implies that the physical model of propagation in the cellular environment described above is the radiation field associated with a line source. Namely, the power decreases with the distance from the transmitter by 30 dB per decade for most of the practical area within a typical cell, as the antennas are located quite high from the ground. Then the fading and shadowing due to buildings and large obstacles appear as variations around the 30 dB per decade slope line, as seen in the measured data in the plots of Figs. 5–7. Almost none of the physical models take fields produced by a line source into consideration such as the dielectric canyon model, flat edge model, and sophisticated ray-tracing models (Fujimoto 2008; Ji et al. 2001, 2002).

In summary, the ray theory can never predict a decay of the fields as $\rho^{-1.5}$. The analysis of Van der Pol (1935) presented here provides a physical picture of how the wave, which is not a surface wave,

DOI 10.1007/978-981-4560-75-7_120-1

propagates over an imperfect ground from the base station antenna to the mobile device. In short, besides the direct ray from the source, there are fields from a line source generated by the image of the original source over the imperfectly conducting ground which can be easily visualized in Figs. 17 and 18.

Conclusion

The objective of this chapter has been to illustrate that an electromagnetic macro model can accurately predict the propagation path loss in a cellular wireless environment as the buildings, trees, and so on are the secondary source of the propagation path loss, the primary being the mechanism of electromagnetic wave propagation over an imperfect ground. Documentary evidence using both theory and experimental data from multiple sources has been provided to illustrate these subtle points.

In addition, it is shown that experimental data collected from various sources illustrate that the macro model is quite accurate and provide a basic physical understanding of the propagation mechanism. Some of the salient features are as follows: The nature of the ground like urban, rural, suburban, or water has essentially the same effect in a cellular environment. The larger height of the base station antenna is not a good choice, and if it is brought closer to the ground, it may provide a better and cheaper solution including less usage of power.

Finally, an optical analog is provided for the propagation mechanism to illustrate that the image of an antenna radiating over an imperfect ground can be characterized by an image which is essentially an infinite line source which extends from the same height at which the antenna is placed over the ground, but now it is located below the ground and extending to negative infinity. This line source is responsible for predicting the proper propagation path loss. Such a mechanism cannot be explained either through a statistical model, through a multiple ray model, or through diffraction as none of these modes of analysis deal with the imperfect ground representing earth which is the main source influencing the radio wave propagation in a cellular wireless environment.

Antennas in MRI Systems

Sven Junge*
Bruker BioSpin MRI GmbH, Ettlingen, Germany

Abstract

Today the Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging are very well-established methods for noninvasive investigations of live objects, substances and materials. The radio frequency (RF) coil is the first component where the Magnetic Resonance (MR) signal is stimulated and received and therefore is one of the most important components of a Magnetic Resonance Imaging (MRI) system. The design of properly developed RF coils is the key to achieve the best clinical, preclinical or experimental result for MRI scientists or clinicians. In this chapter a detailed overview on RF-coil concepts for MRI is presented. This article contains some results of my personal work and the study of many articles, reference textbooks, and other people's work. The intention of this chapter is to give the reader a rough summary of the state-of-the-art knowledge and physical background of MRI RF coils engineering in an easy-to-understand format. This chapter contains three main sections. The first section is a simple introduction to MRI and will provide a basic understanding of MR physics behind the detection of RF signals for MRI for students who do not have any knowledge of MRI or NMR. The RF engineer must be familiar with these basic principles in order to design and build successfully a MRI RF coil. The next section is related to the basic types of RF coils. It is divided in multiple subsections covering volume coils and their basic design principles, local RF coils including their arrangement for so-called array RF coils, and last but not least cryogenically cooled RF coils. The last section discusses further directions and challenges in the field of MRI RF coil engineering and gives a brief description of active shaping of the RF field within a given volume and its challenges. While this section gives only a rough overview about the topics of MRI RF coil engineering, the interested reader will find the most interesting textbooks and articles in the reference section.

Introduction

Magnetic Resonance Imaging – MRI

Today the Nuclear Magnetic Resonance (NMR) is a very well-established method for noninvasive investigation of substances and materials and plays a major role in the medical and preclinical community. NMR is based on nuclear magnetic resonance of the nucleus inside an external magnetic field $B_0 = |\boldsymbol{B}_0|$. For this discovery Bloch and Purcell (Bloch 1946; Purcell et al. 1946) received the Nobel Prize in 1952. With the introduction of an additional temporary magnet field gradient Lauterbur, Mansfield, and Damadian (Lauterbur 1973) generated the first spatial images in 1973 based on Fourier transformation of the nuclear magnetic resonance signals. From that time (Mansfield 1996; Damadian 1981) until today

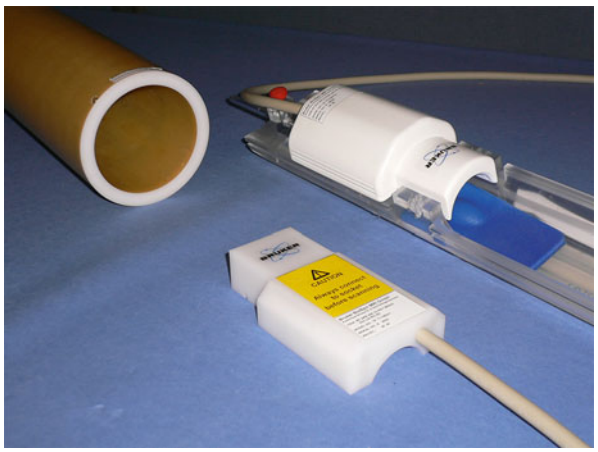

Fig. 1 A Set of RF coils for preclinical imaging of small objects consists of a volume coil for RF transmission and a two local RF coils for MRI signal detection

the development of this noninvasive method advanced quickly for medical diagnostics, material research, and preclinical imaging.

Today typically four types of MRI systems are distinguished by their magnetic field strength in Tesla (T):

1. Low-field systems: 1–0.5 T
2. Midfield systems: 0–1.5 T
3. High-field systems: 0–7.0 T
4. Ultrahigh-field systems: 0 T–21 T

Low-field systems with a proton-resonance frequency of 8.5–17 MHz are commonly equipped with recessive or permanent magnets and are generally used as open MRI systems, e.g. for interventional surgery. Today the low signal strength and the low raw image quality can be compensated with extensive postprocessing on high-performance computer systems or with the introduction of cryogenically cooled RF antennas. Mid-field systems with a proton-resonance frequency of 42–63 MHz provide a better image quality and have been commonly used as standard MRI systems in the clinical environment for a long time now. High-field MRI systems with a proton-resonance frequency of 125–300 MHz offer a higher signal-to-noise ratio (SNR) and potentially higher contrast-to-noise ratios, spectral resolution, and can provide a much better image quality for certain applications. With the introduction of 3 T and 7 T clinical MRI systems at the beginning of this century, new doors were opened for medical diagnostics. Ultrahigh-field systems are commonly used only for research and provide in specific circumstances a significantly increased SNR. MRI systems up to 21 T (950 MHz) are available and commonly operate in a frequency range of 200–600 MHz in the area of preclinical imaging. But the effort with respect to the RF engineering increased significantly to achieve high SNR and a homogenous image contrast.

The RF coil is the first component where the MR signal is stimulated and received and therefore one of the most important components of a MRI system. The design of properly developed RF coils is the key to achieve the best clinical, preclinical or experimental result for MRI scientists or clinicians.

Before going into details of RF coils for MRI, a basic understanding of the signal reception and excitation for NMR and MRI is necessary. The RF coils are not stand-alone devices and part of a complex imaging system. Full-length textbooks about the design of RF coils for MRI are already published

DOI 10.1007/978-981-4560-75-7_121-1

(Vaughan and Griffiths 2012; Mispelter et al. 2006; Jin 1999) and in this section a brief introduction into the design and theory of MRI coils is given (Fig. 1).

Requirements for Antennas in NMR and MRI Systems

Basic Introduction to the Principle of NMR and MRI

To understand the design goals of RF coils for MRI, it is first necessary to explain the basic principles of NMR and MRI. A correct explanation of a so-called spin ensemble inside an electromagnetic field requires a quantum mechanical prediction. Nevertheless the semiclassical prediction is sufficient for the description of the effects for NMR and MRI that are important for RF coil design. A more detailed explanation can be found, e.g., in (Lawrence 1996; Haacke et al. 1996). The fundamental characteristics of nuclei used for NMR and MRI are characterized by a nonzero nuclear spin **I** that is linked by

$$\boldsymbol{m} = \gamma \cdot \boldsymbol{I}$$

to the angular momentum $\boldsymbol{m}$. The so-called gyromagnetic ratio γ is specific for each nucleus. Some values $v_0 = \frac{2\pi}{\gamma}$ that are important for NMR and MRI are listed in Table 1.

Based on the so-called Zeeman effect (Zeeman 1882) the energy levels of $\boldsymbol{I}$ split into 2I + 1 discrete level inside an external magnetic field $\mathbf{B_0}$. By convention the $\mathbf{B_0}$-field points in the z–direction $\mathbf{B_0}$ = (0,0, B_0). The nuclei listed in Table 1 can adopt one of the two spin states 1/2 and -1/2. These spin states correspond to the two possible orientations of the magnetic momentum $\boldsymbol{m}$ parallel or anti-parallel to $\mathbf{B_0}$ with an angular orientation of about $\Omega_0 = 54.7°$ and can be evaluated by the magnetic momentum μ and its corresponding z-component (Fig. 2).

The energy difference *dE* between these two adjacent energy levels is

$$dE = \gamma h \cdot B_o \tag{1}$$

where *h* is the so-called Planck's constant. The nuclei can undergo a transition between these adjacent energy levels by absorbing or emitting of a photon, e.g., sending or receiving an electromagnetic wave. For example nuclei in the upper energy level emit an electromagnetic wave and end up in the lower energy state. The energy of this photon is E = h* *v* and matches exactly the energy difference between these two levels

$$dE = h\nu_0 = \hbar\omega_0 \tag{2}$$

where v_0 is the frequency of this photon and ω_0 is the angular frequency. Combining Eqs. 1 and 2 the so-called Larmor frequency

Table 1 List of most commonly used nuclei for MRI and NMR. The most significant nucleus for a large range of MRI studies is the proton ^{1}H because of the natural concentration of water in live objects under investigations, e.g., humans or animals

is obtained which ranges for protons (^{1}H) commonly from about 42 MHz up to 900 MHz (1 T – 21 T field strength of the external magnetic field) at MRI. This is the frequency-range for operation of NMR and MRI RF coils.

In the object under investigation a bulk sample is considered which consists of many nuclear spins. The energy levels of the nuclear spins are governed by the Boltzmann statistics. The probability of the number of spins of the different energy levels is assigned by the so-called Boltzmann factor $e^{-\frac{dE}{kT}}$. At the equilibrium the lower energy level is more populated than the upper one (anti-parallel) and the small difference of the energy levels is responsible for the relatively intrinsic low sensitivity of magnetic resonance that can be increased by applying a high as possible external magnetic field (see Eq. 1). This is the major cause for the ongoing trend to increasingly higher magnet-field strength for MRI. The sum over all magnetic spins in the volume under investigations (V) is called magnetization

DOI 10.1007/978-981-4560-75-7_121-1

$$\boldsymbol{M} = \left(M_x, M_y, M_z\right) = \frac{1}{V}\sum \mu_i. \tag{4}$$

When a sample is placed in a uniform magnetic field $\boldsymbol{B}_0 = (0, 0, \mathrm{B}_0)$ aligned in the z-direction, it develops a net magnetization in the same direction. In addition a force on the magnetization is applied by $M \times B_0$ and results in a movement of the magnetization that can be described by the differential equation

$$\frac{d}{dt}\boldsymbol{M}(t) = \gamma \boldsymbol{M}(t) \times \boldsymbol{B}_0 \tag{5}$$

The movement of the magnetization is called precessing and moves with the Larmor-frequency ω_0 on a torque aligned with the external magnetic field $\boldsymbol{B}_0$.

A rotating coordinate-frame (laboratory frame) aligned with the external magnetic field $\boldsymbol{B}_0$ is introduced. By convention the magnetization vector is fixed. The magnetization in the rotating laboratory-system with the basis vector $\boldsymbol{e_x}$, $\boldsymbol{e_y}$, $\boldsymbol{e_z}$ rotates with the Larmor frequency $\omega_0 = \gamma \cdot B_0$ in the same direction as the spin-system. Without limiting the generality a second **B**-field (Fig. 3 left) is introduced that results in an effective magnetic **B**-field $\boldsymbol{B_{eff}} = \boldsymbol{B} - \frac{\omega_0}{\gamma}\boldsymbol{e_z}$. The result for the equation of motion within the rotating frame is $\frac{d'}{dt}\boldsymbol{M}(t) = \gamma \boldsymbol{M}(t) \times \boldsymbol{B_{eff}}$.

The effect of an oscillating RF magnetic field $\mathbf{B}_1$ is considered that is linearly polarized in the x-direction (Jin 1999) and can be expressed by two time dependent components in the xy-plane

$$\boldsymbol{B}_1 = A \cdot \boldsymbol{e}_x \cos \omega t = \boldsymbol{B}_{cw} + \boldsymbol{B}_{ccw}$$

where $\boldsymbol{B}_{cw} = \frac{1}{2}A\left(e_x \cdot \cos \omega t - e_y \cdot \sin \omega t\right)$ and $\boldsymbol{B}_{ccw} = \frac{1}{2}A\left(e_x \cdot \cos \omega t + e_y \cdot \sin \omega t\right)$ are rotating magnetic fields: one, $\boldsymbol{B}_{cw}$ is rotating clockwise and $\boldsymbol{B}_{ccw}$ is rotating counterclockwise.

When the $\mathbf{B}_1$-field oscillates with the same frequency $\omega = \omega_0$, than the two components of the so-called circularly polarized fields is given by

$$\boldsymbol{B}_{cw} = \frac{1}{2}A \cdot e_x \quad \text{and} \quad \boldsymbol{B}_{ccw} = \frac{1}{2}A\left(e_x \cdot \cos 2\omega_0 t + e_y \cdot \sin \omega_0 t\right) \tag{6}$$

When applying the $\mathbf{B}_1$-field then the value of the effective magnetic field $\boldsymbol{B_{eff}}$ in the rotating frame becomes

$$\boldsymbol{B_{eff}} = \left(B_0 - \frac{\omega_0}{\gamma}\right)\boldsymbol{e_z} + \frac{1}{2}A \cdot e_{x'} \tag{7}$$

Due to the rotation $\omega = \omega_0$ of the laboratory frame (the system is on-resonance) the external magnetic field $\boldsymbol{B}_0$ has no influence on the motion. The z-component disappears and the magnetization is precessing on a torque aligned to $\boldsymbol{B_{eff}} = \frac{1}{2}A \cdot e_{x'}$ and the resulting rotation has the angular frequency $\boldsymbol{\omega}_0 = \gamma \cdot \boldsymbol{B}_{eff} = \gamma \cdot \boldsymbol{B}_1$. It should be noted: the magnetization vector rotates to any desired angle α away from its equilibrium position (Fig. 3 right) when a magnetic field $\mathbf{B}_1$ oscillating with an angular frequency $\omega = \omega_0$ is applied that is perpendicular to the static field $\boldsymbol{B}_0$. In practice this$\mathbf{B}_1$-field is applied by RF coils using a RF-pulse with a frequency of $\nu_0 = \frac{2\pi}{\gamma}$. The final angle is dependent on the duration τ of the RF-pulse and the Amplitude of the applied transversal $\mathbf{B}_1$-field and is given by the integral of the envelope of the RF-pulse

DOI 10.1007/978-981-4560-75-7_121-1

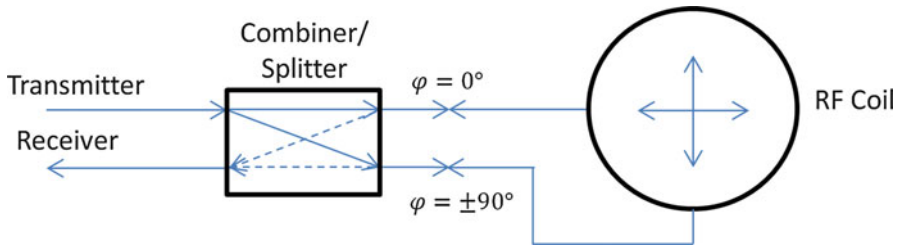

Fig. 4 Combiner/Splitter: The splitter separates the transmit power into two RF-channels and introduses a 90° phase shift in one of the channels to provide a circularly polarized $\mathbf{B}_1$ RF-field. During reception the Combiner adds the two signals with a -90°-phase shift

$$\alpha = \int_0^\tau \gamma \cdot B_1(t)dt \tag{8}$$

Quadrature Detection and Reception

The counterclockwise rotating component $\boldsymbol{B}_{ccw}$ has no effect on the magnetization vector **M**. This can be demonstrated by the same argumentation of the previous section where the laboratory frame rotates counterclockwise and results in an effective magnetic field

$$\boldsymbol{B}_{\boldsymbol{eff}} = \left(B_0 + \frac{\omega_0}{\gamma}\right)\boldsymbol{e}_{\boldsymbol{z}} + \frac{1}{2}A \cdot e_{x'} = 2B_0\,\boldsymbol{e}_{\boldsymbol{z}} + \frac{1}{2}A \cdot e_{x'}. \tag{9}$$

While the magnitude of $\mathbf{B}_0$ (in a range of few T) is much larger than the magnitude of $\mathbf{B}_1$ (in a range of few μT) the effect of the counterclockwise component is negligible and only the right hand side component of the transversal RF-field $\mathbf{B}_1$ has a significant effect on the magnetization vector. But for a linear polarized RF-field, only half of the energy will be used for reversing the magnetization vector.

To feed the whole energy of a transversal RF-field to the magnetization vector **M** a clockwise rotation $\mathbf{B}_1$-field $\boldsymbol{B}_1^{cw} = \mathbf{A}\left(e_x \cdot \cos\omega t + e_y \cdot \sin\omega t\right)$ can be used. Then the effective $\boldsymbol{B}_{\boldsymbol{eff}}$ becomes twice the amplitude compared to the linear RF-field $\boldsymbol{B}_{\boldsymbol{eff}} = A \cdot e_{x'}$ and takes twice as much energy into the spin-system to deflect the magnetization to a given angle α.

The components of the $\mathbf{B}_1$-field $\mathbf{B}_1 = \boldsymbol{B}_1^{cw} + \boldsymbol{B}_1^{ccw} = \boldsymbol{B}_1^{(+)} + \boldsymbol{B}_1^{(-)}$ in the field of MRI are commonly called left-hand and right-hand side component and are expressed in notation of complex numbers $\left(i = \sqrt{-1}\right)$ by

$$\boldsymbol{B}_1^{(+)} = B_{1x}^{(+)} + iB_{1y}^{(+)} = \frac{B_{1x} + i\,B_{1y}}{2} \quad \text{and} \quad \boldsymbol{B}_1^{(-)} = B_{1x}^{(-)} + iB_{1y}^{(-)} = \frac{\left(B_{1x} - i\,B_{1y}\right)^*}{2} \tag{10}$$

Knowing that the right hand side component is responsible for flipping the magnetization vector in the positively rotating frame it should be noted (Hould 2000) that the signal received is proportional to the left-hand side component (section Bloch Equations and Reciprocity). In practice a circular rotation RF-field is synthesized by two geometrically orthogonal $\mathbf{B}_1$ RF-fields; each oscillating linearly with a phase shift of 90° phase difference.

Commonly well-known devices from microwave technology, such as branch lines or ring hybrids (3 dB coupler) are used for quadrature splitting or combining of the RF-signals (Fig. 4). During transmission the input power is split into two RF-signals with a phase shift of 90°, while during reception the RF-signals from the coil are combined with the opposite phase shift for detecting the left-hand side polarized

DOI 10.1007/978-981-4560-75-7_121-1

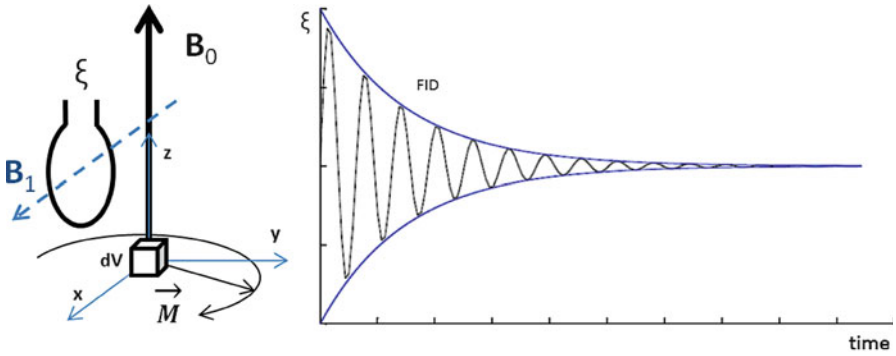

Fig. 5 *Left*: Schematic coil configuration for detection of the NMR signal; *Right*: Graph of the Time depending MRI signal, the so-called free induction decay (FID)

RF-signal from the sample. These two signals from the combiner/splitter are combined in a manner that the two RF-fields are perpendicular to each other and generate a circular $\mathbf{B}_1$-field. In this case the entire input power will be used for excitation of the nuclear spins or the whole energy from the reception process of the spin system can be detected from the object under investigation. Simply following the rules for signal theory, when the two phase correlated signals of a quadrature detected RF signal are combined, the resulting signal is doubled. The associated noise voltage, being uncorrelated, only increases by a factor of $\sqrt{2}$. This results in an increase of the SNR by a factor $\sqrt{2}$ compared to the detection of linearly polarized RF-fields. A good isolation of at least 20dB or more of the two quadrature channels is required.

Bloch Equations and Reciprocity

After application of the $\mathbf{B}_1$ RF pulse to the nuclear spin system the magnetization vectors are flipped and are precessing in the xy-plane. But the magnetization does not precess infinitely due to the losses and turns back to the equilibrium state aligned with $\mathbf{B}_0$. This process is called relaxation and is qualified by two different time constants T_1 and T_2. The time-constant T_1 describes the so-called longitudinal relaxation and is a result of the spin interactions with the lattice. The second relaxation process called transversal relaxation described by T_2 concerns the fact that an energy transfer beneath the spins occurs and the phase coherent movement of the magnetization vectors of the spins gets lost. These time constants are strongly dependent on the material of investigations (sample) and on the magnetic field strength.

The loss of coherent magnetization M_z is called Free Induction Decay (FID – Fig. 5 right). The so-called Bloch equations are a phenomenological model and provide one of the simplest models for the behavior of a nuclear spin system after a RF-pulse excitation. The Bloch equations in the laboratory frame (Bloch 1946) may be written:

$$\frac{dM_{x,y}}{dt} = \gamma(\boldsymbol{M} \times \boldsymbol{B})_{x,y} - \frac{M_{x,y}}{T_2} \tag{11}$$

$$\frac{dM_z}{dt} = \gamma(\boldsymbol{M} \times \boldsymbol{B})_{x,y} - \frac{M_z - M_0}{T_1} \tag{12}$$

For the case of the on-resonance condition $\Delta\omega = 0$ in the rotating frame the vector-product results in a time depending signal with the basic frequency ω_0 that is generated by the magnetization rotating with ω_0. The exponential envelope of the FID based on the two time constants T1 and T2 come from dephasing and longitudinal relaxation mechanisms (Fig. 5 right)

DOI 10.1007/978-981-4560-75-7_121-1

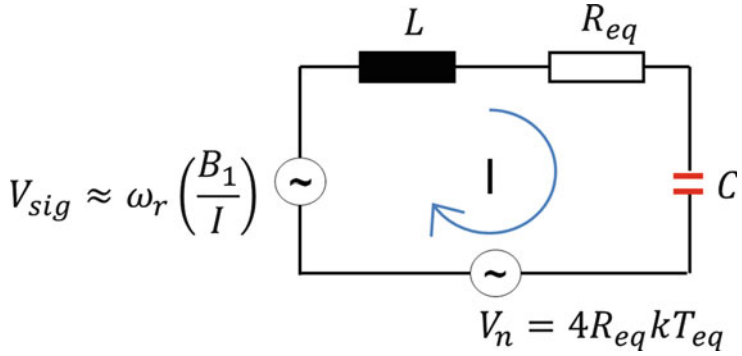

Fig. 6 Equivalent circuit for a MRI coil; including the noise source V_n

$$M_z(t) = M_0\left(1 - e^{t/T_1}\right) + M_z(0)e^{-t/T_1}$$
$$M_{x/y}(t) = M_{x/y}(0)e^{-t/T_2} \tag{13}$$

Consider the case that the $\mathbf{B}_1$-field is applied in the x-direction considering Eq. 11. A unit current is introduced that would be produced by a DC unit current flowing through the RF coil (Fig. 5 left). For times less than the transversal relaxation time T_2 the two Bloch-equations can be written in right hand notation (Hould 2000) $\frac{dM_x^+}{dt} \approx \gamma B_{1y}^+ M_z$ and $\frac{dM_y^+}{dt} \approx -\gamma B_{1y}^+ M_z$. For small flip angle approximation the case is considered that the pulse duration τ is short and only a small flip-angle ($<10°$) is applied. For this case $M_z = M_0$ is the result. When this short pulse with the duration τ is applied, the magnetization follows $M_x^+ \approx \gamma\tau M_0 B_{1y}^+$ and $M_y^+ \approx \gamma\tau M_0 B_{1x}^+$ or in complex notation for the positive rotating frame

$$M^+ = M_x^+ + iM_y^+ \approx \gamma\tau M_0 B_1^+ \tag{14}$$

This relation called *principle of reciprocity* make clears that the (complex) transversal magnetization following a RF-pulse is proportional to the right hand side component of the $\mathbf{B}_1$-field strength (10). Following the *principle of reciprocity* it can be shown that the receive signal ξ induced in a pickup coil (Fig. 5 left) by a magnetization in a voxel dV is given in the negatively rotating frame by

$$\xi = 2\omega M^+ B_1^{-*} = \omega M^+\left(B_{1x} - iB_{1y}\right) \tag{15}$$

and corresponds to the left hand side component of the $\mathbf{B}_1$-field strength (Hould 2000).

It should be noted for the transmit/receive case: the transmit/receive signal is only proportional to squared B_1-field strength for small flip angle and at low external magnetic field strength B_0 where the phase of the transmit/receive $\mathbf{B}_1$-field is independent from the position.

If the dielectric constant and/or conductivity of the sample causes the $\mathbf{B}_1$-fields to be complex and leads to a position dependent phase change, e.g. at high field applications, then the complex notation of the right and left hand side of the $\mathbf{B}_1$-field has to be taken into account. The *principle of reciprocity* is more than the statement that a good transmit coil is also an efficient receive coil!

Efficiency, Losses and Signal to Noise Ratio

In most cases the small voxel sizes of the detected NMR/MRI-signals are correlated to the detection of small signals. Consider a RLC circuit illustrated in Fig. 6 and in accordance with Kirchhoff's yields to equation

DOI 10.1007/978-981-4560-75-7_121-1

$$V = R_{eq}I + \frac{i}{\omega C}I - i\omega L \tag{16}$$

where ω denotes the angular frequency. For the case R $= 0$ this reduces to $I = V\left[\frac{L}{i\omega}\left(\omega^2 - \frac{1}{LC}\right)\right]^{-1}$ and for the boundary limiting case $I \to \infty$ the resonance condition $\omega = \omega_r = \frac{1}{\sqrt{LC}}$ is obtained where ω_r is the resonance frequency and where the RF coils must operate. In practice the resistance R cannot vanish completely and the magnitude of I cannot be infinity but in any case the current I would be at maximum at the resonance frequency ω_r. While the resistance R cannot be zero, some energy will be dissipated in the RLC- circuit and the efficiency is decreased. To provide a quantitative value that can be measured, a so-called quality factor is defined by $Q = 2\pi \frac{\text{Maximum stored energy}}{\text{Total dissipated energy per period}}$. For the RLC-circuit the quality factor can be found as

$$Q = \frac{1}{R_{eq}}\sqrt{\frac{L}{C}} \tag{17}$$

In principle the determination of the values of R, L and C can be difficult and per convention the Q-value is obtained as

$$Q = \frac{\omega_r}{\Delta\omega} \tag{18}$$

where $\Delta\omega$ denotes the so-called bandwidth. It must be noted: for comparison reasons it must be considered if the RF-coil is match to 50 Ω or not and that corresponds e.g., to a 3 dB or 6 dB bandwidth and yields to a change of the Q-value by a factor of 2.

The power signal-to noise ratio is given by $\text{SNR}^2 = \frac{V_{sig}^2}{V_n^2}$. With the introduction of so-called Johnson noise a very general formulation of SNR (neglecting the bandwidth of the measurement) is given by (Darrasse and Ginefri 2003)

$$\text{SNR} \approx \sqrt{F}\frac{\omega_0\left(\frac{B_1}{I}\right)}{\sqrt{4K_B T_{eq} R_{eq}}}\Delta V M_T \sqrt{\frac{t_0}{t_R}}\sqrt{t_{\text{scan}}} \tag{19}$$

We assume that all terms that are not strongly related to the RF-coil sensitivity can be neglected; this includes the noise factor F (which accounts for the additional noise power from the MR system), transversal magnetization M_{T}, the total scan time t_{scan}, the repetition time t_{R}, the sampling window duration t_0 and the elementary encoded volume ΔV. In addition, the bandwidth of the measurement is also neglected. For simplicity the coil current **I** is set to unity and to unit current, respectively. In this case the formula 19 is simplified and the SNR is expressed as follows:

$$\text{SNR} \approx \frac{\omega_0 B_1}{\sqrt{4K_B T_{eq} R_{eq}}} \tag{20}$$

A gain in SNR can be achieved either by increasing the effective RF-field strength B_1 per unit current in the sample volume or by reducing the noise sources (loss mechanism) represented by the term $R_{\text{eq}}T_{\text{eq}}$. Several different noise sources interact with the RF coil and are represented by four major terms:

DOI 10.1007/978-981-4560-75-7_121-1

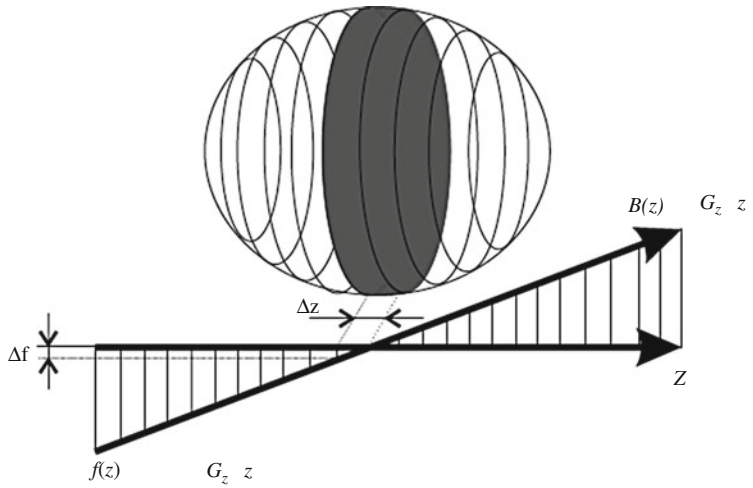

Fig. 7 The principle of slice selective excitation for MR imaging

$$R_{\text{eq}} = (R_{\text{M}} + R_{\text{E}}) + R_{\text{c}} + R_{\Omega} = R_{\text{s}} + R_{\text{c}} + R_{\Omega} \tag{21}$$

where R_{M} is the magnetic loss by magnetic field induced currents in the sample, R_{E} is the electric loss by stray capacitive coupling between the sample and the RF coil, R_{c} is the resistive loss of the RF coil, and R_{Ω} is the radiative loss. The magnetic loss R_{M} and electric loss R_{E} are combined into the so-called samples loss R_{s}. Simplifying these four loss mechanism to the two dominant parts of losses for RF detection that are most important and are temperature dependent, the SNR can be expressed as

$$\text{SNR} \approx \frac{\omega_0 B_1}{\sqrt{R_s T_s + R_c T_c}} \tag{22}$$

Basics of MRI imaging

There are numerous textbooks about MRI and a brief description can be found in the Encyclopedia of NMR (Lawrence 1996) or other basic textbooks about MRI (Canet 1996; Haacke et al. 1999). For MR-imaging (tomography) a spatially resolved signal is required which can be achieved with a spatially dependent Larmor-frequency $\omega_L = \gamma \cdot |\boldsymbol{B}_0|$ when an additional field gradient is present.

A constant field gradient $G = \begin{bmatrix} \frac{\partial B_x}{\partial x} & \frac{\partial B_x}{\partial y} & \frac{\partial B_x}{\partial z} \\ \frac{\partial B_y}{\partial x} & \frac{\partial B_y}{\partial y} & \frac{\partial B_y}{\partial z} \\ \frac{\partial B_z}{\partial x} & \frac{\partial B_z}{\partial y} & \frac{\partial B_z}{\partial z} \end{bmatrix} = \{g_{ik}\}$ is used which is aligned with the external magnetic field at z-axis. Only the 3rd row of G is from interest when $B_0 \gg \|G\| \cdot a$ is assumed, where a is the length of the imaging region. The field gradient G can be summarized to a vector $\boldsymbol{g} = (\frac{\partial B_z}{\partial x}, \frac{\partial B_z}{\partial x}, \frac{\partial B_z}{\partial z}) := \left(g_x, g_y, g_z\right)$ and commonly termed as field-gradient. With the use of this field gradient in addition to the external static magnetic field an allocation of a position x is provided. The Larmor-frequency for a voxel dV at this position is given by $\omega_L = \gamma \cdot (B_0 + \boldsymbol{g} \cdot \boldsymbol{r})$. It should be mentioned that with only one component of $\boldsymbol{g}$, e.g., g_x, a clear allocation of the frequency and position is impossible. It is required to measure ω_L for numerous field-gradients $\boldsymbol{g}$ to allocate the position in a three dimensional

DOI 10.1007/978-981-4560-75-7_121-1

volume. Today multiple different methods exist and in the following the principle of MRI is explained by one simple method – the spin warp gradient echo.

First a slice selective excitation is used when a RF-pulse with a carrier-frequency f_c and a bandwidth df is applied in presence of a field-gradient $\mathbf{g} = (0,0,g_z)$ (Fig. 7). The nuclear spins only in the slice $z = z_f = \text{const}$ corresponding to the carrier-frequency $f_c = \frac{\gamma}{2\pi} \cdot \left(B_0 + g_z \cdot z_f\right)$ are excited in the way explained in section Basic Introduction to the Principle of NMR and MRI. The slice thickness Δz is given by the bandwidth df corresponding to $df = \frac{\gamma}{2\pi} \cdot g_z \cdot \Delta z$ and can be chosen freely within technology limited boundaries.

The signal $\boldsymbol{S(t)}$ picked up by the receiver from a voxel at position $\boldsymbol{r} = \left(x, y, z_f\right)$ is (neglecting all relaxation effects) the sum of all spins in the selected slice with the spin density $\rho(\boldsymbol{r})$

$$\boldsymbol{S(t)} \propto \int \rho(\boldsymbol{r}) \cdot \boldsymbol{e}^{\,i\int_0^t \boldsymbol{\omega}(\boldsymbol{r},\boldsymbol{t'})\boldsymbol{dt'}} \boldsymbol{d^3r} = \boldsymbol{e^{i\omega_0 t}} \int \rho(\boldsymbol{r}) \boldsymbol{e}^{\,i\boldsymbol{\gamma}\int_0^t \boldsymbol{g}(\boldsymbol{t'})\boldsymbol{dt'}\boldsymbol{r}} \boldsymbol{d^3r} \tag{23}$$

When substituting the exponent by $\boldsymbol{k} = \boldsymbol{\gamma}\int_0^t \boldsymbol{g}(\boldsymbol{t'})\boldsymbol{dt'}$ where t denotes the time when the field gradient is applied and omitting the spatially independent frequency ω_L yields to

$$\boldsymbol{S(k)} \propto \int \rho(\boldsymbol{r}) \cdot \boldsymbol{e^{ikr}} \boldsymbol{d^3r} \tag{24}$$

And in this form the signal $\boldsymbol{S(t)}$ can be recognized as Fourier transform of the spin density $\rho(\boldsymbol{r})$ and the spin density itself can be determined by the inverse Fourier transform to the receiver signal

$$\rho(\boldsymbol{r}) \propto \int \boldsymbol{S(k)} \cdot \boldsymbol{e^{-ikr}} \boldsymbol{d^3r} \tag{25}$$

The so-called k-space is defined by the reciprocal space vector $\boldsymbol{k} = \left(k_x, k_y, k_z\right)$. After slice selective excitation the encoding is done in the two dimensional plane and one spatial dimension is encoded by a spatial frequency modulation by applying a constant gradient-field, e.g., g_x in x-direction. The received one-dimensional signal is sampled at N_x discrete points in time intervals of dt_x:

$$\boldsymbol{S}(k_{\boldsymbol{x}}) = \int \rho(\boldsymbol{r}) \cdot \boldsymbol{e}^{ik_x x} \boldsymbol{d^3r} \quad \text{with} \quad k_x = \gamma G_x \cdot t_x \tag{26}$$

The second spatial dimension is encoded by the phase of the signal (so-called phase encoding) and is carried out between the slice selective excitation and the signal acquisition by the gradient g_y for a duration of t_y. This gradient g_y is perpendicular to the gradient g_x in x-direction. This modulation of the spin phase persists through the following read-out procedure of the signal and results in a spatially dependent phase $\varphi(y) = \gamma g_y t_y y$. This phase encoding has to be repeated several times by changing the gradient strength of g_y in order to cover the entire two dimensional k-space.

With $k_y = \gamma G_y \cdot t_y$ the signal originating from the selected slice can be written as:

$$S\left(k_x, k_y\right) = dz \cdot \int \rho(x,y) \cdot e^{i\left(k_x x + k_y y\right)} dxdy \tag{27}$$

DOI 10.1007/978-981-4560-75-7_121-1

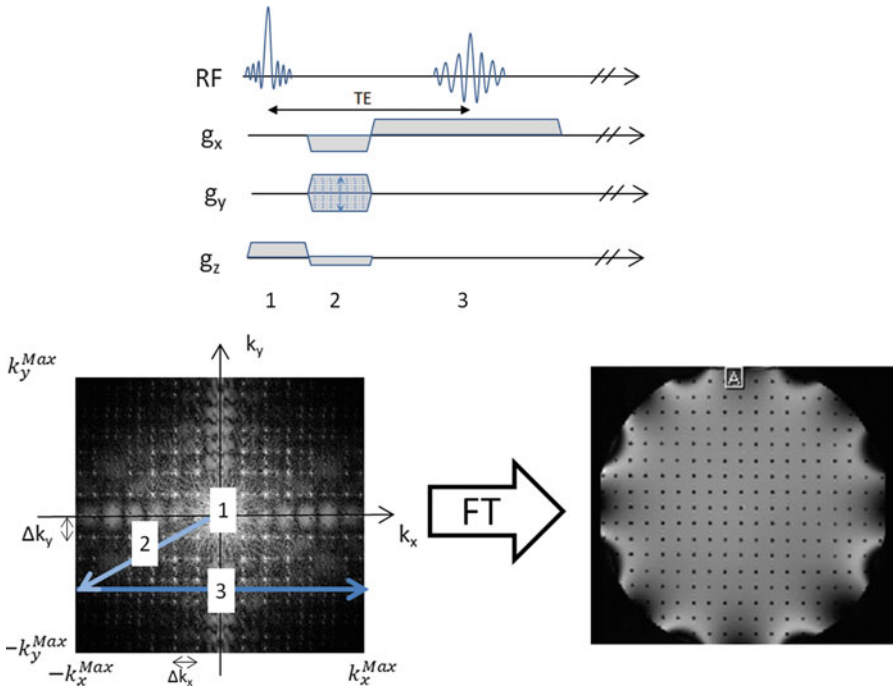

Fig. 8 Special encoding in MRI – *Top*: The principle diagram of a typical spin-warp gradient echo sequence; *Bottom*: The corresponding so-called k-space trajectory in the so-called Fourier-space for spatial encoding and the generation of the final image after Fourier-transform of the sampled data

In Fig. 8 a simple gradient echo experiment using a so-called spin-warp trajectory for phase encoding is shown. In the first step (1) the slice selection is carried out by applying the RF-pulse during the constant field gradient g_z. In the second step (2) a negative gradient g_x is applied to move the trajectory in the k-space to $-k_x^{\max}$ and at the same time the phase encoding gradient g_y is applied to move the trajectory in k-space to a specific k_y position. In addition a so-called rephase lobe of the slice selective gradient g_z is applied for alignment of the phase of the spin-system. In the last phase (3) a read out gradient g_x switches on that corresponds to move at a certain k_y -position in k-space from $-k_x^{\max}$ to $k_x^{\max}$. To cover the whole k-space in y-direction this procedure must be repeated with N_y steps with multiple phase encoding gradients with values running from $-g_y^{\max}$ to $g_y^{\max}$.

Apart from the SNR the imaging speed is one of the most important MR sequence parameters in MRI. The total time T_{tot} for acquiring an image is given by the number of required RF-excitations N_z, the number of phase encoding steps N_y, the number of repetition times N_{rep} and the repetition time TR. The repetition time TR is defined as time interval between the RF-excitations and is a fundamental limiting factor in terms of imaging speed and sensitivity predominant effects caused by the relaxation time of the different tissues. The total time for MRI scans is calculated by $T_{tot} = N_z\, N_y N_{rep} \cdot TR$.

In the past multiple imaging strategies such as FLASH have been developed for imaging time reduction allowing very short TR. Single shot or multi-shot sequences were developed, such as EPI or TSE. These sequences use multiple phase encoding steps during one repetition time TR. However with the introduction of so-called parallel imaging a decrease of the imaging time can be achieved without further need of enhanced gradient performance.

Parallel imaging is based on the principle of partially replacing the time consuming spatial encoding field-gradients. The spatial sensitivity information of the coil-elements of so-called array-coils

DOI 10.1007/978-981-4560-75-7_121-1

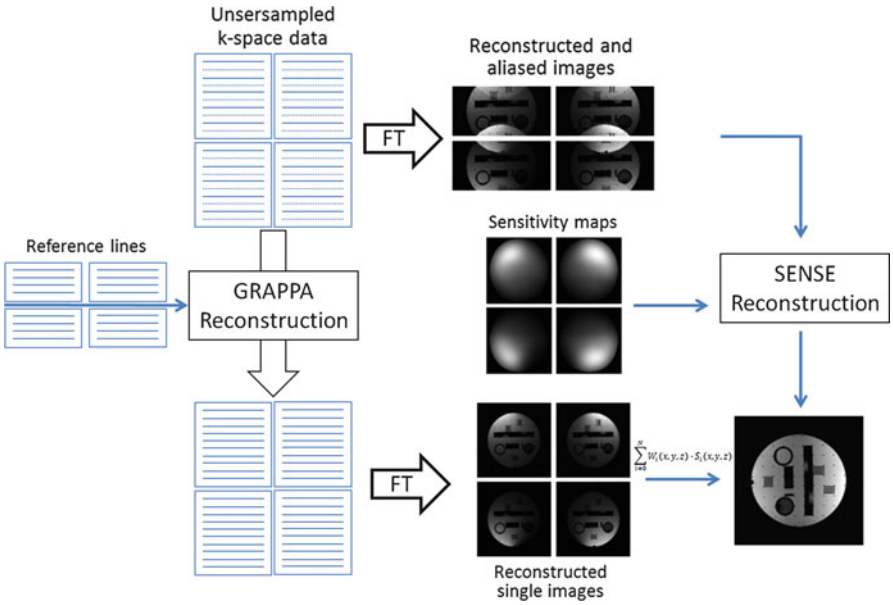

Fig. 9 Principle description of parallel imaging techniques in k-space or image domain

(section Cryogenically Cooled Coils, Double Tuned RF Coils) is used in a manner that only a fraction of the phase encoding steps has to be acquired. This results directly in an accelerated image acquisition.

The most prominent parallel imaging techniques are GRAPPA (Griswold et al. 2002) based on a *k*-space reconstruction approach and SENSE (Pruessmann et al. 1999) based on an approach in the image domain (Fig. 9). For parallel imaging the k-space is sampled with a rate of phase encoding steps that is below the Nyquist theorem, e.g., for an under sampling by a factor $R = 2$ only every second k-space line will be acquired using the phase encoding by the field gradients. The parallel image reconstruction can be directly performed in the k-space by solving the missing k-space lines. For that purpose every line in the center of the k-space is aquired so-called auto-calibration lines (ACS-lines). Using the ACS-lines for each coil element the missing k-space lines of the under sampled image are reconstructed and the finally the reconstructed image is the result of an inverse Fourier transform. For parallel imaging techniques using SENSE- algorithms the under sampled image is reconstructed via inverse Fourier transform and results in so-called aliased images for each coil-element. These images with a reduced FOV contain information from multiple equidistantly distributed pixels in the desired fully sampled image. With usage of the complex coil sensitivities of the individual coil-elements of the array, the superimposed pixels can be unfolded for a fully resolved image (see section Receive Array Coils for Parallel Imaging).

Hardware of MRI Systems

In this section a brief introduction of the general hardware for MR topography is presented. The RF coils are only one part but nevertheless play an important role in the transmit/receive chain of the MR -imaging system.

In Fig. 10 a sketch of an MRI system is shown and thereby explains the basic function of such an instrument. The largest component and in most cases also the most expensive component of a MRI-system is the magnetic field coil. For high and ultra-high field magnet systems superconducting magnets are commonly used. On one hand a higher magnetic field strength provides in general better SNR that can be used for better special or temporal resolution, but on the other hand the costs should be economically feasible.

DOI 10.1007/978-981-4560-75-7_121-1

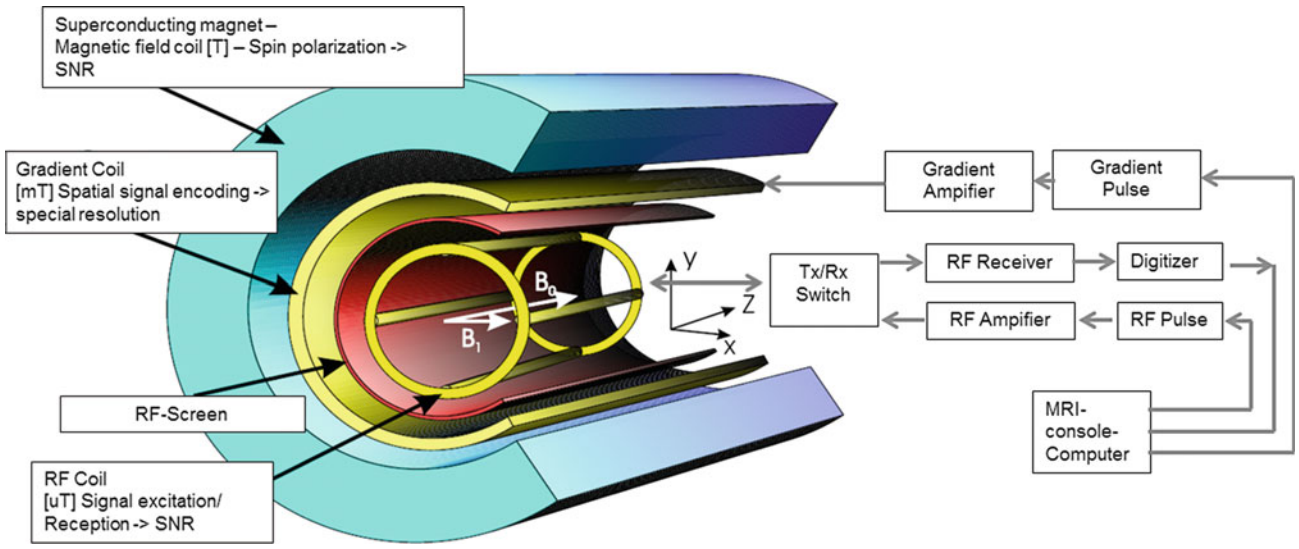

Fig. 10 Principle sketch of an MR-imaging system

The main magnet generates the external magnetic field $\boldsymbol{B}_0 = (0, 0, \mathrm{B0})$ used for spin polarization which is most as possible uniform over the volume of interest (VOI). For imaging applications the homogeneity is in order of a few parts per million (ppm) over a spherical volume up to 50–80 cm in diameter for clinical MRI systems. Increased demand with respect to the homogeneity of 1 part per billion over a spherical volume of a few cm is required for high resolution spectroscopy. For these reasons so-called shim coils are commonly employed as part of the gradient system or part of the main magnet for adjusting the uniformity of the main magnetic field $\boldsymbol{B}_0$ in the VOI locally.

The gradient coils are used for flexible switching of the linearly independent gradient fields $\boldsymbol{g} = \left(g_x, g_y, g_z\right)$ and these are temporarily superimposed to the main magnetic field $\boldsymbol{B}_0$. In this manner the spatial origin of the signal contributions are actively encoded either in its frequency or phase. Fast and so-called real-time imaging applications are limited in most cases by the gradient performance.

At the inner wall of the gradient coil or as outer part of the RF coil, a RF screen is included. This screen protects the inner volume from the outer space so that no additional noise is introduced into the received signal and prevents undesired RF-coupling of the RF-coil to the gradient system.

For applying the $\mathbf{B}_1$RF-field into the sample and receiving the RF-electromagnetic field from the sample the so-called RF coils, also known as RF resonators or RF-probes are used. This RF coil operates at a resonance frequency $v_0 = \frac{\omega_0}{2 \cdot \pi}$ in the general frequency band that is fixed by the desired Larmor-frequency and corresponds to the main magnetic field $B_0 = |\boldsymbol{B}_0|$ (section Basic Introduction to the Principle of NMR and MRI).

In principle three main RF systems of RF coils are distinguished:

- RF systems for excitation and reception (Tx/Rx) of the $\mathbf{B}_1$ electromagnetic RF field; commonly volume resonators and local coils and so-called RF-array coils are used.
- RF systems of excitation-only (Tx-only) of the $\mathbf{B}_1$ electromagnetic RF field; commonly volume resonators and dedicated transmit RF-array coils are used.
- RF systems for reception-only (Rx-only) of the $\mathbf{B}_1$ electromagnetic RF field; commonly local RF coils and so-called RF-array coils are used.

DOI 10.1007/978-981-4560-75-7_121-1

Until today, so-called volume coils were used for Tx/Rx operation. These RF coils generate a homogenous RF-field $\boldsymbol{B}_1$ inside a given volume of interest (VOI). Today these volume coils are generally used for imaging whole-bodies and deeper structures inside the VOI and for MRI systems where the wavelength of the RF-field $\boldsymbol{B}_1$ is much larger than the dimensions of the object under investigation. The $\boldsymbol{B}_1$ RF-field is generated by a suitable current distribution (see section The General Principle of Volumetric RF Antennas with Homogenous RF-Field Based on Magneto Static Theory) on conductive wires and structures. In most cases the RF coil is equipped with a RF screen. The distance of the conducting wires and the RF screen is an important parameter with respect to the efficiency of the RF-coil (see section Shielding of Birdcage Coils). While the magnetic field strength $\boldsymbol{B}_0$ increased rapidly over the years, the wavelength of the RF-field became comparable to the dimensions of the object under investigation. New imaging techniques were needed and so-called Tx/Rx RF-array coils were introduced. These coils consist of multiple independent small RF-structures (surface coils) that are arranged around the VOI and driven by their own RF-chain independently (see section Receive Array Coils for Parallel Imaging). Since the early days of MR imaging small loop Tx/Rx surface coils were used. Today this kind of coils is commonly used for applications where only a small VOI is of interest, inhomogeneous RF-fields can be tolerated and a high signal to noise ratio (SNR) is required. This is the case, e.g., for double resonance spectroscopy experiments (MRS) where the RF-coil operates on two different frequencies for detection of multiple nucleus at the same time or same application e.g., $^{1}H/^{13}C$, $^{1}H/^{31}P$.

For Tx-only operation commonly volume coils are used and for clinical MRI-systems these RF coils are often called “body-coils.” The key point is that these coils are only used for excitation of a homogenous RF-field $\boldsymbol{B}_1$ inside a well-defined VOI. These volume coils are geometrically optimized for a large diameter as possible of the accessible volume and have in most cases a less optimum RF-efficiency. In addition, these RF-coils are equipped with so-called active decoupling circuits for actively and temporally switching the active RF-elements out of the resonance frequency ω_0 . For the detection of the MR-signal a separate RF-system is used –a receive-only RF coil system.

The RX-only coil systems are subdivided in three main receive RF-systems (volume coils, surface coils and array coils): The RF- circuits of all these coils are actively or passively decoupled from the transmitter RF coil system in a manner that the transmitting and receiving RF-system is mutually switched off from the Larmor-frequency ω_0 for minimized RF coupling of the Tx and Rx subsystems. This so-called decoupling prevents the splitting of the resonance modes during the transmit or receive operation. The Rx-only volume coils work on the principle of the transmit-only counterparts but the geometrical dimensions are optimized for the highest possible efficiency. In most cases these RF coils are designed in a manner that the RF screen is missing and the inner volume of the RF coil fits as tight as possible to the objects under investigation. In most cases the geometry of these coils is a compromise between RF-efficiency, homogeneity of the RF-field $\boldsymbol{B}_1$, usability and user-handling. In contrast to Rx-only volume coils so-called Rx-only surface-coils provide inhomogeneous electro-magnetic RF-fields $\boldsymbol{B}_1$ and are used for dedicated imaging applications where the VOI is localized to a small area. Because of the dedicated localization of the RF-field and additional preamplifiers located directly at the RF-structure, these coils provide a high SNR which is in most cases much higher than that of volume coils.

Several surface coils can be arranged into a set of independent antennas around the VOI; this arrangement is called RF array coil (section Receive Array Coils, Transmit Sense/RF Shimming). For imaging with array-coils the MR signal is detected by the multiple independent RF array-elements and each of them have their own RF receiver-chain. The signals are combined by the software (section Receive Array Coils). In most cases the result image is more inhomogeneous compared to volume coils, but has the advantage of a very high SNR based on the pre-amplification of the MR signal and the close proximity of the array coil elements to the VOI.

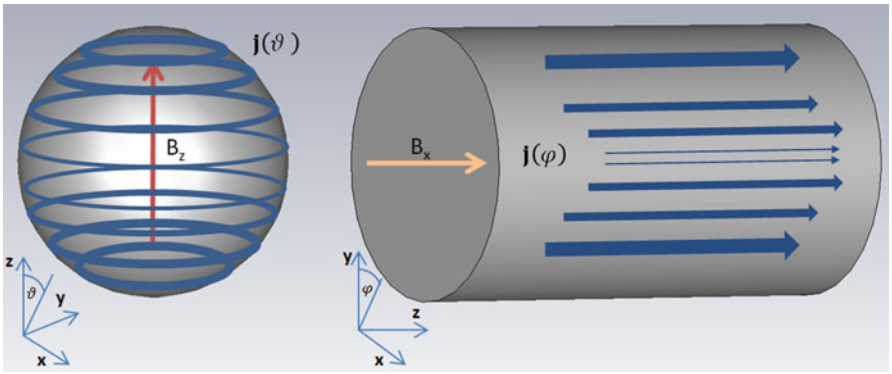

Fig. 11 Sinusoidal surface current distribution for generation of a homogenous transversal magnetic field

Design of MRI Coils

Design Principles of Volume RF Antennas for MRI

The General Principle of Volumetric RF Antennas with Homogenous RF-Field Based on Magneto Static Theory

The basic principle of volume RF coils is based on magneto static theory and on the general solution of the magnetic field in a source-free region, e.g., in spherical coordinates. Under the consideration that the current density **j** is zero outside of the surface of a sphere than **j** is defined in spherical coordinates at the surface with the radius $r = R$ (Fig. 11) by

$$\mathbf{j}(r, \vartheta, \varphi) = \left(\mathrm{j_r}, \mathrm{j}_\vartheta, \mathrm{j}_\varphi\right) = (0, 0, \mathrm{j}_0 \cdot \sin\vartheta) \tag{28}$$

Based on the Gauss's-law and Ampere's law in a source free region the following conditions apply

$$\nabla \cdot \mathbf{B} = 0 \tag{29}$$

$$\nabla \times \mathbf{B} = 0 \tag{30}$$

The scalar magnetic potential $\Phi^i(r, \vartheta, \vartheta)$ and $\Phi^a(r, \vartheta, \vartheta)$ at the inside and outside of the sphere $\mathbf{B}^{ia} = -\nabla\Phi^{ia}$ can be defined and this yields with Eq. 29 to the well-known Laplace equation $-\Delta\Phi^{ia} = 0$. The general solution can be written in spherical coordinates by

$$\Phi(r, \vartheta, \varphi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \left(C_{l,m} \cdot r^l + D_{l,m} \cdot r^{-(l+1)}\right) Y_{l,m}(\vartheta, \varphi) \tag{31}$$

and the current density at the equator is defined by the total current I by $\mathrm{j}_0 = \frac{I}{2R}$. Since j is independent from φ only terms of $\mathrm{m} = 0$ of the Eq. 31 are considered

$$\Phi(r, \vartheta) = \sum_{l=0}^{\infty} \left(C_{l,0} \cdot r^l + D_{l,0} \cdot r^{-(l+1)}\right) Y_{l,0}(\vartheta) \tag{32}$$

While the term $C_{l,0} \cdot r^l$ is regular at $\mathrm{r} = 0$ and goes to infinity for $r = \infty$ and the term $D_{l,0} \cdot r^{-(l+1)}$ is undefined at $\mathrm{r} = 0$ the scalar potential inside and outside of the sphere is defined by

DOI 10.1007/978-981-4560-75-7_121-1

$$\Phi^i(r,\vartheta) = \sum_{l=0}^{\infty} C_{l,0} \cdot r^l \cdot Y_{l,0}(\vartheta) \tag{33}$$

$$\Phi^a(r,\vartheta) = \sum_{l=0}^{\infty} D_{l,0} \cdot r^{-(l+1)} \cdot Y_{l,0}(\vartheta) \tag{34}$$

Based on $\nabla \cdot \mathbf{B} \equiv 0$, the normal component of B must be continuous at r = R and this yields to

$$\left(\frac{\partial \Phi^a}{\partial r} - \frac{\partial \Phi^i}{\partial r}\right)\Big|_{r=R} = 0 \tag{35}$$

$$\sum_{l=0}^{\infty} \left(l \cdot C_{l,0} \cdot R^{l-1} + (l+1) \cdot D_{l,0} \cdot R^{-l-2}\right) \cdot Y_{l,0}(\vartheta) = 0 \tag{36}$$

While the Eq. 36 is valid for every angle ϑ every member of the sum over l must be zero and the result is

$$D_{l,0} = -\frac{l}{l+1} R^{2l+1} \cdot C_{l,0} \tag{37}$$

The finite surface current **j** at the surface of the sphere results in a discontinuity of the tangential component of **B**. This can be expressed by the normal vector **n** of the spherical surface by

$$\left(\boldsymbol{B}^a - \boldsymbol{B}^i\right) \times \mathbf{n} = \mu_0 \cdot \mathbf{j} \tag{38}$$

By definition of Eq. 28 the current density has only nonzero components for the φ component and the discontinuity is only valid for components of ϑ

$$\left(\mathbf{B}^a_\vartheta - \mathbf{B}^i_\vartheta\right) = \mu_0 \cdot \mathrm{j}_0 \cdot \sin\vartheta \; at \; r = R \tag{39}$$

This yields

$$\mathbf{B}^a_\vartheta(R,\vartheta) = -\frac{1}{R}\frac{\partial \Phi^a(r,\vartheta)}{\partial \vartheta}\Big|_{r=R} = \sum_{l=0}^{\infty}\left(\frac{l}{l+1} \cdot C_{l,0} \cdot R^{l-1}\right) \cdot \frac{\partial Y_{l,0}(\vartheta)}{\partial \vartheta} \tag{40}$$

$$\mathbf{B}^i_\vartheta(R,\vartheta) = -\frac{1}{R}\frac{\partial \Phi^i(r,\vartheta)}{\partial \vartheta}\Big|_{r=R} = -\sum_{l=0}^{\infty}\left(C_{l,0} \cdot R^{l-1}\right) \cdot \frac{\partial Y_{l,0}(\vartheta)}{\partial \vartheta} \tag{41}$$

and substituting Eqs. 40 and 41 into 39 leads to

$$\sum_{l=0}^{\infty} C_{l,0} \cdot \left(\frac{2l+1}{l+1}\right) \cdot R^{l-1} \cdot \frac{\partial Y_{l,0}(\vartheta)}{\partial \vartheta} = \mu_0 \cdot \mathrm{j}_0 \cdot \sin\vartheta \tag{42}$$

The only valid derivate $Y_{l,0}(\vartheta)$ that is proportional to sin ϑ is $Y_{1,0}(\vartheta)$. With Eq. 42 and

$$\frac{\partial Y_{l,0}(\vartheta)}{\partial \vartheta} = -\sqrt{\frac{3}{4\pi}}\sin\vartheta \tag{43}$$

DOI 10.1007/978-981-4560-75-7_121-1

it can be concluded that all $C_{l,0} = 0$ for all $l \neq 1$ and $C_{1,0} = -\frac{2}{3}\sqrt{\frac{4\pi}{3}\mu_0 \cdot j_0}$. This yields for the scalar potential inside the sphere $\Phi^i(r,\vartheta) = \quad = -\frac{2}{3}\mu_0 j_0 \cdot r \cdot \cos\vartheta = \quad = -\frac{2}{3}\mu_0 j_0 \cdot z$.

In conclusion: A constant **B**-field $B\left(0,0,\frac{2}{3}\mu_0 j_0\right)$ inside the sphere in the z-direction is generated when a sinusoidal current distribution $\mathbf{j}(\vartheta,\varphi) = \mathbf{j}(0,0,j_0 \cdot \sin\vartheta)$ is applied. Using $j_0 = \frac{I}{2R}$ and $\mu_0 = 4\pi \cdot 10^{-7}\frac{Vs}{Am}$ a magnetic field **B** inside the sphere aligned with the z-direction of $B_z = \frac{4\pi}{30}\frac{I}{R}[\mu T]$ is the result with current I [A] and the radius R in [m].

This approach of sinusoidal current density modulation is the basic approach for generating a homogenous transversal **B**-field inside the volume of RF coils. From experience it is generally known that this approach is only valid for static currents and field distributions. But a static current distribution as an approach can be successfully used as long as the wave-length of the electro-magnetic fields is much larger than the dimensions of the object under investigation.

While access is needed to the inner volume of the resonator, the approach using a sphere is useless in practice. In general, a cylindrical structure is used to provide this access. The approach of applying a sinusoidal current distribution on a cylindrical surface will lead also to a homogenous **B**-field at the middle of an infinite long cylinder but requires also a defined current distribution at the fronts of a finite cylinder.

A homogenous magnetized finite long cylinder is considered. The material equation describes the relation between $\boldsymbol{B}$ and **H**-field and the magnetization $\boldsymbol{M}$

$$\boldsymbol{B}(x) = \mu(x)\,\mu_0 \boldsymbol{H}(x) + \boldsymbol{M}(x) \tag{44}$$

The current density **J**(**x**) in the areas inside and outside the cylindrical surface is zero and based on the 1. Maxwell equation the Eq. 44 can be written

$$0 = \nabla \times \mathbf{H}(\mathbf{x}) = \nabla \times 1/(\mu(x)\mu_0)(\boldsymbol{B}(x) - \boldsymbol{M}(x)) \tag{45}$$

It is considered that the permittivity in the inner cylinder is constant and is independent from position **x**. With the introduction of the vector potential **A** by $\boldsymbol{B} = \nabla \times \boldsymbol{A}$ the Eq. 45 yields to the so-called Poising equation $-\nabla^2 \boldsymbol{A} = \nabla \times \mathbf{M}$. This equation can be derived as volume integral (Kohlrausch 1956) while the magnetization **M**(**x**) is unequal zero only in a finite volume and the permittivity is constant:

$$\mathbf{A}(x) = \frac{1}{4\pi}\int \frac{\nabla' \times \mathbf{M}(\mathbf{x}')}{|x - x'|} dV' \tag{46}$$

For a finite volume where the magnetization **M** switches to zero at the surface of the body, the Eq. 46 can be written (Becker 1973) using the surface element $\mathbf{df}' = \mathbf{n}' \cdot \mathrm{d}f'$

$$\mathbf{A}(x) = \frac{1}{4\pi}\int \frac{\nabla' \times \mathbf{M}(\mathbf{x}')}{|x - x'|} dV' + \frac{1}{4\pi}\int \frac{\mathbf{M}(\mathbf{x}') \times \boldsymbol{n}'}{|x - x'|} df' \tag{47}$$

The vector potential A can be written by using the current density **J** as

$$\boldsymbol{A}(\boldsymbol{x}) = \frac{1}{4\pi}\int \frac{\mathbf{J}(\mathbf{x}')}{|x - x'|}\, dV' \tag{48}$$

DOI 10.1007/978-981-4560-75-7_121-1

On one hand it is considered that the magnetization of the body is constant and from Eq. 45 follows that the field **B** is also constant. On the other hand from Eq. 47 the volume integral disappears under this consideration.

The conclusion is: there are only surface currents on the body and the current density has no component in direction of the surface normal **n**. For that case Eq. 48 can be written by using the surface current density **j** to

$$\boldsymbol{A}(\boldsymbol{x}) = \frac{\mu_0}{4\pi} \int \frac{\mathbf{j}(\mathbf{x}')}{|x - x'|} df' \tag{49}$$

While the volume integral of Eq. 47 disappears than the surface integrals of Eqs. 47 and 49 must be equal and result in the surface current density of

$$\mathbf{j}(\mathbf{x}') = \frac{1}{\mu_0} \boldsymbol{M}(\boldsymbol{x}) \times \boldsymbol{n}' \tag{50}$$

This result means that a surface current density **J**(**x**) generates a constant **B**-field **B**(**x**') under consideration of a constant magnetization **M**(**x**) defined at a surface S' with a surface normal **n**'. This is an exact result that can be used now for a finite cylinder (Fig. 11 right).

The magnetization $\boldsymbol{M}$ is aligned to the x-axis: $\mathbf{M}(\boldsymbol{x}) = \boldsymbol{M}_0 \cdot \boldsymbol{n}_x$. The surface-normal on a cylindrical surface is defined by $\mathbf{n}' = (\sin\varphi, \cos\varphi, 0)$. With Eq. 50 the surface current density is given by

$$\mathbf{j}(\mathbf{x}') = \frac{1}{\mu_0} \boldsymbol{M}_0 \cdot \cos\varphi \cdot \boldsymbol{n}_z \tag{51}$$

This is the current density that is expected: a cosine or sinusoidal surface current distribution. While the cylinder has a finite length the surface current distribution on the fronts of the cylinder is required for a homogenous magnetic field. The surface-normal of the front side is defined by $\boldsymbol{n}' = (0, 0, \pm 1)$ and with Eq. 50 a constant surface current at the front sides of the cylinder $\mathbf{j}(\mathbf{x}') = \pm\frac{1}{\mu_0}\boldsymbol{M}_0 \cdot \boldsymbol{n}_y$ is the result. While access to the inner area of the cylinder is needed for the object under investigation this current distribution can be practically realized only at one side of the cylinder. The RF coils that are closed at one side are called end-caped RF coils.

Saddle- and Birdcage- Coils – An Approximation of an Ideal Current Distribution

A continuous sinusoidal or cosine current distribution is only a theoretical model and in principle this current distribution is approximated by two basic principles (see Fig. 12). (1) the current distribution can be approximated by conductive wires placed on nonequidistant angles using a fixed current $I = I_0$. (2) the current distribution is approximated on radially equidistant positions of the wires on the cylindrical structure and the current I is modulated by a sinusoidal or cosine current I_0.

The simplest case is the approximation by two currents I_0 and $-I_0$ at opposite positions at the cylindrical surface (Fig. 12a). A special case of this approach is the "Aldeman Grant" or "Slotted tube" resonator (Alderman and Grant 1979; Schneider and Dullenkopf 1977) where the current distribution is approximated by two rectangular conducting surfaces. These resonators were used in the early days of MRI. Still today they are common solutions for other applications such as electron paramagnetic resonance (EPR).

The approximation of the current distribution on four points leads to so-called saddle coils (Hoult 1979) (Fig. 12b) and consist of two 120° rotated saddle based on two conductive wires with the current I_0 that are

DOI 10.1007/978-981-4560-75-7_121-1

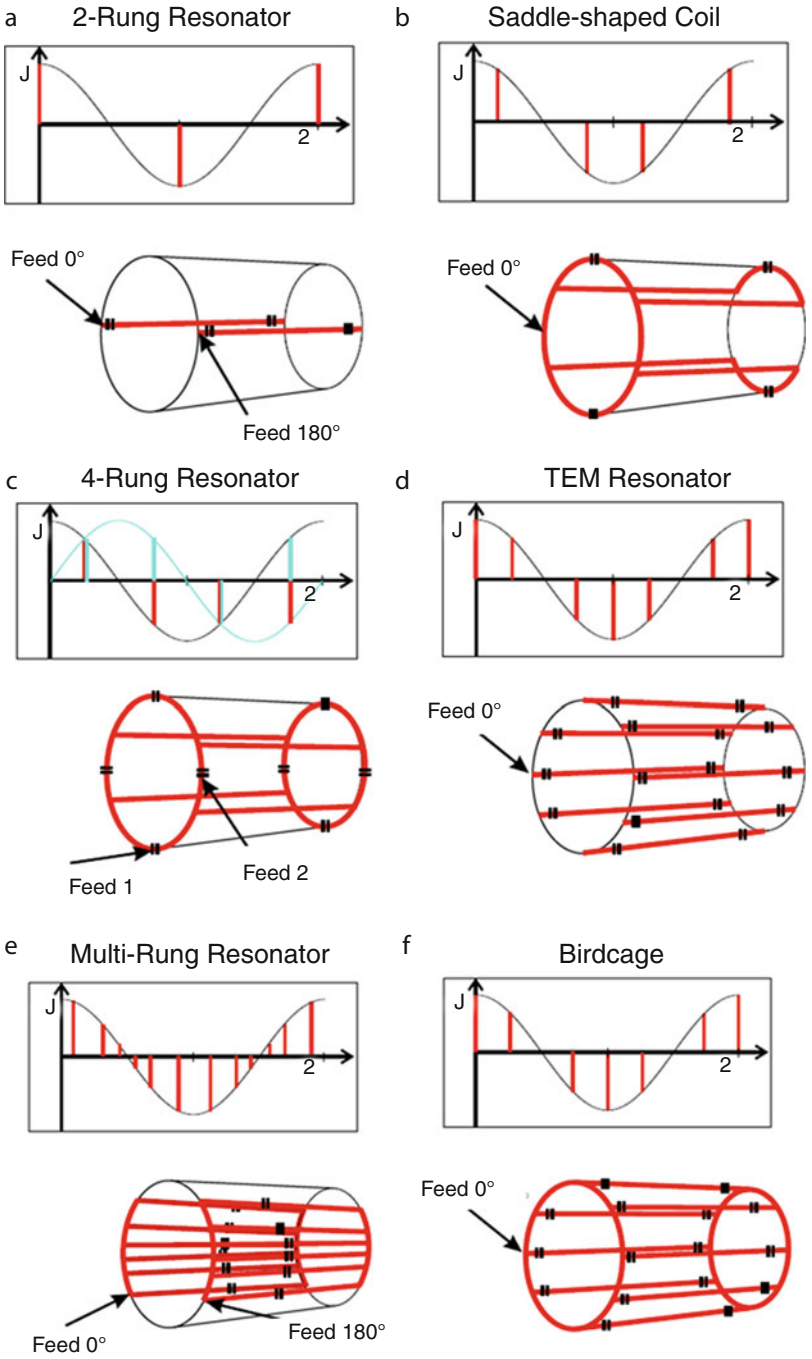

Fig. 12 Approximation of the ideal current distribution by RF coils (Link 1992. With permission of Springer)

rotated by 60° to each other. The value of this angle follows by the demand of the optimal bisection of the Integral of the cosine function in the area of 0° to 90°. This type of RF coil is very popular for the usage in low-field MR systems and for RF coils where the diameter is small enough compared to the wave-length of the RF-field. One drawback is the increased inductivity of the coil wire and the practical usage of this principle is limited by the self-resonance of the coils structure. Below this frequency the coil's structure can be adjusted to every resonance frequency that is required by the introduction of capacitors and can be optimized by the introduction of multiple capacitors that are placed symmetrically on the coil structure. Another draw-back is that saddle coils could not be easily built for quadrature operation

DOI 10.1007/978-981-4560-75-7_121-1

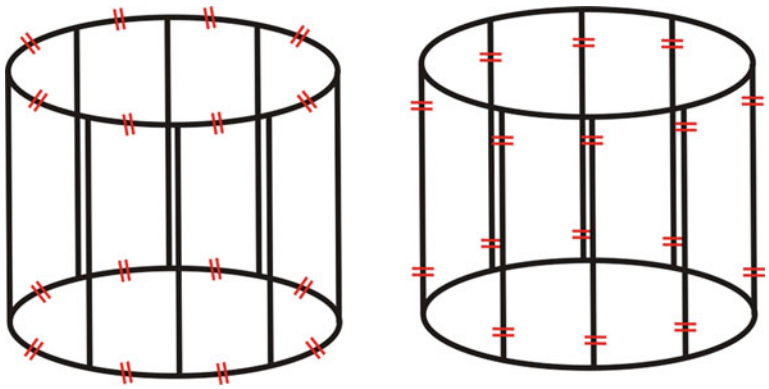

Fig. 13 Principle sketch of a Highpass birdcage RF coil (*left*); Lowpass RF coil (*right*)

(see section Quadrature Detection and Reception). Today saddle coils are commonly replaced by so-called Birdcage-coils (Hayes et al. 1985) since the diameter and Larmor frequency of the MR-system increased in the course of the time. The birdcage coil has become the "golden standard" volume RF coil in MRI systems because of its intrinsic excellent field homogeneity and ability to operate easily in quadrature excitation/reception based on the radial symmetry.

The birdcage coils are based on the approximation of the ideal current distribution on many equidistant points and the principle structure is based (see Fig. 13) on two conductive rings at the front side of the cylindrical surface connected by multiple conductive wires.

There are two basic types of birdcage coils: on one hand the high-pass birdcage on the other hand the low pass birdcage. The name is based on the structure of the latter network (see Fig. 14). Each mesh is based on a low-pass or high-pass filter and either the capacitors C_1 on the end-rings or C_2 at the rungs (legs) between the end-rings are being used. For a cylindrical structure the values of C_1 or C_2 for a low-pass or high-pass birdcage respectively have in principle the same values. When high- and low-pass birdcage structures are combined into one structure, this leads to so-called band-pass or hybrid birdcages.

A birdcage ladder network can be analyzed with the use of the nodal or mesh method based on the Kirchhoff law. In strict terms these rules are only valid if the maximum length of each conducting element is kept below app. 1/20 of a wavelength and if the structure is planar. But in practice the matrix treatment of Leifer (1997) based on the ladder network theory and the Kirchhoff's law (Tropp 1989, 1997) explains the Eigen-modes of the birdcages in a sufficient manner and can be used successfully in many cases (Chin et al. 2002a).

First a low-pass birdcage consists of N legs and meshes is analyzed. Following the rule of the Kirchhoff's voltage law, the sum of all voltages in a mesh equals zero. On the nth mesh (Fig. 14) the voltage of C_2 is on the left hand side $\frac{I_n}{j\omega C_2} - \frac{I_{n-1}}{j\omega C_2}$ and on the right hand side $\frac{I_n}{j\omega C_2} - \frac{I_{n+1}}{j\omega C_2}$. The voltage with respect to the self-inductance of the mesh is $j\omega L_n \cdot I_n$ and the voltages corresponding to the mutual inductances are added $M_{mn}\, m \neq n$ of the mesh cell n to all other meshes m: $j\omega \sum_{m \neq n} M_{mn} \cdot I_m$. Multiplying all terms with $j\omega$ yields to

$$-\omega^2 \sum_{m \neq n}^{N-1} (M_{mn} \cdot I_m + L_n \cdot I_n) + \frac{1}{C_2}(2I_n - I_{n+1} - I_{n-1}) = 0 \tag{52}$$

This equation rules for all meshes n = 1…N of the birdcage under the assumption that all designed meshes are equal and have the same self-inductance $L_n = L =: M_0$. Because of the cylindrical symmetry with N legs the mesh n = N + 1 corresponds n = 1 and n = 0 corresponds n = N. The Eq. 52 can be rewritten for all meshes n = 1..N

DOI 10.1007/978-981-4560-75-7_121-1

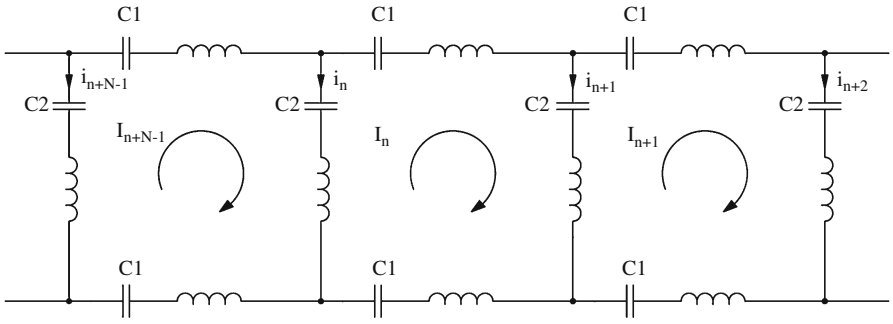

Fig. 14 Ladder network showing reactances and currents of a birdcage RF coil

$$-\omega^2 \sum_{m=0}^{N-1} M_m \cdot I_{m+n} + \frac{1}{C_2}(2I_n - I_{n+1} - I_{n-1}) = 0 \tag{53}$$

and these N equations are yield with the self-, mutual inductances (M_0, M_m) and the capacities C_2 to a linear system of equations (Leifer 1997)

$$\tilde{E}I - \omega^2 \cdot \tilde{M}I = 0 \tag{54}$$

with

$$\tilde{M} = \begin{pmatrix} M_0 & M_1 & \cdots & M_{N-1} \\ M_{N-1} & M_0 & \cdots & M_{N-2} \\ \vdots & \vdots & \vdots & \vdots \\ M_1 & M_2 & \cdots & M_0 \end{pmatrix} \tilde{E} = \begin{pmatrix} -\frac{2}{C_2} & \frac{1}{C_2} & 0 & \cdots & \frac{1}{C_2} \\ \frac{1}{C_2} & -\frac{2}{C_2} & \frac{1}{C_2} & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \frac{1}{C_2} & \cdots & 0 & \frac{1}{C_2} & -\frac{2}{C_2} \end{pmatrix}$$ and the Column vector

$$I = \begin{bmatrix} I_0 \\ \vdots \\ I_N \end{bmatrix}.$$

The Eq. 54 has only solutions for discrete values of ω and can be rewritten to an eigen value equation

$$\tilde{M}^{-1}\,\tilde{E}I = \lambda I \tag{55}$$

The Eigen-frequencies given by the eigen values $\lambda = (i\omega)^2$ and are calculated from the properties of circulant matrices with respect to periodic functions. The Eigen-frequencies are given for a

$$\text{Lowpass birdcage } \omega_k = -\sqrt{\lambda} = \sqrt{\frac{\widetilde{E}}{\widetilde{M}}} = \sqrt{\frac{2}{\widetilde{M_k}}}\left[\frac{1}{C_2} \cdot \left(1 - \cos\frac{2\pi k}{N}\right)\right] \tag{56}$$

Using this approach in the same manner for high pass or band-pass birdcage the results are:

DOI 10.1007/978-981-4560-75-7_121-1

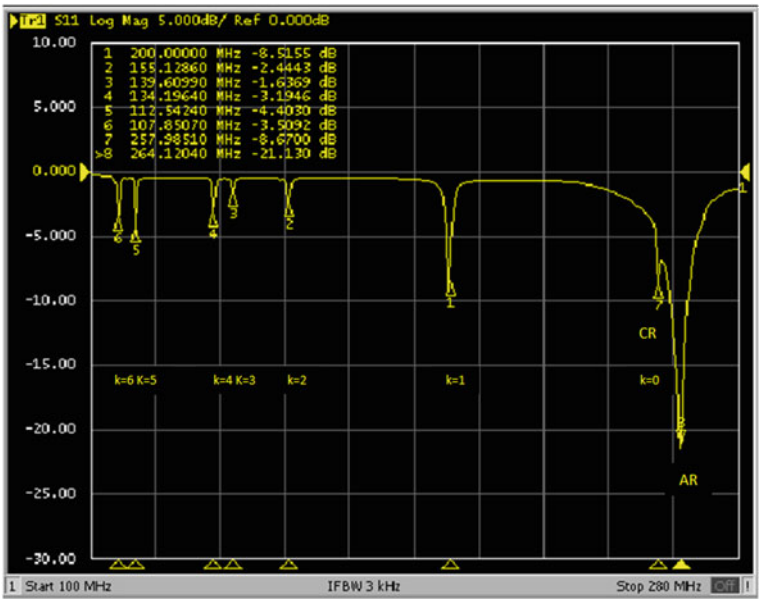

Fig. 15 Meassured eigenmode spectrum of a 12 rung high-pass-birdcage operating for MRI applications at 200 MHz. The modes are labeled with the wave number k and the ring-modes are labeled with AR and CR for the anti- and co-rotating ring-modes. The operating mode for high-pass-birdcages is the secound highestmode with k = 1

$$\text{Highpass birdcage} : \omega_k = \sqrt{\frac{2}{\widetilde{M}_k} \cdot C_1} \tag{57}$$

$$\text{Band-pass birdcage} : \omega_k = -\sqrt{\lambda} = \sqrt{\frac{\tilde{E}}{\tilde{M}}} = \sqrt{\frac{2}{\widetilde{M}_k}\left[\frac{1}{C_1} + \frac{1}{C_2} \cdot \left(1 - \cos\frac{2\pi k}{N}\right)\right]} \tag{58}$$

$$\text{where} \quad \widetilde{M}_k = \sum_{n=0}^{N-1} M_n \cdot e^{-i2\pi kn/N} \tag{59}$$

Based on the symmetry of the matrixes $\tilde{M}$ and $\tilde{E}$ and its periodic function the number of degenerated Eigen-modes pairs are limited to N/2-1.

With this approach all Eigen-modes and their current distributions can be calculated by using the given inductance values and capacity values. For the high-pass and bandpass birdcage two additional modes are present. These modes are a result from the coupling of the end-rings forming a co-rotating or counter-rotating mode. The frequency of the co-rotating mode can be calculated by the Eqs. 57 and 58 using the coefficient k = 0. The counter-rotating mode is calculated (Leifer, 1997) by the number of mesh-cells, the ring capacitors C_1, the self-inductance L_r of the end-rings and their magnetic coupling

$$M_{\text{ring}} : \omega_{cro} = \sqrt{\frac{N}{C_1\left(L_r - M_{\text{ring}}\right)}} \tag{60}$$

The magnetic **B**-field both of these modes are aligned in direction of the cylindrical axis (z-axis). These modes are at the two highest frequencies of the Eigen-mode spectrum. In most cases these modes are uninteresting for MRI due to the fact that the external **B**-field $\mathbf{B}_0$ points in the same direction. Among the number of N/2-1 degenerated Eigen-mode pairs of a birdcage with N rungs there exists only one

DOI 10.1007/978-981-4560-75-7_121-1

Eigen-mode that fits the requirement of Eq. 28, a cosine or sinusoidal current distribution. Apart from the ring-modes the frequency of this Eigen-mode for the high-pass and low-pass birdcage is at the highest frequency (k = 1) and at the lowest frequency of the Eigen-mode spectrum, respectively (Fig. 15).

In principle the structure and dimensions of a RF coil and the operating frequency ω_0 are predefined and the values of the resonance capacitors C_1 and C_2 are unknown. With knowledge of the inductances and mutual inductances these capacitor values can be calculated that are needed for an Eigen-mode at ω_0 and for the required sinusoidal current distribution on the legs of the birdcage. Based on this approach the necessary capacitance values can be calculated by approximation of the inductances and mutual inductance values (Grover 1946; Chin et al. 2002b)..

In most cases, especially when the wavelength of ω_0 is much larger than the dimensions of the RF-coil, this approach is useful for the identification of the desired frequency of the Eigenmode spectrum. The final tuning of the resonant frequency ω_0 can be done by fine adjusting the capacitor values C_1 or C_2 respectively (Fig. 14).

With introduction of numerical field calculation basically based on the Method-of-moments (e.g., commercially provided by Concept II, TET, TU Hamburg-Harburg; FEKO, Altair), Finite Difference –Time domain or Finite element Methods (e.g., commercially provided by MicroWave Studio, CST Darmstadt; Semcad, SPEAG; ANSOFT, ANSYS; XFdtd, RemCom) the calculation of the required capacitor values is much more precise and finally the designer gets the entire field-distributions of the **B** and **E**-fields. In addition the coil structures can be optimized easily by so-called parameter sweeps.

Following the sinusoidal current distribution on the legs or their corresponding cosine voltage distribution (Fig. 17) on the positions of resonance capacitors the desired field distribution on the coils structure can be forced in numerical field simulations by applying the corresponding voltage- or current-sources at the positions of the resonance capacitors. The capacitor value C_n can be calculated from the imaginary part of the input impedance of the multiple sources $Z_{C_n} = \frac{1}{i\omega C_n} = \frac{U_n}{\hat{I}_n}$ where $\hat{I}_n$ is the complex current at the position of the capacitor.

As outlined in section Quadrature Detection and Reception for the calculation of the MRI relevant RF-fields the circularly polarized RF-field has been taken into account. On one hand the counter clockwise rotating component B_1^+ is responsible for excitation anon the other hand the counter clockwise component B_1^- – is the component of the RF-field that is received. In order to qualify the performance of MRI RF coils different $\mathbf{B}_1$-field maps have to be taken into account, depending on the operation mode of the RF-coil for transmission/reception-only or as transmit/receive coil. A typically filed pattern of the transverse $\mathbf{B}_1$-field is presented in Fig. 16 for a high pass birdcage that consists of 12 rungs for the approximation of the required sinusoidal current distribution. The RF-field is linearly polarized and homogenous with respect to the amplitude and phase over a large area of the RF-resonator.

Feeding and Tuning of Birdcages RF Coils

The feeding of birdcage coils is based on the basic principles for feeding of high frequency RF-circuits. Generally all known varieties of feeding networks can be applied for power matching the RF coils to a 50 Ω source. Apart from the inductive coupling of a RF-coil, the capacitive coupled feeding is the most common method connecting RF coils to the RF-chain of an MRI-system. In the following, the high-pass birdcage will be used for a brief introduction on the basic principles.

The diagram below shows the theoretical current- and voltage-distribution on the endrings based on quasi static theory for a balanced (symmetric) feeding. For an unbalanced (asymmetric) feeding the Eigen mode and the corresponding transversal **B**-field points in the same direction as the feeding and the voltage and current distribution change their characteristic distribution vice versa.

DOI 10.1007/978-981-4560-75-7_121-1

Based on the symmetry of birdcages and the cosine or sinusoidal current distribution, the direct feeding on the position at a rung is not preferred while the current on the 90° positioned rung becomes zero and will not contribute to the $\mathbf{B}_1$-field of the coil. In general the feeding is done at one of the end-rings in the geometrical middle of birdcage mesh cell by a symmetric or asymmetric feeding of the resonance capacitor. For asymmetric feeding any known balun-transformation can be applied. The simplest way for feeding a quadrature birdcage is the symmetric feeding by splitting the resonance capacitor C_1 by two capacitors of the value $C_3 = 2 * C_1$ that creates a so-called virtual ground that is required for the perpendicular mode. The RF-shield is used as a common ground of the RF-circuit if the RF structure and the RF screen are in close proximity. The symmetry of the Eigen mode on the birdcage structure is dependent from the feeding and also changes the orientation of the transversal $\mathbf{B}_1$-field inside the structure. Balanced (symmetric) feeding generates a standing wave that is perpendicular to the feeding point and yields to a transversal $\mathbf{B}_1$-field that is perpendicular as well. For an unbalanced (asymmetric) feeding the standing wave is symmetric to the direction of the feeding and yields to a transversal $\mathbf{B}_1$-field that is aligned in same direction.

With the introduction of a serial capacitor C_m to the feeding point the RF-coil is matched to a source impedance of 50 Ω as long as the input impedance of the RF-coil is above 50 Ω. While the RF-coil is loaded with different subjects, additional losses and stray capacitance (section Efficiency, Losses and Signal to Noise Ratio) are introduced. This will change on one hand the input impedance to lower values compared to the empty case and on the other hand the stray-capacities shift the resonance frequency down to lower values. For this reason variable capacitors are required for adjusting the match and tuning of the RF coil. Following the principle of section Quadrature Detection and Reception for quadrature excitation, the coil is fed at two ports that are rotated by 90° from each other.

In principle the frequency of the Eigen-mode of the coil can be affected by changing the capacitance of each of the mesh capacitors, but the optimal position for tuning the frequency of each Eigen mode is at the position of the capacitor with the highest voltage drop (Fig. 17). Using a virtual ground for symmetric feeding the RF-coil (Fig. 18) the optimal tuning-capacitor C_4 + C_1 is 90° rotated with respect to the feeding port V_1. This position is at the opposite side to the port V_2 of the second channel for quadrature feeding of the birdcage. Because of the rotational symmetry and the cosine or sinusoidal voltage distribution, the effect of this capacitor for the second channel is minimal (the smallest voltage drop for the second channel). This assures an independent tuning and matching of the two quadrature channels of the birdcage.

Based on the theory (section Saddle- and Birdcage- Coils – An Approximation of An Ideal Current Distribution) the resonance-capacitors C_1 or C_2 of the mesh cells have the same capacitance value (Fig. 14) if an ideal cylindrical symmetry is provided. The capacitance value C_4 + $C_{T1/2}$ for the tuning is optimal at approximately the same capacitance value of C_1 (Fig. 18). To keep the rotational symmetry this capacitance value needs to be chosen carefully because of the ideal cosine or sinusoidal current distribution that is needed for a perfect homogenous RF-field inside the birdcage. A perfect rotational symmetry is in practice not the case and leads to an inhomogeneity of the transversal RF-field in any case. But this effect can be minimized by building the coil as symmetrically as possible. Different loss loadings will introduce different stray capacities to the coil structure including additional losses to the RF-circuit and for that case the tuning capacities must cover a tuning-range from unloaded to heavy loaded conditions.

In case that the asymmetry of the capacitor value introduced by capacitance C_4 + $C_{T1/2}$ varies widely from the ideal capacitor value of the resonance-capacitor C_1, specific balanced feedings have to be implemented (section Balancing of Birdcage Coils). The Eigen modes of the two channels must be perpendicular for quadrature operation. Any asymmetry leads to a so-called coupling of the modes and can be readjusted by the capacitors (C_5 + C_b) that are positioned diametrically to the feeding ports. At these points the effect for slightly shifting the zero-point of the voltage at the opposite feeding ports of

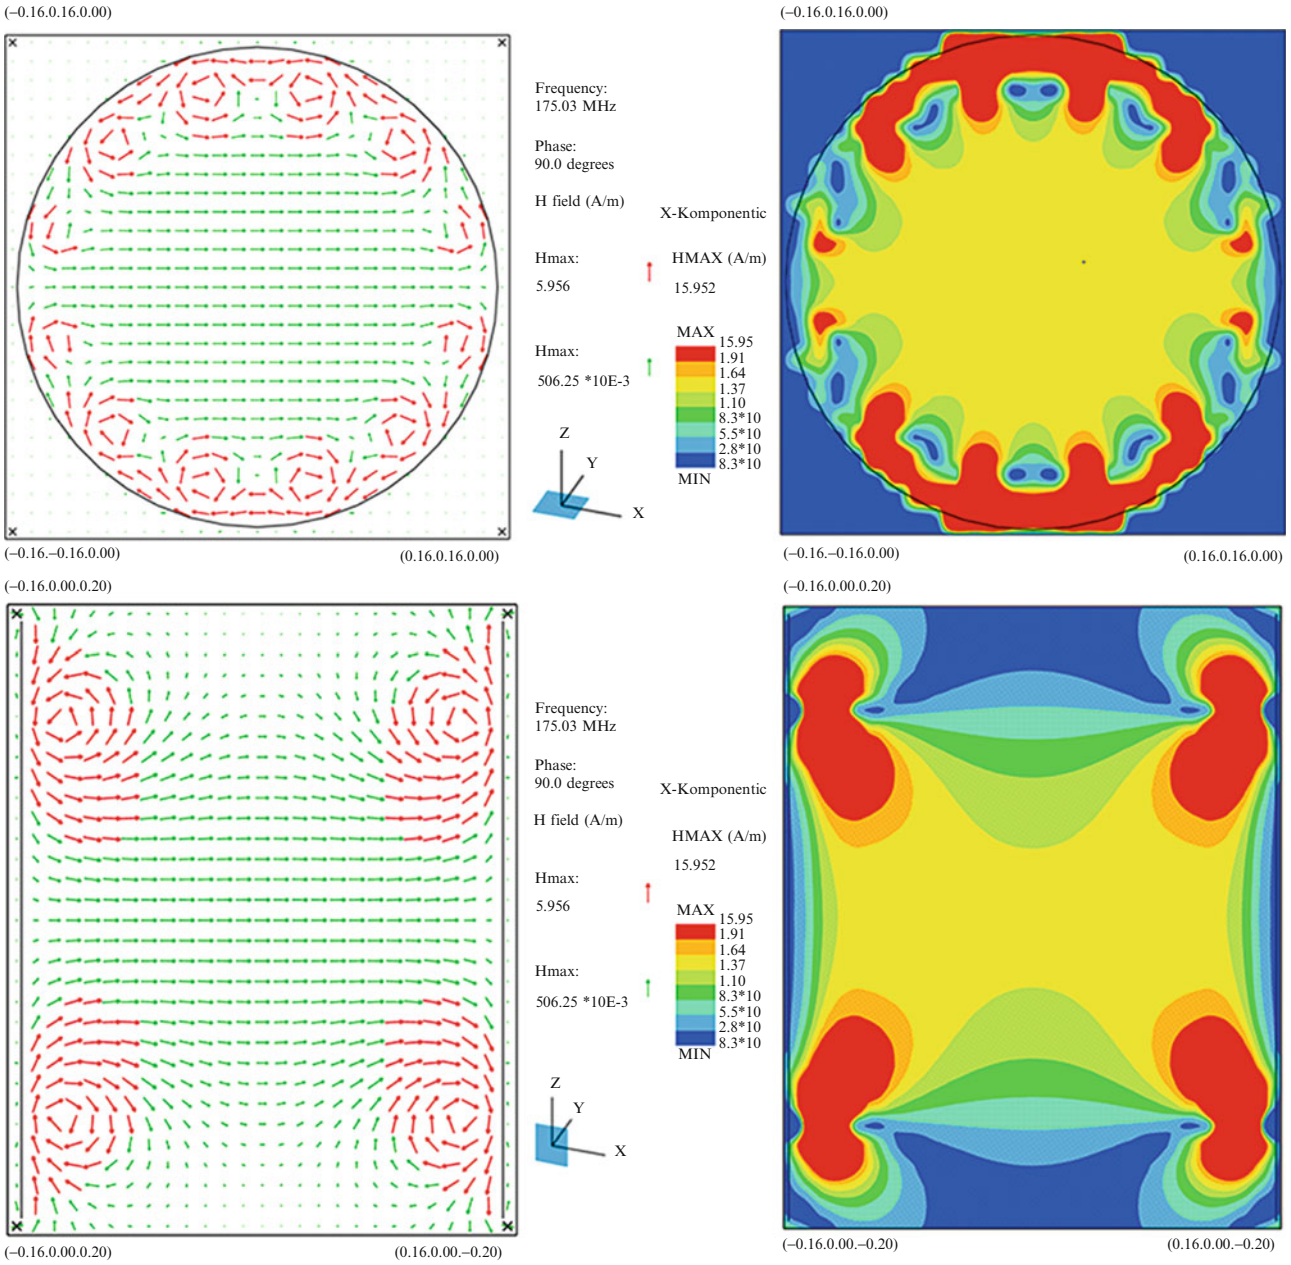

Fig. 16 Simulated $\mathbf{B_1}$-field distribution (MoM using Concept II, TUHH Hamburg, Germany) inside an empty high-pass birdcage operating at 175 MHz fitting the size of a human head. The transversal $\mathbf{B_1}$-field is homogenous over at least 2/3 of the diameter of the RF-coil. The longitudinal homogeneity is limited by the length of the birdcage for a specific operating frequency

both Eigen modes works in the same manner and is done by minimizing the power transfer S12 or S21 of the two quadrature RF channels.

In practice the capacitance values for a real designed birdcage are a compromise to fit the homogeneity of the RF-field, the independency of the quadrature modes and the value range of the variable capacitors to fit the requirements for shifting the resonance frequency of the homogenous Eigen mode for different loading conditions. When the birdcage is used as transmit-only coil (so-called body-coil) in some cases it is sufficient that the body-coil is adjusted once. This adjustment fits an optimal power-matching of a maximum load and the matching is not changed with respect to the different loading conditions. In case of

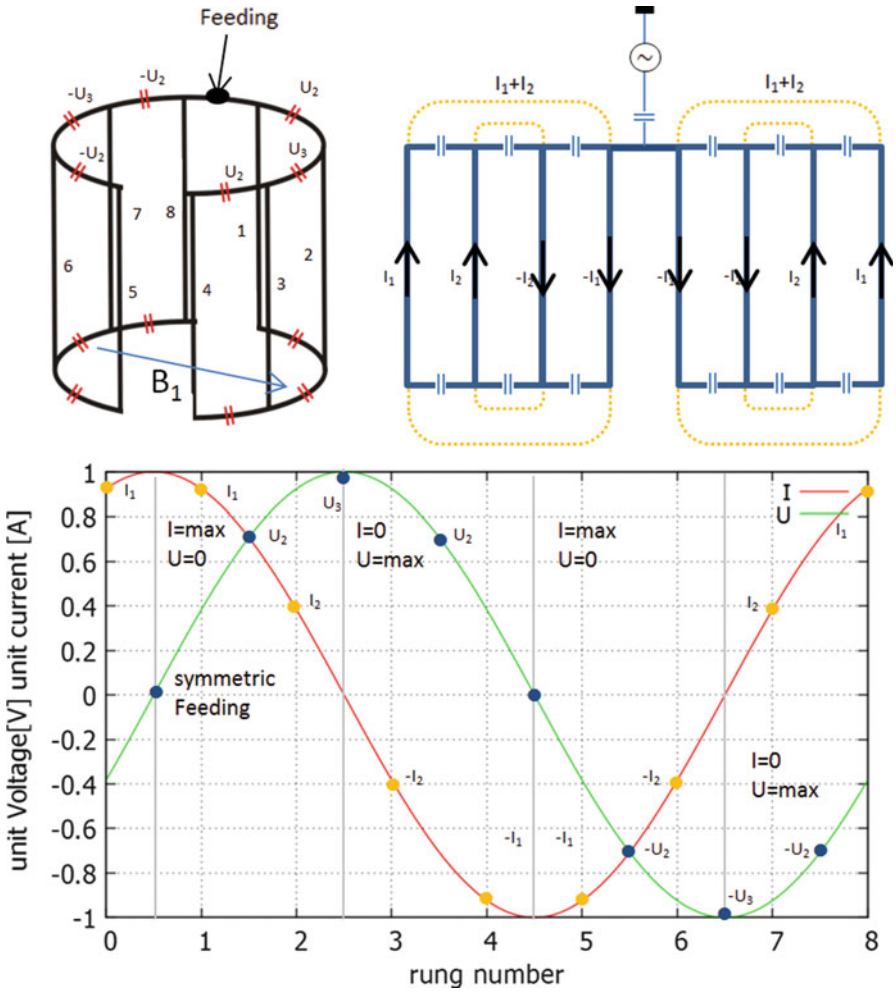

Fig. 17 Voltage and current distribution on a birdcage driven by linear excitation. A standing wave perpendicular to the feeding point is generated that yields to a transversal $\mathbf{B_1}$-field inside the structure

light loading the reflected power will be absorbed in a dummy load, e.g., on one port of the quadrature hybrid. However, in most cases birdcages are tuned and matched for optimal performance with respect to high SNR and low power losses.

Shielding of Birdcage coils

When the birdcage is used as transmit/receive coil, the outer shell of the coil includes in most cases a so-called RF-screen or RF-shield that is most important when the RF coil structure is close to the gradient coil. If the space between the RF-coil and the gradient coil is limited, this screen is glued or molded on the inner surface of the gradient coil. The screen performs three key tasks:

- It minimizes the RF power losses while the screen prevents the coupling of the RF magnetic fields to the gradient coil windings.
- It suppresses the residual RF noise radiated from the gradient coil and shim coil.
- It establishes a well-defined environment for the RF coil in order to generate a homogenous RF-field.

DOI 10.1007/978-981-4560-75-7_121-1

To achieve these tasks the RF shield should perform as a low-pass filter which should be transparent to the magnetic field of the gradient coil that operates at audio-frequency (couple of kHz). The RF shield should also be opaque with low loss to the $\mathbf{B}_1$RF magnetic field of the RF coil. In general the RF screen is designed as a conductive closed cylindrical screen with the thickness of a several RF skin-depth in a manner that the thickness is much smaller than the skin-depth of the audio-frequency of the gradient coil. But such a closed conductive RF screen can support eddy currents induced by the gradient field and thus increases the rise time of the switching gradients and results in imaging artifacts and distortions of the required homogenous $\boldsymbol{B}_0$ -field.

Even if the screen is thin compared to the audio-frequency skin-depth, it is not completely transparent to the high frequency components of the switch gradient field. This results in addition in an interference of the high frequency response and distortions of the gradient waveforms.

The presence of a cylindrical conductive shield can be quantitatively analyzed by the method of images (Smythe 1968) with some approximation to its finite length. Each element of current that is surrounded by a conductive cylinder creates a mirror image with the same current in the opposite direction and located outside of the conductive cylinder. A shield of a diameter D reduces the RF-field at the center compared to an unshielded coil carrying the same currents (Mispelter et al. 2006) by $B_1^{\text{shielded}} = B_1^{\text{unshielded}}\left[1 - \left(\frac{d}{d_s}\right)^2\right]$. The RF shield has also an overall effect in a reduction of the transverse homogeneity of the RF-field compared to unshielded coils. All these effects are strongest for closely fitting RF screens, but in any case the dimensions shield- versus coil-diameter are parameters that can be optimized if the overall geometrical dimensions of the MR-system support this. The current distribution produced by a linear excited birdcage is shown in Fig. 19. The currents on the RF shield are the mirror currents resulting from the currents on the birdcage-structure and forming saddle-shaped loops (Fig. 19). For linear excitation of the birdcage this saddle-shaped current distribution is stationary on the screen but rotates with the resonance frequency when the birdcage is fed in quadrature operation.

To prevent eddy currents on the shield and fit the requirements of a closed RF-screen, double sided copper sheets (Jin 1999) based on a thin dielectric layer (e.g., FR4 fiberglass or polyimide circuit board material) are commonly used.

The general design is based on the principle that each copper sheet is divided into multiple rectangular elements by etching or cutting narrow gaps (Fig. 19 bottom). The pattern on the other side is designed in the same manner and includes an offset of half of the elements-width of the rectangular elements. The overlapping elements separated by the dielectric layer serve as capacitor and the shield itself can be considered as a number of capacitors in series. The capacitance is proportional to the overlapping area and is inversely proportional to the thickness of the dielectric layer. The main impedance of the shield is inversely proportional to the frequency and capacitance.

For RF the conductive elements separated by the gaps of one side are capacitively coupled to the ones of the other side and therefore when the overlapping areas are sufficient in size, the conductive layers are electrically shorted. The shield serves as a single continuous conductor for the high frequency $\mathbf{B}_1$RF field. The eddy currents caused by the gradient coils are suppressed if the rectangular elements are sufficiently small. The gaps between the elements interrupt the current path of the eddy currents induced by the gradient fields. For example a shield having an impedance of 1 Ω at 64 MHz would have an impedance of 6.4 k Ohm at 10 kHz – this means that the shield will be opaque for RF and transparent for the low frequency gradient fields. The element-width and -length and the number of gaps are different for each RF-coil/gradient coil design and have to be optimized for optimal performance of the RF-coil e.g., by introduction of additional discrete capacitors in areas of high RF- current densities.

Balancing of Birdcage coils

Many birdcage coil parameters can be optimized but in most cases the freedom for optimization is for practical reasons (unfortunately) limited. The minimum coil length is given by the homogeneity that is required by the application that will be performed and the maximum coil-length is limited by the gradient-field linearity. Ideally the RF coils should be built as short as possible while the SNR decreases with an increased RF-coil volume.

The number of rungs can be optimized with respect to the transversal homogeneity and the coil losses introduced by the mesh capacitors and find its limits with respect to the number of rungs by the so-called "Millipede Coils" (Wong 2001) including a couple of dozen rungs. The inner and outer diameter is in most cases limited by the inner diameter of the gradient-coil and the subject under investigations. The distribution of the electrical field, parasitically high electrical fields caused by local capacitors, can be optimized using distributed capacitors and locations as far away as possible from the loading.

But, beyond this optimization the most challenging part for coil optimization is the balancing with respect to the homogeneity of the transverse $\mathbf{B}_1$-field that the birdcage operates optimally for all loading conditions. The tuning presented in section Feeding and Tuning of Birdcages RF Coils has its limit when the tuning capacitor values are too far from the optimum value to generate an ideal current distribution. In most cases the acceptable deviation of the current from the ideal one have to be less than 10 % and larger deviations typically lead to inhomogeneous $\mathbf{B}_1$-field distributions shown in Fig. 20. Within the last decades many clever methods have been developed to improve the tuning range of birdcages so as to maintain its symmetry.

Multi-port feeding for the excitation of birdcages to keep the symmetry for a broad tunable range of different loading conditions is explained a later section. The use of so-called tuning-rings for balancing the meshes of a birdcage is another option. This principle is based on the capacitive connection on two diametrically opposed points of the tuning-rings to the birdcage (Fig. 21). The tuning-ring must be capacitively shorted to prevent eddy currents and connected to the end-ring of the birdcage via a tuning capacitor and a short connection or by two tuning capacitors, respectively. The currents from the feeding port split equally to the two tuning-ring segments and the capacitive coupling to the tune-ring moves the resonance-frequency of the desired homogenous mode without change of any capacitor values C_1 of the mesh cells of the birdcage. The principle of balancing by tuning-rings can be extended to both ends of the

DOI 10.1007/978-981-4560-75-7_121-1

end-rings (Mispelter et al. 2006) and is only limited by the mechanical effort for driving the tuning capacitors in equal and symmetric manner.

Volume Coils for High- and Ultra-High-Field MRI Applications – TEM Coils

For dimensions where the wavelength of the RF-resonance frequency becomes comparable with the dimensions of a volume coil the use of low and high-pass birdcage coils comes to a limit. The resonance frequency and inductance are dependent and limited by the dimensions of the end rings that are restricted by the inner diameter. The so-called transmission line (TEM) resonator is a good choice if volume resonator designs are associated with problems regarding coil-efficiency at high magnetic fields $\mathbf{B}_0$. The basic TEM design derives from the first coaxial cavity resonators for NMR of Pound and Purcell (Purcell et al. 1946) and further developed by Roeschmann (Röschmann, 1995) and Vaughan et al. (1994).

In principle when the "floating" end rings of a low-pass resonator are connected to the ground on the RF-shield, this design leads to a transmission line resonator (TEM coil) (Fig. 22). The TEM coils return path of the rung-currents follows now on the RF-shield rather than on the end-rings. The transversal homogeneity is dependent from the number of transmission-lines and provides in principle at the center of the RF coil the same transversal homogeneity as standard low and high pass birdcages with the same number of rungs and dimensions. While the end rings are missing, this design can be easily adapted to split-coil designs when the access to the inner volume is limited, e.g., for dedicated small volume coils for extremities of humans. For this case only the RF-shield has to be split in two parts and that can be realized much easier than for birdcages while the end-rings of the birdcages need an electrical connection in addition to the split RF-shield.

The longitudinal homogeneity is different from that of birdcages while the effects of interferences of the end ring currents are missing. For that reason the TEM-coils can be built shorter in z-length than birdcages for the same transaxial homogeneity. In Fig. 23 the transaxial homogeneity for two RF coils (in dimensions identical) are simulated and the normalized magnitude of the transversal RF-field is plotted along the central axis aligned with the z-axis. The RF-field of the TEM-coils has much less drop and provides at the end of the FOV approximately ± 30 cm, a 3 dB higher transversal RF-field. For same cases this effect can yield in a higher efficiency of the TEM-coil compared to standard birdcage coils. However the effort to build a homogenous TEM coil is in most cases more difficult than compared to standard birdcages. Especially for heavily loaded cases the excitation of the RF-coil at only one feeding port results in an inhomogeneous transversal RF-field. The Balancing by tuning rings in the same manner as for low- and high-pass birdcages could not be implemented and multiport excitation of the ring-structure is required either with the use of lambed elements circuits or a power-splitter/combiner (Fig. 24).

A common method for driving a TEM-coil is the multiport excitation that requires additional power splitter/combiner (Vaughan and Griffiths 2012, pp. 158). In Fig. 24 left the feeding of a quadrature driven transmit/receive TEM-coil is presented. The first transmit/receive switch separates the incoming power to the TEM-coil from the receive path of the MR-system. The power-splitter/combiner splits the power in two 180° phase shifted signals. These signals are split by two additional quadrature hybrids in four in amplitude identical signals that are phase shifted by 0°, 90°, 180°, 270°. For the reception the receive signal is combined in the reverse direction. Instead of using discrete power-splitters/combiners, cable baluns and cable networks can be used, e.g., half-wavelength baluns. The driving of a TEM-coil by multiport excitation can be easily extended to all TEM-rungs (Vaughan and Griffiths 2012, p. 169ff). This yields to TEM-arrays became popular within the last years for ultra-high field applications. For this purpose neighboring transmission line-elements are capacitive decoupled and each TEM-element is matched to 50 Ω and driven independently (Fig. 24 bottom). For receive RF-arrays commonly so-called local surface RF coils are used.

Local RF Coils

From the early days of MRI to today local RF coils play an important role when high sensitivity is required, e.g., for enhanced spatial resolution. This includes single-loop RF coils and multi-loop coils of various shapes (Fig. 27). These coils are generally much smaller than volume coils and have therefore a higher SNR because they receive only noise from nearby regions and provide a much higher sensitivity when they are carefully designed. These local coils are optimized for high SNR within a certain volume of interest (VOI) and typically do not provide a homogenous sensitivity like a birdcage volume-coil. Local RF coils are commonly used either as transmit-receive coils for dedicated MRI and magnetic resonance spectroscopy (MRS) applications or used in receive-only RF coils in combination with a volume coil providing the required homogenous $\mathbf{B}_1$-field for excitation.

Single-loop coils can be arranged as elements of a large-scale RF-array (section Receive Array Coils) for simultaneous parallel reception (section Receive Array Coils for Parallel Imaging) of the MR receive signals. Dedicated MRI applications can be performed by so-called under sampling of the k-space with the result of a significant acceleration of image acquisition time (section Receive Array Coils for Parallel Imaging). This imaging technique based on the prior information of the sensitivity profiles for each of these array-elements. When the local surface coils operate as transmit/receive or transmit-only array coils these coils can be used for parallel excitation while the generated $\mathbf{B}_1$-field of the RF coil array is applied for shaping the transmit $\mathbf{B}_1$-field in a specific manner (section Transmit Array Coils).

DOI 10.1007/978-981-4560-75-7_121-1

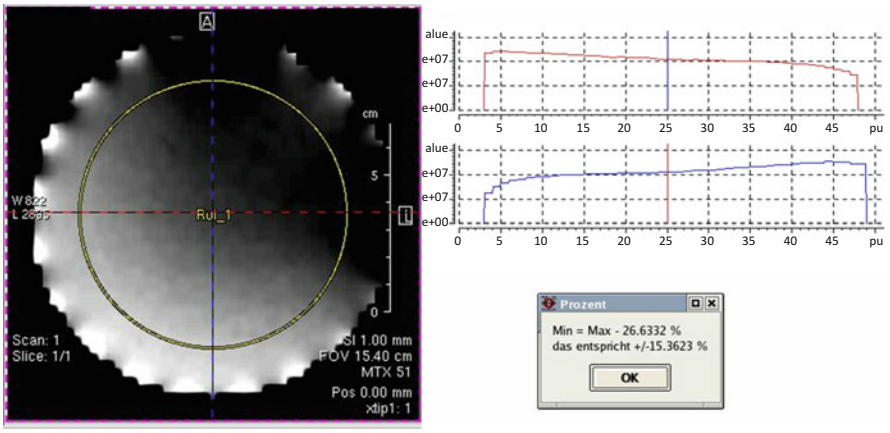

Fig. 20 Inhomogeneities of the transversal RF-field of a birdcage resonator caused by adapting the frequency-shift and impedance match to 50 Ω when the coil is loaded by an conductive, lossy load; *Right*: the diagrams plotted the sensitivity along the central axis though the center of the RF-coil. *Left*: nonoptimized RF-coil – inhomogeneities caused by change the RF-coil tuning and matching from unloaded to loaded conditions

The most commonly used and simplest surface coil is the planar loop coil. For the design of the loop coil the coil dimensions should be chosen carefully to maximize the SNR within the desired VOI. In the following we consider quasi-magneto static conditions and that the planar loop coil is placed directly onto a semi-infinite conducting load aligned in the z-x-plane. Then the magnetic field on the central axis of the loop coil is given by (Mispelter et al. 2006)

$$B_1 = \frac{\mu_0}{2} I \cdot \frac{R^2}{\left(y^2 + R^2\right)^{\frac{3}{2}}} \tag{61}$$

R is the loop radius and y the distance on the coil axis to the sample. If the case is considered that the coil resistance is smaller than the sample losses (sample loss dominates regime) then the coil losses could be neglected. Under the boundary condition of a semi-infinite sample, ignoring the gradient of scalar potential and considering only the vector potential A, the sample resistance R_s can be approximated (Vaughan and Griffiths 2012, pp. 42) as

$$R_s \approx \frac{1}{3} \mu_0^2 \sigma \omega^2 R^3 \tag{62}$$

Where R is the average radius of the coil and σ is the tissue conductivity. Finally for the SNR setting the coil current I to unity (unit current) the result for the SNR is:

$$\mathrm{SNR} \approx \frac{\omega_0 B_1}{\sqrt{R_s T_s}} \propto \sqrt{\frac{R}{\left(y^2 + R^2\right)^3}}. \tag{63}$$

The required coil radius R_0 for maximum SNR at a predetermined depth y is found to be

$$R_0 = \frac{y}{\sqrt{5}} \tag{64}$$

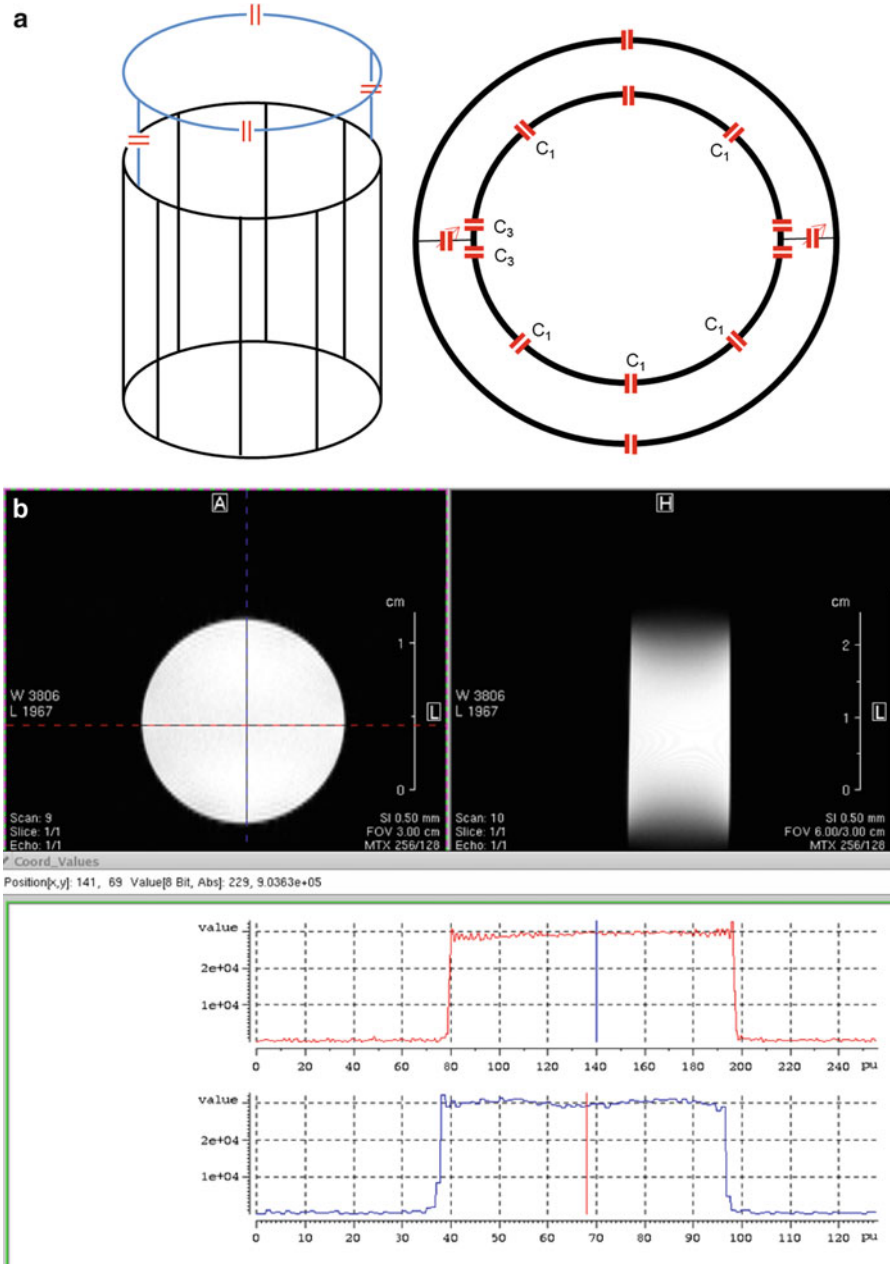

Fig. 21 *Top*: Balancing by a guide ring for homogenous $\mathbf{B}_1$-field distributions inside birdcages for the tuning of different loading conditions; *Bottom*: optimized birdcage – "quasi" perfect homogeneity of the transversal RF-field also for heavily loading conditions

by the differentiation of the Eq. 63 with respect to R. This is the simplest main design rule for planar loop coils. A loop coil with a radius smaller than R_0 is insufficient with respect to the sensitivity at the required depth. A loop coil with a radius larger than R_0 is too sensitive to sample noise. This is clearly a rough estimation only and the approximation considers only the sample noise and that the RF wavelength is large compared to the sample- and coil- dimensions. But this result gives a good starting point for more detailed investigations with respect to optimization e.g., by numerical field simulations.

Another common operation mode of local RF coils is the receive-only operation in conjunction with a homogenous so-called actively decoupled volume RF-coil. These receive RF coils are optimized for high

SNR within a certain volume of interest. For this purpose the RF circuit consists of the following components (Fig. 25):

1. The RF-coil structure: the size is optimized to fit the maximum SNR inside the required VOI (MRI coil).
2. Active decoupling/detuning circuit: suppression of induced currents during transmission of the RF from the transmitter coil.
3. Tuning and matching network of the RF-coil: for power matching the Rf coil to 50 Ω.
4. Impedance transformation network: minimization of the noise contribution of the preamplifier.
5. Low noise preamplifier with low or high input impedance: for so-called preamplifier decoupling.
6. Shielded RF-cable.
7. Balun or cable traps; minimization of so-called shield currents on the RF-cable and thus prohibit the cable itself from action as RF-antenna.

The Receive-only coils must be decoupled from the surrounding RF-Coil during the transmission of the RF-power. The transmission RF-power must never penetrate the receive chain. In addition induced currents must be avoided at the receive coil structure that disrupt the homogenous transmit RF-field. The currents induced in the receive coil during transmission create a magnetic field that adds or subtracts from the homogenous RF-field of the transmission RF coil. There are a few of different designs for such decoupling circuits but mostly based on the principle of actively switching PIN diodes for introduction of

an additional circuit that generates high impedance. Very common is the introduction of so-called pole circuits (Fig. 25 top). During the transmission the diode D (Fig. 25 bottom) is forward biased and forms with one of the resonance capacitors or the symmetry matching capacitor C_s a blocking resonant circuit using an additional inductance L_D.

During the receive operation the diode is reversed biased, thus removes the blocking circuit from the resonance structure. The DC-connections to the diode are in general made by so-called chock inductances, a high inductance having a large impedance value at the resonance frequency ω_0. These inductances block the RF from the DC-path and isolate the RF coils structure from additional noise from the DC-connections. Some other common used decoupling techniques for decoupling receive-only coils from a transmitter RF-coil are briefly mentioned:

1. Transmission lines –quarter wavelength cable
2. Passive decoupling by crossed diodes
3. Diodes in the RF coil circuit

For optimum performance with respect to SNR it is advantageous to place the preamplifier as close as possible to the feeding port of the RF-coil. The preamplifier is assumed to be calibrated to $R_{opt} = 50\,\Omega$ so that the noise performance optimum is at this impedance. Then, the coil is tuned and matched to R_{opt}. However in the reverse direction the input impedance Z_{in} of the preamplifier is usually considerably larger or smaller than R_{opt}. The preamplifier impedance Z_{in} is transformed via impedance transformation circuits (e.g., Γ-transformation) to a quasi-open circuit at the feeding port of the RF-coil (Fig. 25 top). This procedure is called preamplifier decoupling (Roemer et al. 1990; Reykowski et al. 2002). This blocks the currents even though the RF coil is receiving the MRI-signal, but if very little current flows in the RF coil, no noise or signal is coupled to other RF coils. This technique is commonly used for the decoupling of RF-structure that cannot be decoupled by traditional decoupling techniques such as inductive or capacitive decoupling e.g., when the RF coils are nonadjacent and too far away from each other.

The basic principle for inductive decoupling is based on the reduction of the mutual inductance of adjacent RF coils. A pair of identical resonant loops are considered with their self-inductance L_1 resonating at the same frequency ω_0. If these loops are brought into close proximity, the resonance will

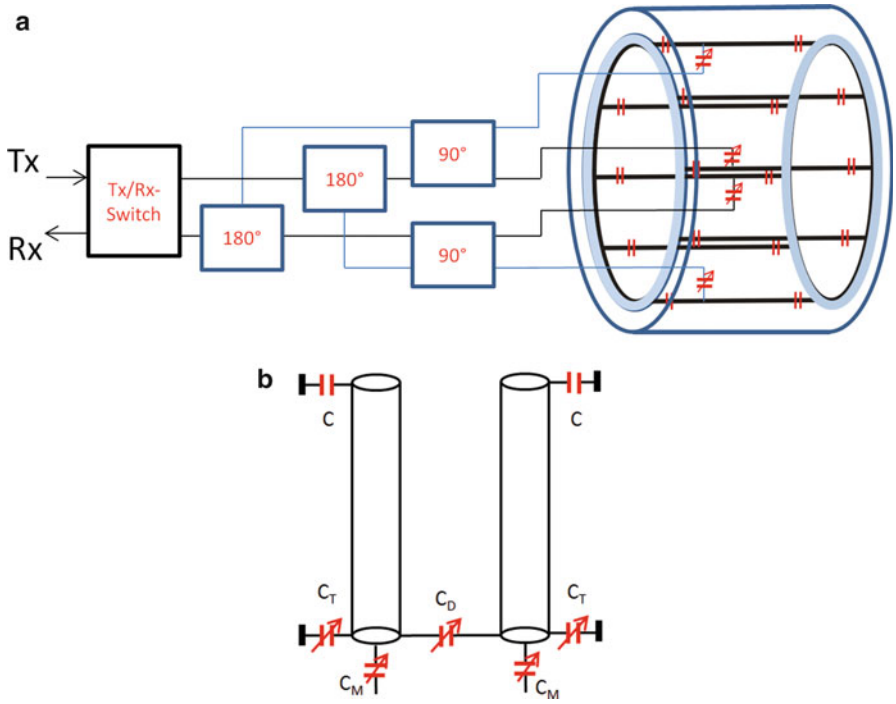

Fig. 24 *Left* – Four-port drive for the excitation of a RF-coil; the RF coil is feeded at 4 ports that are rotated by 90°. The power at the ports have almost the same amplitude and phase shifts of 0°, 90°, 180° and 270° right – Capacitive decoupling of neighboring elements by C_D; the elements tuned and matched by C_T and C_M respectively, the capacitors C and C_T connected to the ground shield.

split into two frequencies, one shifted above and the other shifted below ω_0, and results in a loss of sensitivity at ω_0. This coupling of the RF coils can be characterized by the coupling coefficient (Mispelter et al. 2006)

$$k = \frac{L_{12}}{L_1 \cdot L_2} \tag{65}$$

and the two frequencies can be calculated as

$$\begin{aligned} f_{\text{upper}} &= f_0(1+k) \\ f_{\text{lower}} &= f_0(1-k) \end{aligned} \tag{66}$$

Since the circuits now resonate away from their original resonance frequency ω_0, the efficiency of the combined coil is highly reduced. In addition, signal and noise are also transferred though the mutual inductance L_{12} from one coil to the other. The simplest method to reduce this coupling is the relative positioning by an overlap of the adjacent coils to force the mutual inductance to zero (Fig. 27) when the mutual inductance is predominant. For a set of two circular loop-coils the optimum distance of the centers of the coils is approx. 0.78 times of the loop diameter. For two identical rectangular loop-coils the optimal distance increases to 0.86 times of the linear dimension of the coils. For combinations like butterfly and single loop coils (Fig. 27. bottom right) the maximum decoupling can be achieved when the coil centers overlap exactly.

Here are other popular decoupling methods:

DOI 10.1007/978-981-4560-75-7_121-1

- Inductive decoupling by transformers uses two small inductors coils each connected to one of the RF coils and placed very close to each other so that their mutual coupling neglects the mutual coupling of the two RF coils. This method is useful if nonadjacent RF coils can't be decoupled by an overlap. In some cases, where overlapped RF coils are not suitable (e.g., for parallel imaging) the use of transformers is a good choice.
- Capacitive decoupling uses capacitors and for adjutant coils. So-called shared capacitors are used that replaces the inductive decoupling of the both RF coils.
- Extending the capacitive decoupling to multiple surface coils (e.g., array coils) yields to so-called external latter networks (so-called open-circuit voltage method). The capacitive or inductive elements needed for the decoupling are calculated as part of a 2n-port circuit network connecting the n input ports of the array with the n ports of the receiver or transmitter channels. In theory it is possible to transform a coupled n-port-system characterized by an impedance matrix Z into a decoupled system by a latter network (Lee et al. 2002).

Receive Array Coils

A major drawback of local RF coils is the limit with respect to the field of view (FOV). But this limitation can be overcome by combination of multiple surface coils. The signals detected by the individual coil-elements of the array coil are fed into the separate receiver channels and the final signal combination is done on a pixel-by-pixel basis on the individual processed images of the array coil elements (Roemer et al. 1990). This approach preserves the high SNR of each coil-element and offers the advantage so that the array covers a much larger FOV (Figs. 28, 32).

The performance of array coils highly depends on minimal coil coupling and thus on the signal distribution and noise correlation among the coil-elements in the array. Array coil-elements that are directly positioned to each other can be decoupled by inductive/capacitive decoupling as described in section Local RF coils. The coil-elements that are not direct neighbors usually have a fairly low mutual coupling that can be sufficiently reduced by preamplifier decoupling as described in the previous section.

After simultaneous acquisition of the RF-signals, the MR-data are reconstructed and the result are N individual images for each of the N each array-elements. The performance of the individual coil elements is not the only one design requirement. The overall performance of the array coil is dependent both on the sensitivity-distribution of the local coil-elements and on the coupling between the individual coil-elements. For optimal signal-to-noise ratio (SNR) the pixel signals $S_i(x,y,z)$ from each reconstructed image are weighted by a complex weighting factor $W_i(x,y,z)$ and added up to a combined signal (Roemer et al. 1990; Reykowski et al. 1995)

$$S_c(x,y,z) = \sum_{i=0}^{N} W_i^*(x,y,z) \cdot S_i(x,y,z) = W^H S \tag{67}$$

where W^H is the conjugate transpose of the column vector W including all weights W_i and S is the vector including all signals S_i. The noise correlation between the coil-elements can be expressed in a noise correlation matrix $\Psi = \begin{bmatrix} n_{11} & n_{21} & n_{j1} \\ \vdots & \ddots & \vdots \\ n_{1j} & n_{11} & n_{ij} \end{bmatrix}$ where n_{ij} is the noise power added by coil i to the coil j and all

DOI 10.1007/978-981-4560-75-7_121-1

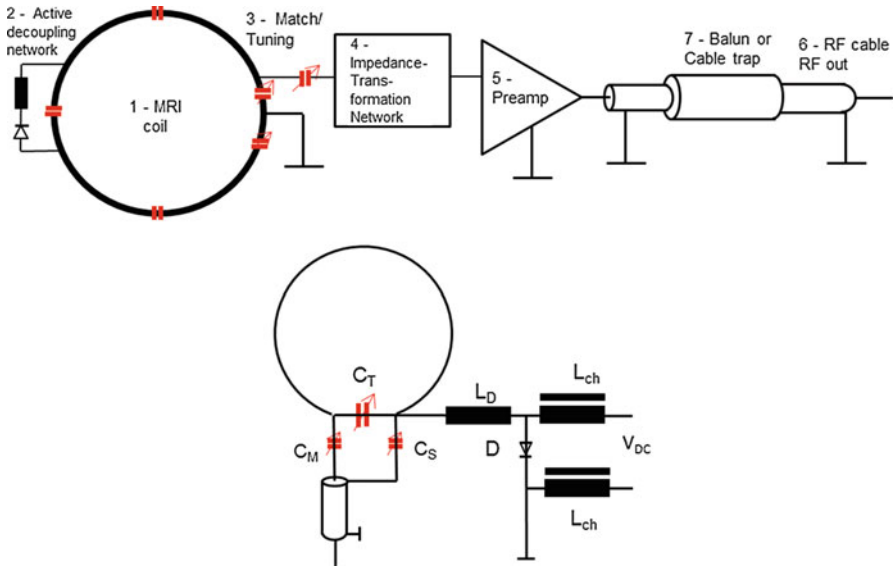

Fig. 25 *Top* – Brief description of a local receive-only coil system; *Bottom* – simple circuit for symmetric feeding and decoupling of a receive-only coil

diagonal elements n_{ii} are the noise power of the individual coils in absence of the other coil-elements. The squared SNR^2 can be expressed now by

$$\mathrm{SNR}^2 = \frac{\left(W^H S\right)^2}{W^H \Psi W} \tag{68}$$

The differentiation of the Eq. 68 with respect to the weights W and sets the result to zero, this yields in a set of optimal weights

$$W^{\mathrm{opt}} = C \ \ \Psi^{-1} S \tag{69}$$

Including a normalization factor C. The best obtainable SNR is dependent on the signals of the individual array coil-elements and the noise correlation between the coils-elements

$$\mathrm{SNR}^2_{\mathrm{opt}} = S^H \Psi^{-1} S \tag{70}$$

The information of the noise correlation is required to achieve the optimal SNR in the combined image. If the noise correlation between the individual coil-elements is sufficiently low, the noise correlation Matrix Ψ can be reduced to a diagonal matrix where the off-diagonal elements are zero and the squared SNR can be expressed by

$$\mathrm{SNR}^2_{\mathrm{opt}} = \sum\nolimits_i \frac{S_i^2(x,y,z)}{n_{ii}} = \sum\nolimits_i \mathrm{SNR}_i^2 \tag{71}$$

Thus the sum-of-squares combination is the simplest method for combining images of array coil-elements and yields in a SNR that is equal or larger than the individual coil-elements. Most important for achieving good results with this approach is an efficient inter coil-**de**coupling of all coil elements.

