An approach involving the utilization of fence of ground via holes surrounding the antenna element introduced is adapted in this design due to its relatively small profile and ease of implementation. First, a clearance with a radius $r_{\text{clear}} = 1.03$ mm which encompasses the bottom patch is designed. The region outside the clearance in M4 is metallized to function as an RF ground. The dimension of r_{clear} is found to have limited effect on the reflection coefficient of the antenna element under conditions that remains greater than 0.95 mm. Afterward, fences of ground via holes penetrating from M4 to M7 are designed to surround the antenna element with a circular radius r_{fence} of 1.15 mm and via hole pitch $d_{\text{pitch}} = 0.344$ mm. The diameter of the ground via holes in this subsection is set to $d_{\text{via}} = 75$ um throughout this subsection. Figure 38 presents the simulated electric fields and the corresponding three-dimensional radiation patterns of the antenna element as a function of the presence or absence of the designed fence of ground via holes. In the presence of implementing fence of ground via holes, it can be observed that the fringing fields on the edges of the FR-4 substrate are relatively reduced in magnitude. The effect of the fence of ground via holes is further ascertained by the reduction levels of the ripples in the simulated three-dimensional radiation patterns throughout the frequency of interest.

The relatively high material loss tangent of the FR-4 substrate at mmWave frequencies has been the primary restricting factor for widespread usage at 60 GHz frequency band. Excessive levels of signal loss incurred by the antenna feedline can potentially have an adverse effect on the overall system link budget, resulting in a more stringent design requirement for the RFIC. Therefore it is imperative to first closely examine the impedance matching and insertion loss properties of the antenna feedline structure prior to integration with the antenna element.

A stand-alone topology of the antenna feedline is first designed for verification purpose as illustrated in Fig. 39. The antenna feedline consists of two vertical coaxial transitions that are each connected to the corresponding ends of a stripline structure located in M8. The impedance of the stripline is designed to 50 Ω by adjusting the width $W_{st} = 50$ um. Fences of ground via holes are implemented along the edges of the stripline with via hole-to-stripline distance $d_{\text{strip}} = 150$ um and minimum via hole-to-via hole pitch $d_{\text{pitch1}} \leq 310$ um. Careful modeling of the fence of ground via holes surrounding the stripline is determined to be an extremely critical factor in preventing two commonly occurring degradations: (1) anomalous resonances ("suck out") and (2) mutual coupling and signal cross talk. The two vertical coaxial transitions are identically designed using one 75 um diameter signal via hole and a series of ground via holes situated around the signal via hole with $d_{\text{pitch2}} = 452$ um, functioning as a coaxial outer conductor. This configuration translates to a calculated input impedance of less than 26.5 Ω. The

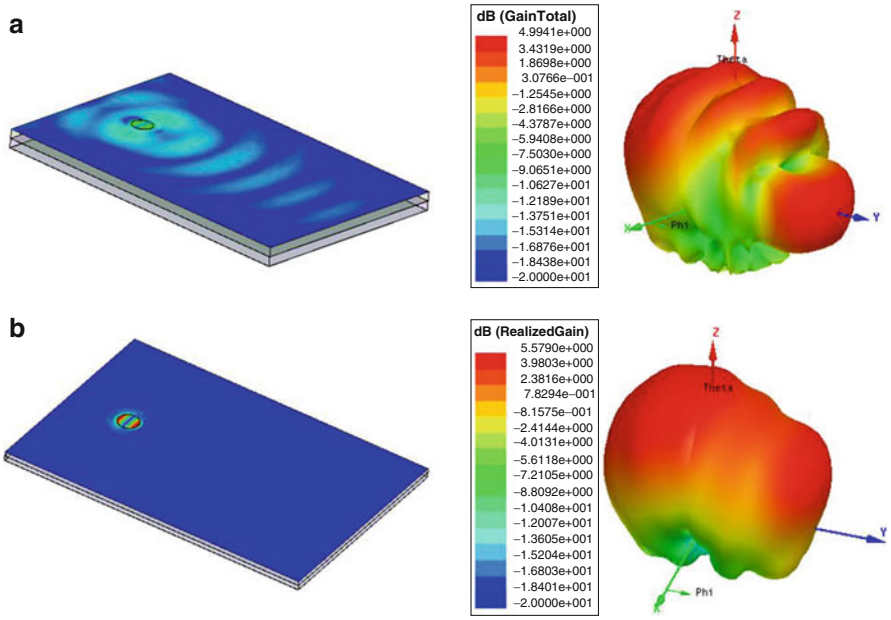

Fig. 38 Simulated electric fields and 3D radiation patterns. (**a**) Without fence of ground via holes. (**b**) With fence of ground via holes (Hong et al. 2013)

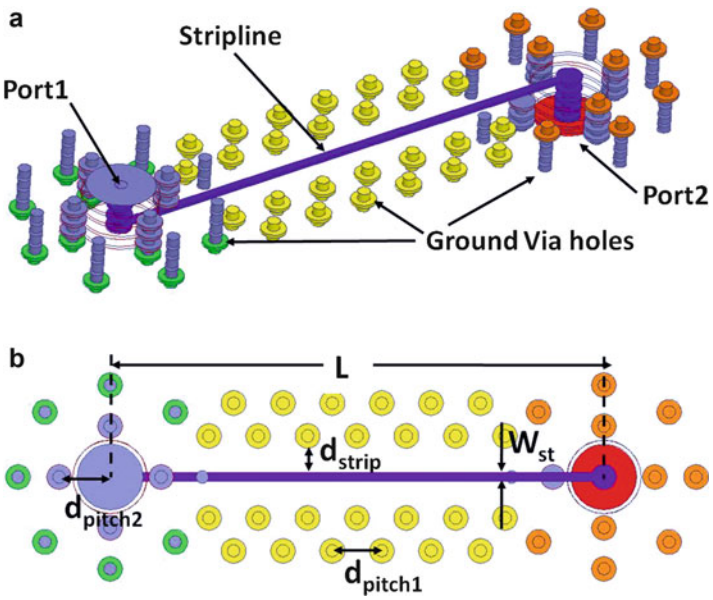

Fig. 39 Measured S-parameter amplitudes of the antenna feedlines (Hong et al. 2013)

simulated insertion loss is approximately 0.3 dB due to the small electrical height of the vertical transitions. Two GSG (ground-signal-ground) ports are connected to each of the vertical transitions at M1 and M12, respectively. Simulation indicates negligible difference when the two GSG ports are located on the same layer such as M12. Four antenna feedline test samples with length $L = 5, 10, 15, 20$ mm are collectively fabricated. The opposite locations of the two GSG ports hinder the usage of conventional RF probe stations. A multi-port in-house RF probe station which is capable of performing simultaneous S-parameter measurements in both the front and backside of the DUT (device under test) is custom

DOI 10.1007/978-981-4560-75-7_64-1

designed and built. Short-open-load-thru (SOLT) on-wafer calibration is performed prior to S-parameter illustration of the antenna feedline: (a) 3D view and (b) top view.

The measured amplitude of the S-parameters of the fabricated antenna feedline test samples are plotted in Fig. 40. It can be observed that the devised antenna feedline structure features less than −10 dB input reflection coefficients (S11, S22) within the frequency of interest. From the insertion loss (S21, S12) of the four test samples, the average unit loss is calculated to be 0.55 dB/mm. The relatively high unit loss compared to LTCC- or LCP-based antenna feedlines is primarily attributed by the loss tangent of the FR-4 substrate.

Figure 41 shows the measured and simulated far-field radiation patterns of the antenna element. Due to mechanical restrictions of the antenna measurement setup, the radiation patterns are measured within the range of ±90° in the elevation plane. The measured antenna element features an omnidirectional co-polarized radiation patterns in both the E- and H-planes as predicted by HFSS simulations. Cross-polarized measured and simulated radiation patterns indicate a much weaker correlation due to the following attributes: (1) the omission of the antenna measurement environment such as RF cables, adaptors, and chuck in the simulated numerical simulation model due to computation limitations; (2) measurement errors due to various scatterers such as RF cables, chuck, RF probes, etc.; and (3) limited dynamic range of the antenna measurement setup. Additional measures are being investigated to improve the accuracy between the two results. A pair of identical standard gain V-band horn antennas is used to measure the gain of the antenna element at boresight. First a CW signal is transmitted from the TX horn antenna and the RX horn antenna is used to record the received power. Afterward, the RF horn antenna is replaced with the AUT, and the received power is recorded in a similar manner. Losses in the RF probe, cables, and connectors are calibrated out during the gain calculation process. The loss incurred in the antenna feedline is not subtracted. The measured average gain is determined to be 4.8 dBi. Using the directivity derived from the simulated far-field radiation patterns, the average radiation efficiency of the devised antenna element is calculated to be approximately 71 % between 57 and 66 GHz.

Phased-Array Antenna Module

The designed antenna element and antenna feedline structure is employed to devise a 4×2 antenna array, composed of eight antenna elements within the 60 GHz antenna module for phased-array applications. Each of the antenna elements are independently connected with corresponding GSG ports located in M12. Therefore the antenna array also consists of eight independent antenna feedlines. A 20×20 mm^2 region at the center of the FR-4 carrier board is allocated for direct integration of the antenna array. Details of the

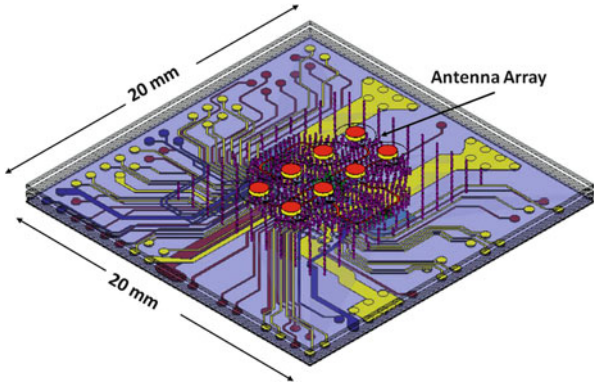

Fig. 42 Simulation setup of the eight-element antenna array. The region of the FR-4 carrier board is not shown for brevity (Hong et al. 2013)

PDN and low-speed and high-speed interfaces are included in the modeling and simulation process of the 60 GHz array antenna as illustrated in Fig. 42. The antenna element spacing are configured to $d_{\text{ant}} = 2.5$ mm in both the x and y direction to achieve minimum mutual coupling while avoiding undesired grating lobes during beam steering scenarios. The physical dimensions of the antenna elements which compose the array antenna module remain identical.

The antenna array feedlines are designed to exhibit identical phase properties and minimum insertion loss. Figure 43 presents the sliced top view of the modeled antenna array feedline layout. The antenna array feedlines are modeled using a commercial CAD program in a quadrant symmetric manner. The maximum deviation among the antenna array feedlines is 14 um. Fences of ground via holes are densely implemented with maximum via hole-to-via hole pitch of 310 um. The ground via holes are determined to be instrumental in shielding the antenna array feedlines from undesired spurious emissions that occur

DOI 10.1007/978-981-4560-75-7_64-1

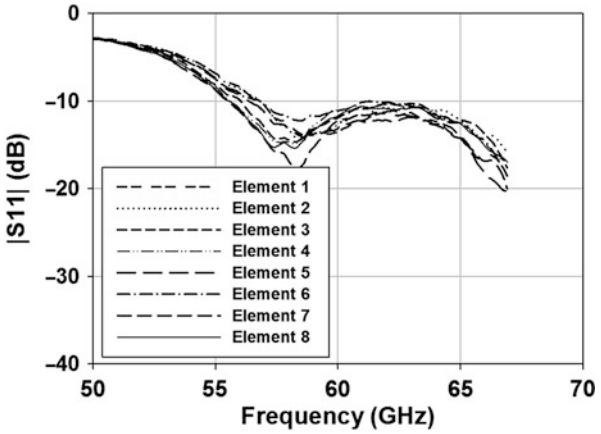

Fig. 44 Measured S11 amplitude of the antenna array (Hong et al. 2013)

from various active components that are implemented on the FR-4 carrier board. Simulation and measurement indicate the stand-alone model of the antenna array feedlines feature $|S_{11}| < -9.6$ dB and $|S_{21}| < 2.2$ dB between 57 and 66 GHz. The maximum measured phase deviation is determined to be less than 7.1°. Amplitudes of the input reflection coefficients of each of the antenna elements are measured one at a time. During measurement, the rest of the GSG ports are configured to be open. Measurement result of the antenna array is presented in Fig. 44. It can be observed that all eight antenna elements within the antenna array exhibit a −10 dB bandwidth of more than 9 GHz from 57 to 66 GHz, sufficiently meeting the bandwidth specification for WiGig/IEEE 802.11ad applications worldwide. Measurement errors occurred during the RF probing procedure and discrepancies between the antenna feedlines are identified as the primary cause for port-to-port variations.

Phased-array and beam steering characteristics are evaluated in the anechoic chamber using a far-field measurement setup. An enhanced serial interface (ESI) control board is connected to the antenna module through wired interface. Custom-made software program installed on the computer that is connected to the ESI board emulates the digital functions of the 60 GHz transceiver system. Beam steering is realized by modulating the phase distributions of equal-amplitude 60 GHz signals that feed each of the antenna elements. Eight 2-bit phase shifters within the RFIC are modulated to produce specific phase distributions for the corresponding beam steering scenario based on a predetermined beam table. A V-band standard

gain horn antenna is used to transmit and receive a series of CW signals within the 57–66 GHz range to and from the DUT. The CW signals are up converted and down converted to 54 MHz intermediate frequency (IF) in both the transmitting and receiving end. The normalized measured and simulated far-field radiation pattern of the antenna module is presented in Figs. 45 and 46 in the E- and H-plane for both boresight and preset beam tilt angle of −45° and 30°, respectively. The designed 60 GHz antenna module exhibits 3 dB beamwidth of 28° and 50° at boresight in the E- and H-plane, respectively. The maximum scan range is determined to be approximately 50° in both planes. The measured gain values at preset beam tilt angle of −45° and 30 ° are 11.3 dBi and 11.6 dBi at 61.5 GHz, respectively.

mmWave Antennas for 5G Cellular Phones

Introduction and Background

Based on the remarkable technological advancements, the cellular market sector continues to maintain a healthy growth rate – according to the International Telecommunication Union (ITU), during 2013 Mobile World Congress (MWC), worldwide cellular phone subscriptions will exceed world population by 2014. Numerous approaches are being discussed and researched around the world to create a future cellular network which would one day succeed the incumbent 4G/LTE network. While the data capacity of the 4G/LTE service continues to improve quite remarkably, classical information theory established by Claude Shannon and Ralph Hartley points out that the bottleneck in achieving the desired cellular Gbps data rate mostly lies on the currently crammed spectrum bandwidth. In retrospect, it becomes possible to introduce an entirely new cellular technology by employing a higher frequency spectrum which contains a

DOI 10.1007/978-981-4560-75-7_64-1

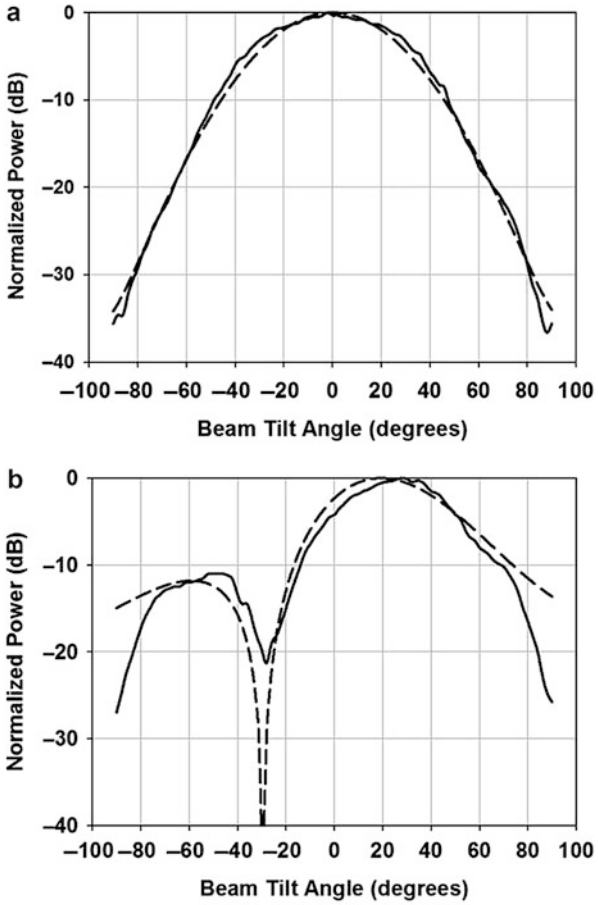

Fig. 46 Normalized far-field radiation pattern in the H-plane. (**a**) Boresight. (**b**) 30° beam tilt. *Solid*: measured. *Dash*: simulated (Hong et al. 2013)

much larger allocated signal bandwidth. The ongoing proliferation of small base stations denoted as microcells and picocells carried out by the cellular carriers becomes enormously instrumental in mitigating the relatively high free-space loss caused by the atmospheric conditions and penetration at extremely high frequencies. Adaptive beam steering technology discussed in section "Theory" can be utilized to get around obstructions, signal blind spots, and other NLOS propagation conditions. Theoretical study and measurement results of a 5G prototype operating at millimeter wave have been presented and discussed in detail in Roh et al. (2014). In the aforementioned study, a 28 GHz prototype exhibits a sharp radiation beam consisting of an array of multiple antennas which continually sweep the atmosphere to identify the strongest connection.

The implementation of a mmWave transceiver within a cellular phone introduces unprecedented challenges that are far from trivial. The enormity of this task is particularly exacerbated by the unique nature of user scenarios associated with cellular phones. In comparison to portable computers and wireless docking stations, cellular phones are much more compact in size and its user scenarios are highly diversified owing to the proliferation of smartphones. The 5G cellular phone must guarantee secure and reliable link accessibility of Gbps speed anywhere, anytime. Among key elements constituting the mmWave 5G radio, the antenna requires one of the most radical changes design wise. This is due to the relatively simple fact that every cellular standard up to present has operated below the 3 GHz spectrum. Present-day cellular antennas can be classified as electrically small antennas and are inherently omnidirectional. The antenna gain of these antennas typically falls in the range of −8 to 0 dBi. The much higher

DOI 10.1007/978-981-4560-75-7_64-1

gain that is needed to compensate the higher signal attenuation at mmWave frequencies introduces the concept of antenna arrays for cellular phones for the first time in the history of wireless communications. In this subsection, pragmatic methodologies to design and selectively utilize up to 32 antenna elements operating at 28 GHz within a future 5G cellular prototype are demonstrated. A number of key antenna design considerations that stem from the unique nature of mmWave bands are discussed in detail. Based on these considerations, a novel but practical 28 GHz phased array is designed and illustrated. While it is important to note that the 28 GHz carrier frequency has yet to be ratified for 5G communications, this design technique can be scaled to other mmWave frequencies in future applications.

Key Considerations for mmWave 5G Antenna

Determining the optimum placement of the 28 GHz antenna within a cellular handset is one of the most defining factors prior to the actual design. While it is difficult to accurately envision a future cellular handset device down to the detail, it is projected that radio functions will closely resemble its present-day counterpart. A conventional cellular phone chassis is examined and classified into a number of key segments as presented in Fig. 47. Major segments such as the rear case, battery cover, and the main PCB are predominantly based on polycarbonate and FR-4. For these materials, the loss tangent versus frequency relation is coherent with studies reported in (Hong et al. 2013). Therefore it would be valid to predict that the gain of the 28 GHz antenna will likely experience a non-negligible degradation when placed within the cellular handset device. A loss of 1.4 dB in gain of a rudimentary 28 GHz patch antenna is calculated when placed within in the top left corner of the presented chassis using electromagnetic numerical simulators. The metallic segments within the cellular handset such as the LCD bracket, LCD, and the battery are expected to be perceived as a finite conductive layer at 28 GHz. Consequently, the designed antenna must be implemented within the 5G cellular phone which excludes these regions.

The placement of the 28 GHz antenna is further complicated by the uncertainty of the user's hand. At 28 GHz, the user's body functions as a formidable absorber which is expected to have negative effects on the gain, radiation pattern, and return loss of the antenna. Figure 48 presents a simulation of the performance degradation of a conventional broadside 28 GHz antenna array implemented within the presented chassis. More than 9.5 dB decrease in gain is estimated when the user's hand fully encompasses

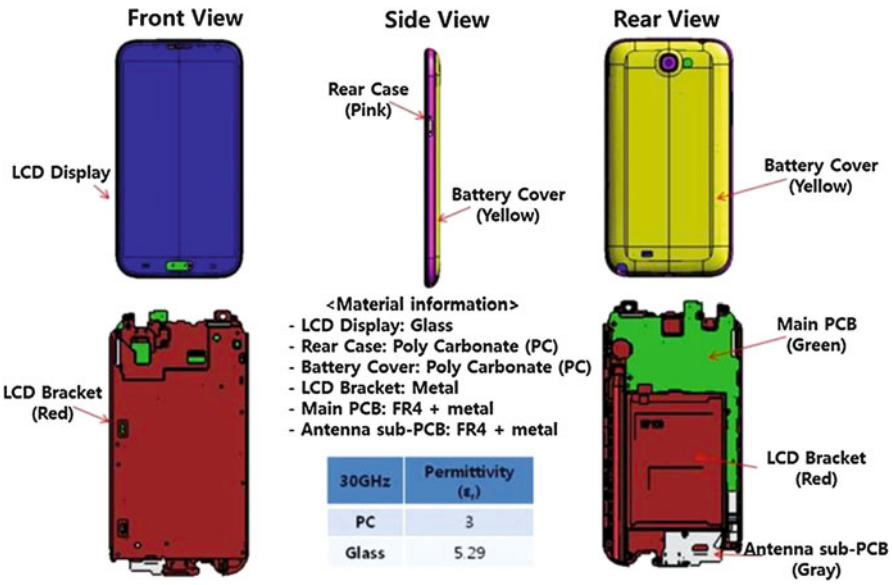

Fig. 47 Illustration of the material properties of the major segments of a conventional cellular handset (Hong et al. 2014a)

DOI 10.1007/978-981-4560-75-7_64-1

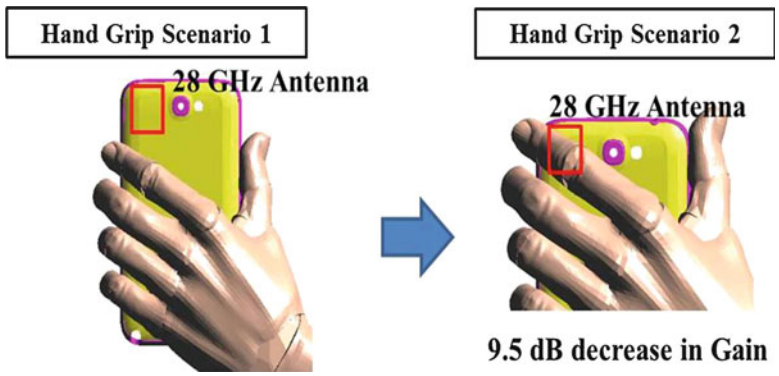

Fig. 48 Simulation of the effect of the user's hand on a rudimentary 28 GHz antenna array placed within a cellular handset (Hong et al. 2014a)

the region of the 28 GHz antenna array. One way of alleviating the potential performance risk caused by the user's hand would be to implement plural number of antennas within the cellular device.

Mobility requires cellular phones to operate virtually anywhere. It is statically and empirically impossible to predict the angle of arrival (AoA) of the strongest signal path. The omnidirectional patterns of 3G/4G cellular phone antennas today are advantageous in this regard. Likewise at mmWave frequencies, the incoming waves impinging on the antenna are predicted to be distributed across the entire sphere. This introduces a paradoxical situation for the antenna engineer that given a finite amount of energy, the antenna needs to radiate with extremely high intensity around the sphere. Since simultaneous radiation at all angles violates the classical laws of physics, phased-array beam steering as that employed in the previous subsection is applied.

In this subsection, Cartesian coordinates (x,y,z) and spherical coordinates θ (ranging from 0 to π and defined as the elevation angle) and φ(ranging from 0 to 2π and defined as the azimuth angle) will be used to describe the maximum allowable trajectory of the main lobe of the phased-array antenna. Based on the realistic physical limitations of antenna placement options within a cellular phone as described earlier, two-dimensional (planar) phased-array topology is deduced. With selected withstanding exceptions, the antenna elements are placed at least half wavelength apart to avoid spatial aliasing or also known as grating lobes.

For $1 \times N$ antenna array geometries, the scanning angle is a function of θ or φ. The scanning angle is a function of θ and φ for $N \times M$ antenna geometries. In addition, the scanning angle range of the main lobe is inversely related to the number of antenna elements (i.e., antenna array gain). Due to the high signal attenuation at 28 GHz, the antenna must be placed in very close proximity to the 28 GHz RFIC and the front-end module. Implementing the antenna array directly on the PCB of the 5G cellular device will therefore keep the insertion loss between the antenna and RFIC to be minimal. This implies that a placement of the RF blocks within the 5G architecture before the intermediate frequency (IF) stage will be dependent on the placement of the 28 GHz antenna array within the cellular phone. Collectively considering the aforementioned design environment, a minimum set of two 28 GHz antenna arrays are conceived for mmWave 5G cellular phones. As presented in Fig. 49, the two antenna arrays are implemented on the top and bottom portion of the cellular device. This is somewhat of an intuitive approach since similar to 3G/4G antennas, the large LCD display panel and the battery prohibit the antenna arrays from being placed in the center region of the cellular phone. This topology is applicable for both single-input single-out (SISO) and multiple-input multiple-output (MIMO) systems. Each 5G antenna array located on the top and bottom portion of the cellular phone is designed to respectively

cover the corresponding hemisphere in the form of spatial diversity. For SISO, the secondary antenna array becomes instrumental when a secure link cannot be established using the primary antenna.

It is a rarity for thickness of cellular phone PCBs to exceed 1 mm. In the fiercely competitive consumer electronics arena, increasing the PCB thickness is directly related to the rise in production costs and bulkier designs. At 28 GHz, the free-space half wavelength is slightly larger than 10 mm. This discrepancy prohibits phased-array beam steering in the elevation plane (*zx* plane) and leads us to a one-dimensional beam steering approach using a 1 × N antenna array topology. Moreover, a very broad beamwidth is required in the elevation plane to compensate for the inability to beam steer.

mmWave 5G Mesh-Grid Antenna Array Design

In order to synthesize a highly directive fan beam, it is imperative to maximize the allowable number of antenna elements inside the cellular phone. Avoiding unnecessary loss in the antenna radiation is critical at mmWave since this is correlated to the wireless link budget and eventually the power consumption. Therefore each of the antenna elements is designed to be at least a quarter of λ_g large, which is the minimum threshold before the radiation efficiency starts to sharply deteriorate due to the rise of stored energy in the near-field region of the antenna. As mentioned in section "Key mmWave Antenna Design Techniques," mmWave planar dipoles are by far the most popular fan-beam antennas in the wireless industry. However, as it was also discussed in section "Key mmWave Antenna Design Techniques," the fan-beam radiation characteristics of planar dipole are preserved under the condition that the metallic patterns and tracelines are removed below the planar dipole topology. The elimination of the metallic patterns becomes problematic especially with the advent of smartphones due to the increased degree of integration of the PCB. Cellular phone PCBs which are less than 1 mm thick typically consists of 6–12 layers that are tens of μm in thickness respectfully. Within that space run various signal lines ranging from low-speed to high-speed interfaces and power distributed networks. Removal of the signal line traces for the implementation of the half-guided wavelength planar dipole structure puts a serious strain on the PCB layout. As an alternative, a low-profile antenna design which can coexist with the signal line traces and yet exhibit a fan-beam radiation characteristic is designed.

DOI 10.1007/978-981-4560-75-7_64-1

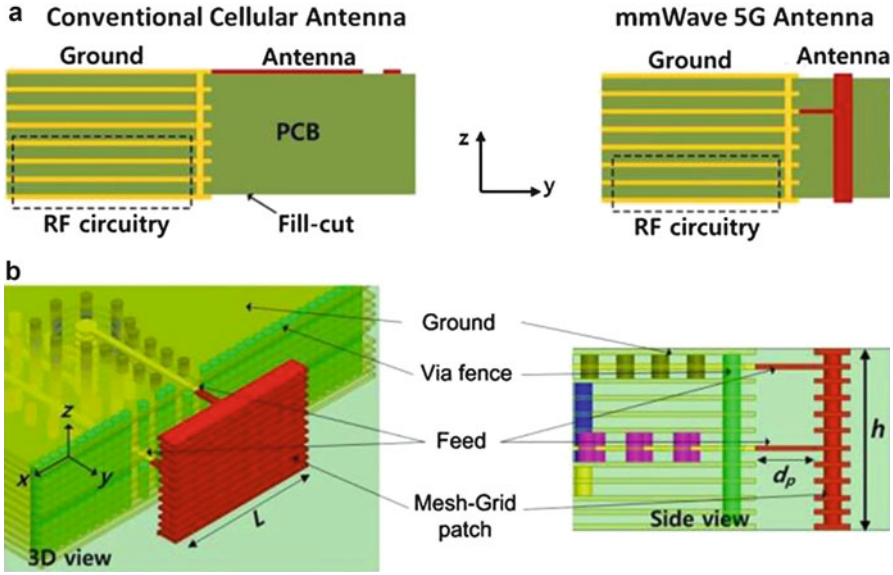

Fig. 50 (**a**) Simplified comparison between conventional cellular antenna and proposed mmWave 5G antenna topology. (**b**) Detailed view of the mesh-grid patch antenna (Hong et al. 2014b)

Illustrated in Fig. 50, in contrast to planar dipole antennas that spans across the *xy* plane, the newly devised structure is situated along the *zx* plane which can reduce the planar antenna footprint from the previous half λ_g to a fraction of a hundreds of a λ_g. The real estate in the *xy* plane is solely determined by the length of the dual antenna signal feed lines denoted as d_p. The entire radiating body of the antenna structure consists of tightly spaced via holes creating a mesh type grid as it can be observed from the *zx* plane. Hence, this antenna topology is named as the mesh-grid patch antenna by the authors. The physical dimension of the mesh-grid patch antenna ranges from quarter to half of the λ_g along the *x*-axis. The height denoted as *h* determines the number of PCB layers required for the specific mesh-grid patch antenna design and affects the elevation beamwidth in the θ angle. The mesh-grid antenna is designed to support multi-polarized MIMO based on any combination consisting of vertical, horizontal, and circular polarizations as illustrated in Fig. 51. Two antenna feedlines are configured to respectively enable horizontal and vertical polarizations. The polarization configurations are summarized in Table 2. Figure 52 presents the simulated and measured far-field radiation pattern of the mesh-grid patch antenna in the elevation plane. The measured −10 dB return loss bandwidth is approximately 1 GHz with a center frequency of 27.9 GHz.

The mesh-grid antenna elements are expanded and arranged in two sets of 1 × 16 phased arrays in the top and bottom portion of the cellular phone PCB as illustrated in Fig. 53. The high antenna gain realized by a reconfigurable and scalable array consisting of 16 antenna elements alleviates the linearity and power consumption requirements of the 5G amplifiers. The mesh-grid antenna elements situated at each corner of the PCB are arranged in slanted angles of approximately 50°. The conformal topology further maximizes the range of the beams steering scanning angles in the azimuth plane. Moreover, the slanted topology conforms to the cellular device and enables the designed mmWave antenna array to appear as an extremely low-profile metallic trace lines which encompasses around the edges of the PCB. The width of the trace lines is less than 0.2 mm which is even less than the 1 mm spacing required from the PCB edges for conventional surface-mount technologies (SMT). From the vantage point of the hardware layout, the inclusion of a total of 32 mmWave antenna elements requires negligible antenna footprint. Based upon this antenna solution, a truly massive MIMO antenna system may be realizable for mmWave 5G in the long term.

The measured and normalized radiation patterns of the mesh-grid antenna array in the azimuth plane are plotted for different main beam scanning angles in Fig. 54. The antenna array prototype is first measured in a stand-alone state denoted as free space. Afterward, the measurement is repeated after the AUT is integrated within the cellular phone prototype. Measurements ascertain a scanning angle range of approximately $\pm 70^{o}$. By combining the two antenna arrays, nearly spherical radiation coverage can be

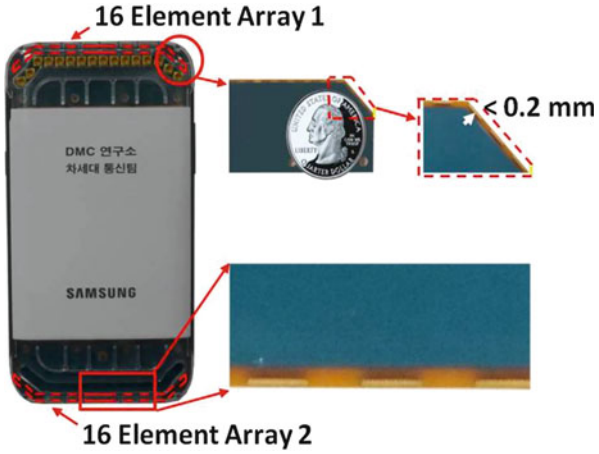

Fig. 53 Photographs of the mmWave 5G antenna system prototype integrated inside a cellular phone and zoomed in views of the mmWave antenna region (Hong et al. 2014b)

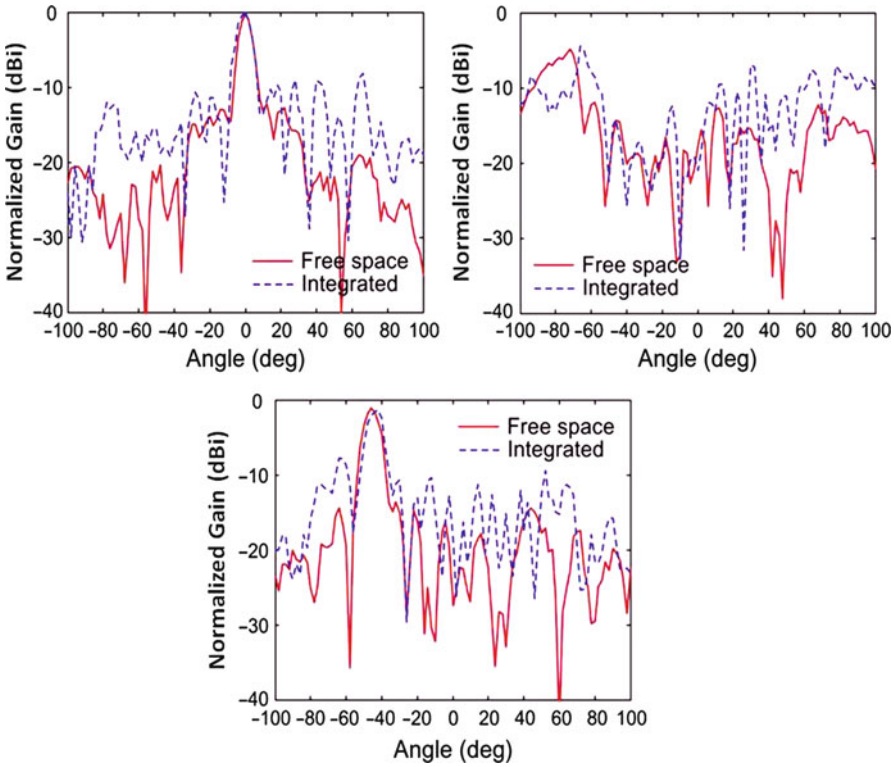

Fig. 54 Measured and normalized radiation patterns of the 16-element mesh-grid antenna array in the horizontal polarized configuration (Hong et al. 2014b)

attained. The radiation pattern discrepancies between the free space and integrated condition indicates the occurrence of pattern deformation caused by diffracted and refracted electromagnetic waves between the antenna elements and the cellular phone chassis. The discrepancy level is expected to vary as a function of the design and material composition of the cellular device. The 3 dB beamwidth in the azimuth plane is approximately 12° generating a null-free beam scanning coverage. The peak gain of the antenna array within the cellular device is calculated to be more than 10.5 dBi. Major loss factors include the 2.8 dB loss

from the mesh-grid antenna feed point to the K-type coaxial connector, 2.2 dB cable loss between the K-type coaxial connector and the RF unit, and the estimated 1.8 dB dielectric loss incurred by the polycarbonate chassis of the cellular phone prototype used in the measurement.

Biological Implications and Considerations

Assessing the biological implications on the user may be one of the most important parameters for mmWave 5G cellular devices in the future. The level of electromagnetic absorption by the human body is strictly and universally regulated by governmental bodies under the specific absorption rate (SAR) guideline. Every cellular device must pass a regulated SAR test prior to certification. Likewise although permissible SAR levels at mmWave frequencies do not exist at this point in time, it is possible to analyze and compare mmWave SAR levels with that of 3G/4G cellular phones. To investigate this, the measured radiation patterns of the two sets of mesh-grid antenna arrays are imported into a commercial numerical simulator.

With the inclusion of a human head phantom, the average SAR levels are calculated. As it can be observed in Fig. 55, the electromagnetic fields absorbed by the user at 28 GHz tend to be localized in comparison to that of a 3G/4G cellular frequency band. The penetrated skin depth of the absorbed 28 GHz signal is confirmed to be approximately 3 mm. In comparison the penetrated skin depth at 1.9 GHz exceeds 45 mm. This implies that majority of the absorbed energy is confined to the epidermis at mmWave. The average calculated SAR at 28 GHz for the antenna array situated in the bottom region of the cellular phone is found to be less than a factor of 18 compared to SAR levels retrieved at 1.9 GHz. The ability to beam steer the main lobe is projected to further reduce the SAR levels in the future.

Conclusion

As discussed in this chapter the exploitation of mmWave frequencies is projected to become the backbone of future mobile networks. mmWave wireless communication aims to enable unprecedented and intuitive

DOI 10.1007/978-981-4560-75-7_64-1

user experience with enhanced accessibility to the general public. However, it is vital to emphasize that mmWave spectrums will not render presently used microwave spectrum to become obsolete. The inherent limitations of the mmWave signals imply coexistence with legacy wireless architectures, and integrations will become an ever-important issue as widespread interest of mmWave communications continue to grow. In severe propagation conditions, mmWave radio systems will be designed to fall back to conventional radio systems to ensure the overall quality of service (QoS) of the wireless network. As the number of antennas required inside wireless mobile terminals such as cellular phones and small access points continue to increase on a yearly basis, the limited space constraints for mmWave antennas is projected to become an major issue. Researching novel mmWave antenna topologies which are easier to integrate with the rest of the legacy wireless RF system and the microwave frequency spectrum antennas will be an important area. In addition, the demand for three-dimensional, reconfigurable mmWave antennas is anticipated followed by the proliferation of wearable communication devices and the advancements of three-dimensional printing technologies. The mmWave antenna design philosophy must prioritize and focus on the wireless system performance such as link reliability and power consumption efficiency.

Another key area where mmWave antenna technologies are projected to be vital is associated with the emergence of multi-node/massive MIMO transmissions and receptions. Massive MIMO antenna architectures are composed of a very high number of antenna elements with the purpose of enhanced wireless capacity. They benefit from simplified MAC layers, enhanced latencies, and signal cell channel capacity. Devising efficient mmWave antenna topologies capable of three-dimensional, simultaneous multi-beam steering that is scalable remains a notable technical challenge. Future massive MIMO antenna technology must be investigated with full consideration of multi-heterogeneous networks (multi-HetNeT) which is composed of multiple carrier frequencies. The increasingly technical complexity related to interoperability and mutual dependency between the radio hardware and the wireless network researchers underlines the multidisciplinary nature of future mmWave antenna research. The anticipated Internet of Things (IoT) era will further introduce numerous wireless devices with diverse shapes and forms. The author predicts mmWave antennas will evolve from the current planar multilayer PCB types to conformal topologies based on novel materials and integration concepts.

Conformal Array Antennas

Lars Josefsson[a]* and Patrik Persson[b]
[a]Lars Microwave, Askim, Sweden
[b]Antenna System Technology, Ericsson Research, Gothenburg, Sweden

Abstract

The history, including the theory and the technology, leading to today's conformal array antennas (nonplanar array antennas) is discussed. Since the apertures of these antennas are curved (usually convex), the traditional methods for planar array analysis and design cannot be used. An important aspect is the mutual coupling between radiating elements due to the diffraction along the curved surface. Beamforming, phase modes, geodesics, and polarization are concepts that are dealt with.

Several applications of conformal array antennas are mentioned including wide angle (360°) coverage antennas for mobile base stations, antennas built into the skin of vehicles such as aircraft and satellites, spherical arrays for simultaneous tracking of signals from many directions, etc. Compared to planar arrays, the steering and control of conformal arrays is more complicated. However, the rapid growth in computer power (software and hardware) opens up for new solutions. In particular digital beamforming (DBF) looks promising for the future.

Keywords

Circular array; Commutating; DBF; Digital beamforming; Geodesic; Icosahedron; MIMO; Phase mode; Polarization; Spherical array; UTD; Wullenweber array

Introduction

Definition

A conformal array antenna conforms to a particular shape, e.g., a sphere, cylinder, paraboloid, etc. This is different from most array antennas that are typically planar and not curved.

The IEEE Standard Definitions of Terms for Antennas (IEEE Std 145-1993) gives the following definition:

2.74 conformal antenna (**conformal array**). An antenna (an array) that conforms to a surface whose shape is determined by considerations other than electromagnetic; for example, aerodynamic or hydrodynamic.

2.75 conformal array. *See*: **conformal antenna**.

An array antenna might have its shape determined by a particular electromagnetic requirement such as the angular coverage or beam shape characteristics, leading to a cylindrical or other particular shape. The term conformal is used also in such cases although it is not strictly according to the IEEE definition cited above. Technically it makes no difference.

DOI 10.1007/978-981-4560-75-7_65-1

Motivation

Why conformal array antennas? For several applications conformal antennas offer advantages over traditional planar antenna solutions. Some of them will be discussed briefly.

Aircraft antennas: Modern aircraft have antennas for radar, navigation, communication, instrument landing, altimeters, etc. There can be as many as 20–70 antennas on a typical aircraft, several of them protruding from the aircraft skin causing considerable drag and increased fuel consumption. Integrating these antennas into the curved aircraft skin is highly desirable (Hopkins et al. 1997).

Mobile base stations can benefit from a cylindrical array arrangement with steering of beams within 360° of coverage instead of using several planar arrays, each covering a fixed sector. For communication with aircraft and satellites from ground stations, even spherical or semispherical antenna arrangements may be required.

Also in *urban environments* – densely populated areas – more and more antennas are used. It is often desired to integrate these antennas into existing structures (lampposts, chimneys, flagpoles, etc.) to make them less obtrusive and more acceptable to the public eye.

Even *modern cars* can benefit from antenna functions integrated into the body (navigation, Internet, radio, television, collision avoidance, and so on).

Communication systems onboard *satellites* sometimes require large angular coverage leading to a need for curved arrays. One example is in low-orbiting, spin-stabilized satellites.

Conformal array antennas are also of interest for *defense applications* (radar, communication, and warning systems). These systems typically require large angular coverage and handling of many simultaneous targets as well as integration of the array antenna in the surface of various vehicles. With conformal arrays a separate radome might not be required.

History

A system of dipole elements arranged on a circle was proposed as an anti-fading broadcasting antenna in the 1930s (Chireix 1936). By sequential phase excitation, omnidirectional radiation was obtained in the horizontal plane, while signals reflected from the ionosphere at higher elevation angles (causing the interference and fading) were reduced. The first system was implemented in France, with only four radiators for cost reasons. Hence, the element phase excitation around the "circle" was 0°, 90°, 180°, and 270°. This is an example of a *phase mode* excitation (more about this later) (section "Array Theory").

Circular dipole arrays, so-called Wullenweber arrays, were developed in the 1950s for signal intelligence gathering and direction finding (Gething 1966). These arrays were quite large with diameters of several hundred meters. Most of them are now dismantled, however, and their functions have been replaced by satellite-borne systems.

Technical Progress

The circular (or ring) array is attractive for many reasons: it is relatively simple and proper excitation schemes enable a directive beam to be steered 360° in azimuth. Pattern synthesis methods based on phase mode theory and beam steering schemes have been developed (Knudsen 1953; Davies 1983). The applications are found in broadcasting, communication, navigation, direction finding, and radar. An interesting radar concept using circular arrays and beamforming on receive has been described by Dorey et al. (1989).

Several circular arrays can be placed on top of each other in order to increase the directivity, as in the electronically scanned TACAN (tactical air navigation) antenna. The antenna radiates a rotating phase-coded signal that helps aircraft to find their position in relation to, e.g., an airfield (Christopher 1974).

Many of the above circular arrays were made up of dipole elements. A dual structure of fundamental interest consists of aperture elements, or slots, in metallic cylinders (Wait 1959). This type has been

DOI 10.1007/978-981-4560-75-7_65-1

investigated using modal expansion techniques and high-frequency diffraction techniques, including mutual coupling effects (Hessel 1970; Pathak et al. 1980).

The step from cylindrical arrays to conical arrays may seem straightforward. Such arrays in the nose area of aircraft or missiles would be of great interest. However, arrays with elements near the pointed tip are difficult to manage (Munger et al. 1974). Another attractive arrangement for aircraft is an array conformal to the shape of the wing leading edge (Steyskal 2002). Also spherical arrays have been proposed (Liebman et al. 1975).

Array elements with associated electronics including feeding and cooling systems, etc. may be difficult to build on a curved surface, especially if the curvature is large and varying over the surface. However, good results have been obtained in many cases by approximating the curved surface with plane facets. Each facet forms a planar subarray with a small number of modular elements (Tomasic et al. 2003).

During the last decades, sophisticated software tools for analysis and optimization of complex electromagnetic structures have been developed. This development has been stimulated by the availability of advanced high-speed computers, without which many conformal arrays could not have been rigorously analyzed. Finite element methods as well as high-frequency diffraction methods have been developed. The uniform theory of diffraction (UTD) has been combined with the theory of geodesic lines on curved surfaces (see section "Analysis").

The steering and control of conformal arrays integrated into the skin of various structures must be matched by the proper processing of transmitted and received signals. Array calibration is another critical aspect. The beamforming function is probably most efficiently done by digital means. Hence, DBF, or digital beamforming, is an area very much related to conformal array technology, at least for more complex systems. Of course, analog beamforming will still find its place (see section "Beamforming in Conformal Array Antennas").

Conformal array antenna technology has been the focus of several workshops, conferences, and publications; see the reference list at the end of this chapter.

Array Theory

ULA Versus UCA

The *uniform linear array*, or ULA, can be seen as the fundamental building block of planar array antennas. Similarly, the *uniform circular array*, or UCA, is the fundamental building block of conformal rotationally symmetric array antennas, including cylindrical and conical shapes. The two arrays are illustrated in Fig. 1. Much of the theory for circular arrays applies to cylindrical arrays as well.

It should be observed that the term *circular array* is sometimes understood as a circularly shaped planar array (cf. rectangular array, elliptical array, etc.). However, this is not the meaning here. Another word for the UCA is *ring array*.

There is an important difference between ULAs and UCAs regarding the influence of the element patterns. In the linear array all elements point in the same direction. The ULA radiation pattern function can be written as the product of an element factor and the array factor:

$$E(\phi) = EL(\phi)\sum_{n} V_n e^{jnkd\sin\phi} \tag{1}$$

DOI 10.1007/978-981-4560-75-7_65-1

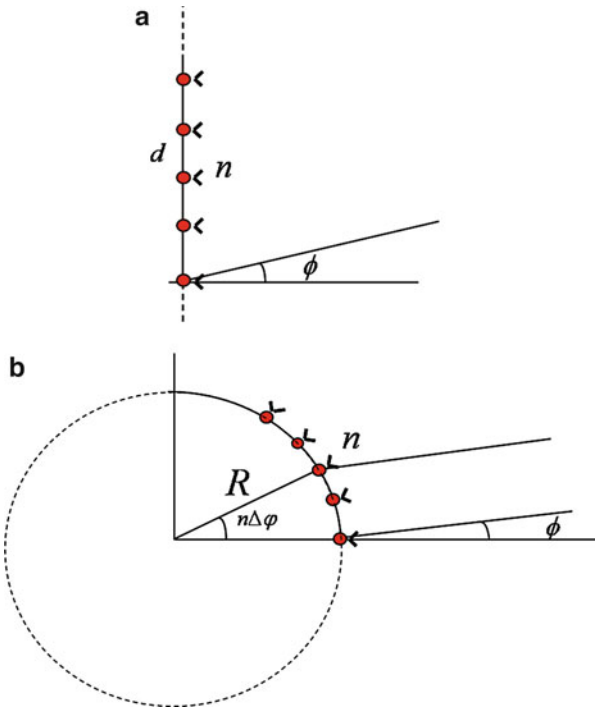

Fig. 1 Uniform linear array (**a**) and uniform circular array (**b**)

where

$EL(\phi)$ is the element pattern function (element factor)
V_n is the element excitation
d is the element spacing
$k = 2\pi/\lambda$

For the UCA an element factor can in general not be factored out; hence,

$$E(\phi) = \sum_n V_n EL(\phi - n\Delta\varphi) e^{jkR\cos(\phi - n\Delta\varphi)} \tag{2}$$

where $\Delta\varphi$ is the element angular spacing and R is the circular array radius.

Let us assume the elements to be isotropic, i.e., the element pattern $EL(\phi) = 1$ in all directions. If the element excitations are all equal, say, $V_n = 1$, the ULA would have a radiation pattern similar to a $\sin x/x$ function with a narrow beam, provided the element spacing d is less than a wavelength. The same assumptions for the UCA result in a more or less omnidirectional pattern in the plane of the array. Two problems may arise for both arrays: grating lobes for the ULA and pattern distortion (ripple) for the UCA. The common cause is a too large element spacing which results in the appearance of undesired higher modes.

In the following the focus will be on the UCA, the circular array antenna. Linear and planar phased array antennas are treated in other chapters.

Phase Mode Theory

An example of a practical UCA is shown in Fig. 2, where radiating elements in the form of vertical dipoles are suggested.

DOI 10.1007/978-981-4560-75-7_65-1

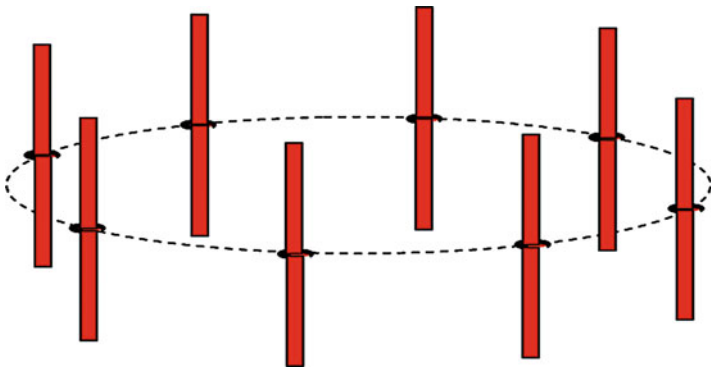

Fig. 2 A uniform circular array with vertical dipole elements

Table 1 Definition of the first few phase modes

Mode 0	Phase = constant	For one turn around the ring
Modes ± 1	Phase change ± 1 × 2π	"
Modes ± 2	Phase change ± 2 × 2π	"
Modes ± m	Phase change ± m × 2π	"
etc.		

The vertical dipoles in Fig. 2 are omnidirectional in the horizontal plane. Since the elements have identical patterns for all positions in the array, the element pattern can be factored out in the radiation function. More important is perhaps that the polarization remains vertical for all directions, and there is no cross polarization. This generic type of array is often used in radio communication and direction finding systems.

An idealized case is a UCA with a *continuous* ring excitation, thus approximating an array with densely spaced isotropic elements. The first phase mode excitations $V(\varphi)$ for this idealized ring are shown in Table 1.

A general excitation of the ring can be expressed as a summation of several phase modes with amplitudes C_m:

$$V(\varphi) = \sum_{-\infty}^{\infty} C_m e^{jm\varphi} \tag{3}$$

which is a Fourier series representation of the periodic function $V(\varphi)$. The period is 2π, one revolution around the ring. The Fourier coefficients C_m are

$$C_m = \frac{1}{2\pi} \int_{-\pi}^{\pi} V(\varphi) e^{-jm\varphi} d\varphi \tag{4}$$

Also the far field must be periodic and can be written as

$$E(\phi) = \sum_{-\infty}^{\infty} A_m e^{jm\phi} \tag{5}$$

Alternatively, the far field can be written (cf. Eq. 2) as

DOI 10.1007/978-981-4560-75-7_65-1

$$E(\phi) = \frac{1}{2\pi} \int_{-\pi}^{\pi} V(\varphi) e^{jkR\cos(\phi-\varphi)} d\varphi \tag{6}$$

Combining Eqs. 3 and 6 gives

$$E(\phi) = \sum_{-\infty}^{\infty} \frac{1}{2\pi} C_m \int_{-\pi}^{\pi} e^{jm\varphi} e^{(jkR\cos(\phi-\varphi))} d\varphi \tag{7}$$

Comparing this with Eq. 5 gives a relation between the coefficients A_m and the coefficients C_m:

$$A_m = C_m \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{jm(\varphi-\phi)} e^{jkR\cos(\varphi-\phi)} d\varphi \tag{8}$$

This can also be written as

$$A_m = j^m C_m J_m(kR) \tag{9}$$

where the function $J_m(z)$ is the Bessel function of the first kind and order m. Thus, the Bessel function has a major impact on the relation between *radiation* and *excitation*, i.e., between the A_m and C_m coefficients. A graph of the Bessel function for the first few orders m is presented in Fig. 3.

From the magnitude of $J_m(kR)$, it is evident that for a given size kR only orders m up to about $m = kR$ will radiate efficiently. This "modal cutoff" is not very sharp for small sizes. However, it is more distinct for larger sizes, e.g., $kR = 100$. The limit $m = kR$ corresponds to a phase variation of 2π per wavelength along the periphery. Twice the number of modes can be used if also negative m values are included.

A second observation from Fig. 3 is that the Bessel function nulls will severely attenuate radiation for arguments kR close to these nulls. This problem can be studied in terms of the mode stability $|A_m/C_m|$. It will be shown that the mode stability improves considerably if directive elements are used.

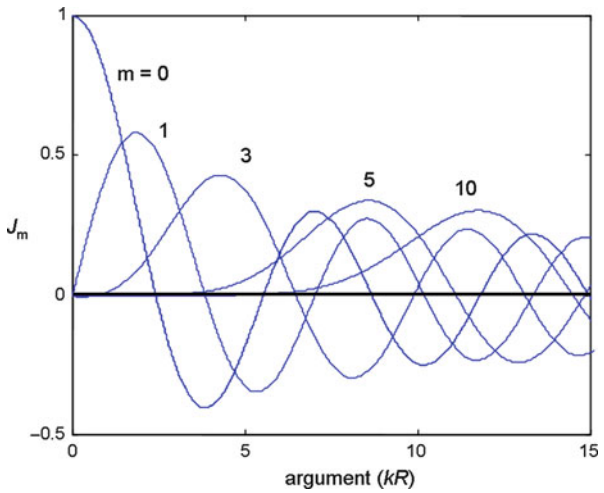

Fig. 3 The Bessel function $J_m(kR)$ for different orders m

DOI 10.1007/978-981-4560-75-7_65-1

Discrete Elements

The continuous ring array studied above approximates a real array with densely spaced radiating elements. A more realistic case is an array with evenly spaced discrete elements. To begin with it is still assumed that the radiating elements are isotropic radiators.

Consider the simplest case of a ring array with only the mode $m = 0$, i.e., a continuous and constant excitation, $V(\varphi) = V_0$. The Fourier expansion, Eq. 4, will have just one spectral term C_0, the "DC component." However, sampling this excitation at N points, corresponding to the N discrete element positions, will result in a line spectrum with harmonics at multiples of N/T, where T is the period 2π. If instead a phase slope $m > 0$ is considered, the same mode spectrum will result after sampling, but shifted by m/T.

A more complex excitation with several modes will form a spectrum of the modes used, repeated at intervals of N/T after sampling. These spectra should not overlap (no aliasing), i.e., it is required that $|m_{\max}| < N/2$. This implies that the number of elements should be large enough so that spectrum overlap is avoided. At the same time the array size should be large enough so that the desired number of modes is free to radiate. Finally, the "Bessel window" should block the undesired higher harmonics. These requirements are repeated below in mathematical form:

$$N > 2|m_{\max}| \tag{10}$$

$$kR > |m_{\max}| \tag{11}$$

$$\alpha kR < N - |m_{\max}| \tag{12}$$

Here it is assumed that a desired mode spectrum extending over a range of $\pm |m_{\max}|$ is used. Note the factor α introduced in Eq. 12, which nominally should be unity, but a factor up to perhaps 1.5 may be needed in some cases.

Figure 4 illustrates a situation with a desired spectrum extending over ± M modes. The related harmonics are not overlapping and the "Bessel window" admits most of the desired phase modes. In this case, assuming $M \approx kR$, an element spacing around the periphery of d/λ <0.5 is typically required.

A UCA with Omnidirectional Pattern

The following parameters are assumed: eight isotropic elements, uniform amplitude, one mode $m = 0$, and element spacing $d/\lambda = 0.65$. This gives $kR = Nd/\lambda = 5.2$. Summing up the element contributions (Eq. 2) gives the pattern below.

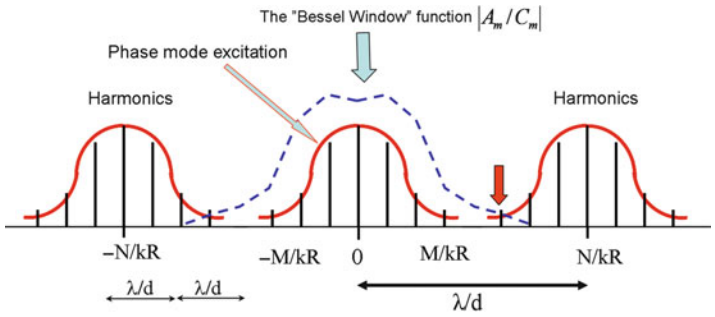

Fig. 4 Mode spectra: desired spectrum (*center arrow*) and part of the harmonic spectrum (see *right arrow*) causing some interference

DOI 10.1007/978-981-4560-75-7_65-1

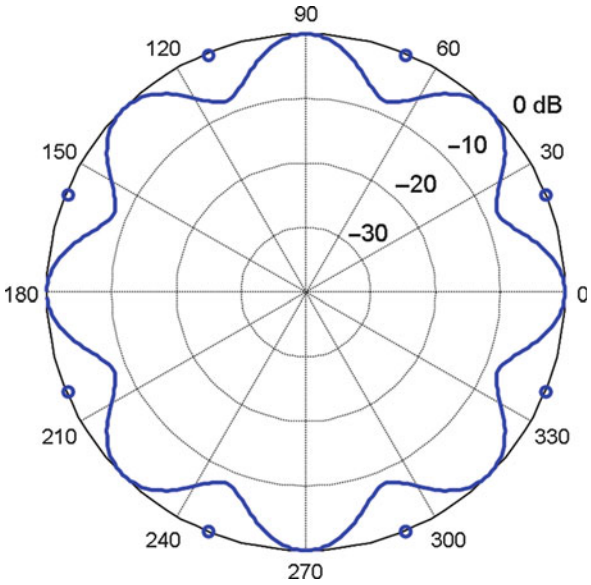

Fig. 5 Pattern from an eight-element UCA with $kR = 5.2$, isotropic elements (Josefsson and Persson 2006) (Copyright IEEE)

The "omnidirectional" pattern in Fig. 5 exhibits a rather severe ripple of about 8 dB. The reason is interference from two higher modes $m = \pm 8$ that are not sufficiently attenuated by the "Bessel window" (Fig. 4). The mode relative amplitudes (radiated) are found to be -0.215, 1.0, and 0.215.

Directive Beam

A second example is a UCA with isotropic elements, uniform amplitude, focused to radiate a narrow beam in the $\phi = 0$ direction. This implies that the elements are given a "cophasal" excitation. In the continuous case this results in an ideal pattern with -8 dB sidelobes:

$$E(\phi) = J_0\left(2kR\sin\frac{\phi}{2}\right) \tag{13}$$

This ideal pattern is shown in Fig. 6 together with a discrete example for the same kR value: 16 elements and $d/\lambda = 0.6$.

Directive Elements

With isotropic elements there was no element factor, as in Eq. 6. With the element factor inserted, the following far-field pattern is obtained:

$$E(\phi) = \frac{1}{2\pi}\int_{-\pi}^{\pi} V(\varphi)EL(\phi-\varphi)\mathrm{e}^{jkR\cos(\phi-\varphi)}d\varphi \tag{14}$$

The element pattern is the same for all elements although the elements point in different directions. Since it is periodic, period 2π, the element pattern can be written as

$$EL(\alpha) = \sum_{p=-\infty}^{\infty} D_p e^{jp\alpha} \tag{15}$$

DOI 10.1007/978-981-4560-75-7_65-1

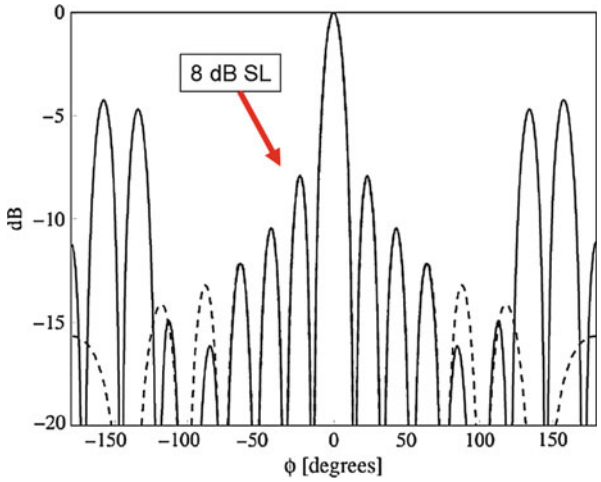

Fig. 6 Cophasal patterns for UCA with $kR = 9.6$. *Dashed curve*: Ideal case, continuous ring. *Solid line*: Discrete case with 16 elements and $d/\lambda = 0.6$ (Josefsson and Persson 2006) (Copyright IEEE)

Inserting this into Eq. 14 yields

$$E(\phi) = \frac{1}{2\pi} \int_{-\pi}^{\pi} V(\varphi) \sum_{p=-\infty}^{\infty} D_p e^{jp(\phi-\varphi)} e^{jkR\cos(\phi-\varphi)} d\varphi \tag{16}$$

Now, the excitation $V(\varphi)$ can be expanded in a Fourier series (Eq. 3). Taking out just the contribution from phase mode number m, the result is

$$E_m(\phi) = C_m e^{jm\phi} \sum_{p=-\infty}^{\infty} D_p \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{j(m-p)(\varphi-\phi)} e^{kR\cos(\varphi-\phi)} d\varphi \tag{17}$$

or

$$E_m(\phi) = C_m \left[\sum_{p=-\infty}^{\infty} j^{m-p} J_{m-p}(kR) \right] e^{jm\phi} = A_m e^{jm\phi} \tag{18}$$

Thus, a new relation between C_m (excitation) and A_m (radiation) results (cf. Eq. 9). The mode stability ratio $|A_m/C_m|$ is much more favorable here since the expression within brackets in Eq. 18 has no nulls within the region of most interest, which makes the design less critical, and more bandwidth is attainable.

Much of the results for the UCA, the uniform circular array, apply also to cylindrical arrays.

Phase Mode Impedance

As in any phased array antenna, the mutual coupling among the elements plays an important role; several examples will be given in section "Design." In the UCA, the uniform circular array, there is a symmetric structure, and it is possible to define a phase mode impedance, i.e., the active impedance for a particular phase mode m excitation:

DOI 10.1007/978-981-4560-75-7_65-1

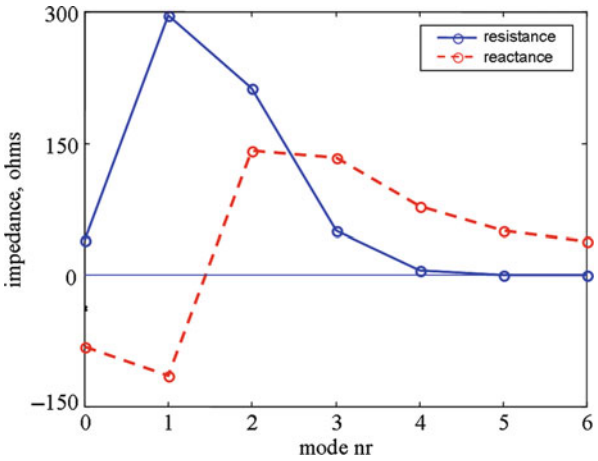

Fig. 7 Phase mode impedance vs mode order. UCA with 16 half-wavelength dipoles, $kR = 2.67$

$$Z^m = \sum_{k=1}^{N} Z_{ik} e^{2\pi j(k-1)m/N} \tag{19}$$

Here Z_{ik} is the mutual impedance between elements i and k. Because of the symmetry the impedance Z^m is independent of i and the same for all elements.

An example is shown in Fig. 7 for a 16-element circular array with parallel dipole elements spaced $d = \lambda/6$. The dipole mutual impedances Z_{ik} can be calculated from well-known formulas; see, e.g., Elliott (1981, p. 332) and Kraus (1988, p. 424). Since $kR = Nd/\lambda \approx 3$, in this case modes up to about $m = 3$ can be expected to radiate. This is also reflected in the figure; for higher modes the mismatch increases as the resistance approaches zero. Compare also with the Bessel function J_m (Fig. 3).

Doubly Curved Arrays

The ultimate conformal array antenna is a "smart skin" mounted on a part of an aircraft body or some other given structure. If the surface is only slightly curved, the design procedure might follow that of planar arrays (with some phase corrections due to curvature). The radiating elements would have to be directional, pointing outward from the surface. With increasing curvature it is obvious that all elements will not radiate efficiently in all scan directions. There would typically be an active sector to be moved (commutated) as the beam direction is changed.

Many systems require hemispherical coverage, for example, a ground-based surveillance radar or communication system, where the desired coverage is from zenith to horizon. Among the possible conformal array shapes are the half sphere, the cone, the paraboloid, and also the three- or four-sided pyramid. The latter, however, with planar surfaces, is not as efficient as the curved alternatives.

On the doubly curved arrays, it is not possible to lay out a perfectly periodic element grid. However, a reasonable quasiperiodic grid is possible, as the following element lattice on a paraboloid shows (Fig. 8).

The example shows circular elements laid out in rings (each ring is a UCA). A practical maximum look direction for each element is about $\pm$ 60° from the normal of the surface. For a beam direction 30° from zenith, this means that in this case only about half of the elements can contribute in this direction.

Another interesting shape is the half sphere, which can be thought to match quite well to the requirement for hemispherical coverage. A suitable configuration can be developed on the basis of one of the regular polyhedral shapes: the octahedron, the dodecahedron, and the icosahedron. These shapes approximate a sphere with 8, 12, and 20 equal plane facets, respectively. The last one with 20 triangular facets can be modified giving 12 pentagonal and 20 hexagonal surfaces (truncated icosahedron). The

DOI 10.1007/978-981-4560-75-7_65-1

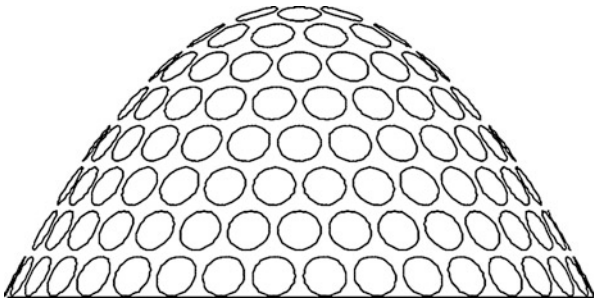

Fig. 8 An element lattice on a rotationally symmetric, parabolic surface (Josefsson and Lanne 2003)

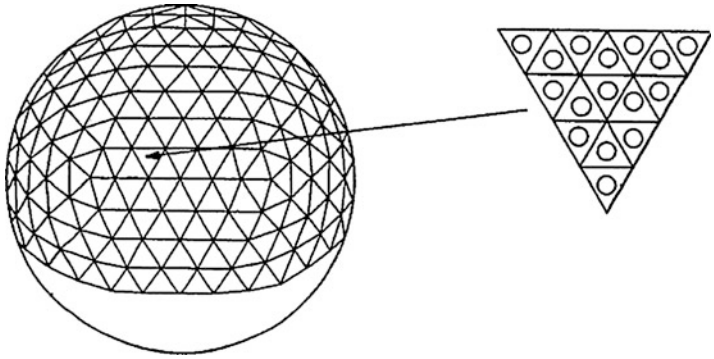

Fig. 9 A spherical surface built from triangular facets (Bondyopadhyay 2002) (Copyright IEEE)

facets can be subdivided into triangles projected onto the surrounding sphere where they can be further subdivided, etc. The result is a quasiperiodic lattice with some variations in element distances (see Fig. 9). All of these doubly curved arrays will have to use some kind of polarization control system or use circular polarization.

Analysis

Introduction

In the previous section UCA was introduced to present the fundamentals behind conformal antennas. So far the antenna elements considered have been positioned in free space, but in many applications there is a supporting structure as well. To fully predict the characteristics, the supporting structure should be included in the analysis.

This is not a trivial task since conformal array antennas can take many shapes. Furthermore, the surface is often electrically large (in terms of wavelengths) and it may be convex or concave or both. As illustrated in Fig. 9, faceted surfaces are also an alternative and this introduces edges or other discontinuities. Depending on the antenna design, dielectric layers may also need to be considered in addition to a PEC (perfect electric conductor) surface. Altogether, the surface can be very complex.

To some extent analytical methods can be used to derive the equations needed to solve the electromagnetic problem. But numerical methods will be needed to do the final analysis. Typically a combination is used, i.e., one uses analytical methods to take the first steps but then numerical methods need to be used. Many of the results presented in this chapter are based on such analyses. It should however be noted that today many of the commercially available codes such as HFSS and CST can analyze very complex and large surfaces. Hence, with the available computer power of today, a large surface is not as difficult to

DOI 10.1007/978-981-4560-75-7_65-1

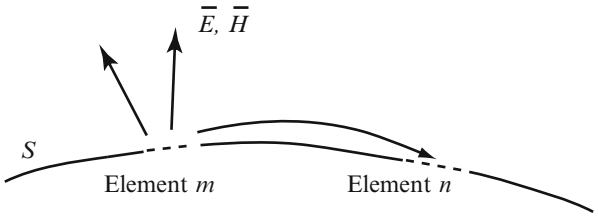

Fig. 10 The problem: find the field outside the curved surface *S* due to one or more radiating elements on the surface *S* (Josefsson and Persson 2006) (Copyright IEEE)

analyze due to memory requirements and time consumption as it was some years ago. Nevertheless, the focus here is to give a brief overview of some of the methods used traditionally when analyzing conformal antennas. Understanding the methods and theory behind is a very good starting point and makes it easier to also understand the results.

Note that the focus in this section is not to describe different analysis methods in detail, but to address some key aspects when analyzing conformal antennas.

The Electromagnetic Problem

As a start it is important to understand the problem to be solved and the associated electromagnetic problem. When having found a solution to the electromagnetic problem, it is possible to start analyzing the conformal (array) antenna. For the radiation problem, some approximations can be used when considering the far-zone region. A brief overview of circular array antenna theory was presented in the previous section to give an understanding about the fundamentals. Furthermore, the mutual coupling among the elements is essential in order to predict the characteristics of (conformal) array antennas. The electromagnetic solution to the problem also gives us the tool to study this, i.e., the surface field or the near field in order to find the mutual coupling among the radiating elements. This analysis is often difficult since no far-field approximations are possible.

Figure 10 illustrates the electromagnetic problem to be solved. It is a boundary value problem and now the field representation outside the surface *S* needs to be matched with the supposedly known field or current distribution at the antenna elements. When the solution has been found, the Green's function $\left(\overline{\overline{G}}\right)$ has been found for the antenna problem. Thus, the field outside *S* is related to the radiating element current $\left(\overline{J}\right)$ simply by the following general formula:

$$\overline{E} = \sum_{n=1}^{N} \int_{S_n} \overline{\overline{G}} \cdot \overline{J} dS \tag{20}$$

where the sum is taken over the number of elements considered. Unfortunately, the number of geometries where an explicit field representation outside *S* can be found is very limited. In many cases asymptotic expressions are needed, and in some cases a numerical representation is the only possible solution.

Calculating the mutual coupling between two radiators implies finding the field at element 2 due to the source at element 1 and then matching the boundary conditions at 2. This can typically be expressed as

$$Y_{12} = \frac{1}{V_1 V_2} \int_{S_2} \overline{E}_2 \times \overline{H}_2(1) d\overline{S} \tag{21}$$

DOI 10.1007/978-981-4560-75-7_65-1

By taking out two radiators like this out of a large array, with the other radiators short-circuited in case of apertures (or open-circuited for dipole-type elements), Eq. 21 represents an element in the mutual admittance (impedance) matrix. From this matrix the scattering matrix can be derived for the full array, i.e.,

$$\mathbf{S} = (\mathbf{I} - \mathbf{Y})(\mathbf{I} + \mathbf{Y})^{-1} \text{ or } \mathbf{S} = 2(\mathbf{I} + \mathbf{Y})^{-1} - \mathbf{I} \tag{22}$$

Modal Solutions: The Classical Solution

The classical way of analyzing conformal antennas is to use separation of variables and express the solution in a modal representation, i.e., in a vector harmonic series representation. This is possible only for special shapes, such as a perfectly conducting circular cylinder, elliptic cylinder, cone, or sphere. In the book *Electromagnetic Radiation from Cylindrical Structures* by J. R. Wait, a very good summary is found on the early work on cylinders (Wait 1959).

To briefly illustrate the technique of using separation of variables, an example will be given by using a circular cylinder. The cylinder is assumed to be infinitely long and perfectly conducting. In this example the antenna element is an aperture antenna. It is assumed that the tangential electric field distribution ($E_{\tan}$) on the surface is known as indicated in Fig. 11.

As a first step the problem is reduced to a two-dimensional problem by applying a Fourier transform with respect to the symmetry axis (here the cylinder or z-axis). Thus, define $\tilde{E}_{\tan}$ as a Fourier transform of the tangential components of $\bar{E}$ as

$$\tilde{E}_{\tan}(n, k_z) = \frac{1}{2\pi} \int_0^{2\pi} \int_{-\infty}^{\infty} E_{\tan}(r, \varphi, z) e^{-j(n\varphi + k_z z)} dz d\varphi \tag{23}$$

with the inverse given by

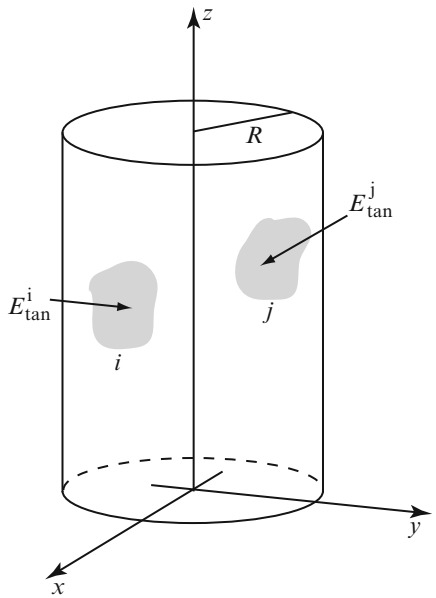

Fig. 11 Two apertures (i and j) in a conducting circular cylinder (Josefsson and Persson 2006) (Copyright IEEE)

DOI 10.1007/978-981-4560-75-7_65-1

$$E_{\tan}(r,\varphi,z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty}\int_{-\infty}^{\infty}\tilde{E}_{\tan}(n,k_z)e^{j(n\varphi+k_z z)}dk_z \tag{24}$$

The wave functions A_z and F_z are now constructed in a similar fashion as Eq. 24 but expressed in terms of the second-order Hankel function $H_n^{(2)}(k_r r)$ representing outward traveling waves. Using the boundary conditions, it is possible to find field expressions that are valid outside the cylinder $(R \le r < \infty)$ in terms of the known Fourier transform of the tangential electric field at the apertures. The electric field and the corresponding magnetic field are given in Eqs. 25–28:

$$E_\varphi(r,\varphi,z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[g_n(k_z)k_r H_n'^{(2)}(k_r r) + \frac{nk_z}{j\omega\varepsilon r}f_n(k_z)H_n^{(2)}(k_r r)\right]e^{-jk_z z+jn\varphi}dk_z \tag{25}$$

$$E_z(r,\varphi,z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{k_r^2}{j\omega\varepsilon}f_n(k_z)H_n^{(2)}(k_r r)e^{-jk_z z+jn\varphi}dk_z \tag{26}$$

$$H_\varphi(r,\varphi,z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty}\int_{-\infty}^{\infty}\left[-f_n(k_z)k_r H_n'^{(2)}(k_r r) + \frac{nk_z}{j\omega\mu r}g_n(k_z)H_n^{(2)}(k_r r)\right]e^{-jk_z z+jn\varphi}dk_z \tag{27}$$

$$H_z(r,\varphi,z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty}\int_{-\infty}^{\infty}g_n(k_z)H_n^{(2)}(k_r r)e^{-jk_z z+jn\varphi}\frac{k_r^2}{j\omega\mu}dk_z \tag{28}$$

where

$$f_n(k_z) = \frac{j\omega\varepsilon\tilde{E}_z(n,k_z)}{k_r^2 H_n^{(2)}(k_r R)} \tag{29}$$

$$g_n(k_z) = \frac{1}{k_r H_n'^{(2)}(k_r R)}\left[\tilde{E}_\varphi(n,k_z) - \frac{k_z}{k_r^2}\frac{n}{R}\tilde{E}_z(n,k_z)\right] \tag{30}$$

and $k_r^2 = k^2 - k_z^2$.

The above solution has poor convergence if the radius of the cylinder is electrically large ($kR \gg 1$). This can be understood by recognizing the harmonic series as a series of standing waves around the cylinder. Therefore, the required number of terms in the summation over n is directly related to the size of the cylinder – many terms are necessary for an electrically large cylinder.

Now, the integral (in k_z) which represents the inversion to obtain the 3D solution from the spectrum of 2D solutions has to be solved. In general this must be done numerically, except for the far zone $(r \to \infty)$ where the radiating field can be found by using an asymptotic formula for the k_z-integral (Harrington 1961). Thus, the quite simple far-field expressions obtained from Eqs. 25 to 26 (when rewritten in spherical coordinates) are

DOI 10.1007/978-981-4560-75-7_65-1

$$\begin{pmatrix} E_\theta \\ E_\varphi \end{pmatrix} = \begin{pmatrix} j\omega\mu \\ -jk \end{pmatrix} \frac{e^{-jkr}}{\pi r} \sin\theta \sum_{n=-\infty}^{\infty} e^{jn\varphi} j^{n+1} \begin{pmatrix} f_n(-k\cos\theta) \\ g_n(-k\cos\theta) \end{pmatrix} \tag{31}$$

If the above (aperture) antenna is coated with one or more dielectric layers, the procedure can be extended to include these layers, although the complexity of the solution increases as well as the numerical burden. Explicit formulas for a single layer can be found in, e.g., Persson and Rojas (2003) and Thors and Rojas (2003), and multiple layers are treated in, e.g., Sipus et al. (1998).

High-Frequency Methods

As indicated earlier some special techniques may be needed when the surface becomes electrically large due to numerical problems. One way of avoiding these problems is to use a high-frequency approach. This means that asymptotic techniques are used to find an approximate solution. A well-known high-frequency method is the uniform theory of diffraction (UTD), which is a ray-based theory. Key references in the area are Pathak and Wang (1981), Pathak et al. (1980, 1981), and Pathak (1992). The reader is referred to these papers for explicit equations of the surface fields and radiated fields due to sources on smoothly shaped convex PEC surfaces.

Some of the approximations used for non-coated surfaces turn out to give non-satisfactory results when a coating is applied. Several attempts have been made, but some of the first ones to actually succeed in the analysis are presented in Ertürk and Rojas (2000) and Ertürk et al. (2004) where the microstrip antenna is considered, and the coated aperture antenna is solved in Persson and Rojas (2003) and Thors and Rojas (2003). Some later advances in the evolution of high-frequency methods can be found in Alisan and Ertürk (2010) and Akyuz et al. (2011).

Geodesics

Before concluding this part, it is important to highlight one of the key aspects of ray-based high-frequency methods: the geodesics. The geodesic is the key and will be needed in order to find how the electromagnetic field is propagating from one position to another on a curved surface. It should, however, be stated clearly that a geodesic is not just the shortest line, or any arbitrary line, connecting two points on a surface. A geodesic needs to fulfill certain requirements. To summarize, a definition of a geodesic only based on the length is not a useful one. A more general definition of a geodesic is given in Struik (1988) where a geodesic is defined as "a curve of zero geodesic curvature." This definition can also be expressed as: "the osculating plane of a geodesic contains the surface normal" or "along the geodesic the principal normal $(\hat{n})$ coincides with the surface normal $(\hat{N})$." Figure 12 illustrates a situation when a curve along the surface is not a geodesic.

Note that the normal property strictly fails in the case of a straight line on a (plane) surface, since the principle normal $\hat{n}$ is indeterminate. But, still, the straight line on flat surface is a geodesic. This fact, according to some authors writing about geodesics, has been taken as a reason for not using the above general definition of a geodesic. However, this definition will be adopted in this text since it gives an intuitive way of defining geodesics on curved surfaces.

By using differential geometry, it is possible to derive the geodesic equation that will solve the problem for any type of surface (Struik 1988). To solve this equation, extensive numerical analysis is needed, but fortunately it is possible to reduce the numerical complexity by restricting the analysis to certain types of surfaces such as cylinders, spheres, paraboloids, and hyperboloids. All of these surfaces are in fact very useful and can serve as valid approximations of a realistic surface to be considered. Assuming this, the geodesic equation can be reduced and in fact be solved analytically.

DOI 10.1007/978-981-4560-75-7_65-1

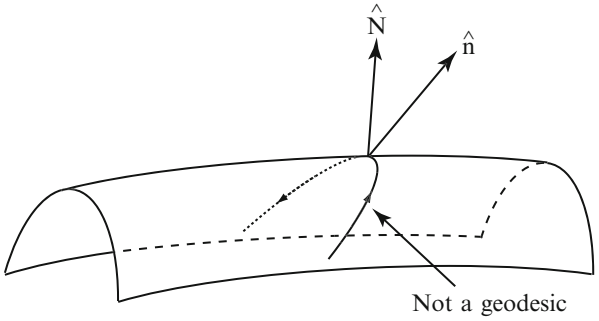

Fig. 12 A curve along a surface but not a geodesic surface ray (Josefsson and Persson 2006) (Copyright IEEE)

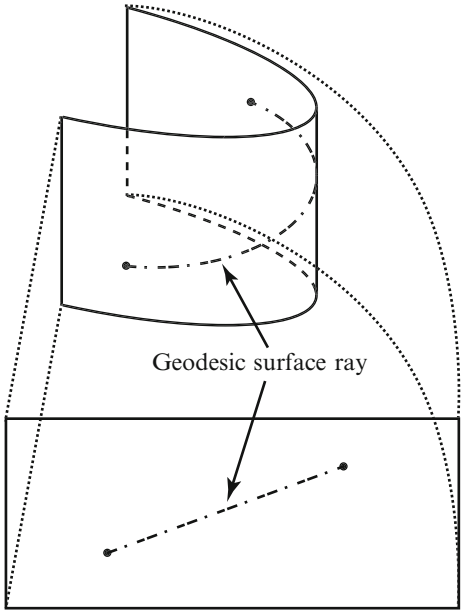

Fig. 13 A developed cylindrical surface (Josefsson and Persson 2006) (Copyright IEEE)

To better understand this, let us start with singly curved surfaces. Singly curved surfaces may also be denoted developable surfaces since they can be unfolded and analyzed as a flat surface and the key parameters are obtained from a two-dimensional analysis; see Fig. 13. As a consequence the geodesics on any singly curved surface can always be found, at least numerically. Thus, the singly curved surfaces can be studied without solving the geodesic differential equation.

Next, doubly curved surfaces will be considered, in particular rotationally symmetric surfaces. Solving the geodesic equation for doubly curved surfaces is of course more difficult than for singly curved surfaces. Often the equation has to be solved numerically resulting in a time-consuming analysis. However, as will be shown here, the geodesic equation for rotationally symmetric doubly curved surfaces can in many cases be solved in closed form. This simplifies the analysis of doubly curved surfaces and makes it possible to use a ray-based theory to analyze doubly curved conformal array antennas.

As a start, the surface needs to be represented as a parametric equation. For doubly curved rotationally symmetric surfaces, the parameterization is written as

$$x = f(u)\cos v, \quad y = f(u)\sin v, \quad z = g(u) \tag{32}$$

DOI 10.1007/978-981-4560-75-7_65-1

and the solution to the geodesic equation for rotational symmetric doubly curved surfaces then becomes

$$v(u) = \int \frac{\pm\alpha\sqrt{(f'(u))^2 + (g'(u))^2}}{f(u)\sqrt{(f(u))^2 - \alpha^2}} du + \beta = \mathcal{I}(u, \alpha) + \beta \tag{33}$$

The constants α and β are unique for a specific geodesic between the given points A and B. They can be obtained by solving

$$\begin{aligned} v_A &= \mathcal{I}(u_A, \alpha) + \beta \\ v_B &= \mathcal{I}(u_B, \alpha) + \beta \end{aligned} \tag{34}$$

The geodesics on any doubly curved rotationally symmetric surface can now be found by quadrature. However, analyzing doubly curved surfaces gets even more interesting when it turns out that the integral in Eq. 33 can be solved in closed form for many rotationally symmetric doubly curved surfaces, in particular those belonging to the Eisenhart coordinate system. In fact, Eq. 33 can actually be solved also for some non-Eisenhart surfaces as long as they are defined in the so-called geodesic coordinate system, i.e., the parameterization is such that the parameter lines are orthogonal (Jha and Wiesbeck 1995). One example of a non-Eisenhart surface is the ogive (Jha et al. 1989).

One thing to keep in mind is that for a closed, singly curved surface, the number of geodesics connecting two points is infinite. For doubly curved surfaces, on the other hand, the number of geodesics can be more than one, but it is bounded. Just illustrating the complexity of finding geodesics on a doubly curved surface, Fig. 14 shows a general paraboloid of revolution (GPOR) where one first-order geodesic is found in the positive φ-direction as well as a nontrivial second-order geodesic in the positive φ-direction.

Hybrid Methods

Before concluding this section, it is worth mentioning that a single method (separation of variables, a high-frequency method, etc.) is seldomly used alone. Often hybrid methods are used where one tries to combine the good things with several methods in order to analyze a complex problem. A very good combination is to use the numerical method called method of moments (MoM) together with a high-frequency method. A high-frequency method such as UTD can analyze electrically large objects; it is quite simple to use and can incorporate other solutions into its format. The MoM is useful for small objects since the unknowns become small in number; it can treat arbitrarily shaped objects and can give information about antenna parameters. The major disadvantage is that asymptotic formulations are still to be found for certain geometries. Nevertheless, combining UTD and MoM is probably the hybrid solution most often used when analyzing conformal antennas.

The main idea with a hybrid UTD-MoM method is to start with an exact formulation in terms of an integral equation formed at the boundary between the defined exterior and interior regions. The kernel of this integral equation is the exact Green's function, now replaced with an asymptotic version. Note that the asymptotic Green's function is not valid in the near field of the antenna (i.e., when the distances between the source and observation points are small). Often, the Green's function of the corresponding planar case is used to overcome this limitation. After this step the solution to the integral equation is not any different from solving traditional integral equations with the MoM procedure.

Design

Introduction

In this section examples will be given to illustrate some of the characteristics of conformal antennas. The results have been obtained by using a hybrid UTD-MoM method unless otherwise stated. The purpose is to provide some fundamental knowledge about the characteristics of conformal antennas so that the reader can use this knowledge when advancing further into the topic, perhaps by analyzing more advanced conformal array antennas.

The examples to be considered are two conformal antennas with aperture-type radiating elements flush mounted on a conducting circular cylinder and a paraboloid of revolution, respectively. These two surfaces represent two important classes of conformal antennas. The analysis of such canonical problems provides insight into many of the characteristics of singly curved and doubly curved conformal antennas.

The Circular Cylinder

In the examples to follow, the circular cylinder is assumed to be infinitely long. The apertures have a rectangular shape with either axial or circumferential orientation. The aperture field is given by a combination of rectangular waveguide modes. In many cases a single-mode approximation is enough, but in the text several waveguide modes will be used to demonstrate their influence and importance if accurate results are required.

The geometry and all relevant parameters are defined in Fig. 15. The radius of the cylinder is denoted by R and equals 5λ; in most of the cases to be presented, the apertures are described by the width and height, w and h. s is the geodesic length between the centers of the apertures. The angle α is also defined in Fig. 15.

DOI 10.1007/978-981-4560-75-7_65-1

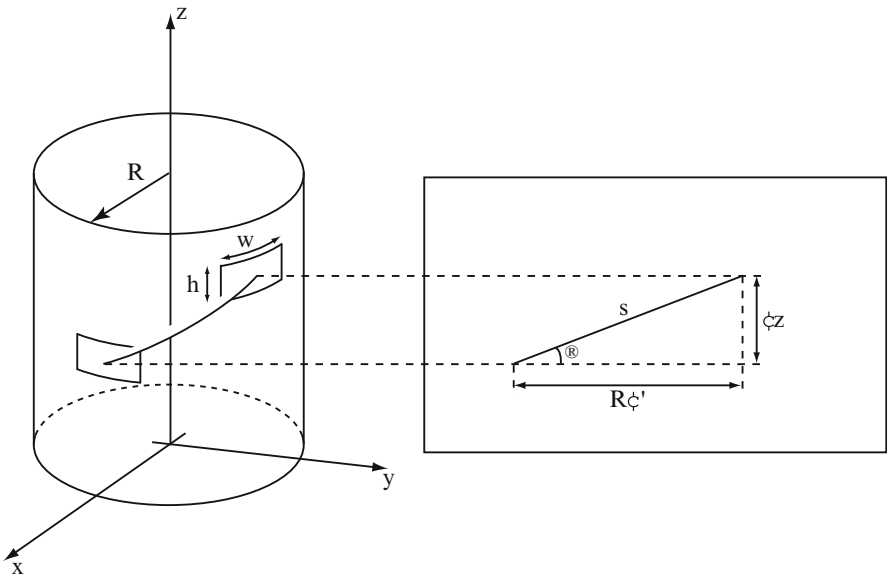

Fig. 15 Geometry for the study of the characteristics of azimuthally oriented aperture antenna elements on circular cylinders, i.e., vertical polarization (Josefsson and Persson 2006) (Copyright IEEE)

The apertures are linearly polarized (excited by the fundamental TE_{10} mode). Figure 15 shows a typical case with $w > h$ and axial (vertical) polarization. Axially oriented apertures, hence $w < h$, represent a case with circumferential (horizontal) polarization.

Isolated Mutual Coupling

The first example is about analyzing the isolated coupling, i.e., the mutual coupling between two elements only. The aperture dimensions are $0.27\lambda \times 0.65\lambda$. Figure 16 shows the *E*-plane coupling (i.e., $\alpha = 0°$) as a function of the cylinder radius. The following radii are used: $R = 2\lambda$, 5λ, 10λ, 20λ, and 50λ. The results are shown versus the geodesic length between the apertures. The corresponding planar result $(R \to \infty)$ is included for comparison.

As indicated in Fig. 16, the circular cylinder solution approaches the planar solution when the radius is increased, as expected. Another interesting result is that the planar solution seems to be surprisingly accurate for small distances (this also applies for H-plane coupling not shown here; see Josefsson and Persson (2006) for more results and details). This is a feature often used when analyzing arrays on curved surfaces. By using the planar solution, approximate values of the mutual coupling can be found easily for neighboring elements as well as between elements along the axis. However, the effect of the curvature of the surface is quite strong for larger distances. For a 50λ radius, the planar solution and the cylinder solution deviate considerably after a distance of approximately $6-8\lambda$.

Array Mutual Coupling

The next step is to study the *array* mutual coupling, i.e., the coupling among the elements in the array environment with all elements present and terminated in matched loads. At this point higher-order modes will be used in the calculations to increase the accuracy of the aperture field solution. The calculated results will be compared with measured data (Lindgren and Josefsson 1998) obtained from an experimental antenna built by Ericsson Microwave Systems AB in Mölndal, Sweden, as a test bed for singly curved conformal antennas. The surface is a circular cylinder with three rows of rectangular apertures (see Fig. 17). The main dimensions are the following:

DOI 10.1007/978-981-4560-75-7_65-1

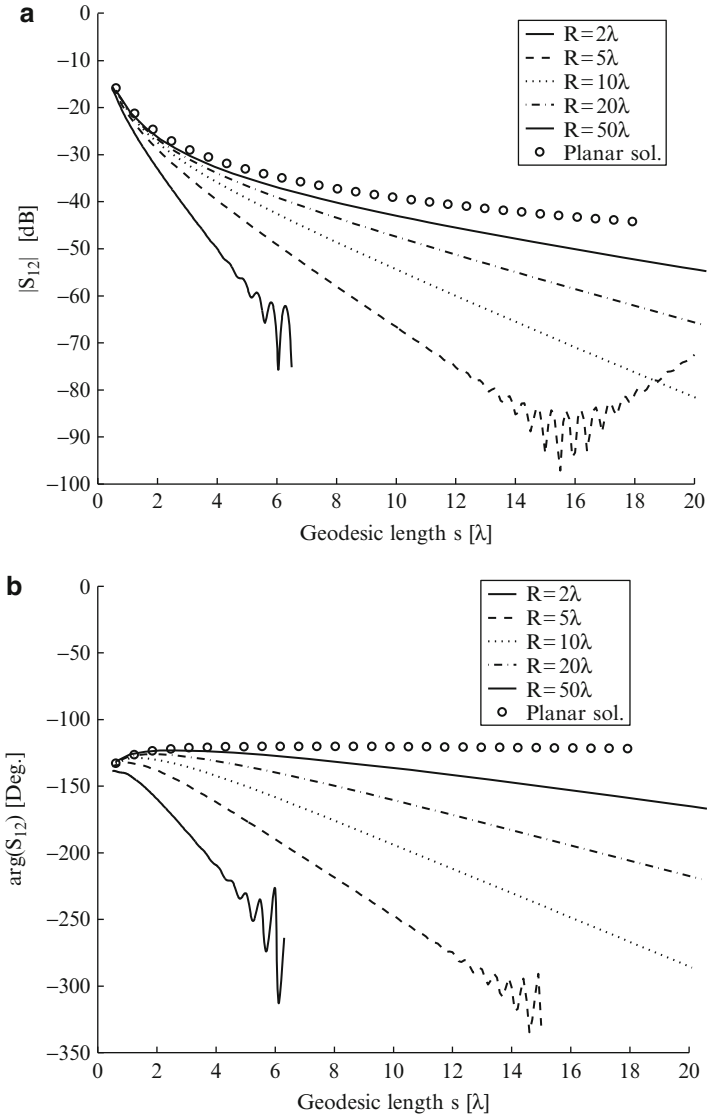

Fig. 16 The isolated *E*-plane mutual coupling along the circumferential direction of a cylinder with different radii. (**a**) The amplitude. (**b**) The phase, with the free space wave contribution subtracted (Josefsson and Persson 2006) (Copyright IEEE)

Element apertures	39 × 16 mm
Element grid	Rectangular, 3 × 18 elements
	Extending over about 120°
Element spacings	37.1 mm in azimuth
	41 mm in axial direction
Polarization	Circumferential
Cylinder radius	300 mm
Frequency interval	4.3 → 6.8 GHz
Cutoff freq. of second-order mode	$f_{c,20} \approx 7.6$ GHz
Frequency used here	$f = 5.65$ GHz

In the calculations no surface rays encircling the cylinder were taken into account since the cylinder is truncated at the rear due to practical reasons. Absorbers were placed on all edges to minimize edge effects.

The following numbering of the apertures is used: the aperture in the lower-left corner of Fig. 17 is aperture number 1; aperture number 54 is located in the upper-right corner.

In Fig. 18 the array mutual coupling is presented for $f = 5.65$ GHz. Additional results for other frequencies can be found in Persson and Josefsson (2001). Figure 18 shows the result for the mutual coupling in the *E*-plane for the first row of elements (1 → 18) and for the second row of elements (19 → 36) using a single-mode approximation. As can be seen, there are some differences between the first and second row depending on the different element surroundings. Furthermore, even with a

DOI 10.1007/978-981-4560-75-7_65-1

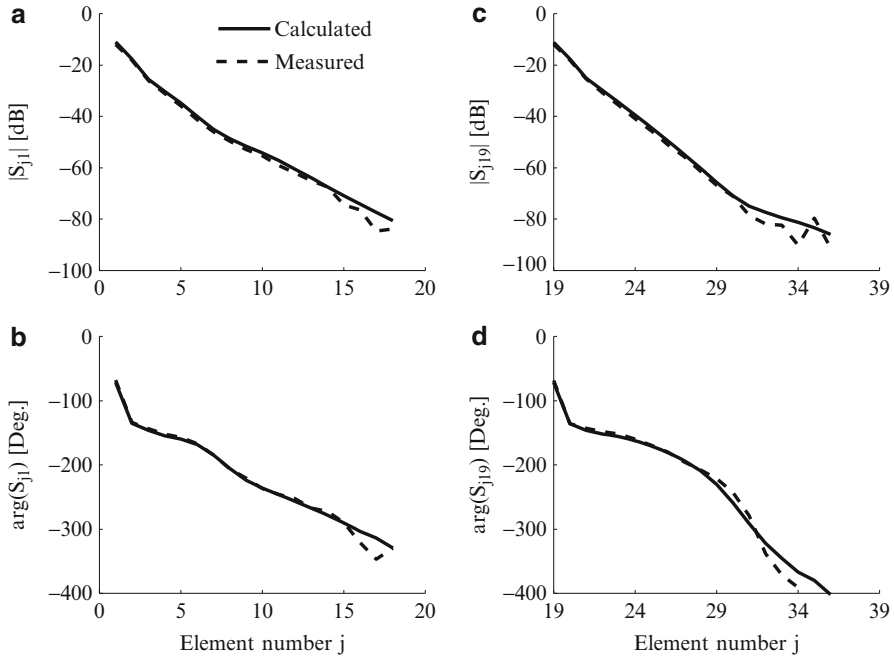

Fig. 19 The mutual coupling in the *E*-plane for the first row (elements 1 → 18) and the second row (elements 19 → 36). Five-mode approximation, $f = 5.65$ GHz. *Solid line*: Calculated. *Broken line*: Measured. (**a**) Amplitude, first row. (**b**) Phase, first row. (**c**) Amplitude, second row. (**d**) Phase, second row (Josefsson and Persson 2006) (Copyright IEEE)

single-mode approximation, the mutual coupling diagrams show good agreement between the measured and the calculated results, at least down to about –60 dB. For elements far away the agreement is not so good, but here the coupling levels are very low.

In order to improve the accuracy even further, higher-order waveguide modes were included in the analysis. With the four lowest TE modes (in increasing cutoff order, i.e., TE_{10}, TE_{20}, TE_{01}, and TE_{11}), only small differences were observed. But when taking also the TM_{11} mode into account, a significant improvement was obtained (see Fig. 19). Now the simulated results show good agreement with measurements down to coupling levels as low as –80 dB. The agreement of the phase is also improved. Using even more modes (up to 20 modes were tried) improved the results very little (Persson and Josefsson 2001).

The importance of the TM_{11} mode is probably explained by the fact that this mode is the first mode with a field component parallel with the direction of propagation. Obviously, this component is important for a precise modeling of the aperture field.

Embedded Element Patterns

As shown earlier the magnitude of the mutual coupling among the elements on a curved surface is less than for the corresponding planar case. However, the effects of the mutual coupling on the embedded element patterns can still be considerable for the curved case. The embedded element pattern gives an indication of the performance of the fully excited array and serves therefore as a valuable tool in the array design process. This will be illustrated by one example by considering a circular array with the elements uniformly spaced and covering the complete circumference of the cylinder. Thus, no edge effects are present in azimuth, and all azimuth element patterns are identical. This resembles the infinite planar array case, and the patterns for the two cases will be compared.

Figure 20 shows the gain of the *E*-plane embedded element pattern for a single ring of circumferentially polarized rectangular apertures for different cylinder radii. The element spacing is kept constant, equal to 0.6λ. The patterns are also compared with the corresponding planar case. As seen, there are no major

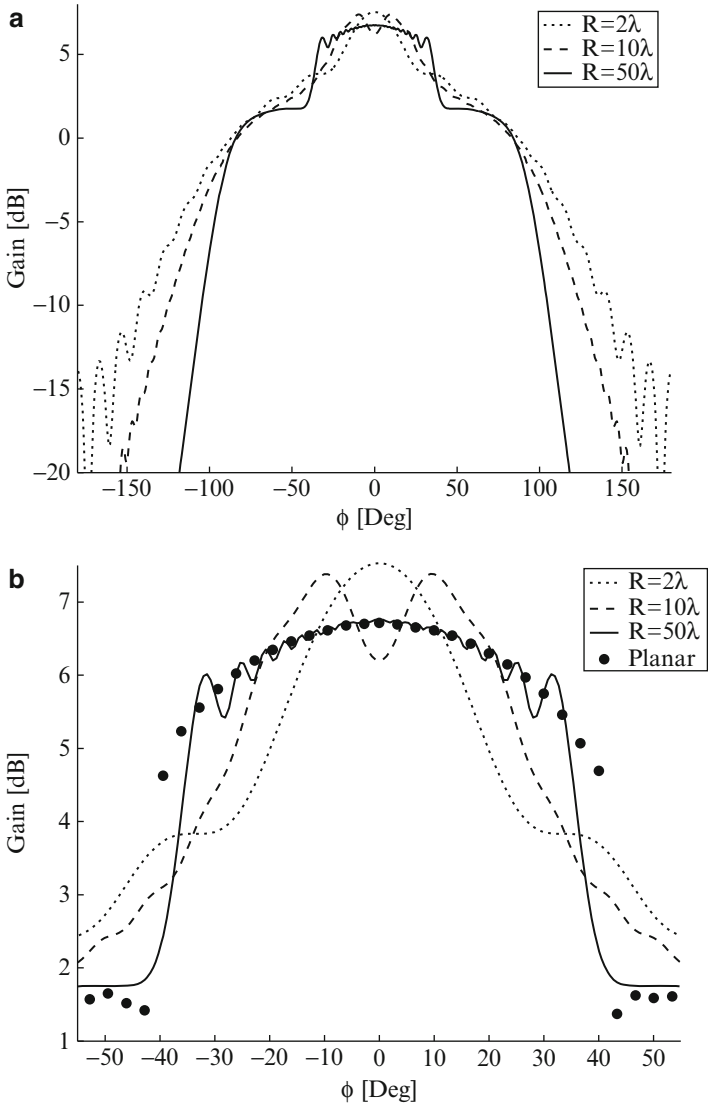

Fig. 20 The gain of the *E*-plane embedded element pattern for a single ring array in azimuth versus the radius of the cylinder for a fixed element spacing ($d = 0.6\lambda$). (**a**) Overview for $R = 2\lambda$, 10λ, and 50λ. (**b**) The corresponding planar case is shown in the close-up view (Josefsson and Persson 2006) (Copyright IEEE)

differences between the pattern for the planar case and the pattern for a cylinder with a large radius in the forward direction within the broadside region. Both patterns exhibit a clearly visible drop-off near $\phi = 42°$. This drop-off in the planar case is due to an end fire grating lobe at $\phi = 41.8°$. Its counterpart in the cylindrical array is a "cylindrical end fire grating lobe" (Mailloux 1994). It should be noted that the cylindrical grating lobe is not as distinct as in the planar case due to the curved surface. However, the phenomenon is caused by the same mechanisms in both cases.

Since the cylindrical grating lobe is more diffuse in the cylindrical case, the pattern dips are not as deep as in the (infinite) planar case. In the cylinder case there is a finite number of elements participating; the smaller the radius, the fewer the elements.

Another interesting observation is the ripple in the broadside region for the circular cylinder, not observed in the (infinite) planar case. The ripple is not caused by an edge effect since there is no discontinuity in the angular direction; instead it is due to the mutual coupling among the elements on this nonplanar geometry. The embedded element pattern is given by a superposition of the isolated

DOI 10.1007/978-981-4560-75-7_65-1

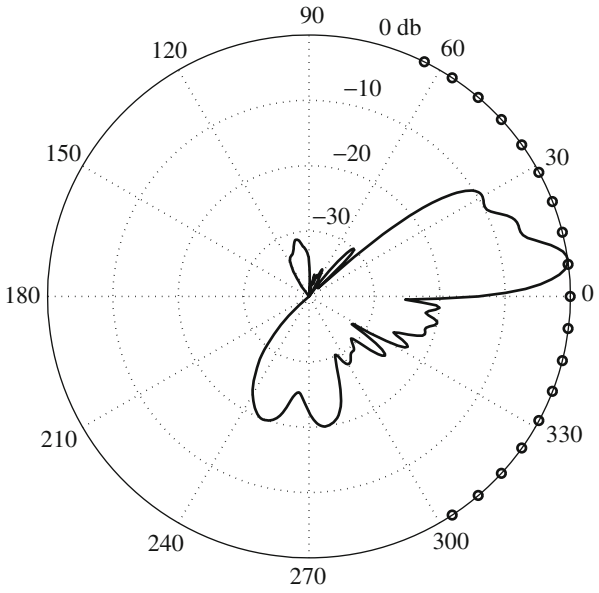

Fig. 21 Synthesized pattern with coupling after 100 iterations, also showing element locations (Josefsson and Persson 2006) (Copyright IEEE)

element patterns of all elements when excited through mutual coupling. When added together the interference between the different contributions will result in an oscillating behavior.

Array Synthesis

This section will be concluded by presenting a pattern synthesis exercise for a simple but typical application and shows the results in terms of pattern performance including mutual coupling effects. The geometry considered is the cylindrical array antenna that has been referred to several times (see Fig. 17), and the synthesis method used is the method of alternate projections (Bucci et al. 1990). The assumed requirements include both the sidelobe region and the shape of the main beam. The effect of the mutual coupling is included in the synthesis; neglecting the mutual coupling leads otherwise to poor results, especially in the shaped beam region (Josefsson and Persson 1999).

For simplicity, the elements are assumed to have a $\cos\phi$ isolated pattern, and only one row of waveguide aperture elements is studied. They are spaced 0.53λ on an arc of about 120° on the 4.3λ radius cylinder. The mutual coupling data is the results presented earlier in this section.

The following requirements are used in the synthesis procedure: a cosecant-squared main beam with unequal sidelobe envelopes. In more detail:

−180–0°	Maximum −20 dB sidelobes
0–35°	Cosec^2 within ± 1 dB
0–180°	Maximum −30 dB sidelobes

The pattern is iteratively modified in regions where the requirements are not met. A synthesized beam pattern after 100 iterations is shown in polar form in Fig. 21, where also the locations of the 18 radiating elements are indicated by small circles.

If the synthesis is repeated again, now assuming that the mutual coupling effect is neglected, there will be changes in the pattern. Figure 22b shows a close-up of the main beam analyzed with mutual coupling but synthesized without coupling. It is apparent that the mutual coupling plays an important role; it is essential to include the mutual coupling in the synthesis.

DOI 10.1007/978-981-4560-75-7_65-1

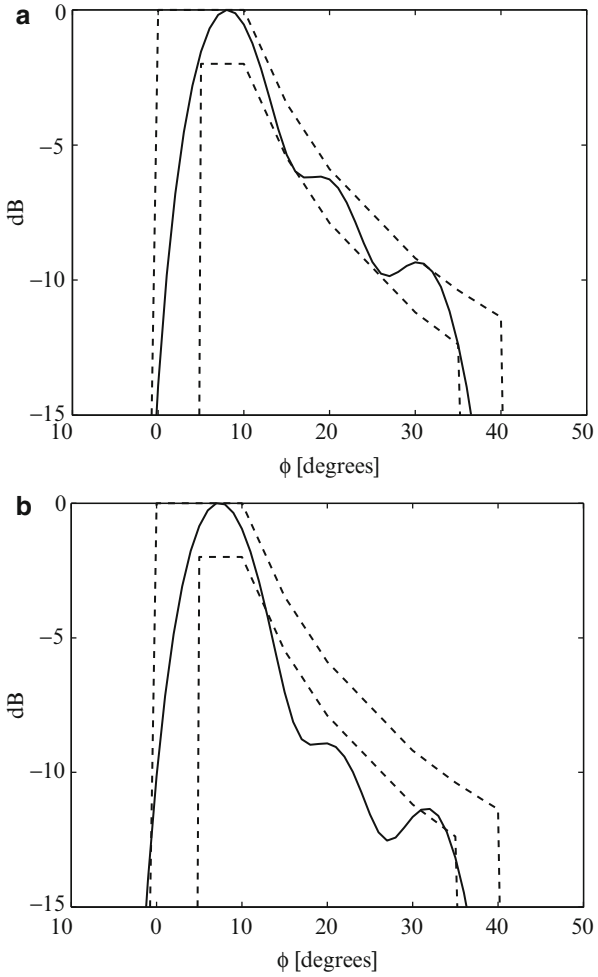

Fig. 22 Pattern synthesis with coupling (**a**). The pattern in (**b**) demonstrates the effect of the mutual coupling if not included in the synthesis (Josefsson and Persson 2006) (Copyright IEEE)

Doubly Curved Surfaces

It may have been understood from the discussion on geodesics that the analysis of doubly curved surfaces is a bit more challenging than the analysis of cylindrical surfaces but also more interesting. A doubly curved surface can more accurately model, e.g., realistic airborne or space-borne antennas than a singly curved surface can do. However, in many applications, a singly curved approach gives results accurate enough to be useful in the first stage of the design of a doubly curved antenna. Nevertheless, new features are introduced with doubly curved conformal antennas, and these features become important in a new way and must be accounted for. One such feature is the co-polar/cross-polar aspect of the radiation pattern since all elements on a doubly curved surface point in different directions.

In this section a few examples will be given to illustrate some properties of doubly curved array antennas. The analysis presented here is based on perfectly conducting general paraboloids of revolution (GPOR), and some of the results are also verified with measurements. Once again a hybrid UTD-MoM method is used. The antenna elements are circular waveguide-fed apertures; a single-mode approximation is used, i.e., only the dominant TE_{11} mode is accounted for in the simulations. Figure 23 illustrates the surface that is analyzed including an experimental antenna that was built.

The doubly curved experimental antenna shown in Fig. 23 was built at Ericsson Microwave Systems AB in Mölndal, Sweden, in 2000. The experimental antenna is shaped as a paraboloid of revolution with

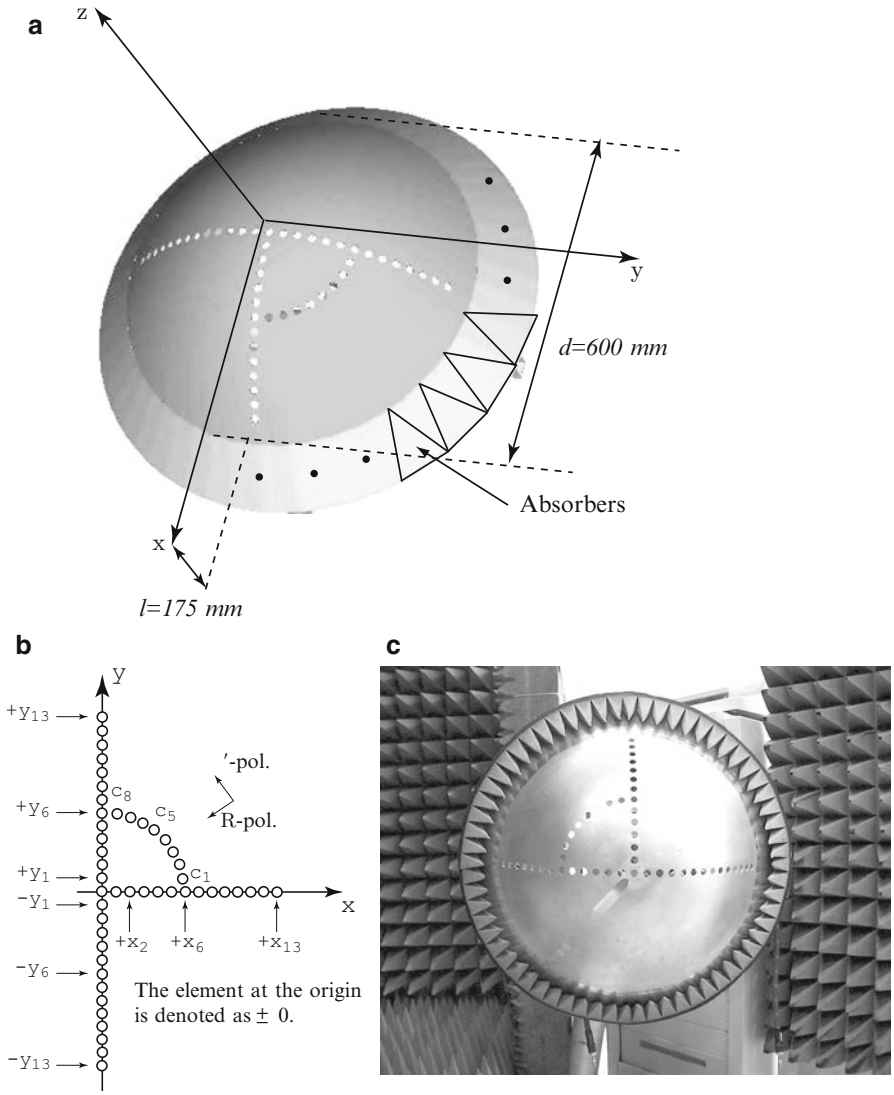

Fig. 23 (**a**) The geometry of the experimental doubly curved antenna with the coordinate system used in the analysis. (**b**) The numbering of the elements (Josefsson and Persson 2006) (Copyright IEEE). (**c**) A picture of the antenna on location for mutual coupling measurements (Courtesy Saab AB)

f/$d \approx 0.22$, and the diameter of the surface is approximately 600 mm with a depth of approximately 175 mm (see Fig. 23a). The surface is extended with a conical sheet of metal to gain extra space for the absorbers at the edge. The circular waveguide-fed apertures with diameter 14.40 mm are filled with Rexolite ($\varepsilon_r = 2.53$). The cutoff frequency for the dominant TE_{11} mode is 7.65 GHz. The nearest mode in cutoff order is TM_{01} with 9.99 GHz cutoff frequency. A single isolated element has a return loss (S_{11}) of about -8 dB.

Isolated Mutual Coupling

To illustrate the typical behavior of the mutual coupling on a doubly curved surface, one example is given to show the effect of the dependency on the polarization of the elements. Figure 24 shows the isolated mutual coupling between an element on the circular arc and elements along the positive *y*-axis. Here, the results are explained mainly as polarization effects. To illustrate this, the geodesic length is included in

DOI 10.1007/978-981-4560-75-7_65-1

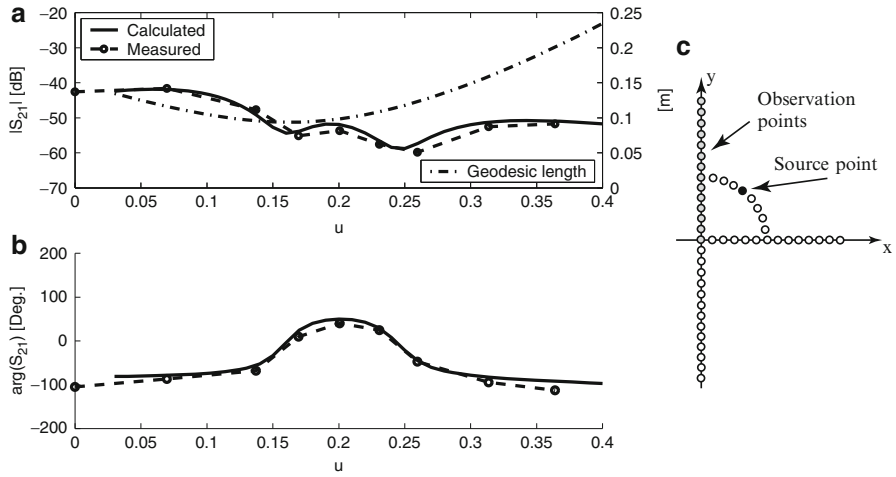

Fig. 24 Isolated coupling, [*R*, *R*]-polarization. The reference/source point is element c_5. (**a**) The amplitude. (**b**) The phase. (**c**) The geometry (Josefsson and Persson 2006) (Copyright IEEE)

Fig. 24 where the [*R*, *R*]-polarization case is considered; i.e., both the source and observation elements are *R*-polarized (see Fig. 23b).

More results can be found in Persson et al. (2003). Element patterns have also been measured and simulated (Josefsson and Persson 2006).

Polarization in Doubly Curved Arrays

As indicated in Fig. 24 the polarization issue is important and more complicated for doubly curved arrays compared to cylindrical arrays (Josefsson et al. 2002). This is because in general the radiating elements point in different directions, and they must be individually polarized in order to generate a desired polarization in the main beam direction. With circular polarization, however, rotation is not necessary since the rotation does not change the polarization. If not correctly oriented, there will instead be a phase error, but this can be compensated by the phase control that must be applied to each element in any case.

In order to simplify the modeling, it is assumed that the radiating elements are of type short dipoles, i.e., the element pattern is $E_0 \sin\theta$ with θ the angle from the dipole axis. The elements do not radiate "through" the parabolic surface, however. The dipoles are tangential to the curved surface and initially oriented in a vertical plane (see Fig. 25a). When considering curved array antennas, it is also of importance to introduce an active region since many elements may not radiate in the desired beam direction and should therefore be turned off in order to avoid sending unwanted signals into other parts of space. The active region is defined from the desired nominal beam direction $\hat{r}$ and the normal direction to the surface $\hat{n}$. The active region is obtained as the area encompassing all elements for which

$$\hat{r} \cdot \hat{n} \geq \cos\theta_{s\max} \tag{35}$$

where $\theta_{s\max}$ is a chosen maximum useful local scan angle, typically 45–60°. An example of an active region is shown in Fig. 25b.

In order to align the far-field contributions properly, each dipole is rotated around the surface normal until the far-field contribution in the main beam direction has the correct polarization. Additionally, the phase of each dipole is adjusted so that they add coherently to a plane phase front. However, it is generally not possible to obtain the same polarization throughout the pattern; thus, there will be some cross polarization. Figure 25c illustrates how the radiating elements are all aligned for the same (vertical) polarization in the main beam direction. When viewed from another angle (Fig. 25d), it is clear that a

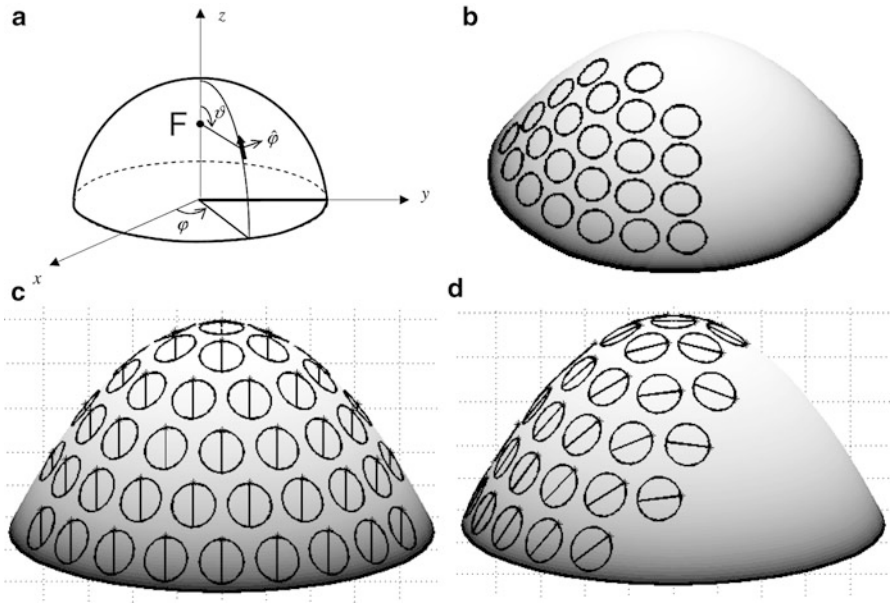

Fig. 25 (**a**) Illustration of the antenna element used. (**b**) An example of an active sector when scanning the beam. (**c**) Example of an array where the elements are aligned to give vertical polarization in the main beam direction. (**d**) As in (**c**), but now viewed from a different angle (Josefsson and Persson 2006) (Copyright IEEE)

certain degree of cross polarization will radiate in the sidelobe region. These are some aspects related to conformal array beamforming, to be discussed in the next section.

Beamforming in Conformal Array Antennas

Introduction

An array of radiating elements alone does not make a conformal antenna system. As a minimum, some kind of phase compensation for the array curvature is needed together with a summation network. In addition it may be required to move around the active sector of the array (commutating), to apply amplitude control, and to steer the polarization as well. All of this may sound complicated and expensive. However, there are many advantages that may be gained from the extra flexibility of conformal solutions such as multibeam capability, large angular coverage, large bandwidth, reduced RCS (radar cross section), etc. Some of the beamforming systems that have been developed will be described, in particular those that are used for circular and cylindrical arrays.

The principal function of an analog beamformer is illustrated in Fig. 26a, where the received signal is obtained after summing of the element signals with proper amplitude and phase weights.

The analog beamforming in Fig. 26a is illustrated for a receive situation. However, it can in principle also be designed for transmitting. Special analog networks have been used for generating simultaneous multiple beams, both constrained feed networks and optical type feeds (microwave lenses). The digital beamformer (Fig. 26b) is even more flexible. Several simultaneous beams can be generated from the digital processor. Corresponding digital solutions for the transmit case are also possible but not equally easy to implement.

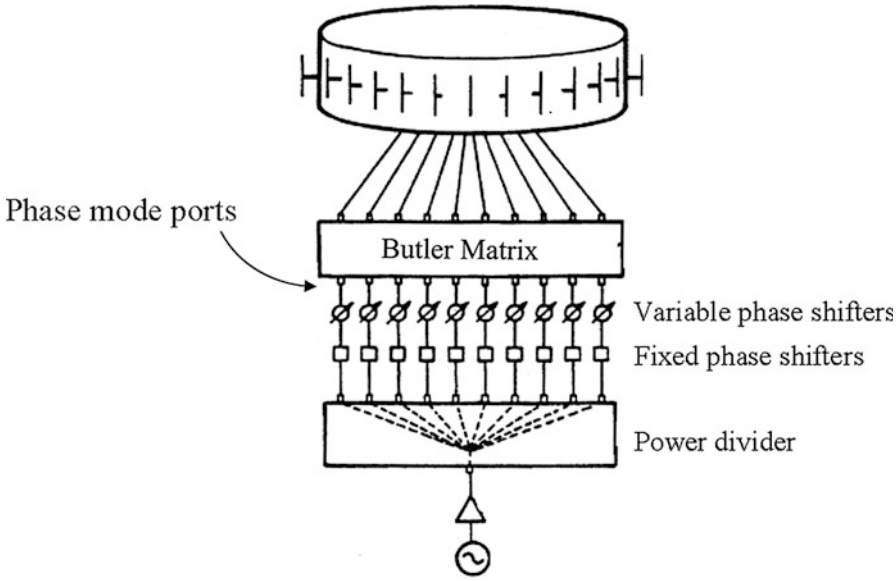

Fig. 27 The scanning multimode array (Sheleg 1968) (Copyright IEEE)

The Butler Matrix

The Butler matrix (Butler and Lowe 1961) is a passive network with N input ports and the same number of output ports. Feeding one of the input ports will generate equal amplitudes on the output ports but with a linearly varying phase from port to port. The phase slope will depend on which input port is excited. Thus, a set of (linear) phase mode can be generated. Connecting the output ports to a linear array antenna will produce sin *x*/*x* type patterns. Connecting to a circular array antenna (UCA) will produce the circular phase modes discussed in section "Phase Mode Theory."

A very interesting application of the Butler matrix is found in the scanning multimode array (Fig. 27).

In this system a beam can be steered 360° in azimuth by adding a linear phase shift to the phase mode ports, which simply shifts the excitation setup by the power divider and fixed phase shifters, i.e., a *commutating* function.

DOI 10.1007/978-981-4560-75-7_65-1

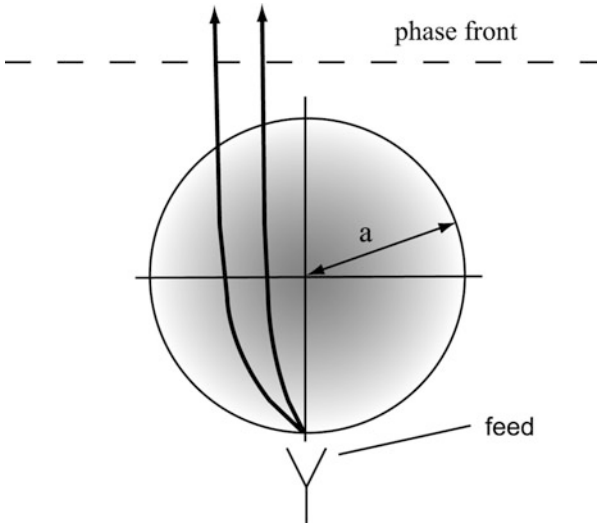

Fig. 28 Focusing by a Luneburg lens (Josefsson and Persson 2006) (Copyright IEEE)

A UCA with a Butler matrix feed can be used as a bearing discriminator (Rehnmark 1980). By extracting the phase values on a few phase mode ports, the DOA (direction of arrival) of received signals can be determined.

RF Lenses

RF lenses are based on optical analogies and can be used for focusing, beam shaping, and beam steering. In this way the amount of discrete components required in matrix-fed systems can be reduced significantly. An example is found in the Luneburg lens (Luneburg 1944) (Fig. 28).

In the Luneburg lens the spherical lens has a refractive index n that varies with radius as

$$n(r) = \sqrt{\varepsilon_r} = \sqrt{2 - (r/a)^2} \tag{36}$$

Several feed horns can be arranged to focus beams in different directions.

The R-2R lens and the R-kR lens are two lens types using parallel plate structures. The latter one requires a dielectric loading of the circular lens with a permittivity of $\varepsilon_r = 4$ or higher. An example of a compact R-kR lens-fed array on a high-permittivity substrate ($\varepsilon_r = 10.2$) is shown in Fig. 29. With this array ten beams separated by 10° were realized.

The Dome antenna makes half-sphere scanning possible from just one active planar array. The concept is illustrated in Fig. 30.

In the Dome antenna a planar array illuminates the concave inside of the passive spherical lens. Also other shapes such as ellipsoidal are possible. The phase gradient of the lens can be optimized for the desired elevation coverage. However, this revolutionary idea has not been put to much practical use because of its rather high cost and limited bandwidth.

Digital Beamforming

As already shown in Fig. 26, it seems that everything that can be done with analog beamforming can also be done digitally. The digital solution leads to strict requirements on data transmission, storage, and signal processing, especially for large arrays. However, these problems are more easily solved today than in the past, thanks to the rapid growth of computer power, both software and hardware. In analog receive beamforming, the element signals are combined with weights determined by feed networks

DOI 10.1007/978-981-4560-75-7_65-1

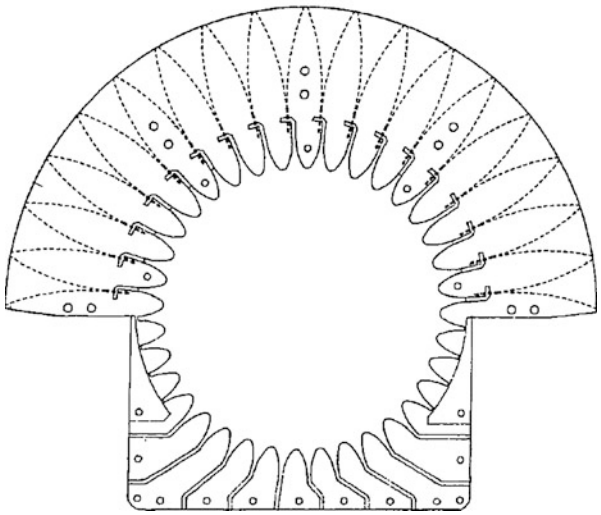

Fig. 29 An R-2R lens feed integrated with tapered slot elements in a high-permittivity substrate (Sierra and Bernal 1989) (Copyright IEEE)

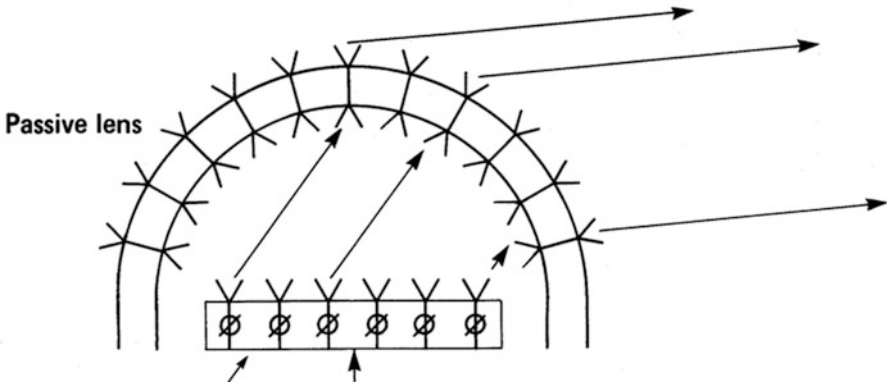

Fig. 30 The Dome antenna concept (Liebman et al. 1975) (Copyright IEEE)

and/or phase- and amplitude-controlled receive modules. The same operations can be performed in a digital computer on the element signals after analog-to-digital conversion. It is interesting to note that the Butler matrix performs the same transformation in the spatial domain as the FFT (fast Fourier transform) often used in the time/frequency domain. The digital approach allows the formation of simultaneous receive beams, even overlapping, without the feed losses that are incurred in an analog system. The element modules in the digital case have low-noise amplifiers (LNAs) preceding the analog-to-digital conversion. The signal-to-noise ratio is set by the LNAs, and it is therefore not affected by transmission losses in the further processing, hence "lossless beamforming."

Digital beamforming has been used mainly in linear and planar arrays. However, the following example shows a case applied to a circular 16 element array with 0.5λ element spacing. The elements are pointing radially, each with a cosα pattern. In this scenario it is assumed that there is one desired signal at 10 dB above noise level and two interference signals at 40 dB above noise level. For suppressing the interference, an adaptive nulling algorithm (SMI, sample matrix inversion) according to Applebaum (1976) is used. The geometry and the resulting patterns are shown in Fig. 31. The results show that the interfering signals are suppressed by at least 25 dB.

DOI 10.1007/978-981-4560-75-7_65-1

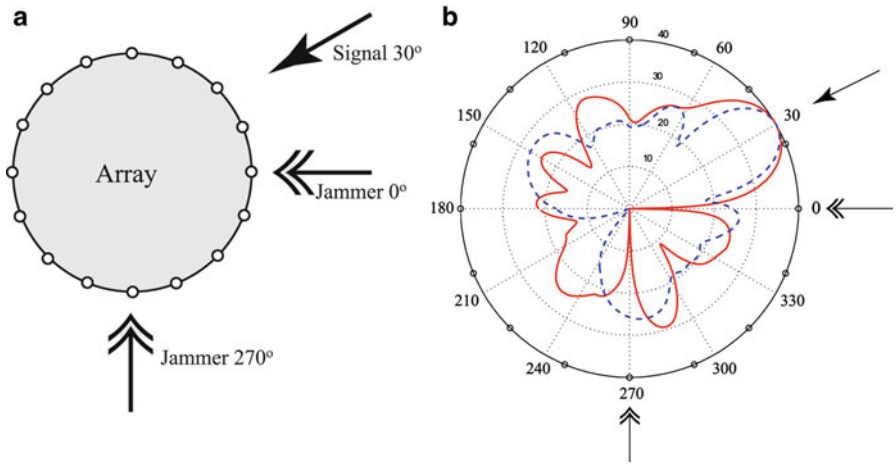

Fig. 31 (**a**) Scenario with one desired signal and two jamming signals. (**b**) Circular array patterns without interference suppression (*dashed line*) and with adaptation (*solid line*). Signal direction is from 30° and interfering signals from 0° and 270° (Josefsson and Persson 2006) (Copyright IEEE)

In Steyskal (1989) an interesting DBF experiment is described, using a 64-monopole element circular array with digitally formed low sidelobe patterns. Using in total $2M + 1 = 35$ phase modes in the synthesis, a sidelobe level of about -30 dB is successfully obtained over 40 % bandwidth (corresponding to $2kR$ values between 41 and 62). However, with more phase modes added in the synthesis, the pattern starts to deteriorate, e.g., $2M + 1 = 51$ is more than the "Bessel window" can accommodate at the low-frequency end (cf. Fig. 4).

Summary

The conformal array technology makes new antenna shapes possible, not necessarily limited to linear or planar configurations. Possibilities include structural integration in aircraft, very wide angular coverage, and reduced RCS (radar cross section); sometimes no radome is needed.

The electromagnetic problem of wave propagation on curved surfaces is now well understood, and the tools for analysis and design are available. Calibration, beam steering, and polarization control may still seem challenging in some cases. However, shifting the analog/digital interface closer to the radiating elements opens up new solutions, including DBF. New signal processing schemes show promise, e.g., sparse arrays, MIMO for radar (Dorey et al. 1989), compressive sensing (Migliore and Pinchera 2011), and so on. At the same time small systems with circular or cylindrical arrays will find increased use in communication and sensing systems in urban environments.

Multi-beam Antenna Arrays

Bybi P. Chacko*, Gijo Augustin and Tayeb A. Denidni
Centre for Energy, Materials and Telecommunication, National Institute of Scientific Research (INRS), Montreal, QC, Canada

Abstract

This chapter begins with a brief introduction of basic concepts in antenna arrays which is followed by slightly advanced concepts including smart antennas and related systems. This helps the readers to acquire basic knowledge necessary to understand the concepts of multi-beam antennas and various beam-forming networks outlined in the sessions that follow. The world of engineered materials which become an important research area is also outlined to broaden the knowledge of the readers. This chapter concludes with some recent multiple-beam antenna design examples with metamaterial technology.

Keywords

Antenna arrays; Multi-beam antenna arrays; Directive antenna arrays; Cylindrical antennas; Sectoral antennas; Beam scanning; Beam formers; Intelligent antenna system; Nimble radiation pattern; Multifunctional beams

Introduction

In layman's language, an antenna array is defined as a set of aerials arranged in a specific fashion in space so that the resulting radiation characteristics can be modified. As per IEEE standard definition of terms for antennas (IEEE Standard 145–1993), an array antenna can be defined as "an antenna comprised of a number of identical radiating elements in a regular arrangement that are excited to obtain a prescribed pattern." As explained by Randy L. Haupt (2010), the antenna array can be visualized as a system to collect rain. To collect more rain, it is necessary to use a very big bucket or employ large number of buckets and combine all of them. In the same way, in order to receive more electromagnetic radiation, it requires either a large aperture antenna, such as the Arecibo radio telescope in Puerto Rico (305 m wide), or an antenna array with more number of elements such as the square kilometer array as shown in Fig. 1.

The array can be formed by two or more individual elements which may or may not be identical in their radiation characteristics. However, in most of the simple antenna array designs, each individual element is designed to have identical radiation properties. The shape of the radiation pattern in an array with identical elements is determined by the following parameters (Balanis 2005):

- The shape of physical arrangement of each element in space (linear, rectangular, ring, etc.)
- The distance between each element
- The amplitude of the excitation signal to individual elements
- The phase of the excitation signal to individual elements
- The radiation pattern of the individual elements

Improve the S/N ratio	Satellite receivers
Find direction of arrival	Radar systems

In modern world of wireless communication, this concept of antenna array is of high interest and is employed in various scenarios outlined above (Table 1).

Before proceeding further in this section, following definitions related to antenna array would be handy:

Radiation pattern: Radiation pattern of an antenna is the plot of radiated power variation around an antenna estimated in a constant distance from it.

Isotropic antenna: An antenna which radiates its energy equally in all directions. In reality, no such antenna physically exits. An isotropic antenna is used as the reference antenna to compare the characteristics of actual antennas.

Omni-directional antenna: Antennas having an isotropic pattern in one plane and directional pattern in an orthogonal plane.

Directional antenna: An antenna which radiates or concentrates its power to a particular direction or angular regions.

Bore sight: It is the direction at which the beam maximum of an antenna is pointed.

Beam forming: The process of combining signals from different elements of an antenna array is known as beam forming. The direction in which the array has maximum gain is said to be the beam-pointing direction. If the signals from the antenna elements are combined without any change in amplitude or phase, a broadside beam is produced. Beam forming can be generally categorized as analog beam forming and digital beam forming. As the name implies, in analog beam forming, the amplitude and phase of each antenna elements are controlled in the analog part of the system. Phase shifters are commonly used in the analog beam-forming-phased array configurations to control the phase of each antenna element and steering the main beam. On the other hand, in digital beam-forming method, the amplitude and phase of a signal are controlled in the digital part of the system.

DOI 10.1007/978-981-4560-75-7_66-1

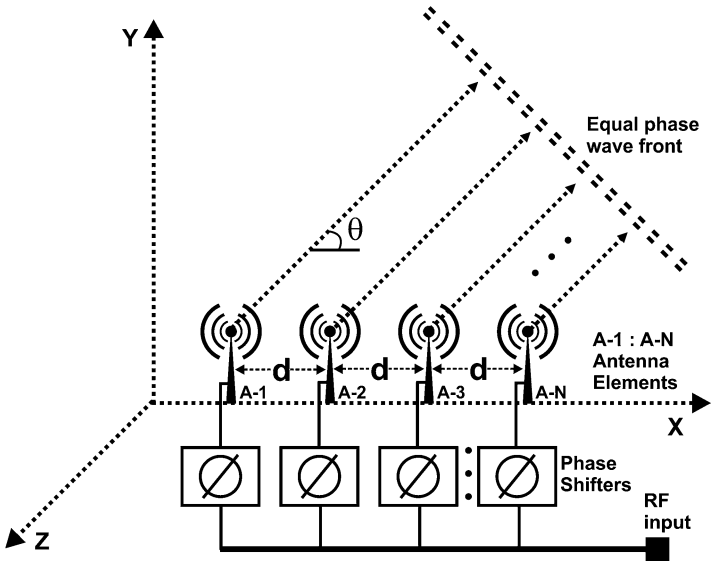

Fig. 2 Uniform N elements linear array

Beam steering: IEEE standard definition of terms (IEEE Standard 145–1993) defines beam steering as "changing the direction of the main beam of antenna." By mechanically moving, the main beam from any given array may be pointing to any direction; this is called mechanical steering. Electronic beam steering is accomplished by appropriately delaying the signals before combing. That is the beam-pointing direction, or the main beam direction can be controlled by changing the phase difference among different antenna elements.

Antenna Array Factor

The concept of an antenna array can be best understood through an example of a simple uniform array shown in Fig. 2. It consists of N identical antenna elements arranged in x-axis with an equal distance. Each antenna element possesses identical radiation characteristics and is fed through separate phase shifters so that each element is excited with progressive phase shift.

The radiation pattern of the linear array is formed based on the concept of pattern multiplication as expressed below:

$$\text{E Total} = \text{E (Single element)} * \text{Array Factor}$$

where E Total is the total field radiated from the antenna array and E (single element) represents the radiation pattern of the single element (A-1, A-2, etc.).

Array factor: It is a mathematical expression formed by the physical arrangement of an array and also with the properties of the excitation signal. The array factor varies from one type of array to another. This clearly indicate that the overall radiation pattern of an antenna array can be entirely different than that of the antenna element.

DOI 10.1007/978-981-4560-75-7_66-1

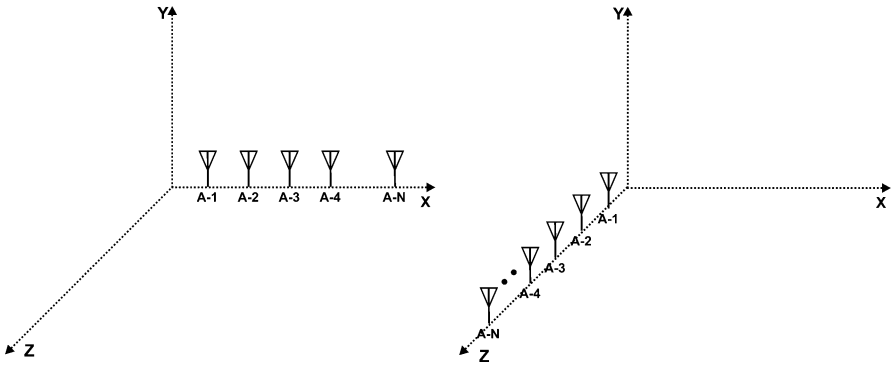

Fig. 3 Linear array with elements positioned in x-axis and z-axis

The array factor of the antenna described in Fig. 2 is defined as

$$AF = \frac{\mathrm{Sin}\left(\frac{N}{2}\ \varphi\right)}{\mathrm{Sin}\left(\frac{\varphi}{2}\right)} \tag{1}$$

$$\varphi = kd\cos\theta + \beta \tag{2}$$

where β is the difference in the phase excitation between the successive elements (progressive phase shift), d is the distance between the elements, k = 2*pi/ λ, and θ is the polar angle.

Configuration/Different Types of Arrays

There are various approaches in classifying antenna arrays. On the basis of the arrangement of the antenna elements in three-dimensional surfaces, the arrays are classified as:

1. **Linear or one-dimensional array:** In this configuration, each antenna element is arranged on a straight line in one dimension. Please note that it is not the shape of the individual antenna elements which needs to be in one dimension but the location of the individual elements. The elements can be simple dipoles to 3D conformal structures which are entirely based on the design objective of the communication system. Figure 3 illustrates some examples in which the antenna elements are distributed in a line parallel to x-axis and z-axis. During the design of the linear array, the expected radiation characteristics need to be taken care of. For example, when designing a linear array oriented along y-axis with array elements of omnidirectional radiation pattern, the broadside pattern will be directional and interferences from the neighboring elements will be minimum. This type of arrays is employed for application where a directional beam is desired and is useful when broad coverage in one plane and narrow beam in the orthogonal plane is required.
2. **Planar or two-dimensional arrays:** The planar array or two-dimensional array is designed with individual elements in a two dimensional plane as illustrated in Fig. 4. This configuration is widely employed for radar applications since it can facilitate highly versatile beam forming.
3. **Volumetric or three-dimensional arrays:** In this configuration, the array elements are designed to conform inside a three-dimensional space as depicted in Fig. 5. Conformal antenna arrays are also defined as a type of volumetric antenna arrays. Compared to the earlier antenna array designs, the volumetric arrays need relatively complex design strategies.

DOI 10.1007/978-981-4560-75-7_66-1

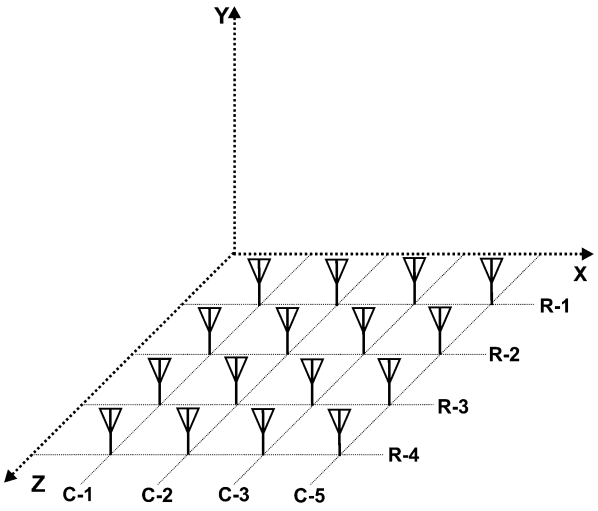

Fig. 4 Planar array arranged in XZ-plane

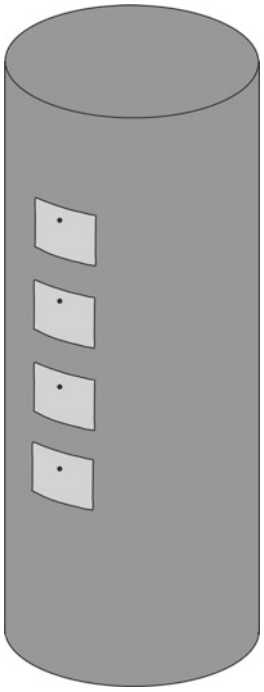

Fig. 5 Volumetric array

Another classification based on the radiation pattern is:

1. **Broadside Array:** In broadside arrays (Fig. 6), the direction of the main beam is perpendicular to the axis in which the array elements are arranged. The IEEE standard definition of terms states broadside antenna array as "A linear or planar array antenna whose direction of maximum radiation is

DOI 10.1007/978-981-4560-75-7_66-1

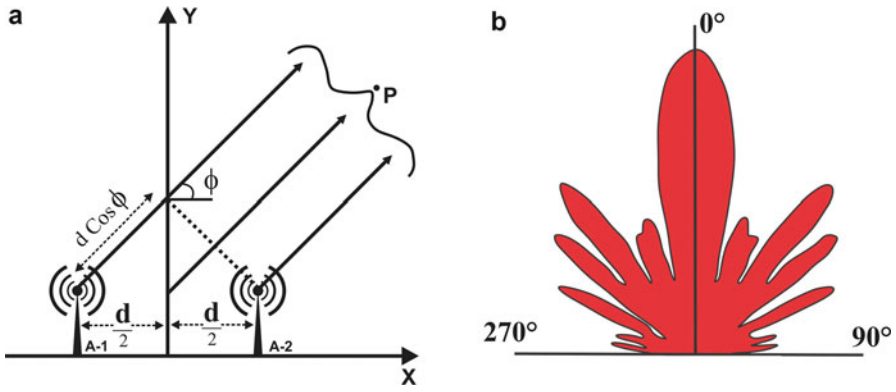

Fig. 6 Broadside array (**a**) configuration, (**b**) radiation pattern

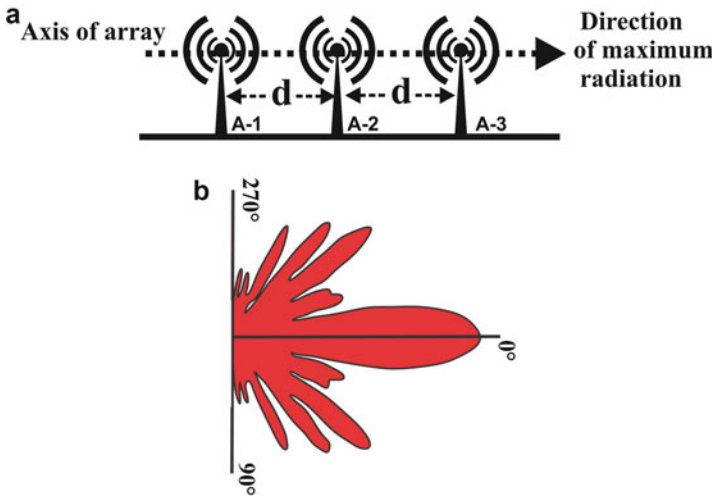

Fig. 7 End-fire array (**a**) configuration, (**b**) radiation pattern

perpendicular to the line or plane, respectively, of the array." The broadside pattern can be obtained in a linear array with identical elements by exciting them with equal magnitude and phase.

2. **End-Fire Array:** In these types of antenna array (Fig. 7), the beam maximum is focused along the axis of the array. Most of the planar or linear arrays can be configured to have a beam maximum that is pointing toward the array axis by exciting the individual antenna elements with equal magnitudes and progressive phase shift.
3. **Collinear Array:** The term collinear indicates that the individual antenna elements are connected end to end along a single line as shown in Fig. 8. In this configuration, the beam maximum is perpendicular to the axis of the array as in the case of broadside array. However, in this case, the fan beam is focused to every point perpendicular to the array axis resulting in a "donut"-shaped pattern as illustrated in Fig. 9. In order to get this pattern shape individual array, elements are excited with currents equal in magnitude and phase.

Smart Antenna

In reality, antennas are not smart; an antenna along with its associated systems makes the antenna system smart. Basically, a smart antenna is a multielement antenna in which the signals received at each antenna element are intelligently combined to improve the performance of the wireless system. As illuminated by Balanis and Ioannides (2007), the working of a smart antenna can be better visualized by considering two persons carrying on a conversion inside an isolated room. Human's auditory system has the ability to distinguish and concentrate on a particular person's voice among a group of peoples talking simultaneously. In the same way, in a smart antenna, any unwanted signal is attenuated. Better range/coverage, increased wireless system capacity, multipath rejection, and reduced expenses are the main advantages of the smart antenna system.

The two basic configurations of smart antenna systems are:

Switched – multi-beam antenna: Either a number of fixed beams with one beam turned on toward the desired signal or a single beam (formed by phase adjustment only) that is steered toward the desired signal

Adaptive antenna array: An array of multiple antenna elements where the main beam is put in the direction of the desired signal, while nulls are in the direction of the interference

Multi-beam Antenna Arrays

In this section, various antenna systems that are employed to generate multiple beams are discussed. In a broad perspective, the multi-beam antennas are defined as antennas that generate either multiple numbers of beams simultaneously or switch between beams in multiple directions. The IEEE standard terms for antennas (IEEE Standard 145–1993) defines multi-beam antenna as "an antenna capable of creating a family of major lobes from a single non-moving aperture, through use of multiport feed, with one-to-one correspondence between input ports and member lobes, the latter characterized by having unique main beam pointing directions."

Some of the earlier designs utilized conventional lenses or modified reflectors to generate multiple number of radiating beams. However, the challenges such as shadows created by the cluster feeds led the researchers to focus on the development of phased array antennas that made the entire antenna system more "smart." The multiple-beam antenna systems facilitate the following advantages compared to single-beam antennas:

- Ability to focus the radiation to a desired direction
- Increase the capacity of the wireless system
- Combat signal fading by suppressing interfering signals
- Facilitate tracking of the objects in radar systems

These key benefits are obtained through relatively higher system complexities in contrast with less complex mechanically scanned or switched design concept. In the following section, the classical designs are first discussed that include designs such as a lens fed by various array feed horns, a reflector illuminated by different feed horns, and phased array concepts. In the later part of the section, relatively new concepts of using engineered materials for the formation of multi-beam antenna arrays are discussed.

Historical Review of Multi-beam Antenna Arrays

Early History (1906–1970)

Even though the concepts behind the first antenna array design were well established by 1920s (Fleming 1919), the natural outgrowth of the array to multiple-beam antennas or beam scanning antennas took almost another decade to flourish into the level of successful experiments. In fact, it is reported that Marconi performed several experiments in the antenna of his wireless communication system to enhance the performance of his receiver in certain directions as early as 1906 (Marconi 1906). There were enormous amounts of research interest fuelled by the Second World War to develop an efficient electromechanically scanned antenna system for radar applications. One classical example is the SCR-270 (Fig. 10) developed during Second World War by the US Army installed in Hawaii that provided Japanese formation during the Pearl Harbor attack. The initial approaches to scan the beam using electromechanical systems were successful and widely developed by 1940s. The technological limitations made some of the key challenges such as mutual coupling between the array elements a major barrier in the design optimization in this period (Brown 1937).

In the 1950s, the special situations after Second World War powered considerable funding for the scientific research related to military applications. The invention of ferrite-based phase shifters (Button 1984) in between 1954 and 1955 provided the technological seed that led to the development in the field of electronically scanning antenna systems (Sarkar et al. 2006). This led to the initial theories and experimental validation of beam-steering antenna arrays by changing the phase of the signals that excite the antenna elements (Braun 1925; Friis et al. 1934). These initial discoveries of mechanically scanned arrays led to many advanced design variations including large ground-to-ship radars and complex airborne radar arrays. Due to various system level limitations, most of these initial discoveries were spread across HF band and then later to EHF range. One of the rich resources that outlines the

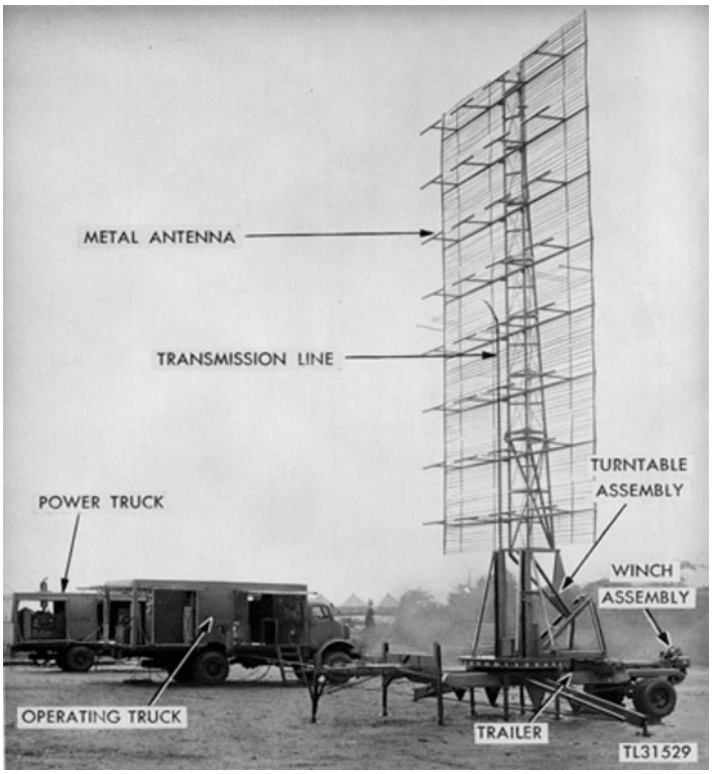

Fig. 10 SCR 270 antenna array with mechanical rotator

DOI 10.1007/978-981-4560-75-7_66-1

developments during this postwar period around the globe is entitled "Microwave Scanning Antennas" edited by Hansen (Hansen 1964, 1966). Until 1960s, the system cost was a major factor that prevents further developments on radar systems for nonmilitary applications. The evolution of printed circuit technology by late 1960s played a critical role in reducing the overall system expenses and thereby accelerating the research and development in broader areas of engineering physics. Even though the microstrip patch antennas were theoretically visualized by G.A. Deschamps in 1953 (Deschamps 1953), it took several years until early 1970, when Robert Eugene Munson succeeded in implementing the same in a sprint missile data link (Munson 1972).

Computational Challenges and Early Algorithms

While empathizing the challenges faced by researchers around the globe, it is important to note that by late 1950s even if the electromagnetic theory was quite established, the use of computer to solve these theories was completely nonexistent. It is quite interesting that, during the 1950s, the JPL in NASA used the word "computer" to represent an individual than a machine, where a specific group of people were designated to perform mathematical calculations by hand. By 1960s, the invention of mainframe computers made the complex electromagnetic calculations based on earlier algorithms (Mei 1965). Many of these initial computations were performed using point-matching solutions of Hallen's integral equation for metallic wires (an earlier version of method of moments) (Harrington and Harrington 1996). Hallen's equations were powerful enough to accurately model dipole antenna arrays. The introduction of algorithms based on geometrical theory of diffraction (GTD) was another breakthrough during the 1960s (Albertsen et al. 1975; Keller 1962). This enabled researchers to utilize well-established theories based on geometrical optics to accurately calculate the radiation properties of popular shapes such as edges and corners. Majority of the earlier computational techniques based on Green's functions were quite general, and most of them are in frequency domain compared to present-day tools which provide both frequency and time-domain solutions. The contributions from Schelkunoff and Dolph for the analysis of phased array antennas were another milestone. These contributions in the late 1940s utilized static weighting schemes (Dolph 1946; Schelkunoff 1943) and accelerated the development of antenna arrays with low side-lobe level. Another major work during the late 1960 by A.P Applebaum (1966) made key contributions to change the array weights which become one of the fundamental concepts behind the adaptive and reconfigurable antenna arrays. The concept of a retro-directive array that receives electromagnetic signals in one direction and retransmits in a mirror-image direction was originated in the late 1950s and credited with a US patent to Van Atta (1959).

Advanced era (1970–present): It is logical to classify the advanced era from a period in history when there were computational tools available, and many fundamental ideas were matured enough for practical implementation. During this period, the application spectrum of multi-beam antennas becomes much broader with the technological advancements. The availability of more efficient computational electromagnetic algorithms along with associate hardware made the research in this field of engineering rich. These scientific advancements enabled the researches to provide contributions with multi-beam antenna arrays with higher number of elements that are operating at the higher end of the spectrum. One of the earlier attempts for the implementation of passive electronically scanned array (PESA) took place by the early 1970s facilitating more efficient scanning than a mechanically rotating antenna. Another research focus during this era was on the development of conformal multi-beam antenna arrays for broadcasting, navigation, and directional finding. A notable development during the Cold War period (1962–1979) was the development of experimental Wullenweber arrays that are circular arrays designed for direction-finding applications. One of the prototypes, the 300 m diameter array with 120 radiating elements, was developed at the University of Illinois (Gething 1966). The initial ideas behind adaptive arrays begin with the motivation to control the receive pattern so that the interference of signals from unwanted directions

DOI 10.1007/978-981-4560-75-7_66-1

can be effectively minimized. One of the inventions during the late 1960s by P.W. Howells (1965) triggered the research across the globe leading to various key contributions in this exciting field of beam-scanning antenna arrays. The research during this period also diverted in various related areas including huge developments in many classical concepts in the field of multiple-beam antennas. Some of the earlier concepts to produce multiple beams were the use of digital/analog beam formers. In addition to these techniques, the antenna hardware concepts based on Butler matrices also evolved by this time (Butler 1961, 1965). The implementation of various lens implementations such as Rotman lens and Gent bootlace lens to produce multiple beams was also introduced in the 1960s (Gent 1957; Rotman and Turner 1963) which facilitated multiple focuses for one scanning plane. A decade later, some of these techniques were extended for various applications using microstrip technology (Archer 1984). The invention of P-I-N diodes and varactor diodes during this period attracted various researchers around the world to focus their research in the development of microwave phase shifters using this technology (White 1968, 1984). Even after a decade from the invention of P-I-N diodes and varactor diodes, the technology was not grown enough for high-power applications. At present, there are P-I-N diode-based microwave phase shifters that can handle kilowatts of peak power. Another important event in the mid-1970s is the development of microstrip antenna array by Munson. This development along with the cavity-based theory presented by Y.T.Lo et al. (1978) accelerated this exciting field of engineering. These developments along with the availability of low-cost fabrication technologies triggered the research world during the late 1980s with massive contributions in the development of multi-beam antenna arrays based on printed technology. The modern world of wireless communication is gifted with plenty of multidisciplinary technologies which accelerated this amazing field of engineering. Some of the exciting focus areas of multi-beam antenna research in this modern world include reconfigurable reflect arrays (Hum and Perruisseau-Carrier 2014), planar ultra-wideband modular arrays (Logan et al. 2013), and phased arrays with broad scanning capacity (Kavitha and Jacob 2013).

Types of Multi-beam Antennas

In general, the multi-beam antennas are classified as lens-based designs, reflector antennas, phased array antennas, and hybrid designs. These classifications are made based on the key system component that produces multi-beam. Each of these designs is detailed in the following sessions.

Lens Antennas

The basic working principle of lens antennas is based on the collimated action of any optical lens which forms a focused electromagnetic radiation. These antennas can be configured with single-feed or multi-feed elements. One of the generally used configurations of lens-based multi-beam antenna is outlined in Fig. 11. In a single-feed configuration, a single source illuminates the aperture and generates a beam based on the lens characteristics. The multiple-feed configuration or discrete lens array (DLA) excites the lens

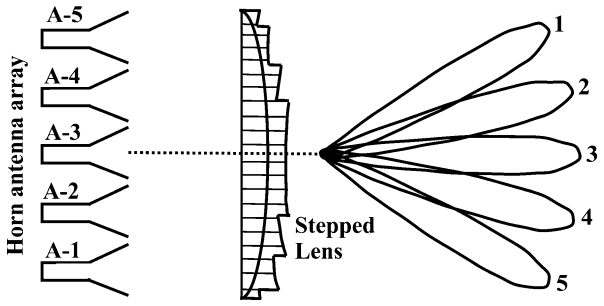

Fig. 11 Lens-based multi-beam antenna

DOI 10.1007/978-981-4560-75-7_66-1

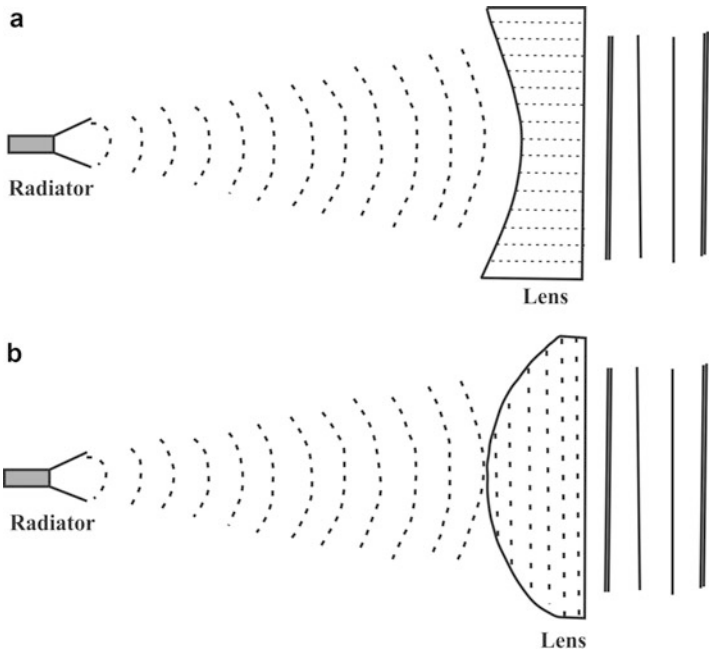

Fig. 12 (**a**) Fast-wave lens, (**b**) slow-wave lens

aperture and forms a constituent beam. By simultaneously exciting these beams, multiple beams can be formed based on the principle of superposition. Based on the properties of the lens, either constructive or destructive interactions can happen at a specific point in space, resulting in the formation of the beam pointing to a specific direction.