DOI 10.1007/978-981-4560-75-7_121-1

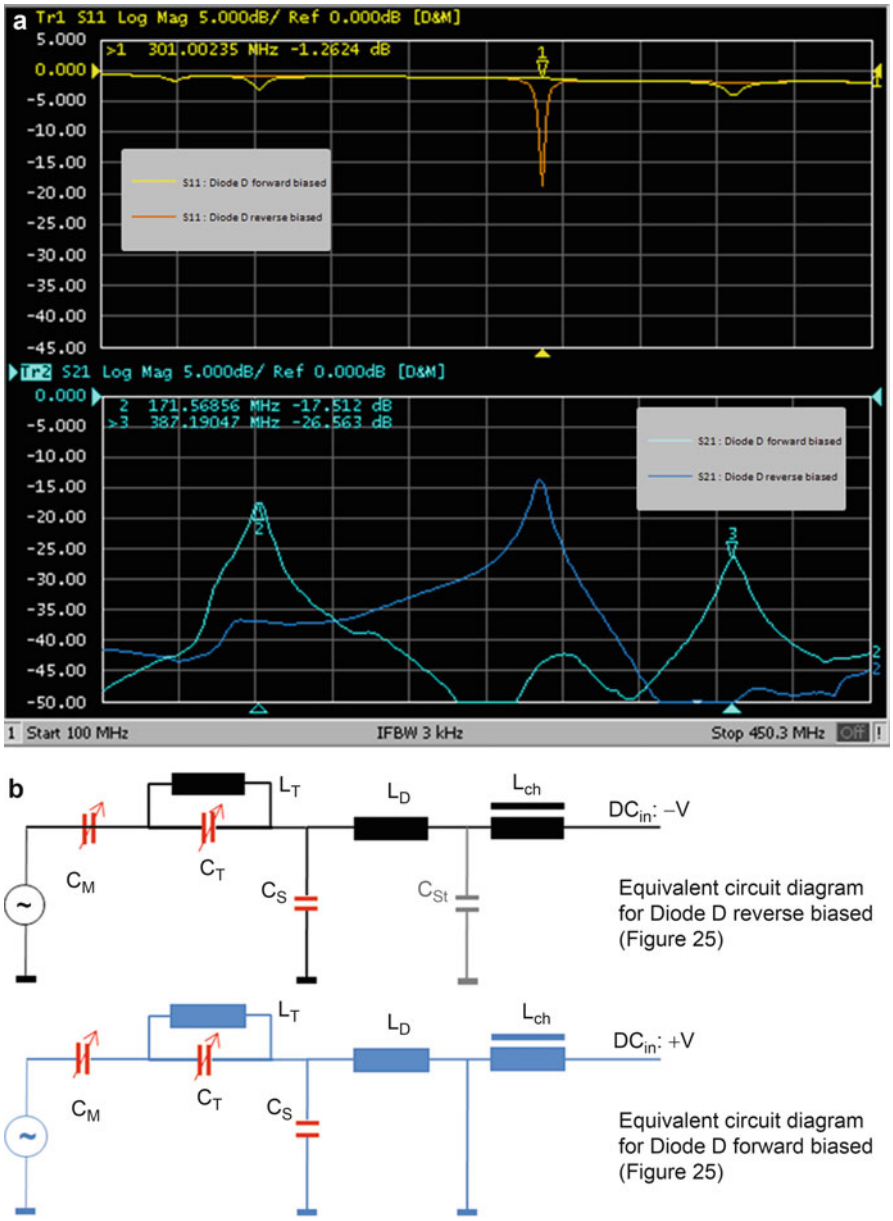

Fig. 26 Pole insertion method for active decoupling a receive-only coil: *Top*: Measured reflection coefficient S11 – is typically a minimum for a matched and tuned probe at the desired frequency ($f_0 = 301$ MHz) – *brown curve* and the corresponding *blue curve* shows the transmission S12 measured with a small so-called pick-up loop. The reversed biased diode behaves as a small capacitance C_{st} that can be neglected in most cases. When the diode is biased than the inductor L_D comes parallel to C_S resulting in a splitting of two resonances (*magenta line*) below and above the desired frequency ω_0 and the RF-coil is almost off-resonant (*yellow line*)

While an array coil consists of a set of local RF coils the field distribution and sensitivity is inhomogeneous over the VOI. There is no universally accepted or general design rule that fits all array coils. The optimal design of the array coils is highly dependent on the application that will be performed. Figure 29 demonstrates the basic principle of local sensitivity changes with an increased number of array elements under the boundary condition to cover a cylindrical FOV with a diameter of 60 mm and a z-length of 60 mm. Four rectangular coil loops (55 × 60 mm) surrounding the cylinder of 60 mm are the starting point. Remembering the Eq. 64 ($y = 30$ mm- $> R_0 = 13$ mm) the performance for loaded

DOI 10.1007/978-981-4560-75-7_121-1

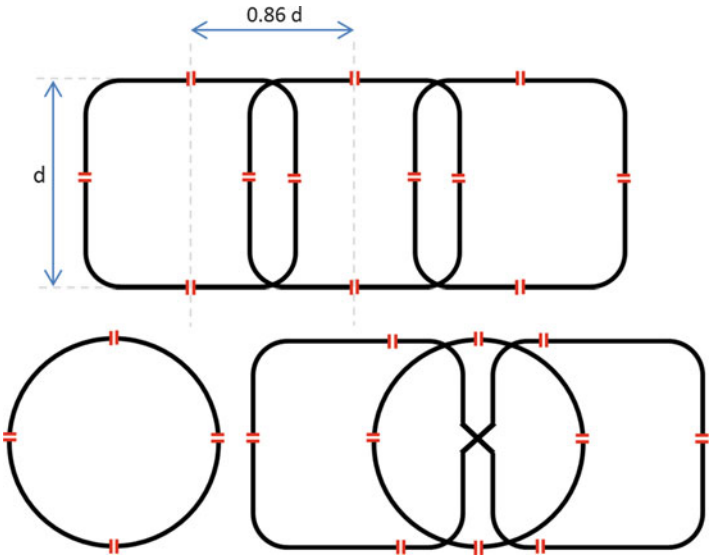

Fig. 27 Draft illustration of surface coils bottom left: single-loop surface coil; arrangement of surface coils that consists of three loop-coils working as separate coil-elements of an array-coil or as quadrature surface coil when driven in combination with fixed phase shifts. The adjacent coils are overlapped to set their mutual inductance to zero and prevent the splitting of the resonances for the nearest neighbor coils. For that case the center of the rectangular coils are separated by 0.86 times of the diameter of the coil elements.

conditions of these rather large surface coils is low because the coil-elements are much too sensitive to the sample noise. With an increased number of array elements the coil size in the radial direction is changed to 37 mm, 28 mm and 23 mm respectively. The length of the coil-elements in z-direction is kept constant to 60 mm to cover the whole FOV. The overall sensitivity increases, but the increase of sensitivity reaches its limit in the middle of the VOI. When enlarging the number of array coils the sensitivity benefits only at the edges near the surface of the array coil. For this example it is evident that an increase of number of array coil elements by more than 10 elements makes no sense if the main application requires a sufficient SNR over the whole area and not only at the edges of the FOV. One must remember that with an increased number of coil-elements the effort for decoupling of these array elements increases much in particular for opposite coil elements. For opposite array elements the method of choice is the decoupling by preamplifier decoupling or an external latter network. An example of the noise correlation for a 8-element volume array coil is shown in Fig. 30.

The values range from nearly zero up to 25–30 % when the elements are only decoupled by preamplifier decoupling. The next neighbor elements decoupled by overlap and preamplifier decoupling and the second next coil-elements decoupled by transformer (inductive decoupling). In principle the design of array coils is very challenging when the SNR of a comparable quadrature volume coil in the center of the VOI is targeted under the consideration that the dimensions of the RF-active elements of both coils are comparable in size and diameter. In most cases the SNR of array-coils are only higher than standard volume-coils for off-center positions.

Another example is shown in Fig. 31 and compares the SNR distribution of a quadrature surface coil (2 elements) with 4-element array coil. This array coil is used for applications where the target FOV is near the surface of the RF coils. The quadrature coil consists of two elements bent on a curved cylindrical surface with an area of 25 $\times$ 25 mm and the coil-elements are decoupled by a shared capacitor or overlap. The 2x2 array coil has been designed by four independent coil-elements with a size of 13 $\times$13 mm. All coil-elements are inductively decoupled by more than 20 dB. The highest gain in SNR to a factor greater than 2 is achieved at the edge of the surface of the array coil and decreases rapidly with the distance to the

array-elements. The average SNR of the array coil is higher compared to the quadrature surface coil but is for a greater distance from the coil elements in the same magnitude.

Receive Array Coils for Parallel Imaging

In the last decades the array-technology was driven by the rapid developments of parallel imaging techniques. Most commonly used parallel imaging methods are SENSE, GRAPPA or SMASH. A detailed discussion of parallel MR image reconstruction (Pruessmann et al. 1999;Sodickson and Manning 1997) is beyond the scope of this chapter and therefore, only a very brief review is presented. These technologies pushed the envelope of RF-coil technology rapidly in the late nineties. The array coil design plays a major role in achieving the desired performance with respect to the SNR when image sequences are accelerated with respect to acquisition time (section Basics of MRI imaging).

Parallel MRI methods for accelerated image acquisition are based on extracting the spatial information from the sensitivity patterns of the RF-array coil elements and using this information to generate the data that normally is acquired by sequentially applied field-gradients $\boldsymbol{g} = \left(g_x, g_y, g_z\right)$.

The design considerations for arrays coil elements used for spatial encoding imply additional design requirements and these lead to an increased number of receiver channels and array coil-elements. As result commercial clinical MRI-systems with 32 channels or more have become routinely available and prototype systems with more than 128 channels in development.

In general a MR signal received from a coil-element l at a *k*-space position k_m can be written as (Vaughan and Griffiths 2012, p. 84 ff)

DOI 10.1007/978-981-4560-75-7_121-1

$$S_l(\boldsymbol{k}_m) = \sum\nolimits_{voxel\,j} C_l(\boldsymbol{r_j}) M(\boldsymbol{r_j}) e^{j\boldsymbol{k}_m \boldsymbol{r}_j} + \boldsymbol{n_l}(\boldsymbol{k_m}) \tag{72}$$

where n_l is the noise, $C_l(\boldsymbol{r_j})$ is the spatial sensitivity of element l and $M(\boldsymbol{r_j})$ is the precessing transverse magnetization (see Basic Introduction to the Principle of NMR and MRI). When the signals, noise and magnetization are written in column vectors this equation can be written in a general manner $\boldsymbol{S} = \boldsymbol{EM} + \boldsymbol{n}$, when the encoding matrix $\boldsymbol{E}$ is given by

$$\boldsymbol{E}_{(lm),j} \equiv C_l(\boldsymbol{r_j}) e^{j\boldsymbol{k}_m \boldsymbol{r}_j} \tag{73}$$

The matrix $\boldsymbol{E}$ is a rectangular matrix and within the formalism of parallel imaging the challenge is to find a Matrix $\boldsymbol{F}$ where the $\boldsymbol{EF}$ is equal to the identity matrix. There are many choices and it has been shown (Pruessmann et al. 1999) that the minimum norm solution to reconstruct an image with the least possible noise is given by

$$F_{\min norm} = \left(E^H \Psi^{-1} E\right)^{-1} E^H \Psi^{-1} \tag{74}$$

For parallel imaging the encoding functions 73 are generally spatially not orthogonal with the consequence that the reconstruction matrix 74 is typically not unitary. That yields to spatially varying noise increase. The image reconstruction used in Eq. 74 is a linear transformation. The noise power can be calculated from the encoding matrix and is given by

$$\left(\sigma_j\right)^2 \propto \left[\left(E^H \Psi^{-1} E\right)^{-1}\right]_{j,j} \tag{75}$$

The change in SNR that results from accelerated parallel imaging can be generally written as

$$\left(\frac{\mathrm{SNR}_j^R}{\mathrm{SNR}_j^{\mathrm{Full}}}\right)^2 = \left(\frac{\sigma_j^{\mathrm{Full}}}{\sigma_j^R}\right)^2 = \frac{\left[\left(E_{\mathrm{Full}}^H \Psi^{-1} E_{\mathrm{Full}}\right)^{-1}\right]_{j,j}}{\left[\left(E_R^H \Psi^{-1} E_R\right)^{-1}\right]_{j,j}} \tag{76}$$

For the special case of Cartesian sampling the Eq. 76 can be rewritten:

$$\mathrm{SNR}^R = \frac{\mathrm{SNR}^{\mathrm{Full}}}{\sqrt{R\left[\left(E_R^H \Psi^{-1} E_R\right)^{-1}\right]_{j,j}\left[\left(E_R^H \Psi^{-1} E_R\right)^{-1}\right]_{j,j}}} = \frac{\mathrm{SNR}^{\mathrm{Full}}}{\sqrt{R}g} \tag{77}$$

The so-called geometry factor is introduced and defined as:

$$g_j \equiv \sqrt{\left[\left(E_R^H \Psi^{-1} E_R\right)^{-1}\right]_{j,j}\left[\left(E_R^H \Psi^{-1} E_R\right)^{-1}\right]_{j,j}} \tag{78}$$

The factor $\sqrt{R}$ in the dominator of Eq. 77 is the result since the overall loss in SNR simply occurs by acquisition of fewer k-space points in the under-sampled image. The geometry factor g is always greater or equal than one and quantifies the fractional loss in spatially reduced SNR due to the nonorthogonality of the encoding functions based on the coil-element sensitivities. This factor g has become of general importance for qualifying the performance of coil arrays for parallel imaging.

DOI 10.1007/978-981-4560-75-7_121-1

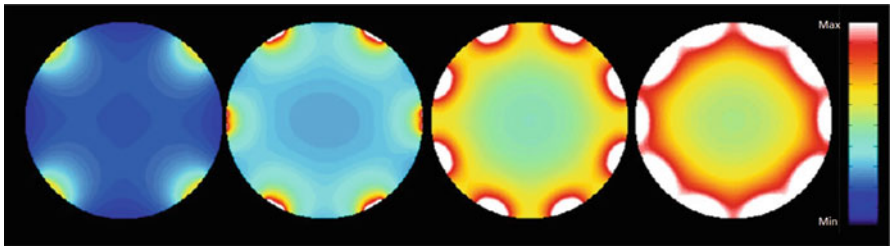

Fig. 29 Simulated field-distribution of the B_1^+ for an array coil with an inner diameter of 60 mm at 300 MHz (7 T) consists of 4,6,8 and 10 coil-elements under loaded conditions neglecting inter-coil coupling of the array-elements

The g-factor is a function of the coil sensitivities and the pattern of the acquired k-space lines. Therefore the pattern will be different for different undersampling factors, phase encoding directions and objects under investigations. Any change in the coil geometry and sample load, yields in a different g-factor and has an effect on the parallel imaging performance. In any case when the imaging acquisition is accelerated, the SNR will be decreased at least by a factor of $\sqrt{R}$. This factor will be even higher when the g-factor is larger than 1 (g>1). The imaging acceleration by factor of 2 leads to an SNR-decrease of more than 40 % compared to nonaccelerated imaging with the same imaging sequence parameters.

In addition, the noise correlation plays also an important role when drastic changes in the noise correlation affect the array's g-factor. The complex spatial sensitivity functions $C_l(\boldsymbol{r}_j)$ can be written based on the principle of reciprocity in terms of the two transverse components of the $\mathbf{B}_1$-field of the coil-elements (Vaughan and Griffiths 2012, p. 86)

$$C_l(\boldsymbol{r}) = \left[\widehat{B}_x(\boldsymbol{r})\right]_l - i\left[\widehat{B}_y(\boldsymbol{r})\right]_l \tag{79}$$

The noise correlation matrix elements can be computed in terms of the electrical fields of the individual coil-elements that are normalize to the unit current that flows around the conduction path

$$\Psi_{l,l} = 4kT\Delta f \int \sigma(\boldsymbol{r})\hat{\boldsymbol{E}}_l(\boldsymbol{r}) \cdot \hat{\boldsymbol{E}}_{l'}^*(\boldsymbol{r}) d^3\boldsymbol{r} \tag{80}$$

Where k is the Boltzmann constant, Δf the receiver bandwidth, T the temperature and σ is the conductivity of the sample. With these equations the theoretical evaluation of any prospective array coil can be performed, e.g., for optimization purposes. A typical pattern of the g-factor map is shown in Fig. 32 for reduction factors of 2, 3 and 4 for an under sampling in the left-right direction. For evaluation of this 8 channel array coil, a model in CST-microwave studio was designed. The model includes all conductive coil elements including the lumped elements, feeding ports and cylindrical conductive phantom as load. The sensitivity functions are calculated using the approach above. The g-factor was calculated for an under sampling with acceleration factors R = 2,3 and 4 that reduce the FOV by a factor 2,3 or 4. The pattern shown in the figures results in a folding from multiple equidistantly distributed data points (section Basics of MRI imaging).

The g-maps in Fig. 32 are normalized individually to the highest g-factor for the individual reduction factors g = 1.04, 1.50 and 3.88 and with Eq. 77 that yields a maximum spatial noise-increase compared to the unaccelerated image acquisition by a factor of 2.08, 2.6 and 7.76 including the factor of $\sqrt{R}$ for the intrinsically noise-increase for accelerated image acquisitions. As conclusion from the g-map pattern this coil will give reasonable results with respect to the noise introduction up to an acceleration factor of 3 (section Future Directions and Open Problems). While the structure of this coil and the loading has a

Cryogenically Cooled Coils

Demands on high spatial or temporal resolutions require a high signal-to-noise ratio (SNR). For applications on small animals, spatial resolutions are required, that are up to a factor 10 higher than for human applications, which leads to a decrease of the sensitivity by a factor of the order of 1,000.

The SNR can be increased simply by increasing the static magnetic field $\mathbf{B}_0$. Today commercial animal-scanners up to 21 T are available. In some cases the decrease of the sample-noise and the noise contribution of the different receive-chain components of the MR-system are a common cost-effective option. The optimization of room-temperature (RT) coils is in most cases limited by theoretical and practical limitations. In most cases the design changes will lead to an increase of several percent in the sensitivity of the optimized coils. For dedicated MRI applications such as for small animals, the observed tissue volumes are of a size that renders the sample noise contributions comparable or smaller than the thermal noise contribution of the RF coil and associated components of the MRI-system receive-chain. The SNR can thus be enhanced by decreasing the noise of the sample. Noise contributions from the sample are the thermal noise, due to the thermal motion of the charge carriers and the so-called dielectric losses due to the electrical field of the RF-field.

Decreasing the temperature of living samples is usually not possible, but a reduction of the thermal noise and the resistive losses of the RF receive-chain will produce a significant increase of the SNR (section Efficiency, Losses and Signal to Noise Ratio – Eq. 22)

$$\mathrm{SNR} \approx \frac{\omega_0 B_1}{\sqrt{R_s T_s + R_c T_c}}.$$

The denominator of Eq. 22 describes the losses (noise) and their dependency upon temperature and frequency. Two domains can be distinguished. On one hand the case when the sample-losses dominate $R_s T_\mathrm{s} \gg R_c T_\mathrm{c}$; for this case the SNR is independent of the resistive coil-losses R_c and their temperature T_c. On the other hand, using better conductive coil conductors or lowering the coil temperature yields to an increased SNR when the coil-losses dominate $R_s T_\mathrm{s} \ll R_c T_\mathrm{c}$.

For the design of cooled RF coils it is required to know how the boundary between these two domains is dependent on the coil-size and frequency. In Fig. 33 a rough estimation regarding the limits of the coil-size for cryogenically cooled coils is presented. For this purpose the sample resistance R_s and coil resistance R_c for a single-loop copper coil under the boundary condition of a semi-infinite sample was examined (Darrasse and Ginefri 2003). The cross-over in a frequency band from 100 to 800 MHz between the two domains for room-temperature copper-coils is given by coil radii between 2.5 cm and 0.9 cm.

Above these radii the sample losses are dominating! For cooled copper coils at 77 K (LN2) will halve the respective coil radii. This will have an influence on $\mathbf{B}_1$-field distribution and the reduction of the sensitivity and so-called penetration depth (see Eq. 64). Even lower temperatures e.g., to 30 K for cooled copper coils or the usage of HTS-material can still improve the sensitivity. But with respect to frequencies from 100 to 800 MHz the coil radius has to be reduced to approximately 1.2 cm to 0.45 cm. Important to know is the SNR-gain that can be achieved by cryogenically cooled RF coils with respect to the frequency and the coil radius. The SNR gain for cryogenically cooled coils is evaluated from the SNR ratio at room temperature (RT) and low temperature (LT)

$$\mathrm{SNR}_\mathrm{gain} = \frac{\mathrm{SNR}_{LT}}{\mathrm{SNR}_{RT}} = \frac{\sqrt{R_s T_\mathrm{s} + R_{c,RT} T_{\mathrm{c,RT}}}}{\sqrt{R_s T_\mathrm{s} + R_{c,LT} T_{\mathrm{c,LT}}}} \tag{81}$$

For the quantification of the SNR gain for a circular loop coil in terms of parameters that can be measured the quality factor $Q = \omega L/R$ can be used. The inductance L of the RF coil is taken into account and for the

other expressions, an equivalent Q is defined by using the appropriate resistance term in (81). The term ωL cancels out, and leads to

$$\mathrm{SNR}_{\mathrm{gain}} = \frac{\mathrm{SNR}_{LT}}{\mathrm{SNR}_{RT}} = \sqrt{\frac{T_{RT} \cdot Q_{UL,RT}^{-1} + T_{RT} \cdot Q_{\mathrm{sample},RT}^{-1}}{T_{LT} \cdot Q_{UL,LT}^{-1} + T_{RT} \cdot Q_{\mathrm{sample},LT}^{-1}}} \quad Q_{\mathrm{sample}}^{-1} = Q_L^{-1} - Q_{UL}^{-1} \tag{82}$$

where the inverse of the quality factor of the sample (Q_{sample}) is calculated by the difference of the inverse of the quality factors for the loaded (Q_{L}) and unloaded ($\mathrm{Q_{UL}}$) coil condition. A very rough estimation of the SNR-gain for cooled RF coils can be used for the boundary limiting case $T_{LT} \rightarrow 0$. For this SNR-gain estimation the values only at room temperature are sufficient. For this case the Eq. 82 will change to

$$\mathrm{SNR}_{\mathrm{gain}=} \frac{\mathrm{SNR}_{LT}}{\mathrm{SNR}_{RT}} = \sqrt{\frac{1}{1 - \frac{Q_{L,RT}}{Q_{UL,RT}}}} \tag{83}$$

For room temperature surface coils commonly discrete elements are used to build the R-L-C-resonance circuit. Apart of possibly limited temperature operating specifications of commercially available capacitors, the soldering introduces several technological difficulties for cryogenic operation of resonance circuits built by discrete elements. Alternative approaches are the so-called monolithic designs and the use of distributed capacitors.

So-called transmission-line resonators (TLR: Fig. 34 top) or "Twin-Horseshoe resonator (Gonord and Kan 1994) and multi-turn transmission-line resonators (MTLR: Fig. 34 bottom) (Vaughan and Griffiths 2012, pp.236, Darrasse and Ginefri 2003) made either of copper or HTS material are commonly used for self-resonant high-Q structures. The TLR consists of a pair of planar, electric conductive rings facing each other and separated by a dielectric substrate. The gaps on the rings are diametrically opposed to each other. The MTLR based on the same principle consists of several concentric rings on different radii connected in series. Because of the increased inductance value of the MTLR the useful frequency domain is more limited compared to the TLR. The design for MTLR is best used for lower frequencies.

Copper material (conductivity $\sigma = 58{\cdot}10^6$S/m at 20 °C) exhibits a nearly linear dependency of the resistivity $\rho = 1/\sigma$ with respect to temperature down to approximately 30 K. A reduction of the thermal noise in the order of magnitude of about 20 at 77 K and even more at lower temperature (Ginefri et al. 2007) can be achieved. With the usage of HTS material cooled below their critical temperature even higher reduction factors of the thermal noise can be achieved. Very high Q-values in a range from 1,000 to 500,000 dependent on the coil-size, temperature, frequency and the static magnetic field can be attained. But it must be mentioned that HTS material loses its superconducting properties depending on the strength and orientation of the magnetic field. In any case a reduction of the high Q-values for HTS RF coils cannot be prevented inside MRI-systems.

There are several strategies for the cooling of superconducting coils. The simplest method is the direct immersion of the RF-coil in a bath of cryogenic liquid such as liquid nitrogen (LN2) placed inside a container for thermal isolation. The MR-measurements can only be performed after all the coolant has been consumed because of the mechanical vibrations caused by the boiling of the coolant. But the most common method is the use of closed-cycle cry coolers. The RF coil is cooled by a so-called cold finger by a cold-head either in the direct vicinity of the RF-coil or located at a certain distance from the cryogenic probe.

The image acquisition can be accelerated upto a factor of 3 in one direction without limitations by imaging artifacts. *Right*: model for simulation of an 8 channel loop using CST Microwave Studio (CST-Darmstadt, Germany) coil modelconsisting the overlapped loop coil elements, all lumped elements and a lossy cylindrical phantom

The principle design (Haueisen et al. 2006) of a cryogenic probe-head is shown in Fig. 35. The RF-coil (1) is mounted on a cold finger (2) surrounded by housing (3) – dewar. The most efficient way for isolation is the use of vacuum to protect the object under investigations (5). This object has a temperature equal to or slightly higher than room temperature and needs to be isolated from the cryogenic temperatures of the RF-coil (20–30 K). The dewar-housing with a residual vacuum of about 10^{-6} mbar reduces the two dominant heat transmission processes (heat conduction and heat convection). For MR-imaging the conventional coating by mirror material cannot be used for additional reduction of the radiation. For this reason the dewar-wall would be cooled in an undesired fashion by heat radiation and this may have undesirable consequences, especially for living subjects under investigation. To protect the subject, the separating wall of the dewar is used as a heating device and is temperature-controlled for a suitable

Double Tuned RF Coils

For the general study and treatment of diseases the combination of MR-imaging (MRI) and MR-spectroscopy (MRS) is an indispensable tool. The growing interest in applications of NMR spectroscopy for studies of biological systems has placed unique demands on the MR-systems and their instrumentation. In most cases MRI and MRS are combined into one study where MRI is used for so-called shimming (make the external **B**-field as most as possible homogenous) and for localization of the targeted region for the MRS-application. The MR-spectroscopy is used to obtain the metabolic information by acquiring spectra's of specific nucleus such as ^{31}P, ^{23}Na, ^{13}C and ^{19}F commonly so-called "X-nucleus" (corresponding frequencies see Table 1, section Introduction). This purpose demands that the RF coil has to be tuned to multiple frequencies.

In some cases, when two interacting nuclear spin-system are excited simultaneously, the received resonance-signal from the spin-systems can be enhanced or extenuated, e.g., by proton (^{1}H) decoupling (Luyten et al. 1989), Overhauser effect. For this purpose the RF coil has to operate for transmission and reception at two separate frequencies simultaneously. For proton-decoupling an excitation pulse is first applied at lower frequency (X-nucleus) and then simultaneously with the signal reception of the X-nucleus, the RF-power at the ^{1}H-channel is applied. A basic hardware scheme for such applications is shown in Fig. 36. On each transmit/receive path of the double resonance coil a RF-filter is introduced. For the higher frequency (^{1}H) a band-pass-filter is implemented and for the channel of the X-nucleus a low-pass-filter is used to suppress of out-of-band noise. On one hand the NMR-signal from the X-nucleus is in most cases very small (e.g., ^{13}C inverse NMR-spectroscopy) and every noise introduction from ^{1}H-transmission will over saturate the NMR-signal from the X-nucleus. On the other hand the broad-band noise level of the ^{1}H- transmitter can saturate the preamplifier of the X-channel easily if the filter and decoupling of both channels are not sufficient. A decoupling of the two channels at any point of the transmit/receive chain of more than 100 dB is commonly required for dedicated MRS- applications. These multiple frequency applications can be performed by double resonance surface coils, volume coils or by

DOI 10.1007/978-981-4560-75-7_121-1

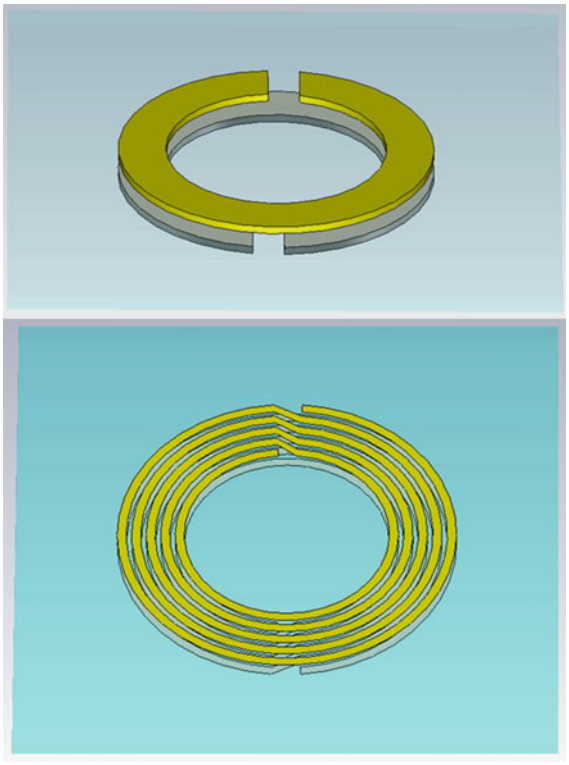

Fig. 34 *Top*: Transmission-Line resonator: Two planar split rings deposited on each side of a dielectric substrate. The gaps in the rings are diametrically opposed. – *bottom*: Multi-Transmission Line resonator: Two planar multi-turn split rings deposited on each side of a dielectric substrate. The gaps in the rings are diametrically opposed

combinations of the two. In this chapter only a brief description can be given while a wide number of various schemes have been introduced over the last decades.

The most common double-tuned circuits are based on two basic principles using so-called multi-pole or transformer-coupled RF-circuits. Multi-pole circuits have already been introduced in section Receive Array Coils for Parallel Imaging where these circuits are used for active decoupling of surface coils and the resonance-frequency ω_0 is split in two frequencies at a lower and at a higher frequency with respect toω_0.

For double resonance coils the multi-pole circuit inserts a discrete parallel resonance circuit (Fig. 36) into the coil and creates a pole in the reactance curve that creates a second capacitive reactance to resonate with the inductance L_s at a second frequency. The first and lower frequency is tuned by a serial capacitance C_L. While a second circuit is introduced into the RF-coil, special attention is required to the second inductor L_H that introduces a detectable resistive loss to the RF-circuit. The efficiency of a double resonance coil at the high- and low-frequency mode is given by (Schnall et al. 1985):

$$E_L = \sqrt{\frac{L_S}{L_H + L_S}} \tag{84}$$

$$E_H = \sqrt{\frac{L_H}{L_H + L_S}} \tag{85}$$

under the boundary condition of a loaded RF coil and that the resistance of the inductors is proportional to the inductance. The efficiency E_L for the low frequency will be the best if the Inductance L_H is small

The surface RF-coil is interfaced via a transmit-receive-switch and a low- or band-pass-filter to the MR-system. The multiple channels are matched with C_M and tuned by C_L and C_H to the low- and higher frequency mode

compared to L_S and vice versa. In practice a good starting point for the ratio L_S/L_H is a factor of 4-5, yielding an efficiency of about 90 % for the low-frequency mode and about 45 % for the high frequency mode. For double resonance coils the focus is commonly on the performance of the low-frequency (X-nucleus) channel. Losses with respect to the higher efficiency on the ^{1}H-channel will be accepted. It must be clearly mentioned that the performance of the two frequencies of double resonance coils will

DOI 10.1007/978-981-4560-75-7_121-1

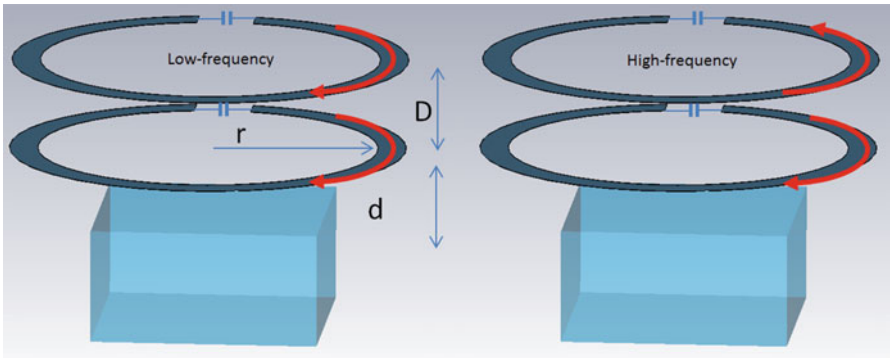

Fig. 37 Double resonance coil created by two identical inductive coupled and tuned circular loop coils. The final resonator has two modes, one with in-phase currents at low frequency and one with out-of-phase currents for the higher frequency. The design can be optimized with respect to the inter-coil distance D, the distance d to the sample and the radius r of the loops respectively

never achieve the performance of well-designed single resonance RF coils at the same frequencies. This fact should be taken into account for the chosen RF coil setup for a required application.

The basic principle of transformer coupled circuits (Fig. 37) based on the mutual coupling of tuned coils that was still introduced in section Local RF coils. The coupling constant and the frequencies are given by Eqs. 64 and 66 and for double tuned coils a large coupling constant k is required: The double resonance coils operate in the over coupled regime (dependent on the distance D) where the currents are split between the two frequencies (Fig. 37). As result a co-rotating mode at the lower frequency and a counter-rotating mode at the high frequency are generated. The generated RF fields are added at the lower frequency but subtracted at the higher frequency. As result the RF-efficiency at the low frequency is equivalent or slightly higher than a single coil but clearly underperform at the high frequency by approximately 50 %.

Multi-frequency birdcage coils have to be designed on the principle of preserving the sinusoidal /cosine current distribution around the cylindrical structure for both frequencies. The feeding is done in the same manner as for double resonance surface coils by introduction of band-pass- and low-pass-filters at the high-frequency (1H) and low-frequency channel (X-nucleus) respectively. For volume coils like bird-cages the principle of multi-pole circuits can be introduced as well and was one of the first methods that have been used for double resonance volume coils. The multi-pole circuit is introduced at the position of the resonance capacitors at the end rings for the high-pass birdcages or at the rungs for the low-pass birdcages (Fig. 38 left).

In the same manner as for surface coils the series capacitor C_L (Fig. 38) is used for the low frequency. The parallel capacitor C_H that has a smaller value as the series one is used for adjusting the high frequency. The adjustments of the circuit must be done very carefully on each position to maintain the coil symmetry and is a very time consuming procedure. Easier to build are double resonance birdcages that use alternatively the rungs for the both frequencies (Fig. 38 right). To maintain the coil-symmetry for the higher frequency (^{1}H) a trap for the lower frequency is introduced at the rungs for the 1H and prevents the destruction of the current distribution of the higher mode by the currents of the lower mode. The relatively small tuning capacitors at the ^{1}H-rungs generate at the low frequency high impedance and therefore the corresponding mode at the low-frequency is not disturbed by the high frequency mode. This method also relies on a very careful adjustment of the trap circuit on each position and needs a very careful and iterative adjustment procedure. These two designs-principles using the same birdcage-structure and both modes can be driven in quadrature because of the intrinsic symmetry of these structures.

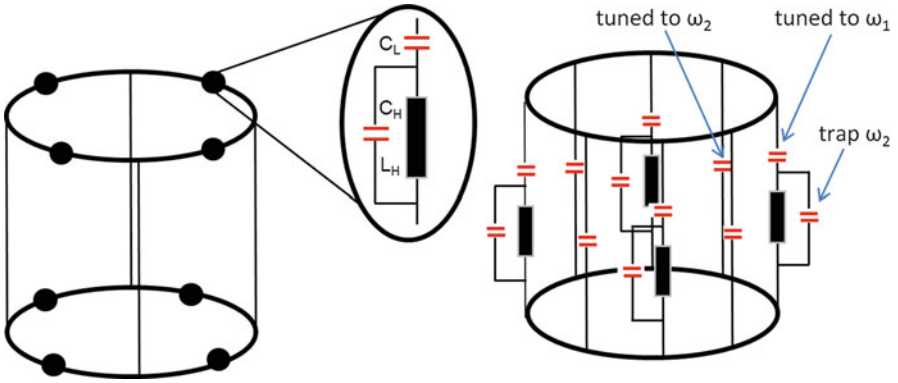

Fig. 38 *Right* – principle sketch for a low-pass double resonance birdcage. At the positions of the resonance capacitors the multi-pole circuits are introduced. *Left* – Double resonance Birdcage built on alternating legs that are tuned to the high-frequency ω_1 and low frequency ω_2. The parallel resonance circuits for the low-frequency-legs are tuned to the high-frequency ω_1 and operate as a trap and prevent the destruction of the current distribution of the lower mode by the currents of the higher one

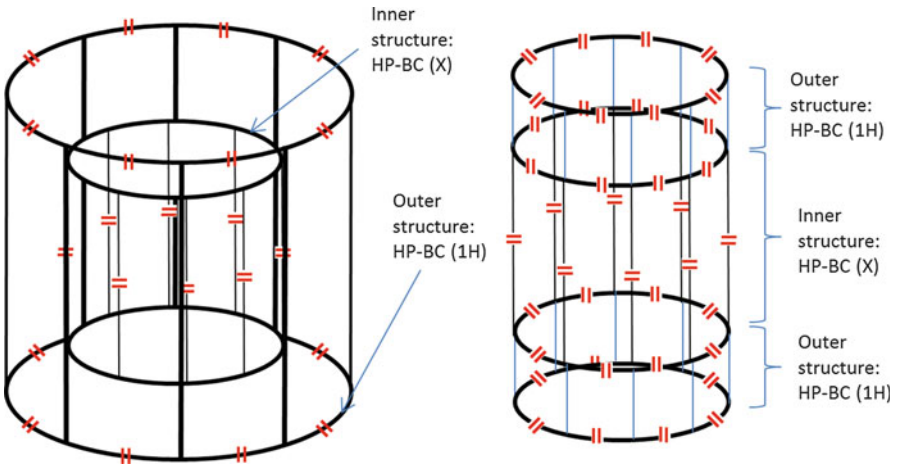

Fig. 39 *Left* – principle sketch of a double-resonance coil consisting of two imbricated birdcages. The inner birdcage is a low-pass-birdcage (LP-BC) that operates at the low-frequency (X-channel) and the outer structure designed as a high-pass-birdcage (HP-BC) that operates at the higher frequency (^{1}H). *Right* – lowpass-highpass birdcage combination of a Four-ring double resonance birdcage. The inner structure operates at the low-frequency while the two outer structures generate a transversal mode at the higher frequency. Due to the inductive coupling the co-rotating mode of the outer birdcages generates a common transverse, homogenous mode at the high frequency (^{1}H)

One of the easiest solutions for double resonance volume coils is the design principle based on TEM-coils. For this purpose the rungs are alternately tuned at the low and high frequency respectively. The adjustment procedure is in principle the same as for a single tuned TEM-coil and could be implemented in straight manner. The two modes can be driven in quadrature and fed in the same manner as birdcages via external low- and band-pass filters.

Another method to build double resonance-volume coils is the introduction of multiple cage-structures on different diameters (Fitzsimmons et al. 1993). In many cases these RF coils include a high-pass and a low-pass birdcage (Fig. 39 left). Also arrangements of high-pass or low-pass bird cages with saddle coils are commonly combined for multi-frequency volume coils. For such geometries the birdcage on the smaller diameter is used for the lower frequency while the larger diameter is tuned to the higher frequency (^{1}H). The strong inductive coupling effects between the coil structures have be to taken into account. To

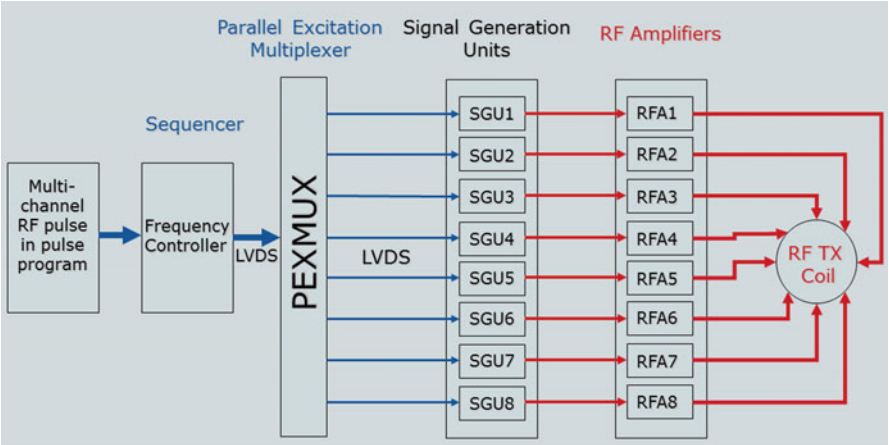

Fig. 40 Schematic of an example for parallel transmission systems based on a AVIII spectrometer platform (Bruker BioSpin, Rheinstetten, Germany)

achieve the optimal orientation to each other the proximity of the end rings needs special attention. The coupling of the modes of the two RF structures is minimized by slightly rotating one coil with respect to the other. In addition one of the coils can be built longer than the other but the implementation of quadrature driving of these structures can be quite cumbersome to build. One coil is usually a high-pass and the other one a low-pass birdcage structure according to the frequency and dimensions. It must be taken into account that the losses with respect to the performance of the two modes are strongly dependent on the mode coupling of the two separate electrical RF structures. In some cases it makes more sense with respect to the design-cost relationship to build the volume coils for linear excitation/reception than for quadrature-drive operation because of the reduced intrinsic coupling by adjusting the two modes perpendicular to each other. For some cases it is advantageous using the inner structure for the higher frequency (^{1}H) and the outer structure for the low-frequency e.g., for inverse ^{13}C-spectroscopy applications (Lanz 2000). In this special case the mode of the low-frequency that generates a linear RF field does not induce a significant current in the high frequency birdcage-structure due to its high impedance at the low-frequency. The sensitivity is recovered for both the coil-structures but this resonator cannot be driven in quadrature.

The issue of good circuit isolation and less coupling of the RF modes is intrinsically better solved by so-called four-ring birdcages (Murphy-Boesch et al. 1994). The principle structure is based on a birdcage that is merged together with two additional birdcage-structures and placed directly on the shared endrings of the inner structure (Fig. 39 right). The inner structure is built as a low-pass birdcage and the outer structures can be built as low or high-pass birdcage. The two identical outer structures are coupled inductively through the inner structure and generate a pair of two quadrature modes based on a co- and counter rotating current distribution of the outer structure. One of these modes produces a homogenous transversal RF-field and is operating at the higher frequency (^{1}H). The inner structure is tuned to the lower frequency. While the currents of the multiple frequencies flow substantially in different structures the circuit interactions between the frequencies are relatively small. This makes the construction and tuning of the four-ring birdcage relatively straightforward to construct.

Future Directions and Open Problems

Since the early days of MR-imaging many different RF-coil concepts have been developed and today an almost unlimited amount of RF coil designs are in use. Birdcage- and local surface-coils are still commonly used in standard MRI-systems. The last two decades have been dominated by a rapid development of RF-array coils that are dedicated for parallel imaging. Many investigations have examined the upper bound on sensitivity of RF coil array with the use of the concept of the "ultimate" SNR (Lattanzi and Sodickson 2012; Wiesinger et al. 2004; Ohliger et al. 2003). The sensitivity profiles from

DOI 10.1007/978-981-4560-75-7_121-1

arbitrary coils outside a spherical sample based on a set of base functions satisfying the Maxwell equations were evaluated. A linear combination was found that maximizes the SNR at multiple locations in the sample (Ocali and Atalar 1998; Wiesinger et al. 2005). Based on the analysis of the ultimate SNR for accelerated imaging the number of 32 array-channels was found to be close to the theoretical limit at the center of the phantom for clinical MR-coils (Wiggins et al. 2005; Wiesinger et al. 2004). But there is substantial room for improvement towards the periphery of the array coil that is mainly influenced by the increased number of array coil elements. Array coils with 96-channel arrays have been built onto a helmet shaped former that fits closely to the head. The design of the individual circular surface coils was based on the combination of hexagonal and pentagonal symmetry of the soccer ball. Apart from the design effort of building these high count channel RF coil arrays the number of array coil elements reaches its limits today by the availability of receiver channels that are commercially available and economically feasible.

As seen from the theoretical investigations (Wiesinger et al. 2004) the sensitivity gain for accelerated imaging is a function of the number of array-elements and improves at higher field strengths. At higher field strengths where the wavelength is in the same range as the dimensions of the subject under investigations, a homogenous excitation performed by traditional birdcages or TEM-volume coils is impossible. For that reason the trend today goes to so-called transmit-arrays where the profile of the transversal $\mathbf{B}_1$-field can be tailored depending on the demands of the application, e.g., by RF-shimming for a more homogenous excitation in the subject under investigations. The trend to even higher magnet field strength for MR-imaging opens the door and creates new challenges for innovative RF coil designs and concepts.

Transmit Sense/RF Shimming

Transmit Array Coils

The basic idea of parallel-receive imaging techniques is the simultaneous use of multiple receiver coils. This principle can be adapted for parallel transmission of the spatially selective RF-pulses. A multi-dimensional RF-pulse follows a specific trajectory in k-space analogous to data acquisition and shorting this trajectory shortens the pulse duration. Using multiple transmitter channels, each has its individual time-dependent waveform and the spatial sensitivity distribution of the numerous array coil elements compensates for the missing parts of the k-space. Despite the shorting of the pulse duration, the reduction of $\mathbf{B}_1$-inhomogeneity's by tailoring the RF-pulses with Transmit SENSE (Katscher et al. 2003; Ullmann et al. 2005) has recently been successfully performed.

The design principle of receive-array coils can be extended to the transmit-only or the transmit/receive case and all commonly used methods for inductive or capacitive decoupling of the individual coil-elements can be used. When multiple array coil elements are fed by conventional voltage sources then the impedance of the mating network becomes a function of the current amplitude and phase of each of the RF elements. In order to have accurate control over the amplitudes and phases of the currents on each RF element it is necessary to have an accurate knowledge of the mutual coupling.

For proper handling of the mutual coupling so-called multi-port networks (Butler-matrix) have been developed for driving multiple ports with a defined phase and amplitude (Butler et al. 1963; Alagappan et al. 2008). The Butler matrix is a passive circuit network based on hybrid couplers, phase shifters and crossovers that corrects the shared impedances of the n-port coil interface by an $n \times n$ impedance network. The ports to the amplifier have possibly zero shared impedance and can be driven independently. While the impedance on the coil ports changes with different loadings the adjustments of the Butler-matrix network would be possible but are challenging for a high count channel system. The Cartesian feedback (Hoult et al. 2004a, p. 57; Hoult et al. 2004b, p. 64) can be a good choice. The output signal is fed back into the input before and after mixed-up and down. Alternatively the mutual coupling can be reduced by

DOI 10.1007/978-981-4560-75-7_121-1

so-called RF current sources using power- MOSFETS. The principle of using the high or low impedance of the amplifier (section Receive Array Coils for Parallel Imaging) is utilized to mitigate the effect of the mutual coupling (Kurpad et al. 2006).

An example of a multi-transmit MRI-system that consist of numerous independent transmit channels is given in Fig. 40. This system is based on a standard MRI platform that features up to 6 so-called frequency controllers. Each controller drives via a LVDS interface (Low voltage differential signaling – a high speed serial communication), one so-called signal generation unit (SGU). By using the digital frequency, amplitude and phase information issued by the frequency controller, an analogous RF signal is generated by the SGU. This analogous signal working on individual frequencies is fed into a high power RF amplifier (RFA) that generates the high power RF-pulse. For the extent of the 6 transmit channels a so-called Parallel Excitation Multiplexing Component (PEXMUX) is used in order to increase significantly the number up to 48 transmit channels for parallel excitation (PEX) applications e.g. Transmit SENSE. The multiplexing of the signals is performed entirely on the digital side. With this infrastructure standard pulse programs can be used by replacing the normal used RF-pulses by such multi-shape pulses. The individual RF waveforms are specific for each transmit channel and are generated simultaneously.

For PEX the generated transversal magnetization pattern M(**x**) can be expressed as a linear, sensitivity-weighted combination (Ullmann et al. 2005; Katscher et al. 2003) of virtual single-element magnetization patterns $M_n(\mathbf{x})$:

$$M(\mathbf{x}) = \sum_n S_n(\mathbf{x}) M_n(\mathbf{x}), \quad \text{where } M_n(\mathbf{x}) = i\gamma M_0 \int_0^T B_{1,n}(t) e^{-i\,\mathbf{x}\cdot\mathbf{k}(t)}\, dt \tag{86}$$

Where S_n is the sensitivity of the n-th array coil element in which the RF-waveform $B_{1,n}$ is incorporated and $\mathbf{k}(t)$ is the (reduced) k-space trajectory traversed during the RF-transmission. One of multiple approaches for the determination of the RF-waveforms $B_{1,n}$which are necessary to excite a given pattern $M(\mathbf{x})$ is the direct temporal and spatial discretization of the Eq. 86. That leads to the following linear system (u and v are the spatial and temporal indices respectively):

$$\mathbf{m} = \mathbf{A}\mathbf{b}, \quad \text{where } A_{u,(n,v)} = i\gamma M_0 S_n(\mathbf{x}_u) B_{1,n}(t_v) e^{-i\mathbf{x}_u\cdot\mathbf{k}(t_v)} \Delta t \tag{87}$$

For a given magnetization vector **m** the waveforms **b** can be calculated by expressing the linear system (87) as a minimization problem. An example of a PEX-experiment is given in Fig. 41. The transmit sensitivity of all eight coils were determined and converted to the sensitivity-map of the whole array-coil. With this information the individual transmitter channels of an 8 channel transmit-coil were independently driven to perform a homogenous transmit-RF-field with a birdcage-like excitation mode.

Apart from the flexibility for RF-shimming to overcome the problems of standing wave phenomena in the subjects under investigations any desired excitation pattern can be performed (Fig. 42). For this experiment an overview scan was carried out first. In this overview scan a region for excitation was selected (brain domain). Using parallel excitation (Ullmann et al. 2005) this region was then scanned with a full FOV and a reduced FOV.

Another strong motivation for the introduction of local transmitter arrays is an additional degree of freedom for steering E an B-fields, e.g. with respect to the specific absorption rate (SAR) at high-field MRI. The specific absorption rate (SAR) often limits the specific use of imaging methods with respect to the flip-angle or the number of slices at high and ultra-high fields. In addition the nonuniform excitation by traditional volume coils yields also to hot spots where the SAR-values exceed the permitted values locally. But with the usage of transmit excitation with multiple channels the user has more control about the **E** and

DOI 10.1007/978-981-4560-75-7_121-1

B-field distributions. But some practical issues for SAR-control and supervision are still under development and needs further investigations.

With the introduction of a multiple transmit/receive array especially at high and ultra-high magnetic field strengths, the development of new surface array coil elements advanced in new directions within the last years. At lower magnetic fields only the so-called near field of the RF coils is commonly of interest. The $\mathbf{B}_1$-field, which is close to the coil generated by the currents on the RF structure, is in most cases much higher than the electrical field that is generated simultaneously. Only a small fraction of the **B**-field is associated to a propagating wave. With the introduction of MR-systems >=7 T for human applications and increasing the field-strength up to 21 T for preclinical MR-systems, the so-called far-field is becoming more interesting for the design of MRI RF coils depending on whether the target region is located "far" away from the antenna or not. The so-called traveling wave imaging is under development. The waveguide modes supported by the scanner RF-shield are used to excite the MRI signal in the objects under investigations that maybe several meters away from the antenna.

By increasing up the magnetic field strength of MRI-magnets and expanding the resonance frequency of MR-coils to new horizons it becomes more important to investigate in directions that MRI RF coils perform as antennas. Potentially more concepts of commonly used antenna technology, e.g., from telecommunication, will have impact on the designs of antennas for MR-imaging in the future.

Electrical and Electronic Engineering Department, Public University of Navarra, Pamplona, Navarra, Spain

Abstract

This chapter deals with the analysis of several kinds of space antennae with a special section devoted to THz antennae. In particular, horn antennae, either corrugated as spline profiles for data downlink and uplink communications and TT&C applications are developed. More innovative antenna designs based on the use of Electromagnetic BandGap (EBG) or Metamaterial structures (MTM) are included. These ones exhibit very promising properties to be used in applications such as TT&C or Navigation. Finally, due to the increasing interest in scientific missions operating at THz frequencies, a section including the last results of using MTM technologies for implementing antennae at THz bands for imaging space applications is presented.

Keywords

Horn antennae; Corrugated antennae; TT&C; Space antennae; Electromagnetic band gap technology (EBG); Metamaterials; Terahertz antennae

Introduction

Following the IEEE standard definitions, an antenna is that part of a transmitting or receiving system, which is designed to radiate or to receive electromagnetic waves. In satellite communications, the use of antennae is fundamental in order to keep the satellite in operation or to be able to run the different applications such as TV broadcasting, data transmission, etc.

Each satellite needs different kind of antennae, and their requirements are very dependent on the applications: scientific, commercial, civil, etc. In general, the antennae on board of a satellite platform can be divided into three groups: antennas for telemetry, tracking, and control (TT&C) which control the satellite operation, antennae for high-capacity transmission, which are mainly in charge of the communications, and finally antennae for the different instruments mounted in the satellite which are fully related with the mission.

For each of the aforementioned groups, there are different antenna technologies, which can be applied in order to comply with the expected performances of the antenna. In the literature, it is possible to find from planar antennae to horn antennae, including arrays or reflectarrays. Anyway, this chapter will focus on two kinds of antenna developments. The first one will be horn antennae, either based on smooth or corrugated profiles. The second case will be devoted to more innovative antennae, which will follow Metamaterial concepts for their implementation.

Horn antennae are well known for many years. They exhibit very good radiation performances which make them very suitable to cover most of the needs for the radiation patterns in a satellite. They present very good pattern symmetry, very low cross-polar levels, very low sidelobe levels, and a wide bandwidth

response. Even in the last years, new profiles have appeared making them very competitive versus other kind of antennae by reducing their overall size (length). This chapter will mainly present the performances of a new kind of corrugated horn antennae, named Gaussian Profile Horn Antennae (GPHA), which have been used in the last years to comply with the stringent requirements of the radiation performances of many different space missions or communication systems. The performances of different GPHA antennae for TT&C, high-capacity, or space instruments will be included.

On the other hand, Metamaterial-based antennae have been recently appeared as a new approach in the development of antennae. In particular and focusing on the space sector, there are different proposals which make use of Metamaterial concepts for improving antenna performances. This chapter will deal with the use of metasurfaces in satellite antennae for TT&C and GPS applications. This innovative concept is an alternative to conventional technologies which can be applied in those applications for improving overall performances, including mass and cost aspects.

A special section on THz space antennae is included. This one will mainly be centered in the progress of MTM antennae operating in this frequency range for space missions.

Data Downlink and Uplink Feed Horn Antennae for Spaceborne Communications

Introduction

Data feed horn antennae on today's communication satellite systems are of very different types. It is not possible to cover all feed horn antenna solutions for all types of spaceborne communications missions, but the following section provides an overview of the most common designs employed nowadays for geostationary communication satellites.

Not much information can be found from actual satellite programs since trade secrets in this highly competitive commercial field protects new developments from being disclosed. However, a lot of useful information from author's experience has been included, supported with several examples and highlighting the main constraints for each antenna type.

Spaceborne communications requirements for data feed horn antennae are always in evolution since next generation systems require higher capacity and flexibility complicating the feed horn design.

Geostationary satellites offer Fixed Satellite Services (FSS) and Broadcasting Satellite Services (BSS) that are often used for broadcasting to and from television networks and local stations. They can also be used for video conference, broadband internet, and general commercial telecommunications. The most common frequencies employed in actual commercial geostationary satellite communications are the Ku band from 12 to 18 GHz, and in K and Ka bands together (often referred simply as Ka band) from 18 to 40 GHz. Typically, Ku band uses the frequencies from 10.7 to 12.7 GHz for the downlink (Tx from the satellite) and 12.8–14.5 GHz for the uplink (Rx from the satellite's view). Note that in some cases, the uplink moves to the 17.3–18.2 GHz range. On the other hand, Ka band usually employs for the downlink (Tx) the 18.3–20.2 GHz range and the 27.2–31.2 GHz range for the uplink (Rx). It is common for FSS/BSS satellites to carry a multitude of feed horn antennae, which are operating at different frequency bands.

Metallic feed horns are the preferred feed elements for most spaceborne communications, because their size is reasonably small and because they have great power handling capability. Additionally, horn design techniques have evolved to the point where very good polarization purity, pattern symmetry, gain performance, reflector aperture illumination control, and frequency bandwidth are readily achievable through the synthesis of the internal horn wall profile. Several horn types are widely used for this type of antennae, but the most widely used nowadays are high-performance corrugated horns and high-

DOI 10.1007/978-981-4560-75-7_123-2

performance smooth-walled spline profile feed horns. Advanced synthesis techniques of rather complex horn wall profiles are able to optimize performance at a number of selected frequencies and therefore significantly widen the frequency band or achieve a very good dual-band performance covering both the Tx band and the Rx band.

Spaceborne Reflector Technology

Feed horn antennae for spaceborne communication missions usually employ reflectors to form contoured beams from the geostationary orbit. There are two main methods to cover the earth's surface from a geostationary satellite:

- A shaped reflector which consists in shaping the energy radiated by a single feed element (usually a high-performance corrugated feed horn) into a contoured beam to form the desired coverage area over the earth's surface (Viskum and Sorensen 1994). The shaping is done by appropriate reflector surface optimization.
- Multibeam reflector antennae where the coverage over the earth is divided in beams that cover the earth surface with cells. This technology employs several reflector surfaces (three or more) which are usually offset parabolic reflectors and a single feed horn per beam (usually high-performance smooth-walled spline profile feed horns) over the earth (Rao 1999). So all the beams must be covered by an array of feed horns.

One of the problems with shaped reflectors, as opposed to multifeed parabolic reflectors, is that only one beam can be generated per reflector profile. For higher rate communications and to allow more reuse of frequencies and more reconfigurability, multiple spot beams and contoured beams are actually the preferred solution.

These systems may use different antennae for Tx and Rx or common Tx/Rx antennae. Mass and cost-saving considerations increasingly drive the design into common Tx/Rx antenna solutions. One challenge in this case is to design the antenna for optimal performance in two widely spaced frequency bands over the same coverage spots on the ground. Designs have evolved to address this challenge. Clearly, the design antennae for Tx only or for Rx only is generally much simpler and often leads to slightly better gain performance across the coverage region. The mass and cost penalties are, however, quite high.

RF Performance Parameter Considerations in Spaceborne Antennae

RF performance parameters include gain (minimum gain across the coverage region as well as peak gain), isolation (gain levels on the predefined isolation areas on the ground) and cross-polarization discrimination (XPD) calculated as the copolarized gain minus the cross-polarized gain in dB.

Minimum gain across the coverage region must be optimized by means of proper reflector and feed horn design. Feed horn copolar radiation pattern plays a key role in this optimization since it should keep a pattern decay at the reflector edge as constant as possible over the whole frequency band as well as minimize spillover radiation to improve the isolation between different areas on the ground.

On the other hand, cross-polarization discrimination is also crucial since it must minimize the crosstalk interference between transmissions using alternative polarizations. Cross-polarization generation in spaceborne antennae is caused mainly by four factors: feed horn inherent cross-polarization, reflector surface curvature, feed horn location away from the focal point and inclination angle of the feed horn relative to the parabolic main axis. Other secondary order, but potentially important contributors to cross-polarization are scattering effects by support struts and feed lines, reflections of the horn primary pattern and the reflector radiated near fields by neighboring structures including the adjacent spacecraft panels.

DOI 10.1007/978-981-4560-75-7_123-2

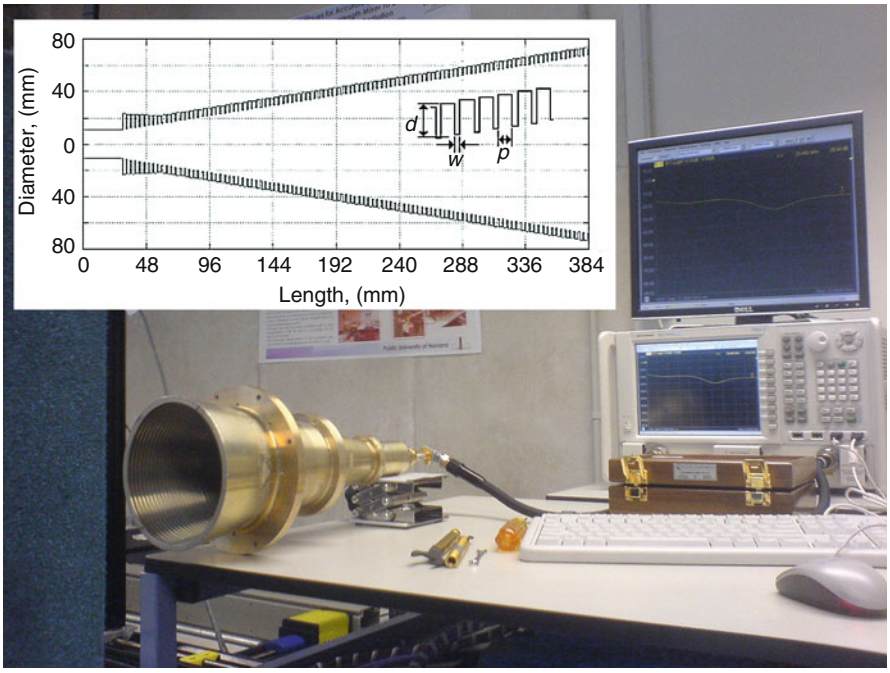

Fig. 1 Conical corrugated horn antenna

These effects should be quantified, analyzed and tested since they can potentially degrade performance significantly.

High Performance Corrugated Feed Horns

Spaceborne communications usually require the use of corrugated horn antennae to feed the shaped reflector surfaces designed to generate contoured beams that illuminate the desired coverage regions over the earth. The reason to use corrugated horn antennae and no other type of feeds is that these type of antennae offer, with improved performance over a quite wide bandwidth; low crosspolar levels, low sidelobe levels and high return losses as well as nice gaussian-like radiation patterns. Therefore, the performance of corrugated horns usually maintains high performance for both the Tx and Rx frequency bands.

A disadvantage of corrugated horns is that they are generally bulky with larger aperture diameter than smooth walled horns for a comparable gain. They are also heavier and more expensive than smooth walled horns. The basic corrugated horn profile is a linear corrugated flare angle leading to a long corrugated feed horn, see Fig. 1.

There is a very wide variety of corrugated horn profiles (Rudge et al. 1982; Olver et al. 1994; Teniente et al. 1999; Granet et al. 2000; Maffei et al. 2000; Hay et al. 2001; Teniente et al. 2002a; Granet and James 2005), some of them but not all of them are: linear, sinusoidal, sine-squared, exponential, gaussian, hyperbolic, polynomial, etc. However, new software tools are now available to facilitate and enhance the effectiveness of corrugated horn profile optimization, making it possible to design this type of horns to meet an even wider variety of performance requirements and volume constraints. Modern commercial software packages, use efficient full-wave analysis techniques such as mode matching, are usually employed in horn design (http://www.mician.com). The agreement between predictions and measured results has become excellent, such that horn prototyping is usually no longer required. Other analysis techniques, such as the finite element method and the method of moments, are also occasionally used, but they are not as computationally efficient as the mode matching method of analysis.

DOI 10.1007/978-981-4560-75-7_123-2

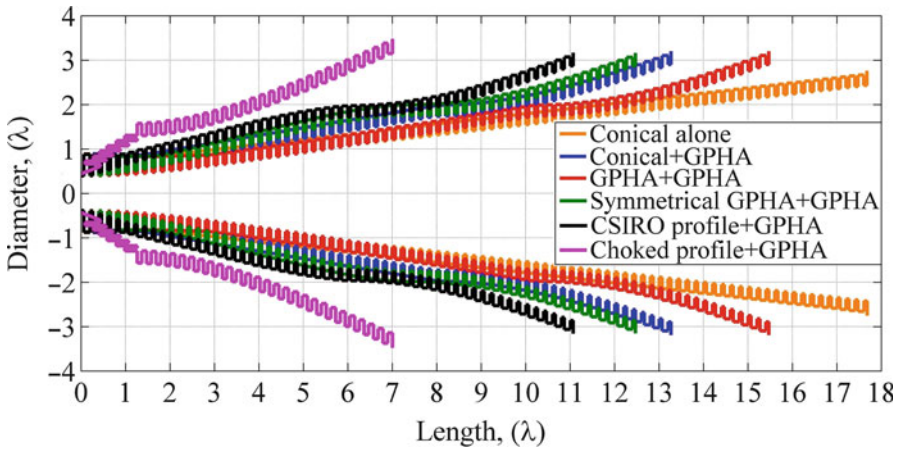

Fig. 2 Length comparison between different-profiled corrugated horn antennas (Teniente 2003) of the same directivity

After the simple conical corrugated profiles, different profiled corrugated profiled appeared, see Fig. 2. This new designs were shorter and the possibilities of optimization increased with the profile shape.

Nowadays, thanks to the available software tools and the speed of computers, the design of a corrugated feed horn for spaceborne communications is usually not any form of profile function. In fact, actual antenna designers leave every corrugation depth and step between corrugations free in the optimization process leading to efficient profiles that cannot be met by simpler profile formulas as the ones used previously.

The shortest corrugated horn profile and indeed very suitable for spaceborne communications as it presents reduced mass and volume is the horn antenna that combines horizontal corrugations (known also as axial corrugations (Bird 2008) or choke horns (Milligan 2005)) for the throat region and vertical corrugations (known also as radial corrugations) for the flare region, see Fig. 2. These horn antenna designs have been used in modern communication satellite feeders as well as in other applications, (Gonzalo et al. 2002; Teniente et al. 2005, 2006; Teniente et al. 2009).

This type of horn antenna achieves significant improvements in axial length, return loss over a wide bandwidth, computation complexity and manufacture complexity, when compared to a conventional corrugated horn with perpendicular corrugations. The only disadvantage is that, depending on the design, the manufacture could require splitting the horn in two pieces, one for the horizontal corrugations and another for the vertical corrugations. Both sections must be bolted together and aligned properly with special care to join them assuring a tight contact, to prevent narrow radiating slots (Granet et al. 2008).

Example of a Ku-band Corrugated Horn to Feed a Shaped Reflector for Spaceborne Communications

As an example, a Ku band communication satellite feedhorn whose specifications are given in Table 1, is presented here. Such feed horn have more than 50.2 % bandwidth and the partial bandwidths are 22.2 % for Tx and 4.9 % for Rx bands respectively. It can be observed that the overall requirements are extremely severe, since a return loss value above 32 dB and a crosspolar level below −45 dB for the whole frequency bands, are required. Note that this kind of profile is very short for a corrugated horn antenna.

Anyway, it is important to remark that every satellite has its own frequency plan that usually determines the feed horn design. However, all of the horn antennae for spaceborne communications that feed a shaped reflector need usually a simulated crosspolar maximum level below −45 dB and a copolar radiation pattern with a certain variation along the frequency band to assure the footprint of the radiation pattern from the satellite over the earth to be frequency independent, see Table 1.

DOI 10.1007/978-981-4560-75-7_123-2

Table 1 Example Ku band spaceborne corrugated feed horn specifications

Parameter	Value requested
Electrical specifications	
Frequency bands	Tx: f_{min1} to $1.25 \cdot f_{min1}$ GHz
	Rx: $1.62 \cdot f_{min1}$ to $1.67 \cdot f_{min1}$ GHz
Maximum crosspolar level	< -45 dB in a range of +/− 22 deg
Return loss	>32 dB in the whole frequency bands
Taper at 20°	~ −9.5 to −16 dB at Tx
	~ −19 dB at Rx
Maximum sidelobe level	<23 dB for angles above +/− 20 deg
Mechanical specifications	
Total length	$<10 \cdot \lambda(f_{min1}(GHz))$ mm
Maximum external diameter	$<3.55 \cdot \lambda(f_{min1}(GHz))$ mm

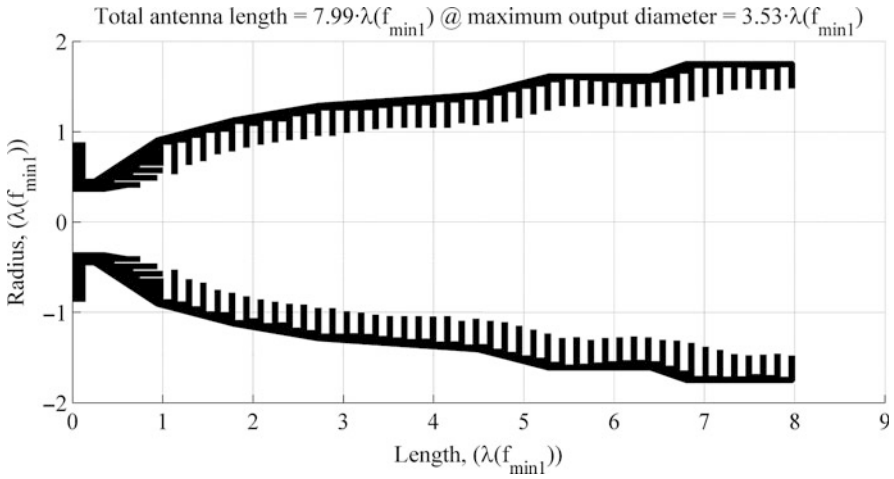

Fig. 3 Optimized corrugated feed horn for ku band

One of the best possible results to comply with the specifications given in Table 1 was a profile with 3 axial corrugations and 44 perpendicular corrugations, see Fig. 3. The resultant length was 20 % shorter ($8 \cdot \lambda(f_{min1}(GHz))$ mm), than the maximum specified, so the mass reduction is really remarkable. The rest of the specifications were met, see Fig. 4. The optimization process selected individually all the corrugation parameters (except thicknesses) and the length and angle of the initial linear taper at the throat. A total of 97 variables were individually optimized for the final design. Final results are shown in Figs. 4 and 5. The results are in good agreement with the specifications.

The resultant radiation patterns can be seen in Fig. 5. The results presented are mode matching simulations [1], but this method as it has been said previously is so accurate that the measurements are extremely similar if the feed horn is properly manufactured. This horn antenna was manufactured in a single piece, see Fig. 6, and is successfully operating onboard a geostationary satellite.

High-Performance Smooth-Walled Spline Profile Feed Horns

Applications requiring higher data rates, such as high-speed Internet services for consumers and small businesses, call for much higher antenna gains and wider frequency bandwidths. Large antenna gains are associated with a small coverage region on the ground and with large antenna aperture diameters in terms of wavelength. Realizing wider bandwidths is increasingly easier as the frequency of operation increases,

since then the bandwidth as a percentage of the center frequency remains relatively small. For these reasons, this type of service has been typically provided with multiple spot beam antennae (with small

DOI 10.1007/978-981-4560-75-7_123-2

Fig. 6 Manufactured corrugated feed horn of the example (Reproduced with permission from ANTERAL company)

circular coverage spots) operating at K/Ka-band (Rao 1999). The coverage spots are typically arranged in a tight hexagonal grid on the Earth, where either all spots have the same diameter or different diameters are used to address different expected traffic density conditions.

These systems may use different antennae for Tx and Rx or common Tx/Rx antennae. Mass- and cost-saving considerations increasingly drive the design into common Tx/Rx antenna solutions and usually smooth wall horns are the preferred solution to reduce drastically the mass of the feed horn array since a lot of horns must be arranged together.

For these systems, known as spot beams, a high efficiency of the horn aperture is needed to ensure better edge of coverage gain (Amyotte and Martins-Camelo 2012; Bhattacharyya and Goyette 2013). This aspect also drives to the use of smooth wall feed horns since an aperture efficiency near 90 % can be met in Tx and Rx bands at the same time with modern spline profiles. On the other hand, if corrugated feed horns are selected, it is difficult to achieve better than 70 % aperture efficiency (aperture efficiency is the relation between effective area and physical area at the horn antenna aperture).

Nowadays, for these kinds of applications, the best solution for spot beams is the use of smooth-walled spline profile feed horns (Granet et al. 2004). Spline-profiled feed horns are longer than corrugated horns, their performance regarding crosspolar level and bandwidth is worse but they are low weight (suitable mass reduction in arrays for spaceborne communications) and aperture efficient. Crosspolar level around −30 dB can be achieved in Tx and Rx bands at the same time which for this kind of multiple spot beams where the reflectors are not shaped is considered enough to ensure the required crosspolar isolation or discrimination (XPI or XPD).

However, simulation of a smooth-walled horn is not as easy as a corrugated horn. A corrugated horn is discrete; their profile is well defined by steps, so the number of steps to analyze would be the number of corrugations multiplied by two. However, smooth-walled horns must be discretized to be analyzed and such discretization must be enough to assure good performance. This issue leads to have above 500 steps in a normal horn, much more steps than in a corrugated horn. In this situation, the designer has not such freedom and must rely on a certain formula to define the profile. Up to now, the best approach is the use of spline profiles. Some results can be found in for a 6 radii case in (Granet et al. 2004) and for higher number in (Zeng et al. 2010).

Table 2 Example Ka band spaceborne smooth-walled spline profile feed horn specifications

Parameter	Value requested
Electrical specifications	
Frequency bands	Tx: f_{min1} to $1.04 \cdot f_{min1}$ GHz
	Rx: $1.5 \cdot f_{min1}$ to $1.54 \cdot f_{min1}$ GHz
Maximum crosspolar level	< -26 dB in a range of +/− 15 deg
Return loss	>40 dB in the whole frequency bands
Taper at 13°	Spillover at Tx < 0.5 dB
	Aperture efficiency at Rx > 0.85
Mechanical specifications	
Total length	$<14 \cdot \lambda(f_{min1}(GHz))$ mm
Maximum external diameter	$<4.8 \cdot \lambda(f_{min1}(GHz))$ mm

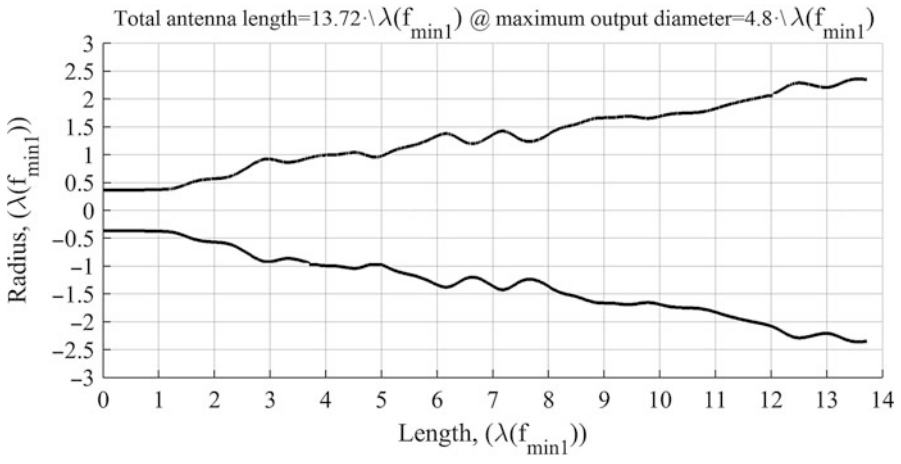

Fig. 7 Optimized smooth-walled spline profile feed horn

Example of a Ka-band Smooth-Walled Spline Profile Feed Horn to Feed Multibeam Reflector Antennae for Spaceborne Communications

As an example, a Ka band communication satellite feedhorn whose specifications are given in Table 2, is developed. Such feed horn has more than 42.3 % bandwidth and the partial bandwidths are 3.5 % for Tx and 2.4 % for Rx bands respectively. It corresponds with a very stringent requirement for a smooth-walled horn, since a return loss value above 40 dB and a crosspolar level below −26 dB for the whole frequency bands, are required. Furthermore, it is expected to present a reduced length.

The design employs 40 radiuses to define the profile, see Fig. 7. The result is rather curved inside for a smooth-walled horn, but with this profile, see Figs. 8 and 9, the requirements can be met.

The resultant radiation patterns are plotted in Fig. 9. This horn antenna was manufactured and it is successfully operating onboard a geostationary satellite where it forms part of a feed horn array for spot beam communications.

Navigation Antennae

Navigation systems are commonly used nowadays. They provide geospatial position with global coverage to users. There are different navigation systems as GPS from USA, GLONASS from Russia, Compass

from China, and Galileo from the European Union. Their operational frequencies cover two bands: 1150–1300 MHz and 1559–1611 MHz. The frequency band from 1300 to 1560 MHz is reserved for other radio users such as military, telemetry, radio astronomy, Earth-to-space operation, and satellite Internet services. There are frequency overlaps between systems, creating a compatibility between them and allowing users to obtain their position using several systems at the same time. The working frequencies of each system can be seen in Table 3.

The accuracy of these systems needs to be improved. Geosynchronous satellite Navigation antennae (GSNA) are used to provide GPS/GALILEO/GLONASS signal corrections for better position accuracy and to certify signal integrity. The accuracy of Navigation systems has been improved by the used of these complementary systems as the Wide Area Augmentation System (WAAS) in USA, EGNOS in Europe, and MSAS in Japan.

In this section, the Wide Area Augmentation System (WAAS) has been taken as GSNA reference application. WAAS is an extremely accurate navigation system developed to complement the Global Positioning System (GPS). One of the important components of this system is the Tx L-Band navigation antennae providing global Earth coverage from geostationary satellites. These on board antennae operate in circular polarization with Axial Ratio (AR) values lower than 1.5 dB and provide gain values around 17 dBi over the entire 18° beamwidth of the conical coverage area representing the antenna Field of View (FoV). The intended Navigation Antenna application requires also to achieve a precise and stable antenna phase center location (<20 mm) over both the antenna Field of View (FoV) and the operating frequency bandwidth, to allow for maximum overall system positioning accuracy. The required WAAS channel fractional bandwidth is relatively small and represents about 1.5 % of the positioning system L1 channel center frequency in L-Band. The main requirements from antenna point of view are shown in Table 4.

Conventional technology offers different solutions to comply with GSNA specifications. Array configurations with 9–19 elements size are necessary to obtain the desired gain values in the coverage area. Different solutions are given using patches or helixes elements to create the array. The number of elements in these arrays is not such a critical parameter. The main problem in these configurations is the Beam Forming Network (BFN) design, cost, and mass. The fabrication process of the helixes antennae could also be not either easy.

EBG GSNA Configuration

Electromagnetic Band Gap (EBG) technology offers new alternatives to design competitive solutions to conventional technology. EBG designs can obtain similar and even better, radiation performances (complying with all the radiation specifications) while the cost, dimensions, and manufacturing process complexity is minimized. The BFN can be simplified by reducing the number of radiating elements in the array configuration using the gain enhancement mechanism given by a superstrate EBG configuration. EBG technology can be applied to these applications due to the reduced required bandwidth (≅1.5 %).

In this section, an alternative to conventional technology based in EBG technology is presented. The EBG superstrate configuration complies with the RF requirements, while it reduces the cost and height and simplifies the BFN considerably. The comparison between the prediction and measurements will be shown.

The theory of the EBG gain enhancement phenomenon has its foundation in the pioneering work of Von Trentini (1956) on the gain enhancement properties of cavity antennae. It consisted in a partially reflective surface (PRS) located a quarter wavelength from a ground plane. The structure forms a Fabry-Perot cavity. Power is reflected and transmitted (radiated) in each bounce of the trapped waves. When the power radiated is in phase over the partially reflective surface, a directivity increase is achieved. Under this condition, the radiation aperture has been increased. Out of the resonance band of the cavity waves are radiated out of phase, creating destructive interference in the far field. This gain enhancement phenomenon can also be explained using leaky wave antennae theory (Lovat et al. 2006a, b).

Successively, more studies were done in 1985 (Jackson and Alexopoulos 1985) and 1988 (Jackson and Oliner 1988) where the reflective surface was substituted by a quarter wavelength dielectric. Higher directivity values can be achieved using several dielectric layers (Jackson et al. 1993; Thèvenot et al. 1999a; Feresidis and Vardaxoglou 2001).

Different techniques have been applied to create partially reflected surfaces. Frequency Selective Surfaces (FSS) or EBG with a defect in their periodicity can be used to produce the gain enhancement phenomenon (Biswas et al. 2001; Fehrembach et al. 2001; Cheype et al. 2002; Lee et al. 2005). The introduction of a defect in the stacked structure leads to the apparition of a narrow pass band, where the waves incident to the structure can suddenly be propagated in the now defective crystal. The quality factor of the defective crystal can be adjusted by playing with the permittivity of the slabs, and the quality factor decreases with the decrease of the dielectric permittivity. This quality factor is going to limit the maximum achievable gain and the operational bandwidth of the antenna configuration (Diblanc et al. 2005). The higher the Q-Factor, the smaller the operating relative bandwidth of the structure is.

DOI 10.1007/978-981-4560-75-7_123-2

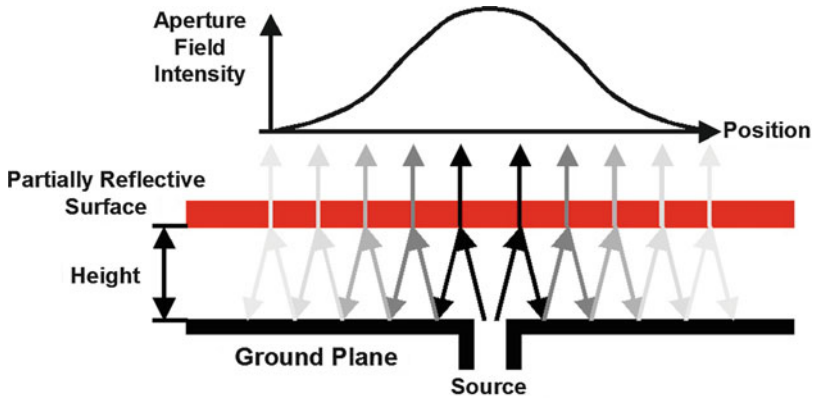

Fig. 10 Depiction of the spatial filtering concept

This technology is intrinsically limited to relatively narrow band applications where the operating relative frequency bandwidth is limited to a few percents. As the frequency increases from the optimum operating frequency providing the antenna peak gain, the directivity decreases and the pattern gets distorted. On the other hand, most of the rays are reflected back by the EBG when the frequency is lower than the optimum gain frequency, therefore trapping the RF energy emitted by the source between the ground plane and the reflecting slab, see Fig. 10.

EBG theory has provided a new and powerful framework for the understanding of the gain enhancement phenomena and has enabled significant advances in the design of antennae using partially reflecting surfaces. The gain enhancement phenomenon is now described in terms of wave propagation in 1D defective EBGs and it has been shown that the gain enhancement factor and the bandwidth are closely interrelated and essentially fixed by the quality factor of the defective 1D crystal resonance (Iriarte et al. 2006). The quality factor of the defective 1D crystal resonance can be adjusted by adjusting the reflectivity of the partially reflective surface and generally increases when the reflectivity of the surface is increased. Thin metallic sheets with holes or etched metallic patterns on thin dielectric sheets can be used to produce lightweight 1D defective EBGs for space antenna applications.

One of the main advantages that the EBG technology could bring to navigation antennae is the reduction of the antenna complexity by reducing the number of radiating elements to just a few or even to a single one. It has been shown in Thèvenot et al. (1999b), that a 1D defective crystal with a high quality factor and a single element source can meet the directivity and Axial Ratio requirements of the WAAS application. However, it has also been found that the phase center stability is significantly degraded with this large gain enhancement configuration. It therefore appears that the phase center stability needs to be traded-off against the quality factor of the defective 1D crystal and the intrinsic directivity of the source illuminating the EBG antenna. A quality factor of about 50 combined with a 2×2 element array exciting the antenna 1D defective crystal structure was found to be a good compromise in order to meet the desired gain and phase center stability requirements of the WAAS antenna application.

An EBG design, frequency scaled to C-Band is shown in Fig. 11. The model has been scaled due to measurement facilities in this frequency range. The result is completely scalable. It consists of a 2×2 array of circularly polarized two-port patches fed in quadrature and placed underneath an EBG superstrate consisting of an etched metallic pattern of circular holes on a thin dielectric sheet. The circular holes are positioned on a regular square matrix. The radiating elements are sequentially rotated in 90° steps to improve the Axial Ratio over the antenna Field of View (Iriarte et al. 2009).

At the edges of the ground plane, four dielectric threaded rods provide support to the EBG layer and allow for adjustment of the height of the layer above the radiating elements and antenna ground plane. The EBG superstrate is etched on a thin 50 μm thick Kapton substrate and tensioned on a fiberglass reinforced

epoxy frame. Johannson Blocks were used to set the EBG layer height above the ground plane with an accuracy better than 50 μm. The height of the EBG layer above the ground plane is about 0.45 λ_0.

RF Performances

The optimum operating frequency band of the frequency scaled-up is from 3,700 to 3,780 MHz. The RHCP directivity elevation cuts at $\theta = 0°$, 45°, 90°, and 135° at 3,740 MHz are provided in Fig. 12, and the axial ratio cuts the same θ° cuts at 3,740 MHz are provided in Fig. 13.

The radiation pattern performance summary of the GSNA configuration is provided in Table 5. The antenna peak RHCP directivity ranges from 20.5 to 21.2 dBi. The worst RHCP directivity over the FoV ranges between 17.9 and 18.3 dBi.

0.47 dB of losses have been estimated for the design. Including the 0.47 dB of losses, the minimum RHCP gain over the FoV is 17.39 over the antenna operating bandwidth. Axial ratio over the FoV is better than 1.2 dB, therefore compliant to the targeted 1.5 dB value.

Worst over the channel bandwidth			
3740	20.51	17.86	1.11

Different phase center calculation methods can be used to estimate the value from the antenna parameters. In this case, standard 3σ deviation and peak-to-peak methods are used to its calculation. The best phase center collocation properties of the GSNA EBG antenna over both the frequency band and the antenna FoV, provided in Table 6, are meeting the targeted specification presented in Table 4 using both methods.

Flight Implementation Considerations

In order to move towards a fully space qualified Navigation antenna product, several issues linked to both the mechanic and electrical environments specific to space applications must still be addressed. In this section, the focus will be on the impact of the thermomechanical distortions on the antenna frequency of operation, and on the evaluation of the available margin with respect to multipaction factor.

Impact of Thermomechanical Distortions

The typical thermal environment of a low-power top-floor antenna with passive thermal control (thermal blankets and sunshields) is stringent when the antenna base is not radiatively coupled to the spacecraft Earth Deck. In this thermal configuration, the antenna can face minimum and maximum temperatures in the order of −130 °C to +120 °C and must remain operational.

The most critical dimension of the antenna is the separation between the ground plane and the superstrate. Any error in this dimension shifts the operational bandwidth of the antenna. In fact, the fractional frequency shift is proportional to the fractional variation of this dimension. Assuming that the manufacturing errors can be leveled out from the design by careful trimming of the antenna structure at ambient temperature (20 °C), the antenna will still suffer from some frequency shifts due to thermal distortions. Although that low Coefficient of Thermal Expansion (CTE) materials can be used in the fabrication of the antenna superstrate structure, such as Kevlar (CTE ~4 ppm/°C) or Invar (CTE ~2 ppm/°C), the fairly large temperature excursions seen by the antenna will lead to some dimensional changes as well as variations of the effective dielectric constant of the dielectric materials.

The separation between the ground plane and the superstrate is approximately $L = \lambda_0/2$ and the temperature variation will result in a variation of the electrical length between the ground plane and the superstrate. The fractional frequency shift Δf and the electrical length fractional variation ΔL_e are given approximately by:

$$\Delta f \approx \Delta L_e \approx \Delta L_p + \Delta k_{eff}$$

where $\Delta L_p = CTE\ \Delta T$ is the fractional variation of the physical separation between the ground plane and the superstrate and Δk_{eff} is the fractional variation of the effective propagation constant.

The dielectric constant of Kevlar varies by approximately 6 % over the −130 °C to +120 °C temperature range. In order to obtain a light low permittivity sandwich supporting the EBG layer, low density Kevlar honeycomb could be used to provide the structural stiffness. A conservative estimate of the filling factor of the cavity with Kevlar is 5 % resulting to an average low-density sandwich relative permittivity of $\varepsilon_{eff} \approx 1.1$. This leads to fractional variations of the propagation constant of:

$$\Delta k_{eff} = \sqrt{\Delta \varepsilon_{eff}}$$

The fractional bandwidth required in the antenna design is therefore given by:

$$\frac{BW}{f_0} = \Delta f + \frac{24}{1575.42} \cong \Delta f + 1.53\%$$

which leads to a required design bandwidth of 29.6 MHz at L1. This corresponds to the 80 MHz bandwidth at C-Band (4 GHz) used in the simulations and measurements of the breadboard.

Considerations on Multipactor

The strongest concern about the power handling capability of this type of antenna configurations in a space environment lies in the field buildup related to the 1D defective photonic crystal quality factor at its

DOI 10.1007/978-981-4560-75-7_123-2

resonant frequency. A multipaction analysis has therefore been conducted on the EBG gain enhanced antenna configuration to understand the power-handling capability of this structure.

Evaluation of the impact of thermomechanical distortions on the antenna operating frequency band shows that the proposed solution can be implemented using low CTE materials to make the critical dimensional parts of the antenna. As well, a preliminary multipaction analysis shows that RF power in the 100 W range can be used with this type of antenna in the space environment.

Telemetry and Telecommand Antennae

Telemetry, Tracking, and Control (TT&C) are vital functions for successful operation of all satellites, because they lead the spacecraft management. The main tasks of a TT&C system are, for instance, to monitor the performance of all satellite subsystems and transmit the monitored data to the satellite control center for routine operational and failure diagnostic purposes. Furthermore, it must represent a tracking platform to earth stations by accomplishing the determination of orbital parameters to maintain a satellite in its assigned orbital slot and provide look angle information to earth station in the network. Besides, the system receives commands from the control center to execute various function of the satellite, for example, power on/off subsystems, change subsystem operating modes, deploy booms, antennae, solar cell arrays, and so forth. Usually, uplink (UL) and downlink (DL) communications with TT&C satellites are carried out at S-band (UL: 1.6–2.2 GHz and DL: 2.2–2.3 GHz) such as in case of Inmarsat or Galileo (Galileo System Requirement 2002), C-band (UL: 5.9–6.5 GHz and DL: 3.7–4.2 GHz), and Ku-band (UP: 14–14.5 GHz and DL: 11.7–12.2 GHz).

For the purpose of providing robust communications with the established receivers, the TT&C antennae located onboard the satellites must provide appropriate earth coverage and work simultaneously with right hand (RHCP) and left hand circular polarization (LHCP). Particularly in the systems working at the C-band, one of the most stringent radiofrequency (RF) requirements regarding the antennae performance is the necessary gain; the typical value is 16.5 dBi at the edge of coverage (EOC), that is, $\pm 9^{\circ}$. Commonly, high bulky horn antennae (up to 4 kg for low C-band frequencies) and 2 kg for high C-band frequencies are implemented for TT&C applications. The reduction in the mass and dimensions of such antennae becomes a major concern for the spatial industry, especially when the carrier satellites are small. Due to this fact, the development of competitive and alternative antenna technologies complying with the overall RF requirements of conventional antennae but providing at the same time the advantage of lightness and compactness represents an attractive research area. TT&C onboard antenna requirements are shown in Table 7.

As it has been shown in the GSNA EBG antenna, the incorporation of EBG technology-based structures in different emerging communication frameworks consolidate them as feasible solutions for different applications, such as wireless and satellite industries (Galileo 2002; Rodes et al. 2006; Brand et al. 2009; Hajj et al. 2009; Iriarte et al. 2009; Oses et al. 2009; Kanso et al. 2011). Requirement of TT&C on board antennae applications can be covered by the use of EBG gain enhancement configuration antennae.

An EBG model which complies with the requirements of the selected TT&C application is presented in next section. These low-mass EBG superstrate antennae are capable to fulfill the given C-band system requirements. Characteristics such as the gain over coverage, dual circular polarization, return loss, isolation, and mass levels demanded by this kind of satellite systems are analyzed. The obtained results confirm the viability of the proposed EBG-based antennae for onboard TT&C antenna configurations.

Anyway, for Ku-band, horn antennae can be used for TT&C since the higher frequency reduces size and the mass. A very compact horn antenna for TT&C is presented afterwards. This horn antenna was

capable to cover simultaneously downlink and uplink frequencies and was connected to a very compact septum polarizer to produce the required circular polarization with enough isolation between ports.

EBG TT&C Antenna

As in the case of GSNA navigation antennae, gain increase can be accomplished by the resonance formed in a cavity, which, in the presented case, is created between a metallic ground plane and an EBG superstrate that is acting as a partially reflective surface. The latter consists of a metallic sheet with a square lattice of drilled holes, see Fig. 14.

The EBG superstrate fixes the operational frequency and the final directivity of the antenna. The radius of the holes determines both the magnitude and phase of its reflection coefficient. Meanwhile the phase determines the resonance frequency, the magnitude relates with the field spread on the superstrate surface and therefore determines the illumination, fixing the directivity.

The radiating system is composed by a 2 × 2 patch array feeding the resonant cavity created between the ground plane and the EBG superstrate (see Fig. 14a). The distance between patches was optimized in order to obtain an improved symmetric pattern with low sidelobe levels. Two feed ports are perpendicularly located at each radiant patch, which are fed with a phase difference of 90 °. In addition, each patch of the 2 × 2 array is sequentially rotated with respect to its adjacent radiators. Thus, not only circular polarization at each patch is ensured but also further improvement in the circular polarization of the complete feed system.

DOI 10.1007/978-981-4560-75-7_123-2

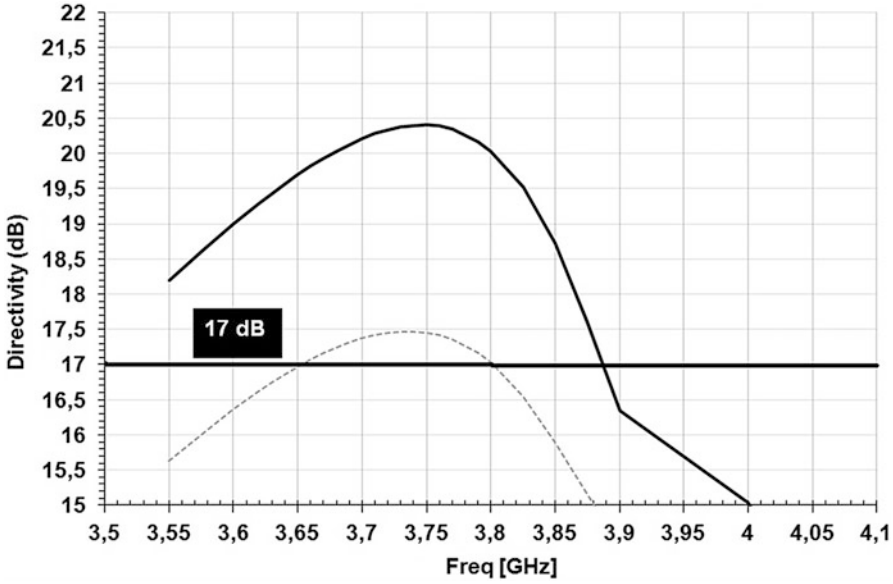

Fig. 15 Directivity vs. frequency at $\theta = 0°$ (*black solid line*) and $\theta = 9°$ (*gray dashed line*)

As the mass is critical in this application, the total dimension of the superstrate is also a critical parameter in the design process. It must be large enough to comply with the maximum directivity requirement stated in Table 7, but at the same time, it must be as light as possible. In a preliminary structure of the proposed configuration, the dimension of the superstrate was set to 365 × 365 mm. Since this area causes a significant increase in overall system weight, a strategy to overcome this problem consisting on truncating the corners of the superstrate is undertaken (see Fig. 14a). This solution does not produce any degradation of the antenna properties as the electromagnetic field is mostly confined in the center of the cavity (see Fig. 14b). After an optimization process trying to keep unaltered the radiation performances of the antenna, the cuts from the corners are stated to L = 110 mm so the resulting total area is 109.025 mm^2.

The EBG layer is placed 0.45 λ_0 at working frequency above the ground plane.

The losses of the radiators and BFN have been considered as 0.15 and 0.16 dB respectively, together with matching and connector losses (0.04 and 0.05 dB). An implementation margin including thermal effects of 0.10 dB has been added so that the total losses are predicted to be equal to 0.5 dB in the final system. Therefore, the gain of the proposed configuration should be above 16.66 dBi in the desired working bandwidth (see Fig. 15).

Figure 16 presents the RHCP and LHCP radiation patterns for 0°, 45°, and 90° phi cuts at 3.66, 3.73, and 3.79 GHz for the EBG-based antenna. Note that the low part of the black rectangular box embedded determines the −25 dB required crosspolar level. It is clear that the designed EBG antenna complies with this RF performance. Similarly, in Fig. 17, the axial ratio parameter is depicted. The AR value is under 1 dB at 3.74 GHz for all the phi cuts. At the same time, the AR for the worst phi cut at EOC is plotted in Fig. 17b with a gray dashed line. Analyzing this result, the AR operational bandwidth goes from 3.61 to 3.92 GHz, fulfilling the 80 or 120 MHz bandwidth stated at the specifications. The directivity and AR for the TT&C EBG truncated superstrate antenna are summarized in Table 8. Regarding the isolation between ports, the appropriate design of the BFN is the key issue. It must provide the optimized amplitude and phase coefficients to the array elements. In this case, uniform excitation has to be settled for both amplitude and phase. The BFN is composed by 1:2 T-dividers whereby supplied amplitudes and phases in each port guarantee RHCP.

The directivity, axial ratio and requirements are met, together with the input matching below 18 dB and isolation level between ports below 25 dB within the operational bandwidth. The overall mass of the proposed EBG antenna system has been calculated taken into account all the constitutive antenna parts, such as the material used to build the brackets, holders, bolts and nuts, and a certain margin for each component. The superstrate is placed over a Kevlar layer to ensure its steadiness, which mass is estimated to be 222 g. The concluding outcome of the overall mass leads to estimation of 870 g. The overweight of 70 g is almost negligible.

EBG superstrate antennae are capable to fulfill the TT&C requirements of a global geostationary telecommunication system working at C-band (3.7 GHz). Other bands can also be covered with this technology as the design is completely scalable. The desired properties in the working bandwidth, as gain

DOI 10.1007/978-981-4560-75-7_123-2

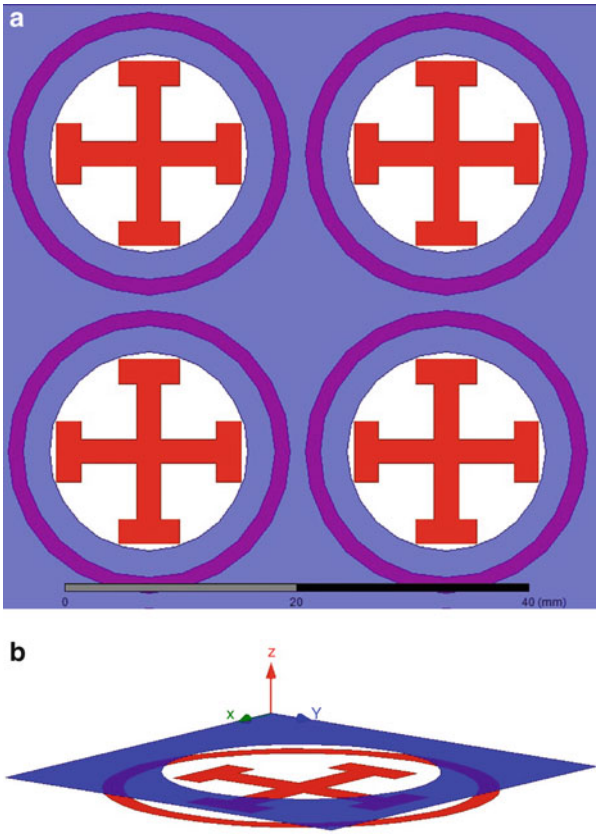

Fig. 18 Detail of the superstrate formed by two EBG layers

over coverage, dual circular polarization, return loss, and isolation values can be achieved with the presented structure. Although mass of the configuration is not under the established threshold, the overweight is almost negligible. Anyway the final mass is well below the typical horn antenna designs. In addition, the use of EBG-based technology antennae makes it possible to obtain gain enhancement with a reduced number of radiating elements; in this case just a 2×2 array of patches.

EBG-based systems could advantageously replace conventional horn antennae and arrays with comlicated BFN working at 3.7 GHz for TT&C applications, by reducing the antenna complexity, mass, and cost, similarly to the case of the GSNA application.

Dual Band EBG Antenna Configuration

TT&C frequency band requirements in C bands usually cover 3.7 GHz and 4.2 GHz bands at the same time. Two different antennae are used in conventional technology to cover these working bands or large arrays of broadband patches are also used to comply the frequency range specifications. Dual band antenna configurations are also being designed by the inclusion of another EBG superstrate in the configuration complying the TT&C requirement in dual band with a single EBG antenna.

The same configuration presented for the single frequency behavior can be used for the dual band with the inclusion of another EBG layer. The second layer is based on the combination of Frequency Selective Surfaces (FSS) metallic rings with Jerusalem crosses (see Fig. 18) inside them, placed just 1 mm below the EBG layer of circular holes in a metallic sheet.

The directivity versus frequency results are shown in Fig. 19. Maximum directivity of 21.74 dB at 3.78 GHz and 21.28 dB at 4.18 GHz is obtained. D(9°) is above 16 dB from 3.7 to 3.8G Hz (2.66 %) and

DOI 10.1007/978-981-4560-75-7_123-2

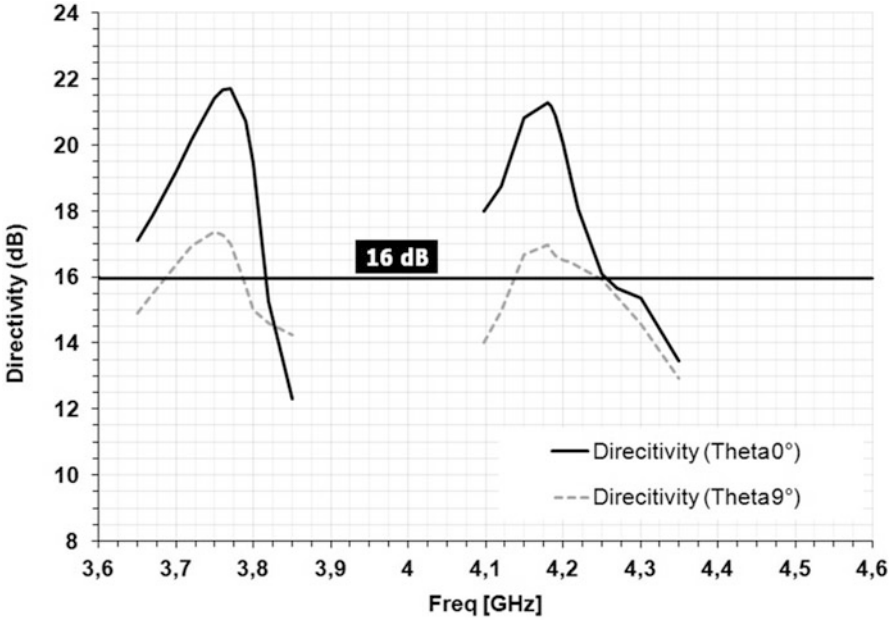

Fig. 19 Directivity vs. frequency for the 0° and 9° cuts of the 2 × 2 array EBG superestrate antenna

from 4.13 to 4.25 GHz (2.86 %). Therefore, 100 MHz working bandwidth is obtained at both frequency bands, complying requirements.

The directivity patterns at 3.76 and 4.32 GHz are shown in Fig. 20. Symmetric directivity patterns with cross polarization level below 25 dB are obtained, therefore fulfilling the specifications.

The overall mass of the proposed system is similar to the single frequency configuration, 870 g., as the second EBG layers is printed in the same sheet used to print the upper layer: one on a the top face of the sheet and the other one on the bottom face. The losses of the configuration have been estimated taking into account the EBG antenna and the feeder to be around 0.5 dB.

Horn Antenna for TT&C at Ku Band

From the geostationary orbit at about 36,000 km above the earth, the earth subtends an angle of 17.4°. With an increased number of satellites orbiting the earth, reducing the possibility of interference with other satellites is becoming more important than in the past. To minimize this interference, the amount of sidelobe energy should be as low as possible, both for the principal and cross-polarized signals. Taking these considerations into account, it is apparent that an ideal full-earth coverage antenna should be circularly symmetric and, therefore, most global coverage antennae are either reflectors or horns.

A corrugated horn can be made very low weight and also space qualified. Materials as carbon fiber reinforced plastic materials are suitable for fabrication of the final corrugated horn for TT&C (Bird and Granet 2008).

One of the first compact corrugated horn designs for low sidelobes and global earth coverage was described by (Granet et al. 2000). This horn exhibits quite low sidelobes (<36 dB) and it is quite compact $5.6{\cdot}\lambda_c$ but it presents two principal disadvantages: it operates in a narrow bandwidth, (less than 5 % for maximum −30 dB sidelobe level and −30 dB crosspolar level and −20 dB return loss) and it is very sensitive to manufacturing tolerances in the throat region (mode generator) (Bird et al. 2000).

Another wideband solution is the corrugated horn antenna that combines axial and perpendicular corrugations (Teniente et al. 2002b), shown in Fig. 21. This antenna presents a measured return loss better than 28 dB for above 22 % bandwidth. The measured sidelobe level is extremely low, below −35 dB for the overall operational bandwidth, and presents a crosspolar level below −35 dB (Table 9).

THz Space Antennae

In the last years the number of space missions where submillimeter wave and Terahertz onboard instruments are operating is increasing. Some of the last missions which incorporate such instruments are PLANK and HERSCHEL with the HIFI instrument; in addition, in the near future scientific mission which are in need of high frequency instruments are expected to be launched, i.e., missions such as SPICA where the SAFARI European instrument will operate at THz frequencies (Goicoechea et al. 2009).

All of these instruments implement antennae which operate in bands covering frequencies between 100 and 900 GHz. At these THz frequencies there are different effects to be investigated. For example, understanding how the first galaxies were formed or the star formation process. Moreover, on a larger scale in this frequencies the development of galaxies can be monitored and studied; a wide range of molecules, including water, absorb radiation; and they can be used to determine exactly what the gases are

DOI 10.1007/978-981-4560-75-7_123-2

composed of and their temperature and pressure. Therefore, antenna technologies able to comply with the instrument requirements need to be developed. Apart from the conventional horn antennae, innovative concepts have been proposed, such as integrated antennae, Metamaterial (MTM) antennae or more recently antenna coupled Kinetic Inductance Detectors (KIDs).

Integrated antennae are the natural solution for the development of large imaging arrays operating in this frequency range. To this end, they would be placed in the focal plane of a collimating reflector or lens. However, they present several fundamental problems related to the use of electrically thick substrates such as the excitation of surface waves, which decrease their efficiency and degrade their performance. Solutions to this problem have been found by conforming the substrate creating a lens or by using a metamaterial substrate, which prevents surface wave excitation. Several antennae making use of substrate integrated extended hemispherical lenses fed by dual-slot antennae, log-periodic and spiral antennae, have resulted in excellent performance at millimeter-wave frequencies. In addition to these, new antennae such as integrated horn antennae, dielectric-filled parabolas or Fresnel plate antennae have been proposed.

A large effort has been dedicated to match these antennae to the detectors. These detectors range from Schottky diodes to bolometers. In principle it should be possible to build planar receivers with performance comparable to the best waveguide-based systems if efficient planar antennae and matching networks are developed. Recently, efforts have been made to integrate Kinetic inductance detectors (KIDs) (Day et al. 2003; Vayonakis et al. 2008; Baryshev et al. 2011) together with planar antennae. These are among the most sensitive cryogenic sensors available for detection of electromagnetic radiation

DOI 10.1007/978-981-4560-75-7_123-2

and probably the most promising sensors to be employed in large focal plane array configurations. They can be coupled to a single on-chip microwave transmission line enabling the read-out of thousands of detectors with just a single coaxial cable pair connecting the on-chip transmission line to room temperature read-out electronics. KIDs can be easily integrated with lens antennae and leaky lens antennae. In particular this last configuration, allows achieving a very large bandwidth, thanks to the phase stability of the leaky lens antenna.

Anyway, this section will focus on the MTM concepts applied to THz antennae. As mentioned, MTM substrates are one of the solutions for surface wave reduction and radiation pattern improvement. This chapter describes in detail the fundamentals behind their use and several applications.

One of the main goals for Terahertz technology is the realization of imaging arrays, which are of great interest for space astronomy and for atmospheric research. Particularly in astronomy most of the spectral line emitting regions are usually spatially extended over many observing beams in the sky and mapping is required to astrophysically understand the regions under study. In atmospheric research multiple beam observing systems allow push-broom measurements for limb scanning experiments. As the regions of interest in astronomy research are usually distributed over many observing beams, the time needed to build an image can be reduced in approximately inverse proportion to the number of elements included in the array.

THz imaging arrays have conventionally been based on feedhorns and waveguide technology and are usually assembled from discrete elements, some recent examples of missions using horn antennae can be found in PLANCK or HERSCHEL (Doyle et al. 2009). The costs, mass and volume associated with this approach may limit the maximum practicable number of pixels. In fact, PLANCK mission implements a focal plane formed by more than 40 antennae ranging from 30 to 857 GHz. On the other hand, HERSCHEL mission, although more focused at Infrared frequencies, also comprises 5 frequency bands covering 480–1,150 GHz with SIS mixers. The SPIRE detectors are spider-web bolometers using NTD germanium thermometers, which are coupled to the telescope by hexagonally close-packed diameter single mode conical feedhorns.

In the last time, the advances on lithography techniques and processes have open the possibilities to develop new THz antenna concepts which can be competitive versus conventional waveguide technologies. Being able to produce lithographically planar receivers with equivalent performance is allowing the realization of much larger two-dimensional arrays. Such an approach is dramatically reducing cost and greatly simplifying manufacture and assembly.

Although waveguide and feedhorn technology provides a natural isolation between adjoining pixels. In contrast, the performance of planar antenna arrays can be severely limited by the parasitic cross coupling of the antennae via surface waves (Pozar 1983). Electromagnetic bandgap (EBG) or Photonic Crystal (PC) structures, working as surface wave suppressing substrates, have consequently attracted much interest (Joannopoulos et al. 1995; Gonzalo et al. 1999; Sievenpiper et al. 1999; de Maagt et al. 2003; Yang and Rahmat-Samii 2003). EBG structures prevent the propagation of radiation, for frequencies within the bandgap, in 1, 2 or 3 spatial directions, the number usually corresponding to the number of dimensions in which the crystal is periodic (Joannopoulos et al. 1995). Whilst 2-D EBG materials have been proven to be an useful substrate for planar antennae (Gonzalo et al. 1999), a 3-D EBG appears to be more desirable because any antenna fundamentally radiates in 3-D and an antenna array by definition extends over at least one dimension perpendicular to the boresight.

Within this section, the performance of these structures as substrate for a dipole antenna will be studied. In particular two different single dipole antennae backed by a 3-D EBG structure are presented. This combination exhibited low back radiation and a higher directivity when compared to the equivalent dipole in free space. Two different EBG substrate shave been used for this purpose: the so-called Woodpile and FAN EBG structures (Ho et al. 1994; Sözuer and Dowling 1994; Martinez et al. 2007). In the case of the

DOI 10.1007/978-981-4560-75-7_123-2

Fan structure it was built with a very high dielectric constant material, Zirconium Tin Titanate (ZTT). This high dielectric material can be of interest for miniaturization. However, the excitation of surface would limit its performance as antenna substrate. This problem can be sort out if an EBG structure is implemented in the substrate. Once the performance of an element is studied a seven element 0.5 THz imaging array will be discussed.

Single Detector THz Configuration

In this section, the performance of a dipole antenna on top of an EBG structure operating at THz frequencies is described. Two cases are discussed. Both of them use as radiating element a printed dipole antenna and either a woodpile EBG or a FAN EBG structure as substrate.

When a dipole antenna is placed on top of a periodic structure, its radiation pattern and input impedance depend on the position and orientation of the dipole with respect to the features on its surface. Complete studies for both configurations can be found in (Gonzalo et al. 2001; Ederra et al. 2013). In summary, for each EBG structure it can be found a polarization dependence of the input impedance. The parallel to the main features (dielectric bars in the woodpile and air channels in Fan's) polarization presents very low input impedance, which can be ascribed to the close to 180° reflection coefficient phase. On the contrary, the perpendicular polarization exhibits higher impedance, easier to match to a CPS line, which would be the most natural feeding circuit for the dipole antennae. Regarding the radiation features, no significant differences are found between positions and polarizations. In all cases, there is an increase of directivity, thanks to the effect of the EBG substrate and coupling between neighboring antennae will be reduced.

For the design of the overall dipole antenna/EBG configuration as a detector, a subharmonically pumped heterodyne receiver was considered. This incorporates a flip chip mounted Schottky diode in the center of the dipole; and the local oscillator signal is delivered along a coplanar stripline (CPS). The low pass filter is a standard high–low impedance filter, which was constructed by widening the tracks of the CPS. Its design was carried out taking into account the loading of the underlying EBG. The filter dimensions were optimized in order to maximize the reflection of RF power at 0.5 THz. The down converted RF signals also passes along the same stripline. A low pass filter is incorporated to prevent the CPS from loading the dipole at frequencies around 0.5 THz. The design procedure was first to optimize the impedance matching when the dipole antenna was fed by a CPS and afterwards the RF power coupled to the diode was maximized.

In the first case, the dipole antenna is placed on the FAN EBG structure. The feeding CPS line and the dipole were printed on a 20 μm thick quartz substrate. Details of the dipole and feeding line dimensions can be found in Ederra et al. (2013). For these dimensions, the impedance of both CPS line and dipole were similar and close to 170 Ω, which assures a good impedance matching.

The Schottky diode was placed as close as possible to the dipole antenna in order to minimize its effect on the radiation pattern of the dipole. The distance between the diode and the low pass filter was optimized so that the power transferred from the incoming RF signal to the diode was maximized.

The circuits were patterned in a gold film, which had been deposited on a fused quartz substrate, using standard photolithographic techniques. The quartz was then cut to size and lapped to a final thickness of 20 μm.

The Fan structure was held to a low loss polymer, TPX high-density polyethylene, support by using cyanoacrylate adhesive. The quartz substrate was then aligned and fixed using a small quantity of the same adhesive at its edges. The output of the choke filter was connected to a coaxial line using gold ribbon and Epotek H20E. A photograph of the manufactured antenna and Fan EBG combination is shown in Fig. 22.

Radiation Pattern Results

The predicted radiation pattern of the complete detector configuration, i.e., dipole, diode, and low pass filter, was computed using Ansoft HFSS. Since the diode and the feeding lines affect the radiation pattern some ripples in the E-Plane are appreciated. The computed directivity, 6.4 dBi, is larger than the directivity of the ideal dipole. This higher directivity corresponds to the peaks of the ripples and not to boresight direction.

The radiation pattern was measured at the University of Bern using an AB Millimeter submillimeter wave Vector Network Analyzer (VNA) from ABmm. Both E and H plane patterns were measured at 0.48, 0.5 and 0.52 THz. The comparison between the measured patterns and the predicted ones are depicted in Fig. 23, where normalization of measured data at boresight has been performed. The above directivity increase with respect to a dipole on a standard substrate can be noticed.

In the second case, a similar design procedure was followed, but in this design, the substrate was a woodpile EBG structure. More details about the woodpile properties and its manufacturing properties can be found in (Gonzalo et al. 2001). The dipole antenna was a lithographically patterned 2 μm microns thick gold structure. A similar receiver configuration was used, where a Schottky diode was used to convert the incoming RF signal at 500 GHz to DC.

The dipole antenna was fed using a transmission line on a quartz membrane and a simple quarter-wavelength, high-low impedance filter was used in order to isolate the RF from the DC signal. The membrane was kept thin enough so as not to disturb the performance of the EBG structure. The RF filter is adjoined to two bonding pads.

The fabricated structure of the dipole on top of the woodpile EBG is displayed in Fig. 24. The woodpile, the antenna, the filter, the membrane to support the feeding line, and the Schottky diode are clearly visible.

The measurement system included a Carcinotron operating at 500 GHz, a computer controlled positioning system with two axes of movement, onto which the configuration is placed and a lock-in amplifier to measure the detected DC signal. The results for the E and H planes are plotted in Fig. 25.

It should be noted that the obtained E-plane beamwidth is $\theta = 60^\circ$ while it is $\theta = 85^\circ$ for the H-plane. These values correspond to an estimated effective area much larger than that of a simple stand-alone dipole that has an effective area of $0.13\lambda_0^2$. This leads to higher directivity values that can be derived to be of the order of 8–10 dB for the EBG backed antenna compared with only 2.14 dB obtained for a simple dipole suspended in air.

In addition, both E and H plane patterns tend to zero at 90° and 270° confirming that the EBG substrate is suppressing the parasitic surface wave mode excitation.

Array Configuration of Single Dipole THz Detectors

The enhanced performance of the single EBG backed element shown in previous sections is followed by the use of this configuration as base for an imaging array. In this case, a seven-element Schottky diode-based heterodyne array for 500 GHz which could be the base for future space instruments in imaging applications has been studied (Ederra et al. 2008). This design represents a significant step towards the goal of a planar technology imaging array. The array was designed to match the typical optical system of a submillimeter wave astronomical instrument: f/25 with a far field beam crossover level of −3 dB. In order to obtain these beam characteristics, a 90° paraboloidal mirror was used to modify the radiation pattern of the detector antennae. The design of the individual receivers was optimized for maximum sensitivity i.e., for best impedance matching between the Schottky diodes and the planar dipole antenna.

Dipole and Array Design

An optimized design of the 500 GHz dipole antenna together with the associated RF choke/ IF transmission line on top of the EBG structure is used for the array design (Fig. 26). Limitations on the

DOI 10.1007/978-981-4560-75-7_123-2

dipole antenna separations arise from the 500 GHz silicon woodpile, which has a 72 μm bar width and 232 μm period in the substrate plane. As the dipoles need to be placed above intersections of the bars in the top two layers, the separation between elements is consequently restricted to multiples of this period.

A previous study of the mutual coupling of dipole antennae on EBG substrates showed that a minimum separation of two periods is necessary to ensure coupling values below −20 dB in both E and H planes. One compact configuration of seven antennae that meets this requirement was developed. Although denser configurations are possible, the selected one offers the advantage that the six outer antennae lie between 3.6 and 4 woodpile periods from the central element. It will be shown later on that it is possible to design matching optics for this array that achieve the desired beam properties: the relatively narrow spread of radii assists in achieving a design that is compliant with the beam crossover point requirement.

The mutual coupling between the array elements was investigated. The results obtained with Ansoft HFSS shows that for the case under study this value is below 40 dB.

Mirror Design

Although in principle a lens could have been used, reflective optics exhibit lower losses and standing waves. The f# requirement on the array imposes the far-field power half- angle, i.e., the directivity of the resulting antenna–reflector combination. To meet the f/25 specification, the beamwidth of the output beams should be 2.2°. Therefore, the reflector must provide the required magnification, increasing the directivities of the radiating elements and simultaneously separating the beams. However, the further the antennae are from the optical axis of the system, the more degraded the directivity and beamwidths of their radiation patterns becomes. The central dipole is located at the optical focus of the mirror and the projection of the mirror on the x-z plane is an ellipse with its major axis in the z direction. To optimize the illumination of the mirror, the dipole array was also oriented with its major axis along the z-axis. Taking this into account, elevation (azimuth) corresponds to the H (E) -plane of the central beam respectively.

The mirror dimensions were optimized to match the array described above. The obtained optimum values were found to be D = 17.3 mm and f = 25.4 mm.

Physical optics GRASP (http://www.ticra.com/products/software/grasp) software was used to calculate the far-field radiation patterns. As an input for this program, the radiation of an isolated dipole on a finite silicon woodpile, containing 11 periods, was computed with Ansoft-HFSS. Predicted individual beamwidths of (2.1 ± 0.1)° were obtained, matching well the desired 2.2° value. GRASP simulations also showed that there was negligible impact on the far-field radiation pattern from mounting the woodpile on either a dielectric, TPX, or a metal plate.

Manufacturing of the Imaging EBG Array Configuration

A monolithic quartz substrate was used for the overall dipole array, this process ensures accurate alignment of all dipoles on the EBG substrate. Standard photolithographic techniques were used to pattern the array in a gold film that had been deposited on a fused quartz substrate. The quartz was then cut to size and lapped to a thickness of 20 μm. Separated and substrate thinned Schottky diodes were fixed in position on the metal using silver loaded epoxy (Epotek H20E). Electrical connections were made from the ends of the choke filters to coaxial lines using gold ribbon and silver loaded epoxy.

The characteristic curves of the Schottky diodes were monitored repeatedly during assembly. No deviation from the initial manufacturer's values was found, apart from for one diode. Here an increase in series resistance was localized to either the diode to substrate connection or to within the diode chip.

The mirror was made from a diamond turned, gold coated, parabolic reflector of 12.7 mm focal length and a projected diameter of 17.3 mm.

Experimental Results

A VNA based measurement technique and apparatus was used for the characterisation of the beam pattern of the array at 500 GHz. As a source, the 100 GHz output of a phase locked Gunn diode oscillator was quintupled in frequency and radiated by a corrugated horn antenna towards the EBG array. A stabilized DC bias voltage was connected to the diodes through a bias-T in the IF transmission line in order to set the optimum operating point of the receiver. In each case, the LO power and applied DC bias were adjusted to maximize the signal to noise ratio of the IF signal.

DOI 10.1007/978-981-4560-75-7_123-2

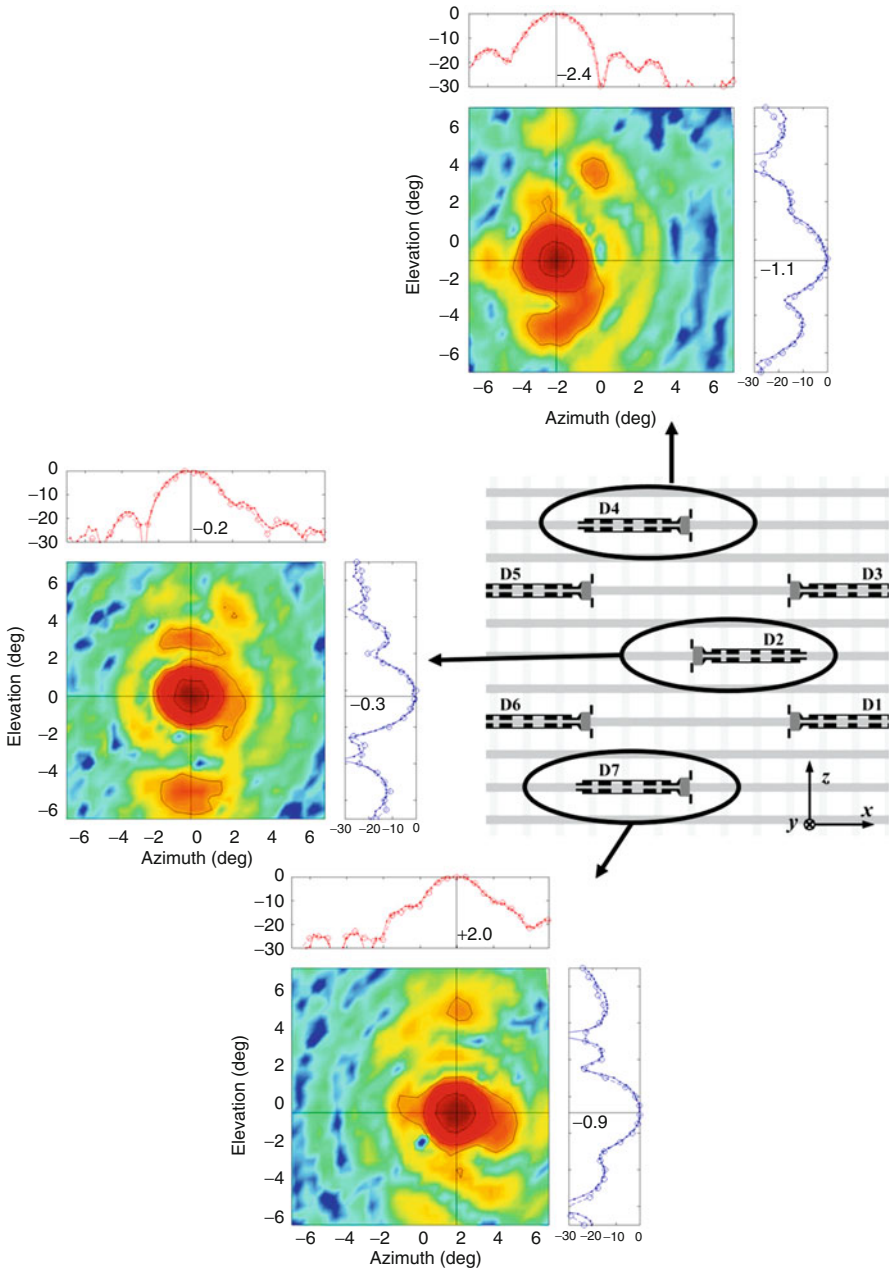

Fig. 28 Measured radiation patterns for the array elements. The −15 dB, −10 dB, −6 dB, and −3 dB contours are shown for beams 2, 4, and 7. Angular range of ±8° with a step size of 0.5°. Operating frequency 500 GHz

The imaging array was mounted so that it could be rotated about azimuth and elevation axes through the optical center of the parabolic mirror: Fig. 27. Beam pattern measurements were made at a feed horn to array separation of 0.8 m with a dynamic range above 25 dB.

Two dimensional beams scans, normalized to their maxima, are presented in Fig. 28 for some of the receivers over an angular range of ±8° with a step size of 0.5°. To improve the presentation quality, interpolation of the data has been performed and −3 dB, −6 dB, −10 dB and −15 dB contour lines added.

To represent better the overall behavior of the array, a contour plot of the −3 dB signal levels for all the beams is presented in Fig. 29. In the measurements the absolute pointing of the array had an offset of 1° in elevation and 1° in azimuth from the nominal optical axis, which has been subtracted for this figure. The

DOI 10.1007/978-981-4560-75-7_123-2

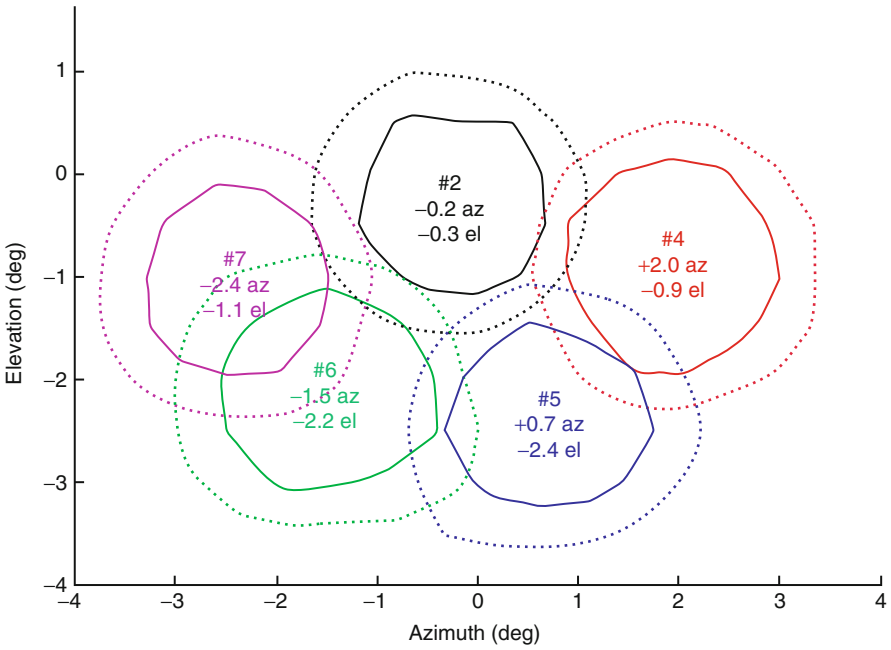

Fig. 29 Comparison of the 3-dB contours of the measured (*solid lines*) after correcting for mirror misalignment and the predicted patterns (*dashed lines*). In the measurements the absolute pointing of the array had an offset of 1° in elevation and 1° in azimuth from the nominal optical axis, which has been subtracted for this figure. Operating frequency 500 GHz

reason for this is probably a slight misalignment of the parabolic reflector and the test setup. Good agreement between patterns is observed, although the individual measured beams are slightly narrower than predicted, which leads to crossover points of around −4 dB. The predicted slightly compressed elevation plane characteristic is also exhibited by the measurements.

Finally, the radiation pattern cuts, azimuth and elevation, of different elements of the array are presented in Fig. 30. These measured pattern are compared with their counterparts obtained by simulation with HFSS software. In general, the agreement is good, some discrepancies can be found in the sidelobe levels, in particular, higher sidelobes are appreciated in the elevation cuts which are attributed to the effect of the mirror holder used in the measurement positioning system.

These results constitute the first demonstration of a planar imaging array based on EBG technology. Although the performance was still far from that obtained with more mature technologies it is the first step towards its application.

Conclusion

This chapter has demonstrated the use of advanced horn antenna profile to comply with the very stringent requirements of space antennae. Nowadays, the most of the space applications is requiring better electromagnetic performances to the antennae; lower cross-polar levels, low sidelobes, higher gains, higher efficiencies, larger operational bandwidths, etc. Conventional designs are not able to comply with these needs and more sophisticated antennae have to be developed. Several examples have demonstrated the possibilities of horn antennae to achieve those high performances with reduced lengths. New proposals based on the use of horizontal and vertical corrugations together with spline profiles have been analyzed and their radiation characteristics have been included.