There are various types of lens antennas based on the principle of operation of the lens system; in a broad perspective, these are classified as:

(i) Fast-wave lenses (refractive index <1)
(ii) Slow-wave lenses (refractive index >1)

As the name indicates, these terms are related to the phase velocity of the wave that travels through the lens medium. These structures are illustrated in Fig. 12.

In fast-wave lenses, the electrical path length is decreased by the medium of the lens, and thus the phase velocity of the wave in the medium will be relatively higher. As shown in Fig. 12a, as the electromagnetic wave passes through the lens medium, the electric length is made shorter as the wave progresses. The fast lens antennas are also known as E-plane lens antennas. In contrast, a delay lens antenna is the one in which the wavelength in the medium will be increased, and this results in a reduced phase velocity as illustrated in Fig. 12b. The slow lens antennas are also known as dielectric lens antennas or H-plane lens antennas and further classified as:

- Lenses derived from conventional dielectrics such as lucite or polystyrene
- Lenses fabricated from artificial dielectric parts, ceramic, or metallic components

There are various lens topologies implemented for various applications including gain enhancement and beam forming. In the following section, various lens topologies that are employed for multi-beam antenna applications are being discussed. A detailed analysis of other lens architectures is detailed in Lee (1988).

DOI 10.1007/978-981-4560-75-7_66-1

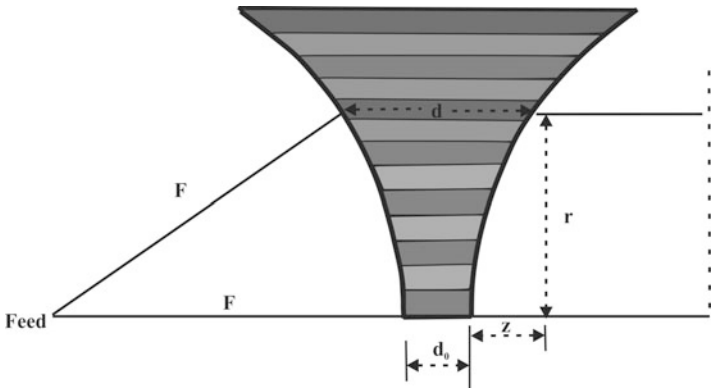

Fig. 13 The topology of a waveguide lens

The key lens topologies employed in multi-beam antennas are waveguide lens, bootlace lens, Rotman lens, and Luneburg lens.

Waveguide Lens The basic topology of a waveguide lens is shown in Fig. 13. It is primarily made of stacking waveguides of different dimensions. The concept is based on the fact that the phase velocity of electromagnetic waves exceeds the speed of light inside a waveguide. The shape of the waveguide is designed in order to provide corresponding phase velocity. More specifically, the distance travelled by the center ray from the source located on one side of the lens to a perpendicular plane on the other side of the lens is made equal to the path travelled by a general ray through other waveguide pieces.

This condition is satisfied from Eq. 3 to Eq. 5:

$$d = d_0 + z/(1 - n) \tag{3}$$

where d_0 is the smallest dimension of the lens.

$$n = \left[1 - (\lambda/\lambda c)^2\right]^{1/2} \tag{4}$$

where n is the refractive index of the lens based on the free space wavelength λ and waveguide cutoff wavelength λc.

$$z = F - \left(F^2 - r^2\right)^{1/2} \simeq r^2/2F \tag{5}$$

where F is the focal length of the lens and r is the distance from the element to the lens axis.

One of the classical applications for a waveguide lens antenna is shown in Fig. 14, formed by an array of waveguides with either circular or spherical cross sections for satellite communication systems. The length of the waveguides is made so as to produce corresponding phase delays when electromagnetic signals propagate through them.

One of the design challenges for the waveguide-based antenna array technology is the limited bandwidth. This is mainly because of the dispersive nature of the waveguide media. That is, the phase velocity of electromagnetic waves inside the waveguide varies with frequency. One of the classical solutions for this challenge is the use of a stepped design as shown in Fig. 15, in which a step is made in the lens. As a general rule, this is done when the lens thickness exceeds [λ/(1−μ)]. Even though the stepping

DOI 10.1007/978-981-4560-75-7_66-1

Fig. 14 Classical application of waveguide lens array antenna used in DSCS-III satellite

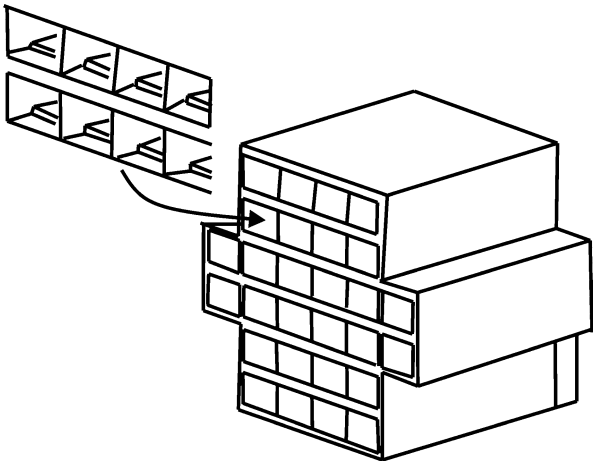

Fig. 15 Stepped waveguide array

can be made on either one or both inner sides of the waveguide, it is suggested to avoid the stepping on the feeding side of the waveguide array to avoid shadow effects.

Bootlace Lens The bootlace lenses are known for its capability to have more than one focal point and thereby provide wide-angle scanning capabilities. It consists of two array geometries that are arranged back to back to form a combined lens system. The array elements on one side are connected to the other side through a processing circuitry that consists of amplifiers and transmission lines. The beam characteristics of the bootlace lens depend on the length of the transmission lines along with the amplitude and phase between the receiving and transmitting elements. The transmission lines that connect the radiators on the inner and outer surfaces are connected through transmission lines mostly with coaxial cables. This gives an appearance of untightened bootlaces which gives the name bootlace lens. The geometry of a bootlace lens is shown below (Fig. 16).

A multi-beam antenna can be formed by employing bootlace lens by placing more than one source antennas at various focus points. Even though the initial designs were only capable of providing two-dimensional scanning (Kales 1964), later designs provided multifocal three-dimensional scanning

DOI 10.1007/978-981-4560-75-7_66-1

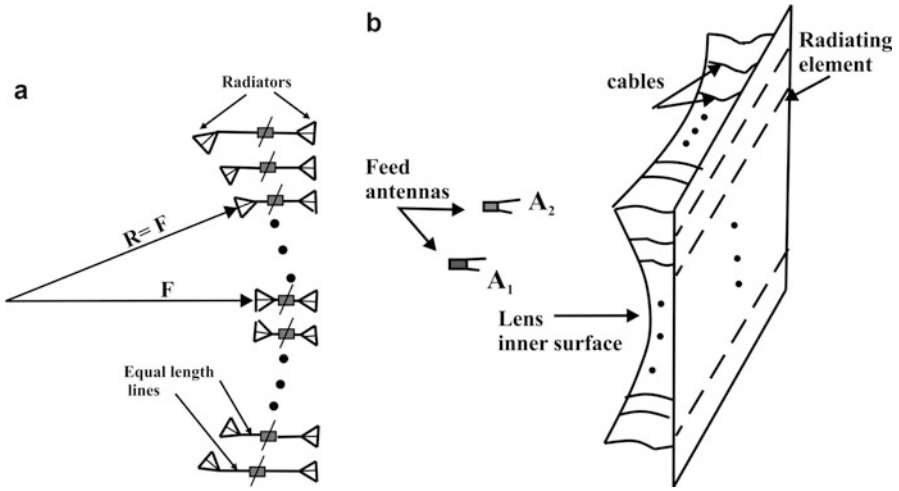

Fig. 16 (**a**) Diagram of bootlace lens, (**b**) geometry of one of the earlier versions of multifocal bootlace lens with three-dimensional scanning proposed by Jaganmohan B. L. Rao (1982)

facility (Rao 1982). One of the general theories developed by Gent in 1957 states that if the lens has a radius of 2R, then its focal points lie on a circle with radius R (Gent 1957).

In general, the bootlace lenses provide the following key features:

- Three-dimensional degrees of freedom for the design.
- The embedded microwave components in between the two lens surfaces facilitate illumination control of the outer surface and thereby provide beam scanning.
- The ability to implement stepping without the issues of shadow effect.

Rotman Lens Rotman lens is capable of producing simultaneous multiple beams when implemented on an array configuration. The diagram shown in Fig. 17 represents a Rotman lens which is a modified version of Gent bootlace lens (Gent 1957). Apart from the bootlace lens, the Rotman lens can provide much wider coverage exceeding scan angles of greater than 50° (Rotman and Turner 1963).

In one of its simplest configurations shown in Fig. 17, the transmitting or receiving antenna elements are mounted on a curved arc which either radiates or receives from the other curved portion of the lens. The array elements are arranged in a straight line at a geometrical plane perpendicular to the lens axis outside the lens. This generates multiple beams that are capable of steering toward the preprogrammed directions without any physical movement of the surface.

In comparison with other lens topologies, Rotman lens is relatively broadband in nature. The feed portion shown in the right-hand side can be implemented either using microstrip or stripline; meanwhile, the bootlace portion represented in the left-hand side can be implemented using coaxial cables. The key design parameters are outlined in Fig. 17b. This include:

- Focal angle, α
- Focal length, f1
- Ratio of beam angle and ray angle, γ
- Focal ratio, β
- Element spacing, d
- Peak beam angle, ψm

DOI 10.1007/978-981-4560-75-7_66-1

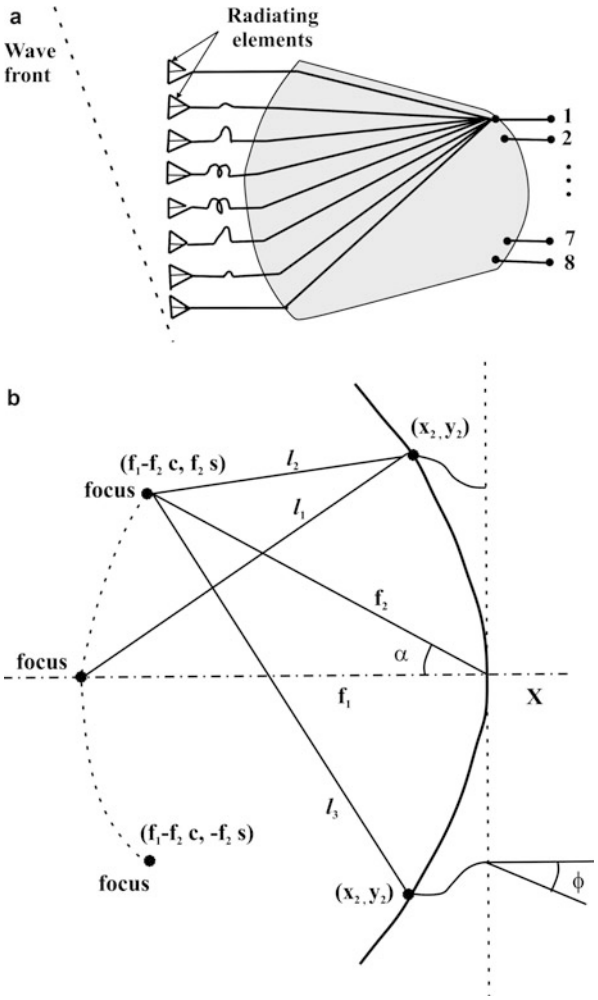

Fig. 17 (**a**) Rotman lens, (**b**) ray geometry of the Rotman lens

The design process is a trade-off between mutual coupling reduction and fabrication limits. Based on the detailed analysis provided in Hansen (2009), the design guidelines are given below:

- The focal ratio β can be calculated from the upper and lower focal length f_2 and f_1 using

$$\beta = \frac{f_2}{f_1} \tag{6}$$

- The beam angle ratio γ is given by

$$\gamma = \frac{\text{Sin}\ \psi}{\text{Sin}\ \alpha} \tag{7}$$

  where ψ is the beam angle and α is the focal angle.
- Another parameter **ζ** relates the distance γ_3 with f_1 and controls a percentage of the phase and amplitude error the lens possess can be calculated from

DOI 10.1007/978-981-4560-75-7_66-1

$$\zeta = \frac{\gamma_3 \gamma}{f_1} \tag{8}$$

- The maximum beam angle, ψm, is a critical design parameter that can be derived from

$$\zeta_{max} = \frac{(NE - 1)\gamma d}{2f_1} \tag{9}$$

where NE represents the number of elements.

- The quadratic lens equation is given by

$$a\left(\frac{w}{f_1}\right)^2 + \frac{bw}{f_1} + c = 0 \tag{10}$$

where the coefficients can be calculated from

$$a = 1 - \frac{(1-\beta)^2}{(1-\beta C)^2} - \frac{\zeta^2}{\beta^2} \tag{11}$$

$$b = -2 + \frac{2\zeta^2}{\beta^2} + \frac{2(1-\beta)}{1-\beta C} - \frac{\zeta^2 S^2 (1-\beta)}{(1-\beta C)^2} \tag{12}$$

$$c = -\zeta^2 + \frac{\zeta^2 S^2}{1-\beta\ C} - \frac{\zeta^4 S^4 (1-\beta)}{4(1-\beta C)^2} \tag{13}$$

$$\text{and} \quad C = \cos\alpha, S = \sin\alpha$$

The element spacing is critical since it has high impact on the grating lobes which can be calculated from

$$\frac{d}{\lambda} = \frac{1}{1 + \sin\psi_m} \tag{14}$$

Luneburg Lens In contrast to the earlier lens topologies, Luneburg lens is a spherically symmetric gradient-index lens whose refractive index decreases radially from center to the outer surface (Fig. 18), theoretically proposed by Luneburg (1944). The geometry of this lens includes two spheres in which one has an infinite radius and the other sphere is the lens surface.

The refractive index, n, of a unit length radius Luneburg lens is defined as

$$n = \left(2 - r^2\right)^{1/2} = \sqrt{\varepsilon_r} \tag{15}$$

where r is the radius of the lens.

The Luneburg lens produces a plane wave when the feed point is at one of the surface regions of the sphere. This in turn enables the Luneburg lens to produce multiple beams either by moving the feed point through the sphere surface or by exciting more than one feed locations around the sphere surface.

DOI 10.1007/978-981-4560-75-7_66-1

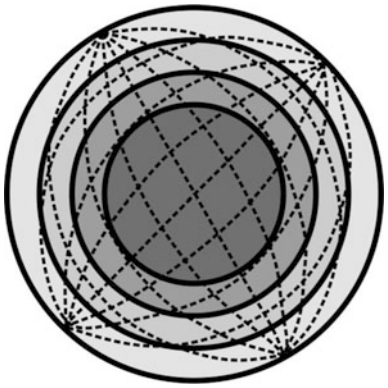

Fig. 19 Cross section of Maxwell's fish-eye lens, with gray shading representing increasing refractive index

Maxwell's fish-eye lens (Fig. 19) is a classical example of generalized Luneburg lens in which the refractive index varies according to

$$n = \sqrt{\varepsilon_r} = \frac{n_0}{1 + \left(\frac{r}{R}\right)^2} \tag{16}$$

Reflector Antenna

In a simple form, a reflector antenna consists of a reflector and an antenna feed. These types of antennas are widely used in long-distance high-gain applications like communication satellites, military satellites, high-resolution radars, etc. In the design, the reflector surface can take any general shape like paraboloid, hyperboloid, spheroid, ellipsoid, cylindrical, etc. The basic working principle of the reflector antenna is that the reflector converts the spherical wave to a plane wave in transmission mode and vice versa in reception mode. One of the most commonly used focal point-fed parabolic reflector antennas is shown in Fig. 20. On receiving mode, as a beam of parallel rays incident up on the parabolic reflector, the reflector

DOI 10.1007/978-981-4560-75-7_66-1

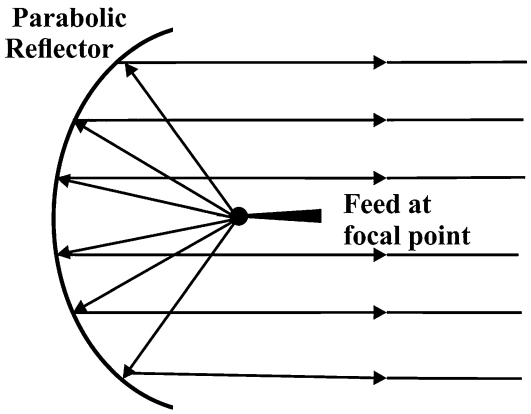

Fig. 20 Reflector antenna

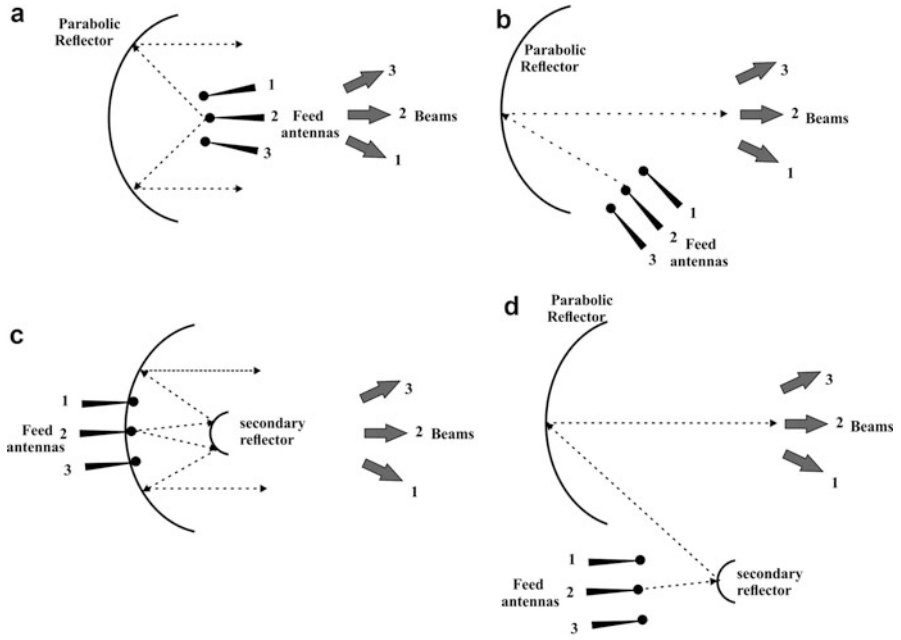

Fig. 21 (**a**) Parabolic reflector multi-beam antenna, (**b**) offset-fed parabolic reflector antenna, (**c**) focal point-fed Cassegrain reflector antenna, (**d**) offset-fed Cassegrain reflector antenna

focuses the entire ray to the focal point. Similarly on transmission mode, the beam is produced by the antenna feed, placed at the focal point, and emerges as parallel rays.

By using antenna array as the primary radiator, these antennas can also produce multiple beams. The performance of the reflector multi-beam antenna is similar to that of a lens antenna. Some of the most commonly used multi-beam antenna configurations based on this concept are shown in Fig. 21.

In a reflector antenna, aperture size of the reflector, type of the reflector, focal length, offset distance, and surface tolerance are the main design parameters to get a desired radiation pattern. The aperture size is a key design parameter that determines the gain and bandwidth of the antenna. In multiple-beam antenna applications, a large aperture size reflector is quite commonly used.

Aperture blockage by the feed and its support is the main disadvantage of a focal point-fed reflector antenna. One of the solutions to reduce this blockage which causes side lobes is the offset-fed reflector antenna. Cassegrain feeding is another solution which helps to overcome both the aperture blockage and

DOI 10.1007/978-981-4560-75-7_66-1

lack of control over the main reflector illumination. As illustrated in Fig. 21b, the reflected wave from a secondary hyperboloidal reflector illuminates the paraboloidal primary reflector. In this design mechanism, the reflectors and the feed antenna are positioned in such a way that the focus of the main reflector and one of the foci of the secondary reflector is coinciding in such a way that the outline of the secondary reflector controls the illumination of the main reflector. Electrically, such a system is same as that of a single reflector antenna with a longer focal length. Therefore, it provides better scanning performance than a single reflector type antenna. The Cassegrain focal point-fed reflector antenna also suffers from the aperture blockage. It can be minimized by choosing the diameter of the secondary reflector same as that of the feed. Another solution to minimize the aperture blockage is to employ offset Cassegrain feeding as depicted in Fig. 21d.

Phased Array Antenna

A phased array antenna is a directive antenna composed of an array of equally spaced individual antennas or elements. In such a design, the shape and direction of the radiation pattern is determined by the relative amplitude and phase of the electromagnetic signal at the individual elements. Similar to reflector or lens antennas, a phased array antenna with a beam-forming network can also be used to produce multiple beams. This configuration is normally preferred when the number of antenna elements ranges between a few to a few hundred. The beam-forming network in a phased-antenna system mainly combines the signals from all the elements in an array to form a receiving beam or conversely distributes the transmitted signal to different elements in an array to form a transmitting beam. Beam forming can be generally categorized as analog beam forming and digital beam forming. As the name implies, in analog beam forming, the amplitude and phase of each antenna element are controlled by an analog circuitry in the system. This includes analog phase shifters that provide smooth beam forming by controlling the phase of excitation of each antenna elements. Most of the modern-phased array systems use much advanced techniques that include digital beam-forming circuits in which the amplitude and phase of excitation of array elements can be software controlled with digital hardware.

Butler Matrix Butler matrix is one of the most popular multiple beam-forming networks employed to feed a uniformly spaced antenna array which was first introduced by Jesse Butler and Ralph Lowe in 1961. It is a feed network with $N = 2^n$ number of input ports and $N = 2^n$ number of output ports, where n is an integer. Thus, a Butler matrix network can provide linear phase distributions when the number of antenna elements is a power of two. In other words, if a signal is introduced at one input port, the matrix will produce equal amplitude excitations with constant phase difference at all output ports, resulting radiation in a particular direction in space. A signal introduced at another port will similarly create another beam pointing to different direction. Regarding the structure of the matrix, hybrid couplers and phase shifters are the basic building blocks of a Butler matrix network. This includes hybrid couplers with 90° and 180° designs along with Butler matrices. For example, the design to produce a broadside beam can employ a 180° hybrid coupler.

A Butler matrix with $N = 2^n$ number of input and output ports comprises Nn/2 number of hybrid couplers and (n-1)N/2 phase shifters. The phase difference between radiating elements in this matrix for the *i*th beam location is given by $(2i-1)\ 180^\circ/N$.

Similarly, the angle of beam title when a signal is introduced at the *i*th input of the matrix can be calculated by the equation

$$\theta_i = \mathrm{Sin}\left(\frac{N+1-2i}{2N}\ \frac{\lambda}{d}\right), \quad i = 1, 2, 3 \ldots .N \tag{17}$$

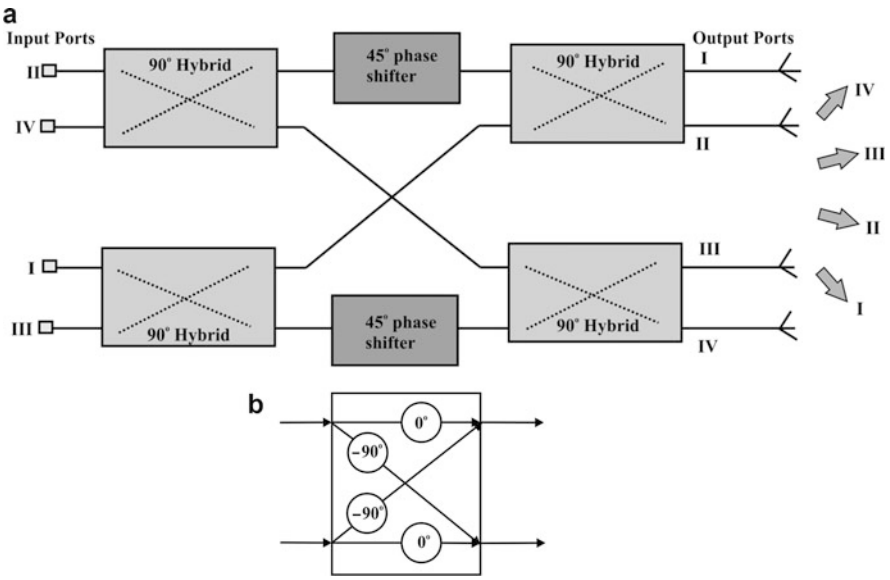

Fig. 22 (**a**) 4 × 4 Butler matrix, (**b**) 90° hybrid coupler

Table 2 Phase distribution and beam direction of a 4 × 4 matrix

Input port		I	II	III	IV
Output port	I	−90°	−45°	−180°	−135°
	II	−225°	−90°	−135°	0°
	III	0°	−135°	−90°	−225°
	IV	135°	−180°	−45°	−90°
Beam direction		48.59°	14.47°	−14.47°	−48.59°

Figure 22 demonstrates the basic functional block diagram of a 4 × 4 Butler matrix using 90° hybrid couplers. As shown, total of four hybrid couplers are arranged in two columns along with two phase shifters in the network topology. Table 2 shows the phase distributions produced by the matrix when a signal is introduced at a particular input port. The corresponding main beam directions from the antenna array are also given.

Another exciting feature of this network is that the antennas can produce multiple beams by simultaneously exciting two input ports. For example, if port 1 and port 4 are excited at the same time, the phase array will produce two beams simultaneously with a beam tilt of 48.59° and −48.59°. One of the limitations of this network is the lack of capability to produce two adjacent beams since there is high tendency to form a merged single beam.

Blass and Nolen Matrix *Blass matrix:* Another interesting matrix design is depicted in Fig. 23, called Blass matrix. It is a multi-beam feed network, in which "N" numbers of antenna array element feeders are connected to M number of beam port lines through directional couplers. In a receiving configuration, each beam-port couple signals from each antenna with the help of series feed lines. In this feed network, the couplers are equally spaced along the transmission line to produce a constant phase shift between elements that results in beam steering in a desired angle. In order to prevent reflections, the beam and element transmission lines are terminated with matched loads. One of the consequences of this

DOI 10.1007/978-981-4560-75-7_66-1

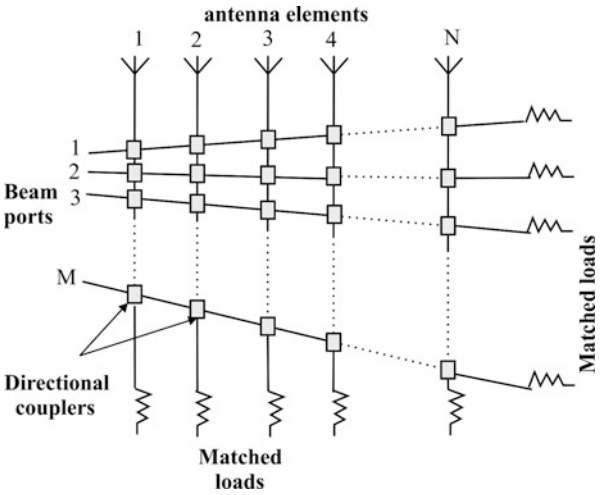

Fig. 23 Block diagram representation of Blass matrix

termination is the reduced efficiency of the entire system. If $\psi_{m,n}$ is the phase length from the m^{th} port to n^{th} element, then the phase difference of any two adjacent elements is

$$\begin{aligned} \Delta\psi_m &= \psi_{m,n+1} - \psi_{m,n} \\ &= \psi_{m,n} - \psi_{m,n-1} \end{aligned} \tag{18}$$

The corresponding output beam m is steered to an angle of

$$u_s = -\frac{\Delta\psi_m}{k\ d} \tag{19}$$

Nolen matrix: This is a combined design of both Butler matrix and Blass matrix in which the design utilizes a unitary coupling matrix circuit as shown in Fig. 24. As in a Blass matrix, the Nolen matrix also has different numbers of antenna elements and beam ports. In the basic configuration, the M^{th} port is coupled from the N^{th} antenna element as demonstrated in Fig. 25. When the number of antenna elements is a power of two, the Nolen matrix can be reduced to a simple Butler matrix.

Metamaterials and Its Application in Multi-beam Antenna Arrays

For the last two decades, metamaterials have been an interesting research area in the scientific community. The terminology metamaterials originated from the Greek term "meta" meaning "after" or "beyond" which implies metamaterials possess some special characteristics that are beyond the natural materials existing in nature. Thus, metamaterials are artificial structures that exhibit electromagnetic properties not usually found. The term metamaterials was first formed by Rodger M. Walser, University of Austin, in 1999. It was originally defined as "macroscopic composites having a synthetic, three dimensional, periodic cellular architecture designed to produce an optimized, not available in nature, of two or more responses to specific excitations." Some of the other definitions that have been found in the literatures are "materials whose permeability and permittivity derived from their structure" and "artificial effectively homogeneous electromagnetic structures with unusual properties not readily available in nature" (Caloz and Itoh 2006). Based on the way in which these materials treat the incident fields of an electromagnetic radiation, they are classified as double-negative materials (DNG), electromagnetic band gap (EBG) or

DOI 10.1007/978-981-4560-75-7_66-1

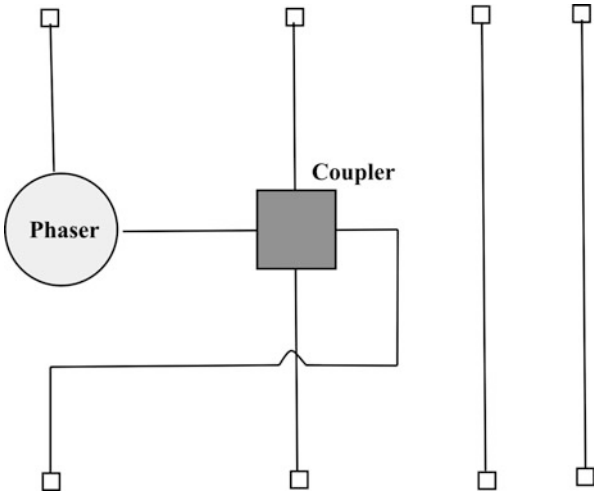

Fig. 24 Unitary coupling matrix

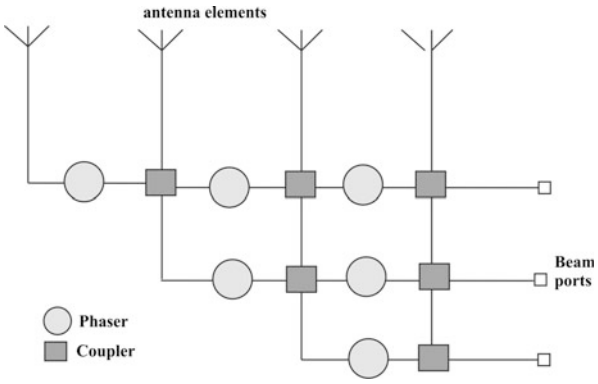

Fig. 25 Nolen matrix

photonic band gap materials (PBG), and frequency-selective surfaces (FSS). In general, they are composed of an array of dielectric or metallic elements in one, two, or three dimensions. The electromagnetic properties of these materials are characterized by various design factors including the element shape, array texture, electrical parameters of the material, and the distance between elements in the array.

As an electromagnetic wave incident up on a DNG material, it provides negative permittivity and negative permeability. These types of materials have found applications in beam-steering antennas, lens antennas, and microwave filters. However, metamaterials like PBG or EBG prohibit the propagation of incident waves across a range of frequency band. As a general rule, the periodicity in these materials is in the range of half wavelength. These materials also found great applications in antenna engineering to enhance the gain and suppress the surface wave, in microwave filters to create band-stop response, and in electromagnetic shielding applications. FSS is a kind of planar metamaterials, which is made of an array of metallic patches or perforated conductors. As the name implies, these materials are transparent to some frequency bands while reflective, absorbing, or redirecting to others. These materials found significant applications in antenna, filters, polarizers, radomes, and electromagnetic shielding. FSS-based EBG surfaces formed by cascading some FSS layers are also used for antenna applications.

As shown in Fig. 26, in terms of permittivity and permeability, materials are generally classified into four categories. A material with permittivity and permeability greater than zero is known as double-

DOI 10.1007/978-981-4560-75-7_66-1

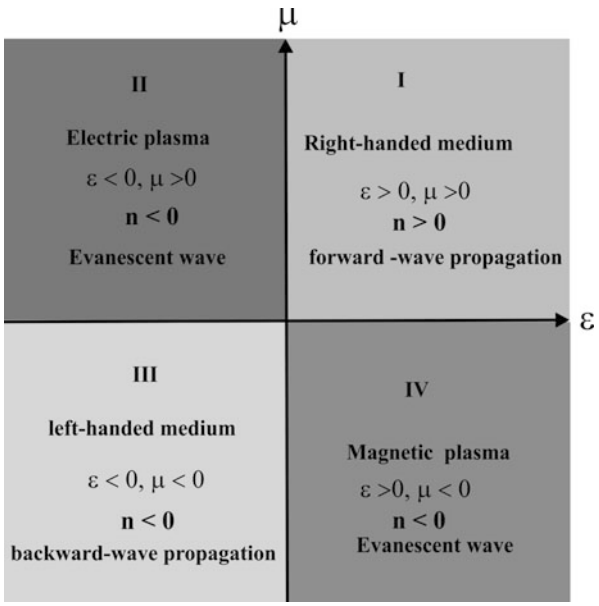

Fig. 26 Material classifications in terms of permittivity and permeability

positive metamaterial or right-handed materials which support forward propagating wave. A material with permittivity less than zero and permeability greater than zero will be designated as epsilon-negative medium. Similarly, a material with permeability less than zero and permittivity positive is known as mu-negative metamaterial. A material with permittivity and permeability less than zero will be designated as double-negative material or LHM which supports backward propagation of waves.

Applications in Antenna Engineering

Short history: The history of metamaterials started in 1968 when Vaselago (1968) proposed the existence of a material with simultaneous negative electric permittivity and magnetic permeability. However, due to the lack of experimental verifications, his invention was ignored for more than three decades. The first revolution of metamaterial occurred in the late 1990s (Pendry et al. 1996) when Sir Pendry demonstrated a wire medium whose permittivity is negative. Then, in 1999, Sir Pendry discovered the split ring resonators having negative permeability (Pendry et al. 1999). Another important landmark was the first artificial left-handed material using a combination of wires and SRRs by Dr. Smith in 2001 (Shelby et al. 2001). The year following this event, LHM was presented almost simultaneously using transmission line approach by three research groups (Eleftheriades, Oliner, and Caloz-Ltoh) (Caloz and Itoh 2002; Iyer and Eleftheriades 2002; Oliner 2003). Any one-dimensional RHM can be resented or equivalent to a conventional transmission line composed of series inductance and shunt capacitance, whereas an LHM can be represented as a transmission line consisting of series capacitance and shunt inductance. In fact, the scenario with a current flow through this structure can be represented as a series capacitance accompanied by an inductance, and a shunt capacitance is accompanied by a capacitance. Thus, eventually, a composite right-left-handed transmission line model has been evolved to represent the RHM and LHM (Caloz and Itoh 2006).

The second revolution of metamaterial has happened with the concept of electromagnetic wave bending using gradient refractive index medium in 2005 (Smith et al. 2005) and the invisible cloaks in 2006 (Leonhardt 2006; Pendry et al. 2006). After these realizations, the interest toward the metamaterial has been considerably increased, and many scientific papers have been published. Due to the extraordinary features, metamaterials have been found and are potential candidates for various engineering

DOI 10.1007/978-981-4560-75-7_66-1

applications. Especially in antenna engineering, metamaterials are widely being used to improve its performances. Examples include antenna substrates for miniaturization, bandwidth enhancement, gain enhancement, and controlling the direction of radiation. Metamaterials as antenna superstrates can be utilized to improve impedance and directivity bandwidth, change the polarization, increase gain, and beam tilting. Instead of conventional transmission lines, metamaterial-based transmission lines can be employed in relatively more efficient feed networks. Compared to conventional design of transmission line-based feed networks, the metamaterial-based feed networks have the advantage of low profile and broad bandwidth. In phased array antennas, metamaterials are employed to improve the impedance matching and beam-scanning range. Another area of interest especially in military applications is in the field of Radom design where the ground plane regions can be realized with metamaterials. In addition, the design flexibility of these engineered materials possesses good potential to be embedded in applications such as Luneburg lens antennas and reflector antennas.

Design Examples

This session outlines some of the recent developments in metamaterial-based multi-beam antenna arrays. The objective of this session is to provide an experimental level demonstration of this magnificent field of engineering.

High-Gain Reconfigurable Sectoral Antenna Using an Active Cylindrical FSS Structure

Sectoral antennas have been widely reported and are popular in various classical applications such as base station antennas and point-to-multipoint communications to cover a specific area. It is a type of directional antenna with a narrow beam width in one plane and a wide beam width in the other plane. A sectoral antenna with radiation pattern reconfigurability provides more design flexibility and in turn enhances the overall system performance. In addition, since the beam is directed toward the desired user, it provides energy saving and thereby higher system efficiency.

One of the practical realizations of metamaterial-based beam-scanning antenna is shown in Fig. 27. It composed of active unit cell-based cylindrical FSS structure around an omnidirectional electromagnetically coupled coaxial dipole array. An array of discontinuous strips and PIN diodes inserted into their discontinuities forms the active FSS unit cell. They are placed cylindrically with an angular periodicity of $\theta_{FSS} = 30^\circ$ and radius of 50 mm on a substrate with permittivity 3, thickness 0.254, and loss tangent 0.0013. High-frequency PIN diodes GMP-4201 are used in the prototype. Two narrow DC feeding lines are used at both sides of the strips for supplying diodes. To produce same amount of current in all the diodes, high-value resistors are also used at the top of each line between the strip and DC feeding line. As shown in Fig. 27b, the ECCD array was also fabricated with a UT-141B semirigid coaxial cable from Micro-Coax.

In order to produce reconfigurable radiation pattern, the cylindrical FSS structure is divided into two semicylinder sectors, one with diodes on and the other with diodes off. The semicylinder with the diodes on operates as an array of continuous strips with high reflection, whereas the other semicylinder with the diodes off operates as an FSS with an array of printed dipole below resonance frequency and allows the transmission of the incident electromagnetic wave. Therefore, the FSS structure converts the omnidirectional radiation pattern of the source into directive pattern. By switching the diode states, the direction of the high and low reflective sectors changes; therefore, the radiation pattern of the antenna can be swept in the entire 360° azimuth plane.

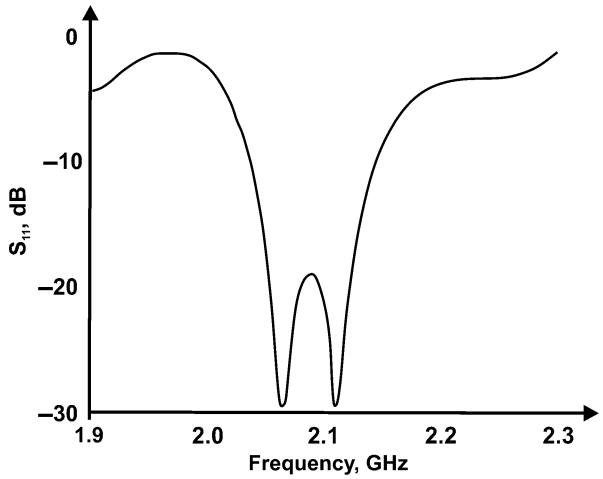

Fig. 28 Reflection coefficient of the FSS-based beam-scanning antenna

During measurement, five columns of diodes were in the off state and seven columns of diodes in the on state. A supply voltage of 0 V is given to the diode for off state, whereas 37 V DC is used for the on state. The S_{11} (Fig. 28) of the reconfigurable antenna indicates ~6 % of 2:1 VSWR bandwidth around the center frequency.

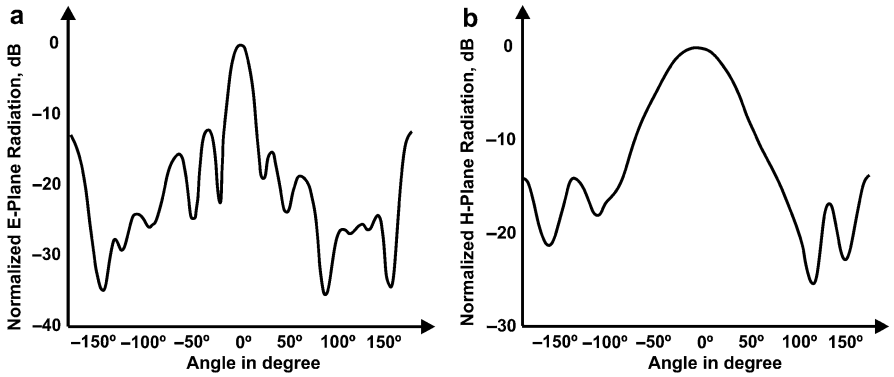

Fig. 29 Normalized radiation patterns of the antenna in two principle planes

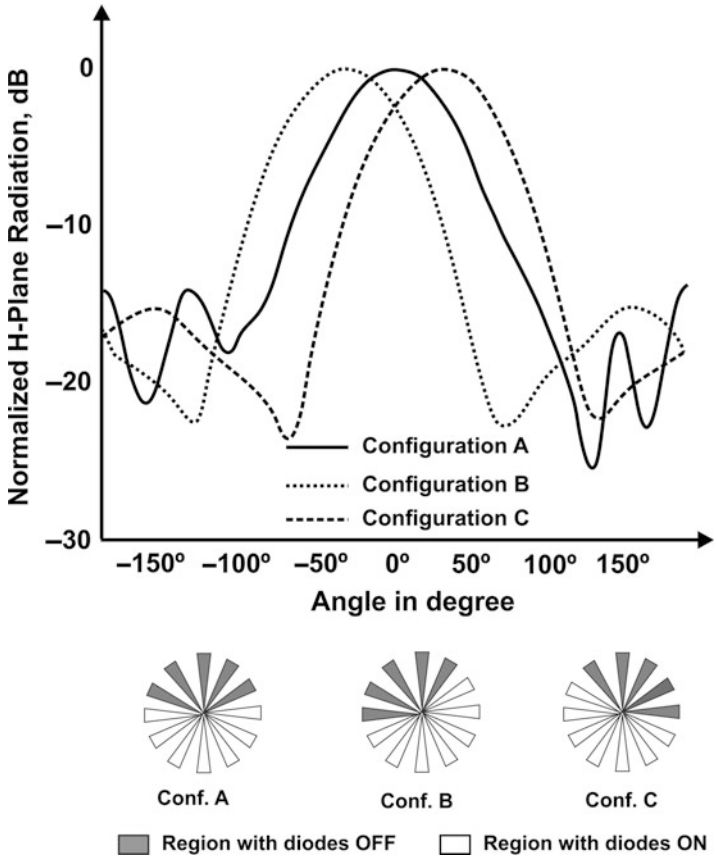

Fig. 30 Beam scanning in H-plane with various diode reconfiguration scenarios

The normalized radiation patterns of the antenna in the E- and H-planes are shown in Fig. 29. The antenna provides a directional radiation pattern with half power beam width of 20° and 70° in the E- and H-plane respectably with a side-lobe level of −13 dB. The H-plane radiation pattern of the antenna, for switching the beam toward 0°,−30° with different reconfiguration scenarios, is demonstrated in Fig. 30. The radiation characteristics show a gain of around 13dBi.

Electronically Radiation Pattern Steerable Antennas Using Active Frequency-Selective Surfaces

Compared to conventional smart antenna systems with phase shifters, the demand for electronically steerable antenna solutions is quite demanding in this modern telecommunication era. The advantages include more flexible design and omnidirectional beam formation. One of the interesting design examples capable of electronic steering of radiation pattern is shown in Fig. 31.

It consists of ten columns of active FSS unit cell-based cylindrical array with a radius of 50 mm. Each column of cylindrical array has 17 unit cells. Special design schemes are employed for biasing through the bottom of the antenna system. Finally, the pair of bias cables is connected with a programmable multichannel voltage controller. The structure of the omnidirectional coaxial collinear source antenna at the center is made of LMR-195 coaxial cable sections.

The antenna operates in three single mode configurations, namely, case-1, case-2, and case-3, as illustrated in Fig. 32. In the case-1 scenario, five columns of the cylindrical FSS are set into reflective mode, and the other five columns are transparent mode. The reflective FSS arrays block the electromagnetic energy, and the transparent FSS array allows passing the beam. The case-2 also works the same as that of the case-1 mode with an additional opaque layer resulting steering of the beam. In case-3, one column of the cylindrical FSS is set to partially opaque using appropriately biased varactor diode, resulting a beam in between 0° and 18°. By changing the different sectors, this particular antenna can provide 360° steerability of the main beam in H-plane. With the same beam control method, multi-beams (two beams) are also generated.

Figure 33 shows the layout of the active FSS unit cell realized on a high-frequency laminate with permittivity 3.5, loss tangent 0.0007, and thickness 0.8 mm. The top side of the unit cell consists of a pair

DOI 10.1007/978-981-4560-75-7_66-1

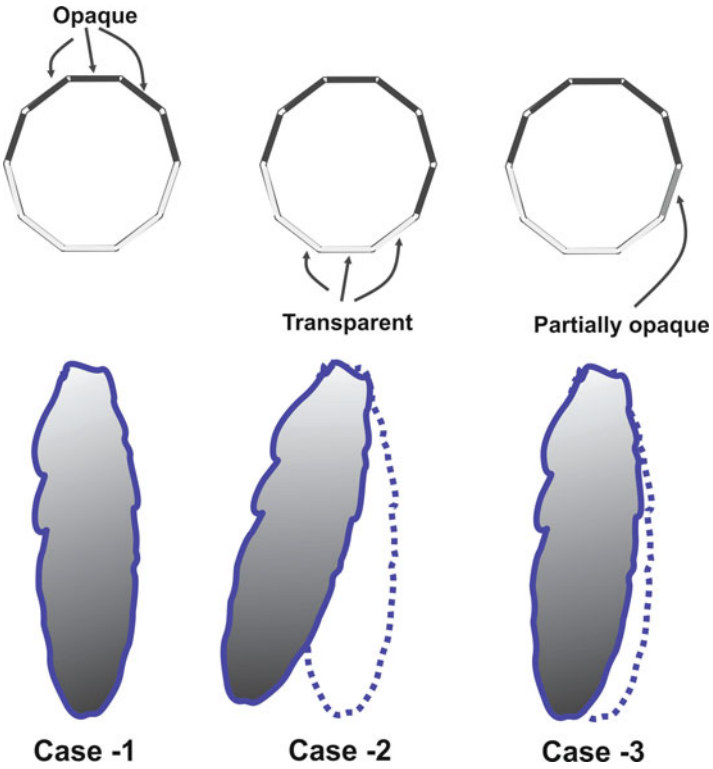

Fig. 32 Single-beam configurations

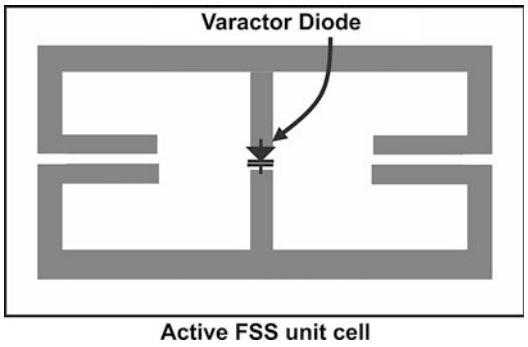

Fig. 33 Unit cell layout

of vertical anchor- shaped metal strips and a varactor mounted in the middle. The unit cells repeat along vertical direction to form an array. The bottom side comprises the DC biasing network. Vias are used to connect the front side strip to the biasing network. RF chokes are also applied between two unit cells and near the vias. BB857 (by Infineon) and 22nH high Q inductor (by Murata) varactor diodes are used. At 1.78 GHz, 6 V and 30 V are set as the voltage for reflection and transmission mode of the cylindrical FSS, respectively. And the voltage for transparent mode is 12 V.

Figure 34 shows the H-plane radiation pattern of the antenna for various reconfigurations. In case-1, the main beam direction is 178° and 3 dB width is 77°. For case-2 configuration, the main beam direction is 196° and 3 dB width is 84°. Meanwhile, with case-3 mode, the main beam direction is 192° and 3 dB width is 88°. Moreover, the case-1 also indicates a null point 51.9 dB smaller than the main lobe, which is an interesting characteristic to isolate from noise source, especially in anti-jammer systems. The antenna

DOI 10.1007/978-981-4560-75-7_66-1

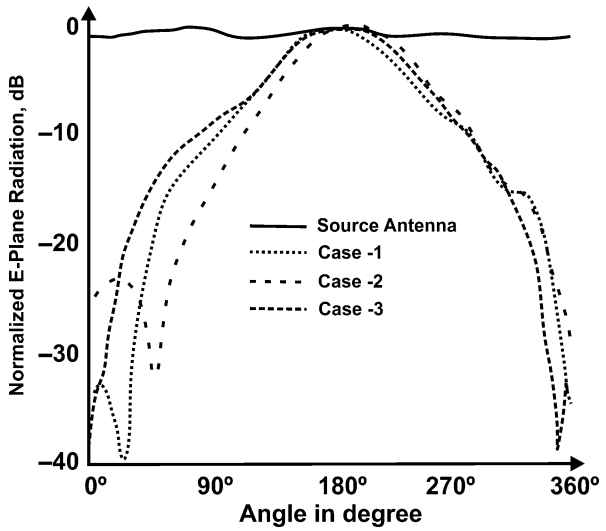

Fig. 34 H-plane radiation pattern of the antenna in various pin diode configurations

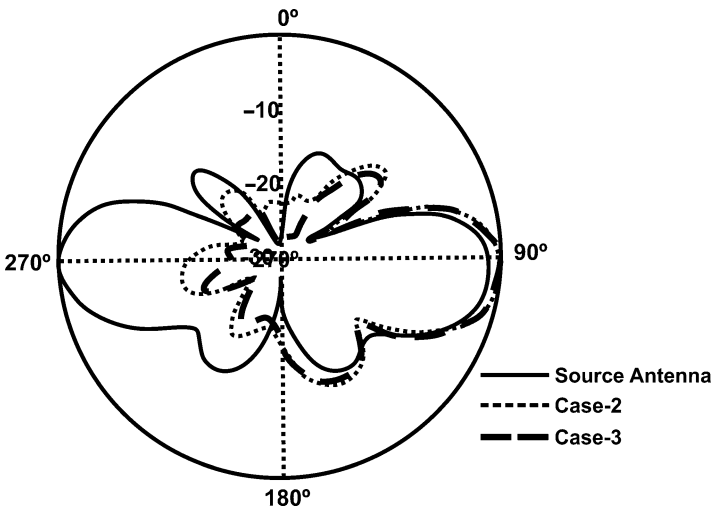

Fig. 35 Radiation pattern in the E-plane for the reconfigurable antenna in various reconfiguration states

also exhibits good cross polar level of 20 dB. The gain of the source antenna is 3.6 dBi. The designed AFSS antenna provides a gain of 7dBi for case-1, 6.9 dBi for case-2, and 6.6 dBi for case-3 mode. The E-plane radiation pattern of the antenna is presented in Fig. 35. The E-plane pattern is mainly decided by the inner omnidirectional source antenna.

The dual beam configurations are shown in Fig. 36, and the corresponding radiation patterns are illustrated in Fig. 37. The two beams of configuration-C point to 54° and 206°. As expected, they are supposed to be 54° and 120°. Moreover, there is less lobe pointing at about 120° that is due to the two columns that are not wide enough to stop the signal, and signal from the other two lobes also contribute to this radiation. Both radiation direction and amplitudes can be controlled.

Conclusion

In this technological era, wireless communication plays a key role in every phase of life. The modern wireless communication systems and related technologies are synergistic products of interdisciplinary areas of engineering. The main objective of this chapter was to introduce the concept of classical and most recent design concepts of multi-beam antenna arrays. Toward this goal, basics of antenna arrays and smart antenna concepts were first presented. A considerable emphasis was given to classical multiband antenna designs and their beam-forming circuits. In order to provide the most recent advancements in multi-beam antenna technology, the idea of metamaterial and its applications were then introduced. Finally, some metamaterial-based multi-beam antenna designs were also provided.

Antenna Measurement Setups: Introduction

Xianming Qing[a]* and Zhi Ning Chen[a,b]
[a]Institute for Infocomm Research (I^2R), Singapore, Singapore
[b]Department of Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore

Abstract

Measurement is an important and necessary way to characterize the performance of an antenna and verify the design of an antenna. This chapter aims to give a brief overview on the basic setups of antenna measurement instead of detailed discussion of measurement techniques for each antenna parameter. The typical setups of far-field and near-field antenna measurements as well as the different antenna test ranges are reviewed. In particular, the setups for the impedance measurement of differential antennas, the on-wafer measurement of antennas, and the measurement of special absorption rate (SAR) are introduced.

Keywords

Antenna measurement; Antenna test range; Near-field; Far-field; Impedance; Anechoic chamber; Free space; On-wafer antenna measurement; Special absorption rate (SAR)

Introduction

In antenna engineering, measurement is basic and crucial for characterizing the performance of an antenna to ensure the antenna to meet specifications, to validate theoretical simulation or design, and to verify the construction and fabrication process of the designed antenna. Many of the basic measurement methods for characterizing antennas had been developed even before World War II. However, new approaches and technologies of measurement have continuously emerged with the rapid growth of modern mobile communications in the last decades (Hollis and Lyon 1972; Kummer and Gillespie 1978; IEEE 1979; Balanis and Birtcher (2008)). Antenna metrology requires not only sound background knowledge in both antenna theory and ample experience in antenna engineering but also sophisticated equipment capable of providing the acceptable accuracy and purity of measured data. Commercial systems specifically designed for a variety of antenna measurements have become available since the 1960s, in particular, due to the strong demand of aerospace, space, and defense industries.

In antenna engineering, impedance, gain, radiation pattern, efficiency, and polarization are certainly the most commonly used parameters to be measured for evaluating the performance of an antenna. For specific applications, some other parameters may be of more importance and interest, for example, antenna temperature is crucial for the antennas in telescope systems, and special absorption rate (SAR) is critical for the antennas in consumer electronics.

Impedance Measurement

To attain the maximum power transfer between a source or a source-transmission line and an antenna (or between an antenna and a receiver or receiver-transmission line), a conjugate impedance matching is essentially desired. In most of wireless systems, the feeding transmission line features a characteristic impedance of 50 ohms so that most of the practical antennas are designed with an input impedance of 50 ohms as well for a good impedance matching.

In a mismatched system, the degree of the mismatch determines the ratio of reflected power to incident or available power at the input antenna terminals. The degree of the mismatch is a function of the input impedance of the antenna under test (AUT) and the characteristic impedance of the feed line. They are directly related to the input reflection coefficient and the input voltage standing wave ratio (VSWR) at the input terminal of the antenna by the standard transmission-line relationships of

$$\frac{P_{\text{refl}}}{P_{\text{in}}} = |\Gamma|^2 = \frac{|Z_{\text{ant}} - Z_{\text{c}}|^2}{|Z_{\text{ant}} + Z_{\text{c}}|^2} = \left|\frac{\text{VSWR} - 1}{\text{VSWR} + 1}\right|^2 \tag{1}$$

where P_{refl} is the reflected power from the antenna, P_{in} is the input power to the antenna, Γ is the voltage reflection coefficient at the antenna input terminal, Z_{ant} is the input impedance of the antenna, and Z_{c} is the characteristic impedance of the feed line.

Rewrite (Eq. 1); the input impedance of the antenna can be expressed as

$$Z_{\text{ant}} = Z_{\text{c}} \frac{1 + \Gamma}{1 - \Gamma} \tag{2}$$

For a single-ended antenna or unbalanced antenna, namely, the antenna is with a ground plane, such as microstrip antenna and monopole antenna, the antenna can be presented using a single port network with a loading impedance of Z_{ant} as shown in Fig. 1. The reflection coefficient Γ is equal to the S_{11} of the equivalent single-port network, which can be easily measured using a vector network analyzer (VNA) as shown in Fig. 2, where the test ports are normally set as the interfaces of coaxial lines.

The impedance of a balanced or differential antenna cannot be measured directly using a network analyzer with unbalanced ports. As shown in Fig. 3, when a balanced antenna is connected to an unbalanced test port, the currents flowing into the two radiators of the antenna are unequal because of

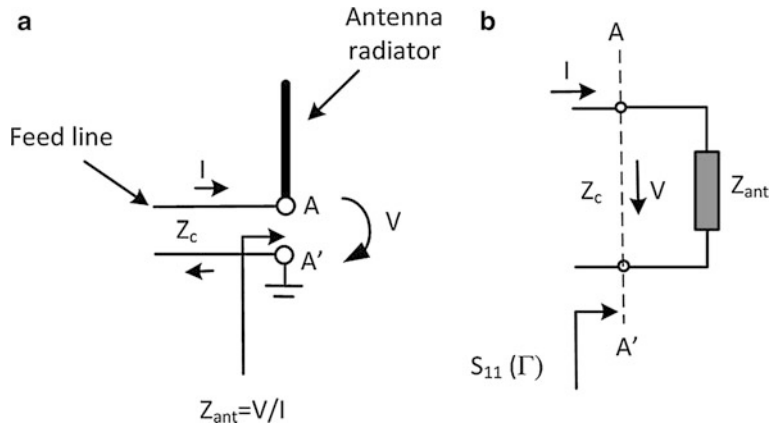

Fig. 1 Single-ended antenna and the equivalent single-port network; (**a**) antenna schematic view and (**b**) single-port equivalent network

DOI 10.1007/978-981-4560-75-7_68-1

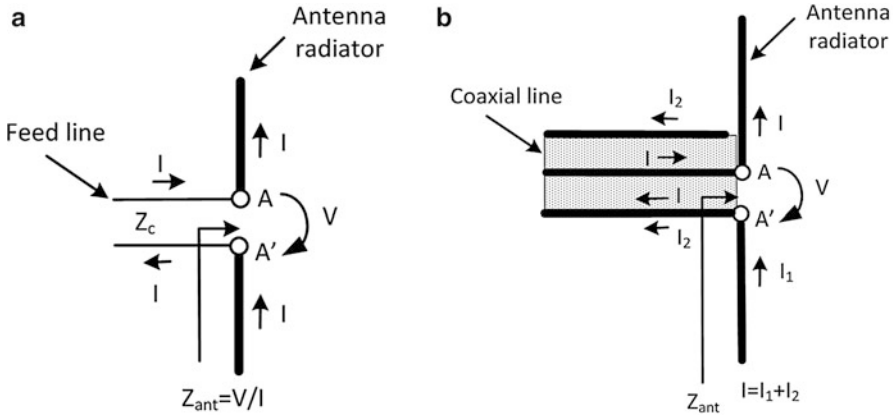

Fig. 3 Current distribution on balanced antenna; (**a**) ideal case and (**b**) fed by single-ended coaxial line

part of the current flowing on the outer conductor of the feed cable so that the impedance of the balanced antenna cannot be characterized correctly. Conventionally, the impedance of a balanced antenna can be measured by adding a balun which forces the current equally to flow in each part of the antenna radiator. However, the accuracy of such measurement results relies on the performance of the balun, especially over a wide testing frequency band. The impedance of a symmetrical balanced antenna can also be measured using imaging method, i.e., mounting half part of the radiators of the antenna on a ground plane which provides a mirror image to configure the other parts of radiators. The impedance of the antenna can be obtained by multiplying a factor of 2 of the measured impedance of the equivalent monopole. However, the accuracy of the measurement results is much dependent on the size of the ground plane used, and this method is valid just for symmetrical balanced antennas (Meier and Summers 1949).

DOI 10.1007/978-981-4560-75-7_68-1

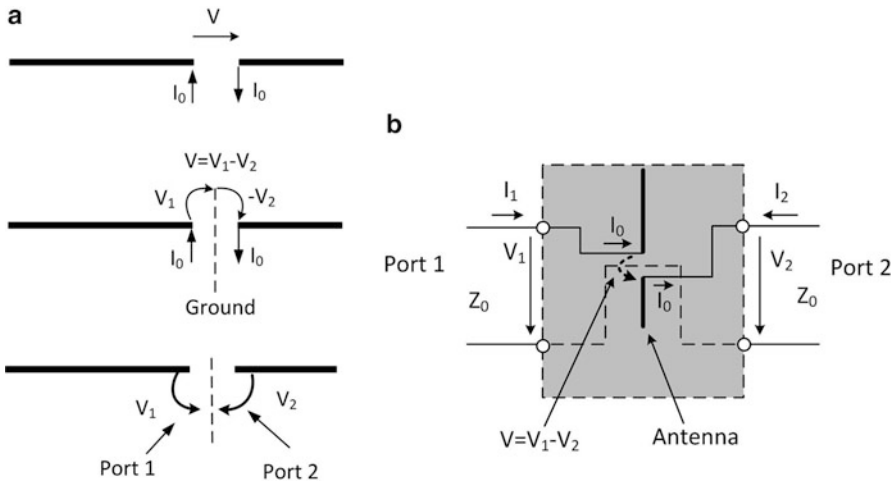

Fig. 4 Balanced antenna and equivalent two-port network; (**a**) excitation and port definition and (**b**) network representation of the balanced antenna

The impedance of a balanced antenna can be measured using a single-ended two-port network analyzer, wherein the full set of the S-parameters of a two-port network instead of S_{11} is utilized (Meys and Janssens 1998; Qing et al. 2009). As shown in Fig. 4a, the positive and negative ports of the source with a voltage of V are connected to the input terminals of the radiators of the balanced antenna, respectively; the driven voltage can be split as V_1 and V_2 with a virtual ground plane without any disturbance of the current distribution on the antenna. Therefore, each terminal of the antenna radiators and the ground plane can be considered as a "port." The antenna can be considered to be equivalent to a "two-port" network as shown in Fig. 4b. The impedance of the antenna, Z_d, is thus related to the network parameters of the equivalent two-port network and can be characterized by the S-parameters of the two-port network.

$$Z_d = \frac{2Z_0(1 - S_{11}S_{22} + S_{12}S_{21} - S_{12} - S_{21})}{(1 - S_{11})(1 - S_{22}) - S_{21}S_{12}} \tag{3}$$

where Z_0 is the characteristic impedance of the feed transmission line, which is 50 Ω for most of the measurement systems.

For a symmetrical balanced antenna, $S_{11} = S_{22}$, and $S_{12} = S_{21}$, and Eq. 3 can be simplified to

$$Z_d = \frac{2Z_0\left(1 - S_{11}^2 + S_{21}^2 - 2S_{12}\right)}{(1 - S_{11})^2 - S_{21}^2} \tag{4}$$

A configuration of the measurement setup is illustrated in Fig. 5. The measurement is conducted using a two-port VNA (Keysight/Agilent N5230A) and a test fixture. Any other VNA which features the port-extension function is suitable for the measurement as well. The test fixture is constructed using two semi-rigid coaxial cables which are soldered together on their outer conductors. One end of the fixture is with two subminiature version A (SMA) connectors and connected to the VNA through the test cables. The other end of the fixture is kept open with the small extensions of inner conductors to form the two tips to connect the AUT.

The measurement is recommended to conduct in an anechoic chamber or a place with controllable environment reflection. The main measurement procedures are as follows:

DOI 10.1007/978-981-4560-75-7_68-1

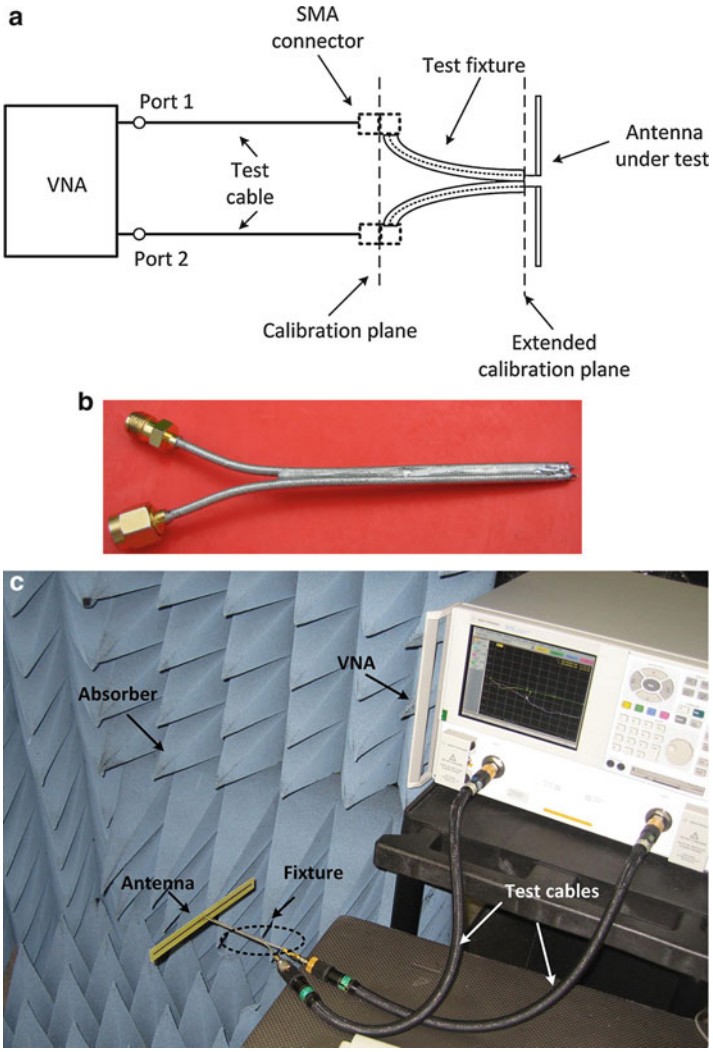

Fig. 5 Measurement setup for input impedance of a balanced antenna; (**a**) schematic configuration, (**b**) fixture prototype, and (**c**) measurement setup using Keysight/Agilent N5230A network analyzer

- Carry out standard VNA parameter setting and calibration.
- Shift the calibration plane through the port-extension technique to de-embed the influence of the text fixture by connecting the test fixture to the test cables and then carrying out the port extension to shift the calibration plane to the tips of the fixture. The fixture is required to be open or short circuited when performing the port extension. Short-circuited configuration (soldering the tips of the fixture and outer conductors of the coaxial cables together) is recommended since perfect "open" condition is very difficult to achieve, especially at higher frequencies.
- Connect the AUT to the fixture and record the S-parameters.
- Calculate the impedance of the AUT using Eqs. 3 or 4.

To validate the measurement methodology, two types of balanced antennas, an asymmetrical dipole antenna and a symmetrical meander line dipole antenna, are prototyped and measured.

Figure 6 shows the antenna prototypes and the detailed dimensions. All the antenna prototypes are printed onto an FR4 print circuit board (PCB) with a dielectric constant of 4.4, a loss tangent of 0.02, and a thickness of 0.504 mm.

parts of the impedance. Figure 8 compares the measured and simulated impedance of the symmetrical meander line dipole antenna as shown in Fig. 6b. Both measured real and imaginary parts of the impedance show good agreement with the simulation across the frequency range of 800−1000 MHz.

Radiation Measurement

The distribution of the fields radiated by an antenna does not assume the same amplitude (or phase) pattern at all radial distances; it evolves with the increasing distance from the antenna. Three regions surrounding an antenna are recognized and classified according to the development of the field distribution (Balanis 2005) as shown in Fig. 9.

Reactive near-field region: In the space immediately surrounding the antenna closer than approximately 0.62 $\sqrt{D^3/\lambda}$ (or $\lambda/2\pi$ for electrically small antennas), where D is the largest dimension of the

DOI 10.1007/978-981-4560-75-7_68-1

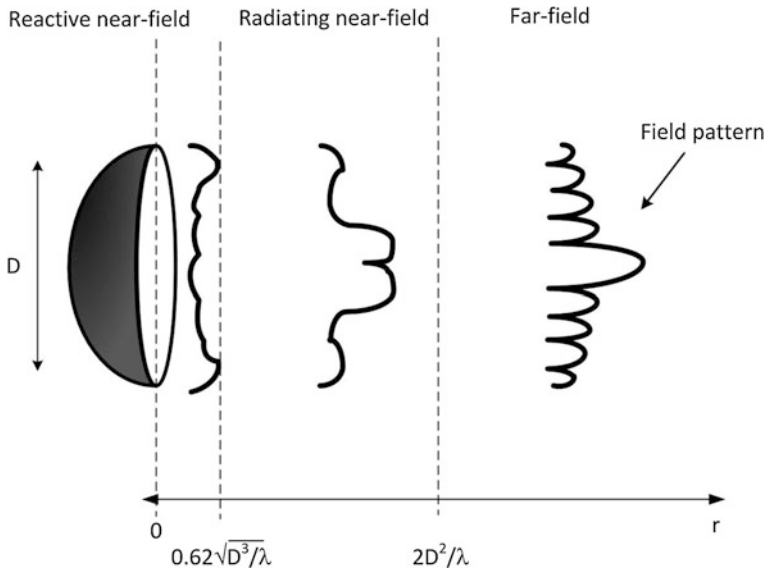

Fig. 9 The field patterns of an antenna as a function of a radial distance

antenna and λ is the wavelength. In this region, the electric or magnetic field does not propagate radially, and the energy is predominantly reactive and decays more rapidly than $1/r$.

Radiating near-field region: Beyond the immediate neighborhood of the reactive field, the radiating field begins to dominate. The extent of this region is $0.62\sqrt{D^3/\lambda} < r < 2D^2/\lambda$. This region can be divided into two subregions. For $0.62\sqrt{D^3/\lambda} < r < D^2/4\lambda$, the fields decay more rapidly than $1/r$ and the radiation pattern is dependent on r. For $D^2/4\lambda < r < 2D^2/\lambda$, the fields decay as $1/r$, but the radiation pattern is dependent on r. The main lobe of the radiation pattern in this radiating near-field region is frequently broadened and bifurcated.

Radiating far-field region: Beyond the radiating near-field region, $r > 2D^2/\lambda$ (or $> 10\lambda$ for electrically small antennas). The fields decay as $1/r$ and the radiation pattern is independent of r. The radiation pattern approaches the same shape that would basically be observed at an infinite distance.

Generally, the antenna measurement techniques can be categorized as far-field antenna measurement and near-field antenna measurement. In the far-field antenna measurement system, the antenna is illuminated by a uniform plane wave and the antenna parameters are measured directly. In a near-field antenna measurement system, the near-field distribution of the antenna is measured using a probe and the far-field characteristics are obtained through near-field to far-field transforms.

Far-Field Antenna Measurement Setup

For far-field antenna measurement, the AUT is required to be illuminated by a uniform plane wave, so that a signal source and a transmit antenna with desired radiation characteristics are needed. The block diagrams of the far-field antenna measurement systems are shown in Fig. 10; the main parts of the systems include:

Signal source: The signal source must be selected so that it has frequency control, frequency stability, spectral purity, controllable power level, and possible modulation.

Transmitting antenna: The antenna is used to generate the plane wave and illuminate the AUT; it should be with a known pattern and controlled polarization. Some frequently used transmitting antennas are shown in Fig. 11.

Receiver: It determines how much power is received by the AUT, where a receiver with great sensitivity and large dynamic range is preferable.

DOI 10.1007/978-981-4560-75-7_68-1

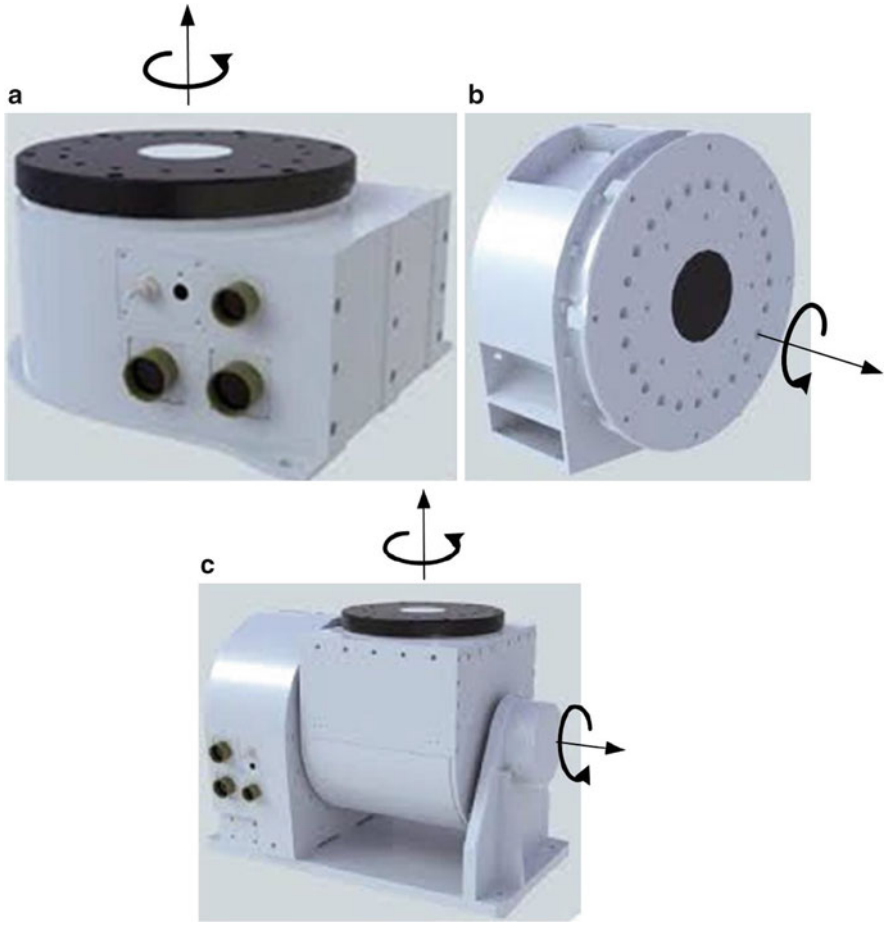

Fig. 12 Positioners (turntable) for antenna measurement; (**a**) one-dimensional positioner, (**b**) polarization positioner, and (**c**) two-dimensional positioner

Positioning system (turntable): This system is used to rotate the AUT relative to the transmit antenna, to measure the radiation pattern as a function of angle. Some positioning systems are exhibited in Fig. 12.

Recording system/data processing system: Modern antenna measurement facilities utilizing a computer and software to coordinate the actions of the positioning and measuring systems, to store and process the acquired data, and to display or plot the resulting measurements. A communication bus connects the computer to the positioner controller and instruments. The IEEE-488 GPIB (general purpose instrument bus) is frequently used.

Apart from the separate signal source and receiver configuration, the VNA has been applied in antenna measurement system for many years since an antenna pattern measurement can be conceptually viewed as the S_{21} between the input connectors of the transmit antenna and the AUT. VNAs exhibit excellent phase stability, spectral purity, sensitivity, and dynamic range (well in excess of 100 dB), which makes it well suitable for antenna measurement.

Far-Field Antenna Test Ranges

The far-field measurement can be performed in outdoor or indoor ranges. In general, there are two basic types of far-field antenna ranges: reflection range and free-space range. In the ground reflection range, the specular reflection from the ground is used to obtain a uniform phase and amplitude distribution over

DOI 10.1007/978-981-4560-75-7_68-1

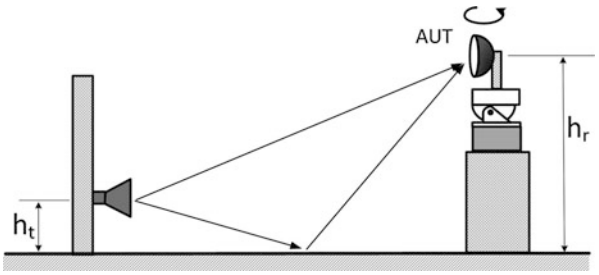

Fig. 13 Configuration of the ground reflection range

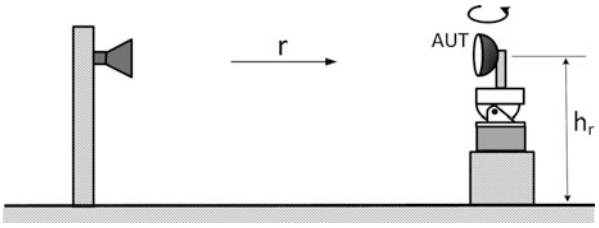

Fig. 14 Illustration of the outdoor elevated range

the AUT. In the free-space ranges, the reflections from the environment are minimized. The typical free-space ranges are elevated range, slant range, anechoic chamber, and compact range.

Ground Reflection Range

In the ground reflection range as shown in Fig. 13, the specular reflection from the ground is used to obtain a uniform phase and amplitude distribution in the test zone, or quiet zone, of the antenna (Hemming and Heaton 1973). This is accomplished by designing the range so that the specular reflections from the ground combine constructively with the direct illumination. The length of the range is designed to meet the far-field criterion of $r > 2D^2/\lambda$; the heights of the transmitting antenna and the AUT are chosen so that the AUT is centered on the first interference lobe of the direct and specular reflected rays. The outdoor type ground reflection ranges are usually employed in the ultrahigh-frequency (UHF) region for measuring antennas with moderately broad beam; they can also be used for the AUTs operating at higher frequencies.

Elevated Range

Elevated range is an outdoor range. In this setup, the transmitting antenna and the AUT are mounted above the ground. These antennas can be on mountains, towers, buildings, or wherever one finds that is suitable. This is often done for very large antennas or at low frequencies (VHF and below, <100 MHz) where indoor measurements would be intractable. The basic diagram of an elevated range is shown in Fig. 14. The length of the range, r, is designed to meet the far-field criterion $r > 2D^2/\lambda$. The height of the AUT, h_r, is determined by two criteria related to the transmitting antenna. The transmitting antenna should be chosen so that the amplitude taper over the AUT is typically no greater than 0.25 dB, to ensure the uniform illumination. In addition, to minimize the range reflections, its first null should point toward the base of the test tower, ensuring that the range surface intercepts only sidelobe energy. These two criteria determine the height of the AUT to be $h_r > 4D$. In the elevated range, diffraction fences are somehow used to further minimize the reflections from the ground. There are two cautions that should be emphasized. First, the diffraction fence should not intercept the main beam of the source antenna. Second, the top edge of the fence should not be straight knife edge but rather serrated to reduce the edge diffraction.

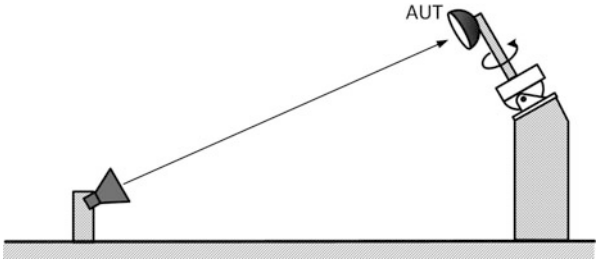

Fig. 15 Geometry arrangement of the slant range

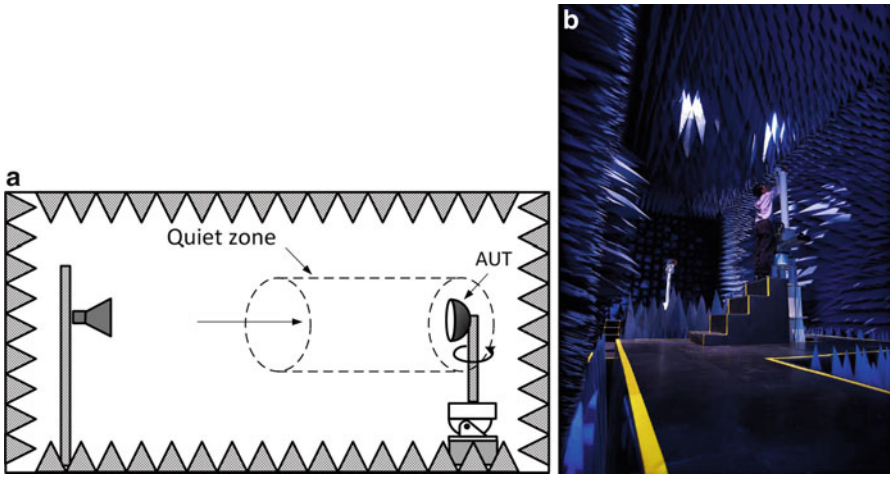

Fig. 16 Anechoic chamber; (**a**) geometry of the rectangular anechoic chamber and (**b**) photo of an anechoic chamber (Courtesy of Institute for Infocomm Research, Singapore)

Slant Range

A slant range (Arnold 1966) is one in which the transmit antenna is located close to the ground and the AUT is mounted on a tower as shown in Fig. 15. The transmit antenna is positioned so that the pattern maximum is oriented toward the center of the test antenna. The first null is usually directed toward the ground specular reflection point to suppress reflected signals. It is desirable that the tower of the AUT be constructed of nonconducting materials to reduce reflections. Slant ranges, in general, require less real estate than the elevated ranges.

Anechoic Chamber

The anechoic chambers are the most popular antenna measurement sites. Compared to the outdoor ranges, the anechoic chamber is able to provide a controlled environment, all-weather capability, and security and to minimize possible electromagnetic interference for antenna measurement. As shown in Fig. 16, an anechoic chamber is a large room, where the walls, floor, and ceiling of which are lined with metallic sheets (normally steel sheet) and all the inner surfaces are lined with RF/microwave absorbers (Hemming 2002). The test zone (quite zone) is able to be generated by arranging the absorbers properly. In the test zone, the amplitude and phase of the incident plane wave from the transmitting antenna are with very little variation such as 0.2 dB and 0.5°, respectively. Anechoic chambers are mostly utilized in microwave frequency regions, but materials have been developed which provide a normal-incidence reflection

DOI 10.1007/978-981-4560-75-7_68-1

coefficient of −40 dB at frequencies as low as 100 MHz. In general, as the operating frequency is lowered, the thickness of RF absorbing material must be increased to maintain a given level of reflectivity performance (Emerson 1973). An RF absorber that meets the minimum electrical requirements at the lower frequencies usually possesses improved performance at higher frequencies.

There are two types of anechoic chambers: the rectangular and tapered chambers. The design of both chamber types is based on the principles of geometrical optics. The goal is to minimize the specular reflections in the quiet zone. The rectangular chamber is usually designed to simulate free-space conditions and maximize the volume of the quiet zone. The tapered chamber has the advantage of tuning by moving the transmit antenna closer to (at higher frequencies) or farther from (at lower frequencies) the apex of the taper. Thus, the reflected rays are adjusted to produce nearly constructive interference with the direct rays at the test location.

The anechoic chamber techniques are discussed in much greater detail in Chapter Anechoic Chamber Design of this Handbook.

Compact Range

The main drawback of the anechoic chamber is the size limitation; the chamber is required to be large enough to meet the far-field conditions so that it is desired to have an anechoic chamber as large as possible. However, the cost and practical constraints often limit their size, especially for electrically large antennas. One solution to this problem is via a compact range as shown in Fig. 14. A compact antenna test range (Johnson, et al. 1969; Johnson 1986) is a collimating setup that generates nearly planar wave fronts in a very short distance (typically 10–20 m) compared to the $2D^2/\lambda$ distance required to produce the same size test zone using the standard system configuration of testing shown in Fig. 16.

As exhibited in Fig. 17, in the compact test range, a transmitting antenna is used as an offset primary feed to illuminate a paraboloidal reflector that converts the impinging spherical waves into plane waves. This is very similar to the principle upon which a dish antenna operates. Compact range configurations are often designated according to their analogous reflector antenna configurations: parabolic, Cassegrain, Gregorian, and so on (Burnside et al. 1987; Pistorius and Burnside 1987; Sanad and Shafai 1990; Gupta et al. 1991). A perfect plane wave is produced by the compact test range if the paraboloidal reflector has a perfect surface, infinite size, and if the feed is a point source with a pattern which compensates for the space attenuation. Of course, such ideal conditions cannot be achieved, and the field distribution in a real compact test range deviates from the uniform plane wave. In general, the deviation is within acceptable parameters in the quite zone which is typically 50 to 60 % the aperture of the reflector. The imperfections of the field in the quiet zone are measured in terms of phase errors, ripple-amplitude deviations, and taper-amplitude deviations. Acceptable deviations for most compact test ranges are less than 10 % phase error and less than 1 dB ripple- and taper-amplitude deviations.

In short, the ground reflection range uses the surface reflections to obtain uniform field distribution along the AUT aperture. However, this imposes very strict requirements on the range smoothness (related to the highest usable frequency), which has cost and maintenance impact. The measurement errors due to the ground reflections in the slant range are lower than that of a comparable elevated range; however, its receiving tower is usually higher than that in the elevated range. This fact puts a limit on the maximum antenna size to be installed at the top of the tower. The elevated range is commonly used in microwave measurements for medium-size antennas. The ground reflection errors encountered in this type of range are minimized using diffraction fences or measurement techniques to determine precisely the reflection level and subtract it from the measurement. Among the far-field antenna ranges, the most accurate one is the indoor compact range because all the reflections can be controlled and minimized. Its size is also minimal compared to the other ranges.

DOI 10.1007/978-981-4560-75-7_68-1

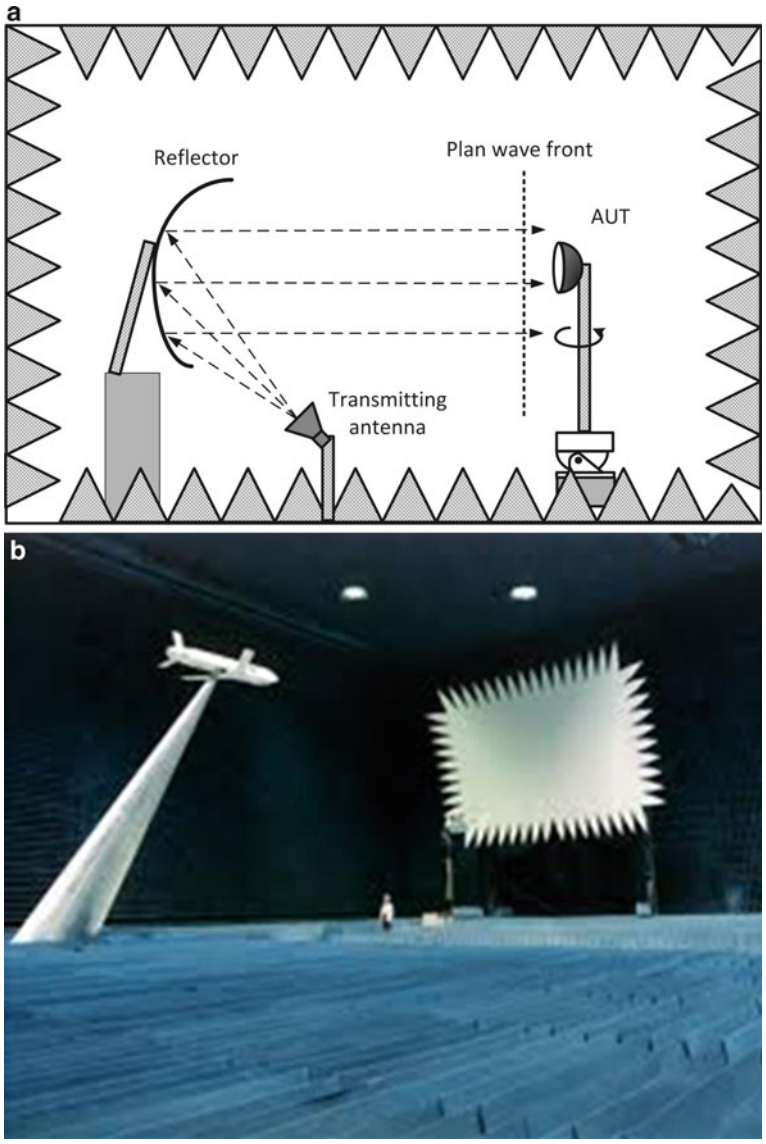

Fig. 17 Compact antenna test range; (**a**) geometry of the configuration and (**b**) photo of a compact test range

Near-Field Antenna Measurement Setup

The dimensions of a conventional antenna test range can be reduced by making measurements in the near-field of the AUT and then using analytical methods to transform the measured near-field data to far-field radiation characteristics (Johnson et al. 1973; Paris et al. 1978; Joy et al. 1978; Yaghjian 1986). This type of range uses a small RF probe antenna that is scanned over a surface surrounding the AUT. Typically, the separation between the probe and the antenna structure is in the order of 4 to 10 wavelengths. During the measurement, the information about near-field phase and amplitude is collected over a discrete matrix of points. The data are then transformed to the far-field using the Fourier transform. In near-field testing, the AUT is usually aligned to the scanner's coordinate system and then either the probe or the test antenna is moved. In practice, it is easier and more cost effective to scan the RF probe over linear axes or the AUT over angular axes. In principle, the measurement can be done over a surface, which can be defined in any of the six orthogonal coordinate systems: rectangular, cylindrical (circular cylindrical), spherical, elliptic

DOI 10.1007/978-981-4560-75-7_68-1

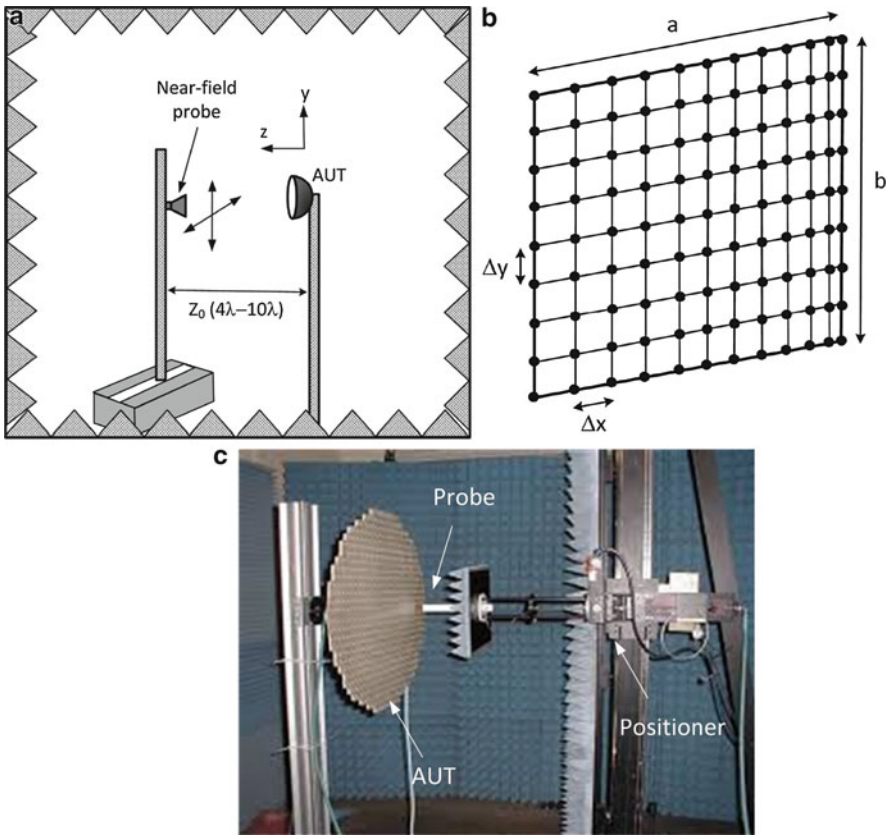

Fig. 18 Planar near-field antenna measurement setup; (**a**) block diagram, (**b**) rectangular scanning surface, and (**c**) photo of a planar scanning near-field antenna measurement system

cylindrical, parabolic cylindrical, and conical. However, only the first three are deemed convenient for data acquisition, and of them, the complexity of the analytical transformations increases from the planar to the cylindrical and then to the spherical surfaces.

Planar Near-Field Antenna Measurement Setup

With the planar near-field scanning setup as shown in Fig. 18, a probe antenna is moved in a plane situated in front of the AUT and the received signal (amplitude and phase) is recorded. The position of the probe is characterized by the coordinates (x, y, z_0) in the xyz coordinate system of the AUT. During the scanning, z_0 is kept constant, while both x and y are varied. The distance z_0 is approximately $4\lambda - 10\lambda$ to avoid sampling of the reactive energy of the AUT. The dimensions of the near-field scanning aperture ($a \times b$) must be large enough to accept all significant energy from the AUT.

Cylindrical Near-Field Antenna Measurement Setup

In the cylindrical scanning technique, the AUT is rotated around the z-axis in $\Delta\varphi$ step, while the probe is moved on the cylindrical surface at various heights in Δz step as shown in Fig. 19. The probe is located at a distance, a, which is the available smallest cylinder radius enclosing the AUT. The cylindrical scanning enables obtaining the exact azimuth pattern but limited elevation pattern due to the truncation of the scanning aperture in z-direction. In accordance with the sampling theory, the sampling spacing is determined from $\Delta\varphi = \lambda/2a$ and $\Delta z = \lambda/2$. A two-dimensional Fourier transform of the near-field data gives the cylindrical vector wave functions that determine the test radiation pattern.

DOI 10.1007/978-981-4560-75-7_68-1

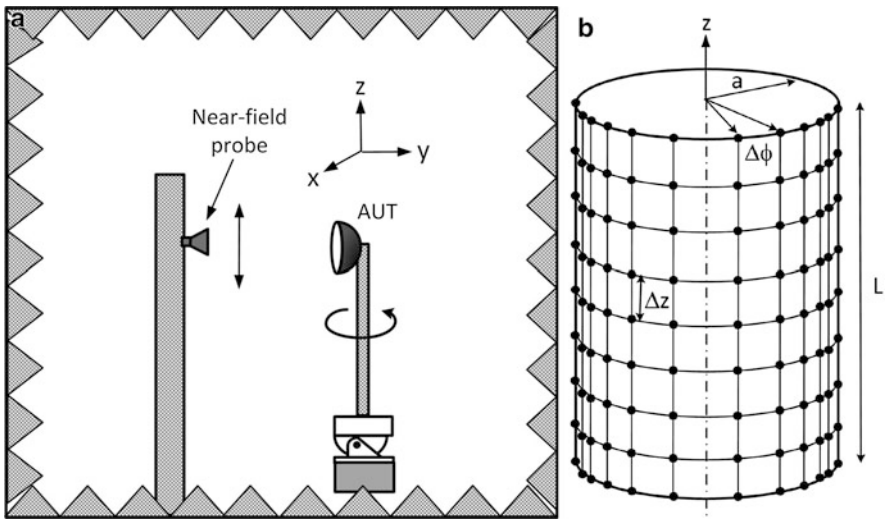

Fig. 19 Cylindrical near-field antenna measurement setup; (**a**) block diagram and (**b**) cylindrical scanning surface

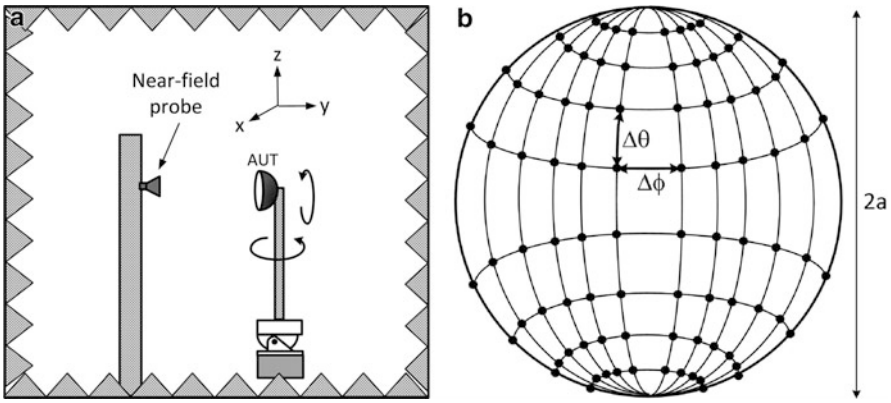

Fig. 20 Spherical near-field antenna measurement setup; (**a**) block diagram and (**b**) spherical scanning surface

Spherical Near-Field Antenna Measurement Setup

In the spherical near-field antenna measurement system as exhibited in Fig. 20, the probe is normally stationary and the AUT is moved in $\Delta\varphi$ and $\Delta\theta$ steps with a spherical scanning positioner. The resulting data are collected over a spherical envelope surrounding the test antenna. The radius of the rotation is "a" which is the available smallest radius enclosing the AUT. Full or nearly full coverage of the test antenna's radiating field can be evaluated with this type of near-field system, so that it is able to provide a three-dimensional pattern. The sampling spacing is determined by the sampling theory to be $\Delta\varphi = \Delta\theta = \lambda/2a$.

Multi-Probe Spherical Near-Field Antenna Measurement Setup

Different from conventional near-field antenna measurement systems using one probe to collect the amplitude and phase responses at the test point, a multi-probe spherical near-field system has been developed for "real-time" measurement (Iversen et al. 2001; Duchesne et al. 2004). A simplified block diagram of the multi-probe spherical near-field system is shown in Fig. 21. The measurement concept is based on a technique that identifies the signal from each probe in an array of probes by perturbing the

DOI 10.1007/978-981-4560-75-7_68-1

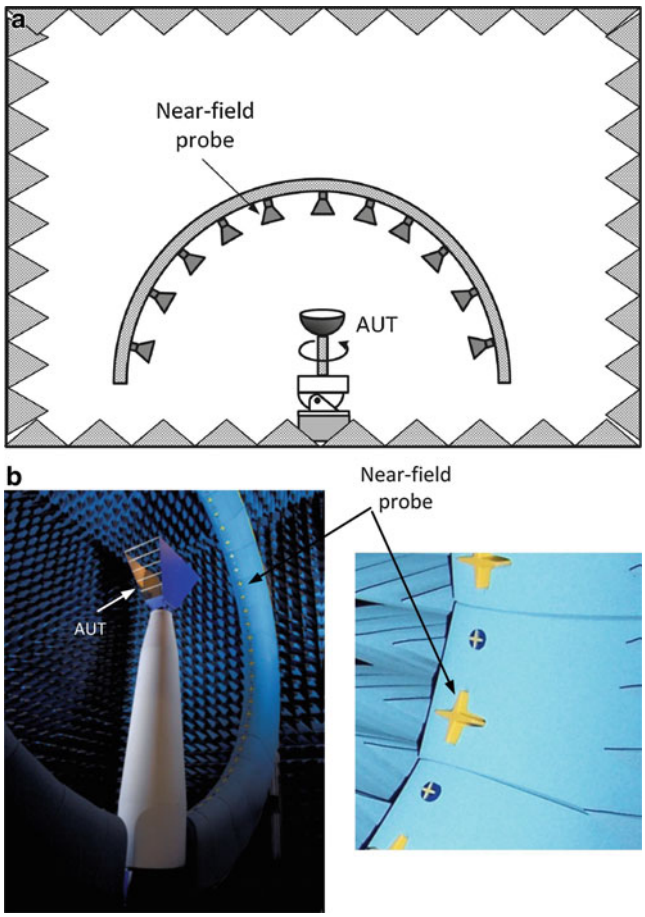

Fig. 21 Multi-probe spherical near-field antenna measurement setup; (**a**) block diagram and (**b**) photo of a multi-probe spherical near-field antenna measurement system (Foged et al. 2010)

electromagnetic properties of the probe (Lasserre et al. 1995; Bolomey and Gardiol 2001). The result of this perturbation is a modulation-frequency component in the output signal, which is directly related to the amplitude and phase of the incident field at the location of the probe. By sequentially modulating each probe, it is possible to measure in "real time" the amplitude and phase at each probe location, without the need for an expensive high-frequency multiplexing network. The near-field measurement data is transformed to a far-field radiation pattern using numerical techniques based on spherical wave expansion.

The near-field antenna measurement techniques are discussed in much greater detail in Chapter Near-Field Antenna Measurement Techniques of this Handbook.

Special Antenna Measurement Setups

On-Wafer Antenna Measurement

To achieve high-performance system with integration at a high level, miniaturize the overall device size, and low manufacturing cost, much effort has been devoted into the development of system-on-chip (SoC) or system-on-board (SoB) and system-in-package (SiP). The realization of antennas on chip offers tremendous advantages as it reduces the chip-to-board design complexity and the associated cost.

DOI 10.1007/978-981-4560-75-7_68-1

However, the adaptation of on-chip antennas in systems is hindered by the lack of accurate characterization methodologies. To design a robust wireless link using fully integrated transceivers with embedded antennas, a systematic method for determining the on-chip antenna gain and radiation pattern is critical.

A number of on-wafer antenna measurement setups have been reported (Zwick et al. 2004; Farinelli et al. 2006; Van Caekenberghe et al. 2008; Tsai et al. 2013; Qing and Chen 2014). Figure 22a shows a typical VNA based on-wafer antenna measurement setup. The probe station includes an anti-vibration table and accessories for on-wafer measurement, which enables a stable and reliable contact between the probe and the AUT. The probe positioner with three-dimensional movement structure offers great convenient for probe contacting with the AUT. The horn antenna on the rotating arm is used for signal transmitting/receiving and connected to the other port of the VNA. The AUT is positioned on a platform on the anti-vibration table. The distance between the horn antenna and the AUT is required to be greater than the far-field criteria; the half-space (180°) patterns in the main cuts are measured. The probe shown in Fig. 22c is another key component; one end of the probe with coaxial or waveguide structure is connected to one port of the VNA, and the other with coplanar waveguide (CPW) tips is connected to the AUT. The typical configurations of the CPW tips are signal-ground (SG), ground-signal-ground (GSG), and ground-signal-ground-signal-ground (GSGSG).

Specific Absorption Rate (SAR) Measurement

Specific Absorption Rate (SAR) is a measure of how transmitted RF energy is absorbed by human tissue. SAR is a function of the electrical conductivity, the induced E-field from the radiated source, and the mass density of the tissue. The SAR is calculated by averaging (or integrating) over a specific volume (typically a 1-g or 10-g tissue):

$$SAR = \iiint_V \frac{\sigma(v)|E(v)|^2}{\rho(v)}\,dv \tag{5}$$

where σ is in siemens/meter, E in the electric field voltage/meter, and ρ in kg/cubic meter.

The units of SAR are W/kg or equivalently mW/g. Various governments have defined maximum SAR levels for RF energy emitted by mobile devices. For example, the SAR limit in the USA for mobile phones is 1.6 W/kg, averaged over 1 g of tissue. In Europe, the SAR limit is 2.0 W/kg averaged over 10 g of tissue.

The value of SAR depends heavily on the geometry of the part of the body that is exposed to the antenna and on the exact location and geometry of the antenna. Thus, SAR measurement must be made with each specific source, such as a specific mobile phone model, and at the intended position of use. The DASYS system from SEGAG (Speag 2014) is the most often used measurement setup for SAR measurement. As exhibited in Fig. 23, the system consists of a human body-shaped hollow tub, a near-field probe, a controlling robot, a receiver, and a computer. The human body-shaped hollow tub is filled with a fluid that has similar properties to human tissue, and the AUT is positioned directly underneath the tub near the head. The robot-controlled near-field probe is immersed into the fluid in the tub to collect the magnitude and phase of the electric field in a specific region. The measured data are then sent to the computer for post processing and SAR calculation.

Conclusion

Antenna measurement is essential to ensure the antenna to meet the desired specifications, to validate theoretical simulation, or to verify antenna construction and design. Among the different antenna measurement setups and test ranges, a proper selection is dependent on many factors, such as the operating frequency range, the directivity of the AUT, the mechanical features of the antenna (size, weight, and volume), and so forth. Furthermore, as the technology progresses, the requirements placed upon wireless communication systems and the antennas will continue to be more stringent, which will push the development of the antenna measurement technique and setup with higher and higher accuracy and more and more powerful measurement capability to meet the needs of the coming advanced antenna systems.

Anechoic Chamber Design

Boon Kuan Chung*
Faculty of Engineering and Sciences, Universiti Tunku Abdul Rahman, Kuala Lumpur, Malaysia

Abstract

An anechoic chamber usually involves a substantial investment both financially and in building space. Hence, there is much interest to attain the required technical performance with lowest possible investment. The screened room must be designed to provide an environment free of extraneous signals. The suitable type of RF absorber must be chosen to line the entire inner surface of the shielded room in order to simulate a free-space environment with no reflection from the walls, ceiling, and floor. Using a suitable computer simulation tool together with the appropriate model which characterizes the absorber scattering behavior, the chamber geometry may be optimized to achieve the cost-effectiveness target. Upon completion of the construction, the performance of the anechoic chamber should be evaluated using the standard acceptance test methods.

Keywords

Anechoic chamber; Electromagnetic; Radio frequency; Antenna; Radiation pattern; Quiet zone; EMC; Radar cross section

Introduction

Free-space electromagnetic wave typically has very low signal levels in the order of −100 dBm or 3 μV. The signal can be easily masked off by extraneous energy in the environment. Hence, measurement of electromagnetic wave must be performed in laboratory facilities which provide high isolation from external electromagnetic environment. Shielded enclosures can provide isolation performance in excess of 100 dB. However, electromagnetic waves propagating in a shielded enclosure will be reflected by the walls, ceiling, and floor back and forth. Consequently, a complex wave front will be formed at the test region where the test antenna is to be placed, as opposed to the desired uniform plane wave. In order to create a free-space environment without reflection so that electromagnetic wave propagates from the source to the receiver in a simple and well-defined manner, suitable absorbing material must be installed over the entire inner surfaces of the shielded enclosure to prevent reflection of the electromagnetic waves. Such laboratory facility is known as anechoic chamber. With no echo and no extraneous energy, the anechoic chamber provides a "quiet" environment for electromagnetic wave measurements.

The World War II period gave rise to increasing needs to test radio frequency (RF) devices, antennas, and radar signature. It created the need for anechoic chambers as a means to improve the accuracy of indoor RF measurements. The facilities provide controlled environment, with all-weather capability and minimum electromagnetic interference. The proliferation of mobile and satellite communication industries since the 1980s brought about the design of many chambers with the capabilities to perform a wide

variety of measurements which include antenna gain, radiation pattern, polarization, radar cross section (RCS), radiation hazard, electromagnetic compatibility (EMC), etc. Others have been designed for a specific type of measurement.

Wave Absorbers

The operating frequency range of an anechoic chamber is determined by the wave absorbing material used for lining the chamber walls, ceiling, and floor. Wave absorber with narrowband performance will limit the capability of the chamber. Modern anechoic chambers typically use wave absorbers with superior absorbing properties such as low normal incidence reflection, low forward-scatter and backscatter at wide-angle incidence, lower minimum operating frequency, wide bandwidth, and reduced absorber thickness in the course of improving the "quietness" of anechoic chambers, cost efficiency, and required room size. Wave absorber with flat surface and lossy property (low impedance) will reflect a substantial amount of incident wave and absorb the remaining electromagnetic energy. Impedance discontinuity at the interface between the free space and the absorbing medium causes more reflection and less transmission. When material with higher impedance is used such that there is lesser discontinuity at the air-absorber interface, more energy can be transmitted into the absorbing medium, but a much thicker material will be required to fully dissipate the electromagnetic energy. A method to reduce the required material thickness is to use material property which gradually tapers from free-space impedance (377 ohms) at the front surface to that of a lossy medium at the back surface. It means multiple layers of carbon-impregnated material with increasing loss tangent from the front layer toward the bottom layer must be stacked up. Alternatively, lossy material can be cut into pyramid shape (see Fig. 1a) in contrast to flat front surface. With lower filling factor of lossy material with respect to air at the tip and higher filling factor at the base of the pyramid, the desired impedance taper can be achieved. It can yield a good absorption or low reflectivity level over a very wide frequency range. However, the height of the pyramid must be greater than a quarter wavelength for the absorber to function efficiently. Hence, shorter pyramidal absorber can be used if the anechoic chamber is targeted for higher microwave frequencies. The upper limit of the frequency range is determined by the surface quality and carbon loading of the absorber. A 24-inch pyramidal foam absorber may offer a reflectivity level below −40 dB over the frequency range of 1–40 GHz. If the desired lowest operating frequency of the chamber is set at 30 MHz, the taper length must be greater than 8 ft. The bulky size gives rise to high cost of material, difficulty of installation, and requirement for large room space and thus limits its use to few applications where low-frequency measurements are required.

DOI 10.1007/978-981-4560-75-7_69-1

Wedge-shaped absorber shown in Fig. 1b may give slightly poorer reflectivity level compared to pyramid-shaped absorber for wave at normal incident. However, it can give better performance at wide-angle incident for wave direction nearly parallel to the ridge of the wedge. Hence, it can be strategically used at certain areas of a chamber wall to improve the quietness of the anechoic chamber.

Long pyramid absorber used for low-frequency anechoic chamber tends to droop with age. Twisted pyramid structure has been used to improve the mechanical strength. The pyramid is "twisted" by 45° with respect to the base (see Fig. 1c). The trade-off is a poorer reflectivity performance compared to the standard pyramid.

Hollow pyramid-shaped substrate (some made of paper) can be coated with special resistive material to make lightweight broadband wave absorber. Microscopic particles of metal are dispersed in a nonconducting matrix to adjust the electrical conductivity of the resistive material.

Taper length less than a quarter wavelength may provide the required low reflectivity level using a suitable carbon loading for the pyramidal foam absorber. If the carbon loading is too high, the impedance taper will be too abrupt, and incident wave will be reflected from the region near the pyramid tip instead of propagating toward the pyramid base (hence, degrade the usable upper frequency limit). On the other hand, if the carbon loading is too low, the incident wave may be able to propagate toward the pyramid base, but it may not be sufficiently dissipated (hence, lower the absorber reflectivity performance). With a carbon loading which is optimized for the 200–1000 MHz range (for EMC test chamber) with reflectivity of −20 dB, the short pyramid absorber may not provide adequate performance at higher frequencies where the typical applications in antenna and radar cross-section measurements require absorber reflectivity below −40 dB in the anechoic chamber design.

In the design of EMC test chamber where the lowest operating frequency is 30 MHz, thin absorber with wideband performance is desirable for reduction of chamber size. Ferrite tile absorber with thickness of 0.25 inch may provide a reflectivity level below −15 dB over the 30–600 MHz range. Pyramidal foam absorber with carbon loading optimized to operate at 200–1000 MHz can be combined with ferrite tiles to cover the required frequency range of 30–1000 MHz. This type of absorber is known as hybrid absorber.

As far as the designer of anechoic chamber is concerned, the most important technical specifications of wave absorber are the usable frequency range, normal incidence reflectivity, and oblique incidence reflectivity. To qualify the wave absorber, the simplest measurement method that is currently in use is the arch method which uses a transmit antenna and a receive antenna mounted on a circular arch above the RF absorber surface. The transmit antenna illuminates the RF absorber, and the receive antenna picks up the reflection. The reflection coefficient is obtained by comparing the reflections from the RF absorber to the reflection from a conducting surface placed in the same position as the RF absorber. Different incident/reflection angles are obtained by moving the transmit antenna and the receive antenna along the arch. Parallel and perpendicular polarizations can be evaluated by the appropriate orientation of the linear-polarized antennas. The arch method is usually used above 1 GHz. Since the sample has to be in the far field, a large arch radius would be required. The sample size must be large enough, and the antenna beamwidth must not be too narrow in order to obtain an accurate result. Edge diffraction effects from the sample, direct coupling between transmit and receive antennas, and extraneous reflections from the environment must be reduced to the level below the typical reflectivity of the absorber under test.

In the selection of wave absorber to design an anechoic chamber, the first consideration should be the intended use of the facility. As mentioned above, anechoic chamber for antenna and radar cross-section measurements requires absorber reflectivity below −40 dB. This performance is typically achievable at frequencies above 1 GHz. In fact, the reflectivity performance increases with frequency at approximately 6 dB per octave. Hence, an engineer should make sure the required minimum reflectivity level is achieved at the expected lowest operating frequency of the anechoic chamber. At a much higher frequency when the reflectivity performance reaches its peak, it will start to drop off rapidly as frequency increases.

DOI 10.1007/978-981-4560-75-7_69-1

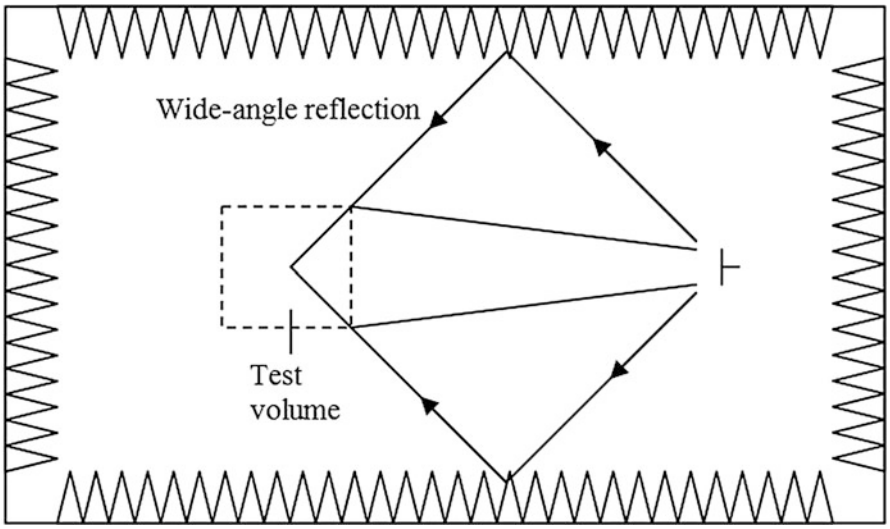

Fig. 2 Plan view of a simple rectangular anechoic chamber

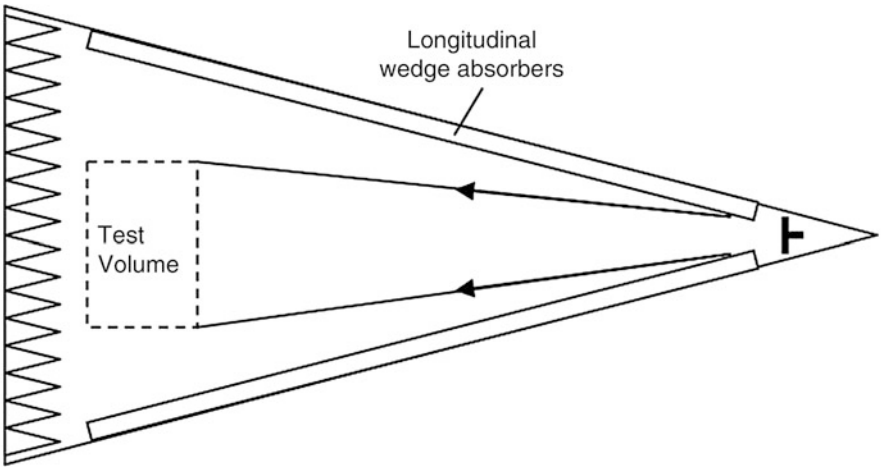

Fig. 3 Diverging geometry of a tapered chamber

This is because when the absorber size becomes large in term of wavelengths, the incident wave front starts to scatter. An optimum carbon loading and aspect ratio will be required to extend the operating frequency of the wave absorber.

Geometry of Anechoic Chamber

A rectangular-shaped chamber is simple to construct and it is also easy for lining of absorbers. One shortcoming of this simple geometry, however, is that the absorbers on the side walls and ceiling may reflect a considerable amount of wave toward the test region. The absorber performance is inadequate when the incident wave approaches it at wide angle of incidence as shown in Fig. 2. As a result, a complex wave front with sharp peaks and nulls is formed at the test region due to constructive and destructive interferences of the reflected waves and the direct-path signal. The nonuniform field distribution will cause errors in various electromagnetic wave measurements.

DOI 10.1007/978-981-4560-75-7_69-1

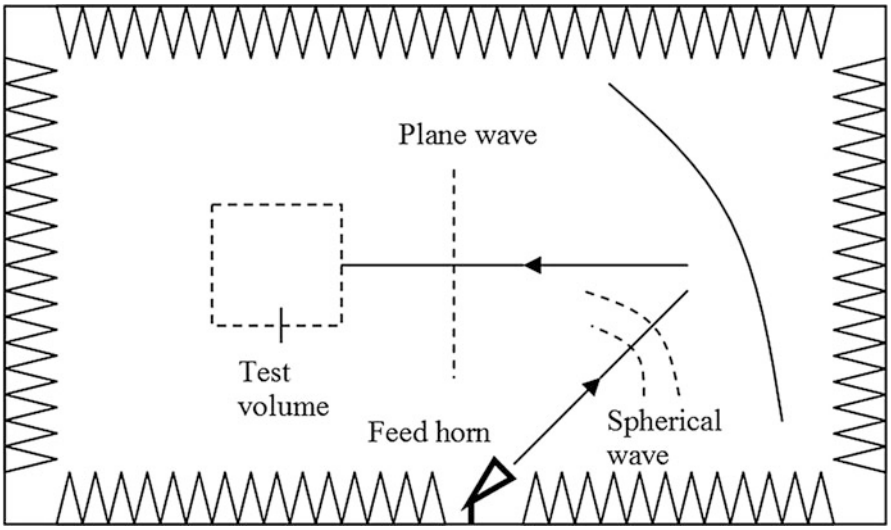

Fig. 4 Compact range anechoic chamber configuration

The problem of wide-angle reflection can be eliminated using a tapered-shaped chamber shown in Fig. 3. The concomitant benefit is the cost saving from the use of less expensive absorbers at the tapered section. The reduced total surface area of the tapered chamber means less number of wave absorber is required, and this provide further cost saving. However, there are a few shortcomings associated with it. Firstly, only a single-source antenna can be accommodated at the taper apex. Measurements involving multiple sources, moving sources, or bistatic radar cross section cannot be performed in the tapered chamber. Secondly, the path loss is different from that of free space due to coupling between the electromagnetic field and the diverging chamber walls. Hence, the chamber is not suitable for measurement involving absolute field strength. At higher frequencies, tapered chamber does not offer any advantage over rectangular chamber because wide-angle reflection can be overcome using antenna with highly directional radiation pattern (i.e., less radiation toward the walls). In addition, absorbers typically have better absorbing property at these frequencies; thus, the reflectivity level may be sufficiently low albeit wide-angle reflection.

The shortcomings of tapered chamber can be overcome using a quasi-tapered geometry. It consists of a small rectangular room, connected to a tapered section, and then followed by a larger rectangular room where the test region is located. This design incorporates the performance advantages of a fully tapered chamber at low frequencies and provides some flexibilities of a rectangular chamber. Wedge-shaped absorbers can be used at the tapered section to improve the chamber quietness performance since the wave transmitted from the smaller rectangular room toward the larger rectangular room will propagate nearly parallel to the ridge of the wedge of which a better absorbing characteristic is offered compared to pyramid absorber.

Microwave antenna and RCS measurements usually require the target under test to be illuminated by a uniform plane wave. Uniform wave front in terms of amplitude and phase can only be achieved in the far-field region and often dictates a very large distance. The distance can be reduced using an offset-feed parabolic reflector to transform spherical wave front into plane wave as shown in Fig. 4. The reduced room size is known as compact range anechoic chamber. The resulting plane wave has very flat phase front and small amplitude taper over the test zone, making the compact range equivalent to a much larger conventional antenna test range. The offset focal point eliminates scattering and shadowing from the feed and feed support.

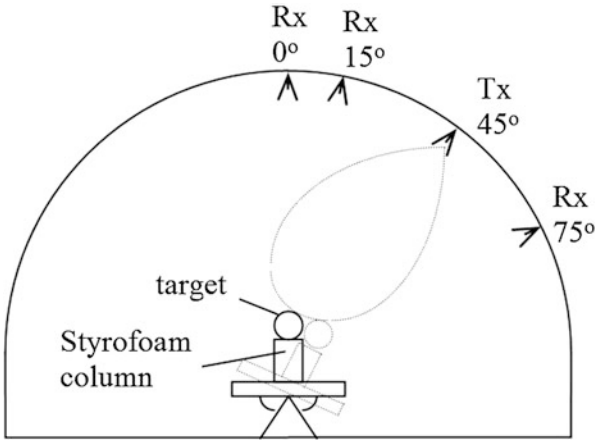

Fig. 5 Dome-shaped anechoic chamber for monostatic and bistatic RCS measurements

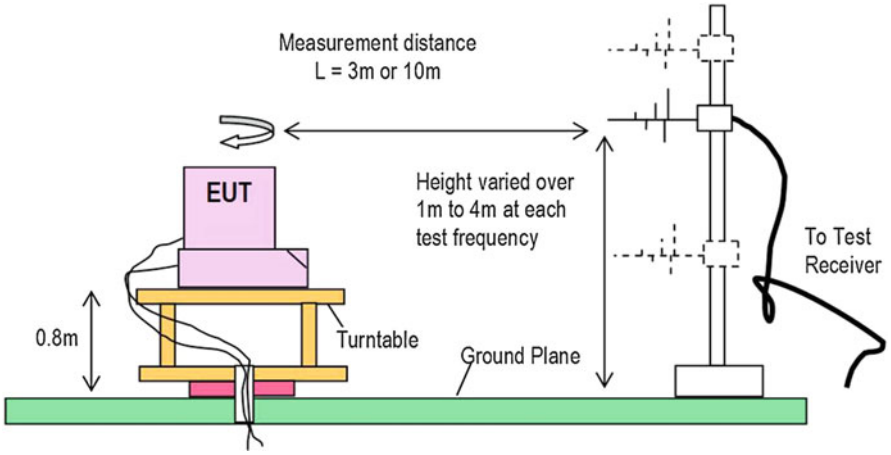

Fig. 6 EMC RF emission test configuration in an OATS

Special-purpose dome-shaped chambers are used at a few research institutions (Chung et al. 1997). The chamber facilitates a variety of monostatic as well as bistatic RCS measurements at a constant range as shown in Fig. 5. A number of antennas are mounted on the dome surface inside the chamber to receive scattered electromagnetic waves from a radar target placed at the center of the spherical space.

A large number of low-frequency (30–1000 MHz) electromagnetic anechoic and semi-anechoic test chambers have been manufactured since the 1980s due to the rapid growth in multimedia and telecommunication industries. Electromagnetic compatibility (EMC) regulation mandates that both intentional and unintentional radiators must meet the EMC requirements before they can be marketed. A full anechoic chamber is commonly used to determine the immunity of products to impinging electromagnetic field. As for the emission limit, electromagnetic interference (EMI) emissions from electronic products are referenced to measurements performed on an ideal open-area test site (OATS) having a perfectly conducting infinite ground plane. The typical test configuration is shown in Fig. 6. A semi-anechoic chamber in which the conductive floor is not covered with wave absorbing material can be used as the alternative test site for this measurement provided it fulfills the normalized site attenuation (NSA) requirements defined in CISPR 16-1-4 and ANSI C63.4. The site attenuation is defined as the ratio of the voltage input to a matched and balanced lossless tuned dipole transmit antenna to that at the output of a similarly matched balanced lossless tuned dipole receive antenna. The instrumentation configuration is

DOI 10.1007/978-981-4560-75-7_69-1

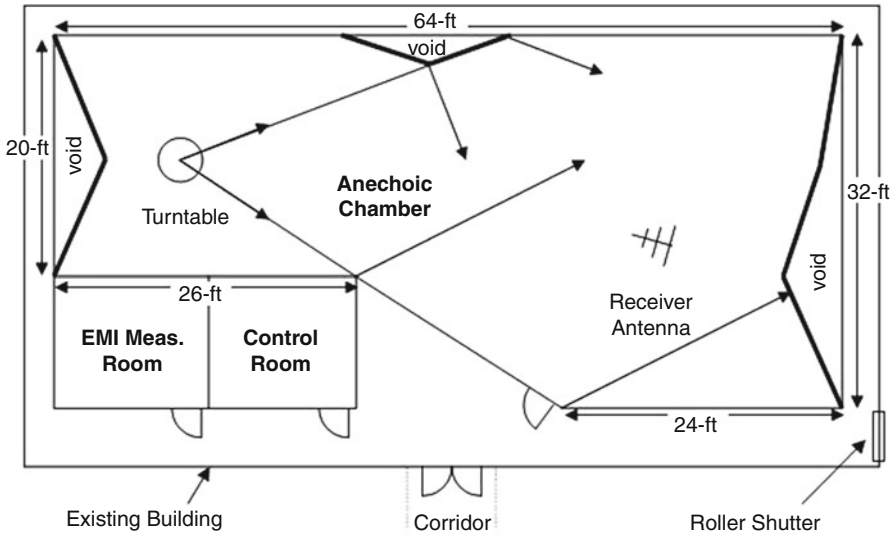

Fig. 7 Floor plan of an asymmetrical-shaped chamber

the same as the setup for product EMC compliance testing except the equipment under test (EUT) is replaced by a known transmitting source. The measured NSA data for both vertical and horizontal polarizations shall be compared to that calculated for an ideal site. A test site is considered acceptable for radiated emission measurements if the measured results are within ±4 dB of the theoretical NSA for an ideal site. The ±4 dB tolerance includes instrumentation calibration errors, measurement technique errors, and errors due to site anomalies. If the measuring distance is 3 m, the mutual impedance correction factors for tuned dipole antennas must be applied to the measurement results.

EMC radiated emission measurement above 1 GHz complying with EN55022:2010 standard is also required for information technology equipment (ITE) shipped into Europe since October 2011. Full anechoic chamber is specified for the measurement up to 400 GHz. For the US market, measurement of radiated emission above 1 GHz up to 40 GHz is also required by the FCC. Before the chamber can be used for EMC compliance measurement, the test site must be validated according to the site voltage standing wave ratio (SVSWR) method defined in CISPR 16-1-4 and/or time-domain reflectivity (TDR) method proposed for ANSI C63.4.

Anechoic chambers that are built specifically for EMC tests are usually not suitable for radar cross section and antenna measurements. Similarly, a microwave anechoic chamber using pyramidal foam absorbers with thickness less than a meter is usually not suitable for EMC tests below 1 GHz. The technical background and the required site performances for different measurement needs are described in the following sections. A multipurpose anechoic chamber was designed and built at Multimedia University (Chung and Chuah 2003). An innovative design technique has been developed, giving rise to the construction of an asymmetrical-shaped anechoic chamber which fulfills the different requirements for various measurement needs using lower-cost materials. The facility can be used for EMC tests, antenna measurements, monostatic and bistatic RCS measurements, RF transceiver testing, calibration of scatterometer, and other electromagnetic research experiments. Figure 7 shows the floor plan of the anechoic chamber. Figure 8 shows the interior view of the anechoic chamber. RF absorbers are glued onto the walls and ceiling to absorb the waves transmitted in the chamber. For treatment of the corners between two walls and between the wall and the ceiling, 12-inch pyramidal absorber and flat foam absorber are cut to fit the angle of the corners as shown in Fig. 9. Wide-angle reflection is reduced due to the asymmetrical chamber geometry in which the plane of some of the walls is parallel to the direction of wave propagation.

DOI 10.1007/978-981-4560-75-7_69-1

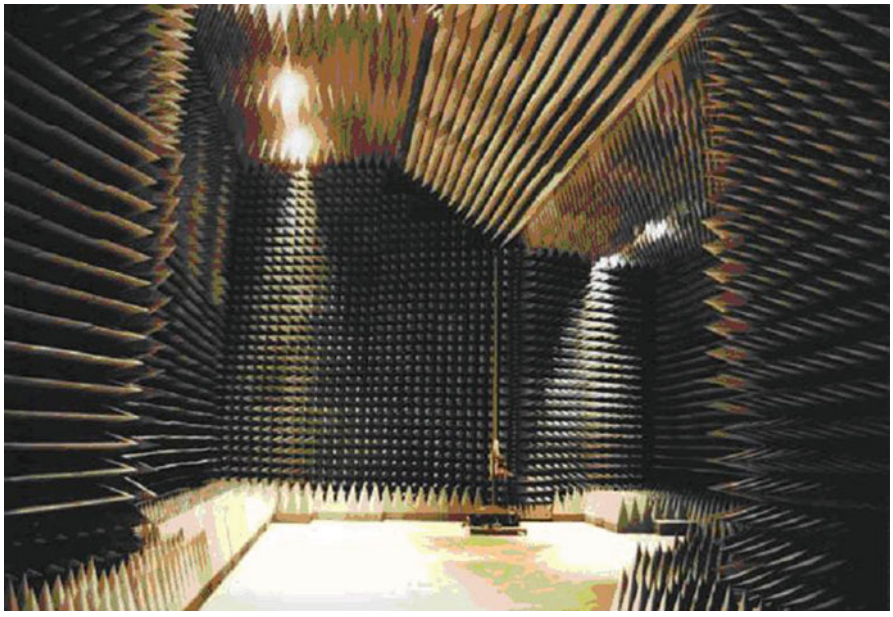

Fig. 8 The interior view of the asymmetrical-shaped chamber

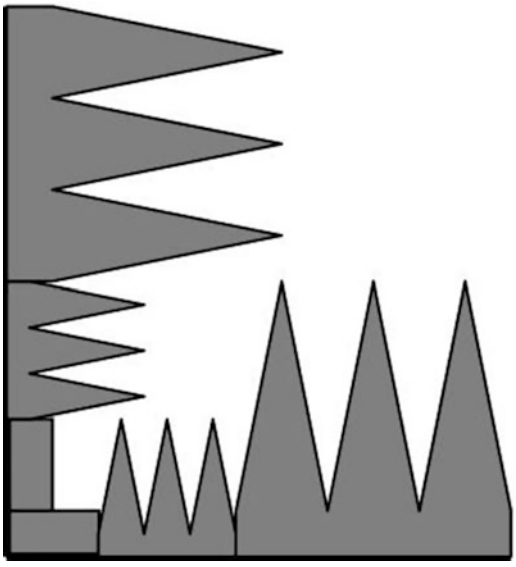

Fig. 9 Treatment of corners in the anechoic chamber

At two ends of the chamber, supplementary wall panels are installed such that the incident waves are reflected away from the test region. The walls and ceiling of the asymmetrical-shaped chamber are designed such that no first-order and second-order reflections (except those reflected from the floor) will propagate into the receiver region. When the electromagnetic rays finally reach the test region after a few bounces off the absorbing walls and ceiling, the wave energy will be sufficiently attenuated. Hence, the required quietness performance can be extended to the low-frequency range even though the absorber reflectivity is poorer at lower frequencies (since the height of pyramid becomes less than a quarter wavelength at frequency below 100 MHz). The required NSA performance can be achieved without utilizing bulky and expensive absorber.

Size of Anechoic Chamber

In a typical antenna measurement, the separation distance between the transmit antenna and receive antenna is defined by the Rayleigh range criterion or Fraunhofer distance. Assuming the transmit antenna is a point source, and the receive antenna has a maximum transverse dimension D, the separation distance must be greater than $2D^2/\lambda$ where λ is the wavelength. This is to ensure the field at the edge and the field at the center of the receive antenna have a phase difference of less than 22.5°, thus providing a near-uniform plane wave front. The same criterion is used for radar cross-section measurement. If D is in the order of half wavelength, the Fraunhofer distance is only $\lambda/2$. This is usually not considered as a far-field distance. However, this separation distance may be sufficient to avoid undesirable near-field coupling or reactive coupling (capacitive or inductive) between transmit antenna and receive antenna, supporting only the desired radiative coupling (since the field strength falls off by $1/r$ vs. distance r). However, if D is several wavelengths such as the cases of antenna array or large radar target, the required Fraunhofer distance increases parabolically. When the separation distance is more than 2λ, it is considered as the far-field distance if the Rayleigh range criterion is fulfilled.

In the design of an anechoic chamber, the measurement facility must be sufficiently large to accommodate the transmit antenna and the receive antennas according to the Rayleigh range criterion. At lower frequency such as 30 MHz or wavelength of 10 m, separation distance of 5 m may be acceptable when the transverse dimension of the intended test volume is less than half wavelength. If the separation distance is only 3 m, such as the case of 3-m range EMC chamber, some degree of near-field reactive coupling may set in. At microwave frequency of 30 GHz or wavelength of 10 mm, and the transverse dimension of the intended test volume is 1 m, the required Fraunhofer distance will be 200 m. Anechoic chamber of this size will be prohibitive in most cases. If the Rayleigh range criterion is to be fulfilled at 10-m range, the dimension of the test volume must be reduced to 22 cm. Alternatively, the upper operating frequency must be limited to 1.5 GHz (for test volume width of 1 m). Higher frequencies can be used if the test volume width or object under test is smaller. Hence, in the specification of an anechoic chamber, specifying the size of test volume does not necessarily mean the full size of quiet zone is usable for antenna or radar cross-section measurement needs.

For antennas with large aperture (large D) operating at high microwave frequency (small λ), the required far-field distance will be very large. Near-field measurement techniques can be used to test the large antennas. A small RF probe antenna is moved over a virtual surface surrounding the antenna under test (AUT) at a typical distance of 4–10 wavelengths. Near-field amplitude and phase are measured over a discrete matrix of points. These data are then transformed to the far-field values using Fourier transform techniques. The far-field antenna pattern can then be presented in the conventional format.

Wave absorber is designed to function at the Fresnel radiative region of radiating source. It is designed to absorb electromagnetic wave which has intrinsic wave impedance (E/H) of 377 ohms. The near-field wave impedance of a dipole-type source is higher than 377 ohms, while the near-field wave impedance of a current-loop-type source is lower than 377 ohms. Hence, the distance between the radiating source and the absorber must be greater than about $\lambda_{max}/2\pi$ (where λ_{max} is the maximum wavelength at the lowest operating frequency) for the specified absorber reflectivity to be achieved. Since the thickness of pyramidal foam absorber must be greater than $\lambda_{max}/4$ to be effective, the length of an anechoic chamber must be longer than the measurement range distance by λ_{max}, and the width must be wider than the test volume size by λ_{max} as well. For a 10-m range with test volume size of 2 m and lowest operating frequency of 30 MHz, the anechoic chamber may have to be larger than 20 m long $\times$ 12 m width $\times$ 10 m height, if 2.5-m long pyramidal foam absorber is used for lining the chamber walls and ceiling. Of course, the chamber size can be greatly reduced if thin ferrite tile or hybrid absorbers are utilized, but the upper operating frequency of the chamber may be limited to 1000 MHz or so.

Chamber Design

RF wave measurement should be performed in an environment free from electromagnetic energy not directly associated with the measurement. The isolation is normally provided by RF shielded enclosure to prevent external extraneous energy from getting into the test region and masking the low-level signal of interest. At the same time, the isolation also protects nearby systems from being interfered by the EM energy generated by radiation source in the shielded enclosure used in the measurement setup.

RF shielded enclosure is a room completely enclosed by metal plates. However, ventilation holes and access door to the shielded enclosure, as well as cables penetrating the shielded enclosure for signal/power interconnection purposes, will cause leakages of electromagnetic waves. The shielding effectiveness is often degraded by these imperfections and limited by the shielding performance of ventilators and access door. Generally, any discontinuity in the metallic surfaces, including metal-to-metal joints and overlapping metal contacts, will allow EM fields to penetrate. High-conductivity metallic gaskets (such as wire knit mesh or beryllium copper "finger stock") are commonly used to close the gaps around the access door. Specialized "honeycomb" vent, comprising a large number of small hollow waveguide tubes welded together in a "honeycomb" fashion, is commonly installed to provide ventilation in the screened room. In most practical cases, shielding effectiveness better than 120 dB is hard to achieve. Doors, vents, filters, and piping must be carefully designed and constructed to maintain the shielding integrity.

Modular clamp-up structure is commonly used to construct smaller screened room. Prefabricated wooden panels laminated with sheet metals are tied together to form the six-sided free-standing room by a framework made of plated steel. Welded construction is normally used when the required room size exceeds 240 ft^2. It provides the required structural strength and long-term high-performance shielding.

The choice of RF absorber to be used is a function of the purpose of the anechoic chamber. The required electrical performances as well as the absorber shape, thickness, weight, mounting method, cost, and logistic must be considered. For antenna and radar measurements above 1-GHz, a 24-inch thick pyramid absorber may be suitable. However, it would not be able to provide sufficiently low reflectivity at lower frequencies. Standing wave will be reinforced by reflections between the opposing walls and between the ceiling and the floor, causing cavity resonance to be established in the shielded enclosure. The absorber may not give sufficient damping of Q-factors of the resonant modes. However, the geometry of the anechoic chamber may be optimized to extend the usable range to lower frequencies.

An anechoic chamber with a floor area of 20 m $\times$ 10 m and 8-m height requires a substantial investment both financially and in building space. The important considerations in an anechoic chamber project may include the specifications, procurement process for various components and instrumentation, logistical arrangements (contract, shipping, insurance, haulage, time to delivery, storage space), construction process, and performance evaluation.

The geometry of the chamber structure must not be too complex so that the screened room can be easily constructed, the shielding effectiveness can be under control, and the RF absorbers can be properly lined on the chamber walls, ceiling, and floor. In order to optimize the chamber design in terms of geometry and combination of RF absorbers, wave propagation simulation is often conducted to compute the vector sum of direct-path signal and the reflected signals. The objective of the simulation is to evaluate the quietness level within the test volume which is indicated by the magnitude of amplitude ripple along the longitudinal and transverse axes.

The calculations of wave components due to reflections from absorber-lined walls and ceiling require a proper model that characterizes the absorber scattering behavior as a function of incident angle, frequency, and polarization. The magnitude and phase must be known in order to calculate the total field due to the sum of the direct wave and the reflected waves.

DOI 10.1007/978-981-4560-75-7_69-1

Wave energy incidents on the absorber will be scattered in virtually all directions much like a rough surface. A geometrical optics modeling method that traces the rays of electromagnetic waves propagating from the transmitter to the receiver assumes specular reflection at the walls, ceiling, and floor. The calculated field quantities may not compare well with the measurement results. The only reliable modeling method is to compute a complete 3D solution of Maxwell's equations over the entire interior of the chamber. Finite-difference time-domain (FDTD) methods have been used in the analysis of compact anechoic chamber by Luebbers et al. (1991). This method is very laborious in terms of specifying the exact dimensions and material properties of the chamber structure, fixtures, and absorber configuration, and it involves extremely long computation time. In all practical cases, the measured results will be different from the predicted performance due to the simplified models of the chamber fixtures (such as antenna mast, turntable, lighting, CCTV camera, "honeycomb" waveguide vents, penetration panels, etc.) and neglecting the imperfection in lining the absorbers. Hence, the use of geometrical optics method together with a reasonable model that represents the absorber-lined surfaces will suffice to predict the approximate chamber performance prior to the chamber construction.

Holloway and Kuester (1996) have used a geometrical optics (GO) method to predict the site attenuation of a semi-anechoic chamber (SAC). The method of homogenization (Holloway and Kuester 1994) has been used to model the RF absorber. A rectangular chamber shape was considered, and only a single bounce of the rays off the absorbing walls and ceiling was accounted in the calculation of the total field strength. Reflections due to waves that make more than one bounce off the absorbing surfaces were assumed negligible. This assumption may only be valid if a good quality absorber has been used. Site attenuation measured at two chambers lined with 4-ft and 5-ft pyramidal absorbers shows poor correlation with the calculated values with deviations more than 4 dB for both horizontal and vertical polarizations. Larger deviations were found for horizontal polarization and for frequencies below 80 MHz (Mayer et al. 1998). One of the reasons for these deviations is due to the variation in material properties over the bulk of the pyramidal absorber. Average permittivity and conductivity from a few material samples are typically used in the theoretical analysis. The other error factors are mutual impedance between the antennas, near-field effects (between each antenna and the conductive floor), poor low-frequency performance of the absorber (that more than one bounce must be considered), and room resonance.

Geometrical optics (GO) is the most popular technique for modeling of wave propagation behavior. Ray representations of electromagnetic waves are traced from the transmitter, changing ray direction as they undergo reflection and refraction, and the field quantities of those rays that arrive at the receiver are determined. The geometrical theory of diffraction (GTD) and uniform theory of diffraction (UTD) methods are extension to GO rays to include the effects of diffraction. The behavior of the diffracted wave at edges and corners can be determined from an asymptotic form of the exact solution for simpler canonical problems. For example, the diffraction around a sharp edge is found by considering the asymptotic form of the solution for an infinite wedge. The geometrical optics methods are only accurate when the dimensions of objects being analyzed are large relative to the wavelength of the field.

There are two basic categories of ray-tracing propagation models: brute-force shoot and bounce ray (SBR) (Yang et al. 1998) and image-based methods (Kimpe et al. 1999). Conventional SBR methods suffer large kinematics error due to the use of reception sphere. Image-based methods do not have such problem. However, without an efficient image generation algorithm, they are not manageable for complex scene. A hybrid SBR-image model that improves the efficiency of image generation has been developed by Chen and Jeng (1997). The choice of SBR technique would govern the performance of the hybrid model. The basic classes of SBR techniques that can be used are ray, tube, and beam approaches.

In the use of ray approach, individual rays are launched and traced. The separation between various rays launched from the transmitter is critical. It must be small enough that two adjacent rays never straddle and miss a potential scatterer or receiver. On the other hand, it must not be too small that the computation time

DOI 10.1007/978-981-4560-75-7_69-1

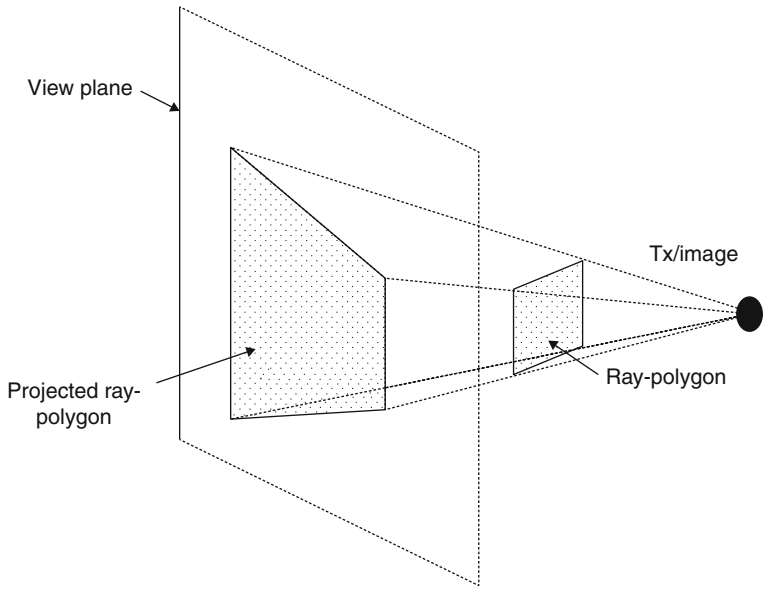

Fig. 10 Projection of ray polygon to a view plane

is excessive due to the huge number of rays. The optimum ray separation is difficult to determine because the ray separation increases with distance. Different ray separations must be used for different scenes. Reception has to be validated by a backward-tracing process. A significant number of backward-tracing efforts may end in invalid reception and discarded. This kind of trivial effort grows with the number of receivers or observation points.

A ray-tube approach where several rays are grouped to form a tube with simple polygon cross section (e.g., triangle or rectangular) has been developed by Chen and Jeng (1997). It enhances the reception validation process by eliminating backward ray tracing of invalid ray paths. A more complicated tube-tracing algorithm is required. Ray separation or tube size remains critical, and the concerns of optimum ray separation also apply here.

Improvement using large ray tubes is provided by a beam-tracing method (Fortune 1998). Beams with irregular cross section, representing infinite number of rays, are used. Ray separation is not a concern, and the beam size is not critical. Ideally, one beam represents one ray path, in contrast to the large number of rays or ray tubes required for keeping track of one ray path in the ray or ray-tube approach. The beams also assist in reception test by eliminating trivial backward tracing of invalid ray paths. However, the beam tracing is also the most complicated to code among the SBR techniques.

A variant of beam-tracing technique has been developed by Teh and Chuah (2003). Generic polygons are traced instead of the beams. Thus, the technique is called polygon-tracing method. A generic polygon may consist of one or more polygons which may be concave or convex, is self-intersecting, or contains holes. Scatterers are modeled as objects with polygonal facets. Reception sphere is not required, thus giving rise to very low kinematics errors. In a problem where a large number of receivers are involved, a minimum number of beams can cover all the receiver locations. Hence, the required computation time can be dramatically reduced. This feature is particularly useful in calculating the field strength at different positions of the receiving antenna in typical RF measurement site validation methods.

The polygon-tracing method shoots and bounces polygonal projections from the transmitter and its images. The ray polygon may be transformed to a different polygonal shape when projected onto an arbitrary view plane as illustrated in Fig. 10. Each view plane is selected to coincide with a plane object at the scene. The footprint on the view plane represents the region illuminated by the transmitter or the image source.

DOI 10.1007/978-981-4560-75-7_69-1

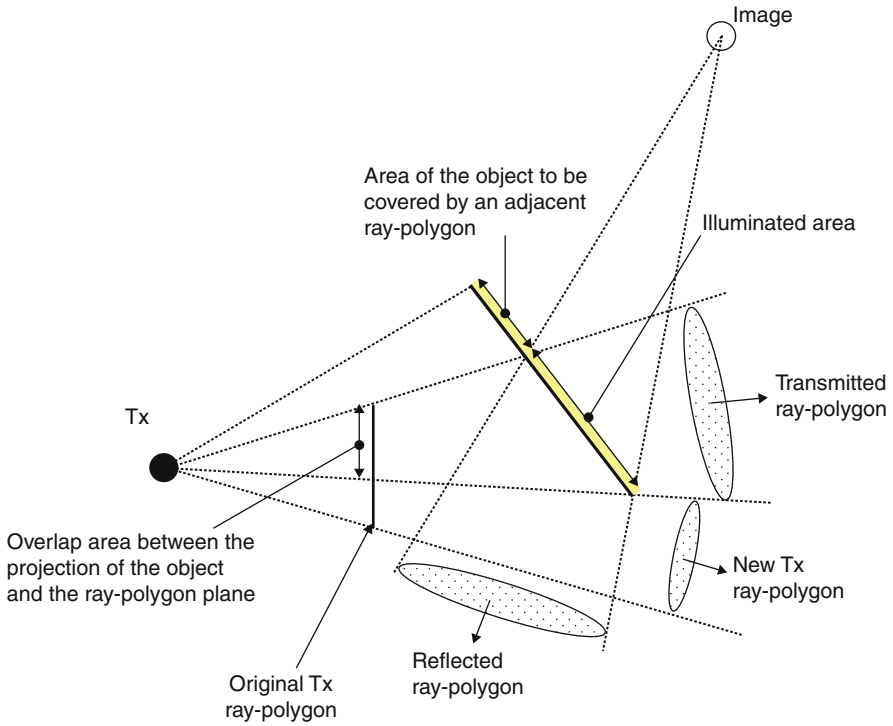

Fig. 11 Creation of transmitted and reflected ray polygons

To cover rays in all directions, the original transmitter ray polygons may be represented by the six faces of a rectangular box enclosing the transmitter. To begin tracing a ray polygon, the entity (scatterer or receiver) nearest to the source is projected onto the plane containing the ray polygon. The center of projection (COP) is the position of the source. If the projection of a receiver lies within the ray polygon, the receiver will receive a ray from the source. Backward ray tracing is then performed to determine the exact path information for electromagnetic field calculations based on GO and UTD. In the case of a scatterer entity, the overlap area between the projection of the object and the ray-polygon plane indicates the area where the beam energy will be intercepted. Reflection and transmission ray polygons that take the shape of the illuminated area of the object are created and queued for further tracing to the subsequent scatterer or receiver at the scene. Other areas of the object will be illuminated by an adjacent ray polygon. An illustration of the polygon-tracing mechanism is given in Fig. 11.

To include diffraction, edges of the polygonal object plane that fall within the projection of the ray polygon are considered. Diffraction ray polygons are created and traced for their subsequent reflection and transmission. However, the projection of the ray polygon based on the diffraction law is rather complicated. The projection for a straight line may become a curved line. Since the diffracted wave amplitude is usually very weak, the subsequent reflection, transmission, and diffraction may be negligible.

In a GO or polygon-tracing method, the electric field strength $|E_r|$ in free space (with no ground reflection) at a distance r from the transmitter antenna is given by:

$$|E_r| = \frac{|E_1|}{r} \tag{1}$$

where $|E_1|$ is the radiated electric field strength at a distance of 1 m from the transmitter antenna. At the quiet zone or test volume of an anechoic chamber, the electric field strength $|E_{obs}|$ observed at a receiver position will be given by the vector sum of the direct-path signal and all the reflected signals.

DOI 10.1007/978-981-4560-75-7_69-1

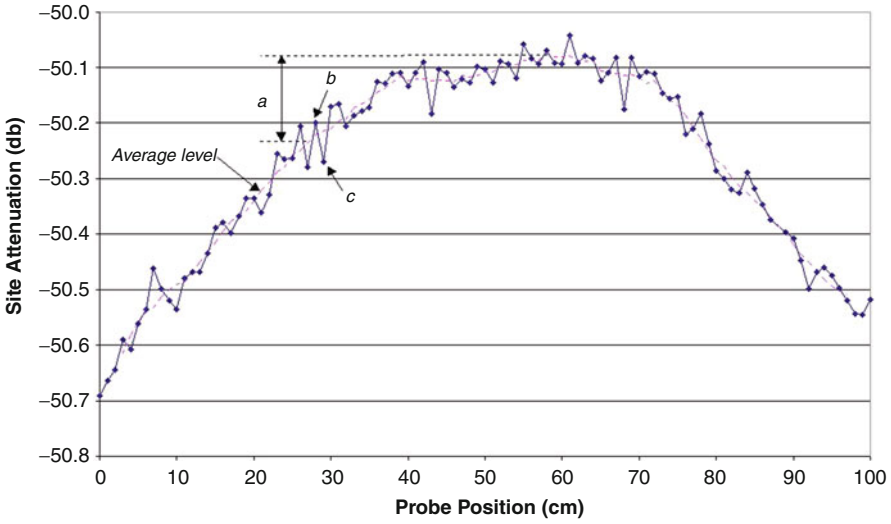

Fig. 12 Amplitude variations within the quiet zone

The magnitude of $|E_{obs}|$ at various positions within the test volume is to be found. In the computer simulation program, an impulse is transmitted from a dipole antenna, and it propagates in all directions in the form of ray polygons. For every bounce from the absorbing wall, the electric field strength is multiplied with the reflection coefficient. The degradation of the absorber reflectivity at oblique incidence is taken care of by the appropriate absorber model. Instead of calculating $|E_{obs}|$ for a large number of discrete frequency points, the received impulses resulting from various multipath propagations (with different time delays) are combined to give a time-domain impulse response. A fast Fourier transform (FFT) is performed to obtain the desired frequency-domain results.

If the chamber has a rectangular shape, multiple first-order reflections and second-order reflections would interfere with the direct wave at the receiving antenna as illustrated in Fig. 12. To improve the quietness performance, the chamber geometry can be designed such that no first-order and second-order reflections will propagate into the test volume. When the electromagnetic rays finally reach the receiver antenna after a few bounces off the absorbing walls, the wave energy will be sufficiently attenuated.

An asymmetric anechoic chamber shown in Figs. 7 and 8 has been designed and constructed at Multimedia University (Chung and Chuah 2003). With no symmetry, waves reflected from the walls will have different path lengths, and therefore the possibility of two waves with about the same amplitude to add in phase is very low. The required quietness performance can be achieved without the need to utilize bulky and expensive absorber.

Field Uniformity of Quiet Zone

Full anechoic chambers are commonly used for antenna and radar cross-section (RCS) measurements at microwave frequencies above 1 GHz. The performance of the chamber is defined by the uniformity of the illuminating field over the *quiet zone*. It is the region in which the antenna under test or radar target is to be placed. The size of the quiet zone may be specified in terms of the amplitude and phase variations of the field from the center of the quiet zone to the edge of the zone. The illuminating field over the quiet zone will deviate from that calculated based upon ideal range geometry because of reflections from various mounting structures, cables, and obstacles on or near the range surface and from irregularities in the range surface. Amplitude ripple and cross-polarization may result.

DOI 10.1007/978-981-4560-75-7_69-1

In an anechoic chamber, the size of the usable quiet zone is dictated by the Rayleigh range criterion. The phase variation of the direct wave from the center of the quiet zone to the edge of the zone must be less than 22.5° (equivalent to λ/16). Larger phase variation may cause the measured antenna pattern to depart appreciably from the true far-field pattern. For a fixed range distance R of 10 m, the diameter of the quiet zone decreases with frequency from 1.22 m at 1 GHz to 28.9 cm at 18 GHz.

The amplitude taper from the center to the edge of the quiet zone must be minimized so that it will not adversely affect the electromagnetic wave measurement accuracy. This can be achieved when the 3-dB beamwidth of the transmit antenna is much wider than the quiet zone. Amplitude ripple may result due to interference of the direct wave with reflections from the walls, ceiling, and floor of the anechoic chamber. The effect of wide-angle reflection may be reduced by the use of directional transmit and receive antennas. Hence, the amplitude ripple depends on the radiation pattern of the antennas, and standardized figure of merit cannot be defined for an anechoic chamber.

The quietness of the quiet zone may be defined as the average ratio of reflected energy to that of the direct wave. The "free-space voltage standing wave ratio" field probe technique (IEEE Std. 149–1979) is usually used to evaluate the quietness level. An antenna with stated directivity is used as the probe. A probe carriage is utilized for the probe to move continuously along a transverse line. The interference pattern of the field is recorded along with the linear motion of the probe. Measurements are made for horizontal and vertical transverse directions with both horizontal and vertical polarizations. Standard gain horn antenna is usually used as the probe.

Figure 12 shows an example of signal strength variation similar to a standing wave pattern measured over a quiet zone. The amplitude of the ripples varies across the graph due to the complicated variation in reflected field amplitude with position. At the same time, the average level of the standing wave curve varies slowly due to the change in "eyesight" angle between the transmit antenna and receive antenna as well as the distance variation between them. One can see this as the composite variation in pattern level of the antennas.

Referring to Fig. 12, the pattern level at probe position of 28 cm is a, and the detected signal level varies from b to c when the direct wave E_d and the reflected wave E_r are detected in phase and out of phase, respectively. Then,

$$b(dB) = 20 \cdot \log \frac{E_d \cdot 10^{a/20} + E_r}{E_d} \tag{2}$$

$$c(dB) = 20 \cdot \log \frac{E_d \cdot 10^{a/20} - E_r}{E_d} \tag{3}$$

$$R_c(dB) = 20 \cdot \log \frac{E_r}{E_d} = a + 20 \log \frac{10^{(b-c)/20} - 1}{10^{(b-c)/20} + 1} \tag{4}$$

where R_c is known as the reflectivity level of the quiet zone. As there are more than one reflected field received by the probe at any one time, what is really established by Eq. 4 is an equivalent reflected wave which is the aggregate effect of all reflected waves incident upon the probe antenna. The result obtained will depend on the directivity of the antenna. For example, an omnidirectional antenna will yield a higher reflectivity level (i.e., poorer apparent performance) since the equivalent reflected wave is composed of all the reflected waves from all surfaces of the chamber. If directional source antenna and/or directional probe antenna are used, less number of reflected waves will be received by the probe. Hence, a lower reflectivity level (i.e., better apparent performance) will be obtained, although both results refer to the same anechoic

DOI 10.1007/978-981-4560-75-7_69-1

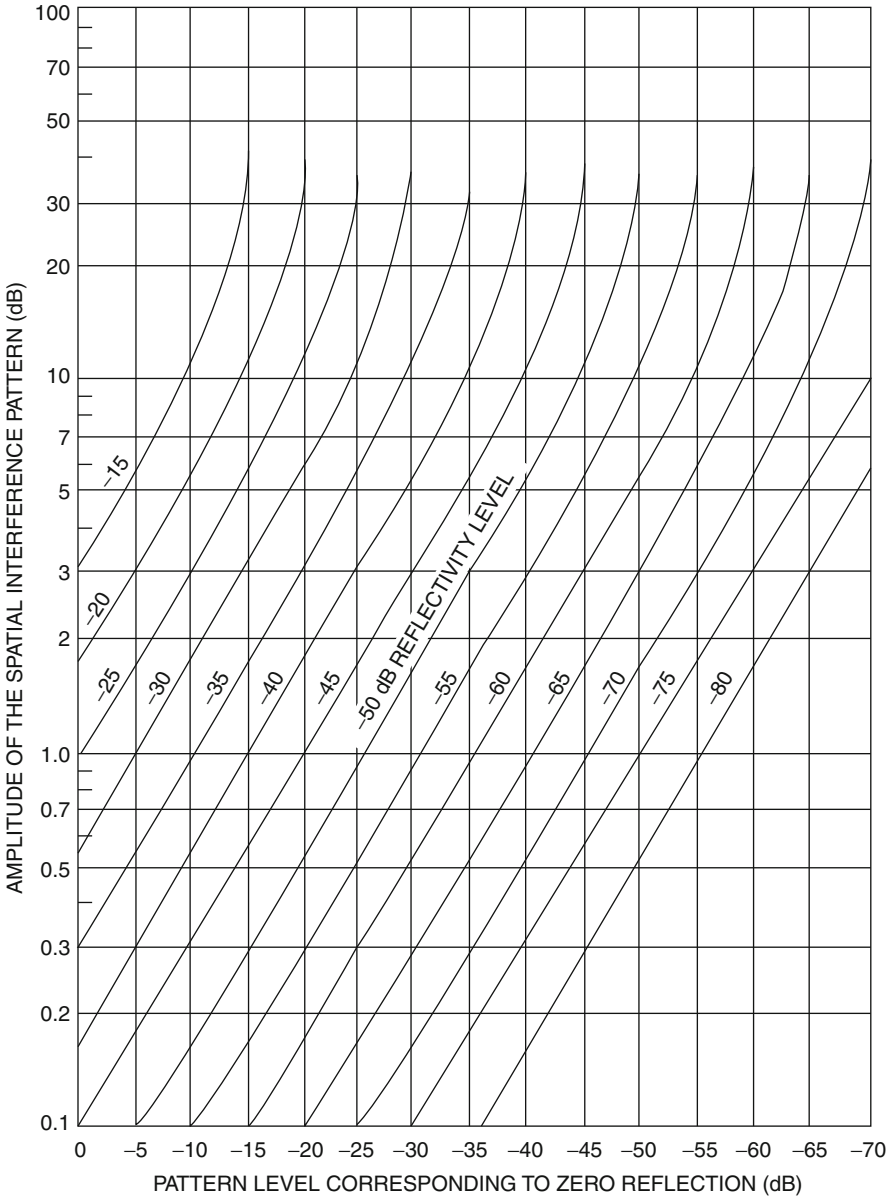

Fig. 13 Tabulated graph for determining the reflectivity level of an anechoic chamber

chamber. Anyway, a standardized reflectivity level has little usefulness other than for benchmarking purpose because "poorer reflectivity" may not appreciably affect the measurement accuracy if the AUT directivity is high.

In the analysis of the standing wave curve, the maximum peak-to-peak interference amplitude (b–c) must be determined. The average level of the interference pattern is used to determine the pattern level, a. The reflectivity level R_c can be calculated using Eq. 4 or using the tabulated graph in Fig. 13. It is apparent that R_c depends upon the pattern level a at which (b–c) is found. For the same value of (b–c), the reflectivity level R_c increases with the pattern level. For the pattern level $a = -0.15$ dB and peak-to-peak interference amplitude (b–c) = 0.1 dB, the reflectivity level of the anechoic chamber is −45 dB. If the same (b–c) = 0.1 dB is obtained at pattern level $a = -5$ dB, it indicates the anechoic chamber has a better reflectivity of −50 dB.

DOI 10.1007/978-981-4560-75-7_69-1

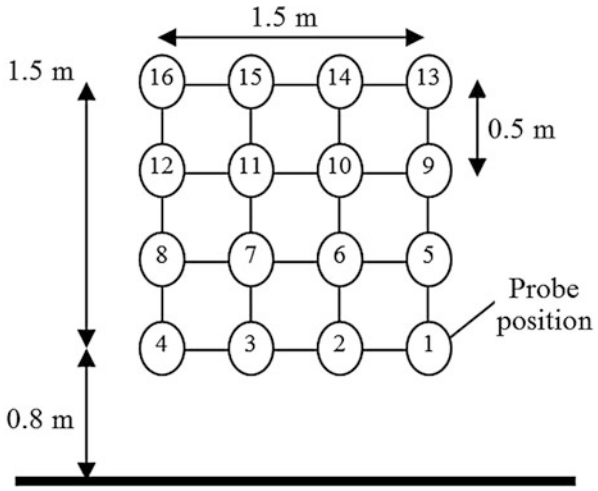

Fig. 14 Positions for field uniformity test

Low-frequency full anechoic chambers are used for radiated RF field immunity tests required by European EMC standard EN61000-4-3. In this test, a strong RF field is radiated from a transmit antenna toward the equipment under test (EUT). The standard field strengths for severity levels 1, 2, and 3 are 1 V/m, 3 V/m, and 10 V/m, respectively. Illumination of the electromagnetic field is applied at four faces of the EUT with both vertical and horizontal polarizations. The most susceptible configuration and operating mode of the EUT are to be set up. A set of parameters that represent the operation of the EUT are monitored from the control room. Any degradation of the operating parameters is recorded. The standard requires the field at the EUT's position to have uniform amplitude distribution from 80 to 2700 MHz (EN61000-4-3:2006 + A2:2010). To validate the chamber for RF field immunity tests, field uniformity test is made at 16 points over a grid covering a plane area of 1.5 m × 1.5 m with the lowest point at 0.8 m above the floor as illustrated in Fig. 14. The test site is considered acceptable for radiated RF immunity test if the field strength at 12 of the 16 points is within the tolerance of −0 dB/+6 dB of the test level. The large tolerance is allowed because the standard takes into practical consideration that wave absorbers typically have poor reflectivity performance at lower frequencies.

RCS Chamber Acceptance Test

Radar cross section (RCS), σ, is a parameter used in characterizing the radar signature of an object. Given the actual target echo at the receiving system, σ is the effective area which would intercept sufficient power out of the transmitted field to produce the given echo at the receiving system by isotropic reradiation. This parameter is a function of the material properties (such as conductivity, electric permittivity, and magnetic permeability) and the shape of the target and is unique for a particular frequency and polarization. It is evident that σ can be greater than the physical cross section of the target if the object is highly reflective and/or has a preference direction of scattering which is in the direction toward the receiving system. Similarly, σ can otherwise be less than the physical cross section. The measured value of σ may be influenced by the transmitted waveform (CW, pulse, or FM) and wave front (plane or spherical).

Radar technology has advanced into the spectrum of millimeter and micrometer wavelengths. The application of radar equipment is no longer confined to looking up at aircraft or out at ships. Airborne and spaceborne radars, capable of producing images of ground, have been developed and extensively used in

DOI 10.1007/978-981-4560-75-7_69-1

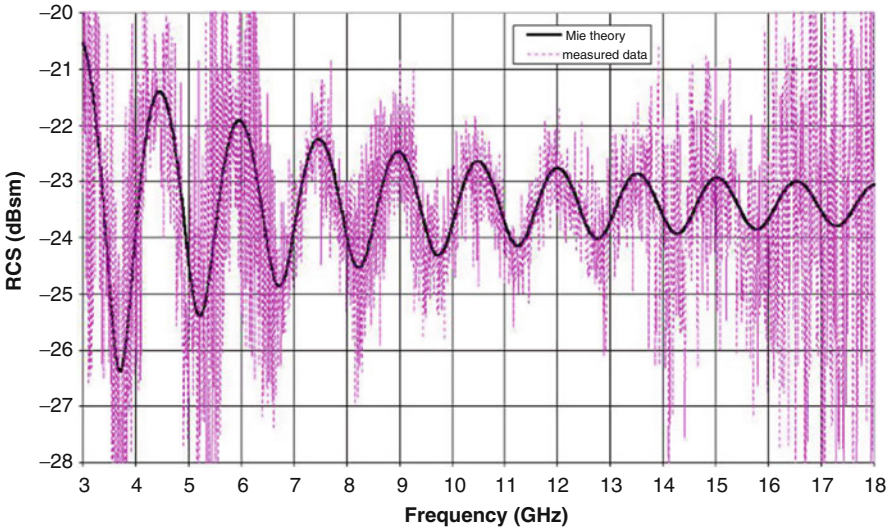

Fig. 15 Comparison between measured and theoretical monostatic RCS of a 3-inch sphere, without time gating

remote sensing applications. Clutter due to backscattering from ground in the early imaging radar has been utilized as useful information associated to the vegetation cover and underground materials. RCS control has also progressed from RCS reduction using radar-absorbing materials to body shaping and impedance loading (loading the body surface with distributed or lumped impedance). A considerable amount of researches have been directed to RCS enhancement when, in some applications, it is desirable to enhance the radar cross section above the physical cross section of the body, over a specific range of aspect angles. One example of these applications is in the tracking of civilian aircraft where a strong and relatively steady return is desired for good tracking accuracy by ground radar. Methods for this purpose include the use of impedance loading, corner reflectors, dielectric lenses, and retrodirective arrays. Dihedral and trihedral corner reflectors have been extensively used in the calibration of polarimetric radars.

RCS of deterministic target is usually measured in an anechoic chamber. Chamber for this measurement has an additional requirement to provide low background level. The performance criterion is therefore defined by its apparent RCS measured in the absence of any target placed at the test region. The background RCS is effectively the total system sensitivity of the measurement system which includes the anechoic chamber as well as the RCS measurement instrumentation. It determines the smallest RCS that can be measured.

Vector network analyzer with time-gating capability is typically used in the instrumentation. A known target such as a flat reflecting metal sheet or a metallic sphere is placed at the target pedestal. The scattered signals are measured in a series of step-frequency continuous wave transmission. Figure 15 shows an example of co-polarized RCS measurement result of a 3-in. metal sphere. Note that the measured RCS (expressed in dB square meter or dBsm) is oscillating around the theoretical value. This is primarily due to the coupling effect between the target and the pedestal. The electromagnetic wave scattered from the pedestal to the target, and vice versa, follows a longer path and interferes with that scattered directly from the target surface. This results in constructive or destructive interference, depending on the wavelength.

The result is converted to its time-domain equivalent in Fig. 16 using inverse discrete Fourier transform computation. Errors due to target-pedestal coupling appear as secondary impulses after the “arrival” of the main impulse. The noise level in the vicinity of the target indicates the minimum detectable RCS or the apparent RCS of the chamber. A time window can be applied to remove the unwanted signal. When the time-gated transient RCS is converted back to the frequency domain using a discrete Fourier transform computation, the RCS of the target in frequency domain can be obtained.

DOI 10.1007/978-981-4560-75-7_69-1

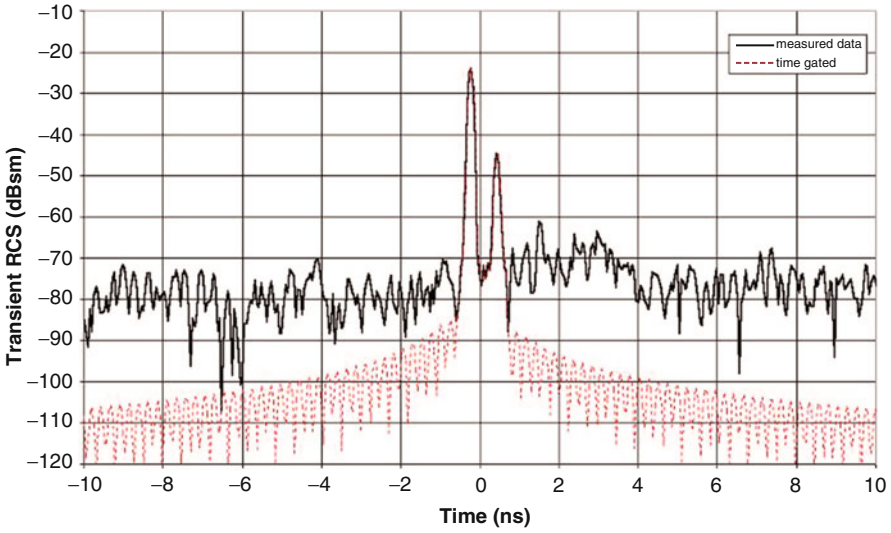

Fig. 16 Transient RCS of a 3-inch sphere with 3–18 GHz bandwidth, before and after time gating

In the acceptance test of an RCS chamber, the metallic sphere is moved through the quiet zone. The radar returns may vary depending on the ripple in the illuminating field. The peak-to-peak ripple in the radar returns can be related to the extraneous signal level in the test region.

Conclusion

Anechoic chamber may be designed for different measurement needs. The performance criteria employed to evaluate the anechoic chamber depend on the type of measurements to be made in the facility. Accordingly, the chamber geometry and wave absorber to be used should be carefully considered in the design. In addition, the design must include the necessary features such as access doors, ventilation, lighting, electrical power supply, filters, connection panels, cables, pneumatic air supply, turntable, motorized antenna mast, etc. Wave propagation simulation should be conducted to compute the vector sum of direct-path signal and the reflected signals. The objective is to evaluate the quietness level within the test volume which is indicated by the magnitude of amplitude ripple along the longitudinal and transverse axes. The proper model that characterizes the absorber scattering behavior as a function of incident angle, frequency, and polarization should be used in the calculations of wave components due to reflections from absorber-lined walls and ceiling. After the construction of the anechoic chamber, acceptance tests should be performed according to the available standards.

Radiation Efficiency Measurements of Small Antennas

Yi Huang*
Department of Electrical Engineering and Electronics, The University of Liverpool, Liverpool, UK

Abstract

This chapter deals with a range of antenna radiation efficiency measurement methods and techniques: from the traditional to the state-of-the-art. The most widely used methods are discussed in details, along with their backgrounds and scientific foundations. The relevant measurement setup, procedure, and data processing techniques are also given. A comparison of these methods is made at the end of this chapter, and their advantages and limitations are identified.

Keywords

Antenna efficiency measurement; Radiation efficiency measurement; Antenna measurements; Small antennas

Introduction

The antenna *radiation efficiency* (η) is one of the most important parameters since it is the most useful and informative measure of how efficient an antenna is to radiate or receive the radio wave at a desired frequency. It is defined as the ratio of the total power radiated by the antenna (P_r) to the total power accepted by the antenna (P_a) at its input terminal.

$$\eta = \frac{P_r}{P_a} \tag{1}$$

It is normally expressed in percentage although some people prefer to express it in dB. A good and efficient antenna should have very high radiation efficiency, ideally 100 % (i.e., 0 dB). It should be pointed out that the radiation efficiency is a function of the frequency but not a function of the radiation direction. It is determined by the antenna loss but does not include the antenna impedance mismatch. The mismatch between the feedline/connector and the antenna is taken into account by the total efficiency of the antenna (η_T) which is defined as the ratio of the total power radiated by the antenna (P_r) to the total power supplied to the antenna (P_s) and can be expressed as

$$\eta_T = \frac{P_r}{P_s} = \frac{P_a}{P_s}\frac{P_r}{P_a} = \left(1 - |\Gamma|^2\right) \cdot \eta \tag{2}$$

where Γ is the reflection coefficient (the same as the S-parameter S_{11} or S_{22}) which is a complex number (note: some published papers did not use the magnitude in this equation which is not correct) and can be easily measured using a vector network analyzer. When the reflection coefficient is zero (the perfect match

*Email: Yi.Huang@IEEE.org

DOI 10.1007/978-981-4560-75-7_71-1

case), the power accepted by the antenna is the same as the power supplied to the antenna, and there is no mismatch; thus, the total efficiency is the same as the radiation efficiency – this is an ideal case. In reality, the radiation efficiency is always larger than the total efficiency of the antenna.

The term "antenna efficiency" can cause confusion in reality since it could mean the radiation efficiency or the total efficiency. Although they are closely linked as shown in Eq. 2, they can be very different: an antenna may have a radiation efficiency of 90 % but a total efficiency of just 9 %! Thus, it should be made clear and specific especially when a value is mentioned. In this chapter, the radiation efficiency will be used since the total efficiency can be obtained easily using Eq. 2 if it is required.

The radiation efficiency is a very important figure of merit and needed for the computation of the radiated or received power once the input power is known. For some applications, the antenna efficiency is a much more important parameter than the radiation pattern. Take mobile phones as an example; the battery power drain is a big and bottleneck problem and significantly affected by the antenna efficiency, while the antenna radiation pattern (very important for many applications) is not important in this case since the field around a mobile phone is relatively random (especially in the urban environment) and the way we use the phone is also relatively arbitrary. Thus, an efficient antenna can be considered as a power amplifier without the need for a power supplier – it is the best solution to make an efficiency radio system. In this example, an efficient antenna can improve the mobile system performance and extend the battery life. The antenna efficiency is therefore of huge interest to a wide range of applications. However, this parameter is actually not easy to obtain: the theoretical or numerical value is normally not accurate or reliable because the antenna material electromagnetic properties may not be ideal or known, and sometimes complex supporting and/or housing structures are involved. Just like the antenna gain, the measured antenna efficiency is preferred in practice. There has been a lot of interest in how to make accurate measurements on the antenna efficiency. A number of measurement methods and techniques have been proposed and studied over the years (Wheeler 1959; Newman et al. 1975; Pozar and Kaufman 1988; Johnson and McRory 1998; Schantz 2002; Huang et al. 2003, 2010, 2011; Huynh 2004; Rosengren and Kildal 2005; Schroeder and Gapski 2006; Fur et al. 2009; Holloway et al. 2012). Some have already gained wide recognition and have been adopted in practice, but some are still subject to further investigation and/or improvement for real-world applications. In this chapter, mainly the well-developed and matured methods and techniques will be introduced. Some newly developed promising methods will also be introduced and discussed. The antennas of interest are physically small and can be measured in a standard laboratory.

Measurement Methods

Many radiation efficiency measurement methods have been developed, and it is very hard to say which method is the best since each method has its advantages and disadvantages – it is also linked to the specific antenna. Some methods are particularly suitable for certain types of antennas. The intention is to provide a relatively comprehensive review of the radiation efficiency measurement methods in this section. A comparison of these methods will be provided at the end of the chapter.

Pattern Integration Method

Background and Theory

This is probably the oldest conventional method to measure the antenna radiation efficiency, and it is based on the definition (i.e., Eq. 1) which means that the power accepted by the antenna and the power radiated by the antenna are required. The accepted power can be calculated using

DOI 10.1007/978-981-4560-75-7_71-1

$$P_a = \left(1 - |\Gamma|^2\right) \cdot P_s \tag{3}$$

The power supplied to the antenna (P_s) can be measured using a power meter (or a receiver), and the reflection coefficient can be measured using a vector network analyzer. The difficulty is how to measure the total radiated power. In theory, it is

$$P_r = \oint U \cdot d\Omega = \int_0^{2\pi} \int_0^{\pi} U(\theta, \phi) \cdot \sin\theta d\theta d\phi \tag{4}$$

where U is the radiation intensity in W/unit solid angle and linked to the radiated electric field E in the far field by

$$U = r^2 \cdot |E \times H| = r^2 \cdot \left|E^2\right| / 120\pi \tag{5}$$

where r is the distance from the antenna to the observation/measurement point. Thus, one needs to measure the field E in the three-dimensional (3D) space at a fixed distance r (which should be large enough to be considered in the antenna far field). The integration over the whole spherical space for the antenna field (pattern) has to be conducted, which is why this method is called the pattern integration method. In reality, the E field can be decomposed to two orthogonal components (E_θ and E_ϕ) and measured at discrete sampling points (i, j), thus the total radiated power:

$$P_r = \frac{r^2}{120\pi} \sum_{i,j} \left(|E_\theta(i,j)|^2 + \left|E_\phi(i,j)\right|^2\right) \sin\theta_i \Delta\theta_i \Delta\phi_j \tag{6}$$

The accurate measurements of these fields in the 3D space could be very time-consuming and difficult.

Facility and Equipment

Typically, the measurement should be conducted in an anechoic chamber, which is a large room lined with radio-absorbing materials (RAMs) on the walls, the ceiling, and the floor. It is an indoor facility to simulate the free space. Alternative facilities such as the open area test site (OATS) and near-field probe system are also fine. A power meter or receiver is required to measure the power supplied to the antenna and the E field at the selected sampling points. A calibrated field probe or antenna is required for the E field measurement as well. A vector network analyzer (VNA) is needed to measure the reflection coefficient of the antenna. Since only the magnitude of the reflection coefficient is needed, other equipment (such as a network analyzer) or methods could be used to replace the VNA to determine the reflection coefficient magnitude (Fig. 1).

Measurement Setup and Procedure

For the E field measurement, a typical setup in an anechoic chamber is shown in Fig. 2.

The procedure to obtain the radiation efficiency can be summarized by the following six steps:

1. Measure the power supplied to the antenna using a power meter or a receiver.
2. Measure the antenna reflection coefficient using a VNA.
3. Calculate the power accepted by the antenna using Eq. 3.

DOI 10.1007/978-981-4560-75-7_71-1

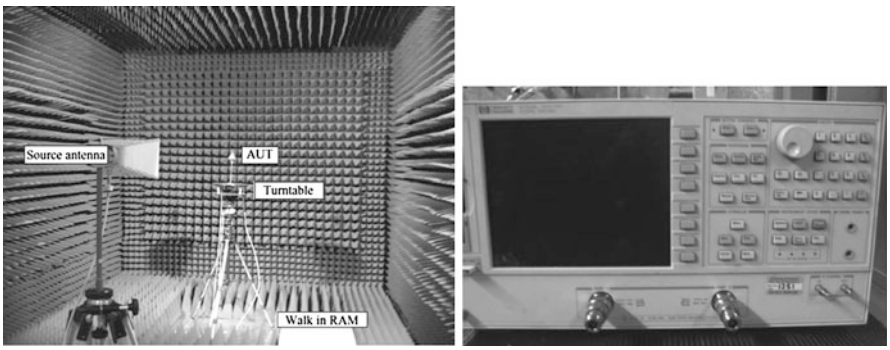

Fig. 1 An anechoic chamber and a vector network analyzer

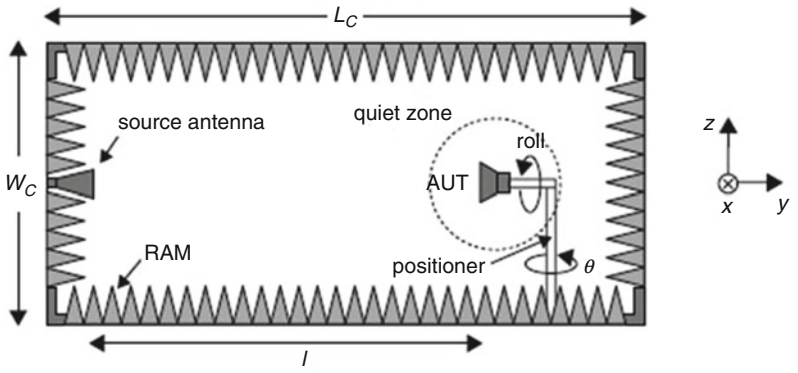

Fig. 2 Antenna radiated field measurement inside an anechoic chamber

4. Measure the *E* field in 3D at a fixed distance.
5. Calculate the total radiated power using Eq. 6.
6. Calculate the antenna radiation efficiency using Eq. 1.

Discussion and Conclusions

The beauty of this measurement method is that it is closely linked to other antenna characterization measurements such as the antenna impedance (via the reflection coefficient measurement) and radiation pattern measurements. The same facilities and equipment are used. However, it needs the integration/summation of the measured radiated field to obtain the total radiated power. This could be a very time-consuming process since the antenna field/pattern measurement should be done in 3D; the results are of high uncertainty (>10 %) (Pozar and Kaufman 1988). Furthermore, when the operational frequency is relatively low, it may not be possible to obtain its radiated field pattern in a standard laboratory (either a large test site would be required to meet the far-field condition or a near-field facility should be used).

Directivity/Gain Method

Background and Theory

From the antenna theory, we know that the antenna radiation efficiency is the ratio of the gain *G* to the directivity *D*:

$$\eta = G/D \tag{7}$$

DOI 10.1007/978-981-4560-75-7_71-1

The directivity does not take the antenna loss into account but the gain does. Thus, the gain is normally smaller than the directivity and can be measured using a number of well-known measurement methods. The most straightforward approach is to use the comparison method where a reference antenna with a known antenna gain is employed; the gain is obtained by comparing the received powers with the antenna under test (AUT) and the reference antenna. Another popular approach is to employ two identical antennas as the transmitting and receiving antennas. Using the Friis transmission formula, we can obtain the antenna gain:

$$G = \left(\frac{4\pi r}{\lambda}\right)\sqrt{\frac{P_R}{P_a}} \tag{8}$$

where λ is the wavelength, P_R is the received power in watts, and P_a is the power accepted by the transmitting antenna in watts. It is assumed that the polarizations of the antennas are matched and the peaks are aligned with the line of measurement. The measurement should be conducted under the far-field condition.

The directivity of the antenna cannot be measured directly, but it can be computed from its definition formula:

$$D = \frac{4\pi U}{\int_0^{2\pi}\int_0^{\pi} U(\theta,\phi)\cdot \sin\theta d\theta d\phi} \tag{9}$$

Just like the pattern integration method, the E field measurement has to be conducted in 3D at discrete sampling points. Thus, this process can be very time-consuming and expensive. However, here we can use the normalized field or power radiation pattern, the distance information is not required, and there is no need to obtain the absolute field value; thus, the computed directivity can be more accurate, and the resulted radiation efficiency can therefore be more reliable than the previous method.

If the antenna is directional and the radiation is in the main lobe, the directivity is closely linked to the beamwidths (θ_{HP}, ϕ_{HP}) in the E- and H-planes; thus, the directivity can be estimated using (Huang and Boyle 2008)

$$D \approx \frac{4\pi}{\theta_{HP}\phi_{HP}} \tag{10}$$

This method is much quicker and simpler than the pattern integration method by using Eq. 9, but the accuracy is very much dependent on the directivity value obtained using Eq. 10.

Due to the significant advancement in computational electromagnetics (CEM), it is now relatively easy to obtain the antenna directivity using a numerical simulation tool such as CST Microwave Studio or HFSS. Since the directivity does not include any loss of the antennas, the simulated directivity can be very close to the measured directivity. Thus, instead of measurement, it is also acceptable to use the simulated directivity (but care has to be taken to ensure the simulation is conducted properly. It is easy to obtain inaccurate results using a very good simulation tool). This approach is also simple, accurate, and fast.

Facility and Equipment

Again, the measurement should be conducted in an anechoic chamber. Alternative facilities such as an open area test site (OATS) and a near-field measurement system are also acceptable.

DOI 10.1007/978-981-4560-75-7_71-1

Unlike the pattern integration method, here we just need to measure and compare the relative gain and *E* field values; thus, there is no need to use a power or receiver to obtain the absolute values. A VNA is sufficient since it can be used to measure the field (power) difference of two antennas, the reflection coefficient, and the radiation pattern of the antenna. If the antenna directivity is to be obtained via the computer simulation, relevant simulation software and detailed antenna configurations are also required. If the antenna gain is to be obtained using comparison method, a standard reference antenna with a known antenna gain is required.

Measurement Setup and Procedure

For the antenna gain and directivity/pattern measurements, a typical setup in an anechoic chamber is basically the same as the pattern integration method which is shown in Fig. 2.

The procedure to obtain the radiation efficiency can be summarized by the following three major steps:

1. Measure the antenna gain using one of the recommended methods (such as the comparison method).
2. Obtain the antenna directivity using one of the recommended methods (using Eq. 9 or Eq. 10 or via computer simulation).
3. Calculate the radiation efficiency using Eq. 7.

Discussion and Conclusions

Like the pattern integration method, standard antenna measurement equipment and facility are required. But only comparative measurements are to be conducted, and no calibration is required. This measurement method may provide more accurate results than the pattern integration method.

Wheeler Cap Method

Background and Theory

As we have seen that the determination of the radiation efficiency, one of the most important antenna parameters, was not easy, more efficient and convenient methods were required. In 1959, Wheeler introduced a theory about the radiansphere (Wheeler 1959), which has a radius of $\lambda/2\pi$ and is defined as the boundary of the reactive field and radiating near-field regions. The field inside the radiansphere is mainly involved in the loss power and stored energy, while the field outside the radiansphere is dominated by the radiation power, and the ratio of the electric field to the magnetic field equals to the intrinsic impedance (about 377 Ω in free space). "For purposes of measurement, it may be desired to remove the radiation resistance of a small antenna while retaining its other properties (loss resistance, capacitance, inductance). This can be accomplished to a close approximation by enclosing the antenna in a radiation shield which ideally is a perfectly conducting spherical" (Wheeler 1959). This method has now become the well-known Wheeler cap method which is the most popular radiation efficiency measurement method for small antennas due to its simplicity, speed, repeatability, and accuracy.

Basically, when the antenna is capped by a conducting cap, the power consumed by the antenna in this case is considered as the antenna loss power P_{cap}. While the antenna is placed in free space (or an anechoic chamber), the power accepted by the antenna P_{free} is viewed as the summation of the loss and radiation powers (i.e., $P_{\text{free}} = P_{\text{cap}} + P_r$). Linking the power and resistance of the antenna, we have

$$\eta = \frac{P_r}{P_a} = \frac{P_{\text{free}} - P_{\text{cap}}}{P_{\text{free}}} = \frac{I^2 R_{\text{free}} - I^2 R_{\text{cap}}}{I^2 R_{\text{free}}} = \frac{R_{\text{free}} - R_{\text{cap}}}{R_{\text{free}}} \tag{11}$$

DOI 10.1007/978-981-4560-75-7_71-1

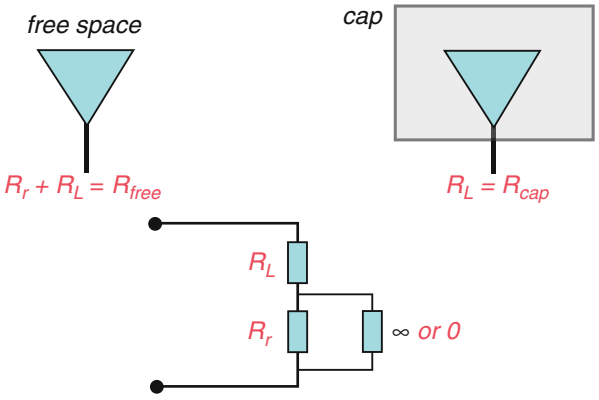

Fig. 3 The equivalent circuit for the Wheeler cap method

We therefore need to measure the resistance of the antenna in free space ($R_{\text{free}} = \textit{antenna resistance} + \textit{loss resistance}$) and its resistance inside the cap ($R_{\text{cap}} = \textit{loss resistance}$) separately and then use Eq. 11 to calculate the antenna radiation efficiency. This process can also be explained using the equivalent circuit theory as shown in Fig. 3 where the reactance of the antenna impedance is ignored since we are only interested in the resistance of the antenna. When the antenna is placed in free space, the resistance is the summation of the radiation resistance and the loss resistance which is in parallel with an open circuit (the impedance is infinite). When the antenna is placed inside the cap which acts as a short circuit (the impedance is zero) in parallel with the radiation resistance, thus, the antenna resistance is just the loss resistance.

The conditions here are:

- The antenna is small (electrically).
- The cap is made of a very good conductor (the loss is negligible compared with the antenna loss).
- The radius of the cap is small, typically about $\lambda/2\pi$ which is the boundary between the reactive and the radiating near fields of a small antenna.

The current on the antenna is also assumed unchanged during the measurement when it is inside and outside the cap. This is reasonable since the current distribution along an electrically small antenna is not sensitive to the environment (following a sine function for a dipole antenna).

Facility and Equipment

The Wheeler cap method is very straightforward. To obtain the radiation efficiency, one has to measure the antenna impedance (resistance more specifically) when the antenna is placed inside and outside the conducting cap. Thus, the essential equipment and facilities required are:

- A suitable sized conducting cap
- A VNA for impedance measurement

Ideally, the impedance measurement should be conducted inside an anechoic chamber. If the antenna is not very directive (all small antennas are not very directive), the measurement can be conducted in an OATS or just a big room.

It should be pointed out that, in reality, the cap does not have to be a sphere or hemisphere in shape. Other shapes (such as a rectangular shape) are also fine as long as the conditions above are met.

DOI 10.1007/978-981-4560-75-7_71-1

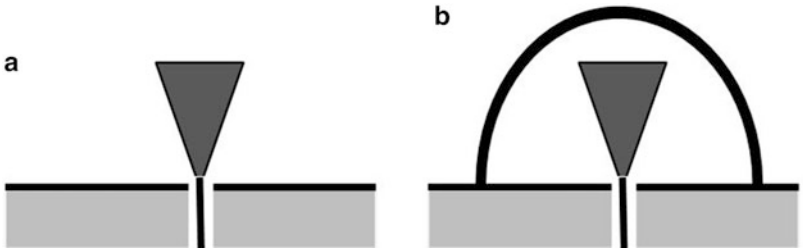

Fig. 4 Antenna measurement (**a**) in free space and (**b**) in a Wheeler cap

Measurement Setup and Procedure

A typical measurement setup is shown in Fig. 4. A calibration should be conducted before the measurement, and the cap size should be large enough to accommodate the antenna.

The procedure to obtain the radiation efficiency is to:

1. Measure the antenna impedance (resistance) when it is in free space (anechoic chamber).
2. Measure the antenna impedance (resistance) when it is in a Wheeler cap.
3. Calculate the antenna radiation efficiency using Eq. 11.

Discussion and Conclusions

To use the Wheeler cap method, one just needs a VNA and a conducting cap to obtain the radiation efficiency with a minimum of data processing. It is simple, fast, cost-effective, and accurate. However, it also has some drawbacks and challenges:

(a) It is only suitable for electrically small antennas. This means that the method cannot be applied to the antennas which are comparable or larger than the wavelength; thus, a large number of antennas cannot benefit from this wonderful method, which include broadband antennas (they are not electrically small).

(b) The cap cannot be too small or too large; although $\lambda/2\pi$ is just a guideline, it can be slightly larger or smaller in practice. The real condition is that no resonant modes can be generated inside the cap as we will see later. This means that for different antenna sizes, we may need different caps.

(c) For some antennas, such as a short dipole or monopole, the reflection coefficient is very close to 1, and the impedance solution is not unique. Because the reflection coefficient for an antenna with input impedance Z_a is

$$\Gamma = \frac{Z_a - 50}{Z_a + 50} = \frac{R_a - 50 + jX_a}{R_a + 50 + jX_a} \tag{12}$$

when the reflection coefficient is close to 1, the solutions could be (i) any resistance R_a but large reactance X_a or (ii) large resistance and any reactance. Thus, it is actually very hard to obtain the impedance accurately in practice. Any small errors in the measured reflection coefficient can result in large errors in the impedance. How to measure the impedance of an electrically small antenna accurately is actually a challenging task.

(d) The assumption that the antenna impedance can be modeled by either a series or parallel RLC circuit may not hold for some antennas (such as circularly polarized antennas or complex antennas) and result in errors (McKinzie 1997; Cho et al. 2014).

DOI 10.1007/978-981-4560-75-7_71-1

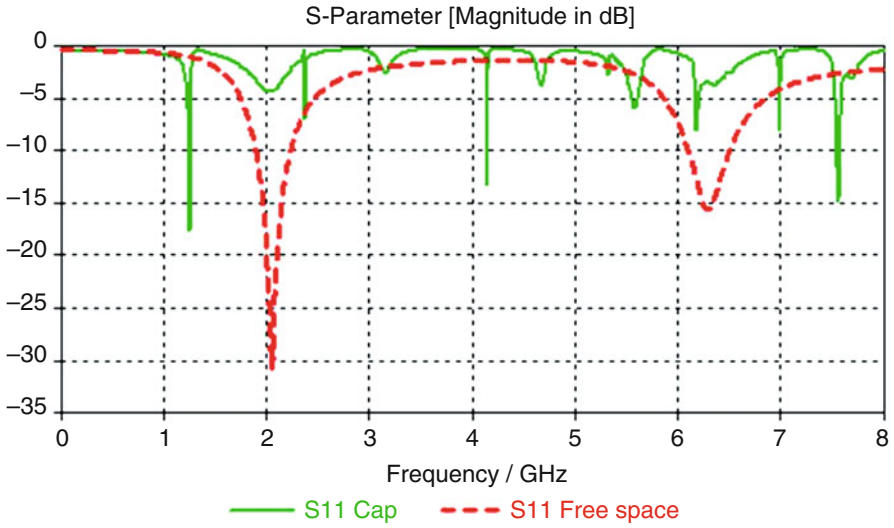

Fig. 5 Typical dipole antenna reflection coefficients inside and outside (free space) the Wheeler cap when the cap size is comparable with or larger than the wavelength

Modified Wheeler Cap Methods

Background

As compared with other antenna efficiency measurements, the Wheeler cap method offers the most attractive features but only suitable for electrically small antennas. Thus, there have been many attempts to modify the original Wheeler cap method in order to measure the antenna which is not electrically small.

When an antenna which is not electrically small is placed inside a cap, the cap will not be electrically small (at least comparable with the wavelength) – this means that resonance can be generated inside the cap. In this case, the real part of antenna impedance includes not just the loss resistance of the antenna but also the loss of the cap. At a resonant frequency, the loss of the cap can be significant which results in a small reflection coefficient. Take a lossy dipole antenna with a resonant frequency around 2 GHz as an example; a typical reflection coefficient in free space is shown in Fig. 5 as a broken line. When this antenna is placed inside a conducting cap which is larger than this half-wave dipole, the reflection coefficient in this case is shown as a solid line with many dips/nulls which are caused by the cap resonance, and the corresponding "antenna impedance" is no longer just determined by the antenna. Thus, Eq. 11 is no longer valid for calculating the antenna efficiency, and the Wheeler cap method cannot be used. To resolve this problem, a number of modified methods have been proposed and investigated.

Sliding Wall Cavity Method To remove the resonance, a sliding wall cap/cavity was employed to conduct the measurement as shown in Johnson and McRory (1998) and Huang et al. (2003). A typical measurement setup and a measurement result are shown in Fig. 6. The cap/cavity is made of a good conductor, but its size can be much larger than $\lambda/2\pi$. The input resistance of the AUT inside and outside the cap/cavity should be measured as in the standard Wheeler cap method. If a cavity mode appears near the operation frequency at which the measurement is taken, the cavity resonance is tuned by moving the sliding walls until the resonance peak is shifted away from the operation frequency. Thus, a range of measurements at different sliding wall positions may have to be undertaken. The antenna efficiency can be calculated using Eq. 11. Johnson and McRory (1998) described a method to obtain the S-parameter by measuring the same antenna with several dimensions, using a sliding wall. These measurement results form a circle in the Smith chart. If the maximum ($\Delta_{S,\max}$) and minimum ($\Delta_{S,\min}$) S_{11} differences

DOI 10.1007/978-981-4560-75-7_71-1

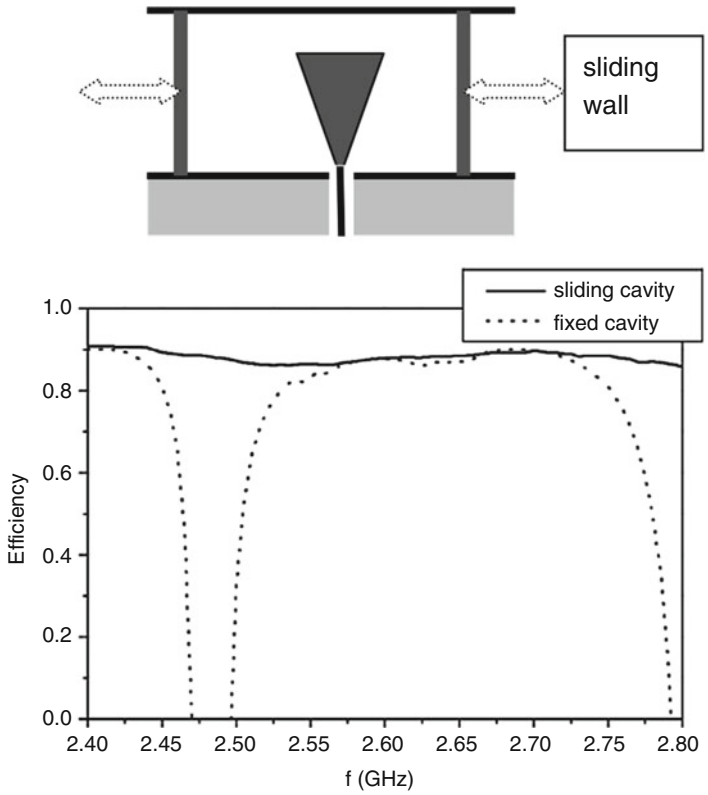

Fig. 6 A typical setup for the sliding wall cavity method and a measurement result (Huang et al. 2003)

(in absolute values) from the free space reflection coefficient S_{11} are obtained, the antenna radiation efficiency can be calculated using the following equation:

$$\eta = \frac{2}{\left(\Delta_{S,\max}\right)^{-1} + \left(\Delta_{S,\min}\right)^{-1}} \cdot \frac{1}{1 - |S_{11}|^2} \tag{13}$$

The data processing for this approach is more complicated than the Wheeler cap method.

The sliding wall cavity method is an effective way to remove the resonance and has kept most advantages of the original Wheeler cap method. The results are reasonably accurate for most antennas. The main drawback is that a conducting sliding wall is required, and the connectivity of the wall and the cavity could be a major source of errors – a gap between the sliding wall and the cavity may act as a slot antenna to introduce additional loss. In addition, the resonant mode at the desired frequency should be removed which could be tricky in some cases since the power loss could be resulted from the resonance as well as the antenna.

UWB Wheeler Cap Method Broadband antennas are normally comparable or even larger than a wavelength. There has been a great deal of effort to make the Wheeler cap method suitable for broadband antenna measurement. Due to the enormous interest in ultra-wideband (UWB) antennas, the UWB Wheeler cap method was introduced in 2002 by Schantz (2002). The basic idea behind the method is that the cap should be much larger than $\lambda/2\pi$, and the radiated wave from the AUT can be treated as a ray (far field) as shown in Fig. 7. Thus, the total power reflection coefficient of the AUT inside the cap is

DOI 10.1007/978-981-4560-75-7_71-1

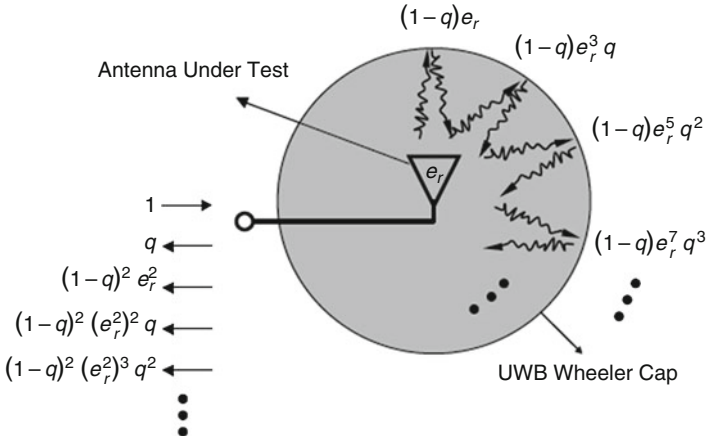

Fig. 7 The AUT inside a UWB Wheeler cap ($e_r = \eta$ is the antenna radiation efficiency) (Huynh 2004)

$$\left|S_{11\,\mathrm{cap}}\right|^2 = q + (1-q)^2\eta^2 + (1-q)^2\left(\eta^2\right)^2 q + \ldots = q + (1-q)^2\eta^2 \sum_{n=0}^{\infty}\left(\eta^2 q\right)^n \tag{14}$$

where $q = |S_{11\,\mathrm{free}}|^2$ is the antenna power reflection coefficient in free space (outside the cap) and the power reflection coefficient of the cap is assumed to be 1. $S_{11\,\mathrm{cap}}$ and $S_{11\,\mathrm{free}}$ are the antenna (voltage) reflection coefficients when it is inside the cap and free space, respectively. The solution of this equation for the radiation efficiency is found to be

$$\eta = \sqrt{\frac{\left(\left|S_{11\,\mathrm{cap}}\right|^2 - \left|S_{11\,\mathrm{free}}\right|^2\right)}{\left(1 - 2\times\left|S_{11\,\mathrm{free}}\right|^2 + \left|S_{11\,\mathrm{cap}}\right|^2 \times \left|S_{11\,\mathrm{free}}\right|^2\right)}} \tag{15}$$

This equation is the same as that in Eq. 9 but different from Schantz's original one which has an error.

Again, one needs to measure the antenna reflection coefficients inside and outside the cap in order to obtain the radiation efficiency. The measurement is straightforward and quick. The method shares many advantages of the conventional Wheeler cap method. Compared with the sliding wall cavity case, more resonant modes are excited in the UWB Wheeler cap at the frequencies of interest. The resonance is reflected on the S_{11} curve as sharp narrowband dips as shown in Fig. 5 which needs to be removed in the data processing. The common approach is to smooth the S_{11} by taking the largest value of the raw data over a frequency window (such as 100 MHz) and then use the processed S_{11} and Eq. 15 to compute the radiation efficiency. An example of the measured and simulated total antenna efficiencies of a monopole antenna is given in Fig. 8. More examples can be found from Schantz (2002) and Huynh (2004).

However, in reality, the cap cannot be made too large; thus, the ray approach may not be accurate. Also the loss of the cap has not been taken into account which could result in a considerable error (Lu et al. 2008). Thus, Eq. 15 is just an approximation, and the result tends to be more optimistic. But at higher frequencies, the mode density is very high, and the smooth technique may overestimate the loss of the antenna which results in smaller radiation efficiency.

Source-Stirred Cap/Chamber Method The concept of the "source-stirred chamber" was originally proposed in 1992 for electromagnetic compatibility (EMC) measurements (Huang and Edwards 1992), and the operational principle is similar to the reverberation chamber (to be discussed in the next section).

DOI 10.1007/978-981-4560-75-7_71-1

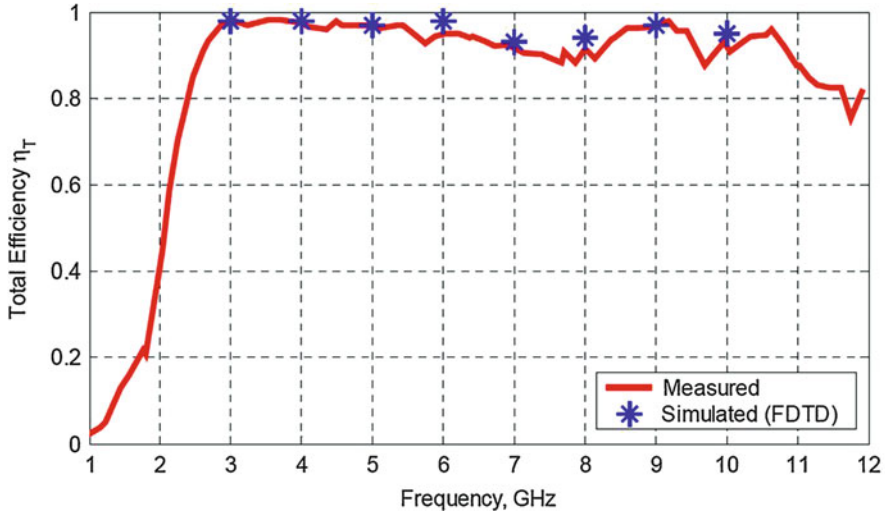

Fig. 8 The measured and simulated total efficiency of a UWB monopole antenna (Huynh 2004)

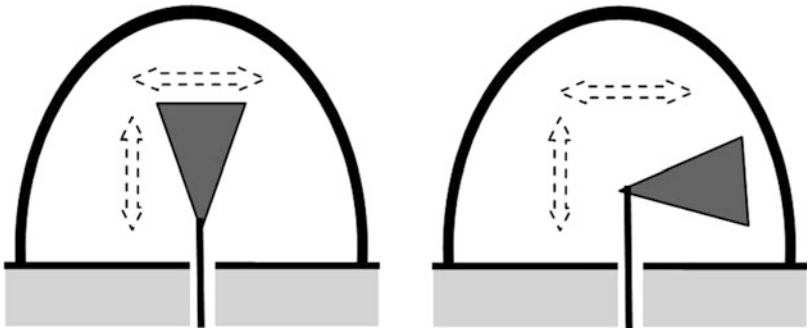

Fig. 9 Illustrative examples of the AUT placed inside the cap at different locations and orientations

Using this idea for antenna efficiency measurement, the antenna under test (AUT) should be placed in different locations inside the source-stirred cap/chamber (SSC) with different (better orthogonal) orientations (Huang et al. 2010, 2011) as illustrated in Fig. 9. The conducting cap/chamber should be large enough to accommodate significant field and mode changes. Having measured the reflection coefficients S_{11} of the antenna in free space and inside the SSC, one can use either Eq. 15 or Eq. 11 (they are about the same at over-mode cases) to calculate the radiation efficiency and plot the results obtained from each position on the same figure, as shown in Fig. 10 where three measurement results (with three orthogonal orientations represented by three colors) are displayed. One can link the peaks using a smoothed line which is the final antenna radiation efficiency – the peaks are not significantly affected by the resonant modes since they are considered to have the least effect by the SSC and mainly determined by the antenna (loss resistance). At nonresonant frequencies, the cap is considered as a short circuit in parallel with the radiation resistance as in the conventional Wheeler cap method.

It is apparent that this method is relatively simple to implement and requires very limited data processing (like the traditional Wheeler cap method): one just needs to stir the source (AUT) to different positions inside the cap and measure its impedance. Compared with the sliding wall cap/cavity method, this technique utilizes a fixed cap, and the resonant modes are tuned away by moving the AUT rather than sliding the wall. Compared with the UWB Wheeler cap method, this method has a similar data processing scheme, but there is no need to apply a window to smooth the data. Another important feature is that this method can better remove the resonant mode effects by changing both the antenna location and

DOI 10.1007/978-981-4560-75-7_71-1

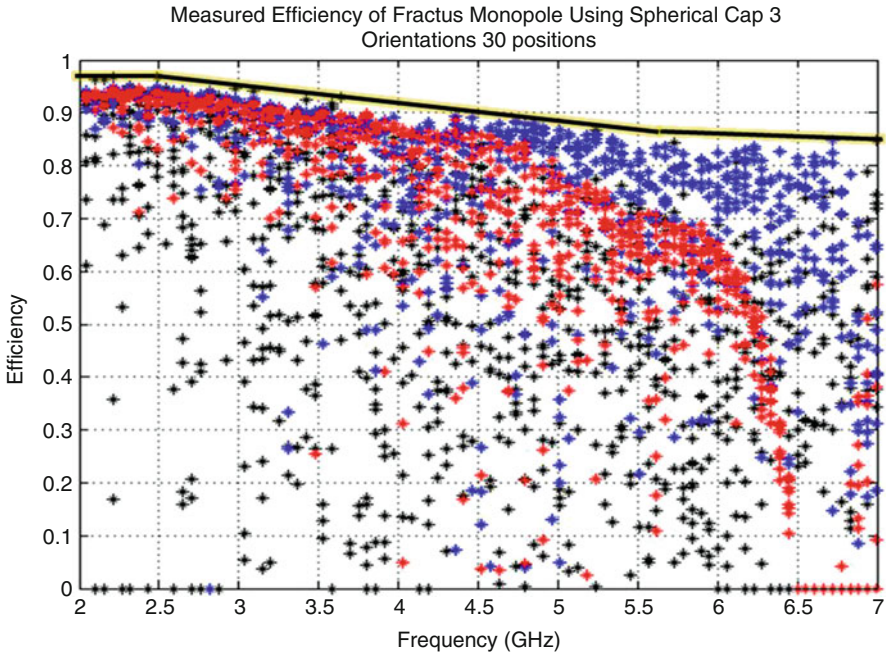

Fig. 10 An example: measured efficiency using the raw S_{11} data for three different AUT orientations (indicated by colors) inside the cap (Huang et al. 2010, 2011)

orientation inside the cap. Take Fig. 10 as an example; using the UWB Wheeler cap method, the antenna efficiency is obtained by linking the peaks of the red dots which are very small at higher frequencies (about 0 % between 6.5 and 7 GHz). This results in a considerable error since this particular orientation of the antenna inside the cap has a large loss over the higher frequency band. However, if we use the data from three orientations, the combined results can give much more accurate results since some resonant modes were not generated.

Since the measurement is conducted when the AUT is placed at different locations and orientations inside the cap/cavity, there is a section of cable inside the cap/cavity which could be a source of errors by introducing losses. The selection of the feeding cable (the type and length) is an important consideration. The cable effects inside the cavity must be minimized.

Reverberation Chamber Methods

Background

The reverberation chamber (RC) is an electrically large conducting cavity/chamber with one or two conducting mode stirrers to stir the field modes inside the chamber. Unlike an anechoic chamber (actually just the opposite), the boundary of the chamber is ideally a perfect reflector, and the cost of such a facility is not expensive. The field in the equipment under test (EUT) area is random, but the averaged field is relatively uniform. There are quite a few important parameters for a reverberation chamber. The lowest usable frequency (LUF) is one of them and is mainly determined by the chamber size and stirrer design. For a given chamber and a fixed EUT area, the lower the LUF is, the better the chamber is. If the operational frequency is below the LUF, the field in the EUT area is not random enough to generate the desired (averaged) uniform field; thus, all measurements should be conducted above the LUF inside the reverberation chamber – this is a limitation of the reverberation chamber. More detailed information can be found from IEC Standard 61000-4-21.

DOI 10.1007/978-981-4560-75-7_71-1

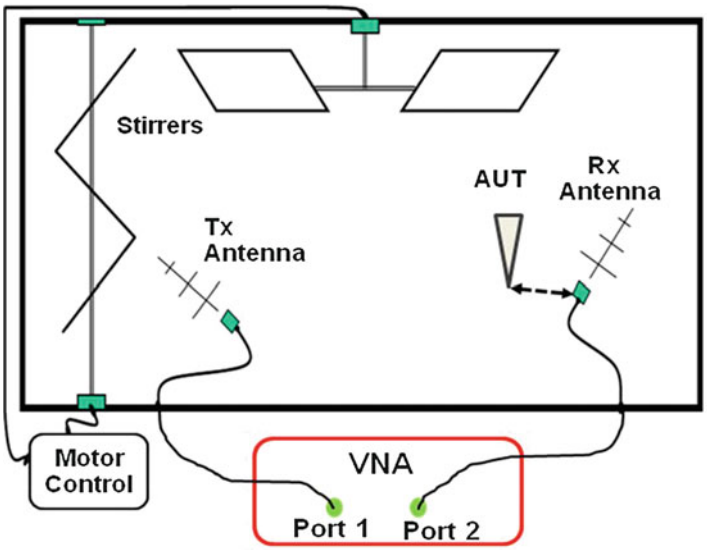

Fig. 11 A typical setup for antenna efficiency measurement inside a reverberation chamber

The reverberation chamber was originally introduced for electromagnetic compatibility (EMC) tests and measurements and is now emerging as a new facility for antenna measurements and characterization. It is particularly useful for the antenna efficiency measurement and MIMO (multiple-input and multiple-output) performance characterization using its multipath environment features (Rosengren and Kildal 2005; Fur et al. 2009; Holloway et al. 2012). For antenna efficiency measurement in a RC, it was first introduced using either a reference antenna with known efficiency or two identical antennas with the same efficiency – this could be a problem in some cases although the measurement is straightforward. More recently, the techniques for determining the antenna efficiency without the need for a reference antenna or two identical antennas have been introduced, and good measurement results have been obtained (Holloway et al. 2012). Thus, the methods with and without a reference antenna will be discussed.

Reverberation Chamber Method with a Reference Antenna The process of using a RC for antenna efficiency measurement is relatively straightforward. In addition to the RC, the equipment required is a transmitter and a receiver/spectrum analyzer or a network analyzer. As shown in Fig. 11, the power transmitted from the source Port 1 (say P_{Source}) will first encounter the reflection by the fixed transmitting antenna (due to impedance mismatch) which has a voltage reflection coefficient S_{11} and radiation efficiency η_F. Thus, the power radiated into the chamber is

$$P_{\text{Chamber}} = P_{\text{Source}}\left(1 - |S_{11}|^2\right) \cdot \eta_F \tag{16}$$

Part of this power arrives at the receiving antenna (which is either the reference antenna or the AUT), and it can be expressed as

$$P_{\text{in}} = P_{\text{Chamber}} - P_{\text{Loss}} \tag{17}$$

where P_{Loss} is the power loss due to the chamber and stirrer ohmic loss and power spreading.

The average power at the receiving antenna is assumed to be the same for both REF (reference) antenna and the AUT (a reasonable assumption for the averaged power in the EUT area), and this power is partially

DOI 10.1007/978-981-4560-75-7_71-1

consumed by the antenna (determined by the antenna efficiency) and partially reflected (due to mismatch between the antenna and cable connector); thus, the average power at the output of the receiving antenna is

$$\langle P_{\mathrm{Rec}} \rangle = P_{\mathrm{in}} \cdot \eta_{\mathrm{Rec}} \cdot \left(1 - |\langle S_{22\mathrm{Rec}} \rangle|^2\right) \tag{18}$$

The symbol $< >$ represents an ensemble average over a rotation cycle of the stirrer (typically 360°). $|\langle S_{22\mathrm{Rec}} \rangle|$ in a well-stirred chamber should be about the same as $|S_{22\mathrm{Rec}}|$ in free space (but smaller than $\langle |S_{22\mathrm{Rec}}| \rangle$). Thus, for the two different receiving antennas, the average power transmission coefficients are

$$\left\langle |S_{21\mathrm{REF}}|^2 \right\rangle = \frac{\langle P_{\mathrm{REF}} \rangle}{P_{\mathrm{Source}}} = \frac{P_{\mathrm{in}} \cdot \eta_{\mathrm{REF}} \cdot \left(1 - |\langle S_{22\mathrm{REF}} \rangle|^2\right)}{P_{\mathrm{Source}}} \tag{19}$$

and

$$\left\langle |S_{21\mathrm{AUT}}|^2 \right\rangle = \frac{\langle P_{\mathrm{AUT}} \rangle}{P_{\mathrm{Source}}} = \frac{P_{\mathrm{in}} \cdot \eta_{\mathrm{AUT}} \cdot \left(1 - |\langle S_{22\mathrm{AUT}} \rangle|^2\right)}{P_{\mathrm{Source}}} \tag{20}$$

Equations 19 or 20 to give

$$\eta_{\mathrm{AUT}} = \frac{\left\langle |S_{21\mathrm{AUT}}|^2 \right\rangle}{\left\langle |S_{21\mathrm{REF}}|^2 \right\rangle} \cdot \frac{\left(1 - |\langle S_{22\mathrm{REF}} \rangle|^2\right)}{\left(1 - |\langle S_{22\mathrm{AUT}} \rangle|^2\right)} \cdot \eta_{\mathrm{REF}} \tag{21}$$

This means that, in order to calculate the radiation efficiency of the AUT, one needs to measure/obtain:

- The S-parameters ($S_{21\mathrm{REF}}$, $S_{22\mathrm{REF}}$, $S_{21\mathrm{AUT}}$, and $S_{22\mathrm{AUT}}$) when the receiving port is connected to the reference antenna and the AUT, respectively
- The radiation efficiency of the reference antenna η_{REF}

From Eq. 21, it can be seen that the measured radiation efficiency has nothing to do with the transmitting antenna performance as long as enough power is radiated into the chamber. A calibration should be conducted to remove the cable loss. It should be pointed out that the reflection coefficient S_{22} is normally not sensitive to the stirrer position when the antenna is placed in the EUT area, but S_{21} is; thus, the S_{21} value in Eq. 21 should be the averaged S_{21} over a cycle of the stirrer rotation. It is very important to ensure that the received power is well above the noise level (Boyes et al. 2013).

Furthermore, the measurement accuracy is linked to the effectiveness of the stirrer and the resolution of the stirrer rotation. The higher the resolution is (or the smaller the step is), the better the accuracy is. But a smaller step means a longer measurement time. Thus, there is a trade-off. Figure 12 is an example of the simulated and measured radiation efficiency of a copper-based textile antenna in free space and on a body chest position. It can be seen that the difference between the measured and simulated results is typically less than 10 %, and the repeatability from one measurement to anther is very high. Another important feature of the method is that it can accommodate large antennas and supporting objects such as the human body, cars, and tanks – this is something that cap-based methods cannot offer since the caps are

DOI 10.1007/978-981-4560-75-7_71-1

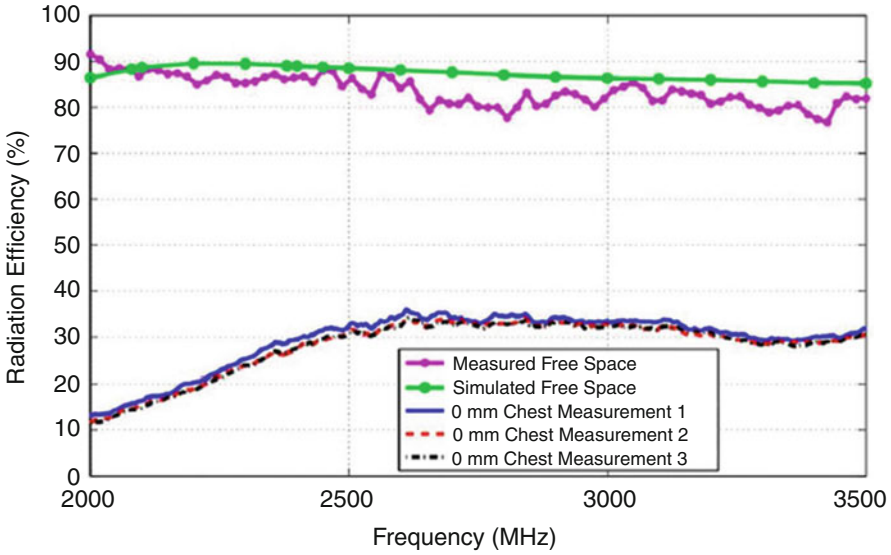

Fig. 12 The radiation efficiency of a copper-based textile antenna in free space and on-body (Boyes et al. 2013)

normally too small to host a human being, while a reverberation chamber is normally a large over-mode environment.

Reverberation Chamber Method Without a Reference Antenna The reference antenna efficiency required for Eq. 21 is sometimes not available in practice; thus, the RC method with a reference antenna cannot be used for determining the antenna efficiency. Recently, the RC method without a reference antenna method was proposed: three different approaches (one-antenna, two-antenna, and three-antenna approaches) were presented for determining the radiation and total efficiency of antennas (Holloway et al. 2012).

For the one-antenna approach, the measurement setup is similar to Fig. 11, but we only need to use the AUT and one port of the VNA. Other antennas are not needed; thus, it is simpler. It was shown (Holloway et al. 2012) that the total efficiency of the AUT can be computed using

$$\eta_{\text{Total}} = \sqrt{\frac{C_{RC}}{2\omega}\frac{\left\langle |S_{11s}|^2 \right\rangle_{RC}}{\tau_{RC}}} \tag{22}$$

where

ω is the angular frequency

$C_{RC} = \frac{16\pi^2 V}{\lambda^3}$ is a chamber constant and V is the volume of the chamber

τ_{RC} is the chamber time constant ($= Q/\omega$, Q is the chamber quality factor)

$\langle |S_{11s}|^2 \rangle$ represents the stirred energy contribution of the AUT S_{11} inside the RC

Thus, a measurement of $\langle |S_{11s}|^2 \rangle$ and τ_{RC} is all that is required to obtain the total radiation efficiency of a single antenna. If radiation efficiency is required, it can be obtained using

$$\eta = \frac{\eta_{\text{Total}}}{1 - |S_{11}|^2} = \sqrt{\frac{C_{RC}}{2\omega}\frac{\left\langle |S_{11s}|^2 \right\rangle}{\tau_{RC}}} \Big/ \left(1 - |S_{11}|^2\right) \tag{23}$$

DOI 10.1007/978-981-4560-75-7_71-1

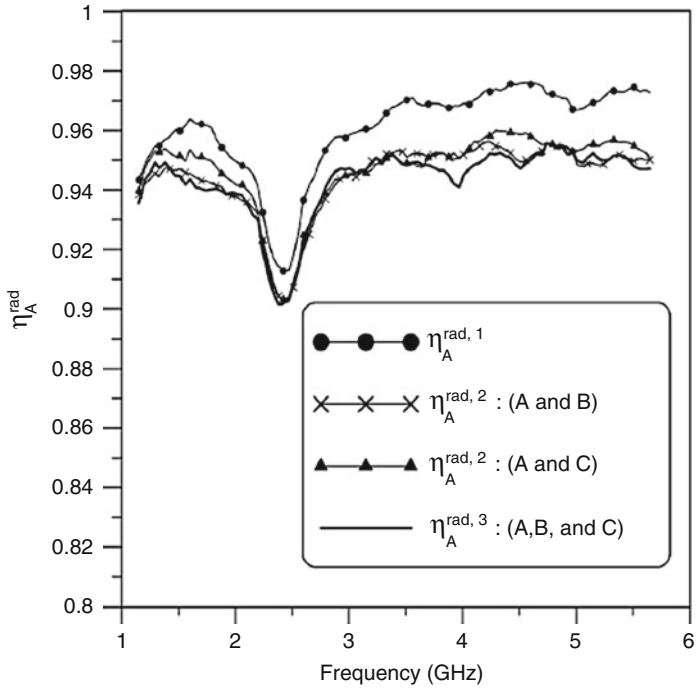

Fig. 13 Radiation efficiency: a comparison of three different approaches for antenna A (Holloway et al. 2012)

The measurement procedures for two-antenna approach and three-antenna approach are very similar. They require the measurements of $\langle |S_{11s}|^2 \rangle$ and τ_{RC} as well. The main differences are in the assumptions about the relationship between the power reflected into the antenna and the power received (Holloway et al. 2012). The three-antenna approach is more general and does not require such assumptions. The measurement results are very similar for all three approaches as we can see from the example in Fig. 13. The two-antenna approach seems to give the smallest uncertainty.

Compared with the RC method with a reference antenna, this method does not require a reference antenna with known radiation efficiency. But one has to calibrate the chamber carefully in the time domain to obtain the time constant – this is a time-consuming exercise. The good thing is that one just needs to calibrate the chamber once if the chamber performance/structure/loading is not changed, and the data can be used repeatedly.

Other Efficiency Measurement Methods for Small Antennas

There are many other methods and techniques developed over the years, but they are less popular or convenient for daily applications.

Radiometric Method

This is a classical measurement method (Ashkenazy et al. 1985); a low-noise receiver like a radiometer is required to measure the output noise power of the AUT in two different environments, typically a "warm target" (such as an anechoic chamber) and a "cold target" (such as the clear sky). A third measurement is required using a lossless standard antenna with a well-known antenna radiation pattern or a calibrated noise source. The antenna radiation efficiency can then be obtained using the results from these three measurements.

The problems of this method are the special equipment needed and the errors that may be caused by the inaccuracy of the noise sources, the mismatch of the AUT, and the drift of the receiver gain (Kraus and Marhefka 2002).

DOI 10.1007/978-981-4560-75-7_71-1

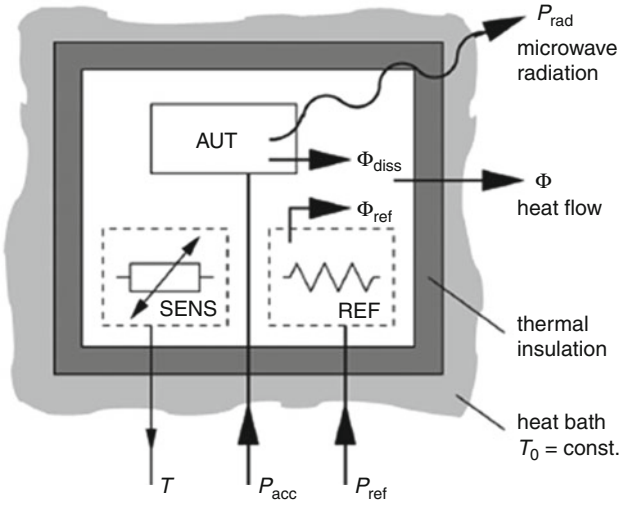

Fig. 14 The calorimetric method (Schroeder and Gapski 2006)

The Q-Factor Method

This technique is based on a comparison of the measured Q to ideal Q (Newman et al. 1975). The Q-factor is determined by energy stored, power radiated, and power dissipated. This method is also just suitable for electrically small antennas, and it is not as accurate and convenient as the Wheeler cap method; thus, it is not widely used.

Colorimetric Method

This interesting approach was proposed in 2006 (Schroeder and Gapski 2006). The operational principle is shown in Fig. 14, and it is based on measurement of antenna dissipation in a heat flow comparator. The most interesting feature is that neither a reference antenna nor site calibration is required. The measurement accuracy is high and suitable for wideband and small antennas. A main drawback seems to be the construction of the heat flow comparator. The measurement equipment and setup are not the standard in a typical antenna laboratory which may be an obstacle for becoming a main antenna efficiency measurement method.

Discussion and Comparison

The radiation efficiency is one of the most important parameters of an antenna, and many measurement methods have been developed. But so far, the "best method" has not been found: they all have their strengths and drawbacks. The search for the best antenna radiation efficiency measurement is still a task to be accomplished. Different methods are used in practice. The comparison of the measurement methods, especially about the accuracy and uncertainty based on published papers, is given in Table 1. The major features and drawbacks of each method are also provided. The provided accuracy limits and uncertainties are for a typical high-efficiency antenna case (for a low-efficiency case, 10 % would be quite significant). In practice, there are many other parameters, and considerations have to be taken into account, but not included here. For example, the Wheeler cap method seems to offer the best accuracy for electrically small antenna measurement, provided that the antenna impedance can be accurately measured – as it was mentioned earlier, this could be a problem for some antennas. If the antenna impedance was not measured accurately, the radiation efficiency error would be >3 %.

DOI 10.1007/978-981-4560-75-7_71-1

Table 1 Comparison of measurement methods

Measurement method	Accuracy (%)	Note
Pattern integration	<20	Suitable for most antennas. 3D radiation measurement required, time-consuming, and poor accuracy
Directivity/gain	<20	Suitable for a wide range of antennas, in particular directional antennas
Wheeler cap	<3	Suitable for electrically small antennas, cost-effective, quick, accurate, and little data processing
Sliding wall cavity	<5	Suitable for many small antennas, cost-effective. A special cavity required
UWB Wheeler cap	<10	Suitable for wideband and small antennas, cost-effective, quick, and simple data processing
Source-stirred cap/chamber	<5	Suitable for a wide range of antennas, cost-effective, quick, and little data processing
RC with a reference antenna	<10	Suitable for both large and small antennas and systems. A reference antenna with known radiation efficiency required, time-consuming, and the frequency >LUF
RC without a reference antenna	<10	Suitable for both large and small antennas and no reference antenna required. A lengthy chamber calibration required and the frequency >LUF
Radiometric	<15	Suitable for many antennas. Special equipment required
Q-factor	<10	Suitable for electrically small antennas, not as simple as the Wheeler cap method
Calorimetric	<5	Suitable for small antennas and systems (e.g., a mobile phone). A special heat flow comparator required

Conclusion

In this chapter, various methods used for measuring antenna radiation efficiency have been discussed. The classical pattern integration and directivity/gain methods are general, but the measurement could be time-consuming, and the measurement accuracy is normally poor. The Wheeler cap method has got many excellent features but is only suitable for electrically small antennas. A number of modified Wheeler cap methods have been discussed in details. The UWB Wheeler cap method and the source-stirred cavity/chamber method are gaining popularity for small antenna measurements. The latter may offer more accurate results for some antennas since it can better control the modes inside the cavity/chamber. The RC methods have received a lot of attention recently, and significant developments have been made. They are suitable for a wide range of antennas, large or small, even installed antennas, which is a very attractive feature of the RC. The application of the RC for diversity and MIMO antenna measurements is another interesting development of this useful facility.

Abstract

This chapter deals with mm-wave and sub-mm-wave probe-fed antenna measurements. First, worldwide state-of-the-art measurement solutions are presented. Then, the most interesting solutions to achieve the RF and mechanical parts of an mm-wave probe-fed measurement setup are described. In a second subpart, the focus lies on possible measurements and associated techniques to perform accurate characterization of probe-fed mm-wave antennas. Special attention is given on reflection coefficient measurements, gain measurements and associated calibration techniques, novel phaseless techniques developed for the characterization of circularly polarized antennas, hybrid total efficiency computations from simulation and measurements, near-field and phase measurements, and possible source of errors taking place in those mm-wave probe-fed measurement setups. A last subpart deals with measurements above 110 GHz as today no coaxial connection exists, and therefore rigid waveguide connections have to be employed at those frequencies. Lastly, open problems are discussed, and future directions for the coming years are proposed.

Keywords

Mm-wave measurement system; Probe-fed antenna; Microelectronic probe; Gain measurement; Calibration technique; Circularly polarized mm-wave antenna; Total efficiency; Near-field measurement; Phase measurement

Introduction

CMOS integrated circuits have already proven to be efficient at mm-wave frequencies. In parallel, there is today a strong interest for several license-free frequency bands in the millimeter-wave spectrum. For example, at 60 GHz, WiGig and Wi-Fi Alliance united in 2013. By 2015, it is expected that products operating in the 60-GHz frequency band will deliver multi-gigabit speeds, low latency, and security-protected connectivity between nearby devices (Wi-Fi). Other frequency bands that are strongly target are 77 GHz for automotive radar system and 94 GHz for imaging radar sensors.

Consequently, there is a strong need of mmW and sub-mmW measurement setups for antenna characterization. It is obvious that as the frequency increases, the size of the antenna decreases, and new problems are encountered with their characterization. In parallel, as the frequency increases, the interconnection losses also increase. Therefore, the antenna needs to be as close as possible to the circuitry. Recent developed solutions have proved that antenna-in-package (AiP) might be an efficient solution (Titz et al. 2012d; Pilard et al. 2012). Measurements in anechoic chambers using connector-fed

DOI 10.1007/978-981-4560-75-7_76-2

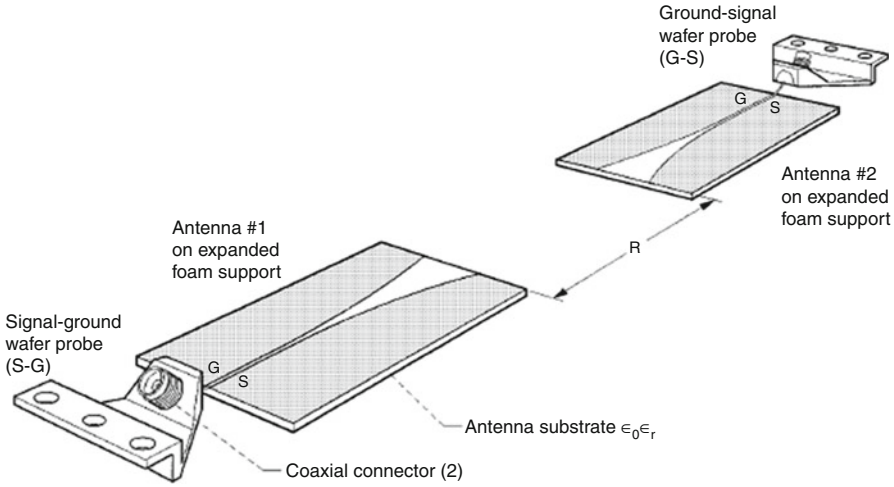

Fig. 1 Gain measurement of two identical antennas on a probe station proposed in Simons and Lee (1999)

antennas are still possible up to 110 GHz. But, above 30 GHz, the wavelength decreases below 10 mm, and the connector begins to be as big as or bigger than the antenna itself. Therefore, it can radiate more than the antenna itself and strongly disturb the radiation pattern from the antenna that wants to be characterized (Ranvier et al. 2009). Moreover, these connectors are difficult to solder to such small antennas. The other solution that can be used even above 110 GHz is to feed the antenna with a waveguide (Lamminen et al. 2008). However, this last solution is not possible or adequate for all topologies of antennas. The last possible solution already used for microelectronic circuit measurement is to feed the antenna under test with a microelectronic probe. This is particularly important for integrated antennas or even AiP as they will be fed exactly where the IC will be connected in the final application. It has been shown that even if it will slightly disturb the radiation pattern, its influence is less noticeable than a connector-fed solution at 60 GHz (Ranvier et al. 2009).

Therefore, in this chapter, the focus will be on probe-fed antenna measurements at mmW and sub-mmW frequencies. After a rapid overview of the worldwide existing setups, all the RF and mechanical parts needed in a probe-fed measurement setup are described. Finally, several measurement procedures are explained and referred to existing setups. A last subpart deals with measurements above 110 GHz, and lastly, open problems are discussed, and future directions for the coming years are proposed.

Building a Probe-Fed Measurement Setup

Overview of Worldwide Measurement Setups

The first on-wafer antenna measurements are reported in 1997 and 1999 by Simons and Lee (1997, 1999). In this setup, the metallic chuck has been replaced by a block of foam to avoid unwanted metallic reflections, and all the surrounding unavoidable metallic parts have been covered with microwave absorbers. Two identical antennas are placed at a distance R from each other, and the gain is computed from the measured S_{21} using the Friis equation. The antenna-to-antenna distance is chosen to be larger than the far-field distance. Using a calibration substrate, the feeding probe of the antenna under test (AUT) is calibrated to the tip of the probe. Measurements are done with an HP 8510C automatic network analyzer (Fig. 1).

DOI 10.1007/978-981-4560-75-7_76-2

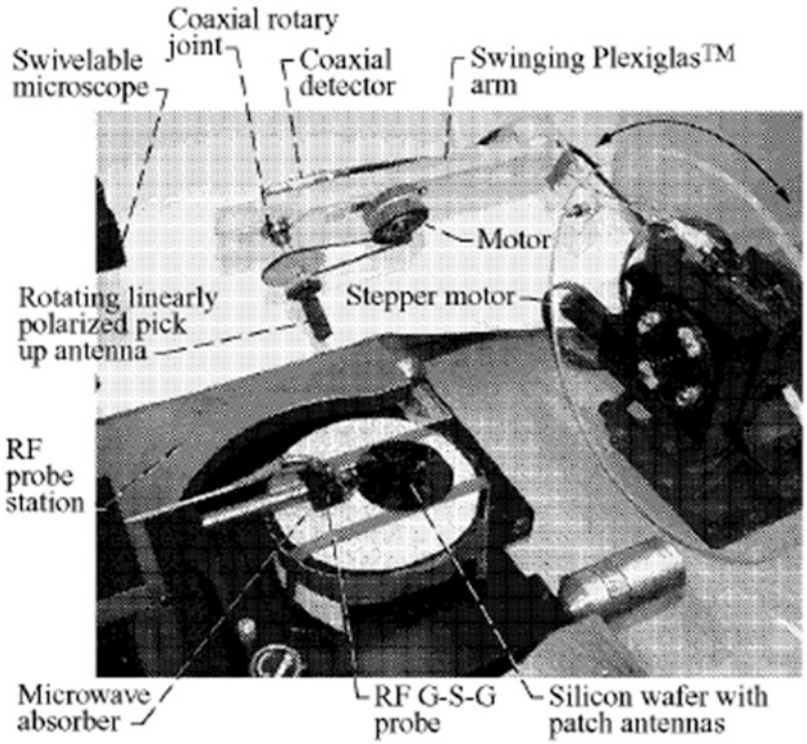

Fig. 2 Radiation pattern measurement of an antenna using a customized probe station proposed in Simons (2002)

However, with this first attempt, the position of the two antennas is fixed, and the gain in the end-fire direction can be measured only. In Simons et al. (2001) and Simons (2002), the classical RF probe station was modified to enhance the measurement possibilities. A small horn antenna or an open waveguide is attached to a Plexiglas arm which can be rotated (using a motor) to acquire the field intensity along an arc. The antenna is still fed using a microelectronic probe, and all the metallic parts remain covered by absorbers. Especially, the wafer where the antenna lies is separated from the metallic chuck by an absorber. Also, the acquisition waveguide can be rotated by 90° to measure co- and cross-polarization gains (Fig. 2).

This setup has still limitations as only the upper part of the sphere around the AUT can be measured because of the blockage of the chuck. The first entirely customized measurement setup for mmW antennas was proposed in Zwick et al. (2004). To avoid unwanted reflections from all the metallic parts of a probe station, the probe positioner was moved out of the probe station and placed in a small anechoic chamber on an isolation table. The AUT is held by a custom holder, and a standard gain horn can be rotated all around it, thanks to a motorized arm. The axis of the motor can be mounted in three different ways so that the radiation patterns can be measured in three different planes. The horn is set at 38 cm from the AUT to ensure a suitable condition for far-field operation. With this setup, S_{11} gain in one direction and in three different planes can be measured using a vector network analyzer (VNA). Special calibration procedures are detailed later in this chapter. For the first time, the radiation of the probe itself is investigated. A complete overview of this setup can be found in Zwick and Pfeiffer (2009; Figs. 3 and 4).

The first quasi-3-D radiation pattern measurement setup was proposed in Ranvier et al. (2009). Using two rotating arms, the gain of the AUT can be measured in all directions with the exception of the region which is blocked by the probe positioner. A very similar setup was developed in parallel and presented in Beer and Zwick (2010; Figs. 5 and 6).

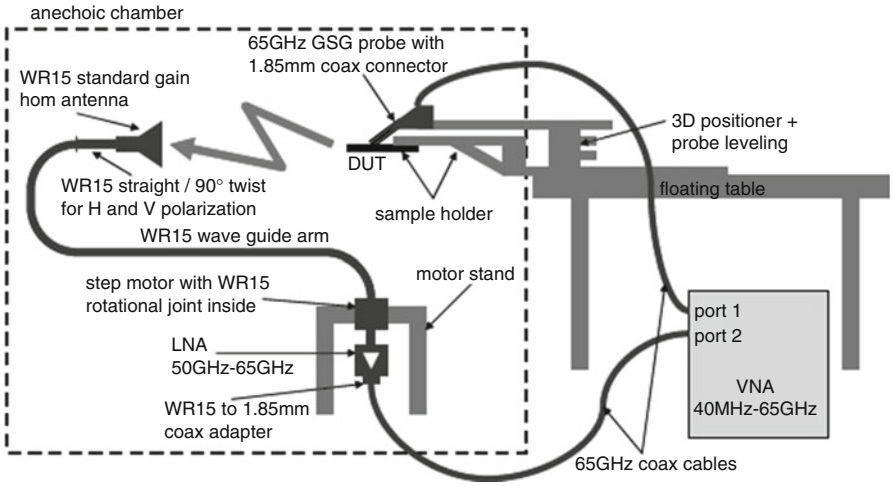

Fig. 3 Probe-fed measurement setup diagram proposed in Zwick et al. (2004)

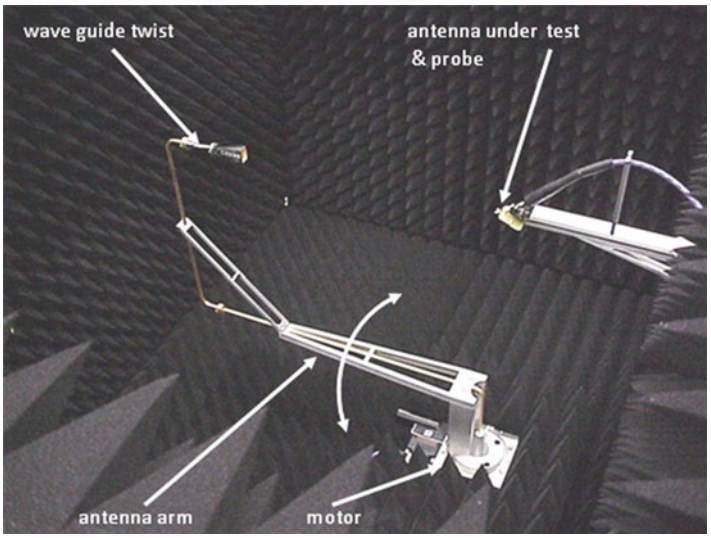

Fig. 4 Probe-fed measurement setup picture proposed in Zwick et al. (2004)

Several other measurement setups have been recently developed worldwide. Most of them have been listed and compared in Table 1. Most of them adopted a probe feeding technique for the AUT. Depending on the implemented RF parts, they are able to measure both S_{11} and gain radiation pattern or, at least, one of them. Depending on the mechanical parts, they are able to measure almost 3-D pattern or only plane cuts.

RF Parts

The RF equipment needed for mmW antenna measurements depends on the measurement which wants to be carried out. Basically, the measurements can be divided in two categories: reflection coefficient (S_{11}) and gain/radiation pattern measurements. As mentioned, the best way to feed an mmW antenna without disturbing it, especially if it is integrated either in a package or a chip, is to use a microelectronic probe. Of course, if the antenna is deported and is connected by a cable or waveguide in the final application, the

DOI 10.1007/978-981-4560-75-7_76-2

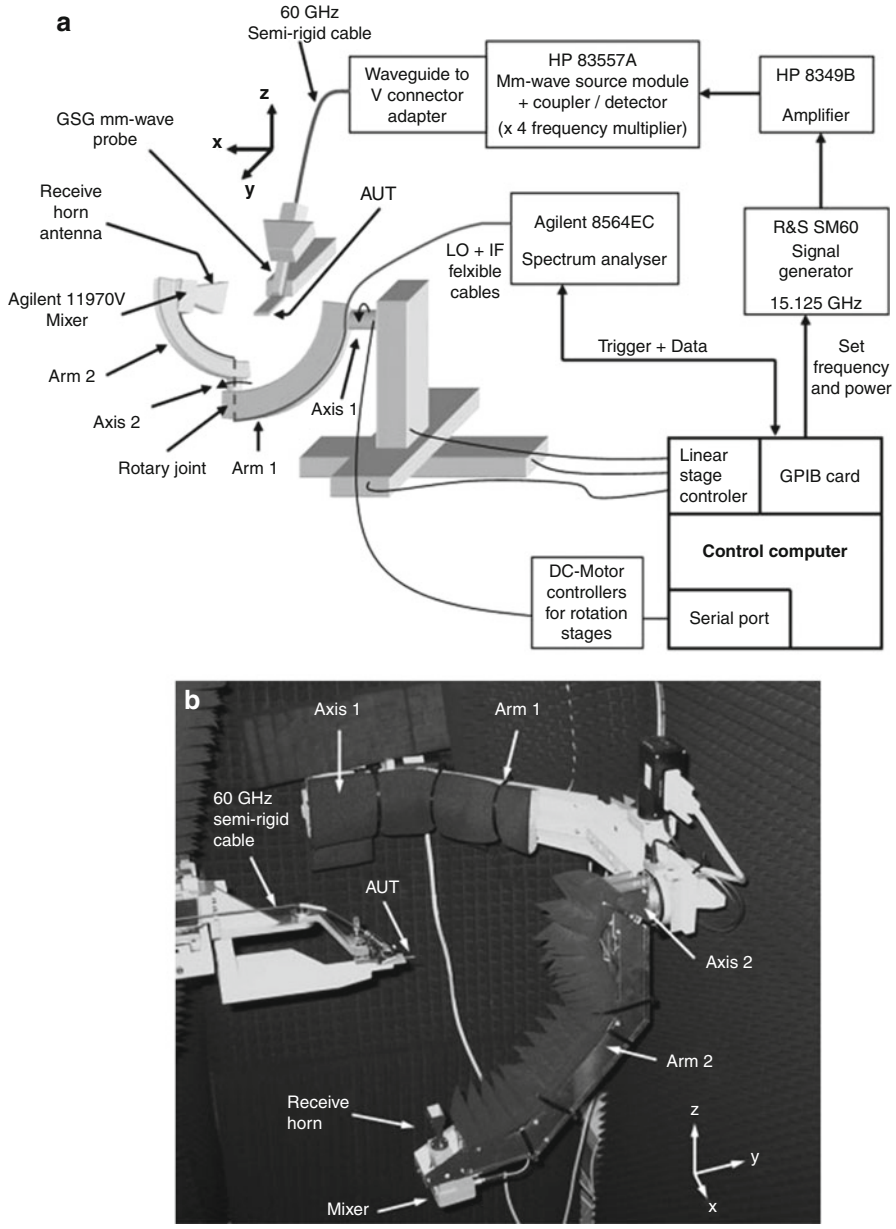

Fig. 5 3-D probe-fed measurement setup diagram (**a**) and picture (**b**) proposed in Ranvier et al. (2009)

probe is obviously not the best option. However, this tends to be less and less true as the operating frequency increases. So, this chapter mainly focuses on probe-fed measurements.

The selection of the microelectronic probe to be used depends on the frequency range and the pitch of the feeding pad of the AUT. Table 2 lists the available microelectronic probes with various pitches and associated losses. Table 3 lists some technical characteristics of the main commercial probes. As the size of the tip of the probe is very small and needs to be aligned on the antenna pads with precision, a microscope and a probe positioner are necessary. Indeed, microelectronic probes are very fragile and expensive, and they especially need to be treated with precaution.

For reflection coefficient measurement, a vector network analyzer (VNA) or PNA is needed. Using a reference calibration substrate (supplied by the probe manufacturer) and a proper calibration method (Fakharzadeh 2014), the reference plane of the measurement can be set at the tip of the probe. The most

DOI 10.1007/978-981-4560-75-7_76-2

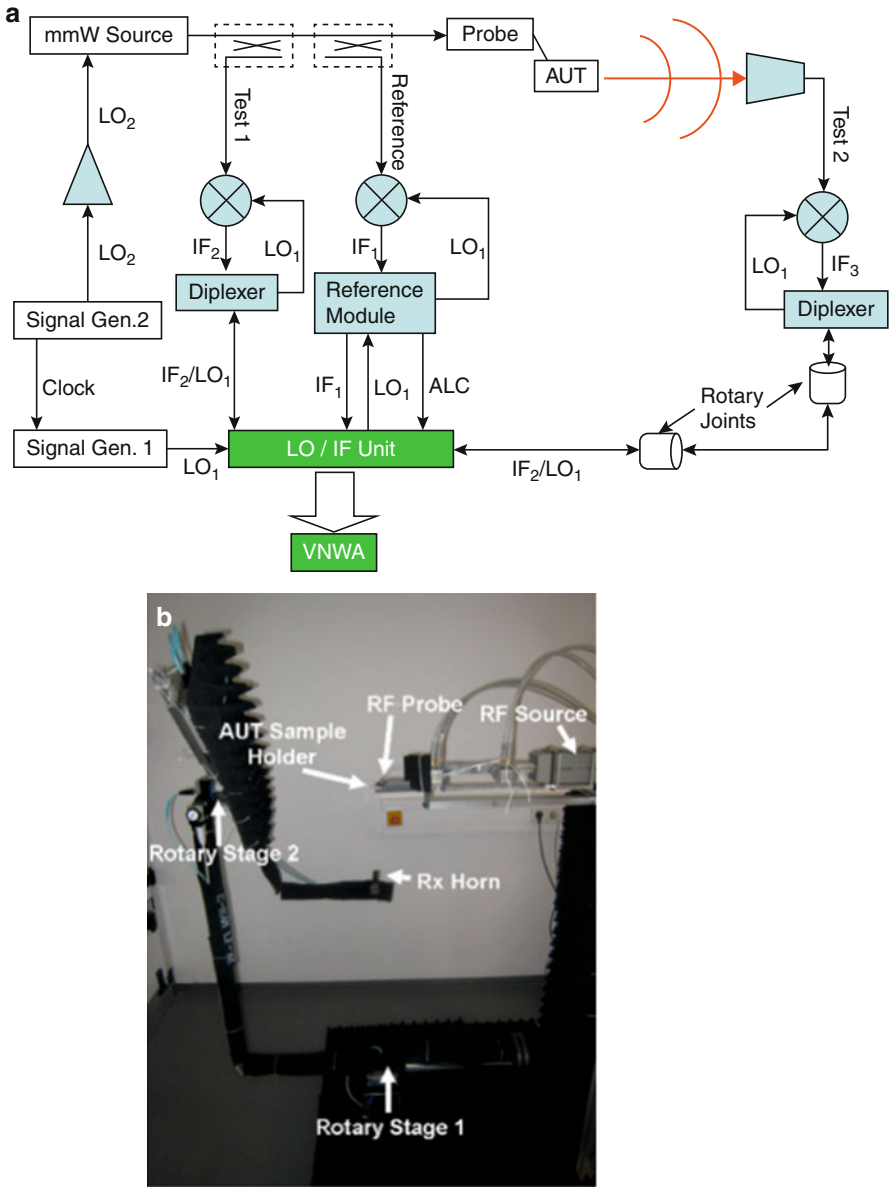

Fig. 6 3-D probe-fed measurement setup diagram (**a**) and picture (**b**) proposed in Beer and Zwick (2010)

commonly used method is a two-port method called the short-open-load-thru (SOLT) calibration. However, this method requires two probes and two positioners and thus is really difficult to achieve apart from a typical probe station. For antenna measurement, a one-port calibration is sufficient. Moreover, it can be done easily by using a short-open-load (SOL) method (Beer and Zwick 2010).

For gain/radiation pattern measurement, the RF equipment can be more varied. Gain and radiation patterns can be indeed measured separately. Gain measurement needs accurate RF equipment and calibration procedure, while radiation pattern can be normalized to the maximum received power. In each case, a signal needs to be generated at the right frequency and received adequately. It has been considered here that the AUT is the transmitting antenna, and a standard horn antenna is used at the receive side.

The signal can be generated by a VNA (Titz et al. 2012b). In this case, both S_{11} and gain measurements can be done with the same RF equipment. The visualization of the S_{11} before any gain measurement is also

quite important to verify that the probe correctly touches the antenna pads. Current VNAs can generate a signal up to 67 GHz. For frequencies above 67 GHz, mmW extenders or mmW transmit/receive (T/R) modules can be used (Bisognin et al. 2014). However, such VNAs are quite expensive, and mmW antennas can be measured as well using a low-frequency signal generator (eventually followed by an amplifier) which frequency is then multiplied by an mmW source module to obtain the desired one (Titz et al 2012b). In this case, S_{11} has to be measured separately (and differently), but the input power delivered to the AUT can be higher hence improving the dynamic range of the measurement setup. In both cases, this input power has to be known to be able to compute the gain of the AUT. Another low-cost solution using a local oscillator at the right frequency is presented in Boone et al. (2011).

At the receive side, the horn antenna can be followed by several equipment. The VNA can be used also in reception. If the horn is fixed, a cable can directly link the horn antenna to the VNA. But at mmW frequencies, this cable should be fixed without moving for an accurate measurement (Hitzler et al. 2014). So, if cuts or parts of the 3-D radiation pattern have to be measured, a better solution is to use a mixer which is attached to the horn antenna to directly down-convert the signal to low frequency. An mmW extender can also be mounted close to the horn antenna, but those extenders are usually quite heavy, and the feasibility of this option depends on the mechanical rigidity of the assembly. The mixer has to be fed by a local oscillator (LO) signal, and it will transmit back an intermediate frequency (IF) signal. These two signals can be conveyed by flexible cables as their operating frequency is much lower than mmW. Some mixers are now integrated with a diplexer, so only one cable is necessary for proper operation.

DOI 10.1007/978-981-4560-75-7_76-2

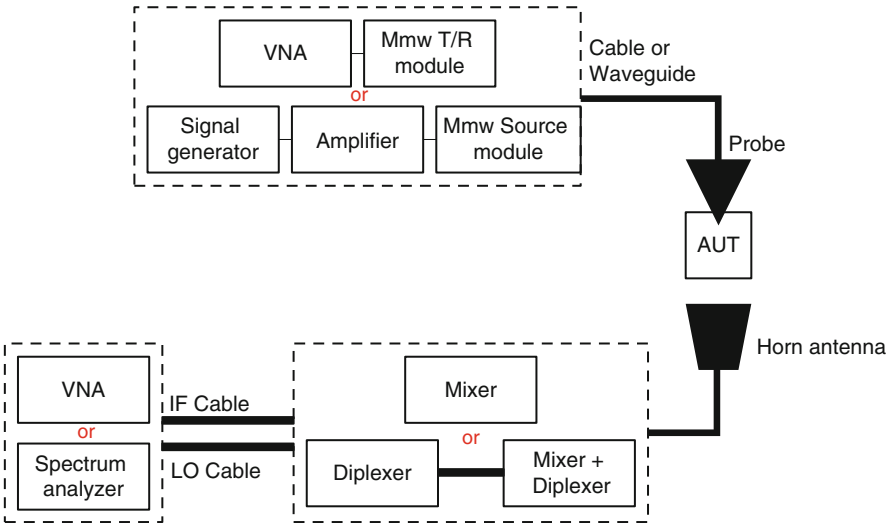

Fig. 7 RF equipment for gain measurement of an mmW antenna

The IF signal can then be received either by the VNA or by a spectrum analyzer. The LO signal needs to be generated by a signal generator. It can also be provided by a VNA or a spectrum analyzer (if they include such possibilities). A diplexer can be used before this equipment to separate the LO and IF signals if only one cable is used. If the reception is done by a VNA, another mixer has to be used for reference purpose. The dynamic range of a spectrum analyzer is usually higher than that of a VNA. So, if low-gain antennas are to be measured, a spectrum analyzer should be preferably used (Van Caekenberghe et al. 2008). Moreover, the noise floor of the spectrum analyzer can be lowered by modifying the bandwidth of the IF filter (Titz et al. 2012b). Figure 7 gives a quick sketch of the main options to measure the gain of an mmW antenna. These RF equipments are different from those used in anechoic chambers at lower frequencies (see chapter on ► Antenna Measurement/Setups-Introduction). An example of the needed RF equipment for measurements at 120 GHz is given in Fig. 8 (Bisognin et al. 2014).

Mechanical Parts

The mechanical parts are probably the most important in an mmW measurement setup. Due to the use of a microelectronic probe to feed the AUT, a fair mix and compromise have to be reached between classical anechoic chambers and microelectronic measurements.

AUT Holder

Indeed, the close environment of a probe tester is usually all metallic, composed of a chuck base, a microscope, the feeding probe(s), and the positioner. The first measurements made in this way proved that the radiation pattern was completely disturbed (Lanteri et al. 2010). Even if the authors from Murdock et al. (2011) proposed a way to remove the interference originating from a wafer probe, it is definitely safer to perform the characterization of the antenna in a very "clean" close environment. A first obvious step is to get rid of the metallic chuck as done in Zwick et al. (2004), Akkermans et al. (2007), Van Caekenberghe et al. (2008), and Pilard et al. (2009). In Zwick et al. (2004), no chuck was used, and the antenna was maintained by two substrate pieces of FR4 (flame resistant 4). In Pilard et al. (2009), the metallic chuck was replaced by a rexolite support. A better solution would be to use a material with a lower permittivity possibly close to one. Hence, the radiation pattern of the AUT would not be disturbed by its holding pieces: the chuck and the holder. In Akkermans et al. (2007), the chuck is made of polystyrene (permittivity close to one). In Van Caekenberghe et al. (2008), a cavity with absorbers is placed below

DOI 10.1007/978-981-4560-75-7_76-2

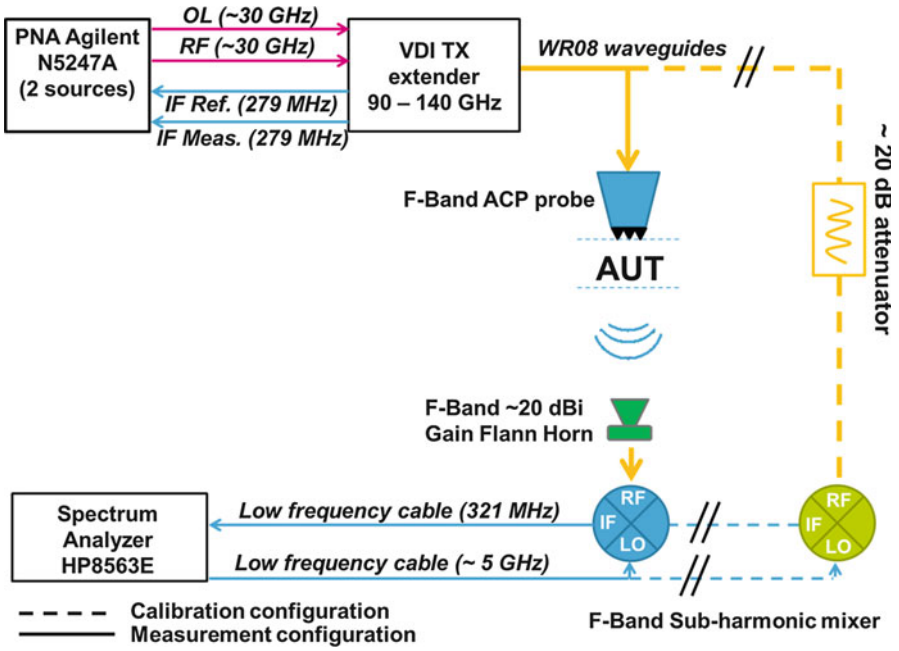

Fig. 8 90–140 GHz measurement setup – RF part from Bisognin et al. (2014)

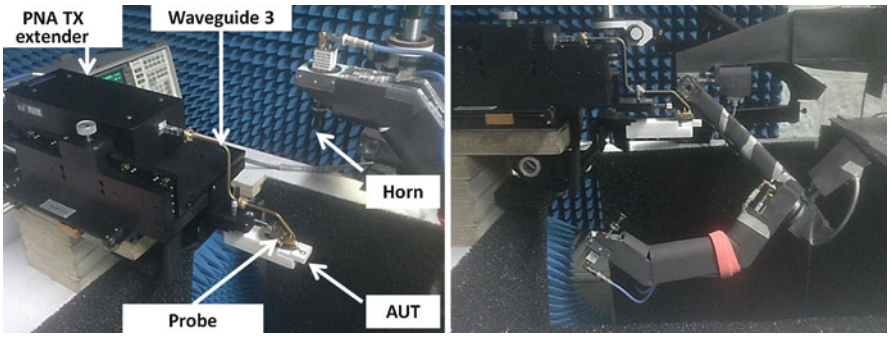

Fig. 9 Picture of the antenna holder in Bisognin et al. (2014)

the wafer. However, only the upper hemisphere of the radiation sphere is reachable by the receiving horn antenna. An even better solution would be to use a special holder made of foam. The radiation pattern below the antenna (if the antenna is fed by the probe on its top face) can thus be recorded, and the foam will not disturb the measurement at all as presented in Beer and Zwick (2010) and Titz et al. (2012a). In Bisognin et al. (2014), for each antenna, a specific foam holder is fabricated and screwed to another carrier foam. This last foam is 1 cm thick to be sufficiently rigid and horizontally planar. A cavity of the size of the AUT is created into the foam to properly maintain it. The special carrier is attached to a three-dimensional positioner, classically used in a probe station. This carrier greatly helps in leaving the space around the AUT free of any objects (Fig. 9). Of course, all remaining close metallic parts of the setup need to be covered with microwave absorbers (Reniers et al. 2014).

Horn Holder and Arms

The other important mechanical part of the setup is the receive area. A special fixture has to be realized to hold the standard horn antenna. To measure one or two cut planes, one arm “loaded” by a small horn antenna can be driven along an arc by a stepper motor as in Simons (2002) and Lanteri et al. (2010).

DOI 10.1007/978-981-4560-75-7_76-2

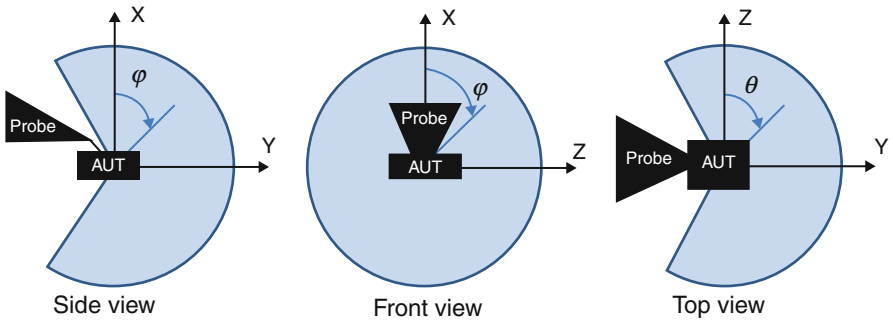

Fig. 10 Measurable parts of the sphere from the setup presented in Titz et al. (2012c)

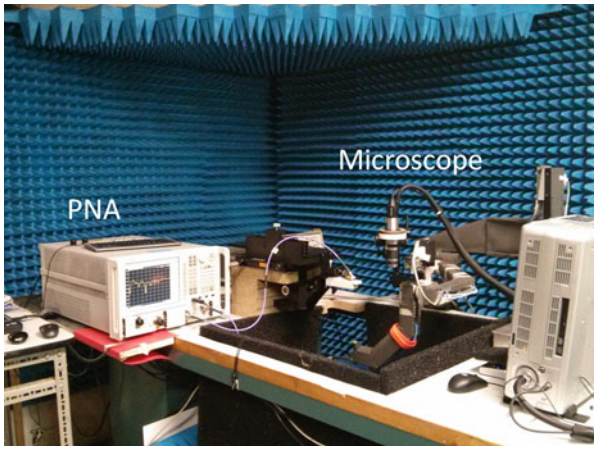

Fig. 11 Overall view of the measurement setup presented in Titz et al. (2012a)

With three different places for the motor, a wider range can be obtained as in Zwick et al. (2004) and Ito et al. (2009). To measure the upper hemisphere, an arm can be driven along a table as in Akkermans et al. (2007), or an arch can be made around the AUT and the horn can move along it as in Willmot et al. (2009) and Sun et al. (2011). The measurement of the lower hemisphere is proposed in Mohammadpour-Aghdam et al. (2011) using a hollowed table. However, to be able to measure almost 3-D pattern around the AUT, at least two arms are needed as in Ranvier et al. (2009), Beer and Zwick (2010), and Chin et al. (2014). Of course, the whole 3-D pattern cannot be measured as the probe positioned will always block a part of the sphere around the AUT (Fig. 10).

Depending on the distance between the receiving horn and the AUT, also the rigidity of the arms has to be taken into account. From Ranvier et al. (2009) to Titz et al. (2012a), the arms were modified from polyurethane to lightweight aluminum because the horn was slightly shaking during the rotation of the arm. Moreover, the weight of the horn and mixer (or the mmW extender if it exists) is not negligible and must be counter balanced if possible as demonstrated in Van Caekenberghe et al. (2008), Beer and Zwick (2010), and Mohammadpour-Aghdam et al. (2011). With a two-arm setup, the cable assembly has also to be treated with care. To avoid twisting the cables from the mixer, one or several rotating joints are necessary (if no diplexer is used).

Finally, the setup has to be positioned on a heavy and anti-vibration table to avoid any vibration during the measurement (which could damage the microelectronic probe). In Titz et al. (2012a), a table was purposely cut to let the rotating arms turning around the AUT (Fig. 11). The table was additionally

DOI 10.1007/978-981-4560-75-7_76-2

covered with absorbers to avoid any electromagnetic reflections. All the RF and mechanical parts are controlled from a laptop via a general purpose interface bus (GPIB) and a custom-made LabView code.

Measuring with a Probe-Fed Measurement Setup

A big task in antenna measurement setups is the calibration of the system in order to get the most accurate measurement results. The calibration is normally divided into three parts: a mechanical calibration to align the AUT exactly within the receiving part of the measurement setup, a gain calibration, and a probe calibration to get an accurate reflection coefficient. The latter two calibrations will be described in the following two sections.

S_{11} Measurement

For reflection coefficient measurements, a vector network analyzer (VNA) or PNA is needed. Using a reference calibration substrate usually supplied by the probe manufacturer and a proper calibration method, the reference plane of the measurement can be set at the tip of the probe. For antenna measurement, a one-port calibration is sufficient: a short-open-load (SOL) method is sufficient to achieve accurate measurements. The short and load standard calibrations are always done by placing the microelectronic probe over a new calibration area. The open standard is achieved by leaving the probe in air, at least 200 μm away from the calibration substrate. It should be noted that sufficient time is needed before starting a new calibration once the mm source or PNA are turned on (few hours). Once this calibration is done, a checking procedure is recommended to verify the accuracy of the achieved current calibration. Therefore, the microelectronic probe is specifically landed over another calibration site and connected to short, open, and load standards. Those measurements give always "worse" values than the values just recorded with the achieved calibration, but the calibration is considered to be sufficiently accurate if short and open S_{11} measurements stay within ± 0.05 dB and if the S_{11} load measurement is below -40 dB (see Fig. 12 for a realistic example achieved with the University of Nice measurement setup).

Gain Measurement and Calibration

If not only the radiation pattern of an AUT but also its gain is needed, a kind of gain calibration has to be taken out. From theory, there exist three kinds of gain calibration methods: the two-antenna method, the three-antenna method, and the gain-comparison method. However, in practice, almost only the gain-comparison method is used. In this method, the receiving power of a well-known standard antenna is measured in the same environment as the AUT will be. Then, the standard antenna is replaced by the AUT and the received power is recorded. With the power ratio of the signal received by those two antennas, the gain of the AUT can then be retrieved.

Figure 13 shows the main block diagram of an mmW antenna measurement setup like the one at Karlsruhe Institute of Technology (Beer et al. 2011). The first step before taking out a measurement is now the calibration of the waveguide output of the VNA extension module. This is done with a "short-open-load" calibration (Fig. 14).

After this is done, a standard horn antenna is placed at the exact same position at which later on the AUT will be mounted. Thus, the free-space losses as well as the transmission losses of the system can be taken into account. Figure 15 depicts the standard antenna measurement. Its gain G_{cal} is obtained from the gain of the horn G_{Horn} and the (negative) gain of the waveguide with which the horn is attached.

$$G_{\mathrm{cal}} = G_{\mathrm{Horn}} \cdot G_{\mathrm{Waveguide}} \tag{1}$$

DOI 10.1007/978-981-4560-75-7_76-2

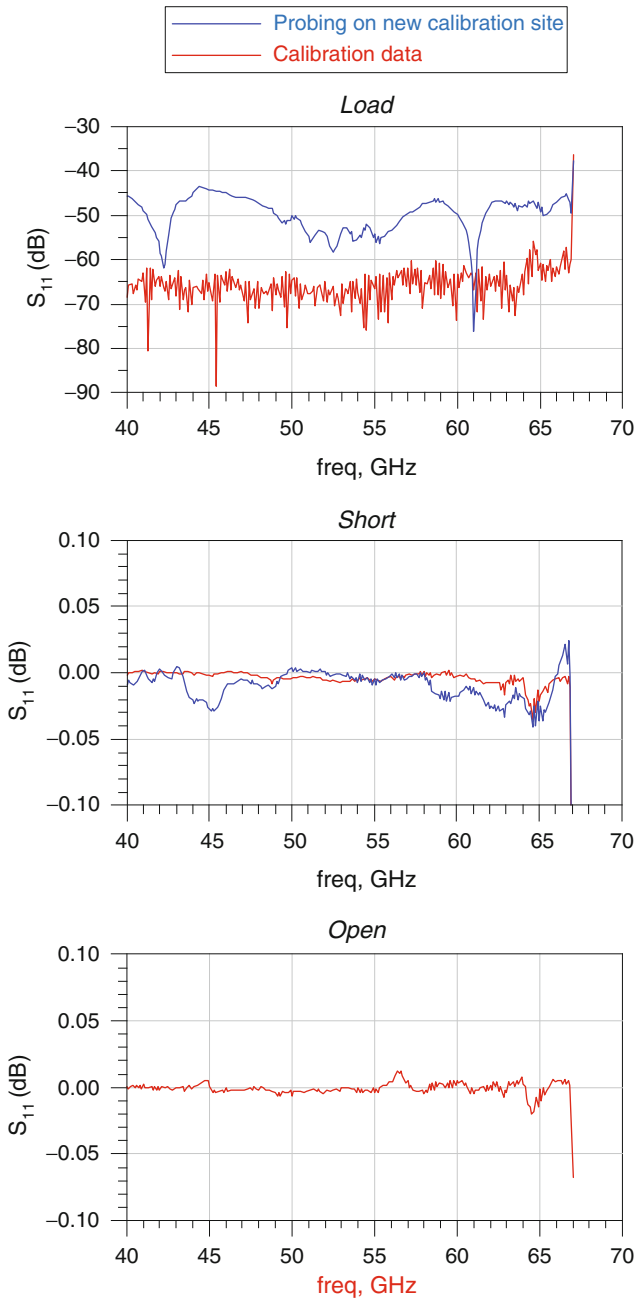

Fig. 12 Checking the calibration accuracy of an ACP 65 AW GSG 200 μm with an ISS: 101-190 substrate by landing the probe over a different site for short, open, and load standards (University of Nice measurement setup)

With the resulting $S_{21,\mathrm{cal}}$ of the transmission measurement incorporating the horn antenna, the system losses G_{System} which represent the system losses, the free-space loss, and the gain of the horn antenna itself can be computed.

$$G_{\mathrm{System}} = \frac{\left|S_{21,\mathrm{cal}}\right|^2}{G_{\mathrm{cal}}} \tag{2}$$

DOI 10.1007/978-981-4560-75-7_76-2

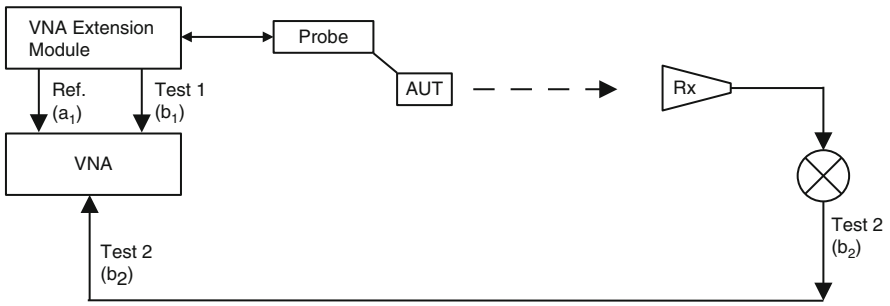

Fig. 13 Block diagram of an mmW antenna measurement setup

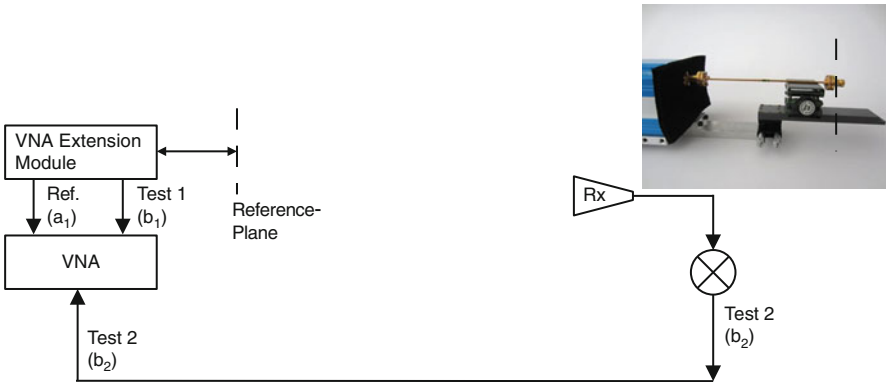

Fig. 14 One-Port SOL calibration at the output of the VNA extension module

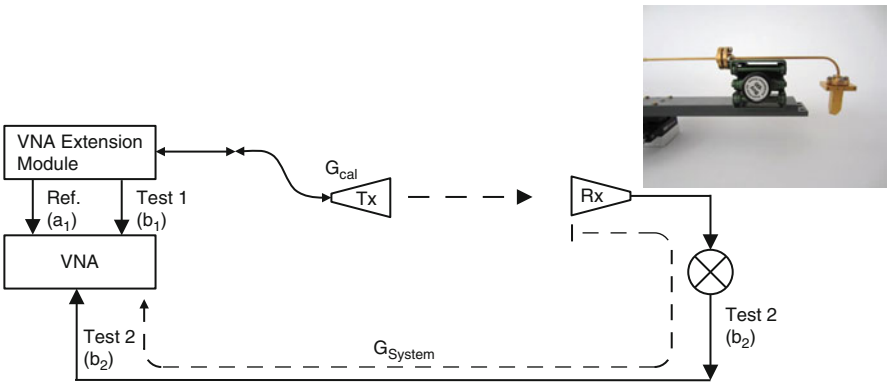

Fig. 15 Measurement of the standard gain antenna

To get now the correct gain of an AUT which is contacted with a probe, the losses of the probe itself G_{Probe} have to be known. Then, the gain of the AUT will be

$$G_{\text{AUT}} = \frac{\left|S_{21,\text{m}}\right|^2}{G_{\text{System}} \cdot G_{\text{Probe}}} \tag{3}$$

where $S_{21,\text{m}}$ is the measured transmission of the AUT. How G_{Probe} is calculated with a SOL calibration is described thereafter.

DOI 10.1007/978-981-4560-75-7_76-2

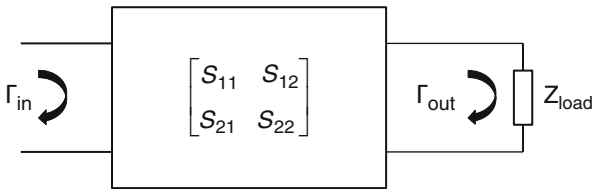

Fig. 16 Schematic of a quadripole loaded by Z_{load}

It should be noted that an alternative method from Purcell (1943) is presented in Brebels et al. (2013). This method is really appealing when applied at mm-wave frequencies, but so far, the initial conference publication was not followed by in-depth journal publication with more analysis and measurement data.

G_{Probe} Extraction Using the Three-Gamma Method

The losses from the probe can be taken from the manufacturer data sheet, but such data do not always exist and sometimes are just given as rough averaged numbers even not as a function of frequency. These probes are indeed different in terms of size, pitch, and design (see Tables 2 and 3). Consequently, they do not always behave as a 50 Ω series device and indeed induce different insertion losses. These losses are non-negligible in the link budget computed during the calibration procedure necessary for a proper extraction of the antenna gain. Therefore, knowing these losses could indeed further improve the overall accuracy of the measurement setup.

In the following, a way is described to extract the S-parameter of any probe using the three-gamma method (Titz et al. 2014).

A representation of a quadripole characterized by S_{ij} parameters and loaded by impedance Z_{load} is given in Fig. 16.

It has an input and output reflection coefficient named Γ_{in} and Γ_{out}. The input reflection coefficient depends on the output reflection coefficient:

$$\Gamma_{in} = S_{11} + \frac{S_{12}S_{21}\Gamma_{out}}{1 - S_{22}\Gamma_{out}} \tag{4}$$

which itself depends on the load Z_{load}. Then, if the quadripole (i.e., the probe in this case) is loaded by three different reference impedances (open, short, and load), three equations with three unknowns may be obtained:

$$\begin{cases} \Gamma_{in\_open} = S_{11\_probe} + \dfrac{S_{12\_probe}S_{21\_probe}\Gamma_{out\_open}}{1 - S_{22\_probe}\Gamma_{out\_open}} \\ \Gamma_{in\_short} = S_{11\_probe} + \dfrac{S_{12\_probe}S_{21\_probe}\Gamma_{out\_short}}{1 - S_{22\_probe}\Gamma_{out\_short}} \\ \Gamma_{in\_load} = S_{11\_probe} + \dfrac{S_{12\_probe}S_{21\_probe}\Gamma_{out\_load}}{1 - S_{22\_probe}\Gamma_{out\_load}} \end{cases} \tag{5}$$

By writing it as a matrix equation

$$\begin{bmatrix} \Gamma_{in\_open} \\ \Gamma_{in\_short} \\ \Gamma_{in\_load} \end{bmatrix} = \begin{bmatrix} 1 & \Gamma_{in\_open}\Gamma_{out\_open} & \Gamma_{out\_open} \\ 1 & \Gamma_{in\_short}\Gamma_{out\_short} & \Gamma_{out\_short} \\ 1 & \Gamma_{in\_load}\Gamma_{out\_load} & \Gamma_{out\_load} \end{bmatrix} \begin{bmatrix} S_{11\_probe} \\ S_{22\_probe} \\ -\Delta_s \end{bmatrix} \tag{6}$$

$$[\Gamma_{in}] = [\Gamma_{3\times3}][S_{probe}]$$

DOI 10.1007/978-981-4560-75-7_76-2

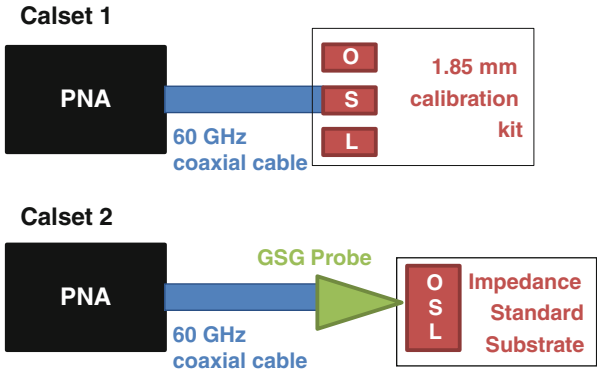

Fig. 17 Procedure for the three-gamma method

The three unknowns are now S_{11_probe}, S_{22_probe}, and Δ_s, defined in

$$\Delta_s = S_{11\_probe}S_{22\_probe} - S_{12\_probe}S_{21\_probe} \tag{7}$$

A passive probe is a reciprocal quadripole, and then S_{12_probe} is equal to S_{21_probe}. Thus, the S_{ij} parameters can be extracted from

$$\left[S_{probe}\right] = \left[\Gamma_{3\times3}\right]^{-1}\left[\Gamma_{in}\right] \tag{8}$$

and further the insertion loss of the loaded probe from the computed S_{21_probe}.

From the developed equations, two sets of data need to be measured: Γ_{in} and Γ_{out}. To do that, two different "one-port" calibrations must be done. The first calibration is done in a physical plane set before the probe, at the end of the coaxial cable (or the waveguide). With this calibration, it will be able to measure Γ_{in} when the probe is loaded with the three reference standards. The second calibration is set in a physical plane taken after the probe, with the help of a calibration substrate. It will give Γ_{out}. After these two calibrations, the probe can be loaded by the reference impedances (open, short, load), and S_{11} can be measured with the two calibrations, calsets 1 and 2. The procedure for the three-gamma method is summarized in Fig. 17.

The global losses of the probe depend on the impedance value of the AUT. Indeed, from the two-port power gain theory, it is known that the transducer power gain (G_T), defined as the ratio of the power (P_{ant}) delivered to the load (here the AUT) to the power (P_{source}) available from the source (here at the end of the cable or waveguide), is given by

$$G_T = \frac{P_{ant}}{P_{source}} = \frac{\left|S_{21\_probe}\right|^2\left(1 - \left|\Gamma_{ant}\right|^2\right)}{\left|1 - S_{22\_probe}\Gamma_{ant}\right|^2} \tag{9}$$

or expressed in decibels:

$$10\log_{10}(G_T) = 10\log_{10}\left(\left|S_{21}\right|^2\right) + 10\log_{10}\left(1 - \left|\Gamma_{ant}\right|^2\right) - 10\log_{10}\left(\left|1 - S_{22}\Gamma_{ant}\right|^2\right) \tag{10}$$

where there is a first term corresponding to the losses of a perfectly matched probe, a second term corresponding to the mismatch loss of the antenna, and a third additional term. G_T clearly depends on the parameters of the probe and the reflection coefficient of the AUT (Γ_{aut}). In some particular cases, this

DOI 10.1007/978-981-4560-75-7_76-2

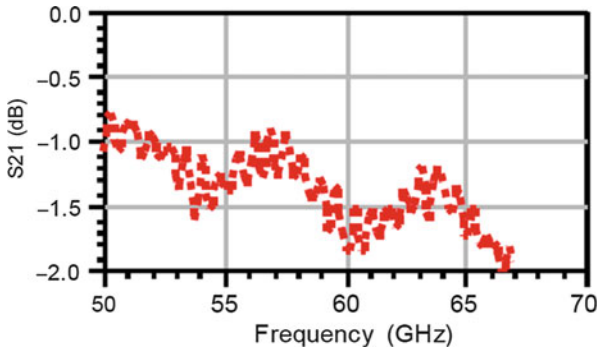

Fig. 18 Procedure for the three-gamma method

equation can be simplified. First, if the impedance of the antenna is purely 50 Ω (reflection coefficient is equal to zero), it becomes

$$G_{\mathrm{T}} = \left|S_{21\_\mathrm{probe}}\right|^2 \tag{11}$$

The global loss is then entirely due to insertion loss of the probe. If the probe is matched to 50 Ω, then S_{22} is equal to zero and it becomes

$$G_{\mathrm{T}} = \left|S_{21\_\mathrm{probe}}\right|^2 \left(1 - \left|\Gamma_{\mathrm{ant}}\right|^2\right) \tag{12}$$

The global loss is then indeed equal to the sum of the insertion loss of the probe and the mismatch loss of the AUT. In the previous part about gain measurement, the antenna is matched to 50 Ω, which means that, in fact, the realized gain is indeed computed. If now the IEEE gain from the measurement shall be computed to extract the mismatch loss, the insertion loss of the probe has to be substituted by the global losses. Therefore, the gain (G) can be extracted from the measured realized gain (G_{real}) using

$$\mathrm{G}(\varphi, \theta) = G_{\mathrm{real}}(\varphi, \theta) \frac{\left|1 - S_{22\_\mathrm{probe}}\Gamma_{\mathrm{ant}}\right|^2}{\left(1 - \left|\Gamma_{\mathrm{ant}}\right|^2\right)} \tag{13}$$

Further examples of such computations can be found in Titz et al. (2014). Figure 18 shows an example of the extracted losses of a 400-µm pitch probe given be 1 dB at 60 GHz by the manufacturer.

Circularly Polarized Antenna Measurements

It was demonstrated in Maltzev et al. (2010) that using circularly polarized (CP) antennas could be interesting when placed each at one side of a radio link, especially when the orientation of the two communicating devices is not a priori known. For 60-GHz WiGig applications, CP antennas could be of great interest to mitigate the effects of polarization mismatch, especially in multipath environments. Several methods have been used in the literature to compute the axial ratio (AR) of a CP antenna from specific measurements. In Liu et al. (2012) and Li et al. (2012), the AR was obtained by comparing the magnitude only of the received power levels of two orthogonal polarizations of the AUT: this is not always an accurate method especially when the polarization ellipse is tilted. In Zhou et al. (2009), another AR determination is presented with moderate accuracy versus simulation, but the computation method is not detailed and the AUT is waveguide fed. In Zhang et al. (2013), the problems encountered for the AR

DOI 10.1007/978-981-4560-75-7_76-2

computation are briefly discussed, namely, the difficulty to accurately record the transmitted phase by the AUT when rotating the receiving horn.

The method presented in the following has been developed to accurately compute the AR of probe-fed CP antennas. Doing this from phaseless gain measurements only, considering the phase acquisition at 60 GHz of any signal, is extremely challenging and difficult to achieve with strong accuracy (Titz et al. 2012a).

The AR is defined as the ratio of the major to the minor axis of the polarization ellipse. Thus, by plotting the ellipse, this AR can be computed. The tilt angle is the angle by which the ellipse is tilted from the horizontal polarization. Knowing the sense of polarization, the right-hand circularly polarized (RHCP) or left-hand circularly polarized (LHCP) components of the field (E_{RHCP}, E_{LHCP}) can be measured. They are related to the axial ratio through

$$AR = \left| \frac{|E_{RHCP}| + |E_{LHCP}|}{|E_{RHCP}| - |E_{LHCP}|} \right| \tag{14}$$

From the IEEE Standard Test Procedures for Antennas, four different methods to compute the AR of CP antennas from measurements can be counted: polarization-pattern method, rotating-source method, multiple-amplitude-component method, and phase-amplitude method. In the "polarization-pattern method" and the "rotating-source method," the horn which receives the linearly polarized magnitude (only) of the E-field of the CP AUT has to be rotated by 360° which is heavily time-consuming. These two methods cannot retrieve the sense of the field rotation which is not an important issue as the simulation data can be trusted for this purpose. The "multiple-amplitude-component method" consists in using six different receive antennas having each a different polarization. This is definitely not easy to design and fabricate at 60 GHz. Then, by post-processing the recorded data, the whole CP characteristics can be extracted. The "phase-amplitude method" allows a fast and complete characterization but needs a measurement setup with phase capability, which is quite difficult to implement with satisfactory accuracy at 60 GHz mainly because a 60-GHz moving cable is involved at the receive side. Another possibility is to attach an mmW source module to the horn, but this solution can be too heavy for the arm of the setup. A solution with less capability is to set the arm in a specific position (broadside, end-fire, or any other position where the AUT produces maximum gain) and measure gain and phase in this direction. In that case, the AR is computed for the parametric equation of an ellipse:

$$\vec{E} = \begin{cases} 0 \\ E_y = E_{0y} \cos\left(\omega t + \varphi_y\right) \\ E_z = E_{0z} \cos\left(\omega t + \varphi_z\right) \end{cases} \tag{15}$$

The method proposed at the University Nice Sophia Antipolis is a modified version of the multiple-amplitude-component technique. The idea is to compute the AR and tilt angle by rotating the receiving horn antenna at 0° (horizontal), 45°, 90° (vertical), and 135° (−45°) and achieve a fast four-point measurement operation. This is possible using two different holders for the receiving horn. The first holder is made for the 0° and 90° positions and the second holder for 45° and −45°. The four positions of the horn are shown in Table 4 for better understanding. When measuring linearly polarized antennas, only the 0° and 90° positions are required, but at least a third position (45° or −45°) is mandatory to be able to compute the polarization ellipse as shown in Fig. 19, when dealing with circularly polarized antennas.

The polarization pattern can be determined from the following equation with G_i being the realized gain of the AUT in the direction θ_i alternatively equal to 0°, 45°, 90°, or −45°:

DOI 10.1007/978-981-4560-75-7_76-2

Table 4 Positions of the horn antenna aperture for the measurement of CP antennas with the setup from University Nice Sophia Antipolis

Position	0°	90°	45°	−45°
Aperture view of the horn antenna				

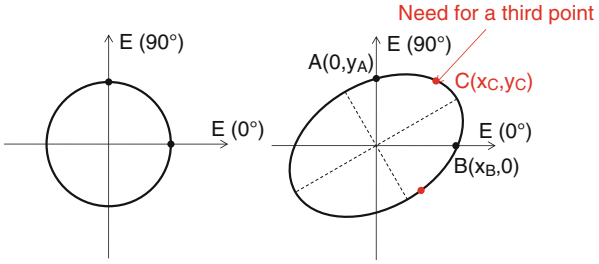

Fig. 19 Polarization circle or ellipse of a the electromagnetic field from a CP antenna

$$G_i = r_i^2 = \frac{b^2}{1 - e^2 \cos^2(\theta_i + \tau)} \quad \text{where} \quad i = 0,\ 45,\ 90,\ -45 \tag{16}$$

This equation corresponds to the ellipse equation in polar coordinates where b is the semiminor axis, e is the eccentricity, and τ is the tilt angle of the ellipse. b, e, and τ can then be computed from only three (out of four) measurements (e.g., G_0, G_{45}, G_{90}) from the following equations:

$$\left[\frac{1}{G_\varphi^2} + \frac{1}{G_\theta^2} + \frac{4}{G_{45}^2} - \frac{2}{G_\varphi G_\theta} - \frac{4}{G_\varphi G_{45}} - \frac{4}{G_\theta G_{45}}\right] b^4 + \left[\frac{4}{G_\varphi} + \frac{4}{G_\theta}\right] b^2 - 4 = 0 \tag{17}$$

$$e^2 = 2 - b^2\left(\frac{1}{G_\varphi} + \frac{1}{G_\theta}\right) \tag{18}$$

$$\begin{cases} \sin(2\tau) = 1 - \dfrac{2}{e^2}\left(1 - \dfrac{b^2}{G_{45}}\right) \\ \cos(2\tau) = \dfrac{b^2}{e^2}\left(\dfrac{1}{G_\theta} - \dfrac{1}{G_\varphi}\right) \end{cases} \tag{19}$$

The fourth measured point (G_{-45} in this example) can be used as a verification check. Indeed, from the four gain measurement points, four different ellipses can be computed, giving four different values for the AR and the tilt angle. When the axial ratio is low (below 3 dB), the four ellipses are nearly the same. When it increases and the polarization of the antenna becomes linear, the four ellipses can be quite different. In fact, the measured cross polarization is usually always higher than the simulated cross polarization, and thus the computed axial ratio is always lower than expected. The accuracy of this method is then worse when antennas with a low AR are measured. Considering having now four AR values and four tilt angle values, two methods are proposed to merge them into a single value.

The ellipse method consists in choosing the ellipse that is the closest to the fourth measured point. Another method that was also implemented plots a unique closer ellipse to the four measured points using

DOI 10.1007/978-981-4560-75-7_76-2

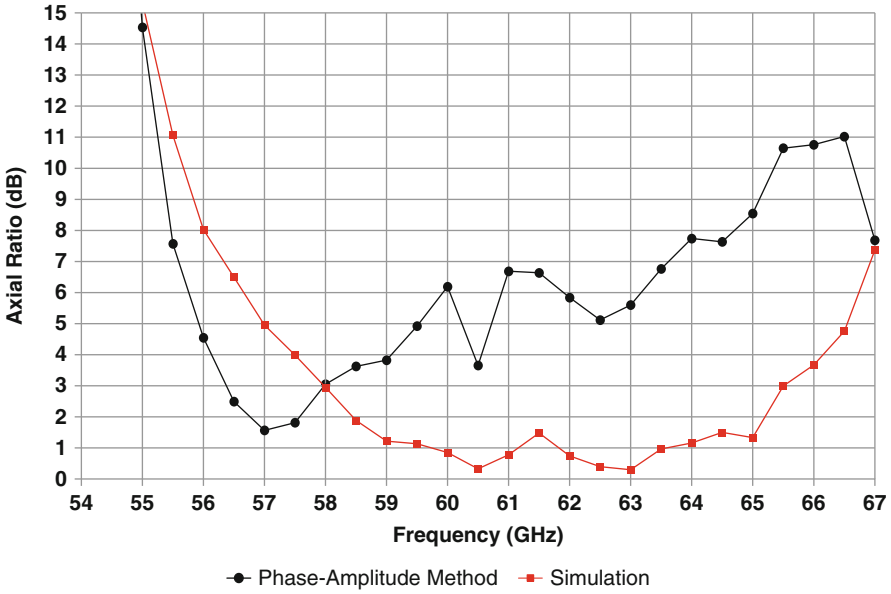

Fig. 20 Simulated and computed AR of a CP LTCC antenna array with the phase-amplitude method

a mean square (MS) optimization algorithm. This method is called the mean square method. Those methods are largely illustrated in Titz et al. (2012a) and have been successfully implemented in Rousstia and Herben (2013).

According to its definition, the AR is then determined using:

$$\mathrm{AR} = \frac{\mathrm{a}}{\mathrm{b}} \quad \text{with} \quad \mathrm{a} = \frac{\mathrm{b}}{\sqrt{1 - \mathrm{e}^2}} \tag{20}$$

The polarization sense cannot be extracted with the proposed methods, but the maximum and minimum values of the LHCP and RHCP realized gains (G_{RHCP}, G_{LHCP}) can be computed from:

$$\begin{aligned} \max(G_{\mathrm{RHCP}}, G_{\mathrm{LHCP}}) &= \frac{G_{\mathrm{tot}}}{2}\frac{(\mathrm{AR}+1)^2}{(\mathrm{AR}^2+1)} \\ \min(G_{\mathrm{RHCP}}, G_{\mathrm{LHCP}}) &= \frac{G_{\mathrm{tot}}}{2}\frac{(\mathrm{AR}-1)^2}{(\mathrm{AR}^2+1)} \end{aligned} \tag{21}$$

Depending on the setup, the presented method can be used to extract the axial ratio in 2-D cuts, 3-D, or only one direction (Titz et al. 2012a).

To demonstrate the accuracy of this method, Fig. 20 shows the simulated and computed AR of a CP LTCC antenna array with the phase-amplitude method, while Fig. 21 shows the same AR computed with the "ellipse method" and the "mean square method."

Efficiency Measurements

Several methods to determine the efficiencies of connector-fed antennas have been developed at low frequencies. For directive antennas, a first approach consists in computing the total efficiency from the ratio of the measured realized peak gain to the peak directivity. However, a very high-quality anechoic chamber is required as this method does not give accurate results if ripples are recorded when measuring the radiation patterns. Other measurement solutions include the Wheeler cap method (McKinzie 1997)

DOI 10.1007/978-981-4560-75-7_76-2

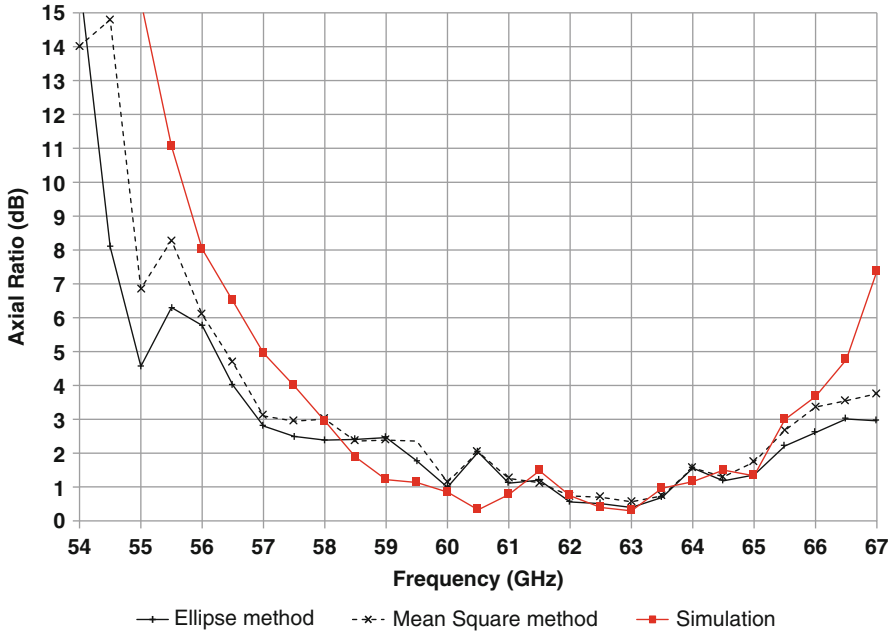

Fig. 21 Simulated and computed AR of a CP LTCC antenna array with the "ellipse method" and the "mean square method"

and the reverberation chamber (Kildal and Rosengren 2004). A Wheeler cap measurement of a probe-fed antenna at 60 GHz has already been presented in Fakharzadeh et al. (2011), but more results are needed to validate the setup. The main problem of this measurement system is the small hole etched in the cap to let passing the microelectronic probe to feed the antenna. Therefore, the expected Faraday cage behavior is not perfect, and the accuracy of the measures is degraded. The reverberation chamber is also a very good candidate to measure the efficiencies of low-frequency antennas, but only few attempts of reverberation chamber setups for probe-fed antennas at 60 GHz have been reported. In Asano et al. (2013), an interesting reverberation chamber operating at 60 GHz is presented, but so far, a 1.85 mm coaxial is used to feed the AUT. The last method consists in the integration of the gain radiation pattern of the antenna under test (AUT) over the full 3-D sphere. This is the method that will be presented in this part (Titz et al. 2012c). It has been developed at the University Nice Sophia Antipolis.

The total efficiency η_{tot} is the ratio of the total power radiated by an antenna to the incident power at the antenna port (IEEE Standard Test Procedures for Antennas 1979). It can be also defined using η_R and S_{11}:

$$\eta_{tot} = \frac{P_{rad}}{P_{inc}} = \eta_R\left(1 - |S_{11}|^2\right) \tag{22}$$

S_{11} is the reflection coefficient of the AUT, and η_R its radiation efficiency. If the realized gain G_{real} of the probe-fed AUT can be measured in any particular direction defined by θ and φ, the incident power at the antenna port can be deduced from

$$P_{inc} = \frac{4\pi U(\theta, \varphi)}{G_{real}(\theta, \varphi)} \tag{23}$$

where U(θ, φ) is the radiation intensity in one particular direction defined by θ and φ. Then P_{rad} is needed to compute the total efficiency. The radiated power P_{rad} is developed as follows:

DOI 10.1007/978-981-4560-75-7_76-2

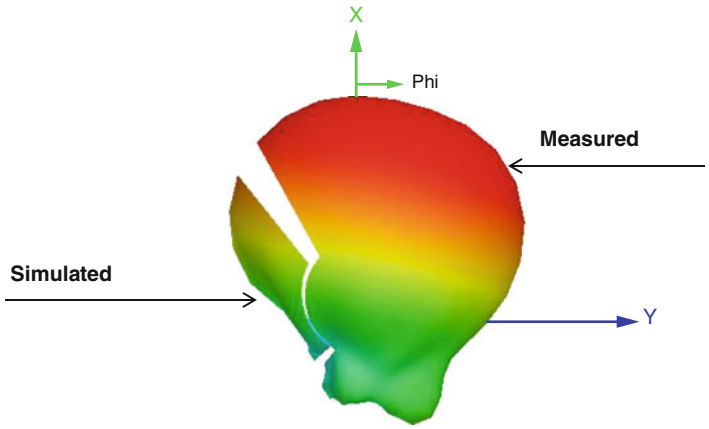

Fig. 22 Illustration of the hybrid method to compute the total efficiency of any probe-fed AUT from the measured 3-D patterns obtained with the setup in Titz et al. (2012c)

$$P_{\text{rad}} = \int_0^{2\pi} \int_0^{\pi} \text{U}(\theta, \varphi) \sin(\theta) \text{d}\theta \text{d}\varphi \tag{24}$$

η_{tot} can then be expressed as:

$$\eta_{\text{tot}} = \frac{P_{\text{rad}}}{P_{\text{inc}}} = \frac{\int_0^{2\pi} \int_0^{\pi} \text{U}(\theta, \varphi) \sin(\theta) \text{d}\theta \text{d}\varphi}{P_{\text{inc}}} = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} G_{\text{real}}(\theta, \varphi) \sin(\theta) \text{d}\theta \text{d}\varphi \tag{25}$$

As the realized gain is measured in θ and φ steps, the equation can be rearranged using discrete points M and N. For that, a gain value is associated to a certain portion of the sphere (surface); the smaller the angle steps are, the smaller the numerical error will be (Balanis 1997):

$$\eta_{\text{tot}} = \frac{1}{4\pi} \Delta\theta \Delta\varphi \sum_{\text{j}=1}^{\text{M}} \sum_{\text{i}=1}^{\text{N}} G_{\text{real}}\left(\theta_{\text{i}}, \varphi_{\text{j}}\right) \sin(\theta_{\text{i}}) \tag{26}$$

θ and φ should respectively vary from 0 to π and 0 to 2π to scan the whole 3-D sphere. However, this is not possible in most of the measurement setups as the probe positioned is blocking a part of the sphere. In Titz et al. (2012c), only 73.5 % of the total sphere's surface can be scanned because θ and φ might respectively vary from −30° to 220° in 10° steps and −30° to 210° in 2° steps. So, the total efficiency is only provided on these 73.5 %. This computed value is surely a lower boundary for the efficiency of the AUT, but it is still not satisfactory for accurate characterization. If the simulated and measured gain radiation patterns are in good agreement over 73.5 % of the sphere's surface, the simulated radiation pattern of the AUT can be trusted over the remaining portion of the sphere's surface (26.5 %) and therefore used to calculate the efficiency over this surface. Therefore, it is just a matter of adding the efficiencies of the measurement (73.5 % of the sphere's surface) and the simulation (26.5 % of the sphere's surface) to obtain the total efficiency of the AUT over the 3-D total sphere. Figure 22 illustrates the proposed hybrid method to compute the total efficiency of one particular AUT. As can be seen, one part of the radiation pattern is measured and the remaining portion is simulated. The radiation efficiency η_{R} can be computed with the measured reflection coefficient of the AUT.

DOI 10.1007/978-981-4560-75-7_76-2

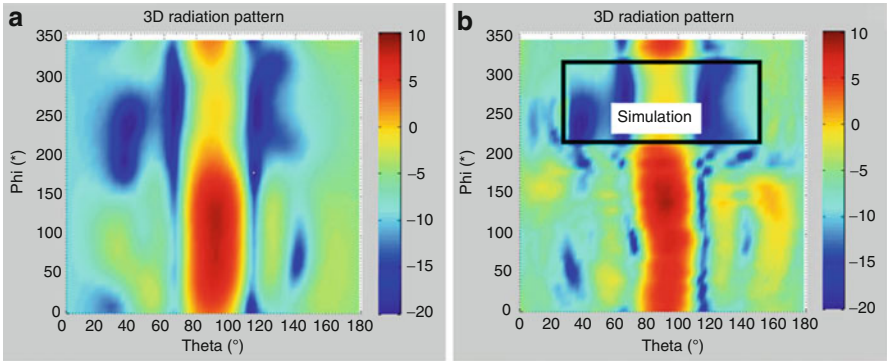

Fig. 23 Illustration of the hybrid method to compute the total efficiency of an end-fire LTCC antenna array at 60 GHz from the measured 3-D patterns obtained with the setup in Titz et al. (2012c). (**a**) Simulated 3-D field, 69.9 % of total efficiency. (**b**) Hybrid measured and simulated 3-D field, 69 % of total efficiency

This method has already proved to be accurate for directive and less directive antennas (Titz et al. 2012c). One example of measurements is shown in Fig. 23.

Near-Field and Phase Measurements

Accurate phase measurements at mm-wave frequencies are really tricky to achieve. So far, several planar scanners exist in many academic labs and companies (Janse Van Rensburg and Hindman 2008), but they rather cope with waveguide-fed AUT. From the magnitude and phase acquisition of the received signal by the open waveguide (also called the probe) over a planar surface, a near-field to far-field transformation enables to retrieve the far-field performance of the measured AUT. In Shamim et al. (2008), the near-field scanning probe is a printed circuit dipole at 24 GHz. After near-field to far-field transformation (for planar scanning), the patterns are compared with simulation. But, the agreement is not really good due to the insufficient scanning range around the antenna. Other planar near-field measurements have also been realized at 60 GHz in Hong et al. (2011) and Tsai et al. (2013) with an open waveguide or a horn antenna. As the measurement range is wider, the measurements are quite close to simulation, but still, ripples and shadow exist in the computed radiation patterns. With those planar near-field measurements, the mmW extender is placed close to the receiving waveguide parts. One setup also able to measure both waveguide-fed and probe-fed AUT seems to exist at NASA, but so far, not so much information is published and it is difficult to know exactly its capabilities and performance (Slater 1994). Recording the phase of the signal transmitted by the AUT allows to measure electrically large antennas at very short distances (in their near-field region). For such antennas (for primarily space applications for instance), the far-field region is too far away from the AUT, and therefore, there are no possibilities to physically place the received open waveguide at very long distance. The free-space loss added to the oxygen absorption of electromagnetic waves at certain mm-wave frequency bands is also an issue: sufficient signal is needed to stay above the sensitivity level of the receiving parts of the setup. Those electrically large antennas for space applications are mostly fed by waveguide, but recently, backhaul and fronthaul deployments with directive antennas in V- and E-band have been widely developed, and in this case, a near-field measurement setup with probe-fed capabilities might be needed for characterization purpose.

Near-field acquisition over a spherical surface is known to produce better results than planar scanning (in terms of near-field to far-field transformation). The main issue is to scan the spherical surface over the AUT with very high accuracy: this is extremely challenging and much more difficult than a planar scan due to mechanical challenges in spherical rotation. So far, rotating the open waveguide dedicated to acquisition over a slightly non-perfect sphere will produce small errors in magnitude but large phase error at mm-wave frequencies. Moreover, this phase error drastically increases when frequency increases. In

DOI 10.1007/978-981-4560-75-7_76-2

this case, correction techniques can reduce those errors. The main technique is to achieve a prior rotation before any measurement, with a laser tracker, and then to record the non-perfect spherical scan to be able, later on, to compensate mathematically the position of the arms for every measured point. This is a time-consuming procedure which considers that the rotating arms of the setup will scan space in exactly the same manner for the calibration step and the following measurement. The choice of the position of the mm-wave head at the receiver side is also of primary importance as one can choose to make it rotate during the measurements or make it stable and faraway from the receive horn, but in this case, the mm-wave head is connected to a 60-GHz cable which will move and pass through a rotary joint during the measurements. At higher frequencies, when cables are no more available and only waveguide connections exist, this option is very difficult to handle. Each solution has pro and cons but will anyway influence the accuracy of the acquisition in different manners.

Recently, two spherical near-field acquisition setups for probe-fed mm-wave antennas have been commercially released by Orbit (μ-Lab Station) and NSI (NSI-700S-360). Those setups have been sold to very few companies and academic labs, but so far, there are not so much available published data yet by the users' only suppliers' advertisement (Orbit Presentation; Janse Van Rensburg and Gregson 2014). Right now, those setups seem to be limited to 110 GHz for an accurate phase acquisition. As at low frequencies, having a commercial measurement system ready to plug is an appealing option, but main drawbacks usually come from low flexibility. If the software flexibility and usability tends to increase from year to year, the main drawback for mm-wave frequencies probe-fed antennas stays in the fact that every AUT to be measured is differently probed, and therefore, a custom foam holder is always necessary for testing. Solutions exist with generic foam support, but they probably will not fit any testing configuration.

In Arboleya et al. (2013), an interesting solution is presented. A planar near-field measurement setup is presented. As the phase measurement is the main difficulty with moving cables, a phaseless measurement technique is proposed using two sampling surfaces. This is probably the best approach for probe-fed measurements at very high mm-wave frequencies.

Measurements Above 110 GHz

As frequencies increase, it becomes more and more challenging to realize accurate magnitude measurement results. This is mainly due to four reasons which will be explained later on in more details:

- Size of antennas decreases which complicates a proper probe contact with the AUT.
- Calibrations usually become less accurate at higher frequencies.
- The dynamic range of the RF equipment (and therefore the setup) gets worse.
- Mechanical vibrations become more critical at higher frequencies.

Since the size of the antenna depends on the operating wavelength, the antenna becomes smaller, as the frequency increases. Thus, it has to be aligned with the receiving horn more precisely. Also, the pitch of the probe that contacts with the pads of the AUT normally decreases with higher frequencies to minimize the parasitic effects of the contact needles. For example, at V-band (50−75 GHz), a pitch width of 300 μm is quite common, whereas at H-band (225−300 GHz), a pitch width of 60−80 μm has to be used. A good microscope and a very fine positioner are therefore needed.

Another issue is the accuracy of the calibration at higher frequencies. At regular probe stations with two ports at frequencies above 110 GHz, normally, a "trough reflect line" (TRL) calibration is taken out. In this calibration, a short standard is used as "reflect," and two pieces of transmission line are used as "trough" and "line." Since the antenna measurement setup needs only one feeding port, a "short-open-load" (SOL) calibration only can be used (as explained in paragraph 1). The drawback of the SOL calibration is that it is

DOI 10.1007/978-981-4560-75-7_76-2

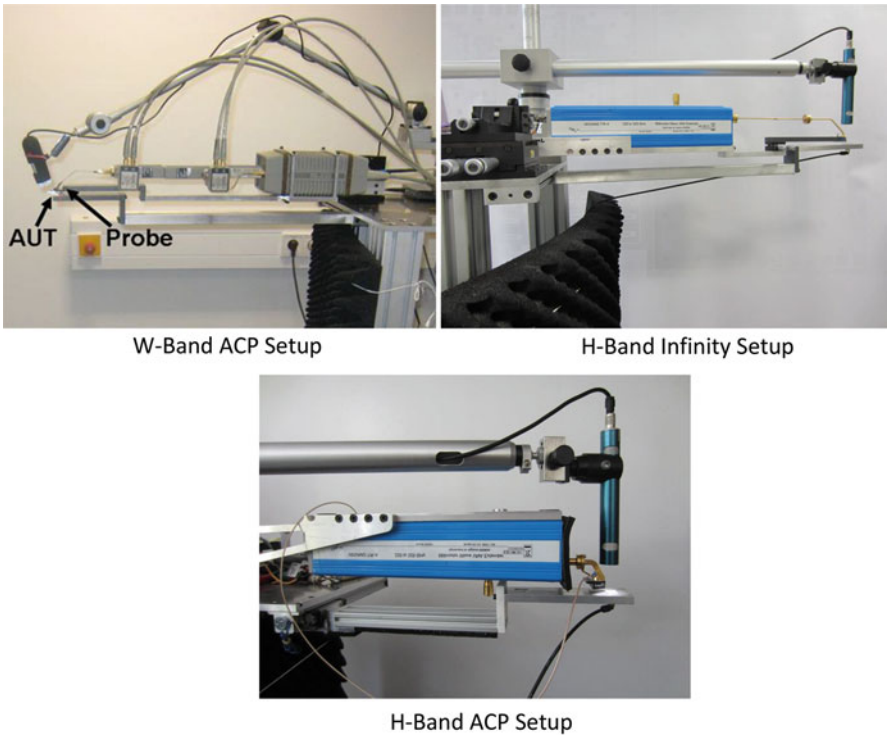

Fig. 24 The setups for W-/D- and H-band from Gulan et al. (2013)

difficult to realize an exact 50 Ω "load" fully constant over the complete frequency band. Thus, a calibration with an antenna measurement setup at frequencies over 110 GHz will usually be worse compared to a two-port calibration at a probe station. As an example, calibrations at different frequency ranges shall be compared in the following. The antenna measurement setup which is used is the one introduced in Beer and Zwick (2010) and Gulan et al. (2013), and the calibration has been done in the W-band (75−110 GHz), the D-band (110−170 GHz), and the H-band (220−325 GHz). The probes which have been used are indicated in Table 3, and the measurement setups are shown in Fig. 24.

If a SOL calibration is performed now, the reflection coefficient of the open probe in air (open-in-air) can be used to indicate the quality of the calibration. Even though this is not absolutely correct (because the probe tips will always act as an antenna), it gives a bit a feeling of the quality of the calibration. In Fig. 25, the reflection coefficient of the open-in-air for the different setups is shown. Figure 25a, b shows the reflection coefficient in W- and D-band. These calibrations have been taken out with so-called air coplanar probes (ACP probes) from GGB (Picoprobe). These probe types have three needles for ground-signal-ground connection. These three needles will always cause parasitic effect since they act like antennas and radiate. As it can be seen, the reflection coefficient of the probes which would be expected to be exactly 0 dB is between −0.2 dB and +0.2 dB in W-band and between −0.4 dB and +0.7 dB in D-band. These are quite reasonable values for SOL calibrations but worse than the ±0.05 dB expected in V-band as explained previously. At H-band, the calibration becomes even worse (Fig. 25c). The reflection coefficient stays between −0.5 dB and +0.5 dB in the 200−280 GHz range but begins to increase up to +2.8 dB at 325 GHz. This kind of probe with this kind of calibration is not suitable for this frequency range. An improvement consists in using Infinity probes from Cascade. These probes use a substrate with a printed coplanar waveguide line (CPW line) instead of needles as the contact part. Thus, the parasitic effects due to radiation are minimized. The drawback is that these probes are way more sensitive than the ACP probes; they have to be aligned very accurately with the AUT whereas slight unevenness can be compensated with the ACP probes. The performance of an SOL-calibrated Infinity probe can be seen in

DOI 10.1007/978-981-4560-75-7_76-2

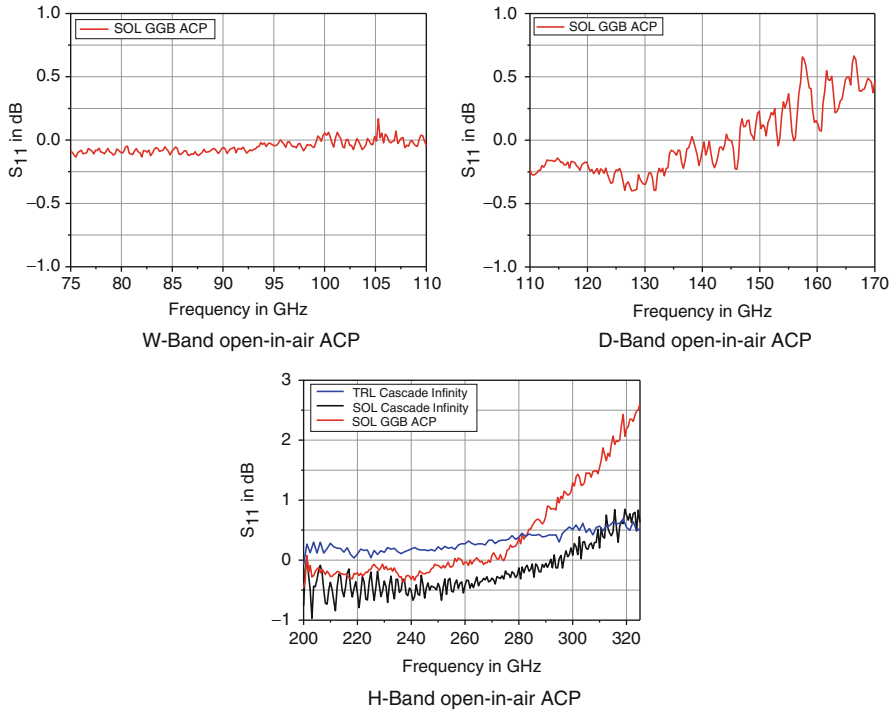

Fig. 25 Reflection coefficient of an open-in-air probe for different frequency ranges and setups

Fig. 25c. Compared to the calibration with ACP probes, the latter one remains in a +/−1 dB area even at higher frequencies. As a reference, a two-port TRL calibration which has been made at a probe station at KIT is also shown in Fig. 25c. Obviously, this calibration is more stable than the two SOL calibrations.

The next point which has to be taken into account when frequency increases is the dynamic range of the setup. A measurement above 110 GHz normally means a lower output power to feed the antenna, higher free-space losses, and higher conversion losses of the mixer which down-convert the received signals to an IF. As an example, the link budget of the antenna measurement setup from KIT is compared for different frequencies. The link budgets are shown in Table 5. In all cases, an AUT gain of 10 dBi is assumed.

While the input power of the VNA at 77 GHz and 120 GHz is quite high (−77 dBm and −81.2 dBm), it is strongly degraded at 220 GHz (−114.7 dBm) and 325 GHz (−130.5 dBm). The main components which have an influence on the link budget are the output source of the VNA, the free-space loss, and the conversion loss of the down-converter/mixer attached to the receiving antenna. Whereas the output power of the W-band source at 77 GHz is 0 dBm (Agilent 83558A mm-wave source module), it is only −9 dBm at 120 GHz (OML V06VNA2 millimeter-wave VNA extender) and decreases to −26 dBm at 325 GHz (OML V03VNA2 millimeter-wave VNA extender). In the case of this setup at H-band, Virginia Diodes offers a VNA extender with an output power of −9 dBm at 325 GHz (VDI Model: WR3.4-VNAX) which would give additional 18 dBm in the link budget. The free-space loss is determined by the distance between AUT and receiving antenna. In the case of the setup from KIT, the distance is set constant to 75 cm. At 325 GHz, the setup allows a far-field measurement of an AUT with about 35 dBi of gain. The down-converters used are passive diode mixers. The conversion loss normally increases with frequency. Especially, the down-converter at 325 GHz has a really high conversion loss of 45 dB. A good way to further increase the link budget would be the use of a low-noise amplifier (LNA) between the receiving antenna and the down-converter. However, broadband LNAs for H-band are not commercially available yet.

DOI 10.1007/978-981-4560-75-7_76-2

The following section will give a short overview of some known measurement setups above 110 GHz. Since the high millimeter-wave region is an area of ongoing research (and especially companies do not necessarily publish their available setups), it will be concentrated on three published setups from universities. These are the setups of:

- The Karlsruhe Institute of Technology, Germany
- The Institute for Infocomm Research, Singapore
- University Nice Sophia Antipolis, EpOC Lab, France

Even if some performance of the setup of the Karlsruhe Institute of Technology (KIT) was described in the previous section, it is compared to other setups in this section. It was first published in 2009 as a measurement setup for V- and W-band (50−75 GHz and 75−110 GHz) (Beer and Zwick 2010) and later extended to D- and H-band (Beer et al. 2011; Gulan et al. 2013). It consists of an Agilent PNA-X with frequency extenders for the different bands. Thus, it is able to measure from 110 to 325 GHz but with a gap between 170 and 225 GHz. However, the lower bound of the H-band can be reduced to 200 GHz by tuning the internal mixer accordingly. The AUT (or the standard antenna for calibration purposes) is either directly connected to a VNA extender from OML (if it is waveguide fed) or it is fed by a microelectronic probe which is in turn attached to the VNA extender. The receiving antenna is mounted on two arms with two rotary stages as shown in Fig. 6b. Thus, it is possible to measure nearly a complete sphere (except the part, which is blocked from the table) around the AUT. Since a second VNA extender module would be too bulky and heavy to be mounted behind the receiving antenna, a kind of self-developed extension module is used. As it can be seen in Fig. 26, the LO output signal of the port 2 of the VNA is amplified and transmitted to a mixer which is directly attached to the receiving antenna. The back path IF signal is transmitted back to the VNA so that the extension module behaves like a commercially available module in receiving mode. For a more convenient transmission of the LO and IF signal along the rotating arms, two diplexers are used to transmit the signals trough the same cable. Thus, the use of only one cable is sufficient. The distance between the AUT and the receiving antenna is fixed to 75 cm for D- and H-bands.

The setup of the Institute of Infocomm Research (I^2R) was introduced in 2014 (Qing and Chen 2014) and actually consists of two different setups for D-band and H-band, respectively. The D-band setup is shown in Fig. 27a, b. Like the KIT setup, it consists of an Agilent PNA-X with OML extension modules. However, in this setup, OML modules are used for both ports of the VNA. The setup is capable to measure two vertical cutting planes. The $\varphi=0°$ plane can be measured from $-90°$ to $+90°$, and the $\varphi=0°$ can be measured from $-90°$ to about $+35°$. The setup can measure probe-fed as well as waveguide-fed AUTs. The setup for H-band is shown in Fig. 27c, d. The electrical components are the same as the ones used in the D-band setup but with adapted OML extension modules. The mechanical setup, however, is different. It can only measure one horizontal plane from $-90°$ to $+90°$ and up to now only waveguide-fed antennas.

The setup of the University Nice Sophia Antipolis (UNICE), EpOC Lab, has been introduced in 2011. It was developed at V-band setup and has been extended to F-band (90−140 GHz) in the meantime. It consists of an Agilent PNA-X with a frequency extension module from Virginia Diodes as source and an HP spectrum analyzer as receiver, which uses an external mixer from OML. To move the receiving antenna around the AUT, it uses two rotating arms. Thus, it is able to measure also three-dimensional radiating patterns. The distance between AUT and receiving antenna is fixed to 20 cm. In contrast to the two previous described setups, radiation efficiency and circular polarization performance measurement methods have been specifically developed. The setup is depicted in Figs. 8 and 9. Table 6 recapitulates the properties of those three setups.

Sources of Errors

In the previous sections, several measurement setups (and associated calibrations) using microelectronic probes to feed the AUT have been presented. The main sources of errors usually come from the calibration accuracy. For example, in the V-band, the setup of University Nice Sophia Antipolis is given within ± 0.8 dB accuracy. In the D-band, this setup gives ± 1.2 dB accuracy. Those numbers have been obtained from the uncertainty of every block in the mm-value chain (transmit, receive, and free-space loss). However, there are also other contributors to the global error produced during a measurement. The microelectronic probe is still a huge metallic part which is closely placed to the AUT. Depending on the way the AUT radiates, some power will definitely hit the microelectronic probe to be scattered, appearing in the opposite direction of the AUT and generating unwanted ripples in the radiation pattern. In Zwick and Pfeiffer (2009), the radiation of an unloaded probe is measured, and a maximum of -15.5 dBi radiation is found. This value is expected to be lower when the probe is loaded by the AUT that is mostly by a radiator having almost 50 Ω input impedance. The 3-D pattern of a loaded probe was measured in Ranvier et al. (2009). The average gain was computed to be around -28 dBi and the maximum gain around -22 dBi. The proposed solution was to cover the microelectronic probe with absorbers, improving the radiation by 2 dB, but so far, no global solution was proposed to this problem.

Table 6 Capabilities of three selected measurement setups above 110 GHz

Setup	Frequency range	Source	Extension modules	Measurement possibilities	Antenna polarization
KIT	D-/H-band	Agilent PNA-X	OML	Gain/3-D radiation pattern	Linear
IIR	D-/H-band	Agilent PNA-X	OML	2-D radiation pattern	Linear
UNICE	F-band	Agilent PNA-X	VDI	Gain/3-D radiation pattern/ efficiency	Linear/circular

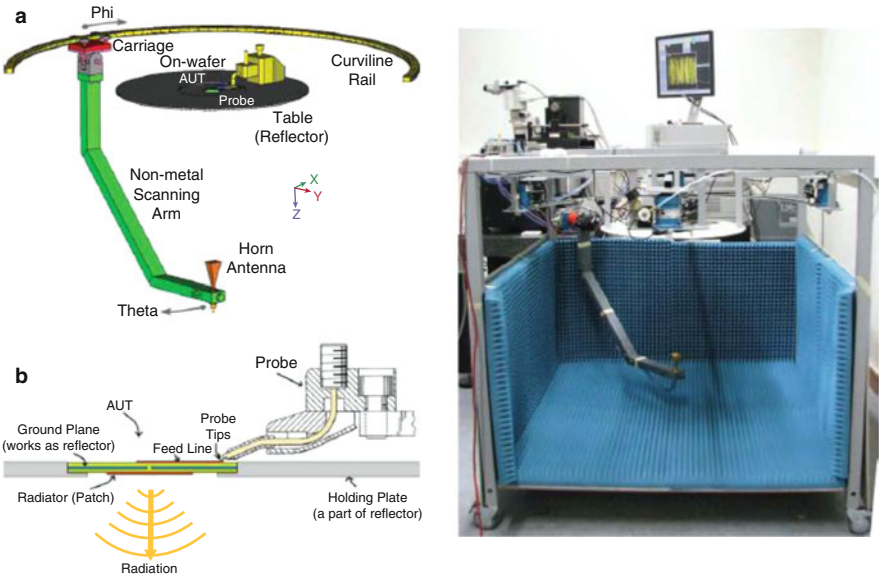

Fig. 28 Schematic and picture of the measurement setup proposed in Mohammadpour-Aghdam et al. (2011)

This phenomenon can be treated in different ways: block the radiation of the probe or including it into the calibration procedure. In Mohammadpour-Aghdam et al. (2011), the RF probe was modeled using a commercial software, and it was demonstrated to have a dipole-like omnidirectional radiation pattern. The authors proposed to shield this radiation (from the region that has to be scanned) by placing a metallic reflector plate behind the microelectronic probe. Following this idea, a robust mechanical setup was proposed by the authors (Fig. 28). The sensitivity was improved by 20 dB. However, only the lower hemisphere can be measured, with an AUT radiating only in the opposite direction of the probe.