DOI 10.1007/978-981-4560-75-7_123-2

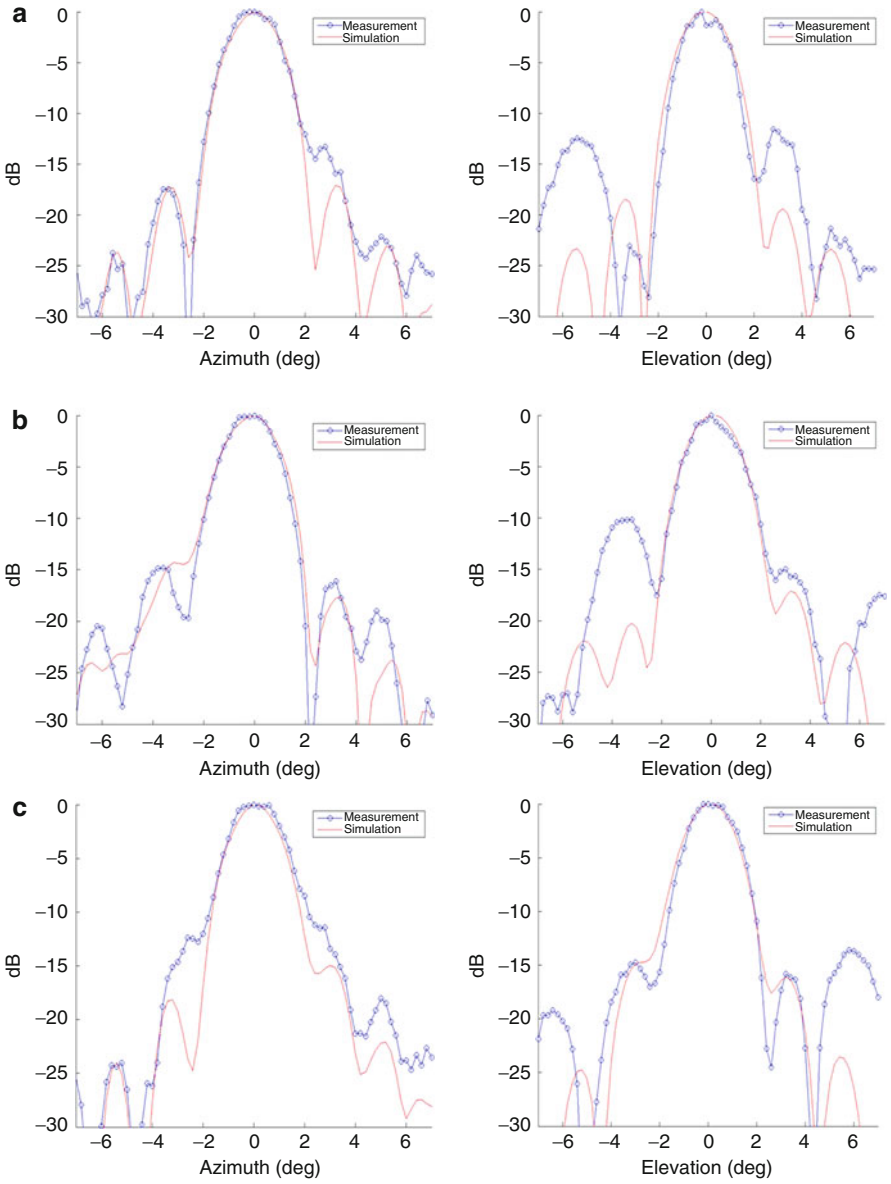

Fig. 30 2-D cuts of azimuth and elevation of beams 2 (**a**), 7 (**b**) and 4 (**c**). Operating frequency 500 GHz (From reference (Ederra et al. 2008) reproduced by permission of © 2008 IEEE)

On the other hand, there are space applications where conventional antennae suffer to obtain the desired radiation performances, mainly as they are heavy and bulky. In that case, this chapter has presented the possibilities of using EBG technology to develop innovative antennae. For instance, EBG-enhanced antennae could advantageously replace conventional array antenna in WAAS applications. This EBG technology simplifies the antenna configuration and leads to lighter and more cost effective solutions by simplifying the antenna BFN. The EBG GSN complies with all the requirements of a GSN application, resulting in a real alternative antenna for navigation on board antennae. Furthermore, EBG superstrate antennae fulfill the requirements TT&C application at C-Band in single and dual frequency performance. The system directivity is up to 17 dB in 100 MHz around 3.7GHz and 4.2GHz; the cross-polarization level is lower than 25d.B. Although mass of the configuration is not under the established threshold, the overweight is almost negligible. Consequently, EBG antennae technology system represents an

DOI 10.1007/978-981-4560-75-7_123-2

interesting alternative to the bulky horn antennae and complicated BFN of array usually used for TT&C applications in current satellites.

As the last part of this chapter, some results of EBG antennae operating at THz frequencies have been included. In particular, two cases are analyzed. In the first case, the enhanced performance of a dipole antenna placed on top of an EBG structure is discussed. The reduction of the back and side radiation and the improvement of the antenna directivity have been reported. These clear advantages have led to develop an array configuration suitable to be used in imaging THz application for scientific instruments. An array formed by seven elements has been presented. This configuration has been designed to comply with typical requirements in imaging applications by means of the integration together with a parabolic mirror. The radiation performances have been measured and good agreement with simulated results has been obtained. This constitutes the first demonstration of a planar imaging array based on EBG technology.

Antennas in Radio Telescope Systems

S W Ellingson*
Bradley Department of Electrical and Computer Engineering, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Abstract

Radio astronomy is the study of the universe by measurement of radio frequency emission at frequencies ranging from a few MHz to the far infrared. Signals of interest are typically extraordinarily weak, necessitating large effective aperture and resulting in some of the world's largest antenna systems. Technologies now commonly employed include reflector antennas ("dishes") using horn-type feeds or feed arrays, beamforming arrays consisting of elements ranging from dipoles to large dishes, and interferometry. Many problems in radio astronomy also require very fine angular resolution, leading to aperture synthesis imaging instruments consisting of antennas distributed over apertures ranging from hundreds of meters to intercontinental distances. This chapter provides a brief review of antenna systems used in operational modern radio telescopes and in anticipated new radio telescopes.

Keywords

Radio astronomy; Reflector antenna; Phased array; Interferometry; Aperture synthesis imaging

Introduction

Radio astronomy is the study of the universe by measurement of radio frequency emission. Radio frequencies provide information which is difficult or impossible to obtain from emission in other regions of the electromagnetic spectrum (in particular infrared, optical, X-ray, and γ-ray) and which is complementary to observations in these wavebands. Ground-based radio astronomy is possible from frequencies of roughly 10 MHz, below which the Earth's ionosphere becomes a barrier, to about 10 GHz, where atmospheric absorption becomes a barrier. Radio astronomy at higher frequencies is possible in spectral "windows" within which atmospheric absorption is sufficiently low, up to the infrared frontier at roughly 1 THz. Radio astronomical measurements include the measurement of total power, power spectral density, and time–frequency distributions (i.e., dynamic spectrum) as well as imaging with resolution as fine as 60 microarcseconds (about 1.7×10^{-8} degrees, achieved by the EHT; see section "Very Long Baseline Interferometry (VLBI)") or fields of view as large as tens of degrees or the entire sky. Nearly all radio astronomical instruments employ antenna systems with extraordinarily large effective aperture, which is necessary because emissions of interest are typically extraordinarily weak, and very fine angular resolution, which is necessary to discriminate sources of interest from the backgrounds or for imaging. This chapter provides a review of modern radio telescopes and in particular of their antenna systems. The focus is on contemporary and emerging systems; for a historical perspective, Baars et al. (2009) (and references therein) is recommended.

To begin, a brief summary of problems of greatest interest in modern radio astronomy is in order, so as to provide context. Much of modern radio astronomy is devoted to the study of neutral hydrogen, the most common material in the universe and detectable at radio frequencies as a narrow spectral line at about 1,420 MHz (about 21 cm wavelength) for material at rest with respect to the Earth. The brightest regions of the Galaxy are observable through doppler-shifted hydrogen emission with brightness temperature on the order of 100 K, and other galaxies are detectable via emission which is orders of magnitude weaker and redshifted by 10–100 s of MHz. Some operational and planned telescopes are striving to detect hydrogen emission associated with the first stars (the "Epoch of Reionization," EoR), which is redshifted to frequencies in the range 100–200 MHz, and earlier (known as the "dark ages" and "cosmic dawn"), which entails observations of hydrogen redshifted to frequencies as low as 30 MHz (section "EoR and BAO Experiments"). Other molecules routinely observed at radio frequencies include the hydroxyl radical (OH, rest frequencies around 1,700 MHz), methyladyne (CH, around 3.3 GHz), formaldehyde (4.8–14.5 GHz), methanol (6.7 GHz), water vapor (22 GHz), ammonia (24 GHz), and many others. These molecules emit detectable emission at frequencies throughout the millimeter and submillimeter range of wavelengths. Observations of the associated spectral lines are used in the study of comets, astronomical masers, emerging solar systems, and astrobiology. Neutron stars emit beams of electromagnetic radiation which are routinely observed as broadband periodic pulsed emission as the beam sweeps past Earth with the rotation of the neutron star. Radio telescopes typically measure both orthogonal polarizations of the emission, both as a means to increase sensitivity as well as to explore the polarization of the emission. Radio astronomy plays an important role in cosmology via precision measurement of the intensity and polarization of the cosmic microwave background in the frequency and spatial domains. This is certainly not an exhaustive list of science topics but should suffice to demonstrate the scope and diversity of projects which are pursued using radio telescopes.

This chapter is organized as follows. The section "Contemporary Radio Telescope Systems" is a review of prominent radio telescopes currently in operation. This review is organized into sections according to the type of antenna system; categories include single-dish instruments (section "Single-Dish Instruments"), beamforming arrays (section "Beamforming Arrays"), interferometers (section "Interferometers"), and EoR and baryon acoustic oscillation (BAO) experiments (section "EoR and BAO Experiments"). The section "Future Directions and Open Problems" addresses trends in radio telescope antenna systems and describes instruments which are planned or in the early stages of development. Principal topics in the section "Future Directions and Open Problems" are (1) the evolution from "single-pixel" feeds toward phased array feeds ("PAFs") and from dishes toward "aperture arrays" (section "Evolution toward PAFs and Aperture Arrays") and (2) the Square Kilometre Array (SKA) project, which is working toward the next generation of large radio telescopes (section "Square Kilometre Array").

Two additional introductory comments: First, this chapter focuses on antenna systems specifically; that is, receiver electronics and signal processing are addressed only at the highest level. For additional reading on how radio telescopes are used as complete systems, Wilson et al. (2013, in particular, Chapters 1 and 10–16) is suggested. Second, it should be noted that this chapter does not attempt an exhaustive accounting of all operational or planned radio telescopes but rather focuses on those which are most prominent on a performance basis (e.g., among the most sensitive or among the highest angular resolution) and those with distinctive features that are relevant from an antenna engineering perspective.

Contemporary Radio Telescope Systems

This section provides a review of prominent currently operational radio telescope systems, categorized by type of antenna system: "single dish" instruments, beamforming arrays, interferometers, and EoR/BAO

DOI 10.1007/978-981-4560-75-7_124-1

experiments. It should be noted that some instruments fall into multiple categories; in particular, the distinction between beamforming arrays and interferometers is potentially ambiguous. In this case, instruments are categorized according to their "primary" use, and alternative uses are mentioned.

Single-Dish Instruments

The term "dish" is of course shorthand for an antenna system consisting of a paraboloidal reflector or a shaped reflector operating according to similar principles. The principles of steerable-dish radio telescope design, from a mechanical perspective, are summarized in von Hoerner (1967). In general, the largest possible dish is desired, since this yields the highest directivity and subsequently the highest sensitivity and spatial selectivity. However, the dish must also provide sufficient surface accuracy, both in terms of overall shape and in terms of local surface errors. Difficulties in achieving sufficient shape accuracy include mitigating deformation resulting from gravity and nonuniform solar heating, whereas local surface errors are due to nominally static features such as seams and rivets, surface misalignments, and surface roughness. Shape error degrades aperture efficiency, distorts beam shape, and introduces pointing error; local surface errors degrade aperture efficiency and tend to determine the highest frequency at which a dish is considered usable (Ruze 1966).

With a few important exceptions described later in this chapter, most existing single-dish instruments use axisymmetric paraboloidal (or nearly paraboloidal "shaped") main reflectors, cassegrain subreflectors, and horn-type feeds. Axisymmetric design is far from optimal due to aperture blockage and scattering associated with feed structures; however, compromise is motivated by design difficulty and cost of alternatives. The preference for Cassegrain optics over prime-focus feeds in axisymmetric systems is motivated primarily by the desire to minimize system temperature. This is because in the VHF band and above, noise from the sky is significantly less than noise originating from the ground. Therefore, mounting feed horns at the vertex of the dish, pointing skyward, tends to reduce the fraction of spillover that intercepts the ground.

There have been two important trends in modern radio telescope dish design that must be mentioned: offset-fed systems and feed arrays. Offset-fed systems are motivated by the limitations of axisymmetric systems (indicated above) as well as by the particular susceptibility of axisymmetric systems to ripple in the frequency response due with standing waves between feed and reflector (Morris 1978). Offset-fed systems also make practical the use of Gregorian (as opposed to Cassegrain) subreflectors, resulting in further reduction of system temperature through ground noise pickup. However, these advantages come at considerable cost and complexity and so have not been consistently adopted in new designs. Prominent examples of offset-fed reflector systems in radio astronomy include the GBT and ATA, the millimeter-wave instruments SPT and ACT, and the space telescopes WMAP and Planck; see later sections for additional information on these systems.

The other important trend has been the adoption of feed arrays. Feed arrays can be broadly classified as either focal plane arrays (FPAs) or phased array feeds (PAFs). (The radio astronomy community is not completely consistent in the use of this terminology, but the definitions employed here are relatively common.) An FPA is an array of "single-pixel" feed elements distributed in the focal plane, often implemented as a replacement for a single feed located exactly at the focus. Each feed element not exactly at the focus corresponds to a beam which points in a slightly different direction. In this way, a telescope with an N-element FPA achieves an effective field of view which is N times greater than that achieved by a single-feed system. This is an enormous advantage for science requiring observations over large areas, such as hydrogen intensity mapping, pulsar surveys, and certain cosmology experiments. However, N is limited to $\mathcal{O}(10)$ or so by the degradation of sensitivity and beam shape with increasing distance from the focal point, which constrains the area in the focal plane over which feeds may

DOI 10.1007/978-981-4560-75-7_124-1

effectively be positioned. Most of the largest single-dish instruments in the world now have FPAs, including GBT, Arecibo, and Parkes; see descriptions of these instruments below for additional details.

In contrast to an FPA, a PAF is a feed consisting of an array of a large number of low-gain antennas which are combined to form beams or cross-correlated to form images. Processing of the array elements is typically done in the digital domain, introducing the possibility of optimizing the main lobe or sidelobes (perhaps even dynamically) and performing interference mitigation by nullforming; see, e.g., Landon et al. (2010). Experimental phased array feeds have been demonstrated on small axisymmetric prime-fed systems (see in particular Elmer et al. 2012) and on Arecibo (Warnick et al. 2011) and will soon become the primary (permanent) feed systems for the WSRT and ASKAP (section "Other Prominent Interferometer-Type Radio Telescopes").

The Green Bank Telescope

The Green Bank Telescope (GBT), shown in Fig. 1, is the world's largest fully steerable filled-aperture radio telescope. (In fact, it is currently the world's largest land-based two-axis steerable structure of any kind.) It is located in Green Bank, West Virginia (USA) (Prestage et al. 2009). The main reflector of the GBT is an offset 100 m × 110 m paraboloidal section. The offset design positions the feed support structure outside the optical path, resulting in low sidelobe levels and avoiding the troublesome spectral ripple problem noted above. The main reflector consists of 2,004 separate panels employing 2,209 mechanical actuators used to independently adjust the panels to compensate for mechanical distortion due to gravity and nonuniform solar heating. The resulting surface deviation from ideal is $\leq$400 μm RMS, improving to $\leq$250 μm RMS after corrections for thermal effects. The associated loss of effective aperture due to surface efficiency is $<$1 % below 5 GHz, resulting in an effective area of about 5,500 m^2 and aperture efficiency of about 70 %. The main reflector is considered usable from 100 MHz to 115 GHz.

The GBT uses a 7.6 m × 8.0 m Gregorian subreflector, visible in Figs. 1 and 2, for frequencies above 1.15 GHz. The Gregorian design reduces main reflector spillover relative to a Cassegrain design, subsequently reducing the contribution of ground noise to the system temperature. The effective *f*/*D*

Fig. 2 GBT subreflector and prime focus feed. In this image, the prime focus feed is deployed (Image credit: B. Saxton, NRAO/AUI/NSF)

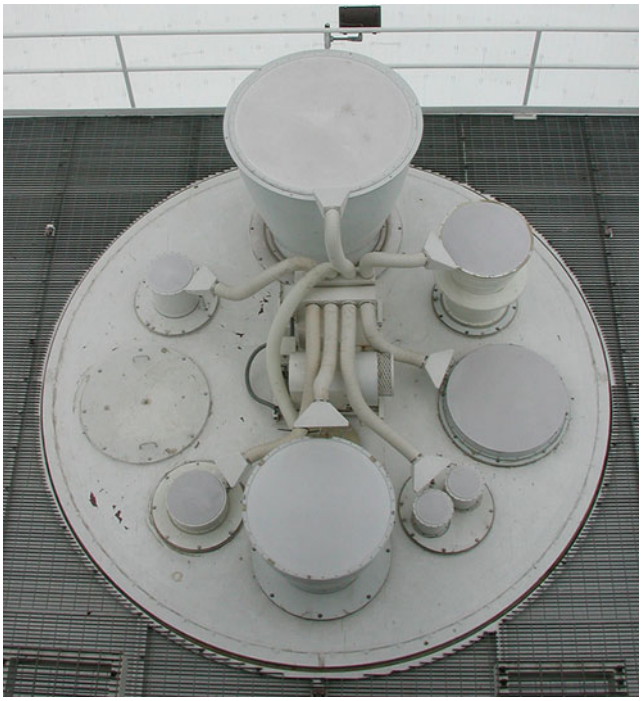

Fig. 3 GBT feed turret (Image credit: B. Saxton, NRAO/AUI/NSF)

when using a Gregorian subreflector is 0.29 referred to the 208 m circular "parent paraboloid." The feeds for this mode of operation are arranged in a turret located on the feed arm, visible in Figs. 1 and 3. The turret rotates the desired feed into the secondary focus. At any given time, the turret accommodates up to eight of the following feed/receiver combinations: Horns for L-band (1.15–1.73 GHz), S-band (1.73–2.60 GHz), C-band (3.95–5.85 GHz), X-band (8–10 GHz), Ku-band (12–15.4), K-band (18–22/22–26.5), Ka-band (26–40 GHz), Q-band (38–48 GHz), and W-band (68–92 GHz). Most of these feeds illuminate the subreflector with about 14 dB edge taper, resulting in about 1 % rear (sky-facing) spillover. The turret also accommodates a K-band FPA and MUSTANG, a 64-element bolometer FPA for 82–100 GHz.

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 4 Arecibo (Image courtesy of the NAIC-Arecibo Observatory, a facility of the National Science Foundation)

Below 1 GHz, the GBT uses a prime focus feed system having an effective $f/D = 0.6$ with respect to the projected diameter of the paraboloid. One horn at a time may be mounted to a support structure which pivots outward to position the feed at the prime focus, as shown in Fig. 2. When extended, the prime focus feed blocks the subreflector. Frequency ranges available in prime focus configuration include 290–395 MHz, 385–520 MHz, and 510–690 MHz using a dipole-type feed and 680–920 MHz using a horn.

Arecibo

The world's largest filled-aperture radio telescope, shown in Fig. 4, is at the Arecibo Observatory, located near Arecibo, Puerto Rico (USA) (Salter 2012). The main reflector of the Arecibo telescope is a fixed spherical section 305 m in diameter, having a radius of curvature of 265 m and subtending a half-angle of 35° as seen from the center of curvature. Surface accuracy is about 2 mm RMS, limiting the instrument to frequencies below about 10 GHz. Feeds are located in a platform suspended above the main reflector by cables, as shown in Fig. 5. The platform rotates for pointing in azimuth, and feeds traverse the curved rail for pointing in elevation up to about 20° from the zenith.

Because Arecibo's main reflector is spherical, there is no prime focus, and feed systems must account for the particular optics of reflection from a spherical surface. The principal feed system consists of Gregorian secondary and tertiary subreflectors, located in the dome visible on the left side of the feed platform in Fig. 5. Illumination reflected by the main reflector arrives first at a Gregorian secondary reflector located in the upper part of the dome and curved downward and is then culminated by a Gregorian tertiary reflector located in the lower part of the dome and curved upward (Kildal et al. 1994). Signals are received by feeds located in a turret on the top side of the dome, opposite the secondary reflector. This system results in roughly uniform illumination of an ellipse on the main reflector approximately 213 m × 237 m in extent, resulting in aperture efficiency (including blockage) of about 75 % below 2 GHz and beamwidth of about 1′ at 5 GHz. Feed systems available via this system include

DOI 10.1007/978-981-4560-75-7_124-1

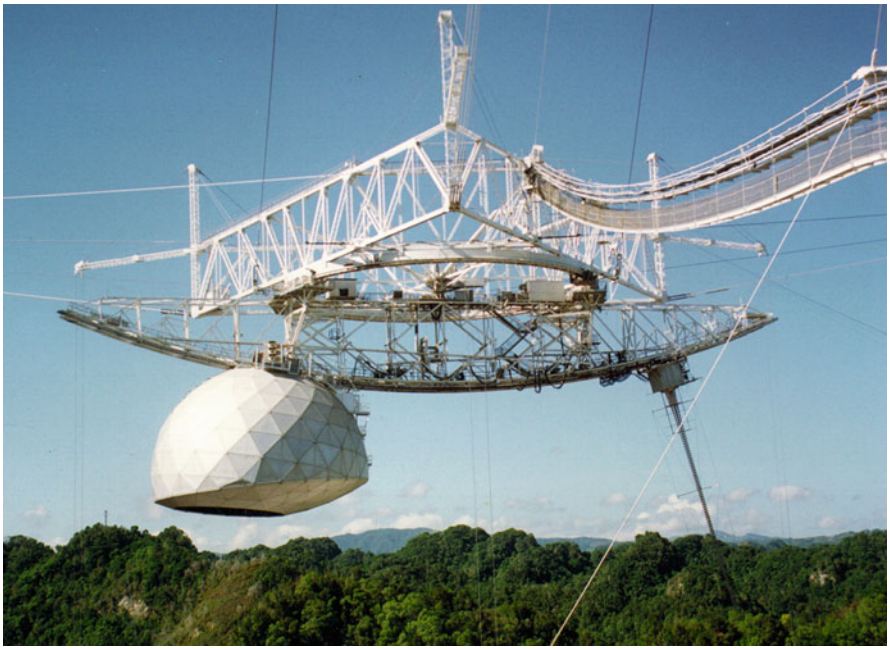

Fig. 5 Arecibo's feed platform (Image courtesy of the NAIC-Arecibo Observatory, a facility of the National Science Foundation)

horns for a 327 MHz band (312–342 MHz), a 430 MHz band (425–435 MHz), a 800 MHz band (705–800 MHz), L-band (1.12–1.73 GHz), S-band (separate feeds for 1.8–3.1 GHz and 3–4 GHz), C-band (separate feeds for 3.85–6.05 GHz and 6–8 GHz), and X-band (8–10 GHz). This system accommodates the Arecibo L-band Feed Array (ALFA), an FPA consisting of seven horns operating at 1,225–1,525 MHz. Arecibo also includes a "line feed" for 430 MHz (visible on the right side of the feed platform in Fig. 5) and a "point feed" for 47 MHz. The line feed is about 29 m long and lies along the caustic associated with the desired pointing direction, yielding a beamwidth of about 11′ over a bandwidth of about 10 MHz. The 47 MHz feed provides a beamwidth of roughly 100′.

Other Large Dishes for cm-Wavelengths and Longer

The world's other operational large single-dish radio telescopes are predominantly two-axis steerable axisymmetric paraboloidal systems. Prominent among these are Effelsburg (100 m, Germany; Hachenberg et al. 1973), Jodrell Bank (76 m, England), and Parkes (64 m, Australia). Parkes is equipped with a 13-beam L-band FPA located at its prime focus. A summary of the world's radio telescopes having dishes greater than 20 m diameter is provided in Appendix A.2 of Ekers and Wilson (2013) (also, Figure 8.7 of this reference shows the Parkes FPA being installed).

For a variety of reasons (see especially the first paragraph of section "Beamforming Arrays"), the construction of new cm-wavelength single-dish instruments on the scale of the GBT, Effelsburg, Jodrell Bank, and Parkes is quite unlikely; nearly all planned or imagined future radio telescopes are either beamforming arrays (section "Beamforming Arrays") or interferometers (section "Interferometers"). A notable exception is the Five Hundred Meter Aperture (FAST) telescope currently under construction in China (Nan 2011). FAST will be similar to Arecibo, only significantly larger – when completed, it will become the world's largest single filled-aperture radio telescope.

DOI 10.1007/978-981-4560-75-7_124-1

Large Single-Dish Instruments Operating at Higher Frequencies

What constitutes a "large dish" at millimeter and submillimeter wavelengths is physically smaller than what constitutes a large dish at centimeter wavelengths. This is because beamwidth is proportional to wavelength but also because surface accuracy emerges as a fundamental limitation on aperture efficiency, requiring more stringent and costly measures to achieve acceptable thresholds. The largest instruments currently capable of mm-wave operation (aside from GBT and Effelsburg, described above) include the Sardinia Radio Telescope (SRT) and the Large Millimeter Telescope (LMT). The SRT consists of a 64-m main reflector usable to 3 mm (115 GHz) with a Gregorian feed. The LMT, located atop Sierra Negra in Mexico, has a 32-m main reflector with plans to increase this to 50 m. The LMT is an axisymmetric cassegrain design and is intended to operate from 4 mm (75 GHz) to 0.85 mm (353 GHz). The instrument includes two FPAs: AzTEC, a 144-element FPA for 1.1 mm (Wilson et al. 2008), and SEQUOIA, a 32-element FPA for 3 mm. Other prominent large millimeter-wave single-dish instruments include the IRAM 30-m dish on Pico Veleta, Spain (Fig. 6), with two FPA systems for 1 mm (Baars et al. 1994), the Arizona Radio Observatory 12 m and 10 m dishes, and the 12 m dish of the Atacama Pathfinder Experiment (APEX) at Llano Chajnantor, Chile.

Prominent single-dish instruments designed to operate at submillimeter wavelengths (and into the infrared, depending on one's definition of wavebands) include the 15-m James Clerk Maxwell Telescope (JCMT) on Mauna Kea, Hawaii, the 10.4-m instrument of the Caltech Submillimeter Observatory (CSO) also on Mauna Kea, and the 10-m South Pole Telescope (SPT; Carlstom et al. 2011). A number of prominent space- and ground-based telescopes dedicated to cosmology (described in the next section) also operate in the submillimeter regime. For additional reading on submillimeter telescopes specifically, Phillips et al. 2013 is recommended.

Cosmic Microwave Background Experiments

There is currently intense interest in millimeter-/submillimeter-wave polarimetric observations of the cosmic microwave background with the aim of detecting large-scale (on the order of degrees) variations in

DOI 10.1007/978-981-4560-75-7_124-1

brightness, temperature, and polarization that would provide insight into the early history of the universe, extending backward to the epoch of inflation, just a tiny fraction of a second following the Big Bang. This is best achieved using an FPA operating as "radio camera" on a relatively small dish for a large field of view. Because the signal of interest is extraordinarily weak, very long observations (on the order of years) are required in order to achieve significant signal-to-noise ratio. Suitable instruments are typically purpose built, as existing instruments are not suitable and are typically not able to provide the necessary observing time. Examples of instruments in this class include the Atacama Cosmology Telescope (ACT; Swetz 2011), the Background Imaging of Cosmic Extragalactic Polarization (BICEP) series of instruments, the Cosmic Background Imager (CBI), and the Q/U Imaging ExperimenT (QUIET). For additional reading on these instruments, Hanany et al. (2013) is recommended; see also the discussion of space-based radio telescopes in the next section.

Space-Based Radio Telescopes

Some applications do not require high angular resolution but rather relatively large bandwidth and extreme sensitivity; for these applications, operation from space is preferable. The cosmology instruments WMAP (Page et al. 2003) and *Planck* (Doyle et al. 2009; Tauber et al. 2010) are small (0.7–1.5 m, respectively) offset Gregorian reflector systems at the L2 Lagrangian point, beyond the orbit of the Moon. Operation at L2 allows coverage of the entire celestial sphere while mitigating the limitations imposed by atmospheric losses and interference from terrestrial sources. *Hershel* (Doyle et al. 2009; Pilbratt et al. 2010) is a 1.5 m cassegrain submillimeter-wavelength radio telescope operating at L2, designed primarily to study star formation in the early universe. Also, Earth-orbiting satellites equipped with single dishes have been used as stations for very long baseline interferometry (VLBI); see the section "Very Long Baseline Interferometry (VLBI)."

Beamforming Arrays

The sensitivity and spatial selectivity of a single-dish instrument is fundamentally limited by the size of the dish, which in turn is limited by mechanical considerations. On the other hand, sensitivity is also limited by receiver noise temperature. Technological improvements over the last two decades have resulted in lower-cost receivers which perform nearly as well as state-of-the-art radio telescope receivers. Taken together, these trends make it quite likely that there will never be another steerable single-dish radio telescope as large as the GBT. Instead, the trend is in the direction of arrays of smaller dishes, each having receivers which are nearly as good as those on the best existing single-dish instruments and which can be distributed over a greater aperture to achieve improved spatial selectivity. These dishes may then be combined to form one or more beams within the beamwidth of the individual dishes. Within the radio astronomy community, this concept is often referred to as "large N small D" (LNSD). Two prominent instruments that are able to operate as beamforming arrays are the Allen Telescope Array (ATA; section "Allen Telescope Array (ATA)") and the Very Large Array (VLA; described in section "Very Large Array (VLA)").

For wavelengths longer than about 1 m (300 MHz), it becomes cost effective to switch from dishes to even larger numbers of lower-gain elements, such as dipoles. This is due in part to the poor directivity of a small dish at these wavelengths and in part due to the dramatically increasing antenna temperature with decreasing frequency associated with the Galactic synchrotron background, which facilitates the use of simpler, less expensive uncooled electronics without significant penalty in sensitivity (Ellingson 2005; 2011). The section "Long Wavelength Array Station 1 (LWA1)" describes the Long Wavelength Array Station 1 (LWA1) as an example of an operational large meter-wavelength beamforming instrument; other low-frequency instruments such as LOFAR (described as an interferometer in section "LOw Frequency ARray (LOFAR)") also have beamforming modes. Beamforming arrays consisting of

DOI 10.1007/978-981-4560-75-7_124-1

large numbers of low-gain elements have some unique issues, including evolution of beam shape and sidelobe structure as a function of pointing, degradation of sensitivity with increasing zenith angle, and high overall system complexity.

Before describing specific instruments, it is worth noting that beamforming arrays are not solely a response to mechanical challenges or engineering economics but are also of interest because of the distinct advantages that beamforming provides. Primary among these is multibeaming – that is, combining the signals from individual elements so that multiple beams, each pointed in a different direction, – can be simultaneously generated. Each additional beam that can be independently pointed is one additional observer that can be simultaneously accommodated – dramatically increasing the scientific productivity relative to a single-dish system. Another advantage of beamforming is the potential to form beams having custom shapes or having sidelobes that are tailored to reduce system temperature or null interference; see, e.g., Raza et al. (2002) and Ellingson and Cazemier (2003). It should be noted that PAFs (and, to a lesser extent, FPAs) offer similar capabilities for dishes; see, e.g., Jeffs et al. (2008).

Allen Telescope Array (ATA)

The ATA (Welch et al. 2009), located in Hat Creek, California (USA), is a seminal implementation of the LNSD concept. The instrument currently consists of 42 6.1-m dishes distributed over an aperture roughly 300 m in maximum dimension. Each dish is an offset-fed paraboloid using a Gregorian subreflector with a dual-polarization log-periodic feed, achieving aperture efficiency of about 60 %. The feed system has an instantaneous tuning range of 0.5–11.2 GHz; however optimum performance requires a frequency-dependent linear mechanical positioning of the feed with respect to the subreflector focus. The dish provides a 2.5° main lobe at 1.4 GHz; subsequent beamforming results reduce this to about 4.3′ per beam, with the ability to position multiple beams located within the field of view defined by the dish pattern.

Deuterium Array

The Deuterium Array, shown in Fig. 7, was an array of low-gain elements which successfully observed the extraordinarily weak and previously undetected 327 MHz spectral line of deuterium (Rogers et al. 2007). The array consisted of 24 “stations,” each consisting of 24 dual-polarization two-element (main + director) Yagi antennas positioned according to a 0.8-wavelength rectilinear grid above a wire

Fig. 7 The Deuterium Array (Image credit: MIT Haystack Observatory)

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 8 LWA1 (Image credit: LWA)

mesh ground plane. Each polarization of every antenna was separately digitized, and beams were formed entirely in software. Although actually a short-lived (2004–2006) experiment, the instrument was significant as a demonstration of the efficacy of digital beamforming for high-sensitivity radio astronomy, and no comparable instrument currently exists with the ability to observe in this frequency range.

Long Wavelength Array Station 1 (LWA1)

LWA1 (Ellingson et al. 2013a, b) is a large modern operational general-purpose beamforming array operating in 10–88 MHz. The instrument, shown in Fig. 8, is collocated with the VLA in central New Mexico. LWA1 consists of about 256 dual-polarized dipole-type antennas. The output from each antenna is individually digitized, and beams are formed using a digital-domain delay-and-sum technique. The dipoles are distributed within a 100 m × 110 m elliptical aperture, resulting in a beamwidth of roughly 2° for zenith pointing at the highest frequencies, increasing to tens of degrees at the lowest frequencies and for pointing at low elevations. The major axis of the aperture is aligned in the north–south direction in order to improve the symmetry of the beam for Galactic center observations, which require pointing to low elevations toward the south. The distribution of antennas is pseudorandom with 5 m minimum spacing to facilitate maintenance. The pseudorandom distribution ameliorates grating lobes, which would otherwise become a problem for frequencies greater than about 30 MHz.

The LWA1 antenna element is a wire-grid bowtie-type dipole, having dipole arms that are angled downward into an inverted "V" configuration to improve uniformity of gain over the sky (Hicks et al. 2012). The useful bandwidth of the antenna element is considerably greater than the impedance bandwidth of the antenna element; this is attributable to the fact that the sky – in particular, the Galactic synchrotron radiation – is very bright in this frequency regime (Ellingson 2005). As a result, the ratio of irreducible external noise after the impedance mismatch to the internal (receiver) noise (about 300 K) is large, and thus the impact of the impedance mismatch on sensitivity is small. For LWA1, the system temperature is dominated by the Galactic synchrotron background by a factor of 4:1 from 24 to 87 MHz; thus improved impedance matching would result in only a very small improvement in sensitivity.

A *disadvantage* of having external noise-limited sensitivity is that the sensitivity of the array does not increase linearly with the number of antennas, due to the deleterious effect of correlation of external noise between closely spaced antennas (Ellingson 2011). Further, the brightness temperature distribution of the external noise varies with time of day, and the specific effect depends on beam pointing direction. So, whereas it is reasonable to characterize the sensitivity of large dishes in terms of effective aperture and

DOI 10.1007/978-981-4560-75-7_124-1

system temperature (i.e., A_e/T_{sys} or, in communications engineering nomenclature, G/T), such a characterization is not necessarily meaningful for modern low-frequency beamforming arrays employing antennas with large impedance mismatch, such as LWA1. In this case, system equivalent flux density (SEFD) is particularly convenient. SEFD is the flux density (i.e., W m^{-2} Hz^{-1}) of a source, unresolved by the beam, which results in a doubling of the apparent system temperature. LWA1 achieves an SEFD on the order of 10 kJy at the zenith. This sensitivity is approximately independent of frequency, because the effective aperture of dipoles increases in proportion to λ^2, whereas the antenna temperature due to the Galactic noise background increases roughly as $\lambda^{2.5}$, and sensitivity is proportional to the ratio.

Other Low-Frequency Beamforming Arrays

Another large modern operational low-frequency array which is sometimes used in a beamforming mode is LOFAR, which is designed primarily as an interferometer and so is described in more detail in the section "LOw Frequency ARray (LOFAR)." Before moving on, however, it is worth noting that essentially all currently operational radio telescopes designed to operate below 300 MHz consist of large numbers of low-gain elements combined to form beams, for reasons described earlier. LWA1 and LOFAR are relative newcomers to this frequency regime; other instruments operating below 100 MHz (and which have been operational for decades as analog beamforming arrays) include GEETEE (35–70 MHz), located in Gauribidanur, India, UTR-2 (Braude et al. 1978, 5–40 MHz), located in Ukraine, and the Nançay Decametric Array (10–100 MHz), located in France.

Interferometers

A distinct category of radio telescopes is *aperture synthesis imaging* instruments, often referred to as "interferometer arrays" or simply as "interferometers." Instruments in this category are designed primarily for imaging, in contrast to the "single pixel per feed" mode of operation associated with single-dish instruments, single-dish instruments using FPAs, and beamforming arrays. (To be absolutely clear: these instruments are *also* routinely used for imaging, e.g., by sweeping a beam across the desired field of view or by using an FPA as a "radio camera." This section addresses instruments which are designed primarily for aperture synthesis imaging.)

The typical method of operation for an interferometer consists of cross-correlating the signals received from widely separated antennas, followed by an application of the Fourier transform to obtain an image via the Van Cittert–Zernicke theorem. The actual processing is considerably more involved but beyond the scope of this chapter; for details, Thompson et al. (2001) is recommended. The principal characteristics of an interferometer are resolution, which is limited by maximum baseline length (i.e., maximum separation between two antennas in the array), and FOV, which is limited by the beamwidth of individual antennas. Useful FOV is also limited by practical considerations, such as imperfect coherence over bandwidth resulting from processing limitations. For this reason, the useful FOV is sometimes referred to as largest angular scale (LAS), which is inevitably less than the dish beamwidth.

Very Large Array (VLA)

The VLA (also known as the "Expanded VLA" (EVLA) and "Jansky VLA" (JVLA)) is perhaps the seminal example of an operational large radio interferometer (Napier et al. 1983; Perley et al. 2009). The array is located in central New Mexico (USA) and consists of 27 25-m dishes arranged in a "wye" geometry as shown in Fig. 9. The individual dishes are transportable along the 21-km-long arms of the wye, facilitating baselines up to 36 km. At 1.4 GHz, the configuration with the longest baselines ("A") facilitates imaging with resolution on the order of 2″, scaling inversely with frequency. The dishes are periodically moved into configurations which are factors of 3 smaller (known as "B," "C," and "D") in order to obtain improved sensitivity over larger angular scales.

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 9 The VLA in its most compact ("D") configuration (Image credit: NRAO/AUI/NSF)

Fig. 10 VLA dishes showing details of cassegrain feed system (Image credit: B. Saxton, NRAO/AUI/NSF)

The individual dishes use a cassegrain-type system in which the feed horns for eight contiguous bands covering 1–50 GHz are located at the vertex of the dish, as shown in Fig. 10. The 2.3-m cassegrain subreflector is mounted with a slight tilt relative to the axis of revolution of the main reflector, allowing feed selection by rotating the subreflector around this axis.

The VLA also has "P-band" (230–470 MHz) and "4-band" (54–83 MHz) feed systems, which are not cassegrain but rather are implemented using dipole feeds mounted between the subreflector and main reflector, using the subreflector as a crude ground plane (Kassim et al. 2007). The 4-band dipoles reduce

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 11 ALMA 12-m dishes (Image credit: W. Garnier, ALMA (ESO/NAOJ/NRAO))

the sensitivity of the higher-frequency cassegrain-mode feed systems and so are only intermittently deployed. An experimental/alternative 4-band feed array has recently been deployed to six dishes. This system consists of four end-fed dipoles positioned outside the optical path of the cassegrain feed system, significantly reducing interference to higher-frequency systems with a small reduction in effective aperture relative to the legacy on-axis dipole system (Harun and Ellingson 2011; Ellingson et al. 2013c).

As mentioned previously, VLA also has a "phased array" mode in which it operates as a beamforming array, which is particularly useful for observations of sources which cannot be resolved by imaging, such as pulsars. In this mode, the VLA achieves a beamwidth approximately inversely proportional to its maximum baseline with an effective aperture of roughly 10,000 m^2 – nearly 70 % greater than that of the GBT.

Atacama Large Millimeter/Submillimeter Array (ALMA)

ALMA (Mangum et al. 2006; Wooten and Thompson 2009) consists of 64 12-m dishes plus a compact array of 7-m dishes located near San Pedro de Atacama, Chile. ALMA just recently (2011) began science operations and represents the current state of the art in millimeter-wave astronomy in many respects. Figure 11 shows ALMA 12-m dishes, which operate in seven bands in 84–720 GHz (3.6–0.4 mm) and are transportable to form configurations with baselines up to 16 km. At 300 GHz (1 mm), this facilitates imaging with resolution of roughly 20 milliarcseconds. Like the VLA, ALMA may also be used as a beamforming array.

Giant Meterwave Radio Telescope (GMRT)

The GMRT consists of 30 45-m dishes located north of Pune, India. Whereas ALMA is essentially the millimeter/submillimeter-wave complement of the VLA, the GMRT addresses primarily lower frequencies, in bands from 50 MHz to 1.5 GHz. The relatively low upper bound on frequency facilitates the use of a wire-grid dish surface, which in turn makes the significantly larger dishes practical and cost effective. Eighteen dishes are fixed in a wye configuration similar to the VLA, with 14-km arms (baselines up to 20 km), and the remaining 12 dishes are concentrated in a 1 km × 1 km pseudorandom configuration at the center. At 610 MHz, this facilitates imaging with resolution on the order of 10″.

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 12 An aerial view of the LOFAR "superterp," a region within the 2-km-diameter "core" region, within which 24 of the stations are located. Nine stations are visible here: 6 within the circular island in the *center* of the image, one at the *lower left*, and two more on the *upper right*. The *square dark-colored* panels are HBA tiles, organized here into 24-tile subarrays. The *smaller dark-colored* patches are the ground screens of individual LBA antennas (Credit: van Haarlem et al. (2013) A&A, 556: A2, reproduced with permission © ESO)

LOw-Frequency ARray (LOFAR)

LOFAR (van Haarlem et al. 2013) is an operational large low-frequency interferometer consisting of tens of "stations" (sites containing beamforming arrays; 48 planned) distributed over Northern Europe. Figure 12 shows several of these stations. Each station consists of a 10–90 MHz "low-band array" (LBA) component and 110–240 MHz "high-band array" (HBA) component. These components use different antenna elements and geometries. LBA arrays consist of 48 or 96 dual-polarized thin-dipole inverted V-shaped antennas over ground screens arranged in a pseudorandom geometry within a circular aperture about 80 m in diameter. (See section "Long Wavelength Array Station 1 (LWA1)" for discussion as to why narrowband antenna elements are effective over multiple octaves in this wavelength regime.) HBA arrays consist of 24, 48, or 96 "tiles" (subarrays), with each tile consisting of a $4 \times 4 = 16$ array of dual-polarized "fat" wire-grid dipoles in a compact rectilinear geometry, with the tiles themselves being arranged in a compact geometry. The HBA tiles use analog beamforming; the LBA dipole outputs and HBA tile outputs are digitized, and all subsequent processing is digital. The stations are distributed in a pseudorandom manner with baselines ranging from 68 m to 1,158 km, facilitating imaging with resolution ranging from 0.5° to subarcsecond scales, depending on frequency, ionospheric conditions, and interplanetary scintillation. Although intended primarily as an aperture synthesis imaging instrument, LOFAR may also be operated as a beamforming array.

Other Prominent Interferometer-Type Radio Telescopes

Other prominent large currently operational radio interferometers include the Australia Telescope Compact Array (ATCA) (6 transportable 22-m dishes, maximum baseline 6 km, recent description: Wilson et al. 2011) and the Westerbork Synthesis Radio Telescope (WSRT; 14 25-m dishes, maximum baseline 3 km, Baars et al. 1973). WSRT is being retrofitted with a PAF system known as APERTIF ("APERture Tiles In Focus," van Cappellen and Bakker 2010). Each APERTIF PAF is a compact rectilinear array of 112 Vivaldi-type broadband horns operating from 1.0 to 1.7 GHz. In this application, the PAF serves to

DOI 10.1007/978-981-4560-75-7_124-1

Fig. 13 Three ASKAP dishes with PAFs visible (Credit: Schinckel AET, Bunton JD, Cornwell TJ, Feain I, Hay SG (2012) The Australian SKA Pathfinder, Proc. of SPIE Vol. 8444:2A)

simultaneously increase the imaging FOV and facilitates sophisticated spatial filtering techniques for mitigation of interference.

Associated with the SKA project (see section "Square Kilometre Array") are two "pathfinder" instruments that are expected to become operational over the next few years. The Australian SKA Pathfinder (ASKAP, Schinckel et al. 2012), shown in Fig. 13, consists of 36 12-m prime-focus dish systems in Western Australia. Although not clearly conveyed by the name of the instrument, ASKAP will be a prominent centimeter-wavelength interferometer in its own right and will be particularly well suited to survey-type projects due to large FOV (facilitated by relatively small dish diameter) and an innovative PAF-type feed system consisting of a self-complementary array of 94 dual-polarized square patches (Hay et al. 2011). The South African instrument MeerKAT will consist of 64 13.5 m offset Gregorian dishes with single-pixel feeds for bands between 580 MHz and 14 GHz (Davidson and Jonas 2012).

In the millimeter/submillimeter regime, other prominent interferometers include the Combined ARray for Millimeter Astronomy (CARMA, California, U.S.A.), Plateau de Bure and its successor, NOEMA (France), and the Sub-Millimeter Array (SMA; Mauna Kea, Hawaii; Blundell 2007). At the long-wavelength end of the radio spectrum, the Murchison Widefield Array (MWA, Tingay et al. 2013) has recently begun science operations. MWA is an 80–300 MHz array located in western Australia, intended primarily for angular power spectrum detection of the EoR but well suited to a variety of other science in this frequency band. MWA consists of 128 tiles, each consisting of a rectilinear array of $4 \times 4 = 16$ dual-polarization elements, similar to LOFAR HBA tiles. The tiles are distributed in a pseudorandom fashion with baselines up to 3 km. This results in a relatively large FOV (due to the small size of the beamforming tiles) simultaneously with useful angular resolution.

It should be noted that LWA1 (section "Long Wavelength Array Station 1 (LWA1)") is also able to operate as an interferometer; in the case of LWA1, the FOV is equal to the dipole element pattern – i.e., essentially the entire sky – whereas the spatial resolution is not significantly better than the beamwidth, since both modes are limited by the 110-m $\times$ 100-m physical aperture. Recently, a second LWA station

DOI 10.1007/978-981-4560-75-7_124-1

has been constructed at the Owens Valley Radio Observatory in California (USA) which has been designed primarily for interferometry. The Owens Valley LWA station array is essentially identical to that of LWA1, except the array geometry has been scaled up by a factor of about 2.3 with a corresponding improvement in resolution while retaining essentially full-sky FOV.

Very Long Baseline Interferometry (VLBI)

VLBI is interferometry using baselines extending beyond the boundaries of a particular radio observatory, typically with baselines on continental scales. A prominent operational VLBI instrument is the Very Long Baseline Array (VLBA), which consists of 10 25-m dishes (very similar to VLA dishes) distributed throughout the United States, including dishes in Hawaii and St. Croix (U.S. Virgin Islands), yielding baselines up 8,000 km. This yields spatial resolution on the order of 5 milliarcseconds at 1.4 GHz. Another prominent VLBI instrument is the Multi-Element Radio Linked Interferometer Network (e-MERLIN), consisting of seven dishes distributed throughout the United Kingdom (including Jodrell Bank), with baselines up to 217 km. In the millimeter regime, existing radio telescopes – now including ALMA – may be operated jointly for VLBI.

A prominent example of millimeter-wavelength VLBI is the Event Horizon Telescope (EHT), which aims to image the event horizon of the supermassive black hole at the center of the Galaxy at 1.3 mm wavelength. Finally, it should be noted that existing telescopes in all wavebands – including GBT, Arecibo, and the VLA – are commonly operated together to perform VLBI observations. Because data paths linking these instruments are typically not suitable for real-time correlation, it is common to record the signals from each instrument separately and then to perform correlation at a central location using the recorded data. Using this technique, baselines have been successfully extended even to small-dish radio telescopes in Earth orbit, also known as "space VLBI." A contemporary space VLBI mission is the Russian *RadioAstron* mission, which employs a satellite equipped with a 10 m dish.

EoR and BAO Experiments

As explained at the beginning of this chapter, one of the principal science drivers in modern radio astronomy is the quest to observe the EoR via 21-cm hydrogen emission redshifted to frequencies between (roughly) 100 and 200 MHz. This signal should appear as a millikelvin-scale variation in the spectrum of the CMB or alternatively as a distinct signature in the angular (spatial) power spectrum. The former approach can, in principle, be implemented using a single well-calibrated wideband dipole, since the signal is "global," i.e., is incident from the entire sky. Experiments pursuing the global spectrum approach include EDGES (Rogers and Bowman 2012) and SARAS (Patra et al. 2013). The spatial power spectrum approach requires an interferometer and is being pursued by LOFAR (section "LOw Frequency ARray (LOFAR)"), MWA (section "Other Prominent Interferometer-Type Radio Telescopes") and the "Precision Array to Probe the Epoch of Reionization" (PAPER; Parsons et al. 2010). PAPER is a purpose-built instrument consisting of dual-polarized sleeve dipoles over ground planes. This instrument is transportable, reconfigurable (various array geometries have been used), and scalable with deployments from 4 elements to 128 elements so far.

Due to the extreme weakness of the EoR signal, a detection is expected to require months to years of observation using existing instruments. A much larger interferometer will be required to productively observe the EoR signal. One such instrument now in the early stages of planning and development is the Hydrogen EoR Array (HERA), which will consist of hundreds of 14-m dishes, all fixed to point to zenith. Another instrument which aims to observe the VHF-band EoR signal is SKA Phase-1 Low, discussed in the section "Square Kilometre Array."

A distinct science effort leading to conceptually similar instruments is the quest to observe BAO in the frequency range 400–900 MHz, which promises to constrain the nature of dark energy. This is the primary

DOI 10.1007/978-981-4560-75-7_124-1

science objective of the Canadian Hydrogen Intensity Mapping Experiment (CHIME; Bandura et al. 2014), which would be a transit (fixed pointing) instrument consisting of fixed parabolic cylinder reflectors with line feeds.

Future Directions and Open Problems

This chapter has classified radio telescopes as being primarily single-dish systems, beamforming arrays, interferometers, and EoR/BAO experiments. In each category, prominent existing/operational instruments have been identified as well as instruments which are on track to become operational within the next few years; these include FAST, ASKAP, MeerKAT, NOEMA, HERA, and CHIME. This chapter concludes by looking a little further down the road to instruments that are in the early stages of planning and development and the associated technical trends.

Evolution toward PAFs and Aperture Arrays

A technical trend that seems likely to influence future instruments in most applications is the continuing shift from large filled apertures to arrays of larger numbers of low-gain elements followed by beamforming or interferometry. The primary motivations are addressed in the first few paragraphs of the section "Beamforming Arrays" and include the decreasing cost of electronics compared to filled apertures; the ability to support multiple users or observing programs simultaneously through multibeaming, increased flexibility in beam shape and sidelobe control, and potential for more capable interference mitigation techniques. In applications typically addressed with large single dishes, this trend manifests as growing interest in FPAs, the emergence of PAFs, and the transition to LNSD architectures with larger "*N*" and smaller "*D*." Extrapolating to future decades, it seems likely that in many applications, dishes may be replaced by "aperture arrays," that is, compact planar arrays of low-gain elements with per-element digitization for maximum flexibility in subsequent processing.

At the low-frequency end of the radio spectrum, this architectural approach has already both arrived and matured, as demonstrated by operational instruments such as LWA1 (section "Long Wavelength Array Station 1 (LWA1)") and LOFAR (section "LOw Frequency ARray (LOFAR)") and at 327 MHz by the Deuterium Array experiment (section "Deuterium Array"). Realization of this paradigm is more difficult at higher frequencies, both because the collecting area per element is approximately proportional to λ^2 and because the sensitivity of instruments becomes inevitably internal noise limited above about 400 MHz where the antenna temperature due to sky noise drops below 50 K or so. Thus, the case for new aperture array instruments is most compelling at meter wavelengths, extending into the centimeter-wavelength regime in certain cases. Prominent among experiments exploring this approach is EMBRACE (Kant et al. 2011), a beamforming array of 10,368 dual-polarized Vivaldi-type antenna elements for 500–1,500 MHz collocated with the WSRT, with a smaller version located at Nançay, France.

Square Kilometre Array

Figuring prominently in the future of radio astronomy is the Square Kilometre Array (Dewdney et al. 2009). The SKA project emerged in the 1990s as a concept for a new interferometer that would have an effective aperture of 1 km^2 at 1.4 GHz – hence the name. SKA is now an "umbrella" project coordinating multiple national and international instrument development programs. "SKA Phase 1" comprises three instruments: (1) SKA Phase 1 Low, a new meter-wavelength array architecturally similar to LOFAR, consisting of 900 stations in Western Australia, each consisting of 300 dual-polarized antennas of the log-periodic yagi type, (2) An expansion of ASKAP from 36 to 96 dishes, and (3) an

expansion of MeerKAT from 64 to 254 dishes. SKA Phase 2 would follow and is presumed to include a large meter-/centimeter-wavelength aperture array along the lines described above.

Radiometer Antennas

Markus Peichl*
DLR, Microwaves and Radar Institute, Oberpfaffenhofen, Germany

Abstract

Microwave radiometry is concerned with purely passive sensing of naturally generated microwave radiation of thermal origin. Microwave radiometers are corresponding measuring devices typically designed and built as a very low-noise receiver followed by a signal recording unit. Usually, radiometers contain an antenna as the first reception component collecting the incoming radiation, and they measure radiation power expressed in an apparent temperature called brightness temperature. The observable brightness temperature of any object or surface depends on various chemical and physical quantities, whose concurrence is expressed by the objects' emission (absorption), reflection, and transmission properties and its true temperature. Since the Earth has a temperature typically close to 300 K and the universe close to 3 K, a nearly arbitrary mixture of these two extreme temperatures can be expected. Consequently, our environment can show quite different brightness temperature values depending on the direction of actual observation.

On the one hand, radiometer measurements are carried out stationary with respect to the antenna pointing direction in order to observe time-dependent variations of the brightness temperature. On the other hand, the brightness temperature of a whole scene is scanned in order to acquire locally changing one- or two-dimensional profiles, while the latter ones are assembled as a two-dimensional image comparable to a conventional photograph. Depending on the specific application, various antenna types are considered, where usually hard requirements with respect to beam width, side-lobe level, scan capability, and losses have to be addressed (► Transmission Lines). Radiometric measurements are performed for Earth or planetary observation in space (► Space Antennas including Terahertz Antennas), from aircraft platforms on the Earth's surface and the atmosphere, or on the ground, either sensing the environment or sensing the universe, the latter being performed in radio astronomy (► Antennas in Radio Telescope Systems). Usually, the brightness temperature is rarely used as the physical quantity of interest. More often, it is transferred via adequate physical models to other secondary or third quantities for more direct use in the case of Earth observation (e.g., soil moisture, ocean salinity, rain rate, snow cover, etc.), being performed already since the 1950s of the last century. However, in the last decades, microwave radiometry is as well used in many safety- and security-related applications, for which often only sufficient temperature contrast between an object and its surrounding is required besides spatial resolution for detection and recognition purposes.

In this chapter relevant fundamentals of microwave radiometry are outlined for better understanding of antenna requirements, followed by an overview of typical types of radiometer antenna systems. Some existing antenna systems are discussed in order to illustrate the variability with respect to applications. A section on basic antenna quantities addresses key figures for practical design and verification and illustrates the results exemplarily for selected cases. Finally, a brief summary and an outlook on possible future implementations and other frequency ranges are given.

Introduction

Microwave radiometry addresses the domain of passive measurement of the natural thermally caused electromagnetic radiation of matter at a thermal temperature above 0 K. The thermal or true temperature of an object is usually called physical temperature in order to discriminate it from an apparent temperature, the latter being observable in microwave radiometry or even infrared measurements. This apparent temperature is called the brightness temperature. In the case of Earth observation, significant contrasts can be observed between reflective and absorbing materials due to the impact of reflected sky radiation of cosmic origin (► Radio Wave Propagation Models). Thus, an approximate brightness temperature range from 3 K to more than 300 K can be observed. In the microwave region, the spatial two-dimensional brightness temperature distribution can be used as a daytime and often weather-independent indicator for many different physical phenomena. Hence, interesting application areas incorporate geoscience, climatology, agriculture, pollution and disaster control, detection, reconnaissance, surveillance, and status registration in general. Since little more than a decade, safety and security applications like personnel screening and the monitoring of critical infrastructures are also of major interest. General reading on microwave radiometry and its applications can be found in Ulaby et al. (1981), Janssen (1993), Mätzler (2006), NAS (2007), and Peichl et al. (2007).

Fundamental Quantities

The origin of thermal radiation is given by quantum-mechanical exchange of energy with matter, i.e., in the case of radiation-based interaction, the energy can be either absorbed or emitted in very small but fixed portions. The size of those energy portions is exactly defined by the differences of single-energy levels of excitation states all atoms or molecules of matter can adopt. Since many different energy levels for single atoms or molecules exist and an object can be composed of many different materials, and since the event of a transition from one energy level to another occurs statistically in time, the character of the whole emitted radiation of an object or piece of matter is described by broadband noise. In the same way absorption of radiation energy occurs. Consequently, the capability of a certain matter to emit or absorb radiation energy is identical. These capabilities are denoted and quantified by the quantities of emissivity e and absorptivity a.

For a blackbody, the power distribution of thermally based noise radiation as a function of frequency and physical temperature is given by Planck's law (Ulaby et al. 1982). A blackbody is a hypothetical piece of matter which absorbs all received radiation totally and consequently emits the same amount in the case of thermodynamic equilibrium. So if the total energy exchange between the blackbody and the surrounding is 100 %, or equivalently denoted as 1, the relation $e = a = 1$ is valid. In nature and even our man-made world, a blackbody does not exist, but it can be sufficiently approximated by specific material compositions, as in the case of a microwave absorber used, for instance, in anechoic chambers. For that reason natural objects are often called gray bodies, meaning that their emissivity and absorptivity in fact are equal but lower than the value 1. The residual amount of interacting energy is related to reflected radiation on the surface of the gray body and transmitted radiation through the body. Due to the requirement of energy

DOI 10.1007/978-981-4560-75-7_125-1

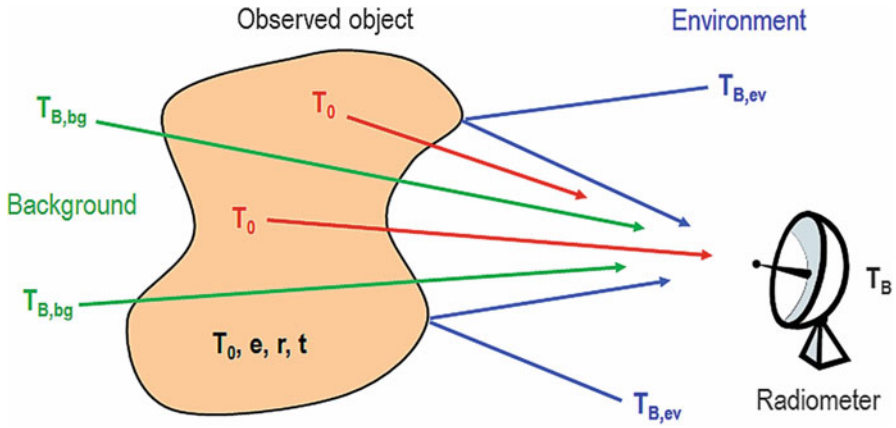

Fig. 1 Contributions to the observed brightness temperature. The object has a physical temperature T_0 and its interaction capability with radiation is described by emissivity e, reflectivity r, and transmissivity t. The radiation is received by the antenna of a radiometer

conservation and by introducing reflectivity *r* and transmissivity *t*, the following relations are valid for natural objects in thermodynamic equilibrium:

$$e + r + t = 1, \quad e, r, t \leq 1, \quad e = a. \tag{1}$$

In the microwave region, Planck's law can be approximated by the Rayleigh-Jeans law for frequencies up to 300 GHz and physical temperatures down to 1 K as given next:

$$B_f = \frac{2 k_B T f^2}{c^2}. \tag{2}$$

The quantity B_f is the so-called brightness (formerly radiation intensity), given in units of watts per steradian and hertz, which is the observed radiation power related to an infinitesimal segment of solid angle and an infinitesimal increment of bandwidth. The quantities T and f are the physical temperature in kelvins and the frequency in hertz; $c \approx 3 \times 10^8$ m/s is the speed of light and $k_B \approx 1.38 \times 10^{-23}$ J/K is Boltzmann's constant. The important fact in Eq. 2 is the linear dependence of the brightness from the physical temperature, which directly relates observed radiation power to temperature at a certain frequency in a simple way. This relationship can be as well applied to radiation originating from a gray body, and in this case, the given temperature is the brightness temperature and in general not identical to the physical temperature. The charm of using that relationship is that, if one uses a radiometer system in an outside area looking at a certain object and being calibrated for brightness temperatures, a low temperature value can indicate a highly reflective material and a high value can indicate a highly absorptive material, depending of course on the direction of observation with respect to sky or space.

Since we can use now the brightness temperature instead of radiation power to describe a certain observation, the brightness temperature can be considered as a composition of several contributions, as shown in Fig. 1, being expressed in a simple notation as

$$T_B = e T_0 + r T_{B,ev} + t T_{B,bg}. \tag{3}$$

The first summand represents the thermal energy content of the object, determined by its physical temperature T_0. The second contribution is the portion of reflected power from the ambience being represented by the brightness temperature $T_{B,ev}$. The third part is the radiation originating from directions

DOI 10.1007/978-981-4560-75-7_125-1

behind the object being able to penetrate it, and $T_{B,bg}$ is the corresponding brightness temperature of this background.

Note that $T_{B,ev}$ and $T_{B,bg}$ for their part can be generated as well according to Eq. 3. Furthermore (3) usually has to be an integral equation summing up all contributions from those directions, which the antenna can receive and which are deflected into that particular direction range. The material properties e, r, and t can depend strongly on frequency, observation angle, and polarization, and so does the observed brightness temperature T_B (▶ Radio Wave Propagation Models).

The equivalence of radiation power and temperature is expressed as well by Nyquist's law for ohmic resistors (Ulaby 1981):

$$P_N = k_B \Delta f T, \tag{4}$$

where k_b again is Boltzmann's constant, Δf is the noise bandwidth of observation, and T is the physical temperature. Since the noise being produced by an ohmic resistor cannot be discriminated from noise provided by a receiving antenna, the latter one assumed for the moment to have no losses, the temperature in Eq. 4 can be replaced by the brightness temperature. In case of radiometric measurements, the range of observable brightness temperatures is roughly in the order of 3–300 K for sensing in space or on Earth, and a typical number for the receiver bandwidth is 100 MHz. Using those values, the expected power range for natural brightness temperature observations is in the range of 10^{-15}–10^{-13} W, which is very small and in the order of the noise power the receivers generate for their own.

Sensing spatially the brightness temperature distribution requires an antenna and a moving sufficiently focused antenna beam to collect the radiation from a certain direction. The observed brightness temperature T_B is called antenna temperature T_A and can be expressed in a spherical coordinate system, using Θ and Φ as elevation and azimuth angles covering the ranges of $0 \le \Theta \le \pi$ and $0 \le \Phi \le 2\pi$:

$$T_A(\Theta', \Phi') = \frac{1}{\Omega_A} \int\limits_{\substack{antenna \\ pattern}} T_B(\Theta, \Phi)\ F_{Pn}(\Theta - \Theta', \Phi - \Phi')\ \sin(\Theta - \Theta')\ d\Theta\ d\Phi, \tag{5a}$$

$$\Omega_A = \int\limits_{\substack{antenna \\ pattern}} F_{Pn}(\Theta, \Phi)\ \sin\Theta\ d\Theta\ d\Phi. \tag{5b}$$

The quantity F_{Pn} denotes the normalized power pattern of the antenna and Ω_A is her effective solid angle from which the antenna would receive if the pattern had constant amplitude. The term $\sin(\Theta)\, d\Theta\, d\Phi$ of course represents the infinitesimal solid angle for the integration. The moving beam is represented by primed coordinates, Θ′ and Φ′, indicating the actual pointing direction of the antenna. Following Eq. 5a, it can be recognized that mathematically the antenna temperature results from a correlation or special convolution (i.e., exchange of $x - x'$ by $x' - x$) of the scene-dependent brightness temperature distribution with the antenna power pattern. The normalizing character of solid angle Ω_A becomes clear when a constant brightness temperature distribution is scanned by the antenna beam, i.e., $T_B(\Theta,\Phi) = T_0 = \text{constant}$. In that case the result for the antenna temperature is always $T_A = T_B = T_0$, and the antenna pattern has no blurring impact on the true brightness temperature distribution. In all other cases of a spatially varying distribution, the antenna pattern determines the obtainable spatial resolution

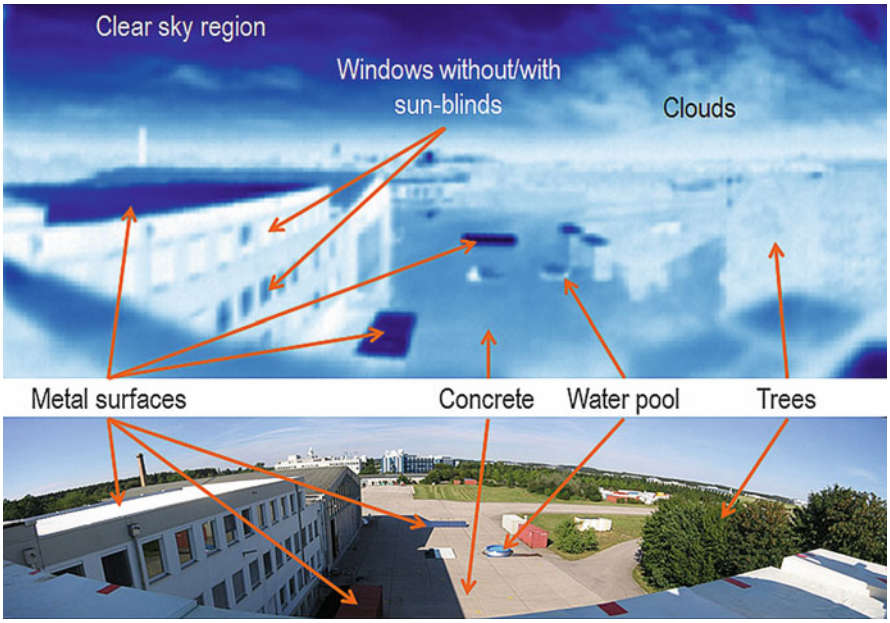

Fig. 2 Radiometer image (*top*) and photograph (*bottom*) of a complex scene for surveillance purposes. The radiometer image was recorded around 90 GHz using a mechanically scanning offset parabola antenna. Both images are geometrically not adapted. *Black* or *dark blue* color indicates low and *white* or *bright blue* indicates high brightness temperature (Peichl et al. 2007)

and contrast of the scanning measurement, as discussed later in section Basic Quantities of Radiometer Antennas.

Application Examples

At this point some practical examples of two-dimensional imaging shall be illustrated and briefly discussed for a few applications, where quite different antenna types have been used. Figure 2 shows an image of a ground-based measurement for surveillance applications.

First of all, the quasi-optical appearance of the radiometric millimeter-wave image and its complexity of details can be observed. Some special objects or materials are indicated in order to illustrate the brightness temperature variance of radiometric Earth observation. Note especially the radiometric "cold" appearance of the sky region and metallic objects reflecting sky radiation and the rather "warm" appearance of trees, the horizon region, and the vertical faces of buildings reflecting ambient radiation from horizon direction.

A second example in Fig. 3 shows a global map of brightness temperature measurements acquired by the SMOS (Soil Moisture and Ocean Salinity) satellite mission launched in November 2009. The SMOS instrument is an L-band two-dimensional aperture synthesis radiometer system using sparse interferometric array technology for imaging (► Space Antennas including Terahertz Antennas), as pointed out in a later section. The antenna array forms a "Y" shape and uses patch antennas (► Microstrip Patch Antennas) for the single elements (ESA 2009).

A last example Fig. 4 illustrates a two-dimensional map of buried objects, i.e., landmine simulants and other targets, measured by a multispectral radiometer. The radiometer uses a broadband Vivaldi antenna (► Ultra-Wideband Antennas) and is scanning a scene by two-dimensional raster motion close to the ground in the frequency range of about 1.5–7 GHz, divided in many different bands of 50 MHz bandwidth (Peichl et al. 2007). Note that the antenna was operated in the near field where usually the antenna pattern is different from far-field conditions.

The objects visible on the photograph (landmine simulants, metal disks, water can) have been buried in the sand in depths between 1 cm and 15 cm. The *right image* is a superposition of several single images at different center frequencies between 2 GHz and 6 GHz

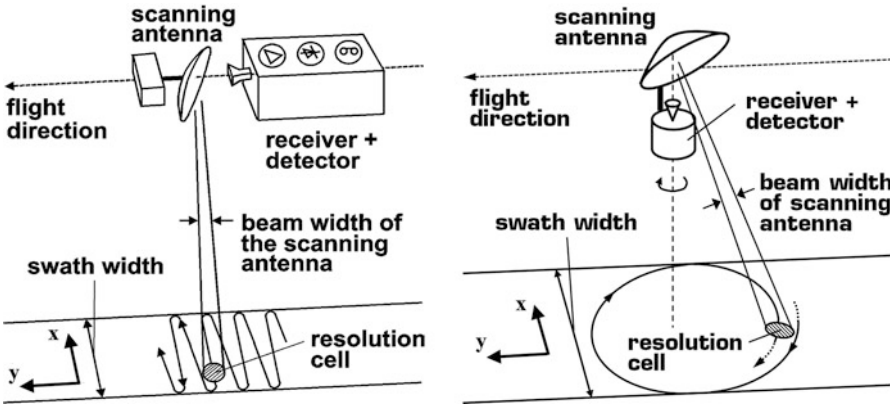

Fig. 5 Principles of fully mechanical scanning of the antenna beam for an airborne situation. In the example (*left*), the reflector of an offset parabola antenna and hence the antenna beam is swinging back and forth across flight direction. In the example (*right*), an offset reflector and hence the antenna beam perform a conical scan around the vertical axis. In both cases, a moving antenna footprint on the ground is produced in conjunction with the platform motion

Already these few examples have shown a high variability of applications and antenna types to be used for microwave radiometry. However, there is much more which cannot be covered or cited in this section, but fundamental insight in basic radiometric quantities and how they relate to the antenna or antenna system have been given. Next, a closer and more formal overview on different antenna types used in microwave radiometry is addressed.

Overview on Radiometer Antennas

Basically, each antenna type could be used for radiometric applications. However, in most cases, the choice of antenna type is driven by the peculiarity of the application and the basic requirement that the antenna should have very low losses for its own (► Transmission Lines). The latter condition again is based on the fact that the observable brightness temperature is in the order of the noise of the receiving system, in which the antenna is the first and radiometric most influential component. Since most applications in microwave radiometry deal with imaging or at least one-dimensional profiling of the

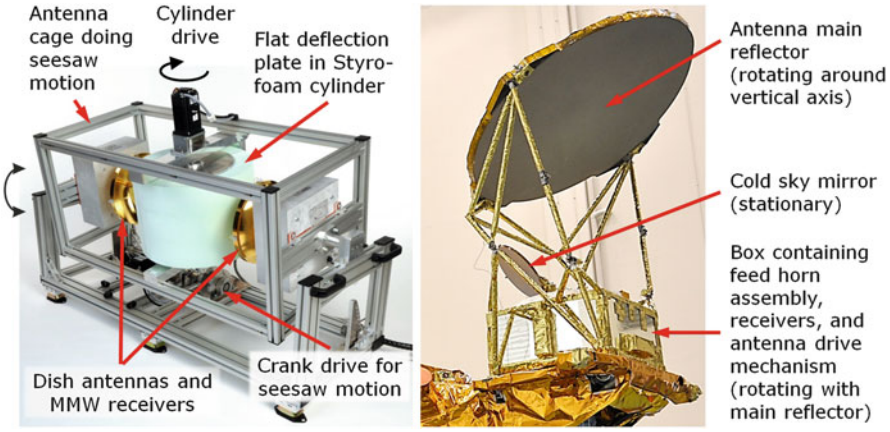

Fig. 6 Examples for fully mechanical scanning radiometer systems. The *left* system SUMIRAD is a vehicle-based imager for security applications like threat detection. The *right* scanner AMSR2 is a spaceborne imager for Earth observation and climate change monitoring (*Right* picture reproduced courtesy of JAXA, Japan)

environment, the intrinsic antenna usually is part of a scanning mechanism being either mechanic, electronic, or a hybrid of both. Consequently rather an antenna system has to be considered for performance characterization instead of the pure antenna element. Next, the most useful and applied scanning mechanisms for antenna beams are briefly discussed.

Mechanical Scanner

The operational principle for mechanical scanning of an antenna beam across a certain scene is illustrated in Fig. 5. In most cases, such a system is using a reflector antenna type realized as direct-fed parabola, offset parabola, or Cassegrain- or Gregorian-type antenna system (▶ Reflector Antennas). The focused beam is either moved by rotating or swinging back and forth the main or subreflector while keeping the feed antenna fixed or an additional flat metallic plate deflects the focused beam by a similar motion. This scanning principle can be applied in either two or only in one dimension. In the latter case the second beam motion is accomplished by use of the platform motion from an aircraft or satellite, for instance. Note that for the seesaw scanning shown left, the incidence angle varies for each sample, while for the conical scan on the right, the incidence angle is always constant.

Figure 6 illustrates two examples of existing fully mechanical scanners. The left system Surveillance in an Urban environment using Mobile sensors Imaging RADiometer (SUMIRAD) (Peichl et al. 2013) is intended for fast imaging of a scene in front of a vehicle during a drive. Two receivers are connected to Cassegrain antennas pointing toward a rotating metallic deflection plate, hence providing the horizontal scan of the antenna beam. The deflection plate is encased by a cylindrical structure made of Styrofoam in order to reduce considerably aerodynamic drag during rotation (up to 2,400 rpm). In vertical direction the whole unit of antennas, receivers, and deflection plate is forced to seesaw motion by a crank drive, providing the vertical scan of the antenna beam. The system works at a center frequency of 90 GHz and a bandwidth of 20 GHz. The angular resolution is about 0.75° (30 cm antenna diameter) and the temperature resolution (i.e., the sensitivity) is <2 K for a frame rate of up to 1 image per second. The system generates simultaneously two images of the identical scene for a field of view of $30° \times 80°$ (elevation $\times$ azimuth), and each linear polarization state can be chosen individually.

The right system AMSR2 (Advanced Microwave Scanning Radiometer 2) is part of GCOM (Global Change Observation Mission) intended for long-term global observation of various geophysical parameters for understanding climate variability and water cycle (Website JAXA; Imaoka et al. 2010). An assembly of feed horns is located in the focal plane of an offset parabola antenna providing tilted beams

DOI 10.1007/978-981-4560-75-7_125-1

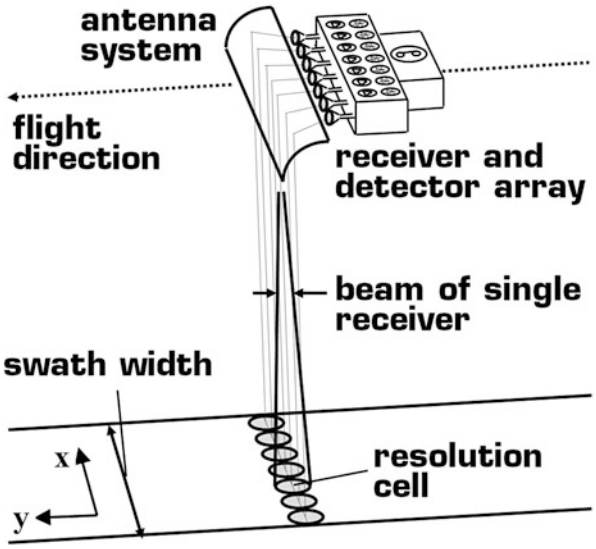

Fig. 7 Principle of focal plane array scanning for a one-dimensional case. Several feed antennas are arranged in the focal plane of a double-curved reflector in order to produce single beams across flight direction. In the illustrated case the second image dimension along flight direction is obtained again by platform motion

with respect to the vertical axis (► Space Antennas including Terahertz Antennas). By rotating the whole setup at 40 rpm (but not the whole satellite), a conical scan at around 47.5° with respect to nadir line is performed simultaneously for all frequency channels, and the satellite motion provides the second image dimension. The system operates at six frequency bands from about 7 GHz to 89 GHz center frequency providing an angular resolution between 1.8°–0.15° (2 m antenna diameter). The corresponding temperature resolution is within 0.4–1.4 K and two linear polarizations are provided. The satellite altitude is around 700 km and the swath width is about 1,450 km. AMSR2 was launched in May 2012.

Of course, many implementations of the mechanical scan can be realized, but the basic procedure of moving any reflecting device mechanically is always required. Consequently this approach has limitations with respect to antenna size and mass inertia when a very large antenna has to be moved very fast to achieve high-resolution and/or real-time imaging capabilities. However, mechanical scanning systems can be realized with relatively low expense and low losses of the antenna system. In addition, calibration of such systems can be performed relatively simply by applying a so-called hot-cold method, where two well-known reference targets on a known and well-separated brightness temperature are used. Finally, it should be noted that, by the mechanical scanning procedure, the antenna beam is always generated instantaneously in angular space. Thus, these antenna systems are called real-aperture antenna systems and they perform real-aperture imaging.

Focal Plane Array

Focal plane arrays (FPAs) are already known for a longer time in optical imaging systems like modern digital cameras (► Multi-Beam Antenna Arrays, Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). The basic principle is to locate an array of small detectors or antennas in the focal plane of a much larger focusing device. The latter usually is a suitable dielectric lens (► Dielectric Lens Antennas) or any curved metallic reflector producing collimated radiation. The situation of a one-dimensional FPA for again airborne radiometric imaging is shown in Fig. 7. For a two-dimensional FPA, the one-dimensional row of N antennas has to be repeated M times to get an image of N × M pixels, where of course an adequate focusing reflector has to be designed to point the single

beams in both directions. FPA technology-based radiometer systems are as well called push-broom systems in Earth observation (Skou and Le Vine 2006).

Figure 8 shows an example of a radiometric FPA system intended for security applications like enhanced vision for aircraft or concealed object detection under clothing or other dielectric obstacles (Appleby et al. 2004). In fact the scanning approach is a hybrid of FPA techniques and mechanical scanning in order to limit the required number of single receivers. The scan is performed by feeding unpolarized radiation from the scene through a polarizing grid to extract only vertical polarization (V), for instance. Then, the radiation passes a quarter-wave plate which rotates the linear polarization by 45° (V + 45°) before it is reflected by a metallic spinning mirror. That mirror is additionally tilted in order to perform a conical scan when rotated. After reflection, the radiation passes again the quarter-wave plate and the polarization is rotated by another 45° in the same direction as before, thus resulting in horizontal polarization (V + 90° = H). The H-polarized radiation now is fully reflected by the curved polarizer grid (transparent only for V polarization) and focused at the focal plane where the FPA is located. Since each element of the FPA produces its own conical scan displaced slightly from all others, a complete scene is scanned during each 360° rotation of the spinning mirror.

DOI 10.1007/978-981-4560-75-7_125-1

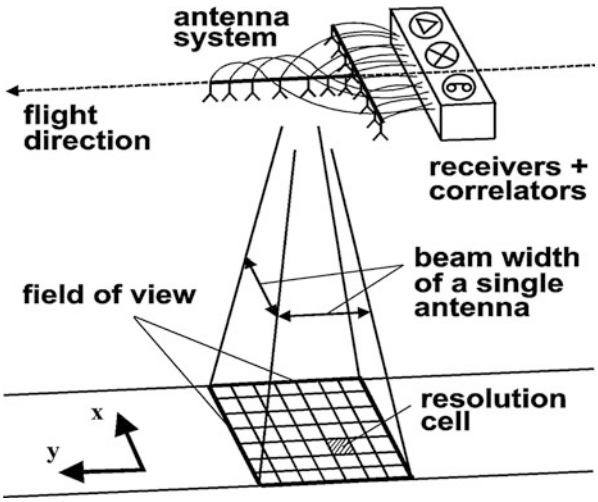

Fig. 9 Imaging principle for two-dimensional aperture synthesis. Each antenna/receiver pair of a sparse array forms an individual two-element interferometer measuring a single spatial frequency. The image is formed by processing the signals from all spatial frequencies. Note that for the shown configuration, a two-dimensional image is already obtained without additional platform motion. Aperture synthesis can be performed as well in only one dimension

The QinetiQ Passive MilliMeter-Wave (PMMW) system works at a center frequency of 94 GHz and a bandwidth of 20 GHz. The angular resolution is about 0.47° (60 cm antenna diameter) and the temperature resolution (i.e., the sensitivity) is about 2 K for a frame rate of up to 25 images per second. The field of view is 30° × 60° (elevation × azimuth), and the FPA consists of 150 single receivers, each one using a small rectangular horn antenna as feed.

FPA technology using many receiver elements is rather new in passive microwave remote sensing due to a former lack in sufficiently small and cheap microwave integrated circuits (MIC) or even monolithic MICs (MMIC). That instance can be noticed still at present in the realization of hybrids of FPAs and mechanical scanning to avoid large numbers of receivers (e.g., hundreds or even thousands), which is applied as well by Heinz et al. (2014) at submillimeter waves (▶ Mm-Wave Sub-mm-Wave Antenna Measurement). For Earth observation only studies have been carried out to date (Nielsen et al. 1989) and no operational system has been built yet. However, it can be expected that future antenna systems for high frame rate imaging will make more use of FPA technology, when the whole FPA unit can be even more miniaturized into a compact block. It should be noted that the physical distance of the single elements does not allow full Nyquist sampling of the scene. Consequently techniques of lateral adjustment of single FPA rows by half the element distance or crossing and overlapping scan patterns as in the case of the QinetiQ PMMW system are applied. Furthermore, calibration issues are more challenging since all receiver elements have to be adjusted to a common scale. It should be noted that by FPA imaging, all antenna beams are generated instantaneously in angular space. Thus, these antenna systems belong as well to real-aperture antennas and perform real-aperture imaging. Finally, the instance of measuring the brightness temperature of all single-antenna beams in parallel requires no mechanical motion. Hence, large antenna structures and high spatial resolution can be obtained.

Aperture Synthesis

Aperture synthesis is an imaging technique used in radio astronomy (▶ Antennas in Radio Telescope Systems) since the 1950s of the last century (Thompson et al. 2001). The goal of this technique is to make use of redundancy in an antenna aperture by only recording the required spatial frequencies of a scene with minimum replication but following the Nyquist sampling law. The spatial frequency is a measure for

DOI 10.1007/978-981-4560-75-7_125-1

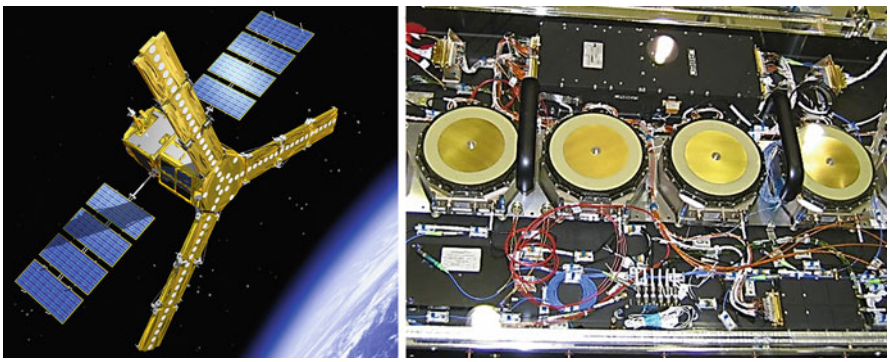

Fig. 10 Artist view of the SMOS instrument in space (*left*) and photograph of four receiver elements and corresponding electronics (*right*) of the real hardware. The single-element antenna type is a dual-polarized aperture-coupled microstrip patch (▶ Microstrip Patch Antennas) of 165 mm diameter with integrated feed network (Reproduced courtesy of CESBIO, France, and EADS CASA Espacio S.L., Spain)

a specific spatial variation of a quantity, e.g., the brightness temperature distribution, so that in general a scene consists of a certain number of differently weighted spatial frequencies, i.e., the spatial frequency spectrum. The measurement of a single spatial frequency is performed by cross-correlating the input signals of two spatially separated antennas, i.e., an interferometer. The spacing between single antennas is called a baseline. The imaging principle of aperture synthesis is illustrated in Fig. 9 again for an airborne situation.

Note that for the shown situation, only a sparse array consisting of two branches populated with antenna elements is necessary instead of a fully filled two-dimensional array. The imaging here is not performed by generating instantaneously the antenna beam through the whole array, but by Fourier inversion of the acquired spatial frequency spectrum for the case of an ideal system. Hence, aperture synthesis performs scanning of a scene in the spatial frequency domain, in contrast to the previously described methods which are scanning in the spatial domain. The sparse array represents a synthetic aperture simulating roughly a real-aperture antenna of similar dimensions. A synthetic antenna beam is only generated by processing which therefore does not exist instantaneously.

As an operational example for aperture synthesis, Fig. 10 shows the Microwave Imaging Radiometer with Aperture Synthesis (MIRAS) instrument of the spaceborne SMOS mission launched in 2009 by European Space Agency (ESA) (▶ Space Antennas including Terahertz Antennas). The SMOS mission is intended to predominantly provide global observations of soil moisture on land and sea surface salinity to improve modeling of weather and climate. It is also used for monitoring vegetation water content, snow cover, and ice structure (Barré et al. 2008; Font et al. 2010).

MIRAS is a Y-shaped aperture synthesis radiometer, the first operational instrument of this imaging type in space. It is operated in a protected band for radio-astronomical observations at a center frequency of 1,413 GHz using a bandwidth of about 20 MHz. Besides the protection, this L-band frequency range is used due to sufficient sensitivity of the brightness temperature with respect to soil moisture and ocean salinity, being harder obtained at higher frequencies. The sparse array consists of 69 receiver elements in total, where 18 elements are located in equal distances of 0.875 wavelengths on each arm of the Y, and the other 15 in the hub. The maximum spacing between two antenna elements is about 7.8 m (arm length 4.5 m) leading to a boresight angular resolution in the order of just under 2°, depending on the weighting function used for the sampled spatial frequency spectrum. The scene-dependent temperature resolution (e.g., for land or ocean) is in the order of about 2–4 K. For a satellite altitude of 758 km, the useful swath on the ground is about 1,050 km. The signal correlation of all antenna pairs is performed by 1-bit digital correlators operated at about 55 MHz clock rate.

DOI 10.1007/978-981-4560-75-7_125-1

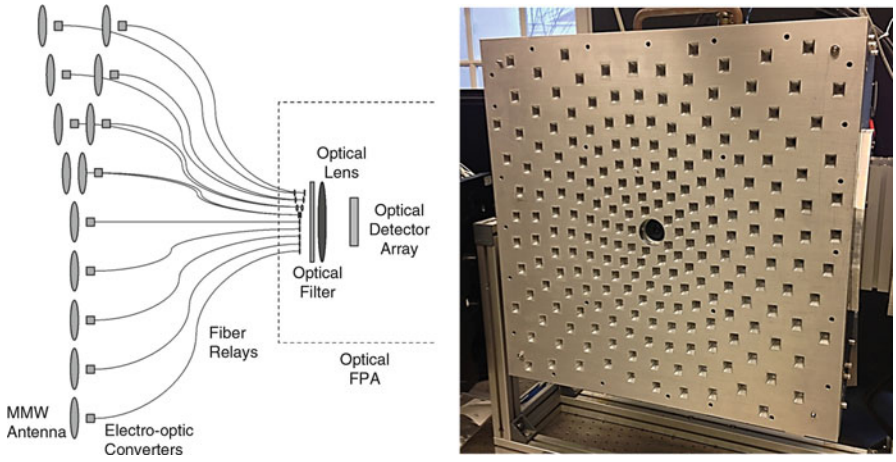

Fig. 11 Principle of aperture synthesis scanning using a Y-shaped array and an optical upconversion approach for optics-based image reconstruction (*left*). On the right the realized millimeter-wave demonstrator using a spiral antenna distribution is shown (▶ Millimeter-Wave Antennas and Arrays). Single antennas are realized as rectangular horns mounted in an aluminum plate (Courtesy of Phase Sensitive Inc., USA)

Another example for the application of aperture synthesis radiometry is realized by a real-time scanner for security screening to pilotage in degraded visual environments (Schuetz et al. 2013). Due to weight and volume restrictions on aircraft or helicopter, a very compact design is required. The realized approach uses aperture synthesis sampling of a scene and immediate upconversion of millimeter-wave signals to optical frequencies as shown in Fig. 11 (left), where directly the image reconstruction is performed by lenses and an optical camera, instead of correlation at Radio frequencies (RFs) and Fourier inversion by computer processing as it is done in the SMOS case (Schuetz et al. 2007).

The system is operated at 75 GHz center frequency using a bandwidth of a few 10 GHz. The antenna array is built in a five-arm spiral pattern consisting in total of 220 single-antenna and receiver elements as shown in Fig. 11 (right). A temperature resolution of around 3 K is achieved at a video rate of 25 frames per second. The field of view is about 20° and the angular resolution is reported for 0.4° in both azimuth and elevation direction for a square aperture size of 0.6 m. As indicated in Fig. 11 (left), the millimeter-wave radiation is collected by the single antennas, low-noise amplified and then directly upconverted to optical frequencies, where further signal configuration and especially full-image reconstruction is performed.

In microwave radiometry, two-dimensional aperture synthesis imaging is an attractive new method for high-resolution imaging at high frame rates without any mechanically moving parts. Due to the considerable thinning of the arrays, large apertures and thus very high spatial resolution can be realized by a reasonable number of single-antenna and receiver elements. However, as shown previously, a few hundred elements for present systems and probably thousands of them in future systems are required. Image reconstruction still is a challenge, since rarely a simple Fourier transform can be applied to the measured spatial frequency spectrum due to imperfections of the real system. Moreover the synthesized beam strongly depends on the specific array configuration (e.g., Y shape, spiral shape, etc.) and consequently how the corresponding sampling pattern of the spatial frequency spectrum fulfills the Nyquist criterion. The synthesis of the antenna aperture and the corresponding sampling character of that principle lead to grating lobes of the synthesized beam and a limited useful field of view without aliasing impacts. The calibration of an aperture synthesis system as well is rather complicated, since the classical hot-cold method as used typically for mechanical scanner systems cannot be applied, since many single elements with slightly different transfer functions influence not only a single pixel in the final image

DOI 10.1007/978-981-4560-75-7_125-1

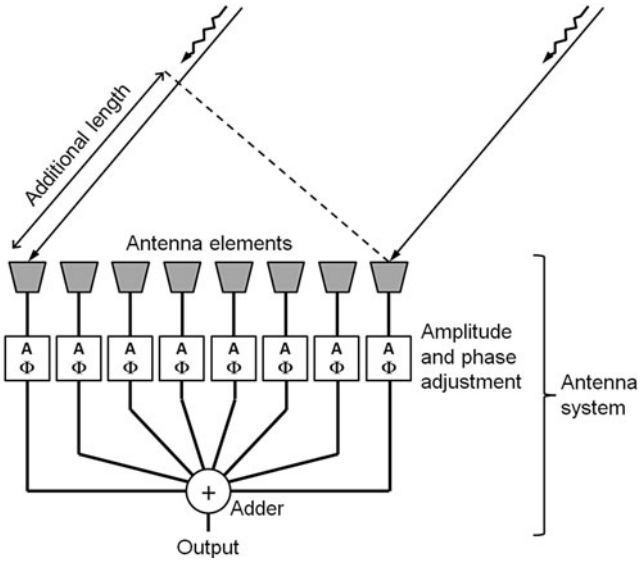

Fig. 12 Basic principle of phased-array scanning for radiometric applications. Brightness temperature radiation is received by single-antenna elements and shifted in phase and weighted in amplitude to add up coherently to the output for only one specific direction. Shown is only one-dimensional operation but two-dimensional scanning is possible as well

but altogether the whole image. Although thinned arrays can be designed, still a high number of single antennas and receivers compared to the mechanical scanners have to be used, making presently such systems rather expensive. An essay about the evolution of aperture synthesis technology for microwave radiometry in Earth observation and security applications for the last 25 years is given by Martin-Neira et al. (2014).

Other Scanning Principles

Previously discussed scanning principles and the corresponding antenna types are the mostly used ones or those with large potential for the future. However, several other approaches exist, at least in theory when up to date no practical system of such type has been realized. These principles are scanning by phased-array technology, frequency scanning, digital beamforming, and lens-based scanning. They are briefly discussed next.

Phased-Array Scanners

Phased-array technology has meanwhile large heritage from radar technology going back already to the 1950s of the last century (► Phased Array). The goal of this scanning principle is to replace a large antenna aperture by an array of small antennas and feed those with adequate phase and amplitude information in order to focus and steer the antenna beam fully electronically (see chapter XXX for further reading). The basic operation is illustrated for one-dimensional beamsteering in Fig. 12. Basically, for each antenna element, the additional path length with respect to a reference element (e.g., the right one) in the case of off-axis steering has to be compensated to produce maximum output signal for a certain pointing direction. This compensation is exclusively done by proper insertion of additional phase shift and time delay, while additional amplitude adjustment allows shaping the beam. Finally, all signals are added up coherently, usually implemented in hardware.

However, for microwave radiometry applications, the phased-array principle has been rarely used to date (Srinivasan et al. 2010; Sönmez et al. 1992). There are two major reasons. The first one is the typically large number of single-antenna elements and, moreover, of phase shifters for the steering and low-noise amplifiers for sufficient temperature resolution. It should be noted that proper beamsteering and

DOI 10.1007/978-981-4560-75-7_125-1

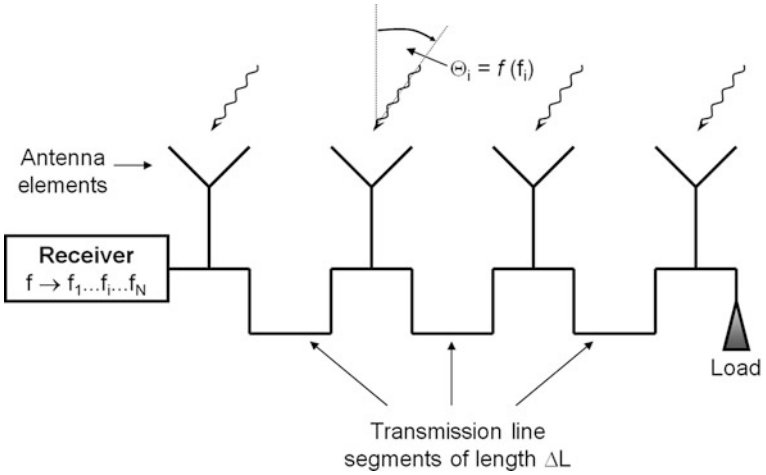

Fig. 13 Principle of antenna beamsteering by changing the operational frequency. The transmission line segments have identical and constant length, so that the amount of linear phase variation along the array is changed by varying frequency f_i, which steers the beam to a corresponding direction Θ_i

shaping requires a high degree of granulation, i.e., a very high number of single-antenna elements, located as close as possible together in a fully populated array. Secondly, the losses in the antenna system have to be kept as low as possible, which can be challenging when either no low-noise amplifiers are available or when such a large number of those are not affordable (► Transmission Lines). Decreasing the number of elements, by increasing the spacing and/or by increasing the single-element aperture size, results in the generation of strong grating lobes and a narrow field of view. In addition, large antenna structures require the implementation of true-time delays, which is performed to date by insertion of additional low-dispersion transmission lines. In conclusive summary, the expense for radiometric phased -array scanning is still very high to date. Nevertheless, it can be expected that increasing miniaturization of components using MMIC technology or a system-on-a-chip approach (► On-Chip Antennas), for instance, will allow the use of even thousands of combined amplifier–phase shifter circuits, possibly with already integrated antenna elements.

It should be further noted that, besides the capability of very fast fully electronic scanning, the beams to scan a scene are generated sequentially in time by common phased-array operation. For that reason the phased-array approach belongs to the classification of real-aperture antenna systems. Hence, the imaging of a large field of view at high resolution requires short dwell time of the beam at each scene location, resulting in reduced temperature resolution. As before in aperture synthesis, the calibration of such an imaging array approach is challenging due to the individual characteristics of the single elements, since all together contribute to a single beam. Here, again the classical hot-cold method is not applicable. Furthermore, the dense positioning of the single antennas in highly granulated arrays can lead to varying and bad antenna impedance matching in dependence of the scan angle, resulting in brightness temperature errors when not sufficiently known and compensated.

Frequency Scanning

In a one-dimensional antenna array, where the single-antenna elements are sequentially fed by equally long interconnecting pieces of transmission line, the phase shift between adjacent elements is equal and depends on frequency or wavelength, respectively. Hence, from the beginning to the end of the array, a linear phase shift between $1 \times \Delta\varphi$ and $(N-1) \times \Delta\varphi$ is obtained with respect to the first antenna with N being the number of antennas. Depending on $\Delta\varphi = 2\pi\,\Delta L/\lambda$, the array-generated beam is steered to a certain off-axis direction $0° \leq \Theta \leq \pm\Theta_{max}$ with respect to boresight, ΔL being the length of

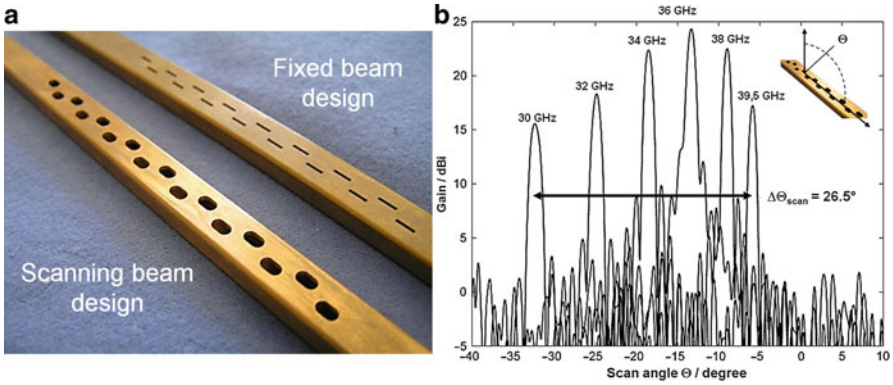

Fig. 14 Photograph of Ka-band slotted waveguide antennas for fixed and scanning beam design (*left*). On the right measured gain profiles of the scanning beam version for different frequencies are superimposed in one diagram to show the dependence on scan angle variation. The waveguide is of standard rectangular WR28 type

interconnecting transmission line and λ the wavelength according to Fig. 13. This beamsteering principle can be also understood as a special type of phased-array scanning (► Phased Array) where, instead of adjusting the phase for a fixed frequency, a frequency change produces a certain phase value (► Beam-Scanning Leaky Wave Antennas).

Such antenna types can be realized by any traveling wave configuration providing a repetitive arrangement of transmission line segment and antenna element (► Travelling-wave Antennas (Including Leaky Wave and Surface Wave Antennas), ► Transmission Lines). In microwave radiometry, it is most important that the antenna structure has lowest losses since it is the first component in the receiving chain to which the total receiver noise temperature is most sensitive. A suitable antenna type especially at higher frequencies, e.g., the millimeter-wave domain, is the slotted waveguide antenna (► Waveguide Slot Antennas and Arrays, ► Millimeter-Wave Antennas and Arrays, ► Tapered Slot Antennas, ► Travelling-wave Antennas (Including Leaky Wave and Surface Wave Antennas)). The waveguide itself is a low-loss transmission line and radiating slots can be relatively simple milled into its broad or narrow metallic walls.

A first approach on radiometric imaging using frequency scanning in combination with phased-array techniques is summarized in Clark et al. (2004). The system operating in W band (75–93 GHz) with 232 single channels using a parallel plate slotted waveguide antenna was intended for real-time security applications like concealed weapon detection. With a square antenna size of 60 cm side length, an angular resolution of about 0.4° and a field of view of around 20° in frequency scanning direction and 30° in the other direction were achieved.

Figure 14 shows another implementation and the scan patterns for Ka band in comparison to the classical slot geometry used for a fixed beam (Schreiber and Peichl 2013). The scanning-type antenna is intended to be used in conjunction with aperture synthesis (► Waveguide Slot Array Antennas) for a fully electronic scanning radiometer system to be used in security applications like enhanced vision for vehicle or aircraft. Noticeably, the slots for the scanning version have formed into rather elongated holes in order to serve the large bandwidth to be used for steering the antenna beam. The shown slot design allows a range of about 26.5° scan angle for a bandwidth of 9.5 GHz resulting in about 2.8°/GHz scan rate according to Fig. 14 (right). The aperture length of the slotted waveguide antenna used for that diagram is 0.5 m, housing 122 equidistant slots in total. Due to the large operational frequency range, the corresponding half-power beam widths are between 1.26° and 0.84° for the lowest and highest frequency. Note that the scan angle range is not centered at 0° boresight direction for mid-band frequency but at about −17°. That shift is caused by required optimization between antenna efficiency, i.e., lowest losses, and

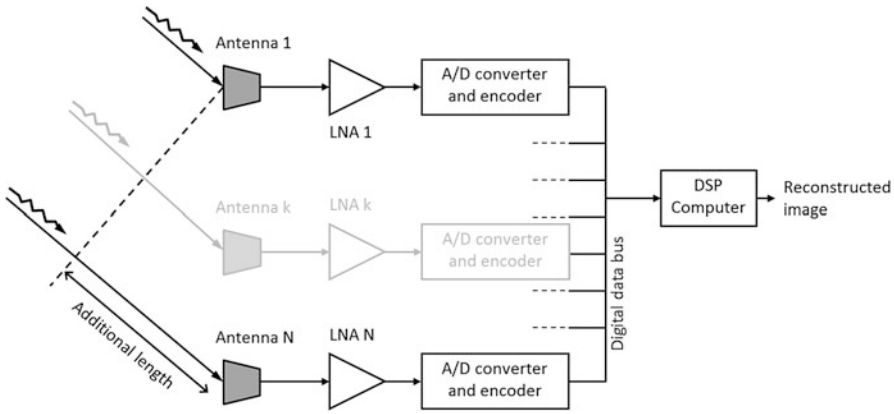

Fig. 15 Imaging principle for one-dimensional radiometric digital beamforming. Brightness temperature radiation is received by each antenna element and preprocessed for A/D conversion and storage. All channels are sampled coherently and the final image is generated by adequate common signal processing of all channels. Only the radiation from one direction is shown, but radiation from all directions is received simultaneously (LNA, low-noise amplifier; A/D, analog to digital; DSP, digital signal processor)

sufficient matching of input impedance (► Impedance Matching and Baluns), i.e., low reflections (Schreiber 2014). The obtained beam efficiency is at least 20 % at the band edges and 90 % in the central band region. Note that for the radiometric operation of this antenna, only an instantaneous bandwidth of around 100 MHz should be used in order to minimize beam blurring due to unintended beamsteering within the bandwidth.

Beamsteering by frequency shift is an attractive method for some radiometric scanning applications, since it can be realized purely electronic without additional expense in multi-receiver designs. However, it can be realized only in one dimension, so that the second scan direction for two-dimensional imaging has to be realized by any other suitable method. In addition, some degrading impacts like varying angular resolution and increased losses at the band or scan region edges have to be accepted, requiring careful design of this antenna type. In addition, only narrow-band operation for a certain scan position can be used, resulting in a decrease in temperature resolution if not compensable by other setting parameters. It should be further noted that applications requiring a certain fixed frequency band for observation cannot be served by this scanning principle due to the frequency dependence of beam pointing.

Digital Beamforming

Digital beamforming (DBF) is an imaging or scanning technique, which generally can be defined as a procedure performing adequate signal sampling by a special arrangement of antennas and the mathematical processing of the sampled signals in order to generate a synthetized focused antenna beam for each position in the image to be constructed (► Multi-Beam Antenna Arrays; ► Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). Consequently the antenna beam of the antenna system does not exist instantaneously in reality but virtually within the data processing and the final image, as it is already the case for aperture synthesis. However, in this context DBF is intended to work according to Fig. 15.

Each channel of an adequately spatially distributed antenna/receiver array is sampled coherently and simultaneously and digitized for storage in a computer or the memory of a digital signal processor. So, no focusing occurs at this point. The digital data then are collectively phase processed such that for each direction the additional path length between the single-antenna elements is compensated, which performs focusing in a certain direction. Since the compensation can be done for each direction using the identical data set, multiple synthesized antenna beams weighted according to the received radiation power for each

DOI 10.1007/978-981-4560-75-7_125-1

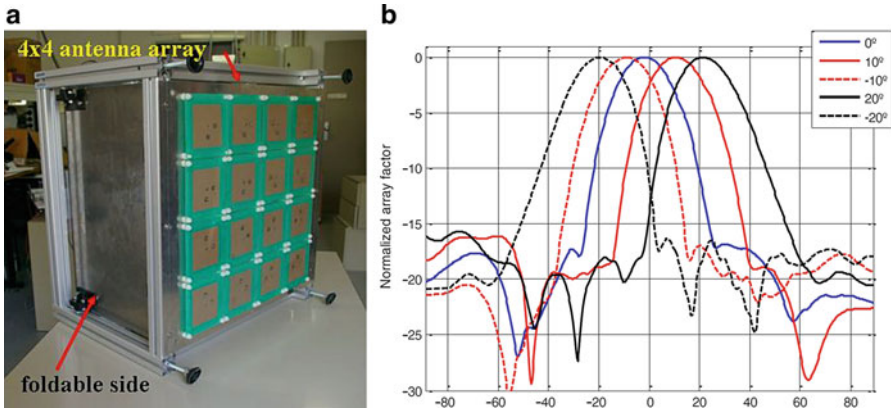

Fig. 16 Photograph (*left*) and measured synthesized antenna beams (*right*) of the PAU-RAD radiometer system working at L band. Multiple antenna beams are generated in one scan direction by DBF techniques. The single-antenna element is realized as microstrip patch (▶ Microstrip Patch Antennas) receiving two linear polarization states (Reproduced courtesy of Bosch-Lluis, UPC, Spain)

required direction are generated in parallel, thus reconstructing altogether the final image. Adequate choice of phase manipulation and amplitude weighting of the single channels allows a high degree in shaping the synthesized antenna beams, even individually, and performing error correction for the imperfectness of the real system.

DBF is a rather new scanning or imaging technique since the required sampling devices have to be provided in large numbers and at usually very high sampling rates according to the desired bandwidth of the radiometer system, which was not possible or too expensive in the past. Conventionally an array has to be fully populated to avoid or minimize grating lobes, which means a high number of single channels for a high spatial resolution and a large field of view, the latter being defined by the single-element antenna pattern. However, first attempts for radiometric applications have been undertaken as shown in Fig. 16 (Bosch-Lluis 2011).

The Passive Advanced Unit-Radiometer (PAU-RAD) system is a demonstrator device intended for ground-based sea surface salinity monitoring of the ocean from an elevated platform. It is a combination of a dual-polarized microwave radiometer and a Global Positioning System (GPS) reflectometer; hence, the center frequency was chosen to be 1,575 GHz for the benefit of using the identical front end, and the bandwidth is 2.2 MHz. DBF is only applied in one array direction and analog fixed beam generation in the other. So, there are 16 single-antenna elements grouped into four channels, each one digitized to 8 bits at 5.745 MHz sampling frequency for each polarization. The lateral length of the square array is about 2.6 wavelengths or 0.5 m (green area of Fig. 16 (left)), resulting in a half beam width of about 24°.

DBF can be considered as the most flexible and powerful imaging technique for future high-performance radiometer systems using fully electronic scanning. Hence, large apertures and corresponding high spatial resolution are possible without any mechanically moving parts. Note that even aperture synthesis imaging using sparse arrays can be performed via DBF, when the digital signal processing is done by complex correlation of all pairs of antennas in the array. However, the data revenue is considerable due to sampling of each channel at a usually high rate. As an example, consider a future array of 1,000 elements, operated at 1 GHz bandwidth for 10 ms integration time and sampled by 8 bit quantization. The corresponding data volume will be at least around 20 GB for tightly fulfilling Nyquist criterion, which has to be processed to the final image. This task is still a hard challenge for present memory and computer technology, especially when there is demand for real-time operation of the system.

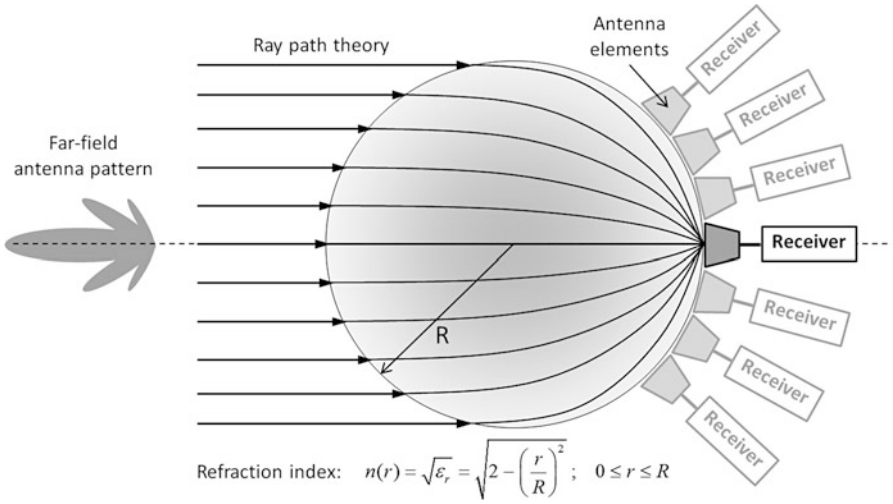

Fig. 17 Imaging principle for a Luneburg lens radiometer system. An antenna array can be located along the surface of a spherical lens, each one being in the focus of a bundle of parallel rays from another direction. The ray bundle is only shown for the central element. The refraction index n of the lens has to change according to the given equation as a function of radius r. The quantity ε_r is the real part of the permittivity of the sphere material

Lens-Based Scanning

Lenses are used in optical systems since centuries for focusing light to a passive detector, e.g., the human retina or a photographic film, for instance. Those detectors basically act as a focal plane array (FPA) in the way as described previously, in order to generate an image in an instant (► Dielectric Lens Antennas, ► Multi-Beam Antenna Arrays, ► Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). For practical reasons the same principle can be applied to microwave frequencies. However, the classic optical lens design, i.e., a thin dielectric body of convex shape, was rather rarely used in the past for microwave radiometry. Main reasons are the required bulky profile and associated weight for a given frequency and aperture size, the impacts of reflection and dielectric losses, and the occurrence of typical imaging errors known from optical systems (e.g., aberrations, astigmatism, coma, etc.), requiring expensive measures for compensation or reduction. Furthermore, the problem of pure FPA systems requiring a large number of receivers/detectors for two-dimensional imaging of a large field of view at a given spatial resolution is still challenging. Nevertheless, some attempts of developing lens-based passive FPA systems in the millimeter-wave range have been undertaken in the last few decades (Richter et al. 2006; Kim et al. 2011, ► Millimeter-Wave Antennas and Arrays).

A special version of dielectric lens is the Luneburg type. It consists of a spherical dielectric medium whose refractive index n varies fully symmetric from the center to the surface of the sphere from a value of $2^{1/2}$ to the value of 1 according to the equation of Fig. 17.

In ray theory this variation of refractive index focuses all incoming parallel rays of any direction to a single point on the opposite surface, where an appropriate antenna element can be located. Of course, the far-field pattern is divergent and has the shape of conventional antenna beams, i.e., finite half-power beam width and side lobes, due to the finite aperture size of the sphere and the wave character of the radiation. However, there are several advantages of this lens type. Since the dielectric constant is one on the surface, proper impedance matching to the antenna element is simplified (► Impedance Matching and Baluns). The maximum value of 2 in the center and the decrease to 1 at the surface implies that the sphere can be manufactured of light-weight materials, so that even for large spheres the total weight can be kept reasonable. Nevertheless, the production of a sphere following exactly the required refractive index is difficult, and mostly the sphere is made of a number of different spherical layers with constant index using

DOI 10.1007/978-981-4560-75-7_125-1

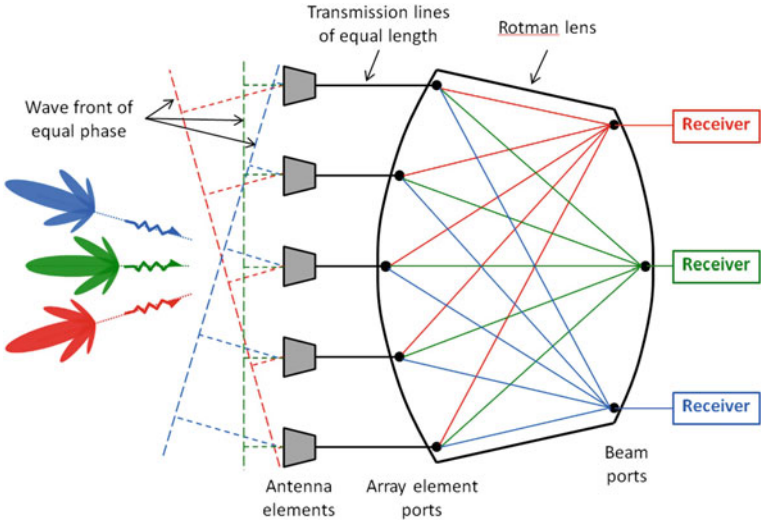

Fig. 18 Imaging principle of a Rotman lens radiometer system shown for m = 5 element ports and n = 3 beam ports. Radiation from a certain direction results in an increasing linear phase shift from the first to the last antenna element of the row. These phase shifts are compensated by the lens such that only at one beam port, all contributions are in phase. The lens has to generate that condition at each beam port, resulting in n simultaneous focused beams *for* n directions

a foam-type material, where the foam density can be used for adjusting the permittivity value of each layer (Bor et al. 2014). Note that antenna coupling of the adjacent antenna elements can lead to impedance mismatch and pattern degradation (► Suppression of Mutual Coupling between Elements in Multiple Element Antennas), and the distance to the surface of the sphere can be different from zero for proper operation. Suitable antenna element types for Luneburg lens systems are horn antennas or open waveguides, for instance. Dielectric losses of the sphere impact the temperature resolution of the radiometer system, especially for larger spheres. However, if sufficiently integrated antenna/receiver circuits are available, a rather simple scanner design for two-dimensional imaging radiometers without mechanical motion can be realized. Although basically considered as an appropriate imaging principle, radiometric imaging systems based on the Luneburg lens have not been realized quite often in the past (Shannikov et al. 2005).

Another interesting lens type for radiometric imaging systems is the Rotman lens (► Multi-Beam Antenna Arrays, ► Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). This lens is a multi-port device consisting of the array element ports, the beam ports, and the lens region according to Fig. 18. The lens can be manufactured in various embodiments like waveguide structures or microstrip technology, for instance, where it typically consists of a port region and a parallel plate region. The first is responsible for proper impedance match (► Impedance Matching and Baluns) and the physical connection to the external circuit parts, and the latter provides the required phase shifts for all beam directions. The shape of the lens is derived from the necessary phase or delay relationships required for each antenna beam simultaneously (Tudosie 2009). The single-antenna element can be of any type useful for the specific realization and frequency range, e.g., horn antennas, patches (► Microstrip Patch Antennas), dipoles, etc.

The antenna elements should be arranged as close as necessary to avoid grating lobes for the single-antenna patterns. The number of antenna elements m has to be chosen according to the demanded field of view and angular resolution. The number of beam ports n has to be selected according to the number of required beam directions to sample the field of view according to the Nyquist criterion. However, it is obvious that a large number of ports are difficult to realize, and the practical implementation of the theoretical principle has limits. Hence, there are restrictions in shaping the beam and, depending on

DOI 10.1007/978-981-4560-75-7_125-1

frequency and realization, high losses of the lens, and the required transmission line structures can be existent, reducing the temperature resolution of the radiometer system. Multiple beams in parallel can be generated, thus scanning the field of view at an instant. Furthermore, several Rotman lenses can be stacked and connected such that two-dimensional scanning is possible.

However, only few radiometer systems based on Rotman lens scanning have been realized in the past (Hall et al. 2001). The main reason might be the complexity and size for realizing systems with a high number of simultaneous beams and the relatively high losses of lens structures especially at higher frequencies. In general, lens-type scanning antenna systems for radiometric applications have been realized rather rarely in the past, although their optical counterpart is widely used since many centuries for focusing light and related imaging systems. A main reason might be the bulky, weighty, and voluminous embodiment required for generating a reasonable number of beams simultaneously especially at lower frequencies. Furthermore, the complex design and manufacturing for suitable beam shapes and low-loss reception of radiation are still a challenge. Last but not least, the FPA-like type of scanning, in particular in two dimensions, requires a large number of single receivers being still expensive at present, as already mentioned throughout this section.

Up to now possible and already realized antenna concepts for imaging microwave radiometer systems have been discussed. The following section will address the basic quantities of radiometer antenna systems as they are important for the design and verification of such devices.

Basic Quantities of Radiometer Antennas

The previous section has illustrated a multitude of applications, realized systems, and scanning methods for one- or two-dimensional radiometric imaging, where the antenna system plays a dominant role in the obtained overall system performance. The contribution of the antenna system can be divided into two major parts, the impact of the antenna pattern and the signal losses introduced by the antenna system. The antenna pattern determines the spatial quality of an image, i.e., the spatial resolution and the shape of intensity transitions in the image. The signal losses are generated by attenuation losses of the antenna structure and material (▶ Transmission Lines), being of ohmic and/or dielectric origin, and losses by impedance mismatch of the antenna itself, the radiometer receiver(s), and the connecting transmission line (s). The losses in total impact the noise level, known as the temperature resolution or sensitivity of the imaging process, i.e., the capability of discriminating small brightness temperature differences in the final image.

As discussed in the previous sections, the imaging process can be basically discriminated between real-beam scanning and synthetic-beam scanning. Real beams are produced by real-aperture systems, i.e., mechanical scanners, focal plane arrays (including reflector- and lens-based systems), phased arrays, and frequency scanning. Synthetic beams are produced by aperture synthesis or digital beamforming. The following discussion is mainly performed for real-aperture antennas, and the peculiarities of aperture synthesis are comprehensively outlined.

Impact of the Antenna Pattern

The basic imaging relation between the brightness temperature distribution to be mapped and the scanning antenna pattern was given for spherical coordinates by Eq. 5a:

$$T_A(\Theta',\Phi') = \frac{1}{\Omega_A} \int\limits_{\substack{antenna\\pattern}} T_B(\Theta,\Phi)\ F_{Pn}(\Theta-\Theta',\Phi-\Phi')\ \sin(\Theta-\Theta')\ d\Theta\ d\Phi. \tag{5a}$$

Because of the convolution character of the antenna power pattern F_{Pn} with the original brightness temperature distribution T_B, it is obvious that the antenna pattern has a smoothing influence on T_B resulting in the blurred version, the antenna temperature T_A, as the imaging result. The amount of smoothing or blurring depends of course on the width and particular shape of the antenna pattern. The width of the antenna pattern can be represented by its half-power beam width $\Delta\Theta$ usually given for the two orthogonal directions at $\Phi = 0°$ and $\Phi = 90°$ or in a similar way by its maximum directivity D_{max}. Moreover, the width or $\Delta\Theta$ is a measure of the spatial resolution which can be achieved in the image, being defined as a measure for the discrimination capability of two adjacent point sources. Since the maximum directivity is related to the beam angle of the antenna by

$$D_{\max} = \frac{4\pi\ \ (\mathrm{sr})}{\Omega_A\ \ (\mathrm{sr})} \approx \frac{41,253\ \ \left(\mathrm{deg}^2\right)}{\Delta\Theta_{\Phi=0}\ \ \Delta\Theta_{\Phi=90}\ \ \left(\mathrm{deg}^2\right)}, \tag{6}$$

the directivity value can be understood as well as the number of point sources $N = D_{max}$, which can be resolved in the solid angle of 4π (Kraus and Marhefka 2001). In the one-dimensional case, it is the number of sources of width $\Delta\Theta$ being resolvable within the angular range of 360°. However, it should be noted that the directivity value does not directly give any statement about the shape of the antenna pattern and its side-lobe distribution.

The shape of the antenna pattern and especially the side-lobe contribution can be expressed in the beam efficiency η_A, which is given by the ratio of power transferred by the main lobe and the total transferred power:

$$\eta_A = \frac{\Omega_{ML}}{\Omega_A}, \tag{6a}$$

$$\Omega_{ML} = \int_0^{2\pi}\int_0^{\Theta_0} F_{Pn}(\Theta,\Phi)\ \ \sin\Theta\ \ d\Theta\ \ d\Phi. \tag{6b}$$

The angle Θ_0 has to be chosen adequately, e.g., as the position of the first null or the first minimum of the antenna pattern. In the hypothetical case of very low side lobes, the beam efficiency approaches the value of 1, and for strong side lobes, it is significantly less than 1. However, it has to be noted that the beam efficiency makes no direct statement about the spatial resolution behavior of the antenna pattern.

Consequently, both quantities – directivity and beam efficiency – have to be used for characterizing the spatial imaging quality of a radiometer system. For a more striking illustration of the spatial imaging quality, the analysis of the response on some canonical scenarios is very helpful. So, for a few basic brightness temperature distributions, the imaging relation (Eq. 4) can be directly evaluated.

DOI 10.1007/978-981-4560-75-7_125-1

(A) Constant brightness temperature scene:

$$T_B(\Theta, \Phi) = T_0, \tag{7a}$$

$$T_A(\Theta', \Phi') = \frac{T_0}{\Omega_A} \underbrace{\int}_{\substack{antenna \\ pattern}} F_{Pn}(\Theta - \Theta', \Phi - \Phi') \sin(\Theta - \Theta') d\Theta d\Phi = T_0. \tag{7b}$$

If the brightness temperature is constant at T_0 for a larger region around the actual field of view of the imaging process, the observed value for the antenna temperature is identical. Hence, the antenna pattern has no impact on the image quality, but of course, the image itself does not contain very much information. On the other hand such a situation is suitable for calibration purposes if the value of T_0 is known with sufficient accuracy.

(B) Brightness temperature source of very narrow width embedded in an otherwise constant background:

If the solid angle covered by the source $\delta\Omega_S$ is very small compared to the equivalent solid angle of the antenna pattern Ω_A, the antenna pattern can be assumed to be constant within $\delta\Omega_S$ and the obtained antenna temperature is given by

$$T_A(\Theta', \Phi') = T_0 + (T_1 - T_0) \frac{\delta\Omega_S}{\Omega_A} F_{Pn}(\Theta_S - \Theta', \Phi_S - \Phi'), \tag{8a}$$

$$\frac{\delta\Omega_S}{\Omega_A} << 1. \tag{8b}$$

Again, T_0 is the brightness temperature of the constant background, T_1 is the brightness temperature of the point source, and Θ_S and Φ_S indicate the angular source position. It is obvious that in this case the obtained antenna temperature for the source shows only a small deviation from the background due to the small value of the solid angle ratio. However, it can be recognized that the angular point source distribution shows with sufficient accuracy the shape of the antenna power pattern. This opportunity can be used for the power pattern measurement of large dish antennas used in radio astronomy (▶ Antennas in Radio Telescope Systems), which cannot be characterized by conventional antenna test ranges due to their size and the challenging compliance of the far-field condition. The following example shall illustrate the situation.

Consider the sun at L band ($\lambda = 20$ cm) having a surface brightness temperature of up to 100,000 K (Reul et al. 2007). Observed from the Earth, the angular diameter of the sun is about 0.5°. Using a dish antenna of $W = 5$ m diameter will have a half-power beam width of about $\Delta\Theta \approx 70° \lambda/W = 2.8°$, and the solid angle ratio is about $\delta\Omega_S/\Omega_A \approx 0.5^2/2.8^2 = 0.032$, which fulfills roughly the small-size requirement for the assumption of a point source. Hence, the observed maximum brightness temperature will be 3,200 K, which would allow with respect to the cosmic background of around 3 K a dynamic range in the order of 30 dB for a pattern measurement.