In Fu et al. (2011), Tsai et al. (2013), and Reniers et al. (2014), several custom probes have been used. The probe tip feeder is extended to increase the distance between the AUT and the body of the microelectronic probe. This solution can reduce the back scattering but also the blocking by the fixture. The probe body can also be reversed as in Fu et al. (2011). However, those custom probes are more expensive than regular probes and provide higher insertion loss.

In Murdock et al. (2011), a probe radiation de-embedding technique is proposed, but two measurements are needed instead of only one.

DOI 10.1007/978-981-4560-75-7_76-2

Future Directions and Open Problems

Today, lots of academics working at mm-wave frequencies have implemented their own measurement system and testing techniques for probe-fed antennas at 60 GHz (in fact, until 67 GHz due to the available PNAs and mm-wave head). In this characterization domain, the main difficulties come from the fact that two engineering worlds are colliding: the antenna world and the microelectronic world. For example, antenna researchers or engineers are usually not aware of probing on silicon, and microelectronic researchers or engineers do not know how to probe on organic substrates usually needed for antenna solutions. The main consequence is the following: every measurement system is custom made and does not look like the one of the neighbor as every academic is gaining knowledge by trial and errors with his own experiments. In parallel, two commercial measurement systems have been released on the market by antenna companies. The lack of microelectronic competencies from those companies makes their measurement systems perfectible, but they are brand new, which implies that the feedback from their users will obviously allow those commercial companies to improve their proposed measurement systems.

In the future, this current situation (the distribution of the measurement setups) will definitely evolve if some applications strongly emerge around 60 GHz. Two markets are currently hot topics around 60 GHz: WiGig applications and backhaul/fronthaul mm-wave links. It will probably be possible to avoid probe-fed feeding to characterize backhaul/fronthaul antenna solutions: SMPM connectors offer today appealing performance, and they are even used at the initial stage of an antenna concept when no functional electronic hardware is yet available. However, the measurements of WiGig probe-fed antenna modules will be of paramount importance especially at the prototyping and mock-up stages of the product. In fact, if the WiGig standard really emerges, the certification of every product to be released on the market will be mandatory. In this case, the required measurements (with functional hardware), performance, and safety threshold will be detailed. Manufacturers of commercial measurement setups will for sure develop the exact needed facility to be certified. Indeed, we are not speaking about probe-fed measurements as functional hardware will be available. As the mobile phone industry at low frequencies, the product to be characterized will be powered up with no physical connection, but it will be wirelessly linked with a "small-cell" emulator to retrieve its characteristics. However, the whole antenna community will benefit from those newest ups because the involved companies will definitely propose a probe-fed option available with their setup, as the probe-fed characterization of the antenna module during the prototyping and mock-up stages will be necessary to avoid any deviation from expected performance. If no standardized application emerges, it is not sure if commercial measurement setups will rise up and dump the market. The specific absorption rate (SAR) testing and certification area is a good example of what could happen or not.

Building a functional probe-fed measurement setup above 110 GHz is today a hot and challenging topic for many academics. As explained in the previous section, only few players entered this game as it is expensive and not straightforward. It should be noted that only researchers with competencies at 60 GHz made some attempts. There is an interest for the available 120−140 GHz and the 200−280-GHz frequency bands, but so far, commercial companies are a bit shy for the moment as they do not yet see any immediate applications. In spherical setup, mechanical stability is the key issue at those frequencies because it will directly translate into magnitude and phase errors. It should be also noted that, today, only waveguide connections exist (microelectronic probes are only waveguide fed) which makes the RF parts of the setup less flexible than at 60 GHz. Therefore, probing an antenna on a foam support is more far difficult than at 60 GHz as the rigidity of the waveguide makes the probing contact difficult to properly ensure. However, the situation could quickly change with the recent introduction of novel connectors (Anritsu 2015). If magnitude and phase acquisition are highly challenging above 110 GHz, planar scanners seem to be the best mechanical solutions. Some results have been even reported by Smith

DOI 10.1007/978-981-4560-75-7_76-2

et al. (2012) and at NASA (Slater 1994), but so far, no probe-fed AUT is described in those papers. If one would like to keep spherical scanning around the AUT when measuring above 110 GHz, phaseless acquisition techniques and appropriate processing for near-field to far-field transformation are probably the best options (Arboleya et al. 2013). More efforts should focus in this direction. The question of available probes above 300 GHz is also of strong interest: interesting innovative solutions have been already designed and measured (Reck et al. 2011a, b). Those probes are fully custom made. Finally, quasi-optical measurement solutions could be an alternative but they need to gain maturity (Neshat et al. 2012; Hirata et al. 2001). When increasing frequency, one main question remains the signal generation being solid state or from photonic solution (Alouini et al. 2014); in this last case, the radiation characterization could be completely different.

EMI/EMC Chamber Design, Measurement, and Instrument

Boon Kuan Chung*
Faculty of Engineering and Sciences, Universiti Tunku Abdul Rahman, Kuala Lumpur, Malaysia

Abstract

An EMI/EMC anechoic chamber represents a substantial investment. A number of careful considerations must be weighted in an anechoic chamber project. The screened room must be designed to provide an environment free of extraneous signals. The suitable type of RF absorber must be chosen to line the entire inner surface of the shielded room in order to simulate a free-space environment with no reflection from the walls, ceiling, and floor. The test site must meet the required performance specified in EMC standards. For frequency range below 1 GHz, the normalized site attenuation (NSA) method is specified by CISPR 16 and ANSI C63.4 for validation of semi-anechoic chamber where the floor is not covered with RF absorber. The reference site method is recently added to the standards as a better option to improve the site validation accuracy. For frequency range above 1 GHz, EMC radiated emission measurements require the use of full anechoic chamber where the floor is also covered with RF absorber. The site voltage-standing-wave ratio (SVSWR) method is specified by CISPR 16-1-4 for test site validation. A time-domain reflectivity (TDR) method proposed by ANSI C63.4 offers numerous benefits compared to the CISPR method. It can produce equivalent values of SVSWR without physically moving the antenna, potentially more accurate in validating the chamber quietness performance, and the measurement process is much less time consuming.

Introduction

Electromagnetic radiation occurs whenever there is an acceleration of electric charges. Hence all electrical devices may radiate RF wave either intentionally or unintentionally. If the radiation is strong enough, it may have some effects on the operation of another electrical device located nearby. When this occurs unintentionally, it is known as electromagnetic interference (EMI).

EMI noise may be coupled from the source to the victim through electromagnetic fields in the space by mean of radiated coupling. In addition, if two appliances share the same power source (such as the main outlets within a building), EMI noise generated by an electrical appliance may appear on the power leads of the other by means of conducted coupling.

Electromagnetic compatibility (EMC) refers to the capability of two or more electrical devices to operate simultaneously without mutual interference. An electrical device must not emit too much EMI noise into the environment. It must also be able to tolerate a reasonable amount of inflicted noise and

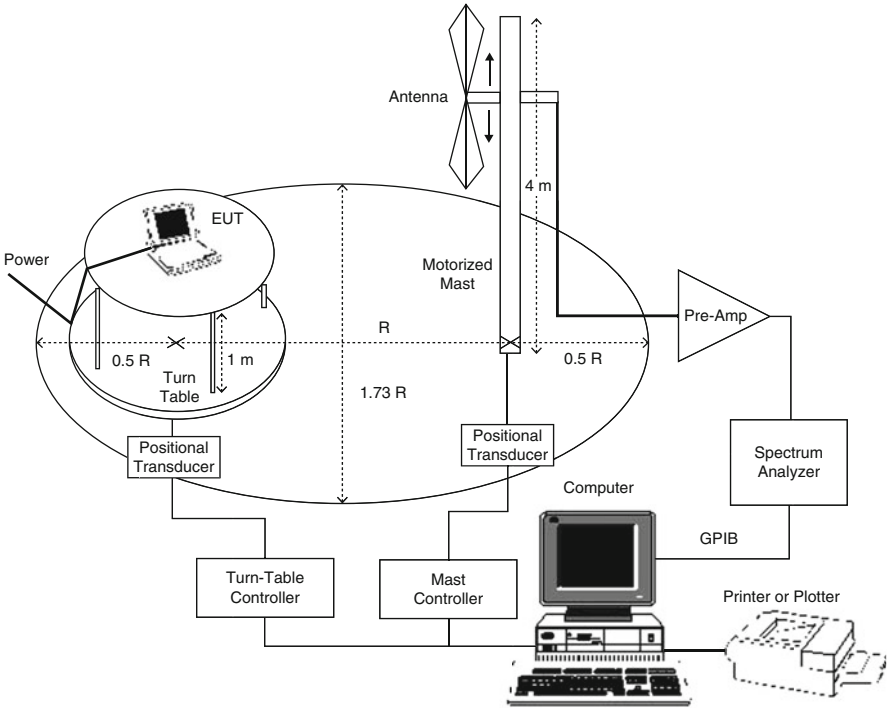

Fig. 1 Typical instrumentation for EMC radiated emission test

function properly in its intended electromagnetic environment. Due to the increasing EMI noise pollution to the environment, EMC standards and regulations have been established worldwide to regulate the absolute limits for both radiated and conducted emissions from electrical devices and the immunity of the devices to EMI emissions.

The International Electrotechnical Commission (IEC) has formed two technical committees devoted to drafting of EMC standards. The TC77 is responsible for basic standards on electromagnetic compatibility between equipment including networks. The CISPR (International Special Committee on Radio Interference) is responsible for setting limits and measurement methods of radio interference characteristics of potential interference sources.

CENELEC (European Committee for Electrotechnical Standardization) is responsible to produce EMC standards for European countries. For telecommunications equipment, ETSI (European Telecommunications Standards Institute) is responsible to produce the standards. Generally, CENELEC and ETSI use IEC/CISPR publications as the basis for preparation of European EMC standards. For example, the EN55022 (Limits and methods of measurement of radio disturbance characteristics of information technology equipment) is equivalent to CISPR Publication 22.

EMC requirements are regulated by the FCC (Federal Communications Commission) in the USA. The technical requirements are detailed in Code of Federal Regulations CFR 47, Part 15 and Part 18. The American standard for EMC measuring instrumentation and test methods is ANSI C63.4. It is roughly equivalent to CISPR Publication 16 in most areas.

Open area test site (OATS) is specified in all the EMC standards for conducting the radiated emission test, in the frequency range of 30–1000 MHz. The OATS is a large outdoor area with a perfectly conducting ground plane and free of obstacles and interfering ambient fields. The test site may be enclosed with nonconductive materials such as canvas or air-supported plastic for protection against weather. The instrumentation is as shown in Fig. 1. The large conductive floor is required so that radiation directed toward the floor can be reflected to the receiving antenna. The sum of the reflected wave and the

DOI 10.1007/978-981-4560-75-7_81-1

wave traveling directly from the equipment under test (EUT) to the receiving antenna will be measured. As the motorized mast carries the receiving antenna to move from 1-m to 4-m height, the conductive floor may cause the electric field amplitude to double at certain angles, due to constructive interference of the direct wave and ground-reflected wave. The radiated emissions must be measured at all directions around the EUT. This is achieved by using a nonconductive rotating turntable as the pedestal for the EUT and a fixed location of receiving antenna. For an automated measurement system, a broadband antenna (such as biconical antenna and log periodic antenna) should be used so that a high-speed scanning over a wide frequency range can be accomplished while the turntable is rotating continuously. This is to search for the EUT's angle and antenna height in which the radiated emission is the highest. The antenna polarization is arranged in the vertical orientation in a sequence of measurements. It is then arranged for horizontal polarization in another sequence of measurements. The EUT must be in its complete system configuration, with all interconnected peripheral equipment connected such that the emission is maximized. The RF field amplitude is then measured by the receiver which is basically a spectrum analyzer. The computer is programmed to automate the measurement process.

The measuring distance, R, between EUT and receiving antenna can be 3 m, 10 m, or 30 m depending on the device class of the EUT. The distance is defined from the nearest perimeter of the EUT to the reference point of the antenna. The ellipse of Fig. 1 defines the area that must be flat and free of reflecting obstacles. The control room where the test instrumentation is housed must be some distance away from the site or constructed directly below the ground plane. The 10-m range is by far the best test environment, whereas the 3-m range has been shown to cause immense problems of measurement uncertainty (Garn et al. 1993).

The characteristics of a minimum standard OATS are defined in CISPR 16 and ANSI C63.4. The required site shall be validated through normalized site attenuation (NSA) measurements at frequencies from 30 to 1000 MHz for both horizontal and vertical polarizations. The instrumentation configuration is the same as the setup for the EUT compliance tests except the EUT is replaced by a known transmitting source. The measured NSA data shall be compared to that calculated for an ideal site. A test site is considered acceptable for radiated emission measurements if the measured results are within ± 4 dB of the theoretical NSA for an ideal site. The ± 4 dB tolerance includes instrumentation calibration errors, measurement technique errors, and errors due to site anomalies. If the measuring distance is 3 m, the mutual impedance correction factors for tuned dipole antennas must be applied to the measurement results.

Absorber-lined semi-anechoic chamber can be used as an alternative site for radiated emission measurements provided it fulfills the NSA requirements. A semi-anechoic chamber is a shielded enclosure with the walls and ceiling covered with RF wave absorbers, except the floor. Hence, there is no RF reflection from the walls and ceiling. It is designed this way in order to emulate the OATS where RF reflection from the conductive floor is required. However, a single-point NSA measurement is insufficient to pick up possible reflections from the walls and ceiling because the RF absorbing materials are not ideal. For semi-anechoic chamber, the test volume is defined as the volume to accommodate the largest equipment to be tested. In validating the site, transmit antenna shall be placed at various points within the test volume with both horizontal and vertical polarizations. The measurements are carried out using broadband antenna. In the European standard, the characteristics of semi-anechoic chamber to be used as an alternative test site are defined in CISPR 16-1-4:2010 (previously defined by EN50147-2:(CENELEC 1997) which was withdrawn in 2008). Semi-anechoic chamber provides a controlled environment with all-weather capability and minimum electromagnetic interference.

On the other hand, the anechoic chamber is often used for radiated immunity measurements according to the EN61000-4-3. In this measurement, a strong RF field is radiated from a transmitting antenna toward the EUT. The standard requires the field at the EUT position to have uniform amplitude distribution from

DOI 10.1007/978-981-4560-75-7_81-1

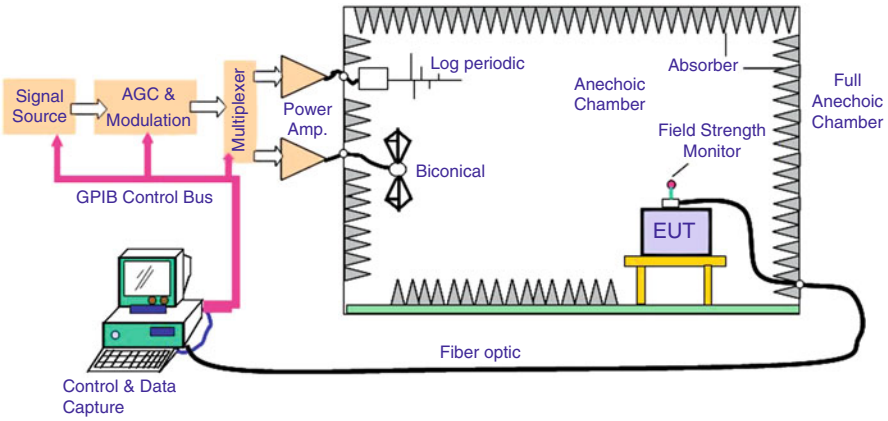

Fig. 2 Radiated RF immunity test setup

80 to 2700 MHz (EN61000-4-3:2006+A2:2010). The field strength at 12 of the 16 points over a grid of plane area (1.5 × 1.5 m with the lowest point at 0.8 m above the floor) must be within the tolerance of −0 dB/ +6 dB. Reflection and resonance effects may cause standing wave in the chamber. In order to meet the field uniformity requirements, the semi-anechoic chamber is converted to a full anechoic chamber by placement of additional RF absorbers on the conductive floor.

A typical radiated immunity test setup is shown in Fig. 2. An electromagnetic field is radiated toward the EUT. Amplitude modulation with 1-kHz signal at 80 % modulation depth is applied and the carrier frequency is swept from 80 to 2700 MHz. Additional test at 900 MHz with 200-Hz pulse modulation may be required by certain product-specific standards. Illumination of the electromagnetic field is applied at four faces of the EUT with both vertical and horizontal polarizations. The applicable electric field strength depends on the expected operating electromagnetic environment. The standard field strengths for severity levels 1, 2, and 3 are 1 V/m, 3 V/m, and 10 V/m, respectively. The most susceptible configuration and operating mode of the EUT are to be set up. A set of parameters that represent the operation of the EUT are monitored from the control room using a CCTV system or other remote monitoring means. For accurate control of the field strength, an isotropic field probe is used to monitor the electric field and adjust the transmitter power level accordingly. The probe is battery powered, and fiber-optic link (instead of electric cable) is used for transferring the measurement data to the control room so that disturbance to the field and EMI leakage to the outdoor space can be minimized.

Changing a semi-anechoic chamber to a full anechoic chamber each time is labor intensive and time consuming. Hence, the study on the use of full anechoic chamber as an alternative site to semi-anechoic chamber for radiated emission measurements was a hot topic of research for some times. The prEN50147-3 (CENELEC 2000) draft standard for emission measurements in fully anechoic chambers was developed by CENELEC. If this test method is accepted as a published standard, a fully anechoic chamber can then be used to perform both radiated emission and immunity tests. However, the draft standard has since been withdrawn in 2012.

EN55022:2010 requires information technology equipment (ITE) shipped into Europe to comply with the new requirement of EMC radiated emission above 1 GHz since October 2011. Full anechoic chamber is specified for the measurement up to 400 GHz. Validation of the test site is to be conducted using the new site voltage-standing-wave ratio (SVSWR) method specified in CISPR 16-1-4 published in February 2007. For the US market, measurement of radiated emission above 1 GHz up to 40 GHz is also required by the FCC. The American National Standards Institute (ANSI) had developed a draft proposal for C63.4 called the time-domain reflectivity (TDR) measurement for validation of test site.

EMC Test Facilities

An OATS must be built on a flat terrain free of reflective obstacles such as buildings, fences, etc. The OATS is exposed to the local electromagnetic ambient environment as well as the weather. EUT emissions may be masked off by the background interference if the frequencies coincide. The background interference (from navigational beacons, telemetry, vehicle ignition, machinery noise, etc.) is often unstable or intermittent, and it makes EUT emissions difficult to be identified. Strong background signals such as FM broadcast transmissions may cause compression and false indications in the spectrum analyzer. A countermeasure to reduce the ambient interference, although not very effective, is to build the OATS in a remote area far away from urbanization.

A screened room can eliminate the problem of ambient interference. With suitable RF absorbers covering the walls and ceiling, undesired reflections can be minimized so that the semi-anechoic chamber (SAC) emulates an OATS. Radiated emission measurement results from the SAC are recognized as having a direct correlation to measurement at an OATS.

Radiated immunity testing is required by the European EMC standards. The OATS is not suitable for radiated immunity test because the transmission of high-power broadband signal for such test in an outdoor environment is prohibited by the radio regulations. For a SAC, RF absorbers may be placed on the floor so that the required field uniformity with maximum variation less than 6 dB over the test volume can be achieved. All these circumstances make SAC much more attractive than OATS as EMC test facility.

The process of achieving product compliance in an electronic product development cycle typically involves a pre-compliance scan to identify the radiated emission spectral lines that are potentially noncompliant to EMC regulations. The pre-compliance test is done using lower-cost test facility and equipment that may not fully meet the standard requirements. Based on the pre-compliance test results, corrective action can be undertaken on the electronic product to eliminate any undesirable emissions that might exceed the regulatory limits, and the outcome can be quickly evaluated in a pre-compliance test facility that is more convenient and accessible. The total test time can be minimized and the overall cost can be reduced. The worst-case EUT configuration can be identified for the final test in a full-compliance test laboratory.

With the absence of background interference, a screened room without RF absorber lining can be used to scan for frequencies of any emissions from an electronic device. However, standing wave will be reinforced by reflections between the opposing walls and between the ceiling and the floor, causing cavity resonance to be established in the screened room. Due to the resonant modes, a large change in the field strength may be encountered with a small change in the antenna position. The coupling between the

DOI 10.1007/978-981-4560-75-7_81-1

source and the receiver antenna at slightly different frequencies can be different by up to 60 dB. The antenna impedance and antenna factor will be much different from the calibrated values. Hence, the emission measurements will be highly unrepeatable, and the results cannot be compared with those obtained in a previous measurement or in other environment. The screened room is therefore not suitable for pre-compliance test.

The gigahertz transverse electromagnetic (GTEM) cell has been widely used for radiated emission/immunity test. It is a tapered coaxial structure. One example is shown in Fig. 3. The taper apex is equipped with a coaxial connector for measurement of EUT emission voltage, or launching of RF wave toward the EUT for immunity test. The other end of the structure is a wide bandwidth termination made of resistors and RF absorbers. There are various sizes of GTEM cells. For desktop equipment testing, a GTEM cell can be 25-ft long with a cross section of 11 ft by 13 ft at the flared end to provide the required test zone volume.

In emission test, the EUT is modeled as a sum of electric and magnetic dipole moments (Brunaugh and Osburn 1991) located at the test zone. The dipole moments are assumed to be in phase. Three apex voltages corresponding to three orthogonal rotations of the EUT are measured. The vector sum of these voltages is equal to the sum of the dipole moments. The total radiated power emitted by the EUT can be determined from the propagation constant and the sum of the dipole moments. The analysis assumes that the transverse electromagnetic (TEM) mode is the dominant propagation mode. Higher-order TE and TM modes are weakly coupled to the GTEM cell, and the broadband match provided by the termination suppresses the formation of the higher-order modes.

To predict the radiated emission of the EUT that will be measured at an OATS, the EUT is modeled as a resonant dipole fed with the total radiated power as calculated from the apex voltages. The prediction method takes into account ground reflection and the effect of receiving antenna scanning in height from 1 m to 4 m. The FCC will accept the test data generated from this technique as equivalent to OATS provided the correlation can be established. Emissions are to be measured using both GTEM and OATS methods for the specific product type as a test case. The correlation will allow for the GTEM results to be accepted in the future.

The dominant radiation source of many products is the cables. The ability to orient the cables for maximum emission is required for the EMC test. The major drawback of the GTEM cell is in measuring cable emissions. Orthogonal rotations of a cable are not very practical within the limited space of the GTEM cell. Products that have test setup or cabling dimensions larger than about 1.5 m cannot be accurately tested in a GTEM cell.

Mode-stirred chamber (MSC) or reverberation chamber is another technique for performing radiated emission/immunity tests (Corona et al. 1976). It is a screened room without RF absorbing material so that the MSC acts as a high-Q resonant cavity. The size of the MSC is typically many wavelengths long. The field distribution in the chamber is very complex and rapidly varying with spatial displacement of the probe. At five times the first cavity resonant frequency, the mode spacing in frequency space is very dense. A motorized conducting paddle wheel or vane is located inside the chamber to provide mode-stirring action. A field maximum occurs at each point in the chamber during one rotation of the paddle. The resonant modes cause the field density within the chamber to become nearly constant over the chamber volume. Effectively the gain of any antenna is forced to become unity.

The MSC can be used to measure differences in radiated emission by an EUT when changes to the EUT are made. The property of unity gain results in repeatable measurements since the effects of cable movement are minimized. The total radiated power measured with the MSC is different from the total radiated power that would be generated by the same EUT at an OATS. Hence, the MSC is only good for statistical averaging of data for improvement/degradation comparisons and for radiated immunity tests. Emission measurements made in a MSC cannot be used for certification purposes.

DOI 10.1007/978-981-4560-75-7_81-1

Large semi-anechoic chambers (SAC) with a measurement distance of 10 m between the EUT and the receiving antenna are by far the best test environments for EMC radiated emission test. The required characteristics of the SAC are defined in ANSI C63.4 and CISPR 16-1-4:2010. Most of the European product standards require the emission measurement to be performed at 10-m range. The FCC also requires emission measurement to be performed at 10-m range for Class A devices, while the use of 3-m range is acceptable for Class B devices. Large measurement uncertainty is inherent in the measurement at 3-m range (Garn et al. 1993). In addition to mutual coupling between the source and the receiver, the antenna factors supplied by the antenna manufacturer may be affected by up to 5 dB in the low-frequency range due to interactions with the nearby walls (Hansen et al. 2000). At higher frequencies, reflection from the wooden turntable may cause a dip of as much as 20 dB in the site attenuation frequency response. Despite the problems, the high cost of 10-m range forces most manufacturers of electronic products to invest in 3-m range SAC for pre-compliance tests. Full-compliance 10-m range SACs are only available at a few test laboratories.

The study on the use of full anechoic chamber (FAC) for radiated emission measurements has been rather intensive. It has long been recognized that the presence of ground plane in OATS and SAC introduces a considerable measurement error especially for horizontal polarization measurements below 70 MHz. Another factor that motivated the development of FAC is the requirement to perform radiated immunity test in such facility. Movement of absorber in and out when converting a SAC to a FAC each time is very labor intensive and time consuming, and it reduces the efficiency of the test laboratory.

In a FAC, the height scan of the receiving antenna in radiated emission test is not necessary because there is no reflection path that could introduce phase cancelation of the field at certain antenna height and frequency. The test time can be significantly reduced. The quasi-free-space environment eliminates the need to consider height-dependent antenna factors for the measurements. A method for correlating the FAC test result to OATS measurement has been developed by Ristau D. and Hansen D. (2000). Under far-field conditions, computing free-space field strength for different measurement distance is straightforward. The levels measured at 10-m distance will be 10.46 dB lower than the levels at 3-m distance since the field strength is inversely proportional to distance (i.e., decays at a rate of 1/r). Over a conductive ground plane, this relationship is not valid due to additional reflections from the floor.

EM Shielded Room Design

The ideal environment for making RF wave measurements should be free from electromagnetic wave not directly associated with the measurements. The isolation prevents extraneous energy from masking measurements of RF wave of interest and protects nearby systems from interference caused by electromagnetic energy generated by radiation source used in the measurement instrumentation.

For various types of RF measurements, shielded rooms are widely used to provide the required isolation from the increasingly crowded electromagnetic environment. A room space completely enclosed by conductive plates will be shielded against electromagnetic radiation. However, leakage of electromagnetic waves is unavoidable due to ventilation holes and access door to the shielded enclosure, as well as cables penetrating the shielded enclosure for signal/power interconnection purposes. The shielding effectiveness is also affected by different construction methods which give rise to varying degrees of imperfection. In the design of a shielded room, the considerations should include the purpose of the shield, the type of equipment involved, the measurement of distance, and the sensitivity of the information being processed.

A conductive shield absorbs and reflects the energy of an approaching wave by allowing induced current to flow on its surface. Smooth flow of the induced current is required to provide efficient shielding

DOI 10.1007/978-981-4560-75-7_81-1

effect. The presence of holes or slots diverts the current and reduces the shielding effectiveness. In all practical cases, openings in a shield are necessary for ventilation, wiring, and access door into a screened enclosure. The effects of the holes can be analyzed as slot antennas, and the length of slot perpendicular to the direction of current flow determines the amount of radiation leakage. A good shielding practice must ensure all slots are shorter than a quarter wavelength at the highest operating frequency. Overlapping conductive sheets without electrical bonding or continuity will not eliminate the effects of the slot. High conductivity metallic gaskets (such as wire knit mesh or beryllium copper "finger stock") are commonly used to close the gaps. Some conductive gaskets designed solely for electrostatic protection are not suitable for EMI shielding. Any increase in local impedance will allow EM fields to penetrate and degrade the shielding effectiveness. Conductive paint or caulk is sometimes used to bond the joints.

Specialized "honeycomb" vents are commonly used to facilitate airflow into and out of the shielded enclosure. The openings are formed using a large number of small hollow waveguide tubes welded together in a "honeycomb" fashion. A waveguide has a high-pass response. The cutoff frequency depends on the cross-sectional dimensions. The waveguide cross section must be small enough so that the cutoff frequency is much higher than the highest operating frequency. Below the cutoff frequency, an EM field entering the waveguide will be attenuated exponentially with the waveguide length.

No conductor should pass through the opening hole or waveguide (except nonconductive fiber-optic cable). A wire passing through a hole can cause much more harms than the hole itself. The wire guides the RF field through the hole and then reradiates it into the air space. Feedthrough capacitors, filters, and common-mode choke are commonly mounted directly in the hole to bypass or impede the flow of the interference current in wires intended for low-frequency signal or power. For cables intended to carry high-frequency signals, the outer conductor of the coaxial cable must be bonded all around the hole. Ferrite ring can be fitted on the coaxial cable to suppress common-mode interference current.

The metals commonly used in screened room fabrication are sheet copper, aluminum, or steel. The 24-gauge galvanized/zinc-plated steel sheet is widely used to laminate onto wooden boards. Theoretically, the sheet metals can offer more than 120-dB shielding effectiveness. However, in all practical cases, shielding effectiveness of screened enclosure in excess of 120 dB is rarely to be achieved (Hemming 1992). It is due to the presence of holes/seams, high-impedance discontinuities, and wires/cables passing through holes in the shield. Shielding integrity can only be maintained when doors, vents, filters, and piping are carefully designed and constructed. On the other hand, resonance effects may cause certain areas within a screened room to exhibit poorer performance.

Smaller screened enclosure can be constructed as modular clamp-up structure using prefabricated wooden panels which are laminated with sheet metals. The panels are tied together to form the six-sided free standing room. Metal-to-metal seal between the panels is provided by the clamping unit which comprises two metal straps brought together by a number of screws. The shielding performance can be easily degraded by discontinuity between the panels and the presence of cracks or breaks between the panels. Attentions to meticulous details are critical in the installation work. Electrical continuity requires cleanliness around the edges of the panels. Painting of the shielding panels is not recommended since the paint may be capillary under the metal clamping straps and degrades the shielding properties of the system.

Modular clamp-up construction has the disadvantage that people moving about the enclosure tend to cause the floor panels to become loose as a result of varying loads and constant stresses. Corrosion of the clamped seams will also degrade the shielding effectiveness. It may incur expensive maintenance and recertification. Water may cause the wooden core to swell and damage the shielding integrity. Hence, modular screened room is not suitable for climate that has continuous high humidity.

When the required room size exceeds 240 ft^2, welded construction must be considered. Large modular system may not be practical because expensive steel support structure will be required to carry the weight

DOI 10.1007/978-981-4560-75-7_81-1

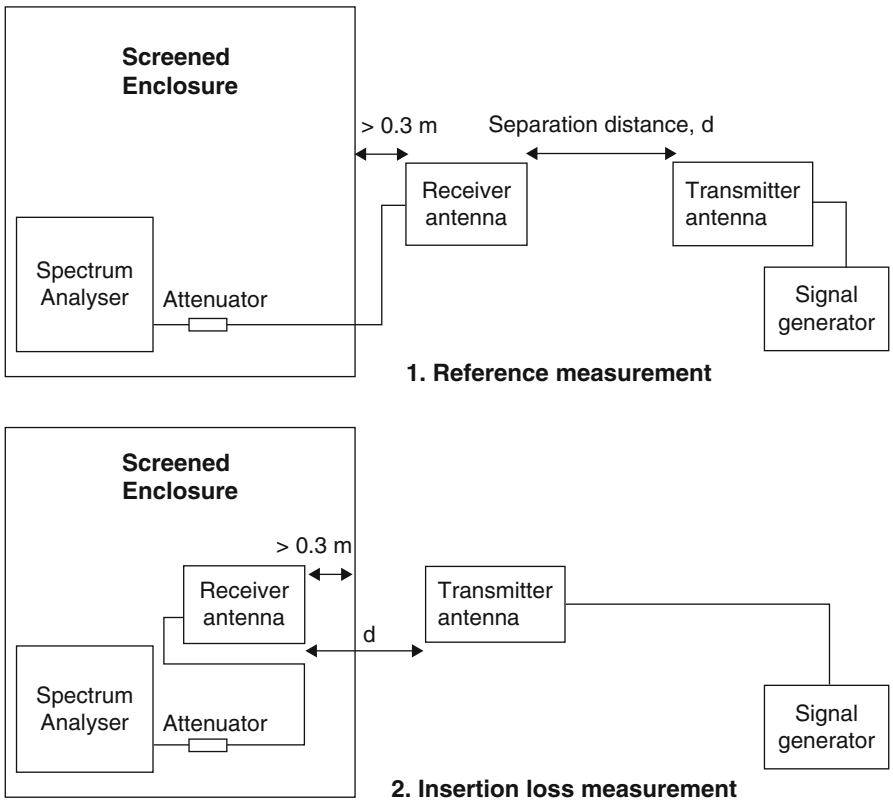

Fig. 4 Method of measuring shielding effectiveness

of the ceiling panels of the screened enclosure. Welded enclosure provides reliable structural and long-term high-performance shielding. Low-carbon steel may be used if reduction of material cost is desirable. However, it has the tendency to rust when exposed to moisture unless it is protected with paints containing a large amount of zinc. Galvanized steel is not recommended because it may produce toxic gas in the welding process.

Many welded shielding enclosures could not meet the expected performance due to lack of attention to proper shielding design and poor field practices. The constructability of the design must be considered for all seams to be properly welded. Sufficient access must be available for welding of corner seams. Well-qualified welders must be engaged to do the work and good quality control must be in place. Metal inert gas (MIG) or shielded metal arc welding process must be used so that high-quality electromagnetic properties can be obtained. The welds must be free of slag, inclusions, gas pockets, worm holes, cracks, or incomplete fusion.

Buckling of the shielding sheet due to heat applied during the seam welding process is difficult to control. It can be reduced using a pan welding technique. The required pan-shaped sheet metal is formed by means of cutting and bending the metal sheet edges. Adjacent pans can be temporarily clamped together for welding at the edge of the pans. The main disadvantages are the amount and cost of shop fabrication and reduced density for transportation.

Butt welding requires no shop fabrication, resulting in lower material cost. Rectangular metal sheets in the largest available size are laid out side by side to be welded together onto a backing structure. For the shield floor, the backing structure can be formed with a network of metal straps or square tubing embedded in concrete slab. Buckling is most troublesome in this welding technique. Tack welding at some intervals along the seam prior to running a continuous weld may ease the buckling effect.

DOI 10.1007/978-981-4560-75-7_81-1

Architectural shielding system where metal foil or sheet metal is built into the walls, floor, and ceiling of existing or new construction is used for application requiring moderate shielding performance. Electrical continuity is maintained by the use of soldering and shielding tapes to join together the metal shields.

The required shielding effectiveness is primarily determined by the operational purpose of the facility. The appearance, HVAC, physical layout, and environmental requirements also depend on the operational purpose. For the construction of 10-m range anechoic chamber for microwave research and EMC tests, a welded shielding enclosure would be the most preferred type.

The methods of measuring the shielding effectiveness (SE) of screened enclosure are specified in MIL-STD-285, IEEE Std 299, EN50147-1, and other government standards (such as NSA 65-6, NSA 73-2A, etc.). The basic principle of the measurements is a method of substitution. A reference reading is made outside the screened enclosure at a prescribed edge-to-edge separation between the transmitter and the receiver antennas. Next, the measurement is performed with the shield barrier placed in between the antennas at the same separation. SE is measured from the decrease of attenuation setting on the receiver which produces the same reference reading. An illustration is given in Fig. 4.

The IEEE Std 299 divides the measurement frequencies into low range (0.009–20 MHz), resonant range (20–300 MHz), and high range (0.3–18 GHz). For the low range, low-impedance magnetic field is measured using 0.3-m-diameter loops placed 0.3 m from the wall. Spot frequency points for shielding measurements are chosen by the owner, and the required levels of SE are specified based on the functions of the screened enclosure. For the resonant range, vertical and horizontal polarization measurements are performed using biconical or dipole antennas placed at separation distance of 2 m. The geometric shape and physical size of the screened enclosure can significantly affect the measurements. Testing at or very near the enclosure resonant frequency shall be avoided. Dipole, horn, biconical, Yagi, log periodic, and other linear antennas are recommended for the high range. Plane-wave test is the most important requirement of a screened enclosure since shielding is primarily needed to provide isolation of ambient electromagnetic interference wave or radiated emissions from the EUT placed in the screened enclosure.

The RF power into the transmitter antenna shall be adequate to obtain the required measurement dynamic range. In all measurements, the receiver shall be located inside the screened enclosure with the transmitter external. This procedure allows the sensitive receiver to be protected from the field of the transmitter antenna and other ambient fields. Ferrite loaded cable shall be used to suppressed the parasitic reflections. Effects from nearby objects or personnel shall be minimized.

The measured insertion loss by method of substitution contains the properties of the shield barrier intermingled with the properties of the measuring circuits (antennas, cabling, attenuator, signal source, and receiver). In general, the properties of the shield barrier cannot be separated from those of the measuring circuits. Hence, the insertion loss cannot be used to estimate the voltage or current induced in an arbitrary internal circuit by an arbitrary external source. One exception is the special case where the source of interference is like the transmitter antenna system used in the SE measurement and the victim circuit to be protected is like the receiver antenna system. The same ambiguity is not experienced by RF circuit designer in characterizing filters, attenuators, connectors, and other RF devices because the devices are measured with 50-Ω terminations and used in 50-Ω circuits. Parasitic coupling of the electromagnetic field with the surrounding devices is usually not an issue of concern especially in the characterization of coaxial devices. In contrast, resonance and other reflective condition effects in shielding measurement may cause a large variation of SE measured at different frequencies.

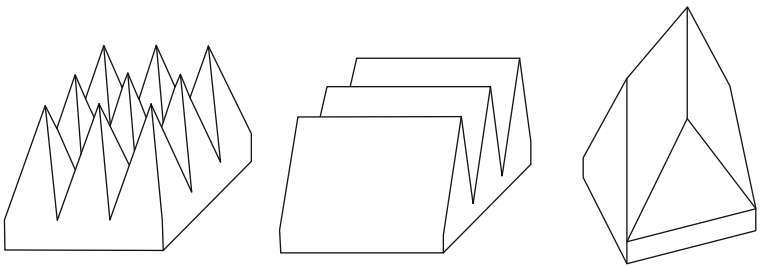

Fig. 5 Absorbers of the shape of (**a**) pyramid, (**b**) wedge, and (**c**) twisted pyramid

RF Absorbers

For antenna, radar, and EMC radiated emission measurements, the shielded enclosure must be sufficiently large so that the receiver can be placed at a far-field distance away from the radiation source. Minimum reflection should take place from the inside of the enclosure walls. Hence, RF absorbing material which has low reflection coefficient and sufficient attenuation is used over the entire inner surfaces of the enclosure to create an anechoic environment. In this case, the strength of the shielding structure must be strong enough to support the weight of the RF absorber. The shielded enclosure must also be sufficiently wide so that the distance between the radiation source and the RF absorber is beyond the reactive-radiative coupling boundary for the absorber to work efficiently.

The choice of RF absorber to be used is a function of the purpose of the anechoic chamber. The required electrical performances as well as the absorber shape, thickness, weight, mounting method, cost, and logistic must be considered. For antenna and radar measurements above 1 GHz, a 24-in.-thick pyramid absorber may be suitable. However, it would not be able to provide a sufficiently low reflectivity at lower frequencies. Standing wave will be reinforced by reflections between the opposing walls and between the ceiling and the floor, causing cavity resonance to be established in the shielded enclosure. The absorber may not give sufficient damping of Q factors of the resonant modes.

Absorbers made of pyramidal shape carbon impregnated urethane foam can provide an extremely broadband performance. The wave impedance gradually tapers from that of free space at the tip of the pyramid to those of a lossy medium at the back surface. However, in order for it to function efficiently, the height of the pyramid must be greater than a quarter wavelength. If the lowest operating frequency is 1 GHz, a 24-in. pyramidal foam absorber may offer a reflectivity level below −40 dB over the frequency range from 1 to 40 GHz at normal incidence. The percentage carbon loading of the foam material can be adjusted to provide optimum performance. For lower frequency of 30 MHz, 6-ft-thick absorbers have been used for construction of EMC anechoic chambers. Although the taper length is several wavelengths for frequencies above 1000 MHz, the long absorbers restricted the application of these chambers to approximately 1000 MHz (German 1982). To reduce the taper length to less than quarter wavelength, a different carbon loading for the foam pyramids must be used to achieve low reflectivity. The impedance taper will be too abrupt if the carbon loading is too high. Consequently, the incident wave will be reflected from the region near the pyramid tips instead of penetrating into the absorber medium. On the other hand, less reflection and more penetration of the incident wave into the absorber medium may result if the carbon loading is too low, but the wave may not be sufficiently absorbed. With a carbon loading to give reflectivity of −20 dB for the 200–1000-MHz range, the pyramids may not provide adequate performance at higher frequencies (Holloway et al. 1997) where the absorber reflectivity must be better than −40 dB for the typical applications in designing antenna and radar cross-section measurement chamber.

Twisted pyramid structure has been used in the fabrication of thick absorbers due to its improved mechanical strength. The pyramid is “twisted” by 45° with respect to the base as shown in Fig. 5. The tips

DOI 10.1007/978-981-4560-75-7_81-1

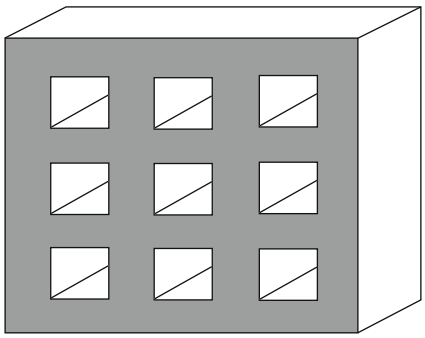

Fig. 6 Ferrite grid RF absorber

of the pyramid will droop less with age than the tips of the standard pyramid. However, some trade-off in its electrical performance will be incurred. Scattering from wedge-shaped absorbers has been reported by DeWitt and Burnside (1988). Better absorbing characteristic compared to pyramidal shape can be obtained for wave directions nearly parallel to the ridge of the wedge.

Resistive material can be made by dispersing microscopic particles of metal in a nonconducting matrix. Hollow pyramid-shaped substrate with a height of quarter wavelength can be coated with the resistive material to make a lightweight wideband absorber. This kind of long pyramid-shaped absorber with adequate mechanical strength has been used for construction of EMC test chamber.

Broadband absorption can also be achieved by increasing the material loss tangent with depth from a flat outer surface. A practical approach is to use multiple layers of carbon impregnated foam. The layers have increasing impedance from the front layer toward the bottom layer, hence achieving an electrical taper that yields a material with good reflectivity level over a wide frequency range. This kind of absorber can be installed at the right-angled corners between two walls or between the wall and the ceiling to absorb electromagnetic wave where long pyramid-shaped absorber is hard to install.

Recently, many EMC test chambers have utilized ferrite tile absorber to obtain low-frequency wideband reflectivity performance. The ferrite tile (NiZn) with a thin profile of 0.25 in. may offer a reflectivity level below −15 dB over the frequency range of 30 to 600 MHz. The reflectivity typically deteriorates rapidly at higher frequencies (Holloway et al. 1997). A ferrite grid is shown in Fig. 6. Combination of the square air section and the ferrite material can be considered as a composite substance having an equivalent complex permittivity and permeability. The filling factor or fraction of space occupied by ferrite can be selected in order to engineer a reflectivity null at a desired frequency. Ferrite grid with a thickness of 0.75 in. may cover the frequency range of 30–1000 MHz (Mayer et al. 1998). Exponentially tapered ferrite grid has been shown to widen the bandwidth to 2400 MHz (Kim et al. 1996).

The ability of ferrite material to absorb electromagnetic wave over a very wide bandwidth is attributed to the availability of ferrite sintering process to precisely control the dielectric constant and complex permeability characteristics of the material. The required relationships are (Mayer and Chaumat 1992)

$$\mu'' \geq 3\mu' \tag{1}$$

$$\frac{d}{\lambda} = \frac{1}{2\pi\mu''} \tag{2}$$

and

$$\varepsilon' = 3\mu' \tag{3}$$

DOI 10.1007/978-981-4560-75-7_81-1

where λ is the wavelength, $\mu = \mu' - j\mu''$ is the complex permeability, $\varepsilon = \varepsilon' - j\varepsilon''$ is the complex permittivity, and d is the thickness of the material. The thickness is much less than a quarter wavelength. As λ decreases with frequency, the material is made to have μ'' decrease at the same rate for relations Eq. 2 to be fulfilled over the desired bandwidth. The wave impedance is close to the impedance of free space, hence allowing the incident wave to penetrate the ferrite tile without significant reflection at the air-to-tile interface. Because the ferrite is magnetically lossy, the penetrating wave is absorbed as it travels through the tile. The wave is subsequently reflected by the metal backing and travels toward the tile/air interface.

The reflectivity of ferrite tiles and grids can be improved by simply adding a dielectric layer between the ferrite and the metal wall (Holloway et al. 1997) of the screened room. Commercial plywood with dielectric constant of about 2 can be used as the ferrite backing. Optimum performance over a wider bandwidth can be achieved by a proper selection of the dielectric thickness.

Ferrite tiles that are effective from 30 to 600 MHz have been combined with thin urethane foam pyramids and wedges that are optimized to operate from 200 to 1000 MHz. This configuration is called a hybrid absorber. It combines the advantages of ferrite tiles and pyramid foam absorbers to cover the EMC frequency range of 30 to 1000 MHz. The carbon loading of the pyramids must be suitably selected such that the low-frequency performance of the ferrite tiles is not degraded.

A general guideline on the selection of RF absorbers has been given by Holloway et al. (1997). For a 10-m SAC, the absorber reflectivity shall be lower than -20 dB at normal incidence throughout the 30–1000-MHz frequency range. Additionally, the reflectivity shall be lower than -15 dB at 45° incident angle. These characteristics may be provided by a 2.5-m pyramidal absorber. Hybrid absorber consisting of a 24-in. pyramid and 0.25-in. ferrite tile may be used to reduce the required screened room size. Ferrite grid (with a thickness of 0.75 in.) and multilayered ferrite tiles are commonly used for construction of 3-m SAC. The hybrid absorber and ferrite grid/tile are very expensive. In addition, their weight (>30 kg/m^2) is generally heavier than foam absorbers. The structural strength of the shielded room must be strong enough to support the weight of the ferrite material. The special room structure adds to the cost of constructing the anechoic chamber.

Small- and medium-size foam absorbers are conventionally glued onto the chamber wall using rubber-based contact adhesive. Pyramid longer than 3 ft is usually supplied with metal base plate to be installed onto a rail-and-clip mounting system on the chamber wall in order to ensure the installation reliability. Ferrite tiles can be installed using glue. However, due to the weight and sharp edges of the tile, overhead net must be installed as safety measure to prevent fallen tile from injuring or killing the personnel who enters the chamber room. A more secure method is to install a plywood panel onto the wall and then fasten the ferrite tile through a center hole onto the plywood panel using self-tapping screws. The gap between adjacent tiles can then be precisely controlled to give better reflectivity performance in contrast to using adhesive in which some glue may get in between the tiles. The plywood panel also acts as the dielectric backing to improve the performance of the ferrite tile.

A good quality absorber alone does not guarantee a good performance for the anechoic chamber in terms of "quietness" of the quiet zone, field uniformity, and site attenuation. The lining of the absorbers must be done carefully to minimize the discontinuity between the neighboring absorber panels. Gaps and misalignment of the pyramids may give a much poorer reflectivity than the manufacturer specification.

In addition to electrical and mechanical specifications of the absorber, the fire retardant property of the absorber must also be considered in order to comply with building safety codes. Lifespan and maintenance needs of the absorber may also be an aspect to consider in the absorber selection criteria.

DOI 10.1007/978-981-4560-75-7_81-1

Test Site Validation Method (Below 1 GHz)

Radiated emission measurement results may be affected by any imperfections in the test site and the characteristics of the receiving antenna. Therefore, the test site must be validated before it can be used for EMC compliance tests. The validation method involves a series of normalized site attenuation (NSA) measurements to be carried out for the given transmitter-receiver separation and heights above a flat conductive surface for both horizontal and vertical polarizations. Antenna spacing used for making site attenuation measurements shall be the same as the spacing used for the EUT radiated emission measurements at frequencies from 30 to 1000 MHz. The measured NSA results shall be compared to that calculated for an ideal OATS. A test site is considered acceptable for EMC compliance test if the measured NSA results are within ±4 dB of the theoretical NSA for an ideal site.

Site attenuation is defined as the ratio of the voltage input to a matched and balanced lossless tuned dipole radiator, V_T, to that at the output of a similarly matched balanced lossless tuned dipole receiver antenna, V_R. From the Friis transmission formula, the site attenuation, SA, is given by

$$SA = \frac{V_T}{V_R} = \sqrt{\frac{P_T}{P_R}} = \sqrt{\frac{d^2\lambda^2}{(A_{\text{eff}})_T (A_{\text{eff}})_R}} \tag{4}$$

where d is the antenna spacing, λ is the wavelength, $(A_{\text{eff}})_T$ is the effective area of the transmitter antenna, and $(A_{\text{eff}})_R$ is the effective area of the receiver antenna.

Antenna factor, AF_R, is defined as the ratio of the electric field strength, E_R, to the receiver antenna output voltage, V_R. The relationship between $(A_{\text{eff}})_R$ and AF_R is given by

$$(A_{\text{eff}})_R = \frac{\text{Received Power}}{\text{Power Density}} = \frac{\eta}{R_o} \cdot \frac{V_R^2}{E_R^2} = \frac{\eta}{R_o AF_R^2} \tag{5}$$

where η is the intrinsic wave impedance (377 Ω) and R_o is the reference impedance (50 Ω). From the reciprocity theorem, the same relationship is also true for the transmitter antenna, given by

$$(A_{\text{eff}})_T = \frac{\eta}{R_o AF_T^2} \tag{6}$$

Substituting Eqs. 5 and 6 into Eq. 4, SA can be rewritten as

$$SA = \frac{V_T}{V_R} = \frac{d \cdot \lambda \cdot R_o}{\eta} AF_T \cdot AF_R \tag{7}$$

Normalized site attenuation (NSA) is defined as

$$NSA = \frac{SA}{AF_T \cdot AF_R} = \frac{V_T}{V_R} \cdot \frac{1}{AF_T \cdot AF_R} \tag{8}$$

In the NSA measurement, V_T is measured with the two coaxial cables disconnected from the two antennas and connected to each other via an adapter. V_R is measured with the coaxial cables reconnected to the two antennas and the maximum signal measured with the receive antenna scanned in height from 1 m to 4 m. With all terms in dB, the measured NSA is given by:

DOI 10.1007/978-981-4560-75-7_81-1

Fig. 7 NSA test setup in an EMC test chamber

$$NSA = V_T - V_R - AF_T - AF_R \tag{9}$$

The antenna factors may be affected by mutual coupling if the transmitter and the receiver are in the near field. For 3-m antenna spacing, mutual impedance correction factors, ΔAF_{total}, must be applied. The measured NSA is then given by

$$NSA = V_T - V_R - AF_T - AF_R - \Delta AF_{\text{total}} \tag{10}$$

V_T and V_R can be measured using a spectrum analyzer. Alternatively, SA or ratio of V_T to V_R can be measured using a vector network analyzer. With a full 2-port calibration performed at the cable ends, the measured S_{21} with the cables connected to the respective antennas gives the value of SA with vector error correction for source mismatch, load mismatch, and transmission tracking errors. Additional 6-dB attenuators can be fitted to the transmitter and receiver antenna terminals to improve the impedance matching.

A discrete frequency measurement method can be used with tuned dipole antennas for OATS validation. Swept frequency method must be used with linearly polarized broadband antennas for semi-anechoic chamber (SAC) validation so that any resonance or undesired reflections that cause large peaks and nulls in the NSA frequency response can be spotted. The frequency sweep speed shall be much faster than the receiver antenna height scan speed. Figure 7 shows the photograph of an NSA test setup in an EMC test chamber. A bilog-periodic antenna is mounted on a nonconductive antenna mast for height scan. Alternatively, swept frequency measurements can be performed at discrete antenna heights, so long as the height step is small enough to detect the maximum signal.

In an EMC compliance test scenario, the EUT size is considerably larger than a point source. When the EUT rotates with the turntable, the source position could be moved. For a SAC, a single-point NSA measurement is insufficient to pick up possible reflections from the chamber structure and RF absorbers covering the walls and ceiling of the chamber. The test volume to accommodate the largest equipment to be tested shall be defined. Volumetric NSA measurements shall be performed with the transmitter antenna placed at various points within the test volume for both horizontal and vertical polarizations.

The positions of the transmitter and receiver antennas for the volumetric NSA measurements are illustrated in Fig. 8. The separation distances are measured with respect to the center of the antenna. The position of the receiver antenna shall be relocated to maintain constant distance. For vertical polarization, the lower tip of the antenna shall be more than 25 cm from the floor. For horizontal polarization measurements in the left and right positions, the center of the antenna is moved toward the center of the test volume so that the extreme tip of the antenna is at the periphery of the test volume diameter. With

DOI 10.1007/978-981-4560-75-7_81-1

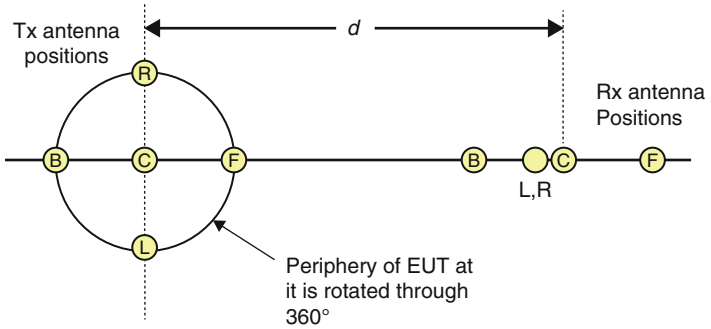

Fig. 8 Antenna positions for volumetric NSA measurements

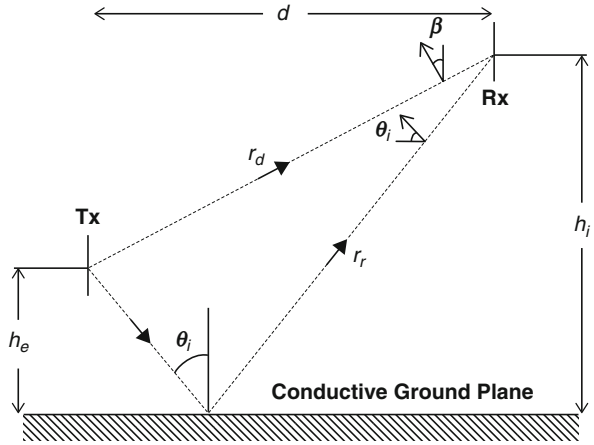

Fig. 9 Geometry of the transmitter and receiver antennas for NSA measurements

5 positions (center, left, right, front, and back), for 2 polarizations and for 2 heights (1 m and 1.5 m for vertical polarization, 1 m and 2 m for horizontal polarization), a maximum of 20 separate NSA measurements are required.

The NSA measurements for the back position would not be required if the closest point of the RF absorber is at a distance greater than 1 m from the rear boundary of the test volume. Further, if the test volume is less than 1-m depth, by 1.5 m in width, and by 1.5 m in height including the turntable, horizontal polarization NSA measurements need to be made at only the center and front positions for 1-m and 2-m heights. The vertical polarization NSA measurements need to be made for only 1-m height at the center, front, left, and right positions. The number of required measurements can be reduced to 8 separate NSA measurements.

The theoretical NSA model has been developed by Smith et al. (1982). For a transmitter power of 1 picoWatt, the theoretical NSA is given by

$$NSA_{TH} = -20\log(f) + 48.9 - 20\log|E_D|_{\max} \tag{11}$$

where f is the frequency in MHz and $|E_D|_{\max}$ is the maximum field strength detected by the receive antenna scanned in height from 1 m to 4 m. For the measurement geometry in Fig. 9, the field strengths $|E_{DH}|$ and $|E_{DV}|$ for horizontal polarization and vertical polarization, respectively, are given by

DOI 10.1007/978-981-4560-75-7_81-1

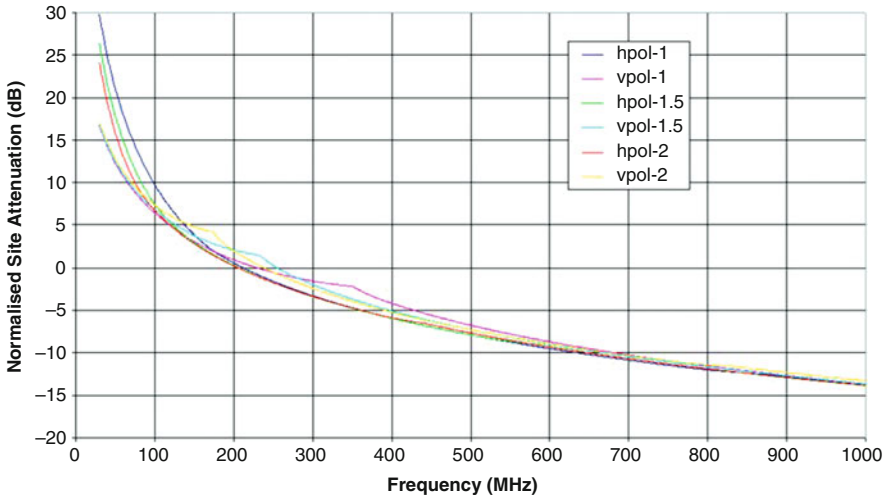

Fig. 10 Theoretical NSA for transmitter antenna height 1 m, 1.5 m, and 2 m ($d = 10$ m)

$$|E_{DH}| = \frac{\sqrt{49.2}\left\{{r_r}^2 + {r_d}^2 - 2r_d r_r \cos\left[\frac{2\pi}{\lambda}(r_r - r_d)\right]\right\}^{1/2}}{r_r r_d} \tag{12}$$

$$|E_{DV}| = \frac{\sqrt{49.2}d^2\left\{{r_r}^6 + {r_d}^6 + 2{r_d}^3{r_r}^3 \cos\left[\frac{2\pi}{\lambda}(r_r - r_d)\right]\right\}^{1/2}}{{r_r}^3{r_d}^3} \tag{13}$$

$$r_d = \sqrt{(h_i - h_e)^2 + d^2} \tag{14}$$

$$r_r = \sqrt{(h_i + h_e)^2 + d^2} \tag{15}$$

The antennas are theoretical half-wave dipoles with antenna gain of 1.64. However, an isotropic radiation pattern is assumed. Large peaks and nulls in received signal strength will be found in the height scan. The receiver antenna height h_i is selected to give maximum field strength. Figure 10 shows the theoretical NSA for transmitter antenna height 1 m, 1.5 m, and 2 m. Figure 11 shows the receiver antenna heights at which maximum field strength is expected to be detected. Detection of maximum signal eliminates the sensitivity of the measurements to nulls due to cancelation between the direct signal and the ground reflection. However, at frequencies below 190 MHz (for $h_e = 1$ m and $d = 10$ m), maximum field strength for horizontal polarization can only be detected at a receiver antenna height above 4 m. Below 4-m height, the direct signal will not be in phase with the ground reflection. Hence, larger measurement errors are anticipated at the low-frequency range.

Accurate antenna factors must be used in determining the measured NSA. Due to coupling to the ground plane, the antenna factors may vary with the height at which the antenna is positioned. The height-dependent corrections for antenna factors are available for tuned dipole antennas (Sugiura 1992). For broadband antennas, the free-space antenna factors are usually used. The height-dependent characteristics are not completely understood; therefore, they are arbitrarily assumed negligible in most cases or lumped into the error budget (±4 dB) of ANSI C63.4 standard. A study by Mann and Marvin (1994) has shown that the antenna factors of biconical antenna (30–300 MHz) may vary significantly (±1 dB) with antenna height above a ground plane.

DOI 10.1007/978-981-4560-75-7_81-1

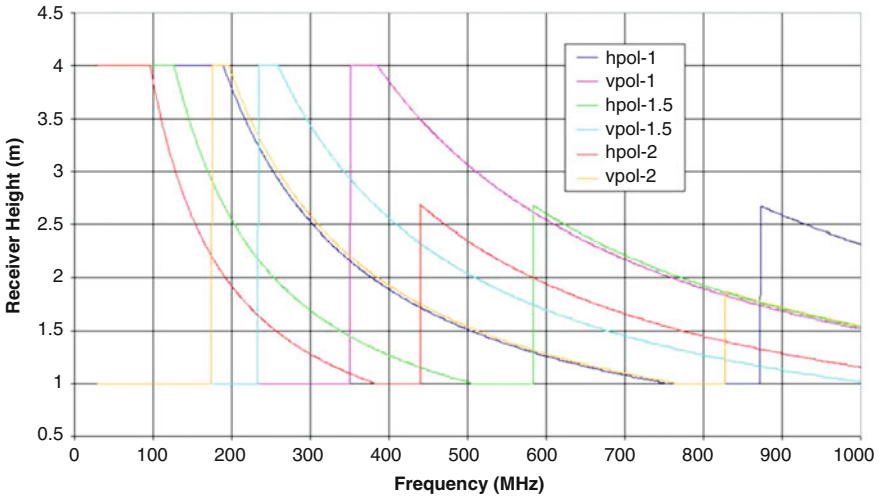

Fig. 11 Receiver antenna heights at which maximum field strength will be detected for transmitter antenna height 1 m, 1.5 m, and 2 m ($d = 10$ m)

A well-constructed OATS may have a measured NSA that deviates from theoretical NSA by typically ±2 dB. If the OATS is used as the reference site, the antenna factors for an antenna individually calibrated according to ANSI C63.5 can defer from the actual value by ±2 dB (Mann and Marvin 1994). The antenna is acceptable for measurement of EMI. For NSA measurement, the pair of antennas may give rise to a measurement uncertainty of ±4 dB. This is already the total error budget of the site validation requirements. Hence, antenna factors provided with the antenna are generally inadequate. The transmitter and receiver antennas that will be used for test site validation purpose must be calibrated in pair at a reference site to obtain the total antenna factor $AF_{\text{total}} = AF_T + AF_R$ so that the error is minimized (Garn et al. 1992). This method is known as dual antenna factor method. In a study by Müllner and Garn (2001), it was shown that AF_{total} of broadband antenna varied with polarizations and heights of transmitter antenna at the test volume (1 m, 1.5 m, and 2 m).

Antenna factors are usually calibrated for horizontal polarization only (ANSI C63.5-1998). The same set of antenna factors is used for vertical polarization. The measured NSA for vertical polarization may have a larger deviation from the theoretical NSA compared to horizontal polarization. In the practical situation, the antenna at vertical polarization is unbalanced (because half of the antenna elements are nearer to the conductive ground plane, hence larger coupling with the ground). A balance-to-unbalance transformer or balun is usually fitted to the antenna terminals to improve the balancing. Residual unbalanced effect will cause undesirable current to flow on the outer braid of the coaxial cable. Ferrite rings can be fitted over the cables to reduce the unbalanced effect.

In the horizontal polarization measurement, the coaxial cables dropping vertically to the ground are orthogonal to the antenna elements. In the vertical polarization, the antenna elements will be parallel to the cables. Hence, parasitic reflections from the cables and also the antenna mast will cause larger errors in vertical polarization NSA measurements than in horizontal polarization. Some errors are also contributed by the mutual coupling between the cables and the antenna elements. Fitting ferrite suppression rings over the cables can reduce the parasitic reflections.

The separation distance between the transmitter and receiver antennas is measured with respect to the center of the antennas. For a log periodic or bilog-periodic antenna, the size of the antenna is typically close to 1.5-m length. The phase center of the antennas varies with frequencies. Hence, the separation distance between the transmitter and receiver antennas effectively changes with frequencies. This may

DOI 10.1007/978-981-4560-75-7_81-1

contribute to some deviations from the theoretical NSA model that assumes point sources. In a 3-m range, larger deviation is expected.

Free-space antenna factors are calibrated in a uniform plane-wave field. In an OATS or SAC, the field distribution is nonhomogeneous due to ground reflections. The field amplitude and phase variation across the length and width of a broadband antenna may be very large. The voltage measured at the antenna terminals is therefore not strictly related to the field strength but the response of the antenna in integrating the nonhomogeneous field distribution. The geometry-dependent antenna factors will be different from the free-space antenna factors.

The theoretical NSA model assumes far-field radiation between the transmitter and receiver antennas that the field strength decays as a function of $1/d$ where d is the separation distance. At low frequencies where the wavelengths approach 10 m, the additional $1/d^2$ term which must be considered at the near-field may cause the measured NSA to deviate from the theoretical NSA. The mutual coupling between the antennas is another error factor that must be corrected. An exact analysis of the mutual impedance correction factors is complex and subject to several assumptions. The approximate values are available for tuned resonant dipoles for specific site geometry with 3-m separation distance. The effect of varying coupling path length due to height scanning of receiver antenna is neglected. For broadband antennas, mutual impedance correction factors are unknown, therefore assumed zero for any site geometry. If the separation distance is less than a wavelength, the change in antenna factor will become significant.

The transmitter and receiver antennas shall be aligned to point at each other, especially for the case of log periodic antenna and bilog-periodic antenna. Misalignment due to antenna tilting to the left, right, down, or up may cause the transmitter antenna beam to be slightly off the end-fire direction of the receiver antenna. Together with misalignment of transmitter-receiver polarization, some measurement errors may be incurred.

The theoretical NSA model assumes maximum power transfer between the signal source and the transmitter antenna and between the receiver antenna and the spectrum analyzer input. Practical broadband antennas will have varying impedance over the wide frequency range of 30–1000 MHz. Reflections within the cables due to impedance mismatch may cause the measurement errors to exceed the NSA tolerance. The use of attenuators (6–10 dB), one at the terminals of each transmitter and receiver antenna, will reduce the mismatch effect.

Other factors that may affect the accuracy of NSA measurement are antenna separation distance error, frequency error, antenna factor frequency interpolation, cable loss, and instrumentation calibration error. Out of the ±4 dB tolerance recommended by the standards, only 1 dB is allocated for site anomalies while the remaining 3 dB is to take care of instrumentation errors and measurement technique errors. As a result, considerable attentions on the setup details and measurement procedure are required in order to demonstrate compliance with the site validation requirements.

The CISPR 16-1-4 Amd.1 Ed. 3.1 (2012) was published in July 2012 to replace Ed. 2.0 (2007). The amendment introduces an alternative site validation method called reference site method (RSM) (Müllner and Garn 2001). In this method, site attenuation $SA_{\text{Ref\_site}}$ is measured at a reference test site with validated performance, using a pair of transmitting/receiving broadband antennas (biconical and log periodic to cover 30 MHz–1 GHz). The same pair of antennas is then used to perform site attenuation SA_{Site} measurement at the chamber that is being verified. The site attenuation deviation (DSA), defined as the difference between SA_{Site} and $SA_{\text{Ref\_site}}$, will give a direct comparison of the two test sites. Deviation not exceeding ±4 dB is considered acceptable. Since the same antennas have consistency between validations, uncertainties such as polarization and height dependency of antenna factors, antenna radiation pattern effect, and non-traceable mutual coupling play no role in site validation anymore. The RSM proves to be a more reliable, traceable, and time-saving site validation method.

Table 1 The upper frequency of EMC radiated emission measurement range

Highest frequency generated	FCC part 15 digital device	CISPR 22/EN55022
<108 MHz	1000 MHz	1000 MHz
108–500 MHz	2000 MHz	2000 MHz
500–1000MHz	5000 MHz	5000 MHz
>1 GHz	5× the frequency but no higher than 40 GHz	5× the frequency but no higher than 400 GHz

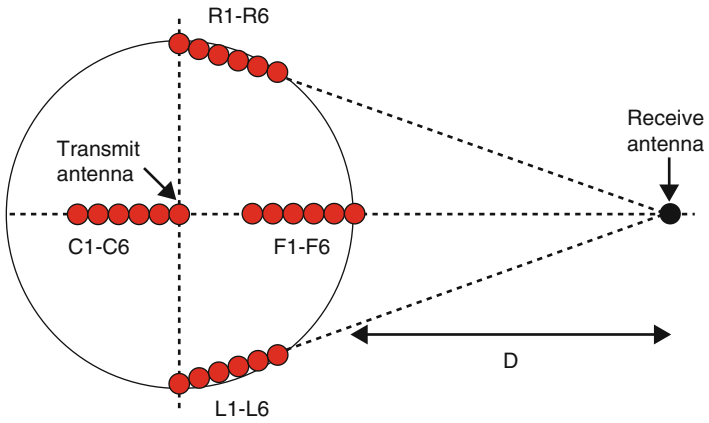

Fig. 12 SVSWR measurement locations and positions

In the design of a semi-anechoic chamber (SAC), the volumetric NSA measurement requirements must be considered. A modeling technique to predict the NSA performance prior to the SAC construction must include the effects of placing the transmitter antenna at various locations in the test volume, scanning the receiver antenna from 1- to 4-m height, reflections from the ground plane, and reflections from the absorber-lined walls and ceiling.

Test Site Validation Method (Above 1 GHz)

The CISPR 16-1-4 requires the use of fully anechoic chamber (FAC) for testing above 1 GHz. With the ground plane covered with RF absorbing material to suppress any reflection, FAC simulates a free-space environment. The upper frequency of radiated emission measurement for the CISPR 22/EN55022 and FCC rules is a function of the highest frequency generated within the product, as summarized in Table 1. If the measurement is performed at 3-m range, the emission level measured can be easily extrapolated for 10-m range by subtracting away 10.46 dB since the field strength is inversely proportional to distance.

The test site validation method specified in CISPR 16-1-4 is called site voltage-standing-wave ratio (SVSWR) method. As with any VSWR measurement, the objective is to measure the maximum and minimum values of a standing wave over a specified travel distance. The ratio of these values is the VSWR. For an ideal free-space environment where there is no reflected wave, VSWR will be unity, i.e., no standing wave. For a practical FAC, reflected waves from the nonideal RF absorbers and chamber structure will give rise to some variation of field strength with respect to distance due to constructive and destructive interferences. Larger value of this SVSWR indicates greater imperfection of the FAC.

The CISPR 16-1-4 proposes to measure the SVSWR by moving a transmitting antenna along a straight line in the chamber and measuring the received voltage with the receiver antenna in the normal location

DOI 10.1007/978-981-4560-75-7_81-1

used for product testing. The test locations and positions are shown in Fig. 12. The received voltages over the broad frequency range (with maximum step size of 50 MHz) are to be measured at only six physical positions of the transmitting antenna for each of the four volumetric locations: 0, 2, 10, 18, 30, 40 cm. It is a compromise to save testing time. Nonuniform spacing is chosen by CISPR 16-1-4 so that the chances of sampling the maximum and minimum values of a standing wave are not totally negated at some frequency points of the sweeping frequencies. Although the true maxima or minima of the standing wave will not be sampled at most frequency points, i.e., a result that is always lower than the true SVSWR will be obtained, the error will not have a direct contribution to measurement uncertainty of EMC product testing.

At each of the four test locations within the test volume, SVSWR measurement must be done for two polarizations and at least two heights. The sampled field strength should be corrected for distance for the six positions. Hence the positioning accuracy of the transmitting antenna directly impacts the repeatability of the SVSWR measurement. The antennas used must meet the antenna pattern requirement of CISPR 16-4-1. Misalignment of the transmitting antenna to the receiving antenna may result in a changed received voltage. The acceptable SVSWR is 6 dB. The site validation procedure is recommended to be repeated annually:

$$E_{\text{relative}} = \frac{E_R}{E_D} = \frac{1 - SVSWR}{1 + SVSWR} \tag{16}$$

The maxima and minima in SVSWR measurement are related to the direct path signal E_D and reflected signal E_R. The ratio of reflected signal to direct signal E_{relative} is related to SVSWR by Eq. 16. Larger value of E_{relative} above zero indicates poorer quietness performance. SVSWR of 6 dB is equivalent to E_{relative} of -10.66 dB. Modern vector network analyzer (VNA) can be used to measure E_D and E_R without the need to physically move the antennas by applying a time-domain reflectivity (TDR) technique. The transmitting and receiving antennas are connected to two separate ports of the VNA, and the ratio of received voltage vector to transmitted voltage vector is determined. Inverse Fourier transform of the frequency-domain data to time-domain data will show the direct signal and reflected signal as impulses arriving at the receiving antenna at different times. In time domain, the direct signal will arrive at the receive antenna first, and the reflected signal will arrive later. By applying time gating, the effect of the direct signal can be separated from the reflected ones. Fourier transform of the time-gated impulses will produce the frequency-domain data of E_D and E_R. Subsequently, E_{relative} and SVSWR can be determined over the measurement frequency range. This TDR method is proposed in ANSI C63.4 draft standard.

From the explanation above, it seems that the SVSWR by spatial movement (CISPR 16-1-4) and SVSWR by time-domain reflectivity (TDR) may produce equivalent data. However, some differences may result due to antenna pattern effect, direction of reflected wave (related to location of chamber imperfection), effect of multiple reflected waves, and the under-sampling pitfall of the SVSWR by spatial movement discussed earlier.

The benefits of the TDR method are numerous. The TDR method does not require physically moving the antenna to a few discrete positions, and the SVSWR from time domain represents the true value of the site (higher than CISPR method). It is much less time consuming. Exact distance between transmit and receive antennas is not required, ditto the field strength values corrected for distance. In addition, TDR method is an excellent tool for troubleshooting site imperfection. Directive horn antenna can be used as the transmit antenna, and its direction can be rotated to identify the azimuth angle that produces the largest peak of E_R. The distance displayed on the VNA screen is the round-trip distance that the impulse traveled from the transmit antenna to the chamber imperfection and back to the receive antenna. The location of chamber imperfection can be confirmed if the peak increases when a large piece of metal is held at the suspected location. Corrective action can then be taken to improve the chamber quietness performance.

DOI 10.1007/978-981-4560-75-7_81-1

Conclusion

An anechoic chamber with a floor area of 20 × 10 m and 8-m height requires a substantial investment both financially and in building space. A 10-m range EMC chamber typically cost more than US$ 2 million. The important considerations in an anechoic chamber project may include the specifications, procurement process for various components and instrumentation, logistical arrangements (contract, shipping, insurance, haulage, time to delivery, storage space), construction process, and performance evaluation. The design must include the necessary features such as access doors, ventilation, lighting, electrical power supply, filters, connection panels, cables, pneumatic air supply, turntable, motorized antenna mast, etc.

The geometry of the chamber structure must not be too complex so that the screened room can easily be constructed, the shielding effectiveness can be under controlled, and the RF absorbers can properly be lined on the chamber walls, ceiling, and floor. Efficient use of available room space is important so that additional screened room can be constructed next to the anechoic chamber for use as the control room to house the test and measurement equipment.

The suitable type of RF absorber must be chosen to achieve the required chamber performance in terms of the purpose of the chamber (antenna, radar, emission, or immunity), measurement frequency range, available room space, required test volume, performance level (NSA, SVSWR, etc.), financial budget, screened room structural strength, and building safety.

Radiated emission measurement results may be affected by any imperfections in the test site. Therefore, the test site must be validated before it can be used for EMC compliance tests. For frequency range below 1 GHz, the NSA method is specified by CISPR 16 and ANSI C63.4 for validation of semi-anechoic chamber where the floor is not covered with RF absorber. Dual antenna factor method is recommended to reduce the measurement error. A better alternative is to use the reference site method to eliminate uncertainties such as polarization and height dependency of antenna factors, antenna radiation pattern effect, and non-traceable mutual coupling effect on the site validation accuracy. For frequency range above 1 GHz, full anechoic chamber to simulate free-space environment must be used. The SVSWR site validation method which involves measuring received voltages at a few discrete positions is specified by CISPR 16-1-4. A TDR method proposed by ANSI C63.4 offers numerous benefits compared to the CISPR method. It can produce equivalent values of SVSWR without physically moving the antenna, potentially more accurate in validating the chamber quietness performance, and the measurement process is much less time consuming.

Abstract

Recently, body-centric wireless communications (BCWCs) have become a very active area of research because of their numerous applications such as security, electric money, smart homes, personal entertainment, and identification systems. Most BCWCs systems have been focused on the development of wearable antennas for on-body and off-body communications and implantable antennas for in-body communications. These antennas are evaluated with different kinds of human-body phantoms. Particularly, it is almost impossible to use a real human body to evaluate implantable antennas experimentally. Instead, human-body phantoms are inevitable for experiments.

This chapter describes evaluation of wearable and implantable antennas with human phantoms. As for tested antennas, two compact wearable dual-mode (on-body mode at 10 MHz and off-body mode at 2.45 GHz) antennas and two UHF band implantable antennas are exemplified in this chapter.

Introduction

Recently, body-centric wireless communications (BCWCs) have become a very active area of research because of their numerous applications such as security, electric money, smart homes, personal entertainment, and identification systems (Hall and Hao 2006; Hall et al. 2009; Zimmerman 1996). In particular, many researchers consider personal healthcare as the biggest potential application of BCWCs, where many kinds of wireless medical devices are attached to the human body, as shown in Fig. 1 (Fujitsu website). However, the environment within and around the human body is often conducive to the transmission of wireless signals. Therefore, as an interface between the transceiver and the propagation environment, antennas should be carefully designed in personal healthcare systems.

BCWCs provide the wireless and maintenance-free communication link between the human body and the surroundings through wearable and implantable antennas. Most BCWCs systems have been focused on the development of wearable antennas for on-body and off-body communications and implantable antennas for in-body communications. These antennas are evaluated with different kinds of human phantoms that are close to the human tissues.

In this chapter, section "Body-Centric Wireless Communications" overviews BCWCs including the IEEE standard and some potential applications of both wearable and implantable antennas/devices.

DOI 10.1007/978-981-4560-75-7_83-1

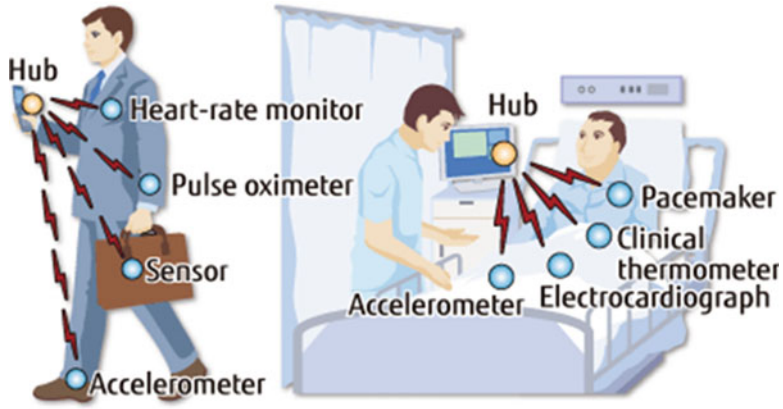

Fig. 1 Medical application of BCWCs (Fujitsu website)

Section "Human-Body Models" summarizes the basics of human-body phantom models to evaluate wearable and implantable antennas. Human-body phantoms are categorized into two groups, namely, numerical phantoms and experimental phantoms.

Then, section "Evaluation of Wearable Dual-Mode Antennas with Human Phantoms" describes evaluation of wearable dual-mode antennas with human phantoms. Here, a dual-mode antenna and a switchable antenna for on-body (10 MHz) and off-body communications (2.45 GHz) are discussed. For on-body communications, *E*-field distributions and received voltages of the receivers on the human body are analyzed, while for off-body communications, reflection coefficients and radiation patterns are discussed.

It is almost impossible to use a real human body to evaluate implantable antennas experimentally. Instead, human-body phantoms are inevitable for experiments. So far, there are few literatures discussing the measured radiation performance of the antennas embedded in the human phantoms. Section "Evaluation of Implantable Antennas with Human Phantoms" describes evaluation of implantable antennas with human phantoms. In this section, dipole antennas are adopted for in-body communications. An upper-body human phantom consisting of a human head, shoulder, and trunk is fabricated to evaluate the performances of the antennas embedded in the human-body phantom.

Body-Centric Wireless Communications

BCWCs can be classified in three communication scenarios (Hall and Hao 2006), as shown in Fig. 2:

- Communications between on-body devices, called *on-body* communications
- Communications with implanted devices, called *in-body* communications
- Communications between on-body and off-body devices, called *off-body* communications

Short-range, low-power, high data rate and reliable wireless communication protocol for use in close proximity to, or inside, a human body are the merits of IEEE 802.15.6-2012 (IEEE standard website_b). Data rates, up to 10 Mbps, are offered to serve a wide and evolutionary set of personal entertainment and healthcare services. This standard supports the combination of security, reliability, quality of service, low power, data rate, and interference protection needed to address the breadth of unique body-centric wireless communication applications. The frequency bands allocated for the IEEE 802.15.6 are summarized in Table 1. Physical channels are classified into three types in accordance with the operating frequency, namely, narrowband (NB), ultrawide band (UWB), and human-body communications (HBC).

DOI 10.1007/978-981-4560-75-7_83-1

When wireless devices are used on the human body, they are equipped with what are known as wearable antennas. They are applied for use in on-body as well as off-body communications, two important scenarios involving BCWCs. In on-body communications, the communication range is limited to the human body itself. Both the wearable transmitter and the receiver are mounted on the surface of the body, and biophysical signals can be transmitted along the human body. On the other hand, off-body communications facilitate communication from the surface of the human body to a nearby external device. At least one antenna is located on the human body, and biophysical signals can then be transmitted wirelessly from the antenna to the external device. A number of biomedical applications can be achieved using both on-body and off-body communications in one system.

In-body communication is one of the body area network (BAN) protocols that may be among the most important future communication applications (Hall and Hao 2006), offering advantages such as unattended data transfer, digital data telemetry over mobile phone networks, instant access to relevant medical records, and tracking of patients implanted with critical devices. With the ongoing development of modern technologies, in order to reduce the pressure on the already-overburdened healthcare system and improve the patient's comfort and care, implantable technologies integrating with wireless functions

DOI 10.1007/978-981-4560-75-7_83-1

have been continually anticipated as a future tool, because of their potential to replace cable connectivity with biological telemetry monitoring to provide contributions to diagnosis, therapy, and disease prevention; such integrating technologies can also control the functioning of the system and report the patient's status (Chow et al. 2013; Kiourti and Nikita 2012a, b; Merli et al. 2008; Karacolak et al. 2009). Today the in-body technology is being used in medical application, where a cardiac pacemaker is embedded into the human body to cure cardiac arrhythmia. Besides, such revolutionary advances of technologies have had major impacts in sensor prosthesis (cochlear implant, retinal prosthesis) and treatment of diseases or impairments (Parkinson's diabetes). Some implantable devices (IMDs) of insulin pumps, deep brain stimulation, glucose monitoring, and endoscopy are a few examples that could be considered to take advantage of remote monitoring and control of an implant unit. Here, animal microchip implants use identifying integrated circuits for tracking and tagging, and it has been hypothesized that in-body technology can be applied in the healthcare field to transfer human-body information such as temperature, blood pressure, and cardiac rate. On the other hand, it is even more attractive because of implants inside the human body providing high privacy and personal security to protect patient's information such as a patient's name, stored diagnosis and history of treatments, and some medical characteristics of allergies and medications (Halperin et al. 2008). Moreover, IMDs can be used particularly for the important institutions of a state.

Human-Body Models

Due to a large amount of communication devices that are used close to the human body, such as cell phones, Bluetooth earphones, and tablet computers, human-body phantoms have become essential tools for not only designing and evaluating performances but also testing safety of such devices. For simulation and measurement of wearable and implantable antennas, various types of human-body models or phantoms have been developed and presented. In order to save computation resource and carry out experiment easily, *simple phantom models* are widely used. However, in some particular cases, for example, to evaluate SAR (specific absorption rate) distribution in the human body, realistic *high-resolution human phantom models* are necessary.

Numerical Phantoms

Simple Phantom Models

Homogeneous (square and cylinder) and layered phantom models are widely utilized to study antenna characterization. Lin et al. reported three kinds of simple two-thirds arm phantom models and discussed the characteristics of a wearable antenna on the three phantoms, as shown in Fig. 3. These phantoms are sometimes used to evaluate implantable antennas which are to be embedded in the human arm. Figure 4 shows a whole-body block model with an antenna (Ito et al. 2009) which has homogenous dielectric property equal to the two-thirds muscle at each frequency and consists of nine rectangular parts that represent head, torso, shoulders, arms, and legs.

High-Resolution Phantom Models

To evaluate the safety of radio waves, it is necessary to make precise evaluations of SAR within the human body. High-resolution whole-body voxel human models with anatomical structures, and models that simulate the body tissues in a simple fashion, are employed to estimate the behaviors of radio waves inside the human body and SAR distribution. National Institute of Information and Communications Technology (NICT) and a few universities in Japan developed various numerical human-body models with the

DOI 10.1007/978-981-4560-75-7_83-1

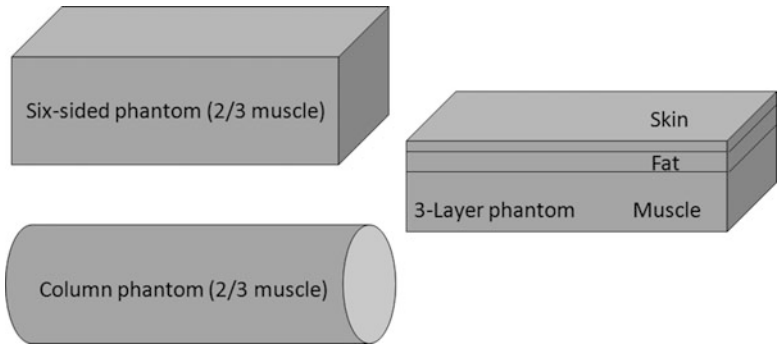

Fig. 3 Three different types of human arm phantom models

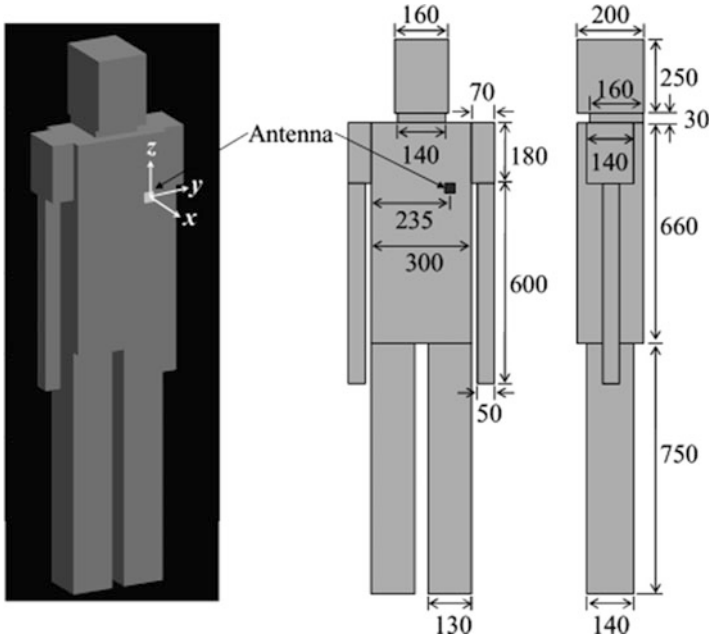

Fig. 4 Whole-body block human model (Ito et al. 2009. © 2009 IEEE)

aim of evaluating the safety of radio waves with respect to the human body and are making them available to the public, as shown in Fig. 5 (NICT website_human model).

Experimental Phantoms

In general, experimental human-body phantoms can be classified into three different types, namely, *liquid* phantoms, *semisolid* phantoms, and *solid* phantoms.

Liquid Phantoms

Liquid phantoms have the average tissue-equivalent materials that have the same electrical characteristics as the tissues in the human body, in the considered frequency range. Liquid phantoms are widely used in SAR measurement and studies, using direct measurement of the electric fields inside the phantom with a small probe. As specified in IEEE Std 1528–2003 (IEEE standard website_c), the permittivity of the phantom shell should be less than 5, the loss tangent less than 0.05, and the thickness of the shell should be 2.0 ± 0.2 mm for the frequencies in the range from 0.3 to 3 GHz. From the documents of MCL-T (MCL-T, London, UK), liquid phantoms are only available up to 6 GHz. As an example, Fig. 6 shows a liquid head phantom in the shell (NICT website_SAR measurement).

DOI 10.1007/978-981-4560-75-7_83-1

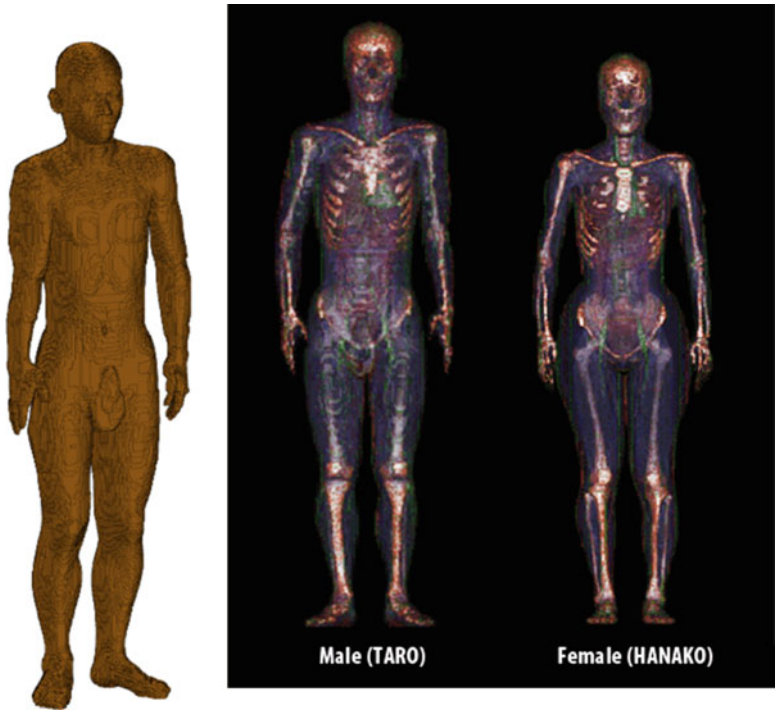

Fig. 5 Realistic numerical human-body models (NICT website_human model)

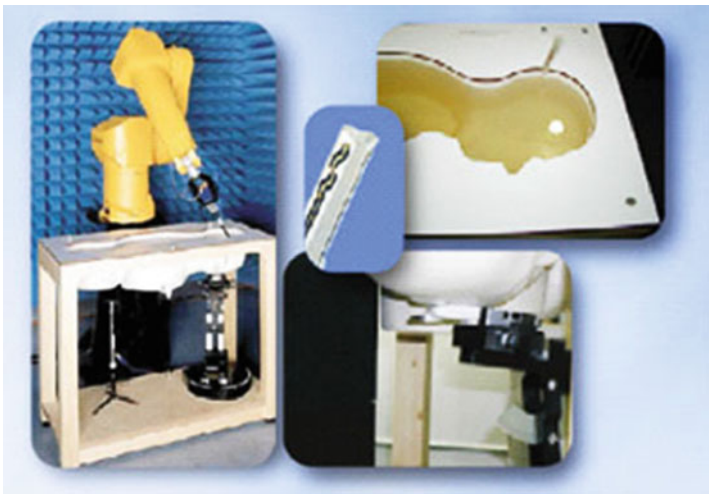

Fig. 6 A head phantom with a predetermined standard size and shape for measurement (NICT website_SAR measurement)

Semisolid Phantoms

By using coagulant agent, it is easy to develop semisolid phantoms capable of self-shaping. Semisolid phantoms are low cost, easy to fabricate, and easy to manufacture into arbitrary shape and multiple layers. They are available at frequencies up to 11 GHz and can be applied for evaluation of antenna performance and SAR measurement. Electrical properties of semisolid phantoms can be adjusted over a wide frequency range. In a single composition ratio, the electrical properties are almost equal to biological tissue over the frequency range of $0.3 - 2.5$ GHz or $3.1 - 10.6$ GHz. Figure 7 presents two types of semisolid phantoms proposed by Chiba University in Japan.

DOI 10.1007/978-981-4560-75-7_83-1

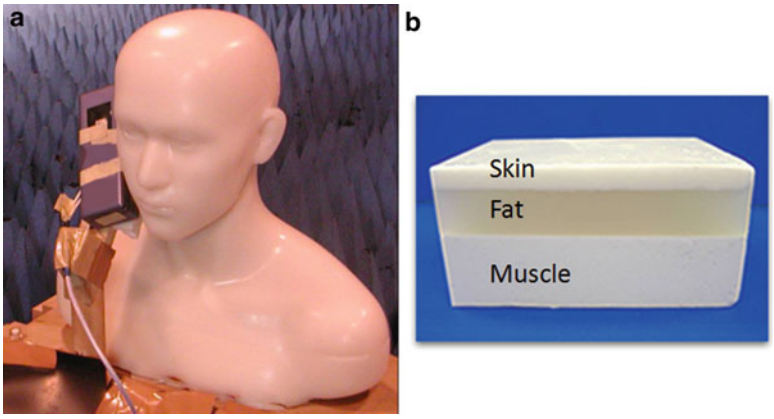

Fig. 7 Tissue-equivalent human phantom. (**a**) Upper body phantom. (**b**) Layered phantom

Fig. 8 Carbon-silicon phantoms (MCL-T, UK)

Solid Phantoms

For measuring the SAR on the surface of the human body, a solid phantom is a good candidate, as shown in Fig. 8 (MCL-T, UK). Compare with liquid and semisolid ones, solid phantoms are capable of keeping their shape for a period of time and designed to fit a wide range of complex permittivity. However, solid phantoms are expensive and require special equipment and complex manufacturing procedures.

Evaluation of Wearable Dual-Mode Antennas with Human Phantoms

Recently, the advance of electronic devices is leading to the creation of body-centric wireless communications (BCWCs), in which wireless devices are attached to the human body. With these devices, as an important application of BCWCs, remote health monitoring will become real. In remote health monitoring, at least two modes of communications are required: on-body communications (collecting medical data) and off-body communications (exchanging data with outside networks). For on-body communications, relatively low frequency bands (tens of MHz) are more suitable (Ito et al. 2012; Fujii et al. 2005; Ito et al. 2009), while for the off-body communications, 2.45 GHz ISM band (2.40 − 2.48 GHz) is a good candidate (Lin et al. 2012a). Thus, a dual-mode antenna is a key component for remote health monitoring. Therefore, two wearable antennas with on-body and off-body modes will be introduced in this section.

DOI 10.1007/978-981-4560-75-7_83-1

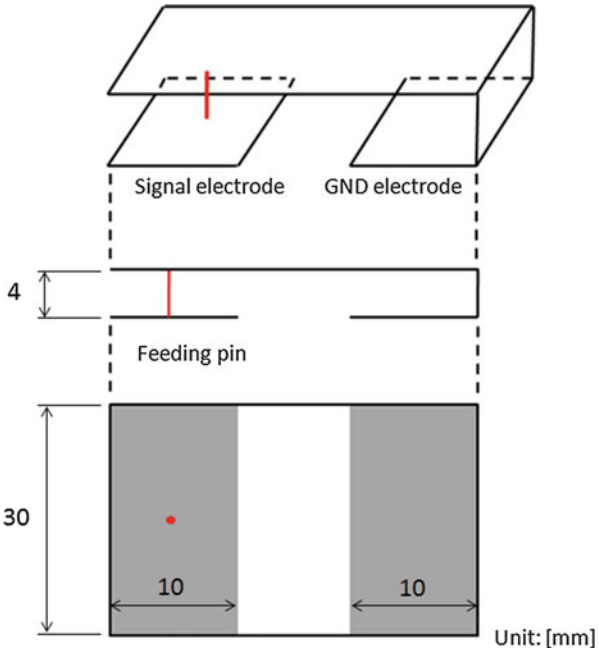

Fig. 9 Structure of the dual-mode antenna

Antenna Design and Human Body

Figure 9 shows a dual-mode wearable antenna (Lin et al. 2012b). It consists of a feeding pin, a signal electrode, and a GND electrode. The size of the antenna is $30 \times 33 \times 4$ mm^3. The height of the signal electrode is 4 mm, and the feeding pin is located in the center of the signal electrode. For the off-body communications, the operating frequency is 2.45 GHz. In this antenna design, in order to concern the equipment packaging, a plastic ($\varepsilon_r = 3$) with 2 mm in thickness is placed between the antenna and the human body. Moreover, in order to confirm the performance of the antenna on the human body and simplify measurement process, a part of chest phantom (electrical constant $\varepsilon_r = 35.2$, conductivity $\sigma = 1.16$ S/m at 2.45 GHz) (Lin et al. 2012b) is adopted to replace the whole human body. However, radiation characteristics of the antenna on the human body should be realized; therefore, the proposed dual-mode antenna on a high-resolution human model in 1.75 m provided by the National Institute of Information and Communication Technology (NICT) in Japan is also concerned in this work, as shown in Fig. 10. Table 2 summarized the computational parameters of the antenna design.

On-Body Mode

As shown in Fig. 11a, one transmitter is attached to the right chest, while four receivers are attached to the left chest, right and left wrists, and abdomen, respectively. Figure 11b presents the variation in received voltage for the four different on-body links on the human body. From the simulated result, the received voltages are around -110 to -160 dB depending on the distance between the transmitter and the receiver. Figure 12 illustrates the *E*-field distributions inside and outside the whole human body at 10 MHz. The *E*-field distribution is discussed according to the received voltage that is calculated from the electric field. The observation plane includes the feeding point of the transmitter. From the result, it can be seen that the level of the electric field distribution are smooth around the human body at 10 MHz. As a result, it can be concluded that the lower frequency such as 10 MHz is suitable for on-body communications.

DOI 10.1007/978-981-4560-75-7_83-1

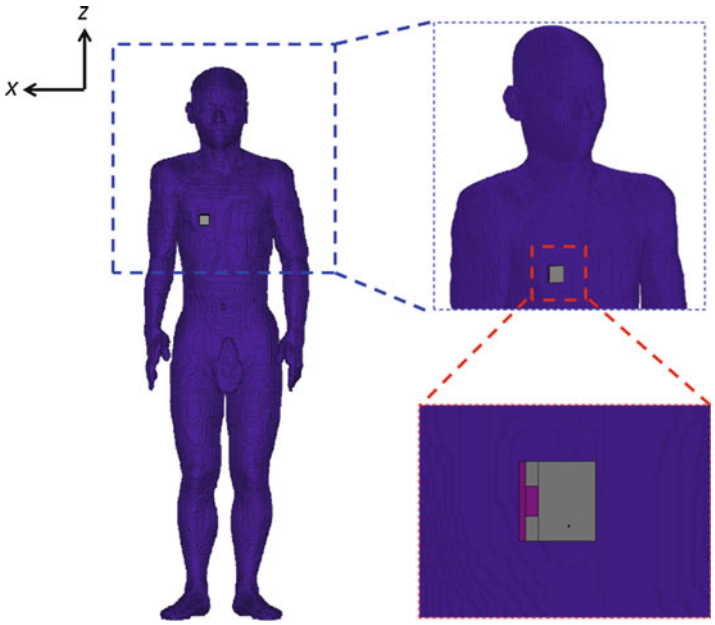

Fig. 10 Antenna on the high-resolution human model

Table 2 Computational parameters for two modes

Mode	On-body mode	Off-body mode
Frequency	10 MHz	2.45 GHz
Cell size	1–2 mm	0.5–2 mm
Computation domain	$1.5 \times 1.5 \times 2\ m^3$	$1 \times 1 \times 2\ m^3$
Number of PML layers	16	8

Off-Body Mode

Off-body mode can be applied to send the received body signals (10 MHz on-body mode) to an external device. The performance such as reflection coefficient and radiation pattern of the antenna on a human body is discussed here. Figure 13 shows simulated and measured reflection coefficients when the antenna is located on a part of chest phantom with the dimension of $200 \times 200 \times 70\ mm^3$ and then attached onto a high-resolution human model. It was found from the result that this antenna works in the ISM band (2.45 GHz). Also, simulated and measured results are in good agreement. The simulated radiation patterns on the chest phantom and the high-resolution human model at 2.45 GHz in *xy*- and *yz*-planes are shown in Fig. 14. From the results, the radiation patterns in both planes are relatively omnidirectional with no deep nulls in the front half-sphere of the human body. Therefore, the antenna is a good candidate for off-body communications.

Switchable Dual-Mode Antenna

When simultaneous operation in both on-body and off-body communications is not necessary, switchable scheme between the on-body and off-body modes is useful in practice. A compact switchable antenna for BCWCs was reported by Lin et al. in which a simple switching circuit is integrated into the shorting plate of PIFA (Lin et al. 2012). As a result, enough gain is obtained since it is equivalent to a PIFA antenna at 2.45 GHz when the switching is turned on. In addition, when the switch is turned off, the antenna is similar to a metal electrode operating as on-body mode at HF band (10 MHz).

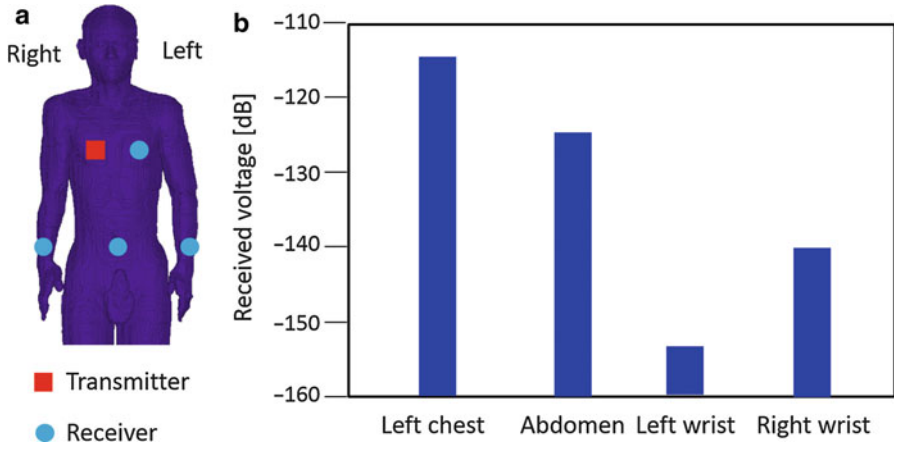

Fig. 11 Simulation. (**a**) Location of the devices. (**b**) Received voltages

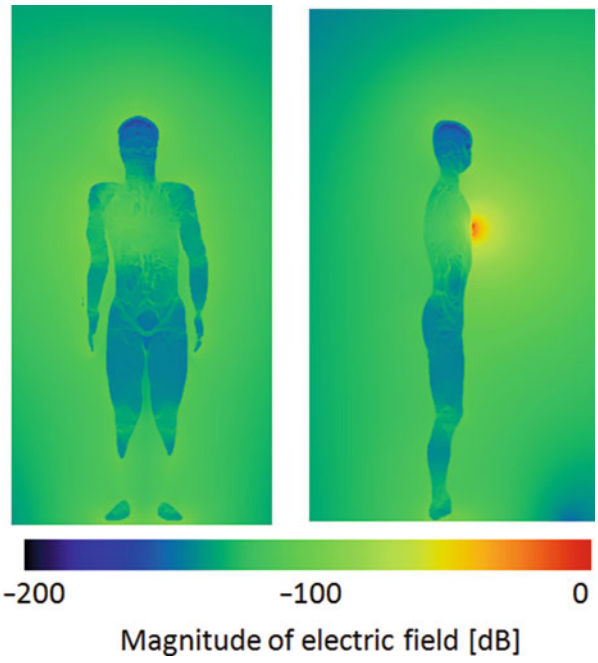

Fig. 12 Electric field distribution at 10 MHz on high-resolution human body

Figure 15 shows the structure of the switchable planar inverted-F antenna. The antenna includes a ground plane, radiator, feeding pin, and a switching circuit board to replace the conventional shorting plate, in which a pin diode was used as the switch component. The radiating top patch and the ground plane have the same dimension of $30 \times 12\ \text{mm}^2$. The height of the antenna is 8 mm. The feeding pin is on the center line of the antenna. In the lower frequency band, the characteristics of the antenna are equivalent to an electrode operating at 10 MHz, while the pin diode located on the circuit board is in the OFF state. The excitation signal for lower frequency is a 10 MHz sinusoidal wave. In a higher frequency band (2.45 GHz ISM band), the antenna operates as a PIFA, while the pin diode is in the ON state. As shown in Fig. 15, the area of the switching circuit board is $10 \times 8\ \text{mm}^2$. It is fabricated on PTFE fluorocarbon polymers (dielectric constant 2.17, 0.8 mm in thickness) with no bottom layer of copper used. In this antenna design, the pin diode HVU131 from Renesas Tech. was selected; thus, a resistor of 200 Ω is used

DOI 10.1007/978-981-4560-75-7_83-1

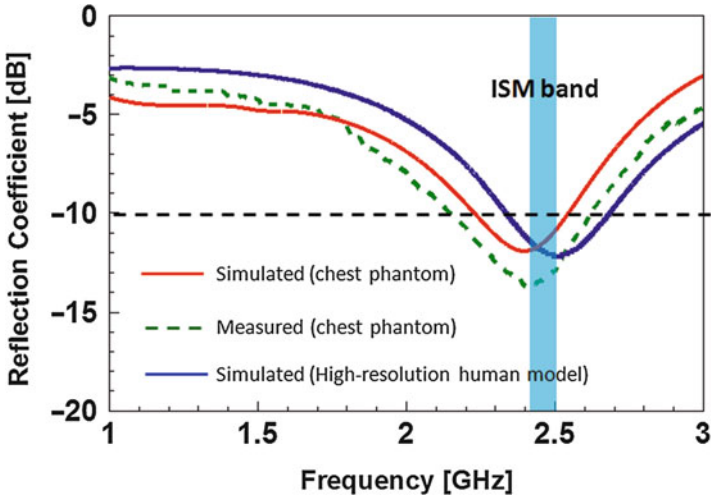

Fig. 13 Simulated and measured reflection coefficients

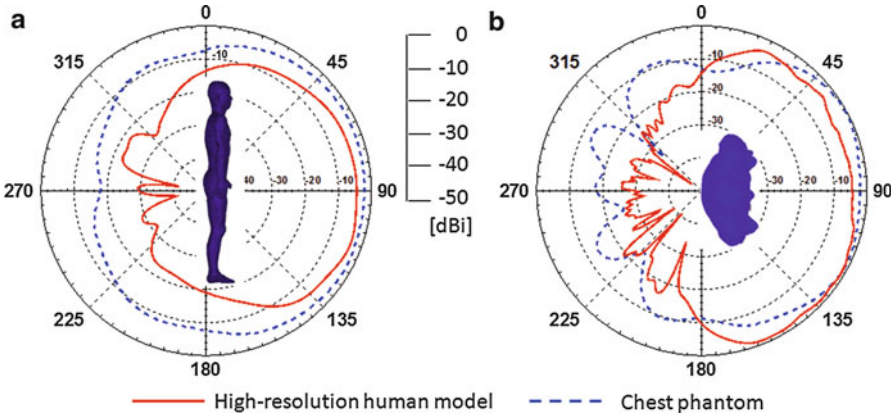

Fig. 14 Radiation patterns. (**a**) *yz*-plane. (**b**) *xy*-plane

to provide the bias for the diode. In addition, an inductor of 33 nH plays the RF choke and a capacitor of 100 pF is used to block the DC voltage, which is similar to the design in Li et al. (2009). The efficiency of the antenna was 46 % at 2.45 GHz as a PIFA. In this study, in all the cases, the radiator is positioned near the phantom and the ground plane is far side, and the space between the antenna and the arm phantom is set to be 2 mm.

On-Body Mode

As shown in Fig. 16a, one transmitter is located to the right wrist while seven receivers are placed to the head, left chest, right chest, abdomen, left wrist, right ankle, and left ankle, respectively. Figure 16b illustrates the simulated *E*-field distributions inside and around the whole human body at 10 MHz. The observation plane includes the feeding point of the transmitter. From the result, it can be seen that the level of the electric field distribution are smooth around the human body at 10 MHz.

During measurement, the transmitter was fed by the 10 MHz sinusoidal wave from a 10 MHz oscillator and the excitation voltage was 4.1 $V_{p\text{-}p}$, while the pin diode on the switching circuit was set in the OFF state, as shown in Fig. 17 a, b. The receiver was connected to a Spectrum Analyzer E4403B with a 50 Ω loading resistance. In order to reduce the effects of the cable and the earth ground on the received voltage, a ferrite transformer is connected between the receiver and the cable from the spectrum analyzer, as shown

DOI 10.1007/978-981-4560-75-7_83-1

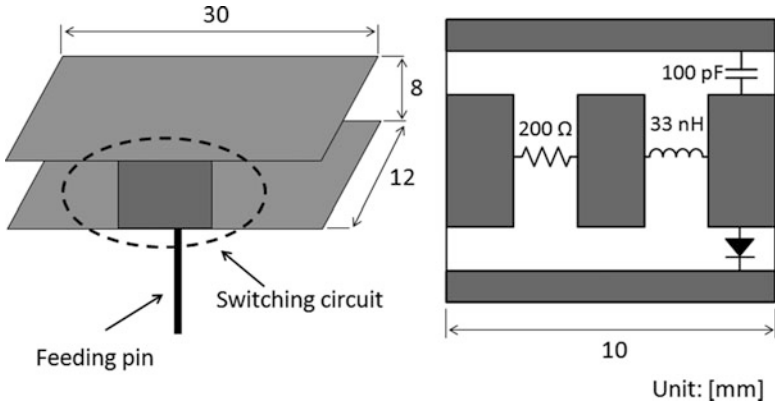

Fig. 15 Switchable planar inverted-F antenna (3D view and switching circuit)

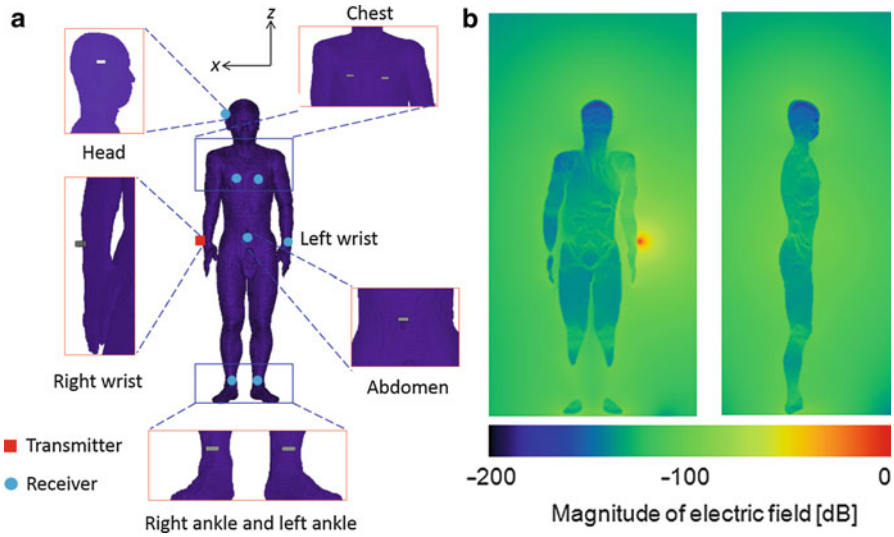

Fig. 16 Simulation. (**a**) Location of a transmitter and seven receivers. (**b**) Simulated *E*-field distribution at 10 MHz

in Fig. 17c. The measurement setup is shown in Fig. 18. The transmitter is excited by a 10 MHz oscillator and each receiver is connected to a spectrum analyzer. In this study, seven sensors are located on the human body which includes the left chest, right chest, abdomen, head, left wrist, left ankle, and right ankle. Measured variation in received voltage for the seven different on-body links on the human body is presented in Fig. 19. From the results, the received voltages are around −98 to −117 dB depending on the distance between the transmitter and the receiver.

Off-Body Mode

Figure 20 shows the simulated and measured reflection coefficients when the antenna is located on a simple arm phantom with the dimension of $50 \times 50 \times 300\ \text{mm}^3$ while the diode was in the ON state (3 V is supplied by battery box), and the results with a high-resolution human model are also given in the same figure. It was found from the result that this antenna works in ISM band (2.45 GHz). The measured bandwidth was 350 MHz (2.30–2.65 GHz) and the measured result was close to the simulated ones.

The simulated and measured radiation patterns on the arm phantom and a high-resolution human model at 2.45 GHz in *xy*- and *xz*-planes are shown in Fig. 21. From the results, the radiation patterns in both planes are relatively omnidirectional with no deep nulls in the front half-sphere of the human body.

DOI 10.1007/978-981-4560-75-7_83-1

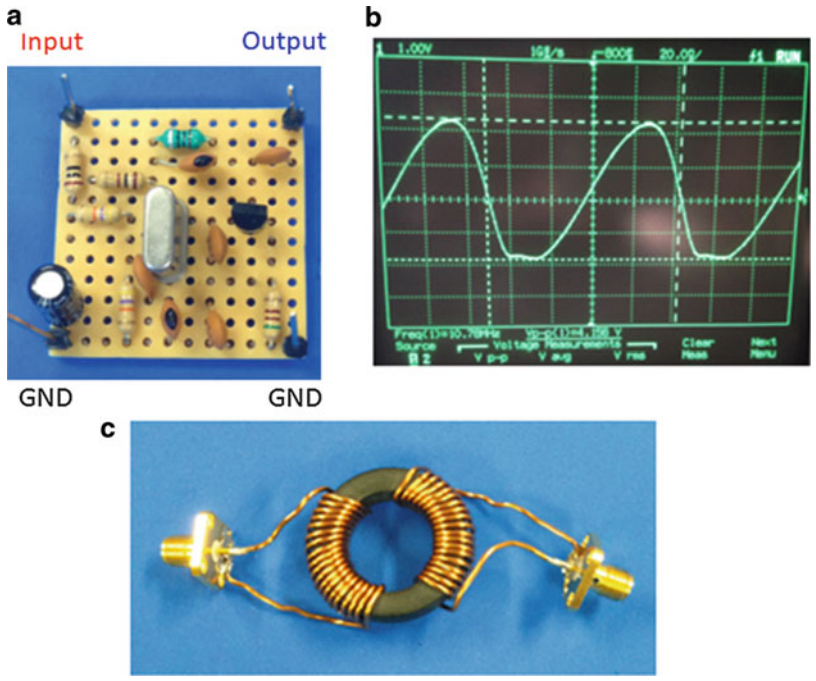

Fig. 17 Measurement. (**a**) 10 MHz oscillator. (**b**) Output signal. (**c**) Transformer

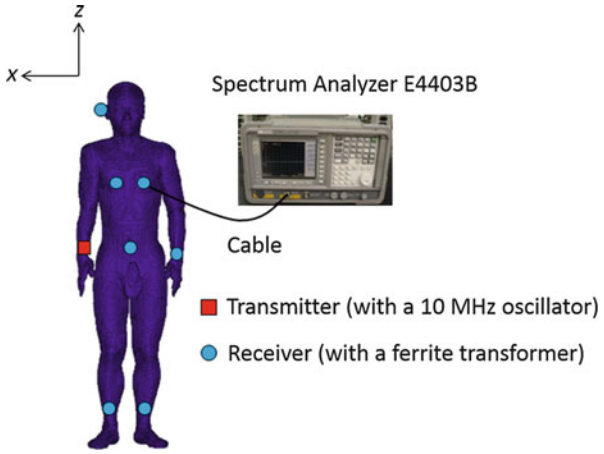

Fig. 18 Measurement setup for received voltage

Therefore, the antenna is a good candidate for off-body communications. The average gain in the two planes of the arm phantom is 5 dBi higher than in Lin et al. (2012), as shown in Fig. 21. It can also be noted that the performance of radiation patterns on the developed phantom is close to the high-resolution human model. Therefore, fabricated phantom can be applied to evaluate wearable antenna performance.

Evaluation of Implantable Antennas with Human Phantoms

It is almost impossible to use a real human body to evaluate implantable antennas experimentally. Instead, human-body phantoms are inevitable for experiments. In general, implantable antennas or devices should

DOI 10.1007/978-981-4560-75-7_83-1

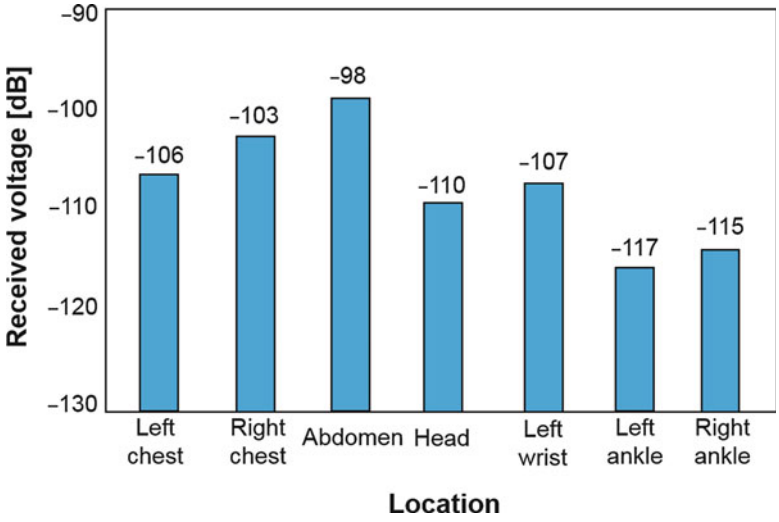

Fig. 19 Measured received voltages at seven locations

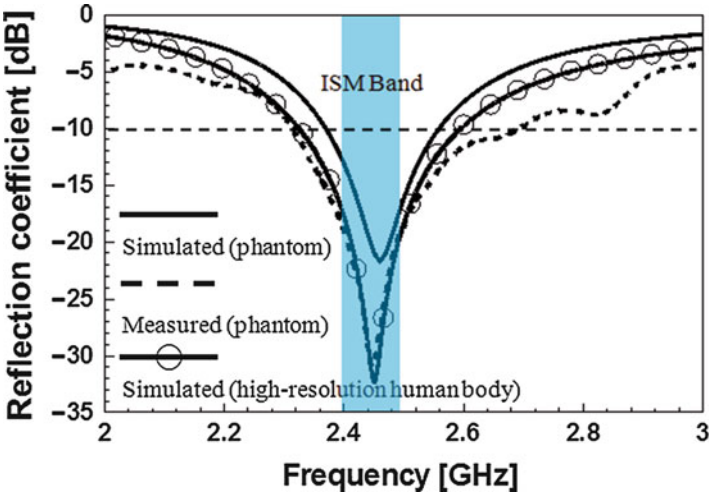

Fig. 20 Simulated and measured reflection coefficients

be small in size, and this will increase the complexity of measurements. This section describes a folded dipole and a simple dipole as typical implantable antennas and how to evaluate such small implantable antennas with human-body phantoms.

Antenna Geometry and Simulation Model

Figure 22a shows the geometry and dimensions of the UHF antenna (Lin et al. 2013). The antenna is fabricated from a narrow strip with a width of 0.1 mm and bent into a folded structure; the whole size is 20.3 mm (L) $\times$ 0.8 mm (w) $\times$ 0.8 mm (h) and the gap is 0.5 mm (g). The L of the antenna is about 0.065 wavelength in the human body at 0.953 GHz. The feed point is in the center of the antenna so as to make it a symmetric structure, and the input impedance is assumed to match a 50 Ω system. With such a slender structure, the radiating elements of the antenna are extremely close, and g, h, and w would be sensitive parameters for impedance matching. In addition to the antenna structure, a coating is generally introduced to decrease the effect of the human body. In this study, a glass coating ($\varepsilon_r = 5.0$) with a whole size of 20.5 $\times$ 1.0 $\times$ 1.0 mm^3 is used for covering the antenna as shown in Fig. 22b, but it can be removed in

DOI 10.1007/978-981-4560-75-7_83-1

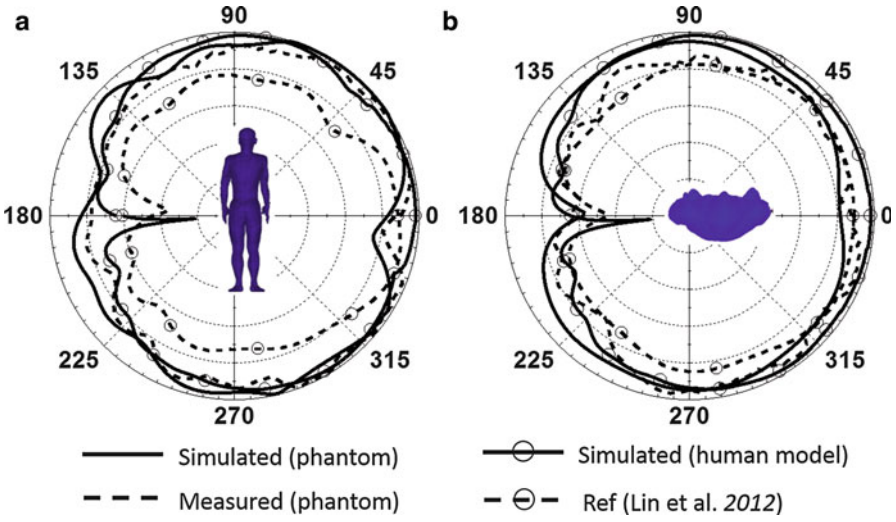

Fig. 21 Radiation patterns at 2.45 GHz. (**a**) *xz*-plane. (**b**) *xy*-plane

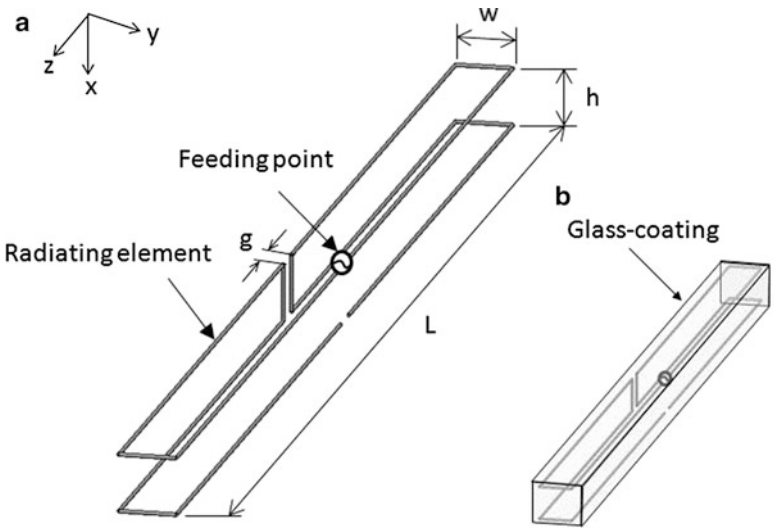

Fig. 22 A folded dipole antenna. (**a**) Antenna structure. (**b**) Glass coating (Lin et al. 2013. © 2012 IEEE)

experiment when the permittivity of the glass coating is close to that of human fat tissue ($\varepsilon_r = 5.45$), which implies that its influence on antenna performance is not strong.

Since the antenna is applied as an implant, it should be evaluated with a realistic human-body model. Figure 23a shows an image of the human body in which the antenna is embedded into the arm and the assumptive communication range is between 90° and 270°. According to Lin et al. (2013), a layered phantom that can be used to represent a part of human arm to confirm the antenna performances, therefore, in the simulation, a model of the human arm using layered phantom, is used as shown in Fig. 23b. The phantom consisted of skin ($\varepsilon_r = 41.14$, $\sigma = 0.88$ S/m), fat ($\varepsilon_r = 5.45$, $\sigma = 0.05$ S/m), muscle ($\varepsilon_r = 54.91$, $\sigma = 0.96$ S/m), and bone ($\varepsilon_r = 12.4$, $\sigma = 0.15$ S/m). These dielectric constants are the values at 0.953 GHz. Moreover, the antenna is generally embedded into the fat layer of the phantoms at a depth (d) of 2.0 mm from the surface of the skin layer, since the loss there is less than at the skin and muscle layers.

Measurement Setup and Experimental Result

Figure 24 shows the measurement setup of this study. In order to keep maximum transmission efficiency in the experiment, the antenna is connected to a quarter-wavelength balun that has a length of 79 mm (0.953 GHz) and then is embedded into the fat layer of the phantom. Photographs of the fabricated antenna, a quarter-wavelength balun, and the layered phantom are shown in Fig. 25a, b, respectively.

Table 3 The permittivity and conductivity of the test phantom at 0.953 GHz (Lin et al. 2013. © 2012 IEEE)

Tissues	Permittivity			Conductivity [S/m]		
	Target value	Measured value	Error %	Target value	Measured value	Error %
Skin	41.14	42.06	2.2	0.88	0.91	3.4
Fat	5.45	5.5	0.9	0.05	0.046	8
Muscle	54.91	53.5	2.5	0.96	0.99	3.1

Figure 25c shows the measurement for testing the reflection coefficient. Tables 3 and 4 show the target and measured electric constant (ε_r and σ) of the human tissues at 0.953 GHz and the compositions of the skin, fat, and muscle. When compared to the target values, all the measured results are below or approaching the 5 % error mark according to Ito et al. (2012). Figure 26 shows the calculated and measured reflection coefficients of the antenna in the layered phantom. It can be confirmed that the measured result of the antenna can cover the desired frequency band (0.951–0.956 GHz) and has a good agreement with the calculated result. The calculated and measured radiation pattern results at 0.953 GHz are shown in Fig. 27, which includes the required antenna gain of −35 dBi and its cover region. The radiation performance of the antenna could also be affirmed, although a slight difference is presented in upper half planes of *xz*-plane and *xy*-plane due to experimental errors such as the position of the antenna and fabricated human arm phantom. In addition, the radiation performance was plotted in the lower half planes of *xz*-plane and *xy*-plane. Here the quarter-wavelength balun is used to ensure maximum transmission efficiency. The measured and calculated results are in agreement, in that even if a coaxial cable is used in the experiment, the feeding gap of the simulation differs accordingly. The maximum antenna gains are about −23.5 and −26.0 dBi in the *x*-*z* and *xy*-planes; at -*x* direction the antenna gains are −28.7 and −30.3 dBi, respectively. Therefore, wireless communication is available since the antenna gain exceeds the required antenna gain of −35 dBi, calculated by the link budget.

Measurement of Implantable Antenna with Physical Human-Body Phantom

In this section, in order to confirm the far-field radiation pattern of implantable antennas by experiment within a human body, an upper-body human phantom consisting of a head, shoulder, trunk, and simple human arm is fabricated and measured. A dipole antenna designed to operate at 1.27 GHz is assumed to be embedded in the human arm. The antenna performance is simulated by the finite-difference time-domain (FDTD) method.

Human-Body Models for Simulation

Because the antenna is used for implants, the antenna performance in the 1.27-GHz band should be assessed with a simple human arm model and high-resolution human-body model as shown in Figs. 28a, b.

DOI 10.1007/978-981-4560-75-7_83-1

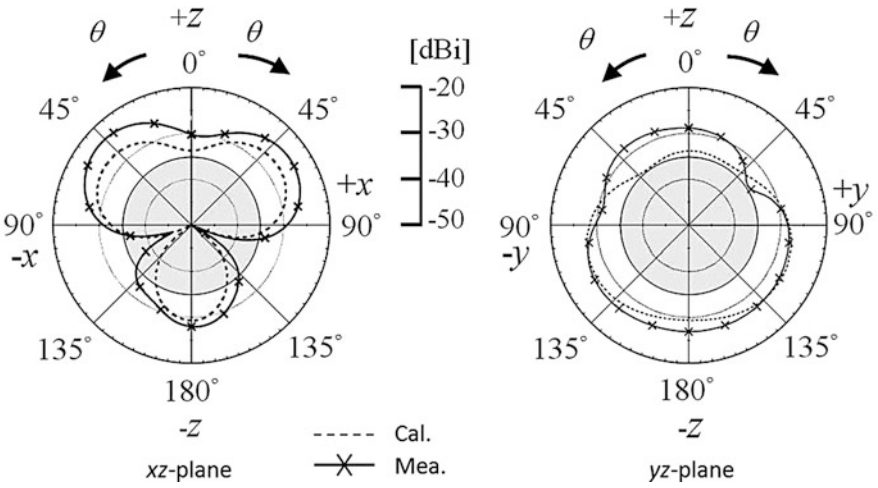

Fig. 27 Radiation patterns at 0.95 GHz in *xz*-plane and *yz*-plane (Lin et al. 2013. © 2012 IEEE)

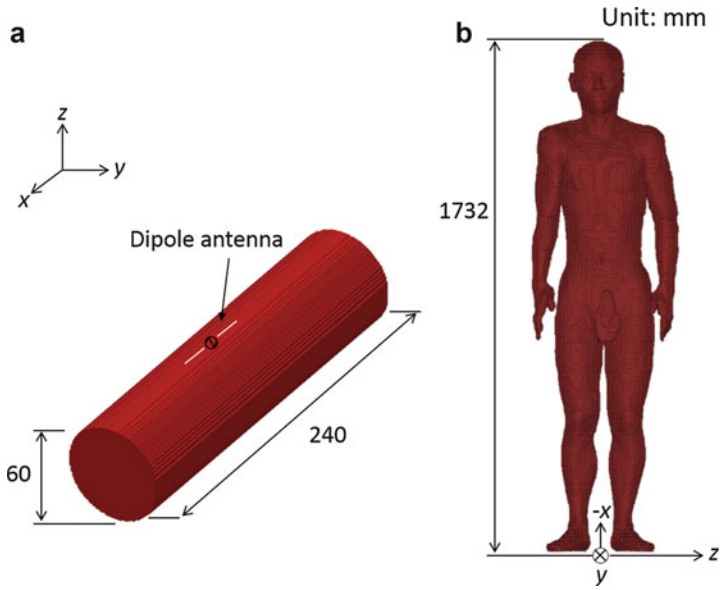

Fig. 28 Simulation models. (**a**) Simple human arm. (**b**) High-resolution human model

In order to maintain simulation consistency between these models, a half-wavelength dipole antenna is embedded into these models at a depth of 4 mm. In addition, the dipole antenna is designed to operate in the 1.27 GHz band; therefore, it has a length of 26 mm.

Figure 28a shows the simple human arm model consisting of a 2/3 muscle-equivalent phantom ($\varepsilon_r = 36.8$ and $\sigma = 0.75$ at 1.27 GHz). This model has a cylindrical structure with a length of 240 mm ($\approx \lambda$) and a diameter of 60 mm. In addition, a high-resolution human model based on the average adult Japanese volunteers (height, 173.2 cm; weight, 65 kg) is introduced in the simulation (Rajagopalan and Rahmat-Samii 2010), and its dielectric constant is the same as the simple human arm model. The cell size of the dipole antenna and that of the human model are set as 0.05 and 2.0 mm, respectively. Thus, the cells of the dipole antenna and human model are nonuniform. Perfectly matched layer boundary conditions (eight layers) are used to truncate the simulation region, and the voltage source is set as the model source. The computational parameters are listed in Table 5.

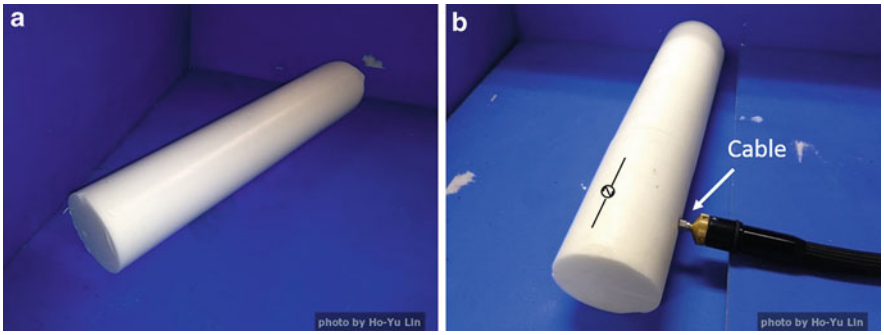

Fig. 29 Measurement. (**a**) Fabricated arm phantom. (**b**) Setup

Fabricated Human Phantom and Measurement Setup

Figure 29a, b depicts the fabricated human arm phantom and measurement setup for reflection coefficient, respectively. The composition of the human arm phantom and the target as well as measured dielectric constants of the 2/3 muscle-equivalent phantom at 1.27 GHz are described in Sani et al. (2009), respectively. All the measured results approach the 5 % error mark when compared to the target values according to Sani et al. (2010). As illustrated in Fig. 29b, the dipole antenna is embedded into the fabricated phantom at a depth of 4 mm. It should be noted that the cable is connected to the antenna, and it does not touch the human phantom, as current might flow through the phantom to cause a change in the input impedance of the antenna.

Figure 30 shows the fabricated upper-body human phantom consisting of a human head, shoulder, and trunk. This phantom has the same dielectric constant and composition as the simple human arm phantom. Figure 31 shows the measurement setup for radiation pattern of the dipole antenna. In the measurement setup in Fig. 31a, the fabricated upper-body human phantom is placed on the turntable, and the simple human arm phantom including the antenna is then connected to the human phantom to represent a human arm. Before measuring far-field radiation patterns, it should be confirmed that these phantoms are fixed properly onto the turntable when rotating because the phantoms are heavy. Photographs of the measurement setup for testing far-field radiation patterns of the dipole antenna are shown in Fig. 31b, c.

Reflection Coefficient and Far-Field Radiation Pattern

Figure 32 shows the simulated and measured reflection coefficients when the antenna is embedded into the simple human arm phantom. As a result, it is confirmed that the antenna can satisfy the desired frequency band of 1.27 GHz. Further, the measured results have reasonable agreement with the simulated results, even though there is a minor difference due to measurement errors such as the position of the dipole antenna and the dielectric constant of the human body. The far-field radiation pattern of the dipole antenna embedded in the human body is also studied. Figure 33 plots the simulated and measured far-field radiation patterns at 1.27 GHz. From the results in *yz*-plane, it is clearly observed that both radiation patterns are mainly in the $+z$ direction (0°); however, the radiation patterns in the $-z$ direction are attenuated owing to the presence of the human body. Furthermore, it is found that the magnitude of the radiation pattern in the $-z$ direction in measured results is higher than in the simulated results. The main reason for this is because the fabricated upper-body human phantom has only one arm that is slightly

different from the simulated model. Moreover, the surface current on the cable line may cause undesired radiation to influence the radiation pattern. In addition, the maximum antenna gains in the simulation and measurement are −19.3 and −17.4 dBi, respectively. In the upper half plane, the simulated and measured results have good agreement. Therefore, the far-field radiation pattern of the antenna in the human body can be confirmed using this measurement setup.

Conclusion

Body-centric wireless communications (BCWCs) systems have an important role in the fields of sports training, biomedicine, and personal healthcare. BCWCs provide wireless and maintenance-free communication link between the human body and the surroundings through wearable and implantable antennas. In order to evaluate such wearable and implantable antennas experientially, human-body phantoms are inevitable. In this chapter, firstly, some typical numerical and experimental phantoms have been summarized. Then, detailed evaluation techniques and results of wearable and implantable antennas with specific human-body phantoms have been described. In the future, so-called "advanced human phantoms" will be needed to evaluate more complicated and sophisticated antennas as well as scenarios. For example, "mm-wave phantoms" to evaluate mm-wave antennas attached to the human body and "dynamic phantoms" to simulate movement of the human body.

Antenna Sensors in Passive Wireless Sensing Systems

Haiying Huang*
University of Texas Arlington, Arlington, TX, USA

Abstract

Antenna sensors have received considerable interests in recent years due to their passive wireless operation, simple configuration, compact size, multiplexing capability, and multimodality sensitivity. Based on the principle of antenna backscattering, an antenna sensor can be wirelessly interrogated at middle range distances without an onboard battery. Since the antenna serves the dual function of sensing and communicating, an antenna sensor can be implemented with minimum number of components. As narrowband resonators, antenna sensors can be easily multiplexed based on the principle of frequency division multiplexing. In addition, different types of antenna sensors that are sensitive to a variety of physical measurands have been demonstrated. Due to these unique features, antenna sensor technology could play a vital role in our drive toward ubiquitous sensing. This chapter provides a comprehensive review of this exciting technology with detailed descriptions on the operational principle and wireless interrogation of batteryless antenna sensors. Four application examples of using antenna sensors for moisture, dynamic strain, temperature, and crack sensing are discussed. Future research directions and open problems are suggested.

Introduction

Sensors, which convert physical measurands into electric signals, are becoming more and more prevalent in this Internet age. As our world becomes increasingly connected, sensors play the fundamental role of integrating the physical domain into the cyberspace. The advent of wireless sensors has fundamentally transformed sensor technologies in the past decades. By eliminating electric wiring from conventional sensors, wireless sensors are inexpensive and easier to install, which makes distributing sensors over a large area and with high density a reality. A typical wireless sensing system is shown in Fig. 1; it composes of two sub-systems, namely, the wireless sensor and the wireless reader. The wireless sensor is responsible for encoding the sensing information into a radio-frequency (RF) signal that can be wirelessly transmitted via an antenna, while the function of the wireless reader is to decode the received RF signal to extract the original sensing information. In most cases, an interrogation signal is transmitted from the wireless reader to the wireless sensor via the uplink. In response, the wireless reader sends the sensing information back to the wireless reader via the downlink. Traditionally, antennas only serve as a communication device for wireless sensors. Recent developments, however, have extended the role of the antennas for sensing.

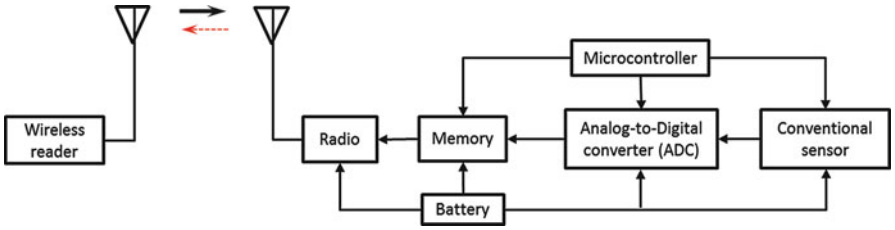

Fig. 2 Architecture of active wireless sensor nodes

This chapter aims to introduce the readers to this new exciting technology with an in-depth discussion of its operational principle, wireless interrogation schemes, application examples, and future directions. For the readers who are not familiar with wireless sensor technologies, a brief review of common wireless sensors is given first.

Active Wireless Sensors

A wireless sensor can be broadly classified as either being active or passive, depending on whether it needs onboard batteries or not. The most common active wireless sensors are based on the Berkeley mote platform, which is illustrated in Fig. 2. This kind of wireless sensor essentially functions as a microcomputer with the capability of wirelessly receiving data from and transmitting data to the wireless reader, also known as the base station. The "brain" of an active wireless sensor is the microprocessor, which controls and schedules the operations of other electronic components including the analog-to-digital converter (ADC), memory, radio, etc. The sensing signal is usually acquired in an analog format using a conventional sensor, e.g., a strain gauge, an accelerometer, a thermocouple, etc., which is then converted to digital signals by the ADC. The digital signals can be transmitted directly by the radio or processed by the microprocessor before transmission. Due to the digital nature of the wireless communication protocol and the onboard radio, wireless sensor nodes can provide reliable and interference-free data communication for a distance of more than 100 m. Active wireless sensor technology has been mature enough that several standards, such as the Bluetooth and ZigBee standards, have been developed, which facilitates the commercialization of such sensors. Currently, active wireless sensors can be purchased off-the-shelf at less than 50 dollars. One major limitation of the active wireless sensors is their requirement for onboard batteries since the electronic components as well as the sensors consume substantial amount of power. Replacing or recharging the battery introduces a significant maintenance challenge. Even though various energy harvesting techniques have been investigated to address this limitation, there is still a significant gap between the power consumption of the wireless sensors and the small energy level that can be harvested from ambient sources.

DOI 10.1007/978-981-4560-75-7_86-1

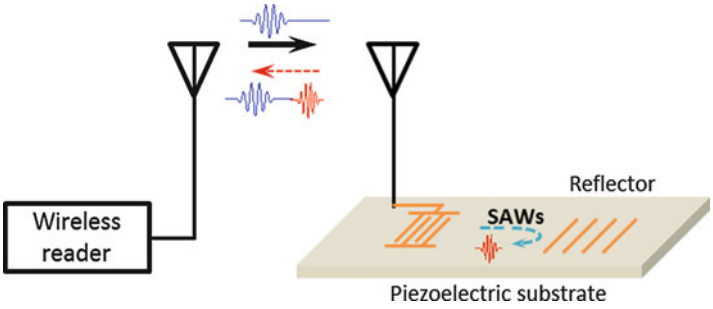

Fig. 3 SAW-based passive wireless sensing system

Passive Wireless Sensors

Passive wireless sensors are viable alternatives to the battery-powered wireless sensors, especially for applications that can tolerate shorter communication ranges. A major difference between an active wireless sensor and a passive wireless sensor is that a passive wireless sensor does not have a radio on board. As such, these sensors either consume no power at all or their power consumption is so low that energy harvested from other sources is sufficient to power them up. Passive wireless sensors can be broadly classified into four categories, namely, the surface acoustic wave (SAW)-based, inductive coupled, radio-frequency identification (RFID) enabled, and antenna sensors. The SAW-based and inductive coupled wireless sensors predate the invention of active wireless sensors. RFID systems, initially developed mainly as an electronic device to replace the barcode for product and inventory tracking, have been extended for low-cost, ubiquitous, passive wireless sensing in recent years. The antenna sensors are the latest arrival of the passive wireless sensor family. They share the same communication principles as the RFID sensors, but they do not need an external sensor and can thus achieve a much simpler configuration than most RFID-enabled sensors.

Passive Wireless SAW Sensors

The schematic illustration of a typical passive wireless SAW sensor is shown in Fig. 3. The wireless sensor consists of a piezoelectric substrate connected to an antenna. Reflectors are patterned on the piezoelectric substrate at short distances from the antenna connection. Taking advantage of the piezoelectric effect, the RF signal received by the antenna is directly applied to excite SAWs propagating along the substrate surface. Upon reaching the reflectors, the SAWs are reflected and converted back to the RF signals at the antenna connections, which is then re-transmitted by the antenna. Because the propagation speeds of the SAWs are much smaller than that of the RF waves, the two-way conversion between the RF waves and SAWs introduces a large time delay between the incident and re-transmitted RF signals. The delay between these two signals is dependent of the distances between the antenna and the reflectors as well as the wave speeds of the SAWs. A physical measurand (e.g., strain, temperature, moisture, etc.) that has an influence on the SAW wave speed can thus be detected from the time delay of the re-transmitted signal. In order to keep the SAW propagation losses reasonably low, the RF frequency used for exciting the SAWs is usually limited to tens of megahertz (MHz). Higher RF frequencies would introduce large SAW propagation losses and thus limit the interrogation distance of the wireless SAW sensors. This frequency limitation makes the miniaturization of the sensor antenna extremely difficult. Moreover, since the wave speeds of the SAWs can be influenced by multiple variants, decoupling their effects on the wave speeds of the SAWs is a challenging task.

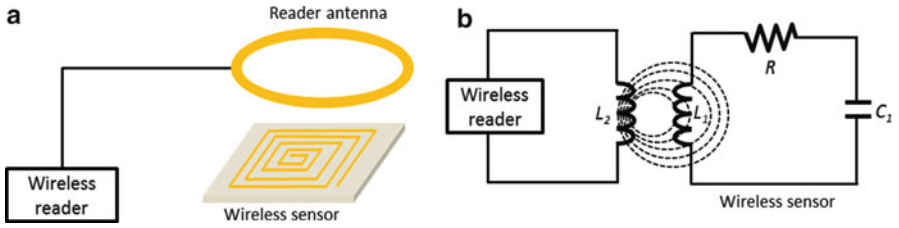

Fig. 4 Inductive coupled passive wireless sensing; (**a**) configuration; (**b**) lump element model

Passive Wireless Inductive Coupled Sensors

The schematic diagram of a simplest inductive coupled wireless sensing system is shown in Fig. 4a. The sensor node is a spiral resonant circuit in the form of a conductive trace patterned on a dielectric substrate. As such, it can be represented by an equivalent lump element circuit having an inductor and a capacitor in parallel (see Fig. 4b). The inductance of the resonant circuit is determined by the geometric parameters of the conductive trace, while its capacitance is related to the gap distance between the conductive traces and the dielectric properties of the substrate. Physical measurands that change these geometric and dielectric parameters therefore will change the inductance and/or capacitance values of the resonant circuit, which in turn cause the resonance frequency to shift. When a reader antenna is placed in the near field of the spiral, the spiral resonant circuit is inductively coupled to the electromagnetic (EM) field of the reader antenna. Therefore, the energy passing through the reader antenna is largely absorbed by the spiral resonant circuit when the interrogation frequency matches with the resonant frequency of the spiral circuit. Sweeping the supplied frequency and monitoring the power of the signal reflected by the reader antenna can thus determine the resonance frequency of the spiral resonance. Compared to SAW-based passive wireless sensors, inductively coupled wireless sensors have a much simpler configuration. A major limitation of such sensors is that the interrogation distance is typically limited to be a few centimeters since the spiral circuit has to be placed in the near field of the reader antenna.

Passive Wireless RFID Sensors

A passive wireless RFID system is shown in Fig. 5a. The RFID reader broadcasts an interrogation signal to the RFID tag, while the RFID tag responds by sending a signal encoded with the identification (ID) number. An RFID tag consists of an antenna and an RFID chip. A detailed diagram of the RFID chip is shown in Fig. 5b. One function of the RFID chip is to harvest energy from the interrogation signal. Once sufficient energy is harvested, the RFID chip is activated to retrieve the ID number from its memory and transmits the ID number via impedance switching of the antenna load. Once received by the RFID reader, the backscattered signal can be processed to retrieve the ID number.

Four common RFID sensor topologies that can incorporate sensing function into an RFID tag are shown in Fig. 6. The Wireless Identification and Sensing Platform (WISP), initially developed by Intel Research, probably is the most complicated and versatile passive wireless RFID sensor. Similar to an active wireless sensor, a WISP sensor is equipped with a microprocessor, an ADC, an external memory, and one or more conventional sensors, as shown in Fig. 6a. The differences between a WISP sensor and an active wireless sensor are as follows: (1) a WISP sensor is powered by energy harvested from the interrogation signal while an active wireless sensor is powered by a battery and (2) a WISP sensor transmits the data by modulating the backscattered signal and thus does not have an onboard radio while an active wireless sensor transmits the data through the radio. Even though a WISP sensor consumes substantially less power than an active wireless sensor, the energy provided by the RFID reader is still not sufficient enough to power the WISP sensor continuously in most cases. Similar to the active wireless sensors, the power management of the WISP sensors remained to be a challenge. An alternative for

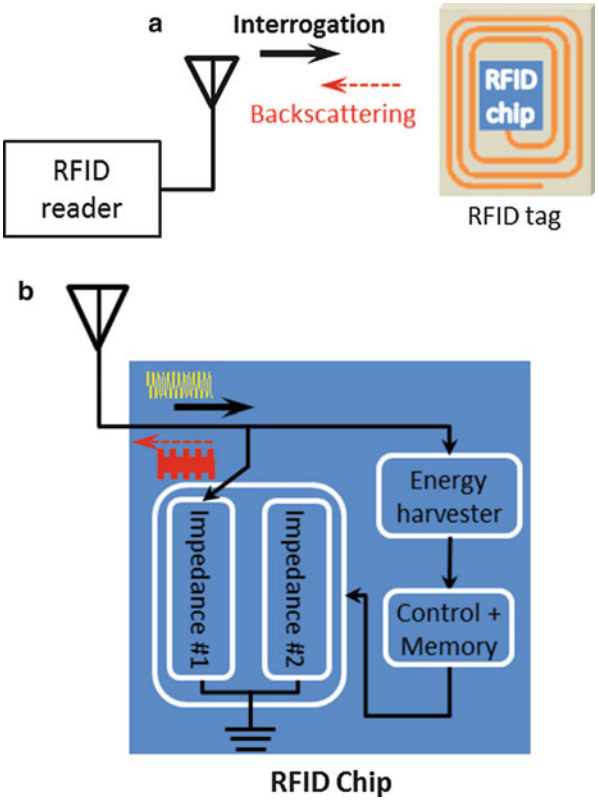

Fig. 5 Passive wireless RFID sensing system; (**a**) system configuration; (**b**) diagram of RFID tag

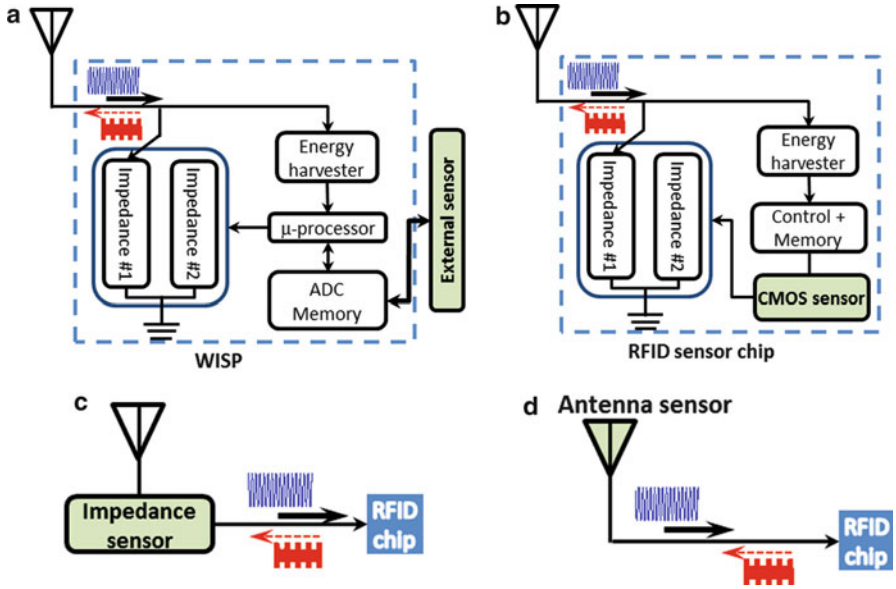

Fig. 6 Four common RFID sensor topologies: (**a**) WISP; (**b**) CMOS-based RFID sensor; (**c**) impedance load-based RFID sensor; (**d**) RFID-enabled antenna sensor

integrating sensing function into an RFID tag is to implement low-power on-chip CMOS sensors into the RFID chip (see Fig. 6b). This approach is compatible with massive integrated circuit (IC) fabrication techniques and can result in very compact, low-power, and sensitive RFID sensor chips. The development

DOI 10.1007/978-981-4560-75-7_86-1

of these chips, on the other hand, required customized chip design and fabrication. In addition, the types of sensor that can be implemented into a CMOS IC chip are also limited. The third type of RFID sensors uses an analog impedance sensor to change the load of the RFID tag antenna, as shown in Fig. 6c. The impedance sensor is designed to change its impedance with the desired physical measurands. Since the radar cross section (RCS) of a loaded antenna is depended of the load impedance, the impedance change of the sensor can thus be detected from the backscattered RFID signal, which in turn can be correlated to the physical parameter that causes the impedance change. The advantage of such sensors is that they do not need special RFID chips and thus can keep the cost of the sensor node low. The fourth type of RFID sensor eliminates the external sensor by employing the RFID tag antenna as the sensor. These RFID sensors can be considered as a subset of passive wireless antenna sensors and therefore will be discussed in detail in this chapter. Among these four types of RFID sensors, the first two encode the sensor data digitally while the other two encode the sensor data in an analog format. In general, digital encoding is more reliable but consumes higher power, while analog encoding is very power efficient but is more susceptible to EM interferences.

Passive Wireless Antenna Sensors

Passive wireless antenna sensors probably have the simplest configurations among all wireless sensors. As shown in Fig. 7, a passive wireless antenna sensor consists of only two components, i.e., an antenna and a modulator. The antennas can be a regular antenna fabricated on conventional dielectric materials or coated with functionalized materials. The main purpose of the modulator is to modulate the interrogation signal received by the antenna so that the signal backscattered by the antenna, i.e., the antenna backscattering, can be separated from the signals backscattered by the surrounding structures, i.e., the structural backscattering. Depending on the sensor design, the modulator can be completely passive or consumes very low power. The sensing function is performed by detecting the change in the radiation characteristics of the antenna sensor, such as the resonance frequency shift. Antenna sensors that are sensitive to moisture, gas, temperature, strain, displacement, crack, etc., have been demonstrated. The unique advantages of these passive wireless antenna sensors can be summarized as the following:

- **Simple configuration**: The antenna itself serves the dual function of communication and sensing. Therefore, no external sensor is needed.
- **Passive operation**: The sensing information is directly encoded in the antenna backscattering. As such, no onboard battery is needed at the wireless sensor node.
- **Multiplexing capability**: The antenna sensors can be multiplexed based on the principle of frequency division multiplexing, spatial division multiplexing, code division multiplexing, etc. This sensor multiplexing capability enables densely distributed sensor networks and parallel interrogation of multiple antenna sensors.
- **Multimodality sensing**: The antenna can be designed to be sensitive to various physical measurands.

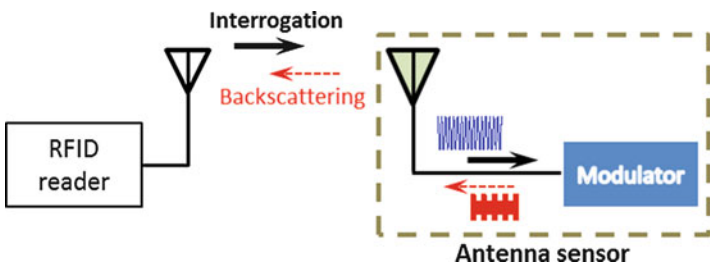

Fig. 7 Passive wireless sensing system based on antenna sensor

DOI 10.1007/978-981-4560-75-7_86-1

- **Low cost**: The antenna sensors can be fabricated on inexpensive materials using conventional printed circuit board fabrication techniques.
- **Planar and conformal**: The antenna sensors can be fabricated on low-profile, planar, flexible substrates that completely conform to the surface it attached to.

Antenna as Sensor

Historical Review

While the first antenna was demonstrated by Heinrich Rudolph Hertz in 1887, using antennas for sensing purposes is a more recent invention. The first antenna sensor found in literature was published by Gagnadre et al. (1995), in which they described a 1.5 GHz circular patch antenna for measuring the moisture content of sludge samples. The sludge sample was contained inside a plastic beaker and placed on top of the circular patch antenna. The moisture content of the sample was calculated from the measured effective dielectric constant of the antenna sensor using the particular model and the Bottcher model. They discovered that their method was able to differentiate about 0.3 % difference in the moisture content of the sludge sample when the moisture content was high. Various antenna sensors, designed for measuring the dielectric constant of snow and soils (Denoth 1997), gas (McGrath et al. 2004; Verma et al. 2013), relative humidity (Chang et al. 2006), soil moisture (You et al. 2010), and glucose (Wiwatwithaya et al. 2011), were demonstrated using wired connections. The first wireless antenna sensor was demonstrated by Sidén et al. (2007). They used a pair of regular RFID tags for relative humidity measurements. One of the RFID tags was covered with a water absorbent material while the other tag was open. Relative humidity was measured from the differences in the turn-on powers of these two RFID tags. Following a similar approach, Bhattacharyya et al. (2010) investigated RFID tags for displacement, filling level, and temperature threshold sensing.

Antenna temperature sensors can be developed by exploiting the temperature dependency of the dielectric material. The first antenna temperature sensor was demonstrated by Bhattacharyya et al. (2011) for temperature threshold detection. The sensor was constructed from a shape memory polymer (SMP) sheet sandwiched between an RFID tag and a metallic plate. The SMP changes its dielectric constant when the temperature crosses a threshold, which in turn can be detected from the turn-on power of the RFID tag. This sensor, however, can only detect two temperature states. Continuous temperature measurements were demonstrated by Yang et al. (2012) and Qiao et al. (2013). Both works used a slotted patch antenna; (Yang et al. 2012) integrated a water pocket in the substrate of the patch antenna, while Qiao et al. (2013) used a high-density polyethylene $Ba_{0.3}Sr_{0.7}TiO_3$ (HDPE-BST) material as the antenna substrate to achieve enhanced temperature sensitivity. Recently, Jiang et al. (2014) investigated a conventional microwave substrate (Rogers Corporation, RO3005) for temperature sensing. Temperature sensitivities of 133.1 ppm/°C and 142.6 ppm/°C, which are equivalent to 665 kHz/°C and 856 kHz/°C, were achieved for the two fundamental resonant frequencies of a rectangular patch antenna. All of the antenna sensors discussed above were based on the principle of measuring the dielectric constant of the antenna and thus can be classified as antenna dielectric sensors. One challenge of developing antenna dielectric sensors is that the relationship between the antenna radiation parameters and the physical measurand is determined by the material property, which in most cases cannot be modelled analytically. As a result, most of the works on the antenna dielectric sensors are experiment based.

The first mathematical derivation of the antenna sensing principle was presented by Tata et al. (2009). Based on the transmission line model, the relationship between the antenna frequency shift and the

DOI 10.1007/978-981-4560-75-7_86-1

applied strain relationship was rigorously derived. The analytical model predicted that the normalized frequency shift of a patch antenna is linearly proportional to the applied strain. This prediction was validated using a rectangular patch antenna installed on a cantilever beam. Following Tata's work, other antenna types, including circular patch (Daliri et al. 2010), folded dipole (Merilampi et al. 2010, 2011) antennas, meander-line dipole (Occhiuzzi et al. 2011), folded patch (Yi et al. 2011), planar dipole (Jang and Kim 2012), embroidered dipole (Hasani et al. 2013), and slotted patch (Salmani et al. 2011; Yi et al. 2014) antennas, were also demonstrated for strain sensing. All these antenna sensors are based on the same principle, i.e., the applied strain changes the dimension of the antenna radiation element and thus causes a shift of the antenna resonant frequency. A different principle was exploited by Bhattacharyya et al. (2009) and Mohammad and Huang (2012a) for displacement and pressure sensing. In Bhattacharyya et al. (2009), an RFID tag antenna was placed below a metallic plate. The capability of the antenna sensor to measure beam deflection was demonstrated by attaching the metallic plate on a simply supported beam; the deflection of the beam changes the distance between the metallic plate and the tag antenna and thus alters the efficiency of the tag antenna, which can be detected from the turn-on power as well as the backscattered signal power. In Mohammad and Huang (2012a), a pressure sensor was constructed by separating a loop antenna and a metallic film using a foam material. Pressure applied on the sensor reduces the distance between the loop antenna and the metallic plate, which shifts the resonant frequency of the loop antenna. A linear relationship between the applied pressure and the resonant frequency shift was demonstrated experimentally.

The first antenna crack sensor was developed by Matsuzaki et al. (2009) using a dipole antenna made of carbon fiber-reinforced plastic (CFRP). They demonstrated that the antenna resonant frequency increases correspondingly when a crack shortens the antenna element. Therefore, it is possible to detect the crack location from the measured antenna resonant frequency increase. Kalansuriya et al. (2013) demonstrated an RFID-enabled crack sensor based on the same principle. Since the antenna sensor can only detect the crack when it severs the dipole element, they also exploited using a tag array to detect the propagation of a crack. Mohammad and Huang (2010) demonstrated an antenna sensor that can detect not only the crack growth but also the crack opening. Later on, the same group also demonstrated that it is possible to use a rectangular patch antenna to detect the crack orientation (Mohammad et al. 2012) and the propagation of a hidden crack (Erdmann and Huang 2011). Similar to the antenna strain sensors, these antenna crack sensors operate on the principle that a crack changes the electric dimensions of the antenna and thus can be detected from the resulting frequency shift. Mohammad and Huang (2012b) also demonstrated an antenna shear sensor based on the same principle.

A list of antenna sensors is given in Tables 1, 2, 3, and 4, grouped based on their sensing measurands in chorological orders. This list includes all the published work on antenna sensors the author found in the literature. The references marked with an asterisk demonstrated wireless interrogation of the antenna sensor, while the references without the asterisk only demonstrated the operation of the antenna sensor using wired connections.

Principle of Operation

The operational principle of an antenna sensor is explained in this section using the microstrip rectangular patch antenna as an example. The operational principles of the other antenna types are similar and can be found in the references given above. A microstrip rectangular patch antenna, as shown in Fig. 8a, consists of four components, i.e., the ground plane, the dielectric substrate, the radiation patch, and the transmission feed line. Both the ground plane and the radiation patch are made of conductive materials. Separated by the dielectric substrate, they form an EM resonance that radiates at specific frequencies. The radiation patch is "fed" by the microstrip transmission line, through which an incident signal can be supplied. This incident signal is either transmitted by the radiation patch or reflected by it. Therefore, the radiation

efficiency of the patch antenna can be defined by the ratio between the reflected power and the incident power, also known as the return loss. Since the patch antenna functions as a resonator, its return loss is frequency dependent. The S_{11} parameter of a patch antenna, which represents the return loss of the patch antenna as a function of frequency, is shown in Fig. 8b. Three radiation parameters can be extracted from the S_{11} parameter, i.e., the resonant frequency, the resonant bandwidth, and the baseline losses. The

resonant frequency is identified as the frequency at which the return loss is a local minimum; at this frequency, most of the incident power is radiated by the antenna, and thus, little energy is reflected back. The resonant bandwidth is usually measured as the frequency span of the resonant valley at a given return loss, e.g., at −6 dB. The baseline loss represents the overall loss of the antenna that is independent of the resonance. In theory, all of these three radiation parameters can be used to transduce the physical measurand into a measurable radiation parameter. In practice, however, the resonant frequency shift is the most commonly used sensing parameter. One of the advantages of the resonant frequency is that it is reference-free, i.e., the measured resonant frequency is not influenced by other parameters such as the interrogation range, transmission losses, etc. Therefore, it can provide absolute, robust, and reliable measurements.

Analytical Model of Antenna Resonant Frequency and Its Sensitivity to Measurands

The resonant frequency of a rectangular patch antenna can be calculated as

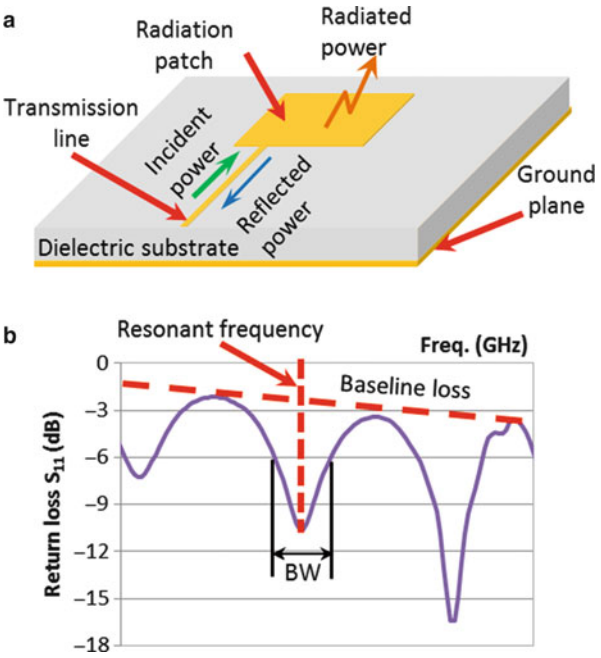

Fig. 8 (**a**) Configuration of a microstrip rectangular patch antenna; (**b**) S_{11} representation of antenna radiation characteristics

$$f_{mn} = \frac{C}{2\pi\sqrt{\varepsilon_{\text{reff}}}}\sqrt{\left(\frac{m\pi}{L_e}\right)^2 + \left(\frac{n\pi}{W_e}\right)^2}, \tag{1}$$

where c is the speed of light and $\varepsilon_{\text{reff}}$ is the effective dielectric constant. The electric length L_e and the electric width W_e can be calculated from the geometric dimensions of the radiation patch and the fringe extensions as

$$L_e = L + \Delta L \text{ and } W_e = W + \Delta W. \tag{2}$$

DOI 10.1007/978-981-4560-75-7_86-1

(m, n) represents the resonant orders; for an antenna with a rectangular radiation patch, the fundamental (1,0) mode, i.e., the TM_{10} mode, has the current flow along the length direction while the fundamental (0,1) mode, i.e., the TM_{01} mode, has the current flow along the width direction. Since Eq. 1 is almost identical for the TM_{10} and TM_{01} modes, the derivations given below will be focused on the TM_{10} mode. The resonant frequency of the TM_{10} mode can be simplified from Eq. 1 as

$$f_{10} = \frac{c}{2\sqrt{\varepsilon_{\text{reff}}}} \frac{1}{L_e}. \tag{3}$$

When the substrate height h is much smaller than the dimensions of the radiation patch, the line extension ΔL can be neglected. Therefore, Eq. 3 is reduced to

$$f_{10} = \frac{c}{2L\sqrt{\varepsilon_{\text{reff}}}}. \tag{4}$$

The relationship between the antenna frequency shift δf_{10} and the changes in $\varepsilon_{\text{reff}}$ and L can be derived by taking the full derivative of Eq. 4, i.e.,

$$\delta f_{10} = \frac{\partial f_{10}}{\partial \varepsilon_{\text{reff}}} \delta \varepsilon_{\text{reff}} + \frac{\partial f_{10}}{\partial L} \delta L, \tag{5}$$

in which

$$\frac{\partial f_{10}}{\partial \varepsilon_{\text{reff}}} = \left(-\frac{1}{2\varepsilon_{\text{reff}}}\right) \frac{c}{2L\sqrt{\varepsilon_{\text{reff}}}} = \left(-\frac{1}{2\varepsilon_{\text{reff}}}\right) f_{10} \quad \text{and} \quad \frac{\partial f_{10}}{\partial L} = \left(-\frac{1}{L}\right) \frac{c}{2L\sqrt{\varepsilon_{\text{reff}}}} = \left(-\frac{1}{L}\right) f_{10}. \tag{6}$$

Normalizing δf_{10} with respect to f_{10} results in

$$\frac{\delta f_{10}}{f_{10}} = -\frac{1}{2} \frac{\delta \varepsilon_{\text{reff}}}{\varepsilon_{\text{reff}}} - \frac{\delta L}{L}. \tag{7}$$

Equation 7 serves as the theoretical foundation for the antenna sensors. The first term represents the sensitivity of the antenna resonant frequency to the effective dielectric constant changes of the antenna, which can be exploited for environment (e.g., temperature, moisture, gas, etc.) and biochemical sensing. The second term represents the sensitivity of the antenna resonant frequency with respect to the dimensional change of the radiation patch, which can be exploited for strain, crack, and temperature sensing.

Dielectric Sensing

An antenna dielectric sensor can be a regular patch antenna with an exposed radiation patch as shown in Fig. 8a or a patch antenna with a superstrate, i.e., the radiation patch is covered with a dielectric material, as shown in Fig. 9. In the latter case, the effective dielectric constant of the antenna sensor is contributed by both the substrate and the superstrate. The effective dielectric constant of the patch antenna can then be calculated by introducing two filling factors q_1 and q_2 as (Bogosanovich 2000)

$$\varepsilon_{\text{reff}} = q_1\varepsilon_1 + q_2\varepsilon_2 + (1 - q_1 - q_1), \tag{8}$$

DOI 10.1007/978-981-4560-75-7_86-1

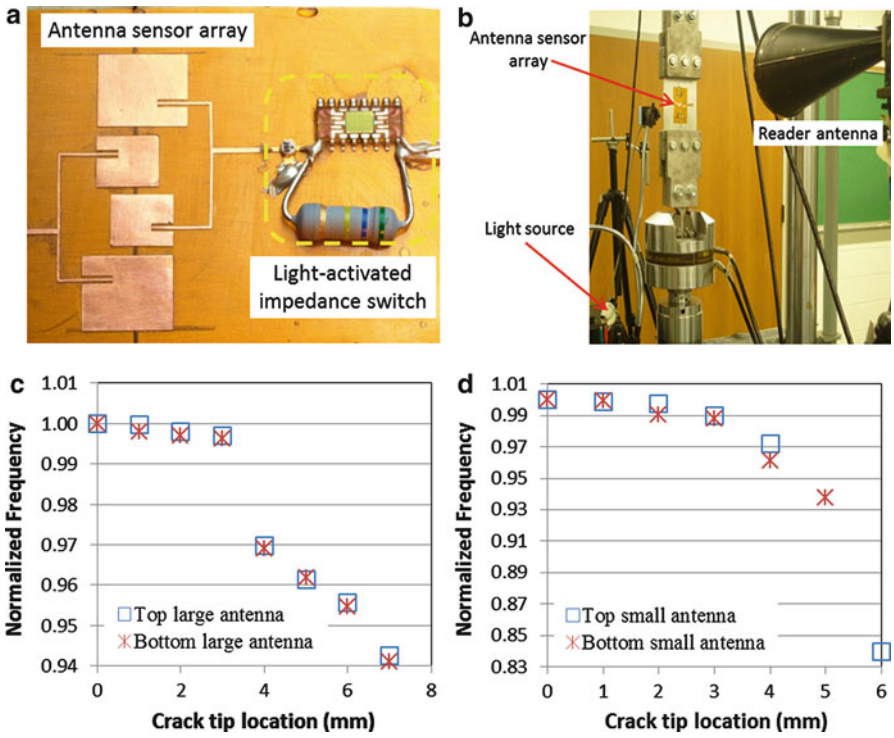

Fig. 9 An antenna dielectric sensor with its radiation patch covered by a dielectric superstrate. The superstrate can be functionalized material for selected sensing

where ε_1 and ε_2 are the dielectric constants of the substrate and superstrate, respectively. The third term accounts for the medium above the superstrate, which is assumed to be air. The superstrate material can be regular materials such as paper for moisture sensing or functionalized material such as carbon nanotubes (CNT) for gas sensing. The relationship between the effective dielectric constant and the physical measurand is usually calibrated by experiments. Representing the physical measurand as μ and assuming the effective dielectric constant can be represented as a function of μ, i.e., $\varepsilon_{\text{reff}} = f_\mu(\mu)$, the relationship between the normalized frequency shift and the physical measurand can then be derived from Eq. 7 as

$$\frac{\delta f_{10}}{f_{10}} = -\frac{1}{2\varepsilon_{\text{reff}}}\frac{\partial f_\mu}{\partial \mu}\delta\mu - \frac{\delta L}{L}, \tag{9}$$

which reduces to

$$\frac{\delta f_{10}}{f_{10}} = -\frac{1}{2f_\mu(\mu)}\frac{\partial f_\mu}{\partial \mu}\delta\mu \tag{10}$$

assuming the length of the patch antenna remains to be a constant.

Strain Sensing

As a direct measurement of the material deformation, strain is one of the most important mechanical properties to be sensed. Since strain can be easily correlated to the stress, external load, vibration, and boundary conditions of a load carrying structure, it is frequently used for evaluating the structural integrity of engineering components. There are two types of strains; the normal strain is defined as the relative change in the size of a structure with respect to its original size and the shear strain is defined as the change

DOI 10.1007/978-981-4560-75-7_86-1

in angle with respect to an original 90° angle. The normal strain along the length direction of the radiation patch is therefore defined as

$$\varepsilon_L = \frac{\delta L}{L}. \tag{11}$$

Assuming the effective dielectric constant is independent of the normal strain, i.e., $\delta\varepsilon_{\text{reff}}/\varepsilon_{\text{reff}} = 0$, and the temperature remains constant, Eq. 7 reduces to

$$\frac{\delta f_{10}}{f_{10}} = -\frac{\delta L}{L} = -\varepsilon_L, \tag{12}$$

which indicates that the normalized frequency shift is linearly proportional to the applied strain. In case the structure is subjected to bidirectional loadings, the strain along the length and width directions of the radiation patch can be calculated from the normalized resonant frequency shifts of the TM_{10} and TM_{01} modes, i.e.,

$$\begin{cases} \dfrac{\delta f_{10}}{f_{10}} = -\dfrac{\delta L}{L} = -(\varepsilon_L - \upsilon\varepsilon_W) \\ \dfrac{\delta f_{01}}{f_{01}} = -\dfrac{\delta W}{W} = -(\varepsilon_W - \upsilon\varepsilon_L) \end{cases} \Rightarrow \begin{cases} \varepsilon_L = -\dfrac{1}{1-\upsilon^2}\left(\dfrac{\delta f_{10}}{f_{10}} + \upsilon\dfrac{\delta f_{01}}{f_{01}}\right) \\ \varepsilon_W = -\dfrac{1}{1-\upsilon^2}\left(\upsilon\dfrac{\delta f_{10}}{f_{10}} + \dfrac{\delta f_{01}}{f_{01}}\right) \end{cases}, \tag{13}$$

where υ is the Poisson's ratio of the structural material. Based on the principle of strain transformation, the normal and shear strains along an arbitrary direction can be calculated from the normal strains along two orthogonal principle directions. Therefore, the strain state of a structure can be uniquely measured using one rectangular patch antenna by aligning the antenna radiation patch along the principle stress directions.

Based on Eqs. 12 and 13, the strain sensitivity of the antenna sensor, measured as the amount of frequency shift per unit strain (i.e., $\delta f_{mn}/\varepsilon$), is linearly proportional to the corresponding antenna resonance frequency f_{mn}. Therefore, an antenna with higher resonant frequencies is more sensitive to strain changes. In addition, it is desirable for a strain sensor to have small size so that it can offer fine spatial resolution. Based on these two considerations, the antenna sensor employed for strain sensing should have the highest resonant frequencies possible, under the constraints of manufacturing uncertainties, interrogation distance, and the costs of the modulation and reader circuits.

Temperature Sensing

Temperature is an important parameter to measure in many applications, including manufacturing process control, environmental monitoring, food production, human and animal health monitoring, etc. For the purpose of temperature sensing, the effective dielectric constant of an antenna temperature sensor should be linearly proportional to the temperature change ΔT, i.e.,

$$\frac{\delta\varepsilon_{\text{reff}}}{\varepsilon_{\text{reff}}} = \alpha_\varepsilon \Delta T. \tag{14}$$

α_ε is called the thermal coefficient of dielectric constant (TCD_k) of the substrate material (Carver and Mink 1981). Due to the thermal expansion effect, the dimensions of the radiation patch are also sensitive to the temperate changes as well. Denoting the coefficient of thermal expansion (CTE) of the antenna sensor as α_T, we can calculate the thermally induced length change as

DOI 10.1007/978-981-4560-75-7_86-1

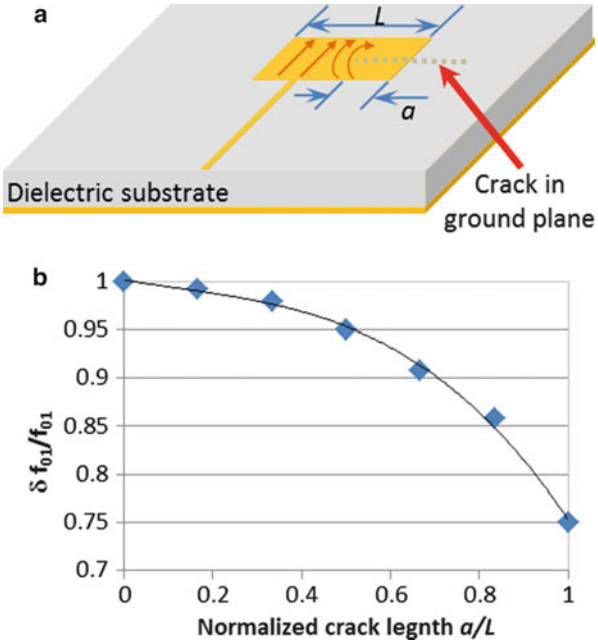

Fig. 10 (**a**) Effect of crack on current distribution of radiation patch; (**b**) reduction of antenna resonant frequency with crack growth

$$\frac{\delta L}{L} = \alpha_T \Delta T. \tag{15}$$

Substituting Eqs. 14 and 15 into 7, we have

$$\frac{\delta f_{10}}{f_{10}} = -\left(\frac{1}{2}\alpha_\varepsilon + \alpha_T\right)\Delta T = k_T \Delta T. \tag{16}$$

k_T, therefore, represents the temperature sensitivity of the antenna resonant frequency. Since both the TCD_k and the CTE are material properties, the frequency shift $\delta f_{01}/f_{01}$ of the TM_{01} mode should have the same temperature sensitivity value k_T, assuming the substrate material is isotropic.

The strain and temperature sensitivity of the antenna resonant frequency are derived separately up to this point. Similar to many other strain sensors, the effects of strain and temperature on the antenna resonant frequencies are coupled. In case the antenna sensor is subjected to uniaxial strain, these two effects can be decoupled by utilizing the two orthogonal antenna radiation modes. The normalized frequency shifts of the TM_{10} and TM_{01} modes under a length direction strain ε_L and a temperature change ΔT can be expressed as

$$\begin{cases} \dfrac{\delta f_{10}}{f_{10}} = k_T \Delta T - \varepsilon_L \\ \dfrac{\delta f_{01}}{f_{01}} = k_T \Delta T - \upsilon \varepsilon_L \end{cases} \Rightarrow \begin{cases} \varepsilon_L = -\dfrac{1}{\upsilon - 1}\left(\dfrac{\delta f_{10}}{f_{10}} - \dfrac{\delta f_{01}}{f_{01}}\right) \\ \Delta T = -\dfrac{1}{k_T}\left(\dfrac{\delta f_{10}}{f_{10}} + \varepsilon_L\right) \end{cases}. \tag{17}$$

If the antenna sensor is subjected to biaxial strains and a temperature change simultaneously, two antenna sensors placed in close vicinity have to be used to extract these three parameters.

DOI 10.1007/978-981-4560-75-7_86-1

Crack Sensing

The presence of cracks is a direct indication of structural damage. If left unattended, some cracks could cause catastrophic structural failures. From a fracture mechanics point of view, in order to accurately predict the effect of the crack on the structural integrity, the crack location, length, and orientation have to be known. The antenna sensor is unique in its capability to provide such detailed crack information. In the derivation of Eq. 7, the radiation patch and the ground plane of the patch antenna were assumed to be perfectly continuous, i.e., there is no slot, cut, or crack in them. If the radiation patch or the ground plane has a crack, however, the crack will disturb the current flow of the radiation patch. As shown in Fig. 10a, a crack parallel to the length direction of the radiation patch will force the current along the width direction to flow around it and thus elongates the electric width of the radiation patch. Similarly, a crack parallel to the width direction will elongate the electric length. In the case of a slanted crack that is parallel neither to the length nor to the width direction of the radiation patch, the crack increases both electric dimensions of the microstrip patch antenna, which causes the antenna resonant frequencies to shift lower. Unfortunately, there is no analytical model that can conveniently calculate the effects of crack on the antenna resonant frequencies. In order to establish the relationship between the crack length and the antenna resonant frequency shifts, either numerical EM simulation or experimental calibration has to be carried out. The resonance frequency – crack growth relationship for an antenna sensor with a crack parallel to its length direction is shown in Fig. 10b. The crack sensitivity of the antenna sensor is defined as the amount of frequency shift per unit crack growth, i.e., $\delta f_{mn}/da$, where da is the crack growth. When the crack just reaches the edge of the radiation patch, the crack sensitivity is relatively low. The crack sensitivity increases as the crack propagates deep into the radiation patch. After the crack tip reaches beyond the half length of the radiation patch, the frequency shift-crack growth relationship is almost linear.

Wireless Interrogation Schemes

Historic Review

Functioning as an EM resonator, a passive antenna can be wirelessly interrogated via near-field or far-field communications. When a reader antenna is placed in the near field of an antenna sensor, these two antennas are inductively coupled. Therefore, the impedance or scattering parameter (S-parameter) of the sensor antenna can be measured directly from the S_{11} parameter of the reader antenna (Potyrailo et al. 2011; Jang and Kim 2012; Daliri et al. 2012). The reading range of the near-field communication, however, is comparable with that of the inductively coupled sensors. The far-field interrogation of the antenna sensors that can offer a much longer range is therefore the focus of this section. Since a passive antenna sensor does not have a radio on board, wireless interrogation is carried out based on the signal reflected by the antenna sensor, i.e., the antenna backscattering. The theory of antenna backscattering can be traced back to papers published by King (1949) and Harrington (1963). The first wireless measurement of the antenna backscattering in an anechoic chamber was presented by Newman and Forrai (1987), which was used to validate the integral equation and method of moments (MOM) solution for calculating the plane wave scattered by a rectangular microstrip antenna. The effect of a load impedance on the backscattering of a microstrip patch antenna was simulated by Pozar (1987) using a spectral domain Green's function. Later on, Aberle et al. (1991) extended this method to evaluate the input impedance and the antenna backscattering of probe-fed microstrip patch antennas. Other numerical simulation methods, such as the finite-difference time-domain (FDTD) method, enable calculating the antenna backscattering over a large bandwidth (Reineix et al. 1993). These theoretical works laid the foundation for the development of RFID systems. Penttila et al. (2006) analyzed the RCS of passive RFID tags for the purpose of system optimization. They also performed scattering pattern measurements of the tag antennas

DOI 10.1007/978-981-4560-75-7_86-1

with four different loads. The differential RCS of the RFID tag was analyzed by Nikitin et al. (2007) and validated with experiment measurement. All these measurements, however, were performed in anechoic chambers.

The first demonstration on the wireless interrogation of an antenna sensor outside of an anechoic chamber was published by Sidén et al. (2007). In this work, a regular RFID tag was employed for relative humidity measurement, and the turn-on power of the RFID tag was selected as the sensing parameter. Since the turn-on power is not only related to the antenna efficiency but also influenced by the read-tag distance and the transmission losses, a reference RFID tag without the sensing material has to be placed at an equal distance from the RFID reader. The relative humidity was then measured from the difference in the turn-on powers of these two RFID tags. Even though the backscattered signal power was introduced by Bhattacharyya et al. (2009) and Marrocco et al. (2009) as an additional sensing parameter for the RFID-enabled antenna sensors, it can only offer a relative measurement and thus share the same limitation as the turn-on power. Wireless measurement of the antenna resonant frequency outside of an anechoic chamber was demonstrated by Tata et al. (2009) and Deshmukh and Huang (2010). Using delayed time-domain reflectometry (TDR) and normalized TDR, they validated the linear relationship between the antenna resonant frequency shifts and the applied strain levels experimentally. Wireless measurement of the antenna resonant frequency using RFID tags was demonstrated by Yi et al. (2011), Qiao et al. (2013), and Hasani et al. (2013). To measure the resonant frequency of an RFID tag antenna, the frequency and/or the power level of the interrogation signal has to be swept. Since it takes some time for the RFID chip to harvest sufficient power for each frequency/power setting, measuring the resonant frequency of the RFID tag antenna can take a long time. Recently, dynamic interrogation of the wireless patch antenna sensor was demonstrated by Yao et al. (2014) based on the principles of amplitude modulation (AM) and frequency-modulated continuous wave (FMCW) radar.

A list of published work on the wireless interrogation of antenna sensors is given in Table 5. Again, the list may not be exhaustive but included all the relevant references the author found in literature.

Theoretical Foundation

An antenna is a wireless transmission device that can receive and radiate EM signals. The power transmission between the reader and an antenna sensor is shown in Fig. 11. Assuming the power transmitted by the reader antenna is P_{tx} and the distance between the reader and the sensor is R, the power received by the sensor antenna can be calculated from the Friis equation as

$$P_{rx} = P_{tx} G_r G_s |\rho_r \rho_s|^2 \left(\frac{\lambda}{4\pi R}\right)^2, \tag{18}$$

where λ is the wavelength, G_r and G_s are the gains of the reader and sensor antenna, and ρ_r and ρ_s are the polarization loss factors of these two antennas, respectively. Since the antenna sensor is connected to a load through the microstrip feed line, the signal received by the antenna propagates along the microstrip feed line until it reaches the load. If the load impedance does not match with the antenna impedance perfectly, a portion of the received power will be reflected. Therefore, the reflected power can be calculated from the impedance mismatch between the antenna and the load as

$$P_\Gamma = |\Gamma|^2 P_{rx} \text{ and } \Gamma = \frac{Z_L - Z_a}{Z_L + Z_a}, \tag{19}$$

in which Z_L is the load impedance and Z_a is the antenna impedance. This reflected power traces its path

back and is subsequently reradiated by the antenna sensor. The power of the backscattered signal received by the wireless reader can again be calculated from the Friis equation as

$$P_{BS} = P_\Gamma G_r G_s |\rho_r \rho_s|^2 \left(\frac{\lambda}{4\pi R}\right)^2 = \left|\frac{Z_L - Z_a}{Z_L + Z_a}\right|^2 P_{TX} G_r^2 G_s^2 |\rho_r \rho_s| 4 \left(\frac{\lambda}{4\pi R}\right)^4. \tag{20}$$

The antenna impedance Z_a is related to the antenna S_{11} parameter and a characteristic impedance Z_0 as

$$Z_a = \left(\frac{1 + S_{11}}{1 - S_{11}}\right) Z_0. \tag{21}$$

Since the S_{11} parameter is a function of the interrogation frequency, the power of the antenna backscattering is frequency dependent as well. For an antenna sensor with a mismatched load, the antenna resonant frequency can then be identified as the frequency at which the antenna backscattering has the highest power, as shown in Fig. 11b.

In theory, the antenna resonant frequency can be wirelessly determined from the antenna backscattering. In practice, however, this is not an easy task since the antenna sensor is usually surrounded by other structures that also reflect EM waves. The signal received by the reader is therefore a combination of the antenna backscattering and structural backscattering (also known as the background clutter). In most cases, the structural backscattering is so strong that it could completely jam the antenna backscattering, creating the well-known "self-jamming" problem. In order to separate the antenna backscattering from the structural backscattering, a modulator has to be implemented at the antenna sensor. Depending on the modulation schemes used in the antenna sensor, the wireless reader has to be equipped with a corresponding demodulation circuit in order to extract the antenna backscattering from the received signal. A few common modulation schemes are described below.

Time-Gated TDR

Time-Gated TDR with Delay Line

The simplest way to interrogate a wireless antenna sensor is to connect a long transmission line to the antenna sensor, as shown in Fig. 12a. Since the received signal has to travel along the long transmission line before it gets reflected by the load, a time delay is introduced between the antenna backscattering and the structural backscattering. In order to provide the needed separation between these two backscatterings, a microstrip meander line is usually employed. The experiment setup for the wirelessly interrogation of such an antenna sensor is shown in Fig. 12b. Assuming the wireless reader is a vector network analyzer (VNA) with a single reader antenna, the S_{11} parameter measured by the VNA is converted to a time-

domain signal by the inverse fast Fourier transformation (IFFT) operation. Short-time fast Fourier transformation (STFFT) can then be applied to calculate the spectrogram of the backscattered signal. Once the starting and ending times of the antenna backscattering are identified from the spectrogram, the signal can be time gated to extract the antenna backscattering. Finally, the antenna resonant frequency can be determined from the frequency spectrum of the time-gated signal calculated by fast Fourier transformation (FFT).

Normalized TDR by Impedance Switching

Introducing a long transmission line to delay the antenna backscattering is simple, but the transmission line increases the overall size of the antenna sensor. A technique to remove the long transmission line is to terminate the antenna sensor with an impedance switch, as shown in Fig. 13a. The load of the antenna sensor is switched between two states, e.g., a short and an open load; a short load reflects the received signal with a 180° phase shift while an open load reflects the received signal without any phase shift. In comparison, the structural backscattering is identical regardless of the switching state of the antenna. Subtracting the received signal acquired at the two switching states therefore cancels out the structural backscattering while doubles the antenna backscattering. The data processing procedure for such a wireless interrogation scheme is shown in Fig. 13b. The S_{11} parameters of the reader antenna are acquired using a VNA at the two switching states. Both measurements are converted to time-domain signals using the IFFT operation. After subtracting these two time-domain signals to remove the structural backscattering, the time gating procedure described above can be applied to extract the antenna resonant frequency.

One limitation of the time-gated TDR is that the frequency resolution of the FFT operation is usually limited to be around 20 MHz for an antenna sensor with resonant frequencies of a few gigahertzes (GHz). In addition, the two methods described above use a VNA as the wireless reader. Even though it is convenient for lab tests, a VNA is too expensive and too bulky for practical sensor applications. Low-cost wireless readers based on the principles described above have been demonstrated. Please see sections "Gated TDR Based on Frequency Stepping and Delay Switches" and "Gated TDR Based on FMCW Radar" for more details.

RFID-Enabled Wireless Interrogation

When an antenna sensor is loaded with an RFID chip, the antenna backscattering can be measured using two parameters, i.e., the turn-on power that is required to activate the RFID chip and the differential backscattered signal power at the two states of the RFID chip. As discussed in the introduction section, there are two fundamental functions of an RFID chip; one is to harvest energy from the interrogation signal and the other is to switch the impedance of the tag antenna. Based on Eqs. 18 and 19, the power received by an RFID chip can be calculated as

$$P_{\text{chip}} = \left(1 - |\Gamma|^2\right) P_{tx} G_r G_s |\rho_r \rho_s|^2 \left(\frac{\lambda}{4\pi R}\right)^2, \tag{22}$$

which is also a function of the interrogation frequency. Since the RFID chip requires a minimum power level to be activated, the power received by the antenna sensor can then be measured by varying the transmitted power P_{tx} and tracking at what power level the RFID chip is turned on. By sweeping the interrogation frequency, the antenna resonant frequency can then be determined as the frequency at which the turn-on power is the minimum. This approach requires varying both the transmitted power level and the interrogation frequency. Therefore, the time needed to determine the antenna resonant frequency is quite substantial. The differential backscattered signal power approach measures the differences in the powers received by the RFID reader at the two ID digits, i.e., digit "1" or "0." Assuming digit "1" is generated when the antenna is connected to impedance #1 while digit "0" is generated when the antenna is connected to impedance #2, the power received by the RFID reader at these two states can be calculated as

$$P^{(1)} = |\Gamma_1|^2 P_{tx} G_r^2 G_s^2 |\rho_r \rho_s|^4 \left(\frac{\lambda}{4\pi R}\right)^4 + P_{\text{structure}} \tag{23}$$

DOI 10.1007/978-981-4560-75-7_86-1

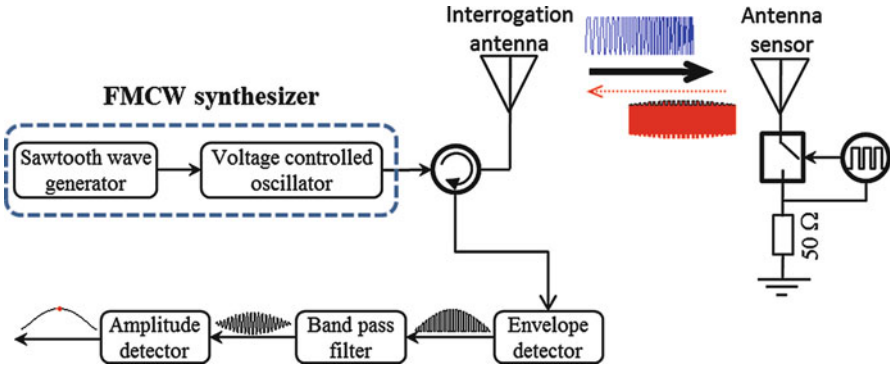

Fig. 14 Dynamic interrogation of wireless antenna strain sensor based on amplitude modulation and FMCW radar

and

$$P^{(0)} = |\Gamma_2|^2 P_{tx} G_r^2 G_s^2 |\rho_r \rho_s|^4 \left(\frac{\lambda}{4\pi R}\right)^4 + P_{\text{structure}}. \tag{24}$$

The power difference between these two states is then

$$\Delta P = P^{(1)} - P^{(0)} = \left(|\Gamma_1|^2 - |\Gamma_2|^2\right) P_{tx} G_r^2 G_s^2 |\rho_r \rho_s|^4 \left(\frac{\lambda}{4\pi R}\right)^4. \tag{25}$$

Again, ΔP is a function of the interrogation frequency and the antenna resonant frequency is determined as the frequency at which ΔP is the largest.

The RFID-enabled approach allows the use of commercially available RFID chips and readers, which makes the sensor fabrication much easier and the cost low. In addition, since each antenna sensor is identified by a unique code, code division sensor multiplexing can be easily implemented. One limitation of such an approach is that the operation frequency of the antenna sensor is limited by the RFID frequency. Most of the published RFID sensors operate at 960 MHz or lower frequencies. As a result, the antenna sensors have relatively large sizes. Another limitation of the RFID-enabled antenna sensors is their low interrogation speed. Because the RFID chip has to harvest sufficient power to be activated, it could take a long time for it to send out the data, especially when there is a large difference between the interrogation frequency and the antenna resonant frequency. Therefore, the RFID-enabled antenna sensor is not suitable for dynamic sensing, such as for vibration measurements that require a fast sensor response.

Amplitude Modulation for Dynamic Wireless Interrogation

Dynamic interrogation of wireless antenna sensors can be achieved based on the principle of amplitude modulation and FMCW radar. As shown in Fig. 14, the interrogation signal is generated using an FMCW synthesizer consisting of a sawtooth wave generator and a voltage-controlled oscillator (VCO). As a result, the FMCW synthesizer generates a chirp signal whose frequency linearly varies with time. By switching the load of the antenna sensor between an open and 50 Ω load using a square wave, the backscattered antenna signal is an amplitude modulated signal whose envelope is a square wave. The amplitude of the envelope is determined by the interrogation frequency; when the interrogation frequency is not very different from the antenna resonant frequency, the amplitude of the envelope is large. In contrast, when the interrogation frequency is very different from the antenna resonant frequency, the amplitude of the envelope is small. The envelope of the amplitude modulated signal can be demodulated

DOI 10.1007/978-981-4560-75-7_86-1

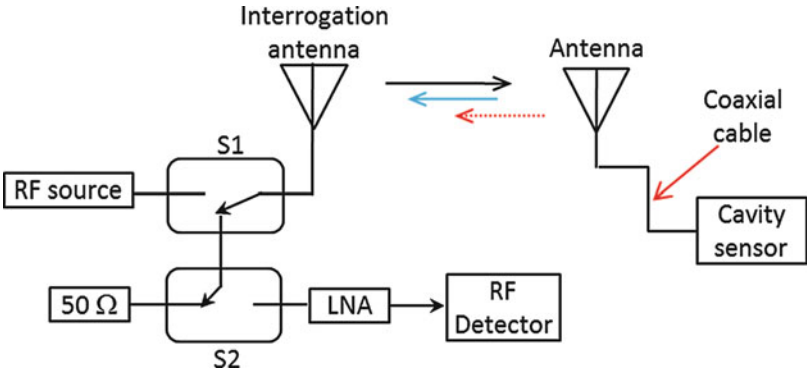

Fig. 15 Time-domain gating approach for wireless interrogation of an EM cavity sensor (Adapted from Thomson et al. 2009)

at the wireless reader using analog components. The envelope of the received backscattered signal is extracted using a microwave envelope detector. Passing the envelope signal through a band pass filter produces a sinusoidal signal with time-varying amplitudes. Finally, a low-frequency amplitude detector can be used to detect the time-amplitude relationship of the demodulated signal. By correlating the frequency-amplitude relationship with the time-frequency relationship of the chirp signal, the antenna resonant frequency can be determined from the filtered envelope signal. Since the FMCW synthesizer can sweep the interrogation frequency at a rate up to a few thousand kilohertz and the demodulation was carried out in an analog fashion, dynamic interrogation of the wireless antenna sensor can be achieved.

Other Wireless Interrogation Schemes

There are other wireless interrogation schemes that have been developed for EM resonant sensors but have not been used for wireless antenna sensors directly. Since an antenna is essentially an EM resonator, these wireless interrogation techniques can be easily adopted for the antenna sensors. Therefore, they are briefly discussed here. A comparison of different wireless interrogation schemes is given at the end of this section.

Gated TDR Based on Frequency Stepping and Delay Switches

To develop a field usable wireless reader for an EM cavity sensor, Thomson et al. (2009) implemented the time-gated TDR using a frequency stepping RF source and delay switches. The cavity sensor has a high quality factor (Q factor) of 1,000 and was connected to an antenna via a coaxial cable. Due to the high Q factor of the cavity sensor, it reradiates the energy in the form of a decaying RF signal after the input signal is switched off. The schematic for wireless interrogation of such a high Q factor cavity sensor is given in Fig. 15. The wireless reader has two operational modes, namely, the transmitting and receiving modes. At the transmitting mode, an interrogation signal is generated using a frequency stepping RF source and broadcasted to the wireless sensor via the reader antenna. It was characterized that the cavity sensor takes about 400 ns to reach equilibrium. 500 ns after the cavity sensor has reached equilibrium, the wireless reader is switched to the receiving mode by connecting the reader antenna to the 50 Ω load using the two switches S1 and S2. After a short delay, the position of S2 is changed so that the reader antenna is connected to a low-noise amplifier (LNA). Due to the time delay, the structural backscattering has largely died out, and thus, the signal amplified by the LNA is dominated by the cavity sensor signal. Detecting the power of the amplified signal using an RF detector at different frequencies therefore enables detecting the resonant frequency of the cavity sensor.

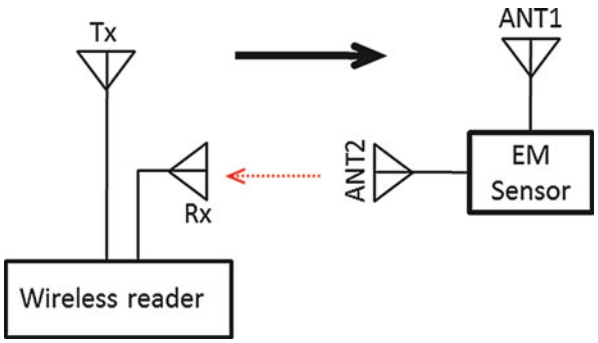

Fig. 17 Wireless interrogation of passive sensor based on orthogonal backscatter scheme

Gated TDR Based on FMCW Radar

The antenna backscattering and the structural backscattering can also be separated based on the principle of FMCW radar as long as the delay between these two backscatterings is sufficiently large (Jatlaoui et al. 2010). As shown in Fig. 16a, the interrogation signal is a chirp signal generated using an FMCW synthesizer. After being amplified by a power amplifier, the chirp signal is broadcasted to the wireless sensor. The time delay between the backscattered sensing signal and the structural backscattering is again introduced by connecting the EM pressure sensor to the antenna using a coaxial cable. Due to the time delay and the linearly varying interrogation frequency, the backscattered signals received by the wireless reader at a given time have different frequencies, as shown in Fig. 16b. A homodyne receiver can then be implemented at the wireless reader to separate the signals with different frequencies. Assuming the frequencies of the structural backscattering and the backscattered sensing signal are f_2 and f_3, respectively, mixing these signals with a reference signal f_1 produces two low-frequency signals $f_1 - f_2$ and $f_1 - f_3$. After

DOI 10.1007/978-981-4560-75-7_86-1

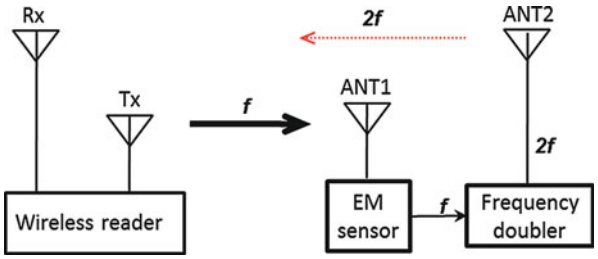

Fig. 18 Wireless interrogation of passive EM sensor based on harmonic radar

filtering the mixer output using a low-pass filter and acquiring the signals using an ADC, the spectrum of the acquired signal is calculated using FFT, based on which the power of the backscattered sensing signal can then be determined. Again, the resonant frequency of the EM pressure sensor is measured from the interrogation frequency-signal power relationship.

Passive Wireless Interrogation Based on Orthogonal Backscatter

The polarization of the antenna radiation pattern can also be exploited to address the self-jamming problem (Mandel et al. 2011; Kubina et al. 2012; Girbau et al. 2012). As shown in Fig. 17, the EM sensor is connected to two antennas with orthogonal polarizations. The interrogation signal is first broadcasted to the antenna sensor along one of the polarization directions. The received signal is input into the EM sensor. By transmitting the sensor output using the second antenna, a 90° difference in the polarizations of the backscattered sensing signal and the incident signal is created. The structural backscattering, on the other hand, will have the same polarization as the incident signal. Due to this polarization mismatch, the structural backscattering will be rejected by the receiving reader antenna. As a result, the signal received by the wireless reader is dominated by the backscattered sensing signal.

Passive Wireless Interrogation Based on Harmonic Radar

A harmonic radar tag receives the interrogation signal at one frequency and transmits the radar signal at twice that frequency (Charvat et al. 2003; Weller and Davidova 2013; Presas et al. 2007). Since the background clutter remains at the interrogation frequency, the radar receiver is able to discriminate the tag return from the clutter in the frequency domain. This principle can be extended for wireless interrogation of passive EM sensors. As shown in Fig. 18, the interrogation signal with a frequency *f* is first transmitted to the wireless sensor by the wireless reader. After interacting with the EM sensor, the sensing signal is input into a passive frequency doubler which outputs a signal having a frequency *2f*. This frequency doubled signal is then transmitted by the second antenna. As such, a wireless reader equipped with a band pass filter centered at *2f* will reject the background clutter and only receives the signal returned by the passive wireless sensor.

Comparisons of Wireless Interrogation Schemes

The comparisons of wireless interrogation schemes discussed above are given in Table 6. It is difficult to provide quantitative comparisons due to the large variations in the configurations, principle, and operating frequencies of the published wireless sensing systems. Therefore, the wireless interrogation schemes are compared in a relative term. Based on the same consideration, one of the important figures of merit, i.e., the distance between the wireless sensor and reader, was left out intentionally. In order to compare the interrogation distances of different wireless sensing systems, the wireless sensing systems should be tested at the same operational frequency and fabricated in a controlled manner, which cannot be achieved without a comprehensive comparison test.

Application Examples

RFID-Enabled Moisture Sensor

The configuration of a wireless moisture sensing system using a pair of regular RFID tags is shown in Fig. 19a (Sidén et al. 2007). The sensor label was implemented by placing two passive 865–868 MHz Gen-2 tags from Alien Technology Corp on a sheet of high-density polyethylene (HDPE). The center-to-center distance between the two tag antennas was 206 mm. Ten sheets of blotting paper, acting as water-absorbing material, were stacked and placed in front, behind, and both in front and behind one of the RFID tags. The other RFID tag was uncovered and served as the reference. An RFID reader from SAMsys was placed at a distance of 1.47 m from the sensor label with equal distances from the two RFID tags. Experiments were carried out in a climate room with temperature fixed at 23°C, and the relative humidity increased from 50% to 90%. The blotting paper samples were left in the climate room for 24 hours before taking measurements. The differences in the turn-on powers of the two RFID tags at different relative humidity levels are shown in Fig. 19b. Three sensor labels were tested; the first sensor label had two open tags, which severs as the baseline case; the second sensor label had an half-open tag, i.e., the tag only had the paper in front; a fully embedded tag, i.e., the tag had paper in front and behind it, was implemented in the third sensor label. It was found that the turn-on powers for both tags were about 16 dBm in an

environment with 50% relative humidity at 23°C. As the relative humidity increased, the power differences for the second and third sensor labels increased while the power differences for the first sensor label remained to be zero. The authors suggested the water-absorbing material should be as thick as possible. In addition, they also pointed out that the paper displayed some hysteresis behaviors, which can be a problem since the memory effects can lead to incorrect readings.

Dynamic Strain Sensor Based on Amplitude Modulation and FMCW Radar

The dynamic antenna strain sensing system presented is illustrated in Fig. 20a (Yao et al. 2014). The antenna sensor is a 5.4 GHz microstrip patch antenna fabricated on a high-frequency dielectric substrate (Rogers Corporation, RT/Duroid 5880). For a substrate dielectric constant of 2.2, the length and width of the radiation patch are 18.0 and 21.6 mm, respectively. The patch antenna was connected to a pseudomorphic high-electron-mobility transistor (pHEMT) with its drain terminal connected to a 50 Ω terminator. The gate termination of the pHEMT was connected to a low-power oscillator (Epson Electronics, SG-3040) that produces 32.78 kHz square waves. The oscillator output changes the gate voltage of the pHEMT between 0 and 1 V. As a result, the termination of the patch antenna is switched between an open and a 50 Ω load. A solar cell (Clare, CPC 1832) supplies the power to the oscillator when it is illuminated by a light-emitting diode (LED).

The wireless reader depicted in Fig. 14 was assembled using commercially available discrete components. For the FMCW synthesizer, the periodic sawtooth wave was generated using a signal generator (Agilent 33250A) and supplied to a VCO (Mini-circuits, ZX95-3100-S+) as the control voltage. The frequency of the VCO output was doubled using a frequency multiplier (Mini-circuits ZX90-36-S+) so that the frequency sweep range covers the antenna resonant frequency. The output of the frequency multiplier was amplified using a microwave amplifier (Mini-circuits ZVE-8G+) to reach a power of 25 dBm before it was transmitted to the interrogation antenna for broadcasting. The analog demodulator was implemented using an RF envelope detector board (Analog Devices, ADL5511) and a band pass filter (Krohn-Hite Model 3944) centered at 33 kHz. Since the output of the band pass filter has a low frequency

DOI 10.1007/978-981-4560-75-7_86-1

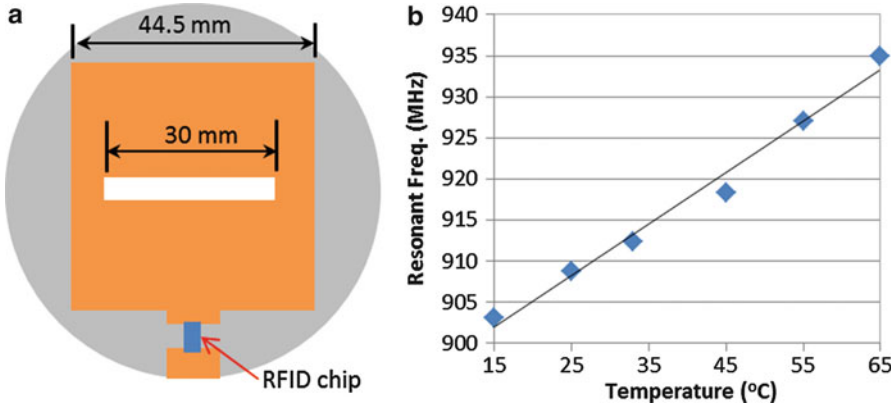

Fig. 21 RFID-enabled antenna temperature sensor (Adapted from Qiao et al. 2013); (**a**) sensor configuration; (**b**) temperature-antenna frequency relationship

of 32.78 kHz, this signal was directly acquired using an oscilloscope (LeCroy, Wavepro 760zi). The acquired signal was processed by a real-time data processing algorithm to extract the antenna resonant frequency.

Mechanical testing of the dynamic strain sensor is shown in Fig. 20b. The antenna sensor was bonded on a tensile specimen and loaded with an Instron mechanical tester. A 12 dBi horn antenna and a 134 lm LED light source (Luxeon Star, MR-H2070-20S) were placed at a distance of 0.9 m from the antenna sensor. The FMCW synthesizer was set to sweep the frequency from 5,325 to 5,430 MHz at a repetition rate of 500 Hz. The sampling rate of the oscilloscope was set to be 1 MHz. Static tensile test of the antenna sensor was first carried out to calibrate the strain sensitivity of the antenna strain sensor. As shown in Fig. 20c, the measured strain sensitivity was 0.661 ppm/με. While this value is about 68 % of the theoretical strain sensitivity, the antenna sensor displayed an excellent linearity. Therefore, a gain factor of 1/68 % = 1.47 was applied to the sensor measurements to account for this discrepancy. The dynamic testing results of the antenna strain sensor are shown in Fig. 20d. The applied load was varied at a frequency of 2 Hz. It was discovered that the measurement results track the theoretical strains very well. Therefore, the performance of the dynamic wireless interrogation system is validated.

RFID-Enabled Temperature Sensor

An RFID-enabled temperature sensor was demonstrated using a 900 MHz patch antenna with an HDPE-BST substrate (Qiao et al. 2013). As shown in Fig. 21a, the 44.5 mm long radiation patch has a 30 mm long and 4 mm wide slot at its center. The slot was introduced to reduce the size of the radiation patch. The radiation patch is fed with a 10 mm wide microstrip transmission line, which was terminated with an Alien Higgs 3 RFID chip. The RFID chip was grounded using another microstrip transmission line. The HDPE-BST substrate material was custom synthesized through extrusion process. The dielectric constant and tangent loss of the HDPE-BST material at different temperatures were characterized at 900 MHz using an Agilent E4991A RF impedance analyzer. It was found that the dielectric constant of the HDPE-BST material decreased from 7.10 to 6.66 while the tangent loss increased from 0.0022 to 0.0034 as the temperature increased from 20 °C to 80 °C. The temperature coefficient of the dielectric constant was therefore estimated to be −1,033 ppm/°C, which is much higher than conventional substrate materials. Wireless measurements of the antenna resonant frequency were carried out in an anechoic chamber. The wireless reader, a Tagformance device, was placed at a distance of 0.5 m from the antenna sensor. The turn-on power of the RFID chip was measured at frequencies ranging from 880 to 960 MHz at different temperature settings. The maximum read range of the RFID sensor was calculated from the measured turn-on powers as

DOI 10.1007/978-981-4560-75-7_86-1

$$d_{\max} = \frac{\lambda}{4\pi}\sqrt{\frac{\mathrm{EIRP}}{P_{\text{turn-on}}}}, \tag{26}$$

where the equivalent isotropic radiated power (EIRP) of the RFID reader was 3.28 W. The resonant frequency shifts of the antenna sensor at different temperatures can then be measured from the frequency-read range plots. As shown in Fig. 21b, the antenna resonant frequency displayed a relatively linear performance for temperatures ranging from 15 °C to 65 °C. The temperature sensitivity of the antenna sensor was estimated to be 800 kHz/°C.

Antenna Crack Sensor Array Based on Frequency Division Multiplexing

The design of the antenna crack sensors is a trade-off between the crack sensitivity and the sensor coverage area (Xu and Huang 2012b). In general, a high-frequency antenna is more sensitive to minute crack growth. On the other hand, the sensor coverage of the antenna crack sensor is confined within the physical dimensions of the radiation patch. Since the resonant frequencies of an antenna sensor are inversely proportional to the size of the radiation patch, a high-frequency antenna sensor offers high crack sensitive but small coverage area. One solution to resolve this dilemma is to use antenna arrays based on the principle of frequency division multiplexing (Xu and Huang 2012b) or RFID code division multiplexing (Yi et al. 2013). A picture of the frequency division multiplexed antenna array is shown in Fig. 22a. The four-element antenna array consists of two pair of patch antennas. Each pair has two antennas of different sizes; the large one operates at 8.4 GHz and the smaller one operates at 12 GHz. Since each antenna resonance occupies a narrow bandwidth, this frequency division multiplexing scheme enables the interrogation of these two antennas with one frequency scan. Each pair is connected to an

DOI 10.1007/978-981-4560-75-7_86-1

impedance switch powered by a solar cell, as shown in the Fig. 22a. Similar to the dynamic antenna strain sensor, the impedance switch was implemented using a pHEMT, a 560 kΩ resistor, and a photocell. The antenna pattern was fabricated from a thin copper film using laser machining and bonded on a Kapton film, which in turn was glued on the aluminum alloy specimen that also serves as the ground plane for the antenna sensors. The fatigue testing of the specimen instrumented with the antenna sensor array is shown in Fig. 22b. A horn antenna and a flashlight were placed at a distance of 0.84 m from the antenna sensors. The S_{11} parameters of the horn antenna were acquired at two states, i.e., when the light was turned on and when it was turned off. The acquired S_{11} parameters were then processed following the procedure described in Fig. 13b to extract the resonant frequencies of the antenna sensors. The specimen was fabricated with two slots for crack initiation, which propagate toward each other under fatigue loading. After the cracks reached the two large antenna sensors, the crack growth was detected from the shift of the resonant frequency at around 8.4 GHz. The reader was able to wirelessly measure the resonant frequencies of the large antenna sensors until the crack reached the last 1 mm of their radiation patches. It took 5,000 more cycles for the crack to reach the small antenna sensors; after which the crack growth was detected from the shift of the resonance at around 12 GHz. The small antenna sensors remained functional until the specimen fractured after 190,000 fatigue cycles. The normalized resonant frequency shifts for both the small and large antenna sensors are shown in Fig. 22c, d. As expected, the small antennas displayed higher crack sensitivities than the large antennas. In addition, the results indicated that the fabrication of the antenna sensors can be controlled to achieve repeatable performances.

Future Directions and Open Problems

Passive wireless antenna sensors that consume substantially less power than active wireless sensors and can be interrogated from middle range distances are promising technologies that could have profound impacts on our drive toward ubiquitous sensing. Unlike active wireless sensors, passive wireless antenna sensors are still in its infancy. Even though the fundamental operating principles have been validated and a variety of practical applications have been demonstrated, more fundamental research and development works are needed to realize the full potentials of these passive wireless sensors. Listed below are a few open problems that need further investigations and development.

Sensor miniaturization: a passive wireless antenna sensor consists of only two components, i.e., the antenna and the modulator. The size of the antenna can be easily reduced by increasing its operation frequency. For example, the strain sensor demonstrated by Tata et al. (2009) is only 5.3 mm long and 4 mm wide, which is comparable with the size of a conventional foil strain gauge. However, the modulator has to be implemented using discrete electronic components, which increases the sensor size as well as the cost. Using RFID chips is an attractive option since all the electronic components are integrated into one IC chip. Unfortunately, most commercially available RFID chips operate at around 900 MHz, which dictates the size of the antenna. Despite different approaches to reduce the antenna size at this frequency, the resulting antennas are still too large for most real-life sensor applications. Hopefully, the maturity of the passive wireless antenna sensors will motivate the IC industry to develop RFID chips tailored for the needs of the antenna sensors, especially at high frequencies and with fast interrogation speeds.

Multimodality sensing and data processing: an antenna sensor can be sensitive to multiple physical measurands simultaneously, including strain, temperature, humidity, pressure, etc. This characteristic can be a double-edged sword. On one hand, a single antenna sensor can be used to measure multiple variables. On the other hand, the coupling of different effects can make interpreting the measurement results extremely difficult. Therefore, it is desirable to develop data analysis techniques that can decouple these effects and extract the physical measurands individually. This cannot be achieved using one sensing

DOI 10.1007/978-981-4560-75-7_86-1

parameter, such as the resonant frequency shift. Additional sensing parameters, e.g., the resonant bandwidth, may be exploited for this purpose. Ideally, system identification algorithms can be developed to identify the physical measurands that match the simulated antenna radiation curves with the measurements. This approach, however, requires the development of flexible and efficient antenna simulation models that are currently not available.

Sensor identification and multiplexing: to realize the full benefits of passive wireless antenna sensors, the wireless antenna sensors need to be arranged in a distributed sensor network with a centralized wireless reader communicating with each individual sensor. This arrangement mandates the development of sensor identification and multiplexing strategy. A frequency and spatial division multiplexing scheme was developed and selective interrogation of four antenna sensors was demonstrated (Xu and Huang 2012b). However, the number of sensors that can be interrogated is limited by the allocated frequency bandwidth. Other sensor multiplexing techniques are needed in order to interrogate tens or hundreds of wireless antenna sensors. The RFID-enabled antenna sensors may hold the key to resolve this challenge, but again the size of the RFID antenna has to be reduced to make this option feasible.

Antenna Systems for Cellular Base Stations

Roland Gabriel[a] and Matthias Geissler[b]
[a]Kathrein Werke KG, Rosenheim, Germany
[b]IMST GmbH, Kamp-Lintfort, Germany

Abstract

Base station antenna systems have undergone a dramatic development within the last decades: in the early days of cellular communications, the cells where more or less of similar size and circular shape, having a base station in the center. This base station typically was equipped with a passive omnidirectional antenna illuminating the whole cell. Since then, the cell topology has become more and more diverse, using different cell sizes and also cell sectorization of higher orders. Moreover, the increasing demand on dynamic control and adaptation of the cell size and of the cell capacity results in complex requirements for both the antenna structure and the transceiver system. Therefore, it makes sense to consider the base station antenna system as a whole, comprising the antenna radiators, the transceiver system, and the data preprocessing.

This system design approach is the basic idea of this chapter: it starts with basic antenna considerations, then different system topologies are described including their functionality and their development over the years, and finally, an outlook into future challenges and design aspects is given.

Base station antenna; Cellular network; Sector antennas; Mobile communication; Antenna array; Beamforming; Adaptive antennas; Smart antennas; Remote radio heads; Downtilt

Introduction

The antenna is part of a transmitting and receiving system; thus, the properties of this element have to be designed and analyzed together with the other elements of the system. Consequently, the design of the receivers and transmitters and furthermore the signal processing have a big influence on the requirements of the antennas. As an example, the correlation of signals of different antennas will result in a beamforming operation – in the sense of a superposition of antennas – if both signals will be combined using a defined phase relation. Instead, if the same antennas will operate in a MIMO mode (MIMO = multiple input, multiple output), the resulting patterns of the superposition of both signal streams will be different and will depend on the channel properties.

Active antenna systems have significant advantages like reduced noise figures for the receiving (Rx) path and lower losses of the transmission (Tx) path. Beside these advantages, the separate steering of different columns or radiators offers extended possibilities of user- or channel-defined beamsteering and multi-MIMO operation. The decision about the operation mode depends however on the supported standards and the available signal-to-noise ratio (S/N ratio) at the mobile and/or the base station. For two-dimensional antenna arrays, the question arises, which dimension of steering (horizontal, vertical) offers the higher gain in the network. Field trials sometimes deliver remarkably different answers to this

DOI 10.1007/978-981-4560-75-7_88-1

question and moreover are not comparable with each other because of different operation modes and scenarios.

The main challenges for the hardware realization of active antenna systems are reliability, cost, and efficiency: due to the high number of electronic modules, the lifetime decreases 4–10 times compared to an equivalent remote radio head (RRH). Innovative solutions are required to overcome this disadvantage in the future. A higher integration level of the electronic components in IC's is maybe the only way towards high reliability. The overall efficiency is also lowered by the separation of the duplex filters and by the medium-power level amplifiers. The best compromise between size and costs on one hand and attenuation and linearity on the other hand needs to be found. Nevertheless, a disadvantage of current system designs is still the limitation to only one operating frequency band, whereas today's technology of passive antennas offers up to five different bands within one antenna.

Cellular networks use distributed terrestrial base stations to serve the different mobile users. The antenna characteristics determine the coverage of the base station and the statistics of the propagation channel. One of the major requirements of a mobile communication network is the knowledge of the availability and the location of any defined user. The second challenge is – different from the broadcast service – the bidirectional traffic. Thus, powerful and flexible technologies have to be defined to coordinate the transmitting and receiving path.

The downlink and uplink coordination is realized using different duplex technologies like time division duplex (TDD) or frequency division duplex (FDD). Also, the combination of different access technologies is possible. Depending on the technology used for the channel separation, one talks about time division multiple access (TDMA), frequency division multiple access (FDMA), code division multiple access (CDMA), or space division multiple access (SDMA).

Historical Review

The localization of the mobiles today is organized in the home location register (HLR); this makes sure that any mobile can automatically be "found" within the network. At the beginning of the mobile communication system, the localization of the users was a big issue: instead of automatic detection, the mobile user had to give a call to announce his current cell location (see A-network, B-network in Germany, 1954–1970, MJ, MK-network USA). The HLR was already introduced in the C-network in Germany as well as in the NMT 450 in the Scandinavian countries. Figure 1 illustrates the technological milestones in the evolution of the mobile communication standards.

First cellular networks typically use omnidirectional antennas. The oldest technology used to achieve transmitting and receiving coordination was the time division duplexing. Thus, the receiver and transmitter use the same frequency channel, but they communicate during different time slots. At the very beginning of mobile communication, this coordination was done manually: first come, first serve or "push to talk." The collisions had to be solved manually by a certain priority logic. Today's TDD networks employ synchronized time slots in the millisecond range; thus, one will hardly recognize any difference to a parallel transmission.

Concerning the antenna design, the TDD system requirements with respect to passive intermodulation (PIM) are very relaxed, as no parallel transmitting and receiving signals exist within the same time slot. Examples of the TDD systems are the TD-SCDMA or TD-LTE system. TD-SCDMA means time duplexing synchronous code division multiplexing network. In this network the switching point between transmission and reception is synchronized over the whole network.

Base station technology finds itself in a continuous evolution process. In Fig. 2, typical key technological milestones are shown. It reveals that in the last 20 years there has been a clear tendency towards the

DOI 10.1007/978-981-4560-75-7_88-1

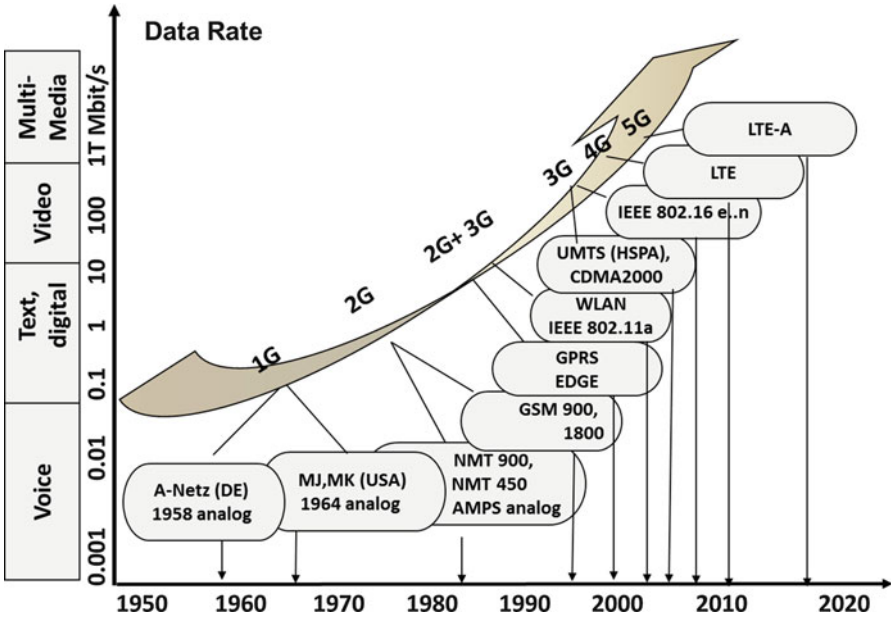

Fig. 1 Historical development of mobile communication systems

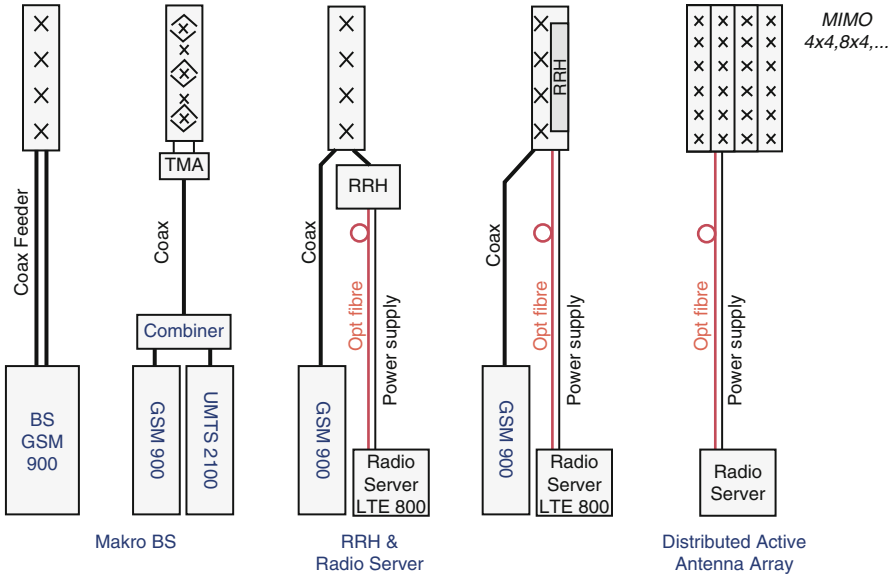

Fig. 2 Technology evolution of base station antenna systems

integration of electronic components into antennas. The first active components near to an antenna were "tower-mounted amplifiers" (TMAs) which amplified the receiving signals of the antenna and bypassed the transmitting signals by means of low-loss filter structures. The acceptance of such electronics near to the antennas is driven by higher reliability figures for the electronic components. In the meantime, the MTBF (mean time between failure) could be increased to values between 100,000 and 500,000 h. The same acceptance problem has prevented for a long time the use of remote radios near to antennas, comprising the receiving as well as the transmitting parts. Nevertheless, today's reliability is high enough,

DOI 10.1007/978-981-4560-75-7_88-1

and the advantage of power saving has forced the breakthrough of the use of RRHs beside the use of TMAs in the fields.

Antenna Design for Base Stations

Background and Definitions

Base stations are used in many different communication standards and can be installed by public authorities, network providers, companies, or private persons. When talking about base stations, two principal types of network philosophies have to be distinguished:

- **Cellular networks** typically use frequency bands which are licensed by a network provider. They consist of several base station antennas serving a network of neighboring cells. The size and shape of the cells, the capacity, and the frequency reuse are coordinated within the whole network. The installation and the service of these networks happen typically under the control of the network provider owning the license.
- **Wireless hot spots** typically use license-free frequency bands; they can be installed by companies, authorities, or private persons to supply a home, an office, or a building area. These base stations are generally not coordinated with other systems in the vicinity in terms of coverage and cell size, nevertheless, in the actual systems the frequency channel allocation is coordinated by means of self organizing features. Therefore, a network provider is not necessarily involved in the installation and the use of this type of base station.

Both types can be used in combination, e.g., a wireless LAN cell within a train wagon, whereas the train itself is connected via GSM to the cellular network. However, both types have to be carefully distinguished when talking about network architecture and corresponding antenna requirements. The main focus of this chapter is on cellular networks; however, the wireless hot spot technology is also described.

Important Communication Standards

Today's wireless and cellular communication use different digital communication standards in several frequency bands, some important are given in Table 1.

UMTS, LTE, and WLAN/WIFI comprise higher frequency bands. Some of the higher bands offer large bandwidth, so they have the potential of a strong increase in capacity. The technical system realization in these higher bands is however much more complex; therefore, they are currently rarely used (see also section "Antenna Related Network Aspects" in this chapter). The allocation of additional frequency bands for cellular applications in the range of 500–800 MHz from the broadcast services as well as in the higher frequency bands are in discussion. The allocations will be decided by the World Radio Conference (WRC).

Cell Topology of the Network

The **mobile communication network is structured** using cells. Each cell is equipped with at least one antenna transceiver system in a fixed mounted installation. The antenna transceiver system can serve the mobile users within the cell by the use of a certain number of channels dedicated to this cell. The effective border of a specific cell is defined by the resulting strength of the signal, the signal-to-noise-and-interference ratio (SNIR), respectively, received by a mobile on the border line of the cell. The mobile phone handover to a neighboring cell is controlled by this received power level: if the received power level of the neighboring cell is higher, the mobile phone switches to that cell.

DOI 10.1007/978-981-4560-75-7_88-1

Table 1 Important communication standards

Comm. standard	Frequency band	Application	Regions
NMT 450/GSM 450	450–470 MHz	Cellular	Scandinavia/Europe
D-AMPS	824–894 MHz	Cellular	North America
GSM	880–960 MHz 1710–1880 MHz 1850–1990 MHz	Cellular	Worldwide
DECT	1880–1920 MHz	Wireless (cordless phones)	Europe, USA, Canada, Japan
UMTS/IMT-2000	824–894 MHz 1710 MHz–2170 MHz Higher bands	Cellular	Worldwide
LTE	700 MHz–960 MHz 1710 MHz–2170 MHz 2500 MHz–2690 Mhz Higher bands	Cellular	Worldwide
Bluetooth	2400 MHz–2480 MHz	Wireless	Worldwide
WLAN/WIFI	2400–2500 MHz 5725–5875 MHz Higher bands	Wireless	Worldwide

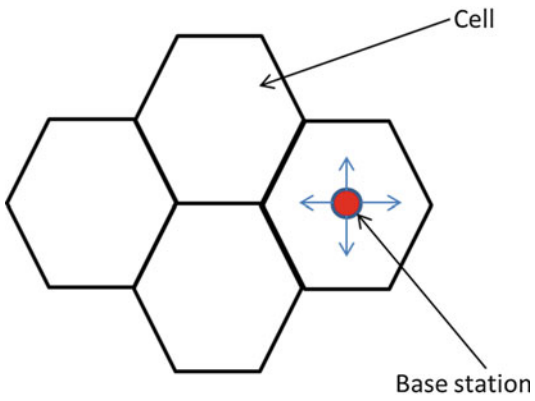

Fig. 3 Cell topology of the mobile communication network

Thus, from the antenna system perspective, the cell border can be defined by controlling the radiated power of the base station and by shaping the radiation pattern of the base station antenna.

In Fig. 3, the cells are displayed as neighboring hexagons, which is an appropriate model for an ideal cell topology, having well-defined borderlines and avoiding any overlapping of cells as well as any coverage gaps between cells. The base station is located at the center of the cell, illuminating the cell by using an omnidirectional antenna.

In order to maximize the capacity as well as the coverage of the mobile communication network, several cells can use the same subset of channels for transmission. In FDMA systems, the different channels are divided by frequency. So a certain subset of frequencies is dedicated to one cell. In order to avoid co-channel interference, these frequencies must not be used in adjacent cells, but they can be used in cells farther apart from each other. So a channel reuse scheme is implemented to make sure that the reuse of the channels happens always with an adequate spatial gap in between.

DOI 10.1007/978-981-4560-75-7_88-1

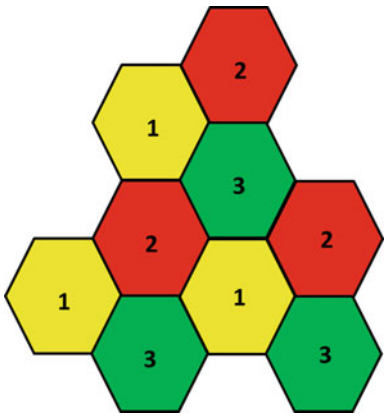

Fig. 4 Example for a frequency reuse scheme in a cellular network

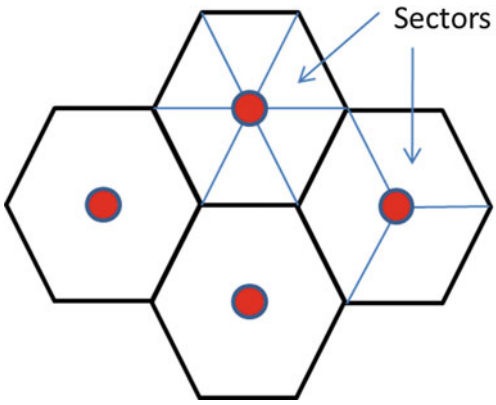

Fig. 5 Cell sectorization for increased capacity

Figure 4 shows the principal: the different cells use different frequency channel subsets 1, 2, and 3. As a result, two cells using the same channel subset always have a minimum distance in between. The reuse factor for a certain channel subset can be described by the value $1/K$, where K is the number of different channel subsets in the network. Typical reuse factors are 1/3, 1/4, 1/7, or 1/12.

In practical implementation, the so-called reuse distance is of importance: this term describes the minimum distance between the borders of two cells using the same frequencies. The propagation loss is typically proportional to the distance. The reuse distance therefore ensures that the signal level of the first cell has fallen down to an acceptable level of interference in the second cell, so that the reuse of the frequencies is possible (Collins 2009).

If the total available bandwidth is B, each cell can only use a number of frequency channels corresponding to a bandwidth of B/K.

In order to increase the capacity, existing cells can be subdivided into sectors. Figure 5 shows an example for sectorization: the cell at the right is subdivided into three sectors, and the cell at the top is subdivided into six sectors. Each of the sectors is treated as a separate cell, having its own subset of frequencies and its own antenna system. If the cell has three sectors, the resulting azimuthal coverage of each base station antenna is 120°, by division into six sectors; the resulting azimuthal coverage is only 60° (Derneryd and Johansson 2009).

Another possibility of adapting the capacity of the network is the use of different cell sizes: if the cell diameter is very large, one can cover a large area with a minimum of antennas. However, this also limits

DOI 10.1007/978-981-4560-75-7_88-1

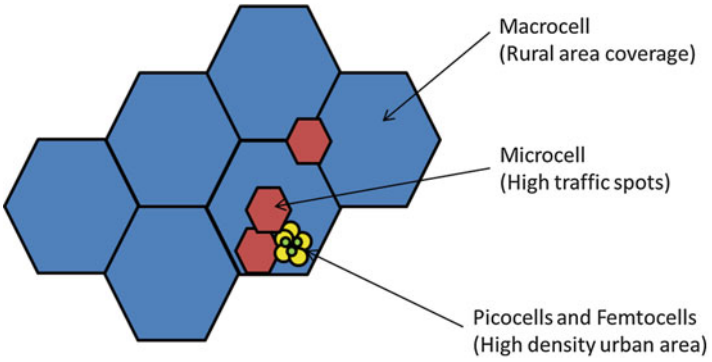

Fig. 6 Cell topology of the mobile communication network (dimensions not to scale)

the capacity, as the number of users in the cell is limited to the number of channels dedicated to this cell. In order to increase the capacity within a specific area, one can subdivide this area into smaller cells, each of them having its own dedicated bandwidth. The following classification related to the cell size has been established:

- **Macrocells** cover mainly rural areas. Their diameter can be up to 30 km or more, depending on the frequency and on the valid power regulation limits.
- **Microcells** have a typical diameter of about 200 m and typically serve hot spot areas like railway stations or inner city spots.
- **Picocells** and **femtocells** can be very small, e.g., in the order of 10–20 m. They are used to cover very small high-density areas like exhibition halls or hotel areas; even the coverage of single meeting rooms is possible (Fig. 6).

Both mechanisms of the adaptation of the cell size and the advanced sectorization can be combined adequately, so that the optimum constellation of coverage versus capacity can be obtained for a certain region.

Antenna Parameters and Definitions

Each cell needs to be illuminated in an appropriate way by the dedicated antenna system. This can be done through shaping the antenna pattern and through the control of the radiated power level. Important antenna parameters are listed in the following section. As basis for the description of the three-dimensional antenna radiation in far field, the following coordinate system shall be used (Linehan and Gianola 2011):

In the coordinate system of Fig. 7, the antenna is located in the origin, and the antenna dimensions are small versus the radius r of the far-field sphere. The x-y plane represents the horizontal plane – parallel to the ground. The horizontal plane is also called the azimuth plane, and the ϕ angle is called the azimuth angle. The z-axis is the vertical axis perpendicular to the ground, the x-z plane and the y-z planes are called the elevation planes, and the θ angle is called the elevation angle.

Power Density

Relevant for the effective range of the antenna pattern is the resulting strength of the transmitted signal at the designated borderline of the cell: the higher the output power, the larger the range. Looking at the antenna far field, where only transversal components of E and H exist and assuming harmonic oscillation, one can describe the power density in the far field as follows:

DOI 10.1007/978-981-4560-75-7_88-1

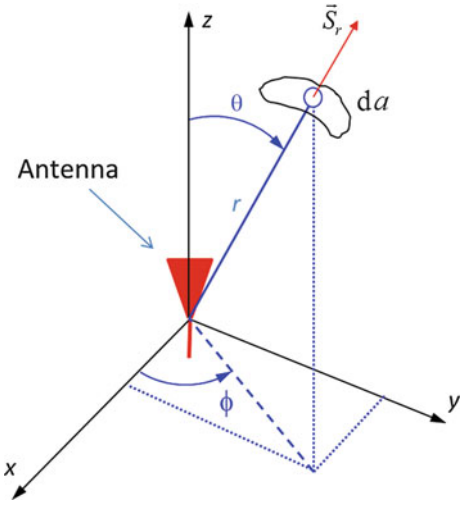

Fig. 7 Coordinate system for the far-field pattern description of an antenna

$$\underline{S} = \underline{S}_r = \frac{1}{2}\left(\underline{E}_\vartheta \underline{H}_\varphi^* - \underline{E}_\varphi \underline{H}_\vartheta^*\right)$$

By integrating the power density over the far-field sphere, one obtains the total radiated power P_{rad} of the antenna:

$$P_{rad} = \int_A S_r df = r^2 \int_{\varphi=0}^{2\pi} \int_{\vartheta=0}^{\pi} S_r \sin\vartheta d\vartheta d\varphi$$

The typical reference antenna is the isotropic radiator for which the power density can be described as follows:

$$S_r = S_i = \frac{P_{rad}}{4\pi r^2} = const_r$$

For a specific antenna device, the power density and the antenna gain are referred to the values of the isotropic radiator.

Far-Field Radiation Pattern

Relevant for the shape of the antenna beam is the antenna pattern, which thus defines the initial shape of the cell or sector that is illuminated. The normalized far-field pattern C of an antenna is defined as follows:

$$C(\varphi,\vartheta) = \left.\frac{\left|\vec{E}\,(\varphi,\vartheta)\right|}{\left|\vec{E}\,(\varphi,\vartheta)\right|_{\max}}\right|_{r=const.,\, r\to\infty} = \left.\frac{\left|\vec{H}\,(\varphi,\vartheta)\right|}{\left|\vec{H}\,(\varphi,\vartheta)\right|_{\max}}\right|_{r=const.,\, r\to\infty}, \text{ with } 0 \le C \le 1$$

Half-Power Beamwidth (HPBW)

The half-power beamwidth (HPBW) describes the angular width of the main beam area, where the power density reduction is 3 dB or less. Please note that for a given sectorial angle (e.g., 120°), the HPBW of the

DOI 10.1007/978-981-4560-75-7_88-1

antenna to be chosen is typically smaller (e.g., 65°) in order to minimize the interference towards the neighboring cells.

Antenna Directivity and Antenna Gain

The antenna directivity is defined as the factor between the power density in the main beam direction versus the power density of the isotropic radiator:

$$D = \frac{S_{r,\max}}{S_i} = 4\pi r^2 \frac{S_{r,\max}}{P_{rad}}$$

The antenna gain G is defined as follows:

$$G = \eta D = 4\pi r^2 \frac{S_{r,\max}}{P_{in}}$$

where D is the directivity and η is the total antenna efficiency of the antenna. The antenna gain is typically given in dBi, whereat the index i indicates the reference to the isotropic radiator ($G = 0$ dBi). Accordingly, the antenna gain can also be calculated by integrating the radiation pattern over the far-field sphere. The following relation is valid:

$$G = \eta D = \eta \frac{4\pi}{\int_{\varphi=0}^{2\pi} \int_{\vartheta=0}^{\pi} C^2(\vartheta, \varphi) \sin\vartheta d\vartheta d\varphi}$$

EIRP

The EIRP is the so-called Effective Isotropic Radiated Power of an antenna. This is a very useful parameter, as it turns the normalized parameter G into an absolute power level. The definition is

$$EIRP = G \cdot P_{in}$$

The EIRP is typically given in dBm or dBW.

Effective Aperture Size

The effective aperture size A_{eff} is a measure for the amount of power that an antenna can extract from a plane wave field. The received power P_R at the antenna depends on the A_{eff} and on the power density S of the incoming field as follows:

$$P_R = A_{eff} S$$

The effective aperture size can be put in the following relation to the gain of the same antenna:

$$A_{eff} = \frac{{\lambda_0}^2}{4\pi} G$$

This relation is generally valid.

DOI 10.1007/978-981-4560-75-7_88-1

Downtilt Angle

Another important parameter for base station antennas is the downtilt angle. In order to illuminate the cell adequately from an antenna mounted on a high tower, the antenna pattern is tilted slightly downwards. The tilt helps to avoid interference with neighboring cells, and it saves transmission power.

The downtilt-angle α is defined as the angle between the horizontal plane and the tilted main beam direction of the antenna. Typical downtilt-angle values are between 2° and 10°. One has to distinguish between "mechanical tilt," realized by a tilted mounting position of the antenna on the mast, and "electrical tilt," realized by an electrical phase shift within a vertically mounted antenna array. Both techniques can be used for a sector antenna; however, the resulting pattern is not identical, as the implementation of a phase shift effectively changes the antenna properties (Collins 2009).

Mechanical and electrical tilt can also be combined within one antenna; moreover, the electrical tilt can be dynamically modified by using remotely controlled phase shifters. Today's phase shifters for implementing electrical tilt are typically realized as electrical delay lines, where the delay can be varied by moving a slider along a set of bended lines (see also section "Antenna Line Devices").

Polarization

Polarization is the orientation of the oscillating field vector of an electromagnetic wave. In far field, the E-field vector is orthogonal to the propagation direction. In most cases of cellular communication, linear polarization is used, that means that the E-field vector is not rotating around the propagation axis. Depending on the field vector's orientation versus the ground, one talks about "vertical polarization" or "horizontal polarization" or "slanted polarization."

Cross-Polarization Ratio

As most of the base station antennas are dual-polarized antennas, there are defined two orthogonal polarizations with two separate antenna inputs. The cross-polarization ratio or cross-polar discrimination defines the ratio of the desired part of polarization to the part of orthogonal polarization in a defined polarization system (e.g., ±45° or horizontal–vertical). This ratio typically is dependent on the direction and can be visualized in a copular and cross-polar pattern. The cross-polar ratio determines the maximum diversity gain in a polarization diversity system; therefore, typically a minimum value of 10 dB is required within the sector of ±60° (see Linehan and Gianola (2011)).

Cross-Polar Isolation

The cross-polar isolation is the measured isolation between the inputs of a dual-polarized antenna and includes the parasitic coupling between the radiators. Values of more than 30 dB are typically required.

Tracking

The port-to-port tracking or port-to-port tracking error describes the gain difference at a given azimuth angle, typically in the ±60° sector, for both ports of the orthogonal polarizations. This is caused by asymmetries of the radiator systems and can be tilt dependent (see also Linehan and Gianola (2011) for more details).

Azimuthal Beam Squint

The azimuthal beam squint determines the difference between the main beam direction derived from the middle between the −3 dB points of the beam and the mechanical bore-side direction of the antenna.

DOI 10.1007/978-981-4560-75-7_88-1

Null Fill and Sidelobe Suppression

Null filling is a measure to avoid coverage gaps and describes the minimum level in the first null below the main beam. The upper sidelobe suppression determines the maximum level of the first or also the second sidelobe above the horizon, typically in a range of $0 \ldots + 20^\circ$.

Front-to-Back Ratio

The front-to-back ratio is important for the interference situation in the rear direction of the antenna. The value is specified exactly in the rear direction or within a given range of angle, typically $\pm 30^\circ$.

Pattern Design Strategy

Based on the preconditions mentioned above, three key aspects have to be fulfilled in order to adapt the antenna pattern optimally to the dedicated cell or sector area: the radiated power, the vertical radiation characteristics, and the horizontal radiation characteristics.

Adaptation and Control of the Radiated Power

By adapting the radiated power of the base station, the effective range can be controlled. This corresponds to the effective radius of the cell or sector.

Based on the known antenna gains G_t of the transmitter and G_r of the receiver and on the distance R between the base station and mobile device, one can calculate the received power at the mobile device using the Friis formula to

$$P_{R,\,mobile} = \left(\frac{\lambda_0}{4\pi R}\right)^2 G_T G_R P_{T,\,basestation}$$

where λ_0 is the wavelength. However, this formula is only valid in ideal scenarios, where both antennas of the base station and of the mobile are pointed perfectly towards each other in line-of-sight (LOS) conditions. In practical cases, the effective field strength within the cell depends on the topology of the area and on the superposition of the reflected signals. Moreover, this formula refers to a free space scenario; it does not take into account the presence of the ground. The reflected ray from the ground interferes with the direct ray from the base station at any point within the cell.

A modified version of this formula using the empirical factor γ can be seen as a more realistic prediction of the received power at the mobile (Beckman and Lindmark 2007):

$$P_{R,\,mobile} = \left(\frac{\lambda_0}{4\pi}\right)^2 \left(\frac{1}{R}\right)^{\gamma} G_T G_R P_{T,\,basestation}$$

The factor γ is found to be in a range between two and five depending on the propagation environment: $\gamma = 2$ is used for very open rural areas, whereas $\gamma = 5$ represents high-density urban areas. So by controlling the radiated power of the base station antennas of neighboring cells, the effective size of the cells can be adapted.

Optimization of the Horizontal Pattern

The horizontal pattern of the antenna defines the adequate illumination of the dedicated sector. The ideal goal would be that the HPBW of the antenna pattern covers the sector with almost constant SNIR at any point of the sector border (which is equal to the minimum acceptable SNIR in this case), avoiding any overlapping with the neighboring sectors.

DOI 10.1007/978-981-4560-75-7_88-1

This theoretical constellation can typically not be realized in practice. However, from practical implementations of 3-sector cells, it turned out that an HPBW of 90° for more rural environments and 65° for high-density urban environments deliver acceptable results in terms of coverage and interference.

Optimization of Vertical Pattern

The optimization of the vertical pattern is important to "guide" most of the radiated power into the cell and to avoid waste of power in unwanted directions. If the base station antenna is mounted at a height similar to the typical height of the user terminals in this cell, the power should be concentrated in the horizontal plane to reduce radiation into the ground or into space. If however the antenna is mounted on a high-elevation position, the additional implementation of a downtilt is necessary, so that the beam is directed downwards into the cell. Moreover, within the illuminated sector, the power density should be as homogeneous as possible, avoiding local maxima or minima.

In order to optimize the vertical pattern, antenna arrays are very often used. The basic principle of antenna arrays is the linear superposition of the single-element radiation based on the relation

$$\underline{E}_{\vartheta} = \underline{F}_{E}\underline{F}_{Ar}$$

where $\underline{E}_{\theta}$ is the resulting electrical field at any point in the far field, $\underline{F}_{e}$ is the element factor, and $\underline{F}_{Ar}$ is the array factor. The element factor describes the spherical geometry of the element radiation as a complex function. The array factor for an arbitrary constellation of antennas of the same type, located in different positions r_n' and radiating with different amplitudes I_0 as well as with different phases δ_n, can be described as follows:

$$\underline{F}_{Ar}(\vartheta,\varphi) = \sum_{n=1}^{N}\left[I_0^{(n)} e^{j\delta_n} e^{jk_0\left(x_n'\sin\vartheta\cos\varphi + y_n'\sin\vartheta\sin\varphi + z_n'\cos\vartheta\right)}\right]$$

Assuming a linear constellation of N elements positioned along one axis having a defined inter-element distance d and a constant inter-element phase shift δ, the array factor can be described as follows:

For x-axis constellations:

$$\underline{F}_{Ar}^{x-axis}(\vartheta,\varphi) = \sum_{n=0}^{N-1} I_0^{(n)} e^{\delta n} e^{jk_0 nd\sin\vartheta\cos\varphi}$$

For y-axis constellations:

$$\underline{F}_{Ar}^{y-axis}(\vartheta,\varphi) = \sum_{n=0}^{N-1} I_0^{(n)} e^{\delta n} e^{jk_0 nd\sin\vartheta\sin\varphi}$$

For z-axis constellations:

$$\underline{F}_{Ar}^{z-axis}(\vartheta,\varphi) = \sum_{n=0}^{N-1} I_0^{(n)} e^{\delta n} e^{jk_0 nd\cos\vartheta}$$

In the case of isotropic radiators, the maximum directivity can be reached with uniform amplitude taper and broadside radiation. The directivity is

DOI 10.1007/978-981-4560-75-7_88-1

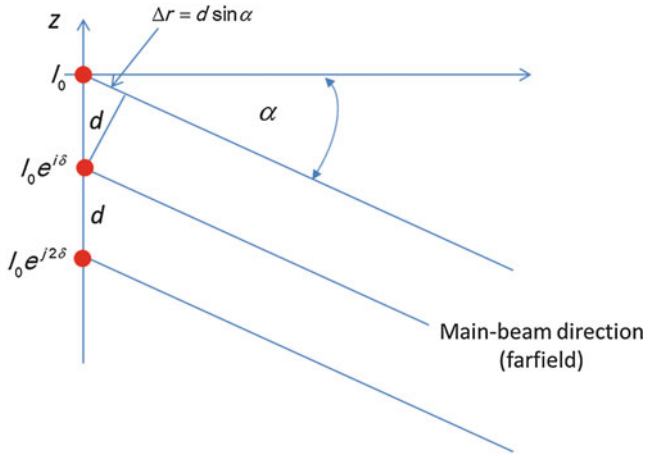

Fig. 8 Beam downtilt realization by introducing a phase shift

$$D(\delta = 0) \approx 2N \frac{d}{\lambda_0}$$

By introducing a phase shift δ, the pattern of the linear array can be tilted (Fig. 8).

Considering the precondition for the main beam direction of

$$\delta - k_0 d \sin \alpha = 0$$

The relation between the tilt angle α and the inter-element phase shift δ is

$$\alpha = \arcsin \frac{\delta}{k_0 d}$$

Besides of the variation of the phase, the amplitude can also differ from element to element. This amplitude taper can be described as discrete values $I_0(n)$, but also as a continuous distribution function $J_F(y)$. Based on the tapering function, the Fourier transform represents the relation between the amplitude distribution and the far-field pattern of the antenna.

$$\underline{J}_F(y) \circ\!\!-\!\!\bullet\, \underline{F}_{Gr}(u)$$

This means that based on the Fourier transform, the antenna pattern can be calculated out of the amplitude distribution and vice versa:

$$\underline{F}_{Gr}(\vartheta, \varphi) = \int_{-\infty}^{\infty} \underline{J}_F(y) e^{juy} \text{ using } u = k_y = k_0 \sin \vartheta \sin \varphi$$

This relation can be used very effectively for the synthesis of a desired pattern shape. The realization of a sector beam, for example, can be done using the Fourier relation of the pedestrian function, which is the sin x/x-function. So the amplitude tapering function in this case goes with

$$J_F(y) = I_0 \sin py / py$$

DOI 10.1007/978-981-4560-75-7_88-1

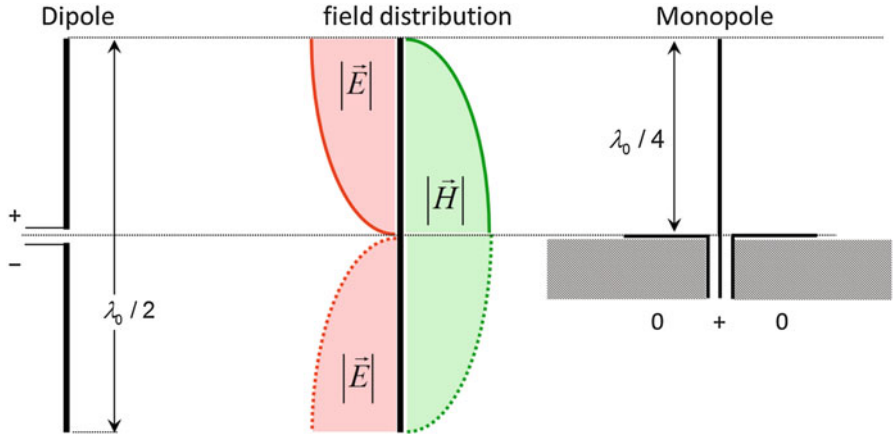

Fig. 9 Basic structure of the dipole and the monopole

for realizing a sector beam. The required discrete amplitude values of the distribution can then be derived by "sampling" the distribution function along the array line. Negative values of the function can be approximated by adding a 180° phase shift to the corresponding array coefficients.

Another very important aspect in vertical pattern synthesis is the filling of nulls in the pattern. Especially the first null just below the main lobe of the vertical pattern can cause a minimum in the sectorial coverage. By modifying the amplitude distribution according to the technique mentioned above, the first null can be filled resulting in a more homogeneous sector illumination.

Antenna Design Concepts

Typical Primary Radiators

Dipole and Monopole

The antenna design for base stations is based on well-known radiator elements: the half-wave dipole, the quarter-wave monopole, the patch antenna, and the planar inverted-F antenna (PIFA) are typical candidates here. A big variety of base station antennas are based on these types (Fig. 9).

The dipole is a wire antenna having an effective length of

$$l_{dipole} = \lambda_0/2$$

It is the smallest unfolded self-resonant structure that is possible. The E-field has its maximum at both ends of the antenna; the H field has its maximum at the center of the antenna. The antenna is typically fed in the center using symmetrical feeding (±). Due to the capacities at both ends of the dipole, the physical length is typically a little shorter than half of a wavelength.

The monopole antenna corresponds to the upper arm of the dipole antenna:

$$l_{monopole} = \lambda_0/4$$

However, this antenna type is not self-resonant; it needs a ground plane as counterpart. If the monopole is mounted on an infinite lossless ground plane, the field distribution along the antenna is similar to that of the upper dipole arm; the field below the ground plane level is zero by definition in this case.

DOI 10.1007/978-981-4560-75-7_88-1

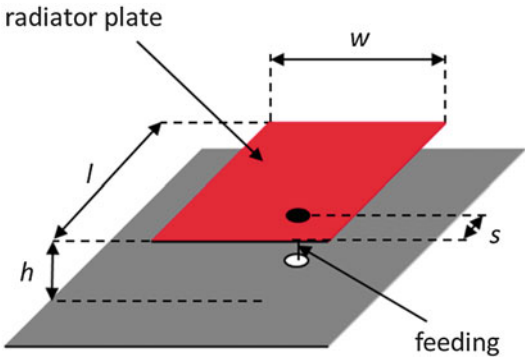

Fig. 10 Basic structure of the patch antenna

Patch

The patch antenna consists of a radiator plate parallel to the ground plane (Fig. 10). The presence of the ground plane defines the antenna properties; however, it is not a functional part of the antenna. The patch is a self-resonant structure; the resonance length is l:

$$\lambda/2 = l_{res}$$

The bandwidth Δf increases with increasing width (w) or increasing height (h) of the patch:

$$\Delta f = f_2(w, h)$$

The input impedance Z_{in} of the patch depends on the location of the feeding point: for $s = l/2$, the input impedance is zero; for $s = 0$ and $s = l$, the input impedance is at its maximum:

$$\underline{Z}_{in} = f_1(s)$$

As the patch is self-resonant and the resonance current is isolated from the ground plane, it is a very good antenna for realizing arrays, for example. Another advantage of the patch is the possibility of realizing two orthogonal polarizations within the rectangular radiator plate, one in l direction and the other one in w direction.

Planar Inverted-F Antenna (PIFA)

The planar inverted-F antenna (PIFA) consists of a radiator plate, which is mounted over a ground plane and a ground contact plate which makes the electrical connection between the radiator plate and the ground (Fig. 11). This antenna is resonant but not self-resonant, as it needs the ground plane as counterpart to function. The design criteria for the PIFA are as follows:

$$h + (w - w') + l = l_{res} \approx \lambda_0/4$$

The antenna is of quarter-wave type; the parameters h, l, and w determine the resonance frequency; and the input impedance can be increased by increasing the feeding distance s from the ground contact plate. More details about the design of PIFA's are given in Taga T. (1992) and Taga and Tsunewage (1987). The bandwidth of the antenna can be increased by increasing the height h.

DOI 10.1007/978-981-4560-75-7_88-1

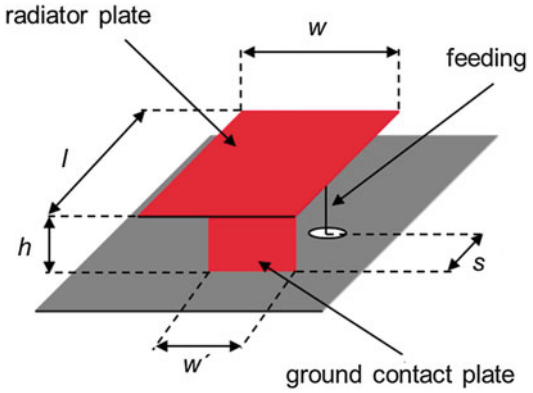

Fig. 11 Basic structure of the planar inverted-F antenna (PIFA)

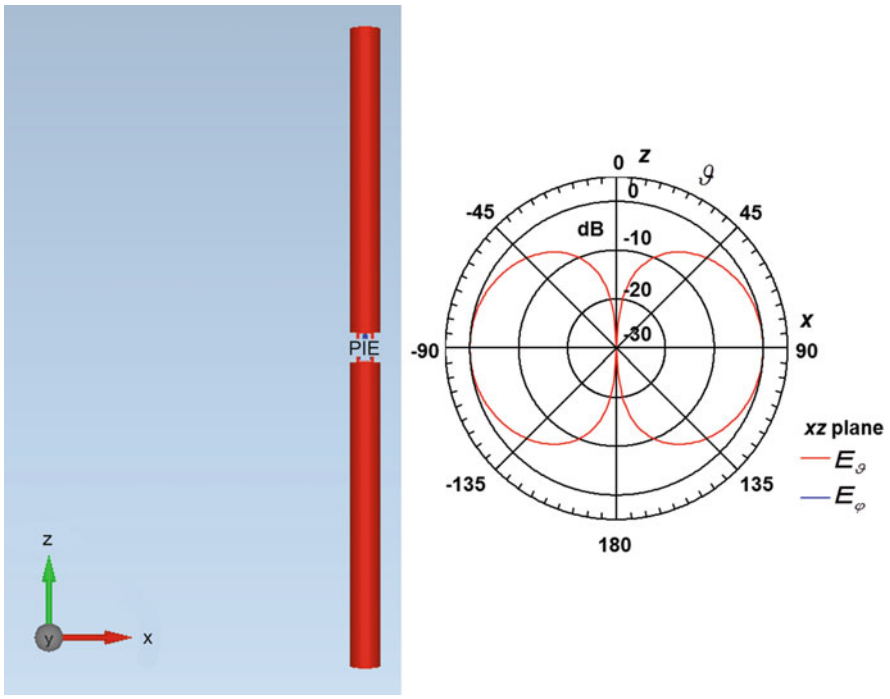

Fig. 12 Half-wave dipole ($f = 2$ GHz, $l_{Dipole} = 60$ mm, $d = 3$ mm, $D = 2.14$ dBi)

As the PIFA is a quarter-wave antenna, it can be designed in a very compact volume. However, the ground plane cannot be decoupled from the resonance current. The polarization direction is defined by the antenna geometry and the orientation; it cannot be changed by modifying the radiator plate only.

In the following sections, typical base station antenna designs using these basic antenna types will be explained.

Single-Element Configurations

Vertical Half-Wave Dipole

The vertical half-wave dipole is a very good antenna for an omnidirectional illumination of a cell. The figure shows a display of a 3D EM simulation model (Empire 2014) (left) of a half-wave dipole and the corresponding far-field pattern results of the 3D numerical simulation (right). The far-field pattern of

DOI 10.1007/978-981-4560-75-7_88-1

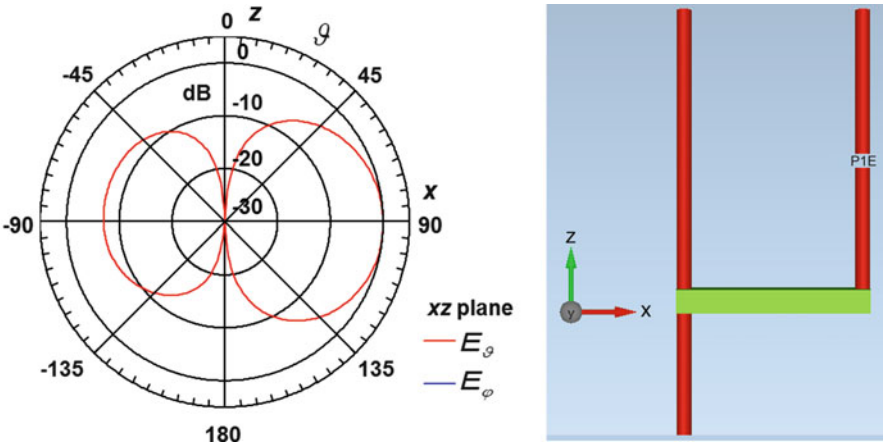

Fig. 13 Dipole (*right side*) in front of a mast (*left side*), both of metal. The dipole is fixed at the mast using a nonmetal support (*green*)

the dipole is a rotation symmetric to the z-axis. In the far-field vertical cut (yz), a null appears along the z-axis, and the maximum gain is obtained within the x-y plane. Due to the rotation symmetry, the horizontal pattern (xy) is circular, so the antenna has its maximum directivity of 2.14 dBi as a constant value within the horizontal plane (Fig. 12).

Looking at these pattern results, it can be seen that this antenna is very good for being positioned within the center of a nearly round cell. The cell should not be too big, as the directivity is low, and the antenna position should not be too high above the users, as there is no downtilt implemented in the antenna beam. So this is a typical antenna for microcells using a central base station positioned at low altitude in the cell center.

Dipole in Front of a Mast

If a dipole is mounted near to a mast, then the radiation characteristic is no longer omnidirectional. Depending on the parameters, this constellation can be used for the adjustment of the coverage of the cell. The mast functions like a passive "director" for the dipole. It absorbs energy out of the reactive near field and starts radiating itself. The far-field pattern results from the linear superposition of the fields of both radiators. Figure 13 shows a dipole in front of a mast and resulting radiation characteristics for a distance of $\lambda/4$ between the dipole and the mast.

Depending on the thickness of the mast, the directivity of the radiation pattern increases, so that it can be adapted to the required cell illumination.

Monopole Antenna on Small Base Station

The monopole antenna is also a very common type for base station applications. However, as the antenna needs a ground plane as counterpart, it is very often directly mounted onto the base station casing.

Typical use cases are the mounting onto picocell base stations which can have a total size of a large book. In the following simulation, a monopole antenna is mounted on a picocell base station, which is modeled as metal-coated box (Fig. 14).

The far-field pattern of this simulation shows a dipole-like pattern in the E-Theta component of the vertical cut (x-z plane). This indicates that the casing of the base station acts as an active counterpole rather than an infinite ground plane. So the monopole together with the casing functions like a dipole antenna.

This happens because the size of the casing is not infinite but in the order of a wavelength. Figure 15 shows the electrical near field in a vertical cut through the whole device: one can see that the field concentration is very high at the dipole, but there is also reactive field around the whole device. The metal

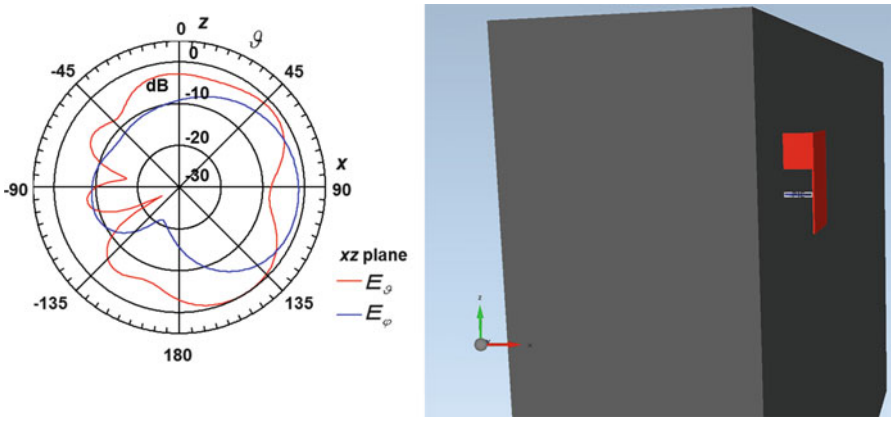

Fig. 16 Planar inverted-F antenna (PIFA) on a small base station ($f = 2$ GHz, box dimensions 70 × 200 × 300 mm^3, dimensions of the PIFA: 8.5 × 20 × 28 mm^3, $D = 2.41$ dBi)

casing acts as a part of the antenna and contributes to the radiation. (The orange frame in the picture limits the rectangular area, in which the near field was calculated).

Planar Inverted-F Antenna on Small Base Station

The planar inverted-F antenna is also very often used for small base stations: this antenna type needs a ground plane as counterpart as well. It can be mounted on the top of a casing, but also on the front side (+x direction) as shown in the simulation setup below. When assuming that the whole base station is mounted on a vertical wall oriented in z direction (wall not implemented in the simulation), the frontside position of the PIFA is advantageous: most of the far-field radiation is directed towards the +x direction away from the wall (Fig. 16). Moreover, the distribution of the reactive near field is blocked by the presence of the casing: this effect can be seen in the near-field cut in Fig. 17, and the reactive near field is concentrated in the vicinity of the antenna, whereas the backside of the casing shows very low field values. Therefore, the backside is less sensitive to the presence and the electrical properties of the wall in this constellation.

Besides of the forward directivity, this front mounting position also avoids a potential detuning of the antenna caused by the presence of the wall. The presence of the casing hides the wall influence from the antenna; it makes the antenna properties less sensitive to the wall effects.

Array Configurations

Dipole Array

If the base station antenna is located in the center of a circular cell, the half-wave dipole antenna can be used as explained above, as it has its maximum directivity in the horizontal plane. The gain of a single half-wave dipole however is relatively low. In order to increase the gain, several dipoles can be arranged in one line, where each of them is radiating at the same amplitude and phase. The resulting pattern has a higher gain in the horizontal plane than a single element, and the HPBW is smaller. So the radiation is directed into the horizontal plane and reduced towards upward and downward elevation directions (Fig. 18).

Sector Antennas

In many cases, cells are subdivided into sectors in order to increase the capacity. In this case, a directive antenna is necessary, and the horizontal pattern has to be adapted to the sector size and shape, whereas the vertical pattern has to be adapted to the cell diameter and the cell-mounting position (Fig. 19).

DOI 10.1007/978-981-4560-75-7_88-1

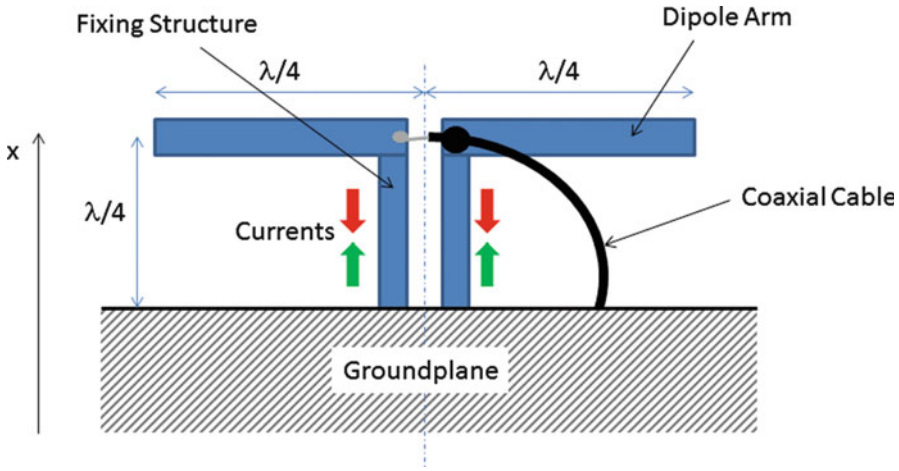

Fig. 19 Antenna element for sector array

A typical basic antenna element for realizing sector antennas is a half-wave dipole mounted over a metal plate. The metal plate acts as a reflector and as a ground plane too. The mounting distance is chosen to λ/4, which has several effects:

1. The mounting distance of *l*/4 transforms the electrical short of the antenna fixing structure into an electrical open at the dipole feeding point, so the fixing structure is electrically "invisible."
2. The ground plane acts as a reflector, and the backward radiation (in –x direction) from the dipole is reflected and interferes constructively with the radiation into +x direction.
3. The fixing structure acts like a balun, converting the unsymmetrical mode from the feeding coaxial cable into the symmetric dipole. Unwanted surface currents resulting from the unsymmetrical feeding (red) are suppressed by reflected currents having the same amplitude but the opposite phase.

So this constellation is a very good basic element for realizing sector antennas. The shaping of the horizontal characteristics can be done by modifying the size and the shape of the reflector as well as the dipole positioning over the reflector. So typically, required HPBW like 90° or 65° can be realized using this type of basic radiator.

The vertical characteristics can be shaped by building an array of dipoles. Figure 20 shows the simulation model of a five-element array. The dipoles are in this case vertically oriented, and the array is also arranged in vertical direction.

If all elements are fed by the same amplitude and phase, the resulting pattern has its maximum in the horizontal plane, and the resulting directivity is 14.11 dBi. Figure 21 shows the vertical pattern of this constellation: the presence of the reflector causes a directivity in +x direction, and the maximum can be found in the horizontal plane. Figure 22 shows the resulting vertical pattern of the five-element array: the directivity is increased versus the single-element case by adding more elements. If all elements are in phase, the resulting maximum remains in the horizontal plane.

In order to realize an electrical downtilt within this array, a phase shift has to be implemented. This phase shift of constant value between neighboring elements causes a declination of the wave front in the E-field, and the propagation direction of the waves is tilted downwards (Fig. 23)

The far-field pattern in Fig. 24 shows the resulting far-field pattern which is tilted downwards. So this kind of antenna array is very well suitable for sector antennas: the horizontal pattern HPBW can be adapted via modifying the reflector shape, the directivity can be increased by the array factor, and the vertical pattern can be adapted by adapting the electrical downtilt.

Realization of Diversity or MIMO

Diversity is a common technique to improve the signal transmission between a base station and a mobile. The use of two antennas allows the compensation for any fading either by switching between the two antennas or by combining the two signals in the receiver.

Most of today's base station antenna systems offer diversity in order to overcome any fading issues. Very often polarization diversity is used. This means that two antenna radiators having orthogonal polarizations are built within the same volume.

Instead of horizontal–vertical arrangements, slanted arrangements of ±45° are commonly used. In this arrangement, the symmetry of the paths is better compared to the horizontal and vertical polarized arrangements. On the other hand, the isolation between the radiator parts and the resulting systems of

DOI 10.1007/978-981-4560-75-7_88-1

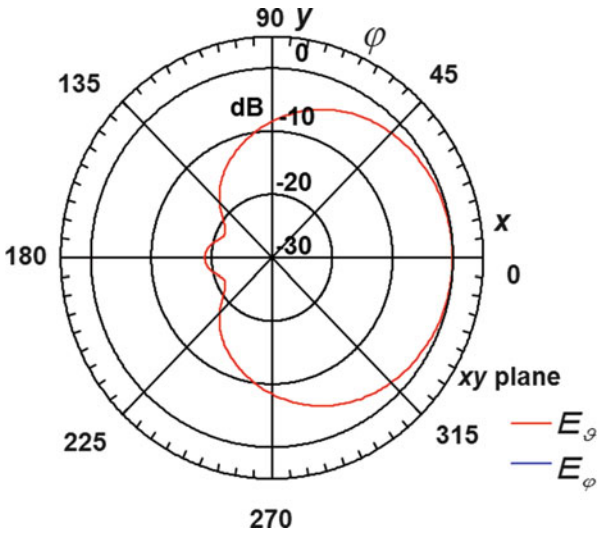

Fig. 21 Horizontal far-field pattern of the 5-element sector array

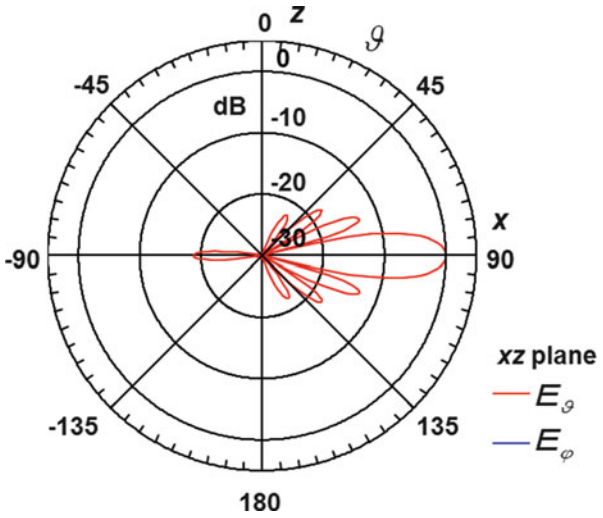

Fig. 22 Vertical far-field pattern of the 5-element sector array

the antennas are great challenges. In Fig. 25, dipole arrangements for different half-power beamwidths are shown schematically. A typical arrangement is based on two orthogonal dipoles, each of them in 45° arrangement versus the reflector plane (Fig. 25). The HPBW can be modified depending on the arrangement.

The orthogonal dipole arrays are then connected via two separate ports, so that the antenna can be used to perform diversity. The combining of the signals is done in the receiver. This constellation allows very good decoupling of the two input ports in the order of 20–25 dB.

Figure 26 shows a realization example of a radiator element which includes diversity: it consists of four square sectors, where two of them are built within one dipole element. The coaxial cables for the two ports are stored in the holes of the shaft and connected to two diagonally oriented elements each. This results in two orthogonal dipoles where the E-field can be oriented according to the red and the blue arrows, respectively.

DOI 10.1007/978-981-4560-75-7_88-1

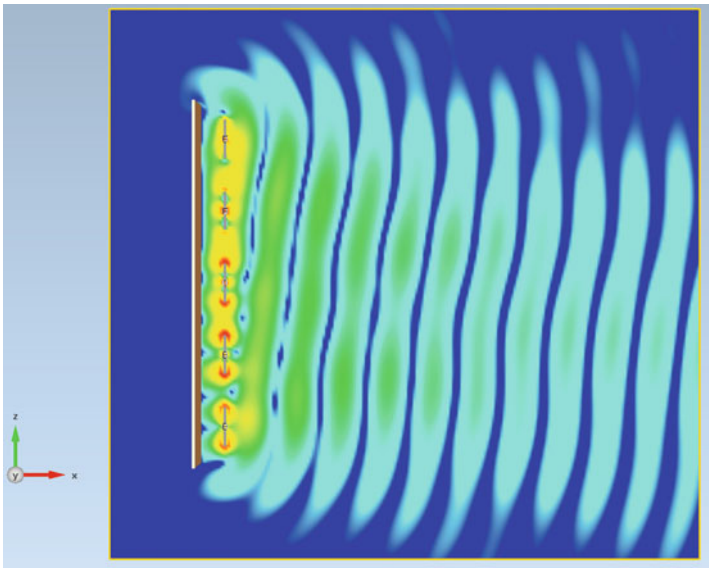

Fig. 23 Sector array with implemented phase shift: E-field distribution in front of the antenna

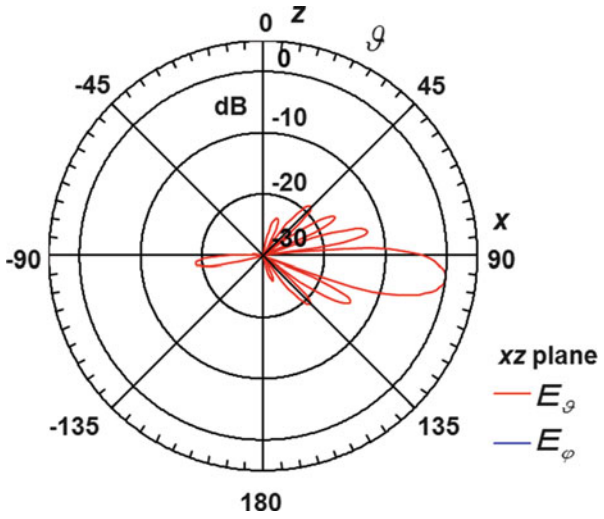

Fig. 24 Far-field pattern of reflector array with electrical downtilt

One challenge to solve is the isolation between both polarizations and both frequency bands within the antenna system. Especially in the slanted configuration, the problem is the projection of the radiating structures; see Fig. 27. This projection together with a non-orthogonal axis to the reflector sides requires additional measures to improve the isolation between the radiators.

This can be done by introducing parasitic coupling elements, which compensate the undesired coupling between the elements. To achieve the desired effect, a phase shift of 180° between the parasitic elements and the undesired coupling needs to be achieved for the operating frequency band. In Göttl (2004) as well as in Gabriel and Göttl (1997), such elements are described in forms of sheets, crosses, or stubs between the single radiators. Effectively, the elements are working only in the near field of the radiators and do not contribute significantly to the far-field radiation.

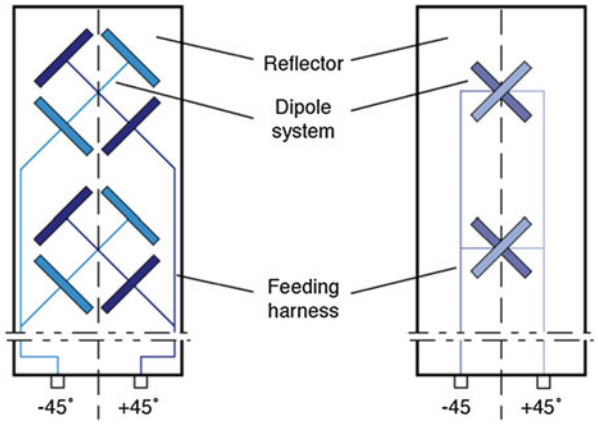

Fig. 25 Principle arrangements of dual-polarized dipole structures for 65° HPBW (*left*) and for 90° HPBW (*right*)

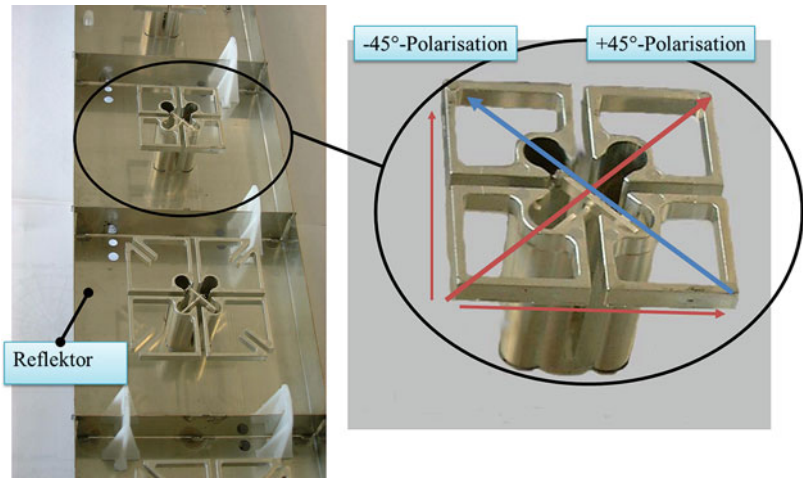

Fig. 26 Realization example of a dipole sector antenna with diversity

Based on these dual polarized antenna structures, MIMO can also be realized: MIMO stands for multiple input, multiple output and describes a technique of using multiple antennas at the transmitter side and at the receiver side to improve the link performance. MIMO configurations can be driven in different transmission modes that perform true MIMO operation, diversity, beamforming, or even spatial multiplex to either improve the S/N, to ensure a certain quality of service, or to maximize the data throughput.

For MIMO realization, the same basic radiator constellations can be used as for diversity: in a dual polarization dipole constellation, both ports can be used to perform a 2×X MIMO. By using several columns in a parallel arrangement, more channels can be provided for higher-order MIMO systems. Today's LTE system uses 2×2 MIMO as basic configuration, and higher order like 4×4 or even 8×8 is already in use.

Realization of Multiband Radiators

As the number of communication standards and the number of available frequency bands rapidly increases, there is an increasing demand for multiband antenna systems. Very often the available integration space at the base station site is very limited, so there is a strong need to implement several frequency bands into one antenna system.

DOI 10.1007/978-981-4560-75-7_88-1

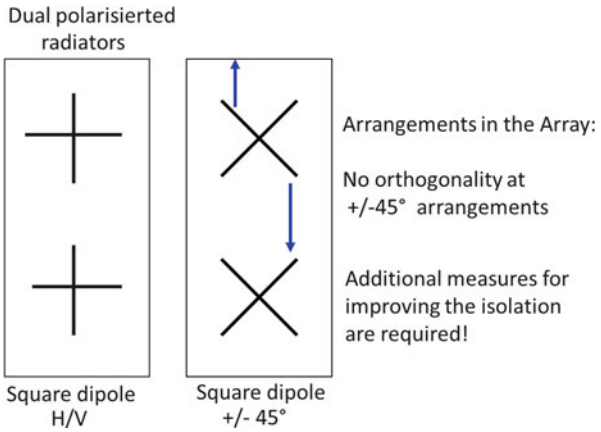

Fig. 27 Reduced isolation in slanted configurations of dual-polarized antennas

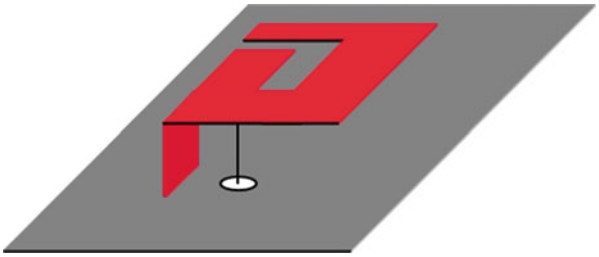

Fig. 28 Multiband PIFA

The integration of bands can happen on the element level and/or at the array level. In Fig. 28, an example for the integration on element level is displayed: the radiator plate of the planar inverted-F antenna is subdivided into two "arms" of different lengths, resulting in two different resonance frequencies. So this kind of antenna can, for example, cover the 900-MHz band and the 1800-MHz band. Based on this principle, three or even four resonances can be realized within one PIFA. This kind of multiband realization can be found especially in picocell base stations, where the PIFA is directly mounted onto the casing of the base station.

In Fig. 29 a dual-band, dual polarization structure is displayed: four dipoles in a square arrangement cover the low frequency, offering two polarizations, whereas a cross-dipole arrangement in the center of the configuration covers the high band. The dipole square operates in parallel as a reflector for the inner cross dipole; therefore, comparable half-power beamwidth for both bands can be obtained. With this kind of arrangement, the integration of the high band into the antenna does not need any more space in comparison to the single low-band antenna. However, the issue of increased mutual coupling between high and low band but also between the two orthogonal polarizations of each frequency band rises. So the whole structure has to be optimized to minimize any mutual coupling. In order to achieve this, special decoupling structures might be integrated as mentioned before. In Fig. 29 the current density of a simulation with the exited cross dipole for the high freqeuncy band, using the simulation tool "CST Microwave Studio" CST (2014) is shown.

Another important primary radiator is the patch structure. The dual-polarized patches use both orthogonal resonances of the patch. An example of a dual-band structure according to Lindmark (2000) is shown in Fig. 30. All patches are working in an orthogonal resonance mode, and the upper patch for the

DOI 10.1007/978-981-4560-75-7_88-1

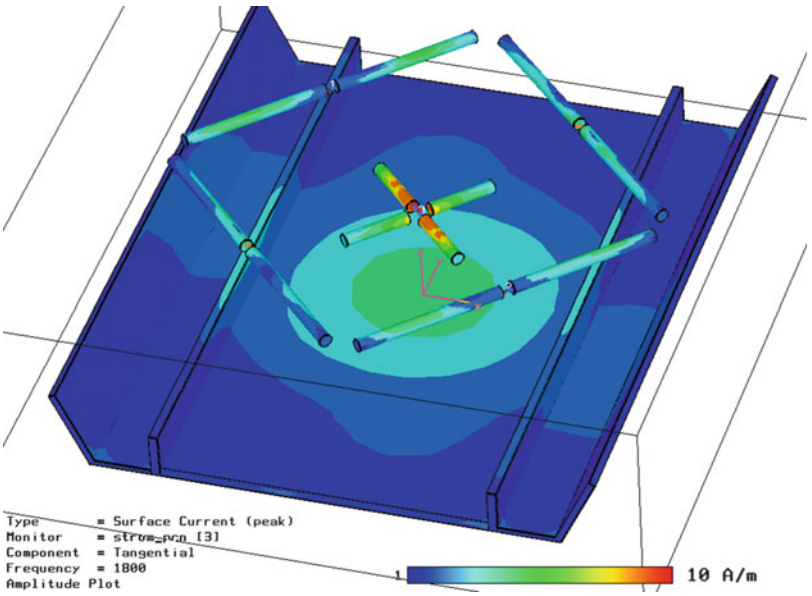

Fig. 29 Dual-band arrangements of dual-polarized dipoles structures

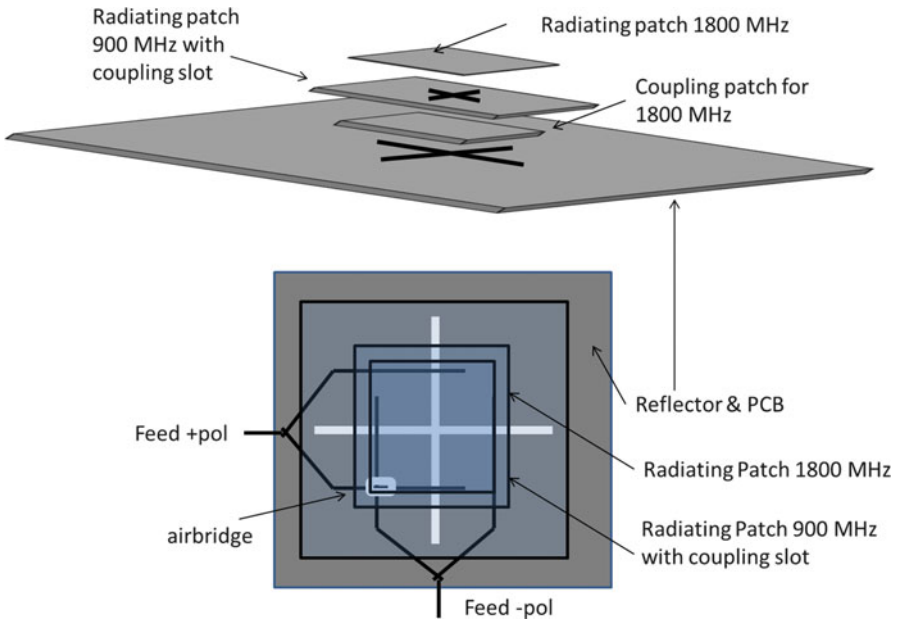

Fig. 30 Dual-polarized, dual-band patch arrangements

1800 MHz band is coupled by the coupling slots in the patch of the 900 MHz band and by means of an additional coupling patch between the radiating patch for the 900 MHz and the reflector.

When realizing multiband antennas, the multiresonant elements are only one issue, and the other issue is the realization of the multiband arrays. As described in the section above, the array performance depends strongly on the distance of the antenna elements, in relation to the wavelength. This leads to the fact that the optimum distance for a low frequency band is different for the optimum distance for a higher frequency band.

DOI 10.1007/978-981-4560-75-7_88-1

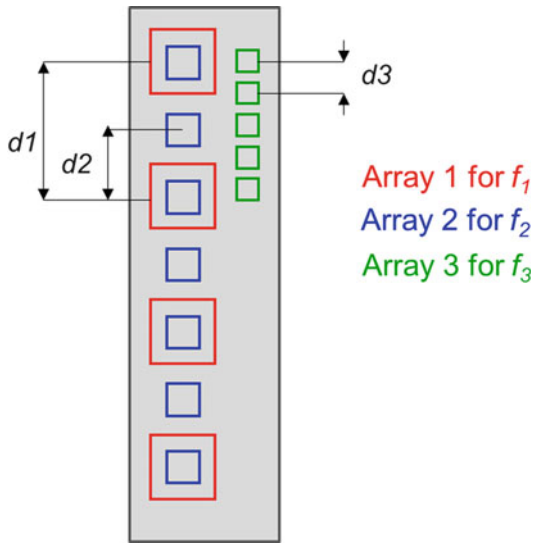

Fig. 31 Multiband sector array, configuration of elements to optimize the array distances

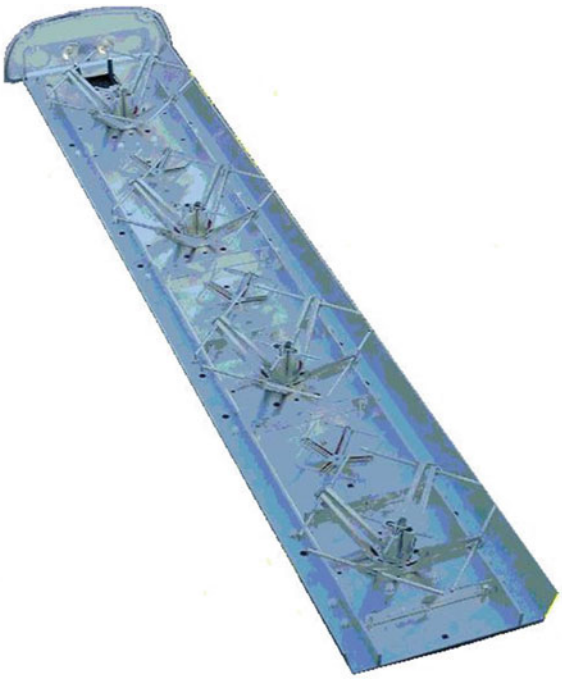

Fig. 32 Dual-band array arrangement

Figure 31 illustrates this issue: assuming that f1 = 900 Mhz, f2 = 1800 MHz, and f3 = 3 GHz, the resulting optimum distances for the arrays within the multiband antenna systems differ significantly. As f2 = f1 × 2, the distance d2 is exactly half of d1. So in this case, array 1 and array 2 can be interleaved as shown in the sketch. Array 3 however does not "fit" into the array grid of d1 and d2, so d3 has to be realized as a separate array.

In Fig. 32, a practical realization of a dual-band sector antenna is displayed (Göttl et al. 1999). One can see the grid of the low-band array and the smaller additional elements of the high-band array in between.

DOI 10.1007/978-981-4560-75-7_88-1

When realizing multiband arrays, not only the issue of different optimum distances has to be solved and integrated but also different tilt angles for the different arrays should be possible, so that the optimum illumination for each frequency band can be realized.

This can be done by using separate phase shifters for each band; however, in this case, the different frequency bands have to be separated by filtering in front of the phase shifters and combined again afterwards (see also section "Antenna Line Devices").

Antenna-Related Network Aspects

The antennas on both sides of the transmission path determine the propagation channel from the base station to the mobile and vice versa. Considering only linear media, the propagation channel is fully reciprocal. Just here the problem occurs that the mobile user transmits at lower-transmitting power compared to the power of the base station, due to the limited battery capacity of the device and due to human exposure limits. This discrepancy is solved by diversity principles. The reuse of resources as time slots or frequencies requires a carefully adjusted beam of the antennas to cover only the desired cell area. The more the coverage of the different sectors overlaps, the higher is the undesired interference of the neighboring sectors, and the reuse of the resources becomes worse. In the networks of the second generation, spatial frequency reuse scenarios of five or seven are typical. So the same frequency carriers can be reused in every seventh sector, and this means the available spectrum has been organized in seven different channel clusters. Networks of the third and fourth generation have a reuse factor of one. Nevertheless, here the different resources of frequency channels, time slots, or resource blocks in the orthogonal frequency-division multiplexing (OFDM) scheme have to be organized in a dynamic manner. So from a statistical point of view, here also neighboring sectors cannot use the same resources for different users, if the level of the undesired channel is still too high (intra-channel interference). On the other hand, the orthogonal channels at other frequencies or orthogonal codes generate an equivalent noise for the desired channel (inter-channel interference). This gives the desired channel to interference ratio, which determines the maximum possible modulation scheme with the maximum data transmission according to the theorem of Shannon–Hartley (Shannon 1949):

$$C = B * \log 2\left(1 + \left(\frac{S}{N}\right)\right)$$

where C is the capacity of the channel in Bit/s, B is the bandwidth in Hz and S/N is the signal to noise ratio. Therefore, the careful design of the radiation characteristics of the antenna and the alignment of the antenna into the desired sector are essential. Especially the adjustment of the mechanical or electrical tilt of the beam influences the C/I in the network. Current technology uses an adjustable tilt mechanism of the antennas, the so-called remote electrical tilt (RET). Here beamsteering of the vertical characteristic of the array is realized by integrated phase shifters, which are driven by motors. Electronically operated phase shifters cannot typically be employed, since most of the systems are sensitive to passive intermodulation and need an extremely high linearity in the components used (Fig. 33).

Influence on Network Planning

Frequency Reuse, Cell Size, and Interference

The mobile communication network is structured into different cells and sectors as mentioned earlier. Typically, every sector uses other resources; thus, an antenna will only serve the desired cell and will not

DOI 10.1007/978-981-4560-75-7_88-1

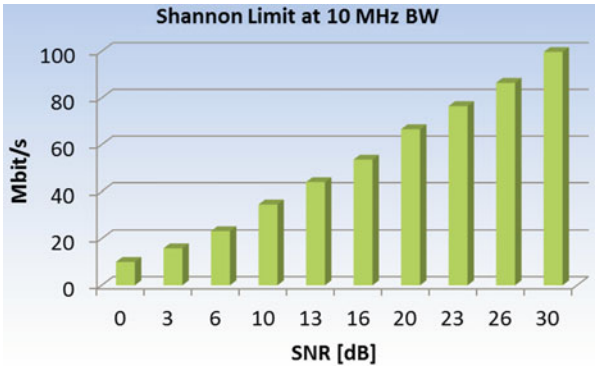

Fig. 33 Maximum theoretical data rate within a 10 MHz bandwidth according to the Shannon theorem

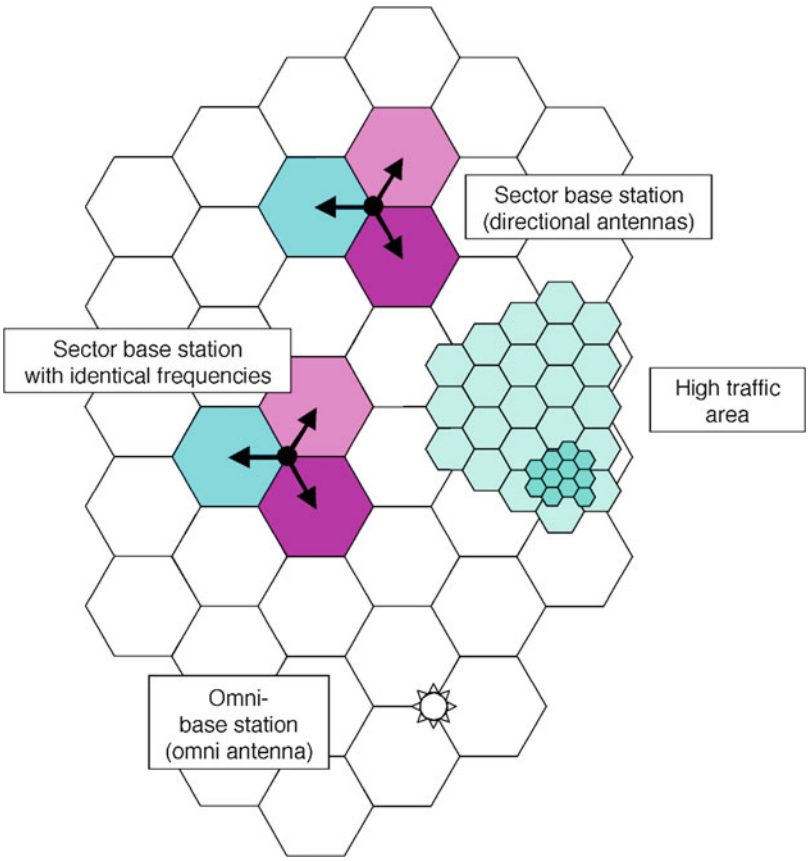

Fig. 34 Different cell topologies

transmit into other cells. This is realized by an optimized design of the horizontal and the vertical shape of the beam. Especially the suppression of upper side lobes and the enhanced front-to-back ratio are essential requirements (Fig. 34).

Thus, the vertical and horizontal beamwidth are important parameters of the antenna as well as the vertical electrical and mechanical tilt. Typically, 65° up to 90° horizontal half-power beamwidth antennas are used for sectored arrangements with three sectors. The theoretical shape of the beam appears in a first approach as 120°; nevertheless, here the overlapping area of neighboring sectors becomes too large, which results in a high interference level. The same adjustment functionality for the interference and

DOI 10.1007/978-981-4560-75-7_88-1

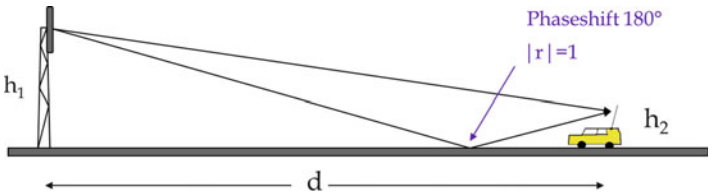

Fig. 35 Two-way model with reflective ground

coverage shows the tilt level of the main beam. Typical values between 2° and 10° can be seen; the smaller the cell, the higher is the tilt level.

Of course, in reality the coverage is not regularly shaped. Therefore, the mobile receives in most locations a mix of different carriers from different cells; the selection of the connected cell will be organized by a handover mechanism. The spreading of pilot carries over different cells causes a lot of handovers and reduces the effective traffic and quality of service.

Path Loss, Link Budget, and Fading Channel

The calculation of the link budget of a channel between base station antenna and mobile depends on the scenario as described in section "Antenna Design for Base Stations." In most cases, no line-of-site connection (LOS) exists, and reflections and scattering lead to a fading of the connecting path between base station and the mobile. The calculation for an LOS connection can be derived from the known gain of the antenna in the main beam direction according to the Friis equation given in section "Antenna Design for Base Stations." The input power P_{in} will be transformed into a radiated transmitting power P_{rad} with certain efficiency of the antenna. The radiated power is distributed over the angle space according to the radiation characteristic of the antenna. In the main beam direction, the maximum power density at a certain distance r can be found to be equal to the product of radiated total power multiplied by the linear gain Gi and divided by the surface of the surrounding sphere.

As already mentioned, the path loss in most of the cases has to include non-line of sight effects as reflections and scattering. This results in a stronger degradation of the received power compared to line-of-sight connections. LOS path loss is proportional to the square of the distance, assuming NLOS connections; the path loss is more proportional to the third up to the fourth order of the distance as described earlier. Derived from measurements, empirical models can be used according to Okumura Hata (Okumura et al. 1968; Hata 1980) where more detailed arrangements can be evaluated, depending on the height of the transmitting and receiving antennas, the distance, and the type of environment (dense urban area or rural area). A simplified model which also yields to a dependency of the receiving level proportional to r^4 is the two-way model, which only takes into account the ground reflection on a flat ground surface (Fig. 35). This gives the relatively simple formula for $d \gg h$:

$$\frac{P_E}{P_S} = G_S G_E \left(\frac{h_1 h_2}{d^2}\right)^2$$

Where P_E and P_S are the the received and transmitted power, G_S and G_E are the gain of the antennas. A typical level dependency of a simulated level according to an LOS path with a dependency of r^2, a simulation with a dependency on distance of r^4, and an equivalent measurement are shown in Fig. 36. The height of the base station antenna is 30 m, and the relevant level is measured or simulated at a height of 2 m.

It can be seen that there is a projection of the radiation characteristic of the antenna on the ground level, but also the nulls of the pattern are filled by reflections and scattering. A comprehensive overview about the used models is given in Walke (2000).

DOI 10.1007/978-981-4560-75-7_88-1

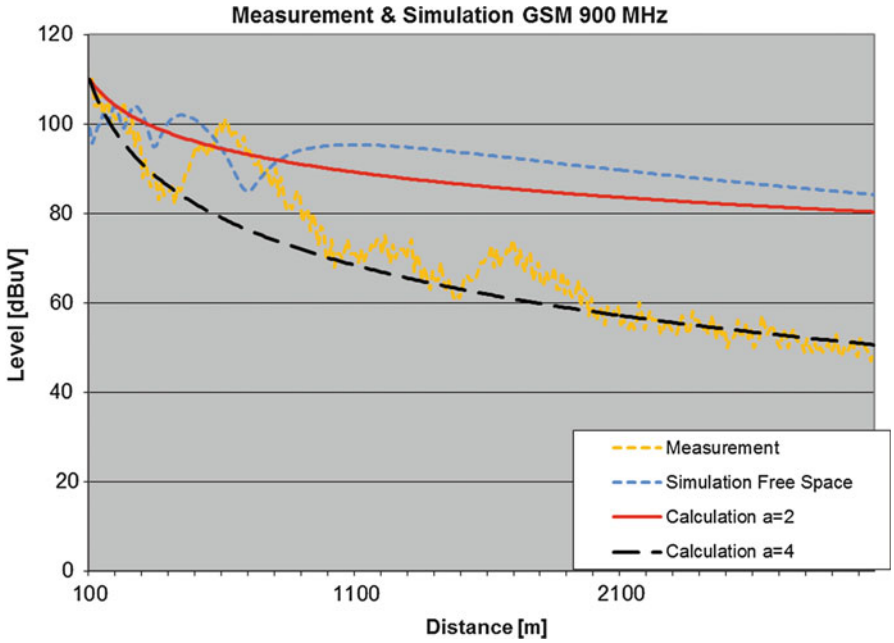

Fig. 36 Measurement and simulation of the signal level with different models

It is obvious that the superposition of more than one path as a direct and reflected wave is strongly dependent on the position and on the environment and also time variant. This causes fading effects and delay spread. The fast change of the phase between different incoming waves results in a fast-fading effect. The fading can happen within the range of some meters or, depending on the location, in a range of some centimeters in the considered frequency bands. The average level of the path is subject to slow fading, which is caused by changing major path properties, e.g., shadowing by buildings or trees. Since the fast fading depends on the phase of incident waves, the superposition will occur in another manner at different frequencies.

The behavior of the path will be different if the transmission frequency changes. The bandwidth, within which the behavior of the path is nearly unchanged or in other words where it is correlated, is called the coherence bandwidth; see Maurer (2005). Typically, the coherence bandwidth is in the range of 20–50 MHz at 900–2000 MHz. Using several frequencies for transmission with a frequency variance higher than the coherence bandwidth leads to a significant reduction of fading. This technique does not only allow high data rates through the large bandwidth used; it also improves the stability of the connection, and it is used in frequency hopping transmission (GSM) as well as in carrier aggregation transmission (LTE) (Fig. 37).

The power level distribution of the signal over time is dependent on the number of incident waves and especially on the strength of the LOS path. Considering a transmission of a short pulse than the incoming signal consists of a sum of delayed pulses, every pulse with a certain power P_i, having a delay τ_i as it is shown in Fig. 38:

$$\tau_{rms} = \sqrt{\frac{1}{\sum_{i=1}^{n} P_i} * \sum_{i=1}^{n} \left(\tau_i^2 P_i\right) - \tau_d^2}$$

DOI 10.1007/978-981-4560-75-7_88-1

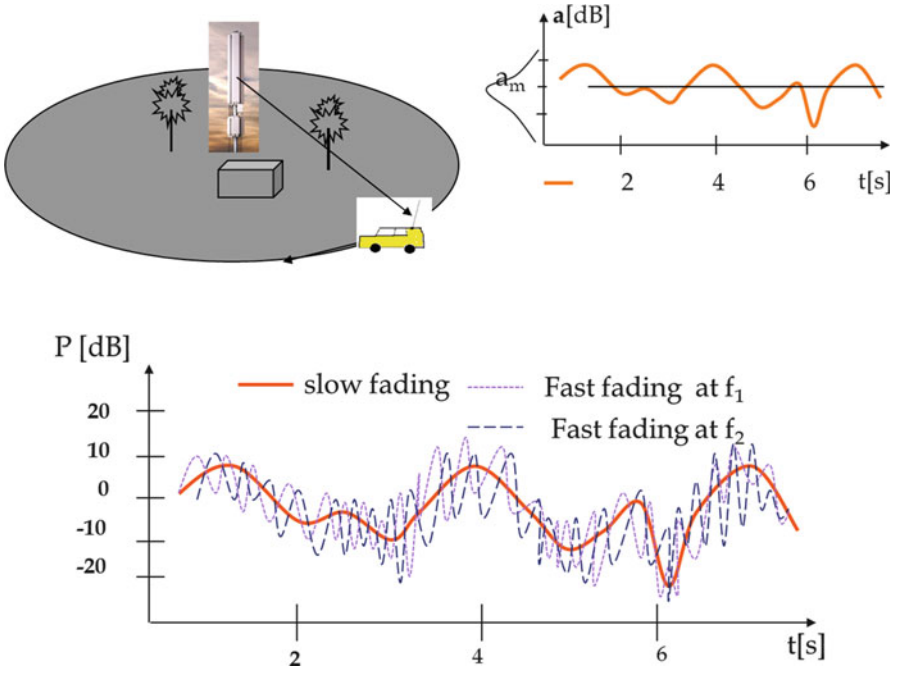

Fig. 37 Slow and fast-fading principle

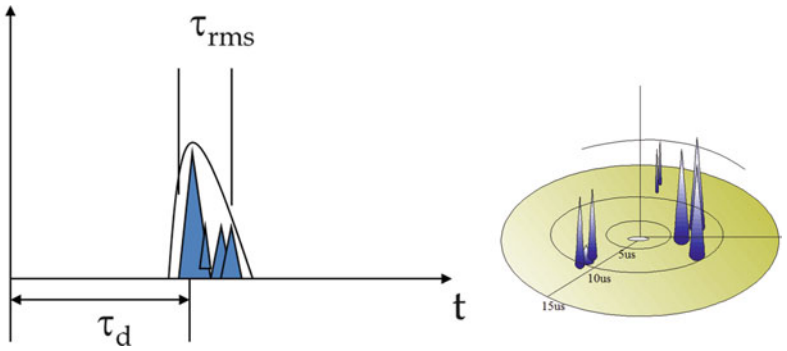

Fig. 38 Delay spread with space dependency

$$\tau_d = \frac{\sum_{i=1}^{n} \tau_i P_i}{\sum_{i=1}^{n} P_i}$$

The delay spread and the average total delay are given by the above expression, whereas the average delay spread is the basis for the coherence bandwidth:

$$B_C = \frac{1}{\tau_{rms}}$$

The given description of the channel properties is important regarding the signal processing implementation used for the matched filtering to restore the original signal: the selection of the proper signaling

DOI 10.1007/978-981-4560-75-7_88-1

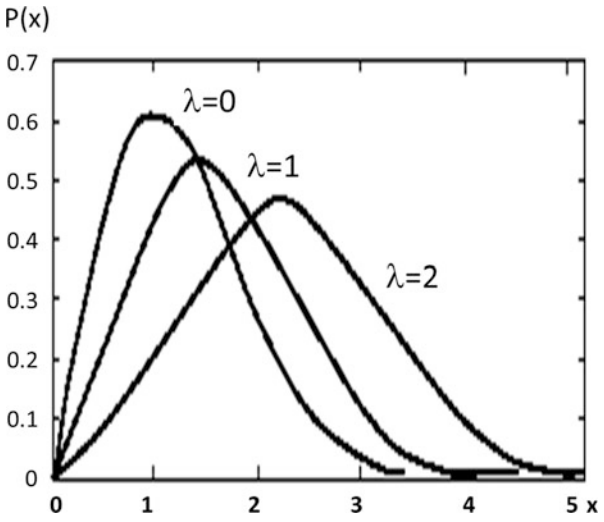

Fig. 39 Rice and Rayleigh distribution

schemes and operation bandwidths is determining significantly the effort in the processing. So the frame length should be long compared to the average delay spread; otherwise, the intersymbol interference is very high. On the other hand, having enough signal processing power available, the multipath propagation can directly be used for transmitting. This might be more effective than having one data stream within a MIMO implementation, as will be described later.

If no LOS path exists and the number of incident waves at a given location is very high, then the resulting signal level distribution is given by a Rayleigh distribution. If on the other hand several waves with an LOS connection exist, the distribution will change to a Rice distribution:

$$\text{Rayleigh distribution} \quad p(x) = \frac{x}{\sigma^2} e^{-x^2/2\sigma^2}$$

$$\text{Rice distribution} \quad p(x) = \frac{x}{\sigma^2} e^{-\frac{x^2+x_s^2}{2\sigma^2}} * I_0\left(\frac{x x_s}{\sigma^2}\right)$$

In these formulas, Io is the Bessel function of first kind, zero order σ is the average variance, x is the normalized magnitude level, and x_s relates to the average LOS part of the magnitude distribution; $\lambda = x_s/\sigma$ is also called the Rice factor. Setting the Rice factor to zero, the Rice distribution is changing to the Rayleigh distribution (Fig. 39).

Diversity

In order to overcome fading effects of the channel and to improve the transmission, diversity arrangements are used. This effectively means that several propagation channels are active. To achieve a certain gain within a rice scenario, the correlation between the different paths should be low, as it can be derived from Fig. 40. Typically, this requires different located antennas or different polarization of the antennas. Space diversity requires a certain distance between the two receiving antennas or antenna elements, typically a minimum of ten wavelengths; see Fig. 42. Polarization diversity, which is the preferred technology today, uses 2 orthogonal polarizations, e.g., ±45° or the combination of horizontal and vertical polarization. The ±45° polarization or the so-called X-polarization shows a better symmetry for transmission than the horizontal–vertical combination.

DOI 10.1007/978-981-4560-75-7_88-1

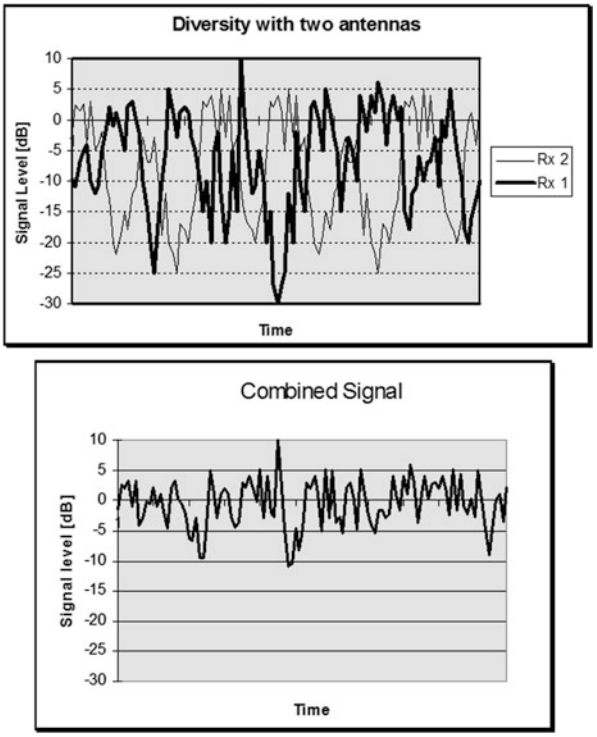

Fig. 40 Combining of fading signals using the diversity principle

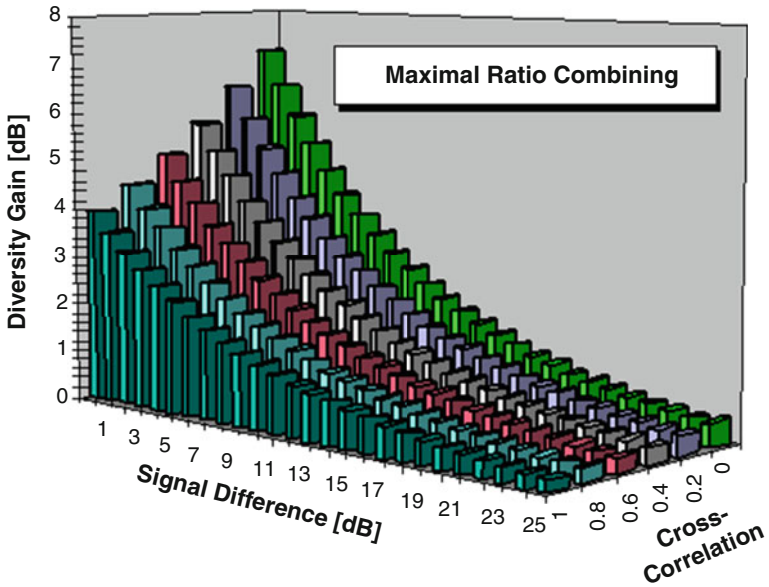

Fig. 41 Dependency of diversity gain on correlation and level difference for a typical GSM system

Within the X-arrangement, the antennas consist of two resulting systems of orthogonally polarized arrays with separate connectors. The challenge is to optimize the isolation of these systems. The typical requirement is a minimum of 30 dB isolation. The diversity gain depends on the level difference of both systems and the correlation between the two levels of the signals over time. In Fig. 41, the dependency of a typical GSM system on both parameters is shown. Besides correlation and power level, the diversity gain

DOI 10.1007/978-981-4560-75-7_88-1

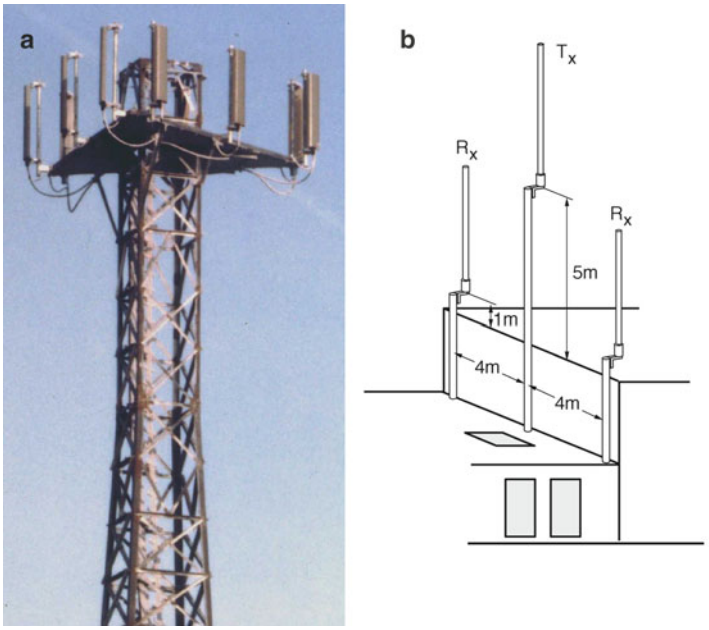

Fig. 42 Space diversity arrangements in a sectored configuration (**a**) and in an omnidirectional configuration (**b**) for 900 MHz

also depends on the system parameters, e.g., the acceptable probability of interruptions or failures. The higher the requirements of availability of the channel, the higher the diversity gain will be. This is obvious since the diversity principle avoids interruptions through fading and will improve signal quality, especially the interruptions of time frames (Fig. 42).

In addition to the gain due to the reduction of failure probability, the diversity also helps to overcome the problem of imbalance between the transmitting power of the mobile and the transmitting power of the base station.

MIMO: Operation

As an extension of diversity, multiple antennas can be operated with more than one signal stream in a MIMO operation (see also section "Historical Review").

The theoretical limits of transmission of multiple data streams are considered in detail in many publications. In Telatar (1995), a theoretical derivation of the maximum capacity of Gaussian channels with Rayleigh fading are considered; in Pontes et al. (2011), implementation-specific scenarios are evaluated and limited knowledge of the channel matrix is considered. A comprehensive work on MIMO systems can be found in Waldschmidt (2004). Here, it should be noted that the multichannel antennas can be used for diversity or MIMO or beamforming operation alternatively, depending on the current situation in the propagation channel. So the beamforming operation can be considered as a special case of MIMO with only one data stream. The capacity of MIMO can be evaluated by the modified Shannon equation with knowledge of the channel matrix H:

$$C = \Delta f \cdot \sum_{k=1}^{n} \log_2 \left(1 + \lambda_k \frac{P_k}{N}\right)$$

where λ_k is the k th eigenvalue of the channel matrix H, which is proportional to the square of the singular values of H, and P_k is the transmitting power of the kth data stream and N the noise. For simplification, the noise is considered to be equal for every data stream in this case. The maximum MIMO capacity can

DOI 10.1007/978-981-4560-75-7_88-1

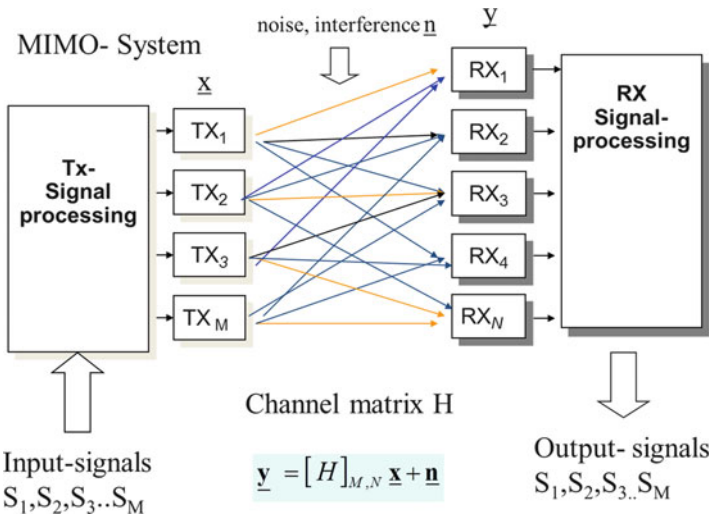

Fig. 43 Principle of an M × N MIMO system

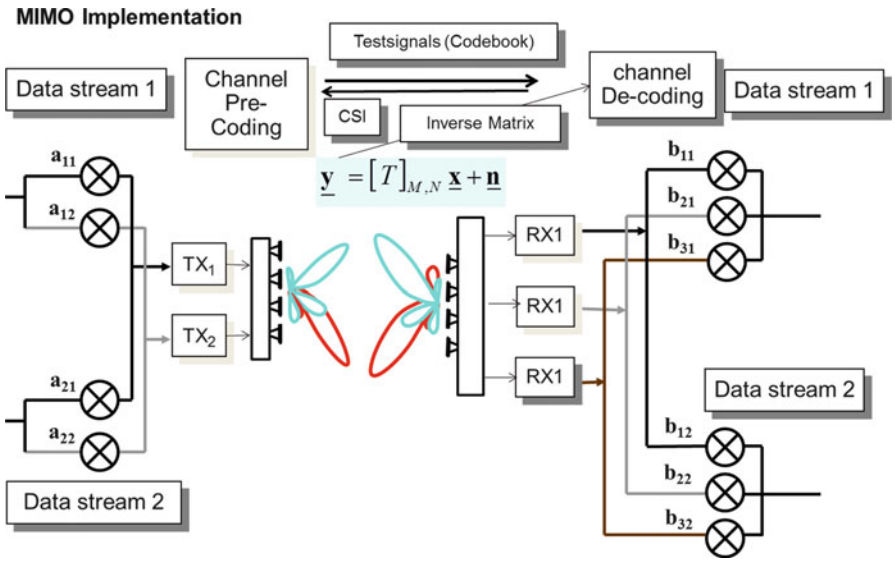

Fig. 44 Schematical 2×3 MIMO implementation

consequently only be achieved having the full knowledge of the channel matrix. The implementation of such adaptive MIMO operation is known as the "waterfill principle"; see also Waldschmidt (2004, pp. 1–17). The maximum capacity therefore depends on the signal-to-noise ratios of the different resulting channels for the connected data streams and cannot exceed the n-times capacity of a single-in-single-out (SISO) channel.

In Fig. 43, the signal model and the basic principle are shown, and in Fig. 44 the more detailed implementation is shown. The challenge is the determination of the channel matrix. This can be carried out by a closed-loop principle; in this operation, the data streams are processed with certain agreed coefficients (training sequences) according to an agreed code book (see also chapter "► Active Antennas"). The best fitting code is selected by evaluation of the best transmission case.

This approach is equivalent to an approximate solution of the channel matrix H inversion and the determination of the eigenvalues by a selection process of limited solutions. Of course, due to the

DOI 10.1007/978-981-4560-75-7_88-1

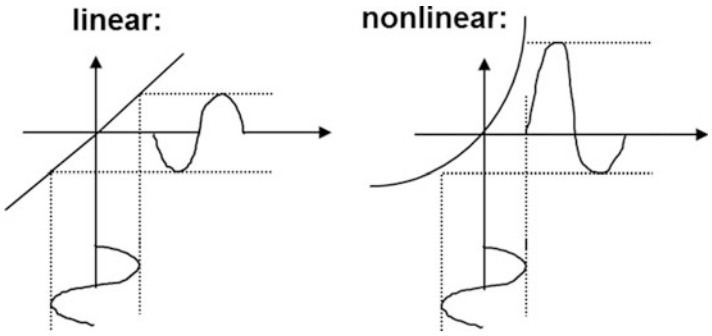

Fig. 45 Linear and nonlinear transfer function and signal

limitation of granularity, the maximum capacity according to the "waterfill principle" cannot be fully achieved.

MIMO operation in the sense of spatial duplex shows good performance if the following provisions are fulfilled: (a) high signal-noise ratio, (b) uncorrelated paths and/or channels, and (c) limited time variance of the channels. The selection of MIMO operation or operation with only one data stream – which is equivalent to a beamforming mode – can be carried out in parallel, while the Rx processing with a rake receiver takes place. Thus, the operation can be switched during a running connection to the best fitting mode. If the signal-to-noise ratio becomes too small, the beamforming operation typically shows better results than the MIMO mode. This is especially true for dynamic modulation schemes: the beamforming gain also increases the signal-to-noise ratio and leads to a higher modulation efficiency.

Passive Intermodulation

Intermodulation is a well-known issue in active component design like amplifiers or mixers. Nevertheless, also in passive components intermodulation becomes relevant if these devices operate within receiving and transmitting signals at the same time. Then the difference of the power levels can be more than 150 dB, which requires extreme linearity of the components in the signal path. If a CW signal is transmitted using a nonlinear device, the sinusoidal function will be changed into a new time-dependent signal, which can be expressed as a series of new sinusoidal functions with higher frequencies.