Equation 7b can be extended by adding a second point source of brightness temperature T_2 at a different location:

DOI 10.1007/978-981-4560-75-7_125-1

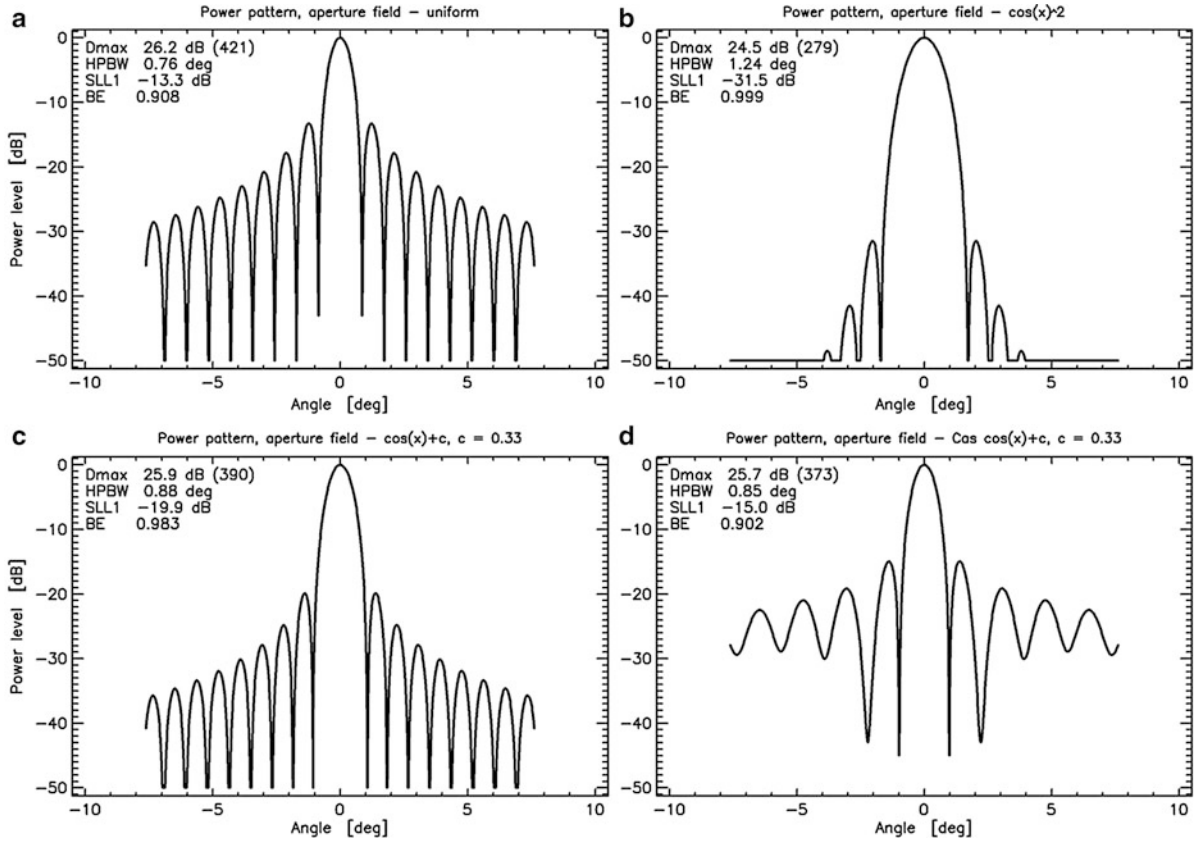

Fig. 19 Various different normalized antenna patterns produced by specific aperture fields having a maximum value of 1: (**a**) uniform, (**b**) $\cos(x)^2$, (**c**) $\cos(x) + c$, and (**d**) $\cos(x) + c$ with 5 % center blockage (Cassegrain type). The cos(x) function is zero at the aperture edges $x = \pm W/2$. Pattern values < -50 dB are not shown. Each graph indicates values for maximum directivity (Dmax), half-power beam width (HPBW), first side-lobe level (SLL1), and beam efficiency (BE). The patterns have been computed for an aperture size of W = 2 m and a frequency of 10 GHz

$$\begin{aligned} T_A(\Theta', \Phi') &= T_0 \\ &+ (T_1 - T_0)\ \frac{\delta\Omega_{S1}}{\Omega_A}\ F_{Pn}(\Theta_{S1} - \Theta', \Phi_{S1} - \Phi') \\ &+ (T_2 - T_0)\ \frac{\delta\Omega_{S2}}{\Omega_A}\ F_{Pn}(\Theta_{S2} - \Theta', \Phi_{S2} - \Phi'). \end{aligned} \tag{9}$$

The numberings 1 and 2 indicate the individual quantities for each source. If the two-point sources are identical but differently located, the observed antenna temperature is given by

$$T_A(\Theta', \Phi') = T_0 + T_\Delta\ (F_{Pn}(\Theta_{S1} - \Theta', \Phi_{S1} - \Phi') + F_{Pn}(\Theta_{S2} - \Theta', \Phi_{S2} - \Phi')), \tag{10a}$$

$$T_\Delta = (T_S - T_0)\ \frac{\delta\Omega_S}{\Omega_A}. \tag{10b}$$

The quantity T_Δ is the maximum change in brightness temperature due to the point sources with respect to the constant background. Equation 10a now can be used for analyzing graphically the impacts of the half-power beam width and the antenna pattern shape on the separation capabilities of the two-point targets, i.e., the spatial resolution, and the contrast of those with respect to the background. For that purpose a

DOI 10.1007/978-981-4560-75-7_125-1

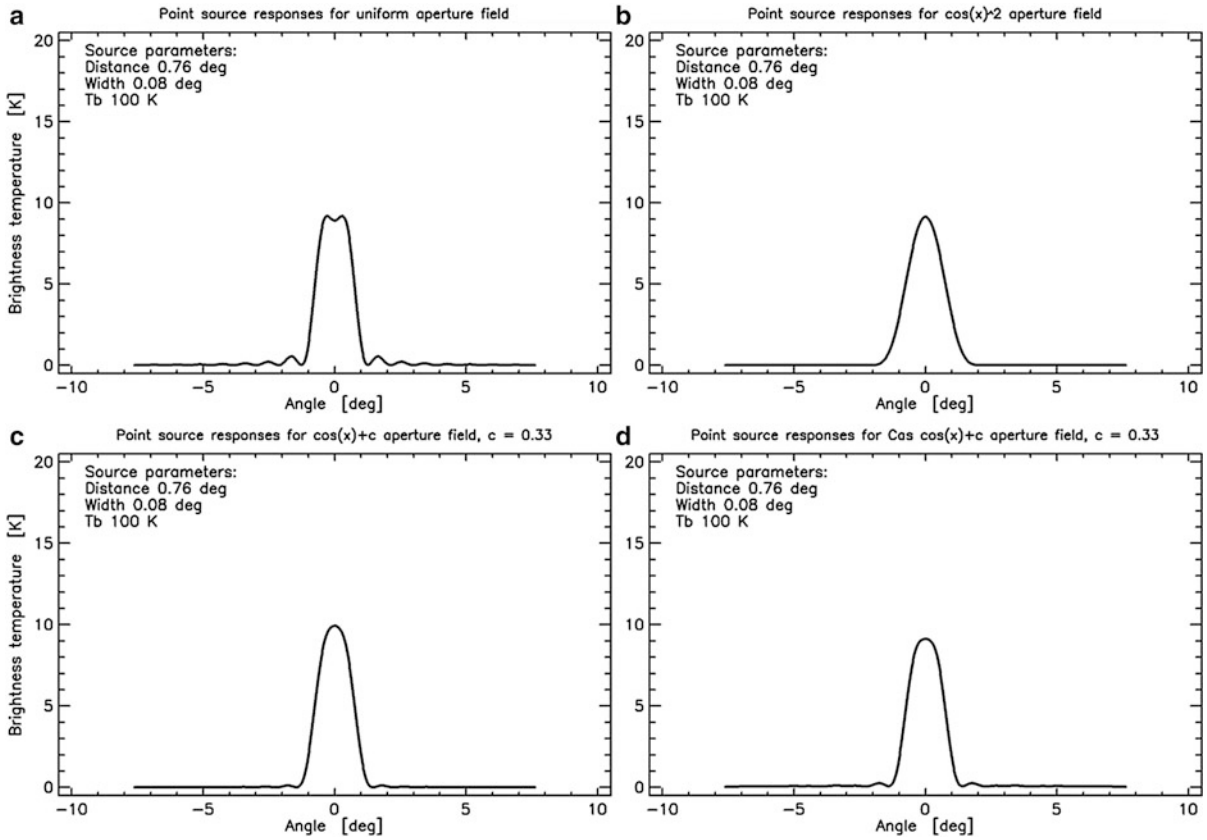

Fig. 20 Imaging result for two identical point sources separated by 0.76°. The brightness temperature level and width of the original sources are 100 K and 0.08°. The scanning antenna patterns correspond to the description of Fig. 19. No additional noise was considered for the simulation

one-dimensional analysis is appropriate and the results are representative for the two-dimensional case as well:

$$T_A(\Theta') \quad = \quad T_0 \quad + \quad T_\Delta \ (F_{Pn}(\Theta_{S1} - \Theta') \ + \ F_{Pn}(\Theta_{S2} - \Theta')). \tag{11}$$

The antenna power patterns can have quite a different shape, according to the half-power beam widths and the side-lobe levels, depending on the specific antenna type and its source field distribution in the aperture plane. For practical reasons the antenna aperture size shall be kept constant in this analysis, since most applications dictate a finite size, i.e., diameter or length and width, due to sensor volume and cost restrictions. In this case the only parameter to influence the antenna pattern is the aperture field distribution. Figure 19 summarizes field distributions and the corresponding power patterns used for the analysis. The patterns show a high variety with respect to half-power beam width and side-lobe level. Note that such aperture distributions can be adjusted in a wide range by choice of amplitude taper for array antennas or the feed pattern in case of dish antenna systems. Summaries of radiation characteristics from aperture field can be found in Olver et al. (1994) and Johnson et al. (1993). For example, the normalized power pattern for the uniform distribution of the aperture field of width W is given by

$$F_{Pn}(\Theta) = \left(\frac{\sin q}{q}\right)^2; \quad q = \frac{\pi W}{\lambda} \sin \Theta \tag{12}$$

DOI 10.1007/978-981-4560-75-7_125-1

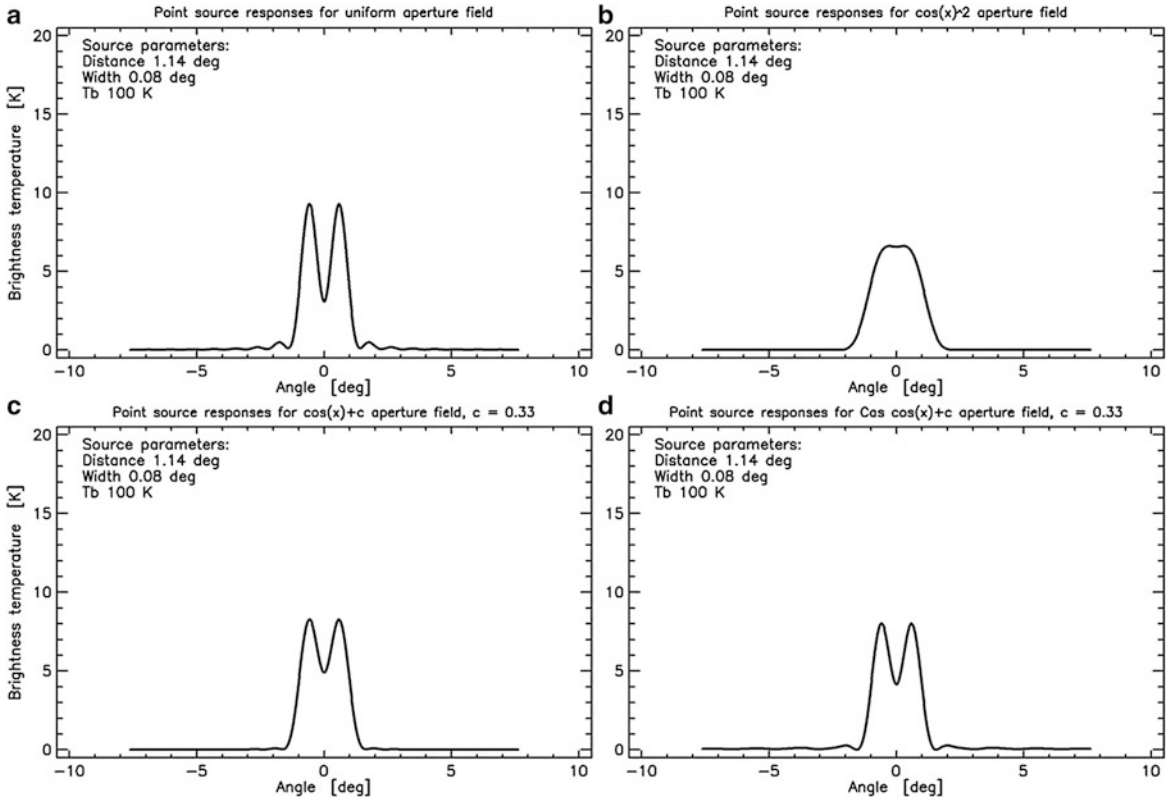

Fig. 21 Imaging result for two identical point sources separated by 1.14°. The brightness temperature level and width of the original sources are 100 K and 0.08°. The scanning antenna patterns correspond to the description of Fig. 19. No additional noise was considered for the simulation

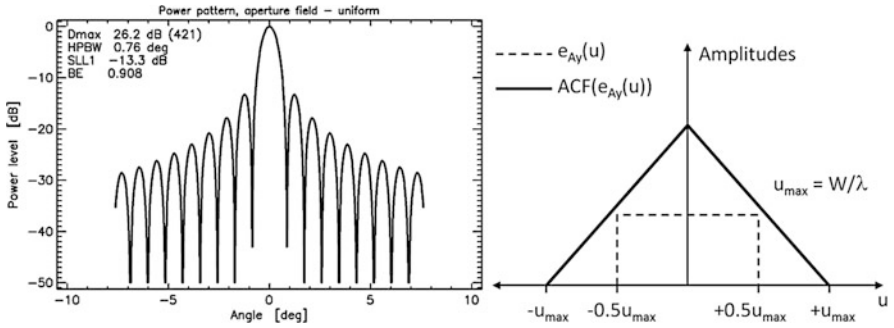

Fig. 22 *Left side*: One-dimensional antenna power pattern according to Fig. 19 and Eq. 12 for a uniform aperture field distribution $e_{Ay}(u)$, W = 2 m, and λ = 3 cm; *right side*: corresponding power spectrum in the spatial frequency domain being the autocorrelation (ACF) of $e_{Ay}(u)$. Note that here for the angle of the left Fig. 1 = sin Θ is valid according to Eq. 16a

The impact of such antenna patterns on the imaging of two identical point sources located at different separation widths is shown in Figs. 20, 21, and 22. The imaging result of Fig. 20 indicates that the two sources can be only separated by the antenna pattern produced by the uniform aperture field. However, this signature shows the highest ringing of the brightness temperature profile in the vicinity of the sources, which can lead to misinterpretation of the true values. In all other cases only one source can be identified from the profile, but always lower-ringing impacts are observed. Consequently the uniform aperture approach is useful where maximum detection capability of any target within a scene is the goal. A strongly tapered aperture field as in the case of the $\cos(x)^2$ case produces maximum smoothing of the true profile

DOI 10.1007/978-981-4560-75-7_125-1

but shows practically no corruption of the brightness temperature values in the vicinity of the transitions from the sources to the background. That behavior is useful for a requirement of high absolute accuracy of the observed profiles. Note that the separation in this case was exactly the half-power beam width of the pattern Fig. 19a corresponding to the uniform aperture field.

Now in Fig. 21, the sources were separated by 1.5 times the half-power beam width of the uniform case. Now the two sources can be separated for all situations with exception of the pattern for the $\cos(x)^2$ aperture field. Again, the separation is best for case (a) where the reconstructed source levels show again as well highest amplitudes, but again the ringing around the transition area is worst.

According to previous analysis, the choice of the antenna pattern, within restrictions on the feasibility, should be driven by the specific application, either if best detection performance or best absolute accuracy performance is desired. It should be noted that these results are valid in general although shown for a specific example.

Spatial Sampling Requirements

In most cases of radiometric imaging, aperture antennas are used for focusing an antenna beam. According to Olver et al. (1994), the co-polar field radiation pattern E_{cp} in the far field of an aperture field e_{Ay}, located in the x-y plane of a Cartesian coordinate system and directed in y direction, can be expressed with sufficient accuracy by

$$E_{cp}(\Theta,\Phi) = A_0(1 + \cos\Theta)\ F_y(\Theta,\Phi), \tag{13a}$$

$$A_0 = \frac{jk\exp(-jkr)}{4\pi r}, \quad k = \frac{2\pi}{\lambda}, \tag{13b, c}$$

$$F_y(\Theta,\Phi) = \iint\limits_{aperture} e_{Ay}(x,y)\ \exp(jk\ (x\ \sin\Theta\ \cos\Phi\ +\ y\ \sin\Theta\ \sin\Phi))\ dx\ dy. \tag{13d}$$

The quantity A_0 represents the far-field phase variation and amplitude decay with distance r, and λ is again the wavelength. If the aperture is large and thus the beam highly directive, the approximation $\cos(\Theta) \approx 1$ is furthermore valid in the beam region. Hence, the normalized far-field and power patterns F_{Fn} and F_{Pn} can be represented simply by

$$F_{Fn}(\Theta,\Phi) = \frac{F_y(\Theta,\Phi)}{\mathrm{Max}\{F_y(\Theta,\Phi)\}} = c_F\ F_y(\Theta,\Phi), \tag{14a}$$

$$F_{Pn}(\Theta,\Phi) = F_{Fn}(\Theta,\Phi)\ F_{Fn}{}^*(\Theta,\Phi) = |F_{Fn}(\Theta,\Phi)|^2, \tag{14b}$$

where c_F represents the normalization constant. Using Eqs. 13d and 14a, most typical antenna patterns for aperture antennas neglecting cross-polarized contributions can be described theoretically. Next, some useful transformations can be applied:

$$u = \frac{x}{\lambda}, \quad v = \frac{y}{\lambda}, \tag{15a, b}$$

$$l = \sin\Theta\ \cos\Phi, \quad m = \sin\Theta\ \sin\Phi, \quad \cos\Theta = \sqrt{1 - l^2 - m^2}, \tag{16a, b, c}$$

$$l^2 + m^2 \leq 1. \tag{16d}$$

Hence, Eq. 13d results in the following form:

$$F_y(l,m) = \iint\limits_{aperture} e_{Ay}(u,v)\ \exp(j2\pi\ (u\ l\ +\ v\ m))\ du\ dv. \tag{17}$$

Now, the well-known fact is obvious that the far-field pattern of an antenna is related to the aperture field by a two-dimensional Fourier transform. Since the directional cosines l and m represent the spatial coordinates of the far-field pattern, the coordinates u and v can be interpreted as the spatial frequency components of the aperture field distribution. This interpretation is identical to the case of the conventional time domain – frequency domain relationship in signal processing. It should be further noted that the aperture field method to estimate radiation patterns is a valuable tool for aperture and especially radiometer antennas, since in most cases the required aperture fields are known with sufficient accuracy. From Eqs. 14b and 17, it is also known that the autocorrelation function of the aperture field is related to the Fourier transform of the antenna power pattern (Kraus and Marhefka 2001):

$$F_{Pn}(l,m) = \mathrm{FT}\{\mathrm{ACF}(e_{Ay}(u,v))\}, \tag{18}$$

where FT denotes the Fourier transform operator and ACF the autocorrelation operator. For the one-dimensional antenna pattern of Eq. 12, as shown in Fig. 19a, the Fourier transform in the spatial frequency domain is shown in Fig. 22.

Now, Eq. 5a can be expressed in the new coordinates given by Eq. 16:

$$T_A(l',m') = \frac{1}{\Omega_A} \int\limits_{\substack{antenna\\pattern}} T_B(l,m)\ F_{Pn}(l-l',m-m')\ \frac{dl\ dm}{\sqrt{1-(l-l')^2-(m-m')^2}}. \tag{19}$$

For narrow antenna patterns (magnitude of l−l′, m−m′ ≪1, for larger values the antenna pattern becomes zero), the square root in the denominator can be approximated by the value 1. If that equation again is interpreted as a cross-correlation integral in the spatial domain, it can be expressed in the spatial frequency domain as the product of the single Fourier transforms:

$$T_A(l,m) = \frac{1}{\Omega_A}\ \mathrm{FT}\left\{t_B(u,v)\ f^*_{Pn}(u,v)\right\}. \tag{20}$$

Theoretically, the spectrum of the brightness temperature distribution $t_B(u,v)$ can have infinite extent, since in nature a transition from one to another brightness temperature level with nearly infinite slope is possible (e.g., a metal plate reflecting cold sky radiation located on a warm background). However, the known smoothing character of the antenna pattern in the spatial domain is produced by a finite extent of its spatial frequency spectrum $f_{Pn}(u,v)$, as can be seen by the one-dimensional example of the triangle function of Fig. 22 (right).

DOI 10.1007/978-981-4560-75-7_125-1

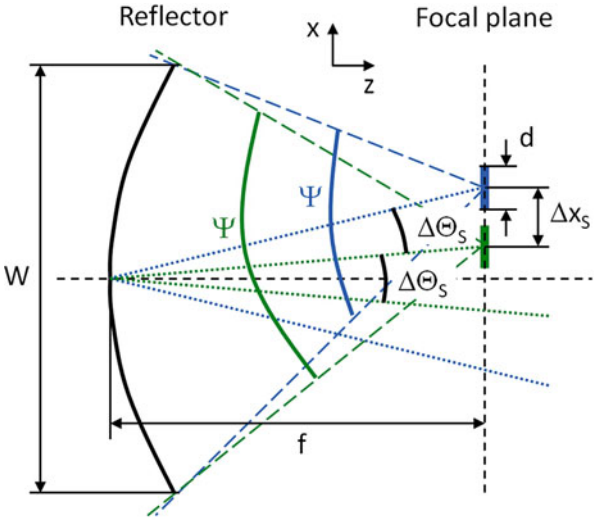

Fig. 23 One-dimensional illustration of focal plane array (FPA) relationships. The FPA elements (*green* and *blue bold lines* on the *right*) are drawn oversized and are usually small compared to dimensions W and f as the overall FPA size should be. Thus, the angular sampling interval $\Delta\Theta_S$ and the illumination angle ψ are similar for each beam generation, whose pointing direction is indicated schematically by the *dotted lines*. Only two elements are shown in asymmetric arrangement for clarity

Now, it is obvious that the imaging of a brightness temperature distribution requires discrete sampling at a finite rate in the spatial domain, either due to a finite image acquisition time or due to the given sampling pattern of a multi-beam imaging system like a focal plane array, for instance (▶ Multi-Beam Antenna Arrays, ▶ Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). Hence, sampling by the antenna at an interval of Δl in the spatial domain produces an infinite repetition of the corresponding spatial frequency spectrum at an interval of $\Delta u_R = 1/\Delta l$, assuming a one-dimensional consideration. Consequently, in order to avoid an overlap of adjacent spectra, i.e., the generation of aliasing impacts on the imaging quality, the sample rate in spatial domain has to follow the sampling theorem:

$$\Delta u_R \geq 2\,u_{\max} \Rightarrow \Delta l \leq \frac{1}{2\,u_{\max}} = \frac{\lambda}{2\,W}. \tag{21}$$

Furthermore, since $l = \sin\Theta$ is valid, it follows that $d\Theta = dl/\cos\Theta$. Hence, the smallest value for $d\Theta$ is given for $\Theta = 0$, leading to the angular sampling rule in radians:

$$\Delta\Theta_S \leq \frac{\lambda}{2\,W}. \tag{22}$$

The same rule of course is valid for the second image dimension assuming a rectangular sampling grid. Now, considering the spatial resolution of the antenna pattern of Fig. 22a and Eq. 12 to be defined by the half-power beam width in radians,

$$\Delta\Theta_{HPBW} = 0.886\ \frac{\lambda}{W}, \tag{23}$$

it follows finally that the angular sampling has to be performed at a spacing of considerably less than the spatial resolution:

DOI 10.1007/978-981-4560-75-7_125-1

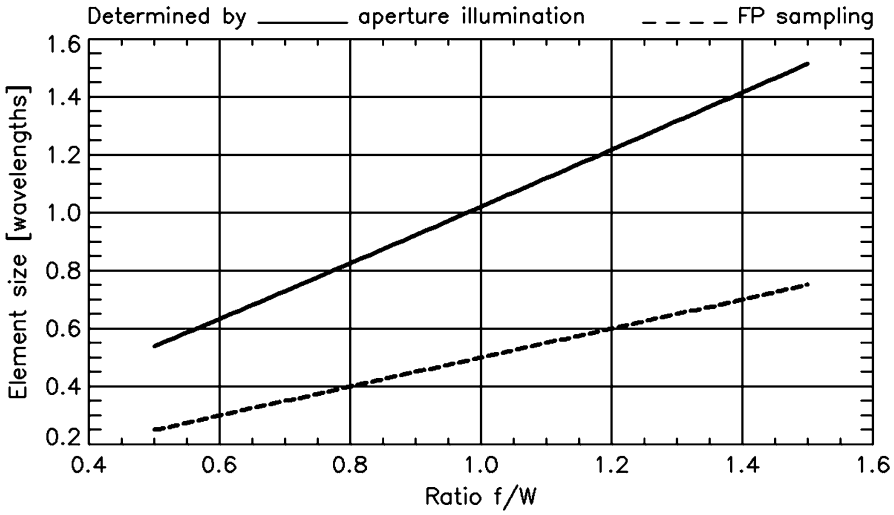

Fig. 24 Requirements on the element size of a focal plane array antenna as a function of f/W ratio of a direct-fed parabolic reflector as shown in Fig. 23. The *solid curve* represents the size as determined by a suitable reflector illumination, and the *dashed line* represents the requirement dictated by proper sampling of the focal plane

$$\Delta\Theta_S \leq 0.564 \;\; \Delta\Theta_{HPBW}. \tag{24}$$

However, it has to be noted that the sampling requirement of Eq. 22 can be relaxed to some extent for a different aperture field distribution producing a lower maximum spatial frequency. This leads on one hand to a reduction of the criterion of Eq. 22 and on the other hand to less spatial resolution (higher value) as for Eq. 23. Furthermore, in the two-dimensional case, the sampling can be performed on a hexagonal grid instead of the rectangular one, providing some higher sampling density.

Focal Plane Arrays

In a first-order approximation, the angular sampling grid as dictated by Eq. 22 is directly related to the sampling pattern in the focal plane of a reflector- or lens-based focal plane array system as given next (Johansson 1995):

$$\Delta\Theta_S \approx \frac{1}{f} \quad \Delta x_S, \text{ or } \Delta x_S \approx \frac{f}{2} \frac{\lambda}{W}, \tag{25}$$

where $\Delta\Theta_S$ is given by Eq. 22, Δx_S is the spacing of the array elements in the focal plane, and f is the focal length of the focusing unit according to Fig. 23.

Now, it has to be considered that in most applications a compact design is required, leading to values for the f/W ratio in the range ≤ 1. Thus, for the maximum element size, $d \leq \Delta x_S \leq \lambda/2$ is valid according to Eq. 25. On the other hand, the reflector has to be illuminated properly by the single element; hence,

$$\Psi \approx \frac{\lambda}{d} \tag{26}$$

is a typical choice being valid for many types of feed antennas as an estimate for the half-power beam width. The illumination angle ψ can be computed, for instance, for the shape of a parabolic reflector (Stutzman and Thiele 1998; ▶ Reflector Antennas), so that for the element size in wavelengths, the following relation is valid:

DOI 10.1007/978-981-4560-75-7_125-1

$$\frac{d}{\lambda} \approx \frac{1}{\Psi}; \quad \Psi = 4 \ \tan^{-1}\left(\frac{1}{4\ (f/W)}\right). \tag{27}$$

Now, the illumination-driven element size of Eq. 27 is plotted versus the sampling-driven element size of Eq. 25 using $d = x_S$ in Fig. 24.

This result shows that it is basically impossible to fulfill both requirements at the same time (▶ Multi-Beam Antenna Arrays, ▶ Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems). Either some undersampling of the focal plane and thus of the scene (use of larger element size and hence larger element spacing) or some more spillover contribution from the background behind the reflector (use of smaller element size producing wider beam width) or a compromise of both has to be accepted to some degree. Note that the result is valid for a staring FPA system and approximations to the basic quantities. In order to fulfill both requirements to a more satisfying level, the following measures can be undertaken:

1. Fine-tuning of parameters of a staring FPA: Since the previous derivation is based on assumptions and approximations, some fine-tuning of the single parameters can move both curves of Fig. 24 closer together. Parameters are the f/W ratio, the aperture size W (i.e., spatial resolution and spillover contribution), the feed element type in the focal plane, the shape of the reflector illumination (i.e., the aperture field distribution of the FPA elements), and the arrangement of the elements (e.g., hexagonal versus rectangular). However, it should be noted that these measures produce only limited improvement and some image distortions might remain. It should be further mentioned as well that by arranging small antenna elements very close together, problems with beam distortion, mutual coupling, and impedance mismatch can occur (▶ Suppression of Mutual Coupling between Elements in Multiple Element Antennas), which may cancel the benefits obtained by denser spatial sampling.
2. The use of other reflector shapes and multi-reflector systems: The use of a parabolic main reflector will produce higher beam distortions for elements at a large off-axis distance. Hence, the use of spherical reflectors can provide improved beam quality. In that case the FPA elements are no more to be located in a plane but rather on a spherical surface at half of the main reflector radius. Curved arrangement of the elements can also improve somewhat the performance for parabolic reflectors especially for large off-axis elements (▶ Reflector Antennas). Furthermore, the use of multi-reflector systems like Cassegrain or Gregorian arrangements can provide another degree of freedom for optimizing FPA performance. Here, as well only limited improvement can be expected, although it will be higher than for Case 1.
3. Additional mechanical motion: When a staring FPA does not sample properly a scene according to the sampling theorem, additional mechanical motion of the whole system can overcome that problem to fill the gaps. That is the way how FPA performance mostly is improved nowadays especially for systems with less constraints on imaging time but high absolute accuracy (e.g., in radio astronomy or for experimental systems) or close-to-real-time images with less accuracy requirements. In addition such an approach can increase the field of view of a radiometric imaging system considerably, since staring FPA systems have rather narrow fields of view due to the limited number of elements and degrading performance for elements at large off-axis operation. However, it should be noted that this approach increases the expense considerably especially for challenges in the FPA design and the necessary high-precision and high-dynamic mechanics.
4. FPA elements designed as phased-array or digital beamforming array: These approaches have been considered in the last decades especially for radio astronomy systems (Padman 1995; Fisher 1996; Fisher and Bradley 2000; Veidt 2006; Warnick 2013, ▶ Antennas in Radio Telescope Systems). The electronic beam-shaping capability of such a design allows applying full sampling in the focal plane

DOI 10.1007/978-981-4560-75-7_125-1

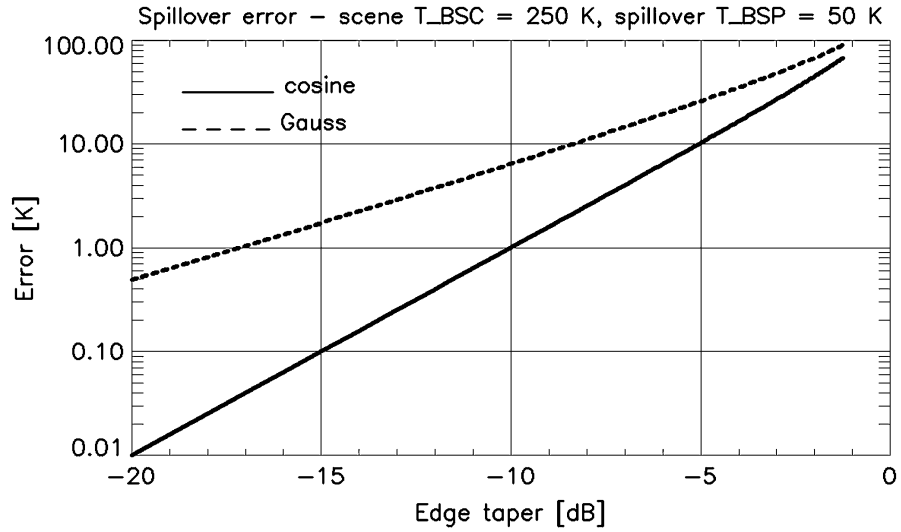

Fig. 25 Spillover error in brightness temperature determination of a scene as a function of edge taper ($p_{dB} = 10 \log p$) for a direct-fed reflector antenna. Two extreme temperature cases for the scene and the spillover region have been used for maximum error impact. The normalized power pattern of the feed element was assumed to be of shape $\cos(b\Theta)$ and $\exp(-b\Theta^2)$, b being in each case a width parameter

and thus the elimination of aliasing impacts without any mechanical motion. However, limitations on the achievable field of view remain and sequential sampling is required in the case of a phased-array approach, which again can be overcome by digital beamforming techniques due to digital generation of all antenna beams in parallel in the computer system. The latter might be the most promising technique for future FPA systems.

Spillover Impacts

Next, the error impact of spillover contributions to radiometric observations shall be briefly discussed for the one-dimensional situation, while results are representative for the two-dimensional case as well. According to Fig. 23, the antenna temperature for a feed element can be expressed as

$$T_A = \frac{T_{BSC}}{\Omega_A} \int\limits_{|\Theta| \le \Psi/2} F_{Pn}(\Theta) \quad d\Theta + \frac{T_{BSP}}{\Omega_A} \int\limits_{|\Theta| > \Psi/2} F_{Pn}(\Theta) \quad d\Theta, \tag{28}$$

where constant brightness temperature of the scene T_{BSC} and constant brightness temperature of the spillover region T_{BSP} have been assumed. Note that T_{BSC} is the brightness temperature within the focused beam of the reflector, i.e., the intended quantity to be measured. Now, the normalized antenna power pattern of the feed shall be represented by $F_{Pn}(\Theta) = \cos(b\Theta)$, which approximates a real situation quite realistically. The constant b is determined such that $\cos(b\psi/2) = p$, $0 \le p \le 1$ is valid. Furthermore, $F_{Pn}(\Theta) = 0$ for $b\Theta > \pi/2$ is assumed. Then, the integrals of Eq. 28 can be computed and the spillover error in the antenna temperature is estimated by

$$\Delta T_{spill} = T_{BSC} \quad - \quad T_A = (T_{BSC} - T_{BSP})\left(1 - \sqrt{1 - p^2}\right). \tag{29}$$

Figure 25 shows a plot of the spillover error for which $T_{BSC} = 250$ K and $T_{BSP} = 50$ K have been assumed. Those values simulate a situation where the radiometer antenna (the main beam) is pointing

toward the Earth and hence the spillover contributions are received from the sky, for instance. In addition, the situation for a Gaussian power pattern is shown which was evaluated numerically.

The spillover error is most important for measurements requiring high absolute accuracy. As can be identified, even an edge taper of −10 dB can produce a brightness temperature error of 1 K for the cosine case and up to 6 K for the Gaussian case so that at least taper values in the range of −10 to −15 dB are preferable for most Earth observation applications. In case of a bad side-lobe level distribution, the spillover impact can be even higher as shown in the examples. Since a high edge taper is accompanied by a loss in spatial resolution of the imaging system, a smaller edge taper magnitude of only a few decibels might be beneficial for security applications. However, a high spillover contribution can lower or blur the achievable brightness temperature contrast within an image. Note that the spillover impact is present for each focusing system using any single-feed or multi-feed subsystem in combination with other focusing units like reflectors (▶ Reflector Antennas) or lenses (▶ Dielectric Lens Antennas).

Sensitivity Considerations

Another important impact influencing strongly the spatial sampling of a scene is given by the requested temperature resolution, also called sensitivity, of the radiometric imaging system, since all other error sources should be kept considerably smaller than this. That instance is based on the first-order assumption that most error sources can be treated like noise and are statistically independent so that the Gaussian law of error propagation can be applied. The sensitivity describes the minimum difference in brightness temperature which can be detected by the system. It cannot be made arbitrarily good since it depends on application-driven system parameters. In a general formulation, the temperature resolution is given by Ulaby (1982):

$$\Delta T = k \frac{T_{sys}}{\sqrt{B\ \tau}} = k \frac{T_A + T_{REC}}{\sqrt{B\ \tau}}. \tag{30}$$

The finite sensitivity is caused by the noisy character of the signals to be detected and depends on the system noise temperature as the sum of the antenna temperature T_A and the average receiver noise temperature T_{REC}, and the product of the system bandwidth B and the integration time τ per spatial sample. The factor k comprises the impact of the specific receiver architecture and the imaging method to be used and can have thus a wide range of values ≥1. The value 1 is valid for a single total-power receiver integrated in a mechanical scanner sequentially sampling a scene, for instance.

Now, an imaging task usually is determined by the requirement to image a scene of certain size at a certain spatial resolution within a given time. Consequently, the integration time per spatial sample can be expressed as follows:

$$\tau = \frac{\Delta\Omega}{4\Omega_{FOV}} t_{frame}. \tag{31}$$

The angle increment ΔΩ represents the two-dimensional angular resolution cell and Ω_{FOV} the two-dimensional field of view, both expressed in square degrees. The factor 4 results from the requirement of sampling at a rate of about half the spatial resolution as discussed previously, and t_{frame} is the duration to acquire a complete image. Combining both equations results in

$$\Delta T = \frac{2kT_{sys}}{\sqrt{Bt_{frame}}} \sqrt{\frac{\Omega_{FOV}}{\Delta\Omega}}, \tag{32}$$

DOI 10.1007/978-981-4560-75-7_125-1

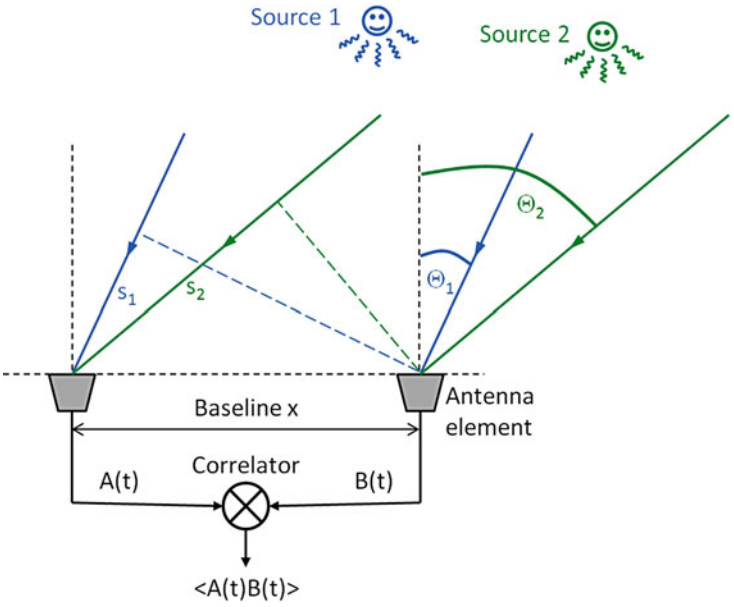

Fig. 26 Schematic principle of a two-element interferometer. Radiation of a certain direction is received by two antennas and fed to a complex correlator providing the time-averaged quadrature components of the signal multiplication. The distance of the two antenna elements is called the baseline x

which is a general relation between spatial resolution and sensitivity of the imaging process. The second term on the right side considers the quantities of the antenna system, i.e., the beam size and the range of scan angles. Equation 32 and practical numbers for the single quantities indicate that for most applications, a compromise between spatial resolution and sensitivity is mandatory. As an example consider the real-beam scanner described in Peichl et al. (2013). Here, the system temperature T_{sys} is about 800 K for an assumed antenna temperature of 300 K, the effective system bandwidth B is about 15 GHz, the image acquisition time t_{frame} is 1 s, the scanned field of view Ω_{FOV} is 360° × 30°, the angular resolution cell is about $\Delta\Omega = 0.75° \times 0.75°$, and the factor k has the value 1 for a single total-power-receiver imaging system. Thus, the corresponding temperature resolution ΔT is 1.8 K.

Aperture Synthesis Imaging

The interest in aperture synthesis imaging for radiometric applications started in the 1980s when high spatial resolution at lower frequencies became of interest (Ruf et al. 1988; Le Vine 1990). That combination requires large antenna structures which cannot be moved any more mechanically at a given speed for reasonable frame rates. As an alternative for focal plane arrays or phased arrays (► Phased Array, ► Applications of Phased Array Feeders in Reflector Antennas), the method of aperture synthesis is a vivid approach, which is used in radio astronomy since the 1950s (Thompson et al. 2001, ► Antennas in Radio Telescope Systems). The big advantage here is that the required number of single-antenna/receiver elements can be reduced considerably compared to the other electronic scanning approaches. In the last decades increased research and development for applying aperture synthesis to various applications has been undertaken (Camps 1996; Peichl et al. 1998; Harvey and Appleby 2003; Barré et al. 2008; Rautiainen et al. 2008; Martín-Neira et al. 2014).

DOI 10.1007/978-981-4560-75-7_125-1

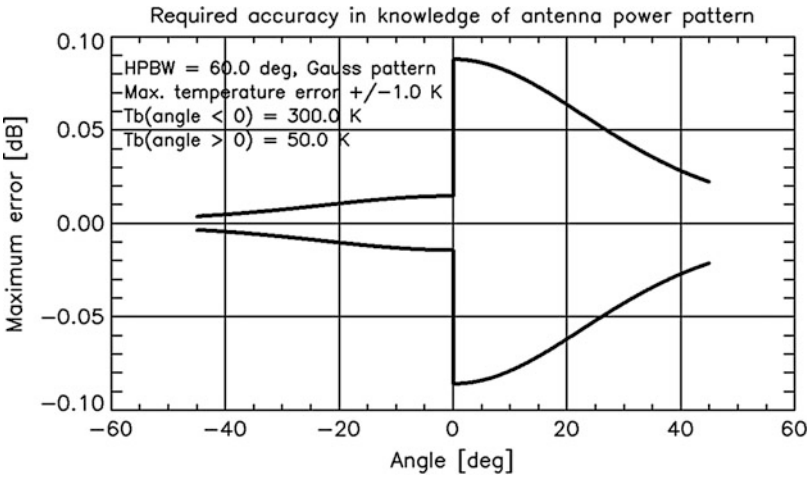

Fig. 27 Required absolute accuracy in the knowledge of the normalized antenna power pattern for two as constant assumed brightness temperature levels (at angles $< 0°$ and $> 0°$). The power pattern was assumed to be of Gaussian shape with a half-power beam width of 60°. A maximum tolerable temperature error of ±1 K was set

The Van Cittert-Zernike Theorem

Aperture synthesis imaging is based on the use of a multitude of two-element interferometers in a suitable arrangement, each one providing a different distance between the elements. The situation for a single interferometer is shown schematically in Fig. 26 for the one-dimensional case.

The interferometer correlates the two signals received by the antenna elements in phase quadrature so that the correlator output is the time average of two signal products, $<A(t)B(t) >$ and $< A(t)B(t\text{-}90°/(2\pi f)>$. Assuming that $B(t) = E_0 \sin(2\pi ft)$ and $A(t) = E_0 \sin(2\pi f(t\text{-}s/c))$, where E_0 is the signal amplitude, f the microwave frequency, and s the path difference between the two signals for a source in the far field located at an angle Θ_i with respect to boresight, the quadrature output can be combined in a complex notation:

$$cor(x) = I(x) + jQ(x) = \frac{1}{2}E_0^2\left[\cos\left(2\pi\frac{x}{\lambda}\sin\Theta_i\right) + j\sin\left(2\pi\frac{x}{\lambda}\sin\Theta_i\right)\right]. \tag{33}$$

Now, it is evident that in the case of a single source, one complex measurement allows to determine the angular position Θ_i of the source and its radiation power proportional to E_0^2, since the baseline x and the wavelength $\lambda = f/c$ are known. If there are two sources as shown in Fig. 26, one single measurement will not be sufficient, since the signals from both sources superimpose and hence no clear discrimination is possible. However, by adding another measurement at a different baseline, x will provide the lacking information. Consequently, by adding more and more sources, more and more baselines will be required. In the end a continuous distribution of sources in space requires a continuous correlation function cor (x) and the relation between the radiation power distribution $E_0^2(\Theta)$ and cor(x) is a Fourier transform, provided that the sources are located in the far field of the interferometers and that the sources are statistically independent or uncorrelated, which is valid for thermal radiation as in the case of radiometric imaging. That instance is called the Van Cittert-Zernike theorem and provides the basis for aperture synthesis imaging. For the two-dimensional case and an ideal system (i.e., identical antenna elements, ideal and identical frequency responses of the receivers, narrow bandwidth, ideal complex correlation), the theorem is given by

DOI 10.1007/978-981-4560-75-7_125-1

$$vis(u,v) = \frac{1}{\Omega_A} \iint_{\Omega_A} \frac{F_{Pn}(l,m)}{\sqrt{1-l^2-m^2}} \; T_B(l,m)\exp(-j2\pi(ul+vm))dl\,dm. \tag{34}$$

The function vis(u,v) now is called visibility function and represents a measurement of the two-dimensional spatial frequency spectrum of the brightness temperature distribution T_B(l,m) of the scene being of course proportional to the radiation power distribution, F_{pn}(l,m) is the antenna power pattern of the single-antenna elements, and l and m are the directional cosines as defined by Eq. 16. The quantity Ω_A again is the antenna element's solid angle, which in the case of aperture synthesis determines the field of view to be imaged. The coordinates u and v are the baseline components in a rectangular coordinate system and represent the metric length in wavelengths, i.e., u = x/λ and v = y/λ.

Impact of the Antenna Patterns

Now, it is evident that from a measurement of vis(u,v), the demanded brightness temperature distribution T_B(l,m) can be determined by an inverse Fourier transform as the image reconstruction procedure. However, the direct transformation result is given by the transform of the whole kernel in the integral, from which T_{Brec} as the reconstructed version of the true temperature T_B can be computed by

$$T_{Brec}(l,m) = T_B{}'(l,m) \; \frac{\sqrt{1-l^2-m^2}}{F_{Pn}(l,m)} \; \Omega_A; T_B{}'(l,m) = \mathrm{FT}\{vis(u,v)\}. \tag{35}$$

Basically, the image could be reconstructed in the whole angular area of the antenna pattern. In doing so the problem is that the power level of the antenna pattern vanishes usually more rapidly than the square root function of Eq. 35 does, and hence a division by small numbers can occur. That instance will amplify unavoidable errors in the knowledge of the antenna power pattern considerably, making results at these locations useless. Now, the uncertainty in the knowledge of the antenna pattern can be assumed to be F_{Pn}'(l,m) = F_{Pn}(l,m) + ΔF_{Pn}(l,m). So if a maximum temperature error of ± ΔT is given, the required accuracy in the knowledge of the antenna power pattern can be determined from Eq. 35 where F_{Pn}' is used instead of F_{Pn}:

$$\Delta F_{Pn}(l,m) = -F_{Pn}(l,m) \; \frac{\Delta T}{T_B(l,m) \; + \; \Delta T}. \tag{36}$$

A plot of the required accuracy for the knowledge of the antenna power pattern is shown for a Gaussian shape F_{Pn}(l) = exp(−b l^2) in Fig. 27 where again l = sinΘ is valid. It can be identified that even in the center direction, a high accuracy in the knowledge of the antenna pattern is required to keep the desired temperature error in the given limit. In the outer regions of the pattern, this requirement is even much stronger. Pattern knowledge accuracy in the order of a few hundreds of a decibel is hard to achieve by measurements or keep over the lifetime of an instrument so that the regions far out from the center are not to be used when high absolute-temperature accuracy is demanded. However, the accuracy requirement is more relaxed when a lower brightness temperature level is observed.

Based on the previous insight, it is evident that another approach to address the influence of the antenna pattern in the application of aperture synthesis has to be used. A practical way is to combine this task with the overall calibration of the imaging system. While for classical scanner systems using single receivers, the so-called hot-cold method is applicable for calibration (Ulaby 1982), where two well-known but different temperature references are measured by the receivers, a synthesis system has to use the overall scene within the field of view of the single-antenna element. The challenge now is to find large enough

DOI 10.1007/978-981-4560-75-7_125-1

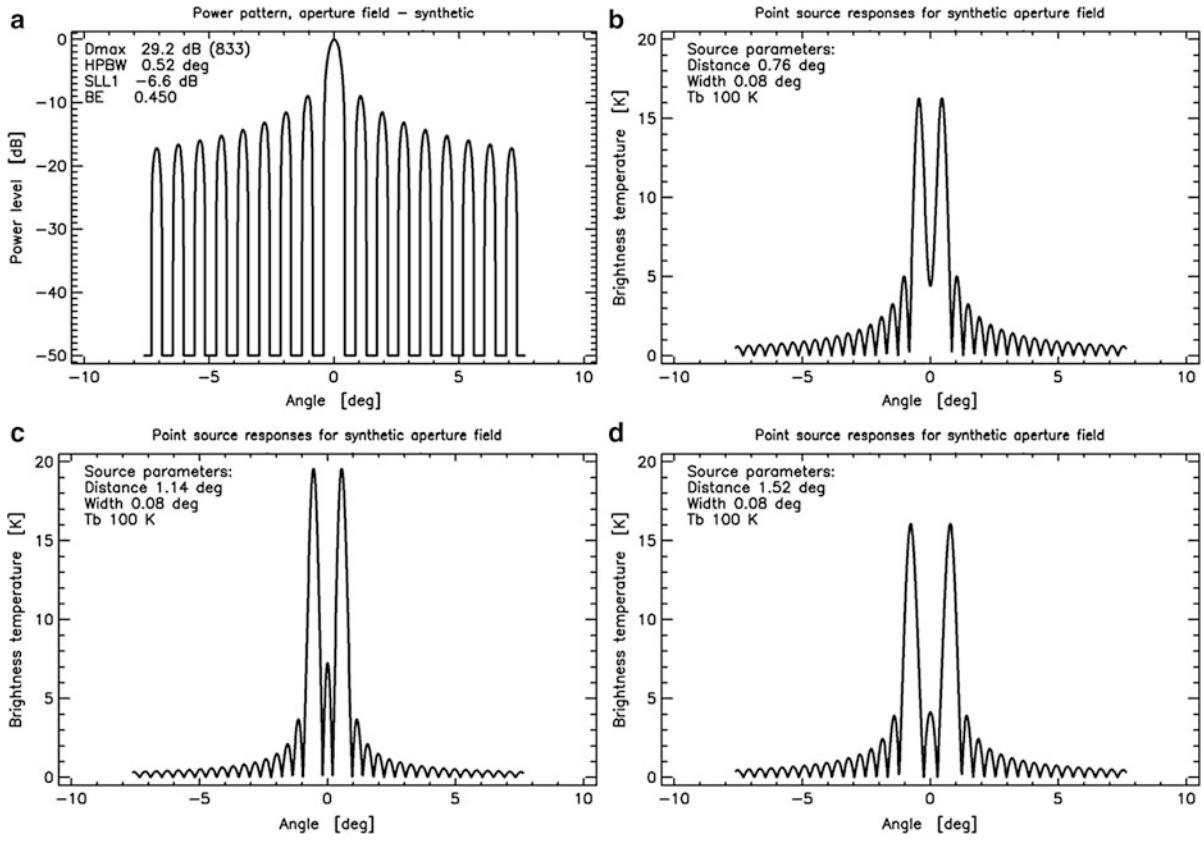

Fig. 28 Image (**a**): Normalized synthetic power pattern of an aperture synthesis system having identical parameters as the antenna types of Fig. 19. The spacing W here corresponds to the maximum baseline. Images (**b**–**c**): Point source responses of the identical situation as in Figs. 20 and 21. Image (**d**): Response for an additional separation of the two-point sources. Note that the magnitude of the brightness temperature is shown in (**b**–**d**) for better comparison (some side-lobe areas would have negative values)

angular regions in nature offering a well-known brightness temperature distribution. In the case of spaceborne radiometers, such an area is given by the galactic pole to which the instrument is pointed from time to time to perform the calibration measurement (Brown et al. 2008). Other regions on Earth are, for instance, the open ocean or regions on the Antarctic or the rain forest in South America. For ground-based systems, the sky region can be used under clear-sky conditions. However, in most of the last examples a model of the true brightness temperature distribution has to be used additionally in order to address angular dependencies of the brightness temperature. A more controlled calibration environment is given by the use of an anechoic chamber at known physical temperature, but in that case no in situ calibration during a later system operation is possible and only a characterization prior to a mission is feasible. A more detailed treatment of the impact of antenna patterns in aperture synthesis systems is discussed in Camps et al. (2006).

Sampling the U-V Plane and Spatial Resolution

Since the visibility function can only be sampled by a finite number of antennas in an aperture synthesis array, again the sampling theorem has to be considered. As described previously, the antenna power pattern determines the field of view to be imaged and hence the range of spatial coordinates in l and m direction to be considered. Assuming an ideally symmetric power pattern of maximum extensions l_{max}

DOI 10.1007/978-981-4560-75-7_125-1

and m_{max} in positive and negative coordinate direction, the sampling requirement for the u-v plane to avoid aliasing in the reconstructed image can be formulated in rectangular coordinates as follows:

$$\Delta u \leq \frac{1}{2\ l_{max}}; \quad -l_{max} \leq l \leq +l_{max}$$
$$\Delta v \leq \frac{1}{2\ m_{max}}; \quad -m_{max} \leq m \leq +m_{max} \tag{37a, b}$$

Note that Δu and Δv again are given in wavelengths. Considering now the full hemisphere for which the l-m representation is valid, i.e., $0° \leq \Theta \leq \pi/2$ and $0° \leq \Phi \leq 2\pi$, the values $l_{max} = 1$ and $m_{max} = 1$ hold and $\Delta u = \Delta v = 0.5$ results. Thus, the smallest spacing of the single-antenna elements has to be half a wavelength for imaging a full hemisphere. If, for instance, $\Theta_{max} = 30°$, then $l_{max} = m_{max} = 0.5$ and $\Delta u = \Delta v = 1$ is required. It should be noted that the single-element antenna pattern is not completely zero for values larger than l_{max} and m_{max}, and hence some aliasing may remain in the final image depending on the pattern power level at those ranges.

Since furthermore the dimensions of the synthesis array cannot extend to infinity, the spatial frequency spectrum has upper limits u_{max} and v_{max}. In accordance with the treatise of section Spatial Sampling Requirements, that instance results in a finite spatial resolution of the imaging process. If now an ideal point source at location l_0, m_0 is measured according to Eq. 35, the visibility function takes the form $vis(u,v) = a_0 \exp(-j(ul_0 + vm_0))$, where a_0 is a constant including all other prefactors. Inserting that visibility function in the inverse transform of Eq. 35, the result for the normalized reconstructed point source response is given by

$$F_{Pn,\,syn}(l,m) = \frac{\sin\left(2\pi\ u_{max}\ (l-l_0)\right)}{2\pi\ u_{max}\ (l-l_0)} \quad \frac{\sin\left(2\pi\ v_{max}\ (m-m_0)\right)}{2\pi\ v_{max}\ (m-m_0)}. \tag{38}$$

Note the notation $F_{Pn,syn}$ for the point source response, being similar to the one of the antenna power patterns of the spatially scanning radiometer systems. The reason for that is that, as previously mentioned, the antenna pattern can be determined by scanning a point source, and hence Eq. 38 is simultaneously interpreted as the synthesized antenna beam of the aperture synthesis array. The synthetic character can be recognized as well by the fact that it can have negative values according to the known sin(x)/x behavior, but it represents a power pattern. Furthermore, Eq. 38 represents a type of natural response, since no weighting was applied to the ideal visibility function prior to reconstruction. Note that Eq. 38 is the result of a continuous function in the u-v plane according to Eq. 34, which can be closely approximated by adequate sampling.

Now, by applying Eq. 11 to the synthesized beam of Eq. 38 again for the one-dimensional case, the imaging result for two adjacent point sources at different distances can be computed again for the previous examples. The synthetic beam and the result for three point source distances are shown in Fig. 28. Note the narrow beam width of 0.52° compared to the real-beam systems shown in Fig. 19 and the very high side-lobe level at −6.6 dB. Since the synthetic beam has negative side lobes, the computation of the directivity is a high number due to the cancelation of positive and negative side lobes in evaluating the integral of Eqs. 5b and 6. However, by considering the directivity as the number of point sources which can be resolved within 360°, this approach is useful. For computing the beam efficiency, the antenna solid angle in this case was computed by using the magnitude of the synthetic power pattern in Eq. 5b. This approach more realistically considers the degrading impact of the side lobes in the imaging quality by providing a rather low value for the beam efficiency.

DOI 10.1007/978-981-4560-75-7_125-1

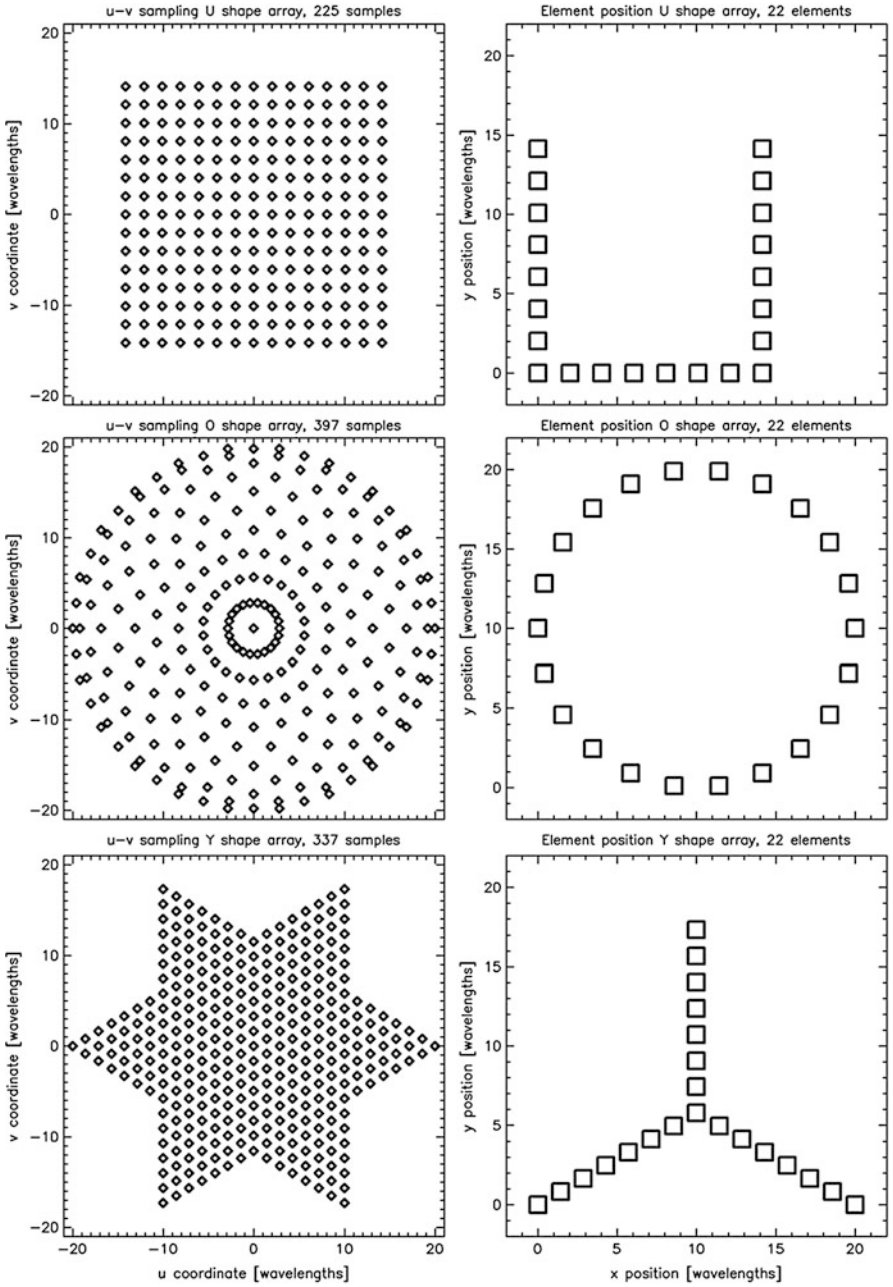

Fig. 29 Array configurations (*right*) for aperture synthesis (U, O, Y shape) and corresponding sampling patterns in the u-v plane (*left*). The maximum baseline for all configurations was set to 20 wavelengths and the number of antenna/receiver elements is always 22

The images (b)–(d) clearly show the result that for a synthetic imaging system of the identical size, the highest separation quality of the two sources can be achieved, thus providing superior capabilities for object detection in security applications, for instance. On the other hand, the high side-lobe contributions can degrade the absolute accuracy considerably. This can be observed by the fact that for the case of image (c), the maximum point source levels are higher than for situations (b) and (d) although this source separation is in between those two examples.

Now, it should be noted that the single-visibility samples can be weighted prior to image reconstruction, in order to manipulate the shape of the synthesized beam, by modifying Eq. 35:

DOI 10.1007/978-981-4560-75-7_125-1

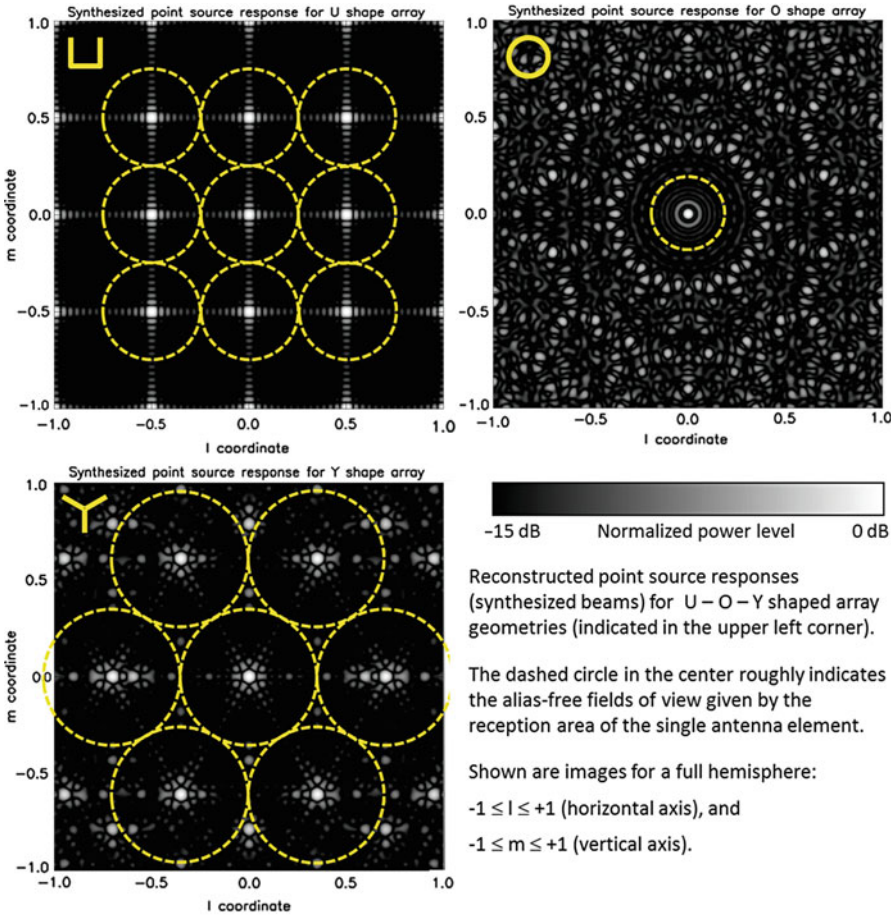

Fig. 30 Reconstructed point source responses for the aperture synthesis arrays of Fig. 29

$$T_B''(l,m) = \mathrm{FT}\{vis(u,v) \quad wsf(u,v)\}. \tag{39}$$

The function wsf(u,v) now can be understood as a twofold operator, one for weighting of the visibility amplitudes at locations (u, v), and another one for the shape of the sampling grid in the u-v plane. The weighting functionality follows exactly the well-known windowing operation of standard signal theory (Harris 1978), and the sampling functionality is briefly discussed next.

Array Design in Aperture Synthesis

Besides high spatial resolution, real-time capability, and large fields of view, the dominant power of aperture synthesis is given by the capability of using sparse arrays to synthesize a full aperture. Since each single element contributes to several baselines, an array can be designed to have low redundancy so that each baseline is only once existent, providing a unique visibility sample. On regular grids for the single elements, some redundancy will remain, but for the addition of some statistical shift in each position, all baselines will be at least slightly different. So, the goal of designing an array besides other constraints will be the maximum performance in synthesized beam shape by using the lowest number of single-antenna/receiver elements.

Now, Eq. 39 can be transformed to the spatial domain, resulting in a convolution of the brightness temperature $T_B'(l,m)$ and the weighting and sampling function WSF(l,m):

DOI 10.1007/978-981-4560-75-7_125-1

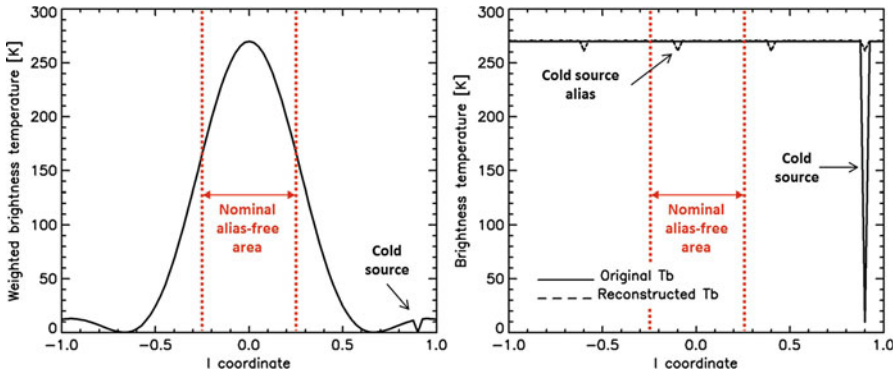

Fig. 31 *Left*: Simulated brightness temperature distribution of a scene weighted by an antenna power pattern as given by Eq. 12. The scene itself consists of a constant background at 270 K and a cold source of 10 K at l = 0.9; *right*: original and reconstructed brightness temperature distributions. For the synthesis array, an element size of W = 1.5λ, a constant distance of Δu = 2λ, and a maximum baseline of $u_{max} = 20\lambda$ have been assumed. The shape of the antenna pattern was corrected for in the reconstruction

$$T_B''(l,m) = \mathrm{FT}\{vis(u,v)\} * \mathrm{FT}\{wsf(u,v)\} = T_B'(l,m) * WSF(l,m). \tag{40}$$

The function WSF(l,m) now is the synthesized beam which the synthesis instrument can provide at best, assuming in other respects an ideal system as done before. If the sampling theorem is fulfilled and the weighting is constant for each u-v sample, the function WSF(l,m) becomes identical to the synthesized beam of Eq. 38. Now, the interesting question is which element locations, together with adequate weighting, deliver what type of synthesized beam. In Fig. 29 some simple array articulations and their corresponding sampling pattern in the u-v plane are shown.

For performance comparison, two important design parameters were set identically, the maximum baseline length of the array, i.e., the displacement between the two most distant elements, and the total number of elements. Three array geometries are considered, U, O, and Y shapes, indicating the basic array structure. As well the distance between adjacent elements is set constant along the basic structures. All three arrays generate very different sampling patterns in the u-v plane. The U shape produces a rectangular pattern and the lowest number of independent baselines, since due to the array geometry, a lot of identical baselines are produced, proving no additional spatial frequency information. The O geometry generates the largest synthesized area and no regular sampling pattern and the medium number of independent samples. The density of samples as well varies depending on the location in the u-v plane. The Y shape produces a hexagonal sampling grid, the highest sampling density in average, and the highest number of independent samples. The size of the synthesized area is in between the O and U cases.

For such arrays the synthesized beam or the point source response is computed for the whole l-m plane, i.e., $l^2 + m^2 \leq 1$, and it is shown in Fig. 30. The impact of the sampling pattern can be clearly identified by the different appearance of fully pronounced spatial repetitions of the point source responses, i.e., the aliases. The rectangular sampling lattice produces the aliases and the side lobes along the cardinal lines in horizontal and vertical direction. At other locations the side-lobe levels are smaller than for the two other cases.

The dashed circles are produced by the boundaries of the symmetrically assumed reception area of an antenna, just avoiding aliasing in the central region of the l-m plane, thus being the alias-free region of the imaging process. It can be observed that the Y array generates a replica of the point source on a hexagonal lattice and the largest alias-free field of view. Accordingly, the U-shape array produces a replica on a rectangular grid and a smaller alias-free field of view. A very narrow alias-free field of view is generated by the O array, since the average sampling density is the lowest one. Due to the irregular sampling grid, no

DOI 10.1007/978-981-4560-75-7_125-1

distinct replica of the point source response is visible, but a high number of lower-level sources and side lobes appear distributed over the whole l-m plane. The O array under the given conditions produces the highest spatial resolution (narrowest synthesized beam), since the highest number of large baselines is available.

It should be further noted that the responses are only shown down to −15 dB and that the high side-lobe levels may be not suitable for radiometric measurements. However, as mentioned before, standard windowing can be applied to reduce side lobes at the cost of spatial resolution. In no case of course, the aliases can be suppressed by such means. As a conclusion the array design has large impact on the imaging quality of an aperture synthesis instrument. Depending on the application, the largest field of view and the highest spatial resolution together with the acceptable side-lobe level have to be balanced against each other for the most suitable design. Several other geometries than the shown ones have been investigated and applied in the past (Thompson et al. 2001; Hall 2006; Jirousek et al. 2010; Dong and Li 2010; Schuetz et al. 2013).

The sampling requirements according to Eq. 37a,b require in theory that from outside the limits given by l_{max} and m_{max}, no radiation is received. Since the visible scene is determined by the single-element antenna pattern, this requirement cannot be fulfilled in practice and a certain nonzero decay of the pattern outside that boundary (i.e., outside the centric circles in Fig. 30) has to be accepted. Mostly, aperture antennas are used for synthesis arrays so that a first-order approximation of such an antenna pattern can be given by Eq. 12, considering a one-dimensional analysis for the moment. If now the visible scene limit is set to the first null of the antenna pattern and by using Eq. 37a,b, it follows

$$l_{\max} = \sin \Theta_{\max} = \frac{\lambda}{W}, \qquad \Delta u = \frac{\Delta x}{\lambda} \leq \frac{1}{2\ l_{\max}} \text{ or } \Delta x \leq \frac{W}{2}. \tag{41a, b}$$

Hence, the metric distance Δx between the spatial frequency samples should be at least half the aperture size W of the antenna element, which cannot be fulfilled everywhere in the u-v plane. Physically, only $\Delta x \geq W$ can be realized as minimum spacing. Possible aliasing impacts on synthesis imaging shall be illustrated exemplarily in the one-dimensional simulation of Fig. 31.

The original brightness temperature distribution weighted by the antenna power pattern, as it is observed by the single element of the synthesis array, is shown on the left. The nominal alias-free area as given by Eq. 37a,b is indicated at $l = \pm 0.25$. A cold source is located significantly outside the alias-free area but it is folded back in the alias-free range in the reconstructed image. This is caused by the fact that the antenna pattern is not zero outside the alias-free range due to its finite aperture size of $W = 1.5\lambda$ and that the element spacing of the synthesis array was chosen on a regular grid at a distance of $\Delta u = 2\lambda$.

As a conclusion from the previous analysis, the following recommendations can be formulated:

- The use of antenna elements whose pattern sufficiently vanishes outside the demanded alias-free field of view to negligible values. This requirement can hardly be fulfilled. Only antenna types whose physical width or diameter can be made sufficiently small in parallel to producing high directivity and low side-lobe levels are valid. Useful antenna types are based on dielectrics like microstrip-based antennas or dielectric rods. However, it should be noted that such antennas in a close arrangement can produce strong mutual coupling (▶ Suppression of Mutual Coupling between Elements in Multiple Element Antennas), which can influence the antenna pattern and the power match in an unacceptable way (reconstruction errors, loss of sensitivity).

- No use of rectangular sampling grids since possible aliases superimpose constructively in the nominal alias-free region. Improved behavior is achieved by a hexagonal sampling grid in the two-dimensional case due to the higher sample density or by non-regular sampling grids, since in that case possible aliases distribute across the whole nominal alias-free area and thus do not impact massively a certain region.

Sensitivity in Aperture Synthesis

In contrast to real-beam imaging systems, an aperture synthesis radiometer generates an image by contributions from all individual antenna/receiver elements to each pixel. Hence, the same is valid for the noise content of the image. Furthermore, a synthesis array artificially produces an effective antenna aperture according to its focused beam, but the physical radiation collecting area is much smaller or, in other words, the number of collected microwave photons from the scene for a certain duration is less. Obviously, that instance has impact on the final temperature resolution of the reconstructed image. The corresponding equation for an aperture synthesis instrument can be approximated by (Le Vine 1990)

$$\Delta T = \frac{T_{sys}}{\sqrt{2\,B\,t_{frame}}}\sqrt{\frac{2}{n\ (n-1)}}\frac{\Omega_{FOV}}{\Delta\Omega} \approx \frac{T_{sys}}{\sqrt{B\ t_{frame}}}\frac{1}{n}\frac{\Omega_{FOV}}{\Delta\Omega}. \tag{42}$$

Here, identical quantities have been assumed for each antenna/receiver, i.e., the system noise temperature T_{sys}, the system bandwidth B, and the antenna element solid angle Ω_{FOV} defining the scene size. The quantity $\Delta\Omega$ represents the solid angle of the synthesized beam, and the number n is the number of antenna/receiver elements given the case that $n \gg 1$ is large and that only nonredundant baselines are accounted for. Note that zero redundancy of a synthesis array is only possible for a small number of elements and that redundancy counts for large n and regular element arrangements have single cluster points instead of a uniform distribution. Hence, the redundancy is often not used for improving the sensitivity in the image in order to avoid entering other errors due to element imbalances. Furthermore, Eq. 42 assumes that no errors are produced by aliasing impacts as described previously. As an example consider the SMOS system (Barré et al. 2008; Font et al. 2010) for $T_{sys} = 450$ K, B = 19 MHz, $t_{frame} = 1.2$ s, n = 69, $\Omega_{FOV} \approx 70° \times 70°$, and $\Delta\Omega = 1.5° \times 1.5°$, resulting in a temperature resolution of $\Delta T \approx 3$ K, which is well in accordance with predicted and measured values.

A comparison of Eq. 32 for the real-beam case and Eq. 42 for the synthetic-beam case results in

$$\Delta T_{syn} = \frac{1}{2\,k\,n}\quad\sqrt{\frac{\Omega_{FOV}}{\Delta\Omega}}\quad\Delta T_{real}. \tag{43}$$

Thus, the sparse array character of aperture synthesis takes effect such that the synthetic-beam sensitivity ΔT_{syn} is degraded by the square root of the ratio of scene solid angle and beam solid angle compared to the real-beam sensitivity ΔT_{real}. That disadvantage is compensated to some extent by two times the number of elements used for the synthetic array. As a rough tendency it should be noted that extreme thinning of the synthesis array and large fields of view at very high spatial resolution will degrade sensitivity, unless some significant redundancy in form of increasing the number of elements (without increasing additionally spatial resolution) is accepted.

DOI 10.1007/978-981-4560-75-7_125-1

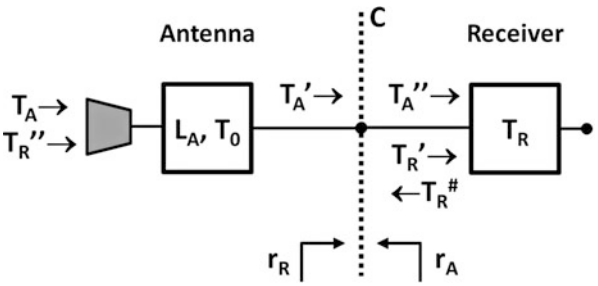

Fig. 32 Simple model for noise computation of the antenna/receiver interaction considering antenna losses due to ohmic or dielectric attenuation and reflection losses due to impedance mismatch (▶ Impedance Matching and Baluns). L_A and T_0 represent the attenuation factor and physical temperature of the antenna, T_R is the receiver noise temperature, and r_A and r_R are the complex voltage reflection coefficients at reference plane C as to be measured toward the antenna and toward the receiver. *Arrows* indicate flow direction of the temperatures or noise power, respectively

Losses of the Antenna System

Sufficient sensitivity of a radiometric imaging system, i.e., sufficient temperature resolution in the final image product, requires a low-noise figure or noise temperature of the system itself, according to Eqs. 30, 32, and 42. The noise contribution of the imaging system has basically two sources: (a) dissipation losses and (b) reflection losses (▶ Transmission Lines). The fundamental rule for computing the overall noise behavior of a receiving system is given by the cascade formula for noisy two-ports (Pozar 2005):

$$T_{cas} = T_{e1} + \frac{T_{e2}}{G_1} + \frac{T_{e3}}{G_1 G_2} + \ldots \tag{44}$$

Here, T_{cas} is the total or equivalent noise temperature of a serial connection of noisy two-ports to be located at the input of the first two-port, assuming in this case all two-ports to be noise-free. The quantities T_{ei} and G_i represent the equivalent noise temperatures and power gains of the single two-ports. It is evident that for the lowest noise temperature T_{cas}, the first components dominate and should have a low-noise temperature and high gain. Note that the term gain can mean either amplification, i.e., $G > 1$, or attenuation, i.e., $0 \leq G \leq 1$. In the latter case it is common to use the reciprocal of G, i.e., $L = 1/G$ with $1 \leq L \leq \infty$, and call it attenuation factor or loss factor.

Since the antenna system is the first component of any radiometric sensing system, its losses are of special interest. Usually, the antenna is a passive microwave structure built to physically collect free-space waves and guide those to a following transmission line and the receiver input. Thus, the basic antenna is an attenuator and its equivalent noise temperature can be described by (Ulaby 1982)

$$T_{att} = (L_{att} - 1)T_0, \tag{45}$$

where L_{att} is the power attenuation factor and T_0 is the physical temperature of the antenna or attenuator, respectively. Furthermore, both, the antenna and the receiver, have individual complex input impedances leading to complex individual power reflection coefficients (▶ Impedance Matching and Baluns), where the latter of course usually should be as low as possible.

Impact of Dissipation and Reflection Loss

In order to estimate both loss types for a radiometer antenna – dissipation and reflection losses –, the equivalent block diagram of Fig. 32 can be used.

The dissipation loss is considered by the single-primed antenna temperature T_A' according to

DOI 10.1007/978-981-4560-75-7_125-1

Table 1 Computed power transfer efficiency p for various values of power reflection coefficients. The worst case has been assumed for which the phase difference of the product $r_A \times r_R$ in the denominator of Eq. 47b is 180°

$\lvert r_A\rvert^2$ [dB] $\lvert r_R\rvert^2$ [dB]	−10	−20	−∞
−10	0.67	0.84	0.90
−20	0.84	0.96	0.99
−∞	0.90	0.99	1.00

$$T_A' = \frac{1}{L_A}\ T_A + \left(1 - \frac{1}{L_A}\right) T_0. \tag{46}$$

Consequently, for minimum dissipation loss $L_A = 1$, the true antenna temperature is transferred to the reference plane C, i.e., $T_A' = T_A$, and for very large losses $L_A \to \infty$, the true antenna temperature is completely blocked, i.e., $T_A'' = T_0$. Usually, the loss factor will be close to 1 for practical antennas but not identical to 1.

The reflection loss can be determined by the double-primed antenna temperature T_A'' following (Otoshi 1968)

$$T_A'' = p\ T_A' + (1-p) T_R^{\#},$$
$$p = \frac{\left(1 - |r_A|^2\right)\left(1 - |r_R|^2\right)}{|1 - r_A r_R|^2}. \tag{47a, b}$$

The quantity p represents the power transfer efficiency determined by the mismatch between the antenna and the receiver reflection coefficients. For ideal match, i.e., $r_A = r_R^*$, the efficiency becomes maximum, i.e., $p = 1$ and $T_A'' = T_A'$. If one or both power reflection factors are maximum, i.e., $|r_A|^2 = 1$ or $|r_R|^2 = 1$, the efficiency becomes minimum, i.e., $p = 0$ and $T_A'' = T_R^{\#}$. Obviously, the practical cases are somewhere in between and the efficiency should become close to one for minimum reflection losses.

The quantity $T_R^{\#}$ represents the noise temperature generated by the receiver and transmitted toward the reference plane C. Two special cases of receiver design have to be discriminated for its value. In the first

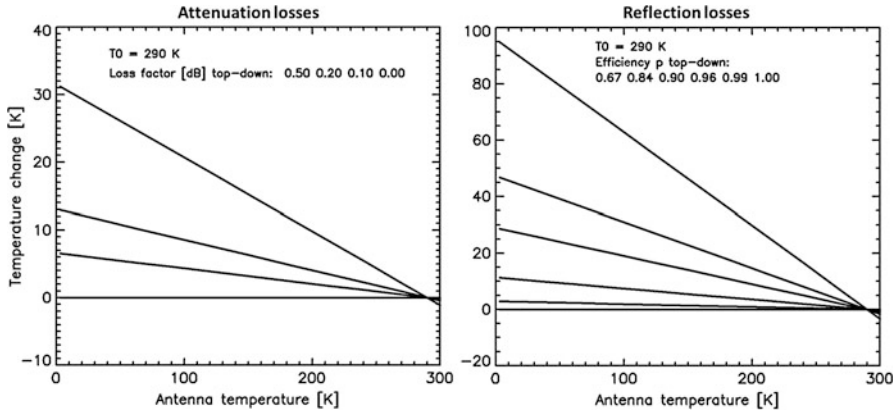

Fig. 33 Change in the antenna temperature T_A'' at the input of the receiver according to Fig. 32. On the left side only dissipation losses have been considered, i.e., $p = 1$. On the right side only reflection losses were simulated, i.e., $L_A = 1$. The values of the efficiency p correspond to the reflection coefficients of Table 1

Table 2 Computed values for receiver noise temperatures at different locations according to Fig. 32 and ratios of temperature resolution including antenna losses ΔT_A over temperature resolution without antenna losses ΔT. ΔT and ΔT_A are computed according to Eq. 30 for k = 1. Parameters are as follows: $L_A = 1.047$ (0.2 dB), $p = 0.84$, and $T_0 = 290$ K

L_I [dB]	T_R [K]	T_R' [K]	T_R'' [K]	$\Delta T_A/\Delta T$ $T_A = 300$ K	$\Delta T_A/\Delta T$ $T_A = 3$ K
No isolator	30	30	57	1.08	1.82
No isolator	300	300	447	1.25	1.49
No isolator	1,000	1,000	1,460	1.35	1.46
1.0	30	113	129	1.04	1.14
1.0	300	453	483	1.04	1.07
1.0	1,000	1,334	1,400	1.04	1.05

case, the first component of the receiver directly at the input is an isolator with a low forward loss factor L_I assumed to have as well a physical temperature T_0. Isolators are often used to improve impedance match (▶ Impedance Matching and Baluns) and to block local oscillator leakage from a possible mixer toward the antenna. Since the isolator has a high attenuation in its backward direction toward the antenna, its equivalent noise temperature is T_0, and hence $T_R^{\#} = T_0$ is valid. In order to avoid additional losses and for very broadband receivers, the isolator sometimes is omitted and then $T_R^{\#} = T_R$ is valid.

Combining Eqs. 46 and 47a,b now allows considering the full impact of all loss types together:

$$T_A'' = p\ \left(\frac{1}{L_A}\ T_A + \left(1 - \frac{1}{L_A}\right) T_0\right) + (1-p)\ T_R^{\#}, \tag{48}$$

$$T_R^{\#} = \begin{cases} T_0 & \text{with isolator,} \\ T_R & \text{without isolator.} \end{cases} \tag{49}$$

In the following the single impact of both loss types shall be illustrated graphically. For the attenuation factor of the antenna, practical values of 0.5, 0.2, 0.1, and 0.0 dB have been considered. The power reflection coefficients were selected according to Table 1.

Figure 33 shows the change of the antenna temperature T_A'' at the input of the receiver in dependence of the true antenna temperature at the antenna free-space terminal and the two different sources of loss. An isolator at physical temperature T_0 on the input of the receiver has been considered. In both loss cases a significant increase of the modified antenna temperature can be observed, especially for low levels of the true antenna temperature. That instance is important for calibration issues when the antenna is not part of the calibration loop, which is the case when internal loads are used and fed to the receiver by switches. In that case, a very precise knowledge of the attenuation and reflection behavior of the antenna/receiver combination is mandatory. If calibration is performed using external reference sources to be observed by the antenna, the losses are included in the calibration process and do not distort correct brightness temperature measurements. However, it is evident that antenna dissipation in the order of 0.1 dB or less and power reflection coefficients of at least −20 dB are recommended.

The other important impact of antenna losses is the increase of the equivalent receiver noise temperature T_R'' at the antenna input terminal according to Fig. 32, leading on the one hand to a decrease in sensitivity or temperature resolution and on the other hand to a reduction of the receiver's dynamic range. Since the total noise temperature directly at the receiver input is $T_A'' + T_R'$, that quantity can be transformed to the antenna input, resulting in $T_A + T_R''$, where T_R'' can now be computed as follows:

DOI 10.1007/978-981-4560-75-7_125-1

Table 3 Conductivity values for different metals

Metal type	Silver (AG)	Copper (CU)	Gold (AU)	Aluminum (AL)	Brass (BR)	Stainless steel (SS)
σ [S/m] $\times 10^7$	6.17	5.81	4.10	3.82	1.50	0.11

$$T_R'' = (L_A - 1)\ T_0 + L_A\left(\frac{1}{p} - 1\right) T_R^{\#} + \frac{L_A}{p} T_R', \tag{50}$$

$$T_R' = \begin{cases} T_R & \text{without isolator,} \\ (L_I - 1)\ T_0 + L_I\ T_R & \text{with isolator.} \end{cases} \tag{51}$$

In case of an isolator at the receiver input, the quantity L_I is again the power loss factor and its physical temperature is assumed to be T_0. In the following Table 2, a few values for practical numbers are given to illustrate the impact.

It can be recognized that the isolator lowers the impact of changing receiver noise temperatures on the degradation of temperature resolution, since for nearly all six cases in the lower-right edge of Table 2, the ratio is quite similar. However, it has to be noted that the original receiver noise temperature T_R is always increased by the isolator according to Eq. 51, being an attenuator as the first input component, and thus the sensitivity ΔT is generally degraded. If no isolator is used, especially the impedance mismatch losses (▶ Impedance Matching and Baluns) can produce a stronger dependence of the sensitivity on the actual antenna temperature. As a rule of thumb, the antenna losses can produce significant degradation of temperature resolution except very low levels $L_A < 0.1$ dB, and high power transfer efficiency $p > 95$ % (see Table 1 for reflection coefficients) can be achieved.

Magnitude of Antenna Dissipation Loss

Generally, it is hard to determine precisely the power dissipation, i.e., ohmic and dielectric losses, of an antenna, especially for the desired low-loss conditions. In fact this quantity is included in the ratio of antenna directivity and antenna gain, but mostly only the gain is measured and the directivity is computed numerically from electromagnetic models. So, the dissipation loss cannot be estimated with sufficient precision. Since radiometric measurements are very sensitive to antenna losses, as pointed out before, they are suitable to perform this task. It should be remembered that even a dissipation loss of 0.01 dB can produce an increase of the antenna temperature of about 0.7 K according to Eq. 46 for $T_A = 10$ K and $T_0 = 300$ K, which can be measured by a properly calibrated radiometer with sufficient accuracy.

The range of antenna systems used for radiometric measurements is quite large as indicated already in section Overview on Radiometer Antennas. There are pure feed-horn-reflector systems in fully mechanical scanners (▶ Reflector Antennas), folded optical systems using quarter-wave plates for focal plane arrays, sparse arrays of patch (▶ Microstrip Patch Antennas) or horn antennas for aperture synthesis, slotted waveguides for frequency scanning (▶ Waveguide Slot Antennas and Arrays, ▶ Tapered Slot Antennas, ▶ Travelling-wave Antennas (Including Leaky Wave and Surface Wave Antennas)), or lens-based approaches (▶ Dielectric Lens Antennas) for multi-beam generation just to mention few of them. Depending on the technology, the antenna dissipation losses can be higher or lower depending on the media (metals and dielectrics) and the path lengths along which the waves have to interact with those. Lowest losses should be expected for pure metallic interaction like for parabolic reflectors and horn feeds, for which a theoretical estimate shall be given next.

For antennas being small compared to the wavelength like short dipoles or narrow loops, the attenuation factor can be computed by

DOI 10.1007/978-981-4560-75-7_125-1

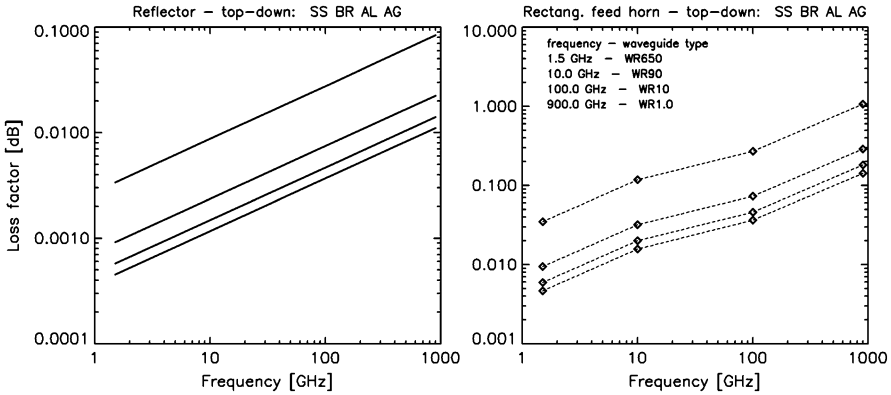

Fig. 34 Computed power loss factors of the reflector part (*left*) and the feed horn (*right*) of a reflector antenna for various metal types as a function of frequency. The metals are indicated as given in Table 3. For the horns standard rectangular waveguides have been chosen according to the frequency, and a length of 5λ has been assumed

$$L_A = \frac{R_{rad} + R_{dis}}{R_{rad}}, \tag{52}$$

where R_{rad} is the radiation resistance accounting for the really radiated/received power conversion and R_{dis} is the dissipation resistance representing power conversion by ohmic and dielectric losses. Note that the sum of both resistances represents the real part of the complex antenna impedance (▶ Impedance Matching and Baluns). For electrically small antennas, analytic expressions for both quantities exist (Stutzman and Thiele 1998), but unfortunately those antennas are rather not used for radiometric applications due to their relatively high dissipation loss and badly shaped antenna pattern. For very low-loss reflector antennas (▶ Reflector Antennas), an experimental approach is described in Skou (1997) using radiometric sky measurements. According to this investigation, the power reflectivity of a well-conducting smooth surface is given by

$$r = 1 - \frac{4R_S}{Z_0}, \tag{53a}$$

$$R_S = \sqrt{\frac{\pi f \mu}{\sigma}}, \qquad Z_0 = \sqrt{\frac{\mu}{\varepsilon}}. \tag{53b, c}$$

The quantity R_S is the surface resistivity of the reflector material and Z_0 is the intrinsic impedance of the medium in which the wave propagates. In case of air or vacuum and a non-ferromagnetic reflector material, the free-space permeability $\mu = \mu_0 = 4\pi \times 10^{-7}$ H/m and the free-space permittivity $\varepsilon = \varepsilon_0 = 8.854 \times 10^{-12}$ F/m can be used and $Z_0 \approx 377\ \Omega$ is valid. The quantity σ is the conductivity of the reflector material and some values for different metals are given in Table 3.

Using Eq. 1 and $t = 0$, and the relation $e = 1 - 1/L_{A,refl} = 1 - r$, the power attenuation factor for a well-conducting reflector now can be computed:

$$L_{A,refl} = \left(1 - \frac{4R_S}{Z_0}\right)^{-1}. \tag{54}$$

Since the reflector antenna furthermore consists of the reflecting surface and a feed antenna, the loss factor of the latter one has to be estimated as well. For that purpose the impact of the feed is approximated by the

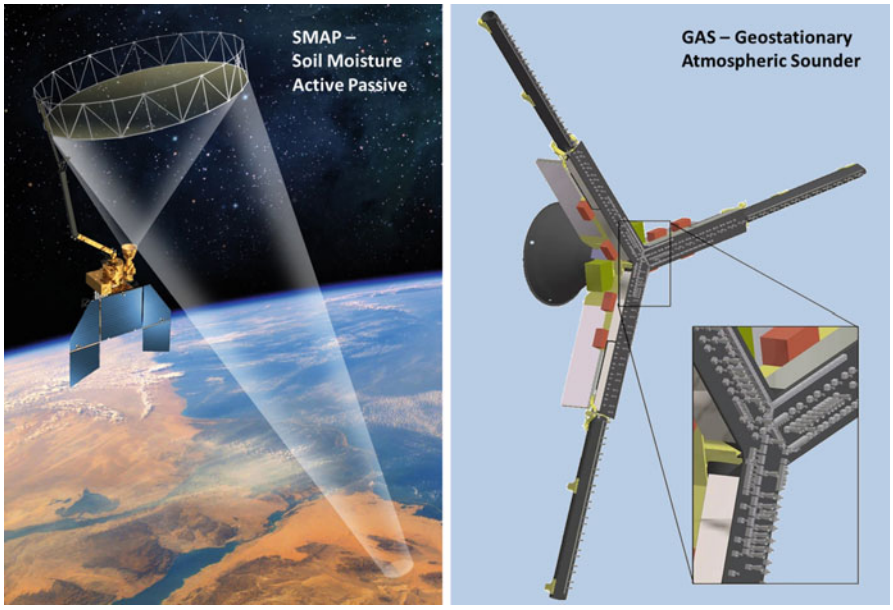

Fig. 35 *Left*: artist view of the SMAP conical scanner system in space (Courtesy of NASA/JPL-Caltech, USA); *right*: drawing of the GAS Y-shaped antenna array. Each frequency band is realized as a separate Y array scaled for identical spatial resolution (Courtesy of ESA-ESTEC, Netherlands)

attenuation of a piece of rectangular waveguide (▶ Transmission Lines), which is representative if the flare angle of such a horn antenna opens smoothly over a certain length Δz. In that case the wall currents in the flare region are similar to those of the waveguide, and the attenuation constant α and the loss factor $L_{A,\text{feed}}$ for the dominant mode TE_{10} are estimated by (Orfanidis 2008)

$$\alpha = \frac{R_S}{Z_0}\left(\frac{1}{b} + \frac{2}{a}\left(\frac{\lambda}{2a}\right)^2\right)\left(1 - \left(\frac{\lambda}{2a}\right)^2\right)^{-1/2}, \tag{55}$$

$$L_{A,\,\text{feed}} = \exp(2\alpha\,\Delta z). \tag{56}$$

The quantities a and b are the width and height of the rectangular waveguide and λ is the free-space wavelength. Thus, the total power loss factor L_A for the reflector antenna is finally estimated to be

$$L_A = L_{A,\,refl}\;\; L_{A,\,\text{feed}}. \tag{57}$$

Figure 34 shows computed results of L_A for the reflector material and the pseudo feed horn as described before. It has to be noted that the total loss of both antennas is given by Eq. 57 and thus by the sum of the decibel values from the figures. As can be observed, the total loss factor is dominated by the feed horn and can reach values of 0.1 dB at high millimeter-wave or even more at submillimeter-wave frequencies (▶ Millimeter-Wave Antennas and Arrays, ▶ Mm-Wave Sub-mm-wave Antenna Measurement, ▶ Photomixer Antennas at Terahertz, ▶ Terahertz Antennas and Measurement). Hence, even the most lossless antenna structure, as the purely metallic reflector antenna is, has to be taken into account when high absolute accuracy in brightness temperature measurements is required. Fortunately, the feed horn has most impacts, and it can be included much easier in external calibration loops as the whole reflector due to size constraints. However, it should be noted that the computation of the reflector losses assumes that the surface is sufficiently smooth with respect to the wavelength and clean and not oxidized, respectively. In

reality, the estimated values can be even much higher due to certain surface roughness being typically in the order of up to few micrometers.

Summary

The previous sections have demonstrated that a multitude of antenna types and antenna systems are used and can be used for radiometric applications in microwave remote sensing. The main candidates are mechanical scanners using typically moving reflector antennas (▶ Reflector Antennas), focal plane arrays using folded microwave optics and horn arrays to produce multiple real antenna beams (▶ Multi-Beam Antenna Arrays, ▶ Radio-Frequency Beam-Forming for Scanned and Multi-Beam Antenna Systems), and aperture synthesis where sparse arrays form synthetically multiple antenna beams based on sampling the spatial frequency spectrum. Promising as well is digital beamforming where the signals of the single channels of an array are sampled and digitized directly and the beam generation is as well done synthetically later in a digital processor. Since this type of sampling an aperture allows highest flexibility in signal processing, a multitude of beam-shaping approaches like in aperture synthesis or phased-array imaging is possible. The present bottleneck here is the amount of data to be stored and processed which can be tremendous for large antenna systems and high bandwidths. Lens-based imaging systems producing multiple real beams are rather rarely used but may become more attractive when highly integrated receiver modules (systems on chip) are available from mass production at affordable cost (▶ On-Chip Antennas).

Independent of the imaging principle, care must be applied to the antenna system design, since it determines the spatial resolution, the field of view or scene size, the amount of aliasing impacts, and the imaging time. In addition, since the antenna is the first component of the radiometer system, it can have a large influence on the sensitivity by dissipation and reflection losses in the case of finite conductivity and/or dielectric attenuation and impedance mismatch between antennas and receivers (▶ Impedance

Matching and Baluns). Although such quantities in the value range of tenths or hundredths of decibels for low-loss antenna structures are not a problem for radar systems or communication links, the error in brightness temperature estimation can be too high since the signals to be measured are similar in power to the radiometer's own noise floor. Hence, the antenna should be incorporated in the calibration loop, if possible, but this is very often not feasible due to its size. In that case precise measurement on component level and sophisticated modeling is required to account for these impacts mathematically.

In Earth observation from space, next-generation systems are still using mechanical scanner technology as it is intended for the National Aeronautic and Space Administration - Jet Propulsion Laboratory (NASA-JPL) SMAP mission to be launched early in 2015 (Entekhabi et al. 2010). Soil Moisture Active Passive (SMAP) is using a 6-m mesh reflector (► Reflector Antennas, ► Space Antennas including Terahertz Antennas) in a conical scan to determine soil moisture over land passively and actively at L-band frequencies, achieving a 40-km ground resolution from a 685-km orbit. An artist view of the system in space is shown in Fig. 35 (left). NASA and ESA both performed studies (Geostationary Synthetic Thinned Aperture Radiometer (GeoSTAR) and Geostationary Atmospheric Sounder (GAS)) on using aperture synthesis technology for high-frequency Earth observation from a geostationary orbit, i.e., at about 36,000 km distance (Tanner 2007; Christensen et al. 2007, ► Space Antennas including Terahertz Antennas, ► Terahertz Antennas and Measurement). Using bands around 50–56, 118, 183, and 380 GHz for the monitoring of atmospheric temperature, humidity profiles, and rain mapping, the Y-shaped arrays have an arm length of maximum 4 m, achieving a ground resolution of about 30 km for the lowest frequency. A schematic of the GAS antenna array is shown in Fig. 35 (right). While the GeoSTAR system is intended to use a stationary Y-shaped array requiring a very high number of single-antenna elements for proper u-v-plane sampling, the GAS system is using a highly thinned around boresight rotating Y array in order to fill up sufficiently the u-v plane. For both systems, the realization is not known yet and a possible launch could be toward 2020.

In a more distant future, it could be possible and attractive for spaceborne Earth observation to use multiple satellites on different orbits for synthesizing very large antenna apertures. Each single satellite can carry an autonomous aperture synthesis array in order to perform like SMOS, but it can be synchronized in phase with the other satellites to build a large aperture when the satellites have a suitable constellation in orbit. Thus, selected areas on the ground could be imaged at very high resolution, provided the satellite constellation can be adjusted accordingly. Such an approach is similar to very-long-baseline interferometry (VLBI) from radio astronomy (► Antennas in Radio Telescope Systems), where array sizes of thousands of kilometers are achieved by connecting coherently several single radio telescopes across the world (Felli and Spencer 1989; Thompson et al. 2001).

Another potential present and future application area for radiometric imaging is given by the security and safety market, where each type of new information source of physically different nature is of big interest. Here, very high spatial resolution and real-time capability are often the main drivers for system design, being especially useful for enhanced vision in surveillance, reconnaissance, or status control in general (e.g., assisted viewing for pilotage, detection of concealed objects, indication of potential dangers, etc.). In order to avoid too large antenna structures, very often millimeter waves or submillimeter waves have to be used (► Millimeter-Wave Antennas and Arrays, ► Mm-Wave Sub-mm-wave Antenna Measurement) if sufficient penetration to media of interest is guaranteed (e.g., atmospheric obstacles, dielectric covers, etc.). The real-time requirement demands for systems of high frame rates, being only feasible by electronically scanning concepts or hybrids of those, and some optional mechanical scanning support.

Figure 36 (left) shows a schematic of an approach combining aperture synthesis and frequency scanning in order to reduce considerably the number of required channels (Schreiber 2014). Such a system is intended for large-area surveillance at longer distances of up to few hundred meters. For a first

DOI 10.1007/978-981-4560-75-7_125-1

system design, it is estimated that by using about 35 slotted waveguide antennas (► Waveguide Slot Antennas and Arrays, ► Tapered Slot Antennas) and receivers, a field of view of 120° × 30° (aperture synthesis × frequency scan direction) at a resolution of 0.4° can be scanned in Ka band (&30-40 GHz). By using adequate high-speed samplers and digitizers, a frame rate of up to 10 f/s is expected for 2 K sensitivity.

Figure 36 (right) shows an approach for three-band imaging at millimeter and submillimeter waves based on a focal plane array consisting of cryogenically cooled integrated antenna-bolometer structures (Luukanen et al. 2013, ► Millimeter-Wave Antennas and Arrays, ► Mm-Wave Sub-mm-Wave Antenna Measurement, ► Photomixer Antennas at Terahertz, ► Terahertz Antennas and Measurement). The system is intended for concealed weapon detection on persons at a close distance of a few meters. The vertical arrangement of the single channels allows in combination with a rotating beam tilting unit to scan an area of about 22° × 11° at angular resolutions of 0.17°–0.46° depending on the frequency band. Sensitivity between 0.2 and 0.8 K shall be feasible at a frame rate of 10 f/s. High losses of the overall antenna structure and the lack of low-noise amplification are compensated by cryogenic cooling of the receivers at 7 K and bandwidths of hundred to several hundred GHz (► Ultra-Wideband Antennas).

Previous examples of near-future approaches have indicated the way forward by using highly integrated receiver technology in combination with suitable antenna array structures as the most promising solutions for many applications. Here, the design of the antenna system plays a central role in the overall system development in order to achieve high sensitivity and high spatial resolution at high frame rates and sufficiently large fields of view.

Transmission Lines

Cam Nguyen*
Department of Electrical and Computer Engineering, Texas A&M University, College Station, TX, USA

Abstract

This chapter presents the theory of transmission lines, which are essential for the design of radiofrequency (RF) circuits associated with antennas and transmission-line-based antennas. It includes the transmission-line equations and important transmission-line parameters such as characteristic impedance, propagation constant, phase velocity, effective relative dielectric constant, dispersion, loss, distortion, impedance, reflection coefficient, etc. It also presents synthetic transmission lines, a class of transmission lines that can be implemented using only lumped elements, which could be useful for RF circuits needed for on-chip antenna interface. Moreover, the chapter covers the most commonly used printed-circuit transmission lines for RF systems, which also include those that can be realized in multilayer structures that are attractive for printed-circuit antennas and associated RF circuits.

Keywords

Transmission lines; TEM transmission line; Quasi-TEM transmission line; TEM mode; Quasi-TEM mode; Coplanar waveguide; CPW; Microstrip line; Coplanar strips; Slot line; Strip line; Multilayer transmission lines; Antenna; Microwave; Millimeter wave; RF

Introduction

Transmission lines are important elements for radiofrequency (RF) systems, which operate at different frequencies in the electromagnetic (EM) spectrum up to terahertz (THz). Transmission lines, both theory and design, are needed not only for specific RF circuits required for antennas to function properly, such as antenna-feeding or antenna-interface circuitry, but also for various antennas such as transmission-line-based traveling antennas – for example, slot-line antennas. The design of RF circuits needed for antennas, and hence antennas eventually, would not be complete, or even optimum, without considering transmission lines. Especially, at extremely high frequencies, such as those in the upper end of the millimeter-wave range, and for on-chip implementations, such as direct integration of RFICs (RF-integrated circuits) and antennas, transmission lines are inevitable. Even when the use of on-chip transmission lines to provide interface with on-chip antennas is not appealing due to their relatively large size as compared to on-chip lumped elements, RF designers should make use of the theory of transmission lines to properly implement on-chip lumped elements to simulate transmission lines for antenna interface to achieve certain features that lumped elements cannot achieve otherwise. Therefore, it is crucial that RF engineers have sufficient knowledge in transmission lines and consider their possible use in antennas. The basics of transmission lines can be found in various textbooks in electromagnetics (e.g., Paul et al. 1998). This chapter will address the fundamentals of transmission lines including transmission-line equations and important transmission-line parameters such as characteristic impedance, propagation constant, phase velocity,

*Email: cam@ece.tamu.edu

DOI 10.1007/978-981-4560-75-7_129-1

effective relative dielectric constant, dispersion, loss, distortion, impedance, reflection coefficient, etc. It also discusses synthetic transmission lines, which enable the design of transmission lines using lumped elements useful for on-chip antenna interface and commonly used printed-circuit transmission lines including those in multilayer structures that are essential for antennas and associated RF circuits.

Transmission-Line Equations

Transmission lines, like other elements in RF circuits, possess certain electrical properties which are needed for circuit design. The characteristics of any transmission line are governed by a set of equations commonly known as transmission-line equations. To facilitate the analysis of transmission lines under different excitations and operating conditions, these equations are classified into two kinds: general transmission-line equations, which are valid for excitations of any time variation, and sinusoidal steady-state or time-harmonic transmission-line equations, which are applicable only when the excitation is a sinusoidal waveform and the transmission line is under a steady-state operation. The transmission-line parameters such as characteristic impedance, however, are the properties of a transmission line itself regardless of the excitation, provided that the magnitude of the excitation is within a certain limit.

General Transmission-Line Equations

A transmission line exists only when it has at least two conductors. Consequently, a (two-conductor) transmission line is normally represented as two parallel lines as shown in Fig. 1a. The transmission line is assumed to be uniform; i.e., its geometry, including the conductor dimensions, spacing between them, and dielectric media around the conductors remain constant along the transmission-line length or its longitudinal (or axial) direction. From electromagnetic (EM) theory, it is known that a signal, or wave, propagating along the line is due to the interchange of the electric and magnetic energy. As a signal traverses the line, it carries with it the electric and magnetic fields. It is also known that as a signal propagates along the line, it suffers losses due to imperfect conductors and dielectrics constituting the line. Using circuit theory, a transmission line can then be characterized electrically as a combination of inductors, representing the magnetic energy; capacitors, representing the electric energy; resistors, representing the loss due to conductors; and other resistors representing the loss due to dielectrics. In view of this and the fact that circuit theory is only valid at frequencies where dimensions are very small compared to the wavelengths at those frequencies, the transmission line is divided into many infinitesimal elements, each having a length of *dz* much shorter than the operating wavelength. Each tiny element can

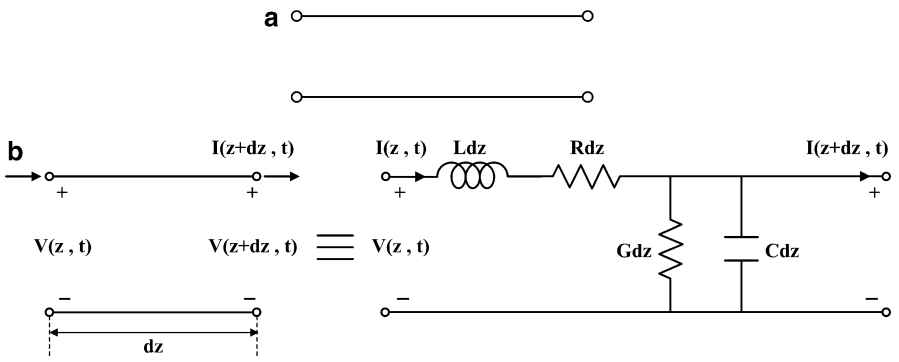

Fig. 1 (**a**) A transmission line represented by two parallel conductors and (**b**) an equivalent circuit of an infinitesimal transmission line; $V(z,t)$, $V(z+dz,t)$, and $I(z,t)$, $I(z+dz, t)$ are the instantaneous voltages and currents at the input (z) and output ($z+dz$), respectively

DOI 10.1007/978-981-4560-75-7_129-1

now be represented by an equivalent circuit consisting of a series inductance *Ldz*, a series resistance *Rdz*, a shunt capacitance *Cdz*, and a shunt conductance *Gdz*, as shown in Fig. 1b. *L*, *R*, *C*, and *G* are the series inductance (*H*/*m*), series resistance (Ω/*m*), shunt capacitance (*F*/*m*), and shunt conductance (*S*/*m*) per unit length of the transmission line, respectively. *L* and *C* account for the respective magnetic and electric energy of the signal stored in the transmission line. *R* and *G* account for the respective losses due to the imperfect conductors and dielectrics used in the transmission line. The loss due to the dielectrics is sometimes called leakage loss. This loss is associated with a shunt current existed across the dielectrics due to their finite conductivity, which represents the leakage current. This leakage current is substantial for high-loss substrates, such as silicon used for RFICs, and has significant effects in RF circuits realized on these substrates, not only because of the resulting dielectric loss in the substrates but also because of the coupling that current causes among different circuit elements. Each transmission line is characterized by its own *R*, *L*, *G*, and *C*, or its series impedance $Z = R + j\omega L$ and shunt admittance $Y = G + j\omega C$ per unit length.

A (finite-length) transmission line can be considered as consisting of many minuscule sections connected in cascade or, electrically, a continuous distribution of R, L, G, and C along the line. As such, a transmission line can be modeled as a cascade of many equivalent circuits, each corresponding to an infinitesimal section as shown in Fig. 1b. This distributed-circuit model for a transmission line is valid only when we assume no mutual impedance exists between adjacent sections making up the transmission line. This implies that there is no mutual coupling between these adjacent elements. Consequently, it can be assumed that there are no longitudinal fields E_z and H_z for the wave traversing the line, assuming *z* is the direction of propagation. The electric and magnetic fields of the wave thus have only *x* and *y* components; that is, they lie in the planes orthogonally transverse to the propagation direction. Such a wave is called transverse electromagnetic (TEM) wave or mode. In practice, however, there exists very small longitudinal fields along transmission lines, and the corresponding wave is referred to as quasi-TEM wave. All equations derived in this section are thus valid only for the TEM or quasi-TEM mode. Other waves having either E_z or H_z, or both, can also exist on transmission lines and are called higher-order waves or modes. These modes are significant only near the feed points to the transmission line, around a discontinuity on the line, or at very high frequencies. For most uniform transmission lines used in practice, TEM of quasi-TEM mode is the principal mode and is referred to as the transmission line's dominant mode.

Applying Kirchhoff's voltage and current laws to the circuit in Fig. 1b gives, after some manipulations,

$$\frac{\partial V(z,t)}{\partial z} + L\frac{\partial I(z,t)}{\partial t} + RI(z,t) = 0 \tag{1}$$

$$\frac{\partial I(z,t)}{\partial z} + C\frac{\partial V(z,t)}{\partial t} + GV(z,t) = 0 \tag{2}$$

$$\frac{\partial^2 V(z,t)}{\partial z^2} - LC\frac{\partial^2 V(z,t)}{\partial t^2} - (RC + LG)\frac{\partial V(z,t)}{\partial t} - RGV(z,t) = 0 \tag{3}$$

$$\frac{\partial^2 I(z,t)}{\partial z^2} - LC\frac{\partial^2 I(z,t)}{\partial t^2} - (RC + LG)\frac{\partial I(z,t)}{\partial t} - RGI(z,t) = 0 \tag{4}$$

For lossless transmission lines, Eqs. 1, 2, 3, and 4 become, after letting $R = G = 0$,

DOI 10.1007/978-981-4560-75-7_129-1

$$\frac{\partial V(z,t)}{\partial z} + L\frac{\partial I(z,t)}{\partial t} = 0 \tag{5}$$

$$\frac{\partial I(z,t)}{\partial z} + C\frac{\partial V(z,t)}{\partial t} = 0 \tag{6}$$

$$\frac{\partial^2 V(z,t)}{\partial z^2} - LC\frac{\partial^2 V(z,t)}{\partial t^2} = 0 \tag{7}$$

$$\frac{\partial^2 I(z,t)}{\partial z^2} - LC\frac{\partial^2 I(z,t)}{\partial t^2} = 0 \tag{8}$$

Equations 1–2 and 5–6 are classified as the telegraphist's equations, and Eqs. 3–4 and 7–8 are called the transmission-line equations. Equations 3 and 4 can also be viewed as the wave equations for lossless transmission lines – similar to the wave equations involving electric and magnetic fields derived from Maxwell's equations. All these equations are general and hold for voltages and currents with arbitrary time dependence and for any transmission line. They become simpler when the applied voltage or current is the sinusoidal time-varying function.

Practical transmission lines are lossy, and the voltage and current waves or signals will be attenuated as they propagate along the line.

Sinusoidal Steady-State Transmission-Line Equations

Another form of transmission-line equations is now derived by assuming that the applied voltage varies sinusoidally with time and the transmission line is operated under a steady-state condition (i.e., no transients). Using the phasor representations, the instantaneous voltage and current can be written, with reference to cosωt, as

$$V(z,t) = \mathrm{Re}\left[V(z)e^{j\omega t}\right] \tag{9}$$

$$I(z,t) = \mathrm{Re}\left[I(z)e^{j\omega t}\right] \tag{10}$$

where $V(z)$ and I(z) represent the phasor voltage and current, respectively, which are functions of location (z) only, and Re (.) denotes the real part. Substituting Eqs. 9–10 into 1–4 yields

$$\frac{dV(z)}{dz} + (R + j\omega L)I(z) = 0 \tag{11}$$

$$\frac{dI(z)}{dz} + (G + j\omega C)V(z) = 0 \tag{12}$$

$$\frac{d^2V(z)}{dz^2} - \gamma^2 V(z) = 0 \tag{13}$$

$$\frac{d^2I(z)}{dz^2} - \gamma^2 I(z) = 0 \tag{14}$$

DOI 10.1007/978-981-4560-75-7_129-1

where

$$\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)} \tag{15}$$

As will be seen later, γ dictates the propagation of voltage and current waves along the line and hence is called the propagation constant of the transmission line. Similarly, α (in Neper/m or Np/m) and β (in radian/m) determine the attenuation and phase per unit length of the transmission line and are called the attenuation and phase constant, respectively. α in Np/m can be converted into α in decibel/m by $\alpha[\mathrm{dB/m}] = 8.686\alpha[\mathrm{Np/m}]$.

Equations 11, 12, 13, and 14 can also be obtained by replacing the partial derivative with respect to t, $\partial/\partial t$, with $j\omega$ in Eqs. 1, 2, 3, and 4, recognizing the equivalence between them for sinusoidal signals. Equations 11 and 12 are called the sinusoidal steady-state or time-harmonic telegraphist's equations, and Eqs. 13 and 14 are known as the sinusoidal steady-state or time-harmonic transmission-line equations or the transmission-line equations in the frequency domain. The transmission-line Eqs. 13 and 14 are especially used to analyze transmission lines operating under sinusoidal steady state, which is encountered in continuous-wave (CW) operations of electrical circuits. It should also be noted that all the transmission-line equations are applicable to any transmission lines. For lossless transmission lines, these equations become, after setting R=G=0 in Eqs. 11, 12, 13, and 14,

$$\frac{dI(z)}{dz} + j\omega CV(z) = 0 \tag{16}$$

$$\frac{dV(z)}{dz} + j\omega LI(z) = 0 \tag{17}$$

$$\frac{d^2V(z)}{dz^2} + \beta^2 V(z) = 0 \tag{18}$$

$$\frac{d^2I(z)}{dz^2} + \beta^2 I(z) = 0 \tag{19}$$

Equations 13 and 14 have the following well-known solutions:

$$\begin{aligned} V(z) &= V_o^+ e^{-\gamma z} + V_o^- e^{\gamma z} = V_o^+ e^{-\alpha z} e^{-j\beta z} + V_o^- e^{\alpha z} e^{j\beta z} \\ &= V^+(z) + V^-(z) \end{aligned} \tag{20}$$

$$\begin{aligned} I(z) &= I_o^+ e^{-\gamma z} + I_o^- e^{\gamma z} = I_o^+ e^{-\alpha z} e^{-j\beta z} + I_o^- e^{\alpha z} e^{j\beta z} \\ &= I^+(z) + I^-(z) \end{aligned} \tag{21}$$

respectively. $V^+(z)$ and $I^+(z)$ are commonly referred to as the forward-traveling voltage and current waves (in the $+z$ direction), and $V^-(z)$ and $I^-(z)$ are called the backward-traveling waves (in the $-z$ direction). The total instantaneous voltage and current at any location on the line and at any time can be written, using Eqs. 9, 10, 15, 20, and 21, as

DOI 10.1007/978-981-4560-75-7_129-1

$$V(z,t) = V_o^+ e^{-\alpha z} \cos\left[\omega\left(t - \frac{\beta}{\omega}z\right)\right] + V_o^- e^{\alpha z} \cos\left[\omega\left(t + \frac{\beta}{\omega}z\right)\right] \tag{22}$$

$$I(z,t) = I_o^+ e^{-\alpha z} \cos\left[\omega\left(t - \frac{\beta}{\omega}z\right)\right] + I_o^- e^{\alpha z} \cos\left[\omega\left(t + \frac{\beta}{\omega}z\right)\right] \tag{23}$$

The first and second terms in the right-hand side of Eqs. 22 and 23 correspond to the forward-traveling waves $V^+(t-z/v)$, $I^+(t-z/v)$ and backward-traveling waves $V^-(t+z/v)$, $I^-(t+z/v)$, respectively. These waves travel at a velocity of

$$v = \frac{\omega}{\beta} \tag{24}$$

Equations 22 and 23 indicate that as the forward or backward voltage and current wave travel along the line at any instant and frequency, their amplitudes at a particular location z are reduced exponentially in accordance with $-\alpha|z|$ and their phases undergo a phase change of βz. α and β determine the attenuation and phase per unit length of the transmission line and are therefore called the attenuation and phase constant, respectively. $\gamma = \alpha + j\beta$ dictates the propagation of voltage and current waves along the line and hence is called the propagation constant of the transmission line.

The instantaneous (sinusoidal) voltage $V(z,t)$ versus time at different locations along the line can be sketched to demonstrate that the voltage travels along the line as time progresses. Note that in contrary to the circuit theory, in which voltage and current are assumed stationary and constant along the conductor of a transmission line, they are indeed (propagating) waves and are a function of the transmission line's characteristics.

Transmission-Line Parameters

It is recalled that components in electronic circuits are physical elements and electrical parameters are used to describe them so that they can be used in circuit analysis and design. For example, an inductor is described by an electrically equivalent inductance, a resistor is represented by a resistance, etc. Similarly, a transmission line is a physical structure, and it is also described by certain electrical parameters. The most useful parameters of a transmission line, at least for circuit design and analysis, are characteristic impedance, propagation constant or attenuation and phase constants, and velocity. The phase constant and velocity are directly related, and, many times, the parameter "effective relative dielectric constant" is also used in lieu of these. Transmission-line parameters can be determined from the per-unit-length inductance, resistance, capacitance, and conductance of the transmission line described in section "Per-Unit-Length Parameters R, L, C, and G." They are independent of the time variation of the applied voltage or current and, in general, the magnitude of the applied signal. As such, expressions for the transmission-line parameters can be derived considering a transmission line operating under a sinusoidal steady state. This would facilitate the solution process. To aid the use of these expressions, three cases are considered: lossy (or general), lossless, and low-loss transmission lines.

General Transmission Lines

For any transmission line operated under a sinusoidal steady state, the phasor current can be written using Eq. 11 as

DOI 10.1007/978-981-4560-75-7_129-1

$$I(z) = -\frac{1}{R + j\omega L}\frac{dV(z)}{dz} \tag{24}$$

Taking the derivative of the voltage in Eq. 20 and substituting it into Eq. 24 results in

$$I(z) = \frac{\gamma}{R + j\omega L}\left(V_o^+ e^{-\gamma z} - V_o^- e^{\gamma z}\right) \tag{25}$$

Comparing Eqs. 21 and 25 and making use of Eq. 15 gives

$$Z_o \triangleq \frac{V_o^+}{I_o^+} = -\frac{V_o^-}{I_o^-} = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \tag{26}$$

which is defined as the characteristic impedance of the transmission line (in Ohms). Its reciprocal

$$Y_o \triangleq \frac{I_o^+}{V_o^+} = -\frac{I_o^-}{V_o^-} = \sqrt{\frac{G + j\omega C}{R + j\omega L}} \tag{27}$$

is called the characteristic admittance of the line (in *mhos*). Note that the characteristic impedance and admittance, as expected, are generally complex as can be seen in Eqs. 26 and 27. It is important to note that these parameters are simply mathematically defined quantities and, as expected through their expressions in Eqs. 26 and 27, they are not and cannot be used as the normal impedance and admittance encountered in the electrical circuit theory. The propagation constant $\gamma = \alpha + j\beta$ of the transmission line is given in Eq. 15, where α and β, as described in section "Sinusoidal Steady-State Transmission-Line Equations," are the attenuation and phase constants of the line, respectively. They are obtained by taking the respective real and imaginary parts of the propagation constant. It should be noted that the attenuation constant is contributed by the conductor attenuation constant (due to imperfect conductors) and the dielectric attenuation constant (due to imperfect dielectrics), which will be examined in section "Dielectric and Conductor Losses in Transmission Lines." As the per-unit-length resistance R, inductance L, conductance G, and capacitance C of a transmission line are different for different transmission lines, the characteristic impedance Z_o and propagation constant γ are also different. In practice, Z_o and γ (or α and β) are normally used to characterize a transmission line instead of R, L, G, and C.

A closed-form expression for the attenuation constant can also be derived based on the time-average transmitted power and power loss per unit length on the line. To that end, an infinitely long transmission line is considered, and the phasor voltage and current at any location are written, from Eqs. 20 to 21, as

$$V(z) = V_o^+ e^{-\alpha z} e^{-j\beta z} \tag{28}$$

$$I(z) = I_o^+ e^{-\alpha z} e^{-j\beta z} \tag{29}$$

The time-average power or, simply, average power transmitted at any point on the line is given by

$$P_T(z) = \frac{1}{2}\mathrm{Re}[V(z)I^*(z)] \tag{30}$$

DOI 10.1007/978-981-4560-75-7_129-1

which becomes, after using Eqs. 28 and 29 and replacing $I_o^+ = V_o^+/Z_o$ with $Z_o = R_o + jX_o$,

$$P_T(z) = \frac{1}{2}\mathrm{Re}\left[\frac{\left(V_o^+\right)^2}{R_o - jX_o}e^{-2\alpha z}\right] = \frac{\left(V_o^+\right)^2 R_o}{2|Z_o|^2}e^{-2\alpha z} \tag{31}$$

Let P_{T0} being the power flow at $z = 0$ and P_{T0}–ΔP_T being the transmitting power at $z = \Delta z$. The average power loss per unit length is obtained as the difference in these powers over the distance, which is essentially the rate of decrease of the average transmitted power as the wave travels along the line and can, therefore, be derived from Eq. 31 as

$$P_L(z) = \lim_{\Delta z \to 0}\frac{(P_{T0} - \Delta P_T) - P_{T0}}{\Delta z} = -\frac{dP_T(z)}{dz} = 2\alpha P_T(z) \tag{32}$$

from which

$$\alpha = \frac{P_L(z)}{2P_T(z)} \tag{33}$$

Note that z is arbitrary and so, for uniform transmission lines whose geometry along the direction of propagation is constant, the power loss per unit length itself is independent of z. This power loss is due to the currents flowing through the resistance R and the conductance G and, hence, can be determined from Fig. 1b as

$$P_L(z) = \frac{1}{2}\left[R|I(z)|^2 + G|V(z)|^2\right] \tag{34}$$

which becomes, after utilizing Eqs. 28 and 29 and $I_o^+ = V_o^+/Z_o$,

$$P_L(z)^L = \frac{\left(V_o^+\right)^2}{2|Z_o|^2}\left[R + G|Z_o|^2\right]e^{-2\alpha z} \tag{35}$$

The attenuation constant can now be obtained from Eqs. 31, 33, and 35 as

$$\alpha = \frac{1}{2R_o}\left[R + G|Z_o|^2\right] \tag{36}$$

For transmission lines fabricated using good dielectrics and conductors, which are normally used in practice, the rate of change of the attenuation constant with frequency is, in general, relatively small. At low frequencies, the attenuation constant is very small and may be neglected. However, the attenuation of a transmission line cannot be ignored when the line is either long, used at high frequencies, or carries a large amount of power creating heat due to ½ (I^2R+V^2G) that must be dissipated. It is noted that the attenuation calculated from Eq. 36 neglects the attenuation due to radiation. An additional resistance representing the loss due to radiation can be defined and included in the per-unit-length resistance R, and hence Z_o, to account for the loss due to radiation. However, radiation loss is usually very small in practical

DOI 10.1007/978-981-4560-75-7_129-1

transmission lines and is, therefore, normally neglected. For some RF circuits that implement transmissions directly on a high-loss substrate such as silicon or without proper shield from that substrate, the attenuation constant, however, cannot be neglected due to substantial loss caused by the substrate. As this attenuation constant is large, it not only reduces the signal amplitude significantly but also causes large (substrate) coupling among circuit elements, degrading the circuit performance and, if not suitably taken care of, may cause the circuit not functioning properly under certain conditions.

The velocity can be derived by letting the phase $\omega t - \beta z$ of the forward-traveling wave in Eq. 22 equal to a constant and differentiating it with respect to time, as

$$v = \frac{dz}{dt} = \frac{\omega}{\beta} \tag{37}$$

This velocity corresponds to a constant phase of the wave and so is normally called the phase velocity, or simply velocity, of the wave propagating on the line. It indicates how fast points of equal phase on the wave move along the transmission line. As all points move at the same velocity, the phase velocity describes the rate at which the wave propagates along the transmission line and, hence, can be considered as the velocity of propagation. The distance, over which the phase is changed by 2π radians at any instant, is defined as the wavelength and is thus derived as

$$\lambda = \frac{2\pi}{\beta} = \frac{v}{f} \tag{38}$$

where f denotes the frequency.

Lossless Transmission Lines

Although all practical transmission lines have loss, lossless transmission lines are sometimes used for easy and fast circuit analysis and design. This assumption is also often used to illustrate some concepts in transmission lines without lost of generality. A lossless transmission line is defined as one having perfect conductors and dielectrics. This results in no resistance and conductance per unit length; i.e., $R=G=0$. Setting $R=G=0$ in Eqs. 26 and 15, we obtain

$$Z_o = \sqrt{\frac{L}{C}} \tag{39}$$

$$\gamma = j\beta = j\omega\sqrt{LC} \tag{40}$$

The velocity is obtained from Eqs. 37 and 40 as

$$v = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \tag{41}$$

Low-Loss Transmission Lines

For most practical transmission lines, the per-unit-length resistance R and conductance G are very small as compared to the per-unit-length reactance ωL and susceptance ωC, respectively. Under these conditions, a transmission line is considered as low-loss transmission line and approximate closed-form equations can

be derived for the characteristic impedance and attenuation and phase constants. Equation 26 can be rewritten as

$$Z = \sqrt{\frac{L}{C}}\left(1+\frac{R}{j\omega L}\right)^{1/2}\left(1+\frac{G}{j\omega C}\right)^{-1/2} \tag{42}$$

Applying the binomial series

$$(1+x)^a = 1 + ax + \frac{a(a-1)}{2!}x^2 + \cdots + \frac{a(a-1)\cdots(a-n+1)}{n!}x^n + \cdots \tag{43}$$

where x and a are real numbers, and retaining up to second-order terms, we obtain

$$Z \cong \sqrt{\frac{L}{C}}\left(1+\frac{R}{j2\omega L}\right)\left(1-\frac{G}{j2\omega C}\right) + \frac{1}{8}\left(\frac{R}{\omega L}\right)^2 - \frac{3}{8}\left(\frac{G}{\omega C}\right)^2 \tag{44}$$

Expanding Eq. 44 and making use of the fact that $R << \omega L$ and $G << \omega C$ yields

$$Z_o \cong \sqrt{\frac{L}{C}}\left[\left(1+\frac{1}{8}\left(\frac{R}{\omega L}\right)^2 - \frac{3}{8}\left(\frac{G}{\omega C}\right)^2 + \frac{RG}{4\omega^2 LC}\right) + j\left(\frac{G}{2\omega C} - \frac{R}{2\omega L}\right)\right] \tag{45}$$

Similarly, we can rewrite Eq. 15 and apply the binomial expression (43) and the conditions $R << \omega L$ and $G << \omega C$ to get

$$\gamma \cong \frac{1}{2}\left(R\sqrt{\frac{C}{L}} + G\sqrt{\frac{L}{C}}\right) + j\omega\sqrt{LC}\left(1+\frac{1}{8}\left(\frac{R}{\omega L}\right)^2 + \frac{1}{8}\left(\frac{G}{\omega C}\right)^2 - \frac{RG}{4\omega^2 LC}\right) \tag{46}$$

from which, we can obtain

$$\alpha \cong \frac{1}{2}\left(R\sqrt{\frac{C}{L}} + G\sqrt{\frac{L}{C}}\right) \tag{47}$$

$$\beta \cong \omega\sqrt{LC}\left[1+\frac{1}{8\omega^2}\left(\frac{R}{L} - \frac{G}{C}\right)^2\right] \tag{48}$$

For most engineering design purposes, it is sufficient to retain only the first-order terms in the binomial expansions. Under this approximation, Eqs. 45, 47, and 48 reduce to

$$Z_o \cong \sqrt{\frac{L}{C}}\left[1 + j\left(\frac{G}{2\omega C} - \frac{R}{2\omega L}\right)\right] \tag{49}$$

DOI 10.1007/978-981-4560-75-7_129-1

$$\alpha \cong \frac{1}{2}\left(R\sqrt{\frac{C}{L}} + G\sqrt{\frac{L}{C}}\right) \tag{50}$$

$$\beta \cong \omega\sqrt{LC} \tag{51}$$

The phase velocity is then obtained from Eq. 37 as

$$v \cong \frac{1}{\sqrt{LC}} \tag{52}$$

It is apparent that the phase constant and velocity of a low-loss transmission line are approximately equal to those of a lossless line.

It should be mentioned here that, for transmission lines implemented directly on (or near) a high-loss substrate such as silicon or without proper shield from that substrate, the transmission lines cannot be considered low-loss and the above-derived equations for low-loss transmission lines may not be applicable.

Per-Unit-Length Parameters R, L, C, and G

In the previous sections, it has been learned that a transmission line and all of its parameters are characterized by its series inductance L, series resistance R, shunt capacitance C, and shunt conductance G per unit length. Expressions for these per-unit-length parameters are now derived.

General Formulation

An infinitely long transmission line consisting of two conductors C_1 and C_2, as shown in Fig. 2, is considered. The inductance per unit length is contributed by two parts, one from the conductors as if they were perfect and another from the skin effect resulted from the imperfect conductors. The earlier inductance portion is called the external inductance and the latter is referred to as the internal inductance. The external inductance L_e, capacitance C, and conductance G per unit length are given, under static conditions, as

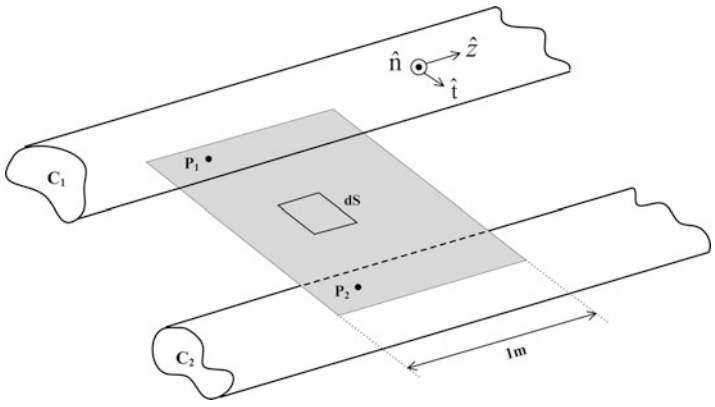

Fig. 2 A transmission line consisting of two conductors C_1 and C_2. $\hat{n}$ is the unit vector normal to the conducting surface; $\hat{t}$ is the unit vector tangential to the surface; and $\hat{z}$ is the unit vector along the longitudinal direction

DOI 10.1007/978-981-4560-75-7_129-1

$$L_e = \frac{\psi}{I_o} \tag{53}$$

$$C = \frac{Q}{V_o} \tag{54}$$

$$G = \frac{I_G}{V_o} \tag{55}$$

where ψ is the total magnetic flux per unit length linking the current, I_o is the total current on the conductor C_1, V_o is the voltage difference between the two conductors, Q is the total charge per unit length on the conductor C_1, and I_G represents the current flowing across the conductance G, which is the total shunt conduction current per unit length. Note that L_e, C, and G are not a function of frequency, assuming frequency-independent permittivity, permeability, and conductivity for the dielectric material.

The total charge per unit length on the conductor C_1 can be determined, assuming perfect conductor, as

$$Q = \oint_{C_1} \rho_s d\ell = \varepsilon \oint_{C_1} \vec{E} \cdot \hat{n}\, d\ell \tag{56}$$

where $d\ell$ is the differential length and the charge density per unit length $\rho_s = D_n = \varepsilon \vec{E} \cdot \hat{n}$ from the boundary condition, with D_n representing the normal component of the electric flux density, $\vec{E}$ being the electric field, $\hat{n}$ standing for the unit vector perpendicular to the conductor surface, and ε being the permittivity of the medium surrounding the conductors. Note that the integral is carried along a contour enclosing the conductor C_1. The voltage between the two conductors is obtained by taking the integral of the electric field along a path between any points on the surfaces of the conductors C_1 and C_2 as

$$V_o = \int_{C_1}^{C_2} \vec{E} \cdot d\,\vec{\ell} \tag{57}$$

where $d\ell$ is the differential-length vector. The capacitance per unit length can be obtained from Eqs. 54, 56, and 57 as

$$C = \frac{Q}{V_o} = \frac{\varepsilon \oint_{C_1} \vec{E} \cdot \hat{n}\, d\ell}{\int_{C_1}^{C_2} \vec{E} \cdot d\,\vec{\ell}} \tag{58}$$

Applying Ampere's law of Maxwell's equations, the total current flowing on the conductor C_1 is obtained by taking the line integral of the tangential magnetic field H_t around a contour enclosing the conductor as

$$I_o = \oint_{C_1} H_t d\ell \tag{59}$$

At the perfectly conducting surface C_1, the electric ($\vec{E}$) and magnetic ($\vec{H}$) fields have only normal (n) and tangential (t) components, respectively, and, for TEM propagating wave, they are related by

DOI 10.1007/978-981-4560-75-7_129-1

$$H_t = \frac{E_n}{\eta} = \frac{\vec{E} \cdot \hat{n}}{\eta} \tag{60}$$

where $\eta = \sqrt{\mu/\varepsilon}$ is the intrinsic impedance of the dielectric medium of the transmission line. Substituting H_t from Eqs. 60 into 59 and using Eqs. 56 yields

$$I_o = \frac{1}{\eta} \oint_{C_1} \vec{E} \cdot \hat{n} d\ell = \frac{Q}{\sqrt{\mu\varepsilon}} \tag{61}$$

The characteristic impedance of the transmission line can be derived, making use of Eqs. 58 and 61, as

$$Z_o = \frac{V_o}{I_o} = \frac{\sqrt{\mu\varepsilon}}{C} \tag{62}$$

from which,

$$C = \frac{\sqrt{\varepsilon\mu}}{Z_o} \tag{63}$$

The total magnetic flux linkage per unit length is obtained as an integration of the magnetic flux density over a surface area extended from the conductor C_1 to conductor C_2 that has a longitudinal length of 1 m between the two conductors, as shown in Fig. 2,

$$\psi = \int_S \vec{B} \cdot d\vec{S} = \int_{P_1}^{P_2} \mu H d\ell = \frac{\mu}{\eta} \int_{P_1}^{P_2} - \vec{E} \cdot d\vec{l} = \frac{\mu}{\eta} V_o \tag{64}$$

where P_1 and P_2 are arbitrary points on the surfaces of the conductors C_1 and C_2, respectively, and P_1P_2 is perpendicular to the flux lines. The external inductance per unit length is, from Eqs. 53 and 64,

$$L_e = \frac{\psi}{I_o} = \frac{\mu}{\eta} \frac{V_o}{I_o} = \sqrt{\varepsilon\mu} \frac{V_o}{I_o} \tag{65}$$

or, upon using Eq. 62,

$$L_e = Z_o \sqrt{\varepsilon\mu} \tag{66}$$

From Eqs. 63 and 66, we can also obtain

$$Z_o = \sqrt{\frac{L_e}{C}} \tag{67}$$

which is the same as that obtained in Eq. 39, with $L_e = L$ for lossless transmission lines.

Equations 63 and 66 also lead to

$$v = \frac{1}{\sqrt{L_e C}} = \frac{1}{\sqrt{\mu\varepsilon}} \tag{68}$$

DOI 10.1007/978-981-4560-75-7_129-1

as given in Eq. 41. It is noted again that the velocity for a lossless transmission line immersed in a medium characterized by ε and μ is exactly the same as that for a uniform plane wave propagating in the same medium due to their same TEM mode.

The conductance per unit length given by Eq. 55 can be rewritten as

$$G = \frac{I_G}{I_D}\frac{I_D}{V_o} \tag{69}$$

where I_D is the (total) displacement current in the transmission line and is given as

$$I_D = \int_S \vec{D}\cdot d\vec{S} = j\omega\varepsilon'\int_S \vec{E}\cdot d\vec{S} \tag{70}$$

where S represents a surface enclosing one conductor (e.g., C_1) and ε' is the real part of the dielectric's complex permittivity $\hat{\varepsilon} = \varepsilon' - j\varepsilon''$ with ε'' being the imaginary part of the dielectric's complex permittivity accounting for the loss in the dielectric. Note that $\varepsilon' = \varepsilon$ where ε is the permittivity of the medium used earlier. This current flows through the shunt capacitance per unit length C and is, thus, also given as

$$I_D = j\omega C V_o \tag{71}$$

The total shunt conduction current per unit length can be obtained as

$$I_G = \sigma\int_S \vec{E}\cdot d\vec{S} = \omega\varepsilon''\int_S \vec{E}\cdot d\vec{S} \tag{72}$$

upon replacing the dielectric's conductivity σ with $\omega\varepsilon''$. The conductance per unit length is then obtained from Eqs. 69 to 72 as

$$G = \frac{\omega\varepsilon''}{\varepsilon'}C \tag{73}$$

Equation 73 with $\varepsilon'' = \frac{\sigma}{\omega}$ shows that

$$\frac{G}{C} = \frac{\omega\varepsilon''}{\varepsilon'} = \frac{\sigma}{\varepsilon'} = \omega\tan\delta \tag{74}$$

upon using the loss tangent of the dielectric $\tan\delta = \sigma/\omega\varepsilon'$, which is a useful relationship between the shunt conductance G and capacitance C per unit length of a transmission line, allowing one parameter to be determined from the other for a given transmission-line medium.

The resistance per unit length R, as recalled, is used to represent the power loss due to imperfect conductors and can be determined from the following known relation:

$$P_L = \frac{1}{2}RI_o^2 \tag{75}$$

where P_L is the total power loss per unit length along the conductors. P_L is the sum of the individual power losses on the two conductors and is given as

DOI 10.1007/978-981-4560-75-7_129-1

$$P_L = \frac{R_S}{2}\oint_{C_1+C_2} \vec{J}_S \cdot \vec{J}_S^{*} dl = \frac{R_S}{2}\oint_{C_1+C_2} \left(\hat{n}\times \vec{H}\right)\cdot\left(\hat{n}\times \vec{H}^{*}\right) dl = \frac{R_S}{2}\oint_{C_1+C_2} \left|\vec{H}\right|^2 dl \tag{76}$$

upon using

$$\left(\hat{n}\times \vec{H}\right)\cdot\left(\hat{n}\times \vec{H}^{*}\right) = \hat{n}\cdot\vec{H}\times\left(\hat{n}\times \vec{H}^{*}\right) = \hat{n}\cdot\left[\left(\vec{H}\cdot\vec{H}^{*}\right)\hat{n} - \left(\vec{H}\cdot\hat{n}\right)\vec{H}^{*}\right] = \left|\vec{H}\right|^2$$

which makes use of the fact that $\hat{n}\cdot\vec{H} = 0$ at a perfect conductor. $\vec{J}_S$ is the surface current density along the z axis; $R_S = 1/\sigma_c\delta_s$ is the (frequency-dependent) surface resistance of the conductor with the skin depth $\delta_s = \sqrt{2/\omega\mu_c\sigma_c}$, σ_c being the conductor's skin depth and conductivity, respectively, and μ_c being the permeability of the conductor (typically equal to μ_o). The magnetic field intensity $\vec{H}$ is taken as that for perfect conductors. Note that the integration is carried around both conductors to obtain the total loss. The resistance per unit length is obtained from Eqs. 59 and 75–76 as

$$R = R_s\frac{\oint_{C_1+C_2}\left|\vec{H}\right|^2 dl}{\left(\oint_{C_1}\left|\vec{H}\right| dl\right)^2} \tag{77}$$

after replacing H_t with $\left|\vec{H}\right|$, which is valid since the magnetic field has only tangential component at the surface of a perfect conductor.

Equation 77 implies that R depends on the frequency as expected due to the frequency-dependent skin effect of the conductors. When the conductors are imperfect, there will be a penetration of the magnetic field into the conductors, causing currents to flow internally within the conductors. This results in an additional inductance for the transmission line and hence increasing the inductance per unit length of the line. This extra inductance (L_i) is called "internal inductance" or "skin-effect inductance." The magnetic energy stored in this inductance is given by

$$W_{L_i} = \frac{1}{4}L_i I_o^2 \tag{78}$$

As the conductors have a finite conductivity, the transmission line exhibits a surface (or skin effect) impedance on the conductors as

$$Z_S = R_S + j\omega L_S = \frac{1}{\sigma_c\delta_S}(1+j) \tag{79}$$

where R_s and L_s are the surface resistance (or resistivity) and inductance of the conductor, respectively. The magnetic energy stored in the surface inductance L_s is

$$\begin{aligned} W_{L_S} &= \frac{1}{4}L_S\oint_{C_1+C_2}\left|\vec{J}_S\right|^2 dl \\ &= \frac{1}{4}L_S\oint_{C_1+C_2}\left|\vec{H}\right|^2 dl \end{aligned} \tag{80}$$

DOI 10.1007/978-981-4560-75-7_129-1

making use of $\vec{J}_s = \hat{n} \times \vec{H}$ on a perfect conductor. Replacing the integral with that from Eq. 76, and using Eq. 75 and the fact that $R_s = \omega L_s$ from Eq. 80, we get

$$W_{L_s} = \frac{RI_o^2}{4\omega} \tag{81}$$

which must be equal to the magnetic energy stored in the internal inductance. This leads to

$$\omega L_i = R \tag{82}$$

The total series inductance per unit length can now be obtained as

$$L = L_e + \frac{R}{\omega} \tag{83}$$

and is frequency dependent. For low-loss transmission lines, $R << \omega L_e$, and hence this additional inductance due to the conductor's finite conductivity is very small and normally neglected. Note that, from Eqs. 77 and 82, R increases as $\sqrt{\omega}$, whereas L_i decreases as $\sqrt{\omega}$. However, the reactance ωL_i is proportional to $\sqrt{\omega}$ and hence cannot be neglected at high frequencies.

As have been seen, the per-unit-length resistance R and internal inductance L_i can be evaluated from Eqs. 77 and 82, respectively. In practice, transmission lines with good conductors are used. For these transmission lines, R and L_i are typically small. Therefore, the transmission line's parameters like characteristic impedance can be accurately determined, and even approximations are used for R and L_i. For good conductors, we can derive approximate closed-form equations for R and L_i as follows.

A plane conductor as shown in Fig. 3 is considered. Its resistance is given, assuming the current is uniformly distributed over the cross section of the conductor, as

$$R_{dc} = \frac{\ell}{\sigma_c A} = \frac{\ell}{\sigma_c h W} \tag{84}$$

where A is the cross-sectional area of the conductor and σ_c is the conductivity, whose value remains almost the same from dc to infrared frequencies. At dc, the skin depth is infinity and the current would reside completely within the conductor, thus distributing uniformly over the entire cross section. Equation 84 is therefore strictly valid at dc and approximate at low frequencies where the skin depth is large. At high frequencies, the skin depth is small, and the current approximately resides within a few skin depths from

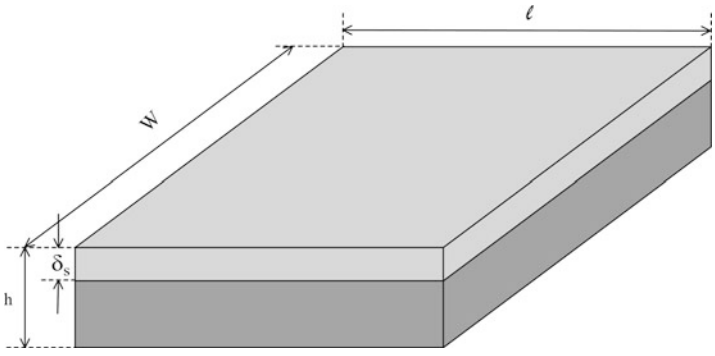

Fig. 3 A plane conductor

DOI 10.1007/978-981-4560-75-7_129-1

the surface, causing nonuniform current distribution over the conductor's entire cross section. However, within one skin depth δ_s of the surface, the current does not vary much and we can approximate the current distribution as uniform. As a result, the resistance per unit length of the conductor at high frequency, corresponding to a cross-sectional area of $\delta_s W$, can be approximated as

$$R_f = \frac{1}{\sigma_c \delta_s W} \tag{85}$$

It is noted herein that the current does not vanish at a depth equal to the skin depth; instead, it takes several skin depths to reduce to a negligible value (e.g., $4.6\delta_s$ to reach 1 % of its initial value) which should be used in determining R_f (for conductors or very lossy substrates.) These distances (e.g., $4.6\delta_s$), however, are not considered here since the resistance is not uniformly distributed over several skin depths. The use of one skin depth results in possible inaccuracy for R_f.

For good conductors, $\delta_s = 1/\alpha \simeq \sqrt{2/\omega\sigma_c\mu_o}$, where α is the attenuation constant, and so

$$R_f = \frac{1}{W}\sqrt{\frac{\omega\mu_o}{2\sigma_c}} \tag{86}$$

for good conductors. Note the relative permeability μ_r for (nonmagnetic) conductors is approximately equal to one. It is then observed that, for a given conductor with conductivity σ_c, as the frequency is increased, the skin depth reduces leading to increased resistance and attenuation constant and hence loss. This phenomenon is indeed expected for increasing frequency. R_f can be rewritten using the surface resistance R_S and δ_s as

$$R_f = \frac{R_s}{W} \tag{87}$$

which is expected since the conductor width can be considered as consisting of W unit widths connected in parallel. The transmission line's per-unit-length resistance can now be estimated as

$$R = \frac{R_{s1}}{W_1} + \frac{R_{s2}}{W_2} \tag{88}$$

where W_1, W_2 and R_{s1}, R_{s2} are the widths and surface resistances of the transmission line's two conductors, respectively, assuming plane conductors.

The internal inductance per unit length L_i of the transmission line is obtained from Eqs. 82 and 88 as

$$L_i = \frac{1}{\omega}\left(\frac{R_{s1}}{W_1} + \frac{R_{s2}}{W_2}\right) \tag{89}$$

As an example, a coaxial transmission line, whose cross section is shown in Fig. 4a, is now considered. Considering the unit-length inner conductor shown in Fig. 4b and assuming the current is concentrated within a skin depth of the surface and the frequency is sufficiently high so that the skin depth is relatively small as compared to the conductor's radius, we can neglect the conductor's curvature and approximate the inner conductor per unit length as a plane conductor having width equal to the circumference $2\pi a$ and thickness equal to the skin depth δ_s, as shown in Fig. 4c. Similarly, the outer conductor of radius b per unit length can also be approximately represented by a plane conductor of width $2\pi b$ and thickness δ_s. The

DOI 10.1007/978-981-4560-75-7_129-1

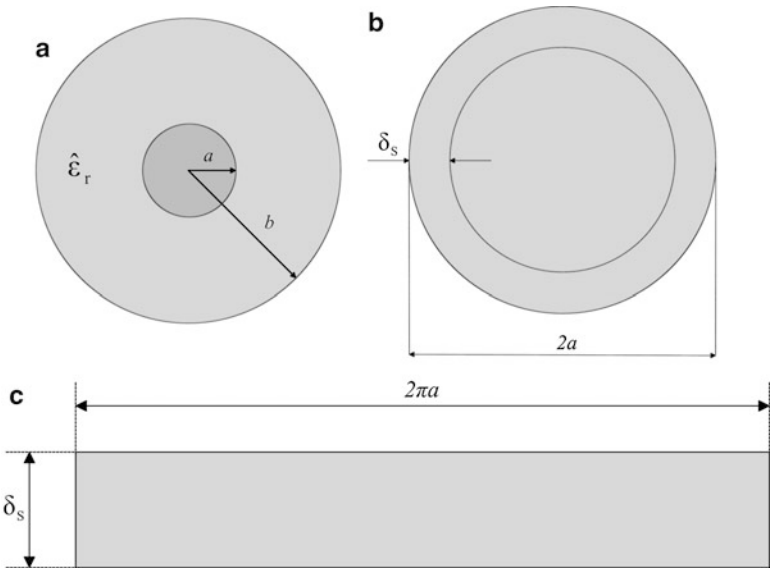

Fig. 4 Cross section of a coaxial line (**a**) and the unit-length inner conductor (**b**) with its approximate plane conductor (**c**)

per-unit-length resistance R and internal inductance L_i can be obtained from Eqs. 88 and 89, respectively, as

$$R = \frac{R_s}{2\pi a} + \frac{R_s}{2\pi b} = \frac{(a+b)R_s}{2\pi ab} \tag{90}$$

$$L_i = \frac{(a+b)R_s}{2\pi\omega ab} \tag{91}$$

assuming same material for the inner and outer conductors. As will be seen later, these results are exactly the same as those in Eqs. 101 and 102 obtained from a more rigorous analysis. It should be noted that for some planar transmission lines, the width of the second conductor (normally, ground plane), along which the current concentrates, may be much wider than that of the first conductor; in that case, a width smaller than the actual width should be used in the calculations. Otherwise, the portions of R and L_i corresponding to that conductor would be zero. For instance, for microstrip lines, the width of the ground plane used in calculations can be approximated as about five times of the width of the strip. Figure 5 shows sketches of the current distributions within the conductors of coaxial and microstrip lines.

Formulation for Simple Transmission Lines

For transmission lines with simple geometry, such as coaxial line, closed-form expressions for R, L, G, and C can be easily derived. For most practical printed-circuit transmission lines, however, these expressions are very difficult – if not impossible – to derive, and numerical methods, for example, spectral-domain method, are normally employed to obtain numerical results for the parameters.

As an illustration of the procedure to determine the transmission line's per-unit-length parameters for simple transmission lines, a (lossy) coaxial transmission line as shown in Fig. 4a is considered. The relative dielectric constant of the medium, assumed to be nonmagnetic, between the two conductors is characterized by $\hat{\varepsilon} = \varepsilon' - \varepsilon''$ and the conductors' conductivity is σ_c. First, the electric and magnetic fields for the coaxial line are determined. To facilitate this formulation, it is assumed that the conductors are perfect ($\sigma \to \infty$) so that the transmission line supports TEM mode regardless whether the medium is

DOI 10.1007/978-981-4560-75-7_129-1

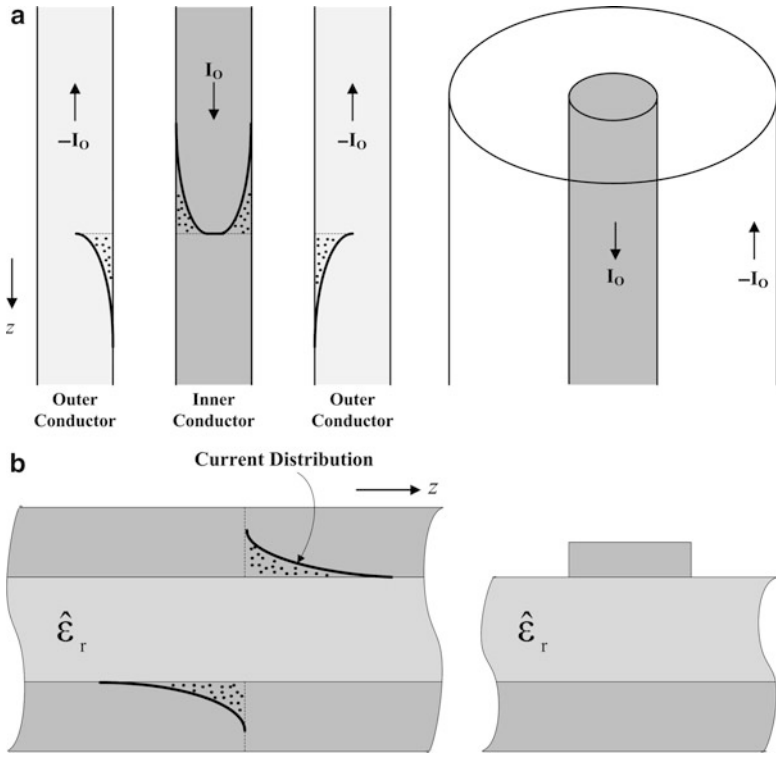

Fig. 5 Sketch of the current distribution in coaxial line (**a**) and microstrip line (**b**)

lossless or lossy. It is noted that TEM mode only exists on transmission lines with perfect conductors immersed in a single dielectric (i.e., the medium surrounding the conductors is homogeneous). For practical transmission lines including coaxial line, the conductors are typically good, and, consequently, the fields can be assumed to be almost the same as that of the TEM mode with perfect conductors. Therefore, the fields for a lossless transmission line are normally employed to evaluate the parameters of these (low-loss) practical transmission lines. For TEM mode, the fields lie on a transverse plane and, consequently, the electric field for the coaxial line has only radial component. Applying Gauss' law of Maxwell's equations over a cylindrical surface enclosing the inner conductor, the total charge per unit length on the inner conductor is obtained as

$$Q = \oint_S \vec{D} \cdot d\vec{S} = \varepsilon \int_0^{2\pi} E_r \hat{a}_r \cdot \hat{a}_r r d\varphi = 2\pi\varepsilon r E_r \tag{92}$$

The voltage between the two conductors is

$$V_o = -\int_b^a \vec{E} \cdot d\vec{l} = \int_a^b E_r dr = \frac{Q}{2\pi\varepsilon} \int_a^b \frac{dr}{r} = \frac{Q}{2\pi\varepsilon} \ln \frac{b}{a} \tag{93}$$

upon substituting E_r from Eq. 92 and taking the integral. The electric field is then obtained from Eqs. 92 to 93 as

$$E = \frac{V_o}{r \ln(b/a)} a_r \tag{94}$$

The magnetic field is given by

$$\vec{H} = \frac{\hat{a}_z \times \vec{E}}{\eta} = \frac{V_o}{r\eta \ln(b/a)} \hat{a}_\varphi \tag{95}$$

The total current is obtained from Eq. 59 as

$$I_o = \oint_{C_1} \vec{H} \cdot d\hat{l} = \int_0^{2\pi} \vec{H} \cdot \hat{a}_\varphi a d\varphi = \frac{2\pi V_o}{\eta \ln(b/a)} \tag{96}$$

Note that the contour C_1 corresponds to $r = a$. The external series inductance per unit length L_e can now be obtained by substituting ψ from Eq. 85 and I_o from Eqs. 96 to 53 as

$$\begin{aligned} L_e &= \frac{\psi}{I_o} \\ &= \frac{\mu}{2\pi} \ln\left(\frac{b}{a}\right) \end{aligned} \tag{97}$$

The shunt capacitance per unit length C is given from Eq. 54 as

$$\begin{aligned} C &= \frac{Q}{V_o} \\ &= \frac{2\pi\varepsilon}{\ln(b/a)} \end{aligned} \tag{98}$$

upon using Eq. 93.

The shunt conductance per unit length G is obtained by substituting C from Eqs. 98 to 73 as

$$G = \frac{2\pi\omega\varepsilon''}{\ln(b/a)} \tag{99}$$

The power loss per unit length on the conductors is obtained from Eq. 76, making use of Eq. 95, as

$$\begin{aligned} P_L &= \frac{R_s}{2} \oint_{C_1 + C_2} \left|\vec{H}\right|^2 dl \\ &= \frac{R_s}{2} \left\{ \frac{V_o^2}{a^2 \eta^2 [\ln(b/a)]^2} \int_0^{2\pi} a d\varphi + \frac{V_o^2}{b^2 \eta^2 [\ln(b/a)]^2} \int_0^{2\pi} b d\varphi \right\} \\ &= \frac{R_s}{2} \frac{2\pi V_o^2}{\eta^2 [\ln(b/a)]^2} \left(\frac{1}{a} + \frac{1}{b}\right) \\ &= \frac{a+b}{ab} \frac{\pi R_s V_o^2}{[\eta \ln(b/a)]^2} \end{aligned} \tag{100}$$

Substituting P_L in Eq. 100 into Eq. 75 and solving for R, leads to, upon using Eq. 96,

DOI 10.1007/978-981-4560-75-7_129-1

$$R = \frac{(a+b)R_s}{2\pi ab} \tag{101}$$

The internal inductance per unit length is obtained from Eq. 82 as

$$L_i = \frac{(a+b)R_s}{2\pi\omega ab} \tag{102}$$

Note that R and L_i in Eqs. 101 and 102, respectively, are the same as those derived in Eq. 90 and 91. The total series inductance per unit length can be obtained from Eqs. 97 and 102 as

$$L = \frac{\mu}{2\pi}\ln\frac{b}{a} + \frac{(a+b)R_s}{2\pi\omega ab} \tag{103}$$

The foregoing analysis can be employed to determine the parameters per unit length for other transmission lines with simple geometry.

Dielectric and Conductor Losses in Transmission Lines

It has been seen in sections "Transmission-Line Parameters" and "Per-Unit-Length Parameters R, L, C, and G" that the loss in transmission lines can be determined exactly from Eqs. 15 or 36 for (lossy) transmission lines and approximately from Eq. 47 for low-loss lines. This loss is attributed by three different kinds: dielectric, conduction, and radiation loss. It is a common practice to compute these three constituent losses, and the results enable us to get insight to the loss phenomena and helps identify the magnitude of each loss contribution. This information is useful for circuit design – for instance, it can help choose a proper transmission line or possibly optimize a transmission-line structure including its substrates and dimensions to reduce a certain loss.

Radiation loss of uniform transmission lines used in practice is normally very small and usually neglected, especially at low RF regions. As a result, the attenuation constant of a transmission line is commonly described as

$$\alpha = \alpha_d + \alpha_c \tag{104}$$

where α_d and α_c represent the dielectric and conductor attenuation constant, respectively, and depend on frequency. Most transmission lines have $\alpha_c >> \alpha_d$, except for highly lossy dielectrics, such as silicon, in which the dielectric loss is the dominant contribution. For homogeneous transmission lines (e.g., strip line), α_d is independent of the geometry of the line, whereas for inhomogeneous transmission lines (e.g., microstrip line), α_d is in general a function of the line's geometry. On the other hand, α_c is always a function of the geometry. It can be written, from Eq. 33,

$$\alpha = \alpha_d + \alpha_c = \frac{P_{Ld} + P_{Lc}}{2P_T} \tag{105}$$

where

$$\alpha_d = \frac{P_{Ld}}{2P_T} \tag{106}$$

$$\alpha_c = \frac{P_{Lc}}{2P_T} \tag{107}$$

with P_{Ld} and P_{Lc} representing the power losses per unit length due to imperfect dielectric and conductors, respectively. Practical transmission lines normally have small losses, and so their electric and magnetic fields are only slightly changed or perturbed from the lossless case. Therefore, a perturbation method can be employed, in which the fields for the lossless transmission line are used to approximate those of the corresponding lossy transmission line, to determine α_d and α_c. The perturbation method is convenient for analyzing low-loss transmission lines since the actual fields of these lines are not needed.

Dielectric Attenuation Constant

From the Poynting theorem, the power loss per unit length of a transmission line due to imperfect dielectric can be written as

$$P_{Ld}(z) = \frac{\sigma}{2}\int_S \vec{E}\cdot\vec{E}^* dS = \frac{\sigma}{2}\int_S \left|\vec{E}\right|^2 dS = \frac{\omega\varepsilon''}{2}\int_S \left|\vec{E}\right|^2 dS \tag{108}$$

where $\sigma = \omega\varepsilon''$ is the conductivity of the dielectric and $\vec{E}$ is the electric field intensity. Note that because of the dielectric's finite conductivity, there is current $\vec{J} = \sigma\vec{E}$ existing between the two conductors. The average power flow along the line is given as

$$P_T = \frac{1}{2}\mathrm{Re}\int_S \vec{E}\times\vec{H}^*\cdot d\vec{S} \tag{109}$$

Replacing $\vec{H}$ with

$$\frac{\vec{H} = \hat{a}_z \times \vec{E}}{\eta} \tag{110}$$

where $\eta = \sqrt{\mu/\varepsilon}$ is the intrinsic impedance of the dielectric medium and applying the vector identity for three arbitrary vectors $\vec{A}$, $\vec{B}$, and $\vec{C}$,

$$\vec{A}\times\vec{B}\times\vec{C} = \left(\vec{A}\cdot\vec{C}\right)\vec{B} - \vec{C}\left(\vec{A}\cdot\vec{B}\right) \tag{111}$$

gives

$$P_T(z) = \frac{1}{2\eta}\int_S \vec{E}\cdot\vec{E}^* dS = \frac{1}{2\eta}\int_S \left|\vec{E}\right|^2 dS \tag{112}$$

which can also be derived as

DOI 10.1007/978-981-4560-75-7_129-1

$$P_T(z) = \frac{\eta}{2}\int_S \vec{H}\cdot\vec{H}^* dS = \frac{\eta}{2}\int_S \left|\vec{H}\right|^2 dS \tag{113}$$

Here, η is assumed real, which is a good approximation for low-loss materials. The dielectric attenuation constant can be derived from Eqs. 106, 108, and 112 as

$$\alpha_d = \frac{P_{Ld}}{2P_T} = \frac{\sigma\eta}{2} = \frac{\omega\varepsilon''\eta}{2} \tag{114}$$

For a low-loss dielectric with (complex) relative dielectric constant $\hat{\varepsilon}_r = \varepsilon_r' - j\varepsilon'', \varepsilon_r'' << \varepsilon_r'$ and its intrinsic impedance

$$\eta = \sqrt{\frac{\mu}{\hat{\varepsilon}}} = \frac{\eta_o}{\sqrt{\varepsilon_r' - j\varepsilon_r''}} \simeq \frac{\eta_o}{\sqrt{\varepsilon_r'}} \tag{115}$$

where $\eta_o = 120\pi\Omega$ is the intrinsic impedance of air. Note that $\varepsilon_r' = \varepsilon_r$ of the dielectric. The dielectric attenuation constant for a low-loss TEM transmission line can now be approximated as

$$\alpha_d \cong \frac{k_o}{2}\frac{\varepsilon_r''}{\sqrt{\varepsilon_r}} \tag{116}$$

where $k_o = \omega\sqrt{\varepsilon_o\mu_o}$ is the wave number in air and ε_r is used in place of ε_r'.

Conductor Attenuation Constant

It is well known that as a signal propagates along a perfect conductor, its energy cannot penetrate into the conductor. However, if the conductor is nonperfect, some of the energy would enter the conductor, yet attenuated in accordance to the attenuation function $e^{-2\alpha_c r}$, where r is the distance from the conductor surface in the direction perpendicular to it. The density of power flow into a conductor is equal to the power dissipated within the conductor itself. Therefore, the power loss per unit length due to an imperfect conductor is given as

$$\begin{aligned} P_{Lc}(z) &= \frac{1}{2}\mathrm{Re}\int_{C_1+C_2}\left(\vec{E}\times\vec{H}^*\right)\cdot\hat{a}_r dS = \frac{1}{2}\mathrm{Re}\int_{C_1+C_2}\left(\hat{a}_r\times\vec{E}\right)\cdot\vec{H}^* = \frac{1}{2}\mathrm{Re}\int_{C_1+C_2} Z_S\left|\vec{H}\right|^2 dS \\ &= \frac{1}{2}R_S\int_{C_1+C_2}\left|\vec{H}\right|^2 dS = \frac{1}{2}R_S\int_{C_1+C_2}\left|\vec{H}\right|^2 d\ell \end{aligned} \tag{117}$$

where C_1 and C_2 represent the two conductors of the transmission line, η_c is the intrinsic impedance of the conductor, Z_S is the surface impedance, and R_S is its real part or the surface resistance (or resistivity) of the conductor as given in Eq. 79. $\vec{H}$ is the magnetic field assuming no loss; that is, its magnitude is equal to the magnitude of the magnetic field at the conductor surface. The conductor attenuation constant can be derived from Eqs. 107, 113, and 117 as

DOI 10.1007/978-981-4560-75-7_129-1

$$\alpha_c = \frac{P_{Lc}}{2P_T} = \frac{R_S \int_{C_1+C_2} \vec{H} \cdot \vec{H}^* dl}{2\eta_c \int_S \vec{H} \cdot \vec{H}^* dS} \tag{118}$$

It can also be derived as

$$\alpha_c = \frac{R_S \int_{C_1+C_2} \vec{E} \cdot \vec{E}^* dl}{2\eta \int_S \vec{E} \cdot \vec{E}^* dS} \tag{119}$$

It is particularly noted that, as a signal propagates along transmission lines, the electric and magnetic fields and current of the signal penetrate into the surfaces of the transmission lines' conductors and reside within a few skin depths of the conductors. The thickness of the conductors in transmission lines should therefore be at least larger than the skin depth at the operating frequencies to minimize the loss due to the conductors. If the conductor thickness is comparable to the skin depth, a significant conduction loss would occur.

As an example for determining the attenuation constant of transmission lines, a coaxial transmission line whose inner and outer radii are a and b, respectively, as shown in Fig. 4a is considered. The dielectric is assumed to be lossy and characterized by $\hat{\varepsilon}_r = \varepsilon_r' - j\varepsilon_r''$ where $\varepsilon_r' = \varepsilon_r$. The conductors are imperfect with a finite conductivity σ_c. Using perturbation method, it is assumed that the fields of this transmission line are given as those of the lossless coaxial line:

$$\vec{E} = \hat{a}_r \frac{V_o}{\ln\left(\frac{b}{a}\right)} \frac{1}{r} e^{-j\beta z} \tag{120}$$

$$\vec{H} = \hat{a}_r \frac{V_o}{\eta \ln\left(\frac{b}{a}\right)} \frac{1}{r} e^{-j\beta z} \tag{121}$$

where V_o is the potential of the inner conductor, r is the radius between a and b, and $\beta = k = k_o\sqrt{\varepsilon_r}$. The potential of the outer conductor is assumed to be zero. The power flow along the coaxial line is obtained as

$$P_T = \frac{1}{2}\mathrm{Re}\int_S \vec{E} \times \vec{H}^* \cdot d\vec{S} = \frac{1}{2}\int_0^{2\pi}\int_a^b \vec{E} \times \vec{H}^* \cdot \hat{a}_z r dr d\varphi = \frac{\pi V_o^2}{\eta \ln(b/a)} \tag{122}$$

The power loss per unit length due to dielectric loss is

DOI 10.1007/978-981-4560-75-7_129-1

$$\begin{aligned} P_{Ld} &= \frac{\omega\varepsilon''}{2}\int_S \left|\vec{E}\right|^2 dS \\ &= \frac{\omega\varepsilon''}{2}\int_0^{2\pi}\int_a^b \left|\vec{E}\right|^2 r dr d\varphi \\ &= \frac{\pi\omega\varepsilon'' V_o^2}{\ln(b/a)} \end{aligned} \tag{123}$$

The dielectric attenuation constant can be derived from Eqs. 106, 122, to 123 as

$$\alpha_d = \frac{k_o\varepsilon_r''}{2\sqrt{\varepsilon_r}} \tag{124}$$

which is the same as Eq. 116 as expected for TEM transmission lines.

The power loss per unit length due to conductor loss is

$$\begin{aligned} P_{Lc} &= \frac{R_S}{2}\int_{C_1+C_2} \left|\vec{H}\right|^2 dl \\ &= \frac{R_S}{2}\left[\int_0^{2\pi}\left|\vec{H}(r=a)\right|^2 a d\varphi + \int_0^{2\pi}\left|\vec{H}(r=b)\right|^2 b d\varphi\right] \\ &= \frac{R_S\pi V_o^2}{\eta^2\ln^2(b/a)}\left(\frac{1}{a}+\frac{1}{b}\right) \end{aligned} \tag{125}$$

The conductor attenuation constant is obtained from Eqs. 107, 122, and 125 as

$$\alpha_c = \frac{R_S}{2\eta\ln(b/a)}\left(\frac{1}{a}+\frac{1}{b}\right) \tag{126}$$

which depends on the transmission line's geometry.

The (total) attenuation constant can now be determined using Eqs. 104, 124, and 126 as

$$\alpha = \frac{k_o\varepsilon_r''}{2\sqrt{\varepsilon_r}} + \frac{R_S}{2\eta\ln(b/a)}\left(\frac{1}{a}+\frac{1}{b}\right) \tag{127}$$

Dispersion and Distortion in Transmission Lines

Dispersion

When the velocity of wave or signal (normally TEM or quasi-TEM) propagating along a transmission line is dependent upon frequency, the transmission line is said to have dispersion. There is no dispersion in an (ideal) lossless transmission line because the velocity, as given by Eq. 41, is independent of frequency.

DOI 10.1007/978-981-4560-75-7_129-1

Any practical transmission line, however, is lossy and its phase constant, in general, does not vary linearly with frequency. This results in a velocity depending on frequency, thus causing dispersion. As an example, the phase constant for low-loss transmission lines, as derived in Eq. 48, is in general a nonlinear function of frequency, and the resultant velocity, from Eq. 37, is hence dependent upon frequency. For good transmission lines, the rate of change of the velocity versus frequency is, in general, relatively small until the frequency reaches an extremely high value. Also, the velocity changes very little at low frequencies. Consequently, narrow-band signals and signals whose spectra consist of very low frequencies suffer relatively small dispersion within the operating bandwidth.

Dielectric substrates used in practical transmission lines usually have relative dielectric constants almost constant versus frequency, particularly in the low RF region. Homogeneous transmission line, such as strip line, has velocity depending exclusively on the relative dielectric constant, as given by $v = c/\sqrt{\varepsilon_r}$, hence possessing very little dispersion. Most transmission lines used in practice, however, are inhomogeneous, having more than one dielectric substrate – for example, microstrip line. An inhomogeneous transmission line has velocity depending on the effective relative dielectric constant, as shown in Eq. 217. Assuming the relative dielectric constant is independent of frequency, calculations show that in general the effective relative dielectric constant increases with frequency, and this change can be substantial, especially for high dielectric-constant substrates. Consequently, the dispersion for inhomogeneous transmission lines can be large. Due to the dispersion, signals of different frequencies travel at different velocities. Since the lengths of transmission lines used in RF circuits are typically viewed in terms of wavelength which varies as $\lambda = v/f$ (even they are given as physical dimension), which are affected by the transmission line's dispersion, the dispersion in transmission lines needs to be considered in the design and analysis of wideband RF circuits. Another effect of the dispersion is the distortion it imposes on a propagating signal whose spectrum contains multiple frequencies occurring simultaneously, which is critical for high-frequency and high-speed circuits.

Figure 6 shows the frequency-dependent effective relative dielectric constant for microstrip lines with SiO_2 and silicon as the substrate that can be used in RFICs. In practice, the relative dielectric constant slightly decreases as the frequency is increased. However, this rate of reduction is relatively small as compared to the rate of increase of the effective relative dielectric constant versus frequency, making it a secondary effect as compared to the effective relative dielectric constant. Some transmission lines have effective relative dielectric constant staying almost constant from dc up to a certain cutoff frequency and then increasing as the operating frequency exceeding that cutoff frequency. These transmission lines can hence have very small dispersion up to the cutoff frequency.

Distortion

There are various kinds of waveforms that may be used in RF circuits. However, for the discussion purposes, three kinds of waveforms are considered here: continuous sinusoidal waveform, periodic waveform, and non-periodic waveform. The sinusoid contains only single frequency and hence retains its original wave shape through linear networks; therefore, signal distortion is not much of an issue except a reduction in amplitude. It is noted that, even for wideband circuits, each signal still only has one frequency. The non-periodic and periodic signals, such as a single sinusoidal pulse or train of pulses, respectively, however, contain multiple constituent signals operating at different frequencies simultaneously. As these composite signals propagate along a transmission line, their amplitude and phase change versus frequency due to the frequency-dependent loss and dispersion of the transmission line, respectively, causing distortion in the signal waveform. This distortion can be significant for some transmission lines and signals with wide bandwidths, especially at very high frequencies, as it can alter the signal substantially as the signal propagates along a transmission line. Distortion, therefore, needs to be considered in transmission-line design as well as in circuit analysis and design. An example is pulse signals propagating in ultra-wideband (UWB) RF circuits or digital circuits, where distortion can be

DOI 10.1007/978-981-4560-75-7_129-1

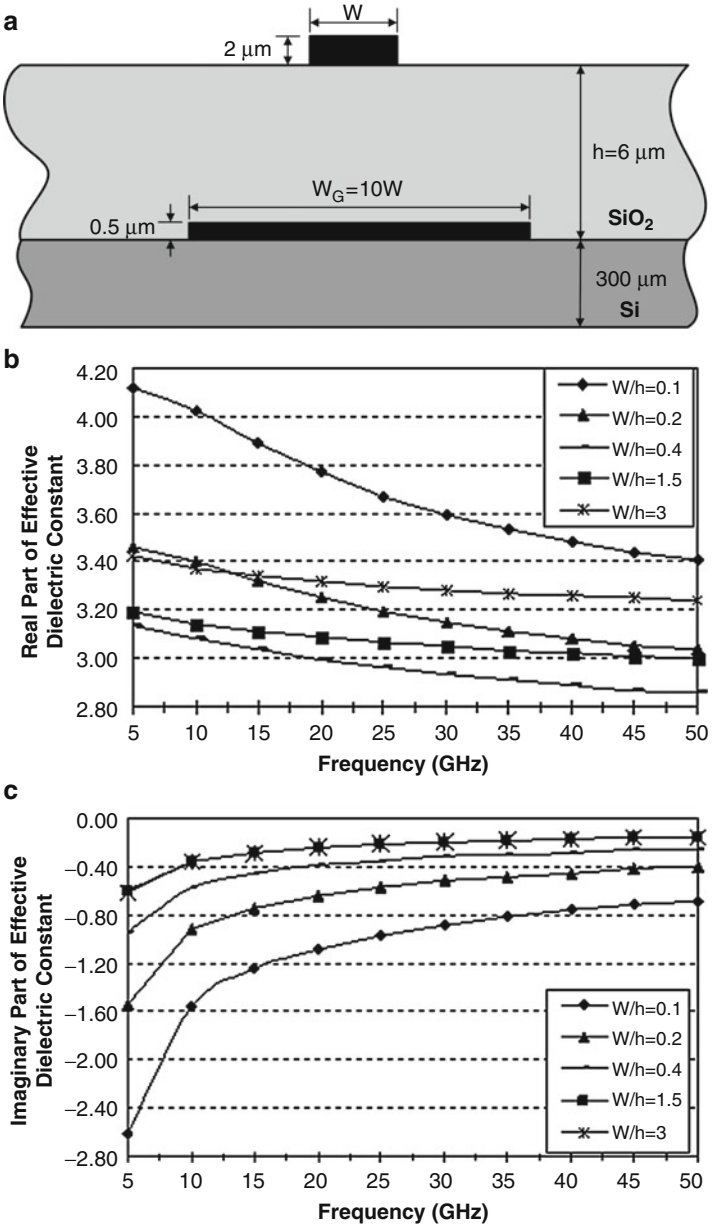

Fig. 6 Microstrip line (**a**) and its real (**b**) and imaginary (**c**) part of effective relative dielectric constant versus frequency for SiO_2 with loss tangent tan $\delta = 0.0002$ and $\varepsilon_r = 4.1$ and silicon with resistivity ρ=5Ω−cm and $\varepsilon_r = 12.5$ (**b**). The conductor is copper having conductivity $\sigma = 5.8 \times 10^7$mho/m

significant within the operating frequency range. It is noted that UWB frequencies are from 3.1 to 10.6 GHz and UWB circuits for both communications and radar can be based on pulse signals operating within this frequency range.

Periodic signals such as a train of pulses can be expressed using Fourier series as

$$\begin{aligned} V(t) &= a_0 + \sum_{n=1}^{\infty} [a_n \cos(n\omega_0 t) + b_n \sin(n\omega_0 t)] \\ &= \sum_{n=-\infty}^{\infty} c_n e^{jn\omega_0 t} \end{aligned} \tag{128}$$

where ω_0 is the fundamental frequency and a_0, a_n, b_n, and c_n are the Fourier coefficients. The signal, as can be seen, consists of multiple sinusoidal signals at discrete frequencies $\omega = n\omega_0$. Non-periodic signals such as a single pulse may also be represented using the exponential Fourier series given in Eq. 128, in which the period is extended to infinity, or using Fourier integral as

$$V(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} V(\omega)e^{j\omega t}d\omega \tag{129}$$

where $V(\omega)$ is the Fourier transform of $V(t)$, which shows that a non-periodic signal also contains multiple sinusoidal signals of different frequencies in a continuous spectrum.

An infinitely long transmission line is now considered, and it is assumed that a signal propagating along the line has a spectrum containing multiple frequencies $f_1, f_2, \ldots, f_N$, that is, the signal contains multiple signals operating at these frequencies concurrently. Since the propagation constant of the transmission line is function of frequency, the amplitude and phase constants of these constituent signals are different. The (phasor) voltage of the composite signal at any location on the line at any given time can be determined as the summation of its constituent signals, using Eq. 28, as

$$V(z) = \sum_{n=1}^{N} V_n(z) = \sum_{n=1}^{N} V_n(0)e^{-\alpha_n z}e^{-j\beta_n z} \tag{130}$$

where $V_n(z)$ and $V_n(0)$ are the voltages of the constituent signal at frequency f_n at z and $z = 0$, respectively, and α_n and β_n are the respective attenuation and phase constant at frequency f_n. Since the constituent signals arrive at z with different amplitudes and phases, they produce a distorted signal when added together. The phase distortion is caused by the dispersion of the transmission line, which typically causes the waveform to spread out and change in shape, while the amplitude distortion is due to the transmission line's loss which results in amplitude reduction. Additional distortion is caused by the reflection and cross-coupling occurred in the transmission line. Figure 7 illustrates the distortion of a signal propagating in a (practical) lossy and dispersive transmission line.

Distortionless Transmission Lines

The idea of distortionless was first proposed by Oliver Heaviside in 1887. It is postulated that the per-unit-length parameters R, L, G, and C of a transmission line are related by the following condition:

$$\frac{R}{L} = \frac{G}{C} \tag{131}$$

The propagation constant of such a transmission line can be written using Eq. 15 and the condition in Eq. 131 as

$$\begin{aligned}\gamma &= \alpha + j\beta = \sqrt{(R+j\omega L)(G+j\omega C)} \\ &= \sqrt{(R+j\omega L)\left(\frac{RC}{L}+j\omega C\right)} = \sqrt{\frac{L}{C}}(R+j\omega L)\end{aligned} \tag{132}$$

from which,

DOI 10.1007/978-981-4560-75-7_129-1

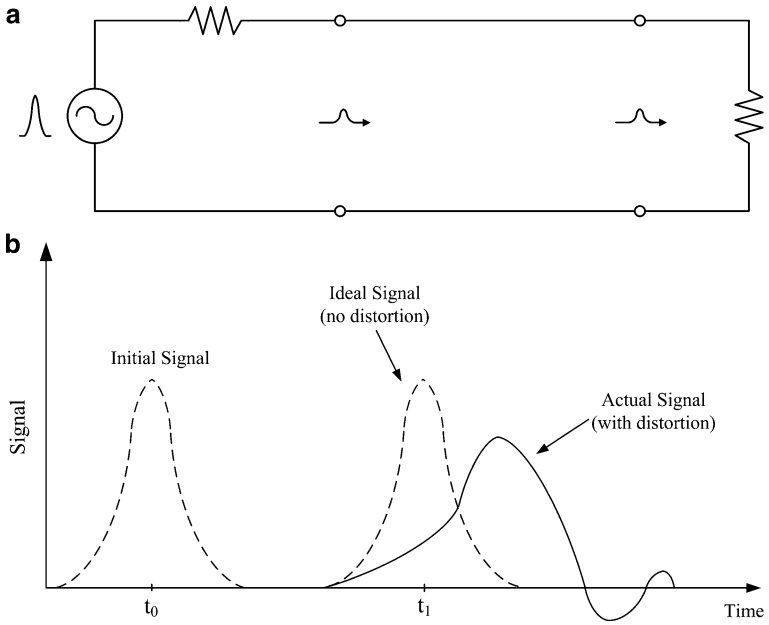

Fig. 7 Pulse signal propagating in a transmission line (**a**) and its distortion at t_1 with respect to the initial signal at t_o

$$\alpha = R\sqrt{\frac{C}{L}} \tag{133}$$

and

$$\beta = \omega\sqrt{LC} \tag{134}$$

are obtained. The characteristic impedance and phase velocity are obtained from Eqs. 26 and 37, making use of Eqs. 131 and 134, respectively, as

$$Z_o = \sqrt{\frac{R+j\omega L}{G+j\omega C}} = \sqrt{\frac{R+j\omega L}{\frac{RC}{L}+j\omega C}} = \sqrt{\frac{L}{C}} \tag{135}$$

and

$$v = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \tag{136}$$

which are exactly the same as those for lossless transmission lines. Equations 133 and 136 show that the transmission line has constant loss and velocity versus frequency, implying that the waveform of signals traversing the line retains its shape (with reduced amplitude) and hence suffers no (phase) distortion. It can therefore be concluded that any transmission line that satisfies the condition stated in Eq. 131 is distortionless. Since R and G affect the loss of transmission lines, a distortionless transmission should only be formed by adjusting L and/or C to meet the distortionless condition – for instance, placing additional series inductors periodically along the conductors of a transmission line to increase the inductance per unit length, assuming the added inductance is distributed uniformly over the segment

DOI 10.1007/978-981-4560-75-7_129-1

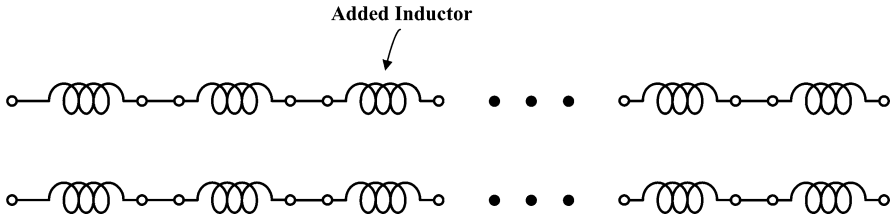

Fig. 8 Distortionless transmission formed by adding series inductors periodically

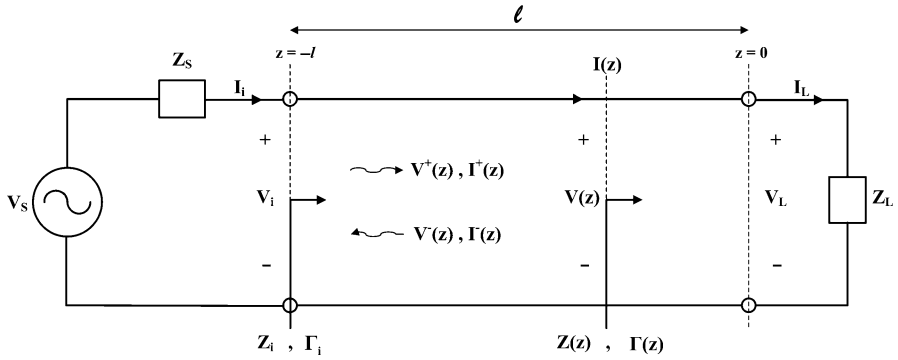

Fig. 9 A finitely long transmission line

where the inductor is added, as shown in Fig. 8. As R, L, G, and C represent a transmission line whose length is very small as compared to wavelength, the smaller the interval (period) that the additional inductors and/or capacitors are placed, the better representation for the transmission line and, hence, the better distortionless transmission that can be realized. Using smaller intervals also makes the assumption of uniform distribution for the added inductors and/or capacitors more valid.

Impedance, Reflection Coefficients, and Standing-Wave Ratios

Impedance

A transmission line of finite length, terminated with a load $Z_L \neq Z_o$, as shown in Fig. 9, is considered. It is also assumed that the transmission line is driven by a steady-state sinusoidal voltage source to facilitate the derivation of equations for the impedance, reflection coefficients, and standing-wave ratios (SWR). This assumption is valid since, like the transmission-line parameters discussed previously, these parameters are also independent of the driving source's time variation. It is assumed that the origin of the coordinate ($z = 0$) is located at the load Z_L and the transmission-line input is at $z = -\ell$. The voltage at any location, obtained as the solution of transmission-line equation, consists of the forward and backward voltage waves as described earlier. The forward voltage wave $V^+(z) = V_o^+ e^{-\gamma z}$ is also called the incident voltage wave, whereas the backward voltage wave $V^-(z) = V_o^- e^{\gamma z}$ can be called the reflected voltage wave. This reflected voltage wave is due to the reflection of the incident voltage wave along the finitely long transmission line.

The voltage V_L and current I_L at the load ($z = 0$) can be derived from Eqs. 20 to 21 as

$$V_L = V_o^+ + V_o^- \tag{137}$$

and

$$I_L = I_o^+ + I_o^- \tag{138}$$

Equation 138 can be rewritten, making use of Eq. 26, as

$$I_L = \frac{V_o^+}{Z_o} - \frac{V_o^-}{Z_o} \tag{139}$$

Dividing Eq. 137 by Z_o and adding the resulting equation to Eq. 139 gives

$$V_o^+ = \frac{1}{2}(V_L + I_L Z_o) \tag{140}$$

or

$$V_o^+ = \frac{1}{2} I_L (Z_L + Z_o) \tag{141}$$

after substituting $V_L = Z_L I_L$. Similarly, dividing Eq. 137 by Z_o, subtracting the resulting equation from Eq. 140, and using $V_L = Z_L I_L$ yield

$$V_o^- = \frac{1}{2} I_L (Z_L - Z_o) \tag{142}$$

Now substituting V_o^+ and V_o^- from Eqs. 141 and 142, respectively, into Eq. 20 gives

$$V(z) = \frac{I_L}{2}[(Z_L + Z_o)e^{-\gamma z} + (Z_L - Z_o)e^{\gamma z}] \tag{143}$$

from which

$$V^+(z) = \frac{I_L}{2}(Z_L + Z_o)e^{-\gamma z} \tag{144}$$

and

$$V^-(z) = \frac{I_L}{2}(Z_L - Z_o)e^{\gamma z} \tag{145}$$

are obtained. Similarly, the current at any point along the transmission line can be derived from Eq. 21, making use of Eqs. 26, 141, and 142, as

$$I(z) = \frac{I_L}{2Z_o}[(Z_L + Z_o)e^{-\gamma z} - (Z_L - Z_o)e^{\gamma z}] \tag{146}$$

which is formed by

$$I^{+}(z) = \frac{I_L}{2Z_o}(Z_L + Z_o)e^{-\gamma z} \tag{147}$$

and

$$I^{-}(z) = -\frac{I_L}{2Z_o}(Z_L - Z_o)e^{\gamma z} \tag{148}$$

The impedance at any location z looking toward the load is obtained from Eqs. 143 and 146 as

$$Z(z) = \frac{V(z)}{I(z)} = Z_o \frac{(Z_L + Z_o)e^{-\gamma z} + (Z_L - Z_o)e^{\gamma z}}{(Z_L + Z_o)e^{-\gamma z} - (Z_L - Z_o)e^{\gamma z}}$$

$$= Z_o \frac{Z_L(e^{\gamma z} + e^{-\gamma z}) - Z_o(e^{\gamma z} - e^{-\gamma z})}{Z_L(e^{-\gamma z} - e^{\gamma z}) + Z_o(e^{\gamma z} + e^{-\gamma z})} \tag{149}$$

Using the trigonometry identities

$$\cos h\,\gamma z = \frac{e^{\gamma z} + e^{-\gamma z}}{2} \tag{150}$$

and

$$\sin h\,\gamma z = \frac{e^{\gamma z} - e^{-\gamma z}}{2} \tag{151}$$

Eq. 149 becomes

$$Z(z) = Z_o \frac{Z_L \cos h\,\gamma z - Z_o \sin h\,\gamma z}{-Z_L \sin h\,\gamma z + Z_o \cos h\,\gamma z} \tag{152}$$

Dividing Eq. 152 by cosh γz gives

$$Z(z) = Z_o \frac{Z_L - Z_o \tan h\,\gamma z}{Z_o - Z_L \tan h\,\gamma z} \tag{153}$$

Taking a reciprocal of Eq. 153, the admittance at any location z looking toward the load can be obtained as

$$Y(z) = Y_o \frac{Y_L - Y_o \tan h\,\gamma z}{Y_o - Y_L \tan h\,\gamma z} \tag{154}$$

where $Y_o = 1/Z_o$ and $Y_L = 1/Z_L$ are the characteristic admittance of the transmission line and the load admittance, respectively. Note that the impedance and admittance calculations based on Eqs. 153 and 154, respectively, only take "negative" values for z. Of particular interest are the impedance and admittance at the input of the transmission line ($z = -\ell$) looking into the load

$$Z_i = Z_o \frac{Z_L + Z_o \tan h\,\gamma l}{Z_o + Z_L \tan h\,\gamma l} \tag{155}$$

DOI 10.1007/978-981-4560-75-7_129-1

and

$$Y_i = Y_o \frac{Y_L + Y_o \tan h\,\gamma l}{Y_o + Y_L \tan h\,\gamma l} \tag{156}$$

Reflection Coefficients

The ratio of the reflected voltage wave to the incident voltage wave is defined as the voltage reflection coefficient and is obtained from Eqs. 144 to 145 as

$$\Gamma(z) \equiv \frac{V^-(z)}{V^+(z)} = \frac{Z_L - Z_o}{Z_L + Z_o} e^{2\gamma z} \tag{157}$$

Equation 149 can be rewritten, upon using Eq. 157, as

$$Z(z) = Z_o \frac{1 + \Gamma(z)}{1 - \Gamma(z)} \tag{158}$$

from which it can be derived that

$$\Gamma(z) = \frac{Z(z) - Z_o}{Z(z) + Z_o} \tag{159}$$

At the load ($z = 0$), the reflection coefficient, namely, the load reflection coefficient, is obtained as

$$\Gamma_L = |\Gamma_L| e^{j\phi_L} = \frac{V_o^-}{V_o^+} = \frac{Z_L - Z_o}{Z_L + Z_o} \tag{160}$$

where ϕ_L is its phase. Combining Eqs. 157 and 160 gives

$$\Gamma(z) = \Gamma_L e^{2\gamma z} \tag{161}$$

Similarly, the current at any point along the transmission line can be derived from Eq. 21, making use of Eqs. 26, 140, and 141, as

$$I(z) = \frac{I_L}{2Z_o}[(Z_L + Z_o)e^{-\gamma z} - (Z_L - Z_o)e^{\gamma z}] \tag{162}$$

from which the current reflection coefficient $\Gamma_I(z)$ can be obtained as the ratio between the reflected and incident current waves

$$\Gamma_I(z) \equiv \frac{I^-(z)}{I^+(z)} = -\frac{Z_L - Z_o}{Z_L + Z_o} e^{2\gamma z} \tag{163}$$

Comparing Eqs. 157 and 163 leads to

DOI 10.1007/978-981-4560-75-7_129-1

$$\Gamma_I(z) = -\Gamma(z) \tag{164}$$

It can be seen, from Eqs. 157 and 163, that the magnitudes of the reflection coefficients in a lossless transmission line are always constant; only their phases vary as a function of location. In practice, the voltage reflection coefficient is commonly used to indicate the reflection coefficient. Note that the reflection coefficient is dimensionless and its magnitude varies between 0 and 1. The magnitude of reflection coefficient is also often expressed in decibel (dB) as $10 \log |\Gamma(z)|^2$, which is known as the return loss.

Standing-Wave Ratio

The voltage at any location along a transmission line is obtained from Eq. 20, upon using Eq. 160, as

$$\begin{aligned} V(z) &= V_o^+ e^{-\alpha z} e^{-j\beta z} + V_o^- e^{\alpha z} e^{j\beta z} \\ &= V_o^+ e^{-\alpha z} e^{-j\beta z} \left(1 + |\Gamma_L| e^{2\alpha z} e^{j(2\beta z + \phi_L)}\right) \end{aligned} \tag{165}$$

Equation 165 indicates that the amplitude and phase of the incident voltage wave reduces as the load is approached, as illustrated in Fig. 10, whereas those of the reflected voltage wave increases. So it is expected that there are locations along the transmission line, at which the amplitudes of the incident and reflected waves are equal, and there are also locations at which the phases of these opposite waves are equal or 180° out of phase. At the equal-phase locations, the two waves will add constructively while they will subtract at the out-of-phase locations.

The magnitude of the voltage at any point on a transmission line can be obtained from Eq. 165 as

$$|V(z)| = \left|V_o^+ e^{-\alpha z}\right| \left|1 + |\Gamma_L| e^{2\alpha z} e^{j(2\beta z + \phi_L)}\right| \tag{166}$$

Replacing $e^{j(2\beta z + \phi_L)}$ with $\cos(2\beta z + \phi_L) + j \sin(2\beta z + \phi_L)$ and taking the magnitude of the resulting equation gives

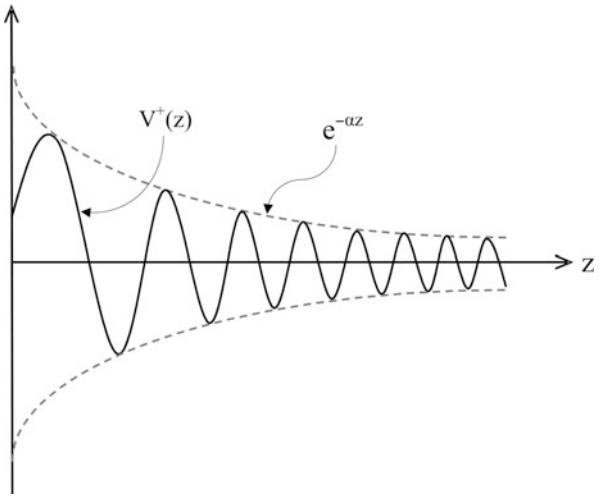

Fig. 10 Illustration of incident wave $V^+(z)$ along a transmission line

DOI 10.1007/978-981-4560-75-7_129-1

$$\begin{aligned}|V(z)| &= \left|V_o^+ e^{-\alpha z}\right| \left\{\left[1+|\Gamma_L| e^{2\alpha z}\cos\left(2\beta z+\phi_L\right)\right]^2 + \left|\Gamma_L^2\right| e^{4\alpha z}\sin^2\left(2\beta z+\phi_L\right)\right\}^{1/2} \\ &= \left|V_o^+ e^{-\alpha z}\right| \left\{\left(1+|\Gamma_L| e^{2\alpha z}\right)^2 - 2|\Gamma_L| e^{2\alpha z}\left[1-\cos\left(2\beta z+\phi_L\right)\right]\right\}^{1/2}\end{aligned} \tag{167}$$

which becomes, after using the trigonometry $\cos 2x = 1 - 2\sin^2 x$,

$$|V(z)| = \left|V_o^+ e^{-\alpha z}\right| \left\{\left(1+|\Gamma_L| e^{2\alpha z}\right)^2 - 4|\Gamma_L| e^{2\alpha z}\sin^2\left(\beta z+\phi_L/2\right)\right\}^{1/2} \tag{168}$$

Examining Eq. 168 reveals that it has maximum values of

$$|V(z)|_{\max} = \left|V_o^+ e^{-\alpha z}\right| \left(1+\left|\Gamma_L e^{2\alpha z}\right|\right) \tag{169}$$

corresponding to

$$z = \frac{n\pi - \phi_L/2}{\beta}, \quad n = 0, 1, 2, \cdots \tag{170}$$

and minimum values of

$$|V(z)|_{\min} = \left|V_o^+ e^{-\alpha z}\right| \left(1-\left|\Gamma_L e^{2\alpha z}\right|\right) \tag{171}$$

corresponding to

$$z = \frac{(n+1/2)\pi - \phi_L/2}{\beta}, \quad n = 0, 1, 2, \cdots \tag{172}$$

These results show that the magnitude of the voltage along a transmission line fluctuates as a function of location between maximum and minimum values at periodic positions. The maximum and minimum voltages are due to the addition between the incident and reflected voltage waves at locations where they have same phase and the subtraction at locations where they are 180° out of phase, respectively. The magnitude also reduces as the signal propagates along the transmission line due to loss in the line, which also results in different values for maximum (minimum) at different locations. This is in contrast with the circuit theory, which indicates that the voltage along a conductor (which is part of a two-conductor transmission line) is always constant. The spacing between two successive maxima or minima is a half-wavelength as can be determined from Eqs. 170 and 172, respectively. Equations 170 and 172 also indicate that the distance between a maximum and its nearest minimum is a quarter-wavelength.

The resultant voltage waveform formed by the incident and reflected signals, as given in Eqs. 165 and 168, is referred to as the voltage standing-wave pattern. It is noted that, at the load, the incident voltage amplitude is smallest with respect to those away from the load, whereas the amplitude of the reflected voltage is largest as compared to others at different locations. These incident and reflected voltage amplitudes at the load are thus not equal (unless $Z_L = 0$ or ∞), thereby do not create a pure standing wave at the load except when $Z_L = 0$ or ∞. However, at certain location z_o along the line, the amplitudes of the incident and reflected waves are equal as discussed earlier, and hence, standing waves would be formed in the vicinity of this location, as illustrated in Fig. 11. Far away from the location z_o in the +z and −z directions, the incident and reflected waves die out, respectively, resulting in the standing waves gradually vanishing as the waves move away from the location. The standing wave is therefore a function

DOI 10.1007/978-981-4560-75-7_129-1

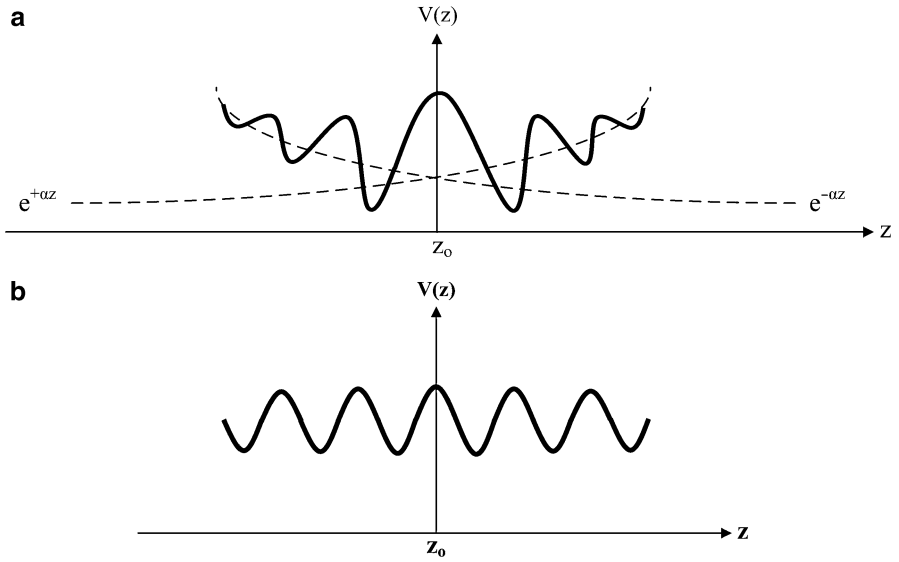

Fig. 11 Standing-wave pattern in high-loss (**a**) and low-loss (**b**) transmission line terminated with load $Z_L \neq Z_o$. The standing-wave pattern for lossless line is similar to that in (**b**)

of location along the line; its magnitude is large near the location z_o and reduces at locations away from z_o. It should be noted that, in general, a pure standing wave does not exist along a transmission line except when $\left|V_o^+ e^{-\alpha z}\right| = \left|V_o^- e^{\alpha z}\right|$, e.g., in a short-circuited lossless transmission line. Indeed, the wave can be considered as having a standing wave and a traveling wave simultaneously at any location and at any time along a transmission line. In practical transmission lines, the loss is normally small, causing an almost constant-magnitude standing-wave pattern along the line as seen in Fig. 11b, which is similar to the standing-wave pattern for a lossless transmission line. True standing wave is only possible in transmission lines terminated with a short, open, or reactance as seen later.

The ratio between $|V(z)|_{\max}$ and $|V(z)|_{\min}$ is defined as the voltage standing-wave ratio (VSWR):

$$VSWR = \frac{1 + \left|\Gamma_L e^{2\alpha z}\right|}{1 - \left|\Gamma_L e^{2\alpha z}\right|} \tag{173}$$

which is, like reflection coefficient, dimensionless and varies between 1 and infinity.

Following the same procedure, it can also be shown that the current along a transmission line oscillates between its maximum and minimum values as the current propagates, forming a current wave consisting of both standing and traveling waves. The maximum and minimum values for the current, however, occur at locations corresponding to the minimum and maximum voltages, respectively. These maximum or minimum locations are also successively spaced a half-wavelength apart. The current standing-wave ratio is equal to VSWR. In practice, VSWR is commonly used instead of the current standing-wave ratio.

Perfect Match and Total Reflection

Perfect Match

When the load impedance is equal to the transmission-line characteristic impedance, it can be obtained respectively from Eqs. 160 and 173 that

$$\Gamma_L = 0 \tag{174}$$

and

$$VSWR = 1 \tag{175}$$

which imply that the transmission line has no reflection and is perfectly matched at the load. Under this condition, all incident voltage and current waves, or incident power, will be absorbed by the load. Similarly, when the source impedance is equal to the transmission-line characteristic impedance, the transmission line is perfectly matched to the source, and no reflection occurs at the source location.

As can be seen in Eq. 161, the magnitude of the reflection coefficient reduces exponentially as the wave moves away from the load. In the limit when the distance is large, this magnitude reduces to zero. At that location, VSWR is also equal to 1. This phenomenon is also encountered in a short transmission line when the loss is high. So when a transmission line has a large loss or long length, it has no reflection at locations far away from the load.

Total Reflection

Total reflection in a transmission line occurs when the reflection coefficient or VSWR equals to 1 or infinity, respectively, as can be seen in the following cases:

Open-Circuited Transmission Line

An open-circuited transmission line is formed when it is terminated by an open ($Z_L \simeq \infty$). The reflection coefficient at the load and VSWR can be obtained from Eqs. 160 and 173 as

$$\Gamma_L = 1 \tag{176}$$

$$VSWR \simeq \infty \tag{177}$$

Equation 176 shows that the reflected and incident voltages are equal, signifying that the incident voltage and power are completely reflected back with equal phase. The transmission line has total reflection. It is noted that VSWR is only equal to infinity when the transmission line has no loss ($\alpha = 0$) or at the load ($z = 0$), as can be determined from Eq. 202. The voltage on the line can be expressed using Eqs. 165 and 176 as

$$\begin{aligned} V(z) &= V_o^+ e^{-\gamma z}(1 + \Gamma_L e^{2\gamma z}) \\ &= V_o^+ (e^{-\gamma z} + e^{\gamma z}) \\ &= 2V_o^+ \cos h(\gamma z) \end{aligned} \tag{178}$$

which clearly represents a pure standing wave. Traveling wave no longer exists along an open-circuited transmission line.

Short-Circuited Transmission Line

A short-circuited transmission line is formed when it is short-circuited at the load ($Z_L = 0$). The reflection coefficient at the load and VSWR are obtained from Eqs. 160 and 173 as

$$\Gamma_L = -1 \tag{179}$$

$$VSWR \simeq \infty \tag{180}$$

The reflected and incident voltages have equal magnitude but opposite phase, indicating that all incident voltage and power are reflected back with the phase reversed. There is total reflection along the line. It is noted that VSWR is only equal to infinity when the transmission line has no loss ($\alpha = 0$) or at the load ($z = 0$), as can be determined from Eq. 173. The total voltage along the line is found from Eqs. 165 and 179 to be

$$V(z) = -2V_o^+ \sin h(\gamma z) \tag{181}$$

representing a pure standing wave. Traveling wave no longer exists along a short-circuited transmission line.

Transmission Line Terminated with Reactance

When a transmission line is terminated with a capacitor or inductor, the magnitude of the reflection coefficient at the load is

$$|\Gamma| = 1 \tag{182}$$

The reflected and incident voltages have equal magnitude, and all incident voltage and power are reflected back.

Lossless Transmission Lines

All equations derived in sections "Impedance," "Reflection Coefficients," "Standing-Wave Ratio," and "Perfect Match and Total Reflection" are applicable for lossy as well as lossless transmission lines. For lossless transmission lines, the attenuation constant $\alpha = 0$ and the propagation constant $\gamma = j\beta$, where β is the phase constant. Making use of these and recognizing that $tan(j\beta l) = jtan(\beta l)$, the following equations can be derived from Eqs. 153 to 156:

$$Z(z) = Z_o \frac{Z_L - jZ_o \tan \beta z}{Z_o - jZ_L \tan \beta z} \tag{183}$$

$$Y(z) = Y_o \frac{Y_L - jY_o \tan \beta z}{Y_o - jY_L \tan \beta z} \tag{184}$$

$$Z_i = Z_o \frac{Z_L + jZ_o \tan \beta l}{Z_o + jZ_L \tan \beta l} \tag{185}$$

$$Y_i = Y_o \frac{Y_L + jY_o \tan \beta l}{Y_o + jY_L \tan \beta l} \tag{186}$$

$\theta = \beta l$ is called the electrical length of the line and depends on frequency. Electrical length actually represents the phase of the transmission line and is frequently used in high-frequency circuit design. Note that the input impedance Z_i and input admittance Y_i are periodic functions with respect to βl and therefore repeat themselves every half-wavelength along the transmission line. From Eqs. 157, 161, and 163, it can be derived that

DOI 10.1007/978-981-4560-75-7_129-1

$$\Gamma(z) = \frac{Z_L - Z_o}{Z_L + Z_o} e^{2j\beta z} \tag{187}$$

$$\Gamma(z) = \Gamma_L e^{2j\beta z} \tag{188}$$

$$\Gamma_I(z) = -\frac{Z_L - Z_o}{Z_L + Z_o} e^{2j\beta z} \tag{189}$$

from which

$$|\Gamma(z)| = |\Gamma_I(z)| = |\Gamma_L| = \left|\frac{Z_L - Z_o}{Z_L + Z_o}\right| \tag{190}$$

From Eq. 173, it can be written that

$$VSWR = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|} \tag{191}$$

and hence,

$$|\Gamma(z)| = |\Gamma_L| = \frac{VSWR - 1}{VSWR + 1} \tag{192}$$

These (lossless) equations are commonly used in practice. It is noted that the VSWR and magnitude of the reflection coefficient in a lossless transmission line are always constant. This is expected as the magnitudes of the incident and reflected voltage waves remain constant as they propagate along a lossless transmission line. The voltage standing-wave pattern on a lossless transmission line is similar to that for a low-loss transmission line as shown in Fig. 11b.

The input impedance of an open-circuited lossless transmission line can be derived from Eq. 185, by letting $Z_L = \infty$, as

$$Z_{io} = Z_o \frac{Z_L + jZ_o \tan\beta l}{Z_o + jZ_L \tan\beta l} = -jZ_o \cot an\beta l \tag{193}$$

The input admittance is

$$Y_{io} = jY_o \tan\beta l \tag{194}$$

Similarly, the input impedance and admittance of a short-circuited lossless transmission line can be derived from Eq. 185 by letting $Z_L = 0$ as

$$Z_{is} = jZ_o \tan\beta l \tag{195}$$

$$Y_{is} = -jY_o \cot\beta l \tag{196}$$

Examining Eqs. 193, 194, 195, and 196 reveals that open- and short-circuited lossless lines behave as an inductor or a capacitor depending on the operating frequency and the transmission line's physical length. At a given frequency, any inductor or capacitor can be theoretically realized by choosing a proper length

DOI 10.1007/978-981-4560-75-7_129-1

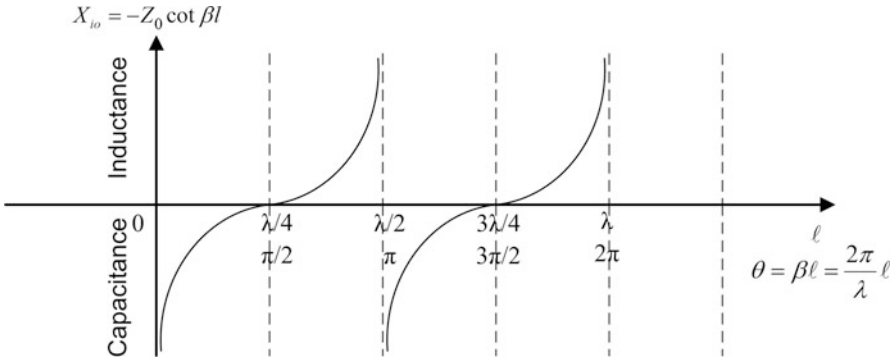

Fig. 12 Impedance behavior of an open-circuited lossless transmission lines versus lengths

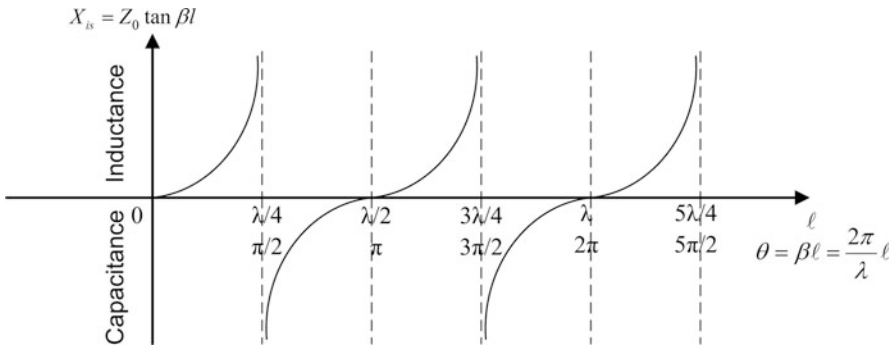

Fig. 13 Impedance behavior of a short-circuited lossless transmission lines versus lengths

for these transmission lines. Figures 12 and 13 illustrate the inductive and capacitive behaviors of open- and short-circuited lossless transmission lines, respectively, versus physical and electrical lengths.

When the transmission line is very short compared to wavelength, $\beta l = 2\pi l/\lambda << 1$. $\tan \beta l$ can then be approximated as βl and it can be obtained from Eq. 193:

$$Z_{io} \cong -j\frac{Z_o}{\beta l} \tag{197}$$

Replacing $Z_o = \sqrt{L/C}$ from Eq. 39 and $\beta = \omega\sqrt{LC}$ from Eq. 40 leads to

$$Z_{io} \cong \frac{1}{j\omega(Cl)} \tag{198}$$

which shows that a very short open-circuited lossless transmission line behaves as a capacitor having a capacitance value of Cl. Note that C is the capacitance per unit length of the line and a transmission line (whether open-circuited or not), whose length is not very short compared to wavelength, does not behave as a capacitor of Cl. Similarly, the following equation for a short-circuited lossless transmission line can be derived when its length is very short compared to wavelength:

$$Z_{is} \cong j\omega(Ll) \tag{199}$$

which indicates that a very short short-circuited line behaves as an inductor with an inductance of Ll. Note

DOI 10.1007/978-981-4560-75-7_129-1

that L is the inductance per unit length of the line and a transmission line (whether short-circuited or not), whose length is not very short compared to wavelength, does not behave as an inductor of *Ll*.

Two special cases worth mentioned are the open- and short-circuited transmission lines whose lengths are multiples of quarter-wavelength. Substituting $l = n\lambda/4$, where n is a positive integer, into Eqs. 222 and 224, we obtain

$$Z_{io} = 0 \qquad \text{for open-circuited lossless line} \tag{200}$$

and

$$Z_{is} = \infty \qquad \text{for short-circuited lossless line} \tag{201}$$

These results indicate that open- and short-circuited transmission lines of multiple quarter wavelengths behave as short and open circuits at their inputs, respectively. Quarter-wavelength open- and short-circuited transmission lines ($l = \lambda/4$) are often used in bias networks for high-frequency narrow-band circuits.

Synthetic Transmission Lines

As discussed in section "Transmission-Line Equations," a transmission line can be approximately represented as an equivalent circuit consisting of many identical sub-circuits, each sub-circuit corresponding to an infinitesimal section of the transmission line, as shown in Fig. 14. For lossless transmission lines, R = G = 0 as seen in Fig. 14b, and a signal would traverse without loss, implying that uniform lossless transmission lines can be operated over extremely wide bandwidths up to the limit of the TEM or quasi-TEM cutoff frequency (theoretically infinite bandwidth.)

Examination of Fig. 14b reveals that synthetic (or artificial) transmission lines may be formed by cascading multiple identical LC sections or cells. It is noted that R and G seen in Fig. 14a represent losses due to the conductors and substrate, respectively, which are undesirable. Therefore, they are not used in creating synthetic transmission lines. Nevertheless, R and G are implicitly included in synthetic transmission lines due to the losses associated with the constituent inductors and capacitors, respectively. These losses essentially limit the operating bandwidth of synthetic transmission lines. It is expected that the larger the number of sections (N) for a synthetic transmission, the closer the resemblance of an actual transmission line. Synthetic transmission lines can exploit the properties of transmission lines to achieve certain functions without using actual transmission lines or eliminate the need of configuring actual

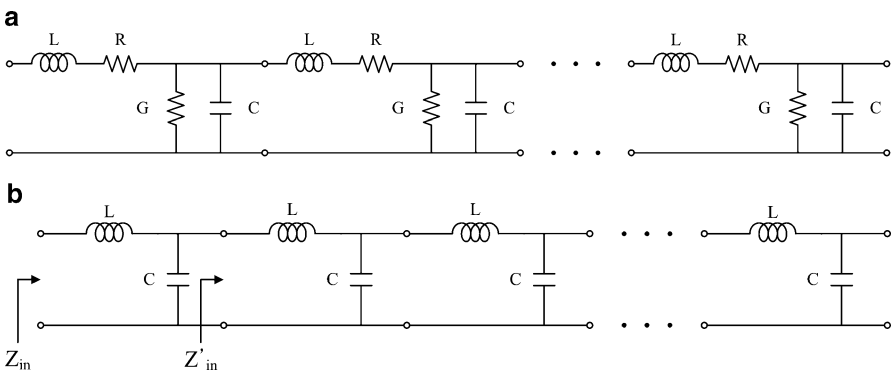

Fig. 14 Approximate equivalent circuit of lossy (**a**) and lossless (**b**) transmission lines

DOI 10.1007/978-981-4560-75-7_129-1

transmission lines in particular fashions (e.g., microstrip line), which might be difficult and/or inconvenient to realize under certain cases. For instance, for silicon-based system-on-chip implementations with embedded antennas, synthetic transmission lines could be used in place of real transmission lines in antenna-feeding circuitry such as Wilkinson power divider to reduce the die size, which is crucial for on-chip applications.

A lossless synthetic transmission line with infinite number of sections ($N \to \infty$) as represented in Fig. 14b is now considered, and the inductors and capacitors are assumed ideal. Its characteristic impedance and phase velocity can be treated the same as those for lossless transmission lines. That is, they can be obtained from Eqs. 39 and 41 as

$$Z_o = \sqrt{\frac{L}{C}} \tag{202}$$

and

$$v_p = \frac{1}{\sqrt{LC}} \tag{203}$$

respectively. Note that herein L and C are the inductance and capacitance of each section making up the synthetic transmission line. The time delay per section of a synthetic transmission line is considered as equivalent to the time delay per unit length of a corresponding actual transmission line and, hence, can be obtained as

$$t_d = \sqrt{LC} \tag{204}$$

It can be seen that a synthetic transmission line provides flexibility in realizing a particular characteristic impedance and phase velocity by properly choosing L and C. It can also achieve certain time delay (small or large) with suitable L, C, and N. Using actual transmission lines may require a long physical length in order to obtain a large time delay.

When the constituent inductors and capacitors have small loss, the corresponding synthetic transmission line can be considered as having low loss, and, similar to an actual low-loss transmission line, its characteristic impedance, attenuation constant, phase constant, and velocity can be obtained from Eqs. 49 to 52 as

$$Z_o \cong \sqrt{\frac{L}{C}}\left[1 + j\left(\frac{G}{2\omega C} - \frac{R}{2\omega L}\right)\right] \tag{205}$$

$$\alpha \cong \frac{1}{2}\left(R\sqrt{\frac{C}{L}} + G\sqrt{\frac{L}{C}}\right) \tag{206}$$

$$\beta \cong \omega\sqrt{LC} \tag{207}$$

$$v \cong \frac{1}{\sqrt{LC}} \tag{208}$$

DOI 10.1007/978-981-4560-75-7_129-1

where R and G are the resistance and conductance representing loss in the inductor and capacitor of each cell, respectively.

The lossless synthetic transmission line as shown in Fig. 14b resembles a low-pass filter, and therefore, it is associated with a cutoff frequency ω_c which defines passband and stopband below and above ω_c, respectively. As N is of infinity, it is justified to assume that (N-1) also approaches infinity. As such, the input impedances Z_{in} and Z'_{in} would be equal. As indicated in Fig. 14b, Z_{in} can be written as a combination of series L and parallel (C, Z'_{in}):

$$Z_{\text{in}} = j\omega L + \frac{1}{\frac{1}{Z_{\text{in}}} + j\omega C} \tag{209}$$

where Z'_{in} in the right-high side has been replaced with Z_{in}. Expanding Eq. 209 gives

$$Z_{\text{in}}^2 - j\omega L Z_{\text{in}} - \frac{L}{C} = 0 \tag{210}$$

which can be solved for Z_{in}:

$$Z_{\text{in}} = \frac{1}{2} j\omega L \pm \frac{1}{2} j \sqrt{\frac{L}{C}} \sqrt{\omega^2 LC - 4} \tag{211}$$

Equation 211 shows that when $\omega^2 LC - 4 < 0$, corresponding to $\omega < 2/\sqrt{LC}$, Z_{in} is complex, and signals with $\omega < 2/\sqrt{LC}$ can propagate along the transmission line, hence signifying a passband. In the limit of ω approaching 0, Z_{in} approaches the characteristic impedance $Z_o = \sqrt{L/C}$. On the other hand, when $\omega^2 LC - 4 > 0$, $\omega > 2/\sqrt{LC}$ and correspondingly Z_{in} becomes imaginary. Signals whose (radian) frequencies are above $2/\sqrt{LC}$ thus cannot propagate on the transmission line, thereby indicating a stopband corresponding to a cutoff frequency of

$$\omega_c = \frac{2}{\sqrt{LC}} \tag{212}$$

For ideal (lossless) synthetic transmission line, the cutoff frequency becomes, making use of Eq. 202,

$$\omega_c = \frac{2}{CZ_o} \tag{213}$$

The cutoff frequency effectively sets the operating bandwidth of synthetic transmission lines from *dc* to ω_c.

A synthetic transmission line should therefore be designed so that its highest operating frequency is below $\omega_c = 2/\sqrt{LC}$. In practice, the number of sections N making up a synthetic transmission line is always finite, so the actual cutoff frequency is smaller (in fact, could be much smaller) than the theoretical value calculated from Eq. 212 which corresponds to infinite N. Therefore, the highest operating frequency may need to be much smaller than ω_c for proper operation. Typically, the cutoff frequency is chosen to be at least three times of the highest operating frequency. Actual simulation of a designed synthetic transmission line needs to be performed to make sure its cutoff frequency is well above the intended operating frequency range. It is particularly noted that a synthetic transmission line is not an exact

DOI 10.1007/978-981-4560-75-7_129-1

transmission line; it only approximates a transmission line over a certain bandwidth, which may be wide or narrow depending on the number of sections used and the values of L and C.

In some applications, such as those requiring signals at multiple frequencies to be transmitted concurrently, such as (time-domain) pulse signals including ultra-wideband (UWB) signals that contain simultaneous components at frequencies within 3.1–10.6 GHz, frequency-independent velocity or linear phase response versus frequency in the passband is needed to avoid signal distortion. The lossless and low-loss synthetic transmission lines have exact and approximate frequency-independent velocities as seen in Eqs. 203 and 208, respectively, and correspondingly producing no and minimum signal distortion theoretically.

A synthetic transmission line can be designed by choosing L and C to achieve desired characteristic impedance per Eq. 202 and desired cutoff frequency (or bandwidth) per Eq. 212. For wide bandwidth, LC is kept sufficiently small to produce a high cutoff frequency. Effectively, there is a trade-off between the operating bandwidth and characteristic impedance (and hence matching for circuits implementing the synthetic transmission line). In order to achieve a certain time delay, the number of required sections can be determined from

$$N = \frac{T_d}{t_d} = \frac{T_d}{\sqrt{LC}} \tag{214}$$

where T_d is the desired time delay.

It is noted that synthetic transmission lines, as suggested in their equivalent circuit, can also be realized using solid-state devices, such as Schottky diodes or MOSFETs, operated in the linear (small-signal) regime to implement both inductors and capacitors, or a combination between lumped elements and solid-state devices. Using solid-state devices would make smaller synthetic transmission lines, which are attractive for low-cost RF applications, yet at possible degradation of circuit performance such as increased noise and reduced linearity, which are not desirable, especially in the receiver front end. Particularly, for large-signal circuits, such as power amplifiers, solid-state devices should not be used due to their nonlinear behavior under large signals, unless they are intended to be used as nonlinear elements in the designed synthetic transmission line.

The main function of a synthetic transmission line is to maintain as close as possible its desired characteristic impedance within a specified tolerance over a bandwidth as wide as possible. Additionally, under some operating conditions, it is also desired to maintain linear phase response as much as possible to avoid signal distortion due to phase nonlinearity. In practice, inductors, capacitors, and semiconductor devices used in synthetic transmission lines have their own parasitics, generally consisting of resistors, inductors, and capacitors, which may severely degrade the transmission-line performance, especially in high RF regions. For instance, the parasitics cause increase in loss and more distortion in the transmission phase, leading to reduced operating bandwidth. Therefore, care must be exercised when designing a synthetic transmission line; all parasitics of its constituent elements must be considered in simulations to make sure that the introduced attenuation and distortion will not ruin the integrity of the signal passing through the transmission line within the operating frequency range. In order to lessen these effects, the number of sections needs to be limited considering trade-off with the operating bandwidth.

TEM and Quasi-TEM Transmission-Line Parameters

Transmission lines with perfect conductors embedded in a homogeneous medium, such as strip line, support pure transverse electromagnetic (TEM) mode or wave. However, transmission lines with more

DOI 10.1007/978-981-4560-75-7_129-1

than two dielectrics (or embedded in an inhomogeneous medium), such as microstrip line, can only support quasi-TEM mode which resembles TEM mode. The TEM or quasi-TEM mode is the dominant mode in transmission lines and has no cutoff frequency, implying that transmission lines can support signals from DC up to very high frequencies at which higher-order modes begin to propagate. The most important parameters of a transmission line for circuit design purposes, assuming the line is not very lossy, are perhaps the characteristic impedance and effective dielectric constant for the quasi-TEM mode. For transmission lines with high loss, the attenuation constant is also an important parameter.

As the operating frequency increases, an infinite number of modes including quasi-TEM and higher-order modes may exist in transmission lines, particularly near discontinuities. Higher-order modes have cutoff frequencies which limit the operating frequency ranges and are undesirable. These modes have either longitudinal electric or magnetic field or both. The modes having longitudinal electric field is called transverse magnetic (TM) modes, and those having longitudinal magnetic field is referred to as transverse electric (TE) modes. The modes having both longitudinal electric and magnetic fields are known as hybrid modes. When a higher-order mode coexists with the quasi-TEM mode above a certain frequency, it will disrupt the circuit performance since it will take away some of the energy of the quasi-TEM mode and, particularly, will generate spurious responses in active circuits. The share of energy that sustains the higher-order mode is inevitable due to the conservation of power and the fact that the total energy propagating in a transmission line is finite.

There are two approaches in analyzing a transmission line: static or quasi-static and dynamic or full-wave approaches. The static or quasi-static approach only produces transmission-line parameters for the TEM or quasi-TEM mode that are theoretically valid only at DC. On the other hand, the dynamic approach not only can produce the frequency-dependent transmission-line parameters for the TEM or quasi-TEM mode but also those for the higher-order modes, whose parameters are functions of frequency.

As stated earlier, transmission line parameters obtained by the static or quasi-static approach are strictly valid at DC. In practice, however, these results can also be used at higher frequencies. The question most engineers would ask is how high of frequency they can use static results. There is no clear-cut answer for this. Some tends to believe that as long as the frequency is different from zero, static results cannot be used. On the other hand, most practical engineers perhaps use static results up to high frequencies such as around 18 GHz. In fact, a number of millimeter-wave circuits operating up to *W*-band (75–110 GHz) developed in the 1980s has been successfully designed using only static results. Nevertheless, at high frequencies, especially those in the millimeter-wave region, a dynamic approach should be employed for more accurate determination of the parameters of transmission lines. The main trade-off between using static versus dynamic results is that the former is simpler to calculate but less accurate.

Static or Quasi-Static Analysis

Static or quasi-static analysis produces transmission-line parameters that are frequency independent. Simple equations can now be derived for the static or quasi-static characteristic impedance and effective relative dielectric constant of transmission lines. Without loss of generality, a lossless microstrip line, as shown in Fig. 15a, is considered as a representative transmission line.

The characteristic impedance of this transmission line is given as

$$Z_o = \sqrt{\frac{L}{C}} \tag{215}$$

where L and C are the inductance and capacitance per unit length of the transmission line, respectively. Let L_a and C_a represent the inductance and capacitance per unit length of the transmission line when the

DOI 10.1007/978-981-4560-75-7_129-1

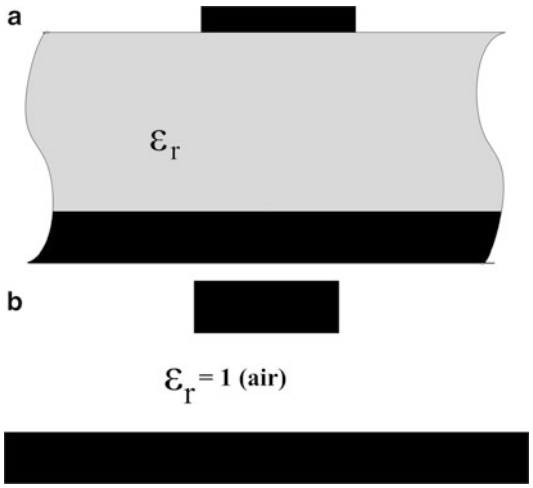

Fig. 15 Microstrip line with (**a**) and without (**b**) substrate

dielectric is replaced by air (i.e., $\varepsilon_r = 1$) as shown in Fig. 15b. Equation 215 can then be rewritten, using the fact that the inductance per unit length does not depend upon the surrounding dielectrics, as

$$Z_o = \sqrt{\frac{L_a}{C_a}\frac{C_a}{C}} = \frac{1}{c\sqrt{CC_a}} \tag{216}$$

where $c = 3 \times 10^8$ m/s is the speed of light in air. The phase velocity of the quasi-TEM wave propagating along the transmission line is given as

$$v_p = \frac{c}{\sqrt{\varepsilon_{\text{reff}}}} \tag{217}$$

where $\varepsilon_{\text{reff}}$ is defined as the effective relative dielectric constant. Squaring both sides of Eq. 217 and making use of $L = L_a$, we obtain

$$\varepsilon_{\text{reff}} = \frac{C}{C_a} \tag{218}$$

The corresponding wavelength is given as

$$\lambda = \frac{\lambda_o}{\sqrt{\varepsilon_{\text{reff}}}} \tag{219}$$

where $\lambda_o = c/f$ is the free-space wavelength. It is now apparent that the static or quasi-static characteristic impedance and effective relative dielectric constant of any transmission line can be determined solely in terms of the transmission line's capacitances per unit length with and without dielectrics.

Dynamic Analysis

Dynamic analysis produces frequency-dependent characteristic impedance and propagation constant and, hence, attenuation and effective dielectric constant of transmission lines for TEM or quasi-TEM as well as hybrid modes. This approach begins by solving the wave equations derived from Maxwell's equations for

DOI 10.1007/978-981-4560-75-7_129-1

the electric and magnetic fields subject to appropriate boundary conditions. The process also yields an eigenvalue equation whose eigenvalue is the propagation constant $\gamma = \alpha + j\beta$.

The phase constant β can be used to calculate the effective dielectric constant as

$$\varepsilon_{\text{eff}} = \left(\frac{\beta}{\text{k}_o}\right)^2 \tag{220}$$

where $k_o = \omega\sqrt{\varepsilon_o \mu_o}$ is the free-space wave number. It should be noted that the phase constant must follow the condition

$$\omega\sqrt{\varepsilon_{\text{o}}\mu_o} \leq \beta \leq \omega\sqrt{\varepsilon_{\text{o}}\mu_o\varepsilon_r} \tag{221}$$

where ε_r has the highest value of relative dielectric constants used for the transmission line.

Using the electric and magnetic fields, the (dynamic) characteristic impedance can be calculated as a function of frequency. It is well known that the characteristic impedance for the TEM or quasi-TEM mode is unique since the mode's voltage and current are uniquely defined. For a hybrid mode, however, the characteristic impedance is not unique. There exist various definitions for the characteristic impedance, and the common ones are based on the voltage and current, power and current, and power and voltage as given respectively below:

$$Z_o^{VI} = \frac{V_o}{I_o} \tag{222}$$

$$Z_o^{PI} = \frac{2P_{\text{avg}}}{|I_o|^2} \tag{223}$$

$$Z_o^{PV} = \frac{|V_o|^2}{2P_{\text{avg}}} \tag{224}$$

where V_o is the voltage across the conductors, I_{o} is the longitudinal current, and P_{avg} represents the time-average power transmitted across the transmission line's cross section. These three characteristic impedances are related by

$$Z_o^{VI} = \sqrt{Z_o^{PI} Z_o^{PV}} \tag{225}$$

It should be noted that different definitions of the characteristic impedance give different numerical results, except at DC. For TEM or quasi-TEM mode, however, all the three definitions give identical results. These definitions are also identical if $P_{\text{avg}} = \frac{1}{2} VI^*$. Generally, this condition is, however, not valid for hybrid modes in a transmission line. The definitions based on the power and current and power and voltage are deduced from a two-conductor transmission line. The choice of a particular definition is not very clear. A possible choice is to use a definition according to a specific use of the transmission line in a circuit. A common definition for transmission lines containing slots, such as slot line and coplanar waveguide (CPW), is based on the power and voltage. For instance, the characteristic impedance of CPW, shown in Fig. 18, can be obtained from Eq. 224 with the voltage and power given as

DOI 10.1007/978-981-4560-75-7_129-1

$$V_o = \int_a^b E_x(x,h)\ dx \tag{226}$$

$$P_{\text{avg}} = \frac{1}{2} R_e \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left(E_x H_y^* - E_y H_x^* \right)\ dxdy \tag{227}$$

The characteristic impedance of the slot line, shown in Fig. 22, can also be defined by Eq. 224, where the power is again given by Eq. 227 and the voltage is obtained as

$$V_o = \int_{-W/2}^{W/2} E_x(x,h)\ dx \tag{228}$$

For other transmission lines without slots, the definitions based on the current and power and voltage and current are normally employed. For the case of microstrip line, shown in Fig. 17, the current, voltage, and power are given as

$$I_o = \int_{-W/2}^{W/2} J_z(x,h)\ dx \tag{229}$$

$$V_o = -\int_o^h E_y dy \tag{230}$$

$$P_{\text{avg}} = \frac{1}{2} R_e \int_o^{\infty} \int_{-\infty}^{\infty} \left(E_x H_y^* - E_y H_x^* \right)\ dxdy \tag{231}$$

where J_z is the current density on the strip along the z direction.

Printed-Circuit Transmission Lines

Printed-circuit transmission lines, typically configured as planar and uniplanar structures, are important in RF circuits. Printed-circuit transmission lines have evolved from the advances of electronic integrated circuits (ICs), and in turn, they have helped pushing the progress of the IC technology, such as making the ICs more compact, more versatile, having better interconnections and improved performance, etc. Not only that printed-circuit transmission lines fulfill their most fundamental objective of delivering signals; they can also be exploited to create various RF components, such as wideband hybrid junctions, by appropriately combining them. Various printed-circuit transmission lines have also been developed. The most commonly used structures are microstrip line, coplanar waveguide (CPW), coplanar strip (CPS), strip line, and slot line; among them, the microstrip line and strip line form the first planar version of the well-known coaxial transmission line. Figure 16 describes these printed-circuit transmission lines.

This section presents a brief discussion of these transmission lines along with the closed-form formulas for computing their characteristic impedances, effective dielectric constants, and losses. In all these equations, infinitely wide ground planes are assumed. However, they are also valid for narrow ground planes provided that the field distributions are not significantly altered. Although these parameters can be accurately determined using various dynamic methods, the closed-form expressions allow convenient and fast computer-aided design and analysis of RF circuits. It is especially noted that all the printed-circuit

DOI 10.1007/978-981-4560-75-7_129-1

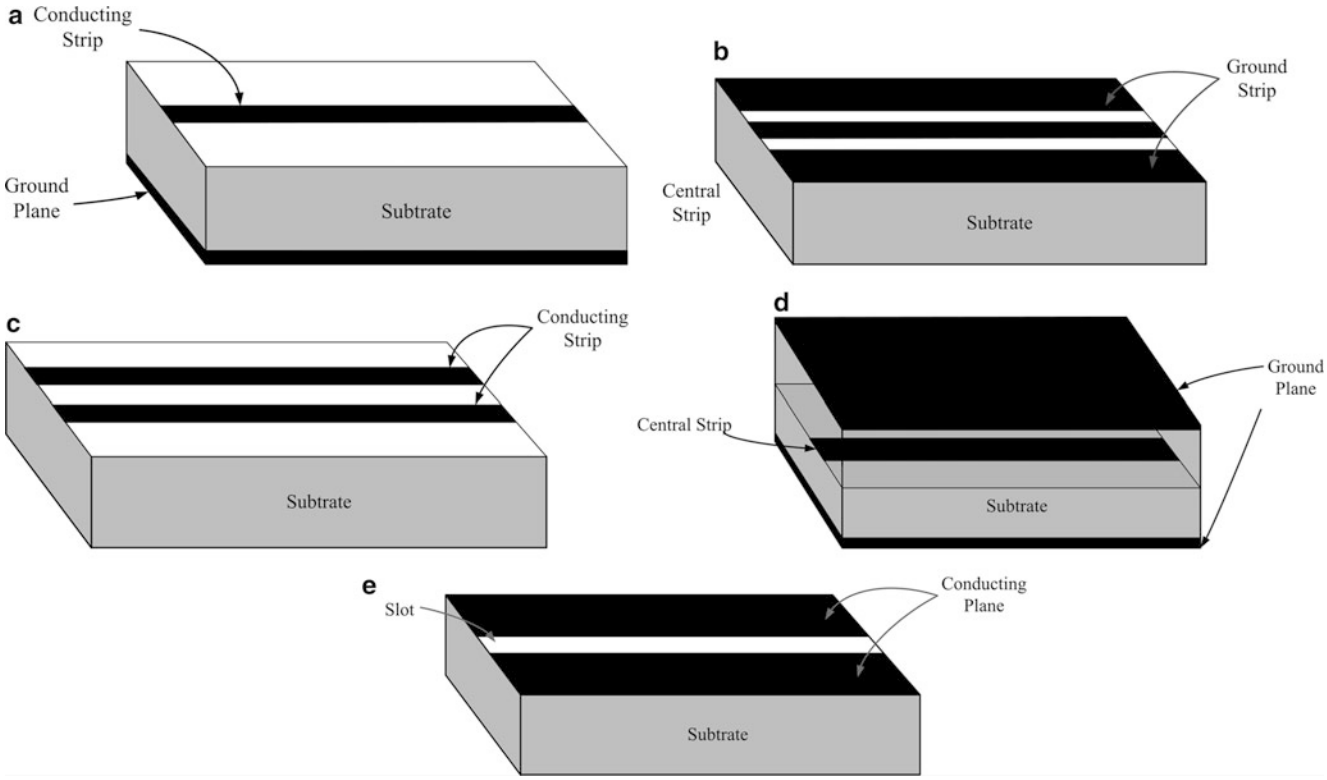

Fig. 16 Commonly used printed-circuit transmission lines: (**a**) microstrip line, (**b**) CPW, (**c**) CPS, (**d**) strip line, and (**e**) slot line

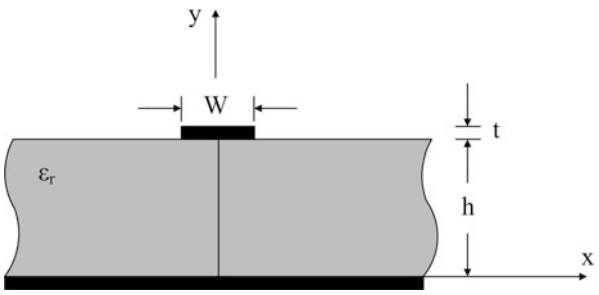

Fig. 17 Cross section of microstrip line

transmission lines are presented with single dielectric, single metal layer, and large ground plane (assumed to be infinitely wide) as conventionally employed. However, multiple dielectrics and metals and/or narrow ground planes can be used to optimize the performance as well as the size of the transmission lines. This kind of implementation is particularly suitable for RF hybrid integrated circuits designed on multilayer substrates such as low-temperature co-fired ceramic (LTCC) and liquid crystal polymer (LCP) materials or RFICs on silicon, which has inherent multiple dielectric and metal layers. Such implementations are, in fact, needed since reducing size is one of the main concerns in RF circuit design.

Microstrip Line

The microstrip line, as shown in Fig. 17, was first proposed in 1952 (Grieg and Englemann 1952), and since then it has become a widely used transmission line due to its planar nature, ease of fabrication using

DOI 10.1007/978-981-4560-75-7_129-1

photolithographic processes, easy integration with solid-state devices, good heat sinking, and good mechanical support.

The closed-form expressions for the characteristic impedance and effective dielectric constant of the microstrip line, assuming zero strip thickness ($t = 0$), are given as (Edwards 1984)

$$Z_o = \begin{cases} \dfrac{119.9}{\sqrt{2(\varepsilon_r+1)}} \left\{ \ln\left[4\dfrac{h}{W} + \sqrt{16\left(\dfrac{h}{W}\right)^2 + 2}\right] - \dfrac{1}{2}\left(\dfrac{\varepsilon_r - 1}{\varepsilon_r - 1}\right)\left(\ln\dfrac{\pi}{2} + \dfrac{1}{\varepsilon_r}\ln\dfrac{4}{\pi}\right)\right\}, & \dfrac{W}{h} < 3.3 \\ \dfrac{119.9\pi}{2\sqrt{\varepsilon_r}} \left\{ \dfrac{W}{2h} + \dfrac{\ln 4}{\pi} + \dfrac{\ln\left(\frac{e\pi^2}{16}\right)}{2\pi}\left(\dfrac{\varepsilon_r - 1}{\varepsilon_r^2}\right) + \dfrac{\varepsilon_r + 1}{2\pi\varepsilon_r}\left[\ln\dfrac{e\pi}{2} + \ln\left(\dfrac{W}{2h} + 0.94\right)\right]\right\}^{-1}, & \dfrac{W}{h} > 3.3 \end{cases} \tag{232}$$

and

$$\varepsilon_{\text{reff}} = \begin{cases} \dfrac{\varepsilon_r + 1}{2} + \dfrac{\varepsilon_r - 1}{2}\left(1 + 10\dfrac{h}{W}\right)^{-0.555}, & Z_o < (63 - 2\varepsilon_r)\Omega \\ \dfrac{\varepsilon_r + 1}{2}\left[1 - \dfrac{1}{2K}\left(\dfrac{\varepsilon_r - 1}{\varepsilon_r + 1}\right)\left(\ln\dfrac{\pi}{2} + \dfrac{1}{\varepsilon_r}\ln\dfrac{4}{\pi}\right)\right]^{-2}, & Z_o > (63 - 2\varepsilon_r)\Omega \end{cases} \tag{233}$$

where $e = 2.7182818$ is the Euler constant and

$$K = \frac{Z_o\sqrt{2(\varepsilon_r + 1)}}{119.9} + \frac{1}{2}\left(\frac{\varepsilon_r - 1}{\varepsilon_r + 1}\right)\left(\ln\frac{\pi}{2} + \frac{1}{\varepsilon_r}\ln\frac{4}{\pi}\right) \tag{234}$$

The accuracy of the characteristic impedance and effective dielectric constant calculated from Eqs. 232 to 233 is within ±1 and ±0.25 %, respectively.

The normalized strip width, W/h, can also be determined from the characteristic impedance and relative dielectric constant as

$$\frac{W}{h} = \begin{cases} \dfrac{2}{\pi}[D - 1 - \ln(2D - 1)] + \dfrac{\varepsilon_r - 1}{\pi\varepsilon_r}\left[\ln(D - 1) + 0.293 - \dfrac{0.517}{\varepsilon_r}\right], & Z_o < (44 - 2\varepsilon_r)\Omega \\ \left(\dfrac{e^K}{8} - \dfrac{1}{4e^K}\right)^{-1}, & Z_o > (44 - 2\varepsilon_r)\Omega \end{cases} \tag{235}$$

where

$$D = \frac{59.95\pi^2}{Z_o\sqrt{\varepsilon_r}} \tag{236}$$

Using Eq. 235, W/h can be determined within ±1 % of accuracy.

Practical microstrip line has finite strip thickness t, which effectively increases the strip width. Equations 232 and 233 can be modified to take into account t for more accurate results as (Gupta et al. 1979a)

DOI 10.1007/978-981-4560-75-7_129-1

$$Z_o(t) = \begin{cases} \dfrac{60}{\sqrt{\varepsilon_{\text{reff}}(t)}} \ln\left[\dfrac{8h}{W_e} + 0.25\dfrac{W_e}{h}\right], & \dfrac{W}{h} \le 1 \\ \dfrac{120\pi}{\sqrt{\varepsilon_{\text{reff}}(t)}}\left[\dfrac{W_e}{h} + 1.393 + 0.667\ln\left(\dfrac{W_e}{h} + 1.444\right)\right]^{-1}, & \dfrac{W}{h} \ge 1 \end{cases} \tag{237}$$

and

$$\varepsilon_{\text{reff}}(t) = \varepsilon_{\text{reff}} - C \tag{238}$$

where

$$\frac{W_e}{h} = \begin{cases} \dfrac{W}{h} + \dfrac{1.25}{\pi}\dfrac{t}{h}\left(1 + \ln\dfrac{4\pi W}{t}\right), & \dfrac{W}{h} \le \dfrac{1}{2\pi} \\ \dfrac{W}{h} + \dfrac{1.25}{\pi}\dfrac{t}{h}\left(1 + \ln\dfrac{2h}{t}\right), & \dfrac{W}{h} \ge \dfrac{1}{2\pi} \end{cases} \tag{239}$$

$$C = \frac{\varepsilon_r - 1}{4.6}\frac{t/h}{\sqrt{W/h}} \tag{240}$$

and $\varepsilon_{\text{reff}}$ is the effective relative dielectric constant with $t = 0$ obtained from Eq. 233.

The frequency-dependent effective dielectric constant and characteristic impedance can be found from Hammerstad and Jensen (1980) as

$$\varepsilon_{\text{reff}}(f) = \varepsilon_r - \frac{\varepsilon_r - \varepsilon_{\text{reff}}(0)}{1 + G\left(\frac{f}{f_p}\right)^2} \tag{241}$$

and

$$Z_o(f) = Z_o(0)\frac{\varepsilon_{\text{reff}}(f) - 1}{\varepsilon_{\text{reff}}(0) - 1}\sqrt{\frac{\varepsilon_{\text{reff}}(0)}{\varepsilon_{\text{reff}}(f)}} \tag{242}$$

where

$$\mathrm{f_p} = \frac{\mathrm{Z_o}(0)}{2\mu_{\mathrm{o}}\mathrm{h}} \tag{243}$$

$$G = \frac{\pi^2}{12}\frac{\varepsilon_r - 1}{\varepsilon_{\text{reff}}(0)}\sqrt{\frac{Z_o(0)}{60}} \tag{244}$$

$\varepsilon_{\text{eff}}(0)$ and $Z_o(0)$ are the quasi-static effective dielectric constant and characteristic impedance, which can be determined using Eqs. 233 or 238 and 232 or 237, respectively, and $\mu_o = 4\pi \times 10^{-7}$ H/m is the permeability of free space.

DOI 10.1007/978-981-4560-75-7_129-1

As for any transmission line, the loss in microstrip line is due to imperfect conductors and dielectrics and is characterized by the attenuation constant $\alpha = \alpha_{c+}\alpha_d$, where α_c and α_d represent the conductor and dielectric attenuation constants, respectively. α_c (in dB/cm) can be determined from Pucel et al. (1968a, b)

$$\alpha_c = \begin{cases} \dfrac{8.68R_s}{2\pi Z_o h}\left[1-\left(\dfrac{W_e}{4h}\right)^2\right]\left\{1+\dfrac{h}{W_e}+\dfrac{h}{\pi W_e}\left[\ln\left(\dfrac{4\pi W}{t}\right)+\dfrac{t}{W}\right]\right\}, & 0<\dfrac{W}{h}\le 1/2\pi \\ \dfrac{8.68R_s}{2\pi Z_o h}\left[1-\left(\dfrac{W_e}{4h}\right)^2\right]\left\{1+\dfrac{h}{W_e}+\dfrac{h}{\pi W_e}\left[\ln\left(\dfrac{2h}{t}\right)-\dfrac{t}{h}\right]\right\}, & 1/2\pi<\dfrac{W}{h}\le 2 \\ \dfrac{8.68R_s}{Z_o h}\left\{1+\dfrac{h}{W_e}+\dfrac{h}{\pi W_e}\left[\ln\left(\dfrac{2h}{t}\right)-\dfrac{t}{h}\right]\right\}\left[\dfrac{W_e}{h}+\dfrac{\dfrac{W_e}{\pi h}}{\dfrac{W_e}{2h}+0.94}\right]\left[\dfrac{W_e}{h}+\dfrac{2}{\pi}\ln\left(\dfrac{W_e}{2h}+0.94\right)\right]^{-2}, & \dfrac{W}{h}\ge 2 \end{cases} \tag{245}$$

where $R_s = \sqrt{\omega\mu_d/2\sigma}$ is the surface resistivity of the conductor, with σ being the conductivity. W_e is the effective strip width, taking into account the strip's finite metallization thickness, given in Eq. 268. α_d can be found by (Welch and Pratt 1966)

$$\alpha_d = \frac{27.3\varepsilon_r(\varepsilon_{reff}-1)\tan\delta}{\sqrt{\varepsilon_{reff}}(\varepsilon_r-1)\lambda_0} \qquad (dB/m) \tag{246}$$

where tanδ is the loss tangent of the dielectric and λ_o is the free-space wavelength. For the microstrip line or any other printed-circuit transmission lines employing low-loss dielectrics, such as SiO_2 used in RFICs, the dielectric loss is normally much lower than the conductor loss. However, when these transmission lines are deposited directly on high-loss substrates such as silicon in RFICs without proper shielding from the high-loss substrates, the dielectric loss becomes dominant.

Coplanar Waveguide

Figure 18 shows cross sections of the conventional and conductor-backed coplanar waveguide (CPW). The (conventional) CPW was first proposed in 1969 (Wen 1969). Since then, it has rapidly gained widespread use due to its many attractive features, such as elimination of via-holes in connecting circuit elements to ground, easy integration with solid-state devices, ease in realizing compact-balanced circuits, and reduction of cross talk between lines. The CPW consists of a central conducting strip (signal line) and two ground conducting strips (ground lines). The two ground lines must be tied together so that they act as a single conductor in order to form a two-conductor transmission line together with the signal line. Otherwise, it can cause propagation problems at high frequencies due to the existence of additional (quasi-TEM) modes of a three-conductor transmission line. In practice, they are connected together via air-bridges. In the simplest equivalence, an air-bridge is modeled as a network consisting of series inductor, resistor, and shunt capacitor, hence resulting in different potentials at the ground lines. For the conductor-backed CPW, via-holes are typically used to connect the back conductor to the ground lines to keep them at equal potential and prevent or minimize the propagation of the other transmission-line modes and parallel-plate waveguide modes within the operating frequency range. However, since a via-hole would electrically consist of at least a resistor in series with an inductor, it inhibits the back conductor from being at the same potential with the ground strips. The unequal potentials are more pronounced at very high frequencies, resulting in potential problems for the CPW to maintain as a two-conductor

DOI 10.1007/978-981-4560-75-7_129-1

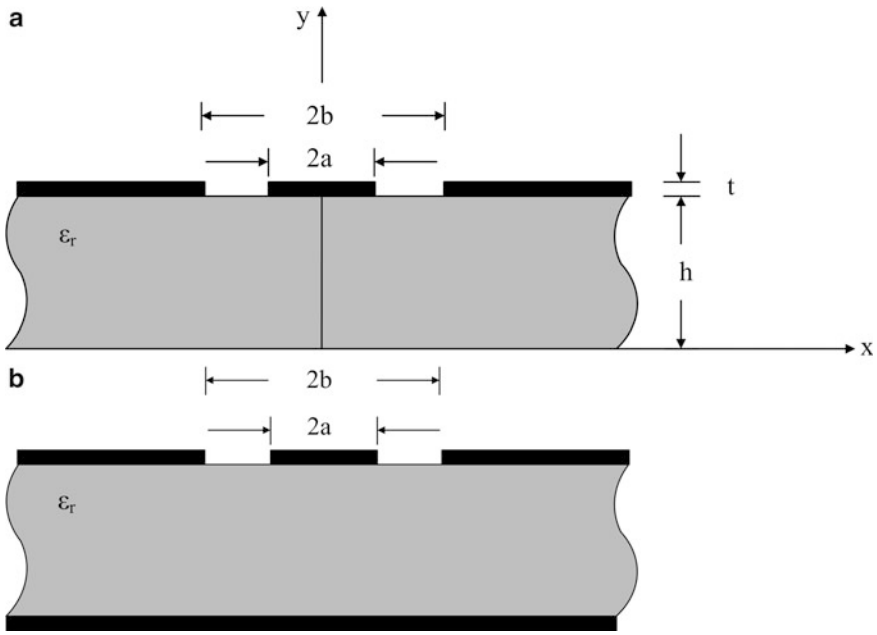

Fig. 18 Cross section of conventional (**a**) and conductor-backed (**b**) CPW

transmission line. The conductor-backed CPW particularly increases the mechanical strength as well as facilitate heat sinking and packaging needed for practical applications. It is operated at narrower bandwidth as compared to the conventional CPW due to the possibility of parallel-plate waveguide mode propagation.

Closed-form expressions for the effective relative dielectric constant and characteristic impedance of CPWs with zero strip thickness and infinitely wide ground strips were derived using conformal-mapping methods (Ghione and Naldi 1983, 1984). For the conventional CPW, they are given according to (Ghione and Naldi 1984)

$$\varepsilon_{\text{eff}} = 1 + \frac{\varepsilon_r - 1}{2} \frac{K(k')}{K(k)} \frac{K(k_1)}{K\left(k_1'\right)} \tag{247}$$

and

$$Z_o = \frac{30\pi}{\sqrt{\varepsilon_{\text{eff}}}} \frac{K(k')}{K(k)} \tag{248}$$

where

$$k = \frac{a}{b} \tag{249}$$

$$k' = \sqrt{1 - k^2} \tag{250}$$

DOI 10.1007/978-981-4560-75-7_129-1

$$k_1 = \frac{\sin h\left(\frac{\pi a}{2h}\right)}{\sin h\left(\frac{\pi b}{2h}\right)} \tag{251}$$

$$k_1' = \sqrt{1\text{-}k_1^2} \tag{252}$$

K represents the complete integral of the first kind, whose values can be determined from an integral or tabulated tables. The $K(k)/K(k')$ ratio can also be approximately obtained by (Hilberg 1965)

$$\frac{K(k)}{K(k')} = \begin{cases} \dfrac{\pi}{\ln\left(2\dfrac{1+\sqrt{k'}}{1-\sqrt{k'}}\right)}, & 0 \le k \le 0.707 \\ \frac{1}{\pi}\ln\left(2\frac{1+\sqrt{k}}{1-\sqrt{k}}\right), & 0.707 \le k \le 1 \end{cases} \tag{253}$$

For the conductor-backed CPW, the effective dielectric constant and characteristic impedance can be evaluated from (Ghione and Naldi 1983)

$$\varepsilon_{\text{eff}} = \frac{1 + \varepsilon_r \dfrac{K(k')}{K(k)} \dfrac{K(k_1)}{K\left(k_1'\right)}}{1 + \dfrac{K(k')}{K(k)} \dfrac{K(k_1)}{K\left(k_1'\right)}} \tag{254}$$

and

$$Z_o = \frac{60\pi}{\sqrt{\varepsilon_{\text{eff}}}} \frac{1}{\dfrac{K(k)}{K(k')} + \dfrac{K(k_1)}{K\left(k_1'\right)}} \tag{255}$$

where

$$k = \frac{a}{b} \tag{256}$$

$$k' = \sqrt{1 - k^2} \tag{257}$$

$$k_1 = \frac{\tan h\left(\frac{\pi a}{2h}\right)}{\tan h\left(\frac{\pi b}{2h}\right)} \tag{258}$$

$$k_1' = \sqrt{1 - k_1^2} \tag{259}$$

DOI 10.1007/978-981-4560-75-7_129-1

When the thickness t of the central strip and ground strips is considered, the widths of the strip and gaps effectively increase and decrease, respectively. The effective dielectric constant and characteristic impedance of the (conventional) CPW can be found, taking into account this effect, using the following formulas (Gupta et al. 1979b):

$$\varepsilon_{\text{reff}}(t) = \varepsilon_{\text{reff}} - \frac{0.7(\varepsilon_{\text{reff}} - 1)\dfrac{t}{b-a}}{\dfrac{K(k)}{K(k')} + 0.7\dfrac{t}{b-a}} \tag{260}$$

where $\varepsilon_{\text{reff}}$ is the effective relative dielectric constant when $t = 0$ given in Eq. 247 and

$$Z_o = \frac{30\pi}{\sqrt{\varepsilon_{\text{reff}}(t)}} \frac{K(k_e')}{K(k_e)} \tag{261}$$

where

$$k_e = \frac{S_e}{S_e + 2W_e} \tag{262}$$

$$k_{\text{e}}' = \sqrt{1 - k_e^2} \tag{263}$$

$$S_e = 2a + \Delta \tag{264}$$

$$W_e = b - a - \Delta \tag{265}$$

$$\Delta = \frac{1.25t}{\pi}\left[1 + \ln\left(\frac{8\pi a}{t}\right)\right] \tag{266}$$

The conductor attenuation constant for the conventional CPW is given as (Gupta et al. 1981)

$$\alpha_c = \frac{4.88 \times 10^{-4}}{\pi} R_s \varepsilon_{\text{reff}} Z_0 P \frac{b+a}{(b-a)^2} \left\{ \frac{\dfrac{1.25t}{\pi}\ln\left(\dfrac{8\pi a}{t}\right) + 1 + \dfrac{1.25t}{2\pi a}}{\left[2 + \dfrac{2a}{b-a} - \dfrac{1.25t}{\pi(b-a)}\left(1 + \ln\dfrac{8\pi a}{t}\right)\right]^2} \right\} (dB/m) \tag{267}$$

where

$$P = \begin{cases} \dfrac{k}{(1-k')(k')^{3/2}}\left[\dfrac{K(k)}{K(k')}\right]^2, & 0 \le k \le 0.707 \\ \dfrac{1}{(1-k)\sqrt{k}}, & 0.707 \le k \le 1 \end{cases} \tag{268}$$

The expression for the dielectric attenuation constant is the same as that for the microstrip line, which is given in Eq. 246.

DOI 10.1007/978-981-4560-75-7_129-1

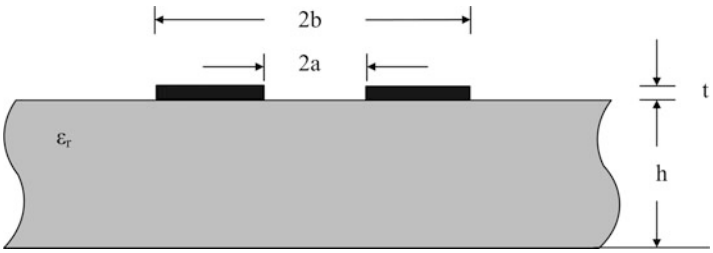

Fig. 19 Cross section of coplanar strips

Coplanar Strips

Coplanar strips (CPS), as shown in Fig. 19, employ two parallel strips on the same side of a dielectric substrate. The CPS structure is also useful for RF circuits, especially balanced circuits due to its inherent balance nature. The CPS structure allows easy connections for series and shunt solid-state devices. The effective dielectric constant and characteristic impedance of the CPS for zero strip thickness can be evaluated using the following closed-form equations derived from a conformal-mapping method (Ghione and Naldi 1984):

$$\varepsilon_{\text{eff}} = 1 + \frac{\varepsilon_r - 1}{2} \frac{K(k')}{K(k)} \frac{K(k_1)}{K(k_1')} \tag{269}$$

and

$$Z_o = \frac{120\pi}{\sqrt{\varepsilon_{\text{eff}}}} \frac{K(k)}{K(k')} \tag{270}$$

where

$$k = \frac{a}{b} \tag{271}$$

$$k' = \sqrt{1 - k^2} \tag{272}$$

$$k_1 = \frac{\sin h\left(\frac{\pi a}{2h}\right)}{\sin h\left(\frac{\pi b}{2h}\right)} \tag{273}$$

$$k_1' = \sqrt{1 - k_1^2} \tag{274}$$

When the strip thickness is considered, the effective dielectric constant and characteristic impedance can be determined using (Gupta et al. 1979b)

$$\varepsilon_{\text{reff}}(t) = \varepsilon_{\text{eff}} - \frac{0.7(\varepsilon_{\text{reff}} - 1)\frac{t}{a}}{\frac{K(k')}{K(k)} + 0.7\frac{t}{a}} \tag{275}$$

DOI 10.1007/978-981-4560-75-7_129-1

and

$$Z_o(t) = \frac{120\pi}{\sqrt{\varepsilon_{\text{reff}}(t)}} \frac{K(k_e)}{K(k'_e)} \tag{276}$$

where

$$k_e = \frac{S_e}{S_e + 2W_e} \tag{277}$$

$$k'_e = \sqrt{1 - k_e^2} \tag{278}$$

$$S_e = S - \Delta \tag{279}$$

$$W_e = W + \Delta \tag{280}$$

$$\Delta = \frac{1.25\text{t}}{\pi}\left[1 + \ln\left(4\pi\frac{b-a}{t}\right)\right] \tag{281}$$

The attenuation due to the conductor loss can be found from Gupta et al. (1981)

$$\alpha_c = \frac{4.34}{\pi}\frac{R_s}{Z_o}P\frac{a+b}{a^2}\left\{\frac{\frac{1.25}{\pi}\ln\left(4\pi\frac{b-a}{t}\right) + 1 + \frac{1.25}{\pi}\frac{t}{b-a}}{\left\{1 + \frac{b-a}{a} + \frac{1.25}{2\pi}\frac{t}{a}\left[1 + \ln\left(4\pi\frac{b-a}{t}\right)\right]\right\}^2}\right\} \tag{282}$$

where P is given in (4.297). The dielectric attenuation constant can be determined from Eq. 268.

Strip Line

Strip line, as shown in Fig. 20, is essentially a printed-circuit version of the coaxial transmission line. Its dominant mode of propagation is pure TEM, assuming perfect conductors. Because of possible excitement of unwanted parallel-plate modes at high frequencies due to the two parallel ground planes, the strip line is in general more suitable for use in low RF regimes. Its characteristic impedance for zero-thickness strip can be determined using the following conformal-mapping formulas (Cohn 1954):

$$Z_o = \frac{30\pi}{\sqrt{\varepsilon_r}} \frac{K(k')}{K(k)} \tag{283}$$

where

$$k = \tan h\left(\frac{\pi W}{4a}\right) \tag{284}$$

$$k' = \sqrt{1 - k^2} \tag{285}$$

DOI 10.1007/978-981-4560-75-7_129-1

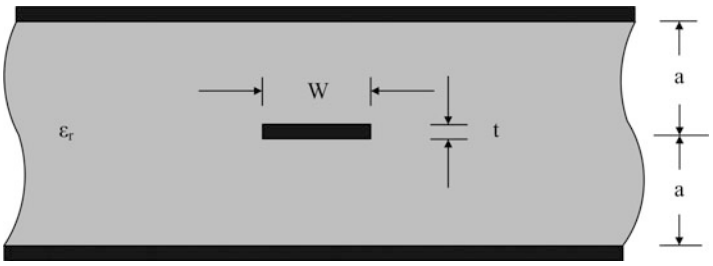

Fig. 20 Cross section of strip line

For finite strip thickness, the characteristic impedance can be found from Wheeler (1978)

$$Z_o = \frac{30}{\sqrt{\varepsilon_r}} \ln\left\{1 + \frac{4}{\pi}\frac{2a-t}{W_e}\left[\frac{8}{\pi}\frac{2a-t}{W_e} + \sqrt{\left(\frac{8}{\pi}\frac{2a-t}{W_e}\right)^2 + 6.27}\right]\right\} \tag{286}$$

where

$$\frac{W_e}{2a-t} = \frac{W}{2a-t} + \frac{\Delta W}{2a-t} \tag{287}$$

$$\frac{\Delta W}{2a-t} = \frac{x}{\pi(1-x)}\left\{1 - \frac{1}{2}\ln\left[\left(\frac{x}{2-x}\right)^2 + \left(\frac{0.0796x}{\frac{W}{2a}+1.1x}\right)^m\right]\right\} \tag{288}$$

$$m = \frac{2}{1 + \frac{2x}{3(1-x)}} \tag{289}$$

$$x = \frac{t}{2a} \tag{290}$$

The strip width can also be determined from the characteristic impedance and relative dielectric constant. For a zero-thickness strip, the expression for the strip width can be derived from Eqs. 283 to 285 as

$$\frac{W}{a} = \frac{4}{\pi} \tan h^{-1}\sqrt{p} \tag{291}$$

where

$$p = \begin{cases} \sqrt{1 - \left[\frac{e^{\pi q}-2}{e^{\pi q}+2}\right]^4}, & q \geq 1 \\ \left[\frac{\frac{\pi}{e^q}-2}{\frac{\pi}{e^q}+2}\right]^2, & 0 \leq q \leq 1 \end{cases} \tag{292}$$

$$q = \frac{Z_o\sqrt{\varepsilon_r}}{30\pi} \tag{293}$$

DOI 10.1007/978-981-4560-75-7_129-1

Using Eqs. 286, 287, 288, 289, and 290, we can drive the following expression for the strip width, taking into account the strip thickness

$$\frac{W}{2a-t} = \frac{W_e}{2a-t} - \frac{\Delta W}{2a-t} \tag{294}$$

where

$$\frac{W_e}{2a-t} = \frac{8}{\pi A} \tag{295}$$

$$\frac{\Delta W}{2a-t} = \frac{x}{\pi(1-x)}\left\{1 - \frac{1}{2}\ln\left[\left(\frac{x}{2-x}\right)^2 + \left(\frac{0.0796x}{\frac{W_e}{2a}+1.1x}\right)^m\right]\right\} \tag{296}$$

$$A = \frac{2B}{C} \tag{297}$$

$$B = \exp\left(\frac{Z_o\sqrt{\varepsilon_r}}{30}\right) - 1 \tag{298}$$

$$C = \sqrt{4B + 6.27} \tag{299}$$

$$m = \frac{2}{1 + \frac{2x}{3(1-x)}} \tag{300}$$

$$x = \frac{t}{2a} \tag{301}$$

The conductor attenuation constant (in dB/m) can be determined from

$$\alpha_c = \begin{cases} \dfrac{23.4x10^{-3}R_s\varepsilon_r Z_o A}{30\pi(2a-t)}, & Z_o < \dfrac{120}{\sqrt{\varepsilon_r}} \\ \dfrac{1.4R_s B}{2Z_o a}, & Z_o > \dfrac{120}{\sqrt{\varepsilon_r}} \end{cases} \tag{302}$$

where

$$A = 1 + \frac{2W}{2a-t} + \frac{1}{\pi}\frac{2a+t}{2a-t}\ln\left(\frac{4a-t}{t}\right) \tag{303}$$

$$B = 1 + \frac{2a}{0.5W + 0.7t}\left(0.5 + \frac{0.414t}{W} + \frac{1}{2\pi}\ln\frac{4\pi W}{t}\right) \tag{304}$$

The dielectric attenuation constant is given by

DOI 10.1007/978-981-4560-75-7_129-1

$$\alpha_d = \frac{27.3\sqrt{\varepsilon_r}\tan\delta}{\lambda_o} \qquad (dB/m) \tag{305}$$

Slot Line

The slot line, whose cross section is shown in Fig. 21, is also useful for RF circuits. Its balance nature is especially attractive for circuits requiring balance topology. It is noted that, in contrast with conventional transmission lines, the two conducting strips forming the slot are kept at equal potential (typically grounded) and the slot line does not support a TEM or quasi-TEM propagation mode. Modes propagating on the slot line are quasi-TE modes, which resemble the TE type. The dominant mode is quasi-TE_{10}, similar to the TE_{10} of the rectangular waveguides. The quasi-TE_{10} mode of the slot line, however, has no cutoff frequency. Due to the propagating mode being quasi-TE_{10}, when the slot line is used together with other transmission lines supporting TEM or quasi-TEM mode in circuits, suitable transitions between them need to be used to allow proper transformation of the fields of the slot line into those of the other transmission lines. In order to be used as a good transmission line, the slot line should be fabricated using a substrate with a high dielectric constant to minimize radiation.