The mathematical derivation of the intermodulation level is given as follows (Fig. 45):

The output signal $i(t)$ can be written as the response of the two-tone input signal $u(t)$ as

$$u(t) = A \cdot \cos(\omega_1 t) + B \cdot \cos(\omega_2 t)$$
$$i(u) = a_0 + a_1 u + a_2 u^2 + a_3 u^3 + \ldots a_N u^n$$

The third-order term is then

$$a_3 u^3 = a_3 (A^3 \cos^3(\omega_1 t) + 3A^2 B \cdot \cos^2(\omega_1 t) \cdot \cos(\omega_2 t) + \ldots$$
$$\ldots 3AB^2 \cos(\omega_1 t) \cos^2(\omega_2 t) + B^3 \cos^3(\omega_2 t))$$

Considering the frequency $2\omega_1 + \omega_2$,

we find

$$1.5A^2 B\{\cos \omega_2 t + 0.5[\cos(2\omega_1 + \omega_2)t + \cos(2\omega_1 - \omega_2)t]\}.$$

Expressed in logarithmical scale, this is evident to

DOI 10.1007/978-981-4560-75-7_88-1

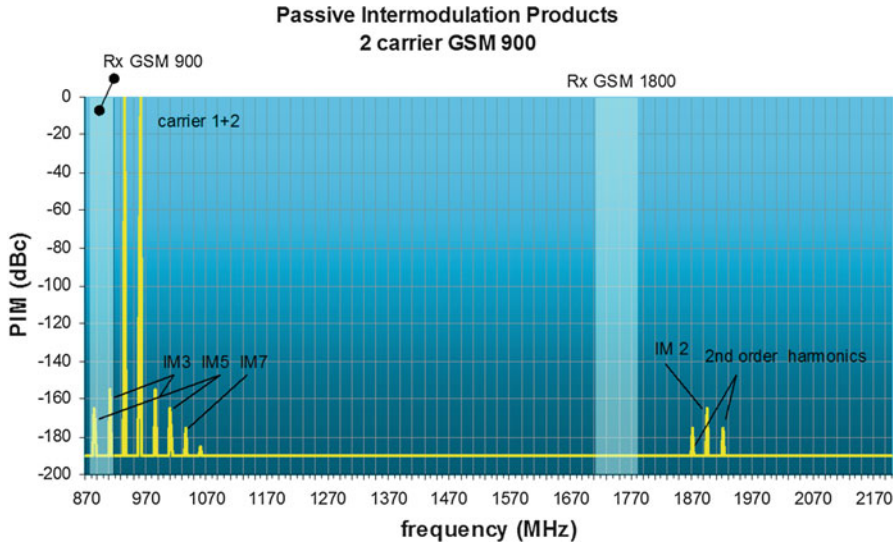

Fig. 46 Two-tone carrier intermodulation products

$$IM_3(2\omega_1 - \omega_2) \sim \log\left(3a_3A^2B/4\right) = \log(3a/4) + 2\log A + \log B$$

$$IM_3(2\omega_2 - \omega_1) \sim \log\left(3a_3AB^2/4\right) = \log(3a/4) + \log A + 2\log B$$

For equal signal levels for both frequencies, this results in

$$IM_3(2\omega_1 - \omega_2) \sim \log\left(3a_3A^3/4\right) = \log(3a/4) + 3\log A$$

For equal signal levels of the transmitting carriers at f1 and f2, it can be seen that the intermodulation level will rise three times faster compared to the input level in logarithmic scale in decibel. This means that if the input level of both transmitting carriers increases by 3 dB, the intermodulation level of the third order will increase by 9 dB!

In Fig. 46, the intermodulation carriers for a two-tone system is shown. The new spectrum of the intermodulation carriers consists of odd and even order spectrum, as the odd order spectrum of the third, fifth, and seventh order can fall into the receiving band of the relevant equipment. So the odd order intermodulation is the most relevant for the distortion of the receiving signals.

The situation becomes more complex when dual-band antennas are considered. Here, the second-order harmonics or second-order intermodulation products can potentially be relevant in the receiving band. This is shown in Fig. 47 for a dual-band antenna. Nevertheless, measurements have shown that the second-order intermodulation products in passive equipment are typically significantly lower compared to the third-order products. A general dependency of the levels of the different intermodulation products is shown in Fig. 48. The noise limited sensitivity of a receiver with a noise figure of 3 dB in 1 MHz bandwidth can be evaluated:

$$\begin{aligned} Noise &= NF \cdot kT\Delta f = NF \cdot 1.38 \times 10^{-23}\text{J/K} \cdot 290\ \text{K} \cdot 1\ \text{MHz} \\ &= NF \cdot 400 \times 10^{-23}\,Ws \cdot \text{MHz} \\ &= NF + (-174\ \text{dBm/Hz} + 60\ \text{dB}) \\ &= -111\ \text{dBm} \end{aligned}$$

DOI 10.1007/978-981-4560-75-7_88-1

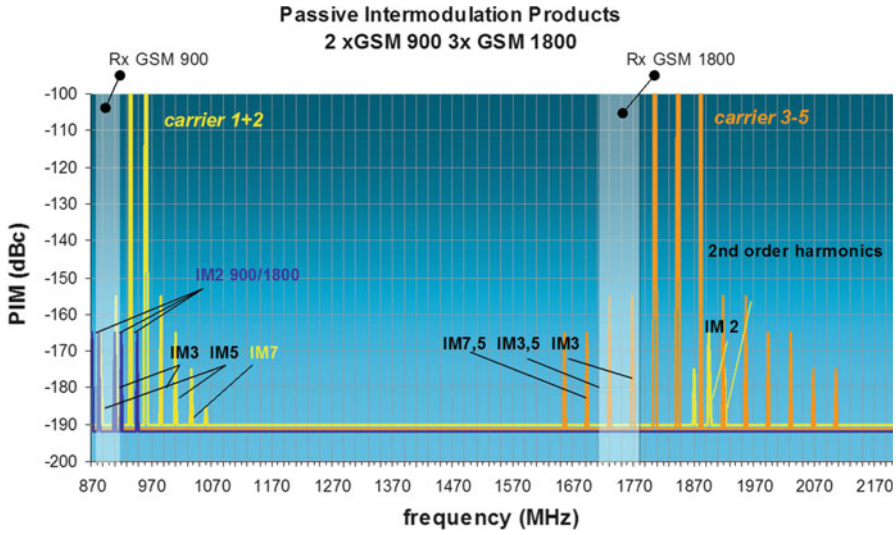

Fig. 47 Intermodulation products of dual-band equipment for 900 and 1800 MHz bands

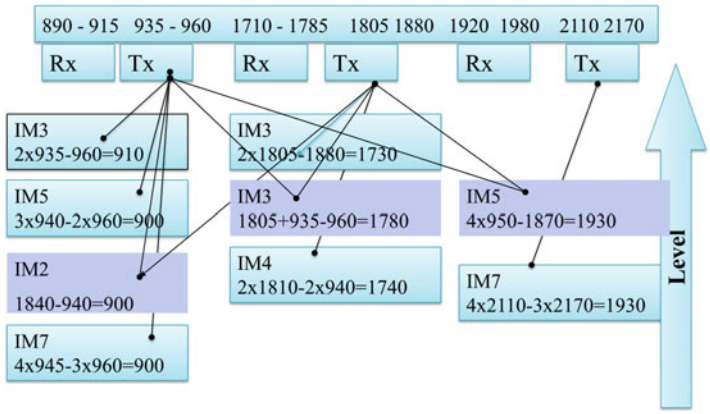

Fig. 48 Schematical level of different intermodulation products

This very hard intermodulation requirements result from the parallel operation for transmitting with typically 20–50 W (which is equivalent to 43–47 dBm) and the receiving sensitivity near to the noise floor with approximately −110 dBm, so the typical level differences are around 150–170 dB.

For an operation bandwidth of 200 kHz within a GSM system, the thermal noise level is −121 dBm (!) and the transmitting level is +43 dBm, which results in a theoretical requirement of −164 dBc. In praxis, the noise level is higher, due to feeder cable losses and jumpers. Assuming therefore that the typical noise figures of the system are approximately 10 dB and there is a higher system bandwidth, the antennas are typically specified with –150 dBc, which is good enough for most applications. Nevertheless, if the intermodulation level exceeds −140 to −130 dBc, this will cause a significant degradation in the sensitivity of the system.

The level increases from one odd order to the next by approximately 8–12 dB; this means if a third-order level of −140 dBc is measured, a fifth-order level of approximately –150 dBc can be expected. The difference depends of course on the special kind of transfer function; nevertheless, these values are typical measured figures. Passive intermodulation is one of the biggest challenges for the production and development practice of base station antennas and related equipment. Careful design of all contacts and

DOI 10.1007/978-981-4560-75-7_88-1

selection of the proper materials are essential to achieve highly linear behavior of the signal path. The sources of the passive intermodulation can be divided into two classes: material-based sources and contact-based sources. The use of the wrong material can include the use of steel or ferromagnetic material, pollution in plastic spacers and surfaces, and the use of nonlinear conductive material. So often, silver-plated surfaces, tin-plated surfaces, copper, and aluminum are used to achieve good intermodulation behavior. However, the use of aluminum is often sensitive with regard to any contacts, as the surface of aluminum oxidizes very fast in contact with air and humidity.

Antenna Line Devices

Antennas are strongly related to the electronic transmitting and receiving equipment. Currently, there is a clear tendency to integrate the electronics into the antenna or to put the electronic equipment, such as amplifiers, close to the antenna. Special control equipment for the steering of the tilt of the antenna, the so-called remote electrical tilt (RET), is commonly used. In state-of-the-art communication systems, the properties of an antenna system cannot be considered for itself anymore, as the parameters of the antenna array influence the system behind it and vice versa. Thus, it is of very high importance for the design of an antenna to basically understand all features and requirements of the system in which the antenna is operating.

Remote Electrical Tilt (RET)

For about 15 years, the remote control of the electrical downtilt has been commonly used for base station antennas. The success of this technology was driven by a worldwide standardization of the control interface in the Antenna Interface Standards Group (AISG 2006). Later, this standard was implemented and extended in certain parameters in the 3rd Generation Partnership Project (3GPP 2006). Whereas in the 3GPP only the RET functionality is standardized, the AISG also supports the interface to other ALD equipment, such as TMAs, sensors for location, and much more. The advantage of the AISG is also that the implementation of specific parameters, such as connectors or supply voltages, is standardized.

The steering of the tilt is provided by passive phase shifters inside the antenna. These phase shifters control the phase of the radiators in such a way that the resulting tilt of the antenna points to the desired direction. The principle for an antenna consisting of five radiators is shown in Fig. 49. It can be seen that for the outer radiators, the phase shift is twice as big as for the inner radiators, while the middle radiator will remain at a constant phase. Due to intermodulation requirements, no electronically operated phase shifters are used, but only passive phase-shifting devices. The principle construction of an example of such passive phase shifters can be seen in Fig. 50.

As the picture shows, the phase shifter is constructed using a microstrip or triplate structure, typically with a nominal impedance of 50 Ω. If the impedance at the end of the arcs is well matched to 50 Ω, then the impedance at the connection of the lever and the arc will remain constant at 25 Ω. The lever, together with the capacities at the connection points at the arc and the rotation center, realizes the transformation as a kind of quarter-wave transformer to achieve again the 50 Ω matching at the input of the phase shifter. In a first development, a combination of two 3-way phase shifters was used. Here, a gear for the rotation speed of the first phase shifter for the outer radiators and for the inner radiators has to be used. A schematic realization is shown in Fig. 51.

In the last few years, new kinds of phase shifters have been developed. In a first step, the 3-way phase shifter was extended to an n-way phase shifter, consisting of more than one arc (Göttl et al. 1999). An example is shown in Fig. 52. This phase shifter realizes, in addition to the phase shift in the right relation

DOI 10.1007/978-981-4560-75-7_88-1

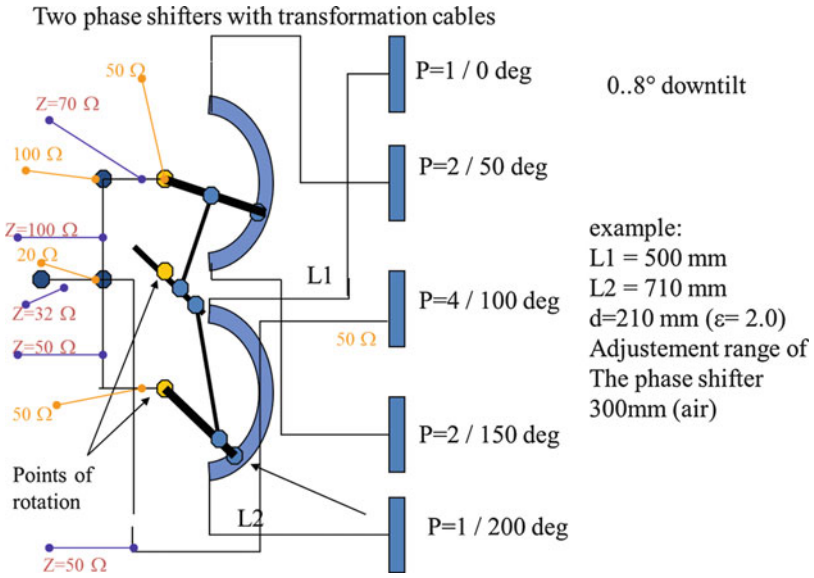

Fig. 49 Phase shifter arrangement for electrical tilt

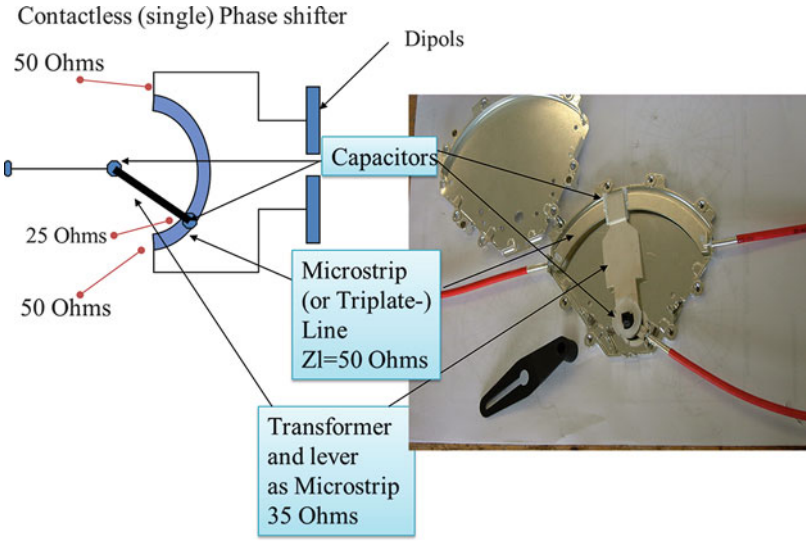

Fig. 50 Principle of contactless phase shifter for three radiators

for the inner and outer radiators, a matched power distribution for the radiators. This can be adjusted by the shape of the lever, the coupling sections to the arc, and the distance of the spacers.

In the meantime, phase shifters are now used with 3, 4, and 5 arcs which can serve up to 11 radiators, working under the same principle.

To drive these phase shifters, motors with control electronics are used. These motors can be integrated into the antenna; however, at the beginning of the use of RET systems, the motors were mounted as upgrade equipment at the bottom of the antenna. Such an upgrading device from the KATHREIN company is shown in Fig. 53. This device is compliant to the AISG specifications, see AISG (2006).

The RET devices have to fulfill a number of requirements: lifetime and failure probability, which is expressed in MTBF values; number of driving cycles; lightning protection; and the operating temperature

DOI 10.1007/978-981-4560-75-7_88-1

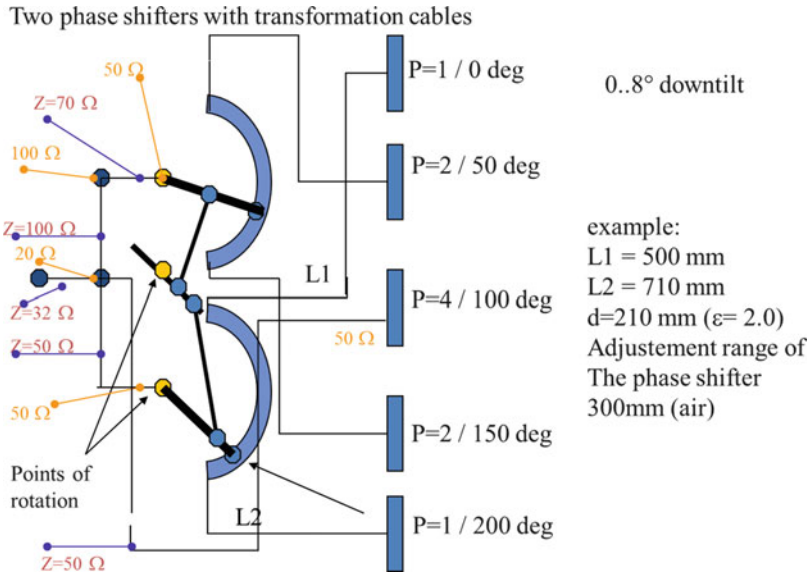

Fig. 51 Phase shifter arrangement with two 3-way phase shifters

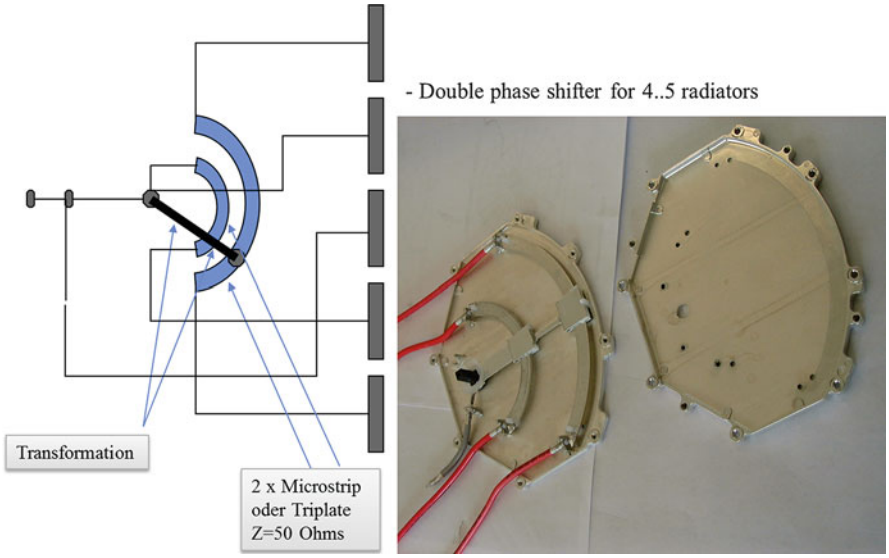

Fig. 52 Double phase shifter design

range from −40° to +50° ambient air temperature. The required number of driving cycles is 10,000–50,000. Nevertheless, the RET functionality is often used to adjust the tilt of the sites in the network, based on measured field results or statistical results in the quality figures of the network.

The beamsteering of the antennas can also be extended to the adjustment of the azimuthal direction. The optimization of both tilt and azimuth gives the best results; however, the misaligning in the azimuthal direction seems not to be so significant, and this is why the RET functionality is commonly used, and the azimuthal remote adjustment is only used in special applications.

Two possibilities exist for implementing the control of the AISG interface: one is the use of separate cables for the power supply and control signal and the other is to use the existing feeder cables for the DC power supply and the control signal. A principal arrangement of such control is shown in Fig. 55. In this

DOI 10.1007/978-981-4560-75-7_88-1

Fig. 53 Device for upgrading remote electrical tilt (RET)

case, smart bias tees are used, which transform the signal onto the twisted pair cable. The RS 485 interface is added to the pilot signal with on/off modulation scheme on the feeder cables (AISG 2006; 3GPP 2006).

Tower-Mounted Amplifiers (TMAs)

Tower-mounted amplifiers are widely used equipment in base station antenna applications. These amplifiers are implemented into the feeder cable between the base station and the antenna. The device amplifies the receiving signals within the relevant band of operation. Different arrangements are shown in Fig. 56. If the feeders are using Tx and Rx in combination, then the amplifier needs duplex filters to separate the transmitting and receiving signals by means of filters as sketched in Fig. 57.

As typically two separate polarizations for diversity purposes are used, the TMAs are realized as double units, so-called double tower-mounted amplifiers (DTMAs). The challenges here are low insertion loss, combined with the required isolation for the Rx path. To not overdrive the Rx amplifier, the linearity of the Rx low noise amplifier (LNA) has to be designed in a matched manner as the Rx filter stop attenuation in the Tx range has to be sufficient, to reduce the rest of the Tx signal at the Rx amplifier so that any intermodulation products are suppressed. An additional requirement in the Rx range is the stop attenuation in the Tx chain regarding the Rx frequencies, to prevent any ripple in the Rx band by the closed loop of the amplifier and to prevent oscillation in any worst case. So typical isolation requirements of 50–70 dB have to be realized in the input of the Rx amplifier and 40–60 dB in the output of the Rx amplifiers. The insertion loss is in the range of 0.2–0.5 dB, and the noise figure is typically in a range between 1.0–2.0 dB.

The TMAs also had to fulfill passive intermodulation requirements of typically −160 dBc at 2 × 20 W transmitting power. The design of the filter components of the TMAs as well as the other ALD devices depends on the following major requirements: (a) the insertion loss, (b) the isolation, (c) the maximum power, and (d) the linearity. Therefore, so far the power requirements have only been fulfilled with coaxial air-filled cavities, ceramic block cavities, or wave guide types. SAW or FBAR filters are not usable due to

DOI 10.1007/978-981-4560-75-7_88-1

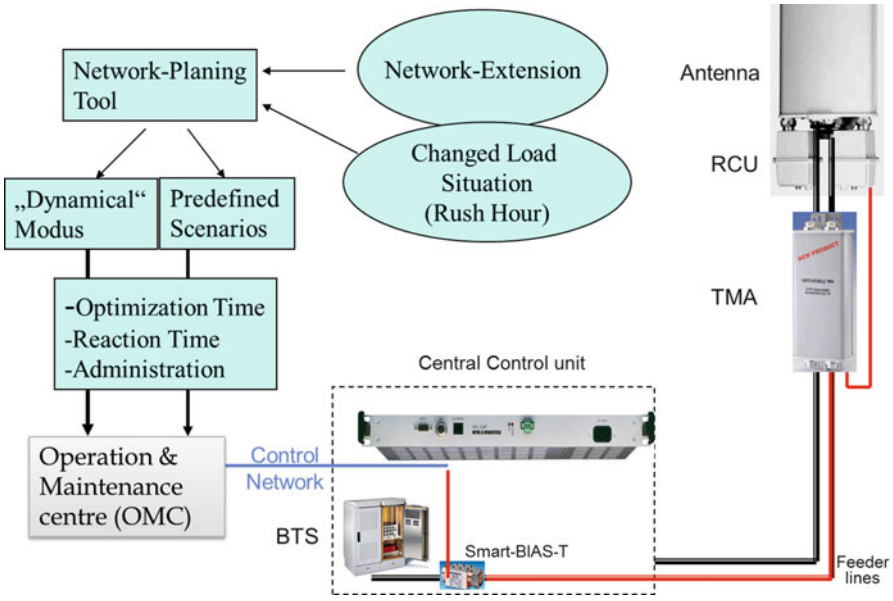

Fig. 55 RET control arrangement for different scenarios

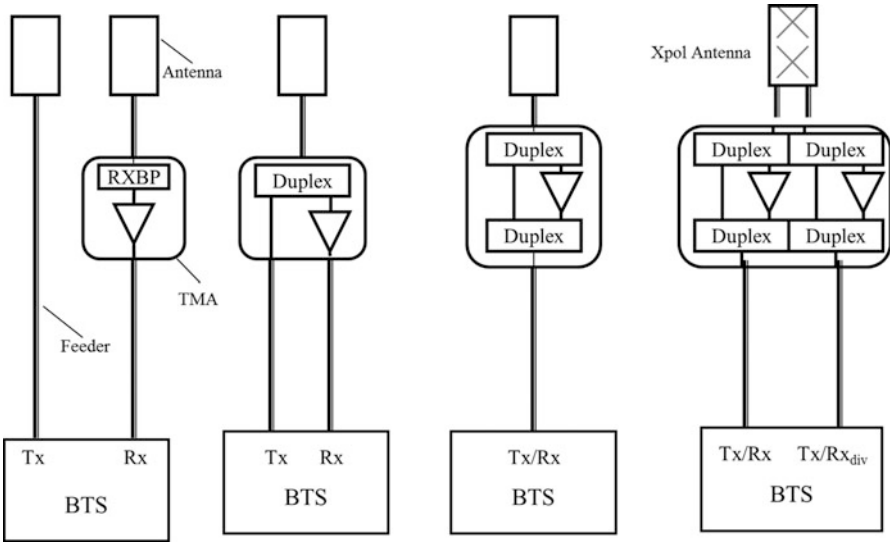

Fig. 56 Different tower-mounted amplifier arrangements

insertion loss, linearity, and maximum power requirements. Monoblock ceramic filters are currently under discussion; nevertheless, the insertion loss is still a little higher compared to air-filled types or block ceramic types (as puck or sphere). A typical filter in a coaxial realization as a part of a TMA is shown in Fig. 58.

The number of cavities that has to be used depends on the required Rx–Tx isolation; the duplex frequency distance, especially the gap between the Rx and the Tx band; and the required insertion loss. In order to fulfill typical requirements of today's TMAs, 6–8 cavities for every part of the Rx and Tx filtering are necessary.

DOI 10.1007/978-981-4560-75-7_88-1

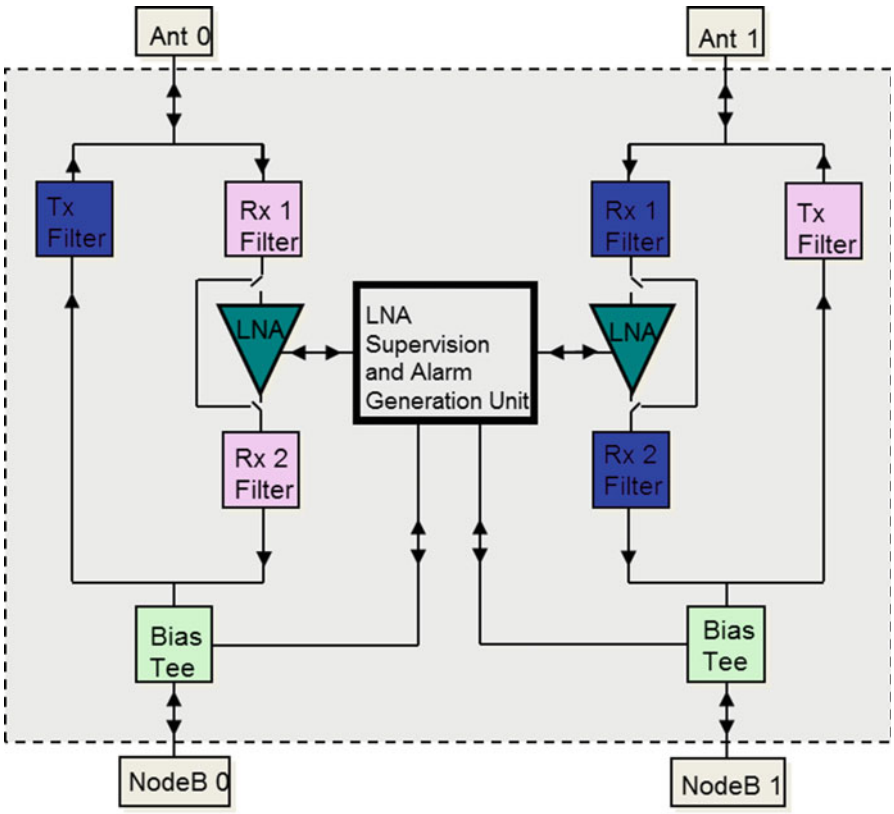

Fig. 57 Principle design of a DTMA

Every cavity of the filter has to be tuned to the right resonance frequencies. Since the manufacturing tolerances do not allow a production of the cavities for just the right resonance frequency, special tuning elements are required for every cavity and also for the coupling between those cavities. In the example shown in Fig. 58, these tuning elements consist of metallic rods, which are moved with a thread in the lid of the cavity. Here, the design of the contact between the rod and the lid is essential regarding the intermodulation parameters.

Filter Combiner

Often, one antenna is used for more than one base station. This can be the case to combine different frequency bands, as well as to combine different operators at the same band or at different bands. Here, frequency selective combiners are used; an example is shown in Fig. 59. Combiners are typically used in the same environment as the antennas; therefore, the same strong parameters are valid regarding the environmental resistance. The combiners have to carry the transmitting and receiving signals and therefore have to fulfill the typical requirements of a low passive intermodulation design. Nevertheless, the isolation can be reduced compared to the isolation of duplex filters. Here, no selection of receiving and transmitting signals is required, but rather the selection of two different frequency bands. Typical isolation requirements should be comparable to the use of two different antennas, as an alternative solution. Thus, 40–60 dB is reasonable for the isolation. For the use of high power up to 200 W, the design is based on standard coaxial resonators as shown in Fig. 58.

Active Antennas

Remote Radio Head (RRH)

Remote radio heads are used to place the transmitter and the receiver near to the antenna and therefore to avoid additional losses in the feeder cables. This increases the available transmitting power at the antenna, the efficiency, and the sensitivity of the whole system. Challenges are the required reliability and the environmental conditions. Compared to the base station equipment, which is typically located in

DOI 10.1007/978-981-4560-75-7_88-1

Fig. 60 RRH 1×60 W WCDMA 2100 MHz

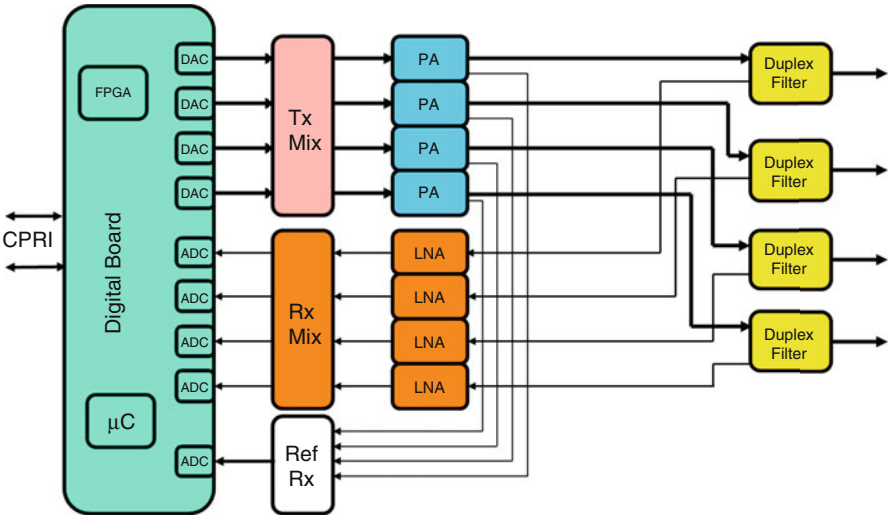

Fig. 61 Principle design of RRH

air-conditioned shelters, the RRHs have to withstand temperature range of −40 °C to 60 °C, vibrations, rain, salt mist, and all other difficult issues within the outdoor base station environment. Due to the limited efficiency, the dissipation power has been dissimilated, and this is one of the biggest design challenges regarding the size of the RRHs (Fig. 60).

In Fig. 61, a principle scheme of an RRH with four Tx and Rx chains is shown. The digital input is typically based on a fiber optical connection. One or two optical lines can be used for the transmitting and receiving signals, depending on the protocol used. Certain protocol standards are used, such as CPRI (Common Public Radio Interface), OBSAI (Open Base Station Architecture Initiative), and ORI (Open Radio Interface). The ORI standard is supported by ETSI (European Telecommunications Standards Institute), whereas the others are widely used industrial standards. The most commonly used standard today is the CPRI interface.

The digital board in Fig. 61 with the microcontroller and FPGA has the following main functions: (a) de-multiplexing of the incoming and multiplexing of the receiving signals into the CPRI data stream, (b) level adjustment and crest factor reduction (CFR) of the transmitting signal, (c) linearization and digital predistortion (DPD), and filtering of the spectrum. The signals then will be transferred into the

DOI 10.1007/978-981-4560-75-7_88-1

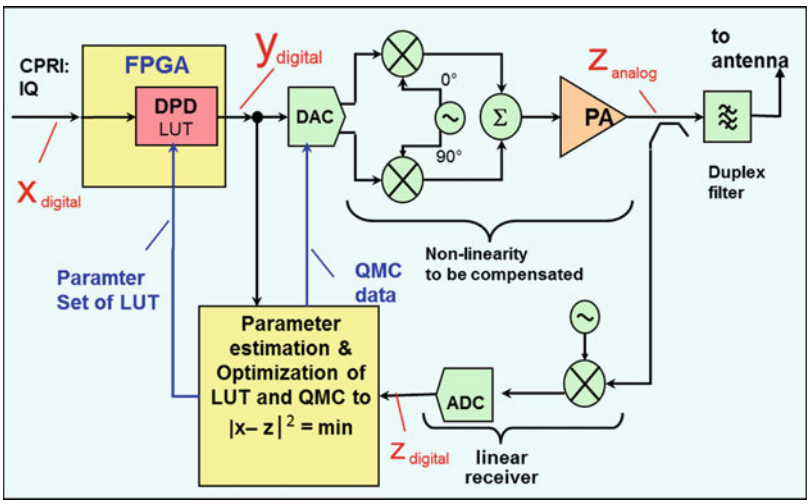

Fig. 62 Principle structure of a digital predistortion

analogue domain by digital analogue converters and mixed into the original frequency band by means of a mixer. Typically, the signals are divided into an inphase and quadrature phase part and mixed by means of a quadrature mixer. The inverted principle is applied for the Rx chain, with the exception that no CFR and DPD are needed. For the DPD, a reference signal is needed from the output of the power amplifier to determine the correction values.

In Fig. 62, the principle of a DPD is shown. Samples of the signal of the power amplifier output are taken, transferred into the digital domain by an analogue digital converter to a signal y, and these samples will be compared with the original input signal x. Different principles are then used to solve the optimization problem for the minimum difference of x and y. One possibility is a "Look-Up Table," LUT, in the FPGA, by means of which the original input signal x is predistorted to then achieve the desired output signal. It is important to know that the problem is a nonlinear problem as the behavior of the amplifier also depends on the history of the signal. For an effective correction, this time-dependent transfer function of the power amplifier has to be taken into account. Often, Volterra sequences are used to describe the transfer function. Other approaches use a nonlinear model of the amplifier to compare the calculated nonlinear signal with the real output signal. Then the minimum deviation between x and y is achieved by tracking the determined coefficients.

In addition, the correction of the DC part and symmetry of the mixer is required, which also causes a disturbed signal. This is corrected separately by adjusting the quadrature mixer correction (QMC).

RRHs increase the power efficiency and the sensitivity of the communication system. Table 2 shows typical figures. Here, it can be seen that the total power efficiency is dramatically higher, and the sensitivity of the site shows significantly better performance. For the calculation of the figures, an attenuation of the feeder cables of 3 dB is assumed, the jumper cables to the antennas have an attenuation of 1 dB, and the noise figures of the TMA and RRH have been determined to be 2 dB. The attenuation of the TMA is considered to be approximately 0.3 dB and the noise figure of the base station to be about 2–4 dB. The higher noise figure of the system with a TMA is caused by the limited amplification of the TMA, so the other noise contributions in the signal chain still increase the noise.

It can be seen that the RRH shows the best performance for the system regarding the sensitivity and power efficiency. That is one driver for the integration of the RRH into the antenna.

DOI 10.1007/978-981-4560-75-7_88-1

Table 2 Comparison of sites with TMA, RRH, and legacy technology

Parameter	Conventional system	System with TMA	System with RRH	System with antenna-integrated RRH
Transmit power at device output	2×60 W	2×60 W	2×40W	2×40 W
Transmit power at antenna	2×24 W	2×22W	2×32W	2×40 W
Input power (DC/AC)	∼700 W	∼710 W	∼400 W	∼400 W
Total power efficiency	6.9 %	6.2 %	16 %	20 %
System noise figure	6..8 dB	3.5 dB	3 dB	2 dB

Antenna Integrated RRH

The steps towards the integration of electronics into the antenna are the logical consequence of improving the efficiency and sensitivity of the system. Nevertheless, the acceptance of electronic integration was strongly related to the reliability of the integrated components. This is true regarding all the already mentioned active antenna line devices, such as TMAs, RET, or RRHs. In the last few years, an acceptable level of reliability has been achieved by careful design of the electronic parts, including a higher integration level and increased power efficiency of the power amplifiers. Therefore, today's equipment shows MTBF values of at least 100,000–200,000 h for RRHs and 500,000 h for DTMAs. Of course, the calculated MTBF values do not exactly reflect the expected lifetime, but they are an important indicator. A great influence is the operating temperature, which is of course much higher in the RRHs than in the TMAs due to the higher dissipation power. Therefore, careful design with regard to the thermal flow is required. In Fig. 63, an antenna with an integrated radio is shown (Antenna Integrated Radio, AIR).

Adaptive Active Antenna (AAS)

For many years adaptive antennas with beamsteering technologies have been discussed. These antennas are called "Smart Antennas" or "Adaptive Antennas." The principle consists of the flexible control of the magnitude and phase of every radiator or of groups of radiators. The principle is well known and is already used in other fields of antennas. For instance, in RADAR systems active antennas with beamforming technologies have been used for many years.

However, the first commercially available realizations for mobile communication systems with FDD had only limited success due to the lack of acceptance in the market. This was mainly caused by costs, reliability, and low efficiency of the antennas realized. For TDD systems, AAS has been used for a couple of years; here, the advantage of the TDD for the exact determination of the direction of arrival (DoA) and the parallel use of the calculated coefficients for Rx and Tx are helpful.

In Fig. 64, a principle structure of such an AAS for FDD operation is shown.

It can be seen that every radiator has its own receiver and power amplifier, together with a duplex filter. For simplification of the mixers, PLLs are not shown in detail; the structure of every RF path is very similar to the structure of an RRH. Of course, the power is smaller compared to the RRH, as the total transmitting power is the sum of the transmitting power of each single radiator. The main functions of the digital part consist in the synchronization and calibration of the phase of the signals at every radiator. This can typically be combined with the signal for the linearization of the power amplifiers. The reference signal for linearization and calibration is selected by means of a coupler from the output of the power amplifier. The correction of the phase, the synchronization, and the digital predistortion for the amplifier linearization can be implemented by central signal processing, if a common board for all the different amplifiers is used – or alternatively separately at the amplifier modules. Nevertheless, to achieve coherent signals at the output of the modules, at least a synchronization of the PLLs and the control of the phase of different modules have to be implemented.

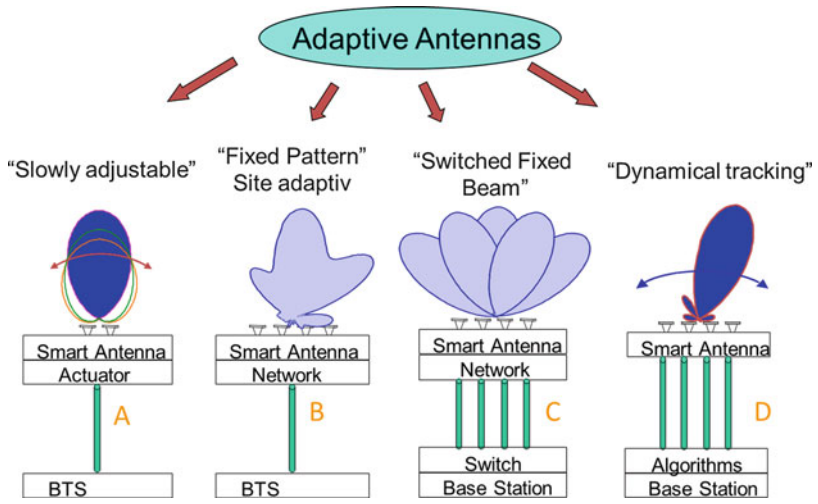

Fig. 65 Different realizations of adaptive antennas

Beamsteering Technologies

The big advantage of adaptive active antennas (AAS) is the ability of user-specific beamsteering to receive and transmit signal. The implementation of beam control can be realized in open- or closed-loop configurations. Open-loop configuration realizes the determination of the direction of arrival (DoA) and approximates the direction of the transmission beam from the calculated coefficients for the DoA of the incident waves. Different possibilities of beamsteering possibilities which are considered as beamsteering antennas or "smart antennas" are shown in Fig. 65.

Simple forms are slowly adjustable antennas, where adjustable phase shifters for multi-column antennas or moveable parts of antenna reflectors can be used. Smart antenna networks use site-specific distribution networks inside antenna arrays. METAWAVE has proposed special solutions in this field (Feuerstein 2001). Nevertheless, the use of such antennas was not widely accepted. Switched fixed beam antennas were demonstrated in successful arrangements. The beamforming procedure is simplified compared to dynamic beamsteering, whereas the results in gain of capacity are not so far from the gain with dynamic beamsteering implementation. The dynamic tracking operation is based on a DoA estimation and a following well-defined beam. All these algorithms are based on a maximization of the desired signal. What is neglected here is the influence of undesired interferers. Taking this into account, the solution may differ from only maximizing the signal. The principle is shown in Fig. 66.

It is obvious that the optimization problem consists in maximizing the signal-to-noise ratio; this is to use a maximum ratio combiner for the adaptive antenna. The problem is well described in literature (Viberg 2005). For isotropically distributed noise, the solution just results in the optimum coefficients for the desired direction of the incident signal. The solution becomes simple for the simplified problem of only one incident planar wave. Assuming that in Fig. 67 the distance r is big enough, then the incident angle will be the same for all antenna elements. In an even more simplified approach, it is assumed that the characteristics of the antenna elements are the same, and the path loss is normalized to one; it can be denoted for the incoming signals at the antenna elements:

$$y = \sum_{i=1}^{n} w_i(x_i + n_i) \quad = s \cdot \sum_{i=1}^{n} w_i C_i(\varphi) \ \exp(-jkr_i) + \sum_{i=1}^{n} w_i n_i$$

If a_s is considered as the normalized vector of incident waves, w is the steering vector of the antenna array, and n is the noise vector, the optimum solution is just given simply by

DOI 10.1007/978-981-4560-75-7_88-1

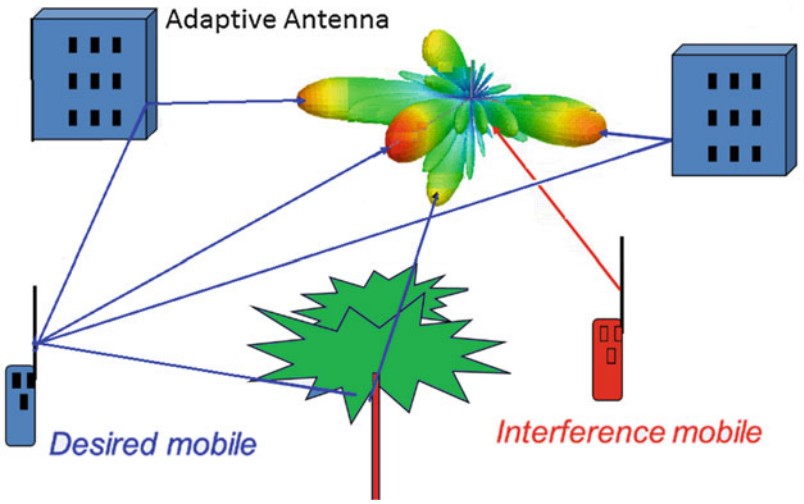

Fig. 66 Adaptive antenna with interferer

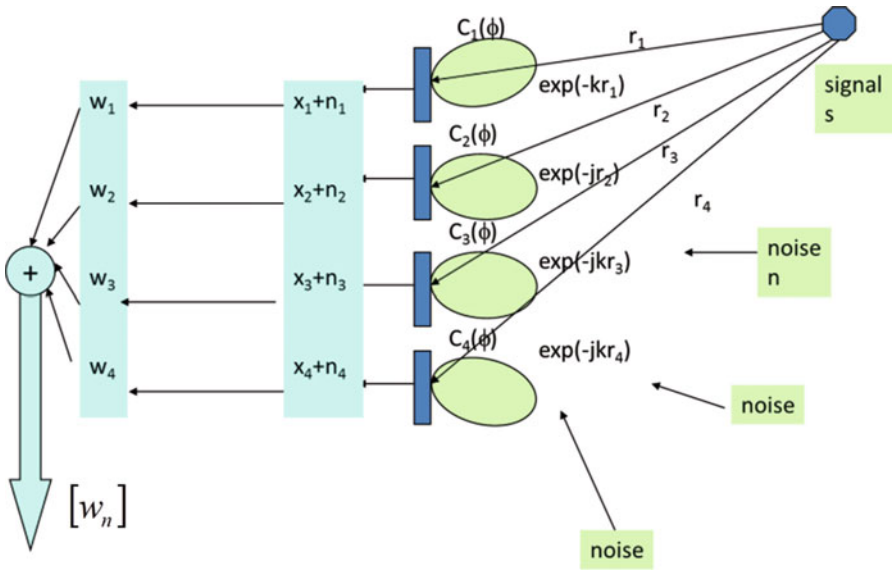

Fig. 67 Schematic beamforming arrangement of an adaptive antenna

$$[w_{opt}] = [x]^*$$

This means that the conjugate complex steering vector of the signals of the incident wave front is required. This is evident, as the resulting beam points exactly in the direction of the incident wave. The realized steering vector $[w]$ realizes a matched spatial filter.

For non-isotropic distributed interferers, the optimum solution depends on the angle-dependent interference. A matched filter then is realized as

$$[w_{opt}] = c \cdot \left\| R_N^{-1} \right\| [x]^*$$

Where R_N is the covariance matrix of the interference signals, $[x]^*$ is the optimum steering vector for the desired incoming signal, and c is a scalar coefficient. This equation is also well known as Wiener–Hopf

DOI 10.1007/978-981-4560-75-7_88-1

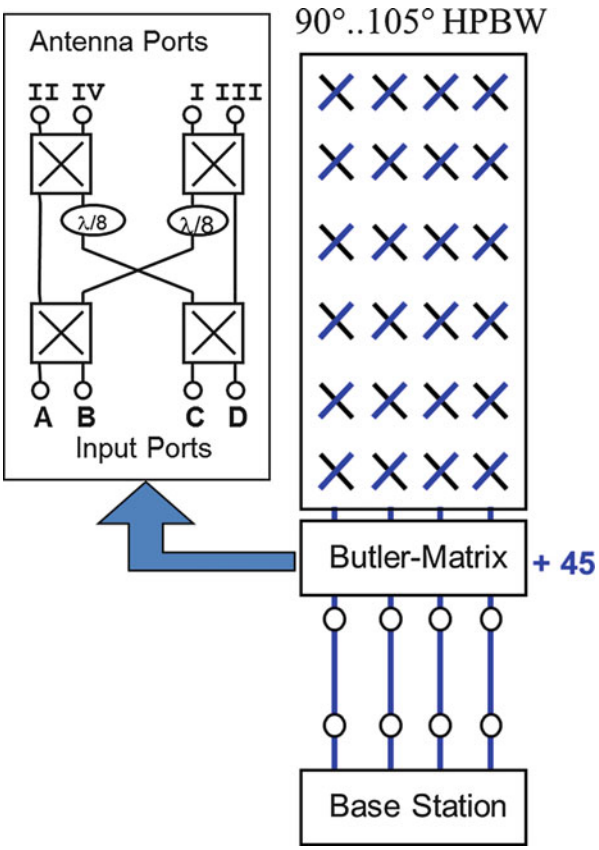

Fig. 68 Beamforming antenna with Butler matrix

equation; see also Konrad (2003), Vega and Rey (2013). The implementation of this algorithm takes the interferer into account and tries to shift a null in the resulting characteristic into the direction of the interferer. This algorithm is also called zero-forcing beamsteering.

Nevertheless, as the incident waves and the interferer are not known per se, different optimization algorithms have to been employed.

Another possibility is the implementation of switched fixed beams. This is typically based on the approach with isotropical interferers. Nevertheless, some interesting hardware implementations exist, e.g., through hardware butler matrixes. In Fig. 68, an antenna with a butler matrix is shown; the input ports and antenna ports produce 4 different beams, whereas the input ports are decoupled. The butler matrix consists of four 3 dB 90° couplers which are connected as shown in Fig. 68. Two additional 45° phase shifters are required in two connection lines, and then four independent beams can be obtained. Nevertheless, the isolation of the ports is limited by the 3 dB couplers used and the reflection of the input ports of the antenna.

MIMO Implementation

The realization of MIMO can be based in principal on the same antenna configurations as for diversity and/or beamforming systems. However, for MIMO implementation-specific restrictions have to be considered:

(a) FDD systems use different frequencies for receiving and transmitting. Therefore, the coefficients for transmitting operation have to be approximated from the coefficients of the DoA at the Rx frequency. This principle only works for a dominant path from the mobile to the base station which has similar

DOI 10.1007/978-981-4560-75-7_88-1

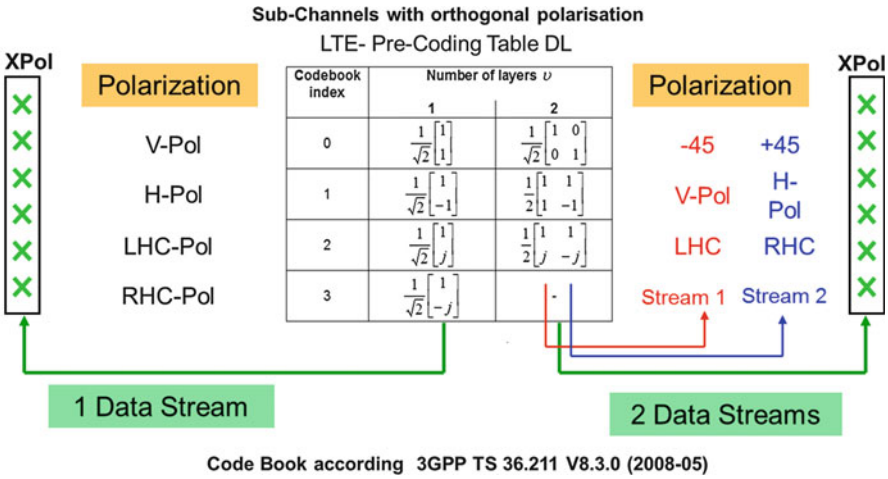

Fig. 69 Code book for two transmission paths resulting in a polarization control

properties for both frequencies. This excludes, for instance, reflections, scatterers, or indirect paths, which have strong frequency-dependent behavior. Also, the duplex distance should not be too big. The phases for transmitting have to be derived from the receiving coefficients, typically by a calculation of a direction of the main incident waves. Based on the determined direction, in a second step the coefficients for the transmitted waves are calculated, which also require an exact calibration of the antenna array.

(b) For TDD systems, the procedure is simplified, as the determined coefficients of the optimum received configuration can be used directly for the transmission. Here, only the time variation of the channel changes path; nevertheless, for short switching times in the ms-range, the constancy of the path is typically good enough.

(c) Closed-loop configurations overcome the problem of calibration and determine the optimum transmission and receiving coefficients by a feedback from the receiver for a given test sequence. The transmitters transmit agreed combinations of coefficients, a so-called code book, and the receiver gives feedback about which code book should be used for the following transmission sequence. The advantage is that by means of the test sequences, the whole transmission matrix from every transmitter to every receiving element can be determined, and the optimum capacity of the connection can be calculated by determining and selecting the right code. The procedure includes the option of MIMO transmission, as the code book can include the transmission of more than one signal stream. The disadvantage here is the limitation of the codes of the code book. So only a certain defined granularity of the code space can be used. In the 3GPP standard for LTE, an example is shown of the code book for a 4×4 system with corresponding beams for beamforming transmission and MIMO transmission (Figs. 69 and 70).

Future Trends

Today's mobile communication has become a key element of modern society, and smart devices are omnipresent: almost everybody communicates over mobile devices at home, in the office, and on travel. Most people use several devices in parallel – e.g., a smart phone, a laptop computer, and a tablet – to cover their needs of voice communication, data exchange, and Internet use (infotainment).

For example, cloud computing requires reliable connections and high data rates to ensure adequate access to this service. Moreover, machine-to-machine communication (M2M) is rapidly growing: new concepts like "Industry 4.0" describe the massive wireless interconnection of machines in a production

DOI 10.1007/978-981-4560-75-7_88-1

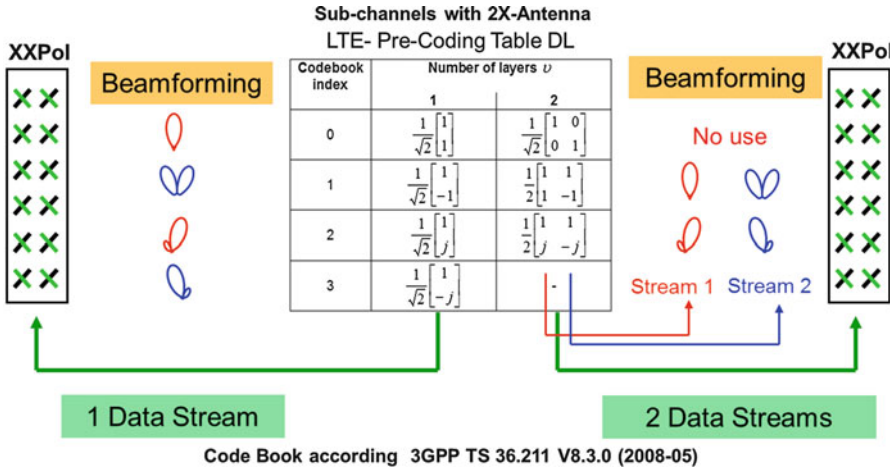

Fig. 70 Code book for two transmission paths resulting in a beamforming for 1 and 2 data streams

facility to enable intelligent, self-organizing production processes. All these aspects will lead to a rising demand in mobile communication coverage as well as throughput capacity enhancement.

Requirements and Challenges

The demand for mobile connectivity will dramatically increase in near future: people want to be connected all the time everywhere and want to use voice and data services to a large extend. These demands result in an ongoing increase of capacity worldwide: from 2008 to 2013, the global mobile data traffic grew by a factor of 45; a factor of 24 is projected for the period from 2010 to 2015. If these developments go on in this pace, the global mobile traffic might increase to extremely high levels, and a growth factor of even 1000 is expected in the 2020s in comparison to 2010 (NTT Docomo 2014; CISCO 2014).

The Vision of 5G

Based on these predictions, mobile communication experts are currently discussing possible architectures regarding a fifth generation network (5G) as follow up for LTE and LTE advanced (which are commonly labeled as 3.9G and 4G, respectively). In order to manage the expected growth and to define a well-suited network for the future demands, the following elements and strategies are discussed:

- **Network densification:** the number of mobile communication cells shall be dramatically increased, whereas the average cell size shall be reduced, so that the total capacity of the network significantly increases.
- **Active antennas:** active (or adaptive) antenna systems shall be an integral part of the cell architecture, so that the cell capacity and coverage can be dynamically adapted to the demand at hand.
- **Spectral efficiency**: the introduction of adaptive coding and higher-order modulation schemes together with smart antennas can lead to a better spectral efficiency and higher reuse factors in the network. This includes also new intelligent receiver architectures and better dynamic methods of interference suppression.
- **Massive MIMO**: in current LTE networks, 2×2 MIMO is widely used; 4×"X" and 8×"X" are already available on the base station side, but very seldom in use. Ongoing projects investigate if a massive use of MIMO with very high number of antennas can lead to a significant improvement of the average data rate in very small cells.

DOI 10.1007/978-981-4560-75-7_88-1

- **New frequency bands**: one of the key items in 5G investigations is the allocation of new frequency resources. As the frequency spectrum below 5 GHz is already occupied (and often congested) by many services, the main focus is on higher frequency bands: especially 30 and 60 GHz are promising candidates, as these bands offer potentially new very high capacity.

The so-called 60 GHz band is an unlicensed band reaching from 57 to 64 GHz, which theoretically sustains data rates up to 50 GBit/s. With respect to this number, it is no surprise that the allocation of higher frequency bands has become a key aspect for all investigations of 5G networks. At 60 GHz the wavelength is, however, only 5 mm, and this results into completely different network requirements and antenna architectures as compared to the established mobile communication standards (NTT Docomo 2014; CISCO 2014).

Antenna Systems for MM-Waves

Requirements

In order to start the discussion on mm-wave antennas, it is very helpful to look again at the Friis formula (see also section "Antenna Design for Base Stations"):

$$P_{R,\,mobile} = \left(\frac{\lambda_0}{4\pi R}\right)^2 G_T G_R P_{T,\,basestation}$$

The power received at the mobile depends on the transmitted power and on the gains of both the base station and the mobile, but also on the distance R and on the wavelength. When changing the frequency from 2 to 60 GHz, the wavelength changes by a factor of 30. Assuming that all parameters in the formula above would not change except for the wavelength, the power received at the mobile when going from 2 to 60 GHz would consequently be reduced by a factor of 30^2=900!

So it is obvious that achieving "reasonable" transmitting distances in the 60 GHz band is a demanding task. The key parameters for achieving an adequate link budget are the distance R on one hand and the antenna gains G_T and G_R on the other hand: if highly directive antennas are used, and the transmitting distance is limited to a short range, a sufficient level for the received power can be obtained. Therefore, most of today's scenarios at higher frequency bands foresee the use of short range only and the implementation of directive antennas on the transmitter as well as on the receiver side.

When the antennas are not omnidirectional but directive, it is essential in the case of moving users that the antenna beams dynamically follow the user's position. So looking at the antenna system requirements, the higher frequency bands do not only require highly advanced RF technology, but they also require the implementation of beamforming and automatic tracking capability on the base station side as well as on the mobile side.

The use of higher frequency bands results in the following challenges to be solved:

- **Use of directive antennas**: typical candidates are antenna arrays or reflector antennas.
- **Active smart antennas**: due to the high cable losses at the higher frequencies, the transceiver electronics have to be mounted rather closely to the antenna aperture.
- **High-density packaging technologies**: due to the short wavelength, the array grid becomes very small. Therefore, advanced high-density packaging technologies are necessary to realize active antenna front ends.
- **Beamforming and tracking**: because of the dynamic user scenario, the base station antennas (and the mobile antennas) need an automatic beamforming and tracking functionality. For regulatory issues,

DOI 10.1007/978-981-4560-75-7_88-1

high power transmitters require a beam with a very small HPBW, which dramatically increases the tracking accuracy requirements.
- **Thermal issues**: due to the high packaging density and the low efficiency of RF components at higher frequencies, the heat dissipation is a key topic in front-end design. In order to avoid liquid cooling, advanced technology concepts have to be developed to ensure an adequate temperature of the front end in function.

Besides these issues, currently the most realistic mobile transmission scenario is the line-of-sight connection over short and medium distances (up to several hundred meters). Non-line-of-sight signals will suffer from high losses at each reflection point of the signal, so that the received power will be quite low. Moreover, any obstacle, which is placed within the link, like a human body or any other objects will lead to significant losses, too. Also, the rain attenuation at 30 and 60 GHz can be very high.

So, the use of higher frequencies brings up demanding challenges in the area of antenna design and RF integration. However, the throughput potential in the higher frequency bands is so enormous that it makes sense to follow that path and to investigate the possibilities hereof. For specific scenarios in very small cells (picocells), the high bands have the potential to fulfill the high-throughput demands of the future. Another advantage within the higher frequency bands is the security aspect: the high path attenuation in combination with the use of directive antennas functions like a "spatial filtering": an unwanted listener can be excluded from the communication just by the dramatic reduce of power level in unwanted directions (Stevens and Graften 2012).

Beamforming Concepts

In order to realize a beamforming antenna, one could think of mounting a reflector antenna onto a mechanical multi-axis platform, so that the antenna beam can be mechanically aligned with any position of the receiver. However, this seems unrealistic in the case of 60 GHz base stations, as the mechanical systems suffer from high maintenance, resulting in limited lifetime due to the mobile user scenarios. Also, the required beam agility – the angular tracking speed that is needed to keep the narrow beam locked onto the desired target – is very hard to fulfill with a mechanical system. Moreover, the integration of a mechanical tracking platform in any mobile device like a laptop is simply unrealistic.

So the focus is on electronic beamforming, on the base station side, and on the mobile terminal side. Electronic beamforming antennas can be designed using different concepts: they can be realized as direct radiating active arrays or alternatively as active feed arrays in combination with a reflector or lens. In order to implement the electronic beamforming, three basic concepts can be used: switched beam, phased array, and digital beamforming (DBF) (Fig. 71).

- **Switched beam** means that beamforming networks are used, each representing a particular beam pointing into a certain direction. One can then switch between the different networks in order to point the antenna beam. As long as the number of beams is low, this method can be applied. One should however not forget that switches at higher frequencies can cause high RF losses.
- **Phased arrays** use analogue or digital phase shifters. These phase shifters allow modifying the phase of any antenna element or group, so that the beam of the array can be steered electronically. This concept is generally more complex than switched beam concepts, but the beamsteering is more flexible.
- **Digital beamforming arrays** consist of antenna elements, each of them having its "own" T/R electronic section, including up/down conversion. In this way, each antenna element signal is available at digital level, and the beamforming can be performed on digital baseband level. This technique is quite complex and requires both a large amount of active RF components and also significant processing power. However, this concept offers the highest beamforming flexibility.

DOI 10.1007/978-981-4560-75-7_88-1

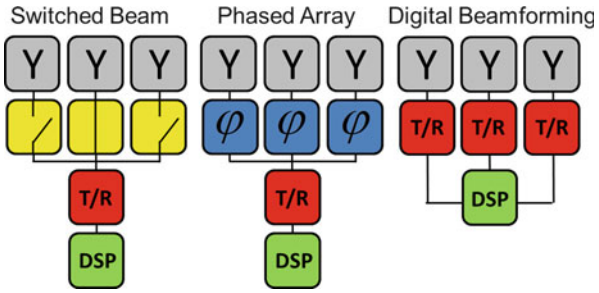

Fig. 71 Different concepts for electronic beamforming (T/R=transmit/receive Module, DSP = digital signal processor)

Before selecting one or the other technique, the requirements have to be carefully analyzed. Factors like the expected angular tracking range, the HPBW, the available size for the antenna, and the costs have to be analyzed. Very often, the different techniques are combined to arrive at an optimum solution in terms of performance, size, complexity, and cost for a given application.

Front-End Examples

Two examples of front-end realizations are presented here: the first example is a front end at 30 GHz. The RF front end of the system is built in LTCC (low temperature co-fired ceramics), which is a material suited for high-density multilayer electronics (Kulke and Uhlig 2010). The front end in Fig. 72 was designed within a German research activity (Holzwarth et al. 2009), and the design requirements were derived from future satellite systems. The front end consists of 64 antenna elements that are part of a 16-layer-LTCC module, including 64 active Tx channels and a calibration network. Liquid cooling channels are integrated within the ceramic material to ensure an adequate operating temperature. The front end is capable of full DBF transmit only at 30 GHz.

In Fig. 73, the measured far-field patterns are shown: the beamsteering of the module covers the region from boresight down to 60° in elevation. The beamforming shows excellent performance at boresight; towards lower elevation angles, the performance degrades due to the reduction of the effective antenna aperture and the characteristic of the antenna element.

Figure 74 shows another antenna front end that was realized in the 60 GHz band. In this case, the chosen technology was also LTCC (Sanadgol et al. 2010). The antenna module consists of 4×6 antenna elements, and electronic beamsteering was implemented in one plane only. The technology applied was substrate integrated wave guide.

The front end was designed for high data rate wireless links over short distances for consumer devices. The measurement results showed excellent beamforming performance and an antenna efficiency of nearly 80 %. Figure 75 shows the simulation model of one array column. The wave guide was formed by metal and vertical planes via fences embedded in the material. The display of the vertical cut shows the field distribution in the network as well as at the antenna element level.

Summary

Base station antenna systems find themselves in an ongoing dynamic evolution process. The first cellular communication systems offer only relatively low data rates for a limited number of users. The main focus of the first cellular networks was to establish a basic connection and to provide basis coverage. The relatively simple passive antenna structures were typically mounted on a tower and had the transceiver electronics stored in a small building at the bottom of the base station.

Since the early days of cellular communications, a dramatically increasing demand in terms of capacity, coverage, and availability of mobile communication has taken place. One of the first changes in mobile networks was the replacement of large cells by a set of smaller cells to increase the total network capacity. In parallel, new standards and frequency bands have been allocated, higher modulation schemes have been implemented, and special carrier aggregation techniques have been realized to increase the number of users in the network and to allow much higher data throughput.

The antenna technology changed from very simple omnidirectional radiators via sector arrays towards active beamforming antennas. Innovative complex arrays were developed to allow a very exact pattern and gain control well suited for a specific cell or sector. Multiband antenna systems were also designed to combine several communication standards within the same form factor. The transceiver electronics moves more and more close to the antenna to avoid cable losses and to improve the signal quality. The remote control of the antenna beam shape allows the dynamic adaptation of the cell size and the alignment of the cell's capacity to the user's demand.

DOI 10.1007/978-981-4560-75-7_88-1

The worldwide communication and data traffic faces a dramatic increase within the coming years. Therefore, the experts currently investigate new concepts for a 5th generation mobile network. One key issue in these concepts is the allocation of higher frequency bands at, e.g., 30 and 60 GHz. The implementation of communication links in those bands will require highly directive antennas, including electronic beamforming. The required technology is complex and quite demanding; however, the successful design of powerful front ends is the key to access these very interesting frequency resources.

Abstract

The antenna is one of the most critical components in wireless charging systems since the power transfer efficiency of the system is largely dependent on the antenna performance. In this chapter, the modeling and analysis of antennas are introduced with a focus on increasing the power transfer efficiency. The relationship between wireless power transfer efficiency and antenna parameters like antenna geometry, ohmic loss, impedance matching circuits, and distance between transmitting and receiving antennas is studied analytically and numerically by using circuit theory and full-wave electromagnetic analysis, in order to provide some fundamental and theoretical knowledge to develop antennas for highly efficient wireless charging systems. Finally, challenges and recent studies of antennas for wireless power transfer systems, as well as standards on this field, are briefly introduced.

Keywords

Near-field coupling; Wireless power transfer; Wireless charging; Wireless power transmission; Antenna; Impedance matching; Efficiency; Equivalent circuit; Scattering parameters; Scattering matrix; Impedance matrix

Introduction

Research on wireless power transfer (WPT) started more than 100 years ago. Nikola Tesla developed the first practical WPT system in 1989 (Tesla 1904) and revealed the system configuration in his U.S. patent in 1914 (Tesla 1914). Reinhold Rudenberg described the fundamental theory of electric power absorption by antennas early in 1908 (Reinhold 1908). Since then, there have been numerous researches of both fundamental and application studies on the WPT. This technology has been widely applied to many applications from wirelessly charging electronic devices to the solar power satellite (SPS) system (McSpadden and Mankins 2002). However, this technology still faces challenges. One of the biggest challenges is keeping high power transfer efficiency (PTE) over a long transmission distance.

Wireless power transfer can be classified into two categories based on how the electromagnetic field is used to transfer power. One is far-field radiation, and the other is the near-field coupling. The near-field coupling approach is also called the inductive coupling method or induction method. This method is effective for a short-range power transfer with a relatively high power transfer efficiency. The near-field coupling approach has already been applied to many practical applications such as wireless charging for cordless phone, electric toothbrush, and passive radio-frequency identification (RFID) tags. On the other hand, the far-field radiation approach is applicable to power transfer over a long distance. But the power transfer efficiency is extremely low, depending on the transmission distance. One of the most well-known

DOI 10.1007/978-981-4560-75-7_91-1

applications is the space solar power system (SPS), which is a big project to collect sunlight in geostationary orbit, convert it to electromagnetic power, and transfer the power to the earth in the form of electromagnetic waves. This method requires directive antennas with high gain to increase the power transfer efficiency, as well as a direction tracking system to track the movements of the antennas. Therefore, the far-field radiation approach is usually limited to the applications in the environment of line-of-sight propagation.

A very efficient near-field power transfer was experimentally demonstrated by introducing a concept called evanescent resonant coupling (Kurs et al. 2007). In the paper, two self-resonant coils were used as receiving and transmitting antennas, and a power transfer for lighting up a 60-W light bulb with 40 % efficiency over distances in excess of 2 m was demonstrated experimentally. This magnetically resonant system was critical to realize power transfer over a relatively long distance while keeping a good power transfer efficiency compared with the conventional induction coupling method. There have been many research papers and reports soon after this publication (for example, Karalis et al. 2008; Cannon et al. 2009; Tak et al. 2009; Ishizaki et al. 2010; Yuan et al. 2010). It was shown that the evanescent resonant coupling method can transmit the energy for longer distance than the previous near-field induction method (Murakami et al. 1996; Hatanaka et al. 2002) and was more efficient than the far-field radiation method where the vast majority of energy was wasted due to the transmission loss (Brown 1984; Matsumoto 2002; Rodenbeck and Chang 2005). It was also found that the electric coupling was effective in wireless power transfer with a high efficiency (Kim and Ling 2007). It was stated in Chen et al. (2012) that the conjugate impedance matching for both transmitting and receiving antennas could bring about the maximum power transfer efficiency instead of using the concept of antenna resonance or magnetic resonance. It was demonstrated in the paper that an efficiency up to 100 % could be achieved in the near-field region when the antennas were perfectly conducting and electrically small if the conjugate-matching condition was satisfied. It was also described that, in practice, loop antennas were superior to the dipole antennas in achieving high efficiency, if the conducting losses of both the antennas and the matching circuits were considered.

In this chapter, modeling and analysis of antennas in wireless charging systems based on the near-field coupling approach by using circuit theory and full-wave model electromagnetic analysis is introduced from a viewpoint of increasing wireless power transfer efficiency for the wireless charging systems. Circuit theory can provide a clear image of how electromagnetic power is coupled through the antennas, and it can give some basic knowledge on finding the key factors to increase power transfer efficiency. Full-wave analysis can give an electromagnetic simulation in a practical situation where antenna characteristics including antenna impedance, radiation, and conducting loss can be evaluated accurately. Because these antenna characteristics play an important role in determining the power transfer efficiency, the full-wave analysis is required to design antennas for a practical wireless charging system. Full-wave analysis of conical models where two types of antennas, dipole antennas and loop antennas, are used for near-field coupling show some general principles for antenna design to achieve the maximum power transfer efficiency for the wireless charging systems. Finally, some recent application developments and standards of the wireless charging technology are introduced.

Configuration of Wireless Charging System and Definition of Power Transfer Efficiency

A typical wireless charging system is generally composed of a source, impedance matching circuits, transmitting and receiving antennas, a rectifier, and a load impedance, as shown in Fig. 1. At the transmitting side, the electromagnetic power is generated by a voltage source V_0 with internal impedance

DOI 10.1007/978-981-4560-75-7_91-1

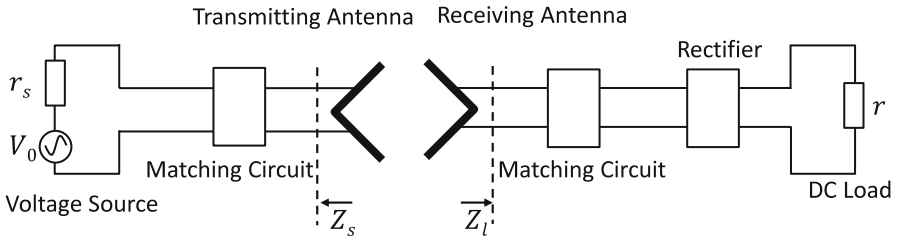

Fig. 1 Configuration of a typical wireless charging system

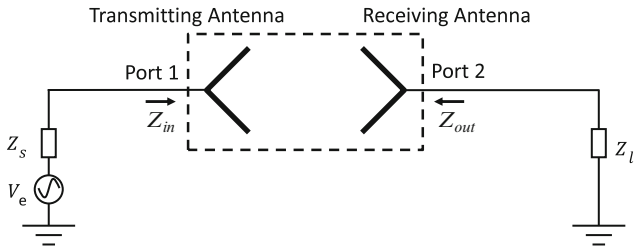

Fig. 2 Transmitting and receiving antennas in wireless charging system

r_s and is transferred through the impedance matching circuit to the transmitting antenna. The electromagnetic field is wirelessly coupled to the receiving side through the receiving antenna, impedance matching circuit, rectifier circuit, and is finally consumed by the resistance r. This configuration is also valid for the far-field radiation approach if the antennas are located in the far-field region.

Because antennas are the main topic in this chapter, it is adequate to consider a more simplified configuration model shown in Fig. 2. In this model, Z_s is the equivalent impedance looking toward the matching circuit and power source, and Z_l is the impedance looking to rectifier circuit and load. Although rectifier is a nonlinear circuit, it is assumed to be a linear parameter which is independent of the received power in this chapter. It is important to note that characteristics of a single antenna, such as the resonant frequency, input impedance, and gain, are useless for evaluating the antenna performance in the wireless charging system based on the near-field coupling approach, because the transmitting and receiving antennas are coupled strongly with each other.

The power transfer efficiency, one of the most important parameters to evaluate performance of the wireless charging system, is defined as the ratio of the absorbed power in the load impedance Z_l to the incident power into the transmitting antenna:

$$\eta = \frac{P_l}{P_{inc}}, \tag{1}$$

In this case, P_{inc} is the incident power and P_l is the absorbed power. The incident power is the maximum power available to the transmitting antenna when the condition of impedance matching is satisfied at Port 1 of Fig. 2.

It will be shown that the power transfer efficiency η reaches the maximum value when the impedances Z_s and Z_l are complex conjugate matching to the input impedance of Port 1 and Port 2, respectively. That is,

$$Z_{in} = Z_s^*, \tag{2}$$

DOI 10.1007/978-981-4560-75-7_91-1

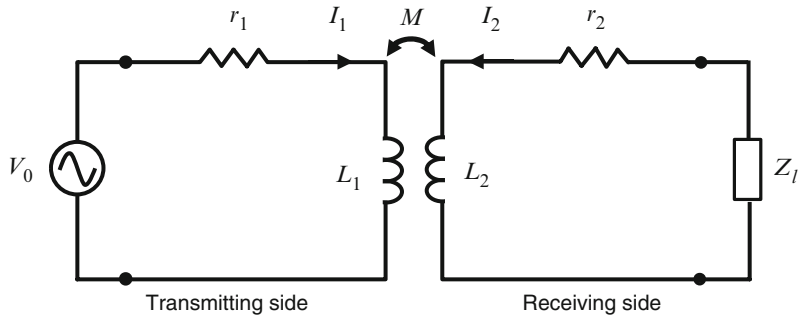

Fig. 3 Equivalent circuit for magnetic field coupling

at Port 1, and

$$Z_{out} = Z_l^*, \tag{3}$$

at Port 2, where Z_{in} is the input impedance looking into Port 1 and Z_{out} is the input impedance looking into Port 2. It should be noted again that Z_{in} is not equal to the input impedance of the transmitting antenna and Z_{out} is not the input impedance of the receiving antenna because the mutual coupling cannot be ignored between the transmitting and the receiving antennas when the near-field power coupling is discussed.

In the following sections, the relationship between the impedance matching condition and the condition for obtaining the maximum power transfer efficiency as well as the relationship between wireless power transfer efficiency and antenna parameters are investigated theoretically and numerically by using circuit theory and full-wave electromagnetic analysis.

Circuit Theory

When wireless charging systems operate at lower frequencies, the radiation from the system can be ignored, and antennas in the system can be approximately modeled using lumped circuit elements. Analysis using lumped circuit elements can be carried out based on circuit theory, which is very simple and provides a straightforward model demonstrating the operating principle of antennas in wireless charging systems.

At low frequency, the electromagnetic field can be assumed to be a quasistatic field, and electromagnetic coupling can be classified into induction through the magnetic field and coupling through the electric field. In this section, the power charge system using the magnetic induction is focused on and discussed.

Magnetic induction can be performed using two inductors, also called coils, as a transmitting antenna and a receiving antenna because coils can produce strong magnetic fields in the near-field area. The coil can be either a single-turn coil or a multiturn coil, but the total length of the wire should be much smaller than the wavelength. Otherwise, electromagnetic power would be radiated from the system, and the power charging efficiency, or power transfer efficiency, would be largely degraded.

An equivalent circuit for describing the basic phenomena of magnetic field induction is shown in Fig. 3. Two inductors for transmitting and receiving are equivalent to two inductors L_1 and L_2 and are coupled to each other with mutual inductance M. r_1 and r_2 represent the ohmic loss of the transmitting and receiving circuits, respectively, mainly caused by the inductors. A voltage source with voltage V_0 is fed to the transmitting circuit. Z_l is the load impedance where the power provided by the voltage source is absorbed.

DOI 10.1007/978-981-4560-75-7_91-1

In the following, it is shown how to obtain the maximum power transfer efficiency by optimizing the value of Z_l. This analysis provides a fundamental knowledge to develop a highly efficient wireless charging system by designing the load impedance.

When Kirchhoff's voltage law is applied to the electric circuit in Fig. 3, the equations

$$(r_1 + j\omega L_1)I_1 + j\omega M I_2 = V_0 \tag{4}$$

$$j\omega M I_1 + (Z_l + r_2 + j\omega L_2)I_2 = 0 \tag{5}$$

are obtained. By solving Eqs. 4 and 5 simultaneously, current at the transmitting side becomes

$$I_1 = \frac{\begin{vmatrix} V_0 & j\omega M \\ 0 & Z_l + r_2 + j\omega L_2 \end{vmatrix}}{\begin{vmatrix} r_1 + j\omega L_1 & j\omega M \\ j\omega M & Z_l + r_2 + j\omega L_2 \end{vmatrix}} = \frac{(Z_l + r_2 + j\omega L_2)V_0}{(r_1 + j\omega L_1)\ (Z_l + r_2 + j\omega L_2) + \omega^2 M^2}. \tag{6}$$

The relationship between magnitude of the currents at the transmitting and receiving sides can be derived as

$$|I_2|^2 = \frac{\omega^2 M^2}{r_2^2 + (X_2 + \omega L_2)^2}|I_1|^2. \tag{7}$$

The input impedance looking into the circuit from the voltage source is derived from Eq. 6 as

$$Z_{in} = \frac{V_0}{I_1} = r_1 + j\omega L_1 + \frac{\omega^2 M^2}{Z_l + r_2 + j\omega L_2}. \tag{8}$$

Then, the real part of Z_{in} becomes

$$R_{in} = r_1 + \frac{\omega^2 M^2 (R_l + r_2)}{(R_l + r_2)^2 + (X_l + \omega L_2)^2}, \tag{9}$$

where R_l and X_l are the real and imaginary parts of Z_l, respectively.

The total power consumed in the circuit generated by voltage V_0 is

$$P_{in} = \frac{1}{2} R_{in} |I_1|^2, \tag{10}$$

and the power consumed in the load Z_l is

$$P_l = \frac{1}{2} R_l |I_2|^2. \tag{11}$$

Therefore, the power transfer efficiency is evaluated as

DOI 10.1007/978-981-4560-75-7_91-1

$$\eta = \frac{P_l}{P_{in}} \tag{12}$$

$$\frac{\omega^2 M^2 R_l}{r_1\left((R_l + r_2)^2 + (X_l + \omega L_2)^2\right) + \omega^2 M^2 (R_l + r_2)}. \tag{13}$$

Now, the load resistance R_l and the load reactance X_l are optimized to achieve maximum power transfer efficiency. For this purpose, the partial derivatives of the efficiency with respect to R_l and X_l should satisfy the conditions

$$\frac{\partial \eta}{\partial X_l} = 0, \tag{14}$$

and

$$\frac{\partial \eta}{\partial R_l} = 0. \tag{15}$$

The optimized value of R_l is obtained by solving the above two equations as

$$R_{lm} = r_2\sqrt{1+\alpha}, \tag{16}$$

and the optimized value of X_l is also obtained as

$$X_{lm} = -\omega L_2, \tag{17}$$

where α is defined as

$$\alpha = \frac{\omega^2 M^2}{r_1 r_2}. \tag{18}$$

Therefore, when the load impedance Z_l satisfies both Eqs. 16 and 17, the power transfer efficiency η reaches to the maximum, expressed as

$$\eta_m = 1 - \frac{2}{1+\sqrt{1+\alpha}} = \frac{\left(1-\sqrt{1+\alpha}\right)^2}{\alpha}. \tag{19}$$

This analysis indicates that the maximum power transfer efficiency can be achieved by the load impedance which satisfies both Eq. 16 for real part and Eq. 17 for imaginary part. Because Eq. 17 is the condition of resonance in receiving circuit, this analysis indicates that the maximum power transfer efficiency can be achieved if both Eqs. 16 and 17 are satisfied simultaneously, while the resonance condition is necessary but not enough. It is also noted that the optimized load resistance is related not only with the resistance of inductor in the receiving side but also with that in the transmitting side through the parameter α which indicates the mutual coupling effect between these two inductors. α can be also expressed as

DOI 10.1007/978-981-4560-75-7_91-1

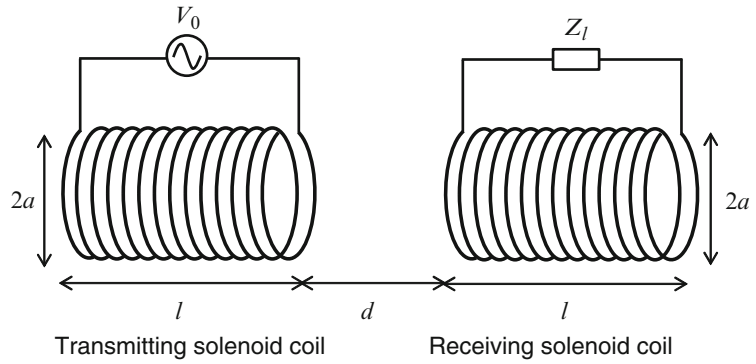

Fig. 4 Analysis model of wireless charging system by using two solenoid coils

$$\alpha = k^2 Q_1 Q_2,$$

where k is the coupling coefficient,

$$k = \frac{M}{L_1 L_2}, \tag{20}$$

and Q_1 and Q_2 are the quality factors

$$Q_1 = \frac{\omega L_1}{r_1}, \tag{21}$$

and

$$Q_2 = \frac{\omega L_2}{r_2}. \tag{22}$$

Therefore, the maximum power transfer efficiency can be expressed as

$$\eta_m = 1 - \frac{2}{1 + \sqrt{1 + k^2 Q_1 Q_2}}, \tag{23}$$

which shows that the maximum power transfer efficiency is dependent on coupling factor k and the quality factors Q_1 and Q_2. A large quality factor and a strong coupling between the coupled inductors will increase the value of the maximum efficiency.

The condition for obtaining the maximum efficiency is not given in the transmitting circuit in the above discussion. It is because the power transfer efficiency is normalized by the input power to the circuit, rather than the incident power in this section. If the efficiency is defined as the absorbed power over the incident power, the efficiency optimization should be made by defining an internal impedance of the power source and then optimizing the internal impedance in the same way as discussed for the receiving circuit.

As a numerical example, a wireless power transfer by two solenoid coils is analyzed by using circuit theory. The analysis model is shown in Fig. 4. Two solenoid coils are used as the antennas for wireless power transfer. The solenoid coils have a length l, N turns per meter, and radius a. The coils are made of conducting wire with radius R_a and conductivity σ. The two coils are separated over a distance d.

DOI 10.1007/978-981-4560-75-7_91-1

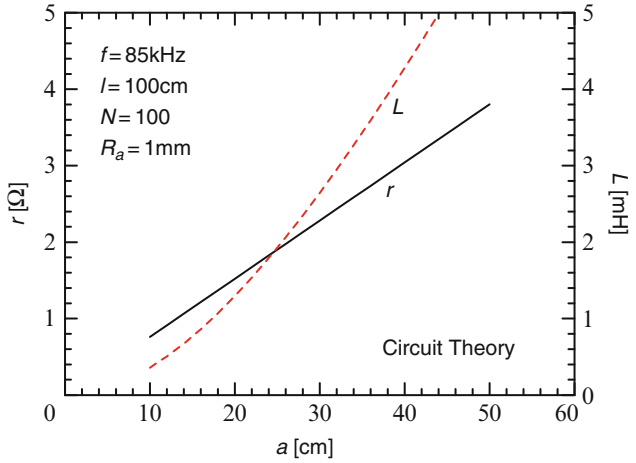

Fig. 5 Equivalent resistance and inductance of the solenoid coils

When the solenoid coil is extremely small compared with wavelength, it can be assumed the current on the solenoid coil is uniformly in-phase distributed on the surface of the conducting wire. The inductance L of the solenoid coil is then given in a closed form as

$$L = \mu_0 n^2 \pi a^2 \left(\sqrt{a^2 + l^2} - a \right), \tag{24}$$

where μ_0 is permeability in vacuum. The resistance r of the coil is derived as

$$r = \frac{2\pi a N}{2\pi R_a \delta \sigma} = \frac{aN}{R_a \delta \sigma}, \tag{25}$$

where δ is skin depth of the wire expressed as

$$\delta = \sqrt{\frac{2}{\omega \mu_0 \sigma}}. \tag{26}$$

It is difficult to give a closed form to express exactly the mutual inductance M between the coils. For simplicity, it is assumed here that the distance between coils is small enough that the coupling factor becomes $k = 1$. Therefore, the mutual inductance M is equal to L.

Consider the case that $f = 85$ kHz, $l = 100$ cm, $N = 100$, $R_a = 1$ mm, and $\sigma = 5.8 \times 10^7$ S/m. Figure 5 shows the equivalent inductance and resistance of the solenoid coils which are calculated using Eqs. 24 and 25. As the radius of the solenoid coil increases, both the inductance and resistance increase as well. Corresponding to the change of radius, the optimized load impedance to achieve the maximum power transfer efficiency can be obtained by using Eqs. 16 and 17, as shown in Fig. 6. The maximum power transfer efficiency, when the load impedance is optimized, is shown in Fig. 7, which is calculated by using Eq. 23. It is shown that the maximum power transfer efficiency is as high as nearly 100 % because the coupling factor between coils is assumed to be 1. Based on this assumption, the maximum power transfer efficiency is independent of the distance between coils. Therefore, the numerical analysis using the circuit theory is limited to simple analysis models where the lumped circuit elements can be accurately evaluated. In practice, because geometry of both transmitting and receiving antennas would be very complicated, it is usually impossible to obtain the exact characteristics of those lumped circuit elements such as the

DOI 10.1007/978-981-4560-75-7_91-1

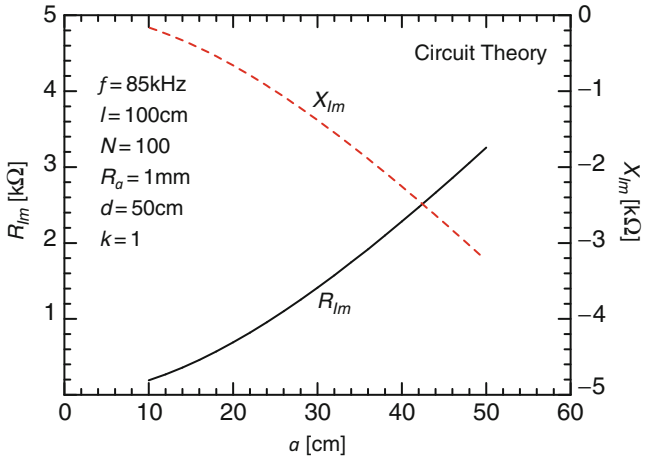

Fig. 6 Optimized load impedance to achieve the maximum power transfer efficiency

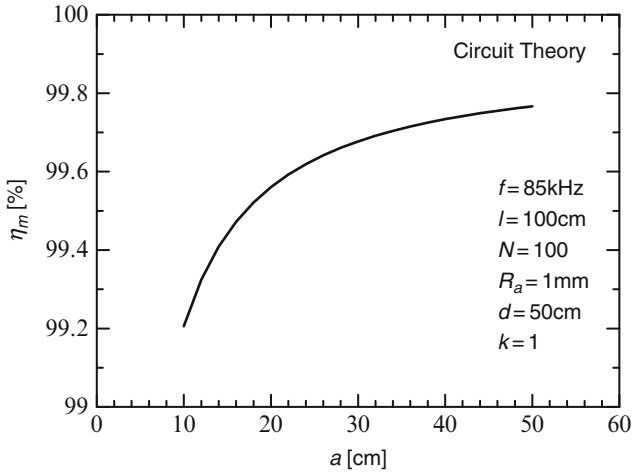

Fig. 7 The maximum power transfer efficiency when the optimized impedance is loaded

inductance and resistance of the coils, as well as the mutual coupling factor in the equivalent circuit. In the following sections, some approaches based on a full-wave electromagnetic analysis are introduced which is capable of accurately analyzing the antennas with complicated geometry and moderate electrical size in the wireless charging system.

Impedance Matrix Approach

In this section, the near-field coupling is modeled by using the impedance matrix approach. The wireless charging system can be expressed in a form of two-port network shown in Fig. 8. Here, Z_s is the internal impedance of the voltage source and Z_l is the load impedance. Both of them have a complex value, expressed as $Z_s = R_s + jX_s$ and $Z_l = R_l + jX_l$, respectively. The relation between the port currents I_1, I_2 and port voltages V_1, V_2 is given in terms of the impedance matrix,

DOI 10.1007/978-981-4560-75-7_91-1

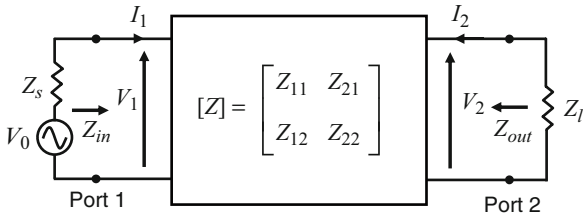

Fig. 8 Two-port network for modeling WPT using magnetic field coupling

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \tag{27}$$

If the geometry of the wireless charging system is known, the matrix impedance in Fig. 8 can be obtained by using some numerical methods based on full-wave electromagnetic analysis.

If Z_{in} is the impedance looking into Port 1 and Z_{out} is the impedance looking into Port 2, they are expressed in the form of impedance parameters (Z-parameters) as

$$Z_{in} = Z_{11} - \frac{Z_{12}Z_{21}}{Z_l + Z_{22}}, \tag{28}$$

and

$$Z_{out} = Z_{22} - \frac{Z_{12}Z_{21}}{Z_s + Z_{11}}. \tag{29}$$

The condition of conjugate impedance matching applied to both ports is expressed as

$$Z_{in} = Z_s^*, \tag{30}$$

and

$$Z_{out} = Z_l^*. \tag{31}$$

By solving these two equations simultaneously, the matched load impedance becomes

$$R_{lmat} = R_{22}\sqrt{(1-\alpha_1)\ (1+\alpha_2)}, \tag{32}$$

$$X_{lmat} = R_{22}\sqrt{\alpha_1\alpha_2} - X_{22}. \tag{33}$$

The matched internal impedance becomes

$$R_{smat} = R_{11}\sqrt{(1-\alpha_1)\ (1+\alpha_2)}, \tag{34}$$

$$X_{smat} = R_{11}\sqrt{\alpha_1\alpha_2} - X_{11}, \tag{35}$$

where $\alpha_1 = R_{12}^2/(R_{11}R_{22})$ and $\alpha_2 = X_{12}^2/(R_{11}R_{22})$.

When the power transfer efficiency is definted as the absorbed power by the load impedance over the input power (not incident power!) to the Port 1, it can be expressed as

DOI 10.1007/978-981-4560-75-7_91-1

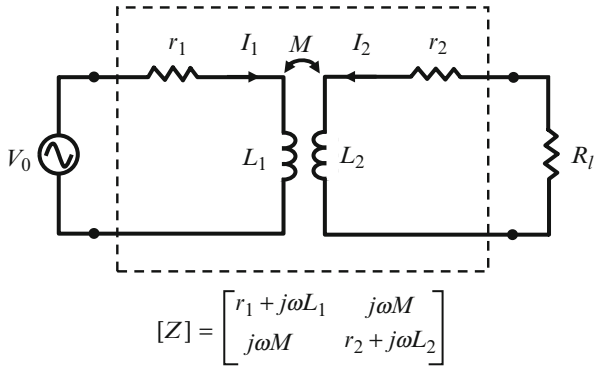

Fig. 9 Two-port impedance matrix network for modeling wireless charging system using magnetic field coupling

$$\eta = \frac{R_l |I_2|^2}{R_{in} |I_1|^2}. \tag{36}$$

By using relation between currents $|I_2|^2$ and $|I_1|^2$

$$|I_2|^2 = \frac{|Z_{12}|^2}{|Z_l + Z_{22}|^2} |I_1|^2, \tag{37}$$

the power transfer efficiency can be calculated as

$$\eta = \frac{R_l |Z_{12}|^2}{R_{in} |Z_l + Z_{22}|^2}. \tag{38}$$

If impedance matching condition is satisfied at Port 2, substituting the matched load impedance R_{lmat} in Eq. 32 and X_{lmat} in Eq. 33 for Z_l, the power transfer efficiency in terms of the input power becomes

$$\eta_{mat} = \frac{\alpha_1 + \alpha_2}{\left(\sqrt{1 - \alpha_1} + \sqrt{1 + \alpha_2}\right)^2}. \tag{39}$$

When the impedance matrix approach is applied to the analysis model in Fig. 3 in section "Circuit Theory," as shown in Fig. 9, the impedance matrix for the two-port network becomes

$$[Z] = \begin{bmatrix} r_1 + j\omega L_1 & j\omega M \\ j\omega M & r_2 + j\omega L_2 \end{bmatrix}. \tag{40}$$

Then, $\alpha_1 = 0$ and $\alpha_2 = \omega^2 M^2/(r_1 r_2) = \alpha$. If it is assumed that the impedance matching condition is satisfied at Port 2, the load impedance can be derived by using Eqs. 32 and 33 as

$$R_{lmat} = r_2 \sqrt{1 + \alpha}, \tag{41}$$

and

$$X_{lmat} = -\omega L_2. \tag{42}$$

DOI 10.1007/978-981-4560-75-7_91-1

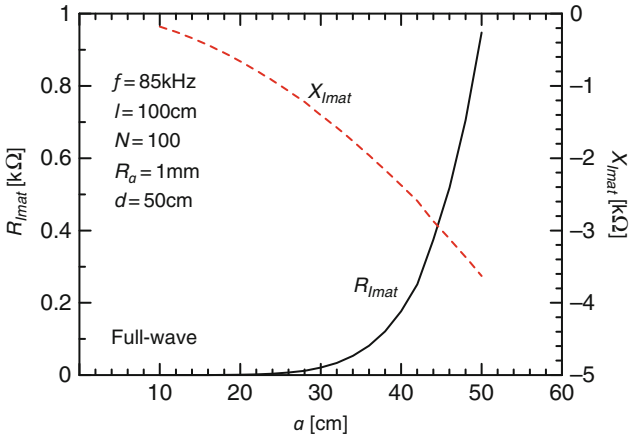

Fig. 10 Matched load impedance versus coil radius for the model using two solenoid coils

The power transfer efficiency in terms of the input power can be derived as

$$\eta_{mat} = \frac{\left(1 - \sqrt{1+\alpha}\right)^2}{\alpha}. \tag{43}$$

Equations 41, 42, and 43 agree completely with Eqs. 16, 17, and 19, demonstrating the fact that the impedance matching condition is nothing but the condition to achieve the maximum power transfer efficiency. Therefore, in developing a wireless charging system based on the near-field coupling approach, the biggest challenge is to keep the impedance matching condition being satisfied when the transmitting antenna and receiving antenna are moving relative to each other. It is required in the practical system design to adaptively change the antenna geometry or the impedance matching network to keep satisfying the impedance matching condition at both transmitting and receiving ports.

Here, the analysis model shown in Fig. 4 is again solved by using the impedance matrix approach, but the impedance matrix is numerically calculated by using the method of moments, one of the most effective full-wave electromagnetic analysis methods.

Corresponding to radius of the solenoid coils, the optimized load impedance to achieve the maximum power transfer efficiency can be obtained by using Eqs. 41 and 42, as shown in Fig. 10. Compared with the results shown in Fig. 6, the reactance is almost the same, but the resistance is very different. The maximum power transfer efficiency, which is calculated by using Eq. 43 under the impedance match condition, is shown in Fig. 11. Efficiency drops greatly when radius of the coil becomes small, which is very different from that obtained in the previous section. The reason for these large differences in calculated efficiency is due to the fact that mutual coupling between coils, radiation loss, as well as conducting loss of the coils are approximately calculated by using the analytical forms in section "Circuit Theory" but accurately calculated by the method of moments in this section. When the distance between the coils changes, the matched load impedance is shown in Fig. 12, and the maximum efficiency under the condition of impedance matching is shown in Fig. 13. These analysis results provide important knowledge to design antenna load impedance and evaluate the maximum power transfer efficiency of the wireless charging system.

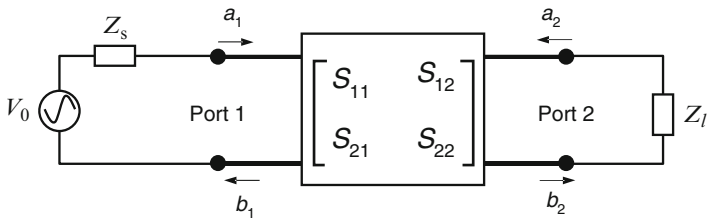

Fig. 14 Two-port network for modeling antennas in wireless charging systems

Scattering Matrix Approach

The antennas in wireless charging system can be also analyzed by using the scattering matrix approach as shown in Fig. 14, where the system consisting of transmitting port and receiving port is again expressed as a two-port network as in the last section. Port 1 is the transmitting port including the transmitting antenna and its load impedance Z_s, and Port 2 is the receiving port including receiving antenna and its load impedance Z_l. Here, instead of impedance matrix, the scattering matrix S is used to express the two-port network properties. The scattering parameters are very effective in evaluating the performance of multiport network, which are easily measured using a vector network analyzer and calculated by many commercial full-wave electromagnetic simulators.

The reflection coefficients of the internal impedance Z_s and load impedance Z_l are

$$\Gamma_s = \frac{Z_s - Z_0}{Z_s + Z_0}, \tag{44}$$

and

$$\Gamma_l = \frac{Z_l - Z_0}{Z_l + Z_0}, \tag{45}$$

respectively, where Z_0 represents the reference impedance of 50 Ω, the same with that in the scattering matrix. The condition of conjugate impedance matching becomes

$$\Gamma_s = \Gamma_{in}^*, \tag{46}$$

$$\Gamma_l = \Gamma_{out}^*, \tag{47}$$

where Γ_{in} and Γ_{out} are the reflection coefficient at Port 1 and Port 2, respectively, and are expressed as

$$\Gamma_{in} = S_{11} + \frac{S_{12}S_{21}\Gamma_l}{1 - S_{22}\Gamma_l} \tag{48}$$

and

$$\Gamma_{out} = S_{22} + \frac{S_{12}S_{21}\Gamma_s}{1 - S_{11}\Gamma_s} \tag{49}$$

The optimal reflection coefficients for maximum power transfer efficiency can be obtained by solving Equations 46 and 47 as

DOI 10.1007/978-981-4560-75-7_91-1

$$\Gamma_{sm} = \frac{B_1 \pm \sqrt{{B_1}^2 - 4|C_1|^2}}{2C_1}, \tag{50}$$

and

$$\Gamma_{lm} = \frac{B_2 \pm \sqrt{B_2^2 - 4|C_2|^2}}{2C_2}, \tag{51}$$

where

$$B_1 = 1 + |S_{11}|^2 - |S_{22}|^2 - |\Delta|^2, \tag{52}$$

$$C_1 = S_{11} - \Delta S_{22}^*, \tag{53}$$

$$B_2 = 1 + |S_{22}|^2 - |S_{11}|^2 - |\Delta|^2, \tag{54}$$

$$C_2 = S_{22} - \Delta S_{11}^*, \tag{55}$$

$$\Delta = S_{11}S_{22} - S_{12}S_{21}. \tag{56}$$

The optimal impedance of the voltage source and load impedance can be obtained using Eqs. 44 and 45 from those optimal reflection coefficients given by Eqs. 50 and 51.

On the other hand, the power transfer efficiency can be expressed in terms of the S parameters and the reflection coefficients at the input and output port,

$$\eta = \frac{|b_2|^2 - |a_2|^2}{|a_1|^2} = \frac{\left(1 - |\Gamma_l|^2\right)\ \left(1 - |\Gamma_s|^2\right)|S_{21}|^2}{|(1 - S_{11}\Gamma_s)(1 - S_{22}\Gamma_l) - S_{12}S_{21}\Gamma_s\Gamma_l|^2} \tag{57}$$

where the efficiency can be calculated if the values of Z_s and Z_l are given while the maximum efficiency is available when Z_s and Z_l are the optimal impedance, namely, complex conjugate matched impedance.

Antenna Modeling and Analysis Using Scattering Matrix Approach

Antenna Models

Two kinds of antennas are studied; dipole antenna and loop antenna. When these antennas are used for near-field coupling, a small dipole antenna is used for electric field coupling while a small loop antenna is used for magnetic field coupling. Although these conical models of the antennas are used in the study, these results and observations from the numerical simulations provide theoretical insight into how to design antennas for wireless charging systems based on the near-field coupling approach.

Figure 15 shows a dipole–dipole model. The length of the wire dipole is $2l$; the antenna distance is d. The two antennas are located parallel with the z axis. The internal impedance of the voltage source is Z_s, and the load impedance connected with the receiving antenna is Z_l. Figure 16 gives a loop–loop model. The circular loop antenna has a diameter of D separated at distance of d. The axes of two loop antennas coincide with x axis. All the antennas are made of conducting wire of radius a.

DOI 10.1007/978-981-4560-75-7_91-1

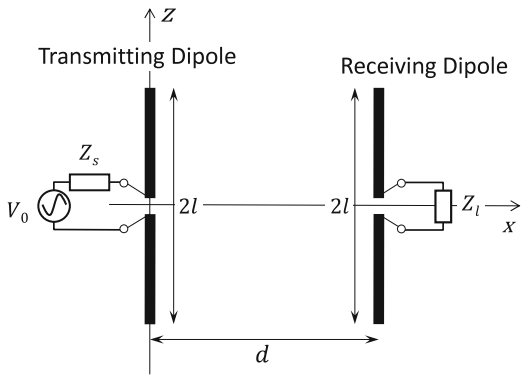

Fig. 15 Dipole–dipole model for wireless charging system

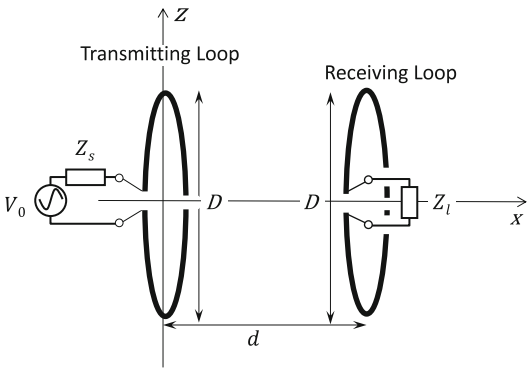

Fig. 16 Loop–loop model for wireless charging system

In this chapter, the method of moments is used to numerically analyze the antennas to calculate the S parameters of the two-port network.

Maximum Power Transfer Efficiency Without Consideration of Loss in Antennas and Matching Circuits

When the antenna size is fixed, the maximum power transfer efficiency under the condition of conjugate impedance matching at the two ports is shown by changing the antenna distance d. The numerical results are shown in Fig. 17. Here, the dipole length $2l$ and loop diameter D are 0.1λ, and it is assumed that the antenna is made of electrically perfect conductor. It is found that the power transfer efficiency rises up to 100 % when transmitting and receiving antennas are coming close to each other. However, in the practical wireless charging system, the power transfer efficiency is degraded by the power loss which includes antenna conducting loss, radiation loss, and return loss of antennas. When the antennas are electrically small and antenna distance is electrically small, the radiation power is much less than the coupled power. Therefore, if the condition of impedance matching at the two ports is satisfied and antenna conducting loss is not considered, it is reasonable that the power transfer efficiency should approach to 100 %. The efficiency decreases when the distance becomes large because the radiation power from the transmitting and receiving antennas increases when the two antennas are moved far away from each other.

In Fig. 18, the relationship between the maximum power transfer efficiency and antenna size is shown. It is found that the maximum power transfer efficiency could be increased by reducing the antenna size to decrease the radiation power. Theoretically speaking, the result is true if the conducting loss is ignored. However, as shown in the following discussion, the conducting loss of the antenna, as well as the

DOI 10.1007/978-981-4560-75-7_91-1

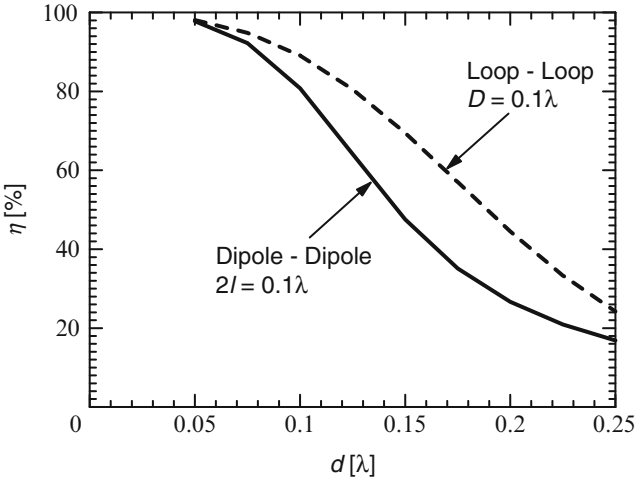

Fig. 17 The maximum power transfer efficiency as a function of antenna distance for dipole–dipole and loop–loop models

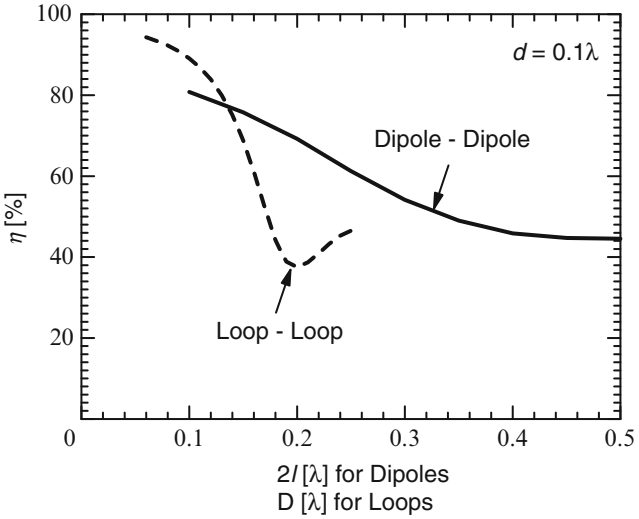

Fig. 18 The maximum power transfer efficiency as a function of antenna size for dipole–dipole and loop–loop models without conducting loss in antennas

conducting loss in the matching circuits of antennas, may dominate the loss when the antenna size becomes extremely small and decrease the maximum power transfer efficiency on the contrary. The efficiency of loop–loop drops more than that of dipole–dipole because the loop has a larger antenna effective aperture and radiates more power than the dipole in the case of $D = 2l$.

Maximum Power Transfer Efficiency with Consideration of Loss in Antennas and Matching Circuits

It was known that antennas in the wireless charging system should be electrically small to reduce the radiation loss as discussed above. However, the conducting loss of the antennas cannot be ignored any more as the antenna is electrically small. Furthermore, the ohmic loss in the matching circuit should be considered in analyzing the maximum power transfer efficiency. The following numerical results show the importance of considering ohmic loss in antennas as well as in impedance matching circuits.

DOI 10.1007/978-981-4560-75-7_91-1

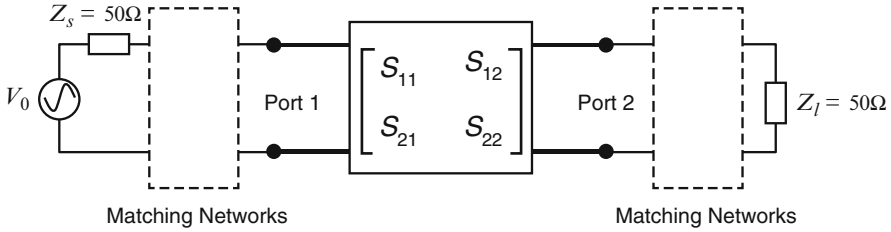

Fig. 19 Two-port network combined with impedance matching circuits for modeling WPT system

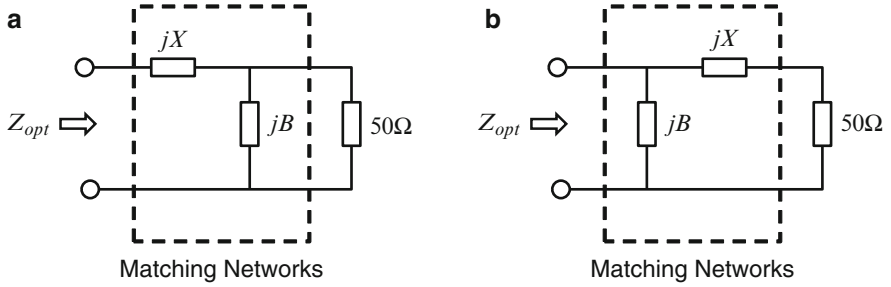

Fig. 20 L-section impedance matching circuits

The impedance matching networks are added into the two-port network to change the optimal impedance to 50 Ω at both sides as shown in Fig. 19. There are many types of the impedance matching networks such as *L*-section matching, quarter wave transformer, and single-stub tuning. *L*-section matching uses two reactive elements to match an arbitrary impedance to an arbitrary desired impedance. This technique is very effective in low-frequency application. In this chapter, the *L*-section matching networks as shown in Fig. 20 are used to match the optimized impedance Z_{opt}, which is required to maximize the efficiency. In this case, the internal impedance of voltage source and the load impedance are assumed to be 50 Ω. There are two configurations for an *L*-section matching network as shown in Fig. 20. Assume that Z_{opt} has a real part of R_{opt}. If the normalized value of $R_{opt}[\Omega]/50$ is larger than unit, the configuration (a) should be selected while if the $R_{opt}[\Omega]/50$ is smaller than unit, the configuration (b) should be used. The reactive elements X and B may be either an inductance L or a capacitance C, depending on the value of normalized Z_{opt}. In the wireless charging applications, because the frequency is usually very low and the matching circuit size is electrically small, lumped element inductors and capacitors can be used. The analytic solutions for the reactive elements X and B are available in reference (Pozar 1998).

The ohmic loss of these lumped elements in the impedance matching circuits is expressed in terms of Q value. It is found that the Q value of a capacitor is generally higher than that of an inductor. A typical Q value of a commercial inductor and capacitor is assumed to be $Q_L = 100$ and $Q_C = 200$, respectively, in this chapter. The antenna conductor is assumed to be copper with its conductivity of $\sigma_{Cu} = 5.8 \times 10^7$ S/m.

Figures 21 and 22 show the relationship between the maximum efficiency and antenna distance when antenna size is fixed for cases of dipole–dipole and loop–loop transmission, respectively. In these figures, the results are compared when only copper loss is considered and when both copper loss and loss of matching circuits are considered. It is found that the copper loss does not degrade the efficiency much, while loss of matching network degrades the efficiency significantly. When transmission distance is the same and the two types of antennas have approximately the same electrical size, the maximum efficiency of loop–loop transmission is larger than that of dipole–dipole transmission. Therefore, the loop–loop

DOI 10.1007/978-981-4560-75-7_91-1

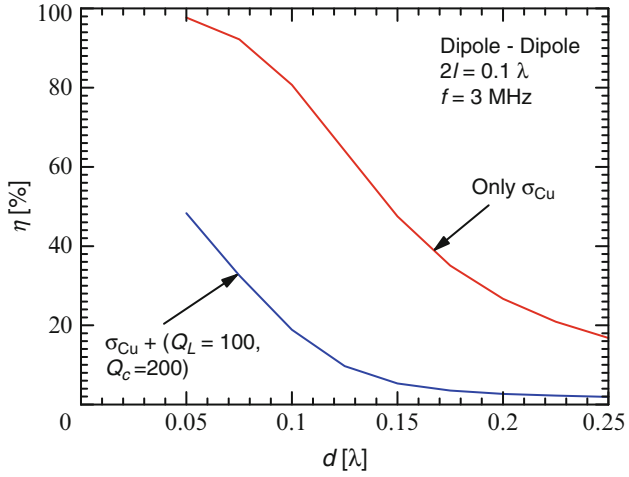

Fig. 21 The maximum power transfer efficiency as a function of antenna distance d for dipole–dipole model when ohmic loss of antennas and impedance matching circuits are considered

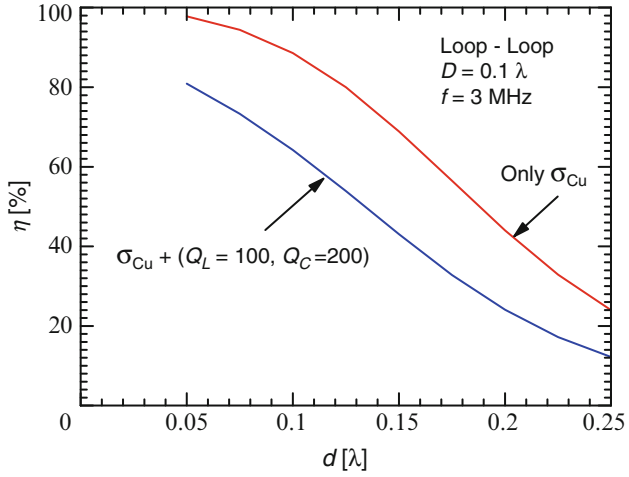

Fig. 22 The maximum power transfer efficiency as a function of antenna distance d for loop–loop model when ohmic loss of antennas and impedance matching circuits are considered

transmission is usually superior to the dipole–dipole transmission in terms of efficiency if the impedance matching condition is satisfied.

Figures. 23 and 24 show the relationship between the maximum efficiency and antenna size when antenna distance is fixed to be 0.1 λ for dipole–dipole and loop–loop transmission, respectively. When the ohmic loss of impedance matching circuits is considered, the efficiency of the dipole system decreases rapidly as the antenna size becomes small. However, for the loop–loop configuration, there is an optimal loop size, in the range of $D = 0.1\ \lambda$ to 0.15 λ. This is because the efficiency is reduced due to the increase of the radiation loss when D becomes large but is also reduced due to the increase of the ohmic losses when D is small. Thus, an optimal loop size exists in the middle. Numerical results of investigation on the loss of power transfer system are shown in Figs. 25 and 26, which give the fraction of loss as a function of antenna size for dipole–dipole and loop–loop models, respectively. Here, a little mismatch loss is observed because the impedance matching circuit was designed when ohmic loss in the matching circuits was omitted. It is found that the loss in the matching circuits dominates the loss and is the most important

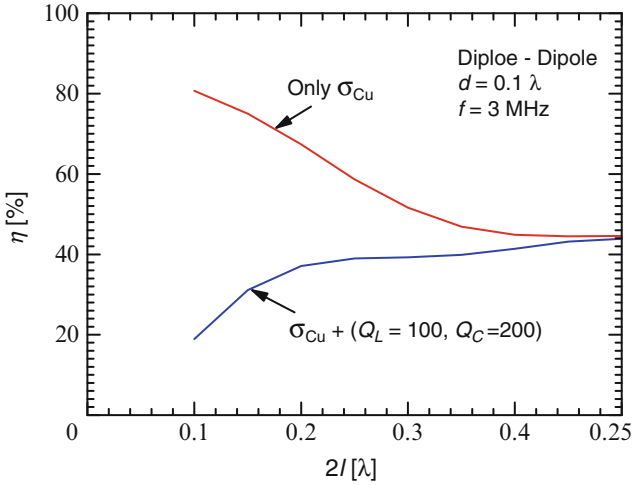

Fig. 23 The maximum power transfer efficiency as a function of antenna size for dipole–dipole model when ohmic loss of antennas and impedance matching circuits are considered

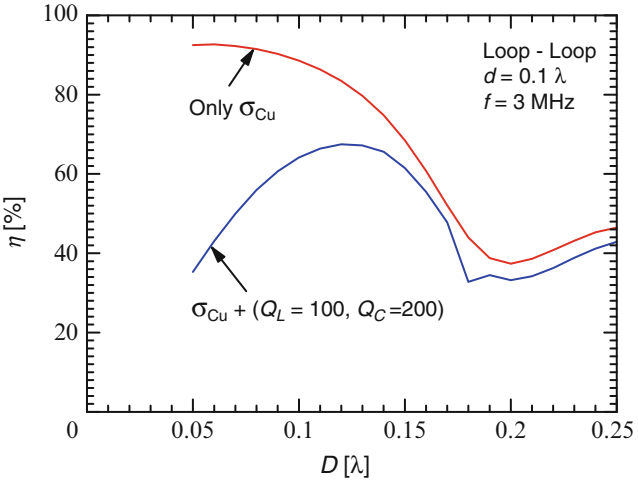

Fig. 24 The maximum power transfer efficiency as a function of antenna size for loop–loop model when ohmic loss of antennas and impedance matching circuits are considered

factor degrading the power transfer efficiency when antennas are electrically small. When antenna size becomes large, the radiation loss increases rapidly and becomes a dominant factor to decrease the efficiency.

Recent Application Developments, Standards, and Challenges

Development and Challenges on Antenna Technology for WPT

As described above, the impedance matching for both transmitting and receiving antennas is required to obtain the maximum value of efficiency of the WPT. However, it is not easy to keep the impedance matching condition for mobile devices where the transmitting antenna and receiving antenna are moving relative to each other. In near-field WPT, because the transmitting antennas and receiving antennas are strongly coupled with each other, a little variation of antenna positions and direction of antenna

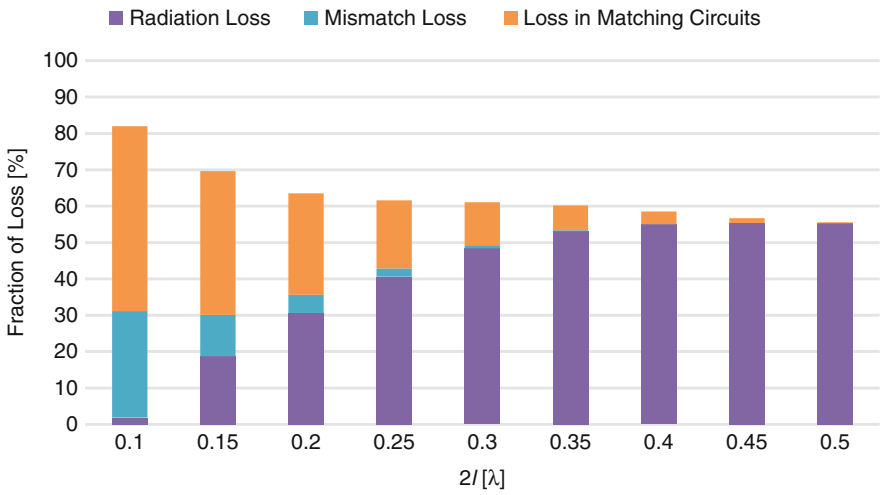

Fig. 25 Fraction of loss as a function of antenna size for dipole–dipole model when ohmic loss of antennas and impedance matching circuits are considered

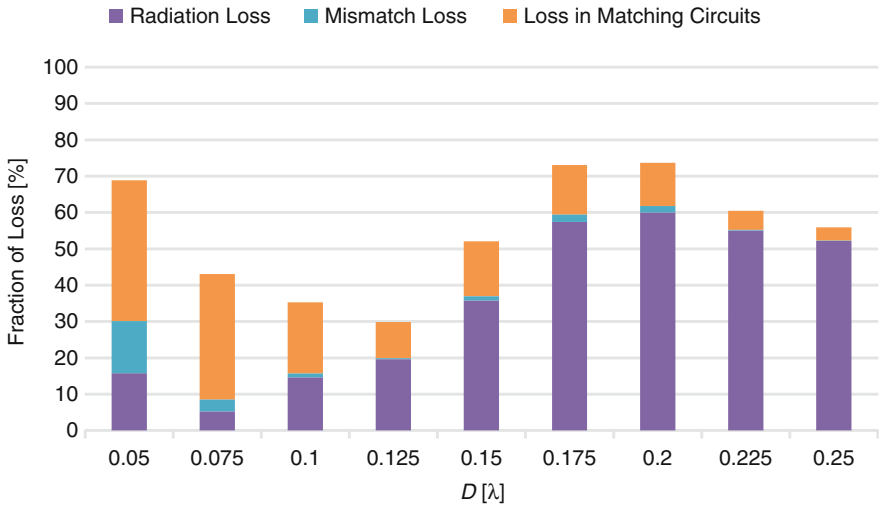

Fig. 26 Fraction of loss as a function of antenna size for loop–loop model when ohmic loss of antennas and impedance matching circuits are considered

polarization may cause a large variation of input impedance of these antennas, significantly decreasing the efficiency. Therefore, there are some researches focused on how to solve the problem of antenna misalignment.

There are two technical approaches to solve this problem. One is to use an impedance matching circuit to adaptively change the impedance at the input and output ports to compensate the impedance mismatching. For example, in Lee et al. (2014), a WPT system with a switchable capacitor array circuit has been presented, for compensating the variation of mutual coupling between two coils. It was demonstrated that the return loss can be improved greatly due to the operation of the capacitor array circuit when the distance between the two coils is changed. This approach was also introduced in Lee et al. (2012) and Aldhaher et al. (2014).

Another technical solution is to design an antenna that performs well even if it is misaligned. For example, a 3D loop with orthogonal polarizations is proposed as a WPT antenna to compensate the

DOI 10.1007/978-981-4560-75-7_91-1

efficiency drop due to the angular and lateral misalignment (Jonah et al. 2013). Also, a coil array was applied to a secondary coil instead of typical single coil to secure a stable power transmission efficiency for implantable devices (Ahn et al. 2014).

It is a big challenge to design antennas and AC-DC conversion circuits with high transmission efficiency for mobile devices. More studies and researches are expected to make a practical near-field WPT system.

Some WPT Standards

It is very important to the wireless charging industry to create a wireless power charging standard on a global scale that can allow electronic products and charging stations to be universally compatible with each other. Currently, several global standards for wireless power transfer have been developed. Some of them are introduced in the following.

Wireless Power Consortium (WPC) developed a standard for wireless charging technology, called "Qi" (Hui 2013). The WPC, established in 2008, is an open-membership cooperation of Asian, European, and American companies in diverse industries, including electronics manufacturers and original equipment manufacturers. The WPC published the Qi for products with an output power of 5 W or less in 2009. The WPC began to extend Qi specifications for medium power-consuming devices delivering power less than 120 W. The Qi specifications are available as free public download from the WPC website.

The Alliance for Wireless Power (A4WP) developed an interface standard called Rezence for wireless electrical power transfer based on the near-field coupling. The A4WP was formed in May 2012 with a goal to create a WPT system using Rezence technology, which consists of a single power transmitter unit and one or more power receiver units for wireless power transfer. The A4WP announced an expansion of the Rezence standard up to 50 W in June 2014, which is expected to expand the range of wireless power transfer for those products including laptops, tablets, and other consumer electronics.

The Power Matters Alliance (PMA), founded in March 2012, is a trade association whose mission is to create a better power paradigm for battery-equipped devices using wireless charging technology. The membership of the PMA is made up of companies across a diverse set of industries including telecommunication, consumer devices, automotive, retail, furniture, surfaces, and more, in order to guarantee consumers interoperable devices that employ wireless power technology. The PMA interface standard describes analog power transfer (inductive and resonant), digital transceiver communication, cloud-based power management, and environmental sustainability. The IEEE established the Wireless Power and Charging Systems Working Group (WPCS-WG) in October 2013, to develop the IEEE P2100.1 Standard Specifications for Wireless Power and Charging Systems following the creation of the PMA. The A4WP and the PMA have signed an agreement aimed at establishing global interoperability of the two standards in February 2014.

Activities of WPT standardization are also very active in Japan in recent years. IEICE Technical Committee on Wireless Power Transfer provides a platform for exchanging new ideas at the frontier of WPT researches. A consortium called Wireless Power Transfer Consortium for Practical Application (WiPoT) was founded in 2013 to accelerate the development of practical applications from the fundamental studies of WPT.

Summary

It was described how to investigate antenna parameters from the viewpoint of antenna theory to obtain the maximum power transfer efficiency in the wireless charging system based on the near-field coupling approach. The antenna parameters include geometry of transmitting and receiving antennas, electrical size

of antennas, impedance matching for antennas, distance between transmitting and receiving antennas, conductor loss (ohmic loss) of antennas, ohmic loss of matching circuits, and so on, in order to clarify the relationship between the maximum efficiency and these parameters. The approaches introduced in this chapter would be helpful to design and develop antennas in the wireless charging systems, and the simulation results can provide theoretical insight to how to optimize antenna design to improve the power transfer efficiency.

Abstract

Biomedical telemetry permits the measurement of physiological signals at a distance, through either wired or wireless communication technologies. One of the latest developments in wireless biomedical telemetry is in the field of implantable medical devices (IMDs). Such devices are implanted inside the patient's body by means of a surgical operation and can be used for a number of diagnostic, monitoring, and therapeutic applications. Implantable antennas, i.e., antennas which are integrated into RF-enabled IMDs, exhibit numerous challenges in terms of design, fabrication, and testing and are, therefore, currently attracting significant research attention. Contributions from researchers of various disciplines build a rich pool of background information, while highlighting future prospects.

Keywords

Biocompatibility; Biomedical telemetry; Industrial scientific and medical (ISM) applications band; Medical implant communication service (MICS) band; Miniaturization; Implantable antennas; In vitro; In vivo; Specific absorption rate

Introduction

Biomedical telemetry permits the measurement of physiological signals at a distance, through either wired or wireless communication technologies. Physiological signals are obtained by means of appropriate transducers, post-processed, and eventually transmitted to exterior monitoring/control equipment. One of the latest developments in wireless biomedical telemetry is in the field of implantable medical devices (IMDs). Such devices are implanted inside the patient's body by means of a surgical operation and can be used for a number of diagnostic, monitoring, and therapeutic applications (Greatbatch and Homes 1991; Chow et al. 2013; Kiourti et al. 2014a).

Nowadays, millions of people worldwide depend upon IMDs to support and improve the quality of their lives. Advances in biological, chemical, electrical, and mechanical sensor technologies as well as in microelectromechanical systems (MEMS) have led to a wide range of IMDs. Specifically, wireless IMDs are already in use for a wide variety of applications, including temperature monitors (Scanlon et al. 1997); pacemakers and cardioverter defibrillators (Wessels 2002); functional electrical stimulators (FES) (Guillory and Normann 1999); blood glucose sensors (Shults et al. 1994); cochlear (Buchegger et al. 2005), gastric, and bladder controllers (Sani et al. 2009); and retinal (Gosalia et al. 2004) implants.

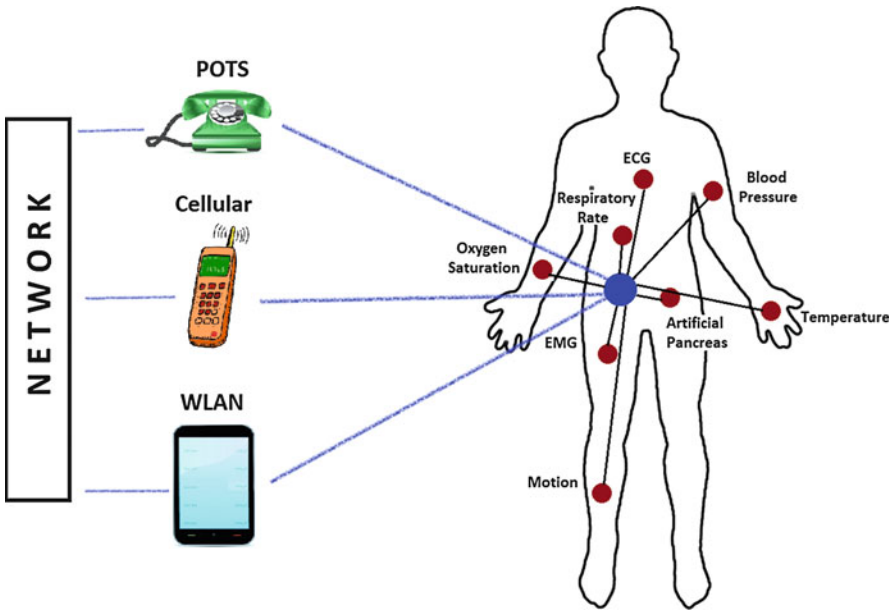

Fig. 1 Schematic of a typical wireless biomedical telemetry system with example IMD applications

As technology continues to evolve, new IMDs are being developed, and their use is expected to rapidly increase from this already large base.

Traditionally, low-frequency (tens to hundreds kHz) inductive links have been employed for the wireless telemetry of IMDs (Tang et al. 1995; Valdastri et al. 2004). However, inductive links suffer from: (a) low data rates (1–30 kbps), (b) restricted communication range (<10 cm), and (c) increased sensitivity to inter-coil positioning. To overcome these limitations, research is recently oriented toward radio-frequency (RF)-linked IMDs. Design of such RF telemetry systems is facilitated by the rapid advances in wireless communications and electronics. As shown in Fig. 1, a key and critical component of RF-linked IMDs is the integrated implantable antenna. In principle, picked-up physiological signals are amplified, digitized, and fed to a transceiver, which will code and modulate the data, and finally lead them to the antenna. The latter enables the IMD's bidirectional communication with the exterior monitoring/control equipment. In a realistic scenario, these implantable antennas are mounted on the existing hardware of the IMD.

Implantable antennas, i.e., antennas which are integrated into RF-enabled IMDs, exhibit numerous challenges in terms of design, fabrication, and testing and are, therefore, currently attracting significant research attention (Kiourti and Nikita 2012a; Chow et al. 2013). Specifically, numerical design of implantable antennas needs to be performed fast and in a way which optimally addresses issues related to operation frequency selection, miniaturization, biocompatibility, patient safety, high-quality communication with exterior equipment, and intersubject variability. Furthermore, prototype fabrication of such miniature antenna structures is highly challenging given their critical tolerance to potential experimental versus numerical inconsistencies. Finally, in vitro and in vivo testing of implantable antennas is highly intriguing given the requirements for (a) phantom formulation that matches the theoretical electrical properties and (b) implantation inside living model animals, respectively. Contributions from researchers of various disciplines build a rich pool of background information, while highlighting future prospects.

Design Considerations for Implantable Antennas

Considerations related to the design and performance of implantable patch antennas include (a) selection of the frequency band of operation, (b) miniaturization of the antenna's occupied volume/size, (c) biocompatibility of the antenna structure, (d) conformance of the implantable antenna to international guidelines which preserve patient safety against radiated electromagnetic (EM) fields (IEEE 1999, 2005), (e) high-quality communication of the implantable antenna with exterior monitoring/control equipment, and (f) intersubject variability. These considerations are discussed in detail in the following.

Frequency Bands of Operation

Selection of the operation frequency of implantable antennas, or equivalently IMDs, is receiving considerable attention from the scientific community as attributed to a number of competing factors.

Until recently, no globally accepted frequency band had been dedicated to the biomedical telemetry of IMDs. The situation changed with the ITU-R Recommendation SA.1346 (ITU-R 1998) which outlined the use of the 402.0–405.0 MHz frequency band for medical implant communication services (MICS). The most recent contribution in the field is the Institute of Electrical and Electronics Engineers (IEEE) 802.15.6 standard (IEEE 2012) which deals with short-range, wireless communications in the vicinity of, or inside, the human body. The standard refers to existing industrial, scientific, and medical (ISM) bands as well as frequency bands approved by national medical and/or regulatory authorities. According to this latest standard, an IMD shall be able to support transmission and reception in at least one of the following frequency bands: 402.0–405.0, 420.0–450.0, 863.0–870.0, 902.0–928.0, 950.0–958.0, 2,360.0–2,400.0, and 2,400.0–2,483.5 MHz. Ultrawide band (UWB) IMDs which implement low band (3,494.4–4,492.8 MHz) or high band (6,489.6–9,984.0 MHz) channels are also supported. For example, Table 1 summarizes recent research studies on implantable antennas operating within various frequency bands.

The ISM band of 2,400.0–2,500.0 MHz (ITU-R 2008) is appearing as one of the most promising solutions. This is because it is already well developed in terms of technology (Bluetooth, Wi-Fi, and WLAN), antennas, integrated circuits, and embedded systems. Furthermore, higher operation frequencies allow the use of smaller-sized antennas and components. It is for this purpose that implantable antennas operating at much higher frequencies (e.g., 5.85 and 31.5 GHz) have also been reported in the literature (see Table 1). However, a high number of operating services are colocated in the aforementioned bands. Therefore, interference issues constitute a limiting factor. Interference may cause harmful effects in terms of false IMD activation, link unavailability, and data corruption.

Table 1 Operation frequencies of implantable antennas reported in the literature

Frequency	References for implantable MDs
402 MHz	Kim and Rahmat-Samii 2004; Soontornpipit et al. 2004, 2005; Abadia et al. 2009; Chen et al.2009; Sani et al. 2009; Karacolak et al. 2009; Sánchez-Fernández et al. 2010; Gemio et al. 2010; Huang et al. 2011; Vidal et al. 2012; Kiourti and Nikita 2012b
433 MHz	Weiss et al. 2009; Gemio et al. 2010; Huang et al. 2011; Kiourti and Nikita 2012b

31.5 GHz	Ahmed et al. 2008

DOI 10.1007/978-981-4560-75-7_94-1

To deal with interference issues, focus for IMDs is mainly on the 402.0–405.0 MHz band, which has been exclusively allocated for medical implant communication services (MICS). The MICS band is currently regulated by the United States Federal Communications Commission (FCC) and the European Radiocommunications Committee (ERC). Its spectrum of 3 MHz allows for 10 channels (bandwidth of 300 KHz each) to operate simultaneously (i.e., multiple IMDs in the same area). It also limits potential interferences from the colocated Meteorological Aids Service band (401–406 MHz). Additional ways of enhancing interference tolerance include (a) automatic repeat request (ARQ) and forward error correction (FEC) techniques to mitigate the effects of impulsive noise (noise which is very short in duration and often of greater amplitude than the IMD signal levels) and (b) the use of frequency agility and channelization as a means of avoiding narrowband interferers (sources with bandwidths comparable to the IMD signal waveform). The MICS band is internationally available and feasible with low power circuits, falls within a relatively low noise portion of the spectrum, and allows for acceptable propagation through human tissue. A review on the regulatory standards for IMDs and the characteristics of MICS transceivers is performed in Savci et al. (2005).

The effect of operation frequency upon the performance of IMDs has been addressed in the literature. Single-cell excitation used to simulate vaginal (Scanlon et al. 2000) and gastric/bladder/cardiac (Sani et al. 2009) implants has been shown to exhibit increased power absorption, higher net body losses, and reduced penetration depths with increasing frequency. Recently, implantable antennas at higher frequencies were found to achieve enhanced gains (a 10.7 % increase in the maximum far-field gain at 915 MHz, compared to the gain at 402 MHz), increased maximum allowable net input power levels (10.1 % and 1.3 % increases imposed by the IEEE C95.1-1999 (IEEE 1999) and IEEE C95.1-2005 (IEEE 2005) safety standards, respectively), and more expanded specific absorption rate (SAR) distributions (Kiourti and Nikita 2012b). Results were attributed to the authors' choice of keeping the antennas' physical dimensions identical and modifying their effective size. Furthermore, the selection of the operation frequency is directly related to the bit rate: higher operation frequencies allow for an increase in bandwidth and enable higher bit rates, which are favorable for high data rate applications. For example, the maximum channel capacity for a band-limited additive white Gaussian noise (AWGN) channel is given by

$$C = BW \log_2\left(1 + \frac{S}{N}\right) \tag{1}$$

where BW is the channel bandwidth, S is the mean signal power, and N is the mean noise power. Therefore, the MICS band (BW 300 kHz) enables low bit rates, and the WMTS (BW 8.5 kHz to 6 MHz) and ISM (selectable BW) bands enable medium bit rates, whereas the UWB (BW $>$ 500 MHz) is appearing as the most promising solution for high data rates. It is remarked that according to the recent IEEE 802.15.6 standard (IEEE 2012), data rates of typically up to 10 Mbps are required to satisfy evolutionary health-care services.

Miniaturization

Recent advances in the technology of IMD electronics lead to ultrasmall designs for IMDs. For instance, implantable retinal prostheses should be small enough to be inserted inside the eyeball (radius of ~12.5 mm), while intracranial pressure monitors should be small enough to fit in standard 12 mm burr holes in the skull (Warty et al. 2008). However, dimensions of the traditional half-wavelength (λ/2) or quarter-wavelength (λ/4) antennas at the frequency bands allocated for medical implants and especially at the low-frequency MICS band make them useless for implantable applications. As an example, the free-space wavelength at 402, 433, 868, and 915 MHz can be computed as 74.6, 69.3, 34.6, and 32.8 cm,

DOI 10.1007/978-981-4560-75-7_94-1

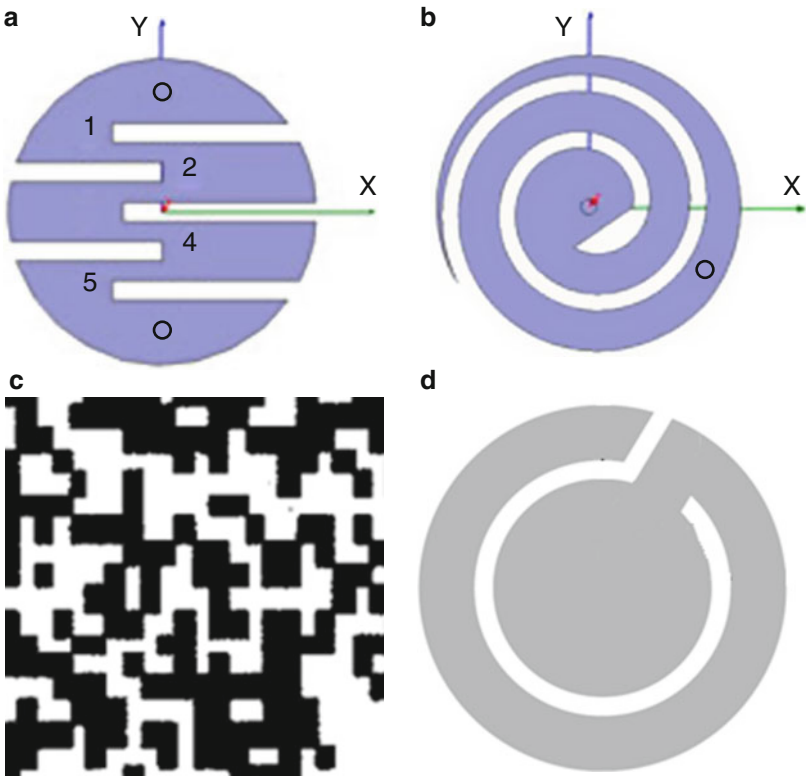

Fig. 2 Lengthening of the current flow path for miniature implantable antennas: (**a**) meandered (Kiourti and Nikita 2011), (**b**) spiral (Kiourti and Nikita 2011), (**c**) waffle-type (Soontornpipit et al. 2005), and (**d**) hook-slotted (Liu et al. 2008a) shaped patches

respectively. Therefore, miniaturization becomes one of the greatest challenges in implantable antenna design.

Fortunately, human tissues in which implantable antennas are intended to operate exhibit high permittivity (e.g., the permittivity of skin at 402 MHz is 46.7 (Gabriel et al. 1996a, b, c)) or, equivalently, reduced wave propagation velocity. This, in turn, increases the effective dielectric constant of the antenna and works to advantageously miniaturize its physical size. As would be expected, additional antenna miniaturization techniques can be concurrently employed. Specifically, miniaturization techniques that have been proposed in the literature for implantable antennas include:

- **Use of high-permittivity dielectric materials**. High-permittivity dielectrics are selected for implantable antennas (e.g., ceramic alumina ($\varepsilon_r = 9.4$) (Kiourti et al. 2011a) or Rogers RO3210 ($\varepsilon_r = 10.2$) (Kiourti and Nikita 2012b)) because they shorten the effective wavelength and result in lower resonance frequencies, thus assisting in antenna miniaturization.
- **Lengthening of the current flow path on the antenna surface**. Longer effective current flow paths excited on the antenna can reduce the resonance frequency and achieve a more compact size for the implantable antenna. For this purpose, meandered (Kiourti and Nikita 2011), spiral (Kiourti and Nikita 2011), waffle-type (Soontornpipit et al. 2005), and hook-slotted (Liu et al. 2008a) shaped implantable antennas have been suggested, as shown in Fig. 2.
- **Addition of shorting pins**. In the case of implantable patch antennas, inserting a shorting pin between the ground and patch planes increases the effective size of the antenna. This, in turn, reduces the required physical dimensions, given a specific operation frequency scenario. The technique works in much the same way a ground plane doubles the height of a monopole antenna, i.e., it typically produces

DOI 10.1007/978-981-4560-75-7_94-1

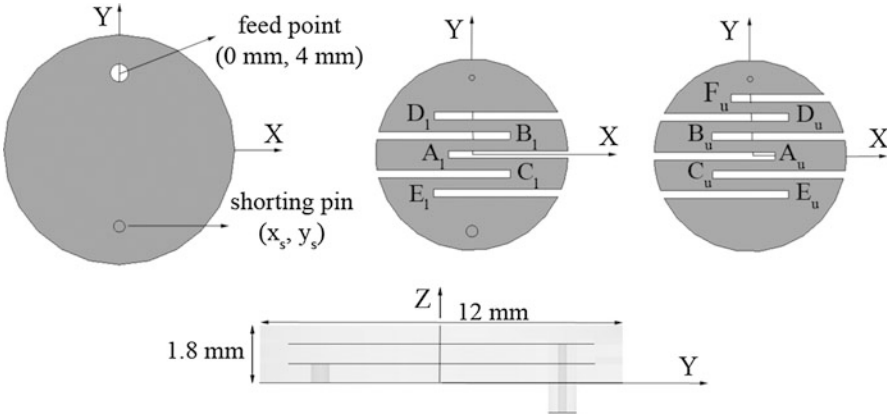

Fig. 3 Geometry of a stacked skin-implantable PIFA with meandered patches (Kiourti and Nikita 2012b)

a planar inverted-F antenna (PIFA) with the same resonance performance as a double-sized antenna without the shorting pin (Soontornpipit et al. 2004).

- **Patch stacking**. In the case of implantable patch antennas, vertically stacking two radiating patches reduces antenna size by increasing (nearly doubling) the length of the current flow path (Kiourti et al. 2011a; Kiourti and Nikita 2012b).

Implantable antennas reported in the literature combine some (or all) of these miniaturization techniques in order to reduce size. Of course, all antenna design parameters, including the location of the coaxial feed, have to be appropriately selected (optimized) for a good 50 Ω match at the desired operation frequency. For example, the skin-implantable antenna of Fig. 3 adapts a stacked PIFA structure of meandered patches built on Rogers RO3210 ($\varepsilon_r = 10.2$) substrate to achieve a miniaturized structure (volume of 214.9 mm^3) resonating in the MICS band (Kiourti and Nikita 2012b).

Nevertheless, it is important to emphasize that implantable antenna miniaturization comes in expense of its radiation and patient safety performance. Specifically, generic results for a skin-implantable antenna placed inside a tissue-simulating cube have indicated degraded gain and SAR performance with a reduction in size. Antenna miniaturization by 32 % and 65 % has been found to reduce the maximum far-field gain values by 5 % and 19 %, respectively, and the maximum allowable input powers imposed by the IEEE C95.1-1999 safety standard (IEEE 1999) by 21 % and 44 %, respectively. The significance of application-specific rather than miniaturization-oriented implantable antenna design is, thus, highlighted.

Biocompatibility

Implantable antennas must be biocompatible in order to preserve patient safety and prevent rejection of the implant. Another consideration is that human tissues are conductive and would short-circuit the implantable antenna if they were allowed to be in direct contact with its metallization. Biocompatibility and prevention of undesirable short circuits are especially crucial in the case of antennas which are intended for long-term implantation. In the literature, there have been reported two approaches for preserving the biocompatibility of implantable antennas and separating their metallic parts from the surrounding biological tissues: (a) covering the antenna structure with a biocompatible superstrate dielectric layer and (b) insulating the antenna with a thin layer of low-loss biocompatible coating.

Specifically, the most widely used approach for preserving the biocompatibility of an implantable antenna, while at the same time separating its metal radiator from the human tissues, is to cover the structure by a superstrate dielectric layer (e.g., Fig. 4a (Karacolak et al. 2008)). Commonly used biocompatible materials include Teflon (permittivity, $\varepsilon_r = 2.1$; dielectric loss tangent, $\tan\delta = 0.001$),

DOI 10.1007/978-981-4560-75-7_94-1

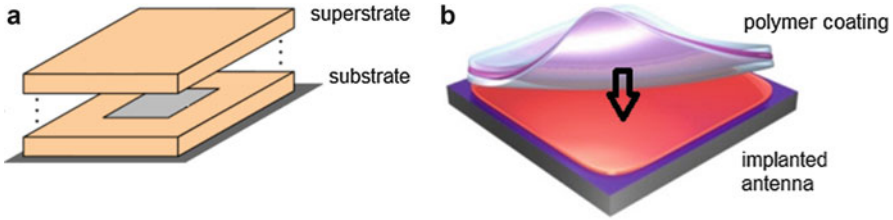

Fig. 4 Biocompatibility issues for implantable antennas: (**a**) addition of a superstrate (Karacolak et al. 2008) and (**b**) thin-layer encapsulation (Karacolak et al. 2010)

MACOR® ($\varepsilon_r = 6.1$, $\tan\delta = 0.005$), and ceramic alumina ($\varepsilon_r = 9.4$, $\tan\delta = 0.006$) (Soontornpipit et al. 2004). It is important to highlight, however, that ceramic substrates do not lend themselves easily to drilling and round cuts (Warty et al. 2008).

Insulating the implantable antenna with a thin layer of low-loss biocompatible coating is another reported approach (e.g., Fig. 4b; Karacolak et al. 2010). Materials proposed for biocompatible encapsulation include zirconia ($\varepsilon_r = 29$, $\tan\delta \approx 0$) (Skrivervik and Merli 2011), polyetheretherketone (PEEK) ($\varepsilon_r = 3.2$, $\tan\delta = 0.01$) (Abadia et al. 2009), polydimethylsiloxane (PDMS) ($\varepsilon_r = 3$, $\tan\delta = 0.005$), Silastic MDX4-4210 Biomedical Grade Base Elastomer ($\varepsilon_r = 3.3$, $\tan\delta \approx 0$), and Parylene ($\varepsilon_r = 2.95$, $\tan\delta = 0.005$) (Karacolak et al. 2010). Because of its electrical properties, zirconia is a better candidate material for biocompatible insulation from an electromagnetic point of view. High permittivity and low-loss tangent values allow the near fields of the antenna to concentrate inside the low-loss encapsulation layer, thus mitigating power loss. However, easiness of preparation and handling must also be taken into account. For example, PEEK and Silastic MDX4-4210 Biomedical Grade Base Elastomer are much easier to prepare and handle. Furthermore, thickness of the biocompatible insulation layer is an important factor in antenna design. Computation of its optimum thickness is, thus, considered to be highly significant for lowering power loss without aimlessly increasing antenna size.

It is remarked that addition of an insulation coating or superstrate layer significantly affects the performance of the antenna and, thus, needs to be taken into account within the design. Furthermore, a biocompatible hermetic package is necessary for housing the electronics, which may be made of low-temperature co-fired ceramic (LTCC), Parylene, liquid crystal polymer (LCP), silicon, or alumina (Chow et al. 2010).

Patient Safety and Specific Absorption Rate (SAR)

It was not until recently that research on the biological effects of IMDs started being carried out. Specifically, issues related to patient safety limit the maximum allowable power incident to the implantable antenna. The specific absorption rate (SAR) (rate of energy deposited per unit mass of tissue) is generally accepted as the most appropriate dosimetric measure, and compliance with international guidelines is assessed. For example, the IEEE C95.1-1999 standard restricts the SAR averaged over any 1 g of tissue in the shape of a cube to less than 1.6 W/kg ($SAR_{1g,max} \leq 1.6$ W/kg) (IEEE 1999). The ICNIRP's basic restrictions limit the SAR averaged over 10 g of contiguous tissue to less than 2 W/kg (ICNIRP 1998). To harmonize with the ICNIRP guidelines, the IEEE C95.1-2005 standard restricts the SAR averaged over any 10 g of tissue in the shape of a cube to less than 2 W/kg ($SAR_{10g,max} \leq 2$ W/kg) (IEEE 2005).

DOI 10.1007/978-981-4560-75-7_94-1

Specifically, the power absorbed by the human body in the presence of an incident electromagnetic field is given by

$$P_{\text{abs}} = \frac{1}{2}\int \sigma |E|^2 dV, \tag{2}$$

where σ is the conductivity of the human tissues and $|E|$ is the intensity of the electric field inside the body (Kim and Rahmat-Samii 2004). Equation 2 indicates that the absorbed power is related to the electric field, so that maximum SAR values are recorded in the areas where maximum electric field intensities occur.

Based on the deduction that peak averaged SAR values are generated from high near fields, novel implantable patch antennas can be designed, which aim at lower electric field intensities. For example, in Kim and Rahmat-Samii (2006), the radiation mechanism of an implantable antenna was discussed, in an attempt to modify its design for reducing the spatial-averaged SAR in human tissue. Replacing the uniform-width spiral radiator of an implantable MICS PIFA with a nonuniform-width radiator was found to decrease the electric field intensity and, in turn, $\text{SAR}_{1\text{g,max}}$. The simulated near electric field distribution showed that the high electric field area of the PIFA employing the nonuniform-width radiator was much smaller than that of the original PIFA. The value of $\text{SAR}_{1\text{g,max}}$ was, thus, limited from 310 to 210 W/kg, considering a net input power of 1 W.

Several safety evaluation studies have been performed for implantable antennas. Of importance is that the IEEE C95.1-1999 standard has been found to be much stricter than the recent IEEE C95.1-2005 standard (Kiourti and Nikita 2012b). The latter has shown to be almost insensitive to changes in the tissue model properties (anatomical features and dielectric parameters) (Kiourti and Nikita 2013a).

Radiation Performance

Biomedical telemetry systems for IMDs are comprised of the IMD and an exterior monitoring/control device, which is placed at some distance (typically 2 m) away from the body. Biotelemetry links may be used for device parameter adjustment, transmission of stored information, as well as real-time transmission of vital monitoring information. Therefore, the implantable antenna should provide a signal that is strong enough to be picked up by the exterior device, regardless of any power limitations. It is important to highlight that apart from patient safety, interference issues also limit the maximum allowable power incident to the implantable antenna. For example, a strict limit of −16 dBm (25 μW) has been set on the effective radiated power (ERP) of IMDs operating in the MICS band in order to prevent interference to the colocated Meteorological Aids Service band (ITU-R 1998).

Given the SAR and ERP power limitations, far-field gain of the implantable antenna indicates the desired receiver sensitivity for achieving reliable biotelemetry communication. In order to increase the range of biotelemetry communication, implantable antennas with enhanced gain are solicited. However, reduced-size antennas exhibit degraded electromagnetic performance: miniaturization degrades gain, while high-gain antennas exhibit relatively increased size. Low values of gain imply poor radiation efficiencies; however, compromises on the system performance are inevitable given the miniaturized antenna dimensions.

Of importance is that (a) the symmetry of the implantation tissue model affects the symmetry of the antenna's far-field radiation pattern, accordingly. Omnidirectional, monopole-like radiation is observed inside symmetrical tissue models (see Fig. 5a; Kiourti et al. 2011a; Kiourti and Nikita 2012b), whereas asymmetrical radiation is recorded within anatomical tissue models which are irregular and inhomogeneous (see Fig. 5b; Kiourti et al. 2011a; Kiourti and Nikita 2012b).

DOI 10.1007/978-981-4560-75-7_94-1

Powering Considerations

All the components of an IMD, including the implantable antenna, require power. Integrated power supplies, such as batteries, are only suitable for applications where the IMD lifespan is short (e.g., IMDs which are intended to be implanted for months or a few years, depending on the duty cycle). To elongate the battery life of IMDs, external power transmission has been proposed for recharging purposes (Kendir et al. 2005). The technique is based on electromagnetic (EM) induction between an exterior-transmitting and an implantable receiving coil, which is placed in close distance and is often wound around a dielectric or ferrite core to improve the efficiency. Furthermore, power scavenging sources including motion, vibration, air flow, temperature difference, light, and infrared radiation have been suggested. For example, a vibration-based generator for implantable IMDs, capable of delivering 2 mJ/cycle, has been designed, while ambient EM energy harnessing has recently been investigated (Mitcheson et al. 2004). Such solutions are solicited for IMDs which are intended for an implantation period of several years or even a lifetime (cochlear implants for the deaf or retina implants for the blind).

To meet potential longevity requirements of the IMDs and guarantee their on demand availability, power conservation techniques can additionally (or instead) be applied. Suggested ideas include pre-configured on-off function of the IMD (Furse 2009) and transmission/detection of a "wake-up" alarm signal (Karacolak et al. 2008). In the first case, devices spend most of their time in an ultraefficient sleep mode followed by short bursts of data transmission. Data mining or compression techniques may be used to reduce the actual bits of data to be transmitted. In the second case, the system uses two frequency bands, one for "wake up" and one for transmission. The transceiver stays in "sleep mode" with low power consumption (1 μW) until a "wake-up" signal is sensed in the 2,450 MHz ISM band. In the normal mode, the IMD is fully powered and exchanges data in the MICS band. Following the data transfer, the IMD transceiver returns back to the "sleep mode." To do so, a transceiver with dual-band operation may be used, such as the commercially available Zarlink ZL70101 Transceiver (Zarlink 2006). The system uses two frequency bands, one for "wake up" and one for transmission. The exterior device may be programmed to wake up the implanted device according to a physician-defined schedule or only when a patient event is detected (Savci et al. 2005).

It is remarked that the employment of "wake-up" techniques requires the design of multiband antennas, i.e., a separate band for data biotelemetry and a separate band for transmission/detection of the "wake-up" alarm signal. For example, a dual-band (MICS and ISM) implantable antenna has been proposed in the literature for continuous glucose monitoring (Karacolak et al. 2008). A meandered antenna configuration was considered for optimizing the antenna surface area, and particle swarm optimization was applied to

DOI 10.1007/978-981-4560-75-7_94-1

achieve the desired resonance characteristics. The simulated and measured bandwidths were found to be 82 and 142 MHz in the MICS band and 103 and 174 MHz in the ISM band, respectively. An innovative dual-band (MICS and ISM) patch antenna with a multilayer configuration and electromagnetic coupling-based feeding has further been proposed for implantation inside the left subpectoral region (Sánchez-Fernández et al. 2010). Recently, a novel antenna design was suggested using a π-shaped radiator with stacked and spiral structure, to support triple-band operation with data telemetry (402 MHz), wireless power transmission (433 MHz), and wake-up controller (2,450 MHz) (Huang et al. 2011). The simulated and measured bandwidths were 86 and 114 MHz in the MICS band and 60 and 70 MHz in the ISM band, respectively.

Intersubject Variability

Since implantable antennas are intended to operate inside human tissue, their performance strongly depends on the surrounding tissue environment. The latter includes (a) the anatomical features of the individual and (b) the dielectric parameters (permittivity, ε_r, and conductivity, σ) of the biological tissues.

For example, smaller-sized (female and low body mass index male) anatomical models have been found to exhibit higher radiated power levels and far-field gain values (Sani et al. 2009). Simplified, single-cell excitation was considered in this study to mimic gastric, bladder, and cardiac implants at 402 and 868 MHz. Anatomical differences considering a realistic model of an implantable antenna have also been assessed (Vidal et al. 2012). In this study, two implantable antennas were designed to operate at 403 MHz within mean head and mean body tissues, respectively, and the exhibited resonance performance was studied. Simulations for head, arm, and abdomen implantation were carried out within four anatomical models (two adults and two children), indicating a maximum detuning of 14 MHz from the reference frequency of 403 MHz.

Tissue dielectric parameters (permittivity and conductivity) also affect the design and performance of implantable antennas. Therefore, variations due to uncertainties in dielectric properties and intersubject variability have to be taken into account (Virtanen et al. 2006). It is remarked that maximum standard deviations of 16 % have been reported in the dielectric parameter values of rat brain tissue (Bao et al. 1997), while age dependency has repeatedly been emphasized (Gabriel 2005; Conil et al. 2008). Decrease in permittivity and conductivity values by 4 % and 10 % has been recorded, respectively, for pig tissue within 4 h after death (Schmid et al. 2003).

Recently, the performance of a MICS scalp-implantable antenna was assessed with respect to variations in head properties, i.e., anatomy and dielectric parameters (Kiourti and Nikita 2013a, b). Five head models (3- and 5-layer spherical and 6-, 10-, and 13-tissue anatomical; see Fig. 6) and seven dielectric value scenarios (variations by ±20 % in the reference permittivity and conductivity values) were considered. Compared with the reference dielectric parameter scenario within the 3-layer spherical head model, maximum variations of −19.9 %, +3.7 %, −55.1 %, and −39.2 % were overall recorded in IEEE C95.1-1999 (IEEE 1999), IEEE C95.1-2005 (IEEE 2005), RL, and G_{max} at 403.5 MHz. More specifically, the performance of implantable antennas was found to considerably depend on the anatomy of the tissue model in the area that is immediately surrounding the implant. In particular, the 6-tissue anatomical head model, which exhibited a bump of skin tissue at the top side of the head (implantation site), demonstrated the highest deviations. As long as anatomical features around the implant are relatively similar, overall anatomy and tissue composition/distribution of the numerical model were found to insignificantly influence the antenna performance. On the other hand, tissue dielectric parameters were found to insignificantly affect the implantable antenna performance. As compared to the reference dielectric value scenarios, variations in IEEE C95.1-1999 (P_{1999}) and IEEE C95.1-2005 (P_{2005}) ranged, on average, between −0.4 % and +0.1 % and between −0.4 % and +0.8 %, respectively. RL varied between −33.1 % and +17.6 % and G_{max} between −0.6 % and +3.1 %.

DOI 10.1007/978-981-4560-75-7_94-1

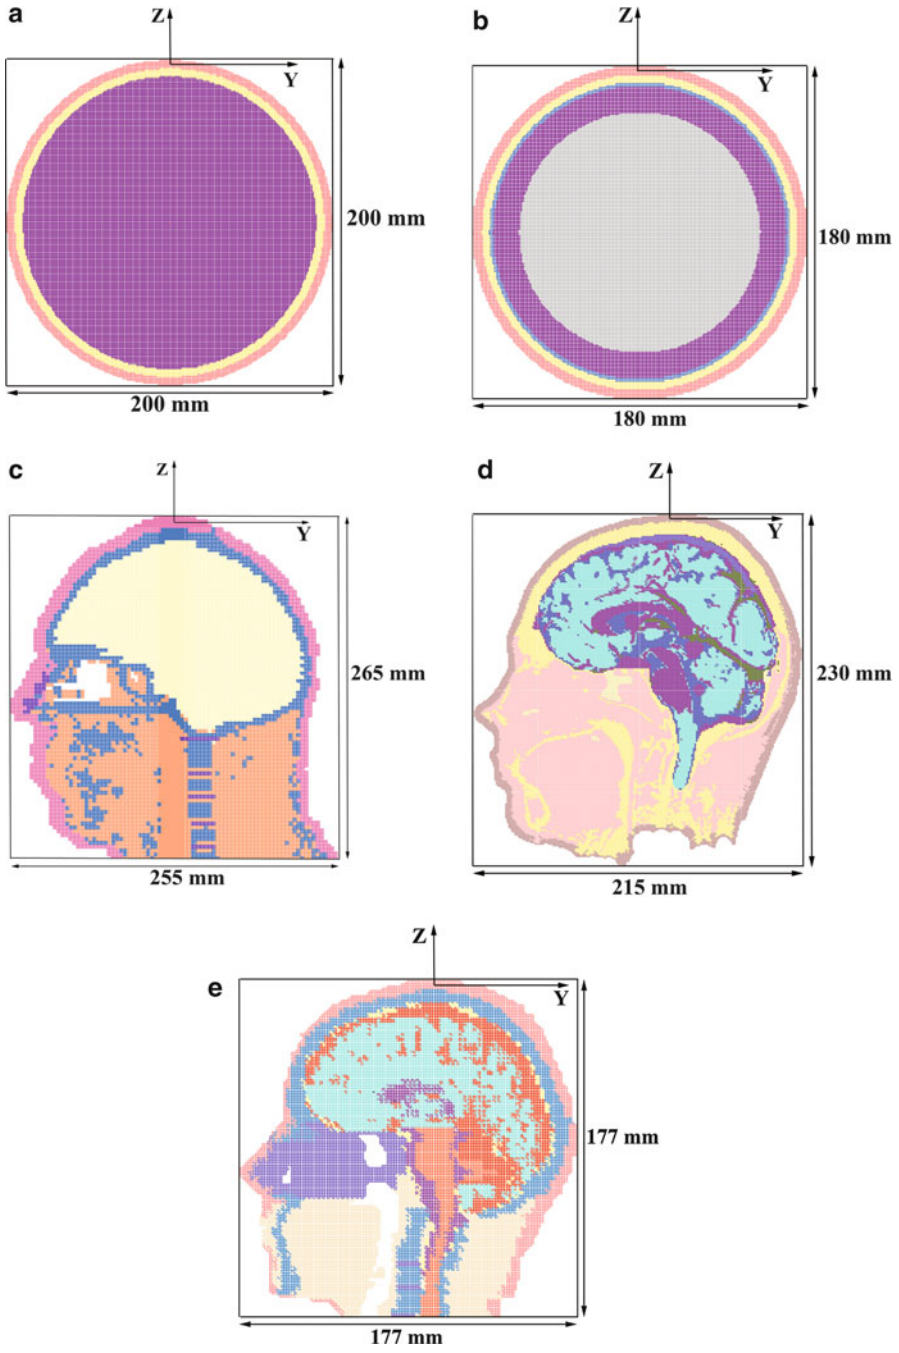

Fig. 6 Antenna implanted inside five numerical human head models: (**a**) 3-layer spherical, (**b**) 5-layer spherical, (**c**) 6-tissue anatomical, (**d**) 10-tissue anatomical, and (**e**) 13-tissue anatomical (Kiourti and Nikita 2013a)

In summary, taking tissue anatomy and dielectric parameter uncertainties into account has been shown to be important for implantable antenna design and performance evaluation. As far as compliance with safety guidelines is concerned, uncertainties inherent to variations in tissue anatomy and dielectric parameters must be taken into account. Nevertheless, it is important to highlight that in contrast to the IEEE C95.1-1999 guidelines, compliance with the recent IEEE C95.1-2005 guidelines occurs to be almost insensitive to tissue properties. Furthermore, results indicate the need for designing implantable antennas with enhanced bandwidth in order to compensate for detuning and impedance mismatch

DOI 10.1007/978-981-4560-75-7_94-1

inherent to intersubject variability. A conservative evaluation of the link budget between the implantable antenna and exterior equipment is also required in order to account for potential degraded gain values and deteriorated symmetry in radiation.

Numerical Design and Performance Assessment of Implantable Antennas

Tissue Models and Design Strategies for Implantable Antennas

The fact that implantable antennas are intended to operate inside biological tissue rather than in free space affects their design and performance in a number of ways. Specifically, given the presence of the human body, design of implantable antennas should be performed either (a) inside free space and further refined for tissue implantation or (b) directly inside an environment surrounded by human tissue. It is noted that in numerical simulations, biological tissues are analyzed as inhomogeneous lossy mediums that have their own permittivity (ε_r), conductivity (σ), and mass density values. These can be either approximated as constant within a narrow frequency range (Kiourti et al. 2011a; Kiourti and Nikita 2012b) or described by means of a Cole–Cole formulation for the complex relative permittivity, according to

$$\varepsilon_c(\omega) = \varepsilon_\infty + \sum_n \frac{\Delta\varepsilon_n}{1 + (j\omega\tau_n)^{(1-\alpha_n)}} + \frac{\sigma_i}{j\omega\varepsilon_0} \tag{3}$$

where ω is the angular frequency, n is the order of the Cole–Cole model, ε_∞ is the high-frequency permittivity, τ_n is the relaxation time, $\Delta\varepsilon_n$ is the pole amplitude, α_n is the parameter that allows for the broadening of the dispersion, and σ_i is the static ionic conductivity (Karacolak et al. 2009; Noroozi and Hojjat-Kashani 2012). Canonical tissue models are often used to speed up simulations and ease the design of implantable antennas. These may be either single layer (e.g., Fig. 7a; Kiourti and Nikita 2012b) or multilayer (e.g., Fig. 7b; Karacolak et al. 2008). To obtain more realistic results, anatomical tissue models (e.g., Fig. 7c; Kiourti and Nikita 2012b) produced by the combination of magnetic resonance imaging (MRI) or computed tomography (CT) data can also be applied.

Suggested design strategies for implantable antenna design include:

- **Strategy #1.** Antenna design in free space and further refinement inside an anatomical model of the intended implantation site. For example, in Rucker et al. (2007), a MICS patch antenna was designed in a free-space environment and further implanted inside the skin tissue of an anatomical head model. Resonance frequency detuning was observed, as attributed to the capacitive loading effect of the surrounding tissues. To refine the resonance, a varactor diode with tuning capabilities was subsequently integrated.
- **Strategy #2.** Antenna design in free-space targeting at high-gain values and further refinement inside a single-layer tissue model. For example, in Abadia et al. (2009), a MICS antenna was designed in free space aiming at high gain (>-20 dB) in order to account for subsequent body absorption losses. The antenna was optimized in free space to minimize size and further covered by a biocompatible layer and placed inside tissue material. Design modifications were performed to account for the frequency shift induced by the presence of encapsulation and human tissue.
- **Strategy #3.** Antenna design directly inside a canonical single-layer tissue model (cubical, rectangular parallelepiped, or cylindrical) of the intended implantation tissue. As would be expected, use of a single-layer tissue model is the simplest and fastest option when designing implantable antennas directly inside tissue material. Following this design strategy, antennas are designed for a "generic" tissue-implantation scenario. Simplified tissue models in the shape of a cube (Kiourti et al. 2011a, b), a

DOI 10.1007/978-981-4560-75-7_94-1

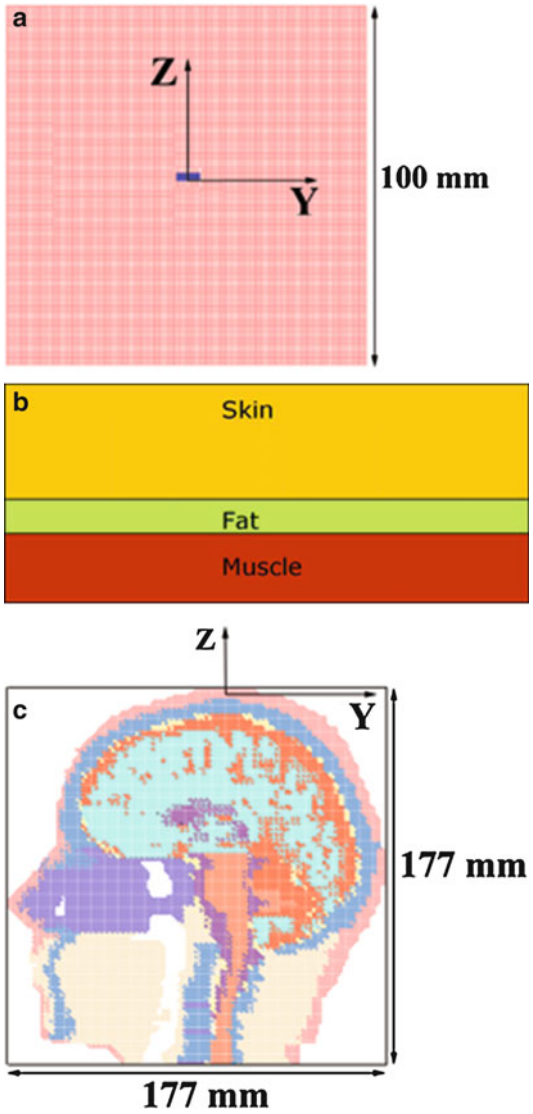

Fig. 7 Tissue models: (**a**) single-layer canonical (skin cube) (Kiourti and Nikita 2012b), (**b**) three-layer (skin/fat/muscle) canonical (Karacolak et al. 2008), and (**c**) anatomical human head (Kiourti and Nikita 2012b)

rectangular parallelepiped (Liu et al. 2008a; Kim and Rahmat-Samii 2004, 2006), and a cylinder (Liu et al. 2008b, 2009) have been used for this purpose. Design is performed by selecting the dielectric material and subsequently optimizing all antenna design parameters to refine tuning at the desired operation frequency.

- **Strategy #4.** Antenna design directly inside a canonical multilayer tissue model (cubical, rectangular parallelepiped, or cylindrical) of the intended implantation tissue. This strategy intends to design the antenna for a specific implantation site by taking into account a specific region of the body. A multilayer tissue model, with either finite or infinite dimensions, is selected. For example, implantable antennas intended for trunk (Karacolak et al. 2008) and chest (Kim and Rahmat-Samii 2004) implantation have been directly designed inside three-layer planar tissue models consisting of skin, fat, and muscle tissues.
- **Strategy #5.** Approximate antenna design inside a cube filled with the intended tissue material and further quasi-Newton optimization inside a canonical model of the intended implantation site (Kiourti and Nikita 2012b). This strategy emphasizes on design speedup and optimized resonance performance

DOI 10.1007/978-981-4560-75-7_94-1

of the implantable antenna inside a specific implantation site. It is remarked that, as far as antenna design is concerned, multilayer canonical models have been shown to provide an acceptable model for the human body. Specifically, highly similar return loss characteristics have been found for implantable patch antennas inside a three-layer planar geometry and a realistic model of the human chest (Kim and Rahmat-Samii 2004), as well as inside a three-layer spherical and an anatomical model of the human head (Kiourti and Nikita 2012b).

- **Strategy #6.** Antenna design inside a small-sized single-layer or multilayer tissue box (Kiourti and Nikita 2012c). Numerical results inside small-sized tissue boxes have been found to be almost identical to those inside canonical models of the intended implantation site, thus, rendering design directly into the latter unnecessary and inadequately slow. The aim is to minimize the use of required computational resources or, equivalently, the required simulation time toward designing implantable antennas optimized for specific medical implantation scenarios. Incorporation of the dielectric loading of the surrounding tissues and exterior air in the design and use of canonical, small-sized tissue models have been found to form the optimum solution for design purposes.

Regarding the numerical performance analysis of implantable antennas, it is noted that analytical methods can only be applied for simplified implantable antennas placed inside canonical tissue models. For example, a spherical dyadic Green's function (DGF) code has been implemented in the literature to characterize a MICS dipole antenna implanted inside a multilayer spherical human head model (Kim and Rahmat-Samii 2004). As a result, emphasis is mainly on numerical methods implemented on commercial electromagnetic simulation platforms. The electromagnetic solvers which are most commonly used in the literature for implantable antenna design are based on the finite element (FE) method (e.g., Ansoft HFSS) (Kiourti et al. 2011b; Liu et al. 2008a, b; Huang and Kishk 2011). The finite difference time domain (FDTD) method is also applied in some studies, because it exhibits simplicity in the implementation of inhomogeneous media and assessment of bioelectromagnetic interactions, while enabling efficient modeling of detailed anatomical human body parts (e.g., CST Microwave Studio, Remcom XFdtd) (Soontornpipit et al. 2004; Kiourti and Nikita 2012b; Kim and Rahmat-Samii 2004, 2006). In all cases, the computational cost heavily depends on the complexity of the tissue and antenna models. Absorbing boundaries (e.g., Mur (Soontornpipit et al. 2004)) or perfectly matched layer boundaries (Soontornpipit et al. 2005) are placed at some distance away from the setups to truncate the simulation domain while extending radiation infinitely far.

A Step-by-Step Example Tutorial to Implantable Antenna Design

In this section, a simple, yet analytical and complete, step-by-step example tutorial is provided on implantable antenna design (Kiourti and Nikita 2014). Simulations are carried out within the framework of a MICS implantable patch antenna for intracranial pressure (ICP) monitoring applications. Nevertheless, the same steps may be applied for any implantable antenna design that the designer may have on hand. It is remarked that the design strategy followed hereafter is the strategy #6 that was discussed in the previous section. As compared to the other strategies, strategy #6 has been shown to result in the fastest design of implantable antennas with optimized resonance characteristics within the medical application on hand. The reason is that it incorporates dielectric loading of both the surrounding tissues and exterior air on the antenna, while employing a canonical (parallelepiped) miniature tissue model, which can be meshed and solved in a relatively easy and fast way (Kiourti and Nikita 2012c). Equivalently, the tissue-simulating box considered in this methodology has been found to be the simplest and smallest tissue model in which the implantable antenna exhibits almost identical reflection coefficient frequency response as it would exhibit inside a canonical or anatomical tissue model of the intended implantation site (Kiourti and Nikita 2012c).

DOI 10.1007/978-981-4560-75-7_94-1

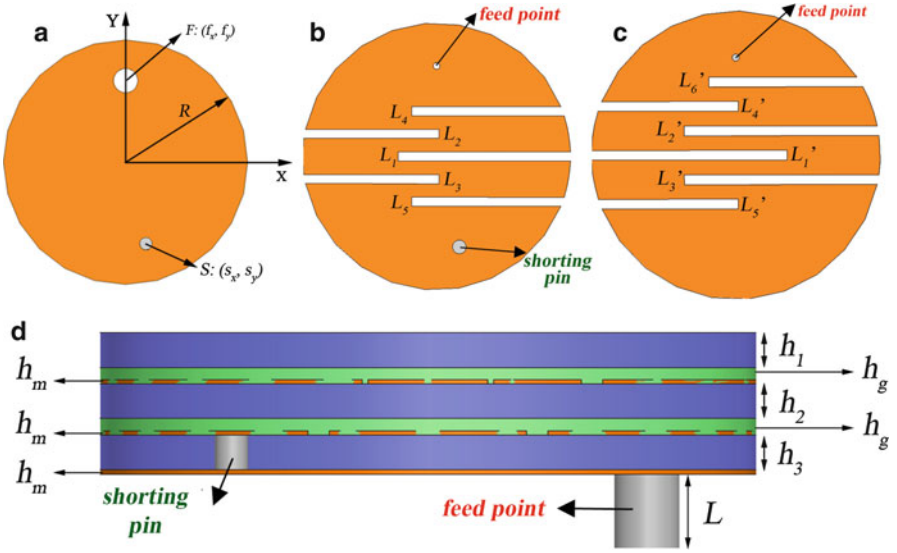

Fig. 8 Parametric implantable antenna model: (**a**) ground plane, (**b**) lower patch, (**c**) upper patch, and (**d**) side view (Kiourti and Nikita 2014)

The parametric implantable antenna model of Fig. 8 is employed to serve the goals of this tutorial. The model consists of a ground plane (radius of R) and two vertically stacked patches (radius of $R = 0.1$ mm each), printed on dielectric substrates (permittivity of ε_{rd} and thicknesses of h_1 and h_2, respectively). Origin of the coordinate system is considered to be located at the center of the antenna ground plane. A dielectric superstrate (permittivity of ε_{rd} and thickness of h_3) covers the structure for biocompatibility purposes. Meanders of variable lengths (L_i, $i = 1$–5, 1–$6'$) and identical widths (0.4 mm) are inserted into the patches to assist in miniaturization. A shorting pin (S: (s_x, s_y)) connects the ground plane to the lower patch, while a 50 Ω coaxial cable of variable type and length (L) excites both patches (F: (f_x, f_y)). Copper sheets (thickness of h_m) are considered for the ground plane and patches, while glue layers (permittivity of ε_{rg} and thickness of h_g) bond the dielectric layers together. It is remarked that, in fabrication, glue layers are to be inserted between multiple substrate layers and/or between substrate and superstrate layers of the antenna for bonding purposes (Kiourti and Nikita 2012a; Abadia et al. 2009). Gluing has been found to be a very critical factor for implantable antenna design and has to be accounted for the following: low-permittivity glue layers isolate the high-permittivity substrate layers, thus decreasing the effective permittivity and electrical length of the antenna, while increasing its resonance frequency. Importantly, due to the miniature size of implantable antennas, inconsistencies between the numerical antenna model and the fabricated prototype might result in a nonfunctional prototype. Therefore, gluing considerations have to be taken into account within simulations.

Once the parametric implantable antenna model has been selected, the next step is to appropriately tune its design parameters using an electromagnetic (EM) modeling and simulation program. The goal is to quickly calculate those parameter values which will optimize the antenna design in terms of impedance matching as well as exhibited radiation and patient safety performance at the desired operation frequency. The flowchart of the design strategy #6 is shown in Fig. 9 (Kiourti and Nikita 2012c). It is hereafter applied within the framework of tuning the parametric implantable antenna model of Fig. 8 for ICP monitoring (Warty et al. 2008) at 402 MHz (MICS band) (Kiourti and Nikita 2012b; Kiourti et al. 2012).

- **"*Fabrication-related*" *parameters*:** Initially, the "fabrication-related" parameters of the antenna are set to the values dictated by the intended fabrication procedure (Table 2). As part of this tutorial, Rogers

DOI 10.1007/978-981-4560-75-7_94-1

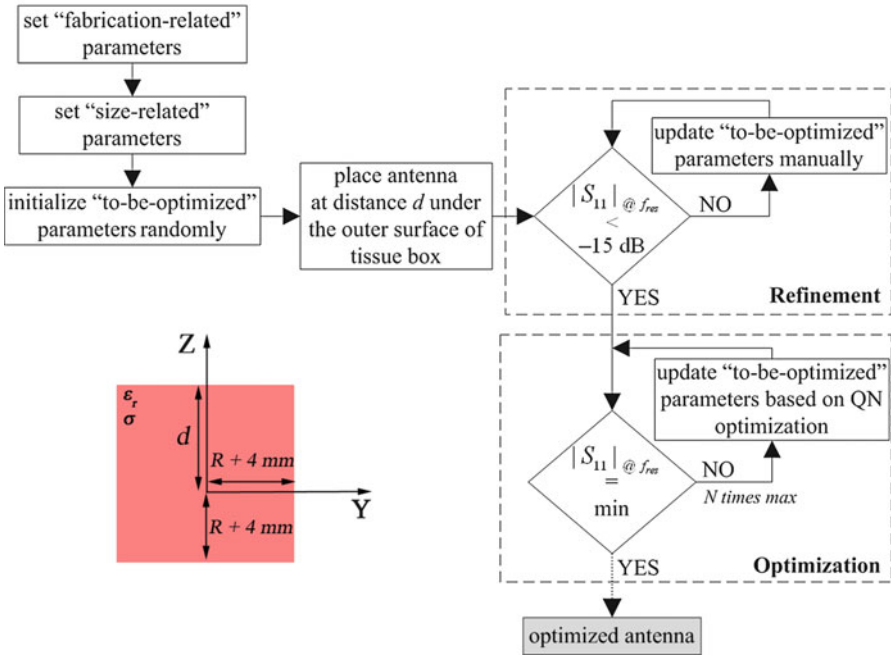

Fig. 9 Flowchart of the methodology for numerical design of implantable antennas

RO3210 ($\varepsilon_{rd} = 10.2$) dielectric sheets with a thickness of 0.635 mm ($h_1 = h_2 = h_3 = 0.635$ mm) are considered. The aforementioned dielectric sheets come premetallized with a 0.017 mm-thick electrodeposited copper foil ($h_m = 0.017$ mm). Sprayable glue 3 M 77 is used to bond the layers ($\varepsilon_{rg} = 2.0$), which has been found to exhibit an average thickness of 0.3 mm ($h_g = 0.3$ mm) for the fabrication process to be followed. The antenna is to be fed by means of a 50 mm-long ($L = 50$ mm) EZ-47 (center conductor diameter of 0.29 mm, PTFE dielectric with a diameter of 0.93 mm, outer conductor diameter of 1.19 mm) semirigid coaxial cable.

- **"*Size-related*" *parameters*:** Next, the "size-related" parameters of the antenna have to be selected, i.e., the parameters which determine the outer dimensions (physical size) of the antenna. In the parametric implantable antenna model considered in this tutorial, these are dictated by the antenna radius, R. Selection of the outer dimensions relies on the expertise and knowledge of the designer and must be performed based on the following two considerations. Firstly, size of the implantable antenna needs to take into account the desired implantation site and medical application scenario, as well as the size of the IMD in which it will be integrated. Secondly, miniaturization should not be set as the sole goal of the design. Previous studies have demonstrated degraded radiation and patient safety performance with size reduction for implantable antennas and have quantified this degradation as a function of size (Kiourti and Nikita 2012d). Given these considerations, a radius of $R = 6$ mm is selected for the ICP monitoring antenna under study (see Table 2).
- **"*To-be-optimized*" *parameters*:** The rest of the design parameters are considered as dimensions in the solution space and have to be tuned for an optimized 50 Ω impedance match at the desired operating frequency ("to-be-optimized"). Design is performed by: (a) setting the "fabrication-related" and "size-related" parameters to the values selected in the previous steps, (b) initializing the "to-be-optimized" parameters to random values, and (c) placing the antenna at a distance d under the outer surface of the tissue-simulating box shown in the inset of Fig. 3 (Kiourti and Nikita 2012c). The distance d corresponds to the actual air-to-antenna separation distance for the desired medical application scenario (implantation depth). The tissue-simulating box extends by $R + 4$ mm in the x- and y-directions (R is

Table 2 Parameter values selected for optimally tuning the implantable antenna model of Fig. 8 at 402 MHz (MICS band)

	Parameters	Values
"Fabrication-related"	ε_{rd}	10.2
	ε_{rg}	2.0
	h_1	0.635 mm
	h_2	0.635 mm
	h_3	0.635 mm
	h_m	0.017 mm
	h_g	0.3 mm
	L	50 mm
	Coaxial type	EZ-47
"Size-related"	R	6 mm
"To-be-optimized"	L_1	7.597 mm
	L_2	10.146 mm
	L_3	10.146 mm
	L_4	3.019 mm
	L_5	3.019 mm
	$L_{1'}$	11.397 mm
	$L_{2'}$	11.146 mm
	$L_{3'}$	11.146 mm
	$L_{4'}$	10.519 mm
	$L_{5'}$	10.519 mm
	$L_{6'}$	8.993 mm
	s_x	1 mm
	s_y	−4 mm
	f_x	0 mm
	f_y	4 mm

the maximum dimension of the antenna in the positive y-axis) and simulates the electrical properties of the intended implantation tissue.

In the "refinement" step of the design strategy, an approximate design is performed for the antenna. The "to-be-optimized" parameters are manually updated in an iterative way, until the magnitude of the reflection coefficient ($|S_{11}|$) at the desired operating frequency (f_{res}) satisfies:

$$|S_{11}|_{@f_{res}} < -15\ dB \tag{4}$$

Manual update relies on the skills and expertise of the designer, who is considered to be aware of the theoretical background related to antenna miniaturization (e.g., longer meanders are expected to increase the length of the current flow and result in lower resonance frequencies (Dey and Mittra 1996).

In the "optimization" step of the design strategy, antenna design is optimized. The "to-be-optimized" parameters are initialized to the values of the refinement step and are optimized based on a software-integrated optimization algorithm. The optimization process terminates when:

$$|S_{11}|_{@f_{res}} = \min \tag{5}$$

DOI 10.1007/978-981-4560-75-7_94-1

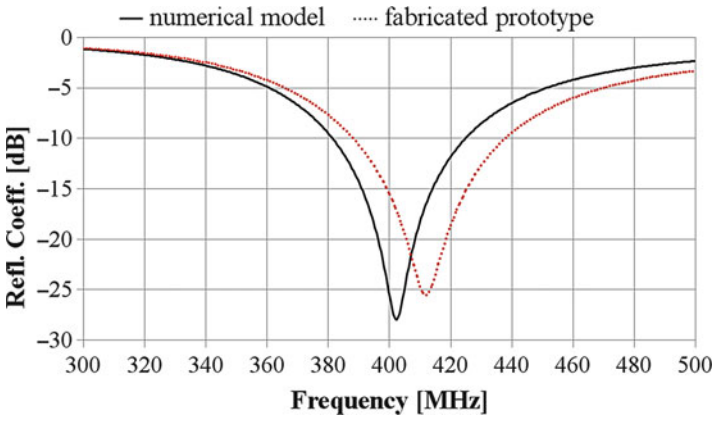

Fig. 10 Numerical and in vitro measured reflection coefficient frequency response of the proposed implantable antenna for ICP monitoring

or when the number of iteration exceeds a pre-defined maximum number.

As part of this tutorial, simulations are performed at a distance of $d = 5$ mm under the outer surface of a small ($R = 6$ mm) tissue-simulating box, which corresponds to the actual average implantation depth of an ICP monitor inside the human scalp. The tissue-simulating box represents skin tissue (scalp) electrical properties at $f_{res} = 402$ MHz ($\varepsilon_r = 46.7$, $\sigma = 0.69$ S/m), which are approximated as constant inside the 300 to 500 MHz range. Using this approximation, the maximum errors of ε_r and σ are given by 6.59 % and 8.89 %, respectively. The "to-be-optimized" parameters of the antenna are optimized based on quasi-Newton optimization (the maximum number of iterations is set to 300), due to its speed and accuracy in cases of insignificant numerical noise (Sun and Yuan 2006). Optimal parameter values are given in Table 2, whereas the reflection coefficient frequency response of the designed antenna is shown in Fig. 10 ("numerical model"). The antenna resonates at 402 MHz with a reflection coefficient of −27.9 dB and a wide 10 dB bandwidth of 44 MHz, which covers the MICS band.

Example Implantable Antennas

Relative position and orientation between an IMD and its exterior monitoring/control equipment counterpart is known a priori. As a result, patch designs are most commonly chosen for implantable antennas because they exhibit directive radiation patterns, lend themselves easily to a number of miniaturization techniques, and are highly flexible in design, conformability, and shape. In a realistic scenario, the implantable patch antenna will be mounted on the existing hardware of the IMD, which will also serve as its ground plane. Table 3 compares the volume occupied by MICS implantable antennas reported in the literature with respect to the applied miniaturization techniques. The bands of operation covered are also included in Table 3. When the number of bands of operation is increased, the size of the antenna is typically increased to cover them. Circular shape is generally preferred in order to avoid sharp edges that could cause injury. The performance of these antennas is further compared in Table 4 in terms of their 10 dB bandwidth (BW), maximum allowable input power levels imposed by the IEEE C95.1-1999 (1 g-avg SAR $\leq$ 1.6 W/kg (IEEE 1999)) (P_{1999}) and IEEE C95.1-2005 (10-g-avg SAR $\leq$ 2 W/kg (IEEE 2005)) (P_{2005}) safety guidelines, and maximum far-field gain (G_{max}). In general, increased-size implantable antennas exhibit more uniform distributions of the electric field and current density across an increased patch surface area, so that lower SAR values are obtained.

Nevertheless, it is remarked that dipole (Kim and Rahmat-Samii 2004), loop (Chen et al. 2009), monopole (Weiss et al. 2009), modified dipole (Scarpello et al. 2011), and 3D spiral (Abadia et al. 2009) antennas have also been reported for implantation purposes.

Fabrication and Testing of Implantable Antennas

Experimental investigations are required in order to confirm the validity of numerical simulations for implantable antennas. Of course, it is not possible to carry out measurements inside real operating scenarios (i.e., inside the human body). Therefore, experimental testing is performed by measuring the fabricated antenna prototypes inside either tissue-equivalent mediums (phantoms) or animal tissue.

Fabrication of Implantable Antennas

Fabrication of implantable antenna prototypes needs to deal with all challenges related to the fabrication of miniature antenna structures. For example, glue layers used to affix all components together strongly affect the antenna performance by shifting its resonance frequency and degrading its impedance matching. Furthermore, the coaxial cable feed used to connect the antenna with the network analyzer may give rise to radiating currents on the outer part of the cable, which, in turn, may deteriorate the

measurements. Therefore, fabrication of implantable antennas is highly intriguing. In the following, the fabrication of implantable antennas will be discussed as part of fabricating the prototype of the design shown in Fig. 8. The latter incorporates several fabrication challenges that any prototype fabrication might have to deal with (e.g., multiple layers, inclusion of a shorting pin, etc.).

Specifically, three key aspects of the fabrication are considered to mainly influence the final antenna behavior: (a) substrate cutting, (b) substrate gluing, and (c) layer alignment. One of the problems is that these three steps are not necessarily independent. In fact, because the substrate material is relatively stiff, it cannot (or is hard to) be cut after the antenna has been assembled: micro-soldering of the coaxial cable and shorting pin are very fragile and cannot withstand the vertical pressure and torsion of the cutting tool. Furthermore, external alignment points are proved to be required for the assembling, to be removed after fabrication. Therefore, a mounting base (Fig. 11a) is suggested to be fabricated in order to help with the antenna's assembly. This base ensures the correct alignment between the three layers, while serving as the antenna support for the different soldering procedures. Based on the above, a typical fabrication methodology includes the following steps (Kiourti and Nikita 2014):

- **Photolithography masks**. Photolithography masks are prepared and printed, as shown in Fig. 12. The masks include: (a) a circular circumference which is used to guide the antenna cutting, (b) four circular marks which indicate the position of the holes that match the four pins of the mounting base (Fig. 11a) during the assembly procedure, (c) a square frame which matches the dimensions of the mounting base (Fig. 11a), and (c) complementary alignment marks to help in the alignment of the two sides of the bottom substrate layer (i.e., ground plane and lower patch).

DOI 10.1007/978-981-4560-75-7_94-1

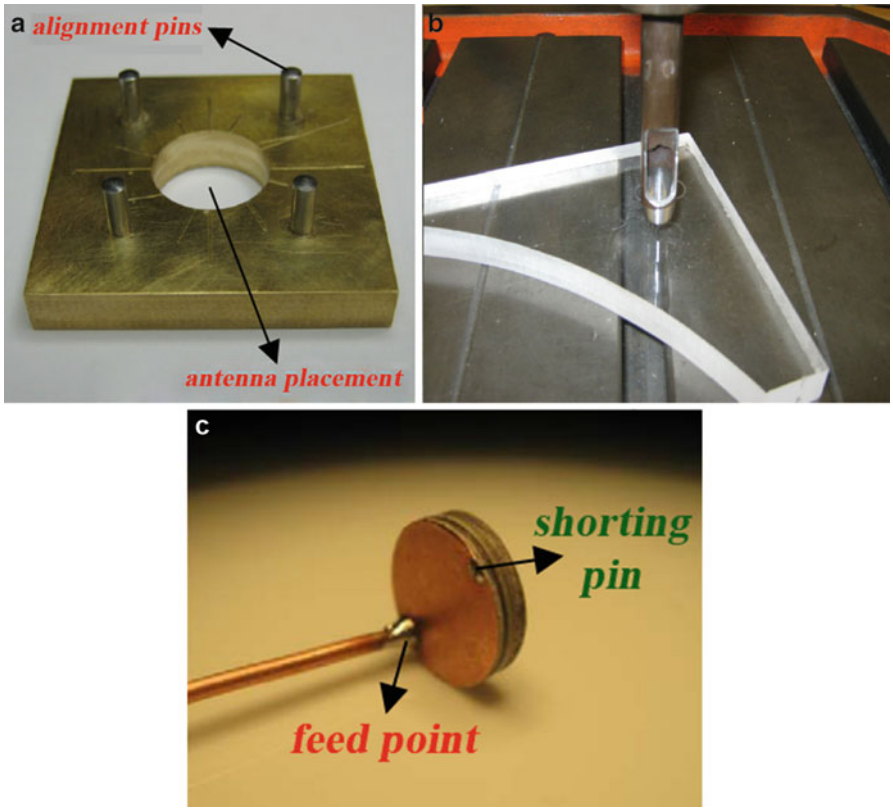

Fig. 11 Fabrication of implantable antennas: (**a**) mounting base, (**b**) circular cutting tool, and (**c**) fabricated antenna prototype

- **Photolithography**. The acquired Rogers RO3210 dielectric layers ($\varepsilon_{rd} = 10.2$, $h_1 = h_2 = h_3 = 0.635$ mm, $h_m = 0.017$ mm) are etched by means of a photolithographic process which makes use of the photolithography masks of the previous step. The lower substrate layer contains the ground plane and the lower patch, the upper substrate contains the upper patch, while the superstrate has no metallization. It is highlighted that due to the unavailability of biocompatible materials in some laboratories, other dielectrics with similar electrical properties may be selected for prototype fabrication. For instance, Rogers RO3210 is often used because it has similar properties as the biocompatible ceramic alumina ($\varepsilon_r = 9.4$, $\tan\delta = 0.006$) (Karacolak et al. 2008; Kiourti and Nikita 2012b; Liu et al. 2008a).
- **Cutting of the layers**. A circular cutting tool is then used to cut the antenna layers, as shown in Fig. 11b. The cutting tool exhibits a nominal diameter of 12 mm, which corresponds to the diameter of the intended antenna prototype ($R = 6$ mm). The adopted strategy is to precut the substrate down to a critical depth, just enough to keep the alignment points solidary with the patch, but weak enough to allow easy detaching without much mechanical stress to the antenna.
- **Antenna assembly**. The antenna is further assembled by making use of the mounting base of Fig. 11a. Layers are aligned and glued (3 M 77 glue: $\varepsilon_{rg} = 2.0$, $h_g = 0.3$ mm), while the shorting pin is set to connect the ground plane to the lower patch through a via. The outer conductor of the coaxial cable gets connected to the antenna ground plane, while the inner conductor gets simultaneously soldered to the lower and upper patches through vias. Nevertheless, detaching the antenna from the excess alignment material has been shown to be relatively hard, thus resulting in some stress to the fragile antenna.

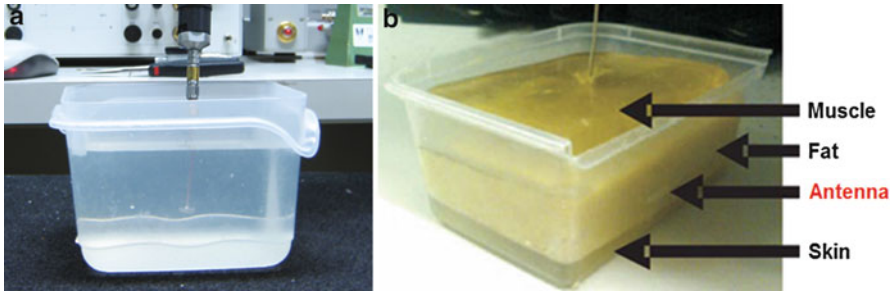

Fig. 13 Canonical phantoms used for testing of implantable patch antennas: (**a**) liquid (Kiourti and Nikita 2012b) and (**b**) multilayer gel (Sani et al. 2010)

The assembled antenna is shown in Fig. 11c. It is remarked that the most critical aspect regarding the fabrication of such miniature implantable antennas occurs to be the control of the glue layer thickness. This is impaired not only by the glue itself but also by the slight bump of the micro-solder near the coaxial cable and the shorting pin that prevents perfect contact between the layers.

In Vitro Testing of Implantable Antennas

Testing inside phantoms is relatively easy and practical to implement. The fabricated prototype is immersed inside a tissue phantom (i.e., a container filled with a liquid or gel material which mimics the electrical properties of biological tissue) and tested.

- **Phantom formulation**. Canonically shaped phantoms have, most commonly, been used for implantable antenna testing (see Fig. 13). In this case, the main challenge lies in the formulation (and, subsequently, characterization) of the tissue-emulating materials. In the literature, there have been several recipes presented for emulation of biological tissues at various frequencies (see Table 5). Gels rather than liquids are to be preferred in cases where multilayer phantoms and, thus, increased realism in experimental modeling are solicited. Deionized or distilled water usually acts as the base ingredient of the phantoms. Addition of sugar or glycerol reduces the permittivity, without, almost, affecting the conductivity. Salt increases the conductivity and, slightly, increases the permittivity (Karacolak et al. 2008). Solidification is usually made possible with agar. Other ingredients may also be used in order to vary the viscosity, preserve the mixture, and further control the permittivity and conductivity (Kiourti et al. 2014b; Ito et al. 2001). To prevent the formation of air bubbles and/or gaps, the mixture must be carefully heated and stirred and slowly poured inside the container of the phantom. Since it is not possible to produce a valid approximation to human tissue for a broad frequency spectrum using a single formula, separate recipes are given for different frequency bands (Karacolak et al. 2008).
- **Measurement of the phantom electrical properties**. In vitro testing of implantable antennas inside phantoms requires experimental measurement of the exhibited electrical properties in order to ensure

DOI 10.1007/978-981-4560-75-7_94-1

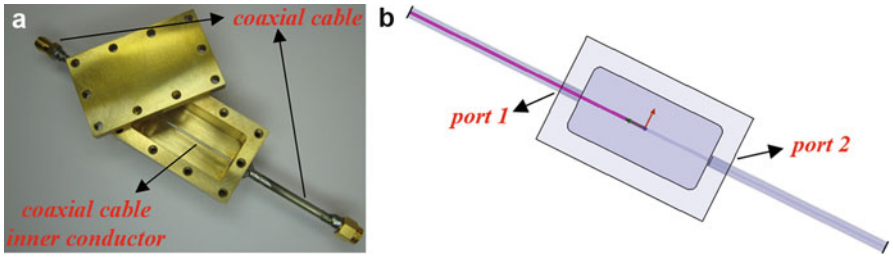

Fig. 14 Complex permittivity measurement of liquid and semisolid phantoms: (**a**) coaxial container and (**b**) numerical model (Kiourti et al. 2012)

conformance with the corresponding theoretical values. Recently, an in-depth analysis has been provided for the measurement of the electrical properties of biological media (Hofmann et al. 2013). In the market, there exist some commercial complex permittivity measurement systems, such as the Agilent Technologies 85071E (Agilent Technologies, Santa Clara, California, USA) or the SPEAG Dielectric Assessment Kit (SPEAG, Switzerland). However, alternative approaches are further solicited for laboratories that are not equipped with such commercial systems. For example, a low-cost and reliable complex permittivity measurement technique has recently been proposed (Kiourti et al. 2012). The measurement setup consists of a parallelepiped container intercepted by the inner conductor of a coaxial cable, as shown in Fig. 14a (exterior container size of 52mm × 32 mm × 32.2 mm, interior cavity size of 40 mm × 20 mm × 20 mm). The coaxial container is filled with the liquid or gel dielectric material under investigation, and once the lid is closed, it represents a transition between coaxial guides with a step characteristic impedance discontinuity. The transfer function between the two coaxial connectors outside the container depends upon the complex permittivity of the container's filling material. This can be de-embedded by comparing the measured scattering matrix (S-matrix) with simulation results for the same structure (Fig. 14b).

- **In vitro measurement of the implantable antenna**. Most studies for implantable antennas are limited to reflection coefficient (S_{11}) measurements (e.g., Kiourti and Nikita 2012b; Soontornpipit et al. 2005; Liu et al. 2008a; Sánchez-Fernández et al. 2010). As part of the experimental setup, prototype antennas are connected to a network analyzer through a coaxial cable, immersed inside the tissue-emulating phantom, and measured. Transmission coefficient (S21) measurements have also been reported. For example, in Warty et al. (2008), a 2,450 MHz PIFA was implanted inside a gel scalp phantom for intracranial pressure monitoring, and a linearly polarized 2,450 MHz chip antenna was used as the receiving (probing) antenna. Recently, in Kiourti et al. (2014b), a miniature broadband implantable antenna and a dual-band on-body antenna were presented along with the transmission performance between the two. The antennas were intended for integration into IMDs and on-body repeaters, respectively.

In Vivo Testing of Implantable Antennas

In vitro verification of an implantable antenna does not guarantee its proper functioning when implanted inside actual biological tissues (Karacolak et al. 2010). Therefore, once functionality of an implantable antenna prototype has been verified in vitro, in vivo testing is recommended to be further performed. Specifically, in vivo testing can be performed either (a) by embedding the implantable antenna inside tissue samples from donor animals (b) or by surgically implanting the antenna inside live model animals.

Use of animal tissue samples provides an easy approach to mimicking the frequency-dependency characteristic of the electrical properties of tissues. This can prove highly advantageous when carrying out measurements for multiband implantable antennas. In this case, the electrical properties of the test tissue

DOI 10.1007/978-981-4560-75-7_94-1

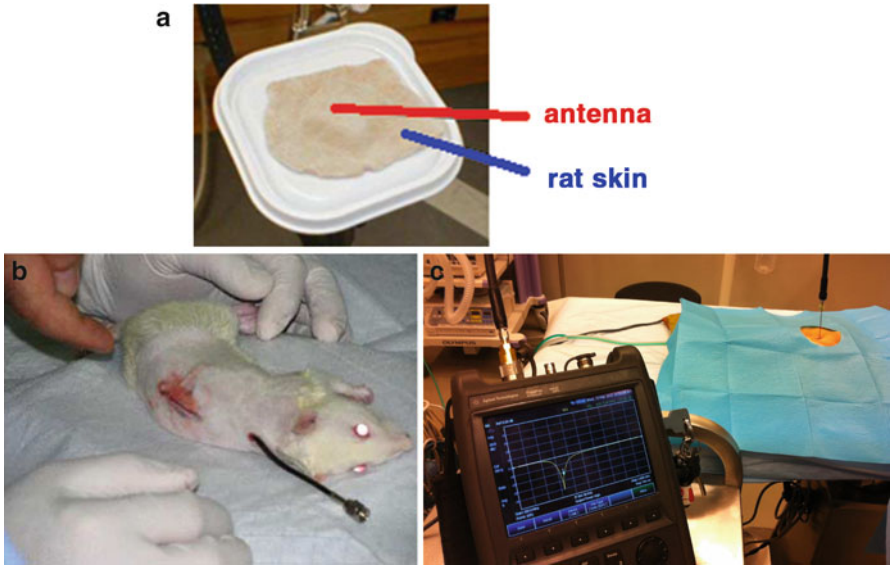

Fig. 15 In vivo testing of implantable antennas: (**a**) Karacolak et al. (2009), (**b**) (Karacolak et al. (2010), and (Kiourti et al. (2013)

can be measured using a dielectric probe kit and a network analyzer. In the literature, an implantable patch antenna with dual resonances at 380 and 440 MHz has been tested inside test tissue obtained by grinding the front leg of pork (Lee et al. 2009). The electrical properties of the adopted pork were found to be between those of human skin and muscle in the MICS band. A dual-band skin-implantable patch antenna operating in the MICS and 2,450 MHz ISM bands has also been tested in real animal skin (Karacolak et al. 2009). Skin samples with dimensions of $50 \times 50 \times 5$ mm^3 were extracted from the dorsal area of three donor rats to cover the designed antenna, and measurements were performed within 30 min of euthanization (Fig. 15a). Finally, a triple-band implantable patch antenna has been tested inside a minced front leg of pork (Huang et al. 2011). Electrical properties of the minced pork were measured and found to correspond to those of human skin and muscle between 100 MHz and 3 GHz.

Investigations inside living animals are also vital in order to investigate the effects of live tissue on the performance of implantable antennas, while providing valuable feedback for antenna design and analysis. The goal is to assess the effects of the following factors which are not accounted for in in vitro experimentation: (a) air gaps between the implanted antenna and the surrounding tissues, (b) presence of multiple types of tissues around the antenna, (c) dependence of tissue electrical properties upon frequency, (d) intersubject variability (anatomy and dependence of tissue electrical properties upon each rat's age, size, sex, internal body temperature, etc.), and (e) variations in the surgical procedures followed (implantation depth, implantation site, length of the wound, closure of the wound with sutures, etc.). In such measurements, the first step is the development of an experimental measurement protocol. The protocol has to be developed in cooperation with an experimental surgery unit, take into account legal requirements regarding the care and use of laboratory animals and address issues related to the type and number of model animals, implantation site of the antenna, anesthesia, surgical procedure, measurements, and post-surgery treatment. As an example, an in vivo experimentation protocol was recently developed for implantable antenna testing (Kiourti et al. 2013). This protocol takes into account the legal requirements regarding the care and use of laboratory animals and can be summarized as follows:

- **Type and number of model animals**. Implantation and measurements are carried out inside rats, which have long been used in the literature as model animals (Karacolak et al. 2010). Wistar outbred

DOI 10.1007/978-981-4560-75-7_94-1

rats (HsdOla:WI) are employed, which exhibit a mean and standard deviation (SD) body weight of 331.3 ± 9.2 g. In order to assess intersubject and surgical procedure variability, each antenna is implanted and measured inside three different rats.

- **Implantation site of the antenna**. Since the antennas under study have been designed for operation inside soft tissues, implantation is carried out within the subcutaneous tissue of the rats' abdomen.
- **Anesthesia**. Each rat is first anesthetized with an intraperitoneal (i.p.) injection of 70 mg/kg ketamine (Ketaset, Fort Dodge, Iowa, USA) and 5 mg/kg xylazine (Rompun, Bayer, Leverkusen, Germany).
- **Surgical procedure**. A wound is further made in the rat's abdomen area, and the antenna is implanted within the abdominal subcutaneous tissue. Following implantation, the wound is closed with 0/4 silk sutures (Silkam, Braun, Aesculap, Tuttlingen, Germany), leaving a 2 mm opening for the feeding coaxial cable to exit the skin.
- **Measurements**. Right after surgery, the feeding coaxial cable is connected to a network analyzer which measured the exhibited reflection coefficient frequency response.
- **Post-surgery treatment**. Once measurement is completed, the implanted antenna is removed, and the rat is euthanized in a CO2 chamber. Time lapse from the start of the surgical procedure to euthanasia of each rat does not exceed 8 min.

In vivo studies reported in the literature are very limited. The return loss frequency response of a skin-implantable antenna has been measured using rats as model animals (Karacolak et al. 2010; Fig. 15b). In this study, the antenna was implanted by means of a surgical operation inside the dorsal midline of three rats (for validation purposes), and euthanasia was applied after the measurements (approximately 13–15 min after the surgery). Canine studies for trans-scalp evaluation of a scalp-implantable antenna at 2,450 MHz have also been presented (Kawoos et al. 2008). Canine models were selected to ensure a large head size, and an intracranial pressure monitoring device with an integrated antenna was fixed to the skull. The monitor was tested while the dog was still under anesthesia. After the measurements, the animal was allowed to emerge from anesthesia and taken to the recovery area. Recently, implantable antennas were tested inside three different rats to assess intersubject variability considerations (Fig. 15c; Kiourti et al. 2013). In this case, numerical and experimental results were found to exhibit quite good agreement. Compared to numerical simulations, percentage changes in the exhibited resonance frequency (f_{res}), reflection coefficient at this frequency ($|S_{11}|@f_{res}$), and 10 dB bandwidth (BW) are found to equal +6.9 %, +51.9 %, and +30.2 %, respectively. Maximum deviations in f_{res}, $|S_{11}|@f_{res}$, and BW recorded among the three measurements in different rats were found to equal 43 MHz, 12.6 dB, and 23 MHz, respectively.

Full Solutions of Commercial IMDs

A number of commercial IMDs have already been reported, as shown in Table 6. Defibrillators and pacemakers are the most common examples of IMDs. Biotronik has recently proposed a small battery-powered electrical impulse generator to be implanted in patients who are at risk of sudden cardiac death due to ventricular fibrillation and ventricular tachycardia (Lumax 540 DR-T) (Biotronik 2012). The Medtronic Adapta with MVP pacing system offers managed ventricular pacing, atrial therapy, ventricular capture, and remote cardiac telemetry (Medtronic 2010a), whereas the Medtronic Revo MRI SureScan pacing system is magnetic resonance (MR) conditional designed to allow patients to undergo magnetic resonance imaging (MRI) under the specified conditions of use (Medtronic 2011a). VeriChip (renamed to PositiveID in 2010) was the only human-implantable microchip to receive approval by the Food and Drug Administration (FDA) in 2004 (PositiveID 2004). The device was typically implanted between the shoulder and elbow of the individual, and, once scanned, it replied with a unique 16-digit number,

DOI 10.1007/978-981-4560-75-7_94-1

Table 6 Example full solutions of commercial IMDs

Commercial IMD	Function of the IMD
Biotronik Lumax	Defibrillator
Medtronic Adapta with MVP	Pacing system
Medtronic Revo MRI SureScan	Pacing system for magnetic resonance imaging
VeriChip/PositiveID	Identity verification
Nucleus Freedom cochlear	Cochlear implant
Medtronic SynchroMed Pump	Drug infusion system
Second Sight Argus II	Retinal prosthesis
Medtronic Guardian REAL-Time	Glucose monitor
Abbott FreeStyle Navigator	Glucose monitor
Dexcom SEVEN PLUS	Glucose monitor
Medtronic MiniMed Paradigm Veo	Glucose monitor

which could be used to retrieve personalized information, for example, identity verification, medical records, etc. However, privacy concerns generated controversy and debate, and marketing was discontinued in 2010. The Nucleus Freedom cochlear implant includes a sound processor which is worn behind the ear and a cochlear implant which is placed under the skin, behind the ear (Nucleus Freedom 2010). The sound processor captures sounds, digitizes them, and sends the digital code to the implant. The implant converts the digitally coded sound to electrical impulses and sends them along an electrode array to further stimulate the cochlea's hearing nerve. The Medtronic SynchroMed Pump is a drug infusion system which provides precise drug delivery for chronic therapy of severe spasticity (Medtronic 2012). In addition to the implanted pump, the system uses a catheter to deliver programmed amounts of intrathecal baclofen to the intrathecal space and cerebrospinal fluid. The Argus II retinal implant was approved by FDA's Ophthalmic Devices Advisory Panel in 2012 (Second Sight 2012). It includes a video camera, a transmitter mounted on a pair of eyeglasses, a video processing unit, and a 60-electrode implanted retinal prosthesis that replaces the function of degenerated cells in the retina. Although it does not fully restore vision, this setup can improve a patient's ability to perceive images and movement. Finally, implantable glucose monitoring systems appear as a promising treatment for diabetes on a continuous basis (e.g., Medtronic Guardian REAL-Time (Medtronic 2010b), Medtronic MiniMed Paradigm Veo (Medtronic 2011b), Dexcom SEVEN PLUS (Dexcom 2008), Abbott FreeStyle Navigator (Abbott 2011)). A tiny sensor is inserted under the skin to measure glucose levels and further transmits this information to an exterior monitor via radio waves.

Conclusion

IMDs with wireless telemetry functionalities appear as a highly promising option toward improving the patients' quality of life and providing medical systems with constant availability, context awareness, reconfigurability, and unobtrusiveness. As such, a key and critical component of RF-linked IMDs is the integrated implantable antenna.

In this chapter, issues related to the design, simulations, and experimental investigations of implantable antennas for biomedical telemetry were discussed. Specifically, design mainly emphasizes on miniaturization issues and biocompatibility. However, electrically small antennas present poor radiation performance and relatively narrow bandwidth. Even though gain enhancement is considered crucial, compromises on the system performance are generally inevitable. Conserving energy to extend the lifetime of the IMD is also significant. Multiband antennas are being designed for this purpose, which

DOI 10.1007/978-981-4560-75-7_94-1

"wake up" the IMD only when there is a need for information exchange. Several methodologies have been proposed for implantable antenna design, all of which need to take into account the host body. Simplified tissue models are proved to be able to substitute for complex anatomical tissue models, thus speeding up simulations. Although a homogenous model is sufficient for basic antenna design, a more realistic model is needed to refine the final antenna design and provide accurate results. Using efficient and accurate simulation tools and tissue models is a key issue for both design and performance analysis. Regarding experimental investigations, implantable antennas exhibit tight fabrication tolerances as attributed to their miniature size. Testing inside tissue-emulating phantoms mainly needs to deal with the formulation and characterization of the tissue-mimicking liquid or gel. To benefit from frequency-dependent tissue electrical properties, testing in animal tissue samples can additionally be performed. The highest challenge, however, lies in measurements within living animals, in which careful consideration is required for developing the optimal testing protocol.

IMDs are a growing technology with a high potential for improving the patients' life and the quality of healthcare. RF technology for IMDs promises many benefits for both patients and caregivers. With rising health-care costs, an aging population, a growing acceptance of home-based medical monitoring, and advances in supporting technology, IMDs are gaining a continually increasing interest in both academia and industry.

Abstract

The exponential growing demand of electricity has stimulated the manufacture of electric equipment with high rated powers withstanding tens and hundreds of kilovolts. These devices have to be insulated to ensure a safe and reliable service while their size and cost are reduced. Unfortunately, insulations deteriorate over time by being in operation under load and exposed to harsh environments that can degrade their behavior and lead to unexpected equipment outages and failures. The continuous monitoring of these assets is paramount in the operation of electric power systems, and one of the most popular methods to evaluate the ageing is the detection of partial discharges. Partial discharges are ionization processes that take place in voids filled with gas or oil inside the insulation, in dielectric surfaces, and in the proximity of sharp metallic objects. The chemical and physical structure of the insulation is changed, and eventually weakened, by the continuous action of the discharges. Then, their apparition can be directly a signal of problems in the insulation, but they can also be the consequence of other degradation processes. Partial discharges can be measured with a wide range of detectors including inductive, capacitive, acoustic, and light sensors. Because partial discharges occur in extremely short times, well below 1 ns, the radiofrequency measurement of the phenomenon in the HF, VHF, and UHF bands is also part of the unconventional methods used for their detection. EM sensors or antennas have the ability of performing a complete study on the measurement of partial discharges. They can detect pulses, localize the partial discharge site, and, to some extent, classify the type of partial discharge online. However, one of the most important challenges when using antennas in the diagnostic of insulations is the difficulty of relating the RF emissions to the severity of the PD. Another determent in the wide application of antennas as partial discharge detectors is the sample rate needed to obtain information from the signals in the time and frequency domains. The chapter also explores the most common configurations of antennas used in the detection of partial discharges as well as how they are installed and used in different electrical machines.

Introduction

The Importance of Insulation Systems

The exponential growing demand of electricity all over the world and the traditional dispersion of power plants from the consumption areas require an expansion of the network capacities, an improvement of their availability, and a reduction of congestion and outages (IEC 2010). The demand has also stimulated the manufacture of electric equipment with higher rated powers, and, considering that voltages have to be elevated to reduce losses in the transmission networks, the consequences are apparatuses withstanding tens and hundreds of kilovolts that have to be separated from ground through relatively small distances. The role of insulation systems is to ensure that the electrical assets can work in a reliable and safe environment while their size and cost are reduced. Unfortunately, insulations deteriorate over time by being in operation under load and exposed to harsh environments, as well as to unpredictable mechanical, thermal, and electric stresses that can degrade their behavior and lead to unexpected equipment outages and failures.

Electric Maintenance

Knowing the condition of the insulation is paramount to the reliability of power systems. For this reason, maintenance strategies are scheduled to keep reliability within a margin of quality throughout the lifetime of assets reducing the costs of malfunction, failure of equipments, and blackouts. These corrective, preventive, predictive, or proactive strategies facilitate the adoption of decisions regarding the management of the assets of the power system through different procedures (Mobley 2011; Gill 2008):

Corrective (or reactive) maintenance is the traditional maintenance strategy based on the replacement or reparation of the asset after its breakdown. It is also called run-to-failure (RTF) maintenance or unplanned maintenance. Its application depends on how critical the asset is in the power system and whether the costs of the failure are affordable. It does not take into account the forecasted life before failure, and the availability of the assets depends on their reliability, so it is implemented for small items that are redundant or unlikely to fail.

In time-based (or preventive) maintenance, the inspections are predefined on a fixed period of calendar time, operating cycles, or operating hours. The substitution is performed after a predefined lifetime, allowing high availability of the asset although the cost of maintenance is also higher. This technique is commonly used in equipment subjected to wear, consumable replacements or when there is a pre-known failure pattern.

With the advancement of technology and the need of higher reliability in electric equipment, new maintenance strategies such as the condition-based maintenance (CBM) and the reliability-centered maintenance (RCM) have been introduced. These strategies are a step forward on preventive maintenance, and, nowadays, they are the leading trends in the maintenance of electrical assets. With these techniques, assets are inspected or replaced depending on their condition and failure history, effectively reducing maintenance costs, failures can be predicted, unscheduled downtime is lower, and machinery life is significantly extended (IEC 2010). Due to its importance, special attention has to be put to condition-based maintenance.

Condition-Based Maintenance

CBM aims to carry out maintenance operations only when there is evidence of abnormal behavior in a piece of equipment. Hence, a correct implementation of a CBM through an effective condition monitoring (CM) significantly reduces maintenance costs by reducing the number of unnecessary preventive maintenance interventions (Jardine et al. 2006). CM contributes to network optimization both in terms of efficiency and reliability, permitting reliable diagnostics using valuable information. In effect, CM reunites all monitored data from the operation of the asset and, with the analysis of deviations or trends in

DOI 10.1007/978-981-4560-75-7_95-1

the variables, estimates the status of the asset and predicts the need of maintenance before serious deterioration or breakdown occurs (Han and Song 2003). Hence, prognosis can predict how much time is left to failure or can predict the probability that an asset operates without faults until the next inspection, which is sometimes much useful because it permits to schedule successive interval inspections. In other situations, when a fault is detected, the evidences of the problem can be found in some of the parameters that are being monitored. In these cases, when the failure of the electrical asset is irremediable, it still is possible to use the processing of the data to make a diagnosis. Under these assumptions, a CBM program would require three main steps (Jardine et al. 2006):

1. Data acquisition or information collecting where the relevant data is recorded to determine the health of the physical asset. The data can be single values such as oil analysis data, temperature, pressure, moisture, humidity, and weather or environment data. In the analysis of tendencies, it is also necessary to acquire time series from CM such as vibration data, acoustic data, and partial discharge pulses during a specific time. Finally, multidimensional data such as image data, infrared thermographs, and X-ray can also be collected.
2. Data processing or information handling. In this step, the data acquired are manipulated, filtered, transformed, and sorted to be understood and interpreted in a better way.
3. Maintenance decision-making or decision-making. At this point, appropriate operations of maintenance are recommended by using statistical approaches, artificial intelligence, explicit mathematical models, and expert decisions to determine the remaining useful life, incorporate prognostics maintenance policies, and select a condition monitoring interval.

The strength of CBM relies on the fact that it is applied online. Off-line testing requires to put electrical assets out of service to perform the necessary tests to provide information about their health. This implies evident related costs, such as electricity production shortages, reduction of power quality supply, labor costs, temporary replacement equipments, etc., which mostly are unaffordable for an optimal system reliability (Klempner and Kerszenbaum 2004). Alternatively, online condition monitoring requires a massive deployment of sensors throughout the network and every single asset that is going to be monitored. In some cases, the expenses are justified such as in power plants with generators with 1000 MVA ratings and more, where the costs of forced outages are undoubtedly higher than the installation of additional instrumentation to do a CBM (Klempner and Kerszenbaum 2004). In other situations, the number of sensors has to be reduced or they have to monitor several assets. In any case, all information generated by the sensor and the instrumentation systems has to be gathered and processed to improve the efficiency of the power network.

Smart Grids

The term *smart grid* is used here in the sense given by (Eur 2010) and defined as an electricity network that can intelligently integrate the actions of all users connected to it in order to efficiently deliver sustainable, economic, and secure electricity supplies. This is a key aspect on the modernization of the networks pursued by all the actors involved in generation, consumption, and regularization of the electricity market. Though there still are many aspects that have to be clarified and negotiated, the roadmap to the final implementation of smart grids has been outlined in the past years by the most important standardization organisms and institutions (IEC 2010; CEN et al. 2011; NIST 2012).

In NIST (2012), the National Institute of Standards and Technology identifies eight priority areas that are considered critical in the ongoing and short-term deployment of smart grid technologies and services. One of the key functionalities in this group is the wide-area situational awareness which includes the monitoring of power-system assets to optimize their management, behavior, and performance as well as to

DOI 10.1007/978-981-4560-75-7_95-1

prevent electrical disruptions. In this regard, the International Electrotechnical Commission (IEC 2010) has also defined the asset management using condition-based monitoring as one of the key aspects in the implementation of smart grids due to the expected growing demand for electrical energy and the consequent congestion and outage problems in the network. These technical reports are addressing new requirements that represent opportunities to develop new measuring and testing procedures for all types of assets. Under these assumptions, the massive deployment of sensors is crucial to gather all useful data that can help in the maintenance of electrical power networks.

Main Causes of Failure

There are many parameters that give information about aging mechanisms that can be used in early-warning systems to prevent the breakdown of high-voltage insulations and, consequently, electrical disruptions (Gill 2008). All these parameters are associated to temperature changes, chemical by-products, vibrations, and abnormal values in electrical quantities such as voltage, current, and power. The continuing presence of any of these indicators can lead to the appearance of partial discharges (PD), or vice versa, the presence of partial discharges can reveal hidden ageing mechanisms.

Power transformers are the core of transmission and distribution networks with the key mission of raising voltage levels at generation stations to reduce losses in the transport of electricity. The insulation in large- and medium-size transformers is cellulose impregnated with oil which also acts as refrigerant. This insulation is subjected to cyclic changes of temperature in function of the demanded power. It can degrade due to chemical changes in the cellulose and to mechanical reasons for the efforts to which the coils are exposed when the transformer is operated under abnormal conditions. Nevertheless, the most important damaging ageing in these assets is water that is traded between cellulose and oil in function of the temperature. Water, as moisture, weakens sharply the dielectric constant of the cellulose–oil insulation (Kiameh 2003), reduces the partial discharge voltage inception, increases cavity sizes inside the insulation, and reduces the effective dielectric margin between high and low voltages. Hence, the monitoring of humidity in oil and the activity of partial discharges are clear indicators of insulation degradation. Other systems that can be degraded are on-load tap changers (OLTC) that are in charge of changing the voltage levels usually in the secondary of transformers (Han and Song 2003). They can induce mechanical and electrical faults and insulation problems that can be monitored with accelerometers, temperature and current sensors, and partial discharge detectors.

Generators are the main assets in the production of electricity. The insulation is manufactured mainly from solid resins and mica coatings. As in the case of transformers, the aging process is caused by thermal, mechanical, and dielectric stresses. Temperature delaminates the insulation, and wedge wearing leads to vibration and abrasion and a general reduction on the thickness of the insulation that increases the dielectric stress. All these processes can cause the appearance of partial discharges that contribute to the insulation damage rate (Kurtz et al. 1980).

Power cable systems transport and distribute electricity, so the reliability of the electrical supply relies on the conditions of these assets. They also represent a large capital investment for electrical utilities that, under some circumstances, have to cope with cables over 30 years old that may be operated, exceeding their ratings (Densley 2001). Most power cable insulation is solid, made from cross-linked polyethylene (XLPE) or ethylene propylene rubber (EPR). The ageing causes are similar to the rest of assets: temperature factors such as high and low temperatures and temperature cycling; electrical in the case of overrated voltages and currents; environmental as humidity, lubricants, corrosive gases and chemicals, and radiation; and mechanical, for example, bending, tension, compression, torsion, and vibration (Densley 2001). Basically, the most popular online monitoring method is the distributed temperature measurement with optical fibers, when available, and partial discharges. Both methods also locate the damaged cable section.

DOI 10.1007/978-981-4560-75-7_95-1

For all electrical assets, there exist common parameters that can be continuously monitored to identify the symptoms of an eventual equipment failure. One of the most popular methods to estimate the aging status of electrical machines and power lines is the measurement of partial discharges. According to the (IEC 2010), PD monitoring is essential in the evaluation of the aging conditions of power transformers, GIS (gas-insulated substations), circuit breakers, isolators and earthing switches, overhead lines, cables, and surge arresters. PD might exist even when the time to failure is still far, so it is necessary to monitor their activity continuously to detect changes in the number of PD per network cycle (50/60 Hz) or the peak of the charge released. The origin and nature of partial discharges is unveiled in the next section.

Types of PD

Partial discharges are ionization processes that take place in voids filled with gas or oil, in dielectric surfaces, and in the proximity of sharp metallic objects (Kreuger 1989; Boggs 1990). The process depends on the electric field intensity applied in the area and the nonuniformity of that field. Being a phenomenon that develops in short gaps, partial discharges may be perceived as rapid and slow-rise-time pulses that generate small electrical sparks or arcs, true pulseless glows, or pseudoglow discharges (Bartnikas 2002). Though all these three types of discharges can occur separately, pulseless glows and pseudoglow discharges are usually accompanied by pulse discharges. The immediate consequence of the discharge are current pulses that can be detected far from the ignition site. From a practical point of view, there are different types of PD attending the geometry and the characteristics of the site where the discharges occur.

Internal

Internal discharges appear in nonhomogeneous areas of a dielectric. Voids within epoxy mica dielectrics used in turn-to-turn and ground insulations in rotating machines may appear when operating at high temperatures. A similar process can occur in oil–paper insulation systems in power transformers with the formation of gas cavities inside the insulation layers (Stone 2005). In the case of polyethylene-insulated power cables (Eager and Bader 1967), the imperfections can appear in different locations during the manufacturing process at the interfaces between the shield, insulation, and conductor. Improper cable assembly can be a common cause of apparition of partial discharges at the connections and cable accessories. Finally, metallic particles erected by electrostatic forces or surface wearing or erosion in gas-insulated switchgear (Niemeyer 1995; Tanaka 1986) can create nonuniformities in the insulation and encourage the apparition of partial discharges.

Once the cavity has been formed, a slow erosion process starts, including one or some of the following phenomena (Tanaka 1986; Mason 1951): ion production inside the void followed by ion bombardment and the final detachment of insulation molecules; high temperature localized at PD sites that can cause a melting of materials and enhances the oxidation of the insulation; and chemical reactions favored by the rise in temperature that attack the insulation. The final effect is an effective increase in the cavity with the formation of channels or treeing and the consequent decrease in the insulation and the open possibility of a total breakdown. Gaseous by-products such as carbon monoxide and carbon dioxide and sometimes hydrogen and methane and liquid by-products such as moisture droplets are found inside dielectrics in the first stages of partial discharges activity (Morshuis 2005). After a continuous activity, hundreds of hours according to (Hudon et al. 1991), solid by-products such as hydrated oxalic acid ($C_2H_2O_6 \cdot 2H_2O$) in epoxy and other crystals in polyethylene are found when the former droplets crystallize under the action of partial discharges. All these chemical reactions modify the shape of the cavities, changing the characteristics of the discharge site and, in consequence, modifying the partial discharge behavior to become a nonstationary process.

The appearance of partial discharges depends on the electric stress in the cavity, the breakdown strength of the cavity (Kreuger 1989), and the residual charge left by the previous discharge activity

DOI 10.1007/978-981-4560-75-7_95-1

(Niemeyer 1995). The stress in the cavity depends on the geometry. Cavities perpendicular or parallel to the applied electric field or spherical cavities have different electric stresses. The breakdown stress depends on the cavity dimensions, the type of gas, and its pressure inside the void. In this case, the Paschen curve that defines the inception voltage in function of the thickness of the cavity and the dielectric constant of the gas plays an important role.

Once the conditions to the appearance of partial discharges have been fulfilled, there are several mechanisms at stake (Bartnikas 2002; Niemeyer 1993, 1995; Morshuis 1993). Weak discharges are characterized by very low and quasi-continuous currents practically undetectable by pulse detection methods. Low-amplitude and slow-rise-time pulses are typical of Townsend discharges, and high-amplitude and fast-rise-time pulses are characteristics of streamer-like discharges. Though most partial discharges lead to a relevant ageing of the dielectric, streamer-like discharges are one of the most harmful in the process of total failure.

All these issues can help to understand the difficulties of identifying and classifying partial discharge pulses to assess the aging status of a piece of electric equipment.

Surface

Surface discharges may also occur in inhomogeneous locations on dielectrics when there exists a tangential component of the electric field parallel to the dielectric surface (Kreuger 1989). The original Lichtenberg figures are surface discharges. The inception voltage is notably lower than in the case of internal discharges. This phenomenon is prone to happen in bushings, insulators, oil–paper interfaces, ends of cables, or when an external discharge touches the surface. The contamination of the surface plays such an important role that there are artificial pollution tests on dielectrics (IEC507 1991). Once the discharge has been triggered, the electric field is modified and the effect can be extended along large areas, provoking a flashover and a total discharge that short-circuits the insulation.

This type of discharges is especially problematic in coastal electrical infrastructures due to salt accumulation, in agricultural areas where there are pesticides and dust, and in highly contaminated urban areas. In the case of electrical machines, surface discharges can occur at the edges of electrodes or when there are small particles adhered to the surface. In oil insulations, the presence of moisture and other oil pollutants are the major cause of surface discharges.

Corona

Historically, the term corona had been used indistinctively to describe all types of discharges. The American Society for Testing and Materials (ASTM) defines corona or partial discharge as a type of localized discharge resulting from transient in an insulation system when the voltage stress exceeds a critical value (Bartnikas et al. 1979), which includes all types of discharges. The same society, when referred to the significance and use of the standard, states that *the presence of partial discharges (corona) in an apparently solid insulation is a potential indication of the existence of internal cavities. Partial discharge tests have been useful in the design and inspection of molded, laminated, and composite insulation, as well as specimens in the form of cables, capacitors, transformers, bushings, stator bars, and rotating machines* (ASTM1868 2013). However, the generalized trend is to refer corona discharges exclusively to those discharges that occur in gases or liquids (oil) under the effect of highly divergent electric fields in the proximities of sharp points (Kreuger 1989).

The inception voltage depends on the radius of the sharp electrode; for a radius of 10 μm, it is around 450 V. Hence, corona starts at relatively low voltages with the ionization of the surrounding air in the negative cycles of the ac (alternating current) voltage. If the voltage is further increased, positive corona appears due to the flow of positive ions away from the electrode.

DOI 10.1007/978-981-4560-75-7_95-1

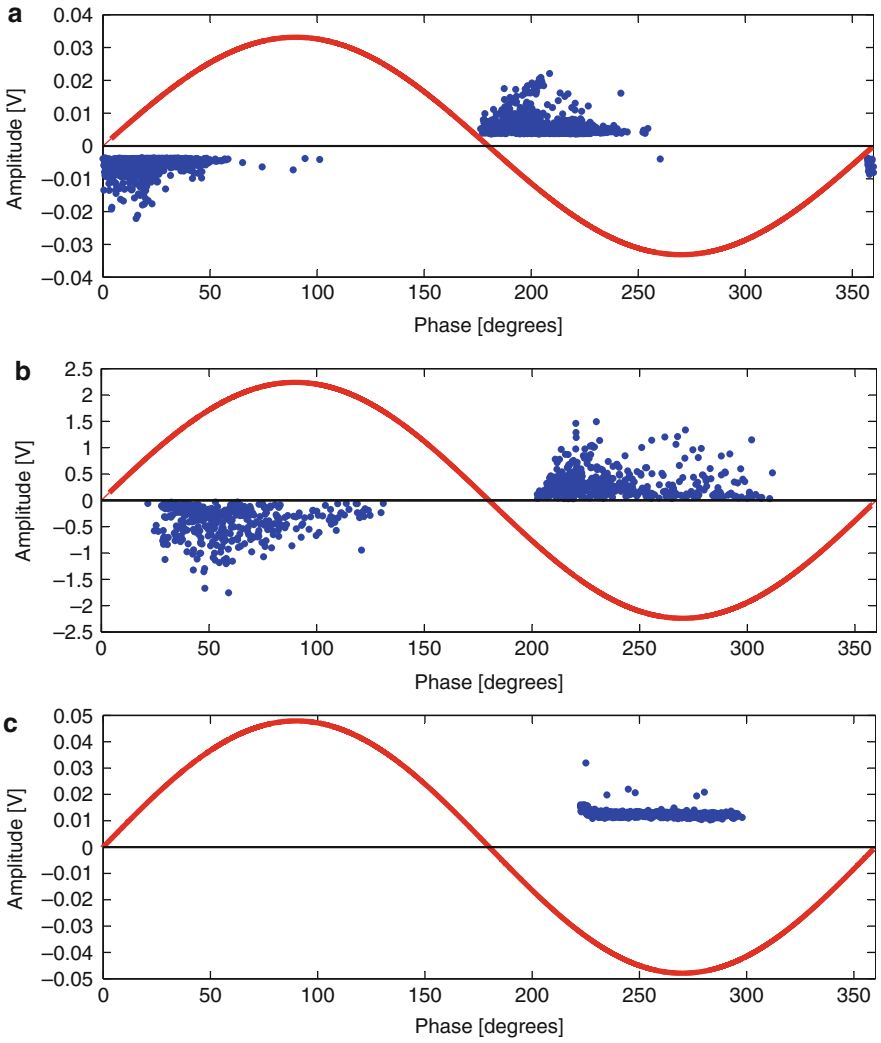

Fig. 1 PRPD patterns (**a**) internal, (**b**) surface, and (**c**) corona

The inherent problems of corona discharges are mainly related to active power losses, radio-electric disturbances, and their influence in the corrosion of conductors. They are not the cause of direct electrical degradation of insulators, but their presence can hide the activity of other harmful discharges such as internal.

Identification and Classification of Partial Discharges

Detecting partial discharges is the first stage in a condition-based monitoring system. The truly valid information should determine the nature and origin of the partial discharge in order to discriminate the insulation problem and set up an efficient maintenance. Many efforts have been directed to obtain fingerprints that are common to partial discharge from similar sources. One of the most popular and trusted methods among maintenance engineers is based on the collection of signals with the same phase referred to the grid frequency, and, hence, phase-resolved partial discharge (PRPD) patterns are analyzed. The shape and duration of the pulses are common characteristics for pulses of the same nature, so other methods are based on the extraction of the time and spectral characteristics of the signal such as time-resolved tools and time-frequency maps. Power spectral density and spectral power share in different

DOI 10.1007/978-981-4560-75-7_95-1

frequency bands have also been proved to be reliable techniques to extract characteristics of the nature of the discharge.

Phase-Resolved Partial Discharge Patterns

Phase-resolved partial discharge patterns are an electrical classification method used to identify noise sources and PD (Kreuger 1989). This method is based on the measurement of the amplitude or peak of the discharge, so it does not really require measurements in the high-frequency (HF) band; below 500 kHz is enough according to the standard IEC60270 (2000). The amplitudes of the partial discharges in pC or mV are plotted versus the phase of the grid ac voltage, Fig. 1. In this representation, all PD phases and amplitudes in a period of time are superimposed to one cycle of the ac voltage. The dot accumulation defines different patterns depending on the type of partial discharge, and by identifying this pattern, it is possible to find the origin of the fault. Internal discharge clusters span from zero crossings, 0° or 180°, of the sinusoidal waveform to 50–70° in the positive cycle and 230–250° in the negative cycle (plot a). Surface discharges are accumulated around the maximum and minimum of the ac signal (plot b). And, patterns for corona discharges only have pulses in one semi-cycle. Figure 1 shows the PRPD patterns for internal, surface, and corona PD measured with a monopole antenna synchronized with the grid ac voltage. Noise is not correlated with the phase of the sinusoidal signal, so in a PRPD plot, it is represented as a dispersed band of points at all phases.

Time-Frequency Maps

In this technique, the problem of PD classification is addressed, considering that the pulses from different sources have different waveforms and durations. Time-frequency (TF) maps are a classification tool commonly used in the field of signal theory and involve the separation of similar-shaped wave pulses into groups (Contin et al. 2002; Cavallini et al. 2003). The equivalent time duration and the equivalent bandwidth are calculated for all pulses. Background noise will have similar durations and spectra, so the signals will be grouped in the same cluster. Interferences are expected to have different parameters than background noise and will be assigned to other zones of the TF map. Partial discharges have also different waveforms and will occupy other areas. The process begins by normalizing all signals with time, $s(t)$:

$$\tilde{s}(t) = \frac{s(t)}{\sqrt{\int_0^T s(t)^2 dt}} \tag{1}$$

Subsequently, the standard deviation of the normalized signal is calculated in the time domain (Eq. 2) and in the frequency domain (Eq. 3).

$$\sigma_T = \sqrt{\int_0^T \left(t - t_g\right)^2 \tilde{s}(t)^2 dt} \tag{2}$$

$$\sigma_F = \sqrt{\int_0^\infty f^2 \left|\tilde{S}(f)\right|^2 df} \tag{3}$$

where f is the frequency, $\tilde{S}(f)$ is the Fourier transform of the pulse $\tilde{s}(t)$, and t_g is the time gravity center for the normalized signal, defined by:

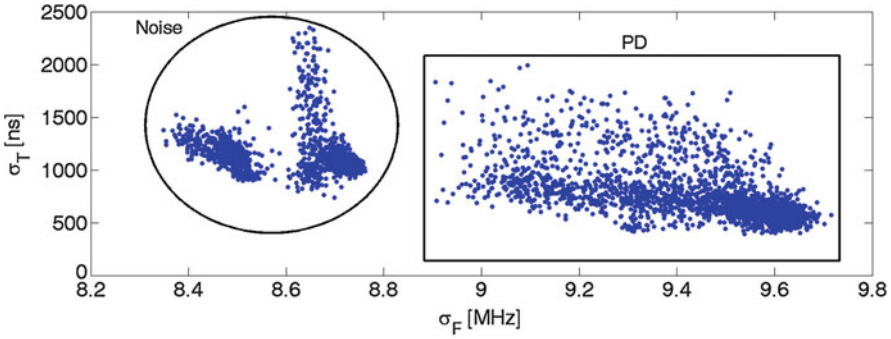

Fig. 2 TF map example for internal PD and electromagnetic noise

$$t_g = \int_0^T t\tilde{s}(t)^2 dt \tag{4}$$

In Fig. 2, a TF map for internal PD and electromagnetic noise measured with a monopole antenna is presented. In this figure, both main clusters of internal and noise sources are distinguished.

Spectral Methods

The characteristics in the pulse waveforms can also be analyzed through the study of their Fourier transform or their power spectral density. The spectrum can be divided in relevant frequencies where signals from different sources show differences. This information can be found with a support vector machine (SVM) by comparing two types of partial discharges or noise and partial discharges using training signals. The SVM selects a set of significant spectra capable of defining the two classes independently, so new pulses will be assigned to one of the classes depending on their similarity.

This method can be simplified when the relevant frequencies are congregated in a continuous band. These bands are selected as those intervals where there is higher dispersion in the accumulated power. The spectrum is previously normalized, and the power in every selected band is calculated as a percentage of the total. There can be as many frequency intervals as necessary; however, for the sake of clearness, only two are selected, an interval in a low-frequency band, PRL, and another in a high-frequency band, PRH. The percentages or power ratios are calculated with Eqs. 5 and 6, respectively, and plotted in a two-dimension map.

$$\%PRL = \frac{\sum_{f_{1L}}^{f_{2L}} \left|\tilde{S}(f)\right|^2}{\sum_0^{f_t} \left|\tilde{S}(f)\right|^2} \times 100 \tag{5}$$

$$\%PRH = \frac{\sum_{f_{1H}}^{f_{2H}} \left|\tilde{S}(f)\right|^2}{\sum_0^{f_t} \left|\tilde{S}(f)\right|^2} \times 100 \tag{6}$$

where $\left|\tilde{S}(f)\right|$ is the fast Fourier transform (FFT) magnitude calculated for the partial discharge pulse, $s(t)$; $[f_{1L}, f_{2L}]$ is the lower frequency band, $[f_{1H}, f_{2H}]$ is the higher frequency band, and f_t, is the highest frequency value to be analyzed.

In some cases, there can be sources with similar PRL and PRH that would give overlapped clusters in the map. Adding a third axis with the duration of the signal (t_{eff}) will simplify the separation of the pulses

DOI 10.1007/978-981-4560-75-7_95-1

(Albarracin et al. 2015). Figure 3 shows the separation of several electromagnetic sources measured with an antenna.

Statistical Methods

Other methods select statistical parameters that define a certain type of partial discharge from the pulse count distribution $H_n(\phi)$ and from the mean pulse height distribution $H_{qn}(\phi)$ at a certain phase of the ac signal ϕ (Contin et al. 2000). The representative parameters for these two distributions are the third moment or skewness that describes the asymmetry compared to a normal distribution, Eq. 7, and the fourth moment or kurtosis that describes the sharpness, Eq. 8. These quantities are different in function of the type of partial discharge.

$$S_k = \sum_{i=1}^{N} \frac{(s_i - s_m)^2}{N} \tag{7}$$

$$K_u = \frac{1}{\sigma^4} \sum_{i=1}^{N} \frac{(s_i - s_m)^4}{N} \tag{8}$$

where s_i is the value of the pulse at sample i, s_m is the pulse height average, N is the number of samples, and σ is the pulse height standard deviation.

The pulse charge height distribution $F(q)$ follows a Weibull distribution, Eq. 9. Finding the scale σ and shape β parameters of the adjusted Weibull distribution will also give information about the type of partial discharge.

$$F(q) = 1 - e^{-\left(\frac{q}{\alpha}\right)^{\beta}} \tag{9}$$

Measuring Partial Discharges

Sensors

As stated in section "Main Causes of Failure," the ignition of partial discharges provokes changes in physical variables such as voltage, current, pressure, light, and electromagnetic radiation. All sensors applied to detect partial discharges have to be designed to measure any of these variables.

The standard IEC60270 recommends the use of a coupling capacitor, C_k, to provide a low impedance path for discharges in the device under test (IEC60270 2000). The capacitor is connected in parallel with

DOI 10.1007/978-981-4560-75-7_95-1

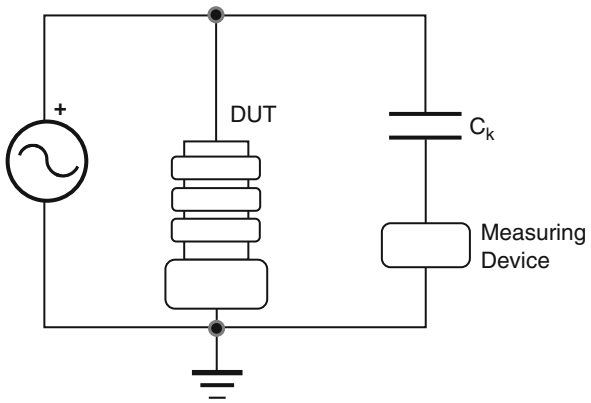

Fig. 4 Indirect measuring circuit as proposed in (IEC60270 2000). The coupling capacitor C_K is in series with a measuring device that can be an impedance or an inductive sensor

the test object directly to ground or through a measuring impedance or detector, Fig. 4. Capacitances are in the range of 80–1000 pF (Stone 2005), with a bandwidth limited below 10 MHz for large capacitances and that can be increased by reducing the capacitance value (Hauschild and Lemke 2014). Other capacitive couplers detect the electric field created by partial discharges in shielded power cables using a pair of electrodes separated by a known distance (Katsuta et al. 1992).

Inductive sensors are based on Faraday's law and measure the induced voltage in a coil through the magnetic field created by the partial discharge pulse. High-frequency current transformers (HFCT) are extensively used in measuring circuits described in the standard in series with measuring impedance, Fig. 4. They have split ferrite cores which improve the sensitivity but limit the bandwidth usually in the HF-VHF range. If current transformers are to be used directly on high-voltage leads, it is preferable to choose Rogowski coils because they have air cores and do not saturate with line currents at grid frequency (Argüeso et al. 2005). Inductive couplers which wound around power cables with helicoidal shield are also used to measure partial discharges (Dubickas and Edin 2004) and, most importantly, locate them along the cable.

Acoustic sensors can detect the pressure wave emitted by the discharge in a wide band of frequencies, including the ultrasonic range (beyond 20 kHz). With corona and some surface discharges, the pulse is clearly audible, so simple microphones could be used (Bartnikas et al. 1979). In the case of internal discharges, it is preferable to use piezoelectric transducers or narrowband microphones with central frequencies in the range from 40 to 150 kHz. Directional microphones are also used to identify the location of the source of surface or corona pulses. The pressure wave can also be detected with fiber optic interferometric sensors which present advantages when compared with electric sensors such as immunity to electromagnetic interferences, wide bandwidth, and chemical inert when installed in oil transformers and nonconducting (Zargari and Blackburn 1996). On the other hand, interferometer installation is expensive, difficult, and intrusive, and they are only valid in equipment with liquid insulation such as oil.

Light sensors have been used in studies of arcing in transformers to provide information about the electron density and temperature (Bårmann et al. 1996). They have to be focused to the partial discharge site so they are not very popular because they are difficult to integrate in real environments where partial discharges can occur anywhere and can even happen inside the insulation, so no light radiation would leak out. On the contrary, there are commercial sensors using light detectors in the ultraviolet range to measure corona in overhead lines.

The next section explains why electromagnetic (EM) sensors, dissected in section "Applications of Antennas in the Detection of Partial Discharges," are also suitable for the measurement of partial discharges.

DOI 10.1007/978-981-4560-75-7_95-1

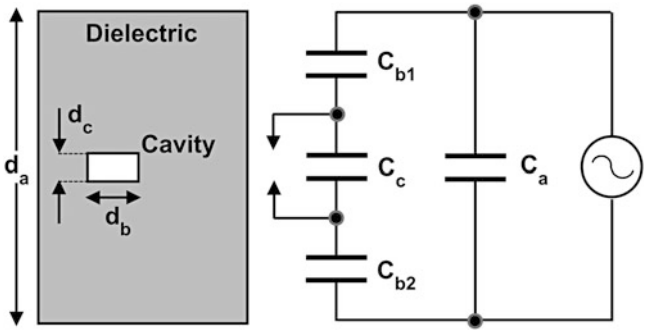

Fig. 5 Capacitive model in internal cavities

Partial Discharge Cavity Modeling

As explained in section "Types of PD," partial discharges involve the displacement of ions, both positive and negative, inside a cavity, along a surface, or in the proximity of areas with high divergent electric fields. These avalanches of particles occur in lapses as short as hundreds of picoseconds or nanoseconds which, in turn, create current pulses with very fast rise times. In general, it is not possible to measure this current at the ends of the PD site, so the actual shape of the pulses is unknown. The closest measurement can be done at the terminals of a test object; however, even under these circumstances, the signal would be deformed due to the attenuation and dispersion suffered inside the insulation from the PD site to the terminals (Hauschild and Lemke 2014). Moreover, if the test object is connected to a measuring system, the true pulse shape is further modified and the signal obtained will be very different from the original. It has been deeply investigated what is the relation between the original pulse and the signal measured at the ends of the test object. Assuming that the cavity has a regular geometric shape such as spherical, cylindrical, or elliptical, the study is greatly simplified and it is even possible to calculate the inception voltages.

Capacitive Model

The equivalent a-b-c circuit shown in Fig. 5 was introduced in the middle of the twentieth century to calculate the ratio between the actual PD charge and the measured charge in the case of internal discharges. C_a is the capacitance of the homogeneous dielectric; C_b is the accumulated capacitance of the dielectric between the electrodes and the cavity, though some authors prefer the use of C_{b1} and C_{b2} representing the dielectric over and below the cavity, respectively (Boggs 1990); and C_c is the capacity of the cavity which is shunted by a spark gap representing the eventual short circuit of the void. The ratio between the charge q_c involved in the discharge and the measured charge q_a is given by:

$$\frac{q_a}{q_c} \approx \epsilon_r \frac{d_c}{d_a} \tag{10}$$

being ϵ_r the relative permittivity of the dielectric and d_a and d_c the thickness of the homogeneous dielectric and the cavity, respectively. Recently, Eq. 10 has been modified under the assumption that during a discharge, the effective geometry of the equivalent circuit changes (Hauschild and Lemke 2014). Then, the ratio is governed by:

$$\frac{q_a}{q_c} \approx \epsilon_r \frac{d_c}{d_a} \left(\frac{d_b}{d_d}\right)^2 \tag{11}$$

DOI 10.1007/978-981-4560-75-7_95-1

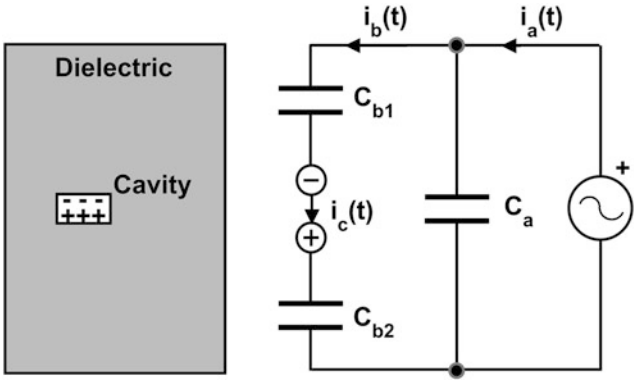

Fig. 6 Dipole model in internal cavities

with d_b the diameter of the equivalent cylinder containing the cavity and the sound dielectric and d_d the diameter of the discharge channel inside the cavity. If the measuring circuit is previously calibrated, injecting a known charge, it is possible to calculate the effective charge displacement during a discharge using inductive sensors connected to the recommended measuring circuits in IEC60270 (2000).

Dipole Model

Another widely accepted approach to the calculation of the charge involved in the ignition of partial discharges, which is alternative to the a-b-c model, is the use of a dipole model (Pedersen et al. 1991) (Fig. 6). The defenders of this model claim that the operation of an equivalent circuit may not correspond with the real physical processes that take place inside the dielectric (McAllister and Crichton 1998). In this case, the cavity turns into a dipole due to the polarization process under the application of an external electric field. The current $i_c(t)$ flowing inside the cavity when the dipole collapses continues as a displacement current $i_b(t)$ through the homogeneous dielectric that can be readily identified as capacitances C_{b1} and C_{b2}. In this case, the measurable charge q_a at the ends of the test object is equal to charge q_c moving inside the cavity (Hauschild and Lemke 2014).

Partial Discharge Pulse Modeling

Traditionally, the idealized partial discharge pulse has been simplified as a Gaussian pulse (Boggs and Stone 1982), but there are other valid approximations such as Wanninger's equation and the double exponential pulses (Reid et al. 2006).

Gaussian Pulses

A Gaussian pulse is shaped as a Gaussian function centered in $t = 0$, with a peak of I_0 amperes and a width at its half amplitude of T_h. From its definition, the proposed current pulse for partial discharges is:

$$i_c(t - t_d) = I_0 e^{-\left(\frac{t-t_d}{t_0}\right)^2}, \quad t_0 = \frac{T_h}{2\sqrt{\mathrm{Ln}2}} \tag{12}$$

where t_d is the time delay that shifts the pulse to the right, placing the peak at $t = t_d$, and t_0 is related to the pulse width and, hence, the standard deviation as $t_0 = \sigma\sqrt{2}$. Considering that the pulse is extinguished at 3σ, the time delay can be chosen as $t_d = 3t_0/\sqrt{2}$. In Fig. 7, a delayed and normalized ($I_0 = 1$ mA) Gaussian pulse is plotted. For this representation, $T_h = t_2 - t_1$ is assumed to be 1 ns, with $t_1 = t_d - t_0\sqrt{\mathrm{Ln}2}$ and $t_2 = t_d + t_0\sqrt{\mathrm{Ln}2}$.

DOI 10.1007/978-981-4560-75-7_95-1

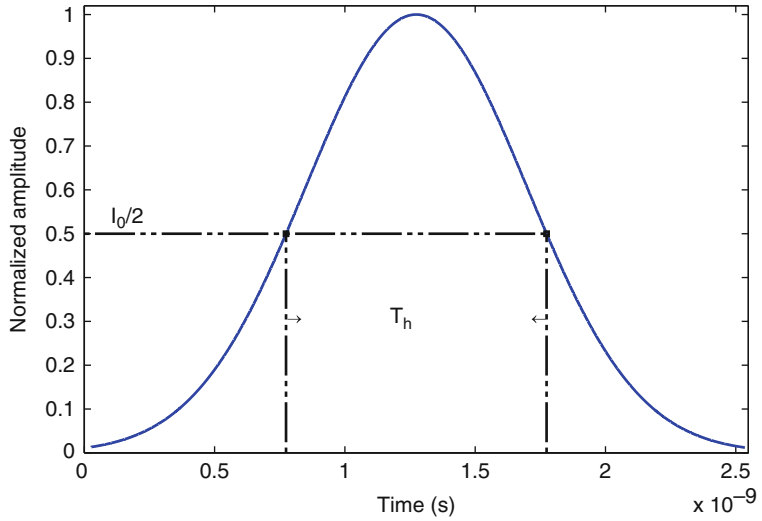

Fig. 7 Delayed and normalized Gaussian pulse with $I_0 = 1$ mA, $T_h = 1$ ns, and $t_d = 3\sigma$

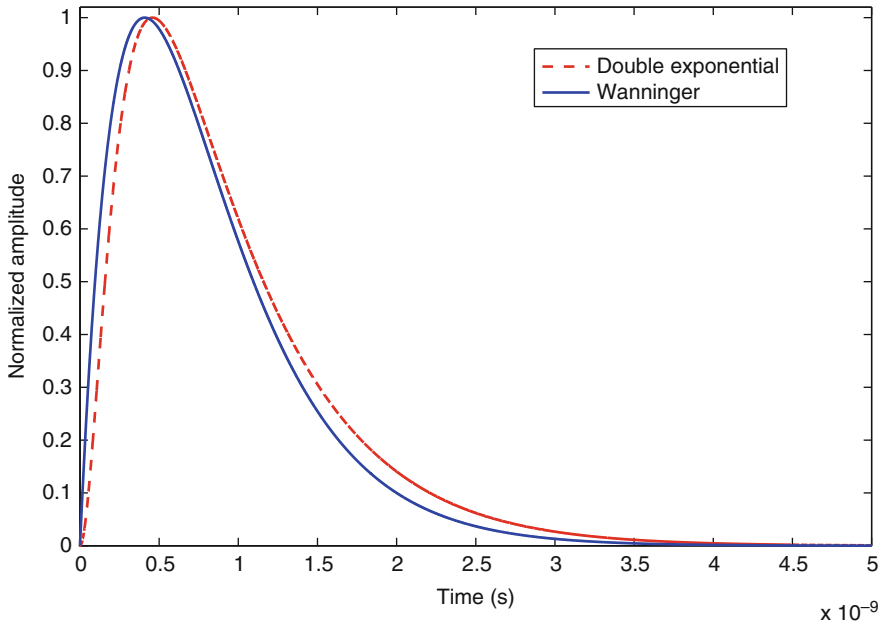

Fig. 8 Normalized Wanninger and double exponential pulses with 1 ns width at its half amplitude

Wanninger's Equation

The Wanninger's equation was used to model idealized discharge currents in (Wanninger 1997) using exponential functions in the time domain as follows:

$$i_c(t) = \frac{I_0}{\tau_1} t e^{(1-t/\tau_1)} \tag{13}$$

where I_0 is again the current amplitude in amperes and τ_1 is the rise time. From this equation, it is possible to represent discharge currents of free moving particles of single, double, and multiple pulses. This is made by combining several equations and varying τ_1 and the ratio of the amplitudes. In Fig. 8, the solid

DOI 10.1007/978-981-4560-75-7_95-1

line is an idealized pulse using the Wanninger's equation with a width at its half amplitude of 1 ns and $I_0 = 1$ mA.

Double Exponential Pulses

The double exponential was used in Ari and Blumer (1987) to represent transient electromagnetic fields due to switching operations and can also be applied to model partial discharges. The time function for the discharge current defined by a double exponential is:

$$i_c(t) = I_1\left[(1 + t/\tau_1)e^{-t/\tau_1} - (1 + t/\tau_2)e^{-t/\tau_2}\right] \tag{14}$$

where I_1 corresponds to the current amplitude in amperes. Noteworthy is that the maximum value of I_1 is 0.6517, while I_0 is 1 for both Gaussian and Wanninger pulses. For this reason, the double exponential function is divided into its maximum value to normalize the representation in Fig. 8. Parameters τ_1 and τ_2 are both time constants in seconds that define the pulse shape. The time at the peak value is calculated as:

$$t_{I_1} = 2\frac{\tau_1\ \tau_2}{\tau_2 - \tau_1}\mathrm{Ln}(\tau_2/\tau_1) \tag{15}$$

so, the condition $\tau_2 > \tau_1$ has to be held to obtain positive values.

Partial Discharge Radiation

Considering that the dipole created in the void explained in section "Partial Discharge Cavity Modelling" is an Hertzian dipole, it is possible to derive the equations of the electrical and magnetic fields radiated by the partial discharge. Let us assume that the dipole is along the z-axis and that the current $i_c(t) = \mathrm{dq_c/dt}$ or $\mathbf{I_c} = j\omega\mathbf{q_c}$ in the frequency domain for sinusoidal time-varying signals. The magnetic vector potential can be calculated as:

$$\mathbf{A_z} = \frac{\mu}{4\pi}\int_c \frac{\mathbf{I_c}}{r}e^{-j\beta r}dz \tag{16}$$

where μ is the permeability of the dielectric, r is the distance from the center of the dipole to a generic point P, and $\beta = \omega\sqrt{\mu\epsilon}$ is the wave number of the medium (Guru and Hiziroglu 2004). In small cavities, the current can be considered the same along the dipole, so Eq. 16 can be simplified as:

$$\mathbf{A_z} = \frac{\mu}{4\pi r}\mathbf{I_c}d_c e^{-j\beta r} \tag{17}$$

Changing into spherical coordinates to simplify the calculations, $\vec{\mathbf{A}}$ yields:

$$\vec{\mathbf{A}} = \frac{\mu}{4\pi r}\mathbf{I_c}d_c e^{-j\beta r}\left(\cos\theta\ \vec{\mathbf{a}}_r - \sin\ \vec{\mathbf{a}}_\theta\right) \tag{18}$$

with $\vec{\mathbf{a}}_r$ and $\vec{\mathbf{a}}_\theta$ defined as unitary vectors. Then, the magnetic field component can be calculated using:

$$\vec{\mathbf{H}}_\phi = \frac{1}{\mu}\left(\nabla\times\ \vec{\mathbf{A}}\right) = \frac{j\beta}{4\pi r}\mathbf{I_c}d_c\left(1 + \frac{1}{j\beta r}\right)\sin\theta e^{-j\beta r}\ \vec{\mathbf{a}}_\phi \tag{19}$$

DOI 10.1007/978-981-4560-75-7_95-1

with $\vec{\mathbf{H}}_r = 0$ and $\vec{\mathbf{H}}_\theta = 0$. The electric field component is obtained from the Maxwell–Ampère equation, assuming that the current density due to free charges is negligible outside the cavity and far from the discharge site:

$$\vec{\mathbf{E}} = \frac{1}{j\omega\epsilon}\left(\nabla\times\ \vec{\mathbf{H}}\right) \tag{20}$$

then,

$$\begin{aligned}
\vec{\mathbf{E}}_r &= \frac{\eta}{2\pi r^2}\mathbf{I_c}d_c\left(1+\frac{1}{j\beta r}\right)\cos\theta e^{-j\beta r}\ \ \vec{\mathbf{a}}_r \\
\vec{\mathbf{E}}_\theta &= \frac{j\beta\eta}{4\pi r^2}\mathbf{I_c}d_c\left(1+\frac{1}{j\beta r}-\frac{1}{\beta^2 r^2}\right)\sin\theta e^{-j\beta r}\ \ \vec{\mathbf{a}}_\theta \\
\vec{\mathbf{E}}_\phi &= 0
\end{aligned} \tag{21}$$

Equations 19 and 21 can be simplified considering far-field conditions at distances r, so $r \gg \lambda$ with $\lambda = 2\pi/\beta$ the wavelength of the electromagnetic field. Then:

$$\begin{aligned}
\vec{\mathbf{H}}_\phi &= \frac{j\beta}{4\pi r}\mathbf{I_c}d_c\sin\theta e^{-j\beta r}\,\vec{\mathbf{a}}_\phi \\
\vec{\mathbf{E}}_\theta &= \frac{j\beta\eta}{4\pi r}\mathbf{I_c}d_c\sin\theta e^{-j\beta r}\,\vec{\mathbf{a}}_\theta
\end{aligned} \tag{22}$$

eliminating the terms in $1/r^2$ and $1/r^3$. Equation 22 is, by definition, a transverse electromagnetic (TEM) wave propagating in the radial direction, so the far fields represent a spherical wave (Guru and Hiziroglu 2004). Note that $\vec{\mathbf{E}}_\theta/\vec{\mathbf{H}}_\phi = \eta$ with $\eta = \sqrt{\mu/\epsilon}$, the intrinsic impedance of the dielectric. Under these assumptions, partial discharges radiate TEM waves that can be captured with antennas in far-field regions. The next step should be to determine what ranges of frequencies have the radiation based on the type of pulse and its time characteristics such as rise time and width.

Electromagnetic Radiation of a Gaussian Pulse

The radiation of a dipole has just been calculated for sinusoidal signals, but it is easy to obtain the electric and magnetic fields at a point P when the dipole is excited with a Gaussian pulse. The magnetic vector potential in spherical coordinates has the following equation in the time domain when the current pulse is Gaussian:

$$\vec{\mathbf{A}} = \frac{\mu I_0 l}{4\pi r}e^{-\left(\frac{t-r/v}{t_0}\right)^2}\left(\cos\theta\ \ \vec{\mathbf{a}}_r - \sin\theta\ \ \vec{\mathbf{a}}_\theta\right) \tag{23}$$

where $v = 1/\sqrt{\mu\epsilon}$ is the speed of propagation in the media. Calculating the magnetic field using the first term in Eq. 19, the result is:

$$\vec{\mathbf{H}}_\phi = \frac{1}{\mu}\left(\nabla\times\ \vec{\mathbf{A}}\right) = \frac{I_0 l e^{-\left(\frac{t-r/v}{t_0}\right)^2}\sin\theta}{4\pi r^2}\left(1-\frac{2r(t-r/v)}{vt_0^2}\right)\vec{\mathbf{a}}_0 \tag{24}$$

DOI 10.1007/978-981-4560-75-7_95-1

Then, using Eq. 20 in the time domain:

$$\begin{aligned}
\vec{\mathbf{E}}_r &= \frac{\eta I_0 l e^{-\left(\frac{t-r/v}{t_0}\right)^2} \cos\theta}{2\pi r^2}\left(1+\frac{t_0\sqrt{\pi}}{2r}\right)\vec{\mathbf{a}}_r \\
\vec{\mathbf{E}}_\theta &= \frac{\eta I_0 l \sin\theta}{4\pi r^2}\left(e^{-\left(\frac{t-r/v}{t_0}\right)^2} - \frac{2r(t-r/v)e^{-\left(\frac{t-r/v}{t_0}\right)^2}}{vt_0^2} + \frac{v\sqrt{\pi}}{2r}\int_0^t e^{-\left(\frac{t-r/v}{t_0}\right)^2} dt\right)\vec{\mathbf{a}}_\theta \\
\vec{\mathbf{E}}_\phi &= 0
\end{aligned} \tag{25}$$

If the measuring point is far from the partial discharge site, the term $1/r$ dominates and the equations can be reduced to:

$$\begin{aligned}
\vec{\mathbf{H}}_\phi &= -\frac{I_0 l e^{-\left(\frac{t-r/v}{t_0}\right)^2} \sin\theta(t-r/v)}{2\pi r v t_0^2}\vec{\mathbf{a}}_\phi \\
\vec{\mathbf{E}}_\theta &= -\frac{\eta I_0 l e^{-\left(\frac{t-r/v}{t_0}\right)^2} \sin\theta(t-r/v)}{2\pi r v t_0^2}\vec{\mathbf{a}}_\theta
\end{aligned} \tag{26}$$

These equations are inversely proportional to t_0^2 which is related to the pulse width. So the narrower the pulse is, the larger the radiation of the partial discharge would be.

Considering that,

$$\frac{\partial i_c(t-r/v)}{\partial t} = -\frac{2I_0(t-r/v)}{t_0^2} e^{-\left(\frac{t-r/v}{t_0}\right)^2} \tag{27}$$

The electric and magnetic fields can be rewritten using the derivative of the delayed Gaussian pulse with $t_d = r/v$. In the case of the electric field is:

$$\vec{\mathbf{E}}_\theta = \frac{\eta I_0 l \sin\theta}{4\pi r v}\ \frac{\partial i_c(t-r/v)}{\partial t}\vec{\mathbf{a}}_\theta \tag{28}$$

Frequency Emission of a Gaussian Pulse

The Fourier transform of the electromagnetic field created by a Gaussian pulse gives the frequency band at which the discharge emits. The following calculations are done for the electric field, but the results are analogous for the magnetic field. The Fourier transform, $\mathcal{F}(\cdot)$, of a derivative function is:

$$\mathcal{F}\left(\frac{\partial i_c(t-r/v)}{\partial t}\right) = \int_{-\infty}^{\infty} \frac{\partial I_c(t-r/v)}{\partial t} e^{-j\omega t} dt \tag{29}$$

From Eq. 27, the derivative depends on a squared exponential function and a time delay. The Fourier transform of a squared exponential function is:

DOI 10.1007/978-981-4560-75-7_95-1

$$\mathcal{F}\left(e^{-t^2}\right) = \sqrt{\pi t_0^2} e^{\frac{-\omega^2 t_0^2}{4}} \tag{30}$$

Besides, the differentiation and time shift properties of the Fourier transform, Eqs. 31 and 32, respectively, must also be applied to solve Eq. 29:

$$\mathcal{F}\left(\frac{d^n i_c(t)}{dt^n}\right) = (j\omega)^n I_c(\omega) \tag{31}$$

$$\mathcal{F}(t - t_d) = \mathcal{F}(\omega) e^{-j\omega t_d} \tag{32}$$

Then, the Fourier transform of the amplitude of the electric field radiated by a Gaussian pulse can be written as follows:

$$\mathcal{F}(E_\theta) = \omega\sqrt{\pi} t_0 I_0 e^{-\frac{\omega^2 t_0^2}{4}} e^{j\left(\frac{\pi}{2} - \omega\frac{r}{v}\right)} \tag{33}$$

Considering only the module of the Fourier transform and substituting $\omega = 2\pi f$, the equation that represents the spectrum amplitude for a Gaussian pulse is:

$$|\mathcal{F}(E_\theta)| = 2\pi f\sqrt{\pi} t_0 I_0 e^{-(\pi f t_0)^2} \tag{34}$$

For a Gaussian pulse defined in terms of its width T_h as in Eq. 12, the Fourier transform is:

$$|\mathcal{F}(E_\theta)| = \pi f\sqrt{\pi}\frac{T_h}{\sqrt{\mathrm{Ln}2}} I_0 e^{-\left(\pi f\frac{T_h}{2\sqrt{\mathrm{Ln}2}}\right)^2} \tag{35}$$

The influence of the width of the pulses in the spectrum is represented in Fig. 9 and has been calculated with varying T_h in Eq. 35. This Figure and Table 1 help to determine the frequency band where partial discharges emit electromagnetic energy in function of their width. The band is $f_{\max} - f_{\min}$ where $f_{\max}$ and $f_{\min}$ are the cutoff frequencies for a drop of 3 dB in the amplitude of the electric field.

In (Shibuya et al. 2010), a compilation of pulse widths for partial discharges in small gaps and conductive particles is reported. The band in which the pulses emit electromagnetic energy from the data in (Shibuya et al. 2010) are calculated and represented in Table 2, sorted by decreasing pulse widths. This table summarizes different phenomena in a wide range of dielectric types. For short duration idealized Gaussian pulses approximately less than 2.5 ns, partial discharges emit energy in UHF. For larger time widths, antennas in the VHF range should be recommended. In any case, the casuistic of partial discharges is so vast that generalizing is sometimes a futile task. The important fact is that PD can be measured with antennas due to their short duration and fast rising front wave.

Applications of Antennas in the Detection of Partial Discharges

Measuring Partial Discharges in Electric Equipment with Antennas

Radiofrequency measurements in the HF, VHF, and UHF bands are part of the unconventional methods used for partial discharge detection (IEC62478 yet). As mentioned in section "Types of PD," partial discharges occur on a limited spot which comes with the property of extremely short breakdown time.

Thus, the electromagnetic radiated pulse contains the combination of different frequency components reaching a few GHz falling within the range of VHF and UHF bands, in the low microwave band.

The detection of PD with EM sensors can be used in any type of insulating material and for multiple electrical assets such as gas-insulated substations, air-insulated substations (AIS), power transformers, insulators in aerial distribution cables, joints and splices of insulated cables, and rotating machinery. The main advantage of detecting partial discharge pulses in RF is the possibility of monitoring these assets online. Most diagnostic techniques such as tangent delta and insulation resistance measurements, frequency response analysis (FRA), surge tests, and hipot tests are carried out off-line or require periodic interventions of operators to take samples such as in dissolved gas analysis (DGA), degree of polymerization, and moisture analysis in power transformers.

EM sensors can detect partial discharge pulses, localize the partial discharge site, and, to some extent, classify the type of partial discharge online. In the detection and localization of PD, there is never a direct connection to the electric equipment. However, to analyze the type of PD, it is necessary to have the reference of the grid frequency to plot conventional PRPD patterns; see section "Phase-Resolved Partial Discharge Patterns." In this case, a voltage divider has to be installed and connected to the acquisition system to record both PD pulses and time (or phase) simultaneously. In this sense, one of the most important challenges when using antennas in the diagnostic of insulations is the difficulty of relating the RF emissions to the severity of the PD (Reid et al. 2006). Currently, it only can be said that there is a direct relation between the energy emitted by the partial discharge and the rate of change of current in the pulse as demonstrated in Eq. 28. Moreover, the sample rate to obtain information from the signals in the time and frequency domains is sometimes prohibitively high, incurring in great expenses, so it is applied only when it is strictly necessary.

On the other side, RF interferences from power lines can propagate into transformers and other electrical assets reducing the PD measurement accuracy when traditional detection, between tens of KHz and several MHz, is used. The UHF PD detection thus takes advantages of strong anti-interference ability over the approach defined by (IEC60270 2000). However, other sources of interference such as FM radio, TV broadcasting, mobile telecommunications, Wi-Fi, etc., could difficult the PD detection as well.

Ultimately, the measurement of PD in the RF range offers new insight into the diagnostic of electrical machines with the possibility of measuring under conditions where other methods may fail or are impossible to apply.

Nowadays, the implementation of UHF sensors in electric equipments is still not widespread. Most of the testing solutions in this field are using adapted spectrum analyzers with a specialized software to process and analyze the data in the time and frequency domains, and they are restricted to conventional air-insulated substations. There are several manufacturers that give partial or global solutions for PD monitoring in UHF in GIS using internal or external sensors. These measuring devices execute automated continuous online monitoring and periodic measurements of PD.

Gas- and Air-Insulated Substations

Partial discharge measurement with antennas took its first steps in the 1960s (Helstrom 1961) and became more relevant at the end of the 1980s, with the detection of PD created by free metallic particles in gas-insulated substations (Hampton and Meats 1988). This reference can be considered as one of the pioneer studies in the measurement of partial discharges in the UHF range. It is also one of the first reports of pulse propagation and location in electric equipment with UHF couplers. The importance of gas-insulated substations relies on the use of sulfur hexafluoride (SF_6) gas as electrical insulation for their high-voltage maneuvering devices and transformers. The SF_6 dielectric strength is about 2.5 times larger than that of air, so the size of a conventional air-insulated substation can be reduced in a 70 % by enclosing high-voltage equipment inside structures with this gas. Its construction requires a sealed

DOI 10.1007/978-981-4560-75-7_95-1

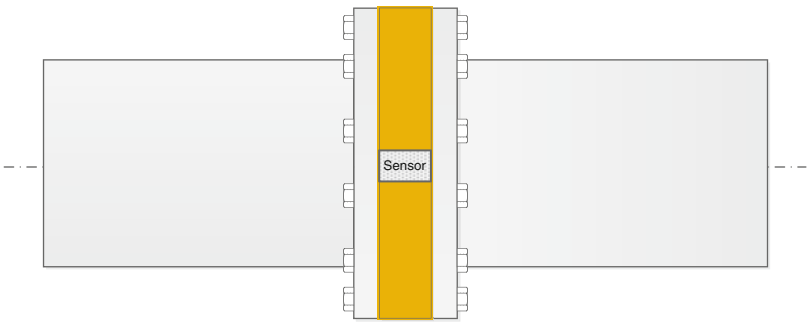

Fig. 10 GIS duct with a joint union, their bolts, and a flange-type sensor

shielding to confine all electrical elements and gas, so, once the substation is finished, introducing probes or installing sensors is practically impossible. The chambers behave as resonant cavities, so their size and shape set their resonance frequencies that can be measured in the range of UHF (Balanis 2012; Pearson et al. 1991). Then, whenever a pulse occurs inside, only a small fraction of the energy escapes the enclosure. For this reason, the most common sensor used to measure PD in UHF range is a capacitive disk coupler mounted on hatch cover plates in GIS substations (Hampton and Meats 1988; Pearson et al. 1991; Judd et al. 1996). Exceptionally, horn, biconical–log-periodic, loop, and monopole antennas have also been used for externally measuring partial discharges whose radiation leaks out through the flange connecting ducts (Kaneko et al. 2009).

The internal sensors are manufactured with metal shields, embedded electrodes, or field probes usually installed on a spare flange of the GIS or on dielectric windows (Judd et al. 2001). Apart from the capacitive disk couplers, some manufacturers also use conical antennas in new GIS substations. In (Chen et al. 2011), a square microstrip antenna and a broadband amplifier are designed, and the instrument is externally displayed for partial discharge measurement in a gas-insulated switch. The installation of internal sensors that have not been previously mounted requires opening the GIS with the subsequent risk of particle contamination. Therefore, this should only be carried out for renovation of aged substations or when the external sensors are not a practicable solution. Aside from avoiding opening the sealed chambers, external sensors are also used when the internal sensors are located too far apart and do not cover sectors where detection is needed. In these cases, the sensors are mounted in unshielded isolated spacers such as joints between conduits. Through these connections, radiation can escape out from within the GIS and can be measured mainly in the UHF range. However, measuring under these circumstances is influenced by several factors. One of them is the arrangement and shape of the resonant cavity that forms the structure of the GIS and defines its resonance frequencies when partial discharges are active. Another factor are the spacers between tanks which are attached with bolts disposed along the circumference as in Fig. 10. The sectors without bolts form small slots that behave as resonant dipole antennas. The greater the number of bolts is, the smaller the slots are and, then, the greater their resonance frequencies are (Kaneko et al. 2009). Conical, ring antennas or dipoles with frequencies bands tuned to the frequency defined by the slot can be placed at a few centimeters to measure the small fraction of the radiation that escapes from the cavities. Alternatively, in substations where there are inspection windows available, external sensors such as flange type are installed, Fig. 10.

Some manufacturers have developed portable spectrum analyzers using directional or resonant antennas to identify radiation sources originating from outside the electric equipment. These analyzers are used in periodic measurements, mainly in open-air substations upon the request of the owner utility. When UHF measurements are carried out in AIS substations, several electromagnetic noise sources and impulsive noise can perturb both the acquisition of PD and their locations (Shan et al. 2011). Conversely, partial discharges as noise can perturb Wi-Fi and ZigBee communications in substations. Nevertheless,

DOI 10.1007/978-981-4560-75-7_95-1

most of the efforts have been directed at localizing the partial discharge site in high-voltage plants (Moore et al. 2005; Portugués et al. 2009).

Transformers

As mentioned before, power transformers are strategic assets in the electrical grid. The oil–paper insulation permittivity directly influences the speed of the electromagnetic waves created by the partial discharges. For example, light mineral oil has a relative permittivity value of 2.9, and the signals travel at a speed of $2.03 \cdot 10^8$ m/s, while oil-impregnated pressboard has a relative permittivity of 4.52 and the speed is $1.46 \cdot 10^8$ m/s (Tang et al. 2006). Additionally, the permittivity does not vary significantly with temperature during transformer operation.

The measurement of PD in power transformers in the UHF range was developed in the 1990s in the last century after the first tests in GIS using also pre-installed hatch sensors or disk couplers. These sensors are mounted in power transformers bushing taps or in windows in the shielding tank. Other sensors, such as monopoles and conical antennas, have been also employed, inserted inside the tank through the drain oil valve of the power transformer (López-Roldán et al. 2008; Tenbohlen et al. 2008), previously emptying the tank. Evidently, there are other severe disadvantages in mounting sensors that have not been previously installed. The power transformer must be decommissioned, incurring in electricity production shortages unless a second transformer is available, which is, in most cases, prohibitively expensive. Furthermore, as in the case of GIS, during the installation, particle contamination in the tank can happen, inducing PD during normal operation once commissioned. A defective installation of a sensor in the shielding tank can cause problems of poor sealing and insulation.

The recommendations for condition monitoring and condition assessment facilities for transformers are reviewed in (A2.27 2008). This brochure takes into account the benefits of a possible standardization of the software for monitoring and identifying locations for mounting PD sensors in power transformers such as drain valve UHF probes.

PD measurement in power transformers with external antennas is an open-research topic (Robles et al. 2013a), wherein the electromagnetic emission of PD is difficult to obtain and only can be measured through dielectric windows of the tank and transformer bushes.

Additionally, there are many studies and applications devoted to the location of the partial discharge inside transformers with antennas. The calculus can be influenced by obstacles such as insulating paper, iron core, columns, and winding that delay the arrival time of the PD to the sensors. Section "Location of Partial Discharges" explains these techniques more thoroughly.

Rotating Machines

Online partial discharge measurement in rotating machines can detect degradation mechanisms that would otherwise have been missed in off-line measurements. The force of the magnetic fields when the machine is in service is the cause of the movement of the stator coils within the slot, provoking vibrations and abrasion and the subsequent deterioration of the insulation (Stone et al. 1992). Apart from loose windings in slots, partial discharge online measurements are able to detect thermal deterioration, load cycling deterioration, semiconductor and grading coating problems, and contaminated windings. Unfortunately, asynchronous and random noise is very present when the machine is rotating, and sophisticated techniques are needed to detect partial discharges and reject all unwanted disturbances. These techniques are different according to the type of rotating machines, hydraulic generators, or large turbine generators. There also exists some punctual research in inverted-fed motors using small monopole antennas inserted directly inside the motor terminal box (Fabiani et al. 2008).

DOI 10.1007/978-981-4560-75-7_95-1

Hydraulic Generators

The detectors are not antennas but coupling capacitors connected to the high-voltage bus and separated at a fixed and known distance. They create a low-impedance path for signals above several megahertz that can arrive from the stator of the machine (partial discharges) or from the line (noise). The pulses will be separated based on their origin using time differences of arrival to the detectors (Stone et al. 1992).

Turbine Generators

Stator slot couplers (SSC), basically two-port stripline antennas or capacitive–inductive couplers, can be installed under the stator wedges or between top and bottom bars in a new or rewound machine (Sedding et al. 1991). They are typically located in the high-voltage end slots of a stator winding where voltage and likely partial discharges are highest. The SSC have a frequency response from 30 MHz to over 1 GHz and are preferentially sensitive to the electromagnetic emission from PD pulses occurring in the proximities. This wide bandwidth helps in the discrimination of partial discharges from electrical noise based on the pulse shapes of both signals and the coupler location very close to the stator winding. Typically, arcing from bushes and partial discharges occurring outside the machine are attenuated by the inductive characteristic of the winding. They reach the coupler as low-frequency signals, while partial discharges in the stator have sharp rise times and high-frequency components. Unfortunately, pulses occurring a slot or two further down in the stator winding are heavily attenuated in the frequency detection range of these couplers, so they can easily be missed.

Other Equipment

The most common discharge in transmission lines and the less dangerous in terms of insulation damage is corona and was firstly measured in (Helstrom 1961). Nevertheless, the detection of PD in these systems is of importance, considering that they can also be surface discharges in the insulators of aerial distribution cables. These discharges can be critical to avoid faults in electrical lines installed in high-polluted or maritime environments with high salinity and humidity. In (Moore et al. 2004), insulation defects in 132 kV overhead lines were detected and localized using an array of four antennas and an acquisition system with a bandwidth of 1 GHz. In (Fernando et al. 2012), a horn antenna is located 1 m away to measure surface discharges from an 11 kV three-phase uninsulated overhead distribution cable system with the aim of designing an RF detection and localization system.

The measurement of PD emission in insulated cables can only be carried out by measuring their radiation through their joints and splices. In (Tenbohlen et al. 2008), on-site and online EM PD acquisitions are made using clamped monopole antennas around the cable terminations in the manhole of a GIS. These so-called antennas are really inductive and capacitive couplers that have also been used by many other authors. There are not evidences of far-field antennas in the measurement of partial discharges in insulated cables.

It is important to bear in mind that the expenses of high-frequency acquisition equipment are an important drawback in the detection of partial discharges in overhead lines because they can be hundreds of kilometers long, and it is impossible to cover all the system with few antennas. As for insulated cables, most of them are actually buried, so the use of antennas is out of the question except when they are placed close to joints. Even in these cases, other alternative methods, such as the use of high-frequency current transformers, are widely preferred.

Other authors have installed microstrip (Yao et al. 2013) or horn (Cai et al. 2014) antennas inside switchgear to monitor partial discharges. In this case, the size of the antenna is one of the most important design constraints due to the lack of space inside the switchgear which is packed with partition boards, circuit breakers, bushings, insulators, bus bars, and other measuring devices such as current transformers. The sensor should be placed far from the current transformers and bus bars because they attenuate the

DOI 10.1007/978-981-4560-75-7_95-1

electromagnetic emission of the partial discharges; insulators would distort the waveform so they should also be avoided; on the contrary, the circuit breakers do not affect RF, so they can be in the path of the partial discharge emission.

Types of Antennas

The different types of EM sensors mentioned in the last section can be identified depending on whether the operation is to couple (capture signal in a cavity) or to pick up signals from air (free space), working as a conventional antenna in a communication system. Hence, depending on the position of the sensor, we can distinguish between:

- Internal sensors: electromagnetic probes coupled to high-voltage equipment where partial discharges take place (Pinpart and Judd 2009; Reid et al. 2011).
- External sensors: antennas working in free space at close range to the device under test. In that case, it is the leaked signal that is picked up and processed (Chen et al. 2011). The antennas operate in near- or far-field conditions depending on the case.

In both cases, the signals can be measured from one or more points if the position of the discharge site is to be determined, section "Location of Partial Discharges."

Internal Sensors

When dealing with internal sensors, safety is always a concern because they are always placed close to hazardous zones. High-voltage equipment such as power transformers, rotating machines, and GIS are usually shielded so they can be considered as lossy inhomogeneous cavities. Hence, when the antenna is used internally, it is typically cavity backed (shielded), screened against electromagnetic interference from external sources. Since the wavelength is relatively small, multiple resonating modes could be simultaneously present when the discharge occurs. Moreover, the antenna response for internal sensors could be highly affected by elements in the vicinity which must be taken into account in the design and integration of the measuring system. Recently, some research has been published in the literature where a transformer is electromagnetically simulated by means of a full-wave analysis computer-aided design (CAD) (Zheng and Bojovschi 2012).

In this type of sensors, we can further distinguish between:

- Dielectric window sensors. The high-voltage equipment includes small dielectric windows in some predefined positions which are manufactured as a part of the tank or encasement so the sensor can be easily connected. Obviously, their sizes should be as small as possible so as not to have any influence in the safety of the equipment in operation. For other dielectric windows, not usually provided by the high-voltage equipment manufacturer, the typical diameter of the sensor is 15 cm (Judd et al. 2005).
- Sensors placed in valves (oil or gas drain valves): When the antennas are placed in valves, they can have a certain maximum width and depth. The typical size of the drain valve is 5 cm in diameter and 10 cm in length.

External Sensors

When signals are picked up externally, the antennas will be located close to monitored equipment in the range from centimeters to a few meters. In these cases, the signal strength will be smaller than the obtained with internal sensors. Interference coming from nearby external sources, mainly from communications systems located in the same frequency bands, will also degrade the measurement. For external antennas

DOI 10.1007/978-981-4560-75-7_95-1

with no volume constraints, dipole or monopole antennas are used in their wired or printed versions, with the usual modifications to widen the matching band or to achieve compact designs.

Antenna Selection

The performance of UHF antennas determines, to a large extent, the quality of the received signal. It is important to note that the antennas for partial discharge detection work only in receive mode and are connected to the receiver device by a feeding line that must be matched in impedance, typically $Z_o = 50\ \Omega$. Oscilloscopes, spectrum analyzers, amplifiers, or analogue to digital converter inputs are set to low impedance.

In what follows, the description of the operation mode of the considered antennas will rely mainly on the radiation pattern (directivity) and the impedance matching. It will also be assumed that there is no dominant polarization for the electromagnetic waves radiated by the discharges.

The power frequency content of the signals from partial discharges can vary considerably, depending on the location of the discharge and the propagation path through the asset and the surrounding high-voltage equipment. Besides, the antenna has a response in terms of amplitude and phase which will affect the received pulse and will give rise to a time domain signal whose complexity will depend on the discharge type, the environment, and the antenna itself. So, the quality of the received signal will be largely affected by these circumstances, resulting in a distorted pulse, hindering its detection and subsequent processing. Thus, depending on whether we want to *detect* the occurrence of the discharge, to *classify* the type of discharge, or to *locate* the position of the point where the PD occurred, the role of the antenna will be more or less important.

Since partial discharges emit radiation over a wide frequency range, it is necessary to use antennas with bandwidths wide enough to optimize the measurement. This implies that the typical parameters of an antenna, such as the voltage standing wave ratio (VSWR) or the S_{11} parameter, and the radiation patterns must be stable throughout the operating band (Choi et al. 2004). Besides, a minimum change in the phase center position is required if the partial discharge site is to be determined using any of the techniques described in section "Location of Partial Discharges."

It is well known that the measurement of the signals emitted by the PD in the wideband mode has advantages over the use of narrow bandwidth (Stone et al. 1992). Partial discharge signal-to-noise ratio shows improvements with the increase of bandwidth and provides more accurate results (Boggs and Stone 1982). Due to this reason, wideband and ultra-wideband (UBW) antennas are of particular interest in partial discharge classification applications, and maximizing the bandwidth while maintaining compactness will be one of the design goals of this type of antennas (Robles et al. 2013c). Log-periodic and fractal schemes can be used to improve the bandwidth although their size can increase substantially when they are used in the low frequency range of the UHF band.

Resonant antennas have multiple resonant modes within the band where the signal is emitted. Furthermore, each resonance frequency corresponds to a different radiation pattern, which can strongly distort the received signal so they can be used in the detection or localization of partial discharges. Some well-known modifications in the geometry of these antennas can be introduced in order to enhance the bandwidth of the fundamental mode (broadband–wideband antennas).

Depending on the exigences of the measurement, the antennas must be balanced or can be unbalanced (grounded). The balanced antennas, such as dipole antennas, require a balun to feed the balanced structure from an unbalanced transmission line such as coaxial cables. If no balun is used, this directly affects both to the impedance matching of the antenna to the feeding transmission line and to the corresponding radiation pattern. The balun can also perform the function of impedance matching, which may be interesting when seeking for compact broadband antennas where the input impedance is high.

DOI 10.1007/978-981-4560-75-7_95-1

In this section, several antenna shapes that have been used in the recent years for PD detection will be simulated in their simplest version for the sake of their comparison. The antennas will be classified in three large groups: wire antennas, printed planar antennas, and aperture antennas. Bibliographic references of each type will also be provided. Among the sensors are short monopoles, monopole-conical shape, top-loaded monopoles, disk antennas, and spiral, fractal, and Vivaldi antennas. The balanced cases have been simulated in their planar versions. When a grounded antenna is simulated, a circular ground plane has been used to emulate the valve cover that closes electromagnetically the high-voltage equipment, with a radius of 5 cm and a maximum height of 10 cm. A FR-4 substrate ($\epsilon_r = 4.3$) with thickness $h = 1.5$ mm has been used in all cases as the antenna base unless otherwise stated.

All prototypes have been simulated in the frequency range 0.3–3 GHz, assuming perfect electric conductors and lossless materials. Ideal $Z_s = 50\ \Omega$ point generators have been used to drive the antennas for both unbalanced-grounded or balanced antennas. For all cases, a sketch of the antenna, its return loss (RL) for a reference impedance of $Z_0 = 50\ \Omega$ versus frequency, will be provided.

Wire Antennas

The simplest wire antennas are dipoles, monopoles, and loops. A complete review of these antennas for PD application can be found in (López-Roldán et al. 2008), where different implementations are compared, including straight, trapezoidal, helix, disk, and conical monopoles and also simple loop and spiral antennas. Table 3 includes the most common cases.

Dipole antennas are widely used for many different communication applications. Such resonant antennas consist of two radiating elements, the arms of the antenna, fed in opposite phases. The radiation pattern has a null in the antenna axis, being omnidirectional in the plane perpendicular to that axis.

Monopole antennas consist of only one resonant element which is fed by a transmission line through a ground plane. Hence, a balun is not required. Besides, with an appropriate design procedure, some monopole antennas can provide a wider bandwidth than dipole antennas. Table 3 shows the reference result for an ideal monopole tuned to a frequency around 750 MHz. The second resonance can be easily recognized on the right.

Many different implementations of monopole antennas which are variations of the simplest case can be found in the literature. The modifications are usually aimed at widening the operating frequency band or achieving more compact antennas, especially in those cases where the antenna must be installed in a transformer valve. In all cases, the central wire is replaced by cylindrical elements (wires or disks), conical elements, or combinations thereof (top-loaded monopoles). Different implementations are reviewed below.

The first modification is to replace the central wire by an inverted cone of about the same height (conical skirt monopole). It is clear that the differences with the response for the conventional monopole are small. An increment in the bandwidth for each of the resonances as well as a slight displacement of the resonance frequencies towards lower frequencies is observed. The radiation patterns do not show significant changes.

In a second variation, a metallic disk is added to configure a top-loaded monopole antenna that typically exhibits an improvement in the matching level, maintaining the same resonance frequencies. Once again, radiation patterns do not exhibit significant changes.

The former elements can be combined in different ways. In patent (Raja 2007), an inner sensor is proposed using a dipolar-like structure where one of the electrodes is a disk and the other an inverted cone. The sensor operates in a frequency range between 0.2 and 1 GHz. In patent (Kato and Oshita 2000), another inner sensor is described, comprising a small dipole whose branches are two semicircular metallic disks.

DOI 10.1007/978-981-4560-75-7_95-1

Table 3 Monopolar antennas

Type		Matching
Monopole (grounded)		Conical monopole		Top-loaded monopole		Disk (centered probe)		
When the antenna is used in a valve as in the latter cases, the metal walls have a significant effect on its electromagnetic response. In López-Roldán et al. (2008), a study is performed about the effect on the sensitivity of the depth of insertion of the cone into the pipe where the conical antenna is located, being the most favorable case when the antenna penetrates further in the transformer.

To show this effect, Fig. 11 represents the result of including an outer metallic cylinder of 8 cm in height in a top-loaded monopole antenna. It is observed how the first resonance frequency around 500 MHz has almost disappeared.

The upper part of the inverted cone can be modified to optimize the performance of the antenna. According to this idea, in Cleary and Judd (2006), a metallic semisphere is used above the base of the cone to achieve an improved response covering a good portion of the UHF band. Going further, the vertical

DOI 10.1007/978-981-4560-75-7_95-1

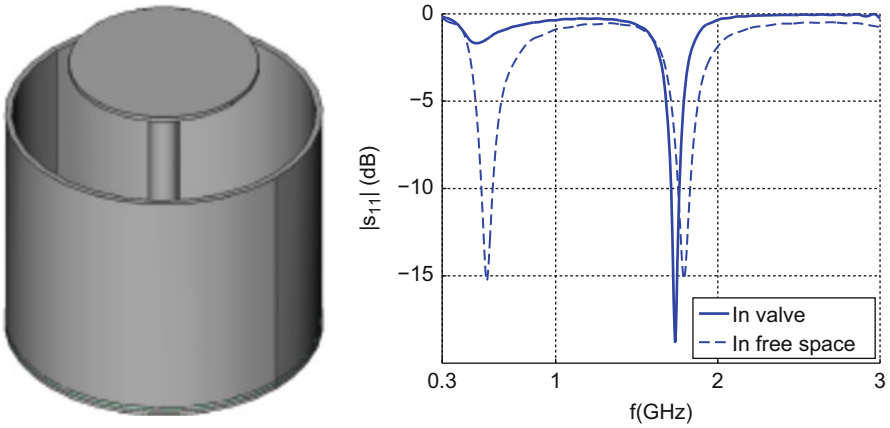

Fig. 11 Top-loaded monopole antenna in a simplified drain valve

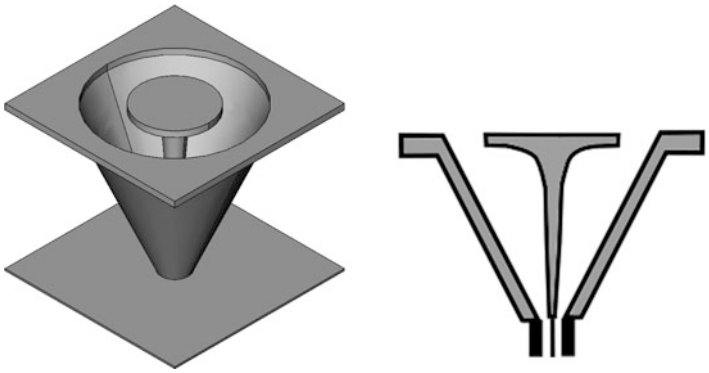

Fig. 12 Optimized top-loaded monopole antenna

monopole wire can be replaced by a different geometric element like in (Petchphung et al. 2007), where a metallic disk with a radius of 14 mm is used instead, achieving ultra-wideband response by means of a very compact sensor in a typical configuration for a UWB communication antenna.

In all the described cases, an optimized profile can be tailored in the central conductor to compensate for the effect of the outer metallic cylinder when the antenna is used as an internal sensor like in Fig. 12. For instance, patents (Reinhardt 1985) and de (Kock and Herbst 1998) are examples of such an approach. The combined effect of the monopole and the outer shielding element could also be seen as a tapered coaxial transmission line.

In a more complex configuration, patent (Fukasawa et al. 2014) describe different top-loaded monopoles shunted with a parallel stub that are used to improve the impedance matching in inner sensors. The stub is shorted to ground by connecting it to the outer metallic shell. Some dielectrics are employed to provide isolation and sealing.

The top-loaded monopole can be modified by increasing the size of the disk and reducing the height of the central post such as described in (Judd et al. 1995). In addition to these elements, some resistors are used in this antenna to earth the disk to the ground plane. In (Judd et al. 2000), a similar antenna that uses a composite material for insulation is presented. This antenna is compared to a single monopole in Ishak et al. (2012) using a finite difference time domain (FDTD) approach.

The disk in Table 3 represents a simplified model of this type of sensor. A PTFE substrate ($\epsilon_r = 2.2$) is used in this case. Note that the antenna radius has been increased to 10 cm. Substrates with higher

DOI 10.1007/978-981-4560-75-7_95-1

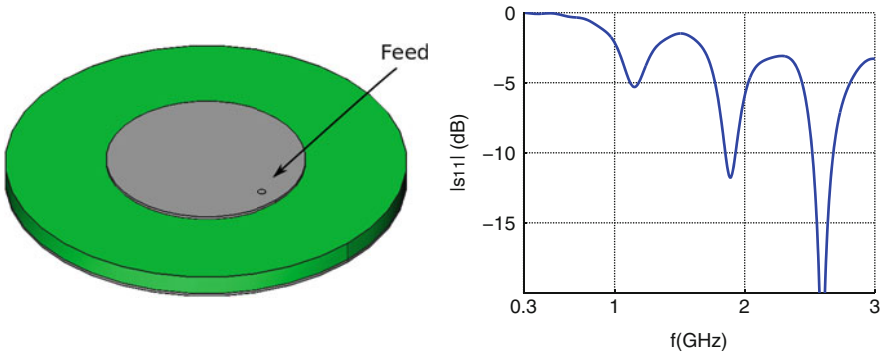

Fig. 13 Disk antenna with offset coaxial probe

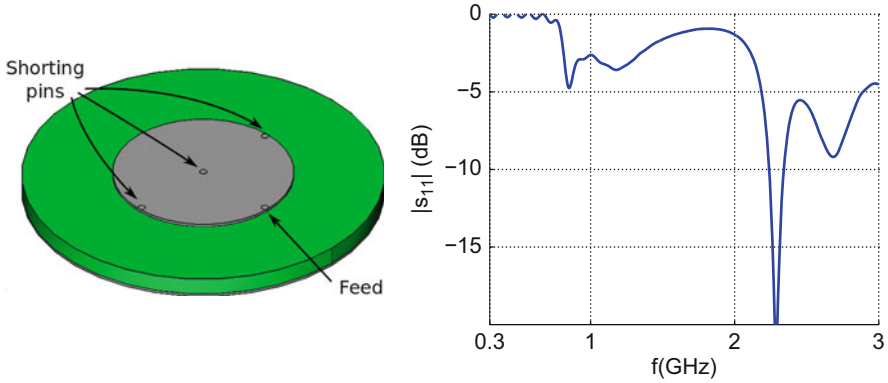

Fig. 14 Disk antenna with offset coaxial probe plus shorting central and lateral pins

permittivities can be used to reduce the antenna size, although this will have an impact on the matching level.

When the disk antenna is excited by a coaxial probe located at a point off-center closer to its edge, a good impedance response with essentially broadside radiation patterns can be achieved. Strictly speaking, this antenna is not a wire type but a circular patch-type antenna though it is shown in this section for simplicity. Figure 13 shows the response for this case. Multiple resonances are present within the band of interest, each having a different broadside radiation pattern depending on the field distribution of each mode.

This antenna supports a simple modification to achieve a compact and well-matched configuration. To this end, shorting pins are used in the center of the antenna and in different optimized positions as indicated in Fig. 14. Note that when a central shorting pin is used, the corresponding resonant mode for the antenna, according to its simplified cavity model, is rotationally symmetric (TM_{01} mode) (González-Posadas et al. 2006), which has a zero at the axis of radiation like a monopole. More pins can be added to improve the antenna response (Vázquez-Roy et al. 2010). Those pins also short to ground the central disk, protecting equipment and personnel of the risk of high-voltage contact.

Loop antennas are simple sensors with low efficiency when their size is not large. For instance, in Jin et al. (2008), small loops are used with relatively good results for detecting discharges in air cavities and surface and corona discharges in oil. Also, in (López-Roldán et al. 2008), a comparison is done with different monopoles with not-so-good results for PD detection in oil-filled transformers.

Loop antennas can be loaded with ferrite cores to improve their response (Ozaki et al. 1992). The radiation patterns are, essentially, the same as the dipole ones. If the direction of arrival of the wave front

DOI 10.1007/978-981-4560-75-7_95-1

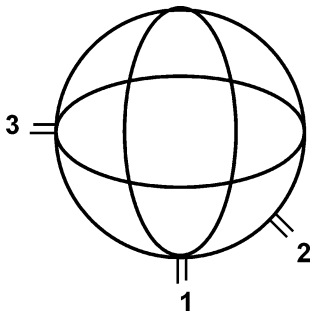

Fig. 15 Three-axis loop antenna for the detection of the angle of arrival of the wave front

in free space is to be estimated, three different loops oriented like in Fig. 15 can be used by properly combining the output of the antennas (Matsumoto et al. 2008).

Printed Antennas

Printed antennas have many interesting features including flexibility, compactness, low profile, and low cost. Many of the different possibilities are described in detail in (Reig and Ávila Navarro 2014). In the most common implementations, the planar structure can be located either perpendicular or parallel to the main radiation axis, in a broadside or end-fire radiation operation. Table 4 includes the most common cases.

Patch Antennas

Patch antennas, also known as microstrip antennas, are one of the most used printed antennas in a great variety of application fields. Some typical patch antenna geometries were patented for the measurement of PD in the 1990s (e.g., see Herbst and De 1996). However, in their basic configuration, they are resonant narrowband antennas, and, due to their big size in terms of wavelength, they have been used for PD detection to a lesser extent compared to other types. An analysis of the response of a rectangular patch antenna can be found in (Shibuya et al. 2010).

Wire Antennas

Many wire antennas can be implemented directly on a printed version. In that case, a low-loss substrate is used as support to print the metallizations on the same side of the substrate or on different sides (coplanar or antipodal antennas). In the same way, the wire in a monopole can be substituted by its planar printed version, and the geometry can be modified in order to optimize the antenna response. When the antenna is intended to work in the low-frequency band, a meandered line can be of use to achieve a compact antenna (Ayob and Ramli 2014; Li et al. 2014).

Logarithm Spiral Antennas

The logarithm spiral printed antenna is a differential wideband sensor commonly used for PD detection. In (Reid et al. 2009), this antenna is compared to a monopole and log-helical antenna using a FDTD algorithm. In Table 4, a result is included for such an antenna in free space. As with wire antennas, if the logarithm spiral is to be used inside a valve, it will operate inside a metallic cylinder which affects the antenna response considerably. Moreover, the radiation pattern curves show an important component of back radiation that could be reduced by placing a ground plane at half a wavelength for one specific frequency within the working band. To mitigate the unavoidable bandwidth reduction, the cavity which closes the antenna in its lower part can be filled up with a wave absorption material. It is worth noting that

Table 4 Printed antennas

Type		Matching
Logarithm spiral (balanced)		Archimedean spiral (balanced)		Hilbert (grounded)		Vivaldi		
this antenna has a null radiation in the plane in which it is contained. With respect to the matching bandwidth, it comprises a very wide margin, with a clearly marked resonance at low frequencies.

The printed branches can be terminated in different ways besides the straight cut. In Zhang et al. (2014), printed butterfly elements are added to improve the bandwidth in a GIS sensor. These elements represent only a small penalty in size, and the manufactured antenna compares quite well with the horn antenna depicted in Fig. 16.

Not only logarithm spirals are used for PD detection. In Wang et al. (2001), an Archimedean spiral like the one shown in Table 4 is used. The response, in terms of matching and radiation pattern, is quite the same as that of the log-spiral antenna.

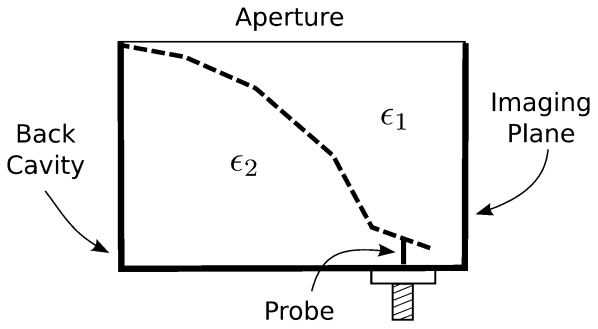

Fig. 16 Half TEM horn

Fractal Antennas

Fractal antennas are composed of long printed lines which are packed within a relatively small area to achieve compactness in a self-similarity structure. Thus, a motif is repeated over different scales providing the different resonances over an operating frequency band. One of the most used schemes is the Hilbert fractal depicted in Table 4. This antenna is analyzed in (Jin et al. 2008) and compared with a small-loop antenna. In (Li et al. 2012), a $N = 4$ order Hilbert antenna for PD measurements is studied, demonstrating how multiple resonances are present in the frequency band between 0.3 and 1 GHz. In that case, the fractal line is printed on a FR-4 substrate in a monopolar grounded configuration, being 1.5 mm the substrate thickness. The feeding point is selected to improve matching, and the sensor is combined with a wideband amplifier. Care must be taken when using this configuration, given the fact that the fractal line is printed on a relatively high permittivity substrate and the radiation efficiency might be very low. Moreover, some of the resonances within the frequency band could be related to dissipation and not to radiation.

To avoid this potential problem, the ground plane of the antenna and the substrate where it is printed can be spaced by air. Then, the coaxial probe must be extended through this space. In Yao et al. (2013), a fractal antenna which uses a Koch motif is designed according to this idea. Note that in the Hilbert antenna included in Table 4, the substrate was raised 3 cm in air. Many different resonances are present between 0.4 and 3 GHz.

Vivaldi Antennas

Wideband detection improves the measurement of the time of arrival when it comes to PD location (Tang et al. 2006). So, ultra-wideband antennas such as the Vivaldi antenna could be of interest to the PD detection antenna designer. Vivaldi antennas are low-profile planar antennas which include a tapered slot and an appropriate transition from a feeding transmission line. Since these antennas are not resonant in nature, bandwidths in excess of 3:1 in return loss can be obtained by optimizing the profile of the slot and the feeding network. Besides, a relatively directive pattern in the end-fire direction with linear polarization is achieved. In its simplest version, a microstrip line is used to feed the balanced tapered slotline and two radial and circular open stubs are included as a part of the feeding network in order to improve the matching. Table 4 includes the result for this type of antenna in an extended frequency range. An analysis of the response of a Vivaldi antenna placed outside the high-voltage equipment is performed in (Robles et al. 2013b). The measured return loss for the built prototype is below 10 dB in the range between 1.5 and 3.7 GHz with a total size of 9×12 cm. The sensitivity at low frequencies is poor, so FM radio bands and low TV broadcasting band are eliminated, obtaining good signals in the time domain.

Aperture Antennas

Aperture antennas are not so common in PD applications and only a few of them can be identified in the literature. For example, in xing (Zhang et al. 2013), a half TEM horn antenna is specifically designed for

DOI 10.1007/978-981-4560-75-7_95-1

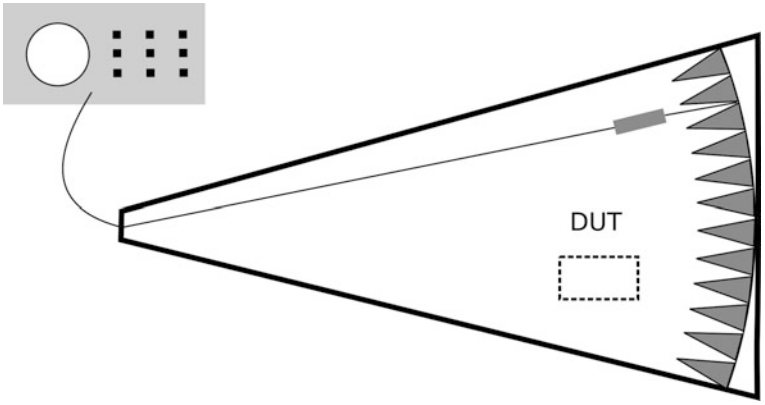

Fig. 17 GTEM cell

PD detection after (Shan et al. 2008). The antenna has the semi-closed cavity-backed structure depicted in Fig. 16. The horn is partially filled with dielectric to enable the reception of EM waves of shorter wavelengths. The simulated prototype is centered around 900 MHz and combines several different resonances to operate up to 3 GHz.

In a more conventional way, the design of a double ridge horn for PD detection in the range from 0.7 to 1.4 GHz is described in (Cai et al. 2014). The horn is fed using a coaxial probe and the set up was optimized for dual working frequency bands, namely, 0.7–0.9 GHz and 1.25–1.4 GHz. The dimensions of the aperture are 28 × 35 cm. This antenna was integrated in a medium-voltage switchgear system and was used to sense spatially distributed PD in AIS. The full transformer is simulated using a finite element method to determine the optimum locations for the sensing antennas.

Antenna Calibration

Due to the casuistic and the procedure typically followed in the detection of PD, a time domain analysis to obtain the involved signals is also of interest. The time domain signal at the output of the receiving antenna includes the nature of the partial discharge, the propagation through shields, metallic bulks and different media, and finally, the response of the antenna.

TEM cells are devices used for establishing a determined electromagnetic field in a shielded environment. They are commonly used for electromagnetic compatibility measurements, but they are also of interest in the context of PD detection since they provide clear reference signals which can be used as calibration references (Karst et al. 2002).

The GTEM cell (Fig. 17) is a frequency extended variant of the conventional TEM cell which can cover frequencies up to some GHz (Judd and Farish 1998). A slightly spherical wave propagates along the structure excited by a coaxial probe to simulate a free space planar wave. RF absorbers are used as a termination to avoid a standing wave buildup.

Several time-domain analyses have been performed to obtain the received signal in some relevant antennas to compare the simplified designs that have been presented in the previous sections. Instead of using TEM cells, a PD has been simulated in free space at a distance of 0.5 m of each antenna. That position has been set to be the optimum one for each antenna regarding radiation pattern with polarization matching. A time domain full-wave analysis algorithm has been used with this purpose like in (Ishak et al. 2012). An oriented point source has been used to drive the simulations. Free space conditions have been considered for the propagation between the source, which is the simulated PD, and the antenna under test. A Gaussian pulse with spectral content in the range of 0.5–3 GHz has been used as excitation signal,

DOI 10.1007/978-981-4560-75-7_95-1

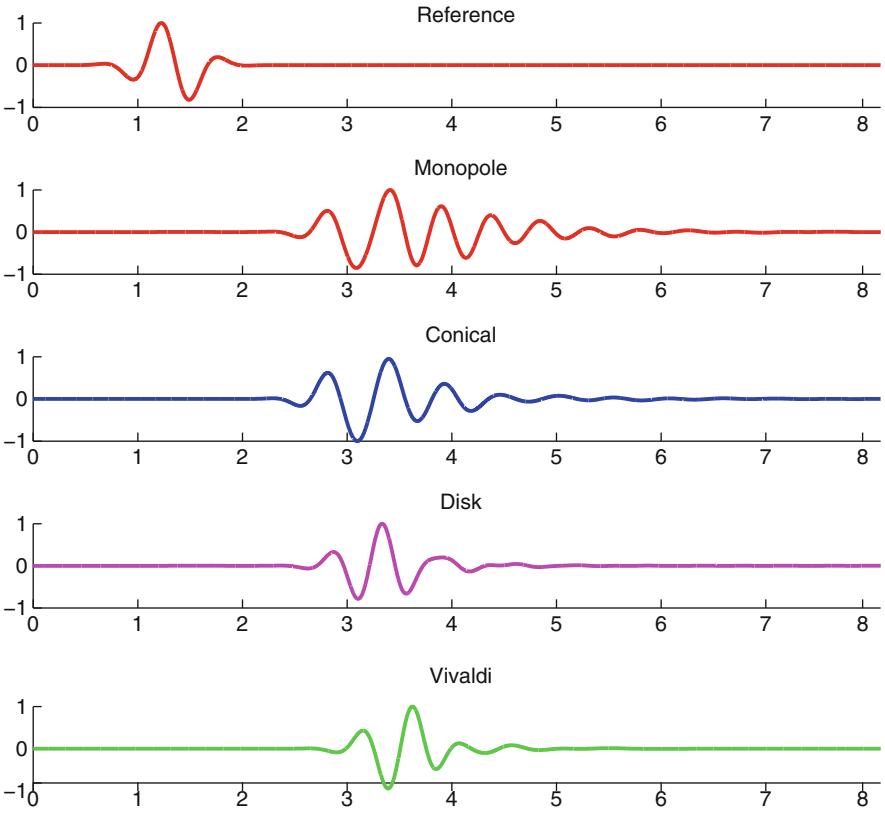

Fig. 18 Received signals in time domain for some of the simulated antennas

simulating, thus, a partial discharge in the order of ns. The results can be interpreted as the best signals that can be obtained with each type of antenna. The disk antenna displayed in Fig. 14 will be used in this case.

Figure 18 summarizes the obtained results where the source signal has also been included as a reference. All signals have been normalized to their maximum value. It can be observed how resonant antennas, such as conventional and conical monopoles, lead to more distorted signals with higher degrees of energy spread along time.

Finally, Fig. 19 displays the comparison of the envelopes of some of the received signals along with the envelope of the reference signal. By plotting all signals together, the degree of distortion introduced by the different antennas becomes more apparent. The signals have been normalized to the maximum of the Vivaldi antenna (best case). The Hilbert antenna of Table 4 is also included. It can be observed that the time delay is the same for all cases, while the different slopes of the leading edges are directly related to the antenna bandwidth. Moreover, the effect of the radiation pattern of the antenna can be deduced from the amplitudes of the pulses: the greater the directivity is, the higher the received signal level will be. This is significantly observed in the case of the Vivaldi antenna and the disk antennas.

As expected, the bandwidth of the antenna affects the received signal. Higher bandwidths will result in clearer time signals, facilitating the detection of the pulse and the subsequent signal processing.

Location of Partial Discharges

Location in Linear Structures

Partial discharges occurring in power cables, gas-insulated switchgear, and windings will travel along the waveguide or conductor and will be reflected at the ends (a bushing or terminal). Inductive sensors or

DOI 10.1007/978-981-4560-75-7_95-1

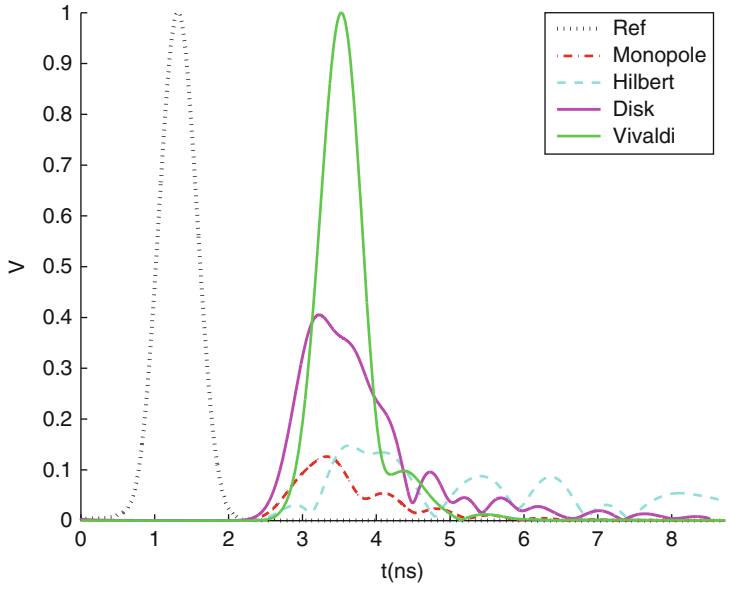

Fig. 19 Signal envelope comparison for some of the simulated antennas normalized to the maximum of the Vivaldi antenna signal

capacitive sensors are used in cables to detect the partial discharge, whereas electromagnetic sensors are used in GIS. Let us consider that the sensor is attached at $x = 0$ and the PD site is at a linear distance in $x = x_{PD}$ (Steiner et al. 1992). The first arriving time will be:

$$t_1 = \frac{x_{PD}}{v} \tag{36}$$

where $v = 1/\sqrt{LC}$, with L and C the inductance and capacitance per unit length of the cable, respectively; or $v = 1/\sqrt{\mu\epsilon}$ with μ and ϵ, the permeability and permittivity constants of the gas, respectively.

The front wave will be reflected at $x = L$, being L the total length of the cable, the GIS section, or the distance from the origin to a junction, terminal, or bushing. Then, the second time of arrival will be:

$$t_2 = \frac{2L - x_{PD}}{v} \tag{37}$$

Measuring $\Delta t = t_2 - t_1$ and knowing L, it is possible to calculate the distance from the PD site to the closest end of the device under test.

$$x_{PD} = L - \frac{1}{2} v \Delta t \tag{38}$$

Errors in the location of PD are caused by different sources (Kreuger et al. 1993). Focusing on the case of GIS, the pulse propagated through the encased switchgear can suffer attenuation and losses and provoke undetermined back reflections that may confuse the instrumentation and assign false arriving times. There has to be a common time base for all detectors to have accurate time differences; notice that an error of 1 ns for pulses travelling at the speed of light means an uncertainty of 0.3 m in the location of the source. Impulsive external noises or high noise levels affect the accuracy of the measurement. And, finally, the total length L of the resonant cavity has to be exactly measured to ensure that the distance to the PD site is accurate.

DOI 10.1007/978-981-4560-75-7_95-1

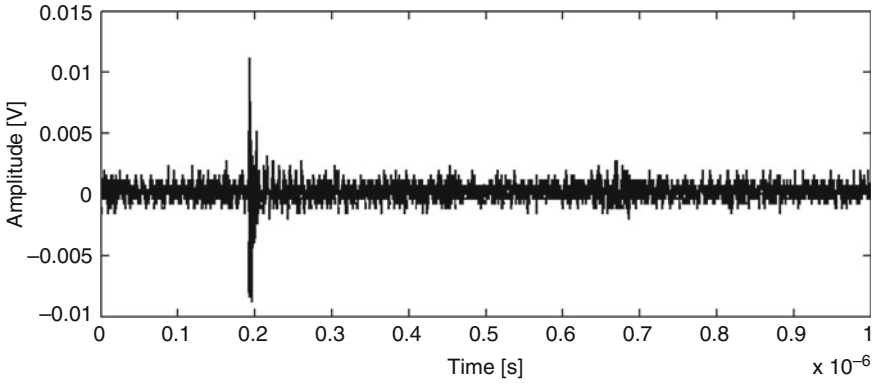

Fig. 20 Internal partial discharge obtained with a 15 cm monopole

Another application of this principle can be done off-line by injecting a known pulse and calculating the time difference of arrival of the pulses reflected at the PD site and at the end of the device under test. This approach is based on the fact that the dielectric properties change when the dielectric degrades. Therefore, when a pulse reaches these inhomogeneous zones, part of it is reflected and part of it is transmitted and then reflected at the open end of the cable. This technique can be applied to cables but not to GIS segments where partial discharges occur due to small particles that will not modify substantially the dielectric properties of the gas. Moreover, the defect can be located in new cables even before there is a continuous partial discharge activity and without energizing the cable.

Location in Three Dimensions

Partial discharges in transformers or open substations can be located using radiometric methods based on the time differences of arrival (TDOA) of the pulses to pairs of antennas.

Calculation of the Time Difference of Arrival

The incident signal emitted from the partial discharge site consists of a direct wave propagation and a long tail of oscillatory cycles due to multipath propagation and scattering. Additionally, the signal contains electromagnetic interferences from radio and TV broadcasting, mobile phones, and Wi-Fi among others, generating a noise floor that hides the start of the first pulse, Fig. 20. The first recommended step is to filter those interferences with any de-noising technique. Once the signal is cleaner, one of these algorithms can be applied to determine the time differences:

Cumulative energy. The energy of the acquisition is accumulated in time (Judd et al. 2005).

$$W_n = \sum_{k=0}^{n} s_k^2 \tag{39}$$

where W_n is the energy accumulation up to sample n and s_k is the signal sample k. First, there is an increment with a constant slope due to the noise acquired in the pre-trigger time span, and then, there is a dramatic change of the slope when the pulse starts. This instant is marked for all four antennas to calculate the time differences, Fig. 21.

Alternative cumulative energy. In this case, the cumulative energy is constantly reduced until the signal starts (Markalous et al. 2008). The minimum of the function is the starting time; see Fig. 22.

DOI 10.1007/978-981-4560-75-7_95-1

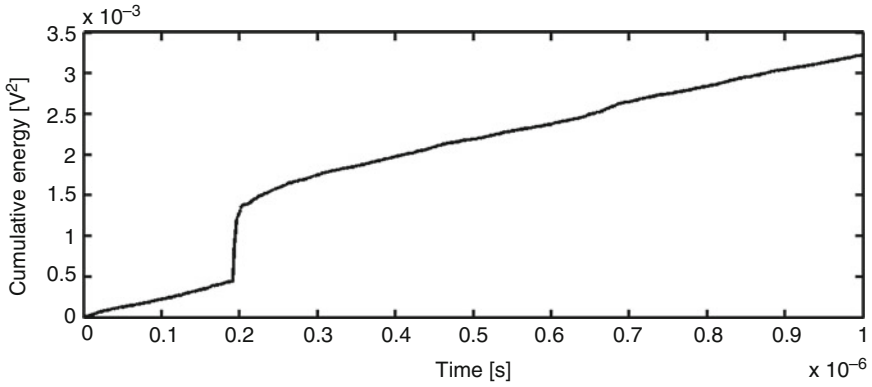

Fig. 21 Energy accumulation for the signal shown in Fig. 20

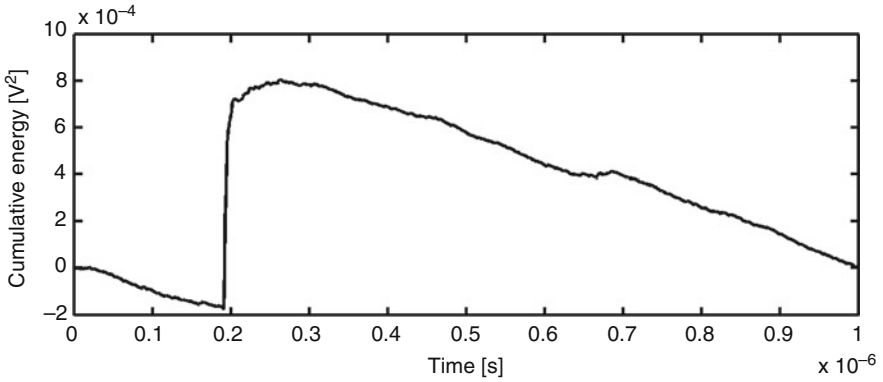

Fig. 22 Alternative cumulative energy. Notice that the minimum of this function coincides with the change of slope in Fig. 21

$$W_n = \sum_{k=0}^{n} \left(s_k^2 - n \frac{W_N}{N} \right) \tag{40}$$

with N the total number of samples and W_N the total energy of the signal.

Cross-correlation. The cross-correlation of the signals from two antennas has a maximum in the delay sequence that gives the time difference. The equation for the calculation of the cross-correlation for the finite sequences s_{k1} and s_{k2} from antennas 1 and 2, respectively, is:

$$r_{l,12} = \sum_{k=l}^{N-|n|-1} s_{k,1} s_{k-l,2} \tag{41}$$

with $n = 0$ for $l \geq 0$ and $n = l$ for $l < 0$.

The generalized correlation method uses weighting functions or pre-filters to enhance useful characteristics of the signals that will improve the peak detection of the standard cross-correlation. These filters are applied in time and modify the cross power spectrum with their frequency response:

$$R_{12}(t) = \int_{-\infty}^{+\infty} \psi(f) G_{12}(f) e^{j2\pi f t} df \tag{42}$$

DOI 10.1007/978-981-4560-75-7_95-1

where G_{12} is the cross power spectral density of the pre-filtered signals and $\psi(f)$ is a weighting function with the idea of accentuating the signals passed to the correlator at those frequencies at which the signal-to-noise ratio is highest. This would have the desired effect of obtaining a large sharp peak in R_{12} rather than a broad one to ensure good time-delay resolution (Knapp and Carter 1976).