Closed-form expressions for the characteristic impedance, Z_o, based on voltage and power and the wavelength, λ_g, for the slot line on high dielectric constant substrates ($9.7 \le \varepsilon_r \le 20$) were obtained (Garg and Gupta 1976) by curve fitting to the numerical results based on Cohn (1969). They are given as

$$\lambda_g/\lambda_o = \begin{cases} 0.923 - 0.195\ln\varepsilon_r + 0.2\dfrac{W}{h} - \left(0.126\dfrac{W}{h} + 0.02\right)\ln\left(\dfrac{h}{\lambda_o}\times 10^2\right), & 0.02 \le \dfrac{W}{h} \le 0.2 \\ 0.987 - 0.21\ln\varepsilon_r + \dfrac{W}{h}(0.111 - 0.0022\varepsilon_r) - \left(0.053 + 0.041\dfrac{W}{h} - 0.0014\varepsilon_r\right)\ln\left(\dfrac{h}{\lambda_o}\times 10^2\right) & \\ \qquad , \ 0.2 \le \dfrac{W}{h} \le 1 \end{cases} \tag{306}$$

$$Z_o = \begin{cases} 72.62 - 15.283\ln\varepsilon_r + 50\dfrac{\left(\dfrac{W}{h} - 0.02\right)\left(\dfrac{W}{h} - 0.1\right)}{W/h} + \ln\left(\dfrac{W}{h}\times 10^2\right)[19.23 - 3.693\ln\varepsilon_r] \\ -\left[0.139\ln\varepsilon_r - 0.11 + \dfrac{W}{h}(0.465\ln\varepsilon_r + 1.44)\right]\left(11.4 - 2.636\ln\varepsilon_r - \dfrac{h}{\lambda_o}\times 10^2\right)^2, \ 0.02 \le \dfrac{W}{h} \le 0.2 \\ 113.19 - 23.257\ln\varepsilon_r + 1.25\dfrac{W}{h}(114.59 - 22.531\ln\varepsilon_r) + 20\left(\dfrac{W}{h} - 0.2\right)\left(1 - \dfrac{W}{h}\right) \\ -\left[0.15 + 0.1\ln\varepsilon_r + \dfrac{W}{h}(-0.79 + 0.899\ln\varepsilon_r)\right] \\ \times\left[10.25 - 2.171\ln\in_r + \dfrac{W}{h}(2.1 - 0.617\ln\in_r) - h/\lambda_o x 10^2\right]^2, \ 0.2 \le \dfrac{W}{h} \le 1 \end{cases} \tag{307}$$

These equations were obtained assuming infinitesimally thin conductors and are accurate to within 2 % for the following ranges:

DOI 10.1007/978-981-4560-75-7_129-1

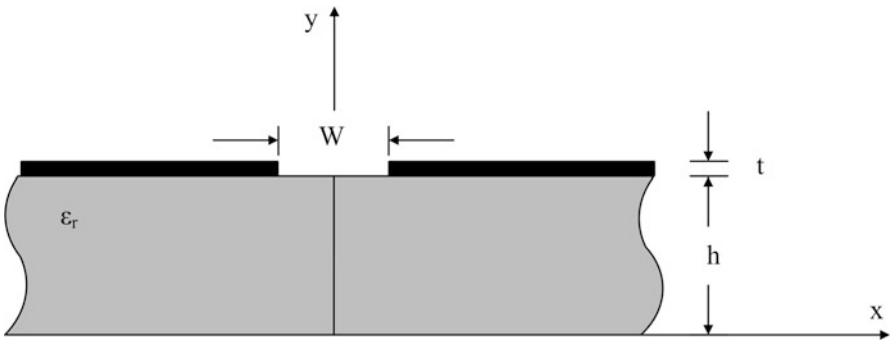

Fig. 21 Cross section of slot line

$$9.7 \leq \varepsilon_r \leq 20 \tag{308}$$

$$0.01 \leq \frac{h}{\lambda_o} \leq \left(\frac{h}{\lambda_o}\right)_c \tag{309}$$

where $(h/\lambda_o)_c$ is the cutoff value for the TE_{10} surface-wave mode on the slot line and is given as

$$\left(\frac{h}{\lambda_o}\right)_c = 0.25\sqrt{\varepsilon_r - 1} \tag{310}$$

Closed-form expressions for the characteristic impedance and wavelength for low dielectric constant substrates were also derived by curve fitting to results of the spectral-domain method (Janaswamy and Schaubert 1986).

Field Distributions

The behavior of a transmission line and the signal propagating on it, governed by the power $\vec{P} = 1/2\mathrm{Re}\left(\vec{E} \times \vec{H}^*\right)$, are dictated by the transmission line's electric and magnetic fields, which affect circuit performance at all frequencies, particularly more pronounced at high frequencies. Therefore, in RF circuit design, it is important and useful to understand the field distributions of printed-circuit transmission lines used in RF circuits. As signals propagate along a transmission line, they carry with them the electric and magnetic fields, and the signals may couple from the transmission line to other circuit elements including transmission lines. The coupling between a transmission line and other transmission lines or circuit elements is caused by the springing of the transmission line's electric and/or magnetic fields onto other lines or circuit elements. There are two kinds of coupling between transmission lines (or between a transmission line and other circuit elements): one is the electric coupling caused by the electric fields between the transmission lines and another is the magnetic coupling caused by the magnetic fields. The field distribution of a transmission line thus helps RF designers to visualize and comprehend the effects of coupling from one transmission line to another, effectively enabling them to optimize circuit layout while considering possible effects on circuit performance. This is especially important in RFICs where circuit elements are placed so close to each other to minimize circuit size. Another important utilization of the field distribution is for the matching between the fields of different kinds of transmission lines – for example, between microstrip line and CPW – when they are connected together. From the circuit theory point of view, two interconnected transmission lines only need to have equal characteristic impedances. This, however, is not sufficient considering EM effects; these equal-characteristic-

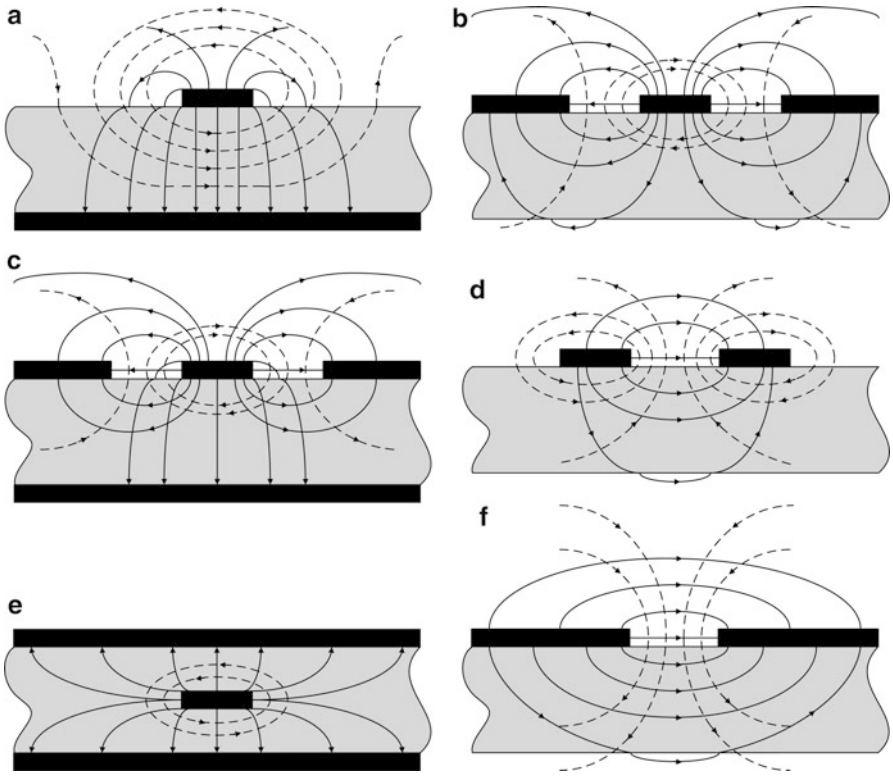

Fig. 22 Field distributions of microstrip line (**a**), CPW (**b**), conductor-backed CPW (**c**), CPS (**d**), strip line (**e**), and slot line (**f**). _____ Electric field - - - - - - - - Magnetic field

impedance transmission lines should also have their electric and magnetic fields matched to each other to minimize possible reflections due to unmatched fields at the interconnecting junction. In general, a transition between these lines should be used to allow the fields of one line to be transformed into those of the other. Figure 22 illustrates the field distributions of the printed-circuit transmission lines shown in Fig. 16. From these field distributions, we can see that the width of the ground strip, whether or not in the same plane of the central strip, does not have to be large; only sufficient width is needed to contain all or majority of the electric fields emanating from the central strip. This field confinement is particularly critical in RF circuits fabricated on high-loss substrates such as silicon-based RFICs, as the electric fields not terminated by the ground plane may enter the (high-loss) substrate, causing significant dielectric loss.

Transmission Lines in Multilayer RF Circuits

Multilayer substrates are essential for RF circuits. Figure 23 shows the cross section of a general multilayer structure that RF circuits could be realized on, which consists of multiple metal layers embedded within multilayer dielectric. The numbers of metal and dielectric layers and their thicknesses vary depending on manufacturing processes and/or intended applications. The metal layer with the thickest metallization produces the lowest conductor loss among the metal layers and is thus preferred for transmission lines. Due to the availability of multiple conductors and dielectrics as illustrated in Fig. 23, together with the use of air-bridges and via-holes, various two-conductor and multiconductor printed-circuit transmission lines can be formed for RF circuits. Such transmission lines facilitate the realization of complicated circuits and, along with the ability of achieving both horizontal and vertical integration through multilayer, ultimately allow very compact, high-density circuit integration. Moreover,

DOI 10.1007/978-981-4560-75-7_129-1

thin dielectric layers can be employed to further reduce circuit size by achieving narrow line widths. The two fundamentals that should be considered in configuring a transmission line for RF circuits are that the characteristic impedance range and the loss should be as wide and low as possible, respectively. Figures 24, 25, 26, 27, and 28 show some possible printed-circuit transmission lines with visual of the electric field lines that can be implemented for multilayer RF circuits. These transmission lines exploit the advantages of multilayer structures as well as the couplings between the constituent strips and slots to improve performance. Using a back conductor with and without slot, they can have wider characteristic-impedance ranges than those of the conventional microstrip line and CPW. In addition, they have several other desirable features such as flexibility and ability to realize complicated, highly dense circuits through appropriate arrangements of the structural elements. The analysis of these transmission lines can be accurately analyzed using full-wave dynamic approaches. Various commercially available EM simulation programs can also be used for accurate calculations of the transmission lines' parameters.

Microstrip Line

Figure 24 shows two examples of microstrip lines in multilayer RF circuits. It is noted that in Figs. 24, 25, 26, 27, and 28, the upper dielectric could consist of multiple dielectric layers having the same relative dielectric constant with different thicknesses. This is especially encountered in silicon-based CMOS/BICMOS processes used for RFICs, which employ multilayer SiO_2 dielectrics of different thicknesses (top layers) above a silicon substrate (bottom layer). The slot in the bottom conductors in Fig. 24b facilitates adjustment of the characteristic impedance by varying its location and/or size. The bottom conductors are kept at approximately equal potential using air-bridges. The top conductor can be located in any metal layer, typically the thickest metal layer for the lowest conductor loss, and the bottom conductor in another metal layer depending on desired characteristics such as characteristic impedance, loss, effective relative dielectric constant, dispersion, etc. These microstrip lines allow easy interface with other components and/or instruments for measurement purposes. The bottom conductor in Fig. 24a and the slot in Fig. 24b may be symmetrical or asymmetrical with respect to the top conductor. These bottom conductors should be sufficiently wide, and the slot should be properly located with respect to the top conductor to prevent all or majority of the electric fields coming from the top conductor from penetrating into the beneath dielectrics in order to eliminate or minimize the effects on the transmission line from other circuits and elements including transmission lines realized on the beneath dielectrics. Possible effects include noise from other circuits propagating into the microstrip line and the coupling between the microstrip line and other nearby transmission lines and circuit elements through the beneath dielectrics. The highest characteristic impedance of the microstrip line shown in Fig. 24a is limited due to the large capacitance per unit length resulting from the bottom conductor. Its characteristic impedance, effective

relative dielectric constant, and loss can be approximately determined using the closed-form expressions presented in section "Microstrip Line." The microstrip line shown in Fig. 24b is particularly attractive since its characteristic impedance can be varied over a large range by simply changing the location and size of the slot between the bottom conductors. This unique tuning feature can be utilized to realize a larger impedance range than that of the microstrip line shown in Fig. 24a. When the slot is far away from the top conductor, the characteristic impedance and effective relative dielectric constant are constant since the slot has negligible influence on the transmission line's characteristics. However, as the slot approaches the top conductor, both the characteristic impedance and effective dielectric constant change because more of the electric field lines penetrate the dielectrics below. These changes are more drastic for larger slot and also when the slot is close to the top conductor due to increased interaction between the dielectrics below and the top conductor via the slot. The maximum change in the characteristic impedance and effective relative dielectric constant occurs when the slot is centered underneath the top conductor, where maximum field lines enter the underneath dielectric. It is noted that achieving large characteristic impedance, and hence wide impedance range, is desirable. However, if this results in more electric fields penetrating the dielectrics below, then it would cause larger dielectric loss if that dielectric has high loss

DOI 10.1007/978-981-4560-75-7_129-1

and, hence, detrimental circuit effects. Therefore, care needs to be exercised when optimizing the characteristic-impedance range using the slot.

Coplanar Waveguide

Figure 25 shows several CPWs that can be implemented in multilayer RF circuits. Any metal layers can be used; however, like the microstrip line or any other transmission lines, the thickest metal should be employed for the signal line for low conduction loss. In general, the CPW has wider characteristic impedance range than the microstrip line due to the possibility of obtaining higher characteristic impedances through using large gaps between the signal and ground lines. The CPW, in general, has larger size than the microstrip line. However, narrow ground lines can be used to reduce the size while not causing significant effects to the line's characteristic impedance and effective relative dielectric constant since the charge and current are distributed primarily along the edges of the strip and the inner edges of all the ground lines. A single ground line can also be used to reduce the size further. Unequal ground lines can be employed to accommodate circuit layout. As for the microstrip line, lower loss can be achieved by using thicker dielectric corresponding to wider signal line. All the ground lines and back conductors need to be tied together through via-holes and air-bridges to maintain at approximately equal potential. A back conductor, when connected to the ground lines, also help increase the isolation between the signal line and adjacent transmission lines since the electric fields springing away from the signal line tend to terminate in the back conductor via the ground lines. In RF circuits with very small size constraint, which causes significant interactions between elements, CPW with enhanced isolation is indeed desirable. On the other hand, when the back conductor is not interconnected with the ground lines, possibly strong coupling from the signal line to adjacent lines can result as the ground lines may serve as a bridge between them. As will be discussed later, the use of a back conductor with slot allows the characteristic impedance to be varied over a large range by simply changing the location and size of the slot. This unique tuning feature, in conjunction with the signal line and upper slots, can be utilized to realize much larger impedance ranges than those of the conventional microstrip line and CPW.

Figure 25a shows the conventional CPW, Fig. 25b shows a modified CPW with single ground line, and Fig. 25c depicts a CPW with the ground lines located in another layer. As can be seen from their electric field distributions, the CPWs in Fig. 25a, b are partially shielded from the beneath dielectrics, which results in better isolation from these dielectrics and hence other circuits and elements including transmission lines on these dielectrics. The degree of isolation from the dielectrics below depends on how far the signal line of the CPWs is located from those dielectrics. Complete isolation may be possible if the CPWs are located far from it and the gaps between the signal and ground lines are sufficiently small to cause the electric fields to focus more within the gap areas. It is noted that the single ground-line CPW, while physically similar to the coplanar strips (CPS), is electrically different since its ground line is held at zero potential, while in the CPS, this line is kept at an opposite potential of the other strip. The CPW in Fig. 25c is similar to the microstrip line shown in Fig. 24b and, as expected from its electric field lines, can be fully shielded from the beneath dielectrics and corresponding circuits even located near it if the gap between the ground lines is narrow, especially at higher frequencies of the RF range since the gap becomes negligible with respect to the operating wavelengths.

Figure 25d, e show the CPWs with a back conductor. Depending on the width and/or location of the back conductor, complete or partial isolation from the dielectrics below can be obtained. For these CPWs, while the characteristic impedance and effective relative dielectric constant stay constant when the edge of the back conductor closer to the slots is far away from the signal line, they decrease as the edge advances near the signal line.

The CPWs in Fig. 25f,g implement a slitting back conductor whose size and/or location of the slot and conductor control the degree of shielding from the dielectrics below. It is noted that the signals see the gap

DOI 10.1007/978-981-4560-75-7_129-1

in the back conductor in terms of wavelength, and so, at very high frequencies, the gap may appear opaque to the signals and hence the transmission line is completely shielded from the beneath dielectrics. In addition to the upper slot, the lower slot formed by the back conductor can also be used to change the characteristic impedance and effective relative dielectric constant. These parameters increase as the width of the lower slot is increased. The change is significantly pronounced when the width is small while virtually unnoticed for large widths. This phenomenon is expected as the transmission line's capacitance per unit length reduces when the lower slot width is increased due to more electric fields penetrating into the bottom layers. Furthermore, the range of the lower slot width that affects the behavior is smaller for smaller upper-slot width, as expected, due to strong interaction between the signal line and the coplanar ground strips when the upper slots are small. Similar to the microstrip line with slot in the bottom conductor as shown in Fig. 24b, when the slot in the back conductor is far away from the signal line, the characteristic impedance and effective relative dielectric constant are constant. However, as the slot approaches the signal line, both the characteristic impedance and effective dielectric constant increase. These changes are more drastic for larger lower slot and also when the slot is close to the signal line. The maximum characteristic impedance and effective relative dielectric constant occur when the slot is centered underneath the signal line.

Figure 25h shows a CPW enclosed by conducting walls which completely shield the transmission line from the dielectrics below and surrounding elements. The vertical walls are formed by lattices of periodic metallic via-holes placed very close to each other. Narrow metal frames on the metal layers between the top and bottom walls are also used to connect all the via-holes together to further confine the fields within the metal channel and enhance the electrical isolation between the signal line and the exterior of the channel. The metal shield prevents fields from entering and leaving the CPW from its left, right, upper, and lower sides, except through the signal line. If the size of the via-holes and distance between them can be made extremely small with respect to the operating wavelength, the via-hole lattices, together with the metal frames, can create vertical walls resembling well solid metallic walls electrically and hence can be used to replace them. Similar conducting walls can also be used for other CPWs with back conductors to provide complete shield to the dielectrics below and other surrounding elements.

Coplanar Strips

Figure 26a, b shows the conventional coplanar strips (CPS) and another version with strips located on two different metal layers, respectively, both consisting of positive (+) and negative (−) signal lines, which could be used for multilayer RF circuits. The top-most metal layer or those nearest to it are preferred for the strips. The widths of the strips are equal in typical implementations. However, unequal widths can also be used to optimize performance. Similar to the conventional CPW, the CPS is partially shielded from the dielectrics below. The coupling between the CPS and the beneath dielectrics and circuits realized on these dielectrics depends on the distance of the strips from the beneath dielectrics and the gap between the coplanar strips or the offset between the noncoplanar strips. Under certain conditions, the coupling can be significant, leading to substantial undesired coupling effects. In general, the dielectric loss depends slightly on the width of the strips, while the conductor loss is a strong function of the strip width. The CPS has larger characteristic impedance than the microstrip line. Compared to the coplanar strips, the noncoplanar strips generally have stronger electric field between the strips which results in larger capacitance per unit length and, hence, lower characteristic impedance. Noncoplanar strips, however, can have less coupling to the beneath dielectrics, and hence less effects from circuits on these dielectrics, due to possible shielding from the lower strip. The coupling is significantly reduced when the lower strip is moved closer to the upper strip. In fact, the transmission line can be completely shielded from the dielectrics below if the lower strip is directly underneath the upper strip and has sufficiently larger size than the upper strip.

DOI 10.1007/978-981-4560-75-7_129-1

Strip Line

Figure 27 shows some possible strip-line configurations for multilayer RF circuits, in which the center conductor is sandwiched between two ground planes. The upper and lower ground planes do not have to be identical, and the dielectrics above and below the central strip may have different thickness in order to optimize the strip line's characteristics. The strip line in Fig. 27b particularly has slit in either or both of the ground planes to allow high characteristic impedances to be obtained for certain applications. Figure 27c depicts a shielded strip line in which vertical walls are used together with horizontal walls to completely enclose the strip line. These vertical walls can be formed using arrays of via-holes similar to those used for the shielded CPW shown in Fig. 27h. The strip line has larger size and less convenience in layout as compared to the microstrip line and CPW and, in general, operates at lower frequencies due to possible propagation of the higher-order parallel-plate waveguide modes. However, it is inherently isolated from the surrounding dielectrics and circuits on these dielectrics and, with proper use of thin dielectrics and sufficient number of via-holes between the two ground planes, can operate at high frequencies into the millimeter-wave range. Properly configured strip line is thus valuable for multilayer RF circuits.

Slot Line

Figure 28a, b show a slot line and shielded slot line, respectively. The shield is realized with horizontal metal strips and vertical metal walls formed by lattices of via-holes. It confines the fields and isolates the slot line from other structures external to the shield including the silicon substrate, other transmission lines, and circuit elements.

Summary

Transmission lines are important and inevitable elements in antennas, not only for antennas themselves but also for associated RF circuits needed for antennas to perform in RF systems. Proper configuration and design of transmission lines, which rely primarily on the thorough understanding of transmission line theory, can help produce antennas with associated RF circuits not only optimum in performance but also optimum in size. This chapter addresses the fundamentals of transmission lines including transmission-line equations and important transmission-line parameters. It also presents synthetic transmission lines, which could be very useful for on-chip antenna interface, and printed-circuit transmission lines essential for antennas and associated RF circuits.

Gap Waveguides

Ashraf Uz Zaman* and Per-Simon Kildal
Antenna Systems Division, Signals and System Department, Chalmers University of Technology, Göteborg, Sweden

Abstract

The coming years will show new applications of wireless communications at higher frequencies (30 GHz and above). Modern wireless technologies like massive MIMO and gigabit transmission will become a reality. The industrial winners will be the companies that can provide the hardware at the lowest cost. This requires new waveguide and mmWave packaging technologies that are more cost-effective than normal rectangular waveguide technology and are more power efficient (lower losses) than PCB-based microstrip and coplanar waveguides. The gap waveguide has this potential.

The present chapter gives the historical background of gap waveguide technology until its invention in 2008 and how it has evolved since then to include many different kinds of gap waveguide types. Several useful waveguide components have been developed for integration in complete RF front ends. Passive gap waveguide parts and components like filters, couplers, and transitions have been realized very successfully, and active microwave electronics have been packaged. The chapter contains also an overview of the gap waveguide antennas that have been developed during the last years.

Introduction

The heavy congestion at the existing radio frequency spectrum allocated for the today's wireless communications motivates and accelerates the research work at mmWave bands or even higher-frequency range where more spectrum is available for various applications. On the other hand, there are plenty of technological factors and mechanical challenges in designing high-frequency microwave RF front ends. These factors are cost pressure, smaller size requirement, increased system density, packaging and cross-talk suppression, and lower power loss dissipation. Usually, RF front ends are composed of both active circuits (ICs) and passive devices; the latter include antennas and filters which are not integrated on the semiconductor substrate. The technological progress in the area of active components in RF systems has propelled with the advancement of monolithic microwave integrated circuit (MMIC) technology, resulting in the fact that the active components of RF systems occupy only a small segment of the module space area. On the other hand, the evolution of passive components have not advanced in a similar manner due to the fabrication tolerance issues associated with geometrical scaling governed by operating frequency. On top of the mechanical tolerance issues at high frequencies, circuit features and components can have dimensions that are an appreciable fraction of wavelength. So, there are some additional complex packaging issues to deal with such as cavity modes, radiation from minor bends or

*Email: zaman@chalmers.se

DOI 10.1007/978-981-4560-75-7_130-1

discontinuities and coupling, and feedback due to surface waves. At lower frequencies, the conventional way of doing the circuit package is to use metal wall cavity and vias in the substrate to isolate each critical circuit component within a microwave front end. The size of the cavity is maintained to be lower than the half guided wavelength $\lambda_g/2$ to avoid cavity modes within the module. Also, lossy absorbers are used to dampen the high-Q cavity modes. However, the cavity size reduction becomes impractical at mmWave frequencies, i.e., the half guided wavelength $\lambda_g/2$ for a GaAs substrate at 80 GHz is only 0.52 mm. Thus, at high frequency, there is a need for rethinking in RF design techniques in terms of improved electrical performance, manufacturing flexibility, packaging, and affordability. In this regard, having upcoming high-frequency applications in mind, some new technology development seems to be important.

In section "Reconsidering Conventional Microwave Technology" of this chapter, some key factors are reconsidered regarding the usage of conventional microwave technologies such as planar microstrip line or the metal waveguide for building and manufacturing high-frequency microwave module or systems. This section puts forward the existing performance gap between the planar transmission lines such as microstrip or CPW and the nonplanar metal waveguides in terms of cost, loss performance, manufacturing flexibility, etc. and motivates the research on gap waveguide technology.

After that in section "Operating Principle of Gap Waveguides and Loss Analysis," the newly proposed and developed gap waveguide technology is presented as a promising solution for high-frequency microwave problems. The basic operating principle of the proposed gap waveguide technology is also discussed. This section shows how periodic structures can be used to form a waveguide between two parallel plates and how electromagnetic wave propagation can be controlled in such waveguides by achieving cutoff condition for global parallel-plate modes over a specific bandwidth. An overview of different variants of available gap waveguide technology is presented in this section. This section also presents a comparison of losses among different gap waveguide geometries.

Section "Design and Optimization of the Parallel-Plate Stopband" deals with parallel-plate stopband design using a periodic structure. The design of the stopband is quite important as it dictates the performance of the gap waveguide components. Typically, a unit cell of the periodic structure is analyzed with eigenmode solver of commercial software to determine the parallel-plate stopband, and this type of study consists of parametric sweeps of all parameters associated with the periodic structure.

Section "Some Analytical Approaches Used for Analyzing the Gap Waveguide" contains an overview of two analytical approaches used so far in the prediction of propagation performance of groove gap waveguide and ridge gap waveguide. One of the approaches is the spectral domain approach in which Green's functions of the considered structure are determined. On the other hand, in the second approach, the modal solution is found by dividing the field problem in different regions and connecting the regions by mode matching. This section also shows the resemblance between the ridge/groove gap waveguide and the conventional hollow ridge/rectangular waveguide, respectively, by using numerical analysis. The dispersion diagrams and characteristic impedances are compared and found to be quite similar within the stopband of the parallel-plate modes. Thus, most of the initial designs of the gap waveguide components can be done using the already known waveguide architectures and topologies instead of deriving rigorous analytical expressions for gap waveguides separately. This also opens up the opportunity to use available numerical ports in commercial full-wave simulators for designing gap waveguide components.

Section "Low-Loss Antennas Based on Gap Waveguide Technology" presents different types of antennas designed by using gap waveguide technology. Due to the low-loss properties of gap waveguide, high-efficiency and high-gain planar antennas can be designed with this technology. Single-layer wide-band slot arrays, double-layer PCB-based slot arrays, horn arrays fed by microstrip gap waveguide, and series-fed groove gap waveguide narrow-wall slot arrays have been designed at different ranges of frequency band.

DOI 10.1007/978-981-4560-75-7_130-1

Section "Transitions Between Gap Waveguide and Standard Transmission Line" covers several transitions between gap waveguide and other standard transmission lines such as microstrip and rectangular waveguide, and these transitions are very important constituent related to gap waveguide components. Most often, other transmission lines have standardized cross sections (e.g., rectangular waveguide) or characteristic impedance (e.g., microstrip line). In order to reduce the reflections from the interface between gap waveguide and standard transmission lines, impedance transformers or matching sections are required. This section contains designs of microstrip to ridge gap waveguide transitions, ridge gap waveguide to standard rectangular waveguide transitions, microstrip-ridge gap waveguide to standard rectangular waveguide, etc.

Section "Gap Waveguide Narrowband High-Q Filters" demonstrates a mechanically flexible narrowband diplexer filter design which is a very critical component in a full-duplex communication wireless link. There is a need for developing new types of high-Q filters which are more robust in terms of mechanical assembly and can be integrated with other modules of passive components such as antennas. The groove gap waveguide-based high-Q filters can be of interest in this case. These high-Q filters can be built in an open parallel-plate structure surrounded by periodic metal pins without any side walls. This opens up the possibility of placing the diplexer filter in an integrated module together with RF electronics and even with the antennas.

Section "Gap Waveguide Packaging Solution for Microwave Modules" shows the gap waveguide packaging solution which can be used in RF modules. Most of the microwave systems have to operate outdoor, under various weather conditions and therefore have to be shielded, i.e., *packaged* in a proper way to provide protection against mechanical stress and environmental condition. Also, to comply with the smaller size requirements and compactness for next-generation microwave modules, large amount of electronic components are to be placed into a confined area. For such high-density microwave modules, RF packaging is more and more important in terms of isolation and interference suppression. So, there is a need for new packaging technology to be used at high frequency, and gap waveguide-based PMC packaging can be a real good solution to overcome the packaging-related problems. In this section, the application of gap waveguide packaging solution for both passive and active microwave circuits is mentioned.

Reconsidering Conventional Microwave Technology

Conventional rectangular waveguides, planar transmission lines such as CPW, or microstrip lines are well-characterized transmission medium which are used in a variety of complex RF component and circuit designs until today. However, there are some factors to be considered while using these conventional technologies at mmWave frequencies or above, particularly for antenna applications.

Typically, standard waveguide components are quite low loss and are manufactured in split blocks. Connection between the split blocks can be achieved by screwing, diffusion bonding, or deep-brazing techniques. These techniques are costly, complex, and often not scalable to higher frequencies. As the frequency of operation of waveguide approaches mmWave frequencies, the physical dimensions of the components decrease, and a "watchmaker" level of precision is required for manufacturing and assembling the split blocks by conventional methods. To remove the tiny gaps between the two split blocks, very good electrical contact as well as good alignment of the two blocks must be achieved. Also, a high-quality surface finishing over the whole metal contact area is required for good mechanical assembly. Contacting surfaces must be protected from corrosion and oxidation over the entire life cycle of the product. These strict mechanical requirements lead to a very high-precision metal machining technique, which increases the cost of manufacturing and causes much delay in the production chain. This effectively precludes mass

DOI 10.1007/978-981-4560-75-7_130-1

production of components for commercial purposes. In the context of high-efficiency waveguide slot array antennas, this electrical contact issue is a very important factor for good electrical performance. In planar slot array applications, where multiple waveguides are needed with narrow vertical walls for separating each waveguide from the neighboring waveguides, it is very difficult to achieve electrical contact between the vertical walls of the waveguide and the radiating slot layer (Kimura et al. 2001; Kirino and Ogawa 2012). This leads to the fact that waveguide slot arrays have not found many commercial applications till today. They have mainly been used in few military applications.

Apart from the manufacturing costs and assembly complications, some other limitations of waveguide slot arrays have been reported in literature (see "Low-Loss Antennas Based on Gap Waveguide Technology"). Series-fed single-layer waveguide slot arrays are simple but have narrow bandwidth due to the long-line effect (SeHyun et al. 2006). In a single-layer structure, it is normally not possible to feed each radiating element in parallel (full corporate feed) because of the space limitations associated with keeping the element spacing smaller than one wavelength (λ_o) to avoid grating lobe (Fujii et al. 2008; Tsugawa et al. 1997). Therefore, there is need for a complex multilayer feed network. Such a double-layer corporate feed network in rectangular waveguide technology is described in Miura et al. (2011).

On the other hand, microstrip and coplanar lines are the most representative planar transmission lines. These are robust, low-cost solutions, and very suitable for integrating active microwave components on circuit boards. Especially, the CPW is widely used in monolithic microwave integrated circuits (MMICs) capable of a very high metal pattern resolution. But, the transmission properties of both microstrip and CPW lines greatly depend on the substrate parameters. Both lines suffer from high insertion loss at mmWave frequency spectrum due to the presence of lossy dielectric material. Published studies in Tsuji et al. (1995), Mesa et al. (2000), and McKinzie and Alexopoulos (1992) show that significant power leakage exists on various printed circuit transmission lines, often related to surface waves in the dielectric substrate causing serious cross-talk and interference problems (see "Gap Waveguide Packaging Solution for Microwave Modules"). Particularly in the case of top-covered microstrip line, this leakage begins at a much lower frequency than expected and becomes a matter of serious concern for power loss as well as cross-talk issue (Mesa et al. 2000). Similarly, conventional packaging of CPW modifies the CPW into a conductor-backed CPW (CBCPW), and this thereby generates power leakage in the form of coupling to parasitic parallel-plate modes. In the context of low-cost planar antennas, the microstrip antenna feed networks suffer from high ohmic and dielectric losses at high frequency (Borji et al. 2009; Pozar 1983). Spurious radiations and leakage in the form of surface waves may become major concerns in microstrip antennas and are difficult to handle (Levine et al. 1989). Spurious radiations from the discontinuities in the feeding network can have a dramatic influence on the radiation patterns of the PCB-based planar antennas. All these lead to substantial reduction in antenna efficiency and thereby gain. One way to reduce the effect of unwanted radiation is to design multilayer printed antennas in order to separate the radiating layer from the feeding line layer. However, high-performance multilayer PCBs bring added challenges to both the fabricator and designer, and most of the advantages of single-layer PCB technology do not hold anymore in that case.

So, there exists a big performance gap between the planar transmission lines such as microstrip or CPW and the nonplanar metal waveguides in terms of loss, manufacturing flexibility, and production cost. One of the main high-frequency microwave research challenges to date is to narrow down the abovementioned performance gap. Researchers aim at finding a solution which is as low cost and flexible as microstrip and also as low loss as metal waveguide. It is expected that high electrical performance and high-density integration techniques, combined with a low-cost fabrication process, should be able to offer widespread solutions for future high-frequency microwave or mmWave commercial applications. Therefore, lot of research has been done in microwave community to meet these requirements. Researchers have come out with technologies such as substrate integrated waveguide (SIW) (Deslandes and Ke 2001;

DOI 10.1007/978-981-4560-75-7_130-1

Feng and Ke 2005; Ke 2006), low-loss thin-film microstrip lines (Six et al. 2005; Nishikawa et al. 2001), and LTCC (Shafique and Robertson 2011; Tze-Min et al. 2007). Each of these proposed techniques has their own merits and demerits. In line with the research activities mentioned above, a new transmission line technology known as gap waveguide was proposed in 2009. This new technology has almost no dielectric losses and is mechanically more flexible than metal waveguide in terms of mechanical or modular assembly. The prevailing idea throughout this chapter is to describe the operating principle of this new low-loss transmission line technology and to illustrate how the critical RF passive components can be designed using this technology. A completely new packaging method for high-frequency microwave modules based on gap waveguide technology will be also presented in this chapter.

Operating Principle of Gap Waveguides and Loss Analysis

Gap waveguide technology appeared as an extension of the research about hard and soft surfaces (Kildal 1990). The soft and hard surface concept is a generic representation of the corrugated surface used in corrugated horn antennas. The soft surface has the ability to stop waves of any polarization propagating along the surface and has similar characteristics as the electromagnetic bandgap (EBG) surface (Sievenpiper et al. 1999). The hard surface can on the other hand enhance propagation along its surface (along the corrugations). This has been already used to reduce forward scattering (blockage) by cylindrical objects in Kildal et al. (1996), almost ten years before such blockage reduction became a popular research topic known under the name cloaking (Schurig et al. 2006). The blockage reduction using hard surfaces has been demonstrated to have 20 % bandwidth for dual-polarized waves, whereas most other cloaking concepts have not been proven to be useable in practice (Kildal et al. 2007). The soft surfaces have mainly been used for horn antennas. Hard horns with large-aperture efficiency have been proposed very early for application in cluster-fed reflectors for multiple beams (Kildal and Lier 1988; Lier and Kildal 1988). The hard horn work included advanced mode-matching modeling and realization of hardware (Skobelev and Kildal 2005; Sotoudeh et al. 2006). The overview article (Lier 2010) describes another trace of work resulting in very unique lightweight and wideband metasurface horns with anisotropic boundary conditions between the soft and hard cases. There is also a third path focusing more on miniaturized hard horns (Kehn et al. 2004, 2006). However, these hard waveguides were extremely narrowband. Still, they are important forerunners of the wideband ridge gap waveguide (Kildal and Kehn 2010). In early 1997, researchers found existence of local surface waves propagating along each groove of a hard surface (Sipus et al. 1997). In 2009, the existence of local waves following even the ridges of a hard corrugated surface has been discovered (Valero-Nogueira et al. 2009). The latter discovery has been further developed as gap waveguide technology by keeping only one ridge and replacing the rest of them with metal pins (Kildal et al. 2009). Ideal gap waveguide uses the basic cutoff of a PEC-PMC parallel-plate waveguide configuration to control the electromagnetic wave propagation between the two parallel plates. As long as the air gap separation between the PEC and PMC plates is less than $\lambda/4$, no wave can propagate between the plates. This can be readily seen by studying a plane wave in the air gap and trying to satisfy boundary conditions at both the PMC and PEC plates. Now, if the PMC surface incorporates a metal strip, EM waves will be able to follow the strip. This is shown in Fig. 1.

PMCs are not available in nature. Thus, in practical applications, the PMC condition is emulated by an artificial magnetic conductor (AMC) in the form of periodic textured structures such as metal pins (Silveirinha et al. 2008) or mushroom structures (Sievenpiper et al. 1999). Thus, in a real gap waveguide structure, the bottom periodic textured has high enough surface impedance to create a stopband over which no parallel-plate modes can propagate. However, the textured AMC surface must also incorporate guiding structures in the form of ridges, grooves, or strips to form the complete waveguide. As a result of

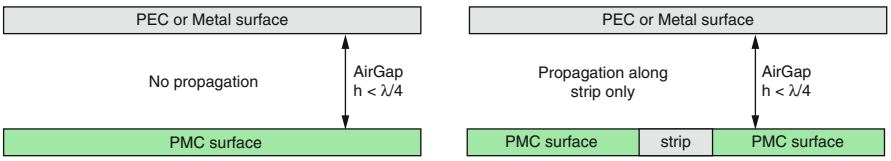

Fig. 1 Cross section of ideal gap waveguide (With permission from Zaman et al. 2014)

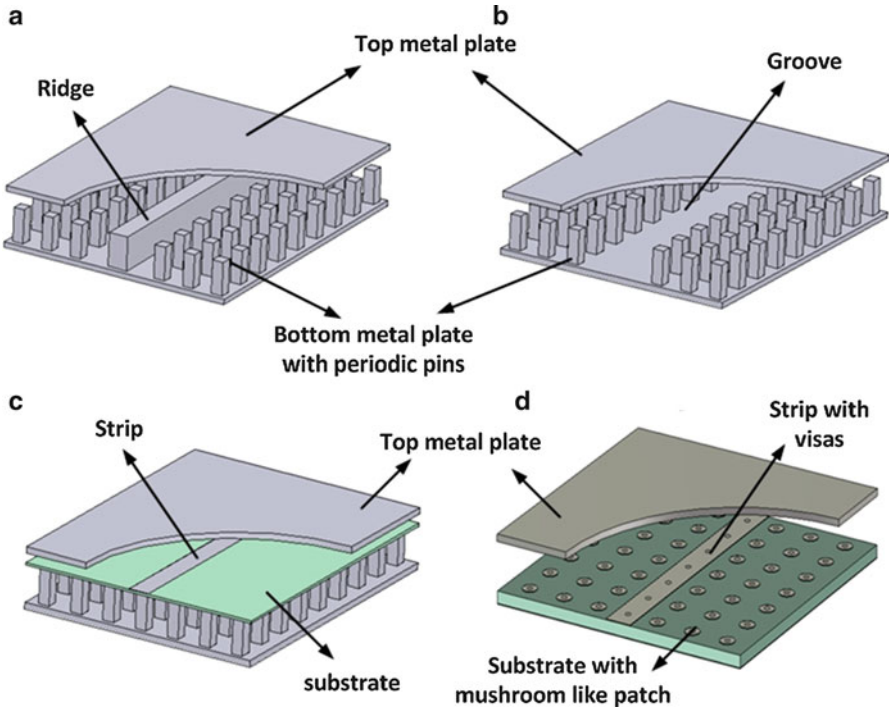

Fig. 2 Different gap waveguide geometries: (**a**) ridge gap waveguide, (**b**) groove gap waveguide, (**c**) inverted microstrip gap waveguide, (**d**) microstrip-ridge gap waveguide (With permission from Zaman et al. 2013, 2014)

the stopband (see "Design and Optimization of the Parallel-Plate Stopband"), the AMC surface creates virtual lateral walls on both sides of the guiding section and thereby prevents the lateral field leakage. Thus, the electromagnetic waves can propagate along these guiding ridges, grooves, or strips without leaking away in other directions. These guiding structures thereby define different gap waveguides or transmission lines, referred to as ridge, groove, and microstrip gap waveguides (Kildal 2009; Kildal et al. 2011; Zaman et al. 2010b; Rajo-Iglesias and Kildal 2010; Valero-Nogueira et al. 2011; Pucci et al. 2012; Raza et al. 2014; Gahete Arias et al. 2013). The different configurations of gap waveguides are shown in Fig. 2.

The main advantage of the gap waveguide structure is that it can be realized without any requirement of metal contact between the upper metal surface and the lower surface, and thereby allowing low-cost manufacturing of low-loss waveguide components at mmWave frequency bands or even higher. The relaxed mechanical requirements pave the way for low or moderate precision machining, lower fabrication time requirements, and may even make possible the usage of some low-cost fabrication techniques such as injection molding and plastic hot embossing. The operating modes in different gap waveguide geometries are also different. The desired mode in ridge gap waveguide, inverted microstrip gap waveguide, and microstrip-ridge gap waveguide is similar in nature, and all of these allow a

DOI 10.1007/978-981-4560-75-7_130-1

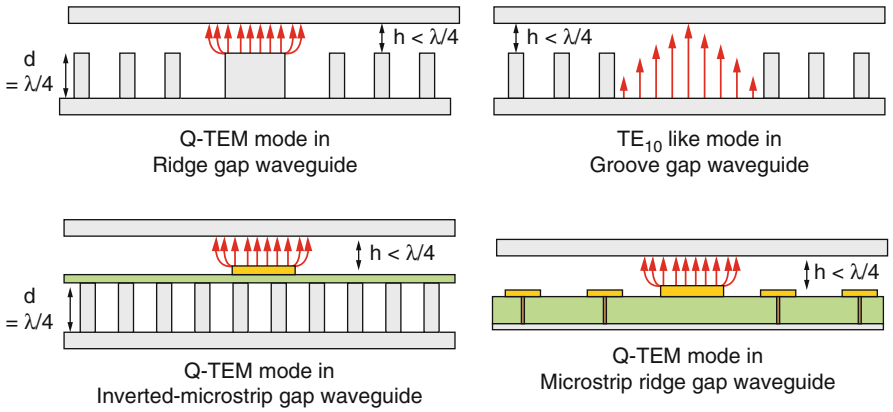

Fig. 3 Desired modes of propagation in different gap waveguide geometries

quasi-TEM mode within the stopband. On the other hand, the desired mode in the groove gap waveguide is very similar to that of the TE_{10} mode of the rectangular waveguide (Fig. 3).

Necessity for Parallel-Plate Stopband and the Dispersion Characteristics of Gap Waveguide

As mentioned in the previous section, the main performance of the gap waveguide is determined by its ability to create parallel-plate stopband for wave propagation in the undesired direction. This stopband is usually achieved by a periodic texture located around the guiding metal ridge, groove, or the strip. The periodic structure functions as a high-impedance surface when placed closely (with an air gap smaller than λ/4) to a metal plate and is often referred to as an AMC surface. The most important thing in designing the stopband is to obtain the lower and upper cutoff frequency of this stopband. Usually, the cutoff study is performed as a function of the geometrical parameters of the periodic structure to be used. This kind of study is well described in Rajo-Iglesias and Kildal (2011). In the present section, the details of the stopband and dispersion characteristics of different gap waveguides are described. At this point, a textured surface made of square pin is considered for emulating the AMC surface over a frequency range of 10–25 GHz. Fig. 4 shows the details of the pin surface. The computed dispersion diagram for this corresponding structure is shown in Fig. 5a and 5b. A large stopband is created within 10–25-GHz frequency band where no EM waves can propagate.

Once the stopband is obtained, a guiding ridge or a groove may be incorporated in the periodic pin structure. Then, there is a mode propagation which follows the light line and is considered as the desired quasi-TEM mode in case of ridge gap waveguide. In the case of groove gap waveguide, a mode similar to TE_{10} mode starts to propagate inside the stopband, and this mode is dispersive in nature. These two scenarios of ridge gap waveguide and groove gap waveguide are shown in Fig. 5c and 5d, respectively.

DOI 10.1007/978-981-4560-75-7_130-1

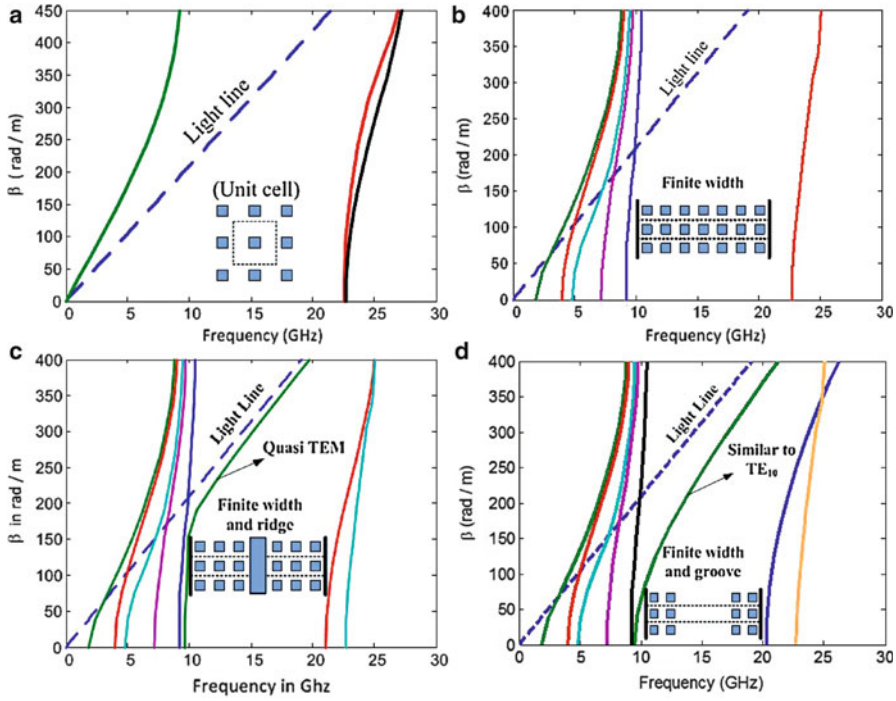

Fig. 5 Dispersion diagrams: (**a**) unit cell of a periodic pin, (**b**) periodic pin structure with finite rows of pins, (**c**) ridge gap waveguide, (**d**) groove gap waveguide (With permission from Zaman et al. 2013)

The dispersion diagram for an inverted microstrip gap waveguide and the microstrip-ridge gap waveguide would look like similar to that of ridge gap waveguide except that the stopband will shrink a bit due to the presence of dielectric material.

Field Attenuation in the Pin Region and Measured Attenuation

One very important aspect for such oversized parallel-plate gap waveguide structures is the level of field attenuation in the periodic structure which has been designed to act as high-impedance surface or AMC surface. At this point, the field decay or attenuation is studied for periodic metal pins also known as bed of nails. The modal field distribution, computed in the transverse plane inside the ridge gap waveguide structure, is shown in Fig. 6. As shown in Fig. 6, field distribution is nearly constant over the ridge, and then it falls almost at a rate of 18–20 dB per row of pins most rapidly near the upper end of the frequency band. This attenuation has been measured also by placing two ridge gap waveguide sections and separating them by three rows of pins. The measured isolation is shown in Fig. 7. The measured results correspond well with the computed attenuation level. The measured isolation between two lines placed side by side has been found to be better than 60 dB over the entire Ku-band.

Losses in Different Gap Waveguide Geometries

In order to verify the performance of the low-loss gap waveguide technology, it is important to be able to characterize its loss in an accurate way. One way to do that is to measure the attenuation of a very long line. However, at low frequencies, it will require impractically long transmission lines in order to measure the low losses accurately. As an alternative, losses can be better characterized in terms of Q-factors of resonators. Thus, several groove gap and ridge gap resonators were built and measured at Ku-band and compared with standard rectangular waveguide resonators (Pucci et al. 2013). But at higher frequency, longer ($\sim 30\lambda$) gap waveguide geometries were manufactured and measured at V-band, 50–70-GHz frequency. Tables 1 and 2 present the losses at two different frequency ranges. It is to be mentioned

Table 2 Comparisons of insertion loss results for 30λ-long gap waveguide structures at V-band

	Simulated maximum loss (dB/cm)	Measured minimum loss (dB/cm)	Measured maximum loss (dB/cm)
Rectangular waveguide (extruded)	0.0134	0.022	0.042
Rectangular waveguide (E-plane split blocks)	0.01355	0.024	0.046
Groove gap waveguide	0.019	0.026	0.045
Ridge gap waveguide	0.0493	0.053	0.073
Microstrip-ridge gap waveguide	0.0805	0.1753	0.22
Inverted microstrip gap waveguide	(0.093)	(0.21)	(0.27)
Normal microstrip line (for Rogers 3003, 0.125-mm thick)	(0.37)	(0.63)	(0.77)

that, at lower frequency, the study was limited to only ridge gap waveguide and groove gap waveguide. But at 60 GHz, inverted microstrip gap waveguide and microstrip-ridge gap waveguide were also included in the loss study. Both these tables show that the groove gap waveguide has the lowest losses among all the gap waveguide structures. The losses of groove gap waveguide are 10–30 % more than extruded rectangular waveguide without split blocks. But the losses of groove gap waveguide become same (in the same order) as that of rectangular waveguides if the rectangular waveguide is manufactured in two parts as split blocks. Thereafter comes the ridge gap waveguide. The ridge gap waveguide is approximately 30–55 % more lossy than rectangular waveguide. The microstrip versions of the gap waveguide are more lossy than the groove and ridge gap waveguide. But they are about three to five times less lossy than a typical microstrip line depending upon the substrate used in microstrip circuit. Some of these manufactured gap waveguide lines are shown below in Fig. 8.

Design and Optimization of the Parallel-Plate Stopband

As mentioned by Kildal (2009; Kildal et al. 2011), the main performance of the gap waveguide is determined by its ability to create parallel-plate stopband which allows the EM wave to remain confined within a region or even propagate toward a desired direction of the parallel-plate waveguide instead of

DOI 10.1007/978-981-4560-75-7_130-1

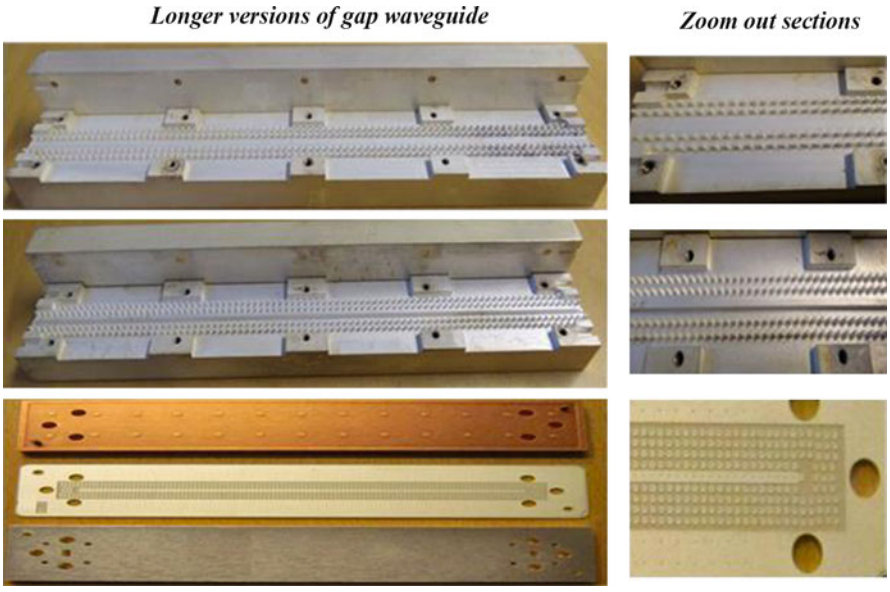

Fig. 8 The longer gap waveguide prototypes at V-band

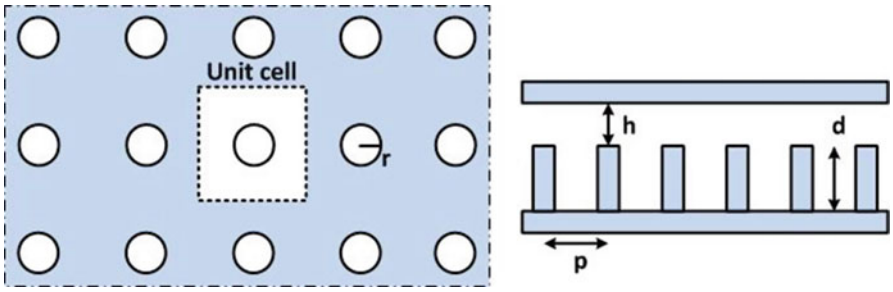

Fig. 9 Geometry of periodic metal pin (With permission from Zaman et al. 2014)

spreading out in all other directions. This stopband is achieved usually by using a metal texture in the form of a periodic structure along with a top metal plate. The periodic structure emulates a high-impedance boundary often referred to as an artificial magnetic conductor (AMC), and this high-impedance condition is achieved only over a specific bandwidth. This section explores the possibilities of creating parallel-plate cutoffs, i.e., the stopband in parallel-plate waveguides, by using different periodic structures. This is done by studying the detailed geometry of a specific periodic structure to be used as AMC and linking the geometric study with the realized bandgap inside a parallel-plate waveguide, in a similar way as people would perform the bandgap study for surface waves in open surfaces. All the analyses presented in this section are based on numerical results obtained from commercial EM solver.

Parallel-Plate Cutoff Realized by Bed of Nails

The first periodic structure to be studied in this section is the periodic metal pin structure also known as "fakir's bed of nails." This is shown in Fig. 9. For convenience, the stopband in this case is defined by the difference between the start frequency (when the parallel-mode propagation is stopped) and the end frequency (when the parallel-plate modes propagate again). The parameters that are important for designing the stopband are the height of air gap h, the height of the pin d, the period of the pin p, and the radius of the pin r.

DOI 10.1007/978-981-4560-75-7_130-1

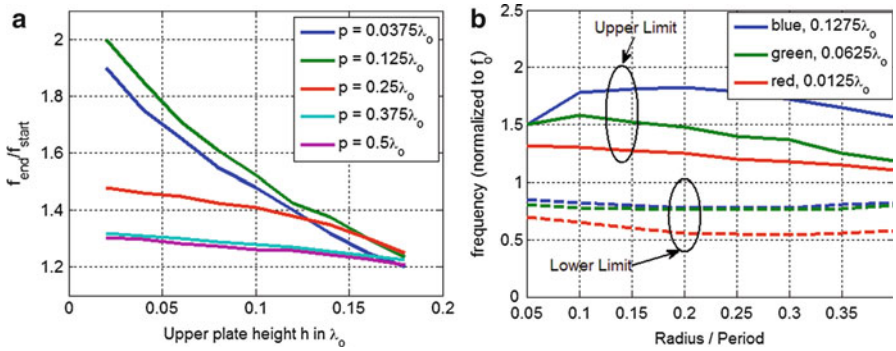

Fig. 10 Parametric effects on the stopband obtained by bed of nails, (**a**) relation between h and p, (**b**) relation between r/p and h

First of all, it has been found that the pin shape (circular or square) does not have any significant influence on the stopband (Rajo-Iglesias and Kildal 2011). If the height d and radius r of the pins are kept constant, for all values of p, the size of the stopband increases when the height h of the air gap decreases (Rajo-Iglesias and Kildal 2011). The start frequency of the stopband reduces when the period of the pins increases owing to increase in effective electrical length of the pins. On the other hand, the stop frequency is almost unaffected by the period as long as this is small enough. If the period becomes larger ($p \geq 0.25\lambda$), the upper limit is dramatically reduced owing to the propagation of new modes. The relative cutoff bandwidth (f_{end}/f_{start}) is summarized in Fig. 10a as a function of period p and air gap height h. Apart from the relation between p and h, the ratio r/p has also some influence on the stopband. The start and end frequencies of the stopband move in opposite directions when the radius-to-period ratio increases, reaching a maximum when the ratio is between 0.05 and 0.2. This is shown in Fig. 10b. The lattice constitutes the last investigated parameter for this geometry. From photonics it is known that the effect of this parameter in the stopband design cannot be neglected. So, in addition to the square lattice considered so far, a triangular lattice has also been studied in Rajo-Iglesias and Kildal (2011) varying the air gap height h and radius r. For the case of square lattice and triangular lattice, the results are not exactly the same, but they are similar enough to consider this parameter as having a secondary effect on defining the stopband properties of this structure. Even though any type of AMC can be used as a textured surface in gap waveguide structures, an important advantage of the bed of nail structure is that it is made from metal and no dielectric material is required. This makes the losses negligible at high frequencies.

Parallel-Plate Cutoff Realized by Mushroom-Type EBG

The mushroom-type EBGs shown in Fig. 11 are known to have the property of high-impedance surface (Sievenpiper et al. 1999). In this part, the parametric analysis for such mushroom-type EBG is presented. The parameters taken into account are air gap height h, substrate thickness d, the separation between the patches g, and radius of the vias r.

Among the parameters of this structure, initially analyzed parameter is the separation gap g. It is noted that the effect of g on the stopband is not very significant, except for the case where the gap height h is small. This is shown in Fig. 12a. The radius of the grounded vias r is another one of the parameters to be taken into account. Its effect on the stopband is presented in Fig. 12b. Actually, the radius r does not directly affect the stopband size but its position in the spectrum. The larger the radius r, the higher is stopband in the frequency spectrum. The next parameter to be considered is the thickness of the substrate d or the distance from the patch to the ground plane. The start frequency is completely shifted in frequency depending on the value of the substrate thickness. The thicker the substrate, the lower is the start frequency and this happens independently of the air gap height h. This effect is shown in Fig. 12c. Finally, the effect of the position of the grounded via in the patch as described in Fig. 11 has been studied.

DOI 10.1007/978-981-4560-75-7_130-1

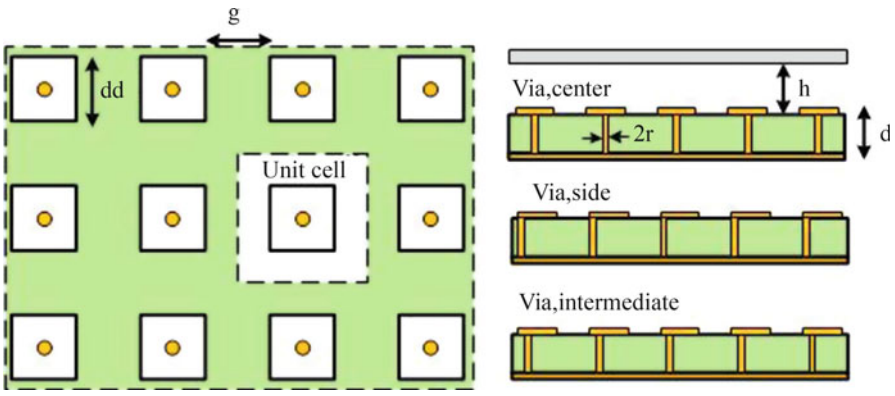

Fig. 11 Geometry of mushroom-type EBG (With permission from Razavi et al. 2014)

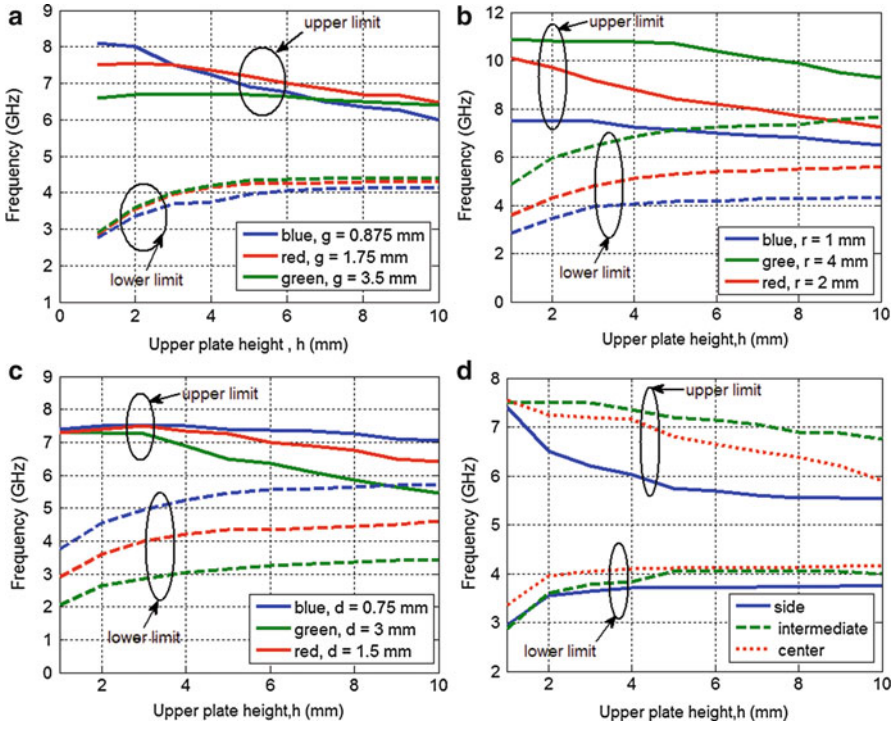

Fig. 12 Parametric effects on the parallel-plate stopband obtained by the mushroom-type EBG, (**a**) effect of *g*, (**b**) effect of *r*, (**c**) effect of *d*, and (**d**) the effect of the position of the grounded via (With permission from Razavi et al. 2014, Zaman et al. 2014)

Three positions for the via, centered, at the edge of the patch, and in an intermediate location between center and edge, have been selected. The results are presented in Fig. 12d. It is observed that, when the mushroom-type EBG surface is inside a parallel-plate structure, the displacement of the grounded via from the center to any other position causes a reduction on the stopband size.

Parallel-Plate Cutoff Realized by Bed of Springs

Apart from the commonly used bed of nails or mushroom-type EBG surface, some other periodic structures have been studied also for low-frequency application where the beds of nails or mushrooms

DOI 10.1007/978-981-4560-75-7_130-1

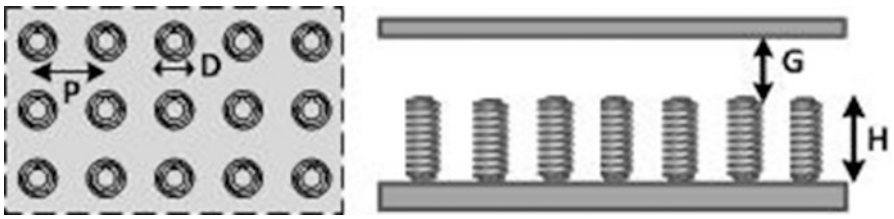

Fig. 13 Geometry of bed of springs

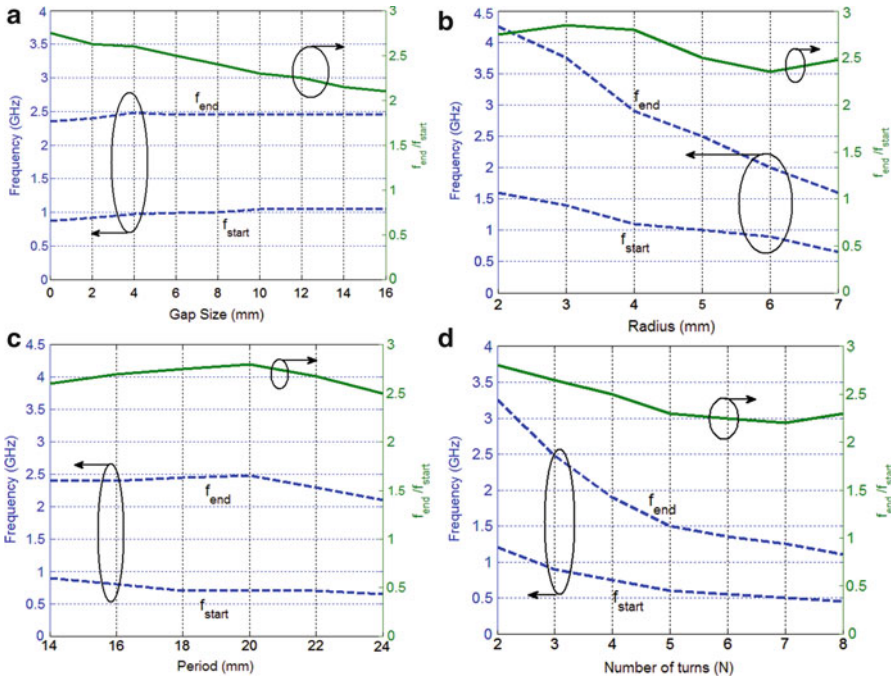

Fig. 14 Parametric effects on the parallel-plate stopband obtained by the bed of springs, (**a**) effect of *G*, (**b**) effect of *D*/*2*, (**c**) effect of *P*, and (**d**) the effect of *N* (With permission from Zaman and Kildal 2014, Zaman et al. 2014)

become too big in size and compact unit cells are needed particularly in applications such as packaging. That is why the bed of springs shown in Fig. 13 has been proposed in Rajo-Iglesias et al. (2012) as an alternative to the bed of nails at low frequencies. The period of a periodic helical structure can be of sub-wavelength, and most importantly due to the wire shape, the total height of the unit cell can also be small. The main parameters to be studied for this type of bed of springs are height of the spring *H*, height of air gap *G*, periodicity *P*, diameter of the spring *D*, and number of turns in each spring *N*, respectively. It is mentioned in Rajo-Iglesias et al. (2012) that the effect of the air gap height in this case is not so critical as compared to the case of bed of nails or mushrooms. This is due to lesser capacitive effect from the top of springs to upper plate, and this makes the gap a minor factor for the design. This is shown in Fig. 14a. The diameter of each spring *D* (keeping the period same) is now considered. The achieved results for this case are presented in Fig. 14b. The effect of this parameter is clear: a larger diameter shifts down all the modes in frequency as the total wire length is increasing, but the relative size of the stopband is not much affected as seen in the figure.

The period of the unit cell is also an important parameter as it determines the number of required unit cells for a given application. A summary of simulation results is presented in Fig. 14c. For this parameter

DOI 10.1007/978-981-4560-75-7_130-1

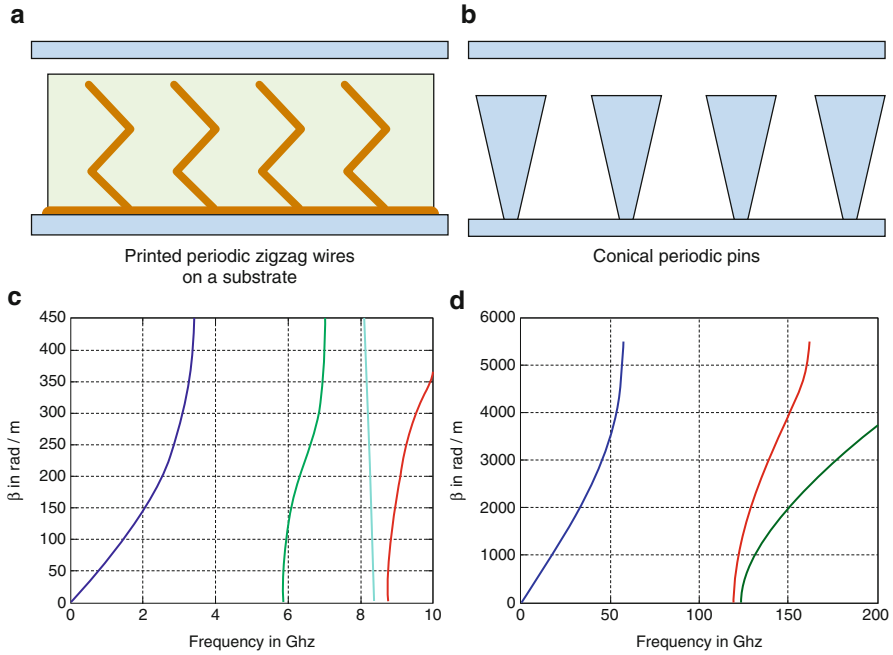

Fig. 15 Geometries of other types of periodic structures, (**a**) printed zigzag wires, (**b**) conical pins, (**c**) dispersion diagram of printed zigzag wires, and (**d**) dispersion diagram of conical pins (With permission from Zaman and Kildal 2014)

changing between 13 and 25 mm (which is small in terms of wavelength), the stopband is not greatly modified. When number of turns N is varied, keeping all the other parameters constant (including the height H), the results are summarized in Fig. 14d. As expected, increasing the number of turns, or, in other words, increasing the electrical length of the wire, all the modes have been moved to lower frequencies as presented in the graph.

Apart from the three periodic structures mentioned above, some other periodic structures have also been studied in Rajo-Iglesias et al. (2013) and Zaman et al. (2011). These are, namely, the printed zigzag wires and conical pins, and these periodic structures are shown in Fig. 15a and 15b, respectively. Both these periodic structures have certain advantages. The dispersion diagrams obtained for such periodic structures are also shown in Fig. 15c and 15d, respectively. As shown in dispersion diagrams, the printed zigzag wires are more suitable for lower frequency, and the conical pins are more suitable for high-frequency application. In terms of stopband size, the printed zigzag wires are very similar to that of the bed of springs. But it is much easier to fabricate the zigzag wires than the springs as they are simply printed on a substrate. For the conical pin case, the stopband size is actually 20 % bigger than that of circular metal pins described earlier. Also, the conical shapes are convenient to manufacture than the straight shapes by micromachining techniques at frequencies above 100 GHz (Rahiminejad et al. 2012).

Some Analytical Approaches Used for Analyzing the Gap Waveguide

From the analysis point of view, the gap waveguide structure is a bit different since the crucial element of this structure is a periodic surface which creates the stopband of the parallel-plate modes. The classical way to determine the fields and currents for such a structure would be the Floquet mode expansion combined with some general approach such as MoM, FEM, or FDTD. Also, a general 3D code could be utilized for the analysis of a finite gap waveguide structure. However, these approaches can be very complex and time-consuming if the source excites a spectrum of plane waves and if the structure is large.

DOI 10.1007/978-981-4560-75-7_130-1

Thus, it is desirable to develop faster analytical or semi-analytical methods which could be used as a first design tool by introducing some simplifications into rigorous approach. Apart from the emphasis on the analytical methods, there is also an immense need to investigate the accuracy of the available numerical ports in commercial EM solvers when applied to realistic ridge/groove gap waveguide microwave components.

Spectral Domain Approach

This sections present study of spectral domain Green's functions of parallel-plate waveguides, where one plate is a smooth metal surface and the other one is an artificial magnetic surface realized by one-dimensional (1D) or two-dimensional (2D) periodic structure. These two geometries are discussed in detail in Bosiljevac et al. (2010). The general idea here is to use some approximate boundary condition replacing the periodic texture and to derive Green's functions for simpler waveguides in the spectral domain. The derivation of Green's functions is obtained in plane-wave spectral domain, and plane-wave spectral domain is defined by

$$\tilde{E}\left(k_x, k_y, z\right) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} E(x, y, z) e^{jk_x x} e^{jk_y y} dxdy \tag{1}$$

where "∼" denotes the two-dimensional Fourier transformation with k_x and k_y the spectral variables. Now, the spectral solutions of the Helmholtz differential equation for E_z and H_z components of the electromagnetic field will have the following form:

$$\tilde{E}_z\left(k_x, k_y, z\right) = A\cos\left(k_z z\right) + B\sin\left(k_z z\right) \tag{2a}$$

$$\tilde{H}_z\left(k_x, k_y, z\right) = C\cos\left(k_z z\right) + D\sin\left(k_z z\right) \tag{2b}$$

where the $e^{-jk_x x} e^{-jk_y y}$ variation is suppressed. Also, here ${k_z}^2 = {k_o}^2 - {k_x}^2 - {k_y}^2$ and A, B, C, and D are the unknowns which are to be determined by using boundary conditions. It is sufficient to determine only the z components of the electromagnetic field as all the other components can be found by using relations in Das and Pozar (1987). Now, the aforesaid asymptotic boundary condition for the considered surface is represented by the homogenized surface impedance/admittance in the plane-wave spectral domain. This remains valid in the limit when the periodicity of the surface approaches zero and the surface admittance components are defined as the following:

$$\tilde{Y}_{yx} = \frac{\tilde{H}_y}{\tilde{E}_x}; \quad \tilde{Y}_{xy} = -\frac{\tilde{H}_x}{\tilde{E}y} \tag{3}$$

1D and 2D Periodic-Type Structure

In this section, parallel-plate structure having 1D and 2D periodic structure at the bottom layer is analyzed. Fig. 16 shows these types of structures. While analyzing these structures, the periodicity at the bottom layer is considered to be much smaller than wavelength. Green's functions for such structures are derived in detail in Bosiljevac et al. (2010). These are also presented here for convenience of the reader.

For 1D case:

DOI 10.1007/978-981-4560-75-7_130-1

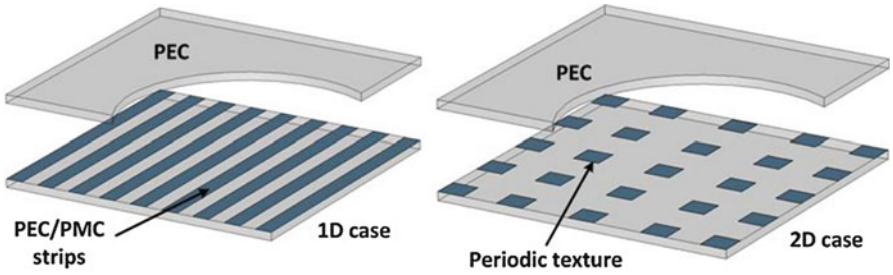

Fig. 16 Illustration of the 1D and 2D periodic-type structure (With permission from Pucci et al. 2014, Zaman and Kildal 2014, and Zaman et al. 2014)

$$\underset{\sim}{\tilde{G}}_{xz}^{HJ} = \tilde{H}_x = j\frac{k_y}{k_o^2 - k_y^2}\left[-\frac{k_x^2 \sin(k_z z)}{k_z \cos(k_z h)} + k_z \frac{\cos(k_z z)}{\sin(k_z h)}\right] \tag{3a}$$

$$\underset{\sim}{\tilde{G}}_{yz}^{HJ} = \tilde{H}_y = j\frac{1}{k_o^2 - k_y^2}\left[\left(k_o^2 - k_y^2\right)\frac{k_x \sin(k_z z)}{k_z \cos(k_z h)}\right] \tag{3b}$$

For 2D case:

$$\underset{\sim}{\tilde{G}}_{xz}^{HJ} = \frac{1}{\beta^2 D_{sw}}\left[C_1 k_x\left(\frac{\cos(k_z z)}{\sin(k_z h)} + \frac{\sin(k_z z)}{\cos(k_z h)}\right) + C_2 k_y \frac{\cos(k_z z)}{\sin(k_z h)} + C_3 \frac{k_y}{k_z}\frac{\sin(k_z z)}{\sin(k_z h)}\right] \tag{3c}$$

$$\underset{\sim}{\tilde{G}}_{yz}^{HJ} = \frac{1}{\beta^2 D_{sw}}\left[C_1 k_y\left(\frac{\cos(k_z z)}{\sin(k_z h)} + \frac{\sin(k_z z)}{\cos(k_z h)}\right) - C_2 k_x \frac{\cos(k_z z)}{\sin(k_z h)} - C_3 \frac{k_x}{k_z}\frac{\sin(k_z z)}{\sin(k_z h)}\right] \tag{3d}$$

where $C_1 = jk_x k_y k_z\left(\tilde{Y}_{yx} - \tilde{Y}_{xy}\right)$; $C_2 = -\beta^2 \eta_o k_o \tan(k_z h)\tilde{Y}_{xy}\tilde{Y}_{yx} - jk_z\left(k_x^2 \tilde{Y}_{yx} + k_y^2 \tilde{Y}_{xy}\right)$

$$C_3 = jk_o^2 \tan(k_z h)\left(k_x^2 \tilde{Y}_{xy} + k_y^2 \tilde{Y}_{yx}\right) - k_z \beta^2 \text{ and}$$

$$D_{sw} = -\tilde{Y}_{yx}\left(k_o^2 - k_x^2\right) - \tilde{Y}_{xy}\left(k_o^2 - k_y^2\right) + jk_o k_z\left[\eta_o \tan(k_z h)\tilde{Y}_{xy}\tilde{Y}_{yx} - \frac{1}{\eta_o}\cot(k_z h)\right]$$

Bed of Nail Structure

The bed of nail or the periodic pin structure is a favorable surface for use in gap waveguides as it can be made of metal only, and this structure can be easily milled. The topology of the surface is shown in Fig. 17. The homogenization method for such a structure is based on modeling the pin structure as uniaxial medium whose permittivity may be characterized by the permittivity tensor (Silveirinha et al. 2008):

$$\underset{\approx}{\varepsilon} = \varepsilon_o \varepsilon_r(\hat{x}\hat{x} + \hat{y}\hat{y} + \varepsilon_{zz}(\lambda, k_z, p, r)\hat{z}\hat{z}) \tag{4}$$

where p and r are the periodicity and radius of the pins, respectively. Using the TE-TM decomposition of the electric point source and by imposing the correct boundary conditions at all interfaces, the reflection coefficients for both polarizations can be derived (Silveirinha et al. 2008; Bosiljevac et al. 2010):

DOI 10.1007/978-981-4560-75-7_130-1

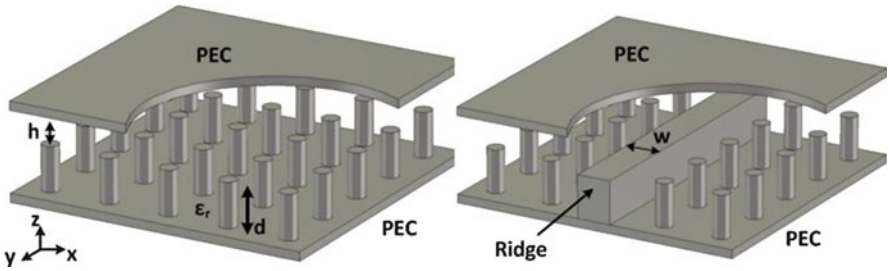

Fig. 17 Illustration of the bed of nail geometry and ridge gap waveguide with a top PEC plate (With permission from Zaman and Kildal 2014)

$$\Gamma^{TM} = -\frac{k_{\text{die}}k_p^2 \tan\,(k_h d) - \beta^2\gamma_{TM}\tanh\,(\gamma_{TM}d) + \varepsilon\gamma_o\left(k_p^2+\beta^2\right)}{k_{\text{die}}k_p^2 \tan\,(k_h d) - \beta^2\gamma_{TM}\tanh\,(\gamma_{TM}d) - \varepsilon\gamma_o\left(k_p^2+\beta^2\right)} \tag{5}$$

where k_{die} is the wavenumber in the metallic pin medium, k_p is the plasma wavenumber of the given pin lattice, $\beta^2 = {k_x}^2 + {k_y}^2$, ${\gamma_{\text{TM}}}^2 = {k_p}^2 + \beta^2 - {k_{\text{die}}}^2$, and ${\gamma_{\text{o}}}^2 = \beta^2 - {k_o}^2$.

For TE case:

$$\Gamma^{TE} = -\frac{\sqrt{k_h^2-\beta^2} - j\sqrt{k_o^2-\beta^2}\tan\left(d\sqrt{k_{\text{die}}^2-\beta^2}\right)}{\sqrt{k_h^2-\beta^2} + j\sqrt{k_o^2-\beta^2}\tan\left(d\sqrt{k_{\text{die}}^2-\beta^2}\right)} \tag{6}$$

After obtaining the reflection coefficient, the surface admittances of the pin structure are found as follows:

$$\tilde{Y}_{\text{surf}}^{TM} = \frac{k_o}{\eta_o k_z}\cdot\frac{\Gamma^{TM}+1}{\Gamma^{TM}-1}; \qquad \tilde{Y}_{\text{surf}}^{TE} = \frac{k_z}{\eta_o k_o}\cdot\frac{\Gamma^{TE}+1}{\Gamma^{TE}-1} \tag{7}$$

Once the surface admittances are derived, the spectral domain Green's functions can be determined by using the following boundary conditions:

$$\tilde{E}_t = 0 \quad \text{at the upper boundary} \quad \tilde{H}_y = \tilde{Y}_{\text{surf}}.\tilde{E}_x \tag{8a}$$

$$\tilde{H}_x = -\tilde{Y}_{\text{surf}}.\tilde{E}_y + \tilde{J}_y \qquad \text{at the lower boundary} \tag{8b}$$

The ridge has been introduced into the analysis via infinite transmission line current with propagation constant k_{eff}. The transmission line current is approximated as $J_y(x')e^{-jk_{\text{eff}}y'}$. The simplest assumption for $J_y(x')$ is to assume that this current is entirely longitudinal with a current distribution almost constant over the width of the ridge. The propagation constant of the quasi-TEM mode can be determined by forcing the suitable boundary condition at the ridge surface. The computed propagation constant is compared to the result obtained by commercially available CST microwave studio solver and is shown in Fig. 18a. The *Hy* component computed 0.5 mm above the ridge surface is also compared with the results obtained from CST microwave studio and is presented in Fig. 18b.

DOI 10.1007/978-981-4560-75-7_130-1

Modal Field Representation and Dispersion Equation for Ridge Gap Waveguide

In this approach, field expressions in the region above the ridge and the two side regions above the surrounding pin surfaces are used to establish the field continuity and match the modes at the interfaces among the regions. The main purpose of this approach is also to model the dispersion characteristics of the quasi-TEM mode in the ride gap waveguide geometry shown in Fig. 17. The fields associated with the quasi-TEM mode are mainly transverse to the direction of propagation, but small longitudinal components of the fields are also anticipated. The field is expected to have an exponential decay laterally away from the ridge into the side regions above the pins.

It is expected that a quasi-TEM modal field propagates along the ridge in the frequency band when the bed of nails acts as an AMC and a parallel-plate stopband is achieved. This mode will match the evanescent modes supported by the surrounding cutoff structure. In the pin region, only the first TM and TE modes (with respect to z) are considered to be present. However, to achieve the field confinement above the ridge region, the evanescent modes must decay laterally away from the ridge along direction x. Under the approximations used above, in the central region above the ridge, the assumed mode is the quasi-TEM mode which is propagating along the y axis. The fields for this quasi-TEM mode can be presented as follows (Polemi et al. 2011):

DOI 10.1007/978-981-4560-75-7_130-1

$$\left.\begin{aligned} E_z &= E_o \cos\left(\hat{k}_x x\right) e^{-jk_y y} \\ H_x &= -E_o \frac{k_y}{\xi k} \cos\left(\hat{k}_x x\right) e^{-jk_y y} \\ H_y &= -jE_o \frac{\hat{k}_x}{\xi k} \sin\left(\hat{k}_x x\right) e^{-jk_y y} \end{aligned}\right\} \tag{9}$$

where E_o is related to the incident power at the input port and $\hat{k}_x$ is the propagation constant along x.

The TM_z evanescent mode fields in the region above the metal pins can also be written as follows (Das and Pozar 1987):

$$\left.\begin{aligned} H_x &= jA_{TM} \frac{k_y}{\sqrt{k^2 - \tilde{k}_z^2}} \tilde{g}(x,y) \times \cos\left[\tilde{k}_z(z-h)\right] \\ H_y &= -A_{TM} \frac{\tilde{\alpha}_x}{\sqrt{k^2 - \tilde{k}_z^2}} \tilde{g}(x,y) \times \cos\left[\tilde{k}_z(z-h)\right] \\ E_x &= -jA_{TM} \frac{\xi}{k} \frac{\tilde{\alpha}_x \tilde{k_z}}{\sqrt{k^2 - \tilde{k}_z^2}} \tilde{g}(x,y) \times \sin\left[\tilde{k}_z(z-h)\right] \\ E_z &= -jA_{TM} \frac{\xi}{k} \sqrt{k^2 - \tilde{k}_z^2}.\tilde{g}(x,y) \times \cos\left[\tilde{k}_z(z-h)\right] \\ E_y &= A_{TM} \frac{\xi}{k} \frac{k_y \tilde{k_z}}{\sqrt{k^2 - \tilde{k}_z^2}} \tilde{g}(x,y) \times \sin\left[\tilde{k}_z(z-h)\right] \end{aligned}\right\} \tag{10}$$

where $\tilde{g}(x,y) = e^{-jk_y y} e^{-\tilde{\alpha}_x(|x|-w/2)}$;

$$k^2 = (-j\tilde{\alpha}_x)^2 + \tilde{k}_z^2 + k_y \tag{11}$$

In Eq. 10, A_{TM} is an unknown coefficient, while Eq. 11 is the dispersion relation for this mode where attenuation constant $\tilde{\alpha}_x$ and propagation constant k_y are also unknown. Apart from the TM_z mode, a TE_z mode is also assumed to be excited in the pin region, and the field equation for this mode is presented in Eq. 12. In Eq. 12, A_{TE} is an unknown coefficient, and the dispersion relation for this TE mode is shown in Eq. 13:

$$\left.\begin{aligned}
E_x &= jA_{TE}\frac{k_y}{\sqrt{k^2-\tilde{\tilde{k}}_z^2}}\tilde{\tilde{g}}(x,y)\times\ \sin\left[\tilde{\tilde{k}}_z(z-h)\right]\\
E_y &= -A_{TE}\frac{\tilde{\tilde{\alpha}}_x}{\sqrt{k^2-\tilde{\tilde{k}}_z^2}}\tilde{\tilde{g}}(x,y)\times\ \sin\left[\tilde{\tilde{k}}_z(z-h)\right]\\
H_x &= -jA_{TE}\frac{1}{\xi k}\frac{\tilde{\tilde{\alpha}}_x\tilde{\tilde{k}}_z}{\sqrt{k^2-\tilde{\tilde{k}}_z^2}}\tilde{\tilde{g}}(x,y)\times\ \cos\left[\tilde{\tilde{k}}_z(z-h)\right]\\
H_z &= jA_{TE}\frac{1}{\xi k}\sqrt{k^2-\tilde{\tilde{k}}_z^2}.\tilde{\tilde{g}}(x,y)\times\ \sin\left[\tilde{\tilde{k}}_z(z-h)\right]\\
H_y &= A_{TE}\frac{1}{\xi k}\frac{k_y\tilde{\tilde{k}}_z}{\sqrt{k^2-\tilde{\tilde{k}}_z^2}}.\tilde{\tilde{g}}(x,y)\times\ \cos\left[\tilde{\tilde{k}}_z(z-h)\right]
\end{aligned}\right\} \tag{12}$$

where $\tilde{\tilde{g}}(x,y)=e^{-jk_yy}e_x^{-\tilde{\tilde{\alpha}}}(|x|-w/2)$;

$$k^2=\left(-j\tilde{\tilde{\alpha}}_x\right)^2+\tilde{\tilde{k}}_z^2+k_y \tag{13}$$

The overall unknowns in the abovementioned equations are six, and these are A_{TM}, A_{TE}, $\tilde{\alpha}_x$, $\tilde{\tilde{\alpha}}_x$, $\hat{k}_x$, and k_y. So, six equations are needed to solve the problem. Three of them are the dispersion relations in the three regions mentioned above and shown below:

$$\left.\begin{aligned}
k_y^2 &= k^2-\tilde{k}_z^2+\tilde{\alpha}_x^2\\
k_y^2 &= k^2-\tilde{\tilde{k}}_z^2+\tilde{\tilde{\alpha}}_x^2\\
k_y^2 &= k^2-\hat{k}_x^2
\end{aligned}\right\} \tag{14}$$

To find the remaining equations, continuity of three field components across different regions is enforced, and the final dispersion equation for the ridge gap waveguide is obtained as follows:

$$\sqrt{k^2-k_y^2}\ \tan\left[\sqrt{k^2-k_y^2}\ w/2\right]\left(k^2-\tilde{k}_z^2\right)+\frac{k_y^2\tilde{k}_z^2-k^2\sqrt{k_y^2-k^2+\tilde{k}_z^2}\sqrt{k_y^2-k^2+\tilde{\tilde{k}}_z^2}}{\sqrt{k_y^2-k^2+\tilde{\tilde{k}}_z^2}}=0$$

Comparison Between the Modal Field Representation and Spectral Domain Green's Function

A comparison study between the two approaches mentioned above has been done in Bosiljevac et al. (2011). Both the ridge gap waveguide and groove gap waveguide have been studied analytically using the two approaches. Results obtained using both the approaches are compared with results from commercial solver CST microwave studio. Very good agreements have been observed among the results

DOI 10.1007/978-981-4560-75-7_130-1

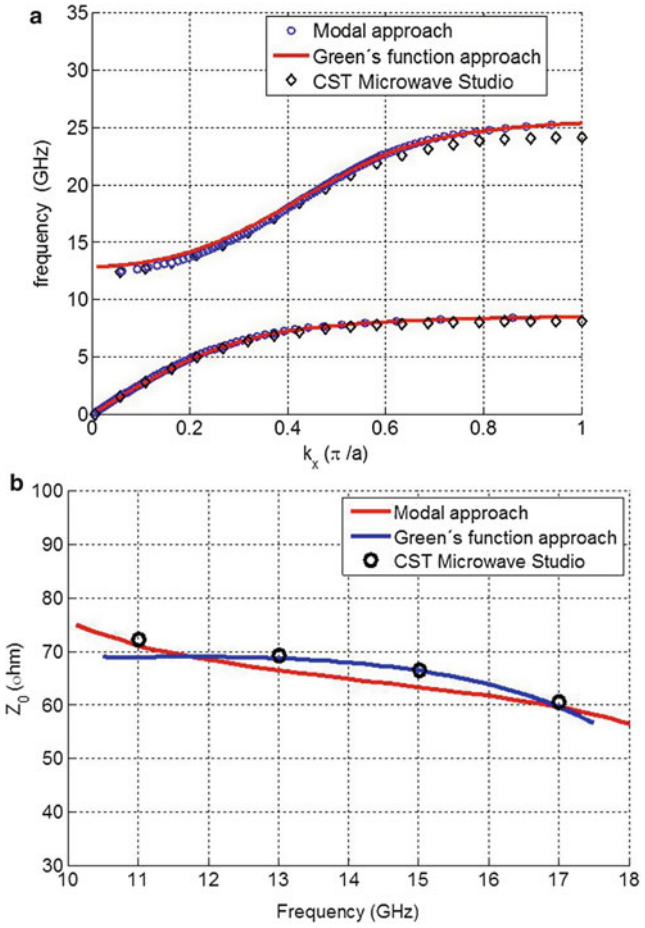

Fig. 19 (**a**) Dispersion diagram obtained by both methods and CST for ridge gap waveguide and (**b**) characteristic impedance calculated by both methods and CST for the same test geometry

obtained in most of the cases. In this section, some results regarding the comparison work are presented only for the ridge gap waveguide geometry. The ridge gap waveguide test geometry used for comparison has the following physical dimensions: pin heights 7.5 mm, air gap height 1 mm, pin size 1×1 mm^2, periodicity 2 mm, and ridge width 5 mm. The dispersion diagrams and characteristic impedances for this test geometry obtained by a different analysis approach are shown in Fig. 19a and 19b.

Numerical Analysis for Gap Waveguide Structures Based on CST and HFSS

Apart from developing rigorous analytical formulations for gap waveguide geometries, there is always a need to determine the correctness of using commercially available EM solvers for simulating gap waveguide components. There exists geometrical difference between the hollow waveguides and gap waveguide structures due to the periodicity of the textured surface. This section validates the use of commercial EM solvers like HFSS or CST, even for such periodic structures. By checking the similarities among hollow waveguides and gap waveguides, it is possible to come to a conclusion that commercial EM solvers can handle the gap waveguide structure with a certain level of accuracy (Raza et al. 2013).

First, the dispersion diagrams of the ridge/rectangular waveguides and the ridge/groove gap waveguides are obtained by using the eigenmode solver in CST microwave studio, where the periodic structure is assumed infinitely long in the direction of propagation. In this section, the material used for the simulation is the perfect electric conductor with zero surface roughness, and the geometry is shown in Fig. 20.

DOI 10.1007/978-981-4560-75-7_130-1

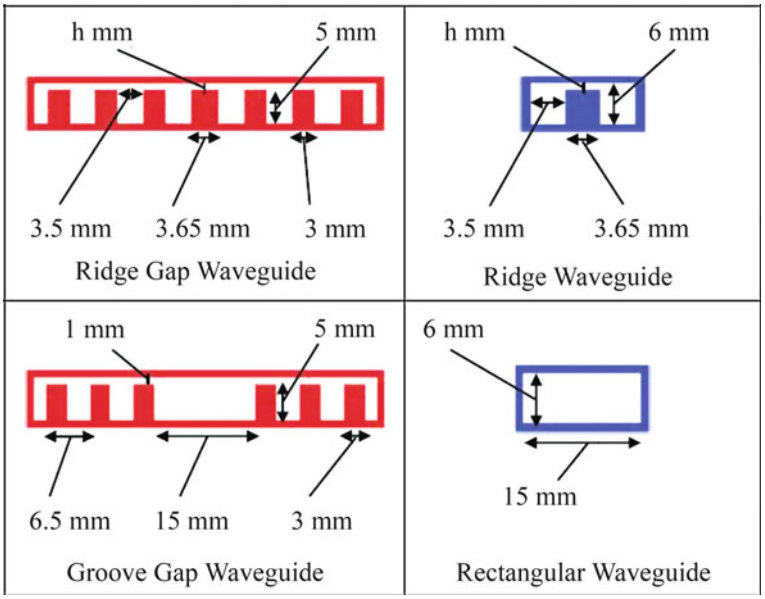

Fig. 20 Details of the geometries investigated for dispersion analysis (With permission from Pucci et al. 2014)

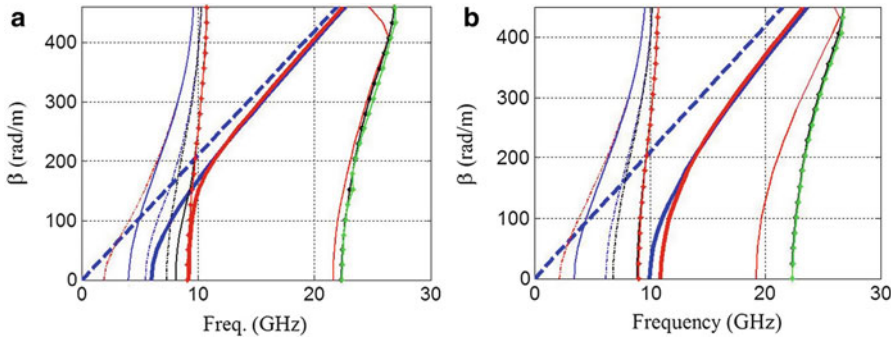

Fig. 21 (**a**) Dispersion diagram of ridge gap waveguide and hollow ridge waveguide (*dashed line*), (**b**) dispersion diagram of groove gap waveguide and hollow rectangular waveguide (*dashed line*)

The dispersion diagrams are shown in Fig. 21a and 21b, respectively, for hollow ridge/ridge gap waveguide and hollow rectangular/groove gap waveguide. From the simulated dispersion diagrams of the ridge gap waveguide and its equivalent ridge waveguide, it is seen that ridge gap waveguide has a dispersion curve (referred to as the ridge gap dispersion curve) very close to that of a TEM mode (the light line). More importantly, within the stopband, the ridge gap dispersion curve is very close to the dispersion curve of the fundamental mode in the equivalent conventional ridge waveguides. Similarly, when compared the dispersion diagrams between a groove gap waveguide and its equivalent hollow rectangular waveguide, the dispersion diagrams of the fundamental propagating modes in both the waveguides are similar within the stopband. In summary, the dispersion diagram of a ridge/groove gap waveguide can be approximated by that of its equivalent ridge/hollow waveguide, which can be easily obtained by either analytical expressions or empirical formulas.

Port Configuration for Simulating Gap Waveguide Components

A numerical port configuration has been studied in the situation where numerical ports are directly attached to the ridge/groove gap waveguide. The extensive study and obtained results are presented

DOI 10.1007/978-981-4560-75-7_130-1

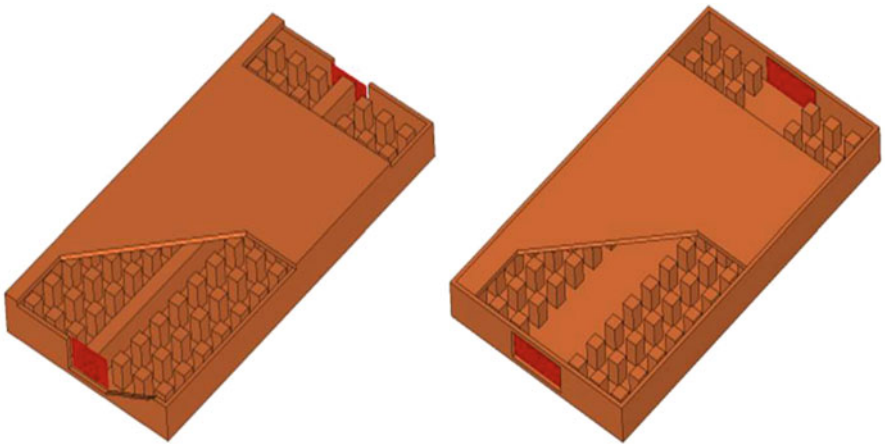

Fig. 22 Port configuration for simulating gap waveguide structures

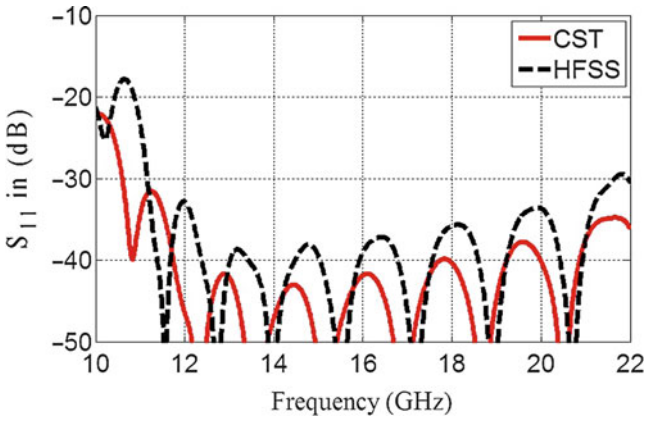

Fig. 23 S-parameters of the groove gap waveguide equivalent hollow waveguide ports in CST and HFSS

elaborately in Raza et al. (2013). However, here in this section, some results are presented only to show the level of port accuracy obtained by commercial EM solvers when the ports are directly placed at the gap waveguide structures as shown in Fig. 22. Ideally, with correct numerical ports, the S_{11} and S_{22} for such straight two-port waveguide would be quite low (in the order of −65 dB). But in this case, the hollow waveguide ports available in commercial EM solver, being the imperfect numerical ports, will give relatively high S_{11} and S_{22} and will induce errors in gap waveguide simulations. However, the level of S_{11} and S_{22} obtained both for ridge gap waveguide and groove gap waveguide is lower than −35 dB within the band of interest. This is shown in Figs. 23 and 24. As shown in the two plots, the matching between the gap waveguide and the equivalent waveguide port is still good, except at the lower end of the stopband. The periodic nature of the reflection coefficient comes from the two interfering reflections, from the ports at both ends of the waveguides. This means that the reflection coefficient from each port interface is 6 dB lower than the peaks of the combined reflection coefficient S_{11}. Thus, it is easy to conclude that the discontinuity effect at the numerical port over most of the stopband is quite small from practical viewpoint, and level wise it is in the same order of magnitude as that of measurement accuracy.

Low-Loss Antennas Based on Gap Waveguide Technology

Wireless communication systems have evolved from cellular telephony with data rates of kilobits per second (kbps) to wireless local area networks (WLANs) and wireless personal area networks (WPANs) that communicate with megabits per second (Mbps). Also, with the advent of gigabit Wi-Fi and more and more commercial applications with higher data rate (Hansen 2011; Smulders 2002), high-gain and large-aperture antennas are becoming more and more important from system perspective.

Although high antenna efficiency can be obtained by using dielectric lens antennas or reflector antennas (Chantraine-Bares and Sauleau 2007; Mall and Waterhouse 2001; Wei et al. 2011), it is difficult to realize planar antennas with such configurations, as they essentially need focal spatial length. Microstrip array antennas can be lightweight, low cost, and low profile, but they suffer from high dielectric losses and ohmic losses at high-frequency bands (Borji et al. 2009). Also, the electrical performances of microstrip antennas depend on the substrate to be used. As a result, it is very difficult to optimize important antenna parameters such as bandwidth and efficiency simultaneously in case of microstrip antennas (Zwick et al. 2006). Furthermore, microstrip antennas are associated with problems such as leakage via surface waves and undesired radiation (Fonseca and Giarola 1984; Komanduri et al. 2013; Levine et al. 1989). Hence, realization of a high-efficiency high-gain microstrip antenna array is quite challenging especially at mmWave frequencies and above.

Slotted hollow waveguide planar array antennas are free from large feed network loss and can be applied to design high-efficiency high-gain or moderate-gain antennas (Hirokawa and Ando 2000; Hirokawa et al. 1992). However, the production cost of waveguide antennas is generally very high because they usually consist of metal blocks with complicated three-dimensional structures (Liu et al. 2009). Also, high-precision manufacturing techniques are needed to achieve good electrical contacts between the slotted metal plate and the bottom feed structure in such waveguide-fed slot array antennas. Consequently, conventional waveguide slot arrays have not been used commercially till today with the exception of few military applications and space applications.

Apart from the conventional microstrip antennas and waveguide slot antennas, substrate integrated waveguide (SIW)-based planar array antennas are also proposed to realize low-cost solutions (Xiao-Ping et al. 2010; Xu et al. 2009). This technology enables integration of active circuits together with the antennas. The losses in SIW are better than microstrip and coplanar structures. Still, losses may be of real concern, especially for high-gain (above 28 $\sim$ 30 dBi) configuration, due to the presence of dielectric material (Bozzi et al. 2011; Awida et al. 2011).

DOI 10.1007/978-981-4560-75-7_130-1

Based on the above discussions, it is implicit that existing antenna technologies have limitations with respect to manufacturing cost, efficiency, bandwidth, and mechanical simplicity, giving an opportunity for more research work on new technologies such as gap waveguide. As mentioned in section "Operating Principle of Gap Waveguides and Loss Analysis," different gap waveguide configurations can exist in practice, giving a unique opportunity to use multiple gap waveguide configurations to build antennas with specific performance requirement and cost. In this section, several antenna works based on gap waveguide technology have been described, and it is shown how different configurations of gap waveguide can be used in designing antennas.

Ridge Gap Waveguide Single-Layer Wideband Slot Array Antenna

In this section, a wideband 4 × 1 element linear slot array and a 2 × 2 element planar slot array designed at Ku-band using ridge gap waveguide technology are demonstrated. Both these antennas are designed for a fixed broadside beam and a 20 % relative bandwidth. The low-loss feed network needed for a high-gain array antenna can be built very easily with the help of ridge gap waveguide concept. In addition, radiating slots can be placed conveniently on the top smooth metal plate of ridge gap waveguide. It is possible to design slot antenna without having strict requirements of good electrical contacts between the slotted metal plate and the bottom feed structure. The details of the ridge gap slot array antenna work are published in Zaman and Kildal (2014).

The initial single slot antenna excited by ridge gap waveguide is shown in Fig. 25a. This single element is quite narrowband as is observed in simulated S_{11} results. Later on, this design has been improved with addition of a T-section ridge (Zaman and Kildal 2012, 2014). The length and the width of the slot element are also varied to have the S_{11} below −10 dB over a significant bandwidth. The improved element design and obtained reflection coefficient for the element is shown in Fig. 25b. The largest bandwidth is obtained when the first resonance from the slot itself and the second resonance from the feeding T-section appeared close to each other. These two resonance dips are clearly seen in the simulated S_{11} plots in Fig. 25b.

Another important component for antenna corporate feed network is the 3-dB power divider in the form of a T-junction. The T-junction usually consists of a quarter-wave transformer section and three 50-Ω lines. The ridge waveguide T-junction power divider and its simulated S-parameters are shown in Fig. 25c. The simulation results show that it is possible to design a wideband feed network for a complete array antenna based on this T-junction.

Linear Array Design

Based on the abovementioned slot element and the 3-dB power divider, a 4 × 1 linear slot array has been designed. At this point, the linear array is designed for a fixed beam in mind. So, the element spacing can be kept 0.80λ to avoid grating lobes, and all the slot elements are excited with equal amplitude and phase. The complete array is shown in Fig. 26a, and it is designed to operate between 11.5- and 14.5-GHz frequency bands. As shown in Fig. 26a, the bottom plate with ridge and texture pin structure holds the feeding network for the array. On top is placed a smooth metal plate with four radiating slots at a distance of 1 mm from the bottom plate. The dimension of the slot element is chosen in such a way that the slot length to width ratio S_w/S_L is kept smaller than 0.5. This ratio is important for the suppression of the cross-polarization. The thickness of the top metal plate is chosen to be 2 mm. A transition is needed from ridge gap waveguide to the standard transmission line for measurement of the entire antenna. This transition can be a simple interface consisting of steps in ridge which allows the quasi-TEM mode to couple to the coaxial mode of SMA connector with extended inner conductor. The measured results for this linear array are presented in Fig. 26b and 26c. As shown in the measured results, the measured S_{11} parameter is in good agreement with the simulated value, and the relative bandwidth is about 20 %. In case of the radiation patterns, the array has more directive beam and symmetric pattern in H-plane as expected. In

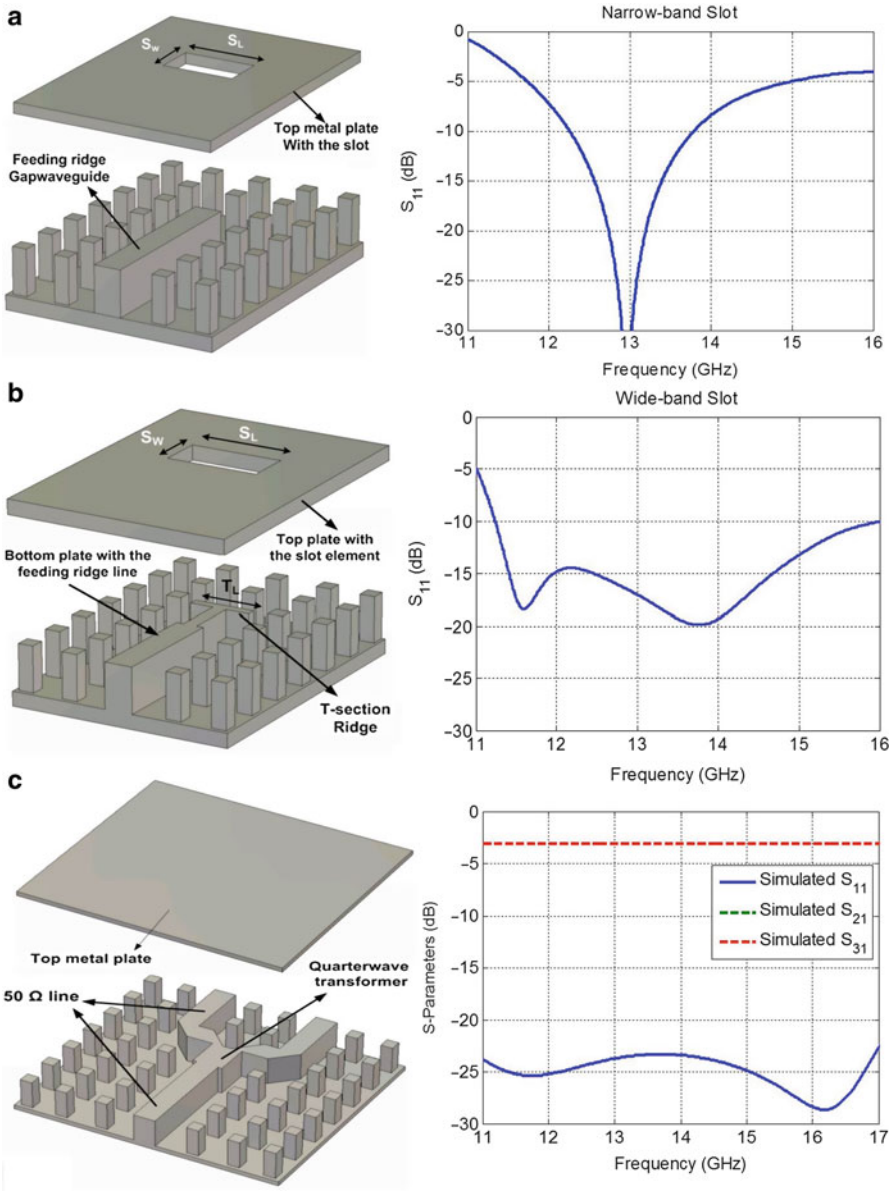

Fig. 25 (**a**) Narrowband slot with dimension $S_L = 11.5$ mm and $S_W = 5.85$ mm and its simulated reflection coefficient. (**b**) Wideband slot with T-section and its simulated reflection coefficient; $S_L = 11.75$ mm, $S_W = 5.85$ mm, $T_L = 8.25$ mm. (**c**) Simulated S-parameters for ridge gap waveguide T-junction

H-plane, the first sidelobe is 11.8 dB lower from the beam peak value which is also common for uniform arrays. On the other hand, in E-plane, the beam is wider and is not really symmetric as the slots are close to the edge on one side. In E-plane, there is a possibility of back radiation as the slots are close to the edge. To avoid this back radiation, few corrugations with quarter-wavelength depth at the lowest frequency of operation have been added.

Two-Dimensional Array Design

After designing the linear array, a simple 2 × 2 element planar array has been designed with ridge gap waveguide technology to operate over the band 12–15 GHz. The 2 × 2 element array is excited in phase and with equal amplitude by a corporate feeding. The element spacing is about 0.875λ at highest frequency of interest. The slot length S_L and slot width S_W are chosen to be 11.45 and 6.25 mm for this

DOI 10.1007/978-981-4560-75-7_130-1

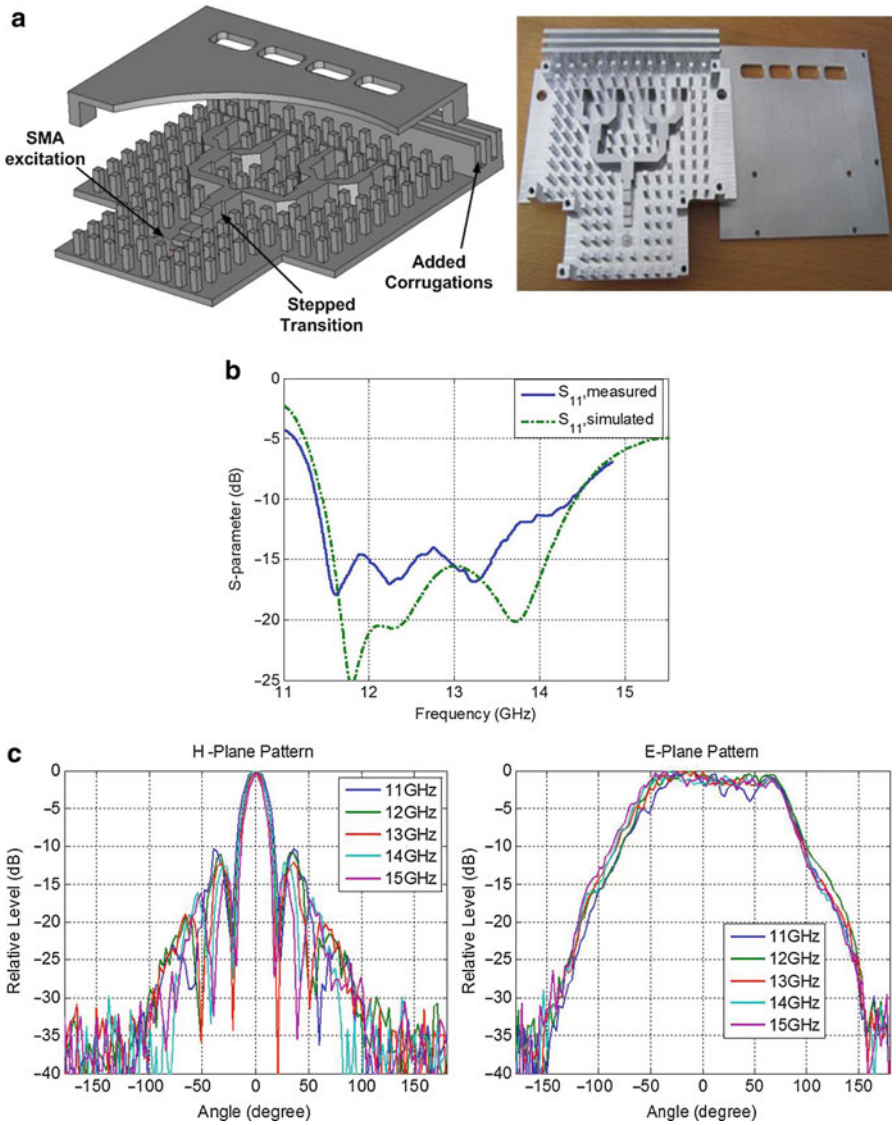

Fig. 26 (**a**) CST model of the linear array and manufactured array. (**b**) Measured and simulated S_{11} for the linear array. (**c**) Measured E- and H-plane patterns for the linear array

particular design. The antenna is excited with a standard Ku-band rectangular waveguide and is shown in Fig. 27a. In a two-dimensional array, it is more difficult to design the corporate feed network because the element spacing must be smaller than one wavelength in two orthogonal directions. For this reason, the feed network must be much more compact. So, in this design, the compact four-way power divider is designed without using a λ/4 transformer section. Instead, the widths of the two divided ridge sections are gradually tapered to make the impedance match (Zaman and Kildal 2014). Fig. 27b and 27c presents the measured reflection and measured principal plane radiation patterns, respectively. For the 2×2 array, the sidelobe is below -12.5 dB in H-plane for all the measured frequency points. In E-plane, the sidelobe levels remain below -10 dB at the lower frequencies, but they rise up to a level of -7.65 dB at the upper end of the frequency band. These high sidelobes are caused by the omnidirectional pattern of each individual slot in E-plane and the large element spacing (close to λ at higher frequency). Also, the array has an extent limited to only two elements in each direction, so we do not have a clear effect of the array factor. For a larger array, this first sidelobe will appear closer to the main lobe and will become lower.

Groove Gap Waveguide Slot Arrays

As mentioned in section "Operating Principle of Gap Waveguides and Loss Analysis," among all the gap waveguide geometries, the groove gap waveguide offers lowest insertion loss, and the loss of this waveguide is very similar to that of conventional rectangular waveguide. So, it is of interest to design slot arrays based on groove gap waveguide, and very recently some work has been done on groove gap waveguide slot arrays (Valero-Nogueira et al. 2013; Martinez Giner et al. 2013). In this section, two groove gap linear arrays having slots in broad wall and narrow wall have been discussed. The field distributions inside the groove gap waveguide for these two cases are shown in Fig. 28.

The approach in designing the groove gap waveguide slot array is similar to the conventional approach. First, it is necessary to obtain the equivalent admittance of the slot in groove gap waveguide. But this is not a trivial problem, as in this case the structure to be analyzed is a periodic waveguide having nonperiodic obstacles such as slots. As a result, the direct use of the Bloch-Floquet theorem is not applicable here. However, an indirect approach is proposed in Valero-Nogueira et al. (2013) to obtain the S_{11} parameter associated to a slot in a groove gap waveguide. The indirect derivation of the reflection coefficient is

DOI 10.1007/978-981-4560-75-7_130-1

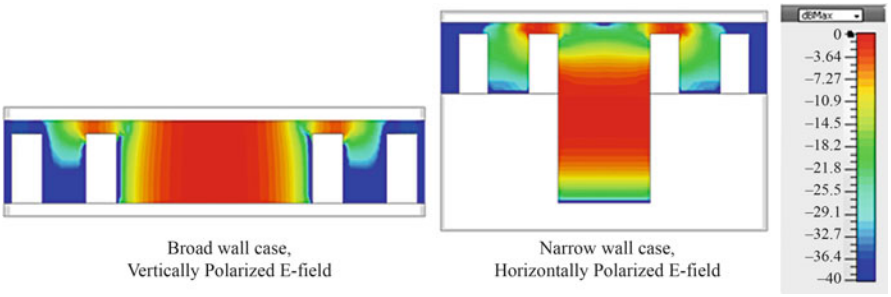

Fig. 28 The field distribution inside the groove gap waveguide for slots in broad wall or narrow wall

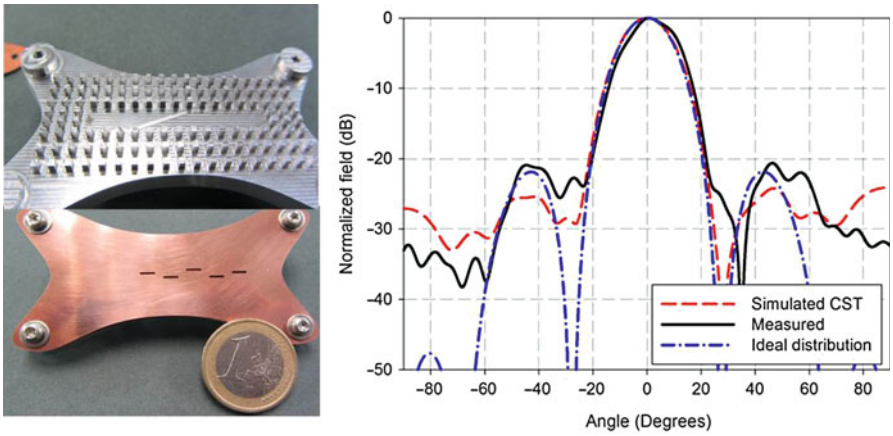

Fig. 29 Manufactured groove gap waveguide with slots in the broad wall and H-plane pattern for this slot array

performed starting from an aperture integral formulation applied to the slot. Using the approach mentioned in Valero-Nogueira et al. (2013), a small linear array having slots on the broad wall of groove gap waveguide has been designed at Ka-band. The manufactured slot array and measured radiation pattern for this slot array are shown in Fig. 29.

Apart from the slot array mentioned above, a resonant 8-element array has been designed in which the slots are in the narrow wall of the groove gap waveguide (Martinez Giner et al. 2013). Typically, when the slots are placed in the narrow wall, the slots are tilted or inclined. This degrades the cross-polar performance of the antenna. To avoid high cross-polar problem, the slots are kept untilted and a substrate etched with tilted parasitic dipoles has been used to excite the slots. This approach is similar to the approach mentioned in Hirokawa and Kildal (1997). The relative angle between the dipole and the slot determines the amount of coupling between these two elements. The schematic of the single element is shown in Fig. 30, and the picture of the manufactured array with radiation patterns is presented in Fig. 31a and 31b, respectively. As mentioned in Martinez Giner et al. (2013), the radiating elements in the array are positioned after every $\lambda_g/2$ position, at the point of each standing-wave maxima. The dipoles are also oriented in an alternating fashion to compensate for the alternate phase pattern of the standing-wave after every $\lambda_g/2$ length.

Horn Array Antenna Fed by Inverted Microstrip Gap Waveguide

This section presents the design of a 16-element quasi-planar dual-mode horn array fed by an inverted microstrip gap waveguide corporate distribution network. The final antenna is intended for 60-GHz application. But a scaled version of that antenna, a prototype working at X-band, is manufactured as a

DOI 10.1007/978-981-4560-75-7_130-1

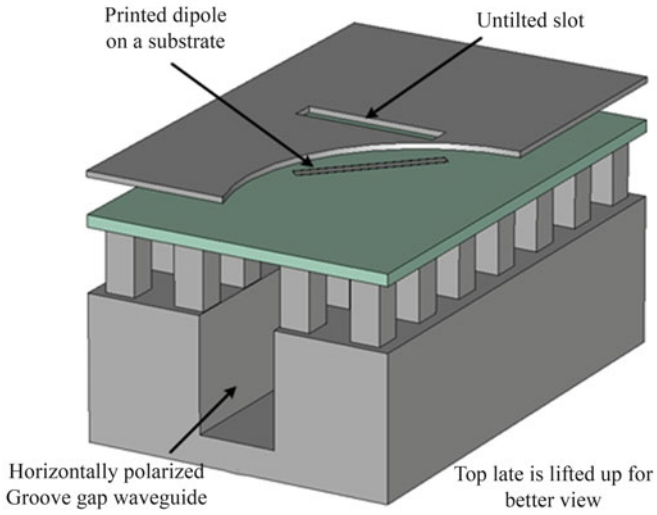

Fig. 30 Schematic of groove gap waveguide with untitled slot excited by parasitic dipole

proof of concept and is presented here. The detailed description of this work is presented in Pucci et al. (2014). The main objective of this work is to demonstrate inverted microstrip gap waveguide-based corporate feed network which works without unwanted leakage via substrate mode and distributes the power properly to a horn array. The emphasis has not been given to the design of the $2\lambda \times 2\lambda$ dual-mode horn element itself. The schematic of the single horn element is shown in Fig. 32. The single horn element is also excited by a T-shaped feed line, similar to the one used in Zaman and Kildal (2014). This makes it possible to achieve a larger bandwidth (over 10 %). In the complete array, horn elements are fed by a corporate feed network realized in microstrip gap waveguide. The feed network is designed by using conventional T-junction power dividers and quarter-wavelength impedance transformers. The input is provided from the central 50-Ω transmission line, which splits the power into two main branches, and then the power division continues until equal amount of power has traveled up to an individual radiator. The matching is obtained by using impedance transformers and by mitering the corner of the bends. The design details of the feed network are also mentioned in Pucci et al. (2014). The picture of the manufactured antenna with all the different parts is shown in Fig. 33.

For the manufactured 16-element planar dual-mode horn array fed by inverted microstrip gap waveguide distribution network, the realized gain is found to be around 24.5 dBi over the design frequency. The main loss in this antenna is found to be the power lost due to grating lobes. This particular antenna has inherently low aperture efficiency due to the high grating lobes originating from the size of the single horn element which is more than one wavelength. After calculating the grating lobe efficiency, it is found that $2 \sim 3$-dB power is lost due to high grating lobes over the frequency band of interest. Otherwise, the inverted microstrip gap waveguide-based feed network has relatively smaller losses, only in the order of $0.4 \sim 0.5$ dB. The radiation patterns and the realized gain plots are shown in Fig. 34a and 34b. However, the main advantage of this antenna lies in the fact that the substrate (on which the inverted microstrip gap waveguide feed network is printed) can be placed easily on top of the uniform bed of nail structure where the periodicity is constant. Such uniform pin structure can be milled with bigger milling tools, or several saw blades can be placed together to cut out such uniform block from bulk metal piece.

60-GHz Slot Array Element Using Two Double-Sided PCBs

In this section, a wideband 60-GHz planar slot array antenna is presented. The unit cell of the slot array is made of two double-sided PCB layers. Between the two PCBs, the bottom PCB is used for the corporate

DOI 10.1007/978-981-4560-75-7_130-1

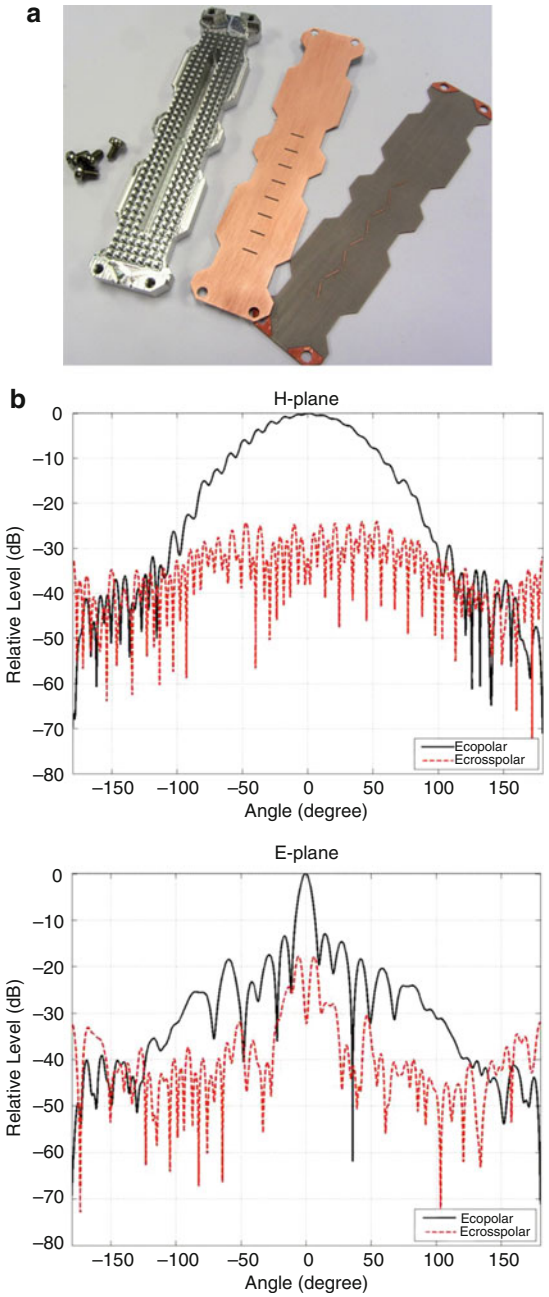

Fig. 31 (**a**) Manufactured groove gap slot array having slot in narrow wall. (**b**) Measured E- and H-plane radiation patterns for the slot array having slot in narrow wall

feed network of the antenna, and the feed network is based on microstrip-ridge gap waveguide. On the other hand, the upper PCB is a SIW cavity layer with internal walls. The ground plane of the upper PCB holds a coupling slot which is used to couple energy from microstrip-ridge gap waveguide feed network to the SIW cavity layer. After that, the energy is radiated from the SIW cavity to the air with the help of the radiating slots which are etched on the top metal layer of the upper PCB. There exists an air gap between the upper PCB and bottom PCB which is needed for the Q-TEM mode propagation along the microstrip-ridge gap waveguide, and this air gap is maintained to be 0.25 mm in this case. In this work, Rogers 5880 substrate ($\varepsilon_r = 2.2$) with thickness of 0.78 mm has been used as the upper PCB. On the other hand, Rogers 3003 substrate ($\varepsilon_r = 3.0$) with a thickness of 0.504 mm has been used as the bottom PCB. The schematic

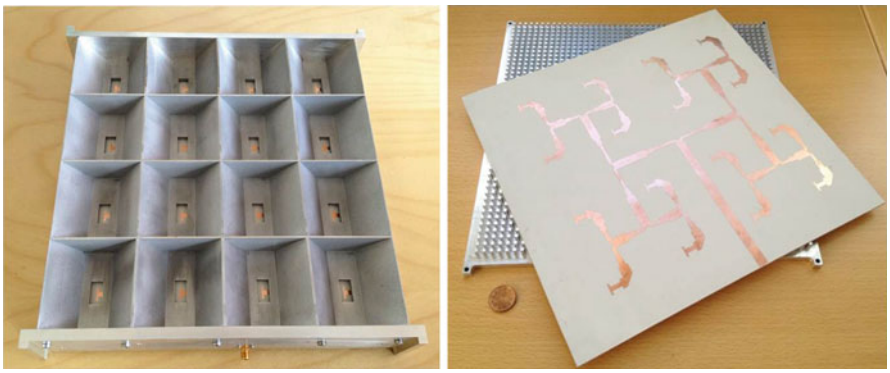

Fig. 33 Manufactured horn array with inverted microstrip gap waveguide feed network

of the 2 × 2 unit cell of the array is shown in Fig. 35a, and the details of the antenna are presented in Razavi et al. (2014). Actually, this work is the part of a larger project to realize a high-gain (∼35 dBi, 32 × 32 element) antenna based on PCB technology only.

In order to obtain the highest aperture efficiency and widest bandwidth, the 2 × 2 slot sub-array dimensions were optimized. It is well known that the slots (or other elements) in an antenna aperture should be uniformly spaced in orthogonal directions with spacing smaller than one wavelength in order to avoid grating lobes in large broadside arrays. This requirement may be relaxed if the element pattern has a null along the ground plane, such as in H-plane of slots. However, in E-plane, this requirement needs to be strictly followed, because slots have more uniform radiation pattern in E-plane. At the same time, the element spacing should be as big as possible in order to keep the total aperture size of the array large enough to have a required gain and directivity. In order to satisfy the above conditions, unit cell dimensions l and w as well as the inter-element slot spacing within the 2 × 2 slot sub-array have been optimized. It should be noted that the slot dimensions w_s and l_s as well as the coupling slot sizes w_c and l_c have been tuned at the same time to achieve good impedance matching over the operating bandwidth. SIW corrugations requiring width of d_c have been also introduced in this design between each 2 × 2 slot sub-array in E-plane, working as a soft surface. By this means, the mutual coupling has been suppressed between sub-arrays, and this made it easier to impedance match the S_{11} in the infinite array environment over 57–66-GHz band. At the same time, there will be a null in the sub-array pattern along the ground plane, and thereby the grating lobe problem is also reduced. The important sub-array dimensions and the SIW corrugations are shown in Fig. 35b. All the dimensional details are mentioned in Razavi et al. (2014).

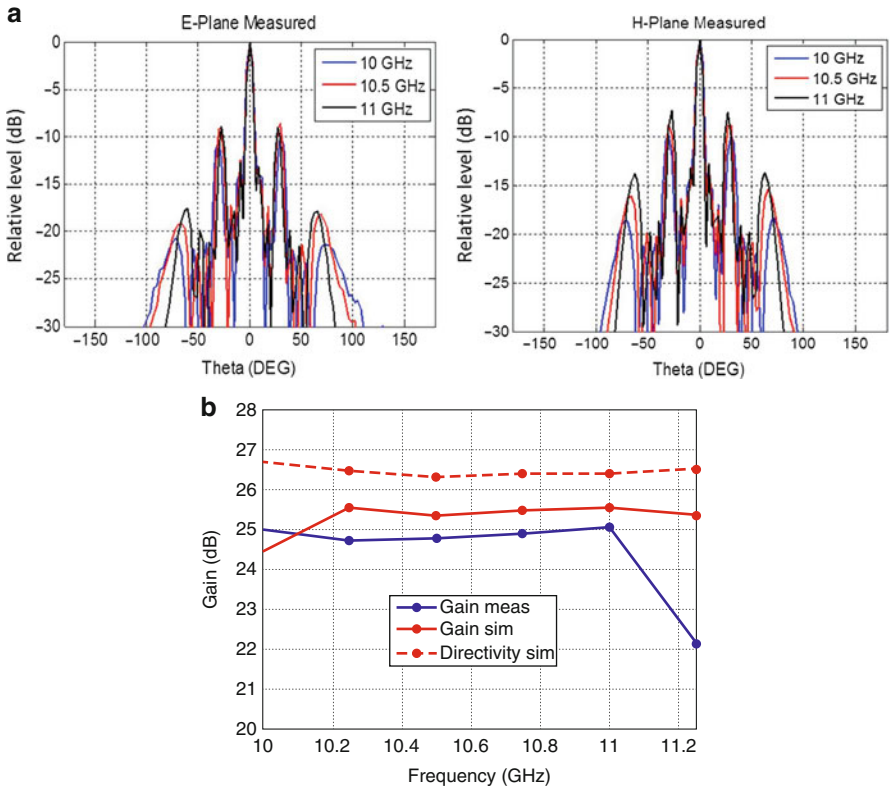

Fig. 34 (**a**) Measured E- and H-plane patterns for the horn array. (**b**) Measured gain and simulated gain for the horn array

After optimizing the 2 × 2 sub-array, a 4 × 4 element prototype antenna has been manufactured and measured to validate the concept. The picture of the manufactured prototype antenna and results for this antenna is shown in Fig. 36.

Transitions Between Gap Waveguide and Standard Transmission Line

The transitions between gap waveguide and other standard transmission lines play an important role and are integral modules related to gap waveguide components. In order to obtain maximum power transfer through a microwave subsystem, all components and modules constituting such a subsystem have to be matched. That is why transitions are needed to connect the gap waveguide passive components (i.e., antennas, filters, etc.) to a microwave subsystem and to have a good matching to standard microstrip line or standard rectangular waveguide. These transitions are also important from measurement point of view while assessing the performance of the designed gap waveguide components. In most of the cases, the rigorous equivalent circuit representations are not available for such transitions. So, optimum designs of these transitions are obtained by full-wave analysis using commercial full-wave solver. This chapter deals with standard microstrip to ridge gap waveguide transition, standard rectangular waveguide to ridge gap waveguide transitions, standard rectangular waveguide to microstrip-ridge gap waveguide transition, etc.

Microstrip to Ridge Gap Waveguide Transition

Successful integration of antenna and MMIC-based active RF circuit is quite critical in designing high-performance microwave modules at millimeter-wave frequencies. Many high-frequency TX/RX microwave modules contain MMIC chips, and they have typically microstrip line both at input and output.

DOI 10.1007/978-981-4560-75-7_130-1

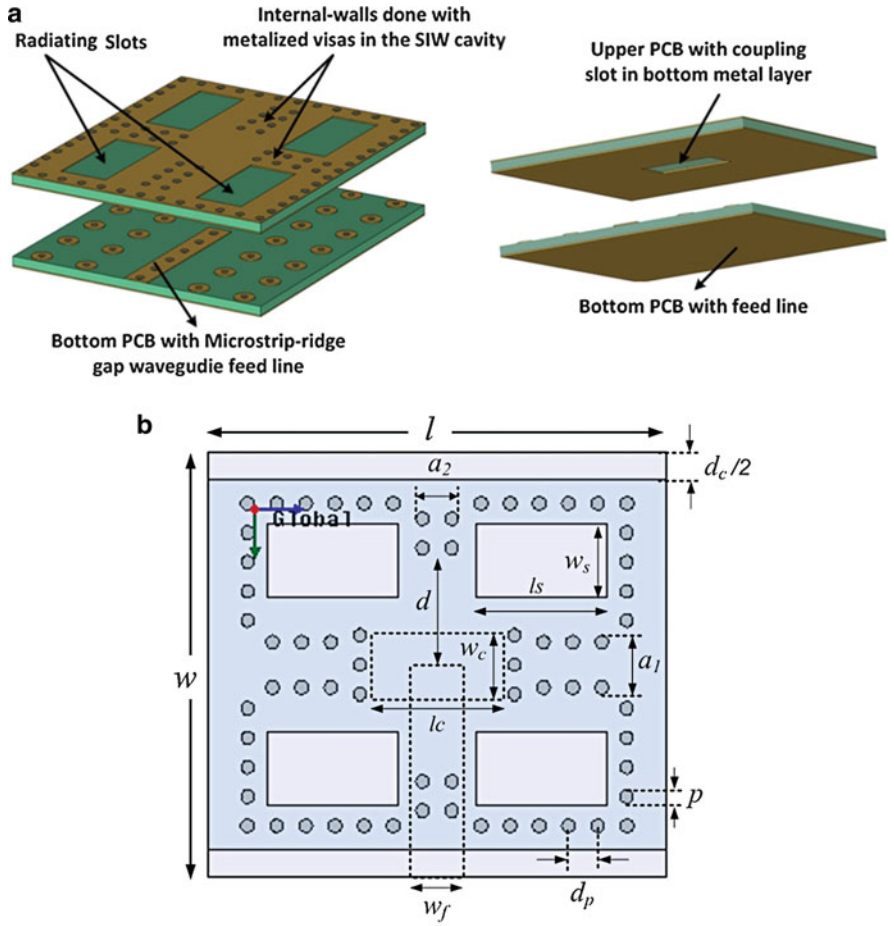

Fig. 35 (**a**) The 2 × 2 sub-array with SIW cavity layer and microstrip-ridge gap waveguide feed line. (**b**) Some parameters of the sub-array which needed to be optimized in an infinite array environment

Therefore, a good transition between microstrip line and gap waveguide is a key element for good integration of MMIC chips. Such a transition needs to be compact and should operate over as large bandwidth as possible. This can only be achieved by accurate impedance matching and mode transformation between these two different transmission lines. In this section, a standard microstrip line to ridge gap waveguide transition is mentioned.

The basics of this transition are based on the fact that the E-field of dominant mode in a microstrip line can be transformed easily to a standard ridge waveguide mode (Hui-Wen et al. 1994; Yunchi et al. 2010). In the case of ridge gap waveguide, it is even simpler as the dominant mode is also a quasi-TEM mode. This is shown in Fig. 37.

Due to such similar field distribution, only requirement for a good transition design lies on transforming E-fields in the dielectric to E-fields in the air. This can be done by tapering down the width of the ridge section in several steps (Zaman et al. 2013). In proposed design, the narrower ridge section is viewed as an extended section of the regular ridge section and is placed just above the microstrip line. The width of the ridge at this section is kept similar to that of the metal strip in microstrip line. In this approach, the tapered ridge section needs to be in electrical contact with the microstrip line and the substrate. This can be achieved by soldering, gluing, or simply pressing the ridge section down. Schematic of the designed transition between the microstrip line and ridge gap waveguide is shown in Fig. 38. A standard Chebyshev transformer based on several $\lambda_g/4$ sections of different widths can also be employed to improve the

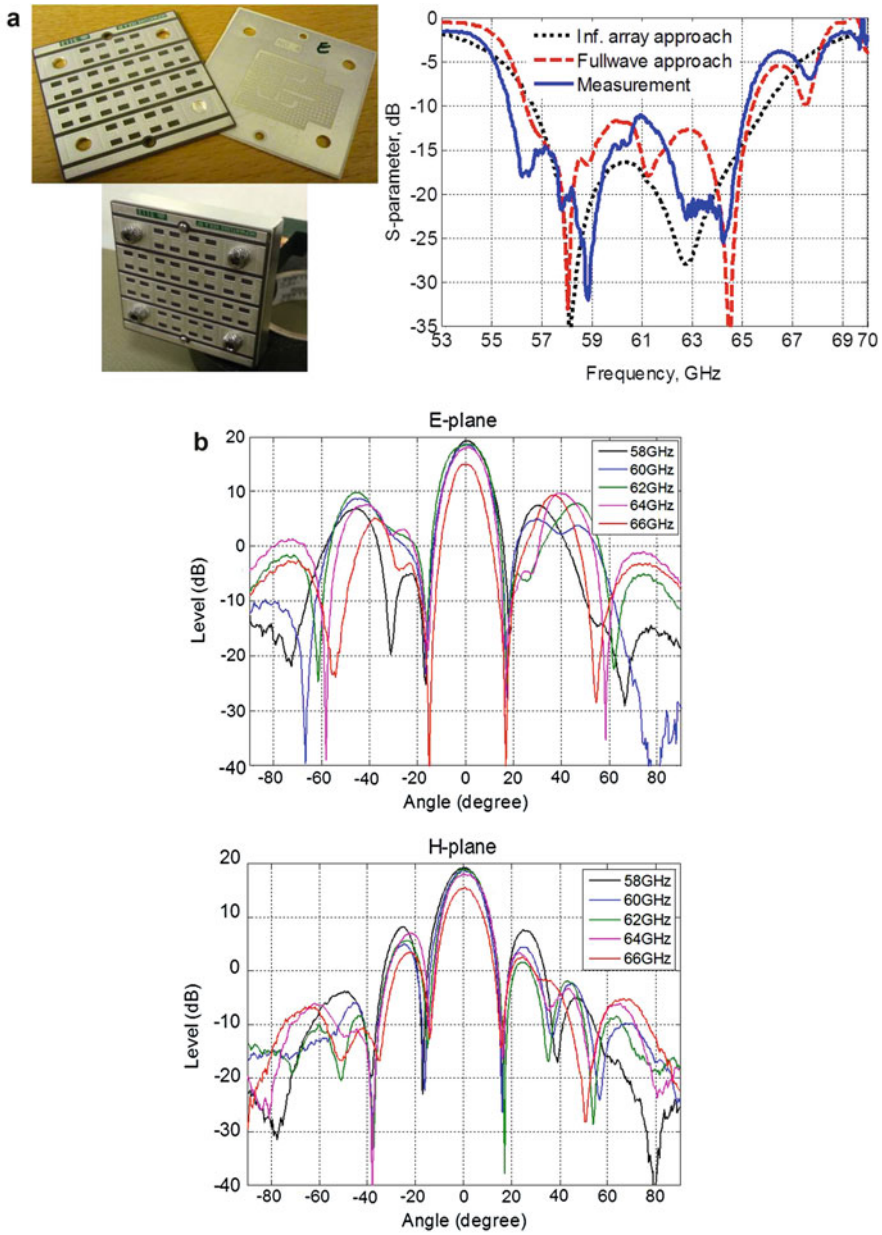

Fig. 36 (**a**) Manufactured prototype and the measured S_{11}. (**b**) Measured E-plane and H-plane radiation patterns over the band of interest

transition. But in this work, only one tapered section of the ridge has been used in a way to keep the overall transition compact. The manufactured transition and the measured results are shown in Fig. 39. The measured return loss is 14.15 dB for the 23–43-GHz band which means that a single transition will have even lower return loss over the entire Ka-band of interest. The maximum insertion loss over the same 23–43-GHz band is found to be 0.32 dB for the back-to-back transition including the losses of the ridge gap waveguide section meaning a loss smaller than 0.16 dB per single transition over the entire Ka-band (Zaman et al. 2013).

Apart from the transition mentioned above, another standard microstrip to ridge gap waveguide transition has been designed at W-band and presented in (Brazalez et al. 2012b). This transition is designed on the principle of electromagnetic coupling, meaning that there is no electrical contact

DOI 10.1007/978-981-4560-75-7_130-1

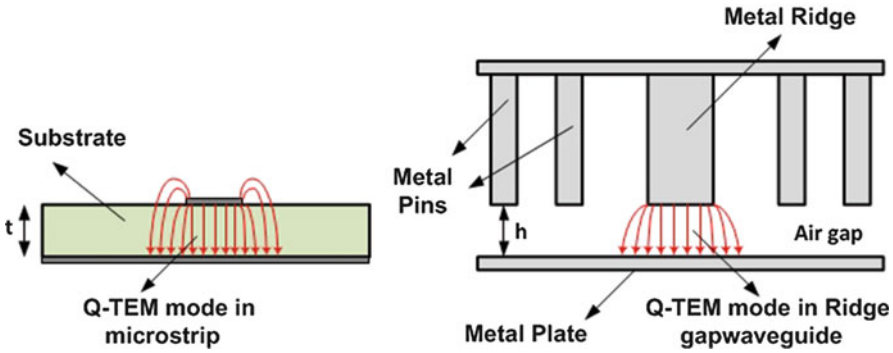

Fig. 37 E-field distributions of dominant mode of microstrip line and ridge gap waveguide

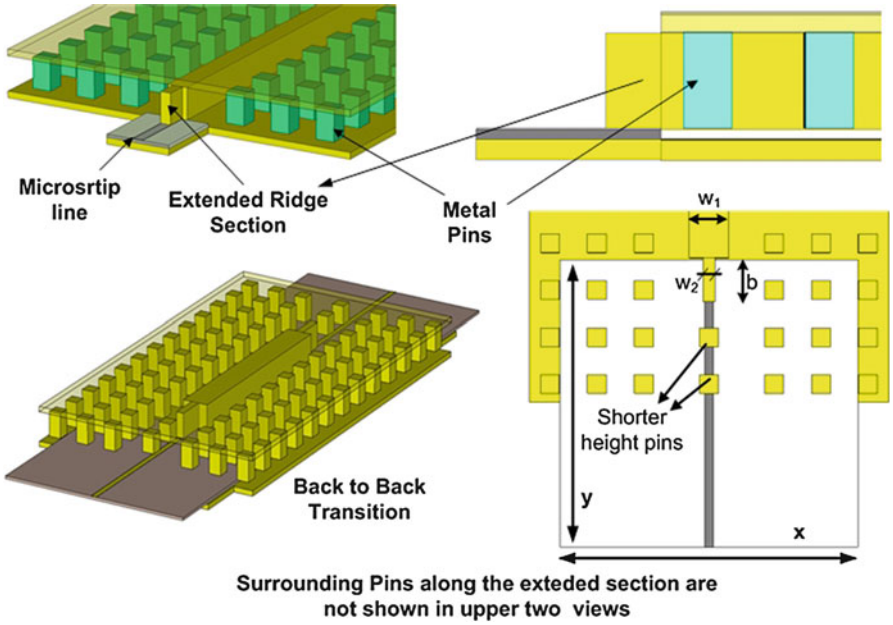

Fig. 38 Schematic details of the proposed transition, $W_1 = 2.65$ mm, $W_2 = 0.72$ mm, $x = y = 20$ mm, and $b = 2.75$ mm

whatsoever, between the typical microstrip line and ridge gap waveguide. The transition is based on overlapping λ/4 sections of transmission lines. There is a microstrip patch section and a ridge gap waveguide section which acts together as coupling sections. Strong coupling is achieved between the fringing EM field around the patch discontinuity and Q-TEM mode of ridge gap waveguide. The schematic of the transition is shown in Fig. 40a. The microstrip substrate is placed and stacked to the smooth metal plate of the ridge gap waveguide section. There exists an air gap of about 0.1 mm between the microstrip section and the ridge gap waveguide section. The ridge gap waveguide section which overlaps the microstrip patch has narrower width compared to the regular ridge section so as to improve the matching. The operating bandwidth of this proposed transition is about 25 %, which is smaller than that transition proposed earlier. But this transition has the advantage of having no direct contact between the microstrip section and the waveguide section. This can be a major advantage from mechanical point of view at W-band (∼100 GHz) or above. The critical dimensions for this transition are as follows: $h_1 = 0.2$ mm, $h_2 = 0.1$ mm, $W_1 = 0.35$ mm, $W_2 = 0.4$ mm, $W_{rid} = 0.55$ mm, $L_1 = 0.43$ mm, and $L_2 = 0.75$ mm. The simulated performance of this transition in back-to-back configuration is also presented in Fig. 40b.

DOI 10.1007/978-981-4560-75-7_130-1

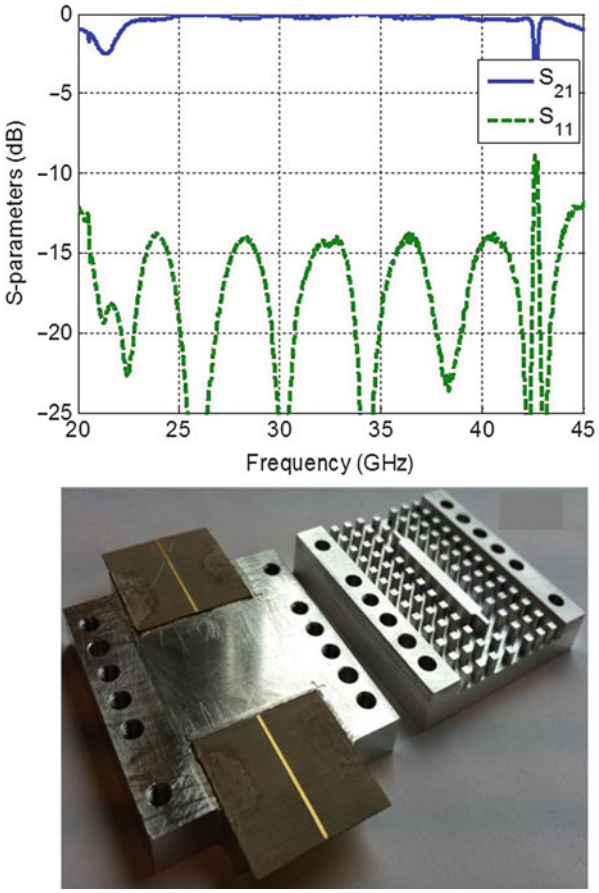

Fig. 39 Manufactured back-to-back transition and measured S-parameters for the transition

Rectangular to Ridge Gap Waveguide Transition

Two wideband transitions from ridge gap waveguide to rectangular waveguide have been designed recently. The first one is the inline transition where the height of the guiding ridge is reduced in several steps to match the height of the empty rectangular waveguide. In the second transition, the ridge gap waveguide is excited by a rectangular waveguide from the bottom. The first transition with stepped ridge sections is designed at Ka-band and is shown in Fig. 41 where the critical dimensions are as follows: $L_1 = 2.46$ mm, $L_2 = 2.27$ mm, $L_3 = 2.17$ mm, and $L_4 = 1.78$ mm and $S_1 = 0.22$ mm, $S_2 = 0.52$ mm, $S_3 = 0.76$ mm, $S_4 = 0.53$ mm, and $S_5 = 0.42$ mm. The starting point in designing this transition lies in the stepped design approach mentioned in Bornemann and Arndt (1987). After getting the initial design dimensions, the structure is numerically optimized to perform well over the entire Ka-band. The simulated performance of this back-to-back transition is also shown in Fig. 41.

The second transition is also a simple transition where the rectangular waveguide is feeding the ridge gap waveguide from the bottom. This type of transition is needed for measuring the ridge gap waveguide antenna where the feeding waveguide has to be placed below the antenna. The transition is designed at Ku-band and is shown in Fig. 42a, and all the critical dimensions for this transition are as follows: $P_L = 3.65$ mm, $P_w = 1.25$ mm, $P_s = 4.25$ mm, $R_w = 4$ mm, and $R = 2$ mm. The simulated performance of the single transition is shown in Fig. 42b. This transition has not been measured alone, but the same transition has been used in the ridge gap waveguide slot array work mentioned in Zaman and Kildal (2014).

DOI 10.1007/978-981-4560-75-7_130-1

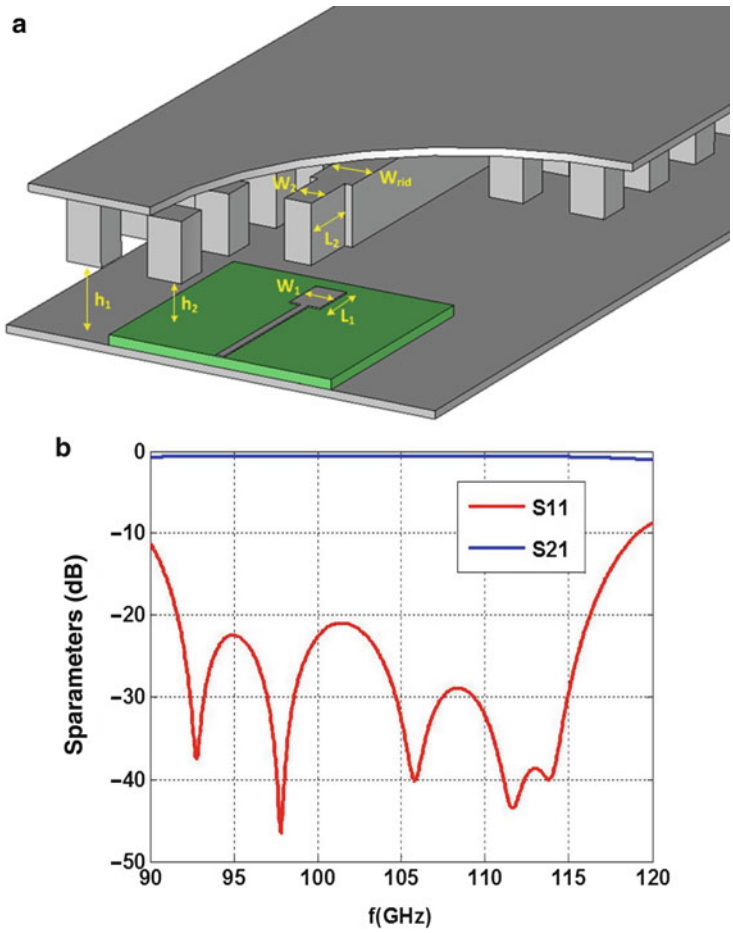

Fig. 40 (**a**) Schematic of the transition which does not need any electrical contact. (**b**) Simulated S-parameters of the transition which does not need any electrical contact

Coaxial to Ridge Gap Waveguide Transition

The first coaxial to ridge gap waveguide transition has been presented in Zaman et al. (2009). Conventional parallel-plate waveguides are easily excited by coaxial probes placed in the center of the broad face of rectangular waveguides with its inner conductor extending a distance into the guide (Williamson 1985; Heejin et al. 1998). In order to avoid the excitation in all directions, a short-circuiting wall or plunger is placed at a certain distance away from the probe. As the ridge gap waveguide is bit different from the conventional rectangular waveguides, the existing coaxial line to waveguide transitions needed to be modified or redesigned to make it appropriate for ridge gap waveguide. In this section, such a modified transition is presented, and the schematic of the transition is shown in Fig. 43a.

The transition is designed at Ku-band and it consists of a hole in the metal ridge having dimension of *de*. This allows the central conductor of the coaxial connector to launch EM field by electromagnetic coupling. Also, the transition has a back-short having a dimension of *b*. In this transition, the guiding metal ridge is short-circuited at both the ends. The critical dimensions for this transition are optimized by full-wave analysis, and these dimensions are as follows: $b = 5$ mm, $de = 3.4$ mm, $wd = 3.65$ mm, $s = 3.5$ mm, $p = 3.5$ mm, $h = 1$ mm, and $d = 5$ mm. The simulated performance for this transition in a back-to-back configuration is shown in Fig. 43b.

DOI 10.1007/978-981-4560-75-7_130-1

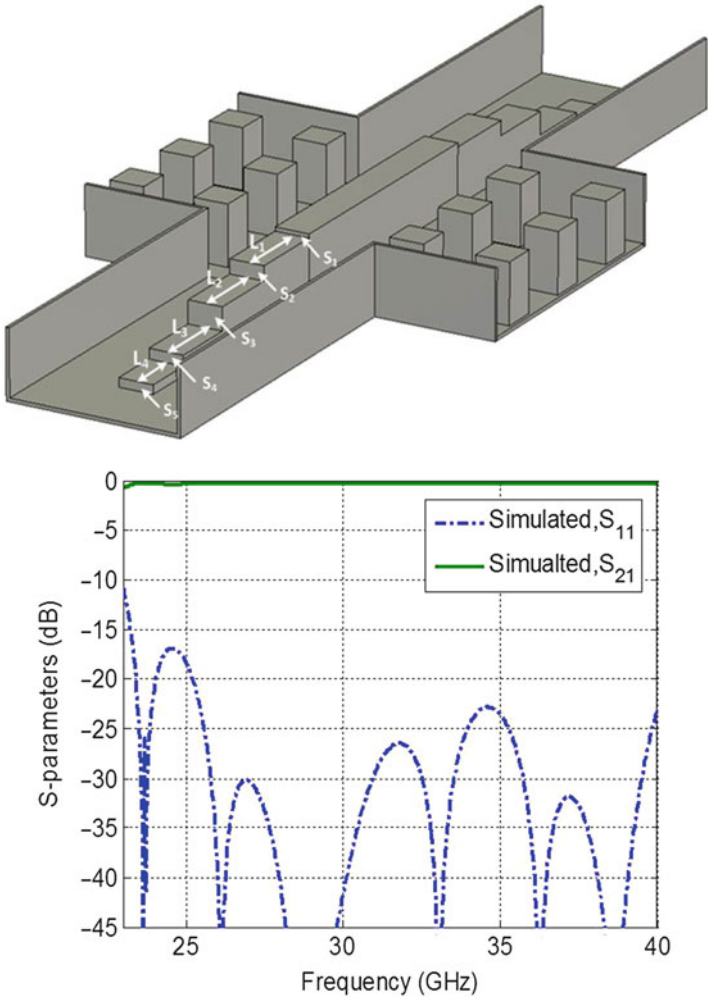

Fig. 41 Back-to-back transition with stepped ridge section (top metal plate not shown here) and the simulated S-parameters for this transition

Microstrip-Ridge Gap Waveguide to Rectangular Waveguide Transition

A simple microstrip-ridge gap waveguide to rectangular transition is described in this section. The vertical transition is designed bearing in mind that it would be used in a planar array having microstrip-ridge waveguide feed network mentioned in Razavi et al. (2014). In this transition, the rectangular waveguide is connected from the bottom to the microstrip-ridge gap waveguide. The schematic of the transition is shown in Fig. 44a. A λ/4 back-short is needed in most of the typical planar transmission line to rectangular waveguide transitions. But in the case of this transition design, there is not enough space for accommodating the required back-short, as this transition has been designed for a planar slot array. As a result, the transition operates over only 15 % relative bandwidth from 57 to 66 GHz. However, this 15 % bandwidth could be enough for many commercial applications as it covers the whole license-free band at 60 GHz. This transition has been manufactured and measured in a back-to-back configuration. Measured loss for a single transition is found to be 0.2 dB over the band of interest at 60 GHz. The detailed measurement results for this transition are presented in et al. (2014).

Gap Waveguide Narrowband High-Q Filters

High-Q filters are in demand in many wireless and satellite applications and are the most critical passive microwave components to be connected with the antenna feed systems. In a full-duplex communication, narrowband RF filters are required after high-power amplifiers (HPAs) and prior to low-noise amplifiers (LNAs). Usually, such full-duplex communication systems transmit and receive simultaneously. The transmitted power in the system is way too high in comparison to the received power. So, the transmitter filter must have very high attenuation in the receive band to stop the intermodulation noise and wideband thermal noise to be fed into the receiver. Also, the loss of the transmitter filter needs to be low due to the linearity and efficiency constraints of power amplifiers. In the receiver case, the noise figure of the receiver is dictated by the losses in the receiver filter as this filter sits before the LNA in the receiver chain. So, the receiver filter should also have a low insertion loss and very high selectivity in the transmit band. Thus, filters that are currently used in wireless applications have very stringent requirements in terms of return loss, insertion loss, and isolation. The current baseline design and manufacturing used today employ 3D structures such as coaxial, dielectric resonator or waveguide filters mainly to achieve high-Q value. Apart from the electrical performance requirement, the filters have to be mass producible and low cost. For this reason, H-plane iris-coupled filters and E-plane metal insert filters are extensively used today.

Both these types of filters have certain drawbacks at high frequency. In case of H-plane filters, filter assembly will exhibit a transitional resistance between the top metal plate and milled waveguide section.

DOI 10.1007/978-981-4560-75-7_130-1

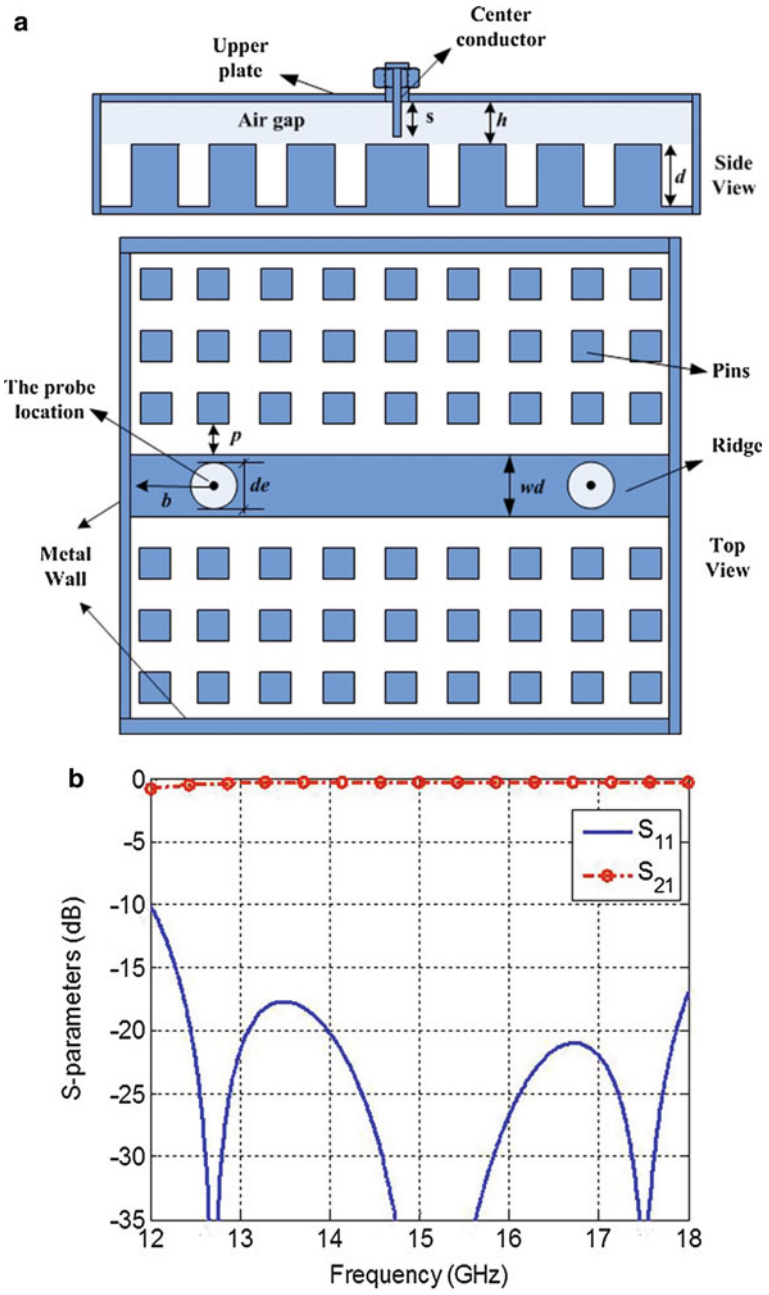

Fig. 43 (**a**) Schematic of ridge gap waveguide to coaxial line transition. (**b**) Simulated results for the back-to-back ridge gap waveguide to coaxial line transition

As this transition occurs at location of high current density, this will have to be taken care of by ensuring good electrical contact between the two parts; otherwise, significant amount of energy will leak through tiny gaps leading to Q value degradation of the resonators (Zaman et al. 2010b). Also, the milling process requires very small tool to manufacture rounded corners with smaller radius (Uher et al. 1993; Bornemann 2001). On the other hand, in case of E-plane filters, the electrical performance of filters is mainly determined by the pattern of the metal inserts. For example, the thickness of the metal insert needs to be thin enough (30–80 μm) for a moderate filter requirement at 38 GHz. The thickness of the metal insert will have to be even thinner at mmWave frequency range to comply with the filter requirements

DOI 10.1007/978-981-4560-75-7_130-1

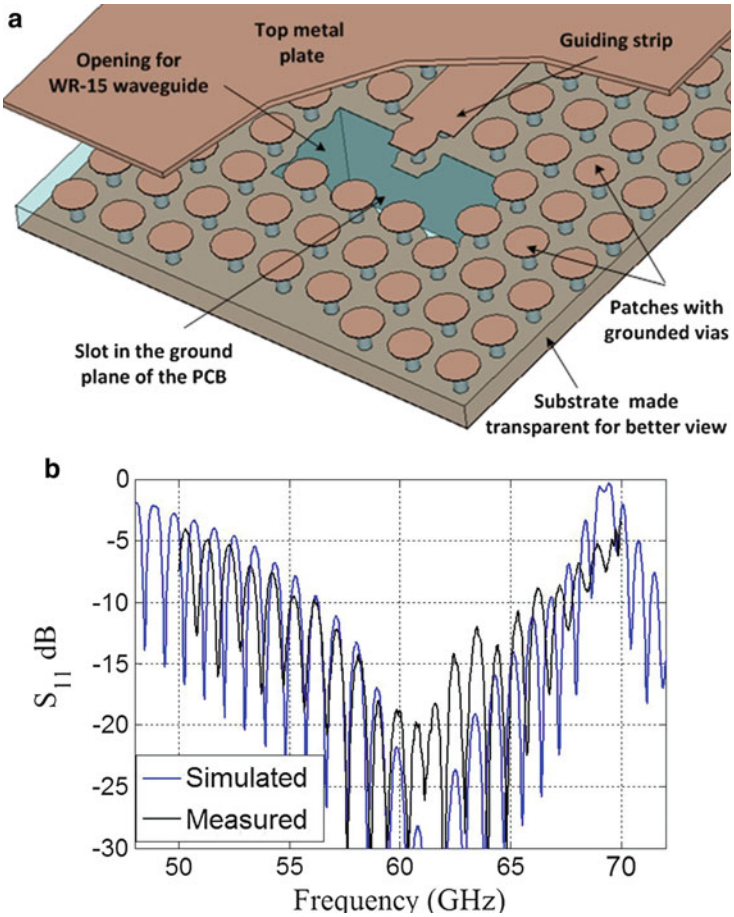

Fig. 44 (**a**) Schematic of microstrip-ridge gap waveguide to rectangular waveguide transition. (**b**) S-parameters for the microstrip-ridge gap waveguide to rectangular waveguide transition

(Ofli et al. 2005). Also, these metal waveguide types of filters are difficult to integrate in a single module with other passive components such as coupler or antennas and active RF components.

In this concern, there is a need for developing new types of high-Q filters which are more robust in terms of mechanical assembly and can be integrated with other modules of passive components such as antennas. The very low-loss groove gap waveguide-based high-Q filters can be of interest in this case. These high-Q filters can be built in an open parallel-plate structure surrounded by periodic metal pins without any side walls. The electrical contact between the parallel plates will not play a major role in the filter performance as the field leakage will be negligible after two or three rows of pins. Also, measured Q values for such groove gap resonator are similar to that of a rectangular waveguide (Pucci et al. 2013; see also Operating Principle of Gap Waveguides and Loss Analysis).

High-Q Groove Gap Waveguide Resonator and Narrowband Filters

The gap waveguide resonator is a resonator that has very controlled leakage of EM energy through the gap between two metal blocks or plates. This type of resonator basically allows a leakage up to a certain level and traps the rest of the EM energy within the structure. It has been mentioned previously in section "Operating Principle of Gap Waveguides and Loss Analysis" that, after two consecutive rows of pins, the field leakage goes down up to a level of −40 to −45 dB over significant bandwidth. This motivates the design of the high-Q resonator-based filters using two metal plates with much more manufacturing flexibility. There is no need for metal walls on each side of the resonator. Also, the electrical contact

DOI 10.1007/978-981-4560-75-7_130-1

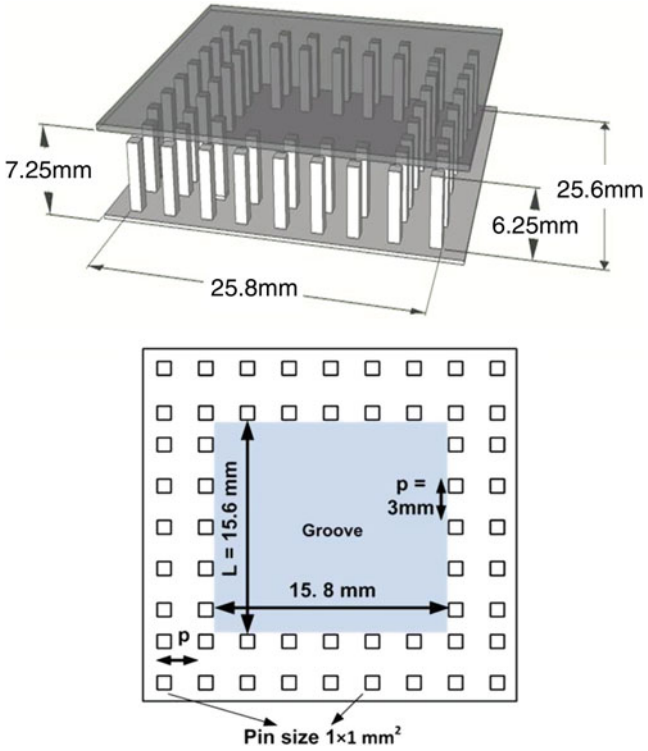

Fig. 45 Geometry of the groove gap resonator at Ku-band, perspective view and top view

between the top and bottom metal plate does not play a significant role in trapping the EM energy. This section describes a description of a groove gap resonator and several narrowband filter designs based on groove gap waveguide. Figure 45 shows the half-wavelength short-circuit groove gap waveguide resonator at Ku-band. The resonator also has only some texture of pins forming a groove in the lower metal plate. The pins are about λ/4 in height. The upper metal plate is a smooth plate and placed at a distance of 1 mm from the pin surface. It was chosen to have two rows of pins on each side of the resonator to make the field decay up to a level of about −45 dB.

The simulated Q value for this type of resonator with conductivity of aluminum is about 4605 which is 13 % lower than the simulated rectangular waveguide resonator at that frequency. Q factor of a practically realized groove gap resonator and a rectangular waveguide resonator is compared more in detail in Pucci et al. (2013). The field distribution inside the groove gap resonator is shown in Fig. 46.

Two coupling mechanisms are studied to achieve the required coupling between two adjacent groove gap waveguide resonators. These are shown in Fig. 47. In the case of ridge coupling, the width, length, and height of the ridge section can be varied to achieve coupling coefficient values varying over large range. For the other case, only the periodicity of the pin rows and distance between the pin rows separating the two resonators are varied. Very low values of coupling coefficients are possible to obtain which is required for very narrowband filters.

Based on these two coupling mechanisms, third-order and fifth-order Chebyshev band-pass filters have been designed at Ku-band. The excitation of the input and output resonators of the filters has been achieved by typical coaxial line using SMA connectors for simplicity of measurements with the help of available vector network analyzer at Ku-band. Simulated results for two third-order filters having 1 % relative bandwidth and passband ripple of 0.032 dB and 0.1 dB are shown in Fig. 48a. Out of these two filters, the filter with 0.1 dB passband ripple has been manufactured and tested. The measured results are presented in Fig. 48b. The details of this filter design can be found in Zaman et al. (2012b). As shown in

DOI 10.1007/978-981-4560-75-7_130-1

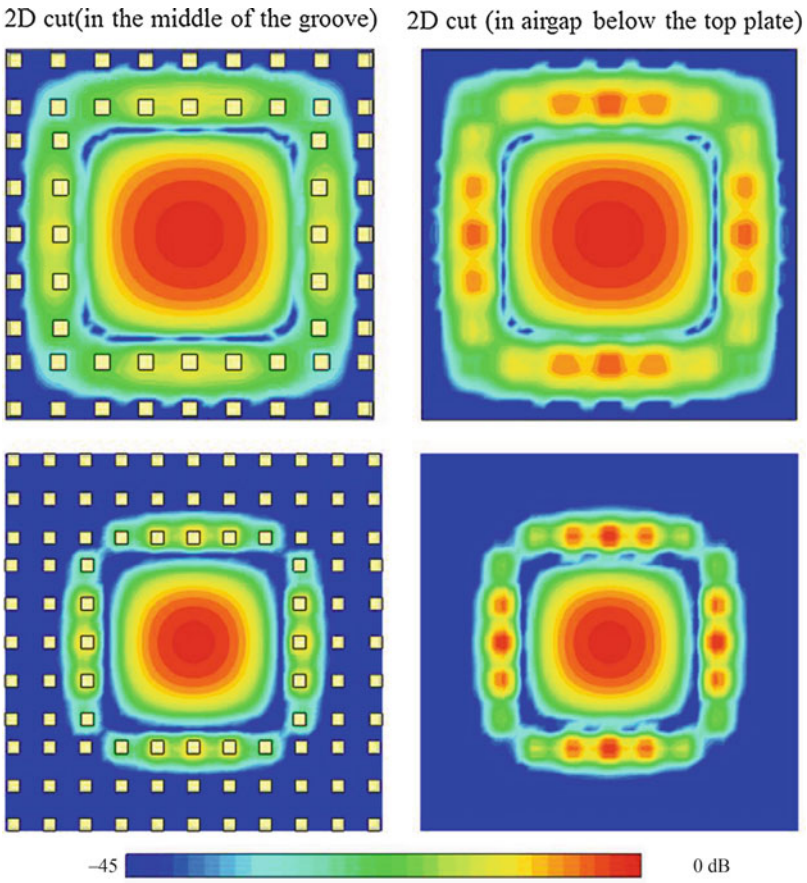

Fig. 46 Vertical E-field distribution for groove gap waveguide resonator

Fig. 48b, the filter response for the third-order filter agrees well with the measurement results. In this case, the measured mid-band insertion loss is about 0.31 dB more than the simulated cases. This extra loss is mainly attributed to the losses in SMA connectors and the degradation of the conductivity of aluminum due to surface roughness.

Ka-Band Filter Design for Commercial Diplexer Application and V-Band Filter Design

Usually, diplexer filters require very low insertion loss in the passband and high selectivity to reject frequencies close to passband. The purpose of this section is to demonstrate the potential of gap waveguide technology to design filters with very stringent commercial specifications. The key filter specifications for commercial 38-GHz diplexers are shown in Table 3.

The general band-pass filter design procedure utilizes the low-pass elements of the prototype filter to determine the required coupling coefficients between the adjacent resonators and the coupling to the external circuit, that is, to the source and load. For a filter with $N = 7$, the low-pass parameters are obtained from Swanson (2007). Once the low-pass parameters are known, the coupling coefficients (K) and external quality factor (Q_{ex}) are easily calculated by using the following equations:

$$K_{i,i+1} = \frac{\text{fractional bandwidth}}{\sqrt{g_i g_{i+1}}}; \qquad Q_{ex} = \frac{g_n g_{n+1}}{\text{fractional bandwidth}}$$

DOI 10.1007/978-981-4560-75-7_130-1

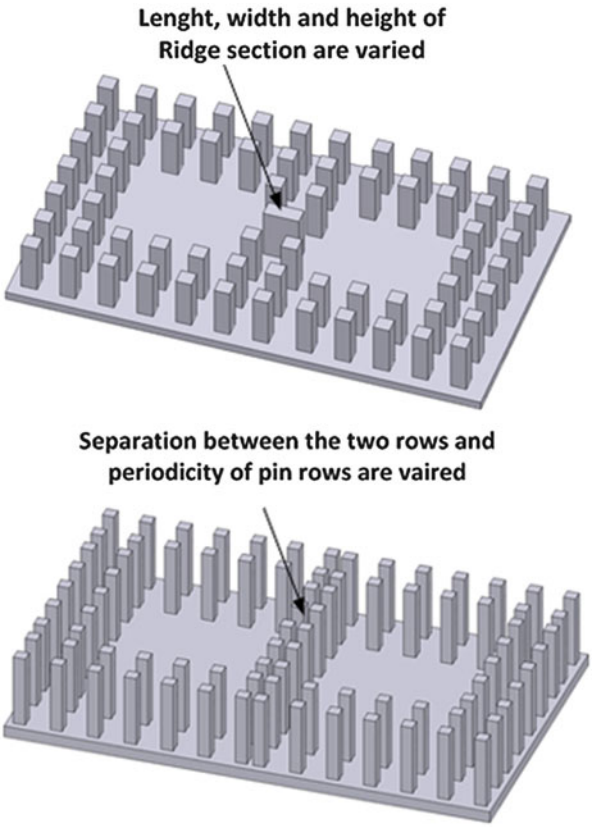

Fig. 47 Two types of coupling mechanism for groove gap waveguide resonators

To design the filter, the ridge coupling scheme presented previously has been chosen. The resonators are designed with pin dimension $0.7 \times 0.7 \times 2.3$ mm^3. The periodicity of the pins has been chosen as 2.1 mm. The manufactured seventh-order filter and the measured response of the filter are shown in Fig. 49. Details of this filter are presented in Alos et al. (2013). Two prototypes have been manufactured: one with aluminum without silver plating and the other one with silver plating. Both the prototypes have S_{11} better than -17 dB. The prototype without silver plating has more insertion loss as expected, and S_{21} has been found to be -1.5 dB. The other prototype with silver plating has an insertion loss of 1.0 dB. Both the filters needed the tuning screws to rectify the frequency shift induced due to mechanical tolerance errors. The performance of this groove gap filter has been compared with a commercially available rectangular filter working at 38 GHz. After comparison, the performance of the groove gap waveguide is found to be very similar to that of rectangular waveguide filter.

The next filter is a V-band filter designed in groove gap waveguide. The designed filter is a Chebyshev band-pass filter centered at 61 GHz, with a fractional bandwidth of 2.5 % (1.525 GHz), having a maximum ripple of 0.01 dB inside the passband. The filter is a fifth-order filter, and the implementation is carried out through cavity resonators coupled through inductive windows. The filters are fed by two 1.85 mm coaxial connectors. The picture of the manufactured filter and the measured performance is shown in Fig. 50. The details of the filter are found in Berenguer et al. (2014).

Table 3 Specification for the 38-GHz diplexer filter

Passband	37.058–37.618 GHz
Stopband	38.318–38.878 GHz
Passband insertion loss	Max. 1.5 dB
Attenuation in the stopband	70 dB
Return loss	−16 dB

Gap Waveguide Packaging Solution for Microwave Modules

Most of mmWave microwave systems have to operate at outdoor, under harsh weather conditions, and therefore have to be shielded, i.e., *packaged* in a proper way to provide protection against mechanical stress and environmental conditions. Also, to comply with the smaller size and form factor requirements for mmWave microwave modules, large amount of electronic components are to be placed into a confined area. For such high-density microwave modules operating at mmWave frequency range, RF packaging is more and more essential in terms of isolation and interference suppression.

In a common microwave module, circuit components such as MMICs are placed on a carrier dielectric substrate which can carry the necessary interconnect lines, the passive components, etc. Enclosing the complete circuitry in a metal package usually degrades the RF circuit performance because of the onset of package resonances and more, in general, due to the interactions of electromagnetic fields (produced by the signal propagating in the electronic circuitry) with the package itself. Published studies in Tsuji et al. (1995) and Mesa et al. (2000) show that substantial power leakage and power loss exist on various printed circuit transmission lines, often related to surface waves in the dielectric substrate causing serious

DOI 10.1007/978-981-4560-75-7_130-1

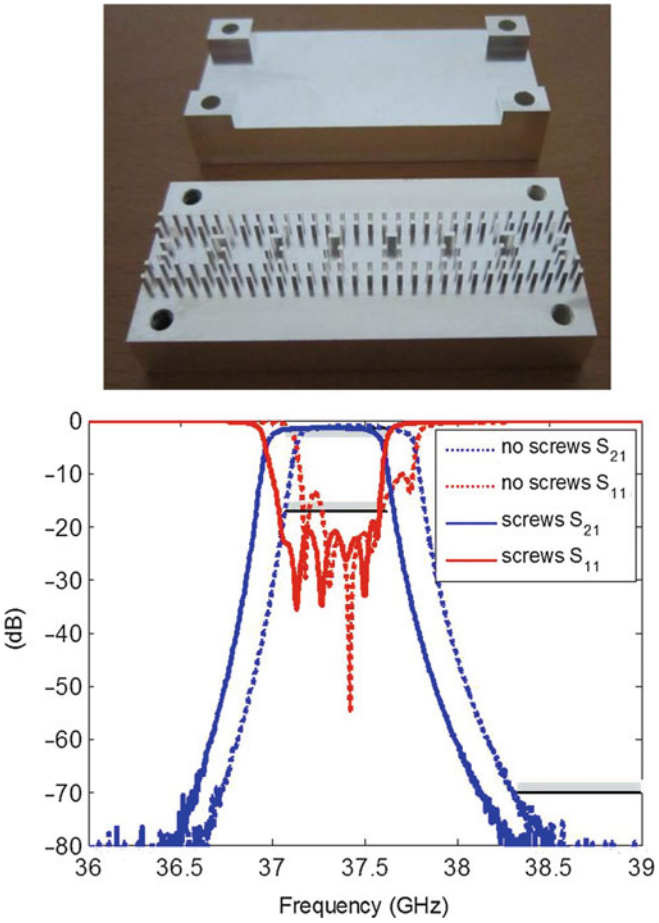

Fig. 49 Manufactured Ka-band seventh-order filter and measured results for the same filter

cross-talk and interference problems. Apart from this problem of surface wave or parallel-plate (Six et al. 2005) mode leakage and radiation, at mmWave frequencies, interconnects and transitions between different components or even the interconnecting signal lines may produce unwanted radiation or standing waves. This can easily get coupled (over the air) to the adjacent circuit elements resulting in interference and cross talk. Figure 51 displays some of the possible ways of electromagnetic field coupling and unwanted energy leakage between the adjacent circuit elements and also shows the conventional prevention techniques mentioned in Williams (1989), Izzat et al. (1996), and Dixon (2005). In practice, the efficiency of the different techniques available for reducing packaging problems and reduction of cross talk goes down with frequency; the higher is the frequency, the lower is usually the effectiveness of the techniques mentioned so far. So, there is a need for new packaging technology to be used at high frequency, and gap waveguide-based PMC packaging can be a real good solution to overcome the packaging-related problems.

Gap Waveguide Packaging Concept for Microwave Modules

The gap waveguide packaging solution is an extension of the basic gap waveguide geometry and is based on the concept shown in Fig. 52. Here, the parallel-plate cutoff is achieved by a PMC/AMC surface when the opposite surface is a perfect electric conductor (PEC) and as long as the spacing between these two surfaces is smaller than quarter wavelength. Once a substrate and the microstrip line are placed, the ground plane of the microstrip substrate acts as PEC surface, and the top lid with periodic texture surface acts as an AMC surface. In this case, the dominant microstrip mode can propagate along the strip, and field

DOI 10.1007/978-981-4560-75-7_130-1

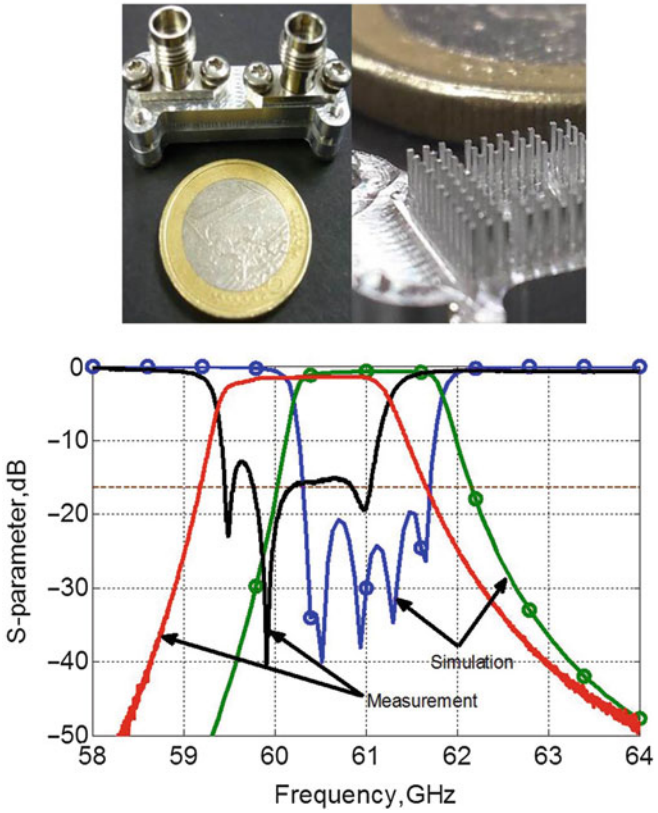

Fig. 50 Manufactured V-band fifth-order filter and measured results for the same filter

propagation in all other direction is stopped by the PEC-PMC parallel-plate cutoff condition. Thus, all the unwanted leakage or radiation via unwanted modes is suppressed within the frequency band when the PEC-PMC cutoff condition is enforced. The newly proposed packaging technique is easily scalable to high frequency and shows consistent performance over different microwave frequency bands extending from X-band up to the W-band (Zaman et al. 2012a; Rebollo et al. 2014).

Apart from the improvements in electrical performance, this new packaging technique offers an advantage while doing circuit design using full-wave simulations based on FTTD or FEM. With this new technique, the designer can reduce the computational domain by using an ideal PMC surface instead of using several matching layers above the circuit of interest at specific height. This saves computer time and requires no big modification afterward (when the circuits are practically realized) as the packaging effects are already considered during the full-wave design (Kishk et al. 2012). The application for gap waveguide packaging was first demonstrated successfully for a passive microstrip line in Rajo-Iglesias et al. (2013). Later, it was applied to a multi-port antenna feed network to improve the performance of well-known coupled line microstrip filter (Zaman et al. 2010a; Brazalez et al. 2012a). In all these cases, it was observed that unwanted cavity modes and surface waves were efficiently suppressed within the band of interest. In the abovementioned references, periodic pin structures have been used to realize the AMC. But recently, several other periodic structures such as periodic metal springs and periodic zigzag lines printed on a substrate have been used to obtain the AMC condition for such kind of work (Rajo-Iglesias et al. 2012, 2013). Some important features of gap waveguide packaging technique are listed below:

- As the energy coupling between the dominant microstrip mode and other leaky modes is reduced or suppressed, the overall insertion loss performance of the complete microwave circuit is also improved.

DOI 10.1007/978-981-4560-75-7_130-1

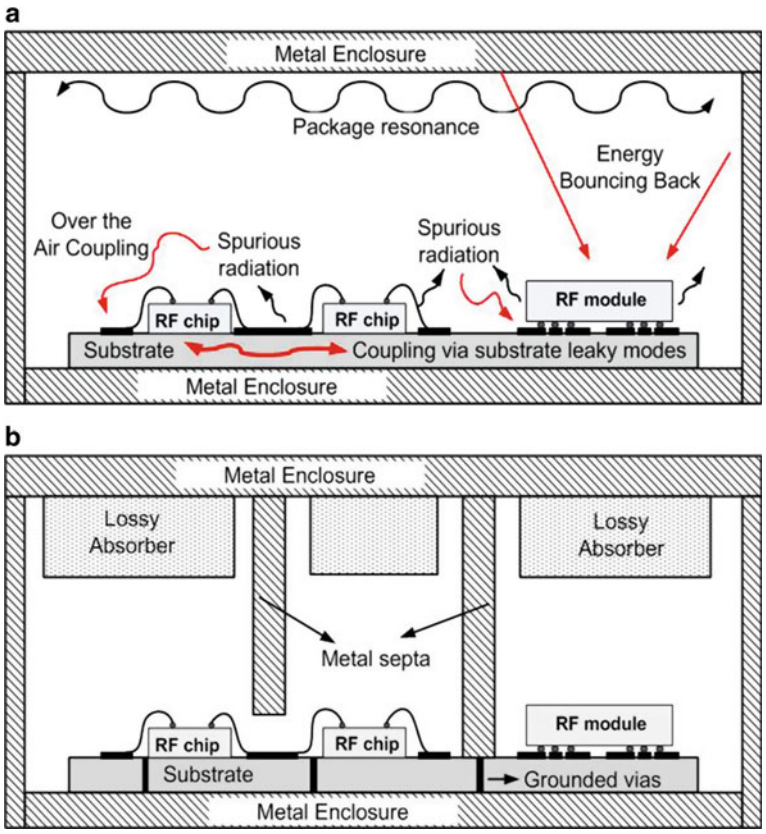

Fig. 51 (**a**) Various undesired coupling phenomena; (**b**) traditional prevention techniques

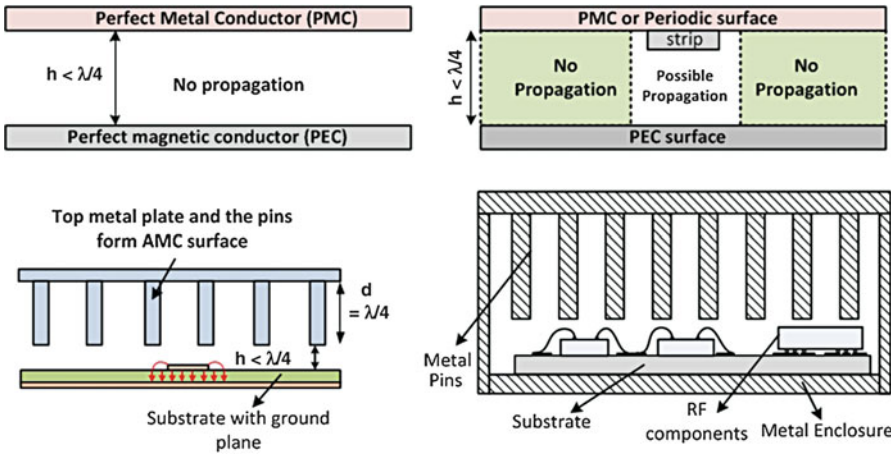

Fig. 52 Gap waveguide packaging concept

- There is no need for time-consuming postproduction trial and error process involving placement of lossy absorbing material within the package after the design has been completed.
- Isolation performance in this packaging technology is not dependent on very good metal contact between the circuit board and the metal enclosure, so to say; there is no need for proper grounding and use of conductive adhesive or gasket material for multi-compartment microwave modules.

Gap Waveguide Packaging for Ka-Band Active Amplifier Chains

Instability in an amplifier chain is mainly the result of unwanted feedback across the amplifier, and such feedback is normally induced by phenomena related to shielding imperfections such as leakage, spurious radiation, etc. This section explains how the newly proposed gap waveguide packaging technique has been applied on a Ka-band high-gain amplifier chain having four cascaded units. At first, one amplifier chain has been characterized by using gap waveguide packaging as well as the conventional absorber-based metal wall packaging solution. After that, isolation test has been performed for two active high-gain

DOI 10.1007/978-981-4560-75-7_130-1

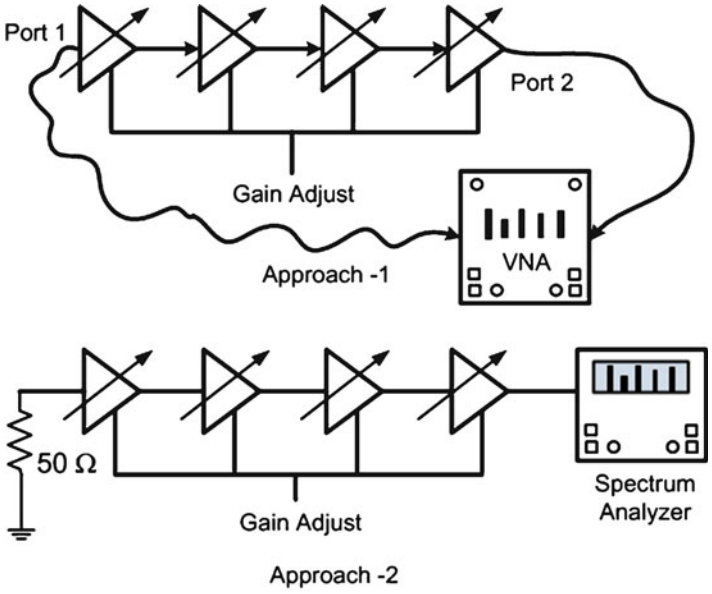

Fig. 54 Test setups for single chain isolation performance test

amplifier chains running in opposite directions so as to emulate the transmit/receive scenario in a real microwave module. Both the test cases are shown in Fig. 53.

Case A: Single Amplifier Chain Isolation

Two experimental approaches have been followed to test the isolation performance of the single chain amplifier: stable gain test and self-oscillation test, both being shown in Fig. 54. In the first approach, the amplifier chain under test is simply connected with Anritsu 36397C VNA, and a universal test fixture (UTF) from Rosenberger is used for launching the signal for S-parameter measurements. The gain in the amplifier chains has been increased by varying the control voltage until there has been an oscillation tendency. The second approach is a self-oscillation test where the input port of the first-stage amplifier is connected with a 50-Ω resistor (and no signal source) and the output of the final-stage amplifier is connected to a spectrum analyzer. Here also, the gain of the amplifier chain has been increased until resonance peaks are observed. The details of these experiments and obtained measurement results are presented in Zaman et al. (2014). In this section, only the results from the second approach have been presented in Fig. 55. From the single chain self-oscillation measurement results, it becomes obvious that no oscillation peaks appear for gap waveguide packaging case (pin lid packaging) even after 65 $\sim$ 70-dB total gain in the amplifier chain. On the other hand, for traditional metal wall packaging with absorbing materials, resonance peaks are observed after 35 $\sim$ 40 dB of total forward gain.

Case B: Side-by-Side Amplifier Chain Isolation

All full-duplex systems which activate both the transmitter and the receiver simultaneously require an excellent isolation between receive and transmit paths for preventing the transmit signal to cause saturation and intermodulation distortion in the sensitive receiver part. Particularly, the coupling between the final-stage transmit amplifier and the first-stage LNA of the receiver chain is of great importance due to the high difference of transmit and receive signal levels. In this work, such two amplifier chains have been placed side by side (to emulate the transmit and receive scenario), and sidewise isolation performance has been measured in the presence of gap waveguide shielding and conventional metal wall shielding. The measured results are presented in Fig. 56.

DOI 10.1007/978-981-4560-75-7_130-1

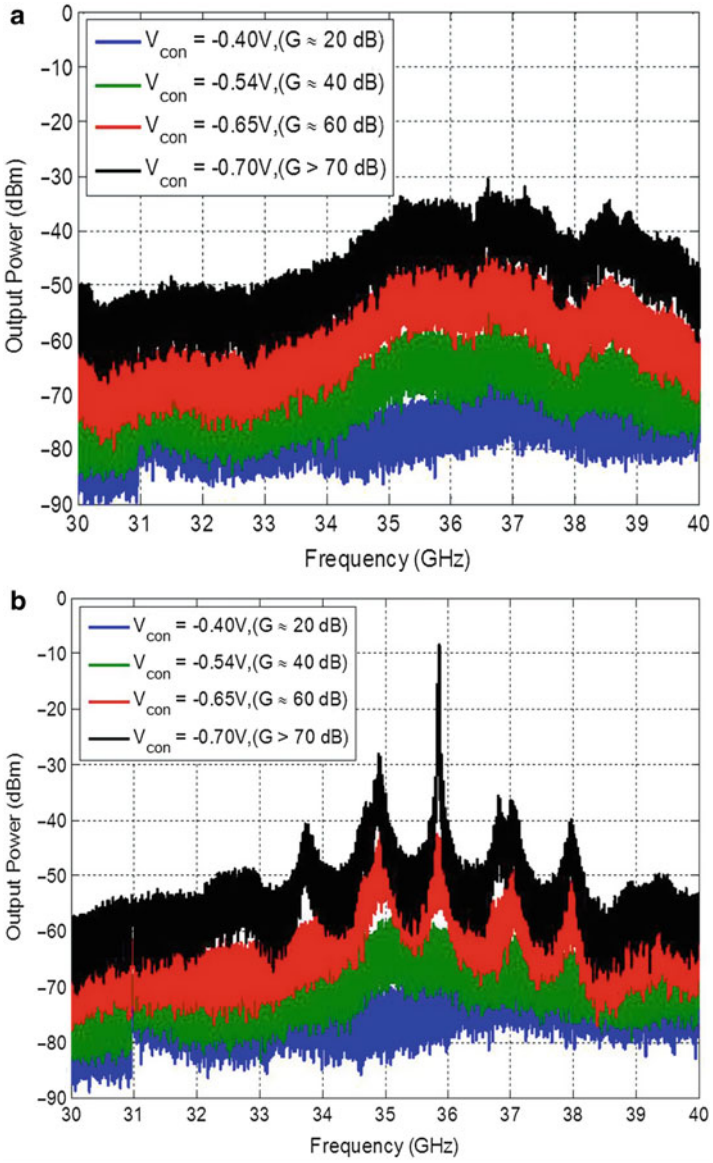

Fig. 55 (**a**) Self-oscillation analysis for single amplifier chain packaged with pin lid, (**b**) self-oscillation analysis for single amplifier chain packaged with conventional metal lid

For the test case of two amplifier chains placed side by side, the measurement results showed that an isolation around 70 dB in average was achieved for a six-row gap waveguide pin lid with isolation value ranging from 64 to 91 dB. Similar isolation trend was observed also for complete metal wall shielding case. For the case of gap waveguide lid having eight rows of pins, better isolation has been observed. The manufactured prototypes are shown in Fig. 57.

Conclusion

Wireless experts have devised all sorts of clever fixes to expand the capacity of today's LTE cellular network (4G) by means of multiple antennas, robust interference mitigation, smaller cells, and smarter

DOI 10.1007/978-981-4560-75-7_130-1

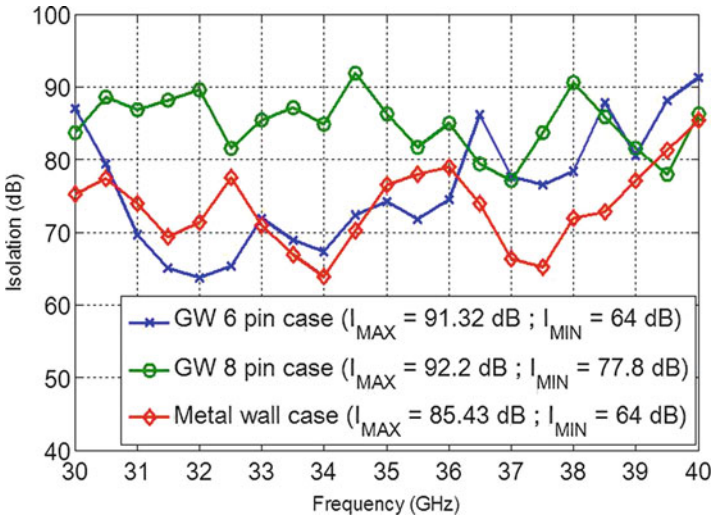

Fig. 56 Isolation between two closely spaced amplifier chains

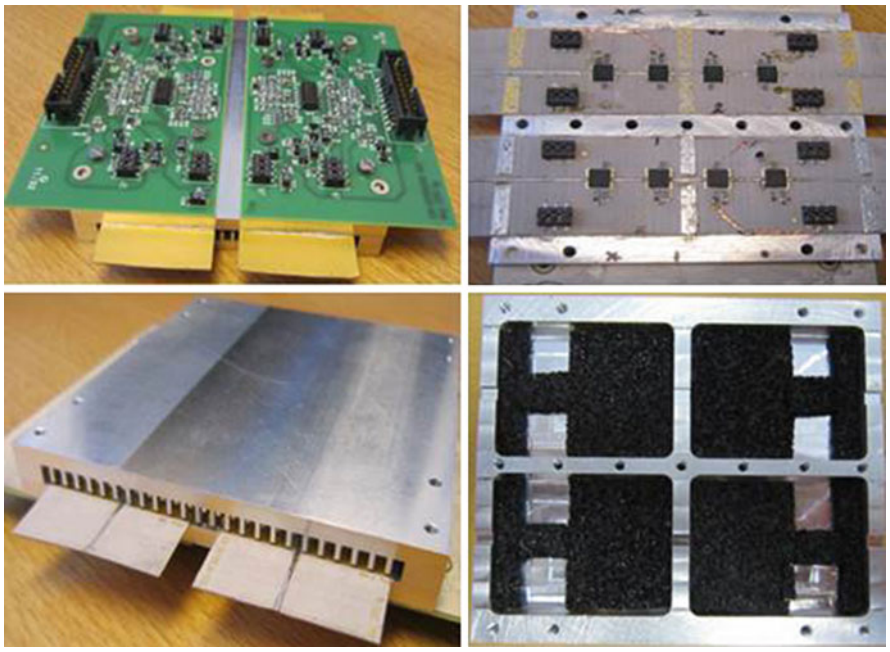

Fig. 57 Manufactured prototypes for testing the isolation in a single amplifier chain and two closely spaced amplifier chains

coordination between devices. But none of these solutions will sustain the oncoming traffic flow which is expected to boom within 4 to 6 years. Industry experts agree that the fifth-generation (5G) cellular technology will arrive by the end of this decade. The telecom operators will undoubtedly need new spectrum and will have to use millimeter-wave frequency band. Thus, the researchers are exploring more and more new concepts such as millimeter-wave massive MIMO where the base stations with very large number of antennas are envisioned to serve a set of relatively simpler co-channel user terminals. Digital beam forming combined with MIMO techniques is also considered to be more lucrative than conventional analog millimeter-wave phased arrays. These new systems will benefit from new waveguide and

electromagnetic (EM) packaging technologies, in order to ensure good performance with low power consumption, i.e., sustainability.

Impedance Matching and BALUNs

Homayoon Oraizi*
College of Electrical Engineering, Iran University of Science and Technology, Tehran, Tehran, Iran

Abstract

In this chapter, the subject matters of impedance transformation and BALUNs are studied, which should be designed for inclusion in the input ports of transmitter and receiver antennas. The Smith chart is commonly used for the design of lumped and distributed circuits for impedance matching in the technical journals and textbooks. Its explanations and usage are readily accessible in the available textbooks. However, the method of least squares is developed here for the design and optimization of various circuits of impedance transformers for microwave and higher-frequency circuits.

The topics discussed here include the following:

The concept of impedance, transmission lines, power gains, varieties of matching networks, impedance transformer design by the method of least squares, the quarter-wave line, theory of small reflections, multi-section transformers, design of step-line transformers, design of taper lines, devices and components for impedance matching, and BALUNs including waveguide and planar circuit implementations.

Keywords

Matched load; Matched source; Maximum load power; Power gains; Impedance transformer; Impedance matching; Method of least squares; Quarter-wave line; Small reflections; Multi-section transformers; Step-line transformers; Taper lines; BALUNs

Introduction

Impedance matching networks are placed at the source and load sides of a network to achieve various system requirements, such as maximum power transfer, maximization of power handling capacity, minimum reflection or reflectionless operation, minimization of noise interference, minimization of power loss, linearization of frequency response, and most importantly matching and transformation of impedance levels. Discrete and lumped components may be used at frequencies lower than 1 GHz, but distributed circuits and transmission lines should be used at microwave frequencies higher than 1 GHz. Analytical methods and graphical procedures such as the Smith chart may be used for the design of impedance transformation networks, which may both be implemented by computer programs. Solutions by analytical equations are quite precise, whereas solution by graphical procedure may give better insight into the physical behavior of circuits. Mixed matching networks combining lumped elements and distributed circuits may also be designed for impedance transformations.

There are different engineering factors to be considered for the selection of a matching circuit, such as DC biasing, stability, frequency response, quality factor, and also availability of discrete components with required values and substrates with suitable dielectric constants. The design of matching circuits for

*Email: h_oraizi@iust.ac.ir

DOI 10.1007/978-981-4560-75-7_133-1

oscillators and amplifiers requires high- and low-quality factors, respectively. L circuits cannot provide high Q; rather higher-order circuits are needed, which have more elements, such as T and π-networks.

The radiation resistance, antenna radiation efficiency, radiation pattern, and gain of an antenna are not affected by its impedance mismatch. Matching serves to transfer the available power from the transmission line into the antenna, reduces transmission loss, and minimizes standing voltage on the line.

What Is the Concept of Impedance, Resistance, and Reactance?

Impedance as an engineering concept was originally defined as resistance for direct current (DC) electric circuits, but it was then extended and generalized to other electromagnetic phenomena and other engineering problems (Valkenburg 1991). In a similar manner, current has also been generalized from the original motion of charged particles to include conduction $\left(\tilde{J} = \sigma\tilde{E}\right)$, convection $\left(\tilde{J} = \rho\tilde{v}, \tilde{J} = k\tilde{v}, I = \lambda\tilde{v}\right)$, electric displacement $\left(\tilde{J}_D = \frac{\partial\tilde{D}}{\partial t}\right)$, magnetic displacement $\left(\tilde{M}_D = \frac{\partial\tilde{B}}{\partial t}\right)$, electric current sources (J^i, J_s^i, I^i), and magnetic voltage sources (M^i, M_s^i, K^i). Ohm's law, considered here as a constitutive relation for conductive media, is expressed as

$$\tilde{J} = \sigma\tilde{E} \tag{1}$$

where $\tilde{J}$ is the electric volume current density (amperes/meter^2), σ is the conductivity of the medium (Simens/meter), and $\tilde{E}$ is the electric field intensity (volts/meter). For linear, homogeneous, and isotropic matter (simple matter), σ is not a function of E and coordinate axes and has identical behavior in all directions.

Consider now a cylindrical object made of linear, homogeneous, and isotropic conductive matter (with conductivity σ) having a uniform cross section (S) and length (ℓ). The voltage drop across its length is

$$v = \int_c \vec{E} \cdot \vec{d\ell} = E\ell = \frac{J\ell}{\sigma} \tag{2}$$

The current through it along its axis is

$$i = \int_S \vec{J} \cdot \hat{n} ds = JS \tag{3}$$

Then, Ohm's law as the relation between v and i is expressed as

$$v = \left(\frac{\ell}{\sigma S}\right) i = Ri \tag{4}$$

where the resistance of the conductive cylinder is

$$R = \frac{\ell}{\sigma S} \tag{5}$$

Equation (4) is the governing relation for resistors. The resistance (R) is defined as the impediment of resistor toward the motion of charged particles (here, free electrons in the metal) due to the voltage

DOI 10.1007/978-981-4560-75-7_133-1

difference across the resistor. The voltage difference is actually defined as the difference of potential energy per unit charge:

$$\Delta v = \frac{\Delta W}{q} = \frac{\vec{F} \cdot \vec{\Delta \ell}}{q} = \vec{E} \cdot \vec{\Delta \ell}$$

Similarly, consider a capacitor, which is a component to store charge and electric energy. The constitutive relation for dielectric media is

$$\tilde{D} = \varepsilon \tilde{E} \tag{6}$$

where $\tilde{D}$ is the electric flux density (Coulombs/meter^2), ε is the permittivity (Farad/meter), and $\tilde{E}$ is the electric field intensity (volts/meter or Newton/Coulomb).

Consider now a capacitor made of two parallel perfect electric conductor plates having area (S) and separated by (d) filled by a linear, homogeneous, and isotropic dielectric matter (ε). According to Gauss' law and definition of voltage difference expressed in Eq. (2) (assuming uniform electric field and ignoring fringing effects),

$$q = \oint_S \tilde{D} \cdot \hat{n} ds = \oint_S \varepsilon \tilde{E} \cdot \hat{n} ds = \varepsilon S E \tag{7}$$

$$v = \int \tilde{E} \cdot \vec{d\ell} = Ed \tag{8}$$

The definition of capacitance is then used as

$$C = \frac{q}{v} = \frac{\varepsilon S}{d} \text{ (Farad or Coulombs/volt)} \tag{9}$$

Note that q is the total charge induced on one plate.

Considering the definition of electric current as the passage of charge increment (Δq) during a time interval (Δt) through a point,

$$i = \frac{dq}{dt} \tag{10}$$

Also

$$i = \frac{d}{dt}(Cv) = C\frac{dv}{dt} \tag{11}$$

where capacitance C is here assumed time invariant. Also

$$v = \frac{1}{C} \int_{-\infty}^{t} i(t) dt \tag{12}$$

DOI 10.1007/978-981-4560-75-7_133-1

Equations (11) and (12) are the governing relations for capacitors.

Consider now a coil of N turns wound on a cylindrical core having a uniform cross section of area (S) and length (l) filled by a linear, homogeneous, and isotropic magnetic medium having the constitutive relation

$$\tilde{B} = \mu\tilde{H} \tag{13}$$

The density of turns in the coil is

$$n = \frac{N}{l}\,(\text{turns/meter})$$

The magnetic flux density B(Tesla, Weber/meter^2) passing through it is

$$\tilde{B} = \mu n i \tag{14}$$

and the magnetic flux ϕ(Weber) passing through it is

$$\phi = \int_S \tilde{B} \cdot \hat{n} ds = \tilde{B}S = \mu n S i \tag{15}$$

The induced voltage in the solenoid is equal to the time derivative of the flux linkage in it due to Faraday's law:

$$v = \frac{\partial \phi}{\partial t} = \mu n S \frac{di}{dt} \tag{16}$$

Here, Lenz's law determines the sense of induced voltage.

On the other hand, inductance L(Henry) is defined as

$$L = \frac{\phi}{i} \tag{17}$$

Consequently, the induced voltage across the inductor is

$$v = \frac{d\phi}{dt} = L\frac{di}{dt} \tag{18}$$

where the self-inductance of the winding is

$$L = \mu n S \tag{19}$$

The following correspondences are now observed among the circuit elements, namely, resistor (R), capacitor (C), and inductor (L):

DOI 10.1007/978-981-4560-75-7_133-1

$$
\begin{aligned}
& v = Ri \quad , \quad i = Gv \\
& q = Cv \ , \ i = \frac{dq}{dt} = C\frac{dv}{dt} \quad , \quad v = \frac{1}{C}\int_{-\infty}^{t} idt, \quad \mathrm{q} = \int_{-\infty}^{t} idt \\
& \phi = Li \quad , \ v = L\frac{di}{dt} \qquad\quad , \quad i = \frac{1}{L}\int_{-\infty}^{t} vdt
\end{aligned}
\tag{20}
$$

The energy and power of the resistor, inductor, and capacitor are

$$
\begin{aligned}
& P_R = \frac{dW}{dt} = vi = Ri^2 \quad , \quad W_R = \int_{-\infty}^{t} vidt = \int_{-\infty}^{t} Ri^2 dt \\
& P_C = Cv\frac{dv}{dt} \qquad\quad , \quad W_C = \int_{-\infty}^{t} Cv\frac{dv}{dt}dt = \frac{1}{2}Cv^2 \\
& P_L = Li\frac{di}{dt} \qquad\quad , \quad W_L = \int_{-\infty}^{t} Li\frac{di}{dt}dt = \frac{1}{2}Li^2
\end{aligned}
\tag{21}
$$

For harmonic sources, the governing equations $\left(with\ \frac{\partial}{\partial t} = j\omega\right)$ for the resistors, inductors, and capacitors are

$$
\begin{aligned}
& V = RI \qquad\quad , \ P_R = \frac{1}{2}R|I|^2 \\
& I = (j\omega C)V = jB_C V \quad , \quad P_C = \frac{1}{2}B_C|V|^2 \ , \ W_C = \frac{1}{4}CV^2 \\
& V = (j\omega L)I = jX_L I \quad , \quad P_L = \frac{1}{2}X_L|I|^2 \ , \ W_L = \frac{1}{4}LI^2
\end{aligned}
\tag{22}
$$

The input impedance of a general one-port network may be indicated as

$$Z(\omega) = R(\omega) + jX(\omega) \tag{23}$$

which is composed of real and imaginary parts denoted as the resistive and reactive parts, respectively.

However, the concept of impedance has evolved from the basic DC electric circuits to other electromagnetic phenomena.

The intrinsic impedance of a medium is

$$\eta = \sqrt{\hat{z}/\hat{y}} \tag{24}$$

where impedivity is defined as

$$\hat{z} = j\omega\hat{\mu} = j\omega(\mu' - j\mu'') = \omega\mu'' + j\omega\mu' \ \ (\Omega/m) \tag{25}$$

and admittivity as

DOI 10.1007/978-981-4560-75-7_133-1

$$\hat{y} = \sigma + j\omega\hat{\varepsilon} = \sigma + j\omega(\varepsilon' - j\varepsilon'') = \sigma + \omega\varepsilon'' + j\omega\varepsilon' \quad (S/m) \tag{26}$$

The plane wave in a homogeneous medium is expressed as

$$\vec{H} = \frac{1}{\eta}\hat{n} \times \vec{E} \tag{27}$$

where $\vec{E}$ and $\vec{H}$ as the electric and magnetic field intensities are perpendicular to the direction of propagation in space $(\hat{n})$.

The transverse wave components in the cross section of a uniform waveguide are related by the wave impedance (Z_w).

$$\vec{H}_t = \frac{1}{Z_w}\hat{u}_z \times \vec{E}_t \tag{28}$$

where Z_w is Z_{TEM}, Z_{TE}, or Z_{TM} for the TEM, TE, or TM modes, respectively.

The forward and backward traveling wave voltages and currents on a transmission line are related by the characteristic impedance (Z_0) of the line, namely,

$$\frac{V^+}{I^+} = \frac{V^-}{I^-} = Z_0 \tag{29}$$

The input impedance in one direction on a line is actually defined by the equation of impedance transformation

$$Z_{in} = \frac{V}{I} = \frac{V^+ + V^-}{I^+ + I^-} \tag{30}$$

where the total voltage and current are the sum of forward and backward traveling voltages and currents, respectively.

The impedance matching from the perspective of electromagnetic fields is the matching of tangential electric fields and tangential magnetic fields at a boundary surface (having no surface currents), whereas from the perspective of circuit theory, it is the matching of impedances based on some specifications.

Connection of the Source to Load Through a Transmission Line

Consider now the case of a source connected to a load through a transmission line and study the behavior of power transfers between them (Rizzi 1988; Pozar 2011; Collin 2000; Gonzalez 1997). The length, characteristic impedance, and propagation constant of the line are l, Z_0, and $\gamma = \alpha + j\beta$ (with attenuation constant α and phase constant β), respectively. The source and load impedances are Z_S and Z_L.

The voltage and current on the line may be written as the sum of forward and backward traveling waves (Fig. 1).

$$V(z) = V_0^+(e^{-\gamma z} + \Gamma_L e^{\gamma z}) \tag{31}$$

DOI 10.1007/978-981-4560-75-7_133-1

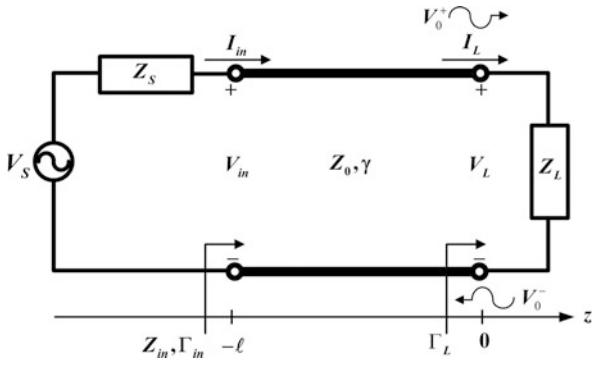

Fig. 1 The transmission line connecting a source to a load

$$I(z) = \frac{V_0^+}{Z_0}(e^{-\gamma z} - \Gamma_L e^{\gamma z}) \tag{32}$$

where the reflection coefficient at the load is defined as

$$\Gamma_L = \frac{V_0^-}{V_0^+} = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{33}$$

Using Eqs. (31), (32), and (33), the equation of impedance transformation on the line is obtained:

$$Z_{in} = \frac{V(z)}{I(z)} = Z_0 \frac{Z_L + Z_0 \tanh(\gamma l)}{Z_0 + Z_L \tanh(\gamma l)} \tag{34}$$

For lossless lines $(\alpha = 0)$

$$Z_{in} = \frac{V(z)}{I(z)} = Z_0 \frac{Z_L + jZ_0 \tan(\beta l)}{Z_0 + jZ_L \tan(\beta l)} \tag{35}$$

The two boundary conditions at the load and source sides of the line are

$$V_L = I_L Z_L \text{ and } V_S = I_{in}(Z_S + Z_{in}) \tag{36}$$

The voltage at the source end of the line is

$$V(z = -l) = V_{in} = I_{in} Z_{in} = V_S \frac{Z_{in}}{Z_{in} + Z_S} = V_0^+ \left(e^{\gamma l} + \Gamma_L e^{-\gamma l}\right) \tag{37}$$

Then, the forward traveling voltage amplitude is

$$V_0^+ = V_S \frac{Z_{in}}{Z_{in} + Z_S} \frac{1}{e^{\gamma l} + \Gamma_L e^{-\gamma l}} \tag{38}$$

This equation may be written as

$$V_0^+ = V_S \frac{Z_0}{Z_0 + Z_S} \frac{e^{-\gamma l}}{(1 - \Gamma_L \Gamma_S e^{-2\gamma l})} \tag{39}$$

by using Eq. (34) and the reflection coefficient at the source defined as

$$\Gamma_S = \frac{Z_S - Z_0}{Z_S + Z_0} \tag{40}$$

The voltage amplitude V_0^+ may be used in Eqs. (31) and (32) to obtain the voltage and current on the line. The standing wave ratio on the lossless line is

$$SWR = \frac{V_{\max}}{V_{\min}} = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|} \tag{41}$$

The power delivered to the load on a lossless line is

$$P_L = \mathrm{Re}\left(\frac{1}{2} V_{in} I_{in}^*\right) = \mathrm{Re}\left(\frac{1}{2} V_L I_L^*\right) = \frac{1}{2}|V_{in}|^2 \mathrm{Re}\left(\frac{1}{Z_{in}^*}\right) = \frac{1}{2}|V_S|^2 \left|\frac{Z_{in}}{Z_{in} + Z_S}\right|^2 \mathrm{Re}\left(\frac{1}{Z_{in}}\right) \tag{42}$$

which may be written as

$$P_L = \frac{1}{2}|V_S|^2 \frac{R_{in}}{(R_{in} + R_S)^2 + \left(X_{in} + {}^{\mathrm{in}}X_S\right)^2} \tag{43}$$

for $Z_{in} = R_{in} + jX_{in}$ and $Z_S = R_S + jX_S$.

Three cases of load impedance may be considered for a fixed source impedance (Z_S).

Matched Load

For the case of the load matched to the line, the relevant parameters are $Z_L = Z_0$, $\Gamma_L = 0$, $SWR = 1$, $Z_{in} = Z_0$, $R_{in} = Z_0$, and $X_{in} = 0$. Therefore, the load power is obtained from Eq. (42) as

$$P_L = \frac{1}{2}|V_S|^2 \frac{Z_0}{\left(Z_0 + {}^{0}R_S\right)^2 + {X_S}^2} \tag{44}$$

Matched Source

For the case of the source matched to the loaded line (Z_L) by choosing appropriate values for Z_L, βl, and Z_0, so that $Z_{in} = Z_S$, $R_{in} = R_S$, $\Gamma_{in} = 0$, and $\Gamma_L \neq 0$. The load power is then given from Eq. (42):

$$P_L = \frac{1}{8}|V_s|^2 \frac{R_S}{\left(R_S^2 + {X_S}^2\right)} \tag{45}$$

Observe that the load power in the case of matched source may be less than the case of matched load.

Maximum Load Power

The condition for the maximum power transfer from the source to the load is then determined. For a fixed source impedance, but variable input impedance $Z_{in} = R_{in} + jX_{in}$, the required conditions are

DOI 10.1007/978-981-4560-75-7_133-1

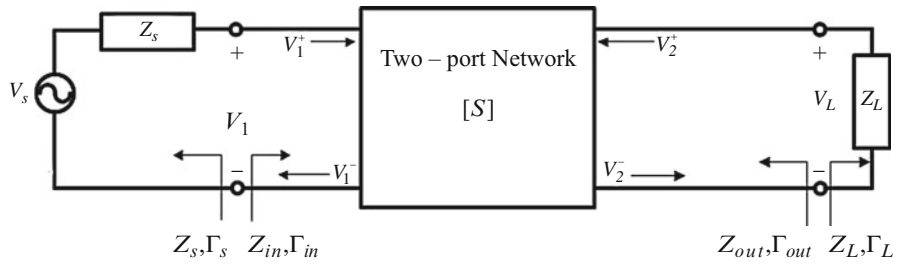

Fig. 2 A two-port network connecting a source to a load

$$\frac{\partial P_L}{\partial R_{in}} = 0 \text{ and } \frac{\partial P_L}{\partial X_{in}} = 0 \tag{46}$$

which lead to two relations $R_{in} = R_S$ and $X_{in} = -X_S$, namely,

$$Z_{in} = Z_S^* \tag{47}$$

Consequently, the conjugate matching provides the condition for maximum power transfer to the load, which is equal to (from Eq. (42))

$$P_L = \frac{1}{8}|V_s|^2 \frac{1}{R_S} \tag{48}$$

The reflection coefficients in this case, namely, Γ_L, Γ_S, and Γ_{in}, are not necessarily zero. Therefore, for maximum power transfer, there may be reflections on the line, which on a mismatched line may actually add up to increase the power transfer to the load.

Observe that the two cases of reflectionless matching $(Z_{in} = Z_S)$ and conjugate matching $\left(Z_{in} = Z_S^*\right)$ do not provide a circuit with optimum efficiency. The power dissipated in the source impedance is

$$P_{ds} = \frac{1}{2}R_S|I_S|^2 = \frac{1}{2}R_S|V_S|^2 \frac{1}{(R_{in} + R_S)^2 + \left(X_{in} + {}^{\text{in}}X_S\right)^2} \tag{49}$$

Now, for the case of the line matched to the source and load (no reflections), the conditions are $Z_L = {}^{L}Z_S = Z_0$ (and $X_S = X_L = X_{in} = 0$, $R_{in} = R_S = R_L = Z_0$)

$$P_{ds} = \frac{1}{2}R_S|V_S|^2 \frac{1}{4R_S^2} = \frac{|V_S|^2}{8R_S} \tag{50}$$

Therefore, half the power is lost in the source impedance (since in this case the source power is $P_S = |V_S|^2/4R_S$), resulting in an efficiency of 50 %.

Power Gains of Two-Port Networks

Consider a two-port network connected to a source and a load, as shown in Fig. 2 (Rizzi 1988; Pozar 2011; Collin 2000; Gonzalez 1997).

Three types of gain are distinguished:

DOI 10.1007/978-981-4560-75-7_133-1

1. Power gain

$$G = \frac{P_L}{P_{in}} = \frac{\text{Load Power}}{\text{Input power to network}} \tag{51}$$

G is independent of Z_S.

2. Available power gain

$$G_A = \frac{P_{avn}}{P_{avs}} = \frac{\text{Power available from network}}{\text{Power available from source}} \tag{52}$$

G_A assumes conjugate matching of both the source and the load. It depends on Z_S but not Z_L.

3. Transducer power gain

$$G_T = \frac{P_L}{P_{avs}} = \frac{\text{Load Power}}{\text{Power available from source}} \tag{53}$$

The definitions of power gains depend on the method of source and load matching. For example, if they are both conjugate matched, then maximum gain is achieved and $G = G_A = G_T$.

Assuming a reference characteristic impedance (Z_0), the reflection coefficients Γ_L and Γ_S are given in Eqs. (33) and (39), respectively. Since the input port of network is generally mismatched, its input reflection coefficient (Γ_{in}) (see Fig. 2) is then derived.

Using the scattering parameters and $\Gamma_L = V_2^+/V_2^-$

$$V_1^- = S_{11}V_1^+ + S_{12}V_2^+ = S_{11}V_1^+ + S_{12}\Gamma_L V_2^- \tag{54a}$$

$$V_2^- = S_{21}V_1^+ + S_{22}V_2^+ = S_{21}V_1^+ + S_{22}\Gamma_L V_2^- \tag{54b}$$

$$\Gamma_{in} = \frac{Z_{in} - Z_0}{Z_{in} + Z_0} = \frac{V_1^-}{V_1^+} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \tag{55}$$

Similarly, for the output reflection coefficient with $\Gamma_S = \frac{V_1^+}{V_1^-}$

$$\Gamma_{out} = \frac{V_2^-}{V_2^+} = S_{22} + \frac{S_{12}S_{21}\Gamma_S}{1 - S_{11}\Gamma_S} \tag{56}$$

At the input port of network

$$V_1 = V_S\frac{Z_{in}}{Z_{in} + Z_S} = V_1^+ + V_1^- = V_1^+(1 + \Gamma_{in}) \tag{57}$$

Therefore,

$$V_1^+ = \frac{V_S}{2}\frac{1 - \Gamma_S}{1 - \Gamma_S\Gamma_{in}} \tag{58}$$

where $Z_{in} = Z_0(1+\Gamma_{in})/(1-\Gamma_{in})$ from Eq. (54b) is used.

The average power delivered to the network is

$$P_{in} = \frac{1}{2Z_0}\left|V_1^+\right|^2\left(1-|\Gamma_{in}|^2\right) = \frac{|V_S|^2}{8Z_0}\frac{|1-\Gamma_S|^2}{|1-\Gamma_S\Gamma_{in}|^2}\left(1-|\Gamma_{in}|^2\right) \tag{59}$$

The load power is

$$P_L = \frac{1}{2Z_0}\left|V_2^-\right|^2\left(1-|\Gamma_L|^2\right) \tag{60}$$

Substitute V_2^- from Eq. (54a) and V_1^+ from Eq. (57) in Eq. (59) to determine the load power

$$P_L = \frac{|V_S|^2}{8Z_0}|S_{21}|^2\frac{|1-\Gamma_S|^2}{|1-\Gamma_S\Gamma_{in}|^2}\frac{1-|\Gamma_L|^2}{|1-S_{22}\Gamma_L|^2} \tag{61}$$

The power gain is now

$$G = \frac{P_L}{P_{in}} = |S_{21}|^2\frac{1-|\Gamma_L|^2}{|1-S_{22}\Gamma_L|^2}\frac{1}{1-|\Gamma_{in}|^2} \tag{62}$$

The maximum deliverable power to the network (P_{in}) is equal to the available power from the source (P_{avs}), which is achieved for the case of conjugate matching between the source and the input of network, namely, $Z_{in} = Z_S^*$ or $\Gamma_{in} = \Gamma_S^*$. Then, from Eq. (58)

$$P_{avs} = P_{in}\big|_{\Gamma_{in}=\Gamma_S^*} = \frac{|V_S|^2}{8Z_0}\frac{|1-\Gamma_S|^2}{\left(1-|\Gamma_S|^2\right)} \tag{63}$$

The maximum deliverable power to the load (P_L) is equal to the available power from the network (P_{avn}), which is achieved for conjugate matching between the output of network and the load, namely, $\Gamma_L = \Gamma_{out}^*$ and $Z_L = Z_{out}^*$. Therefore, the following relation is obtained from Eq. (60):

$$P_{avn} = P_L\big|_{\Gamma_L=\Gamma_{out}^*} = \frac{|V_S|^2}{8Z_0}|S_{21}|^2\frac{|1-\Gamma_S|^2}{|1-\Gamma_S\Gamma_{in}|^2}\frac{1-|\Gamma_{out}|^2}{\left|1-S_{22}\Gamma_{out}^*\right|^2} \tag{64}$$

In this equation for P_{avn}, the input reflection coefficient Γ_{in} must be evaluated for $\Gamma_L = \Gamma_{out}^*$ and $Z_L = Z_{out}^*$.

The following equation is now derived:

$$|1-\Gamma_S\Gamma_{in}|^2\big|_{\Gamma_L=\Gamma_{out}^*} = \frac{|1-S_{11}\Gamma_S|^2\left(1-|\Gamma_{out}|^2\right)^2}{\left|1-S_{22}\Gamma_{out}^*\right|^2} \tag{65}$$

The following quantities are evaluated from Eqs. (54b) and (55):

DOI 10.1007/978-981-4560-75-7_133-1

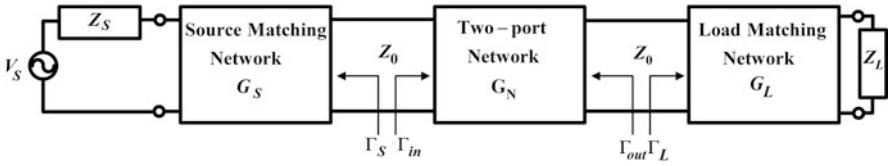

Fig. 3 A two-port network with source and load matching networks

$$\Gamma_{in} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} = \frac{S_{11} - \Gamma_L\Delta}{1 - S_{22}\Gamma_L} \tag{66}$$

$$\Gamma_{out} = S_{22} + \frac{S_{12}S_{21}\Gamma_S}{1 - S_{11}\Gamma_S} = \frac{S_{22} - \Gamma_S\Delta}{1 - S_{11}\Gamma_S} = \Gamma_L^* \tag{67}$$

where $\Delta = S_{11}S_{22} - S_{12}S_{21}$. Substitute Γ_{in} from Eq. (65) and Γ_S from Eq. (66) in the left-hand side of (64) to verify it. Consequently, Eq. (63) reduces to

$$P_{avn} = \frac{|V_S|^2}{8Z_0}|S_{21}|^2 \frac{|1 - \Gamma_S|^2}{|1 - S_{11}\Gamma_S|^2\left(1 - |\Gamma_{out}|^2\right)} \tag{68}$$

The powers P_{avs} and P_{avn} are expressed in terms of source voltage (V_S), which is independent of the input and load impedances.

Using these relations, the available (G_A) and transducer (G_T) power gains are

$$G_A = \frac{P_{avn}}{P_{avs}} = |S_{21}|^2 \frac{\left(1 - |\Gamma_S|^2\right)}{|1 - S_{11}\Gamma_S|^2\left(1 - |\Gamma_{out}|^2\right)} \tag{69}$$

$$G_T = \frac{P_L}{P_{avs}} = |S_{21}|^2 \frac{\left(1 - |\Gamma_S|^2\right)\left(1 - |\Gamma_L|^2\right)}{|1 - \Gamma_S\Gamma_{in}|^2|1 - S_{22}\Gamma_L|^2} \tag{70}$$

When both the input and the output ports are matched for zero reflection, namely, $\Gamma_S = \Gamma_L = 0$, then the transducer power gain reduces to

$$G_T = |S_{21}|^2 \tag{71}$$

For a unilateral transducer (or a nonreciprocal amplifier), $S_{12} = 0$, which leads to $\Gamma_{in} = S_{11}$ from Eq. (54b). Therefore, the transducer power gain is obtained by letting $\Gamma_{in} = S_{11}$ in Eq. (69).

However, matching networks are usually required at the source and load sides of the two-port network to transform its input port to the source impedance and its output port to the load impedance, as shown in Fig. 3.

The transducer power gain (G_T) is appropriate for such a system consisting of the series connection of the source matching circuit, the two-port network, and the load matching circuit, where effective power gain factors are defined for each one. Equation (69) for G_T may be factorized as

$$G_T = G_S G_N G_L \tag{72a}$$

DOI 10.1007/978-981-4560-75-7_133-1

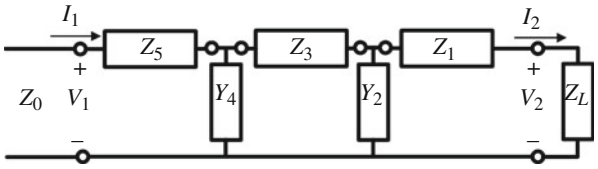

Fig. 4 A general matching network

where

$$G_S = \frac{\left(1 - |\Gamma_S|^2\right)}{|1 - \Gamma_S \Gamma_{in}|^2} \tag{72b}$$

$$G_N = |S_{21}|^2 \tag{72c}$$

$$G_L = \frac{\left(1 - |\Gamma_L|^2\right)}{|1 - S_{22}\Gamma_L|^2} \tag{72d}$$

Varieties of Matching Networks

A general matching network may be represented as shown in Fig. 4, although more sections may be added to increase its bandwidth (Rizzi 1988; Pozar 2011; Collin 2000; Gonzalez 1997; Misra 2001; Ludwig and Bretchko 2000).

The series blocks (Z_1, Z_3, Z_5) and parallel blocks (Y_2, Y_4) may be series or parallel connections of L and C discrete components. They may also be a transmission line of length (l_i), characteristic impedance Z_{0i}, and propagation constant γ_i. The transmission line may be open circuited or short circuited. The different types of blocks are given in Table 1.

The series blocks (Z_1, Z_3, and Z_5) may allow short- or open-circuited stubs as some reactive or susceptive element and also any combination of the other circuit elements. The parallel blocks (Y_2 and Y_4) allow transmission line sections and also any combination of the other circuit elements. Therefore, many circuits may be devised for any impedance matching network as drawn in Fig. 4, of which the blocks are made of any combination of the circuit elements given in Table 1.

Many types of circuits have been devised for impedance matching networks, which are actually special cases of the general network in Fig. 4. For the case of single-frequency operation, the series LC and parallel LC circuits actually reduce to a single L or C component. For the design of impedance matching network for a specified bandwidth, both series and parallel LC circuits are required in its series and shunt sections.

Consider now the matching network usually denoted as L-network as shown in Fig. 5a, b.

For Fig. 5a, the blocks Z_3, Y_4, and Z_5 are removed, but blocks Z_1 and Y_2 are retained as denoted in Fig. 4. For Fig. 5b, blocks Z_1, Y_4, and Z_5 are removed, but blocks Y_2 and Z_3 are retained. For single-frequency operation, four different circuits are distinguished for Fig. 5a and also for Fig. 5b as shown in Fig. 6a, b, respectively.

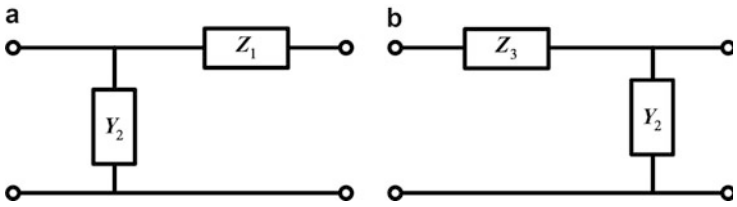

Fig. 5 Matching L-networks

DOI 10.1007/978-981-4560-75-7_133-1

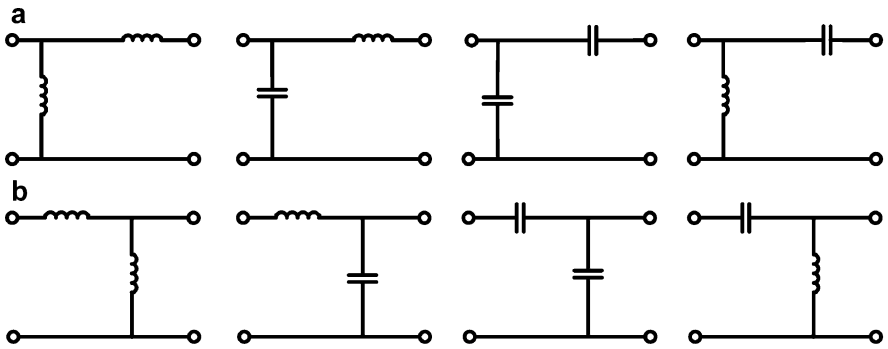

Fig. 6 Several representative impedance matching L-networks

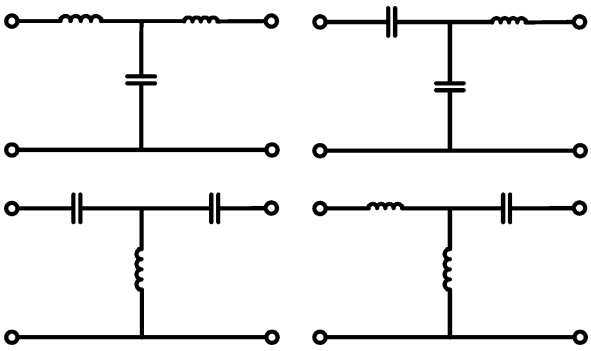

Fig. 7 Several representative impedance matching T-networks

The circuit in Fig. 6a may be used to match the load impedances located outside the circle of unit resistance in the Smith chart, and those in Fig. 6b are used for matching the load impedances lying inside this circle. The values of circuit components may be obtained by algebraic methods and also by graphical methods on the Smith chart.

The details of these methods are available in the textbooks on microwave engineering, where the reader may refer to Rizzi (1988) and Ludwig and Bretchko (2000). However, the method of least squares is used here for their designs.

Consider next the matching circuit usually denoted as T-network as shown in Fig. 7. This circuit is obtained by retaining blocks Z_1, Y_2, and Z_3 but removing blocks Y_4 and Z_5. The blocks Z_1, Y_2, and Z_3 may represent any combination of series and parallel LC circuits. Representative T-networks are drawn in Fig. 7. The circuits may be symmetric or asymmetric.

Consider then the matching circuit commonly called π-networks, as shown in Fig. 8. This circuit is obtained by the network in Fig. 4 by retaining blocks Y_2, Z_3, and Y_4 but removing blocks Z_1 and Z_5. The blocks Y_2, Z_3, and Y_4 may be composed of any combinations of series and parallel LC circuits. Several π-networks are drawn in Fig. 8.

Many other matching networks composed of series and parallel circuits may be devised in the form of the network in Fig. 4. Their general design may be based on the method of least squares to be presented shortly.

Several matching networks may be devised by the implementation of transmission lines. The single-stub tuner is obtained by keeping blocks Z_1 and Y_2 and removing Z_3, Y_4, and Z_5. Block Z_1 is a transmission line section and block Y_2 is a short-circuit or an open-circuit stub, as shown in Fig. 9a. Another

DOI 10.1007/978-981-4560-75-7_133-1

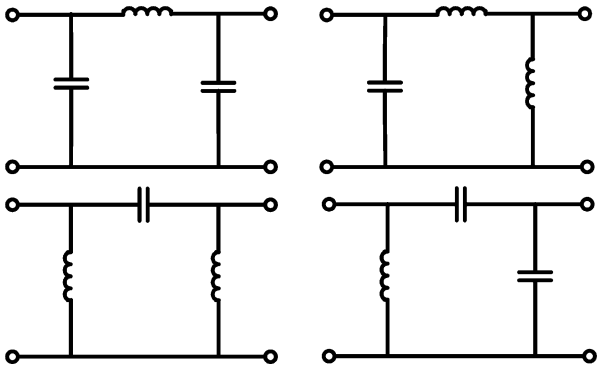

Fig. 8 Several representative impedance matching $R_{in} = R_S$-networks

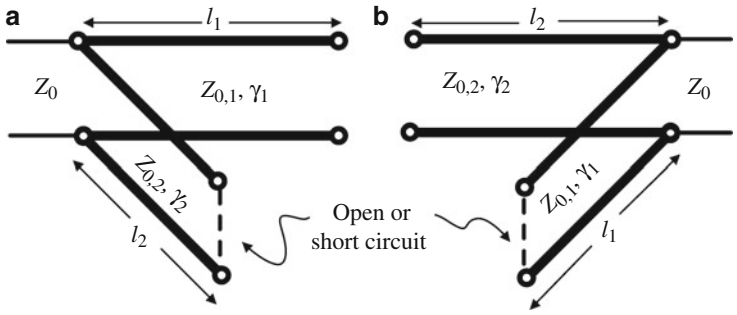

Fig. 9 Two configurations of single-stub tuning

configuration is obtained by keeping blocks Y_2 and Z_3 but removing blocks Z_1, Y_4, and Z_5. Block Y_2 is a short- or an open-circuited stub and Z_3 is a transmission line section, as shown in Fig. 9b.

The double-stub tuner is obtained by keeping all the blocks of the network in Fig. 4. Blocks Z_1, Z_3, and Z_5 are transmission line sections, whereas blocks Y_2 and Y_4 are short- or open-circuited stubs, as shown in Fig. 10.

Triple-stub tuning circuits may also be devised, which are composed of three open- or short-circuited stubs.

The design of single-stub and double-stub tuners may be performed by analytical methods using the equation of impedance transformation and also by the geometrical methods using the Smith chart. However, the method of least squares is used here for their designs.

Other special cases of the matching network shown in Fig. 4 may also be considered. For example, consider the case of assuming block Z_1 as the series connection of a transmission line section and a reactive element as shown in Fig. 11, where in Fig. 4, blocks Z_1 and Z_3 are kept, but blocks Y_2, Y_4, and Z_5 are removed.

The series reactive element in Fig. 11 may be replaced by a short- or open-circuited stub as shown in Fig. 12.

Next, consider the case where blocks Z_1 and Y_2 are kept, but blocks Z_3, Y_4, and Z_5 are removed. Block Z_1 is considered as a transmission line section, where block Y_2 is taken as a discrete element, as shown in Fig. 13. Block Z_n may be considered as a parallel stub of transmission line, which was mentioned earlier.

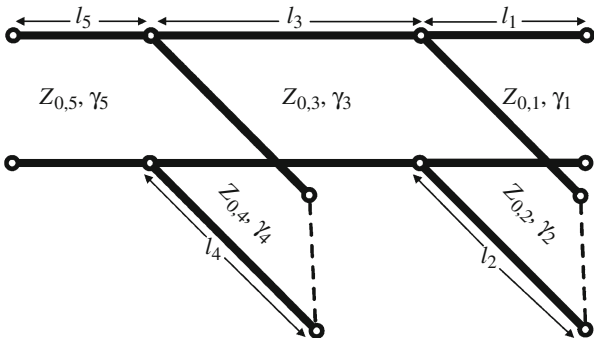

Fig. 10 Double-stub tuning

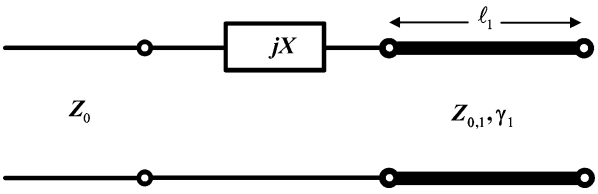

Fig. 11 Series reactive matching network

Impedance Transformer Design by the Method of Least Squares

The method of least squares is now developed for the design of matching circuit as proposed in the general network depicted in Fig. 4 (Oraizi 2001, 2006).

The total transmission matrix of the whole network is

$$[T] = [T_5][T_4][T_3][T_2][T_1] \tag{73}$$

where each transmission matrix $[T_i]$ may be obtained from the appropriate one given in Table 1 for any adopted matching circuit. Now, the input voltage and current are related to the output ones by the network transmission matrix

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = [T] \begin{bmatrix} V_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix} \tag{74}$$

or

$$V_1 = AV_2 + BI_2 \tag{75}$$

$$I_1 = CV_2 + DI_2 \tag{76}$$

The input impedance of the circuit $\left(Z_{in} = \frac{V_1}{I_1}\right)$ may be written in term of the load impedance $\left(Z_L = \frac{V_2}{I_2}\right)$. Then, dividing the two equations in Eqs. (74) and (75) and replacing Z_L, the following relation is obtained:

$$Z_{in} = \frac{V_1}{I_1} = \frac{AZ_L + B}{CZ_L + D} \tag{77}$$

DOI 10.1007/978-981-4560-75-7_133-1

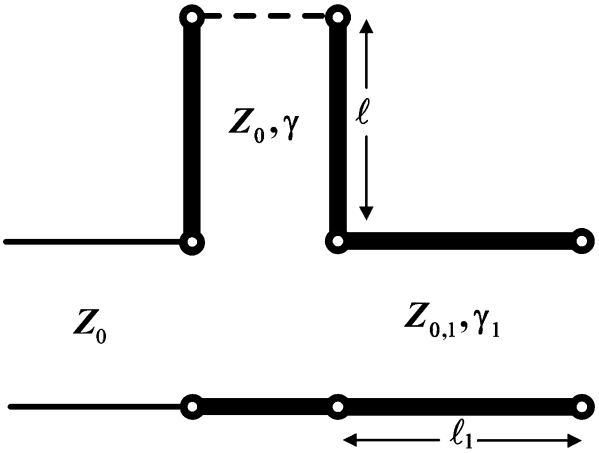

Fig. 12 Matching network using series short- or open-circuited reactive stubs

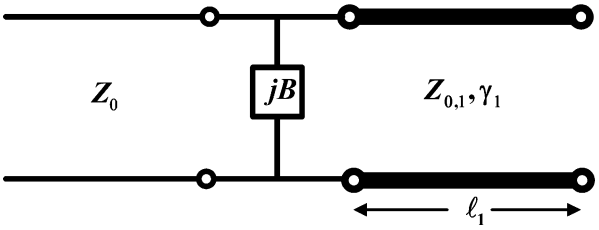

Fig. 13 Matching network using parallel short- or open-circuited reactive stubs

The matching circuit may be designed for reflectionless condition at the input (namely, $Z_0 = Z_{in}$) or for conjugate matching for maximum power transfer (namely, $Z_0 = Z_{in}^*$). Then, an error function may be constructed as

$$error = \sum_k \left| Z_{in,k} - Z_0^* \right|^2 = \sum_k \left| \frac{A_k Z_{L,k} + B_k}{C_k Z_{L,k} + D_k} - Z_0^* \right|^2 \tag{78}$$

where the frequency interval between the limit frequencies (f_1 to f_2) is divided into K intervals with $f_k = f_1 + k\Delta f = f_1 + k\frac{f_2 - f_1}{K}, k = 0, 1, 2, \ldots, K$. If the characteristic impedance of the input line (Z_0) is real, then the conditions for reflectionless line and conjugate matching are the same. For the design of a single-frequency matching circuit, there is no summation on (K + 1) frequencies in Eq. (77). The error function depends on the geometrical dimensions and electrical characteristics of the circuit elements selected from Table 1, for various blocks in Fig. 4. Observe that the matching network may also be implemented for the case of Z_0 as a function of frequency.

The minimization of the error function determines all parameters of the different sections of the matching circuit. If the error function is a quadratic function of the variables, then it has a unique minimum. If it is not quadratic, then it has several minima. A minimization algorithm needs to be used, such as the steepest descent, conjugate gradient, any evolutionary algorithm (such as genetic algorithm, particle swarm optimization, ant colony, or invasive weed method), or any combination of such algorithms.

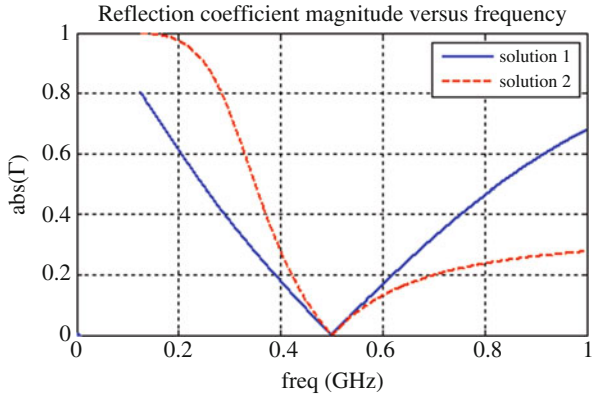

Fig. 15 Example 1. Reflection coefficient magnitude versus frequency

Example 5

Design of various tuning circuits (single-stub tuning with parallel short-circuit stub, single-stub tuning with series short-circuit stub, and double-stub tuning circuit with parallel short-circuit stubs) shown in Fig. 22. Their frequency responses are drawn in Fig. 23.

The reflection coefficients of the various tuning circuits are drawn in Fig. 23 for comparison. Observe that the short-circuit series stub tuning circuit has the broadest bandwidth at the specified operation frequency. The reason is that the length of its stub is shortest among the tuners.

A Quarter-Wave Line as a Basic Unit of Impedance Transformers

Multi-section impedance transformers are used to match two systems of different impedances, such as two transmission lines with different characteristic impedances, two waveguides with different wave impedances, and matching of a radiating system (such as lenses) to free space (Rizzi 1988; Pozar 2011; Collin 2000). The lengths of the sections of transformer may be arbitrary or equal to a quarter wavelength, in which case it is called a quarter-wave transformer.

Quarter-Wave Transformer

Consider a transmission line of length ℓ, characteristic impedance Z_1, and phase constant β_l connecting a load resistor R_L to an impedance Z_0, as shown in Fig. 24.

The input impedance to the line is

$$Z_{in} = Z_1 \frac{R_L + jZ_1 t}{Z_1 + jR_L t} \tag{79}$$

where $t = \tan \beta l$. The reflection coefficient at the line input is obtained by the substitution of Eq. (78) in

DOI 10.1007/978-981-4560-75-7_133-1

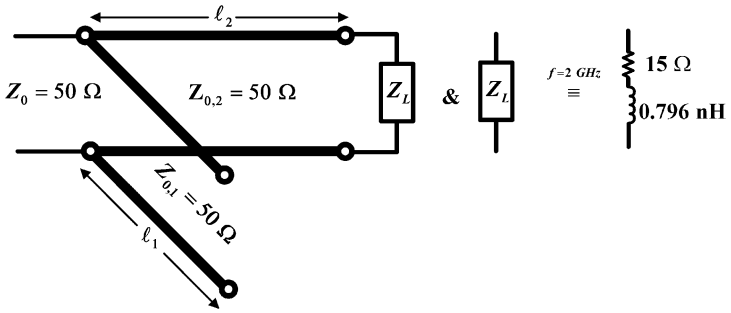

Fig. 16 Example 2. Single-stub tuning circuit with parallel open-circuit stub

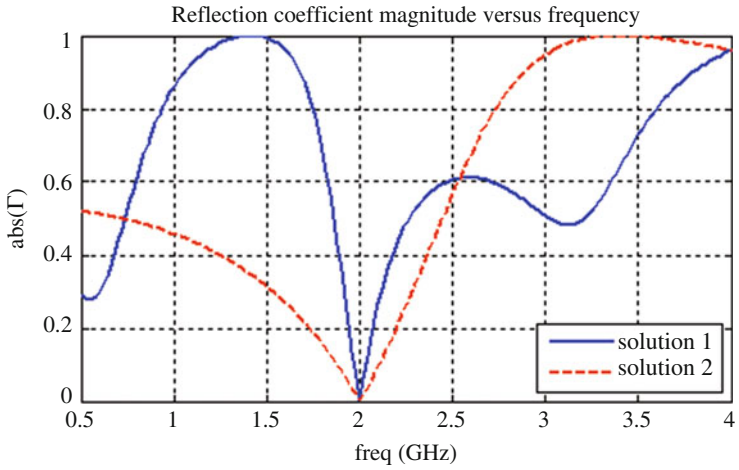

Fig. 17 Example 2. Reflection coefficient magnitude versus frequency

$$\Gamma_{in} = \frac{Z_{in} - Z_0}{Z_0 - Z_{in}} = \frac{Z_1(R_L - Z_0) + jt\left(Z_1^2 - Z_0 R_L\right)}{Z_1(R_L + Z_0) + jt\left(Z_1^2 + Z_0 R_L\right)} \tag{80}$$

If the length of line is equal to a quarter wave at the center frequency (f_0) and the load R_L is matched through the line to Z_0, then $Z_1 = \sqrt{Z_0 R_L}$ and

$$\Gamma_{in} = \frac{R_L - Z_0}{R_L + Z_0 + j2t\sqrt{Z_0 R_L}} \tag{81}$$

The magnitude of Γ_{in} becomes

$$|\Gamma_{in}| = \frac{1}{\left[1 + \frac{4Z_0 R_L \sec^2\theta}{(R_L - Z_0)^2}\right]^{1/2}} \tag{82}$$

For frequencies near the design frequency (f_0), the following relations are valid for a TEM line:

DOI 10.1007/978-981-4560-75-7_133-1

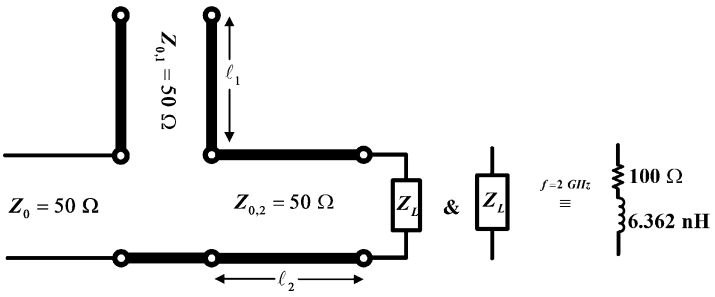

Fig. 18 Example 3. Single-stub tuning circuit with series open-circuit stub

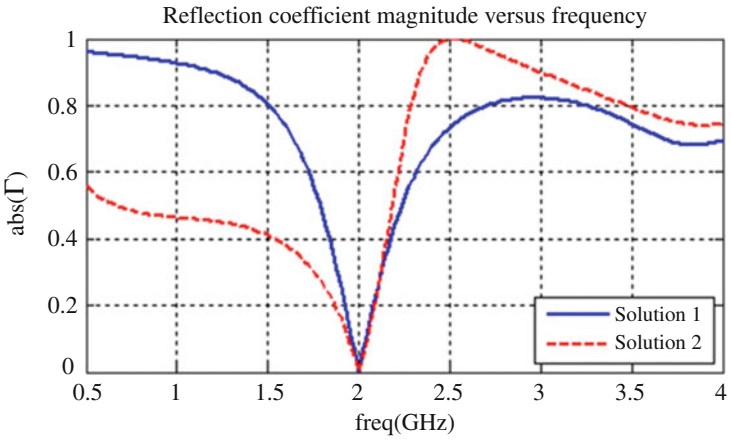

Fig. 19 Example 3. Reflection coefficient magnitude versus frequency

$$\theta = \beta l = \frac{2\pi}{\lambda}\frac{\lambda_0}{4} = \frac{\pi f}{2f_0} \approx \frac{\pi}{2} \quad \text{and} \quad \sec^2\theta \gg 1 \tag{83a}$$

$$|\Gamma_{in}| \approx \frac{|R_L - Z_0|}{2\sqrt{Z_0 R_L}} |\cos\theta| \quad , \quad \theta \approx \frac{\pi}{2} \tag{83b}$$

The input reflection coefficient $|\Gamma_{in}|$ is drawn versus θ in Fig. 25.

For a specified value of reflection coefficient Γ_m, Eq. (81) gives the angle θ_m

$$\cos\theta_m = \frac{\Gamma_m}{\sqrt{1-\Gamma_m^2}} \frac{2\sqrt{Z_0 R_L}}{|R_L - R_0|} \tag{84}$$

Now, define the bandwidth of the transformer referring to Fig. 25 as

$$\Delta\theta = 2\left(\frac{\pi}{2} - \theta_m\right) \tag{85}$$

Then, the frequency of the lower end of the band is

$$f_m = \frac{2}{\pi} f_0 \theta_m \tag{86}$$

DOI 10.1007/978-981-4560-75-7_133-1

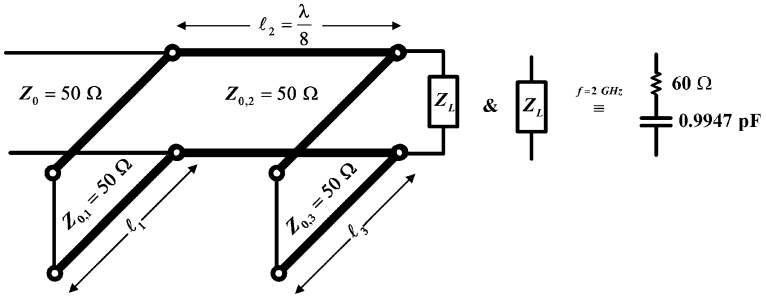

Fig. 20 Example 4. Double-stub tuning circuit with parallel short-circuit stubs

Consequently, the fractional bandwidth is

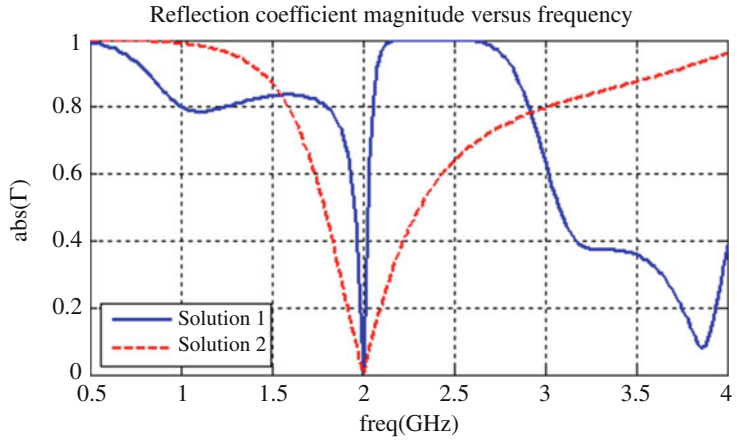

Fig. 21 Example 4. Reflection coefficient magnitude versus frequency

$$\frac{\Delta f}{f_0} = \frac{2(f_0 - f_m)}{f_0} = 2 - \frac{4}{\pi}\theta_m \tag{87}$$

$$= 2 - \frac{4}{\pi}\cos^{-1}\left[\frac{\Gamma_m}{\sqrt{1-\Gamma_m^2}}\frac{2\sqrt{Z_0 R_L}}{|R_L - Z_0|}\right] \tag{88}$$

Observe that the transformer bandwidth increases as R_L approaches Z_0, that is, for the lesser mismatched cases.

The above analysis assumes linear dependence of β on frequency, as for TEM modes. For nonlinear lines, the propagation constant is a nonlinear function of frequency, and the wave impedance is also a function of frequency. The analysis will thus become complicated. However, such frequency dependencies do not affect the analysis for narrowband performance. Furthermore, discontinuities at the junction of transmission lines were ignored in the above solution. Such effects may be considered by adjusting the length of line sections. The effect of discontinuities will be taken into account in the subsequent treatment.

Theory of Small Reflections

Consider a single-section transformer of length ℓ and characteristic impedance Z_2 connecting load impedance Z_L to impedance Z_1, as shown in Fig. 26a (Pozar 2011; Collin 2000). A simple formula is derived for the total reflection at its input (Γ) in terms of partial reflections at its input (Γ_1) and output (Γ_3).

The partial reflection and transmission coefficients at its input and output ports as indicated in Fig. 16b are

DOI 10.1007/978-981-4560-75-7_133-1

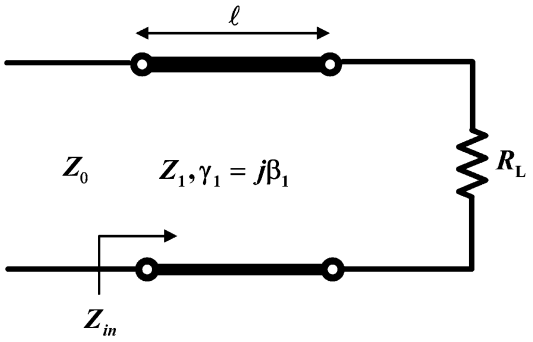

Fig. 24 A transmission line (Z_1) connecting a load (R_L) to a line of impedance (Z_0)

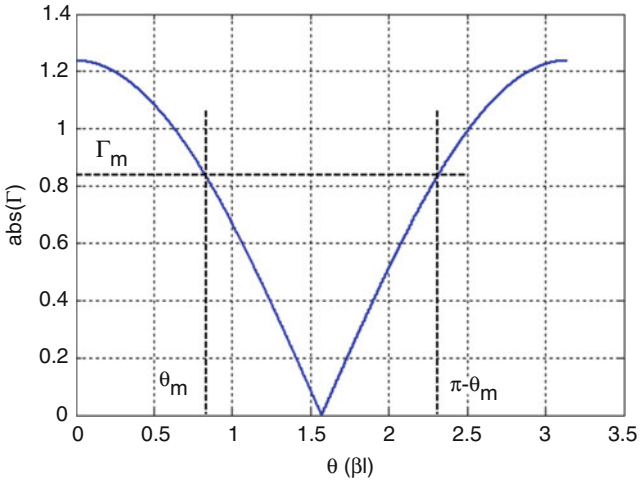

Fig. 25 Frequency response of a single-section quarter-wave transformer

$$\Gamma_1 = -\Gamma_2 = \frac{Z_2 - Z_1}{Z_2 + Z_1} \tag{89a}$$

$$\Gamma_3 = \frac{Z_L - Z_2}{Z_L + Z_2} \tag{89b}$$

$$T_{21} = 1 + \Gamma_1 = \frac{2Z_2}{Z_2 + Z_1} \tag{89c}$$

$$T_{12} = 1 + \Gamma_2 = \frac{2Z_1}{Z_2 + Z_1} \tag{89d}$$

The total input reflection coefficient (Γ) is obtained by the impedance method using the impedance transformation equation for Z_{in}. However, the multiple reflection method is followed here, as indicated in Fig. 26b. The total reflection at the input of the line section is the sum of all multiple reflections at its input and output ends, after they emerge from its input,

DOI 10.1007/978-981-4560-75-7_133-1

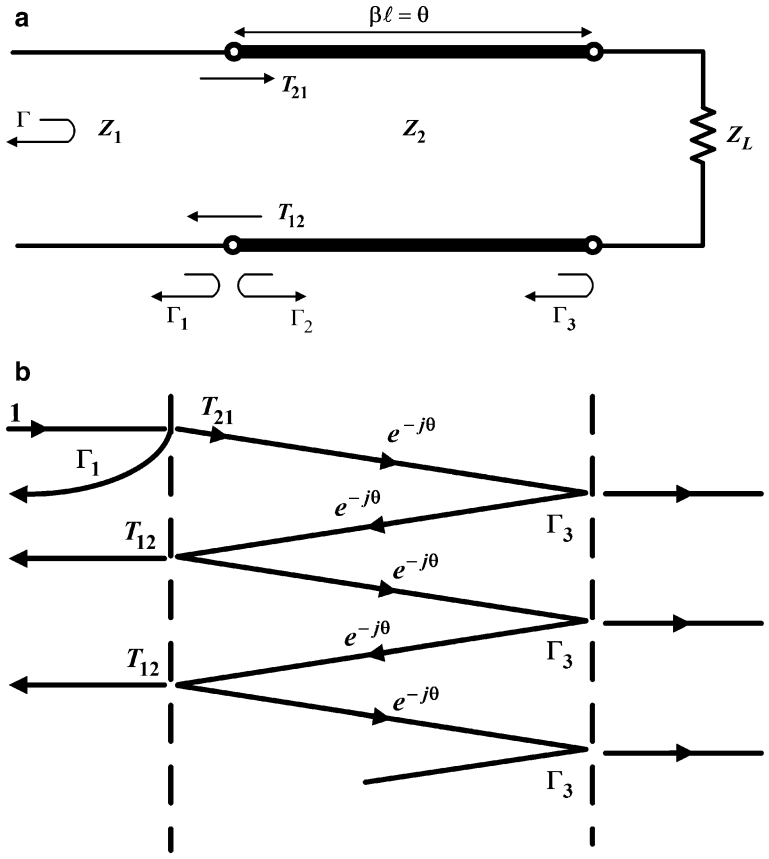

Fig. 26 Partial reflections and transmission on a terminated line section. (**a**) Transmission line; (**b**) partial multiple reflections

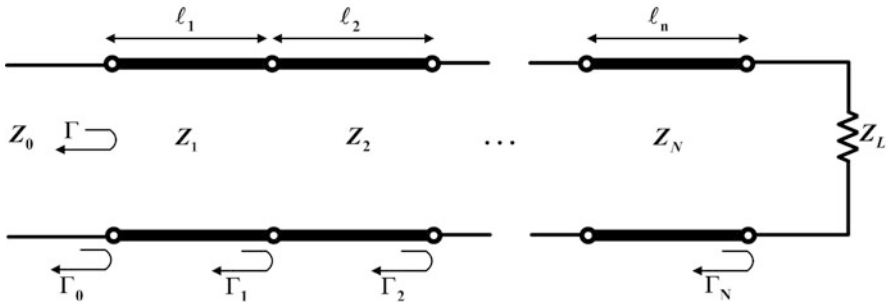

Fig. 27 A general multi-section impedance transformer

$$\Gamma = \Gamma_1 + T_{21}T_{12}\Gamma_3 e^{-j2\theta} + T_{21}T_{12}\Gamma_3^2\Gamma_2 e^{-j4\theta} + \cdots = \Gamma_1 + T_{21}T_{12}\Gamma_3 e^{-j2\theta}\sum_{i=0}^{\infty}\left[\Gamma_2\Gamma_3 e^{-j2\theta}\right]^n \tag{90}$$

Since $|\Gamma_2\Gamma_3| \leq 1$, use the formula for the sum of geometric series to obtain

$$\Gamma = \Gamma_1 + \frac{T_{21}T_{12}\Gamma_3 e^{-j2\theta}}{1 - \Gamma_2\Gamma_3 e^{-j2\theta}} \tag{91}$$

DOI 10.1007/978-981-4560-75-7_133-1

Using Eq. (89), the following equation is obtained:

$$\Gamma = \frac{\Gamma_1 + \Gamma_3 e^{-j2\theta}}{1 + \Gamma_1 \Gamma_3 e^{-j2\theta}} \tag{92}$$

Ignoring the discontinuities on the line and with $|\Gamma_1 \Gamma_3| \ll 1$, the key formula for the case of small reflections on the line is obtained:

$$\Gamma \cong \Gamma_1 + \Gamma_3 e^{-j2\theta} \tag{93}$$

It states that the resultant reflection at the input of the line is equal to the reflection at the input discontinuity plus that of the load including the phase shift due to the signal traveling up and down the line. This relation is the basis of the design of multi-section impedance transformers.

If the length of the line is equal to a quarter-wavelength $\left(\frac{\lambda}{4}\right)$ of the design frequency, then $\theta = \beta l = \frac{2\pi}{\lambda}\frac{\lambda}{4} = \frac{\pi}{2}$ and $e^{-j2\theta} = -1$. It may be substituted in Eqs. (89d) and (90) to obtain its reflection coefficient. If $Z_2 = \sqrt{Z_1 Z_L}$, then $\Gamma = 0$ as expected.

Multi-section Transformer

Consider the cascade connection of N line sections of lengths ℓ_i and electrical lengths $\theta_i = \beta_i \ell_i$, characteristic impedances $Z_{0,i}$, and propagation constants $\gamma_i = \alpha_i + j\beta_i$ shown in Fig. 27 (Rizzi 1988; Pozar 2011; Collin 2000; Gonzalez 1997; Misra 2001; Ludwig and Bretchko 2000). The equal-length (commensurate) lines ($l_i = l$), lossless lines ($\alpha_i = 0$), and dispersionless lines $\left(\beta = \frac{\omega}{\upsilon}\right)$ are all special cases of the general transformer. The resultant reflection coefficient at the line input is then derived.

Consider the partial reflection coefficients at the junctions of line sections.

$$\Gamma_0 = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{94a}$$

$$\Gamma_n = \frac{Z_{n+1} - Z_n}{Z_{n+1} + Z_n} \tag{94b}$$

$$\Gamma_N = \frac{Z_L - Z_N}{Z_L + Z_N} \tag{94c}$$

The characteristic impedances depend on the propagation modes of the waveguide.

The small reflection formula is invoked to compute the overall input reflection coefficient

$$\begin{aligned} \Gamma(\theta) &= \Gamma_0 + \Gamma_1 e^{-j2\theta_1} + \Gamma_2 e^{-j2(\theta_1+\theta_2)} + \cdots + \Gamma_N e^{-j2(\theta_1+\theta_2+\cdots\theta_N)} \\ &= \sum_{n=0}^{N} \Gamma_n e^{-j2\sum_{m=0}^{n}\theta_m} = \sum_{n=0}^{N} \frac{Z_{n+1} - Z_n}{Z_{n+1} + Z_n} \exp\left(-j2\sum_{m=0}^{n}\beta_m l_m\right) \end{aligned} \tag{95}$$

where $\theta_0 = 0$ and $\theta_m = \beta_m l_m = \omega\sqrt{\mu_m \varepsilon_m} l_m$ for the TEM mode. However, for non-TEM modes, the characteristic impedances (Z_n) and phase constants (β_n) are nonlinear functions of frequency.

Consequently, the specified bandwidth from f_1 to f_2 may be divided into K discrete frequencies. An error function may be constructed in terms of the reflection coefficients

$$\text{error} = \sum_{k=1}^{K} |\Gamma_k|^2 \tag{96}$$

There are various formulas in the literature for the characteristic impedance Z_n and phase constant β_n of various transmission lines in terms of their geometrical dimensions and constitutive matter, such as striplines, microstrips, and waveguides. By using such formulas, the error function may be minimized to determine the geometrical dimensions of the transformer.

Now, simplify the transformer design and assume that it is commensurate and the length of line sections is equal to a quarter wavelength $\left(\frac{\lambda}{4}\right)$ and $\beta l = \frac{\pi}{2}$. The error function reduces to the following relation without explicitly considering the frequency bandwidth.

$$\text{error} = \left| \sum_{n=0}^{N} \frac{Z_{n+1} - Z_n}{Z_{n+1} + Z_n} \exp\left(-j\pi \sum_{m=0}^{n} m \right) \right|^2 \tag{97}$$

It is then minimized to obtain Z_n and eventually determine the geometrical dimensions of the transformer.

The binomial and Chebyshev multi-section matching transformers are then developed. Let us assume that Z_L is resistive and real, and Z_n increases or decreases monotonically. Therefore, all Γ_n are real and have the same sign ($\Gamma_n > 0$ for $Z_L > Z_0$ or $\Gamma_n < 0$ for $Z_L < Z_0$). The input reflection coefficient is then from Eq. (94c):

$$\Gamma(\theta) = \Gamma_0 + \Gamma_1 e^{-j2\theta} + \Gamma_2 e^{-j4\theta} + \cdots + \Gamma_N e^{-j2N\theta} \tag{98}$$

Now, assume that Γ_n are symmetrical (but not Z_n), namely, $\Gamma_i = \Gamma_{N-i}$ for $i = 0, 1, \ldots, N$. This leads to a finite Fourier cosine series as

$$\Gamma(\theta) = 2e^{-jN\theta}\left[\Gamma_0 \cos N\theta + \Gamma_1 \cos(N-2)\theta + \cdots + \Gamma_n \cos(N-2n)\theta + \cdots + \frac{1}{2}\Gamma_{\frac{N}{2}}\right] \quad \text{for N even} \tag{99a}$$

$$\Gamma(\theta) = 2e^{-jN\theta}\left[\Gamma_0 \cos N\theta + \Gamma_1 \cos(N-2)\theta + \cdots + \Gamma_n \cos(N-2n)\theta + \cdots + \frac{1}{2}\Gamma_{\frac{(N-1)}{2}} \cos\theta\right] \quad \text{for N odd} \tag{99b}$$

Observe that any desired response may be realized for $\Gamma(\theta)$, because it is expressed in a Fourier cosine series, which may express an arbitrary function, if enough terms are included in it.

A binomial transformer is then obtained, which has a maximally flat response in its passband, provided that its $(N-1)$ derivatives are set equal to zero. Therefore, set

$$\Gamma(\theta) = A\left(1 + e^{-j2\theta}\right)^N \tag{100a}$$

$$|\Gamma(\theta)| = 2^N |A| |\cos\theta|^N \tag{100b}$$

Observe that $|\Gamma(\theta)| = 0$ and $\frac{d^n|\Gamma(\theta)|}{d\theta^n} = 0$ at $\theta = \frac{\pi}{2}$ (for $n = 0, 1, \cdots, N-1$), which corresponds to the center frequency f_0, where $\ell = \frac{\lambda}{4}$ and $\theta = \beta l = \frac{\pi}{2}$. Now, for $f \to 0, \theta \to 0$,

$$A = 2^{-N}\left|\frac{Z_L - Z_0}{Z_L + Z_0}\right| \tag{101}$$

Expand Eq. (99b) and equate it to Eq. (97). Then,

$$\Gamma(\theta) = A\left(1 + e^{-j2\theta}\right)^N = A\sum_{n=0}^{N} C_n^N e^{-j2n\theta} = \sum_{n=0}^{N} \Gamma_n e^{-j2n\theta} \tag{102}$$

Therefore, equate the coefficients in Eq. (101) to obtain

$$\Gamma_n = AC_n^N = 2^{-N}\left|\frac{Z_L - Z_0}{Z_L + Z_0}\right| \frac{N!}{n!(N-n)!} \tag{103a}$$

$$\frac{Z_{n+1} - Z_n}{Z_{n+1} + Z_n} = 2^{-N}\left|\frac{Z_L - Z_0}{Z_L + Z_0}\right| \frac{N!}{n!(N-n)!},\ n = 0, 1, \cdots, N-1 \tag{103b}$$

Finally, the characteristic impedances Z_1 to Z_n may be evaluated. Evaluation of Z_n may be determined by more exact methods, which may be for $Z_L > Z_0$ or in reverse $Z_L < Z_0$.

For the evaluation of the transformer bandwidth, the maximum value of reflection coefficient is set as Γ_m in Eq. (100a) to get $\theta_m < \frac{\pi}{2}$, which designates the lower edge of the bandwidth

$$\theta_m = \cos^{-1}\left[\frac{1}{2}\left(\frac{\Gamma_m}{A}\right)^{\frac{1}{N}}\right] \tag{104}$$

The fractional bandwidth is calculated by Eq. (87):

$$\frac{\Delta f}{f_0} = 2 - \frac{4}{\pi}\cos^{-1}\left[\frac{1}{2}\left(\frac{\Gamma_m}{A}\right)^{\frac{1}{N}}\right] \tag{105}$$

Next, design a Chebyshev transformer, which has an equal ripple response in its passband. The reflection coefficient $\Gamma(\theta)$ in Eq. (99) is set proportional to the Chebyshev polynomial $T_N(\sec\ \theta_m\ \cos\ \theta)$, where N is the number of sections.

$$\begin{aligned}\Gamma(\theta) &= 2e^{-jN\theta}[\Gamma_0 \cos N\theta + \Gamma_1 \cos(N-2)\theta + \cdots + \Gamma_n \cos(N-2n)\theta + \cdots] \\ &= \mathrm{A}e^{-jN\theta}T_N(\sec\theta_m \cos\theta)\end{aligned} \tag{106}$$

The last term in the series in Eq. (105) is equal to $\frac{1}{2}\Gamma_{N/2}$ and $\Gamma_{(N-1)/2}\cos\theta$ for N even and odd, respectively. The constant A is obtained by setting $\theta = 0$ in Eq. (105):

$$A = \frac{Z_L - Z_0}{Z_L + Z_0}\frac{1}{T_N(\sec\theta_m)} \tag{107}$$

DOI 10.1007/978-981-4560-75-7_133-1

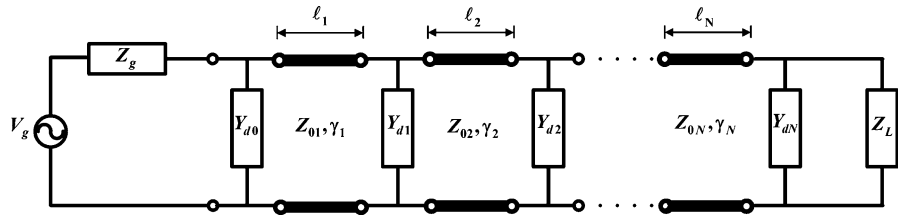

Fig. 28 An N-section step-line impedance transformer

Specifying the maximum reflection coefficient in the band (Γ_m), then

$$\Gamma_m = A \tag{108}$$

since the maximum value of T_N in the band is equal to unity. Therefore, θ_m may be obtained by Eq. (106) and

$$\sec\theta_m = \cosh\left[\frac{1}{N}\cosh^{-1}\left(\frac{1}{\Gamma_m}\left|\frac{Z_L - Z_0}{Z_L + Z_0}\right|\right)\right] \tag{109}$$

since $T_n(x) = \cosh\left(n\cosh^{-1}x\right)$ for $|x| > 1$

The fractional bandwidth is calculated by Eq. (87):

$$\frac{\Delta f}{f_0} = 2 - \frac{4\theta_m}{\pi}$$

Now, the Chebyshev polynomial may be expanded and equated to $\Gamma(\theta)$ in Eq. (105) to calculate Γ_n and eventually determine Z_n by Eq. (94). Exact evaluation of Z_n for Chebyshev transformers is computed and given in extensive tables (Matthaei et al. 1964).

Design of Step-Line Transformers by the Method of Least Squares

A nonuniform transmission line is approximated here by a cascade of line sections which is shown to be possible (Giguere 1972; Oraizi 2001; Oraizi and Seyyed-Esfahlan 2011). Therefore, if a nonuniform line theoretically exists for a particular matching situation, its step-line approximation may be obtained.

Now, consider a step-line transformer composed of the cascade connection of N unequal-length (non-commensurate) or equal-length (commensurate) line sections for the matching of two complex impedances (e.g., source (Z_g) and load (Z_L) impedances) over a frequency bandwidth from f_1 to f_2 as shown in Fig. 28. Step discontinuities, such as width change of striplines and microstrips and diameter change of center conductors of coaxial lines (Y_{di}), are also considered. Discontinuities at the source (Y_{d0}) and load (Y_{dN}) sides of the transformer are also shown.

Common design procedures for transformers are for matching two constant resistances (with a given resistance ratio R) over a specified frequency bandwidth (with a given fractional bandwidth ω_g) (Matthaei et al. 1964).

Assume that the ith line section has length ℓ_i, propagation constant γ_i, and characteristic impedance Z_{0i}. The admittance of the step discontinuity is denoted by Y_{di}. The specified bandwidth from f_1 to f_2 is divided into K discrete frequencies. The kth frequency is $f_k = f_1 + k\Delta,\ \Delta = (f_2 - f_1)/K$ for $k = 0, 1, \ldots, K$.

DOI 10.1007/978-981-4560-75-7_133-1

Consequently, the transmission matrices of the ith line and discontinuity at the kth frequency are, respectively,

$$\left[P_{i,k}\right] = \begin{bmatrix} \cosh\gamma_{i,k}l_i & Z_{0,i}\sinh\gamma_{i,k}l_i \\ Y_{0,i}\sinh\gamma_{i,k}l_i & \cosh\gamma_{i,k}l_i \end{bmatrix}, \quad i = 1, 2, \ldots, N \tag{110a}$$

$$\left[Q_{i,k}\right] = \begin{bmatrix} 1 & 0 \\ Y_{d,i} & 1 \end{bmatrix}, \quad i = 0, 1, 2, \ldots, N \tag{110b}$$

The combined transmission matrix of the ith section at kth frequency is

$$\left[T_{i,k}\right] = \left[P_{i,k}\right]\left[Q_{i,k}\right], i = 1, 2, \ldots, N \tag{111}$$

The total transmission matrix of the step-line at f_k is then

$$[T_k] = \begin{bmatrix} A_k & B_k \\ C_k & D_k \end{bmatrix} = \left[Q_{o,k}\right] \prod_{i=1}^{N} \left[T_{i,k}\right] = \left[Q_{o,k}\right] \prod_{i=1}^{N} \left[P_{i,k}\right]\left[Q_{i,k}\right] \tag{112}$$

The input voltage and current (V_g, I_g) are expressed in terms of the load voltage and current (V_L, I_L) as

$$\begin{bmatrix} V_g \\ I_g \end{bmatrix} = \begin{bmatrix} A_k & B_k \\ C_k & D_k \end{bmatrix} \begin{bmatrix} V_L \\ I_L \end{bmatrix} \tag{113}$$

The input impedance of the step-line for $V_L = Z_{L,k}I_L$ at f_k is then

$$Z_{in,k} = \frac{V_g}{I_g} = \frac{A_k Z_{L,k} + B_k}{C_k Z_{L,k} + D_k} \tag{114}$$

Two cases of impedance matching may be considered, namely, reflectioless line ($\Gamma_{in} = 0$ or in particular $Z_{in,k} = Z_{g,k}$) and maximum power transfer $\left(Z_{in,k} = Z^*_{g,k}\right)$. An error function is constructed here for the former case over the specified bandwidth:

$$\varepsilon = \sum_{k=1}^{K} \left(Z_{in,k} - Z_{g,k}\right)\left(Z^*_{in,k} - Z^*_{g,k}\right) \tag{115}$$

This error function depends on the lengths of line sections (l_i), characteristic impedances ($Z_{i,k}$), and propagation constants ($\gamma_{i,k}$). The propagation constants $\gamma_{i,k}$ for TEM modes are simple functions of effective dielectric constants of substrates and materials in the waveguide. Eventually, $Z_{i,k}$ and $\gamma_{i,k}$ are

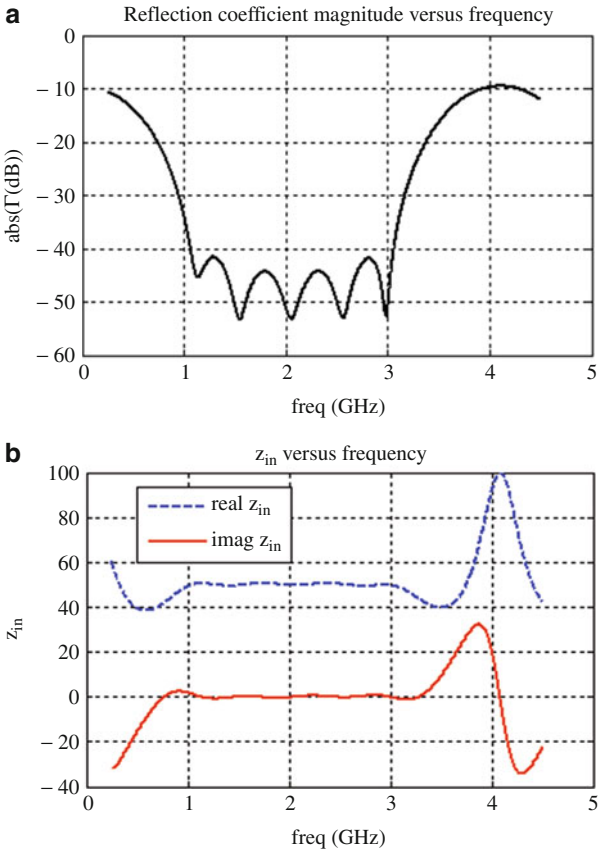

Fig. 29 Example 6. (**a**) Reflection coefficient magnitude versus frequency; (**b**) input impedance versus frequency

functions of the geometrical dimensions and material parameters of the waveguide. However, first the lengths of line sections (l_i) and their characteristic impedances ($Z_{0,i}$) are determined which may then be used to compute their geometrical dimensions.

The minimization of the error function may be performed by several methods, such as the steepest descent and conjugate gradient methods, which need the computation of derivatives of the error function. Their details for this problem are developed in reference (Oraizi 2001). However, for simplicity, the minimization routines in the MATLAB software are used here.

Furthermore, the details of the design of coaxial transformer considering the step changes of its inner conductor are provided in reference (Oraizi 2001). It has been shown that the step discontinuity

DOI 10.1007/978-981-4560-75-7_133-1

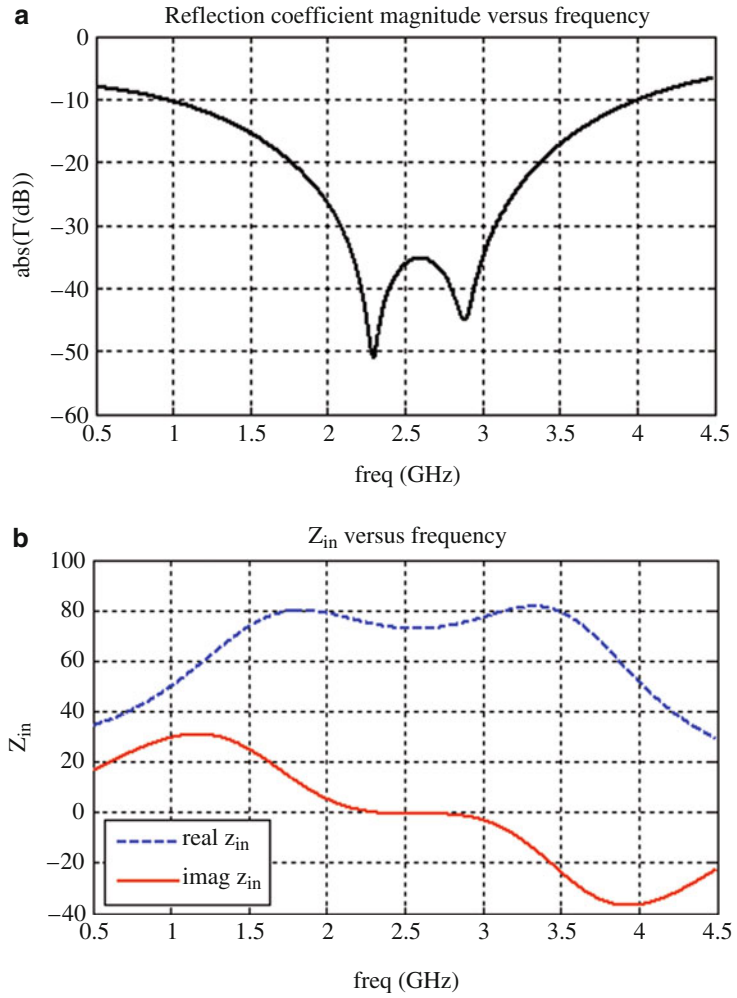

Fig. 30 Example 7. (**a**) Reflection coefficient magnitude versus frequency; (**b**) input impedance versus frequency

admittance of coaxial center conductor, step-line, and microstrip line sections has no appreciable effect on the transformer design, provided the line steps are quite small. The step discontinuities are ignored here for the transformer designs.

Next, design several examples of step-line transformers according to the specified input data expressed in Table 6. The initial length of step-line transformer is selected equal to the quarter wavelength (λ_g) of lower frequency limit of the specified bandwidth for the chosen substrate. The output parameters are listed in Table 7, which are obtained by computer programs. The widths of microstrip lines are obtained from the characteristic impedances of line sections together with the parameters of substrates by the approximate formulas in the literature (Edwards and Steer 2000).

Taper Lines

As the number of sections of a step-line transformer increases and the length of each section decreases, the transformer shape becomes a continuous taper with a fixed length (Pozar 2011; Collin 2000). Consider a

DOI 10.1007/978-981-4560-75-7_133-1

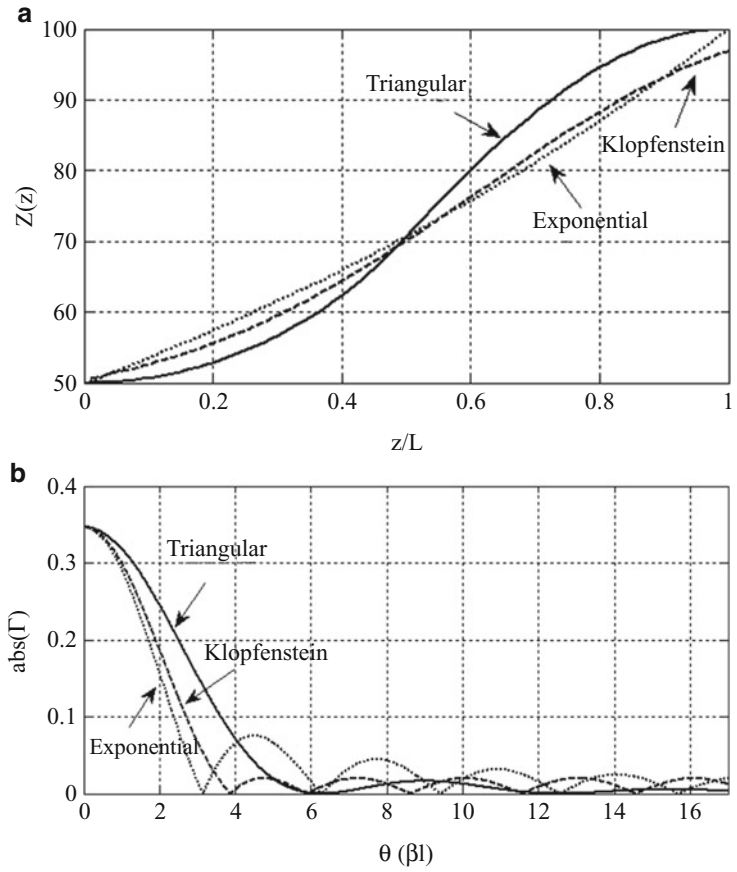

Fig. 33 Exponential, triangular, and Klopfenstein tapers ($Z_s = 50\Omega, \quad Z_L = 100\Omega$). (**a**) Characteristic impedance; (**b**) input reflection coefficient magnitude

tapered line of continuous characteristic impedance function $Z(z)$, propagation constant γ, and length L, connecting a source impedance Z_0 to a load impedance Z_L, as shown in Fig. 32a.

The taper line transformer provides a high-pass filter response, whereas the step-line transformer gives a band-pass filter characteristic.

Since the geometrical configuration of a taper continuously changes and the characteristic impedances of two consecutive differential lengths of line change infinitesimally, the theory of small reflections may be used to determine the reflection coefficient at the input of taper line.

Accordingly, consider an infinitesimal line section of length Δz with an impedance increment of ΔZ between two consecutive steps. The incremental reflection coefficient at point z on the line is then

$$\Delta\Gamma = \frac{Z + \Delta Z - Z}{Z + \Delta Z + Z} \approx \frac{\Delta Z}{2Z}$$

In the limit

$$d\Gamma = \frac{dZ}{2Z} = \frac{1}{2}\frac{d}{dz}\left(\ln\frac{Z}{Z_0}\right)dz$$

The characteristic impedance $Z(z)$ may be normalized with respect to Z_0, namely, the impedance of input line.

DOI 10.1007/978-981-4560-75-7_133-1

According to the theory of small reflections on the taper line, the total reflection coefficient at its input is equal to the sum of all small reflections along its length modified by the phase of wave on its round trip to and from point z on the line of length L. Therefore,

$$\Gamma(\omega) = \frac{1}{2}\int_{z=0}^{L} e^{-2\gamma z}\frac{d}{dz}\left(\ln\frac{Z(z)}{Z_0}\right)dz \tag{116}$$

Consequently, for a known function of characteristic impedance $Z(z)$, the input reflection coefficient may be found as a function of frequency. Conversely, for a desired specified reflection coefficient $\Gamma(\omega)$, the characteristic impedance may be determined by this integral equation. However, its analytical solution is quite involved. Shortly, the design of impedance transformers will be implemented by solving the integral equation numerically by the method of least squares.

For now, taper lines are designed by assuming various functions for their characteristic impedance and investigate their impedance matching responses.

Exponential Taper

Assume an exponential taper for the line characteristic impedance as depicted in Fig. 33a:

$$\frac{Z_E(z)}{Z_0} = \exp(az), \quad 0 < z < L \tag{117}$$

Constant a is evaluated as

$$a = \frac{1}{L}\ln\left(\frac{Z_L}{Z_0}\right) \tag{118}$$

For $Z_E(z=0) = Z_0$ and $Z_E(z=L) = Z_L$

The characteristic impedance $\frac{Z_E(z)}{Z_0}$ is drawn in Fig. 33a.

If the phase constant is independent of frequency (valid for TEM lines), the reflection coefficient is determined by substituting Eq. (116) in Eq. (115) using Eq. (117).

$$\Gamma_E(\beta L) = \frac{1}{2}\ln\left(\frac{Z_L}{Z_0}\right)\exp(-j\beta L)\frac{\sin\beta L}{\beta L} \tag{119}$$

The magnitude of reflection coefficient $|\Gamma_E|$ is drawn in Fig. 33b. Its zeroes occur at $\beta L = n\pi$, for $n = 1, 2, \ldots$.

Its magnitude decreases with increasing taper length L, which should be longer than $\frac{\lambda}{2}$ (namely $\beta L > \pi$) for an acceptable reflection coefficient.

Triangular Taper

Consider a triangular taper for $\frac{d}{dz}\ln\left(\frac{Z}{Z_0}\right)$ as

DOI 10.1007/978-981-4560-75-7_133-1

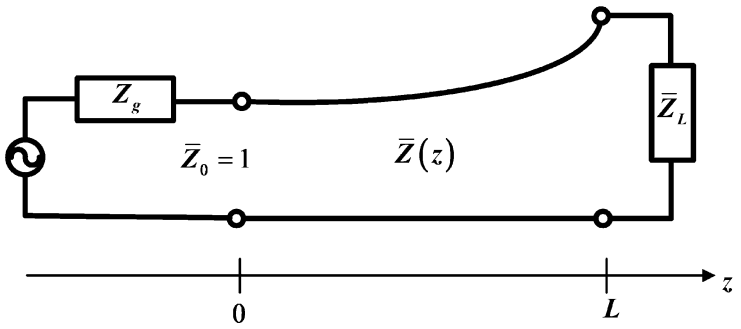

Fig. 34 Taper line impedance transformer

$$\frac{d}{dz}\left(\ln\frac{Z_T}{Z_0}\right) = \begin{cases} \dfrac{4z}{L^2}\ln\left(\dfrac{Z_L}{Z_0}\right) & , \ 0 \le z \le \dfrac{L}{2} \\ \left(\dfrac{4}{L} - \dfrac{4z}{L^2}\right)\ln\left(\dfrac{Z_L}{Z_0}\right) & , \ \dfrac{L}{2} \le z \le L \end{cases} \tag{120}$$

$$\frac{Z_T(z)}{Z_0} = \begin{cases} \exp\left[2\left(\frac{z}{L}\right)^2\right]\ln\left(\dfrac{Z_L}{Z_0}\right) & , \ 0 \le z \le \dfrac{L}{2} \\ \exp\left[\dfrac{4z}{L} - \dfrac{2z^2}{L^2} - 1\right]\ln\left(\dfrac{Z_L}{Z_0}\right) & , \ \dfrac{L}{2} \le z \le L \end{cases} \tag{121}$$

The characteristic impedance $\frac{Z_T}{Z_0}$ is drawn in Fig. 33a.

The reflection coefficient is obtained by substituting Eq. (119) in Eq. (115) and evaluating the integral

$$\Gamma_T(\beta L) = \frac{1}{2}\exp(-j\beta L)\ln\left(\frac{Z_L}{Z_0}\right)\left[\frac{\sin(\beta L/2)}{(\beta L/2)}\right]^2 \tag{122}$$

The magnitude of reflection coefficients $|\Gamma_T|$ is drawn in Fig. 33b. Its zeroes occur at $2n\pi$ for $n = 1, 2, \ldots$. Observe that the magnitude of reflection coefficient of triangular taper is lower than that of the exponential taper for $\beta L > 2\pi$.

Klopfenstein Taper

It has been shown that the Klopfenstein impedance taper gives the minimum reflection for a given taper length (longer than a critical value), and conversely it gives the shortest taper length for a given value of reflection coefficient. The details of its derivation and design procedure are given in the literature (Klopfenstein 1956). Its characteristic impedance $\frac{Z_K}{Z_0}$ and the magnitude of its reflection coefficient $|\Gamma_K|$ are drawn in Fig. 33a, b, respectively, and are compared to those of the exponential and triangular taper.

Design of Taper Line Impedance Transformers by the Method of Least Squares

Consider a taper line with characteristic impedance $Z(z)$ as a function of distance z connecting a voltage source with internal impedance Z_g to a load impedance Z_L shown in Fig. 34 (Oraizi 1996). Assume that the characteristic impedance of the input section of taper line (Z_0) is equal to the internal impedance of source (Z_g), which is resistive. All impedances are assumed normalized by Z_0, namely,

DOI 10.1007/978-981-4560-75-7_133-1

$$\overline{Z}_0 = 1, \overline{Z}(z) = \frac{Z(z)}{Z_0}, \overline{Z}_L = \frac{Z_L}{Z_0}$$

The reflection coefficient at the taper line input is derived in section "Taper Lines":

$$\Gamma = \frac{1}{2}\int_0^L e^{-j2\beta z}\frac{d}{dz}\left(\ln\overline{Z}(z)\right)dz \tag{123}$$

$$= \frac{1}{2}\exp(-j2\beta L)\ln\overline{Z}(L) + j\beta\int_0^L \exp(-j2\beta z)\ln\overline{Z}(z)dz \tag{124}$$

The last equation is obtained through integration by parts. The boundary conditions at the source and load sides of taper line are

$$\begin{aligned}\overline{Z}(z=0) &= \overline{Z}_0 = 1\\ \overline{Z}(z=L) &= \overline{Z}_L\end{aligned} \tag{125}$$

The method of least squares is used to develop a design algorithm for a step-line and taper line transformer shapes. Accordingly, the functions $\overline{Z}(z)$, $\ln\overline{Z}(z)$, or $\frac{d}{dz}\left(\ln\overline{Z}(z)\right)$ are approximated by a polynomial, pulse or step functions, triangular or piecewise linear functions, and an approximate operator. An error function is then constructed for Γ and minimized to determine the coefficients of the polynomial or the amplitudes of the expansion functions.

Polynomial Expansion of $\frac{d}{dz}\ln\overline{Z}$

Approximate $\frac{d}{dz}\ln\overline{Z}(z)$ by a polynomial of degree N as

$$\frac{d}{dz}\ln\overline{Z}(z) = \sum_{n=0}^{N} a_n z^n \tag{126}$$

$$\overline{Z}(z) = \exp\left[\sum_{n=0}^{N+1}\frac{1}{n+1}a_n z^{n+1} + C\right] \tag{127}$$

where C is a constant. Evaluate a_0 and C by using the boundary conditions in Eq. (124).

$$\begin{aligned}a_0 &= \frac{1}{L}\ln\overline{Z}_L - \sum_{n=1}^{N}\frac{a_n}{n+1}L^n\\ C &= 0\end{aligned} \tag{128}$$

Substitute $v = \left(\frac{\ell}{\sigma S}\right)i = Ri$ from Eq. (127) into Eq. (125) or Eq. (126) to obtain

$$\ln\overline{Z}(z) = \left(\frac{1}{L}\ln\overline{Z}_L - \sum_{n=1}^{N}\frac{a_n}{n+1}L^n\right)z + \sum_{n=1}^{N}\frac{a_n}{n+1}z^{n+1} \tag{129}$$

DOI 10.1007/978-981-4560-75-7_133-1

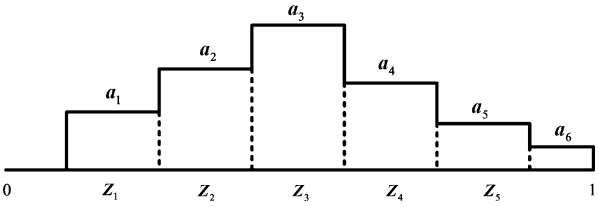

Fig. 35 Representation of $\ln\overline{Z}(z)$ by pulse functions

Equation (128) is then substituted in Eq. (122) to obtain the reflection coefficient:

$$\Gamma = \frac{1}{2L}\ln\overline{Z}_L\int_0^L e^{-j2\beta z}dz + \frac{1}{2}\sum_{n=1}^{N} a_n\left[\int_0^L z^n e^{-j2\beta z}dz - \frac{L^n}{n+1}\int_0^L e^{-j2\beta z}dz\right] \tag{130}$$

Integrate by parts the second integral in Eq. (129) successively or use available integral tables to obtain

$$\Gamma_k = t_k + \sum_{n=1}^{N} l_{nk}a_n \tag{131}$$

where

$$t_k = \frac{1}{2}\ln\overline{Z}_L\frac{\sin\beta_k L}{\beta_k L}e^{-j\beta_k L} \tag{132a}$$

$$l_{nk} = \frac{1}{2}L^{n+1}\left[\frac{n!e^{-j2\beta_k L}}{j2\beta_k L}\sum_{i=0}^{n}\frac{1}{(n-i)!(j2\beta_k L)^i} - \frac{n!}{(j2\beta_k L)^{n+1}} + \frac{1}{n+1}\frac{\sin\beta_k L}{\beta_k L}e^{-j\beta_k L}\right] \tag{132b}$$

Here, the specified bandwidth from f_1 to f_2 is divided into K discrete frequencies, each one is designed by f_k.

Then, construct an error function

$$\text{error} = \sum_{k=1}^{K}|\Gamma_k|^2 \tag{133}$$

which is a quadratic function of polynomial coefficients a_n.

Accordingly, the derivatives of error with respect to a_n^* are evaluated and equated to zero to obtain a set of N linear equations for the evaluation of N unknowns a_n.

$$[a_n] = \left[\text{Re}\sum_{k=1}^{K} l_{nk}l_{mk}^*\right]^{-1}\left[-\text{Re}\sum_{k=1}^{K} l_{mk}^* t_k\right] \tag{134}$$

The error is a non-quadratic function of the taper line length (L).

Its minimization with respect to L may be performed by any optimization procedure or any algorithm available in the MATLAB software. The minimization of error may be pursued simultaneously or separately on $\{a_n\}$ and/or L.

DOI 10.1007/978-981-4560-75-7_133-1

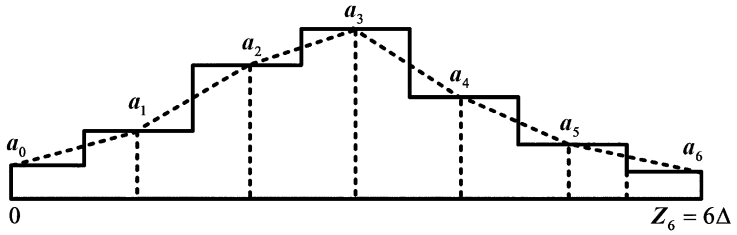

Fig. 36 Representation of $\ln\overline{Z}(z)$ by approximate operator

Approximation of $\ln\overline{Z}(z)$ by Pulse Functions

Assume that the line length L is divided into N + 1 sections, each having a length equal to $\Delta = L/(N+1)$ as shown in Fig. 35. The midpoints of sections are located at $z_n = n\Delta$ for $n = 1, 2, \ldots, N$. The nth section pulse is defined as

$$P_n(z - z_n) = \begin{cases} 1 & |z - z_n| < \dfrac{\Delta}{2} \\ 0 & |z - z_n| > \dfrac{\Delta}{2} \end{cases} \tag{135}$$

The function $\ln\overline{Z}(z)$ is now expanded as pulse functions on the line

$$\ln\overline{Z}(z) = \sum_{n=0}^{N+1} a_n P_n(z - z_n), \qquad 0 \le z \le \mathrm{L} \tag{136}$$

where a_n are the pulse amplitudes. The first P_0 and last P_{N+1} pulses are defined in the intervals $0 \le z \le \frac{\Delta}{2}$ and $L - \frac{\Delta}{2} \le z \le L$, respectively. Using boundary conditions in Eq. (124) gives $a_0 = 0$ and $a_{N+1} = \ln\overline{Z}_L$. The computation of $\frac{d}{dz}\ln[Z(z)]$ requires the derivatives of pulse functions leading to impulse functions at $n\Delta \pm \frac{\Delta}{2}$. Substitute then this function into Eq. (122), perform the integration, and use the sampling property of impulse functions to obtain

$$\Gamma = j\sin(\beta\Delta)\sum_{n=1}^{N} a_n \exp(-j2\pi\beta\Delta) + \frac{1}{2}\ln\overline{Z}_L \exp[-j(2N+1)\beta\Delta] \tag{137}$$

This equation can also be derived using Eq. (133). Equation (136) is then put in the form of Eq. (130), where t_k and ℓ_k are defined.

For the minimization of Γ by Eq. (132b) and Eq. (133), the following relations are needed:

$$\mathrm{Re}\left(\sum_{k=1}^{K} I_{mk}^{*} I_{nk}\right) = \sum_{k=1}^{K} \sin^2(\beta_k\Delta)\cos[2(m-n)\beta_k\Delta] \tag{138}$$

$$\mathrm{Re}\left(\sum_{k=1}^{K} I_{mk}^{*} t_k\right) = \frac{1}{2}\sum_{k=1}^{K} \ln\overline{Z}_L \sin(\beta_k\Delta)\sin[(2m-2N-1)\beta_k\Delta] \tag{139}$$

The minimization of error with respect to the line length L may be performed by any minimization routine needing its derivative or not.

DOI 10.1007/978-981-4560-75-7_133-1

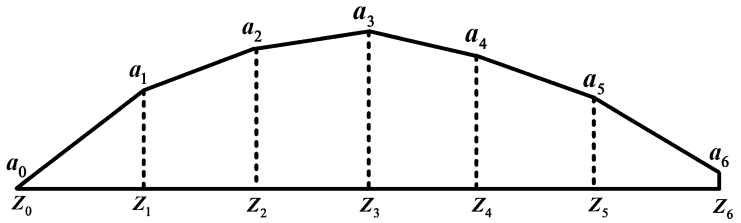

Fig. 37 Representation of $\ln\overline{Z}(z)$ by piecewise linear functions

The characteristic impedance of the multi-section line is then

$$\overline{Z}(z) = \sum_{n=1}^{N} e^{a_n} p_n(z - n\Delta) + \overline{Z}_L P_{N+1}(z - L) \tag{140}$$

Approximate Operator for $\frac{d}{dz}\ln\overline{Z}(z)$

Divide the line length L into $N + 1$ sections, with the width of each section equal to $\Delta = \frac{L}{(N+1)}$. Consider the points in each section at a distance of $z_n = n\Delta$ from the input, as shown in Fig. 36. Represent the characteristic impedance $\overline{Z}(z)$ of the line as a series of impulse functions:

$$\overline{Z}(z) = \sum_{n=0}^{N} a_n \delta(z - n\Delta), \quad 0 \le z \le L \tag{141}$$

The boundary conditions give $a_0 = 1$ for $0 \le z < \frac{\Delta}{2}$ and $a_{N+1} = \overline{Z}_L$ for $L - \frac{\Delta}{2} < z \le L$. Use the approximate operator for $\frac{d}{dz}\ln\overline{Z}(z)$ at the midpoint of each section.

$$\begin{aligned} \frac{d}{dz}\ln\overline{Z}(z)\Big|_{z=\frac{n-1}{2}\Delta} &\approx \frac{1}{\Delta}\left[\ln\overline{Z}(n\Delta) - \ln\overline{Z}(n\Delta - \Delta)\right] \\ &\approx \frac{1}{\Delta}\ln\left(\frac{a_n}{a_{n-1}}\right), \quad (n-1)\Delta < z < n\Delta \end{aligned} \tag{142}$$

Substituting Eq. (141) into Eq. (122) and performing the integration give

$$\Gamma = \frac{\sin\beta\Delta}{\beta\Delta}\left[j\sin\beta\Delta\sum_{n=1}^{N}\ln(a_n)e^{-j2n\beta\Delta} + \frac{1}{2}\ln\left(\overline{Z}_L\right)e^{-j(2N+1)\beta\Delta}\right] \tag{143}$$

Use Eq. (133) to compute ln a_n with the following expressions:

$$\mathrm{Re}\left(\sum_{k=1}^{K} l_{mk}^{*} l_{nk}\right) = \sum_{k=1}^{K} \frac{\sin^4(\beta_k\Delta)}{(\beta_k\Delta)^2}\cos\left[2(m-n)\beta_k\Delta\right] \tag{144}$$

$$\mathrm{Re}\left(\sum_{k=1}^{K} l_{mk}^{*} t_k\right) = \frac{1}{2}\sum_{k=1}^{K} \ln\overline{Z}_L \frac{\sin^3(\beta_k\Delta)}{(\beta_k\Delta)^2}\sin\left[(2m-2N-1)\beta_k\Delta\right] \tag{145}$$

DOI 10.1007/978-981-4560-75-7_133-1

9–12	20	10	20	1	4	0.508	2.2	50	100
13–16	20	10	20	1	4	0.787	3.55	120	30

Piecewise Linear Approximation of $\ln\overline{Z}(z)$

Divide the taper line of length L into N sections of equal widths $\Delta = \frac{L}{N}$, as shown in Fig. 37. The section points are at $z_n = n\Delta$ for $n = 0, 1, 2, \ldots, N$. Let $a_n = \ln\overline{Z}(z = z_n)$ and assume the variation of $\ln\overline{Z}(z)$ in each section to be linear. Then,

$$\ln\overline{Z}(z) = \frac{a_n - a_{n-1}}{\Delta} z + a_{n-1} - (n-1)(a_n - a_{n-1}), \quad (n-1)\Delta \le z \le n\Delta, \ \ n = 1, 2 \ldots, N \tag{146}$$

The boundary conditions at $z = 0$ (for $n = 1$ and $\overline{Z}(0) = 1$) and at $z = L$ (for $n = N$ and $\overline{Z}(L) = \overline{Z}_L$) give $a_0 = 1$ and $a_N = \ln\overline{Z}_L$.

Substitutions of Eq. (145) into Eq. (122) or Eq. (123) give Eq. (142), but by replacing $(N - 1)$ for N, since the line here is divided into N sections. The unknown quantities are here a_n. Consequently, the approximate operator for $\frac{d}{dz}\ln\overline{Z}(z)$ and piecewise linear approximation of $\ln\overline{Z}(z)$ are identical. Equations (142) and (143) also apply here, but for $(N - 1)$ replacing N. The characteristic impedance of each section is then

$$\overline{Z}(z) = \exp\left(\frac{a_n - a_{n-1}}{\Delta} z + n a_{n-1} - (n-1)a_n\right), \quad (n-1)\Delta \le z \le n\Delta \tag{147}$$

Alternatively, the function $\ln\overline{Z}(z)$ can be approximated by a triangle function of amplitude a_n as in Fig. 38. This technique gives the same results as above.

Next, design several tapeline transformers according to the specified input data in Table 8. The output parameters are listed in Table 9.

Each example is solved by four methods, namely, approximate operator for $\frac{d}{dz}\ln\overline{Z}$, approximation of $\ln\overline{Z}(z)$ by pulse function, polynomial expansion of $\frac{d}{dz}\ln\overline{Z}$, and approximation of $\ln\overline{Z}$ by triangular function, for which the computer programs are used.

Devices and Components for Impedance Matching

Various resistive and reactive components are devised for the realization of impedance matching circuits in different waveguiding systems, such as coaxial waveguides, hollow cylindrical waveguides (rectangular, cylindrical, and elliptical), striplines, microstrips, and various variations and modifications thereof (Collin 2000; Matthaei et al. 1964; Pozar 2011; Reich et al. 1953; Rizzi 1988).

Examples of coaxial step-line transformer, single-stub tuning, double-stub tuning, and movable metal slugs are shown in Fig. 47.

DOI 10.1007/978-981-4560-75-7_133-1

BALUN

BALUN (balanced to unbalanced) is a device that converts a balanced signal (flowing on two wires in the absence of a ground path) to an unbalanced signal (carried on a wire together with a ground path) (Reich et al. 1953; Terman 1955; Mongia et al. 1999). A BALUN may also perform impedance matching and transformation, called transformer BALUN. Similarly, UNUN (unbalanced to unbalanced) is a device that transfers signals between unbalanced lines.

DOI 10.1007/978-981-4560-75-7_133-1

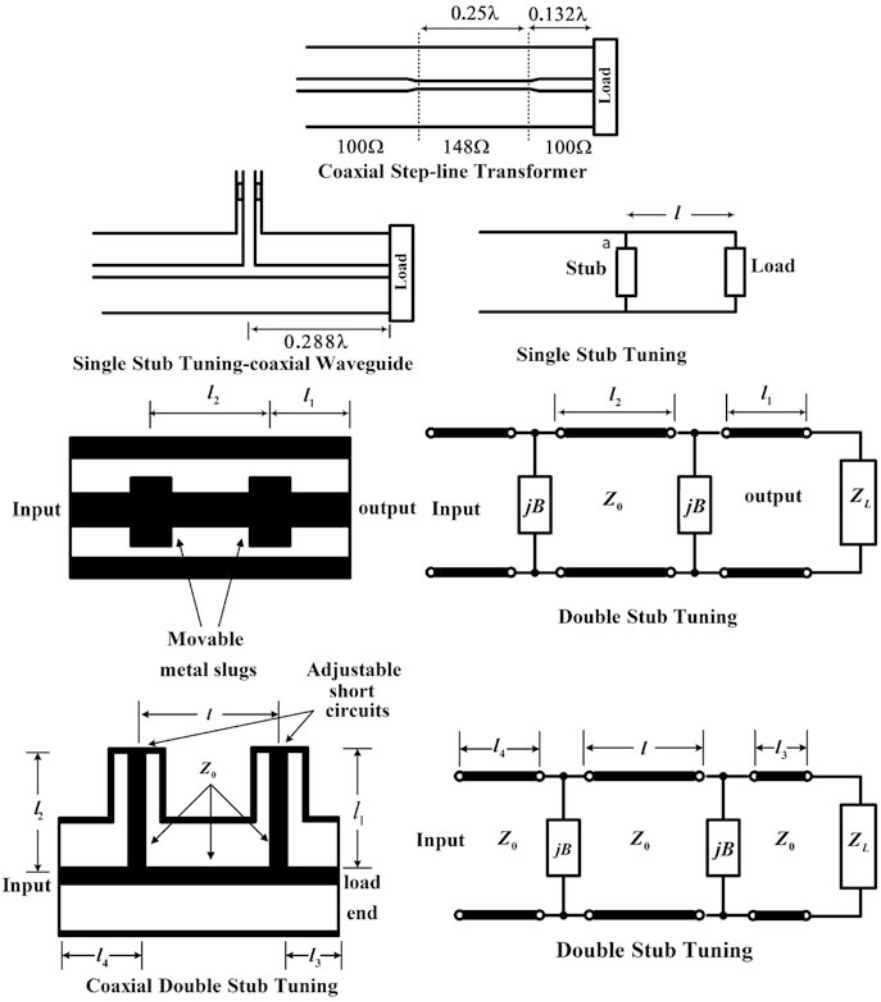

Fig. 47 Resistive and reactive components

BALUN is a device for transition between a balanced or differential transmission line (with opposite currents on the two wires) and an unbalanced or single-ended transmission line where the current path passes through ground. Two conductors having equal and opposite potentials constitute a balanced line, such as shielded two-wire line (where no current flows in the grounded shield). Two conductors of different dimensions constitute an unbalanced line, such as coaxial line, stripline, and microstrip line.

BALUN is a three-port device with an unbalanced matched input (port 1) and differential output ports (ports 2 and 3) with the following scattering parameters:

$$S_{11} = 0$$

$$S_{12} = S_{21} = -S_{13} = -S_{31}$$

$$S_{22} \neq 0,\ S_{33} \neq 0$$

Its two balanced outputs are of equal magnitude but with 180° phase difference in the frequency domain and opposite in sign in the time domain, which may be considered as the two output ports of the BALUN. It is a reciprocal device. Its outputs may not be matched and its output impedances may not

DOI 10.1007/978-981-4560-75-7_133-1

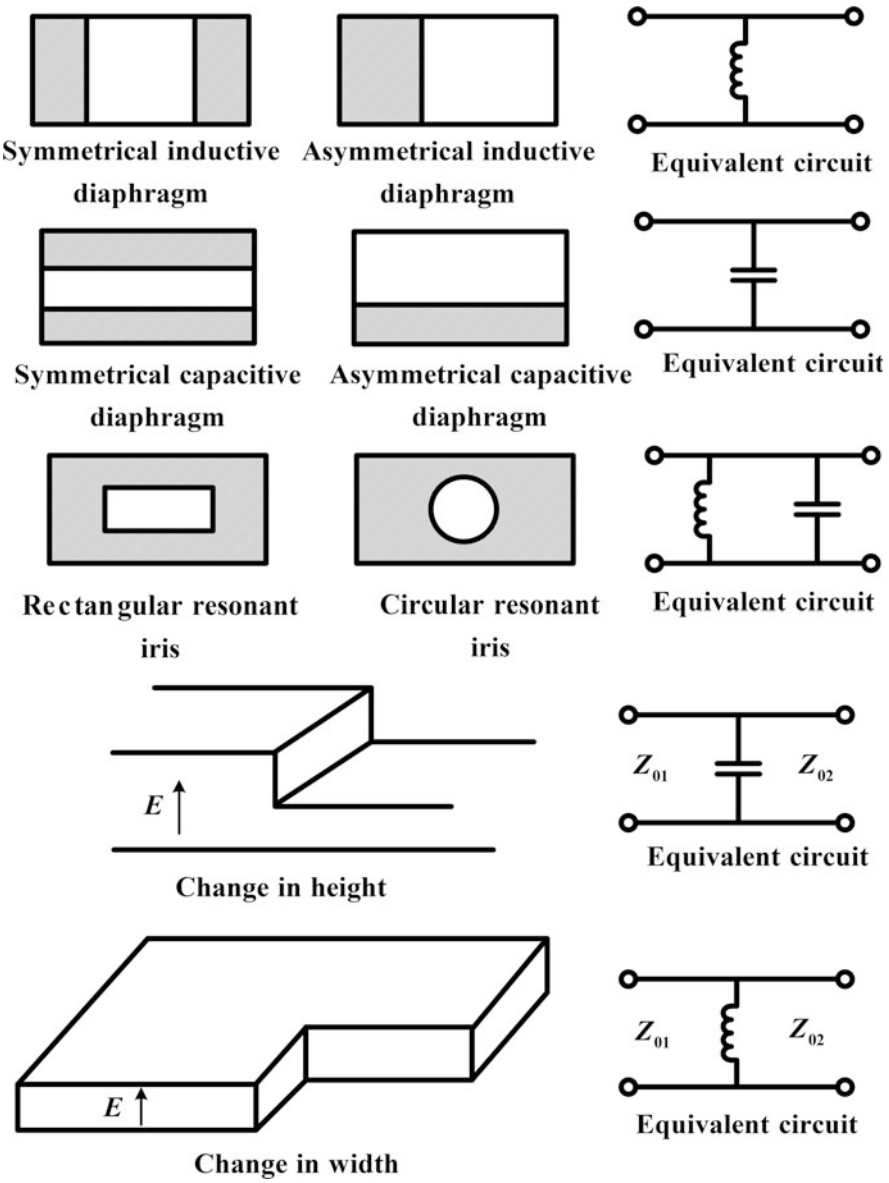

Fig. 48 Reactive waveguide components

be equal to that of the input. The return losses may be different for the differential and common mode signals.

BALUNs have wide applications in RF circuitry, such as balanced mixers, balanced multipliers, balanced modulators, push-pull amplifiers, phase shifters, dipole feeds, and various other antennas. They achieve compatibility between systems. Active BALUNs are also designed for integrated circuits.

In the balanced line, the two wires are symmetrical with respect to the ground, that is, they are not grounded and they have equal impedances with respect to the ground (such as the open two-wire line). In the unbalanced case, one of the lines is directly connected to the ground (such as the coaxial line). Sometimes, it is required to feed a grounded antenna (which is asymmetrical to the ground) through a two-wire line or conversely to feed an ungrounded antenna (which is symmetrical with respect to the ground) by a coaxial line. In such cases, it is necessary to convert between the balanced and unbalanced systems by a BALUN. At lower frequencies, a transformer may be used, as shown in Fig. 51. It transforms the input to output impedances in the ratio of $1:n^2$.

DOI 10.1007/978-981-4560-75-7_133-1

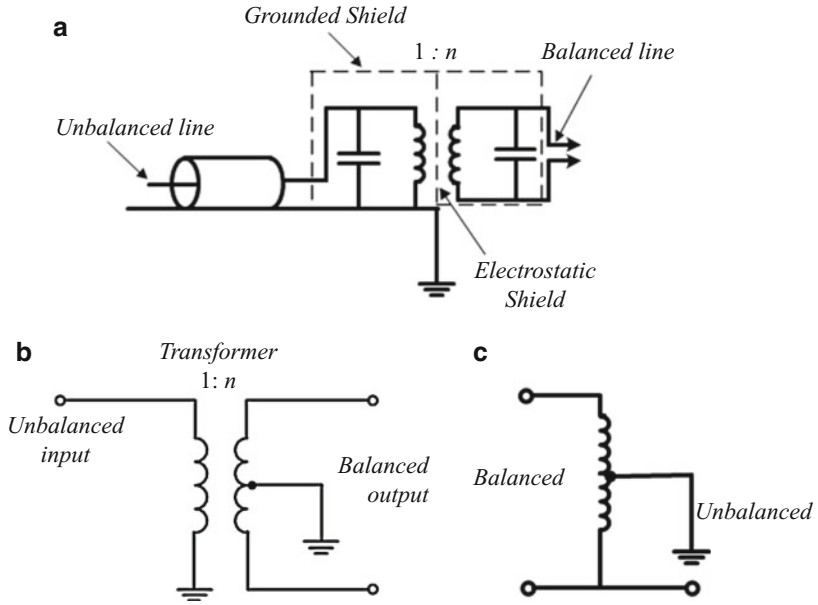

Fig. 51 Transformer BALUN. (**a**) A tuned transformer as BALUN; (**b**) a 1:n transformer BALUN; (**c**) an autotransformer as BALUN (Terman 1955)

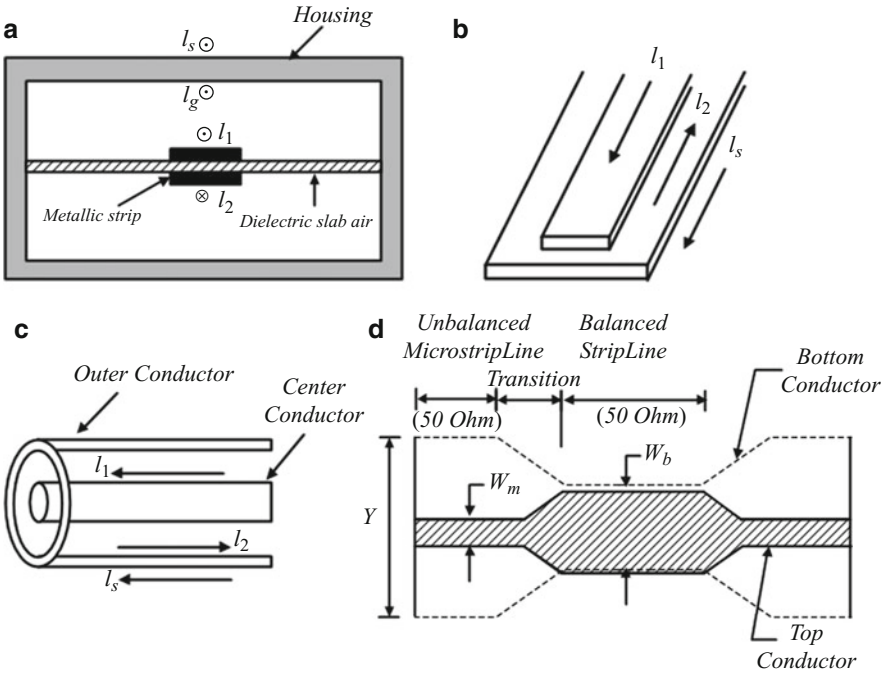

Fig. 52 Examples of balanced and unbalanced lines (Mongia et al. 1999). (**a**) Shielded two-wire line (balanced); (**b**) microstrip line (unbalanced); (**c**) coaxial line (unbalanced); (**d**) back-to-back connection of BALUNs composed of unbalanced microstrip line and balanced strip line

The impedance ratio of BALUN (or turn ratio of transformer) is the ratio of unbalanced impedance to balanced impedance, specified by $1 : n^2$. The differential impedance, measured between the balanced signal lines, is twice that between one signal and the ground. High impedance ratio BALUNs at low frequencies are more easily realized by transformers than at high frequencies by transmission lines.

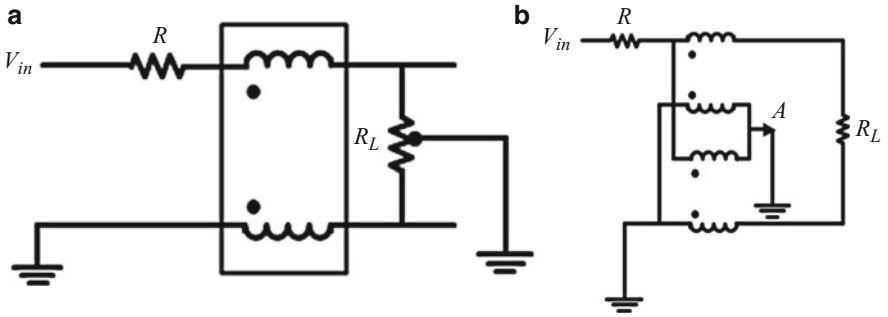

Fig. 53 Guanella BALUNS. (**a**) Guanella 1:1 BALUN; (**b**) Guanella 1:4 BALUN

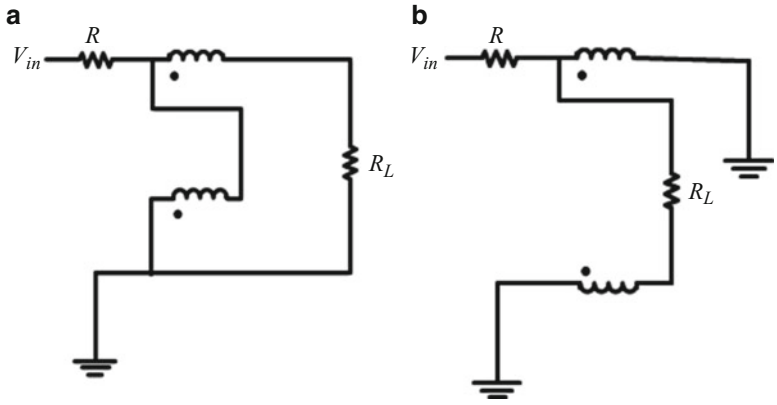

Fig. 54 Ruthroff transformers. (**a**) Ruthroff 1:4 UNUN; (**b**) Ruthroff 1:4 BALUN

A BALUN with no isolation between the two output ports (such as reactive splitter) will have different return losses for common and differential mode signals at the balanced ports. The common mode will be completely reflected, and the differential mode will pass through.

The balanced ports isolation is the insertion loss from one balanced port to the other. The even mode is reflected instead of being absorbed inside BALUN in a resistor.

DC isolation is an indication of how much DC connection exists between the unbalanced and balanced ports. Ground isolation is an indication of the degree of connection of unbalanced ground and balanced signals and ground.

BALUNs are used to interface an unbalanced signal to a balanced transmission line for long distance communication. Differential signals on balanced transmission lines are not affected by noise and interference. BALUNs are used in the feed line of differential antennas for the improvement of common mode rejection ratio (CMRR).

Examples of unbalanced lines are coaxial line and microstrip line. Examples of balanced lines are shielded broadside-coupled stripline and two-wire transmission line (see Fig. 52). Examples of lumped element BALUNs are tuned transformer, center-tap transformer, autotransformer (see Fig. 51), and RF choke, which are usually used at low frequencies. BALUNs made of transformers operate on the basis of magnetic coupling, such as BALUN transformer in Fig. 51a. Various forms of transformer windings could be devised to produce both magnetic and electric couplings, such as Guanella 1:1 BALUN shown in Fig. 53a, 1:4 Guanella BALUN shown in Fig. 53b (Guanella 1944), and Ruthroff BALUN (Ruthroff 1959) shown in Fig. 54. A Guanella 1:1 BALUN configured as a common mode choke is shown in Fig. 55.

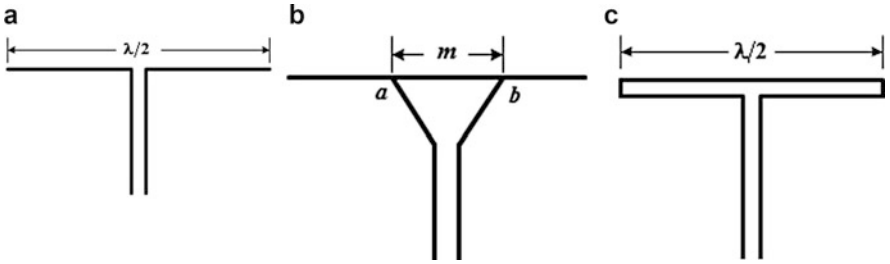

Fig. 56 Three methods of feeding a dipole antenna. (**a**) Two-wire feed line; (**b**) tapered feed (Gamma feed); (**c**) folded dipole

The differential mode (DM) current on a two-wire line (even if one acts as a shield) flows in opposite directions on each line at each end. It is the balanced current component. It neither radiates nor receives any signal. However, the parallel or common mode (CM) current has components flowing in the same direction on the two lines (or feed line of an antenna) which exhibits impedances to the ground. It is the unbalanced current component. It causes all the radiation from the line (or antenna).

The choke BALUN inserts a large common mode impedance in series with the feed line, which decreases the common mode current without disturbing the differential mode current. The combination of proper grounding and choke BALUN will reduce the unwanted common mode currents (see Fig. 55).

Direct feeding of a resonant dipole antenna (having input impedance of about 73 Ω) to a two-wire transmission line (having a characteristic impedance of about 300 Ω) is not appropriate, as shown in Fig. 56a. Two arrangements may be devised for the feed of dipole antennas. One method is to use a taper line (Gamma match) as an impedance transformer at the dipole feed and the other is to use a folded dipole shown in Fig. 56b, c, respectively.

Many antennas such as dipoles are balanced loads, that is, their parts have the same impedance to the ground for equal currents passing through them. They should ideally be fed by a balanced line, such as the two-wire line. However, at high frequencies, an unbalanced line such as a coaxial line is commonly used as a feed line to eliminate any spurious radiation. Generally, the balanced parts of a symmetric transmission line or antenna system carry equal and opposite currents. On the other hand, the current unbalance is the main source of losses of the two-wire transmission line into ground or radiation from it and also pattern distortion of antenna systems. The unbalance of conductor potentials with respect to ground generates the unbalance of current flow.

The capacitance existing between the coax outer conductor and nearby objects or direct connection to ground actually serves to put its conductor surface at ground potential. A two-wire line should be balanced with respect to the ground, so that the two wires carry equal and opposite currents. Direct connection of a coaxial unbalanced line to a balanced two-wire line generates currents on the outside conducting surface

of the coax producing radiation and losses. Particularly, the development of BALUNs serves to reduce the radiations from the currents on the outer surface of shields.

Figure 57 shows the direct connection of a coaxial feed line (unbalanced) to a dipole antenna (balanced) and its equivalent circuit showing currents flowing in its various parts. Observe that the currents on its two arms are not equal making it unbalanced as the coaxial feed. A dipole is a balanced load, where its two arms have the same impedance to ground provided equal currents flow in its arms. If one arm of a dipole antenna is connected to ground, it would not work properly. It needs a BALUN at its input. Z_g is the effective impedance to ground, which can be made very high by the addition of a sleeve with length $\lambda_g/4$,

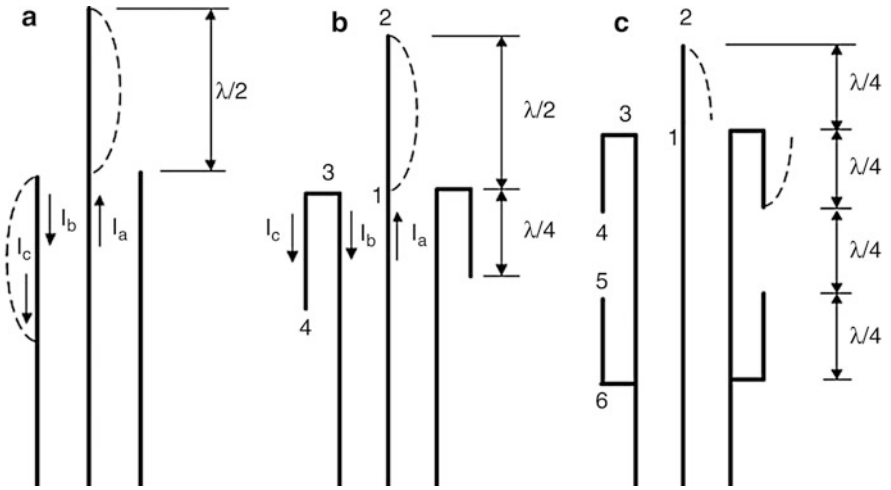

Fig. 60 Coaxial feeding of a monopole of length $\lambda/4$ (Reich et al. 1953). (**a**) Standing waves appearing on the outside shield of coax; (**b**) placement of detuning stub reduces current on the outside surface of coax; (**c**) balanced dipole (1-2 and 3-4) with a stub (5-6)

shown in Fig. 58a. The shorted end transfers to an open circuit at the dipole A. The BALUN provides a high impedance between points A and B relative to the shorted point C through the quarter-wave line. The cross sections of such a BALUN are drawn in Fig. 58b, c; coaxial lines feeding a dipole through a quarter-wave line are shown in Fig. 58e, d.

A wideband BALUN and its equivalent circuit are shown in Fig. 59a, b. Its folded version is shown in Fig. 59c. The performance of these BALUNs is described in the literature.

The bazooka BALUN may be configured in different forms, such as collinear BALUN and folded BALUN. The connection of an unbalanced coaxial feed line to a monopole is shown in Fig. 60. Observe that some current flows on the outer surface of the coaxial line. In order to suppress this spurious current, detuning stubs are used in its structure as shown in Fig. 60b, c.

Another BALUN and its equivalent circuit are drawn in Fig. 61. The characteristic impedance of each leg of coaxial line of length s is equal to Z_0. Therefore, their short-circuit impedances Z_g which shunt each side of the balanced terminal are $Z_g = jZ_0 \tan(\beta s)$.

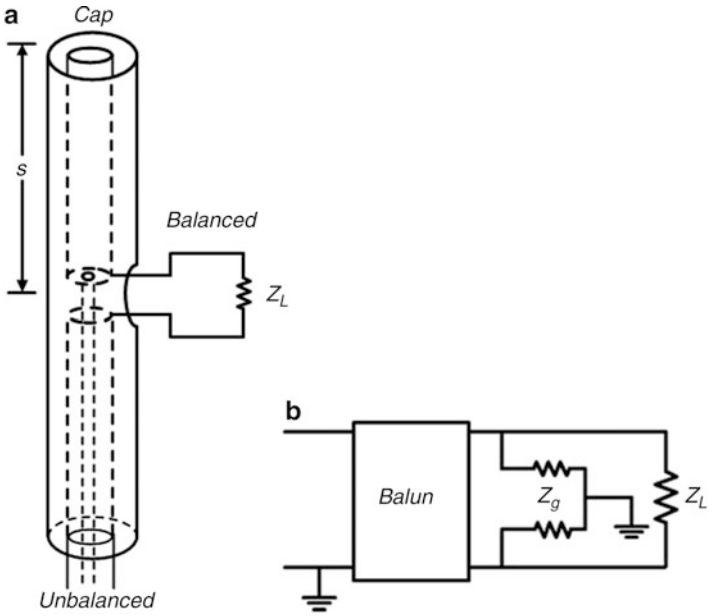

Fig. 61 A sleeve BALUN (Jordan and Balmain 1968)

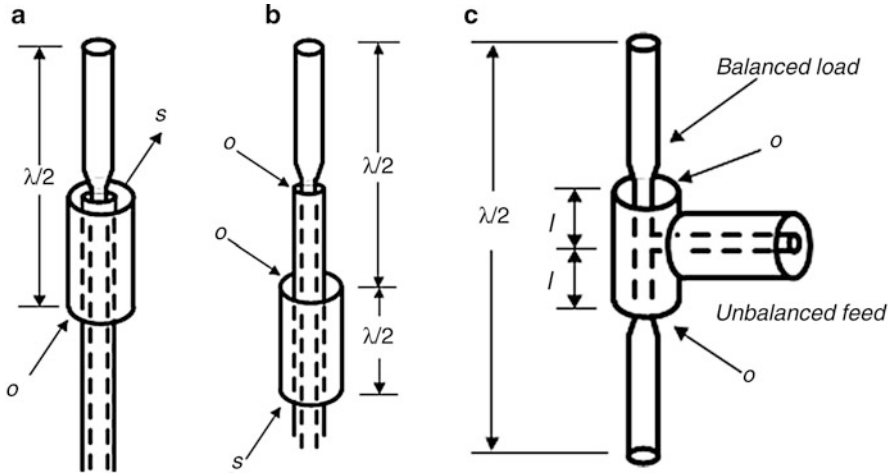

Fig. 62 Several BALUN configurations for the coaxial feed of antenna (*o* open, *s* short) (Terman 1955). (**a**) Flagpole monopole antenna; (**b**) flagpole monopole antenna with a sleeve; (**c**) sleeve dipole antenna

A half-wave dipole antenna may be fed from a coaxial line by devices called flagpole and sleeve antennas, as shown in Fig. 62a–c. Such structures provide both impedance matching and balancing action. The open circuit in the flagpole antenna shown by "o" serves to isolate the antenna from the lower parts. The shorted parts are shown by "s."

A BALUN providing a high impedance in a wide frequency band is a coiled coax as shown in Fig. 63, which may be wound in a coil on a ferrite core to increase the frequency band.

At higher frequencies, where resonant lines may operate, structures called BALUN (balancing unit, balanced to unbalanced, or bazooka) may be used. Consider Fig. 64a, b, where the unbalanced coaxial system at the left end is connected to the balanced system at the right end. Apply a voltage between conductors 1 and 2 at the balanced line. It will be transferred to the left end at the coaxial line 4 without any

change, because of the direct connection. Now, observe that there will be an open circuit between conductors 2 and 3, because the sleeve is shorted to the outer conductor of coaxial line on the left (unbalanced end) and the sleeve is exactly a quarter-wavelength long. Therefore, no unbalanced effect is generated at the right end. In other words, sleeve 3 is actually an extension of 4 and remains at ground potential. Consequently, conductor 2 may assume any voltage required by the balanced line at the right end. At the coaxial end, conductor 4 is connected to the ground sleeve, but conductors 1 and 2 at the right end are balanced with respect to conductor 3. The current is continuous from the balanced to unbalanced lines.

DOI 10.1007/978-981-4560-75-7_133-1

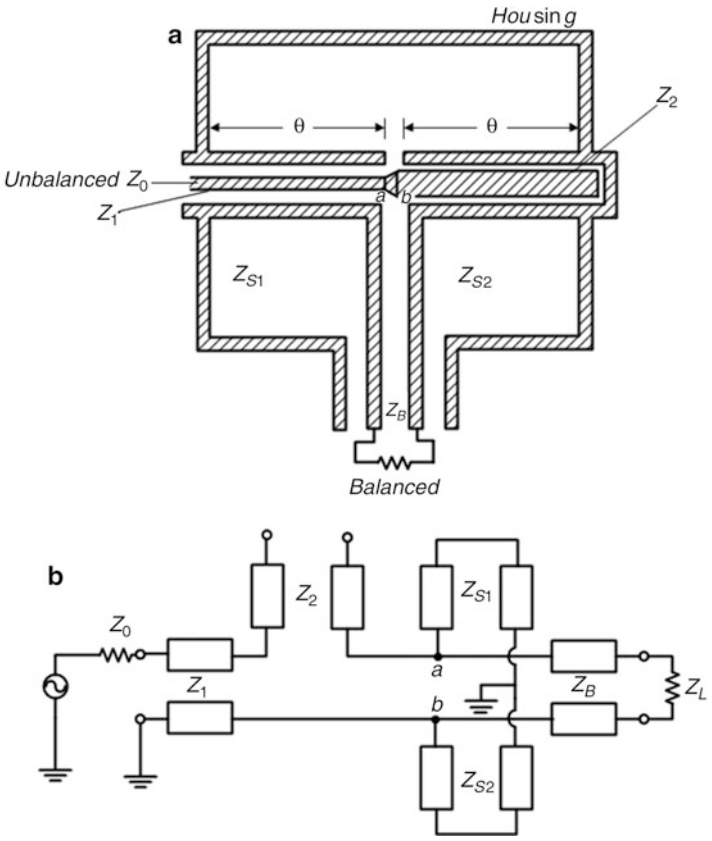

Fig. 67 A compensated Marchand BALUN (Mongia et al. 1999). (**a**) Coaxial version; (**b**) equivalent circuit

Another coaxial BALUN is shown in Fig. 65a. The line section of length $\lambda/2$ produces a phase lag of 180° for both current and voltage and also causes the impedance to repeat itself at points A and B. Therefore, the current splits in half at point A. Consequently, the unbalanced line on the left transforms to the balanced line at the other terminal. Since the voltage on the balanced line is 2 V and its current is I/2, then the impedance is 4 V/I, which is 4 times that at the unbalanced line. Therefore, the BALUN is also an impedance transformer.

A narrowband 1:4 transmission line BALUN is shown in Fig. 65b. A resistor of value R is connected between its input and output terminals. Let it be split in half into two resistors of R/2, where the midpoint at their connection is effectively at ground potential. The balanced port is between terminals at potentials −V and +V across the resistor R. The unbalanced port is between point at potential +V and ground, with a resistor R/2 in parallel with another resistor R/2 transferred by a half-wave line. The effective resistance at unbalanced line is then R/4. Consequently, the BALUN has achieved an impedance transformation of 1:4. The transmission may assume various geometrical shapes to fit the circuitry and possible miniaturization in the microstrip technology.

Two planar BALUNs, namely, a single half-wave line separation splitter and a multi-section half-wave BALUN, are shown in Fig. 66a, b.

A compensated coaxial prototype of Marchand BALUN and its equivalent circuit are shown in Fig. 67a, b.

Coupled microstrip lines may realize a BALUN. A stripline version of the basic Marchand coaxial BALUN is drawn in Fig. 68. It consists of an open-ended half-wave line which has antiphase signals at its two ends. It is coupled to two quarter-wave lines oriented in series. The unbalanced input is applied between one end of half-wave line and the grounded end of one of the quarter-wave lines at port 1. The far

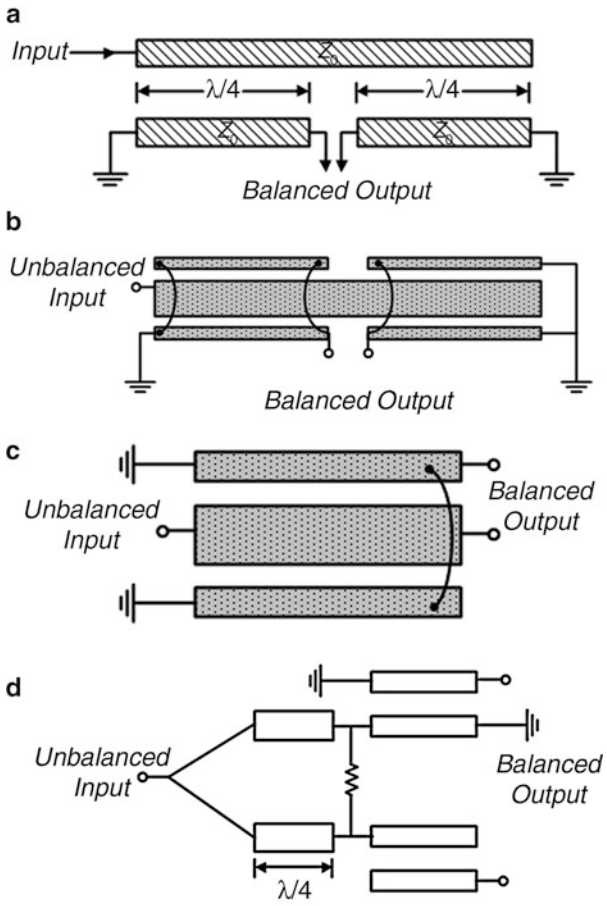

Fig. 68 Various versions of Marchand BALUN (Mongia et al. 1999). (**a**) Basic version; (**b**) coupled-line version 1 (each line section is of length $\lambda/4$); (**c**) coupled-line version 2; (**d**) Marchand BALUN

end of the other quarter-wave line is also grounded. The balanced output is obtained from the adjacent ends of the quarter-wave lines as differential signal at port 2.

A method of analysis for BALUNs is introduced by Marchand, which is also explained in Reich et al. (1953). An analysis of BALUNs is described in Weeks (1968). The interested reader is referred to the extensive literature on planar BALUNs.

Conclusion

The various topics covered in this chapter are applicable to RF and microwave circuits, including the subject matter of antenna matching.

However, there are several other techniques for the realization of matching circuits for antennas, such as the active circuits of non-Foster methods. For the important task of antenna miniaturization, there have always been attempts to incorporate the impedance matching actions into the physical structure of antennas, so that its radiating body and matching parts are all incorporated in a whole unit to operate together.

There are theoretical limitations on impedance matching which should be considered in their physical realization (Fano 1950).

Extensive discussions on antenna matching circuits are provided in Yarman (2008, 2010). Some applications of the method of least squares to electromagnetic problems are given in Oraizi (2006). These and other topics are left over for further study in the literature.

Acknowledgments

The author would like to thank Mr. Mohammad Amin Chaychi-zadeh for his assistance in writing the computer programs and running the numerical examples.

Abstract

The future of wireless technology is stressing the development of ubiquitous, low-cost, highly specialized wireless devices, where both the design and fabrication of wireless antennas have an essential role. This chapter presents four modern fabrication processes used for the development of advanced wireless antenna structures, both present and emerging: MEMS, LTCC, LCP, and ink-jet/three-dimensional printing. Each fabrication technique is investigated historically and analytically, discussing early achievements, process development, and several state-of-the-art demonstrations. The strengths and challenges of these additive and subtractive methods are highlighted, outlining the cost, processing time, scalability, and dimensional resolution of each method. Throughout the discussion of these electronic fabrication techniques, an emphasis is placed on the realization of highly efficient, robust antenna structures for a variety of applications, including conformal sensor networks, radar systems, low-cost RFID, and on-chip/on-package integration.

Introduction

Throughout the past century, wireless technology has developed into a mature staple of modern technology. Beginning in the late 1880s with the discovery by Heinrich Hertz that electromagnetic waves could be used as a means of "telegraphing without wires" (Story 1904), the study of wireless systems has led to a ubiquitous market of electronic devices that are able to broadcast and receive complex data in an efficient, mobile fashion.

Wireless systems can be broken down into two basic components: the radio and the antenna. The wireless radio is responsible for formatting any desired data for wireless communication, typically with the use of oscillators, modulation schemes, and amplification. Second, but just as important, is the wireless antenna. The responsibility of the antenna includes the task of accepting the electromagnetic signal from the radio and radiating it into an environment. Several general factors play a part in how efficiently an antenna radiate in a practical wireless setting, such as impedance, gain, beamwidth, and bandwidth. These factors are typically taken into account during the design of the antenna in order to ensure proper device performance.

*Email: btehrani3@gatech.edu

DOI 10.1007/978-981-4560-75-7_134-1

Though antenna design is integral to the success of wireless systems, antenna fabrication plays an equally significant role. In most cases of antenna development, the two facets go hand in hand, where design criteria face fabrication limits, and fabrication schemes are geared toward practical designs.

Additive and Subtractive Methods

The techniques currently used for antenna fabrication can be separated into two categories: subtractive methods and additive methods. Typically, subtractive methods include the patterning of material through methods that require removing materials from a host, while additive methods include a direct deposition of material onto a host. The general process flows of these two categorical methods are outlined below:

- Subtractive Methods
  - Substrate and material preparation
  - Bulk material deposition
  - Masked patterning
  - Sacrificial etching
- Additive Methods
  - Substrate and material preparation
  - Selective material deposition

In this chapter, a review of several popular methods of electronic fabrication is presented with a specific interest in the realization of highly efficient, robust antenna structures. Processes, challenges, and state-of-the-art demonstrations of these fabrication methods are discussed for a variety of wireless applications, including millimeter-wave, on-chip and on-package integration, wideband flexible RFID systems, and low-cost multilayer radar systems.

MEMS

"Microelectromechanical systems" (MEMS) is a general term for highly miniaturized systems that are created through the integration of many small components, including electrical, thermal, magnetic, optical, and fluidic, with or without moving parts. MEMS devices emerged in the late 1960s following with the development of lithography-based microfabrication techniques including CMOS technologies for highly integrated computer circuit components (Nathanson et al. 1967; Howe and Muller 1982; Senturia 2001). One of the most outstanding features of these micromachining techniques among many other competing fabrication approaches is their ultrahigh precision and very fine resolution capabilities for many different kinds of materials. On the other hand, these microfabrication technologies usually require a clean room environment and are very expensive, especially if the feature size of the structures is very small. Therefore, these technologies have been used mainly on highly integrated circuit core dies including CPUs, memory units, and sensors.

However, in recent years the desire for system miniaturization is getting stronger, especially in the area of mobile electronic devices. In order to realize higher performance and greater functionality with smaller feature sizes, system integration in a larger scale, which can be expressed as system on chip (SOC), stacked ICs and packaging (SIP), and system on packaging (SOP), is becoming more and more important (Tummala 2008). Also, the demand for high frequency antennas following with the exponential increase of data in wireless communication and expansion of millimeter wave use in sensing applications makes MEMS fabrication technologies a reasonable choice for antenna fabrication, a result of the shrinkage of

DOI 10.1007/978-981-4560-75-7_134-1

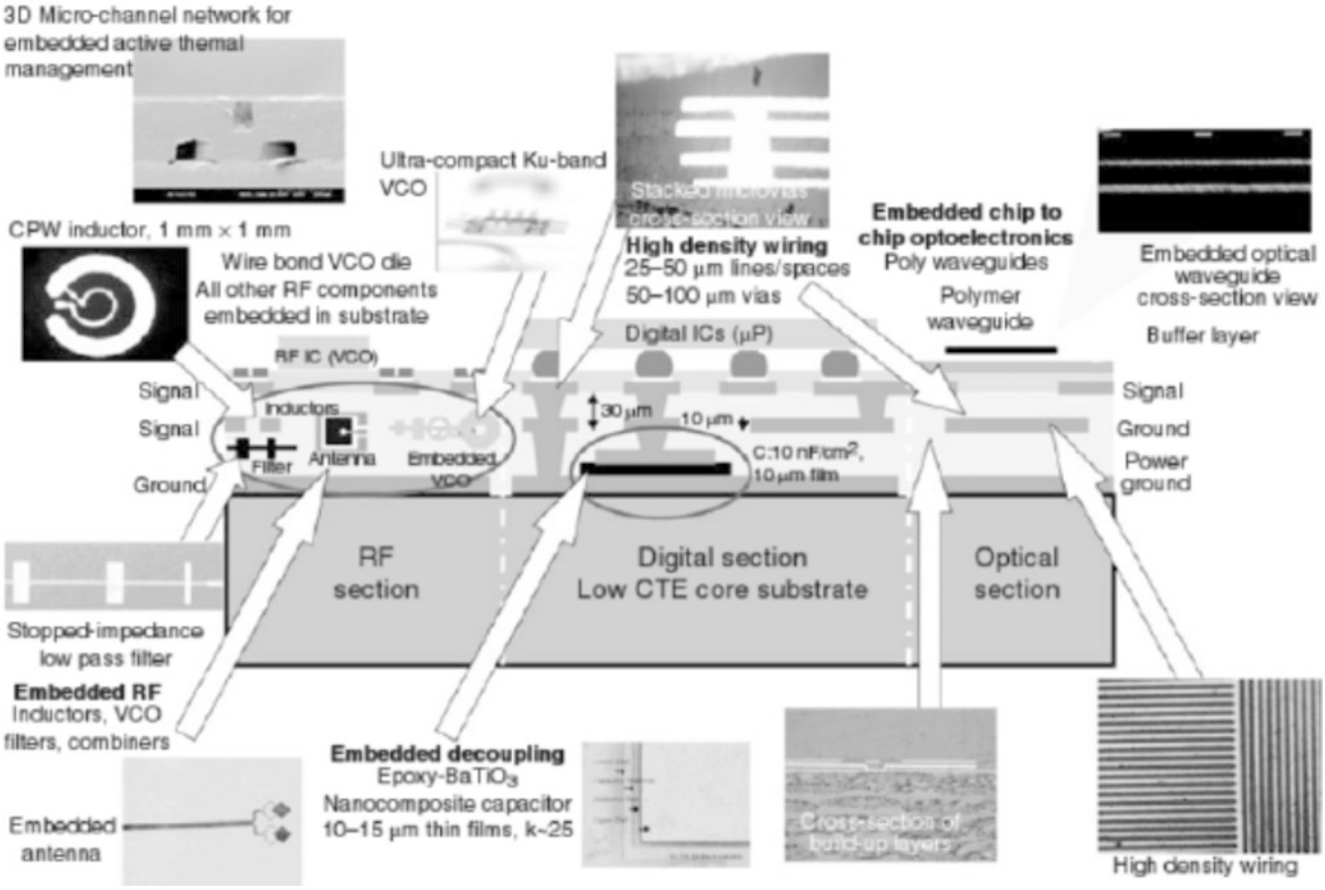

Fig. 1 A cross-sectional view of a typical intelligent network communicator

feature size along with increase in frequency. RF MEMS integration can be conceptualized as intelligent network communicator (INC) as is depicted in Fig. 1.

Microstructures are fabricated with a combination of additive processes, such as chemical vapor deposition (CVD), spin coating, and electroless plating, in conjunction with subtractive processes, such as wet etching and dry etching, depending on the material and thickness of the structure (Madou 2002; Bustillo et al. 1998; Kovacs et al. 1998). With a proper sequential process, it is possible to create 3-D structures applicable for antennas through these well-developed standard micromachining techniques. These methods have the capability to be seamlessly integrated into other CMOS chips and circuitry in the form of on-silicon antennas and on-chip antennas. Generally, micromachining can be categorized into surface micromachining and bulk micromachining with regard to the thickness of the structure.

Surface Micromachining

Surface micromachining is used to create relatively thin-film layers on top of a substrate. The microstructure fabricated is typically released by dry/wet isotropic etching. These thin-film layers could be metal layers for the antenna patterns, dielectric or insulator layers as a substrate or insulation, and polymer layers as sacrificial layers for the metal patterning. Since antennas usually do not require movable parts in them, most of the fabrication can be done only by utilizing surface micromachining. There are several examples of antennas for millimeter-wave frequencies fabricated through CMOS fabrication processes in literature. The top view, side view, and S-parameter frequency response for a 100 GHz quasi-Yagi antenna fabricated with surface micromachining are depicted in Fig. 2 (Sun and Zhang 2007).

DOI 10.1007/978-981-4560-75-7_134-1

Bulk Micromachining

Bulk micromachining is utilized to process relatively thick substrates. Usually, in MEMS devices, the substrate is silicon and can be fabricated by utilizing dry/wet and anisotropic/isotropic etching. These processes can be applied for via fabrication in MEMS antenna structures as is depicted in Fig. 2a. In addition to the fabrication of static structures, it is possible to create movable structures by applying bulk micromachining to release a part of surface-micromachined layers. As an application of MEMS structures into antenna topologies, numerous reconfigurable tunable antennas with RF MEMS switches have been

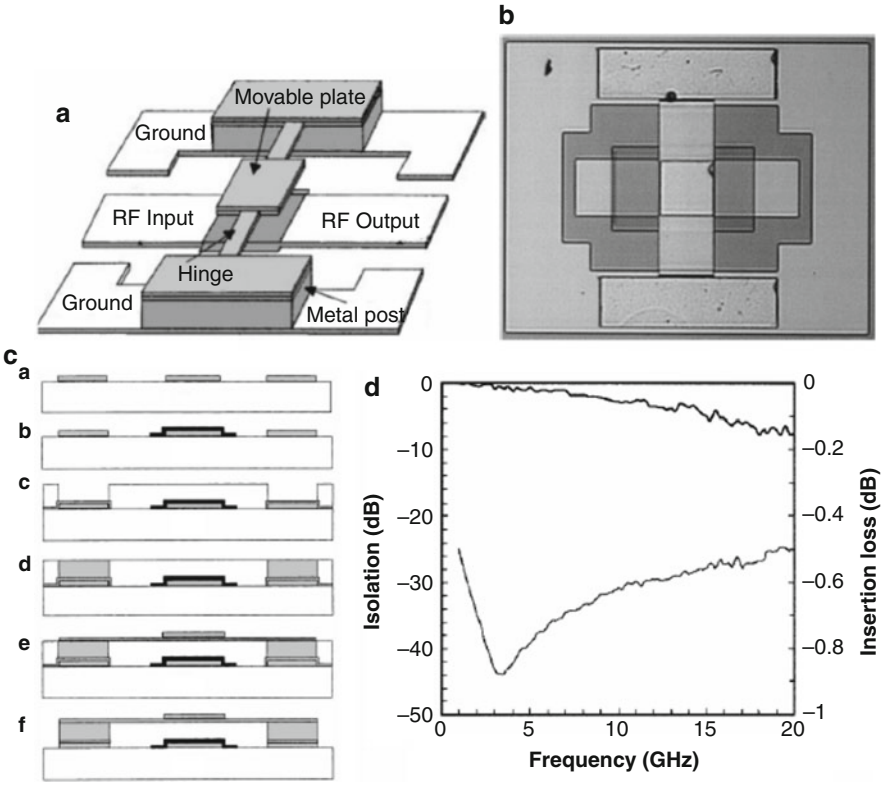

Fig. 3 (**a**) Schematic drawing of RF MEMS capacitive switches. (**b**) Photomicrograph of a fabricated RF MEMS capacitive switch with the hinge structure. (**c**) Fabrication steps of RF MEMS capacitive switches. (**d**) Insertion loss (*upper curve*) and isolation (*lower curve*) of the fabricated RF MEMS capacitive switch

proposed (Weedon et al. 2001; Park et al. 2001). Since both antenna and RF MEMS structures are fabricated through the same CMOS processes, it is possible to realize a highly integrated, seamless antenna configuration using this technology. The design, top view, fabrication processes, isolation, and insertion loss of such an antenna prototype are depicted in Fig. 3.

LTCC

LTCC Technology

The first ceramic technology is believed to have been introduced in the late 1950s at RCA Corporation (Stetson 1965). At the time, the ceramics used required high processing temperatures (1600 °C) for what we now refer to as high-temperature co-fired ceramics (HTCC). These temperatures made it impossible to use low-cost and highly conductive metals (Ag, Cu, etc.) that would melt in such conditions. Furthermore, in the case where LSI components would be connected through the use of flip-chip techniques, problems would arise for ceramics whose thermal expansion coefficient were very different from that of silicon, which features a rather low thermal expansion coefficient ($3.5\ 10^{-6}\ °C^{-1}$). These reasons led, during the 1990s, to the birth of low-temperature co-fired ceramics (LTCC) which only require sintering temperatures lower than 1100 °C, lower than the melting temperature of silver (960 °C) in many cases (Shinohara et al. 1987).

DOI 10.1007/978-981-4560-75-7_134-1

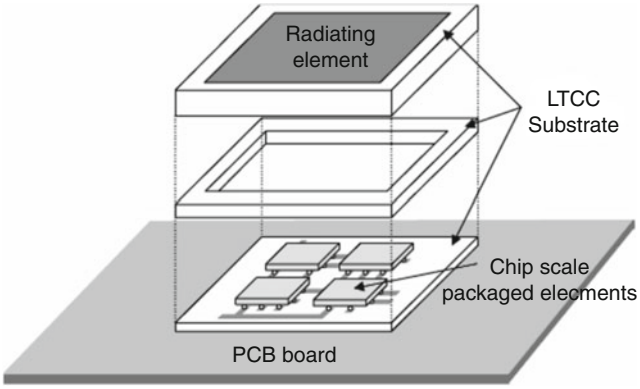

Fig. 4 Package-level integrated antenna integration (Wi et al. 2006)

The fabrication of LTCC components is a five-step process:

1. Slurry, composed of ceramic powder and a binder, is cast using a doctor blade on a thin film to make the green sheet.
2. Holes are then punctured in this green sheet to make vias, cavities, and registration holes.
3. The metal traces are deposited on the sheet to form the conducting pattern, and the via holes are filled with conductive paste. Screen printing of conductive pastes is commonly utilized for this purpose, offering a maximum resolution of 30 pm for line width and spaces. Less conventional methods, such as thin-film deposition technologies, can go down to 10 pm resolution for both lines and spaces (Muller et al. 2006).
4. The different layers are carefully aligned and stacked, using the registration holes or optical methods for improved precision, and laminated with heat and pressure.
5. Finally, the circuit is fired to form the multilayer ceramic substrate component or module.

This fabrication technology offers many advantages because of the high performance of the ceramics, offering a wide range of available permittivities and low dielectric losses ($\epsilon_r = 3.9-487$ and tan $\delta = 0.0007-0.006$ at 1 MHz) (Sebastian and Jantunen 2008). The different processes used for metalization also offer very conductive traces ($3.88-9.66$ m$\Omega/\square$) which can be used to manufacture high-quality RF components (Muller et al. 2006).

Some drawbacks of the technology are the previously mentioned limitations of conductor patterning resolution as well as precise layer alignment difficulties, thickness control, and warping. The major cause for these last issues is the significant shrinkage (9.5−25 %) of the ceramics during sintering. However, given proper material control and reproducibility, these effects can be taken into account and compensated in the design of the components.

Applications

LTCC technology is, by design, a multilayer process. This allows for the low-cost and compact integration of active and passive components as well as the package-level antenna integration, as shown on Fig. 4. These multilayer capabilities and high-performance materials also offer the advantage of making highly efficient multilayer antenna designs possible, as shown in the stacked-patches antenna for GPS applications (reported in Chen et al. 2010) (Fig. 5). As can be seen in Fig. 5b, the fabricated antenna features four very sharp resonances (two near-degenerate modes per patch antenna due to truncated corners) that are very similar to the simulated ones. Only slight shifts in resonant frequencies (from 1241, 1245, 1522, and

DOI 10.1007/978-981-4560-75-7_134-1

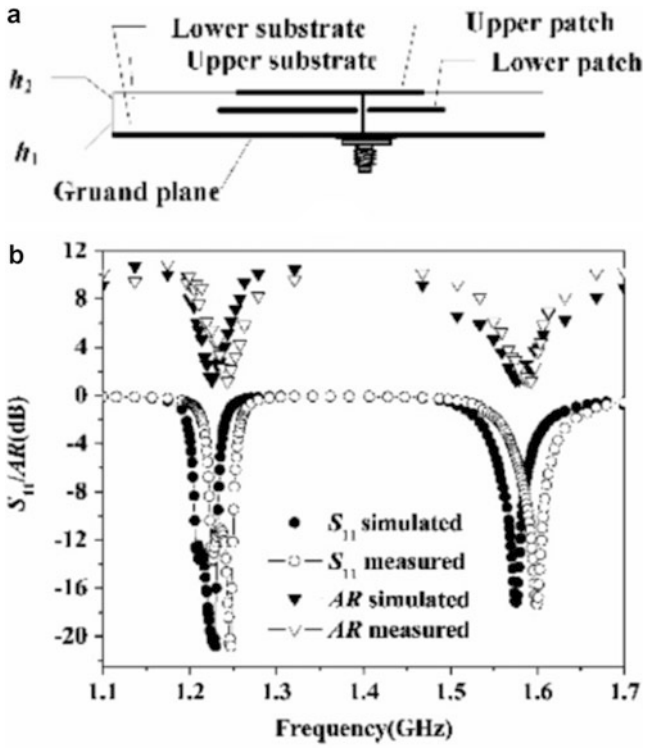

Fig. 5 A stacked-patches antenna manufactured with LTCC technology (**a**) Side view. (**b**) Simulated and measured return loss and axial ratio (Chen et al. 2010)

1584 MHz to 1221, 1233, 1499, and 1577 MHz) can be noticed and are attributed to slight fabrication inaccuracies (Chen et al. 2010).

Antennas can also be readily integrated into complete high-performance and high-complexity systems, even at high operational frequencies. Compact and 3-D integrated filters/duplexers and cross-shaped patch antennas integrated into a complete RF front end for operation in the 60 GHz band are reported in Lee et al. (2006). The antenna component reported excellent performance with a 10 dB bandwidth of 2.4 GHz (4.18 %) at 57.45 GHz and 2.3 GHz (3.84 %) at 59.85 GHz (Fig. 6).

At high frequencies, as the wavelength begins to be on the same scale as the thickness of these rather high-permittivity ceramics, problems can arise from the excitation of surface waves at the ceramic-air interface, resulting in lower gain for the fabricated antennas. This challenge has been tackled in Lamminen and Saily (2008) where an air cavity was placed under a 60 GHz band patch antenna to effectively reduce the overall permittivity of the substrate, thus leading to the beneficial effect. This also had the beneficial effect of increasing the bandwidth of the patch from 5.8 % to 9.5 % and increasing the gain by 2.5 dB. These patches (16 in total) were then used to make a high-performance antenna array (shown in Fig. 7a, b) **that** achieves a maximum gain of 18.2 dBi (Fig. 7c), **which** is a 2.5 dB improvement from its counterpart made of non-air cavity-backed patches.

LCP

A liquid crystal polymer (LCP) gets its name from the fact that its molecules can be mutually aligned and organized (crystal) and that bulk LCP can flow in molten state (liquid). When bulk LCP flows in the liquid state, the rigid segment of the LCP molecules aligns next to each other in the shear flow direction, as

DOI 10.1007/978-981-4560-75-7_134-1

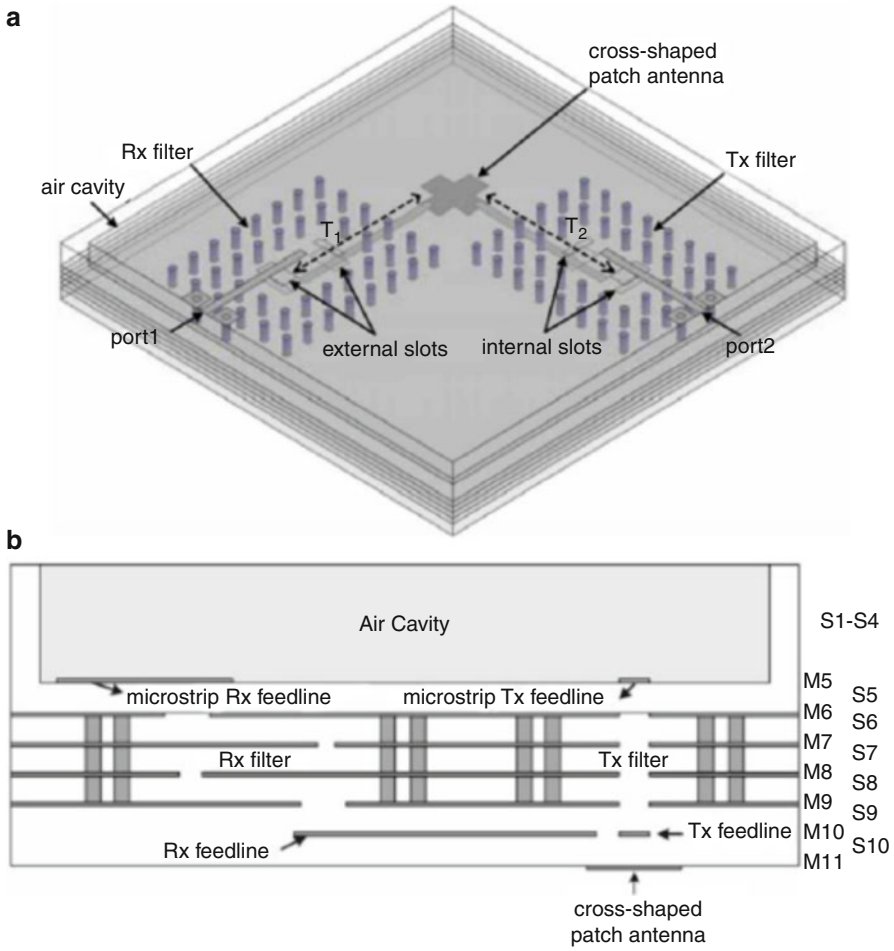

Fig. 6 3-D integrated V-band front-end with cavity filters and antenna, manufactured with LTCC technology (Lee et al. 2006)

shown in Fig. 8, thus creating locally oriented domains that lead to macroscopic-aligned regions. Once formed, the structure and direction of these oriented regions persist (Farrell and St Lawrence 2002). This behavior gives LCP a high mechanical strength at high temperatures, extremely good chemical resistance, inherent flame retardancy, and good durability in rugged ambient conditions (DeJean et al. 2005).

Although thermotropic LCPs possess a variety of properties that make them attractive candidates for electronic substrates, for a long time, standard LCP processing techniques resulted in films with anisotropic in-plane properties. Around 1998, Foster-Miller developed a new process that enables the control of the fibrillary orientation and achieves a biaxial orientation. Currently many electronic designs, especially flexible and conformal ones, including antenna structures, are realized every year using LCP as a host substrate.

LCP as an RF Material

LCPs feature a unique combination of properties that make them ideally suited for antenna fabrication, including: excellent electrical properties at microwave frequencies (low dielectric constant: 2.9, low loss tangent: 0.002 at 20 GHz, as reported by Rogers), low moisture absorption (<0.04 % by weight) and impermeability to moisture, oxygen, and other gases and liquids, and excellent dimensional stability (< 0.1 %).

Electrical Properties at Microwave Frequencies

Various studies have shown that LCP has excellent electrical properties. Several have reported relative permittivity and dielectric loss parameters are shown in Table 1 with a frequency dependence shown in Figs. 9 and 10, respectively.

Fabrication Techniques

To fabricate antennas on LCP, standard two-sided printed circuit boards (PCBs) are typically used.

DOI 10.1007/978-981-4560-75-7_134-1

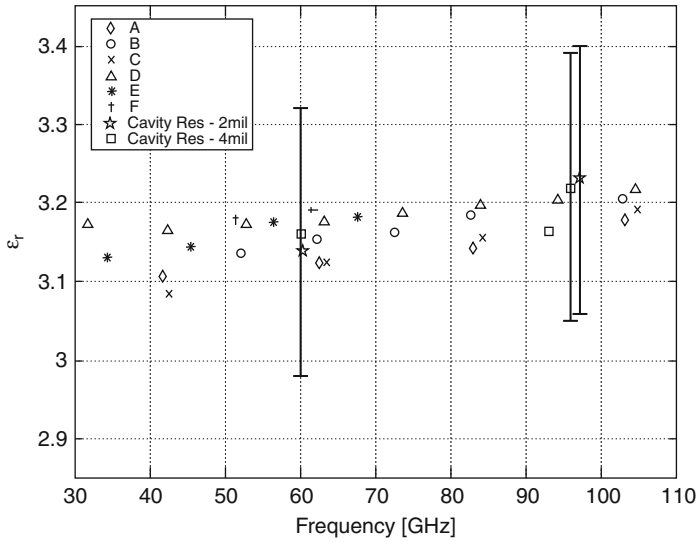

Fig. 9 Extracted dielectric constant using ring resonator designs (AF) and cavity resonators with 2- and 4-mil-thick LCP (Thompson et al. 2004)

- *Imaging and Etching* – LCP is suitable for traditional photolithography processes due to its inherent chemical/moisture resistance that prevents any undercutting at the polymer-copper interface. In this process, a photoresist is first deposited onto the copper clad laminate, followed by exposure (imaging) and stripping to define the desired antenna pattern. Then, the exposed copper is chemically etched out to leave the desired antenna topology.
- *Mechanical Drilling* – For large holes (greater than 8 mils in diameter), mechanical drilling is typically used in standard industry practice. It is shown that lower infeed rates (relatively, in the range of 2–8 mil/in) combined with high retract rates (relatively, in the range of 300–700 IPM) produce a better hole quality (Farrell and St Lawrence 2002).
- *Laser Drilling* – For small holes (less than 8 mils in diameter), lasers are typically used. For LCP materials, the best vias are made with shorter, more frequent pulses along with a higher number of pulses than required for some other standard materials (Farrell and St Lawrence 2002).
- *Desmear* – After drilling, a cleaning step is required and typically achieved by a wet chemical permanganate exposure for most RF substrates. However, this method does not work well with LCP due to its extremely high chemical resistance. Instead, plasma treatment is very effective at cleaning holes.

Applications

LCP has been one of the most preferable conformal RF substrates due to the numerous desirable features previously listed. The dielectric constant is low enough to be used while being conformal and it is easy to

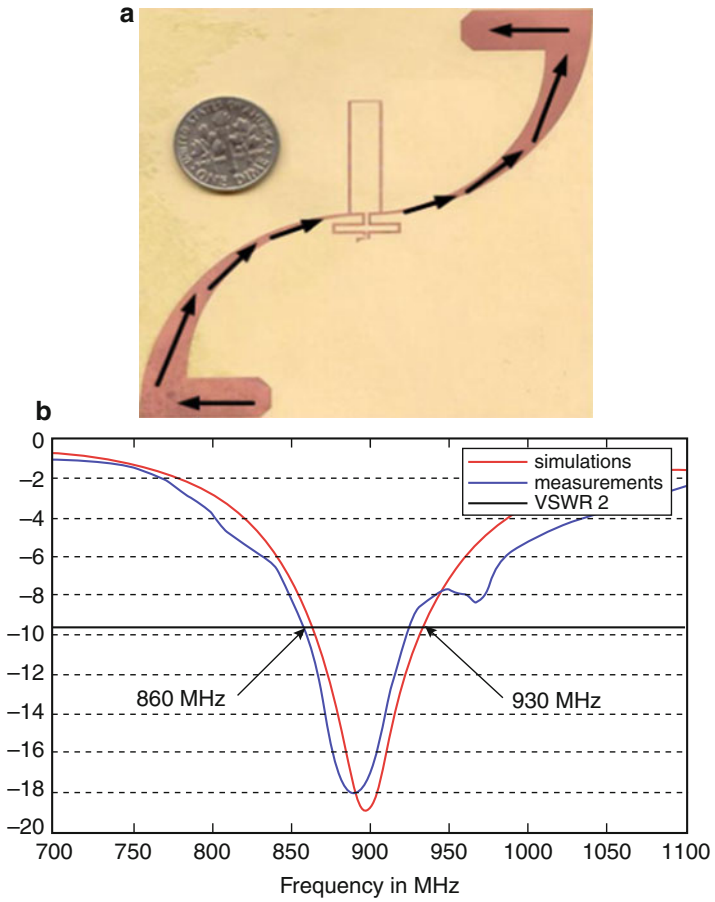

Fig. 12 (**a**) Photo of an RFID tag on LCP. (**b**) Return loss of the RFID (Serkan Basat et al. 2006)

RFID

Requirements in automatic identification in several areas, such as item level tracking, supply chain, and retail applications, have increased the demand for low-cost, flexible radio frequency identification (RFID) tags. LCP as an antenna substrate is considered one of the best candidates for RFID applications, especially in millimeter-wave frequency ranges (mmID's) (Vyas et al. 2007). One of the main required features of most RFID tags is a conformal shape or flexibility in order to be placed on differently shaped objects, such as boxes, cylindrical bins, vehicles, etc. Secondly, since most RFID tags contain no extra packaging and are exposed directly to their surroundings, RFID tags must be able to withstand harsh industrial environments, such as water vapor and high humidity. A third requirement is to have a low dielectric constant value with low dielectric loss for optimal RF power efficiency and transmissivity in embedded objects and optimum power performance, especially in passive RFID systems, where the only power to the tag is the RF power from the reader in its vicinity. A typical passive RFID tag module is shown in Fig. 12 and a Novel 3-D Cubic Antenna is shown in Fig. 13.

Portable Devices

There is a strong need for high-efficiency antennas that can be easily integrated into portable devices where high frequency operation, light weight, and conformability to curved surfaces are required. In recent years there has been an increase in using flexible LCP substrates because of their inherent flexibility and improved loss characteristics. The low loss property of LCPs becomes further important for portable

devices where available power is scarce and cannot be used to compensate for lack of efficiency in individual RF components (Aryanfar and Werner 2010). A 4 × 1 patch antenna array for high-speed ultrabroadband mm-wave portable modules around 60 GHz can be found in Fig. 14.

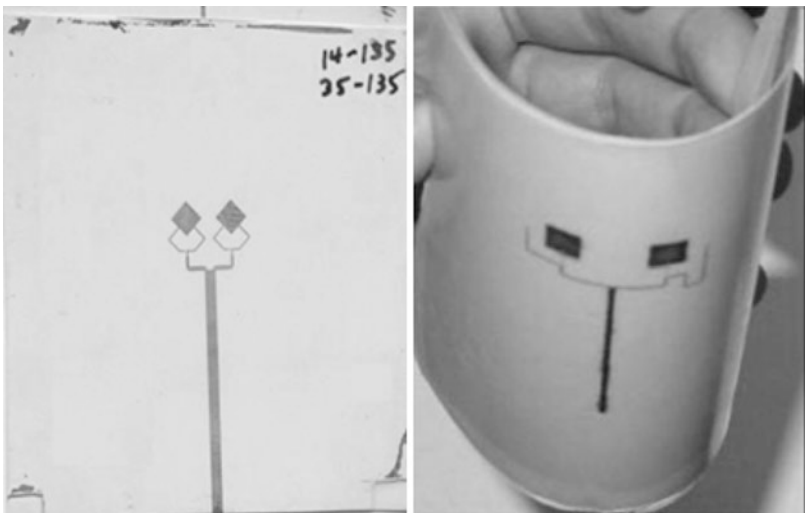

Fig. 15 Photographs of fabricated prototypes of multilayer dual-frequency/dual-polarization flexible antenna arrays in flat and bent configurations (DeJean et al. 2005)

Multilayer Antennas

Due to its inherent capability of multilayer (three-dimensional) vertical integration, good electrical and mechanical properties, and near-hermetic nature, LCP is also a practical choice for the design of low-cost antenna arrays that can be integrated with remote sensing applications operating in the K_u and millimeter-wave frequency bands.

Many thermal and mechanical problems (e.g., stress due to coefficient of thermal expansion mismatches) are inherent in traditional multilayer designs relying on the integration of different materials. However, LCP offers a unique combination of properties with a low dielectric constant and low loss tangent. In addition, LCP has a low CTE (8 or 17) and its CTE can be adjusted through thermal treatments, thus facilitating the integration of integrated circuits in SOP modules. Those properties make LCP an excellent candidate for multilayer structures (Fig. 15).

Printing

The current advancement of wireless technology is pushing toward several improvements within the realm of electronic fabrication, specifically with respect to reducing cost, lowering waste, and increasing functional versatility. Considering the methods of antenna fabrication previously discussed in this chapter, subtractive methods represent a strong majority of antenna fabrication methods typically used in commercially available electronic systems. These methods require the use of patterning masks, electronic plating, planar material growth, chemical etchants, and various other procedures to both deposit and remove materials from host substrates.

Additive material printing offers an alternative approach to the widespread methods of subtractive electronic fabrication. Mass material deposition and subsequent removal is replaced with select, direct patterning, where the only materials used are materials directly constructing the desired electronic patterns and structures.

Through the utilization of conductive and insulating ink/filament materials, direct printing methods such as ink-jet and 3-D printing are capable of fabricating flexible and rigid multilayer antenna structures in a purely additive process (Yang et al. 2007). The entire stack up of a multilayer antenna system, including conductive metallization and thick dielectric substrates, can be achieved with ink-jet printing,

DOI 10.1007/978-981-4560-75-7_134-1

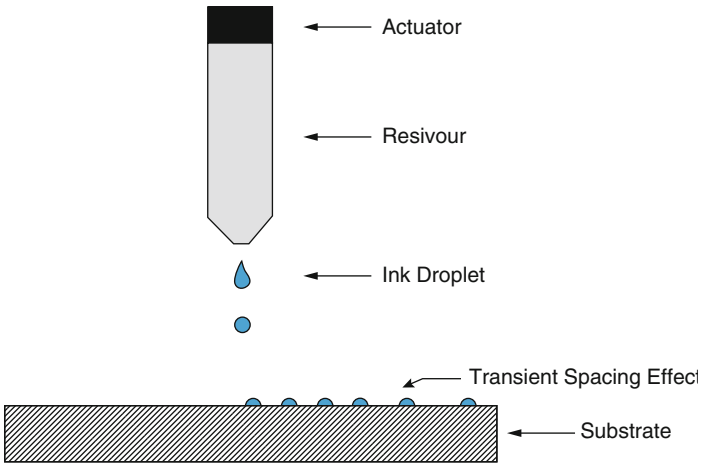

Fig. 16 A typical DOD ink-jet-printing system

removing the need for multi-multilaminate processing, trimming, and bonding while allowing for integration with wireless technologies as a post-processing fabrication method. 3-D printing further extends the versatility of printed systems into an unlimited variety of applications, where flexible plastics and conductors can be used to realize wearable, reconfigurable wireless systems with a feasibly lowered cost and improved functionality.

Ink-Jet Printing

Ink-jet printing is an additive fabrication technology that consists of three general elements: a dispensary apparatus, an ink material, and a host substrate. The dispensary apparatus is typically an ink cartridge consisting of an ink reservoir and a device to eject drops onto a substrate, which is commonly realized through a piezoelectric MEMS device. Ink materials can range in material composition and functionality, including conductive nanoparticle suspensions and polymeric dielectric solutions. The host substrate accepts and is patterned by the ink droplets ejected from the dispensary apparatus, where certain material characteristics such as surface tension and fluidic wetting must be taken into account in order to ensure accurate material patterning.

Ink-Jet Printing Processes

The technology behind ink-jet printing begins with the dispensary methodology. The two main methods of droplet dispensing are known as drop-on-demand (DOD) and continuous. DOD systems utilize a mechanical actuator to feed, form, and eject ink droplets from a dispensing device, where droplets are only dispensed when they are desired to pattern a host substrate. Continuous systems differ in the fact that droplets are always being fed and ejected while a "catcher" structure is used to block or allow dispensed droplets from patterning a substrate. Issues of nozzle clogging are reduced with continuous systems; however, DOD systems are more efficient for small-volume prototyping and allow a larger variety of ink materials, which is especially important for antenna design and fabrication within an experimental setting (Wiederrecht 2009; Magdassi 2010). Figure 16 illustrates a typical DOD ink-jet-printing system (Cook et al. 2014).

The mechanical actuators used within ink-jet printing vary in the physical mechanisms used to dispense ink droplets from a dispensary onto a substrate. For modern ink-jet-printing systems, four main actuators are used:

DOI 10.1007/978-981-4560-75-7_134-1

1. *Thermal* – Ink is heated within a cavity until volume and pressure is increased enough to force a droplet ejection. Very low cost, yet relatively high drop volume (80–100 pL) (Wiederrecht 2009).
2. *Piezoelectric* – Ink is pulled into and ejected in droplets from a cavity with a piezoelectrically actuated membrane. Higher control over droplet formation and wide variety of allowable ink materials.
3. *Electrodynamic* – A large electric field is applied between a nozzle and conductive platten below a host substrate, where ink droplets are forcefully ejected from a nozzle. Capable of producing very small drop volumes (<1 fL), yet requires inks to contain free ions (Choi et al. 2011).
4. *Acoustic* – Ultrasonic waves are focused on an ink meniscus, overcoming surface tension and allowing a droplet to be ejected. Reduced nozzle clogging and increased precision in drop volume variability (Hamazaki and Morita 2009).

Ink Materials

In order to realize robust, multilayer electronic topologies with ink-jet-printing fabrication, a variety of ink materials are required. Specifically for ink-jet-printing antenna structures, extended attention has been drawn to two general ink varieties: conductive and dielectric.

The most efficient conductive inks used within ink-jet printing are metallic in essence but differ in their material composition and processing. Silver nanoparticle solutions of noble metals, such as silver and gold, currently dominate the market of commercially available metallic conducting inks. These inks are composed of a suspension of metallic nanoparticles within an alcoholic solvent solution. Upon printing, the solvent materials are evaporated with a low-temperature thermal treatment and then sintered with either thermal baking (< 250 °C) or laser rastering, offering a method of metallic that does not interfere with low-temperature substrates, such as polymeric or fibrous materials (Cook and Shamim 2012). Non-noble metals, such as copper, are difficult to process as nanoparticles because of their high oxidation rates during sintering. As an alternative, metallic catalyst inks can be used to pattern a latent image of a conductive topology, followed by the electroless chemical plating of metal onto the printed pattern (Cook et al. 2013c). These methods of conductive ink printing are able to achieve conductivity in the range of $1.2 \cdot 10^7$ S/m, 5x lower than that of bulk silver (Cook and Shamim 2012).

Dielectric inks are utilized to pattern insulating structures, where both pattern area and film thickness are variables of interest. Dielectric inks were first developed for ink-jet printing with the purpose of creating thin dielectric films for metal-insulator-metal (MIM) capacitors and transistor gate dielectrics, yielding thicknesses in the ranging from hundreds of nanometers of several micrometers (Cook et al. 2013a; Sanchez-Romaguera et al. 2008; Ko et al. 2007). However, the ability to print thick dielectric structures is integral to the realization of fully printed antenna structures. Recent advancements in ink development have enabled ink-jet printing to effectively pattern thick dielectric substrates for antennas, exceeding 100 μm in thickness (Cook et al. 2013b; Bito et al. 2014; Tehrani et al. 2014). These thick films are achieved with long-chain polymers, such as the SU-8 photoresist, which can yield a high w/w% while maintaining a low viscosity. Per-layer thickness of this printed dielectric ink is within the range of 4–6 μm, which can be used to precisely control the thickness of a desired dielectric substrate, as shown in Fig. 17 (Tehrani et al. 2015).

Ink-Jet-Printed Antenna Structures

Through the utilization of conductive nanoparticle-based and thick dielectric polymer-based inks, ink-jet printing has realized a variety of antenna structures for such applications as millimeter-wave (mm-wave) wireless systems (Cook et al. 2013b; Bito et al. 2014; Tehrani et al. 2015) and microfluidics-enabled tuning/sensing platforms (Su et al. 2014, 2015). Two of the most recent demonstrations of ink-jet-printing antenna fabrication will be presented in this section.

DOI 10.1007/978-981-4560-75-7_134-1

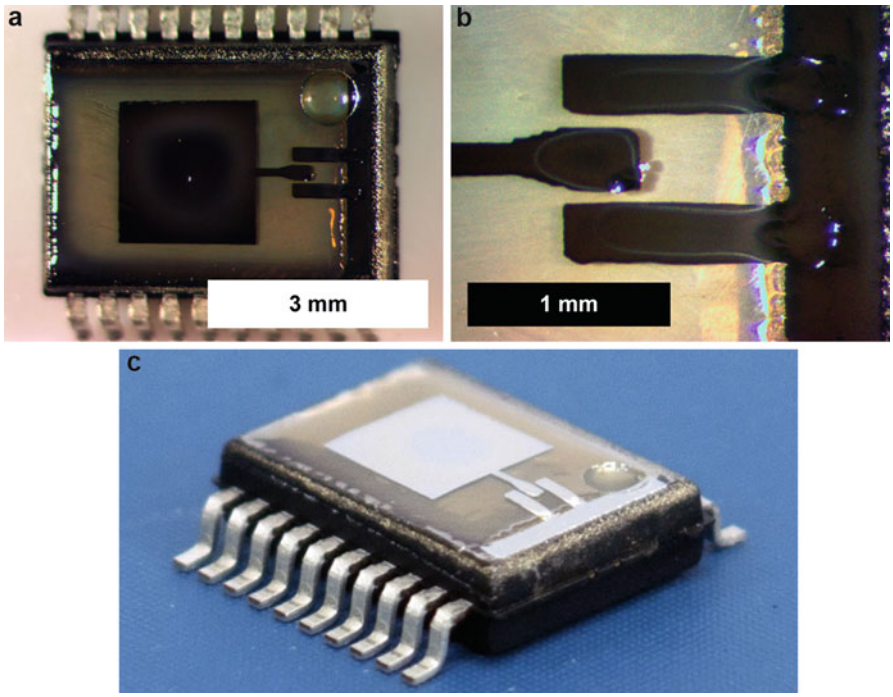

Fig. 18 Ink-jet-printed on-package 30 GHz patch antenna: (**a**) top view, (**b**) coplanar waveguide (CPW) feed and via detail, and (**c**) perspective view

Some of the greatest advantages of ink-jet printing are its fully additive nature and host material flexibility. Conductive and dielectric ink materials can be patterned strictly as needed onto virtually any host substrate, which introduces the application of using ink-jet printing to fabricate multilayer antenna structures in a post-processing fashion into an existing electronic system. An example of this post-processing approach to ink-jet-printing antenna fabrication is demonstrated by B. Tehrani et al. in (Tehrani et al. 2015). In this work, ink-jet printing is used to fabricate a multilayer 30 GHz patch antenna directly onto a wireless integrated circuit (IC) package. Figure 18 shows images of the printed antenna structure, where ground plane, 120 μm thick SU-8 dielectric substrate, and antenna topology are all realized through ink-jet printing. S-parameter measurements are presented in Fig. 19, displaying excellent agreement with simulations and highlighting the predictability and integrity of ink-jet printing as a fabrication process for multilayer antennas.

Another advantage of ink-jet printing is its low-cost nature, which is especially important for applications such as ubiquitous wireless sensor networks and health monitoring platforms. Using a low-cost poly

(methyl methacrylate) (PMMA) host substrate, W. Su et al. demonstrate an ink-jet-printed loop antenna with microfluidics-enabled tuning and matching (Su et al. 2015). Ink-jet-printed antenna topology is stacked with a thicker sheet of PMMA, on which a microfluidic channel is laser etched for fluidic routing and interface, shown in Fig. 20. The bonding between the antenna topology and the microfluidic channel is achieved with the printing and curing of SU-8 polymer ink, acting as a printable epoxy resin. When different fluids are loaded into the microfluidic channel, the dielectric constant of the fluid effectively tunes the antenna as well as the balun, improving matching during fluidic loading. S-parameter measurements are presented in Fig. 21 for the ink-jet-printed antenna with and without microfluidic loading.

3-D Printing

3-D Printing Processes

Almost any additive manufacturing technique that creates three-dimensional objects is considered 3-D printing. While rapid-prototyping techniques involving 3-D printing have existed since the 1980s (Frauenfelder 2013), the recent rapid interest and growth of the technology occurred after the expiration of US patent 5121329 related to fused deposition modeling (FDM) by Stratasys. There exist many 3-D printing processes that vary in materials, resolution, strength, and time. The most commonly used 3-D printing techniques are FDM and stereolithography (SL). Fused deposition modeling is the process of

DOI 10.1007/978-981-4560-75-7_134-1

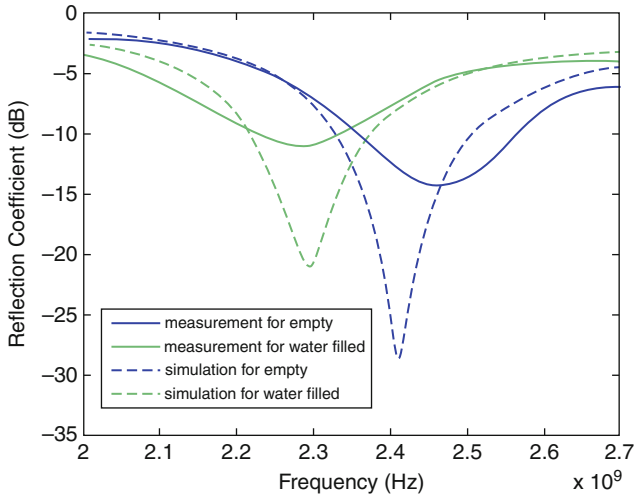

Fig. 21 Reflection coefficient simulations and measurements of an ink-jet-printed microfluidic-enabled loop antenna with and without fluidic loading

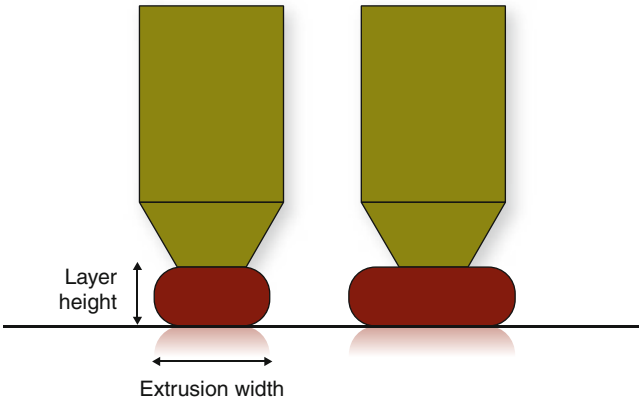

Fig. 22 FDM layer height. The extrusion width is a function of the nozzle diameter (Hodgson 2011)

extruding material, generally a thermoplastic, through a heated nozzle that exceeds the glass transition temperature. FDM techniques, like almost all 3-D printing techniques, print layer by layer. The layer height is a common feature that defines an FDM printer, as shown in Fig. 22, with many consumer-available printers having a layer height of 100 μm (some as low as 20 μm). Stereolithography involves vats of photopolymers that react to laser UV light to harden the polymer at select points. SL printers tend to have higher resolutions, with a common layer height around 30 μm and tend to be more complex with laser or digital light project (DLP)-based systems. Another process is laser sintering/melting, which involves small particles of materials, even metals, which are fused together by a laser.

As this is a relatively new technology that has garnered much public interest recently, many new methods are being developed. There are printers combining ink-jet or paste dispensing techniques that allow conductive materials to be printed simultaneously with the main substrate material, for example, with the electronics printing system from Voxel8 (Voxel8 (13 April 2015). The ability to print highly conductive materials with substrates is a desired feature that is currently rapidly evolving.

3-D Printing Materials

Most 3-D printers involve a polymer-based material. Acrylonitrile butadiene styrene (ABS) and polylactic acid (PLA) are common for FDM-based printers. Multiple materials can be printed simultaneously with an FDM printer with relative ease. A wide variety of materials are available, usually a mixture of a polymer such as ABS or PLA, such as: ceramic, wood mixture, copper mixture, thermoplastic elastomers, conductive mixtures (approx. 1 Ω/cm), PET polymer, iron-based mixture, steel-based mixture, carbon fiber-based mixture, and a variety of other materials. Photopolymers for SL systems are generally a single material print, with much less variety currently. There are SL systems that combine alternative manufacturing technologies to allow multi-material prints (Wicker et al. 2004). PolyJet printing from Stratasys is similar to ink-jet printing, down to 16 μm with a wide variety of polymer materials. A variety of materials have been characterized on multiple types of systems (Deffenbaugh et al. 2013b; Deffenbaugh 2014).

3-D-Printed Antenna Structures

Considerations must be made when using a manufacturing method intended for 3-D prototypes to create dielectric-dependent designs, a necessity for many antennas. Dielectric constants may vary between brand and color of the material, as well as the settings on the 3-D printer. One of the most important settings that will change the dielectric constant is the infill density. Infill density versus dielectric constant has been characterized for several materials (Deffenbaugh 2014). Another issue that may arise, depending on the metallization method, is the surface roughness. This directly relates to the 3-D printing method. SL systems generally have layers below 30 μm, which results in a surface variation less than that. A concern with FDM is the ability for gaps to occur on the material surface, which may cause shorts during metallization of thin layers. This can be overcome and is generally an occurrence of poor manufacturing. With these limitations in mind, several designs are demonstrated utilizing both SL and FDM printing techniques (Deffenbaugh 2014).

Two examples of 3-D printed RF structures are shown in Figs. 23 and 24. The microstrip transmission line is designed on an SL system. The complex structure, in spite of the material having a higher loss tangent than an FR4 laminate, demonstrates lower loss than a planar FR4 structure. The metallization for the 2.4 GHz antennas designed on an FDM substrate is realized with an nScrypt 3Dn micro dispensing system (Deffenbaugh et al. 2013a), to show the feasibility of 3-D printed antennas comparable to typical manufacturing methods.

Future Directions and Open Problems

Throughout the four general methods of antenna fabrication presented in this chapter, there exist fundamental trade-offs between cost, minimum feature size, processing time, and scalability. Lithographic methods are a widespread standard throughout all forms of electronic fabrication and offer the lowest minimum feature sizes; however, high equipment costs, long processing times, and a lack of large-area scalability are factors that must be considered. Additive techniques such as ink-jet and 3-D printing offer relatively quick prototyping, lower cost, and seamless integration with large-scale fabrication; however, an increase in minimum feature size must be considered, where printing techniques offer minimum features nearly $10-100\times$ larger than lithographic techniques.

With the current push toward the development of low-cost, ubiquitous wireless systems throughout emerging technologies, the need for improvement within the realm of antenna fabrication is greatly stressed. This improvement should be realized with methods that reduce material waste, increase productive throughput, and exhibit an ease of reconfigurability, while highlighting current trends in miniaturization and functional diversity. Current advancements in additive manufacturing techniques show great promise for the realization of these goals for efficient antenna fabrication. The growing interest present within both industrial and academic research throughout the areas of ink-jet and 3-D printing offer a glimpse into the future of low-cost, vertically integrated wireless antenna fabrication.