The smoothed coherence transform (SCOT) uses the prewhitening filter shown in Eq. 43 to reduce the cross-correlation when the signal-to-noise ratio is low, assuming that the noise components affecting the two signals are uncorrelated and cannot be filtered since the partial discharge pulses may have broadband and narrowband components.

$$\psi(f) = \frac{1}{\sqrt{G_{11}(f)G_{22}(f)}} \tag{43}$$

The phase transform (PHAT) uses the weighting in Eq. 44 with the aim of avoiding the spreading of the cross-correlation function. Without noise components, the output of Eq. 41 with this filter is a delta function centered at the correct delay.

$$\psi(f) = \frac{1}{|G_{12}(f)|} \tag{44}$$

The maximum likelihood (ML) or Hannan and Thomson (HT) Eq. 45 processor is chosen to improve the accuracy of the estimated delay by attenuating the pulses in the spectral region where the signal-to-noise ratio is poorer.

$$\psi(f) = \frac{1}{|G_{12}(f)|} \quad \frac{|\gamma_{12}(f)|^2}{|\gamma_{12}(f)|^2} \tag{45}$$

with

$$|\gamma_{12}(f)|^2 = \frac{|G_{12}(f)|^2}{|G_{11}(f)| \cdot |G_{22}(f)|} \tag{46}$$

In any case, the accuracy of the TDOA depends ultimately on the sampling frequency. It is expected that the exact time lies between two samples of the cross-correlation or the cumulative energy sequence. An approximation using interpolation can improve the solution, but, nevertheless, it is imperative to have sampling times below 1 ns so the determination of the starting time or the cross-correlation peaks is clear and unequivocal.

Calculation of the Partial Discharge Site

For three-dimensional location, four antennas are necessary. Let us assume that the partial discharge site located in rectangular coordinates in (x_s, y_s, z_s) triggers a pulse in an unknown time t_0. Therefore, if the pulse wave front propagates spherically at velocity v, it eventually reaches antenna i located in (x_i, y_i, z_i) in time t_i. Times of flight t_i have to be calculated as accurately as possible to minimize the error in the location of the partial discharge site.

Then, the distance between the site and the antenna is $v(t_i - t_0)$ which is the radius of a sphere:

DOI 10.1007/978-981-4560-75-7_95-1

$$\begin{aligned} v^2(t_i - t_0)^2 &= (x_s - x_i)^2 + (y_s - y_i)^2 + (z_s - z_i)^2 \quad i = 1 \ldots 4 \\ R_i = v(t_i - t_0) &= \sqrt{(x_s - x_i)^2 + (y_s - y_i)^2 + (z_s - z_i)^2} \end{aligned} \tag{47}$$

The time t_0 and the position of the site are unknown; however, t_0 can be eliminated if the four implicit equations in Eq. 47 are subtracted in pairs. For the first two antennas:

$$v(t_1 - t_0) - v(t_2 - t_0) = v(t_1 - t_2) = vt_{12} \tag{48}$$

Then, $R_1 - R_2 = vt_{12}$. If this is repeated for all three pairs:

$$\begin{aligned} R_1 - R_2 - vt_{12} &= 0 \\ R_1 - R_3 - vt_{13} &= 0 \\ R_1 - R_4 - vt_{14} &= 0 \end{aligned} \tag{49}$$

Equation 49 represents a nonlinear non-convex problem with multiple local minima, depending on the positions on the source and the antennas. Recently, in mobile communications and wireless sensor networks (Xu et al. 2011), these equations have been treated as an optimization problem where the estimation of the source point gives a nonzero solution that has to be minimized, $R_i - R_j - vt_{ik} = \epsilon_e$. The technique to solve the equations converts a non-convex problem into a convex one through semi-definite relaxation so the location of the global minimum is easier.

Other methods that have been already used and proved to obtain (x_s, y_s, z_s) in partial discharge location are Newton–Raphson and, more recently, global search methods that include two types of evolutionary computation algorithms – stochastic optimization methods inspired in biologic processes, natural phenomena, or group behavior – such as genetic algorithms (GA) and particle swarm optimization (PSO). Though classical genetic algorithms are very efficient in searching the entire space and can rapidly locate the region in which the global optimum exists, they are relatively poor and take long times in finding the precise local optimal solution in the region in which the algorithm converges. This is why PSO has a lead over GA in partial discharge location and it is detailed below.

Newton–Raphson The Newton–Raphson method is a popular iterative technique to solve nonlinear equations in the form $f(\xi) = 0$ or systems in the form $\mathbf{F}(\boldsymbol{\xi}) = 0$ with $\boldsymbol{\xi}$ a column matrix. The idea is that $\xi_1 = \xi_0 - f(\xi_0)/f'(\xi_0)$ is a better solution than ξ_0 using the first derivative term of a Taylor's series.

The iterative form is $\xi_{k+1} = \xi_k - f(\xi_k)/f'(\xi_k)$ or $\boldsymbol{\xi}_{\mathbf{k}+1} = \boldsymbol{\xi}_{\mathbf{k}} - \mathbf{J}^{-1}\mathbf{F}(\boldsymbol{\xi}_{\mathbf{k}})$ with:

$$\boldsymbol{\xi}_{\mathbf{k}} = \begin{pmatrix} \xi_1 \\ \xi_2 \\ \vdots \\ \xi_N \end{pmatrix}_k \quad \mathbf{F} = \begin{pmatrix} f_1(\xi_1, \xi_2, \ldots, \xi_N) \\ f_2(\xi_1, \xi_2, \ldots, \xi_N) \\ \vdots \\ f_N(\xi_1, \xi_2, \ldots, \xi_N) \end{pmatrix}_k \tag{50}$$

and the Jacobian matrix **J** defined as:

DOI 10.1007/978-981-4560-75-7_95-1

$$\mathbf{J} = \frac{\partial(f_1, f_2, \ldots, f_N)}{\partial f_1(\xi_1, \xi_2, \ldots, \xi_N)} = \begin{pmatrix} \frac{\partial f_1}{\partial \xi_1} & \frac{\partial f_1}{\partial \xi_2} & \cdots & \frac{\partial f_1}{\partial \xi_N} \\ \frac{\partial f_2}{\partial \xi_1} & \frac{\partial f_2}{\partial \xi_2} & \cdots & \frac{\partial f_2}{\partial \xi_N} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_N}{\partial \xi_1} & \frac{\partial f_N}{\partial \xi_2} & \cdots & \frac{\partial f_N}{\partial \xi_N} \end{pmatrix} \tag{51}$$

The changes in the solution are given by $\Delta = \mathbf{J}^{-1}\mathbf{F}(\boldsymbol{\xi}_\mathbf{k})$ so the iteration can stop when $\max_k|\Delta| \leq \epsilon_e$ being ϵ_e a convergence error.

Equation 49 can be rewritten as:

$$\mathbf{F} = \begin{pmatrix} f_1(x_s, y_s, z_s) \\ f_2(x_s, y_s, z_s) \\ f_3(x_s, y_s, z_s) \end{pmatrix} = \begin{pmatrix} R_1 - R_2 - vt_{12} \\ R_1 - R_3 - vt_{13} \\ R_1 - R_4 - vt_{14} \end{pmatrix} = 0 \tag{52}$$

so,

$$\mathbf{J} = \begin{pmatrix} \frac{x_{s,k} - x_1}{g_1} - \frac{x_{s,k} - x_2}{g_2} & \frac{y_{s,k} - x_1}{g_1} - \frac{y_{s,k} - x_2}{g_2} & \frac{z_{s,k} - x_1}{g_1} - \frac{z_{s,k} - x_2}{g_2} \\ \frac{x_{s,k} - x_1}{g_1} - \frac{x_{s,k} - x_3}{g_3} & \frac{y_{s,k} - x_1}{g_1} - \frac{y_{s,k} - x_3}{g_3} & \frac{z_{s,k} - x_1}{g_1} - \frac{z_{s,k} - x_3}{g_3} \\ \frac{x_{s,k} - x_1}{g_1} - \frac{x_{s,k} - x_4}{g_4} & \frac{y_{s,k} - x_1}{g_1} - \frac{y_{s,k} - x_4}{g_4} & \frac{z_{s,k} - x_1}{g_1} - \frac{z_{s,k} - x_4}{g_4} \end{pmatrix} \tag{53}$$

and then:

$$\begin{pmatrix} x_{s,k+1} \\ y_{s,k+1} \\ z_{s,k+1} \end{pmatrix} = \begin{pmatrix} x_{s,k} - \Delta_x \\ y_{s,k} - \Delta_y \\ z_{s,k} - \Delta_z \end{pmatrix} \tag{54}$$

A single initial point has to be chosen to start the iteration. If it is close to the solution, the convergence will be fast and accurate; otherwise, the algorithm follows simple paths and it is prone to reach local minima, inducing great errors in the location. Under other circumstances, it may not be convergent at all. In these cases, changing the positions of the antennas can help to find a solution.

Particle swarm optimization The idea behind the algorithm is to exploit analogues of social interaction rather than individual cognitive abilities (Poli et al. 2007). In PSO, a certain number of individuals or particles are set to find the best fit to a problem using their own experience and the experience of one or more members of the community. Their position and velocity are changed according to their relative position to their individual best fit $\mathbf{p_i}$ and the group best fit $\mathbf{p_g}$. Then, every individual stochastically oscillates around $\mathbf{p_i}$ and $\mathbf{p_g}$ locations that are updated in every iteration. The movement of particles resembles the behavior of a flock of birds or fish searching for food in which every individual has information about their position to the target and information about the swarm movement.

The algorithm starts with a random deployment of particle positions and velocities in the space. The position of particle j in iteration k is $\mathbf{p_{k,j}} = \left(x_{s,k}, y_{s,k}, z_{s,k}\right)_j$. Then, every particle evaluates the fitness function shown in Eq. 52. If the particle current position gives a result closer to 0 than its individual best, $\mathbf{p_i}$ is updated with the new position, and if the current swarm best is closer to 0 than the previous best, $\mathbf{p_g}$ is

DOI 10.1007/978-981-4560-75-7_95-1

also updated. Then the velocity and positions of all particles are changed according to the following equations:

$$\begin{aligned} \mathbf{v_{k+1,j}} &= \mathbf{v_{k,j}} + \mathbf{U}(\mathbf{0}, \phi_1) \ \left(\mathbf{p_i} - \mathbf{p_{k,j}}\right) + \mathbf{U}(\mathbf{0}, \phi_2) \ \left(\mathbf{p_g} - \mathbf{p_{k,j}}\right) \\ \mathbf{p_{k+1,j}} &= \mathbf{p_{k,j}} + \mathbf{v_{k+1,j}} \end{aligned} \tag{55}$$

where $\mathbf{U}(\mathbf{0}, \phi)$ is a three-dimension vector of random numbers uniformly distributed in $[0, \phi]$ that is generated in every iteration to change the velocity of the particle in all directions (Poli et al. 2007). Sometimes an inertia factor ω is added, multiplying the velocity $\mathbf{v_{k,j}}$ in Eq. 55.

Summary

The great advantage of electromagnetic sensors in the measurement of partial discharges is the capability of detecting the pulses without galvanic connections to high-voltage equipment. All their applications are derived from this characteristic. While other conventional methods need the disconnection of the asset, partial discharge measurements with antennas can be done online, reducing considerably maintenance times and costs.

The first time an antenna was used to measure partial discharges was in gas-insulated substations. In these substations, all high-voltage equipment is insulated with sulfur hexafluoride, so all partial discharges occurring inside the containers would only be detected in the output cables where inductive sensors can be placed. However, connecting antennas to dielectric windows in several sections of the substation can locate the site with insulation problems.

Moreover, partial discharges inside oil-insulated power transformers can only be measured with sensors inside the tank because the inductive nature of the coils prevents the pulses from being detected with systems connected to the bushings. In these cases, antennas connected to dielectric windows are the best option compared to other methods such as acoustic detection. In this configuration, not only are the discharges detected; eventually they can also be localized inside the tank and point out the winding where they are occurring. In this case, several antennas should be deployed inside the transformer and connected to a high-speed acquisition system to carefully obtain the time differences of arrival of the pulses to the detectors. However, this method is still far from being massively applied due to the difficulties of dealing with reflections inside the tank and windings and the attenuation of the pulses when they pass through windings and core.

Currently there are several manufacturers dedicated to the measurement of partial discharges in air-insulated substations in two areas: detection and localization. The detection is basically done by walking around the substation with a spectrum analyzer and detecting anomalies in determined frequency bands where the discharges are emitting. The localization is done with several antennas mounted on vehicle and in the substation that are moved around, obtaining time signals to apply any localization method.

Unfortunately, the use of antennas has also important drawbacks. Though the sensors are inexpensive, the cost of the acquisition system can be sometimes prohibitively high if a detailed signal in the time or frequency domains is necessary such as in the case of localization or detection with spectrum analyzers, respectively. On the contrary, if the user only wants to detect pulses, a simple ultrahigh-frequency pulse detector can be used.

Finally, nowadays nobody has claimed that the identification of the type of partial discharge with antennas is possible. The only way to map the pulses in a phase-resolved partial discharge pattern is with a

DOI 10.1007/978-981-4560-75-7_95-1

synchronizing signal to the network frequency, so it is necessary to disconnect the equipment and connect a voltage divider, loosing the main advantage of antennas, namely, the galvanic insulation. The frequency content of the signals acquired with antennas seems to be related with the type of partial discharge, but nobody can claim that it is possible to do an effective identification in real environments.

The standard IEC62478 *High-voltage test techniques – measurement of partial discharges by electromagnetic and acoustic methods* is expected to see the light of day in the next years. In the meantime, manufacturers and utilities are working together to outline the specifications of detection systems based on antennas that can perform best in gas-insulated substations and transformers.

Antennas in Automobile Radar

Wolfgang Menzel*
Institute of Microwave Techniques, University of Ulm, Ulm, Germany

Abstract

Automobile radars are under investigation since the 1960s. The first operational systems are on the market since 1992 for buses and trucks and 1999 for passenger cars, both in the frequency range around 24 as well as 76.5 GHz; a new frequency band for medium- and short-range sensors from 77 to 81 GHz has been allocated recently in Europe. Requirements for the sensor antennas are high gain and low loss combined with small size and depth for vehicle integration. Great challenges are due to the millimeter-wave frequency range, and a great cost pressure for this commercial application determines design and fabrication. Consequently, planar antennas are dominating in the lower frequency range, while lens and reflector antennas had been the first choice at 76.5 GHz, partly in folded configurations. With increasing requirements toward a much more detailed view on the scenery in front or around the vehicle, multi-beam antennas or scanning antennas have been designed. For actual systems, digital beamforming with a number of integrated antennas is in use or under development, and also MIMO concepts will be exploited. With such development, antennas for automotive radar no longer can be considered as stand-alone devices, but will be part of an "imaging" system including multiple transmit/receive units and digital signal processing.

General antenna concepts, partly including system aspects, as well as several realized antenna and sensor configurations will be described in detail in this chapter.

Keywords

Automotive radar; Millimeter-wave radar; Radar antennas; Microstrip antenna; Grid antenna; Reflector antennas; Lens antennas; Slotted waveguide array; Dielectric antenna

Introduction

With increasing traffic density, an increasing interest has emerged for additional electronic vision to improve comfort and safety, including video cameras, infrared sensors, laser, or radar. Although radar does not provide optical resolution, it has the great advantage of being mostly insensitive to fog or rain, it works independently on ambient light, and it directly provides speed based on the Doppler effect. Consequently, radar was considered as automotive sensor already back to 1959, when Cadillac presented two radar sensors in its experimental car "Cadillac Cyclone" (Cadillac 2013). No detailed information has been published, but the ogive-shaped radomes indicate military-type radars. In the 1970s, a number of companies again investigated automotive radars, starting at 10, 16, and later on 35 GHz (Meinel and Dickmann 2013) (Fig. 1). Later on, other systems were considered at 60 GHz (mostly in Japan, using the license-free ISM band) or 94 GHz based on military

Fig. 2 VORAD radar in front of a bus (own photograph)

developments. The first commercial radar for collision avoidance was introduced in 1992 in the USA by VORAD for buses and trucks, working at 24 GHz (Woll 1995) (Fig. 2). It helped in reducing crashes, but was not really accepted by the drivers who felt too much controlled by this system. In 1998/1999, the first commercial radar in a passenger car was introduced by Mercedes in Germany, working in the 76–77 GHz frequency band, followed by other car manufacturers. These first radar sensors were used mostly in comfort functions, supporting an automatic speed control by keeping a safe distance to the preceding vehicle (adaptive cruise control, ACC).

The aim for further developments during the last years has been to make radar available for safety functions like forward collision alert, rear traffic crossing alert, blind spot detection, or side-impact warning; the latest developments include emergency breaking and autonomous stop-and-go driving (Mercedes E- and S-class). According to such different functions, sensors have to look into all directions around the vehicle with differently defined scanning and distance relations. Rear traffic crossing alert and blind spot detection, for example, operate in the near range and simply give information whether one or more targets are present in a certain area, whereas ACC and forward collision alert have to scan the entire traffic scene not only in the near range but also – dependent on the maximum speed of the object – in the mid- and far range. Typical range designations are low-range (LRR, up to a few 10 m), medium-range (MRR, about 40–100 m), and long-range (LRR, up to 200 m or even 250 m) radars. As a consequence, a much more flexible and wider field of view is required compared to the first applications, resulting in some kind of "imaging" of the scenery in

DOI 10.1007/978-981-4560-75-7_96-1

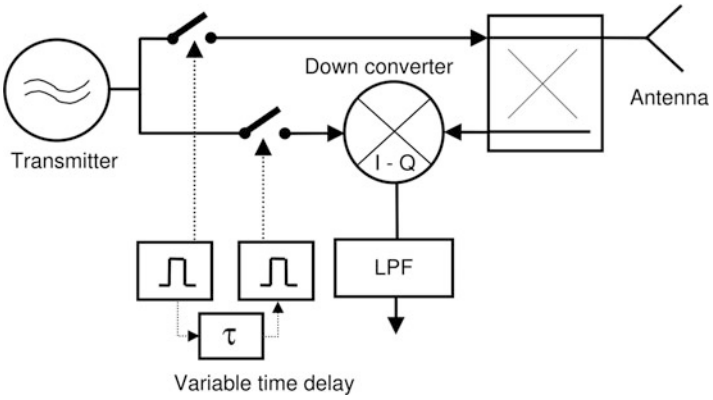

Fig. 3 Basic block diagram of an automotive pulse radar

front of the sensor. This, of course, has to be mapped to the antenna concepts, partly in combination with modified overall sensor arrangements, including multi-beam antennas, scanning antennas, switched antenna concepts, and beamforming approaches with multiple transmit and receive antennas. Recent trends show a change from the scanning or multi-beam antenna principle to the digital beamforming with increasing functional transfer to digital signal processing. As a consequence, automotive antenna concepts must not be considered independently from the overall system concept, but increasingly, the overall range and way of "viewing" the interesting range of angles is determined by an optimal combination of antenna elements, RF front end, and signal processing. The actual field of view of the sensor therefore is determined by the antenna or antenna system diagram but also by the required angle-dependent range (with possibly lower gain in directions away from the main lobe), the minimum radar cross section, and the required minimum signal-to-noise ratio.

Furthermore, when designing automotive systems including antennas, the engineer faces the task that all components must be suitable for mass production, operate in a temperature range from −40 °C to 85 °C or even 105 °C, and be shockproof, and the entire arrangement has to be compact in size. The implications of all these on the choice of materials and even the performance should not be underestimated.

Present frequencies allocations for short range are in the 24.05–24.25 GHz frequency range (ISM band), a 4 GHz wide band around 24 GHz, but with different allocations and restrictions in different countries, and the 76–77 GHz range for the far range. Recently, in the EU the band from 77 to 81 GHz has been allocated for short range and mid-range; efforts are undertaken to make this frequency range available for automotive radar worldwide. In the near future, almost all long- or mid-range antennas will operate in the 76–81 GHz range.

Key Properties of Automotive Radar

Automotive radar sensors provide information about other vehicles, pedestrians, and the road environment by measurement of the flight time of the electromagnetic wave from the radar to a target and back; relative speed is determined, extracting the Doppler frequency shift, and angular information is given by the antenna characteristics. Automotive sensors typically use either a pulse modulation (Gresham et al. 2004) or frequency-modulated constant wave (FMCW) signals with sawtooth or triangular frequency modulation (Hymans and Lait 1960). Most of the automotive pulse sensors operate in a sampling mode with some similarity to a sampling oscilloscope (Fig. 3). The received

DOI 10.1007/978-981-4560-75-7_96-1

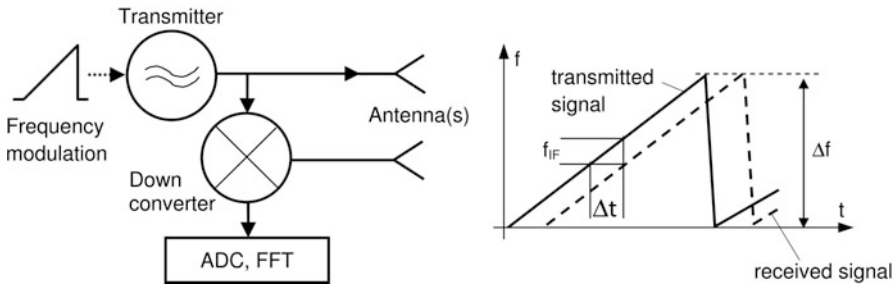

Fig. 4 Basic block diagram and time-frequency diagram of an FMCW radar

pulses are down converted with a pulse delayed by a time τ; an intermediate-frequency (IF) signal occurs only if the time of flight of the pulse is identical to the delay. Together with a low-pass filter (LPF) for the IF signal, bandwidth at the receiver output can be considerably reduced, and a further digital processing with moderate speed is possible. For the FMCW sensor, a signal with a linear frequency ramp is transmitted and then received with the respective delay time (Fig. 4). Down conversion with the actual transmitter signal then results in an IF signal, the frequency of which is proportional to the target distance. A typical further processing is done via analog-digital converter (ADC) and fast Fourier transform (FFT). As transmit/receive diplexer, mostly 3 dB couplers are used to avoid complicated and expensive circulators (as indicated in Fig. 3), or even individual antenna elements are used for transmitting and receiving (as indicated in Fig. 4).

In general, signal bandwidth, either via pulse width or FMCW frequency deviation, determines the minimum range resolution ΔR (separation between two targets):

$$\Delta R = c_0/(2\Delta f) \tag{1}$$

with c_0 as speed of light and Δf the modulation bandwidth. Typical values of ΔR range from about 1 m for early systems to some cm for newer short-range broadband systems (up to some GHz of bandwidth).

While for the first radar sensors, the RF circuits of the front ends were built based on discrete devices like Gunn elements and Schottky diodes, monolithic microwave integrated circuits (MMIC) based on GaAs (Camiade et al. 2000) and silicon-germanium (SiGe) are available today. SiGe MMICs even provide several RF front ends and some basic digital circuits on a single chip (Winkler et al. 2008).

The angular or cross-range observation depends on the sensor application and is determined by its antenna arrangement. In an early stage, when automotive sensors were used solely in comfort functions supporting the automatic speed control by keeping a safe distance to the preceding vehicle, a few (switched) narrow antenna beams were sufficient to monitor the own and adjacent lanes on a highway. Today, for safety purposes both for highway and for dense urban traffic scenarios, much more sophisticated antenna and overall system concepts are required.

Types of Antennas for Automotive Radar

General Requirements and Properties of Automotive Antennas

In general, the beamwidth of antennas is related directly to the physical size of an antenna. A rule of thumb estimates the 3 dB beamwidth ΔΦ by

DOI 10.1007/978-981-4560-75-7_96-1

$$\Delta\Phi = 60^\circ \ \lambda/D \tag{2}$$

where λ is the free space wavelength and D the overall antenna dimension in the respective plane. Requirements for a long-range sensor to restrict the 3 dB beamwidth to a 3.5 m-wide highway lane at a distance of about 50 m result in a beamwidth of 4° in azimuth and an antenna width of 15 wavelengths. This immediately shows that millimeter-wave frequencies are required to be able to integrate a radar sensor into the front of a car. At 77 GHz, this results in an antenna width of 60–80 mm. In elevation, a radar sensor should avoid strongly illuminating any bridge or traffic signs above the street (typically in a height of at least 5 m); this results in similar beamwidth requirements. Antenna gain then is in the range of 30 dB. To also observe neighboring lanes or operating in curves, several beams or some moderate beam scanning is required. At 24 GHz, antenna size and beamwidth typically are larger. Mid- and near-range systems have wider beamwidths and lower gain but require a wider angle of view by scanning, multiple beams, or beamforming.

Antenna losses should be low to maintain transmit gain as high as possible and not to deteriorate the receiver noise figure too much. Sidelobe levels need to be low enough to avoid false detection of targets at larger angles.

Compared to typical targets, wavelengths of about 12 and 4 mm at 24 and 77 GHz, respectively, are generally small, so polarization does hardly have any influence on target reflections. Some additional information may be gained if also orthogonal polarization was received, but this would add the implications of dual-polarization antennas and doubling the receiver part of the radar. In some sensors, polarization is adjusted at 45°; in this case, direct radiation from a radar into that of an oncoming vehicle is reduced. Ground reflections, however, will mostly foil the effects of this measure.

The antenna depth is of concern in integrating the sensor into the vehicle. Finally, antenna fabrication and integration into the sensor should be easy, reproducible, and cost-effective. The overall sensor including the antenna has to withstand shock, vibration, and the required automotive temperature range as mentioned above.

Reflector and Lens Antennas

In first test as well as in the first series versions of automotive radars, standard types of antennas were used, including horn antennas and parabolic reflectors. For sensors used in a car, antenna depth is of great concern for integration into the vehicle surface as well. A prominent example is a lens antenna with short focal length (Binzer et al. 2007), included in the commercial LRR3 sensor by Bosch. Another way to reduce the antenna depth is by "folding" the ray path of reflector or lens antennas as presented in Fig. 5 (Gresham et al. 2001; Millitech 1994). In these antennas, a feed initially radiates against a polarizing filter, and the wave is reflected back toward a planar structure where the wave is reflected again, but with a polarization twisted by 90°.

Such polarization twisting can be achieved by structures as shown in Fig. 6. The incident wave is polarized at 45° with respect to the axes of the reflecting structure (grid or rectangular patches). For the analysis of the reflected wave, the field is decomposed into components parallel to the two axes. In the case of the grid, the component parallel to the grid wires is reflected directly, while the orthogonal component passes the grid and is reflected at the ground plane placed a quarter of a wavelength behind the grid, resulting in an overall detour of half a wavelength or 180°. Combining the outgoing two components again, a wave results with a polarization twisted by 90°. For the structure with rectangular patches, the dimensions of the patches are selected in such a way that the reflection phase angles for the two components parallel to the patch axes differ by 180°, resulting in

DOI 10.1007/978-981-4560-75-7_96-1

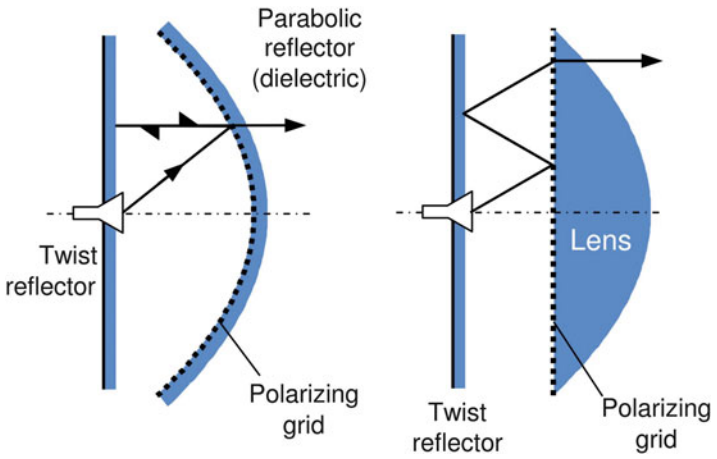

Fig. 5 Folded reflector (*left*) and lens antennas (*right*)

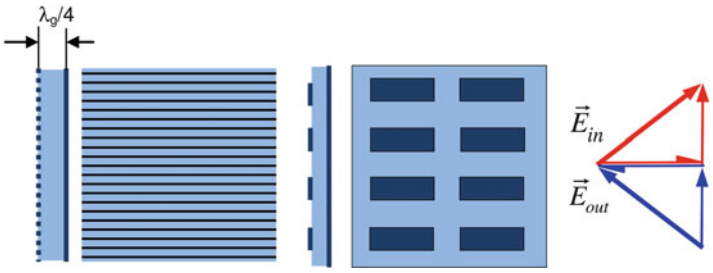

Fig. 6 Principles for polarization twisting (λ_g, wavelength in the dielectric)

the same 90° twisting of the polarization. In this case, the thickness of the substrate does not need to be a quarter wavelength thick.

In Menzel et al. (2002), the complex lens or curved reflector has been replaced by a planar printed structure (reflectarray) which, at the same time, can perform focusing of an incident spherical wave and twist the polarization (Fig. 7, top). The wave from a feed horn is incident on the polarizing grid (with its polarization parallel to the grid lines) and is reflected back to the planar array. Typical reflecting elements of such a reflectarray are rectangular patches which are oriented at an angle of 45° with respect to the incident polarization. Ninety degree twisting of the wave polarization is achieved in the same way as described above. Furthermore, combinations of the length and width of the patches can be selected to additionally give the required absolute phase shift to form an outgoing plane wave. Such an antenna with three beams (generated by three different feed locations) has been implemented into the second generation of Mercedes radars (Fig. 7, bottom), and this principle is also included in the third-generation sensor ARS 300 delivered by Continental (see the second application example in this chapter).

In general, lens and reflector antennas exhibit very low loss, advantageous in combination with millimeter-wave semiconductor elements for power generation of quite moderate level, but they require a non-negligible depth of a few cm; thus, purely planar antennas are gaining more and more interest.

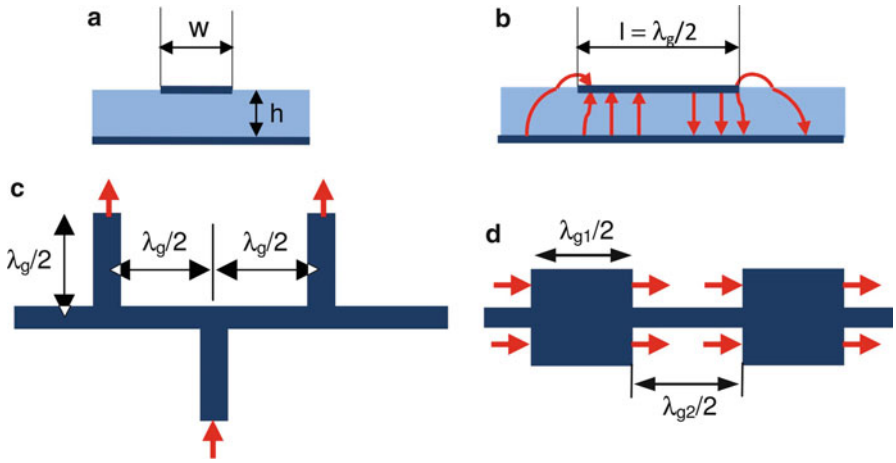

Fig. 8 Microstrip antennas: (**a**) microstrip cross section, (**b**) longitudinal cross section with an electric field of a half-wavelength resonator (patch antenna), (**c**) chain of radiating open-ended microstrip stubs, (**d**) chain of microstrip patches connected by half-wavelength lines

Planar Antennas

Planar antennas are found in various forms; the most common types are microstrip antennas (Carver and Mink 1981; James et al. 1981); for details see also the respective chapter in this book. Most often, half-wavelength resonators or dipoles (patch antennas) or open ends of microstrip stubs (Fig. 8) are employed as single antenna elements. Figure 8b depicts the longitudinal cross section of a radiating patch including the principal electric field distribution. In a very simplified model, the stray fields at the ends are the radiating sources – with this half-wavelength patch, the horizontal components of the stray field have the same direction and combine in phase for a broadside radiation

DOI 10.1007/978-981-4560-75-7_96-1

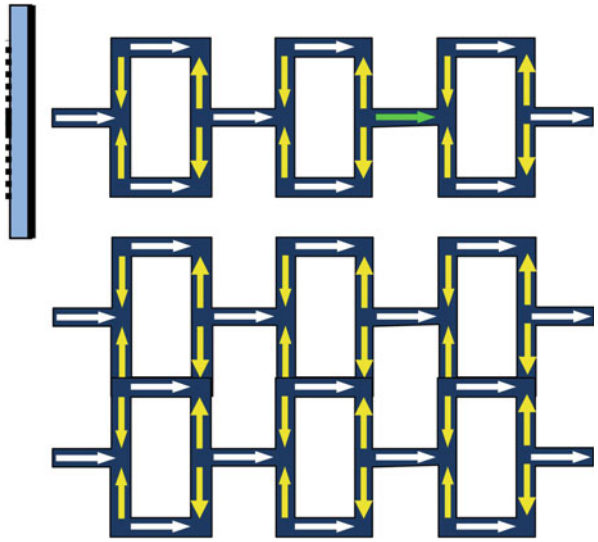

Fig. 9 Single- and double-row grid antenna

(the respective stray fields at the patch sides are in antiphase and cancel to a great extent). For narrower beams and higher gain, such elements can be combined in series and/or parallel arrangements (Fig. 8c, d) to form antenna arrays with the required overall antenna diagram. In Fig. 8c and d, the red arrows show the horizontal stray fields at the radiating edges and indicate the in-phase behavior, resulting in a broadside radiation.

Microstrip patches are resonators and typically exhibit bandwidths in the range of only a few percent with limited antenna efficiency, improving with lower dielectric constant of the substrate and increasing substrate thickness. The latter, however, leads to a higher degree of radiation by the feeding network as well as to the excitation of surface waves. Feed radiation may be mitigated by feeding the patch from the backside via a slot in the ground plane, but surface waves are more difficult to handle.

Single-patch antennas can be employed as feeding elements for a lens antenna (Binzer et al. (2007); see the first application example in this chapter); arrays of microstrip patches can be used directly as automotive antennas (Gresham et al. 2004; Winkler et al. 2008; Russell et al. 1997; Tokoro et al. 2003). With increasing geometrical dimensions of patch antenna arrays, feed network losses, especially for arrays with corporate feed networks, may pose a severe limit for antenna size. Series feeding of patches or open-ended stubs (Fig. 8) is based on connecting line segments of fixed length to ensure proper phase angle adjustment of each element; this however is valid only at a single frequency. Varying frequency, a progressive phase variation occurs from element to element, resulting in some degree of beam scan. For small array with relatively large beamwidth, this generally is of minor importance, but with an increasing length of a series-fed chain, beam scanning is no longer negligible.

Being predominantly resonating structures, patch antennas and radiating stubs exhibit limited bandwidth and increased losses; these effects pose a severe limitation for microstrip substrates with increased dielectric constant, e.g., for highly integrated circuits on low (or high)-temperature cofired ceramic (LTCC, HTCC) substrates. Already in the 1960s, a type of wire antenna was proposed, called grid antenna (Kraus 1964). Conti et al. (1981) proposed a microstrip version of such a grid array antenna. This array consists of a double meander microstrip structure as depicted in Fig. 9, top. All segments are about half a guided wavelength long; the currents (plotted white in Fig. 9) in the longitudinal segments have the same direction and contribute in phase to radiation. As there are no

DOI 10.1007/978-981-4560-75-7_96-1

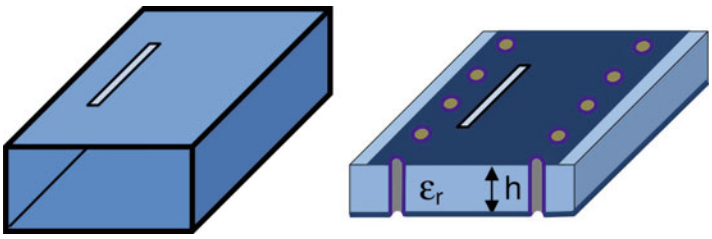

Fig. 10 Metal waveguide and substrate integrated waveguide (*SIW*) with radiating slots

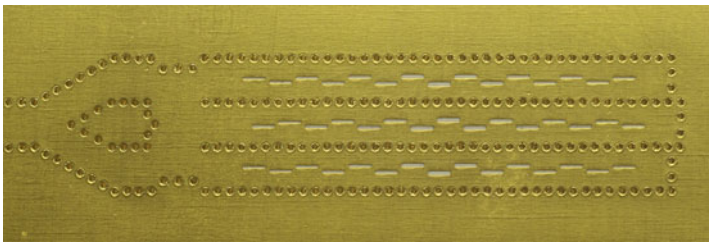

Fig. 11 Photograph of an SIW slotted array example (Massen et al. 2013, own photograph)

strong resonances, this type of antenna is more broadband, even for high-dielectric-constant substrates, and less sensitive to tolerances. Several segments can be aligned together in series, and even two or more chain can be combined in parallel (Fig. 9, bottom). Feeding can be done at one end or at suitable positions within the chain by coaxial or probe-type feeds from the substrate backside (Bauer and Menzel 2011, Bauer et al. 2013), via slot coupling through the ground plane, or even with a symmetric stripline from the side (opening one of the loops of the antenna (Frei et al. 2011)). Feeding a grid antenna chain from one end results in an antenna with slight scanning properties; feeding it in the center results in two shorter sections with reduced scanning into opposite directions and thus in a more broadband design.

The grid antenna has been implemented in different types of application, e.g., 60 GHz communication (Zhang and Zhang 2012), or in an experimental LTCC front end for a short-range automotive sensor (Bauer et al. 2013); this will be described in more detail later on in this chapter.

A well-known type of antenna is the waveguide slotted array (Fig. 10). It consists of a metal waveguide with longitudinal or transversal slots. Once again, radiation from a number of slots superimpose in phase to form the desired radiation pattern. One approach to make this antenna suitable for automotive radar is to machine a waveguide pattern into a metal plate and to glue a metal foil with the slots on top of this (Sakakibara et al. 2006). For an easy and low-cost fabrication, however, a synthetic or substrate integrated waveguide (SIW) can be realized within a dielectric substrate where the sidewalls are formed by rows of vias (Hirokawa and Ando 2000; Xu et al. 2009; Massen et al. 2013). Slotted arrays based on SIW can even be realized with LTCC substrates. As waveguide width is reduced due to the dielectric filling of this waveguide, only longitudinal slots are used. A critical item is tolerances for the dimensions of the slots due to the high frequency and the (high) dielectric constant; with a novel shape of the slots including bends, this problem can be overcome to some extent (Bauer and Menzel 2013a). In some applications, a resonant cavity is placed above each slot, either by an additional metal plate including the cavities (Sakakibara et al. 2006) or integrated within a (LTCC) multilayer substrate (Shino et al. 2005; Bauer and Menzel 2013b), giving a more broadband and better radiation performance.

DOI 10.1007/978-981-4560-75-7_96-1

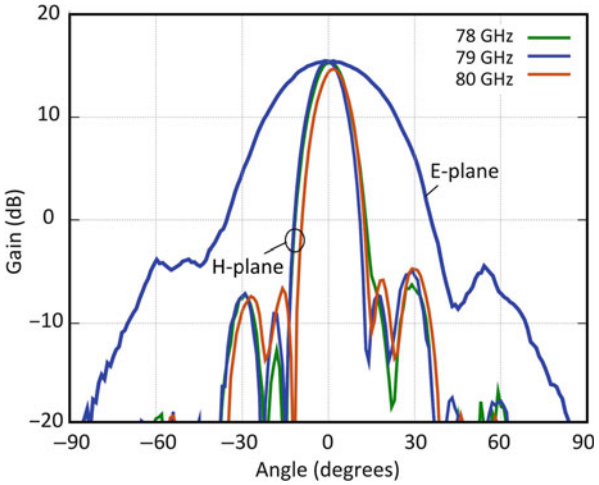

Fig. 12 Measured E- and H-plane radiation diagrams of the array shown in Fig.11

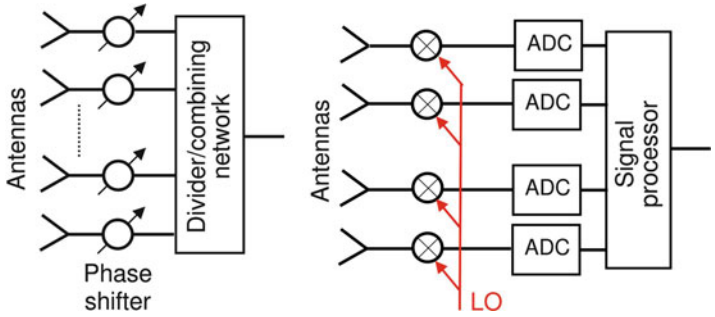

Fig. 13 Basic structures of phased array (*left*) and beamforming antenna (*right*)

As an example, an SIW slotted array is shown in Fig. 11, realized on a Rogers RO3003 substrate. It consists of three rows of SIW with 15 radiating slots in each row, together with a 1:3 power divider in the same technique. The longitudinal distance between the slots is half a wavelength with the SIW; the power distribution along the rows is controlled by the slot widths. An amplitude taper both within the rows and between the rows (unequal power divider) is selected to achieve a −20 dB sidelobe level. Details of the design procedure are given in Massen et al. (2013). H-plane radiation diagrams (perpendicular to the slots) at 78, 79, and 80 GHz are plotted in Fig. 12, together with the E-plane diagram at 79 GHz (the E-plane diagram does not change in the frequency range of interest). Beamwidths of 11° and 34° in H- and E-plane can be found. In both planes, the required sidelobe level is nearly met. A slight beam scan can be observed in the H-plane due to the series-fed slots. This array is one of six subarrays finally integrated on one substrate to form an antenna for digital beamforming (Massen et al. 2013).

Digital Beamforming

Antenna elements of arrays or subarrays as described in the previous subsection often are connected by transmission lines to (larger) arrays and provide fixed beams. Antenna elements or subarrays can alternatively be connected to phase shifters (and attenuators), allowing electronic beam scanning (Fig. 13, left side); this typically results in relatively complex, lossy, and costly arrangements at mm-wave frequencies. An alternative approach is to use several antenna elements or subarrays and

DOI 10.1007/978-981-4560-75-7_96-1

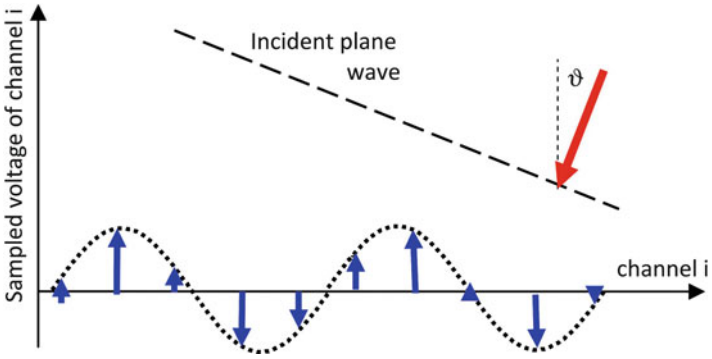

Fig. 14 Real part of IF samples for a slanted incidence of a wave

either switch these successively to a receiver or transmitter or connect them to multiple transmit/receive circuits, easily done with modern MMICs like in Winkler et al. (2008). Figure 13, right side, shows the example block diagram of a receiver with digital beamforming. The scene of interest is illuminated by a separate transmit antenna, or a combined transmit/receive circuit may be connected to one or (successively) several of the antenna elements. The receiver channels down convert and amplify the respective signals. The IF signals are sampled and converted to a sequence of digital values which can be processed further. After range processing for each channel, typically using an FFT for FMCW sensors, amplitude and phase angle are available for each range cell and receive channel. Multiplication with a complex number is equivalent to modify the amplitude and phase angle for the analog signal. A more efficient approach is based on the relations indicated in Fig. 14. An incident plane wave from a given slant angle is received by n receivers; according to the different path lengths, the signal at each receiver suffers a progressive delay (phase angle), resulting, after down conversion, in signals proportional to $\cos(i\, k_0\, d \sin\vartheta)$ with i, the number of the element; d, the distance between the elements; and k_0, the free space propagation constant. Accordingly, the spatial frequency of the sampled values indicated by the dotted line in Fig. 14 increases with increasing angle ϑ of incidence. As a consequence, applying another Fourier transform in cross range, different directions of wave incidence can be detected simultaneously, thus being able to measure the scenery in front of a car with high precision (Gresham et al. 2004; Asano et al. 2001; Stelzer et al. 2010). In comparison to analog beamforming with a phased array, this approach is referred to as digital beamforming.

The beamwidth of the subarray(s) in such an approach must be sufficient to cover the angle range of interest for the respective application. At least two of the subarrays should be placed at a distance as close as possible to half a wavelength to ensure an unambiguous cross-range resolution, but further subarrays may be arranged at larger but different distances between each other, so a high lateral resolution can be achieved, while the different distances can be optimized to remove ambiguities (grating lobes) (Moffet 1968; Md Tan et al. 2008; Feger et al. 2009). Combining this beamforming with configurations as described in the following, even an effective aperture width larger than the physical one can be achieved.

MIMO Concepts for Automotive Radar

In Kees et al. (1995), a concept was proposed to improve the angular resolution of an imaging radar system by transmitter location multiplexing. Today, this concept partly is called MIMO radar (multiple in, multiple out), although in most cases transmitters or receivers (Mayer et al. 2006) are operated successively. Just recently, a concept has been presented to simultaneously transmit via

DOI 10.1007/978-981-4560-75-7_96-1

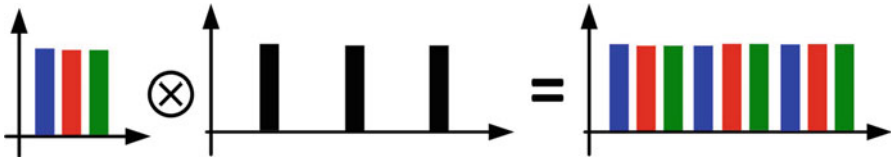

Fig. 15 Convolution principle for MIMO radar

several channels in frequency domain multiplex and to receive in parallel by a respective number of receivers (Pfeffer et al. 2013).

According to antenna theory, the angular distribution of the radiated fields (radiation diagram) of an antenna is proportional to the Fourier transform of its aperture distribution in the respective plane. On the other hand, the signal transmitted from one antenna and received by another one is proportional to the multiplication of the radiation diagrams of these two. Consequently, this product can also be derived from an aperture distribution formed by the convolution of the two individual aperture distributions. Superposition of the measurements from n transmits and m receive subarrays then results in the convolution of the respective excitation distributions (Fig. 15). Accordingly, the configuration as given in the example in Fig. 15 results in a synthetic antenna array with densely arranged subarrays. Other combinations of transmit and receive antennas even result in an increased aperture (Mayer et al. 2006). Weighting the individual measurements with complex numbers (representing phase and amplitude adjustments), different beam directions or modifications of the radiation diagram can be adjusted and evaluated simultaneously.

Fabrication, Packaging, and Mounting Considerations

As already mentioned in the introduction, automotive radars have to operate in a temperature range from −40 °C up to 85 °C or even higher, they have to withstand shock and vibrations, and they have to operate under conditions of rain, snow, or ice. Materials, fabrication processes, packaging as well as mounting of the sensor therefore have to be selected carefully.

Substrate materials need to be suitable for the mm-wave frequency, their physical and electrical properties should be reasonably constant over the temperature range, and they should not absorb moisture. On the other hand, standard microwave substrates may be rather expensive, so a compromise has to be made in this respect. Etching of the planar structures should, as far as possible, be done using standard printed circuit board (PCB) processes but may require accuracies down to 20 µm for the 77 GHz frequency range – this also poses a great challenge toward tolerance-optimized antenna design. Metal surfaces, in addition, need to be protected against corrosion by suitable plating.

Antennas need to be connected to the millimeter-wave circuits and/or MMICs. While bonding at 24 GHz is still not too critical, this provides major efforts and therefore higher cost at 77 GHz. Typically, MMICs have to be placed in some cavity in the circuit board, and bonding is done in the same level to keep parasitics as low as possible (see also the first application example in this chapter). One way out of this is to provide a suitable package for the MMIC as described in Fig. 16 (Wojnowski et al. (2011)), known as eWLB packaging. The MMIC is embedded into a plastic mold, further metallization levels connect the MMIC to lines on the mold, and a ball grid array then allows an easy interconnect to the circuit board, possibly directly to the antenna substrate. In this way, the assembling of antenna and MMICs is feasible without specialized and costly equipment.

The antenna and the radar sensor as a whole, finally, have to be protected by a suitable package. This typically is done by an overall housing, as can be seen also at the examples given in the following section. The cover in front of the antenna (radome) must be transparent to the

DOI 10.1007/978-981-4560-75-7_96-1

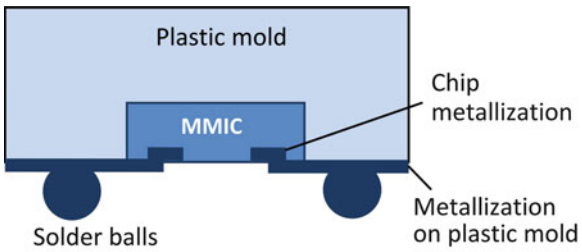

Fig. 16 eWLB package

electromagnetic wave in the respective frequency range, leading to an optimized thickness for the used plastic materials in the order of multiples of half a guide wavelength within the material. This optimized thickness only is perfect for one angle of radiation. For all other angles, there is performance degradation due to reflection. Major efforts are necessary to keep the influence of such a reflection below a given threshold. If the cover is close to the antenna, even a codesign of antenna and cover has to be done.

Mounting of the radar sensor at the car requires a position from which the radar can cover the relevant angle of view, but space limitations and overall car design concepts require some compromise; so typical mounting positions are behind the radiator grille and the bumper. Today, the bumper often is painted, and efforts have to be done to ensure a sufficient transparency of the bumper, even with paintings containing metallic particles. This can be done by optimizing the thickness of the bumper material or by adding some matching layer in front of the radar (Fitzek et al. 2010).

Furthermore, during operation, the radome must not be covered by layers of water, ice, or snow; this would severely deteriorate its performance. To avoid this, a protected mounting position, e.g., behind the bumper, a water-repellent radome surface, or a suitable form or orientation of the radome to blow away water or snow just by the natural airstream of the car, can be selected.

Application Examples for Automotive Antennas

Bosch Sensor LRR3

The LRR3 automotive radar sensor of Bosch came onto the market in 2009. It is based on the FMCW principle, and the mm-wave transmit and receive circuits are integrated on a four-channel SiGe monolithic chip (Winkler et al. 2008) connected to four single microstrip patch antennas combined with parasitic elements to adjust the bandwidth and beamwidth. In the original version, the MMIC is mounted into a cavity in the printed circuit board and bonded to the antenna feed lines. In an advanced version, eWLB packaging as described above is used for the MMIC. The antenna elements are tilted by 45° to reduce interference from oncoming cars. The antenna elements serve as feeds for a lens antenna (Binzer et al. 2007), resulting in four narrow beams. An exploded view of the complete sensor and the planar antenna section is shown in Fig. 17. With overlapping radiation diagrams of the beams (Fig. 18), the angular detection of targets is done by monopulse principles between two neighboring beams, resulting in a resolution considerably better than the beamwidth, provided that only one target is in the respective range cell.

DOI 10.1007/978-981-4560-75-7_96-1

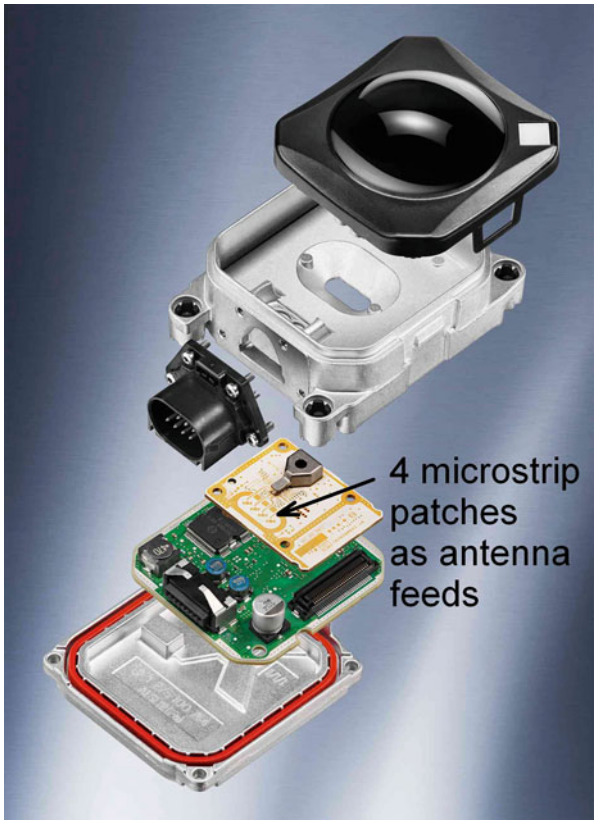

Fig. 17 Exploded view on the Bosch LRR3 sensor and details of the planar antenna elements feeding the lens (Sensor photograph provided by Bosch)

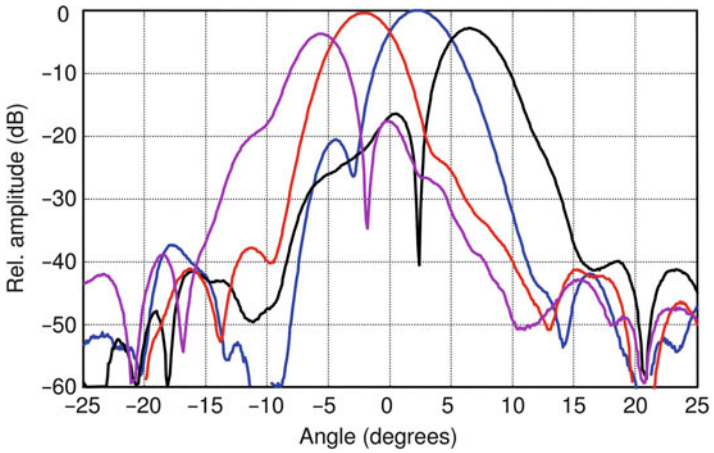

Fig. 18 Azimuth radiation diagrams of the four beams of the LRR3 radar (Fig. 16)

Continental Sensor ARS300

Also in 2009, Continental ADC introduced its third generation of automotive radar with completely new features and a novel approach for the radar antenna. The antenna of the ARS300 scans with a narrow beam over a given azimuth range; it performs auto alignment and is of compact size.

As can be seen in Fig. 19, the entire arrangement consists of a dielectric waveguide in the vicinity of a grooved rotating drum and a folded space consisting of a polarizing grid, also serving as

DOI 10.1007/978-981-4560-75-7_96-1

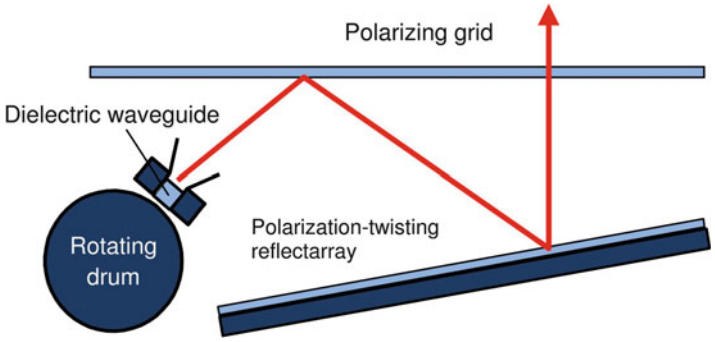

Fig. 19 Principal cross section of the Continental ARS 300 antenna

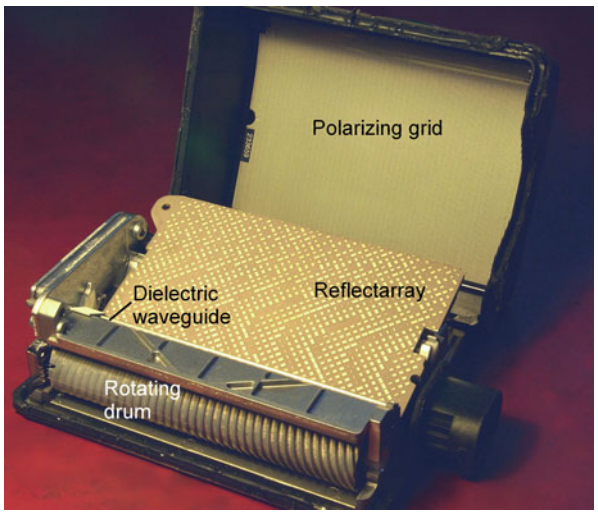

Fig. 20 Photograph of the Continental ARS 300 sensor with opened cover (own photograph)

mechanical protection and radome, and a focusing reflectarray. A photograph of the opened sensor is given in Fig. 20. The basic radiation structure is a dielectric guide with propagation constant k_d. The drum is placed close to the dielectric waveguide, and the metal ridges between the grooves of the drum form periodic perturbations at which the dielectric guide radiates (Fig. 19); the radiated partial fields superpose to form the overall far field radiation. For a given direction of radiation, these partial fields must superimpose in phase. According to Fig. 21, the following relation must hold

$$k_0 \Delta l \ \sin(\delta) + 2\pi = k_d \Delta l \tag{3}$$

where k_0 and k_d are the phase constants of free space and the dielectric guide, respectively, and Δl is the distance between the metal ridges (Fig. 21).

To scan the radiated beam over a given angle, the period of the grooves has to be modified – the groove period depends on the rotational angle, and the actual groove period in the direct vicinity of the guide determines the direction of the radiated beam. Rotating the drum then leads to a scanning of the beam (Manasson et al. 1996). A great effort has been spent in designing the drum in a way to find the optimum shape and size of the grooves such that at each azimuth angle a beam of a given scan angle with sidelobes below a prescribed threshold is obtained. A unique feature of this waveguide drum unit is that it contains different angular sections in which both the direction of

DOI 10.1007/978-981-4560-75-7_96-1

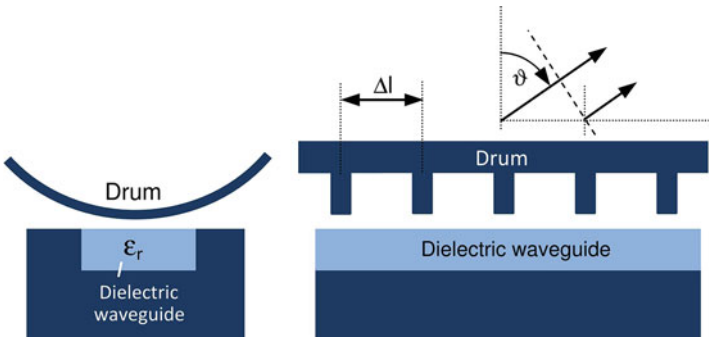

Fig. 21 Details of radiating dielectric guide

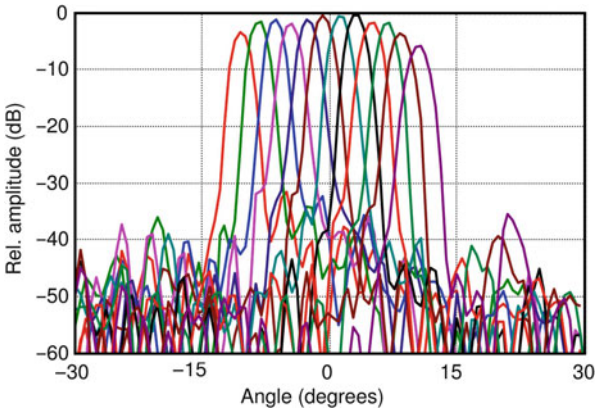

Fig. 22 Selected two-way azimuth radiation diagrams of the Continental ARS 300 sensor

radiation and the beamwidth can be altered such that different sensor modes from short to long range (up to 200 m) can be covered by a single setup.

Additionally, the radiated wave has to be formed to provide a narrow diagram in elevation as well. This is done by a folded reflectarray configuration as described earlier (see also Fig. 7). The required polarizer is integrated into the cover of the sensor such that the beam radiated from the dielectric waveguide/drum unit is reflected toward a reflectarray consisting of a dielectric layer glued onto a conducting plate. Phase angles are adjusted such that a narrow beam results in elevation, together with the necessary polarization twisting. Both the polarizing grid printed to the sensor cover and the reflectarray can clearly be seen in Fig. 19. Measurements of the radiation diagrams have been done using the complete radar, resulting in two-way diagrams. A selection of far field radiation diagrams for different drum positions can be seen in Fig. 22. Two-way beamwidths are in the range of 2.5°.

In addition, this antenna exhibits another unique feature. While the headlights of a car can be adjusted in elevation by any skilled person, this is different for a radar sensor with its non-visible radiation. With this antenna, the reflectarray can be tilted to some extent by a motor unit which performs an auto alignment in elevation.

Experimental 79 GHz LTCC-Based Sensor with Grid Antennas

For high-density 3D integration, low- and high-temperature cofired ceramics (LTCC, HTCC) are gaining increasing interest. The starting point for their fabrication is mixtures of ceramic and glass powder together with binding agent for LTCC and solely ceramic powder with binding agent for HTCC. These materials are pressed into thin sheets (one tenth or a few tenth of a millimeter thick)

DOI 10.1007/978-981-4560-75-7_96-1

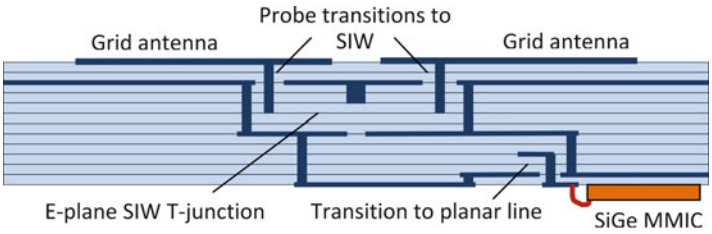

Fig. 23 Cross section of LTCC sensor

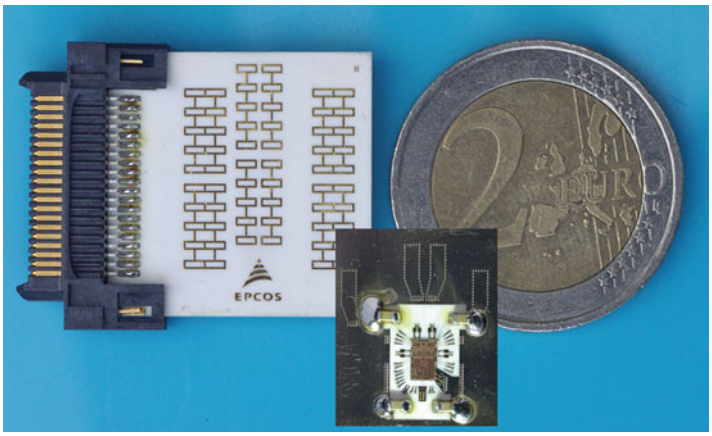

Fig. 24 Photograph of the 79 GHz LTCC sensor; antenna side and MMIC side in inset (own photograph)

and cut into suitable panels. In the first step, holes for vias are punched into the sheets and filled with metal paste. Following this, screen printing is applied to print metal patterns onto each sheet. Finally, a required number of sheets (even several tens of sheets) are laminated and pressed together, precut, and fired. For LTCC, only the glass powder needs to melt, so temperatures in the range of 900 °C are sufficient. For HTCC, the ceramic powder must be joined together, so temperatures of 1,600 °C are required. For very fine and accurate structures on the outer sides of the multilayer, even sputtered and electroplated metal with standard etching processes can be added (partly called “fine line” techniques (Brunner et al. 2012)). Including these processes, LTCC can be extended to the design of highly integrated millimeter-wave circuits.

This technique was applied to develop an experimental 79 GHz short-range sensor using grid antennas and a four-channel SiGe radar front end (Bauer et al. 2013). A principal cross section of the multilayer circuit is given in Fig. 23. The multilayer contains 12 layers of 0.118 mm thickness each. The dielectric constant for the material used here is 7.4. Vias can be fabricated down to a diameter of 0.1 mm, easily enabling SIW structures; the effective SIW width is about 1.2 mm. Two grid antennas with opposite orientations are located on the top surface, fed by probes to a first layer of SIW. An E-plane T-junction feeds the signals to a lower level SIW; from there, another probe-type transition provides a connection to a planar symmetric line at the backside where the MMIC is located and bonded to the planar lines.

A photograph of the antenna side of the sensor together with a section of the backside with the MMIC is depicted in Fig. 24. While the LTCC substrate has dimensions of 23 × 23 mm, the overall usable size for the antenna arrangement is 13 × 20 mm. This consists of four chains of grid antennas, each connected to one channel of the MMIC. As at least two channels need to be closely spaced to ensure unambiguity, two chains consist of single rows, while the other two are double chains to

DOI 10.1007/978-981-4560-75-7_96-1

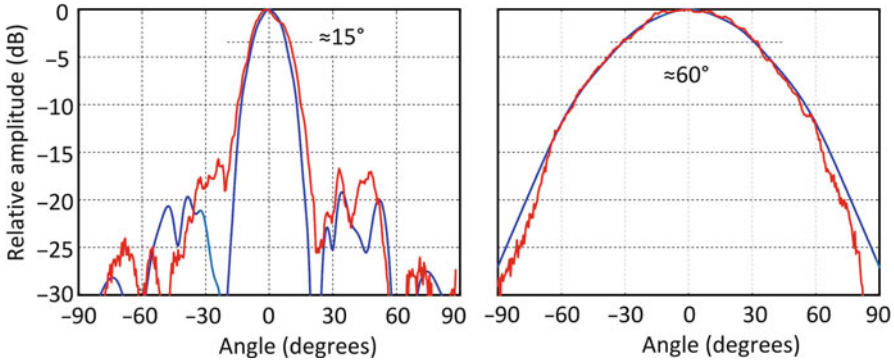

Fig. 25 Elevation (E-plane) and azimuth (H-plane) radiation diagrams of a single-row grid antenna. *Blue* simulation, *red* experiment

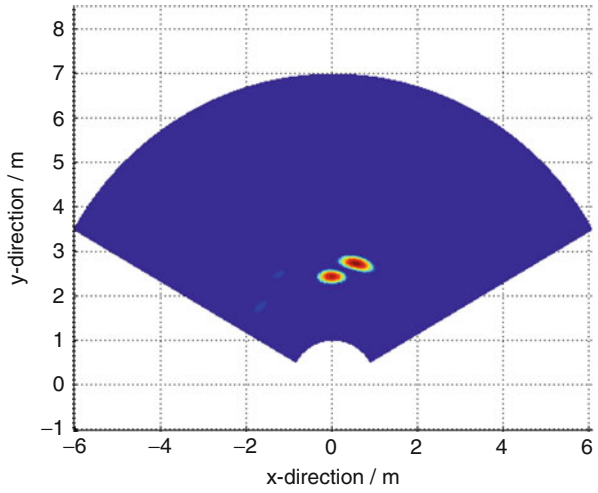

Fig. 26 Close-range image of two targets

increase the overall (processed) signal output (at the cost of a reduced angle of view) and placed at larger distances to the single chains. Mid-to-mid distances between the antenna rows are 3.6, 2.2, and 5.4 mm. Radiation diagrams of a single-row antenna are plotted in Fig. 25; beamwidths in elevation and azimuth are about 15° and 60°, respectively. The elevation diagram of the double-chain antenna is equal to that of the single-row one; the azimuth diagram of the double-row antenna has a 3 dB beamwidth of 40°.

Each radar channel is able to both transmit (FMCW) and receive; all channels are active in receiving whatever channel is transmitting. MIMO principles with optimized weighting functions are then applied for cross-range imaging according to Feger et al. (2009). According to the convolution principle, ten different synthetic antenna positions result with a nearly doubled antenna aperture. The response to a target then has a 3 dB width of about 10° at the broadside (Bauer et al. 2013). Together with the FMCW principle for range, a typical radar image for two targets is shown in Fig. 26. With this experimental sensor, a range of up to 20 m can be covered; employing a new LTCC material with lower losses and a further optimization of the backside transition to the MMIC will increase range further. Of course, also a larger antenna size will do the same.

DOI 10.1007/978-981-4560-75-7_96-1

Conclusion

After an introduction to automotive radar sensors and their principle architecture, this chapter provides a guide to different types of antennas for automotive radars. While in the early approaches more or less standard antenna configurations were dominating, different types of planar antennas and array antennas have been employed later on. As shown in the second system example, also different antenna types like a dielectric line-based radiator with a mechanical scanning unit and a printed and folded reflectarray antenna are combined for best performance. Presently, the original function of "stand-alone" antennas is being replaced by an overall arrangement of antenna elements and arrays, transmit/receive configuration, and digital signal processing, as it is demonstrated by digital beamforming together with (quasi-) MIMO concepts. The latter allows a reduction of transmit/receive modules and antenna elements, and it even allows to generate synthetic apertures larger than the physical ones.

Signal processing is also a means to further increase resolution in all radar relevant domains, i.e., range, cross range, and Doppler frequency. In the present commercial sensors, real-time signal processing is still limited to the basic functions, but soon high-resolution methods like MUSIC (Schmidt 1986), ESPRIT (Roy et al. 1986), or autoregressive (AR) signal estimation (Proakis and Manolakis 1996) will be considered. In a number of studies, AR signal estimation has proven to be quite robust in automotive applications, e.g., Mayer et al. (2006). In cross range – where the antenna configuration is relevant – beamforming leads to a number of sampled values from which the lateral target distribution is calculated using an FFT. Explained in a very simple way, such a series of sampled values can be modeled by a kind of digital filter, and with this, new artificial sampling values can be generated on either side of the original series, typically increasing the number of samples by 2 or 3. An FFT over the enlarged series then results in an improved cross-range resolution, equivalent to an antenna aperture of twice or three times as wide.

With more stringent requirements for safety application, also an improved resolution with respect to elevation gets more and more important – is there any target which the vehicle can run over or pass below, or is it a relevant obstacle? As a consequence, systems – and therefore the antenna configurations – need to be extended, either to switch or scan in elevation as well, or an extra antenna element may be added to observe higher elevation angles.

As discussed in the second chapter, operation frequency of automotive sensors mostly is shifting from the 24 GHz frequency range to the 76/77 and 77/81 GHz range; the driving motivation is toward smaller sensors; basically, the effective size is determined by the antenna. Based on this, also higher frequency ranges are under first investigations (Köhler et al. 2013). Frequencies may be in the 120 or 150 GHz range. For the same antenna aperture as with lower frequencies, gain is increased, or for the same gain, antenna dimensions get smaller. One has to be aware, however, that with smaller antenna aperture size, the received power decreases as well. From the antenna design point of view, a simple scaling of the structure seems to be possible; care has to be taken for increased losses and more critical tolerance requirements. Semiconductor devices show increasing cutoff frequencies (Pfeiffer 2012), but output power will be lower and receiver noise figure higher. Nevertheless, estimations in Köhler et al. (2013) show that MRR and SRR sensors should be feasible. Another challenge with higher frequencies will be interconnects, but efforts are going on to integrate antenna elements directly on a MMIC or providing specific packaging technologies with potentially integrated antenna elements provided by the MMIC manufacturer, e.g., Wojnowski et al. (2011) and Hasch et al. (2012).

Applications of Phased Array Feeders in Reflector Antennas

S. G. Hay[a]* and T. S. Bird[b]
[a]CSIRO Digital Productivity, Epping, NSW, Australia
[b]Antengenuity, Eastwood, NSW, Australia

Abstract

An array feeder for a reflector or a lens provides considerable flexibility in the beams that can be produced. A single beam could be obtained by combining all elements; multiple beams can be created with clusters of subarrays or the elements combined in such a way that a beam is steered by adjusting the phase and amplitude of the elements. A variety of applications of array feeders are possible from satellite communications, radar, and radio astronomy. The latter application is described here through fixed arrays, and individual horns of the cluster are excited step-by-step to produce multiple beams at radio observatories such as Parkes, Australia, and Arecibo, Puerto Rico. A full phased array solution is described for the Australian Square Kilometre Array Pathfinder (ASKAP). For fixed arrays, an optimum excitation is described. It is shown that without coupling effects, the excitation should be the complex conjugate of the focal field. The size of an array is defined and the sensitivity of a multibeam feed is shown to be proportional to $\sqrt{N}$ where N is the number of elements of the array. The theory relating to phased array feeding of reflectors is developed, and the definition of sensitivity is extended to phased arrays. The survey speed of a phased array feed interferometer is defined, and conditions are developed for survey speed as a function of the number and spacing of the beams. The application of fixed arrays as multibeam feeds for radio telescopes is described for the 13-element multibeam feed for the Parkes radio telescope and for the phased array checkerboard feed for ASKAP in Western Australia.

Introduction

There are an increasing number of applications with reflectors that benefit from the flexibility and performance improvement from more sophisticated feeds than a single element. Arrays have been used as feeds sometimes combined and sometimes singly. A phased array is a collection of antennas combined together through the excitation to perform as a single antenna. The beam produced is able to be steered or moved by adjusting the amplitude and/or the phases of the signals rather than by physically moving the entire antenna structure. A phased array feeder is the means of achieving this adaptability with another larger antenna, usually a reflector or a lens as shown in Fig. 1, which is efficient at forming a focused beam. The absence of moving parts enables the beams to be steered rapidly, making the phased array feeder useful in applications requiring one or multiple scanned or adaptable beams such as in radar and radio astronomy. For a description of the latter systems, refer to the chapter "► Antennas in Radio

*Email: stuart.hay@csiro.au

Telescope Systems." The beam of a spherical reflector is steered simply by rotating the feed at the focus. However, spherical reflectors tend to have lower gain and higher sidelobes than a paraboloid. For a parabolic reflector, beam steering is more complicated and can be achieved by a variety of methods. It can be steered over a small range by displacing a single feed transversely from the reflector vertex. Unless the aperture distribution is highly tapered, there is a large reduction in gain. Phase correction can be introduced, but this restricts the beam scanning to within a few beamwidths of the boresight direction before gain loss becomes too large. Lateral displacement of the single feed by a distance d in the focal plane results in a scanned beam at an angle θ_b, which is less than the angle from the focus to the vertex $\theta_v = \text{atan}(d/f)$. This difference is called the beam deviation factor (BDF). Thus

$$\theta_b = \theta_v \text{BDF} \tag{1}$$

where BDF typically has values $0.7 - 0.9$. A useful approximation when the f/D is not small is

$$\text{BDF} \approx \left[1 + \frac{1}{32(f/D)^2}\right]^{-1}. \tag{2}$$

Feeds that are displaced are unable to provide low sidelobes at wide scan angles due to aberrations as a result of not matching the fields in the focal region.

An improved method of achieving a scanned beam is to use information derived from the focal plane field and provide a suitable conjugate match. This means the feed has to be sufficiently flexible to provide the appropriate excitation to generate the required field. This is possible with an array of feeds that contains a sufficient number of elements. In another approach, Rudge et al. (1986) use signal processing to provide a second Fourier transform, as well as the one provided by the reflector, to generate the scanned beam. The transform is of the intercepted electric fields of the focal plane on some defined locus where only phase shifters are needed to correct for aberrations.

Phased arrays have been used as feeds in applications involving rapid beam steering. The complexity of the feeding network, cost, and weight have often in the past been a deterrent to their use. However, in recent years, the flexibility that is possible as well as new methods of feeding has stimulated a reassessment of phased arrays as feeds for reflectors. Some of the advances made in the area will be reviewed in this chapter.

Array Feeds for Reflectors

A reflector antenna radiates a pencil beam when excited from its focal region by a feed antenna as shown in Fig. 1. In most applications, a single feeder is used, which may consist of a dipole, horn, or waveguide. Efficient feeding antennas and associated techniques have been developed for reflectors as described in the chapter on "▶ Reflector Antennas." The reflector could be a single reflector such as a symmetrical paraboloid or a dual-reflector in a Cassegrain configuration as shown in Fig. 1. In order to efficiently illuminate a reflector to produce a beam on boresight or at some angle away from it as in steering, the aperture field of the feed should replicate the focal region field corresponding to that beam in some way. This can be done by operating the reflector in a receive mode with the beam incident from desired directions or in transmit by adjusting the phases of the elements of the array in a controlled manner.

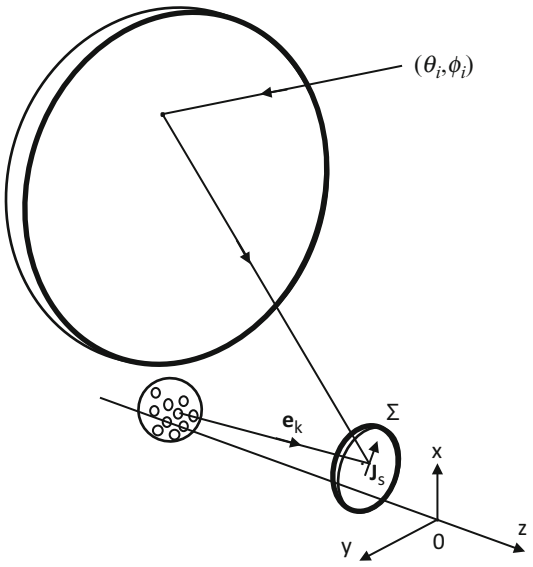

Fig. 1 Reflector antenna with feed array in receive mode with a beam from the direction (θ_i, ϕ_i)

A Dipole Array-Fed Reflector

In an earlier chapter in this book entitled "▶ Reflector Antennas," the field radiated by a single dipole at the focus of a paraboloid has been derived. This analysis is extended here as an initial example to a rectangular array of half-wave dipoles. The array has an odd number of elements in the x-direction N_x with a spacing of d_x and, similarly, N_y elements with spacing d_y in the y-direction. The dipoles are polarized in the x-direction. It is assumed that the array is in the far-field of the reflector and mutual coupling between the dipoles is neglected. Therefore, from Chapter 30 Eqns. 65 and pattern multiplication of the array and element functions, the fields radiated by the array are

$$\mathbf{E}_f = E_o \frac{e^{-jkr}}{r} A(\theta,\phi)\left[\hat{\theta}\,\cos\theta\cos\phi - \hat{\phi}\,\sin\phi\right] \tag{3}$$

$$\mathbf{H}_f = \frac{1}{\eta_o}\hat{r}\times\mathbf{E}_f \tag{4}$$

where

$$A(\theta,\phi) = \frac{\cos\left(\frac{\pi}{2}\sin\theta\right)}{\cos\theta}\sum_{m=-N_{x1}}^{N_{x1}}\sum_{n=-N_{y1}}^{N_{y1}} V_{mn}\exp\left[j\left(mT_x(\theta,\phi)+nT_y(\theta,\phi)\right)\right] \tag{5}$$

consists of the pattern function for a half-wave dipole times the array factor. E_o is a constant, η_o is the wave-impedance of free-space, and the steering phase factors in the x- and y-directions are

$$T_x(\theta,\phi) = kd_x\sin\theta\cos\phi$$

and $T_y(\theta,\phi) = kd_y\sin\theta\sin\phi$.

V_{mn} is the excitation of element mn, and $N_{x1,y1} = \left(N_{x,y}-1\right)/2$. The resulting far-fields of the reflector are given by Eqs. 4.6 and 4.7 of Chapter 30 and are expressed as follows:

DOI 10.1007/978-981-4560-75-7_97-1

$$E_\theta = -\frac{jkfE_o}{\pi}\ \frac{e^{-jkr}}{r}B(\theta,\phi) \tag{6}$$

and

$$E_\phi = \frac{jkfE_o}{\pi}\ \frac{e^{-jkr}}{r}C(\theta,\phi) \tag{7}$$

where

$$B(\theta,\phi) = \int_0^{2\pi} d\xi \cos\xi \int_0^{\psi_c} d\psi\, A(\psi,\xi)\exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi) - (1+\cos\theta\cos\psi))] \times \left[\cos\theta(\cos\psi\cos\xi\cos(\phi-\xi) - \sin\xi\sin(\phi-\xi)) - \sin\theta\tan\frac{\psi}{2}\cos\phi\cos\xi\right]\tan\frac{\psi}{2} \tag{8}$$

$$C(\theta,\phi) = \int_0^{2\pi} d\xi \sin\xi \int_0^{\psi_c} d\psi\, A(\psi,\xi)\exp[jk\rho(\sin\theta\sin\psi\cos(\phi-\xi) - (1+\cos\theta\cos\psi))] \times [\cos\psi\cos\xi\sin(\phi-\xi) + \sin\xi\cos(\phi-\xi)]\tan\frac{\psi}{2} \tag{9}$$

where f is the focal length, D is the diameter of the reflector, $\rho = 2f/(1+\cos\theta)$ is the radial distance from the focus to the surface, and $\psi_c = 2\text{atan}[1/(4f/D]$ is the reflector's half-cone angle.

Radiation patterns computed from Eqns. 6 and 7 are plotted in Fig. 2 for a reflector with a diameter $D = 50\lambda$ and $f/D = 0.35$ that is fed by an array of 3 × 3 half-wave elements. The element spacing is $d_x = 0.55\,\lambda$ and $d_y = 0.5\lambda$. The excitation of the array has been obtained from the complex conjugate of the x-directed electric field in the focal region of a paraboloid with $f/D = 0.35$. A plot of the peak gain as

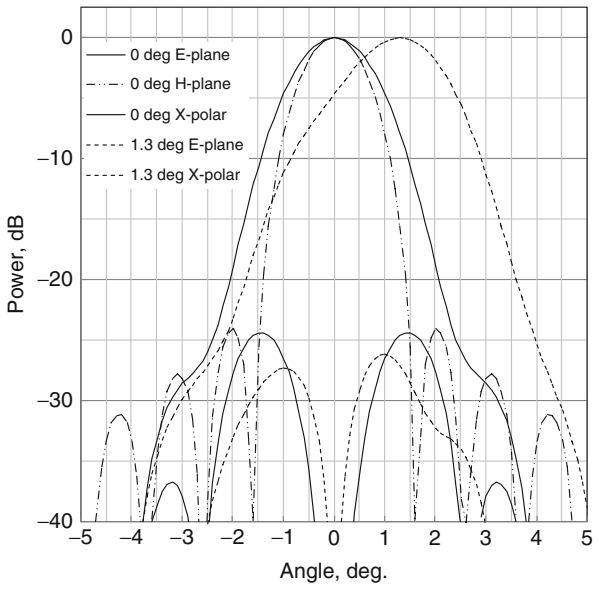

Fig. 2 Normalized radiation pattern of paraboloid reflector with 3 × 3 half-wave dipole feed array with excitation that is a conjugate match to the focal fields. Reflector diameter $D = 50\lambda$ and $f/D = 0.35$

DOI 10.1007/978-981-4560-75-7_97-1

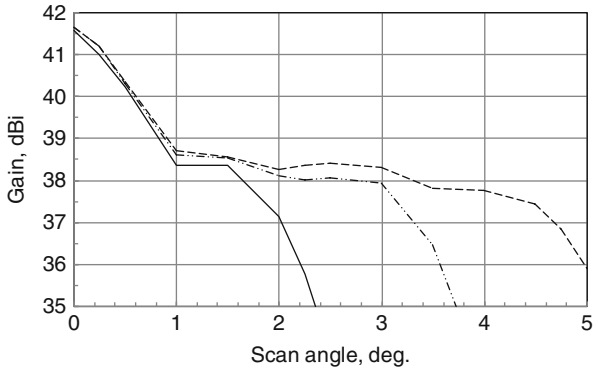

Fig. 3 Gain versus scan angle for paraboloid with half-wave dipole array feed. Reflector diameter $D = 50\lambda$ and $f/D = 0.35$. *Solid line*: 3 × 3 array; *long dashes*: 5 × 3 array; *short dashes*: 7 × 3 array

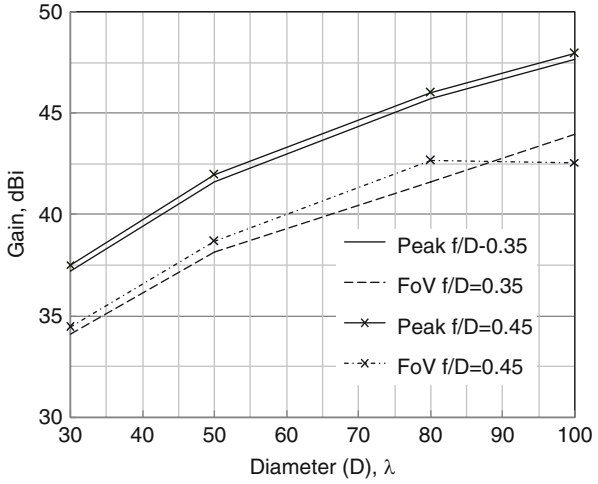

Fig. 4 Gain as a function of diameter D and f/D of a paraboloid with a 5 × 3 element dipole array feed that is matched to the focal fields corresponding to on-axis incidence (peak) and at a scan angle in the field of view at about two beamwidths (FoV)

the beam is steered is shown by the solid line in Fig. 3. It shows that for a 3 × 3 array, the gain decreases with scan angle until it reaches a critical point at about 2° scan angle or about $\sim 2\lambda/D$, after which the gain rapidly falls. This is because the small array, which is centered at the focus, is only able to match part of the focal region fields. As the beam is steered in the x-z plane, the focal region increases in extent in this plane. When the array size is increased further by adding more of elements in the x-direction, the scan in this direction is maintained over a wider scan range albeit with a gain loss of $3dB$. With 5 elements in the scan direction, a $\pm 3^\circ$ scan range is achieved, while with 7 elements, the scan range is over $\pm 4^\circ$. The scan range of $2\Delta\theta$ and hence the field of view (FoV) increase in proportion to the number of elements in the array in that direction. Thus 3 elements can match to a focal field and with conjugate matching can achieve a $FoV = 3^\circ$, while with 7 elements, the $FoV = 8^\circ$.

The scan range and the gain achieved across it are dependent on the reflector diameter and *f*/*D*. For example, Fig. 4 shows the gain achieved in the scan range as a function of paraboloid diameter for *f*/*D* values of 0.35 and 0.45 with the 5 × 3 element array. The peak gain on axis and a typical value of the field of view increase with the diameter as long as the array is large enough to encompass the significant parts of the focal region. If the array does not cover the important parts of the focal region or is incorrectly located, the gain begins to decrease as demonstrated for $D > 80\lambda$ when $f/D = 0.45$. The larger f/D case covers a

DOI 10.1007/978-981-4560-75-7_97-1

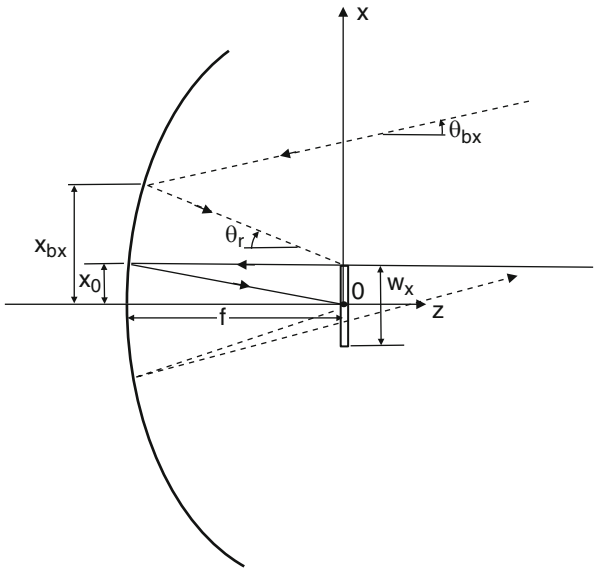

Fig. 5 Estimating array feed size for a symmetrical reflector

wider area of the focal region than for $f/D = 0.35$. It is emphasized that the results quoted above are only an indication of what happens as actual results vary with the feed element type and location and because mutual coupling between the array elements has been neglected.

When coupling is included, the scan performance compared with the uncoupled case can vary significantly and depends on the array geometry and particularly the proximity of the elements. In some configurations, the overall performance improves, while in others, the performance can be worse. However, to ensure the performance is close to the design prediction, it is important to include mutual coupling.

Size of the Feed Array

The size of the array that is required can be estimated by means of the geometric argument illustrated in Fig. 5. This shows a symmetrical reflector with an array feed of width w_x that is illuminated by a plane wave inclined at an angle θ_{bx} in the x-z plane. At this angle, the geometric ray through the antenna is incident on the outermost element of the array. Then, by means of Eq. 1, the array width in the x-direction is

$$w_x \approx 2f \tan\left(\theta_{bx}\left[1 + \frac{1}{32(f/D)^2}\right]\right). \tag{10}$$

Suppose the element spacing is chosen to be d_x. The number of elements required in the x-direction of the array is, therefore,

$$N_x = I\left[\frac{w_x}{d_x}\right] \tag{11}$$

where $I[x]$ is the integer value of the argument x. A similar argument applies in the y-z plane to obtain the maximum dimension and number of elements in the y-direction, N_y, of a rectangular array.

DOI 10.1007/978-981-4560-75-7_97-1

As an example, suppose a $\pm 2^\circ$ scan angle is required with minimum scan loss with a reflector having $D = 100\lambda$ and $f/D = 0.35$. What size of the feed array is required? Suppose the minimum spacing for elements in the feed array is $d_x = 0.55\lambda$. Equation 10 predicts an array width of $w_x \approx 3\lambda$, and as a result, Eq. 11 predicts the number of elements as $N_x = 5$. This compares with the results in Fig. 3 where for the 3×3 array, only about half this number of elements lie in the x-direction. When the number of array elements in the scan direction is increased to $N_x = 7$, which is predicted by Eq. 10 to achieve a scan range of about $\pm 3^\circ$, Fig. 9 shows that the scan angle in that plane has in fact increased to $> \pm 4^\circ$, which indicates Eq. 10 is a conservative estimate when the element spacing is close to 0.5λ. By judicious selection of the array element aperture field, however, the element spacing could be increased, and as a result, the number of array elements in the array feed should be able to be reduced from that predicted by Eq. 11.

Array Feed Excitation

When feeds are displaced from the central focal point, the resulting beam includes aberrations such as coma, and there is a loss of gain depending on the angle from boresight. This can be overcome to some extent by adjusting the array excitation to match the focal field, and with enough array elements, this can be done with several beams at one time or alternatively to create high performance steered beams. To obtain the excitation of a feed array more rigorously, consider an array of N apertures in the focal region of a reflector. A uniform plane wave from the direction $(\theta_\alpha, \phi_\alpha)$ $(\alpha = 1, \ldots, N_b)$, where N_b is the number of beams that are assumed incident on the reflector and hence to the array. By reciprocity, a beam in these directions produced when the array is excited appropriately. Suppose there are M modes in each aperture of the array of which there is access to only J of them through the beamforming network. Thus, there are $L = JN$ accessible ports of the MN available ports. The remaining modes will be excited indirectly through effects such as mutual coupling. As a consequence of the latter between the apertures of the array, the incident and reflected modes are related by a scattering matrix as follows:

$$\mathbf{b} = \mathbf{S}\,\mathbf{a}$$

where

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_{MN} \end{bmatrix}$$

are all the inputs including those that are inaccessible such as for high-order modes.

The normalized power density radiated in a direction $(\theta_\alpha, \phi_\alpha)$ by the reflector antenna is given by

$$\eta(\theta_\alpha, \phi_\alpha, \mathbf{v}) = \frac{Q^* Q}{P_f} \tag{12}$$

where

$$Q = \mathbf{u}^T \mathbf{v},$$

DOI 10.1007/978-981-4560-75-7_97-1

$$\mathbf{v} = \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_L \end{bmatrix}$$

is a vector of the mode amplitudes at the L input ports and

$$P_f = \mathbf{v}^{\dagger} \mathbf{\Lambda} \mathbf{v}$$

is the total radiated power of the array where $\mathbf{\Lambda} = \mathbf{P} - \mathbf{S}^{\dagger}\mathbf{P}\mathbf{S}$,

$$\mathbf{P} = \begin{bmatrix} p_1 & 0 & \cdots & 0 \\ 0 & p_1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & p_{MN} \end{bmatrix}$$

in which p_i is the power contained in mode i. The T superscript indicates the matrix transpose, the asterisk * the complex conjugate, and † is the Hermitian conjugate. The row vector

$$\mathbf{u}^T = \mathbf{t}^T \mathbf{W} \tag{13}$$

includes the effect of mutual coupling as $\mathbf{W}$ is a matrix of dimension $MN\,x\,L$ between the L input ports and the MN output ports with elements given by

$$W_{ij} = \begin{cases} 1 + S_{ii} & ; \quad i = j = 1, 2, \ldots, JN \\ S_{ij} & ; \qquad \text{otherwise} \end{cases}$$

and $\mathbf{t}$ is a vector related to the fields radiated by every aperture in the far-field direction (θ_b, ϕ_b), which for the kth element in receive mode is given by (refer to Fig. 1)

$$t_k(\theta_\alpha, \phi_\alpha) = \frac{1}{4\sqrt{P_{inc}}} \iint_{\Sigma} dS' \;\; \mathbf{e}_k \cdot \mathbf{J}_s(\theta_\alpha, \phi_\alpha | \mathbf{x}') \tag{14}$$

where $\mathbf{e}_k$ is the electric field radiated by the kth output port when all other ports are removed; P_{inc} is the power incident in the plane wave from the direction (θ_α, ϕ_α); and $\mathbf{J}_s(\theta_\alpha, \phi_\alpha | \mathbf{x}')$ is the current induced at $\mathbf{x}'$ on the reflector that is nearest to the feed from an incident wave. An equivalent expression can also be obtained in the transmit mode from the far-field radiated by the reflector due to output port k.

An exact solution exists to Eq. 12 for the maximum gain in any of the beam directions (θ_α, ϕ_α) ($\alpha = 1, \ldots, N_b$). These beams can be sequential as part of a beam scan or randomly required in a search, for instance. In each case, there is a distinct excitation vector $\mathbf{v}_\alpha$ given by

$$\mathbf{v}_\alpha = \mathbf{\Lambda}^{-1} \mathbf{u}_\alpha{}^* \tag{15}$$

where $\mathbf{v}_\alpha$ is obtained from Eq. 15 for direction (θ_α, ϕ_α). If the mutual coupling is negligible or zero, $\mathbf{\Lambda} = \mathbf{P}$ and Eq. 15 reduces to $\mathbf{v}_\alpha = \mathbf{P}^{-1}\,\mathbf{t}_\alpha^*$, which is equivalent to saying that the input amplitudes are a conjugate match to the focal region fields. This is the approximation mentioned at the beginning of this section and for obtaining the results in Fig. 3.

DOI 10.1007/978-981-4560-75-7_97-1

The excitation could also be determined by numerical means such as through optimization of particular requirements on each beam other than for maximum gain, such as through envelope constraints on the sidelobes. In order to apply envelope constraints, define N_s specified points in the coverage region. At the jth point in the region corresponding to the direction (θ_i, ϕ_i) in the far-field, let

$c_{u,j}$ = upper beam level in direction j
$c_{L,j}$ = lower beam level in direction j.

Thus, it is required that

$$c_{L,j} \le \eta\left(\theta_j, \phi_j\right) \le c_{u,j}. \tag{16}$$

Many different methods exist for finding a solution to Eq. 16. One approach is the least pth technique (Bandler and Charalambous 1972). A least pth index is defined by

$$I = H\left[\sum_{f_i>0}\left(\frac{f_i}{H}\right)^q\right]^{1/q} \tag{17}$$

where $H = \max(f_i)$, $q = \mathrm{sgn}(H)p$, and κ is the set of specifications

$$\kappa = \begin{cases} \text{all} \quad f_i \;\; if\, H < 0 \\ \text{positive}\, f_i \quad if\, H > 0 \end{cases}.$$

Equation 17 has the advantage that it will be zero if all constraints are satisfied and then optimization may be terminated. Although, in principle, any p >1 is allowable, p = 2,4 and 10 have been found useful in shaped beam synthesis. If a solution is known approximately, a higher value of p can prove useful. Following an initial estimate of the array excitation coefficients either from Eq. 15 or an earlier search, I is further minimized by one of a number of search methods such as the genetic algorithm or gradient search such as the quasi-Newton method.

Another approach to determining the array excitation is also based on knowledge of the focal plane fields and is the technique initially described by Rudge and Withers (1971). This uses the Fourier transform relation between the aperture fields and the focal plane fields. In particular, a uniform aperture distribution results in a focal region distribution in a paraboloid of the form $J_1(u)/u$ where J_1 is the first-order Bessel function. Suppose the main reflector subtends a maximum half-cone angle ψ_c from the geometric focus. It can be shown that for off-axis incidence, as in scanning, the same relationship is maintained between the aperture and the focal point when the new focal point moves off-axis. The cone angle subtended by the reflector aperture as measured from the new focal point is constant with value given by $2\psi_c$. A new focal plane is defined to be normal to the line from the new focal point bisecting the angle $2\psi_c$. The path of free motion of the feed passes through the new focus as well as the edges of the aperture plane and follows a circle with a diameter

$$f\,\sec\psi_c\left[1+\left(\frac{D}{2f}\right)\right]^2. \tag{18}$$

Once a new focal plane has been obtained, the focal field is a Fourier transform of the aperture field whatever the angle of incidence. A second Fourier transform placed at the center of the new focal region will output a uniform amplitude and a phase that is the complex conjugate of the aperture field. Therefore,

DOI 10.1007/978-981-4560-75-7_97-1

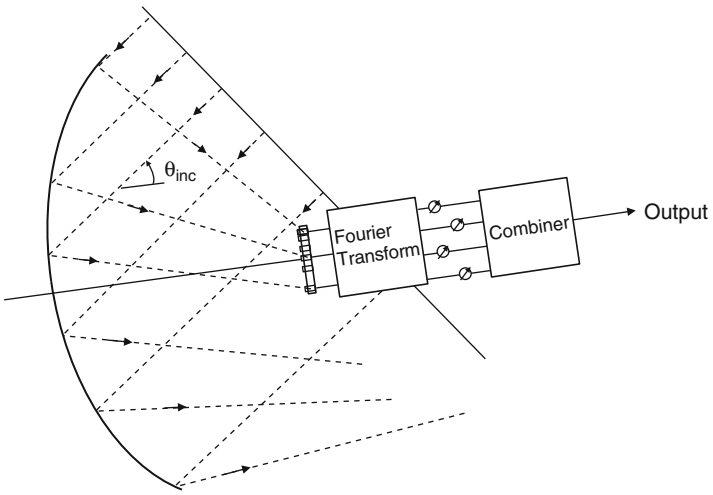

Fig. 6 Reflector with movable Fourier transform feed

the parabola performs as an ideal Fourier transformer of the off-axis incident wave for a feed at the new focal plane. Also, as the second transformer duplicates a uniform aperture field, only phase shifters are required to refocus the antenna. In practice, the second Fourier transformer is often implemented with a Butler matrix. The latter is a beamforming network that can steer the antenna beam in a specific direction in one plane depending on the input port. To create scanning in three dimensions, two Butler matrices can be combined. A single-plane scanner that utilizes a moving Fourier transform feed is illustrated in Fig. 6.

Sensitivity

Of particular importance in radio astronomy is the effective sensitivity of the instrument (Christiansen and Högbom 1969). For a single beam, the measure of sensitivity is the smallest detectable change in noise temperature, which is related to the loss in transmission line, η_t, and the overall change in the system noise temperature, $(\Delta T)_{\min}$, as follows:

$$\begin{aligned}(\Delta T_a)_{\min} &= \frac{1}{\eta_t}(\Delta T_a) \\ &= \alpha M \frac{T_{\text{sys}}}{\left(\sqrt{\Delta \nu \tau}\right)\eta_t}\end{aligned} \tag{19}$$

where T_{sys} is the system noise temperature, Δv is the bandwidth, τ is the integration time, and αM is a multiplier related to the type of detector (Christiansen and Högbom 1969) and selected from experience at a particular observatory. With a single beam telescope, only a fraction of the sky is occupied by the main beam. The remainder is called the stray factor. Therefore, over the main beam region

$$(\Delta T_b)_{\min} = \frac{1}{\eta_b}(\Delta T_a)$$

where η_b is the beam efficiency, which is the antenna efficiency for a single beam. Thus

$$(\Delta T_b)_{\min} = \alpha M \frac{T_{\text{sys}}}{\left(\sqrt{\Delta \nu \tau}\right)\eta_t \eta_b}. \tag{20}$$

DOI 10.1007/978-981-4560-75-7_97-1

The minimum detectable matched flux density is given by

$$k_B(\Delta T_b)_{\min} = A(\Delta S_m)_{\min}$$

where S_m in $Wm^{-2}Hz^{-1}$ is the flux density, ΔS_m is its change, A is the area of the aperture, and $k_B = 1.38.10^{-23}\ WHz^{-1}\text{degree}^{-1}$ is Boltzmann's constant. As a result,

$$(\Delta S_m)_{\min} = \alpha M \frac{k_B}{\left(\sqrt{\Delta v \tau}\right)\eta_t} \frac{T_{\text{sys}}}{A_{\text{eff}}} \tag{21}$$

where $A_{\text{eff}} = \eta_b A$ is the effective area. Equation 21 shows that the sensitivity is proportional $T_{\text{sys}}/A_{\text{eff}}$, which is dependent only on the antenna system.

For a multibeam telescope that has N beams, it is possible to extract N simultaneous pieces of information from a sky measurement. If the sky measurement area is Ω_{map} steradians for the multiple beams and Ω_b is the area mapped with a single beam, the survey speed time is $\tau = \left(\Omega_b/\Omega_{\text{map}}\right)\tau_s$ where τ_s is the total time taken to complete the survey of the sky with a single beam. Hence, the surveying sensitivity is defined as

$$(\Delta SS_m)_{\min} = \sqrt{\left(\Omega_b/\Omega_{\text{map}}\right)}\,(\Delta S_m)_{\min}.$$

If a map or image consists of N beams, then $\Omega_{\text{map}} \approx N\Omega_b$ and

$$(\Delta SS_m)_{\min} = \sqrt{1/N}\,(\Delta S_m)_{\min}. \tag{22}$$

Therefore, an N-beam image-forming reflector has $\sqrt{N}$ times the surveying sensitivity of a single beam instrument. However, the survey speed time is $\tau \approx (1/N)\tau_s$.

Single-Element Feeds and Associated Beamforming Networks

In some applications, clusters of feeds have proved useful for scanning over directions that can be established a priori. In that instance, feed elements of the array have their own feed network. Under computer or autonomous system control, the excitation for a cluster, or a single feed is loaded individually from one beam position to the next. One such application where one horn at a time of the array has been used very successfully is in radio astronomy. Another approach used in satellite communications is that the beamforming network has been segmented. Each segment feeds a sub-array that produces part of the shaped beam. By combining sub-arrays or switching between them, an overall shaped beam can be produced with some re-configurability that can be changed quite rapidly.

The single horn at a time in an array has been used in radio astronomy to avoid a lossy beamforming network and to maintain a low noise temperature. If the array spacing is chosen correctly, the center spacing of adjacent beams from the telescope is about a beamwidth apart. Moving the telescope through half a beamwidth and interleaving the field of view with beams fill in the coverage with relatively little loss of gain at the crossover. In the same way, several horns in the cluster could be combined, but again, this is not used because of losses and higher noise temperature. As will be seen in section "Phased Array Feeds," recent developments have enabled feeds to be developed where low-loss beamforming can be achieved.

DOI 10.1007/978-981-4560-75-7_97-1

In relation to multibeam feeds creating single beams, the Parkes Observatory in Australia, the Arecibo Observatory in Puerto Rico, and the Lovell radio telescope in the UK all have used such arrays in L- and C-bands. The feed horns and spacing of the elements in these arrays are different in each case due to different focal lengths of the reflectors and different frequency bands. However, where possible the horn input diameters have been chosen to be the same to enable the same array of cooled low-noise receivers to be shared. At the observatories mentioned, reflectors are prime focus fed, and therefore, for efficient illumination, wide beamwidth elements are required. Both the Parkes and Lovell telescopes use prime-focus feeds, although the latter dish is deeper (the f/D of Lovell is 0.3 while for Parkes $f/D = 0.41$). The elements of L- and C-feed arrays for Parkes are stepped circular horns. At C-band, the aperture diameter is about 1.05λ, and element spacing in the array is 1.16λ. They were based on the Arecibo multibeam L-band feed array, which was a refinement of the first Parkes L-band design (Bird 1994). The stepped circular horn is unsuitable for a deep dish such as the Lovell telescope, and therefore, coaxial horns, which have a wider beamwidth, were employed on Lovell (Bird 1997).

The main parameters in the design of a fixed multibeam feed are the input waveguide diameter, the aperture geometry to achieve the required edge illumination, the peak cross-polarization level, and a matching network to give a good input match to the receiver. The maximum dimension of elements of the array should be small enough so that there is only about 6 dB between successive beams, and loss of gain at the edge of the outermost feeds is not too significant. This limits the aperture diameter to be $0.8 - 1.2\lambda$. The close spacing between array elements eliminates from consideration many well-known techniques for improving pattern symmetry using the flange such as parasitic rings or back-set corrugated flanges. Nevertheless, from the properties of circular or coaxial apertures, the beam is quite axisymmetric, and there is low cross polarization at a frequency given by $kb \approx 1.25(a/b)^2 - 3.3(a/b) + 3.6$ where a and b are the inner and outer conductor radii. In addition, through the use of steps and irises inside the waveguide, successful feed elements have been produced.

The feed elements in satellite communications have ranged from uniform circular waveguides to tapered rectangular horns. The latter are often preferred in order to maximize the packing density. Also, the latter produces a uniform illumination in the E-plane, and with the excitation of high-order modes or dielectric loading, the aperture field in the H-plane can also be made almost uniform. The element spacing in shaped beams for satellites can be greater as the coverage of a field of view is of importance. The feed arrays can consist of more than 200 elements. The associated beamforming network needs to provide the correct amplitude and phase to each element, and this can be achieved with low-loss power dividers and lengths of transmission line.

To carry out the design of the shaped beam, the reflector, the array, and the beamforming network, a suite of computer programs should be available for the purpose. For instance, the software should be able to analyze arrays in a rigorous manner taking into account such effects as mutual coupling by numerical methods or mode-matching techniques. The latter are sometimes preferred for the feeder because they accurately model the internal geometry of circular and rectangular horns as a series of stepped waveguides and can also separately include the effects of mutual coupling between horns. To minimize extraneous signals reaching the feed and introducing noise, the array is often terminated in a large ground plane. The effect of a finite size array can be included in the radiation pattern by the method of physical theory of diffraction or by the method of moments.

The analysis of the reflector is usually based on the method of physical optics, and this is linked to the feed array software to determine the shaped beams. The beamforming network can be designed separately from the reflector and feed array using techniques based on numerical methods such as finite elements. The results obtained in this way are very accurate as they are able to include variations that are part of the fabrication such as surface imperfections, bends, and twists.

Phased Array Feeds

Phased array feeds (PAF) have been used for feeds for rapid beam steering and in situations usually in reception where the system noise temperature has not been important. The feeding network used to combine the elements of the array in the appropriate amplitude and phase has a significant loss, and this contributes to the overall noise temperature of the antenna. Applications of array feeds have varied widely from the production of multiple beams by individual elements of the array, to a fixed shaped beam such as from a geostationary satellite, and to a fully steered beam with a phased array for rapid tracking such as for missile tracking. In all cases, the array elements must be excited in the correct amplitude and phase by a beamforming network. These can be constructed from microstrip line, coaxial components, or waveguide structures depending on the requirement of low loss.

PAFs have received increased attention over the past decade, particularly for high-sensitivity receiving applications to radio astronomy (Fisher and Bradley 2000). PAFs produce multiple simultaneous antenna beams throughout a contiguous field of view (FoV). They use a dense array of antenna elements, typically spaced by less than half the minimum wavelength. This spacing is important for reception of information in incident fields and control of beam radiation patterns. Various element types have been used, including dipole, tapered slot or Vivaldi, and checkerboard. The PAF beams are formed typically by digital beamforming. Thus, the individual array-element signals are digitized and combined by complex weighting and summing independently in multiple frequency channels. This process allows control of reflector illumination, spillover, and other beam properties such as spacing, sidelobes, and cross polarization. The close spacing of the array elements implies significant mutual coupling, and this requires co-design of the array elements, front-end amplifiers, and beamforming. Beams can be optimized to maximize sensitivity or signal-to-noise ratio and produce wide FoV. Some applications also require operation over large frequency ranges >2:1. A significant benefit for radio astronomy is increased survey speed. In this section, introductory formulations of PAF concepts are provided and also some illustrative examples of recent PAF systems.

Incident Field Representation

The design of PAFs for high-sensitivity receiving application requires use of models of the incident field. The PAF incident field contains both desired signal and noise components and depends on the geometry of the reflectors used to concentrate the signal energy.

The incident field is represented in terms of a spectrum of plane waves produced by an equivalent current in the far-zone of the antenna. Thus, the incident electric field is

$$\mathbf{E}(\mathbf{r}) = \frac{-jk\eta_o\, e^{-jk\,r'}}{4\pi\, r'} \int_{S'} dS' \;\; \left[J_p(\mathbf{r}')\hat{\mathbf{p}}(\mathbf{r}') + J_q(\mathbf{r}')\hat{\mathbf{q}}(\mathbf{r}')\right] e^{jk\mathbf{r}\cdot\hat{\mathbf{r}}'} \tag{23}$$

where $\mathbf{r}$ is the position vector of the observation point, the integral is over a spherical surface S' in the far-zone of the antenna, dS' is the element of area on S', $\mathbf{r}'$ is the position vector of the point on S', $\hat{\mathbf{r}}' = \mathbf{r}'/r', r' = |\mathbf{r}'|$, $\hat{\mathbf{p}}$ and $\hat{\mathbf{q}}$ are orthogonal unit vectors corresponding to co- and cross polarization, respectively, each tangential to S', and J_p and J_q are the corresponding current components. The current components are random variables with spatial independence, and they are represented in terms of temperatures according to

$$\mathrm{E}\begin{bmatrix} J_p(r_1')\overline{J}_p(r_2') & J_p(r_1')\overline{J}_q(r_2') \\ J_q(r_1')\overline{J}_p(r_2') & J_q(r_1')\overline{J}_q(r_2') \end{bmatrix} = \delta(r_1' - r_2')\,\frac{8k_B}{\eta_o}\begin{bmatrix} T_{pp}(r_1') & T_{pq}(r_1') \\ T_{qp}(r_1') & T_{qq}(r_1') \end{bmatrix} \tag{24}$$

DOI 10.1007/978-981-4560-75-7_97-1

where E(.) is the expectation function, r_1' and r_2' are any two points on S', δ is the delta function with respect to dS', and the terms in the matrix on the right are equivalent temperatures in degrees Kelvin.

PAF Sensitivity Formulation

Figure 7 shows a Norton-equivalent network representation of the PAF and first-stage low-noise amplifiers (LNAs). Mutual coupling between the array ports is represented by the admittance matrix Y_A. Fields incident on the antenna and noise associated with loss in the antenna are represented by equivalent sources I_i each equal to the current at the corresponding port when all ports are short circuited. Noise generated in the LNA is represented by an equivalent source comprising the correlation admittance Y_c and uncorrelated voltage and current sources with equivalent resistance R_n and conductance G_n, respectively. All LNAs in the array are of a common design. Subsequent stages of the receiver then produce beamformed outputs that take the form

$$V_{\text{beam}} = w^T V^{LNA} \tag{25}$$

where V^{LNA} and w are column vectors of LNA output voltage phasors and weighting coefficients, respectively.

A sensitivity measure that is related to Eq. 21 is expressed as

$$\frac{A_{\text{eff}}}{T_{\text{sys}}} = \frac{k_B}{S_m}\ \text{SNR} \tag{26}$$

where SNR is the signal-to-noise ratio of the beamformed response of the antenna given by

$$\text{SNR} = \frac{E\left(|V_{\text{beam}}^{\text{signal}}|^2\right)}{E\left(|V_{\text{beam}}^{\text{noise}}|^2\right)}, \tag{27}$$

where $E(.)$ is the expectation function. In Eq. 26 S_m is the power density of the plane-wave field incident on the antenna.

An expression for the array sensitivity Eq. 26 can be derived from the network of Fig. 7. The SNR is readily found as

$$\text{SNR} = \frac{1}{8k_B T_0} \frac{|\left(I^{\text{signal}}\right)^T \phi|^2}{\overline{\phi}^T G_{\text{tot}} \phi} \tag{28}$$

where T_0 is the thermodynamic temperature of the antenna and LNAs, I^{signal} is the vector of short-circuit currents representing the signal field incident on the antenna, the overbar denotes the complex conjugate, and the vector ϕ is related to the beamformer weight vector w through

$$\phi = P^T w \qquad P = Q(Y_A + Y_{in}U)^{-1} \tag{29}$$

where Y_{in} is the input admittance of the output-terminated LNA, U is the identity matrix, and Q is the matrix that maps the LNA input voltages into the LNA output voltages that are selected for beamforming. If all LNA output voltages are selected for beamforming, then Q is a diagonal matrix. Figure 21 (below) illustrates another important case where the LNAs are paired and the differential output voltages of the

DOI 10.1007/978-981-4560-75-7_97-1

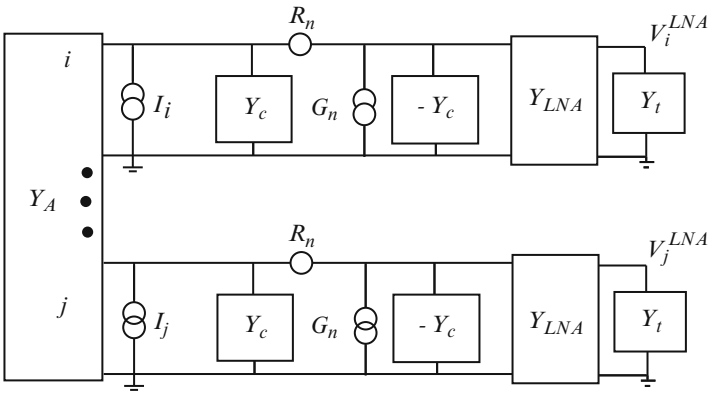

Fig. 7 Norton-equivalent network of the array and low-noise amplifiers

pairs are beamformed, in which case Q is an M/2 × M matrix where M/2 is the number of LNA pairs. This case is considered in the application section.

The matrix G_{tot} in Eq. 28 can be expressed as

$$G_{\text{tot}} = G_{\text{ext}} + G_{\text{loss}} + G_{\text{rec}} \tag{30}$$

where the contributions are due, respectively, to the external noise incident on the antenna, the noise associated with loss in the antenna, and the noise produced by the LNAs. These terms may be expressed as

$$(G_{\text{ext}})_{i,j} = \frac{1}{T_0\,\eta_0}\int_{S'} dS' \left(\overline{\mathbf{E}}_{i,p} \quad \overline{\mathbf{E}}_{i,q}\right) T \begin{pmatrix} \mathbf{E}_{j,p} \\ \mathbf{E}_{j,q} \end{pmatrix} \qquad T = \begin{bmatrix} T_{pp} & \overline{T}_{pq} \\ \overline{T}_{qp} & T_{qq} \end{bmatrix} \tag{31}$$

$$G_{\text{loss}} = G_A - G_{\text{ext}}\Big|_{T=\begin{bmatrix} T_0 & 0 \\ 0 & T_0 \end{bmatrix}} \tag{32}$$

$$G_{\text{rec}} = (F_{\min} - 1)G_A + \quad N\left(\overline{Y}_A^T - \overline{Y}_{\min}U\right)G_{\min}^{-1}(Y_A - Y_{\min}U) \tag{33}$$

where $\mathbf{E}_i$ is the electric field radiated by the array when 1 V exists at port i while all other ports are short circuited and $G_A = \Re Y_A$. Equation 31 follows from the incident field representation Eq. 23 and the reciprocity theorem. In Eq. 33, $F_{\min}$ is the minimum noise figure of the LNA, obtained with the LNA input connected to source of admittance $Y_{\min} = G_{\min} + jB_{\min}$ and $N = R_n G_{\min}$. The quantities $F_{\min}$ and N are Lange invariants, so named because they remain constant under the addition of any lossless impedance-transforming networks to the input or output circuits of the LNA. Thus the noise-match admittance $Y_{\min}$ is the main parameter that can be varied through design of the LNA. The Lange constants are related by

$$(F_{\min} - 1)/4 < N < (F_{\min} - 1)/2. \tag{34}$$

The left side of the inequality in Eq. 34 is a general result, whereas the right inequality has been derived for LNAs composed of field effect or bipolar junction transistors.

In Eq. 28, the vector I^{signal} of short-circuit currents representing the signal field incident on the antenna can be computed from the reciprocity relation

DOI 10.1007/978-981-4560-75-7_97-1

$$I_i^{\text{signal}} = \hat{\mathbf{p}} \cdot \mathbf{E}_i(\mathbf{r}') \sqrt{2\eta_0 S_m} \frac{4\pi |\mathbf{r}'| \exp(jk|\mathbf{r}'|)}{-jk\eta_0}. \tag{35}$$

Equation 35 applies to a plane wave incident from the direction of the far-field position vector $\mathbf{r}'$, with electric field polarized in the direction of the unit vector $\hat{\mathbf{p}}$ and power density S_m.

Array and Amplifier Matching

Of great interest in practice is the maximum SNR obtainable by optimizing the beamforming coefficients and the LNA noise-match admittance $Y_{\min}$. Equations for the optimum values can be found by equating to zero the derivatives of Eq. 26, where the SNR function is given by Eq. 28, with respect to the real and imaginary parts of $Y_{\min}$ and the elements of the beamforming weight vector w. This procedure results in the equations

$$B_{\min} = \frac{\overline{\phi}^T B_A \phi}{\overline{\phi}^T \phi} \quad G_{\min} = \sqrt{\frac{\overline{\phi}^T \overline{Y}_A^T Y_A \phi}{\overline{\phi}^T \phi} - B_{\min}^2} \tag{36}$$

and

$$w = \left(\overline{P} G_{\text{tot}} P^T\right)^{-1} \overline{P} \overline{I}^{\text{signal}} \tag{37}$$

where $B_A = \Im Y_A$. Equations 36 and 37 are readily solved in practice by a small number of iterations.

Spatial-Filtering Interpretation of PAF Beamforming

To show how high-sensitivity operation of the array can be obtained when the elements are closely spaced with large mutual coupling, the equations relating the currents and voltages at the array ports are recast as follows:

$$\begin{aligned} I_{m,n}^x &= \sum_{k,l} Y_{m-k,n-l}^{x,x} V_{k,l}^x + \sum_{p,q} Y_{m-p,n-q}^{x,y} V_{p,q}^y \\ I_{m,n}^y &= \sum_{k,l} Y_{m-k,n-l}^{y,x} V_{k,l}^x + \sum_{p,q} Y_{m-p,n-q}^{y,y} V_{p,q}^y. \end{aligned} \tag{38}$$

In Eq. 38, $I_{m,n}^x$ and $V_{m,n}^x$ are the current and voltage at the x polarized array port at the point $(x,y) = (m,n)\delta/2$, where δ is the spacing of the like-polarized ports and (m, n) are the even positive and negative integers or zero. For the y polarized ports, the summations in Eq. 38 run over the odd positive and negative integers. Equation 38 is possible since, in the regular periodic array, the mutual admittances are functions only of the vector separation of the array ports. Equation 38 becomes the algebraic equations

$$\begin{bmatrix} \hat{I}^x(u,v) \\ \hat{I}^y(u,v) \end{bmatrix} = \begin{bmatrix} \hat{Y}^{x,x}(u,v) & \hat{Y}^{x,y}(u,v) \\ \hat{Y}^{y,x}(u,v) & \hat{Y}^{y,y}(u,v) \end{bmatrix} \begin{bmatrix} \hat{V}^x(u,v) \\ \hat{V}^y(u,v) \end{bmatrix} \tag{39}$$

where the Fourier transforms are defined as

$$\hat{I}^x(u,v) = \sum_{m,n} I_{m,n}^x e^{-jk(mu+nv)\delta/2}. \tag{40}$$

DOI 10.1007/978-981-4560-75-7_97-1

The SNR defined by Eq. 27 can then be re-expressed as

$$\mathrm{SNR} = \frac{1}{8k_B T_0} \frac{\left| \iint dudv \ \left(\hat{I}^{\mathrm{signal}}(-u, -v) \right)^T \hat{\phi}(u, v) \right|^2}{\iint dudv \ \hat{\phi}^{\dagger}(u, v) \hat{G}_{\mathrm{tot}}(u, v) \hat{\phi}(u, v)} \tag{41}$$

and, analogous to Eq. 30,

$$\hat{G}_{\mathrm{tot}}(u, v) = \hat{G}_{\mathrm{ext}}(u, v) + \hat{G}_{\mathrm{loss}}(u, v) + \hat{G}_{\mathrm{rec}}(u, v) \tag{42}$$

and the LNA contribution is given by

$$\begin{aligned} \hat{G}_{\mathrm{rec}}(u, v) = (F_{\min} - 1) \left[\hat{Y}(u, v) + \hat{Y}^{\dagger}(u, v) \right] / 2 \\ + N \left[\hat{Y}^{\dagger}(u, v) - \overline{Y}_{\min} U \right] G_{\min}^{-1} \left[\hat{Y}(u, v) - Y_{\min} U \right] \end{aligned} \tag{43}$$

where $\hat{Y}(u, v)$ is a 2×2 matrix in Eq. 43 and U is the 2×2 identity matrix. With optimum beamforming for maximum SNR, the optimum value of the spectral function in Eq. 41 is readily obtained as

$$\hat{\phi}(u, v) = \hat{G}_{\mathrm{tot}}^{-1}(u, v) \overline{\hat{I}}^{\mathrm{signal}}(-u, -v) \tag{44}$$

with the maximum SNR given by

$$\mathrm{SNR} = \frac{1}{8k_B T_0} \iint dudv \ \hat{I}^{\mathrm{signal}}(u, v)^T \hat{G}_{\mathrm{tot}}^{-1}(u, v) \overline{\hat{I}}^{\mathrm{signal}}(u, v). \tag{45}$$

The admittance function and short-circuit current given in Eqs. 39 and 41 have been computed by numerically solving the integral equation for the current induced on the self-complementary array illustrated in Fig. 8. Figure 9 shows the minimum eigenvalue of the matrix $\hat{G}_{\mathrm{rec}}(u, v)$ and the corresponding integrand in Eq. 45. For comparison, Fig. 10 gives the corresponding results for an array with twice the element density. Increasing the density results in more LNA noise in the spatial frequency spectrum. However, the additional noise occurs outside the spatial frequency bandwidth of the signal, and therefore the resulting sensitivity is high in both cases, provided that accurate optimal beamforming is applied. A detailed design example of a connected array design that was developed for the Australian SKA Pathfinder (ASKAP) application is described in section "Australian SKA Pathfinder (ASKAP) PAF."

Survey Speed of a PAF Interferometer

The survey speed of next-generation radio telescopes such as the Square Kilometre Array (SKA) will be increased greatly by the use of phased array feeds (PAFs). In PAFs, the signals of a dense array of antenna elements are digitized and beamformed, producing multiple simultaneous antenna beams of high sensitivity throughout the field of view. In this section, an early analysis of a connected array PAF for ASKAP (Bunton and Hay 2010) is extended to include optimum linear combining of PAF beam correlations with

DOI 10.1007/978-981-4560-75-7_97-1

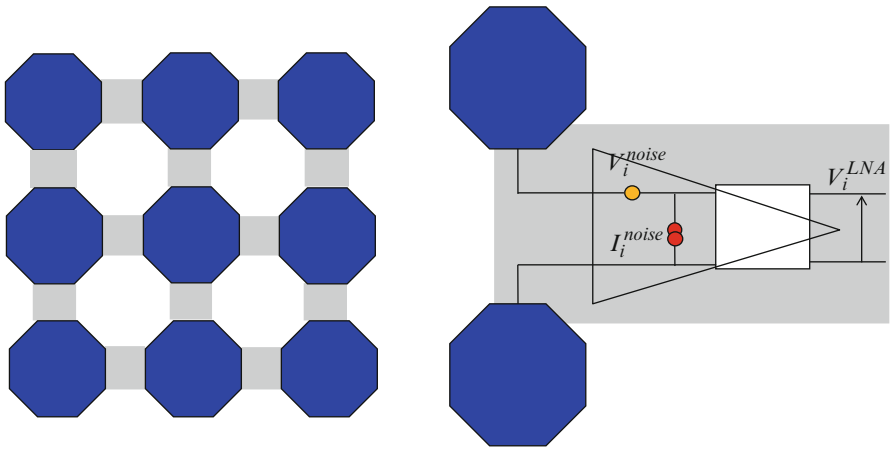

Fig. 8 Schematic of self-complementary patch array with adjacent patch corners connected by a low-noise amplifier (LNA). The LNA produces noise, represented by equivalent current and voltage sources at the input, and its effect on signals is characterized by an admittance matrix Y

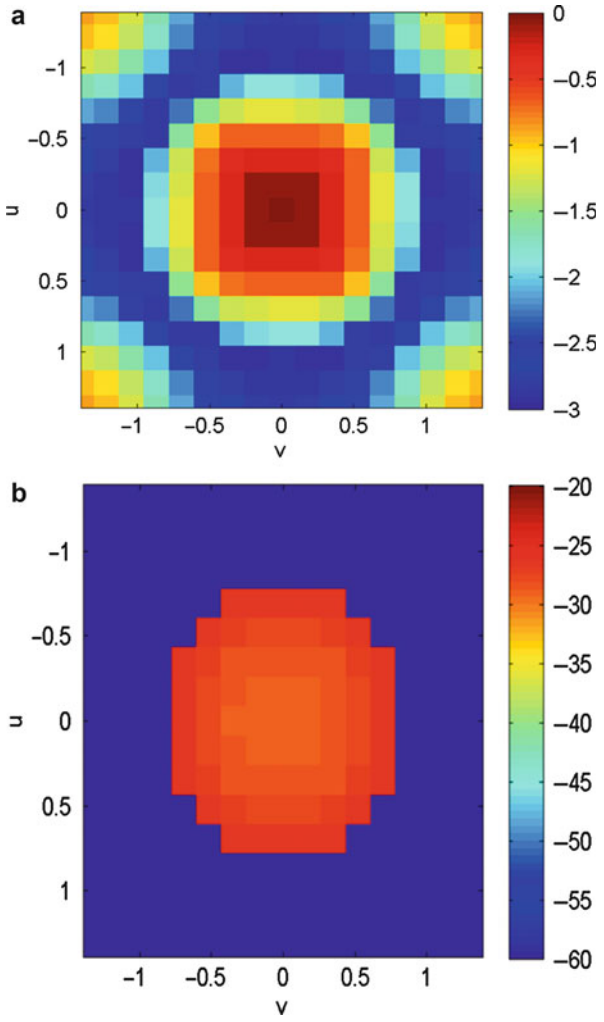

Fig. 9 Minimum eigenvalue of spectral-domain receiver noise matrix given in Eq. 43(**a**) and optimum spectral-domain sensitivity distribution given by the integrand in Eq. 45(**b**) for array with 90 mm element spacing at 1.2GHz. The quantities plotted are magnitudes in dB.

maximum selective sensitivity to all coherence parameters of the incident field. As illustrated in Fig. 11, the ASKAP telescope is an interferometer using PAFs in each antenna. The PAFs expand the field of view by creating multiple simultaneous antenna beams. The simultaneous PAF beams have correlated noise due to common low-noise amplifiers. A general treatment of this noise is provided in the next section.

Formulation

Problem Definition Let $\mathbf{V}^a$ and $\mathbf{V}^b$ be column vectors containing the element voltages at PAFs of antennas a and b, respectively. These vectors are regarded as random variables. Each PAF produces a set of beams in polarization pairs or

$$\tilde{\mathbf{V}}_i^a = \begin{pmatrix} V_{i,1}^a \\ V_{i,2}^a \end{pmatrix} = \left(\mathbf{w}_i^a\right)^T \mathbf{V}^a \quad \mathbf{w}_i^a = \begin{pmatrix} \mathbf{w}_{i,1}^a & \mathbf{w}_{i,2}^a \end{pmatrix} \tag{46}$$

where $\mathbf{w}_{i,1}^a$ are column vectors of complex weights and i is an index of beam directions. It is assumed that the correlator produces sample averages

$$\mathrm{A}\left[\tilde{\mathbf{V}}_i^a \left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right] = \frac{1}{M}\sum_{m=1}^{M} \tilde{\mathbf{V}}_{i,m}^a \left(\tilde{\mathbf{V}}_{i,m}^b\right)^\dagger \tag{47}$$

of M time samples of the 2×2 cross products of antenna a and b beam voltages at each beam direction i, with the sample vectors $\tilde{\mathrm{V}}_{i,m}^a$ independent in the sample index m. The correlator outputs Eq. 47 have expected values

$$\hat{\mathrm{A}}\left(\tilde{\mathbf{V}}_i^a \left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right) = E\left[\mathrm{A}\left(\tilde{\mathbf{V}}_i^a \left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right)\right]$$

$$= \int d\Omega \;\; \mathbf{J}_i^a \mathbf{C} \left(\mathbf{J}_i^b\right)^\dagger \exp\left[jk\left(\mathbf{r}^a - \mathbf{r}^b\right) \cdot \left(\hat{\mathbf{s}} - \hat{\mathbf{s}}_0\right)\right] \tag{48}$$

where the integral is over all directions of propagation of plane-wave components of the incident field, $\hat{\mathrm{s}}$ is the unit vector in the direction from which the plane wave arrives,

$$\mathbf{C} = E\begin{bmatrix} e_1\overline{e}_1 & e_1\overline{e}_2 \\ e_2\overline{e}_1 & e_2\overline{e}_2 \end{bmatrix} \tag{49}$$

is the coherence matrix of the electric-field components e_1 and e_2 in orthogonal directions p and q, respectively, orthogonal to $\hat{\mathbf{s}}$, $\mathbf{r}^a$ is the position vector of antenna a, $\hat{\mathbf{s}}_0$ represents a reference direction in the field of view, and $d\Omega$ is the element of solid angle. In Eq. 48

$$\mathbf{J}_i^a = \begin{bmatrix} J_{i,1,1}^a & J_{i,1,2}^a \\ J_{i,2,1}^a & J_{i,2,2}^a \end{bmatrix} = \begin{pmatrix} \left(\mathbf{w}_{i,1}^a\right)^T \\ \left(\mathbf{w}_{i,2}^a\right)^T \end{pmatrix} \begin{pmatrix} \mathbf{V}_1^a & \mathbf{V}_2^a \end{pmatrix} \tag{50}$$

where $\mathbf{V}_1^a$ and $\mathbf{V}_2^a$ are column vectors of element voltages produced at the PAF of antenna a by reference waves arriving from the direction $\hat{\mathbf{s}}$ with electric fields of 1 V/m polarized in the directions p and q, respectively. The coherence matrix $\mathbf{C}$ in Eq. 49 satisfies

$$\mathbf{C} = \mathbf{U}^\dagger \mathbf{C}' \mathbf{U} \quad \mathbf{U} = \begin{bmatrix} U_{1,1} & U_{1,2} \\ U_{2,1} & U_{2,2} \end{bmatrix} = \begin{bmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{bmatrix} \tag{51}$$

where $\mathbf{C}'$ is the coherence matrix of the field components in any other orthogonal directions p' and q' obtained by rotating p and q by any angle ϕ.

The correlator outputs in Eq. 47 also contain noise. The main sources of such noise are the PAF front-end amplifiers, the ground around the antennas, and the noise associated with loss in the antennas. This noise is large compared to astronomical signals. As a first step in estimating the coherence matrices of the sources in the field of view, the aim is to find a linear transformation of the $A[\tilde{\mathrm{V}}_i^a(\tilde{\mathrm{V}}_i^b)^\dagger]$ that approximates

the coherence matrix $\mathbf{C}'$ of the point source with minimum error due to the noise. As a result, a 2×2 response matrix is given by

$$\mathbf{R}^{a,b} = \begin{bmatrix} R_{1,1}^{a,b} & R_{1,2}^{a,b} \\ R_{2,1}^{a,b} & R_{2,2}^{a,b} \end{bmatrix} \tag{52}$$

which satisfies the requirement for the expected value

$$\hat{\mathbf{R}}^{a,b} = \phi^{a,b}\mathbf{C}' \quad \phi^{a,b} = \exp\left(jk\left(\mathbf{r}^a - \mathbf{r}^b\right) \cdot \hat{\mathbf{s}}\right) \tag{53}$$

and with each element a linear combination of all elements of the $A[\tilde{\mathbf{V}}_i^a(\tilde{\mathbf{V}}_i^b)^\dagger]$. The general linear transformation can be expressed as

$$\mathbf{R}^{a,b} = \sum_i \begin{bmatrix} \overline{\mathbf{L}}_i^{1,1} \bullet A\left[\tilde{\mathbf{V}}_i^a\left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right] & \overline{\mathbf{L}}_i^{1,2} \bullet A\left[\tilde{\mathbf{V}}_i^a\left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right] \\ \overline{\mathbf{L}}_{i,}^{2,1} \bullet A\left[\tilde{\mathbf{V}}_i^a\left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right] & \overline{\mathbf{L}}_i^{2,2} \bullet A\left[\tilde{\mathbf{V}}_i^a\left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right] \end{bmatrix} \tag{54}$$

where

$$\mathbf{L}_i^{\lambda,\mu} = \begin{bmatrix} L_{i,1,1}^{\lambda,\mu} & L_{i,1,2}^{\lambda,\mu} \\ L_{i,2,1}^{\lambda,\mu} & L_{i,2,2}^{\lambda,\mu} \end{bmatrix} \tag{55}$$

are 2×2 matrices, the overbar denotes the complex conjugate, and the dot denotes summation of the products of all pairs of corresponding elements. The expected value of the elements of $\mathbf{R}^{a,b}$ are readily obtained as

$$\hat{R}_{\lambda,\mu}^{a,b} = \sum_i \overline{\mathbf{L}}_i^{\lambda,\mu} \bullet \hat{\mathrm{A}}\left[\tilde{\mathbf{V}}_i^a\left(\tilde{\mathbf{V}}_i^b\right)^\dagger\right]. \tag{56}$$

Using $\mathbf{X} \bullet \mathbf{Y} = \mathrm{Tr}(\mathbf{X}^t\mathbf{Y}) = \mathrm{Tr}(\mathbf{Y}\mathbf{X}^t)$, where $\mathrm{Tr}(x)$ is the trace of x and the identity is applicable to any matrices $\mathbf{X}$ and $\mathbf{Y}$ of equal size, the elements of $\hat{\mathbf{R}}^{a,b}$ can be recast as

$$\begin{aligned} \hat{R}_{\lambda,\mu}^{a,b} &= \left[\sum_i \left(\mathbf{J}_i^a\right)^T \overline{\mathbf{L}}_i^{\lambda,\mu} \overline{\mathbf{J}}_i^b\right] \bullet \mathbf{C} \\ &= \left[\sum_i \left(\mathbf{J}_i^a\right)^T \overline{\mathbf{L}}_i^{\lambda,\mu} \overline{\mathbf{J}}_i^b\right] \bullet \left(\mathbf{U}^\dagger \mathbf{C}' \mathbf{U}\right) \\ &= \left\{\overline{\mathbf{U}}\left[\sum_i \left(\mathbf{J}_i^a\right)^T \overline{\mathbf{L}}_i^{\lambda,\mu} \overline{\mathbf{J}}_i^b\right] \mathbf{U}^T\right\} \bullet \mathbf{C}' \end{aligned} \tag{57}$$

times $\phi^{a,b}$. The transformation requirement Eq. 53 can therefore be expressed by the equations

DOI 10.1007/978-981-4560-75-7_97-1

$$\begin{aligned}
\sum_i \left[\left(\mathbf{J}_i^a\right)^\dagger \mathbf{L}_i^{1,1} \mathbf{J}_i^b \right] &= \mathbf{U}^\dagger \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \mathbf{U} \\
\sum_i \left[\left(\mathbf{J}_i^a\right)^\dagger \mathbf{L}_i^{1,2} \mathbf{J}_i^b \right] &= \mathbf{U}^\dagger \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \mathbf{U} \\
\sum_i \left[\left(\mathbf{J}_i^a\right)^\dagger \mathbf{L}_i^{2,1} \mathbf{J}_i^b \right] &= \mathbf{U}^\dagger \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \mathbf{U} \\
\sum_i \left[\left(\mathbf{J}_i^a\right)^\dagger \mathbf{L}_i^{2,2} \mathbf{J}_i^b \right] &= \mathbf{U}^\dagger \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \mathbf{U}.
\end{aligned} \tag{58}$$

Equation 58 can be written compactly as

$$\sum_{j,\alpha,\beta} P_{(x,y),(j,\alpha,\beta)} L_{j,\alpha,\beta}^{\lambda,\mu} = Y_{(x,y)}^{\lambda,\mu} \tag{59}$$

where

$$P_{(x,y),(j,\alpha,\beta)} = \overline{J}_{j,\alpha,x}^a J_{j,\beta,y}^b Y_{(x,y)}^{\lambda,\mu} = \left(\boldsymbol{\delta}_x\right)^T \mathbf{U}^\dagger \boldsymbol{\delta}_\lambda \left(\boldsymbol{\delta}_\mu\right)^T \mathbf{U} \boldsymbol{\delta}_y \tag{60}$$

$$\boldsymbol{\delta}_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \boldsymbol{\delta}_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

The aim is to solve Eq. 59 and minimize the variance due to noise in each element of $\mathbf{R}^{a,b}$.

Expression for Variance of the Coherence Matrix Estimate The variances are obtained as follows. From Eq. 57, it can be found that

$$R_{\lambda,\mu}^{a,b} - \hat{R}_{\lambda,\mu}^{a,b} = \sum_i \overline{\mathbf{L}}_i^{\lambda,\mu} \bullet \left\{ \mathrm{A}\left[\tilde{\mathbf{V}}_i^a \left(\tilde{\mathbf{V}}_i^b \right)^\dagger \right] - \hat{\mathrm{A}}\left[\tilde{\mathbf{V}}_i^a \left(\tilde{\mathbf{V}}_i^b \right)^\dagger \right] \right\}. \tag{61}$$

Since the samples at different times are uncorrelated,

$$\mathrm{E}|R_{\lambda,\mu}^{a,b} - \hat{R}_{\lambda,\mu}^{a,b}|^2 = \frac{1}{M} \mathrm{E}|\sum_i \overline{\mathbf{L}}_i^{\lambda,\mu} \bullet \left\{ \left[\tilde{\mathbf{V}}_i^a (\tilde{\mathbf{V}}_i^b)^\dagger \right] - \mathrm{E}\left[\tilde{\mathbf{V}}_i^a (\tilde{\mathbf{V}}_i^b)^\dagger \right] \right\}|. \tag{62}$$

Assuming Gaussian distributed random variables, Eq. 62 can be simplified by expanding into a double sum and applying a known result on the expectation of the product of four Gaussian random variables (Janssen and Stoica 1987). Thus, the variance of the elements of $\mathbf{R}^{a,b}$ can then be obtained as

$$\mathrm{E}|R_{\lambda,\mu}^{a,b} - \hat{R}_{\lambda,\mu}^{a,b}|^2 = \frac{1}{M} \sum_{i,j} \sum_{x,y} \sum_{\alpha,\beta} \left[L_{i,x,y}^{\lambda,\mu} E\left(\overline{\tilde{\mathbf{V}}}_{i,x}^a \tilde{\mathbf{V}}_{j,\alpha}^a \right) E\left(\tilde{\mathbf{V}}_{i,y}^b \overline{\tilde{\mathbf{V}}}_{j,\beta}^b \right) \overline{L}_{j,\alpha,\beta}^{\lambda,\mu} \right] \tag{63}$$

where

DOI 10.1007/978-981-4560-75-7_97-1

$$E\left(\overline{\tilde{\mathbf{V}}}^{a}_{i,x}\tilde{\mathbf{V}}^{a}_{j,\alpha}\right) = \left(\mathbf{w}^{a}_{i,x}\right)^{\dagger} E\left(\overline{\mathbf{V}}^{a}(\mathbf{V}^{a})^{T}\right)\mathbf{w}^{a}_{j,\alpha}$$
$$E\left(\overline{\mathbf{V}}^{a}(\mathbf{V}^{a})^{T}\right) = 8k_B T_0 \mathbf{G}^{a}_{tot} \tag{64}$$

in which $\mathbf{G}^{a}_{\text{tot}}$ is the mutual conductance matrix of the PAF of antenna a (Hay 2010) and T_0 is the thermodynamic temperature of the antennas. Equation 63 is compactly written as

$$\mathrm{E}|R^{a,b}_{\lambda,\mu} - \hat{R}^{a,b}_{\lambda,\mu}|^2 = \frac{1}{M}\sum_{i,x,y}\sum_{j,\alpha,\beta} L^{\lambda,\mu}_{i,x,y}\Lambda_{(i,x,y),(j,\alpha,\beta)}\overline{L}^{\lambda,\mu}_{j,\alpha,\beta} \tag{65}$$

where

$$\Lambda_{(i,x,y),(j,\alpha,\beta)} = (8k_B T_0)^2 \times \left(\mathbf{w}^{a}_{i,x}\right)^{\dagger}\mathbf{G}^{a}_{\text{tot}}\mathbf{w}^{a}_{j,\alpha} \times \overline{\left(\mathbf{w}^{b}_{i,y}\right)^{\dagger}\mathbf{G}^{b}_{\text{tot}}\mathbf{w}^{b}_{j,\beta}} \tag{66}$$

The mutual conductance matrix $\mathbf{G}^{a}_{\text{tot}}$ is computed as the sum of three terms

$$\mathbf{G}^{a}_{\text{tot}} = \mathbf{G}^{a}_{\text{external}} + \mathbf{G}^{a}_{\text{loss}} + \mathbf{G}^{a}_{\text{receiver}}$$

representing, respectively, the effects of the external noise field incident on the antenna, noise associated with loss in the antenna, and noise produced by the low-noise amplifiers in the PAF. The component matrices are obtained by detailed modeling of the antenna electromagnetic and front-end electronic system.

Minimizing the Variance of the Coherence Matrix Estimate The solution to the problem of finding the $L^{\lambda,\mu}_{j,\alpha,\beta}$ that minimize the variance Eq. 65 subject to the transformation requirement Eq. 53, expressed by the linear system Eq. 59, can be derived in the form

$$\overline{L}^{\lambda,\mu}_{j,\alpha,\beta} = \sum_{r,s} H_{(r,s),(j,\alpha,\beta)} c^{\lambda,\mu}_{(r,s)} H_{(r,s),(j,\alpha,\beta)} = \sum_{i,x,y} \Lambda^{-1}_{(j,\alpha,\beta),(i,x,y)} P_{(r,s),(i,x,y)} c^{\lambda,\mu}_{(r,s)} = \sum_{(p,q)} G^{-1}_{(r,s),(p,q)} Y^{\lambda,\mu}_{(p,q)} \tag{67}$$

where

$$G_{(r,s),(p,q)} = \sum_{(j,\alpha,\beta)(i,x,y)} \overline{P}_{(r,s),(j,\alpha,\beta)} \Lambda^{-1}_{(j,\alpha,\beta),(i,x,y)} P_{(p,q),(i,x,y)} \tag{68}$$

and the minimum variance is given by

$$\min\ \mathrm{E}|R^{a,b}_{\lambda,\mu} - \hat{R}^{a,b}_{\lambda,\mu}|^2 = \frac{1}{M}\sum_{(r,s),(p,q)} Y^{\lambda,\mu}_{(r,s)} G^{-1}_{(r,s),(p,q)} \overline{Y}^{\lambda,\mu}_{(p,q)}. \tag{69}$$

The representation in Eq. 69 of minimum variance is dependent on the orthogonal directions p' and q' in the definition of the source coherence matrix $\mathbf{C}'$ in Eq. 51. To quantitatively evaluate this dependence, the aim is to find directions p' and q' that minimize the root-mean-square (rms) standard deviation

$$\sigma = \sqrt{\frac{1}{4}\sum_{\lambda,\mu} \min\ \mathrm{E}|R^{a,b}_{\lambda,\mu} - \hat{R}^{a,b}_{\lambda,\mu}|^2} \tag{70}$$

of all elements of $\mathbf{R}^{a,b}$, as follows. From Eqs. 51 and 60

$$Y^{\lambda,\mu}_{(r,s)} = \frac{1}{2}\left[A^{\lambda,\mu}_{(r,s)} + \cos(2\phi)\ B^{\lambda,\mu}_{(r,s)} - \sin(2\phi)\ C^{\lambda,\mu}_{(r,s)}\right] \tag{71}$$

where ϕ is the angle of rotation of p' and q' from reference directions p and q, and the coefficients are given by

$$\begin{aligned}
A^{\lambda,\mu}_{x,y} &= \begin{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}_{(x,y)} & \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}_{(x,y)} \\ \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}_{(x,y)} & \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}_{(x,y)} \end{bmatrix}_{(\lambda,\mu)} \\
B^{\lambda,\mu}_{x,y} &= \begin{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}_{(x,y)} & \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}_{(x,y)} \\ \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}_{(x,y)} & \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}_{(x,y)} \end{bmatrix}_{(\lambda,\mu)} \\
C^{\lambda,\mu}_{x,y} &= \begin{bmatrix} \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}_{(x,y)} & \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}_{(x,y)} \\ \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}_{(x,y)} & \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}_{(x,y)} \end{bmatrix}_{(\lambda,\mu)}.
\end{aligned} \tag{72}$$

Introducing Eqs. 71 and 69 into Eq. 70 gives

$$\begin{aligned}
\sigma^2 = \frac{1}{16M} \times \Bigg\{ & \sum_{(\lambda,\mu),(r,s),(p,q)} \left[A^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} A^{\lambda,\mu}_{p,q} + \frac{1}{2} B^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} B^{\lambda,\mu}_{p,q} + \frac{1}{2} C^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} C^{\lambda,\mu}_{p,q}\right] \\
& + \cos(2\phi) \sum_{(\lambda,\mu),(r,s),(p,q)} \left[A^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} B^{\lambda,\mu}_{p,q} + B^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} A^{\lambda,\mu}_{p,q}\right] \\
& - \sin(2\phi) \sum_{(\lambda,\mu),(r,s),(p,q)} \left[A^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} C^{\lambda,\mu}_{p,q} + C^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} A^{\lambda,\mu}_{p,q}\right] \\
& + \frac{1}{2}\cos(4\phi) \sum_{(\lambda,\mu),(r,s),(p,q)} \left[B^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} B^{\lambda,\mu}_{p,q} - C^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} C^{\lambda,\mu}_{p,q}\right] \\
& - \frac{1}{2}\sin(4\phi) \sum_{(\lambda,\mu),(r,s),(p,q)} \left[B^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} C^{\lambda,\mu}_{p,q} + C^{\lambda,\mu}_{r,s} G^{-1}_{(r,s),(p,q)} B^{\lambda,\mu}_{p,q}\right] \Bigg\}.
\end{aligned} \tag{73}$$

Using Eq. 72, all terms in Eq. 73 involving ϕ can be shown to vanish, giving the result

DOI 10.1007/978-981-4560-75-7_97-1

$$\sigma^2 = \frac{1}{8M} \times \sum_{(r,s),(p,q)} \left[I_{r,s} G^{-1}_{(r,s),(p,q)} I_{p,q} + Q_{r,s} G^{-1}_{(r,s),(p,q)} Q_{p,q} + U_{r,s} G^{-1}_{(r,s),(p,q)} U_{p,q} + V_{r,s} G^{-1}_{(r,s),(p,q)} V_{p,q} \right] \tag{74}$$

where

$$I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad V = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \quad Q = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \quad U = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}. \tag{75}$$

Equation 74 simplifies to

$$\sigma^2 = \frac{1}{4M} \sum_{(r,s)} G^{-1}_{(r,s),(r,s)}. \tag{76}$$

Sensitivity and Survey Speed The equivalent antenna sensitivity in any direction Ω is defined as

$$S(\Omega) = \frac{k_B}{P_{\text{ref}} \sigma} \tag{77}$$

where σ is given in Eq. 76, is the rms noise in the estimate of the coherence matrix, and $P_{ref} = 1/(2 \times \eta_o)$ is the power density of the reference incident fields used in setting up Eq. 48. In using Eq. 76 in Eq. 77, just one time sample $M = 1$ is used, to separate antenna and integration effects. The result Eq. 77 is independent of the choice of coordinate systems used to represent the antennas and coherence parameters of the astronomical sources.

Correlation data obtained at different times with different beams or antenna pointing directions may be linearly combined to achieve maximum signal-to-noise ratio. The maximum sensitivity squared then becomes

$$S^2(\Omega) = \sum_{i=1,2,3,\cdots N_p} S^2_{\text{i}}(\Omega) \tag{78}$$

where $S^2_i(\Omega)$ is the sensitivity squared for pointing i and N_p is the number of pointings. Equation 78 results since the noise at different times is uncorrelated. Dithering of the beam and antenna pointings is used to flatten the sensitivity across the field of view. The survey sensitivity is then approximately equal to the average

$$\begin{aligned} \left(S^2\right)_{\text{ave}} &= \frac{1}{A_{\text{survey}}} \int_{A_{\text{survey}}} d\Omega \sum_{i=1,2,3,\cdots N_p} S^2_{\text{i}}(\Omega) \\ &\approx \frac{N_p}{A_{\text{survey}}} \int_{A_{\text{survey}}} d\Omega \quad S^2_{i^*}(\Omega) \end{aligned} \tag{79}$$

where A_{survey} is the solid angle of the surveyed area of sky and i^* is any representative pointing. Using Eqs. 78, 77, and 76, the square of survey sensitivity given by Eq. 79 is seen to be proportional to the product $N_p \times M$ of the number of pointings N_p and the number of time samples M averaged in the correlations (Eq. 47) at each pointing. The product $N_p \times M$ can also be expressed as $N_p \times M = \tau \times B$

DOI 10.1007/978-981-4560-75-7_97-1

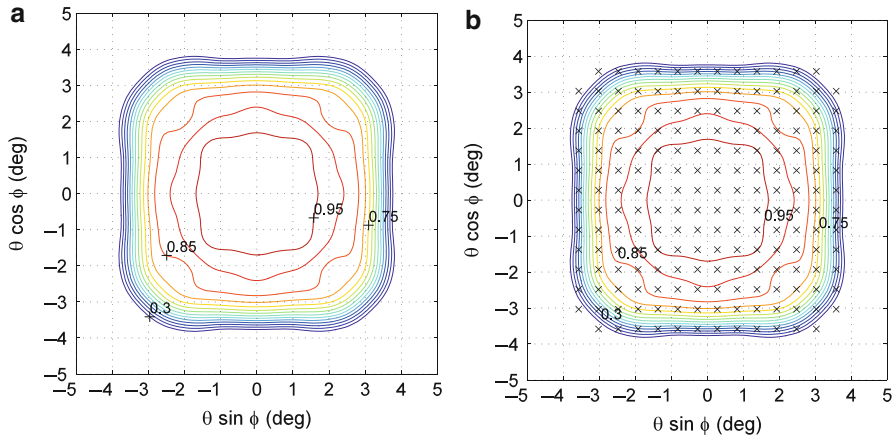

Fig. 12 Sensitivity distributions throughout the FoV of a PAF. Part (a) is the peak sensitivity of single dual-polarized beams at each point. Part (b) is the sensitivity obtained by optimally combining the correlations of a grid of dual-polarized beams in the directions marked with *crosses*. The contour labels refer to the sensitivity relative to the maximum sensitivity in the FoV

where τ is the total survey time and B is the bandwidth of the beamformed signal channels input to the correlator. The survey speed is proportional to

$$\text{SSFoM} = \left(S^2\right)_{\max} \times \text{SSFoV} \tag{80}$$

where

$$\left(S^2\right)_{\max} = \max_{\Omega} \; S^2_{i^*}(\Omega) \tag{81}$$

$$\text{SSFoV} = \frac{1}{\left(S^2\right)_{\max}} \int d\Omega \; S^2_{i^*}(\Omega) \tag{82}$$

is the survey speed field of view. Thus, the survey speed figure of merit is defined as

$$\text{SSFoM} = \int d\Omega \; S^2_{i^*}(\Omega). \tag{83}$$

In Eq. 80 to Eq. 83, $S^2_{i^*}(\Omega)$ is calculated from Eqs. 77 and 76 using just $M = 1$ time sample in order to separate antenna effects from the effects of integration time and channel bandwidth. Clearly, the survey speed is proportional to the square of the physical area of the telescope.

A general result that emerges from the survey speed analysis is that given sufficient number of beams, the sensitivity obtained at each point in the FoV by optimally combining the beam correlations is equal to that of a single dual-polarized beam at the same point. Figure 12 illustrates this in the case of the ASKAP PAF, which will be described in more detail in the following section. Part a of Fig. 12 shows the peak sensitivity of single dual-polarized beams formed at each point in the FoV. Part b of Fig. 12 shows the sensitivity obtained by optimally combining the correlations of a grid of dual-polarized beams, where the beam directions are indicated by the crosses. The beam spacing is $\lambda/(2D)$, where D is the aperture diameter of the reflector antenna. The spacing $\lambda/(2D)$ is sufficient to maximize the sensitivity obtained by optimally combining the beam correlations. This is a general result that can be proved using the bandlimited Fourier

DOI 10.1007/978-981-4560-75-7_97-1

transform relationship between the beam radiation patterns and the aperture fields of the reflector antennas.

Applications in Radio Astronomy

Radio telescopes have a number of special system requirements that many other applications do not have. For an overview of some international radio observatories, please refer to the chapter "► Antennas in Radio Telescope Systems." As well as antenna gain, input match, sensitivity, noise temperature, polarization, and the collecting area, other requirements include the survey speed and image discrimination. Through these largely scientific instruments, some new techniques and components in some unique frequency bands have been trialed in an operating system. In this section, two applications of arrays in radio telescopes are outlined, and unique design details are provided.

Design of a Multibeam Feed for the Parkes Radio Telescope

The 64 m radio telescope located at Parkes in the central west of New South Wales, Australia, was commissioned in 1964. It was involved in many early discoveries of quasars and pulsars, but by the mid-1990s, it needed enhancements. A multiple beam capability was investigated from the early 1990s for observations at a wavelength around 21 cm (actually, the frequency range 1.27 to 1.47 GHz) to undertake deep, large-area surveys of neutral hydrogen emission from external galaxies. In particular, a large-area survey of the southern hemisphere for sources of HI was required. With a single prime-focus feed, it was estimated that this survey would take about 10 years to complete. However, using a feed of N elements, each with two orthogonal linear polarizations, the observing period would be reduced by a factor of about 1/N. To establish a possible feed size, a first approximation is the sample spacing in the u-v plane that is needed to resolve images of extragalactic objects. This indicated that the desired beam spacings were approximately an HPBW (half-power beamwidth) apart, and for this to occur, feeds should be spaced to give beams an integer multiple of HPBW apart. Physically, this would be impossible without dielectric-loaded horns. However, dielectric loading is unattractive in radio astronomy because of losses and mismatch to free-space, both of which increase the noise temperature and significantly reduce sensitivity. In addition, the reflector scan-gain loss and the available number of separate receivers limit the size of the array. An alternative approach is to increase the spacing to about 2 HPBW and to fill in the sample space by moving the reflector as well to point at interstitial positions. As a result, conventional horns were able to be used and arranged in the focal region so that the beam spacing is approximately 2 HPBW. An hexagonal array of circular apertures was chosen because of its efficient packing density, and with limits on the number of receivers, the ultimate number of elements in the array was $N = 13$ after a study was performed with a smaller number of elements (Bird 1994). It was considered that the redundancy provided by the additional elements was worth the extra expense. A circular horn of about one wavelength diameter was selected as an element over other geometries because it has excellent pattern symmetry and cross-polar performance. Circular waveguide is preferred throughout, from the orthogonal mode transducers (OMT) to the horn input. The geometry of the final multibeam feed system is shown in Figs. 13 and 14.

The hexagonal cluster shown in Fig. 13 makes for a compact feed system because the OMTs (in the Dewar) can be attached directly to the rear of the horns to extract both linear polarizations.

Stepped Circular Horn Design

The geometry of the Parkes symmetrical parabolic reflector is summarized in Table 1. The approach taken to the design was to obtain the best possible performance with a single feed horn of the desired diameter

DOI 10.1007/978-981-4560-75-7_97-1

f/D	0.41047
Semi-angle	62.69°

and then to accommodate for any array effects. Initially, both circular and square horns were potential candidate elements as both yielded comparable gain with the reflector. However, circular horns have lower spillover loss, better pattern symmetry, and lower cross polarization than the square horn option. For any parabolic reflector fed at the focus by a circular waveguide, there is an optimum waveguide diameter for maximum gain. A circular waveguide of about one wavelength diameter maximizes the gain with the Parkes reflector and also has low cross polarization and spillover. During design, steps along the profile were introduced to achieve high beam efficiency, low input reflection coefficient, and low inter-element coupling.

There is, however, an upper limit to the feed diameter in the array. This is specified by the beam spacing for effective sampling in u-v space. Making use of the beam angle estimate in Introduction, $\theta_b \approx \mathrm{BDF}\,(s/\lambda)$ where s is the radius of the first ring of the hexagonal array and $2 \times$ HPBWs with a -12 dB edge illumination corresponds to $\theta_b \approx 2.4\lambda/D$. Combining these estimates gives an estimate of the radius of the first ring in the hexagonal array as

$$s \approx \frac{2.4\,(f/D)\,\lambda}{\mathrm{BDF}}\,. \tag{84}$$

For the Parkes radio telescope geometry (Table 1), Eq. 84 gives $s \approx 1.17\lambda$. To allow for an adequate wall thickness and other possible adjustments, the radius of the first ring of $s = 1.2\lambda$ was selected. From Eq. 84, it is seen that the spacing reduces with the reflector f/D. Thus, for the Lovell radio telescope at Jodrell Bank, UK, which has $f/D = 0.3$, based on the same beam spacing, the element spacing should be $s \approx 0.97\lambda$. With an adequate wall thickness, this limits the horn diameter to about 0.9λ, which limits the option for feeds and the use of choke rings in the flange to improve the efficiency and beam symmetry.

DOI 10.1007/978-981-4560-75-7_97-1

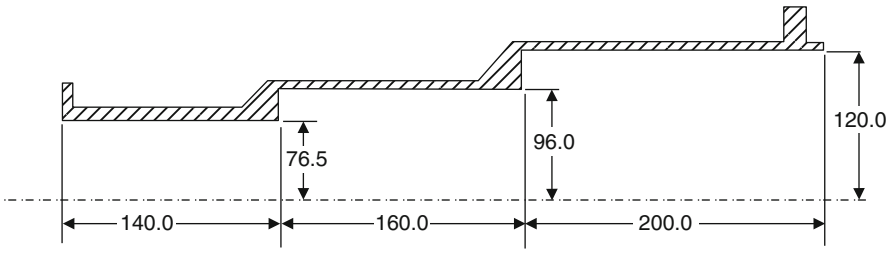

Fig. 14 L-band stepped horn for Parkes multibeam feed. Dimensions in mm

As a result, for the Lovell telescope multibeam feed design, a coaxial horn was ultimately chosen (Bird 1997).

Another important geometric parameter in the design is to establish the diameter of the input waveguide. To minimize losses and effects due to higher order modes, it was decided to have all modes other than the fundamental TE_{11} mode be cut off in the frequency range 1.27 to 1.47 GHz. A 153 mm diameter input pipe satisfies this requirement.

The circular horn with steps along its length were analyzed with mode-matching software CIRCAR to achieve the desired efficiency and reflection coefficient. The software can also be used to analyze mutual coupling between the horns (Bird 1996). This allowed the horns in a 13-element hexagonal array to be analyzed, and, as a result, further minor adjustments were made to the horn geometry while, at the same time, keeping all horns identical. After an investigation of several configurations, it was found that most objectives were attained with the two-step horn design shown in Fig. 14. Low cross polarization is easily achieved with the single isolated feed, but, in the array, significant levels of TM_{01} and TE_{21} modes can be generated. These modes can cause high cross-polar levels, which, in some instances, are as high as for the square horn. However, by adjusting the output aperture diameter and length of the circular waveguide steps, low cross-polar illumination (> -35 dB) of the reflector at the center frequency was ultimately achieved for each horn of the array. The calculated reflection coefficient and insertion loss over the frequency band of interest are shown in Fig. 15. Both mismatch and loss (including ohmic loss) are least near the center of the band and degrade at the band limits. Figure 16 shows the co- and cross-polarized radiation patterns of the central horn (element 1) in the array, and this has been degraded only slightly by the array environment, as are the horn mismatch and loss. Across the band, good beam symmetry is maintained, although the cross-polar level deteriorates to -27 dB at the lower band edge, which was still acceptable. It was found that satisfactory performance could be obtained, both separately and in the array, across an extended frequency range from 1.20 GHz to 1.55 GHz, which provided options for many different types of observations with the multibeam feed.

Multibeam Performance

CSIRO's array feed software was combined with the reflector analysis software to compute the radiation pattern of the overall antenna.

The radiation pattern of the reflector with the array was computed for each beam. It was assumed that the sources to be observed are mainly uncorrelated and, therefore, the signals radiated by the horns are not summed coherently. The computed co- and cross-polarized radiation patterns of one of the beams on the first ring at the band-center frequency of 1.37 GHz are shown in Fig. 17. The patterns were obtained by exciting horn 1 and include reflector aperture blockage, which is 5 m in diameter as a result of the feed cabin. The performance of the four independent beams is summarized in Table 2. The results for the other beams can be obtained from symmetry. At the extremes of the frequency band, the beam efficiency decreases. For example, at 1.27 GHz the efficiency of beam 5 is 69 % and at 1.47 GHz the value is 67 %.

8	60.0	0.24	−37.3	−0.178	−0.428	−0.719	31.8
9	59.8	0.24	−48.2	−0.188	−0.836	0.000	32.2

Spillover efficiency rises with frequency, due to narrowing of the feed horn pattern, from 94 % at the lower to 97 % at the higher frequency.

The radiation pattern of the radio telescope for the central beam both computed and measured results are shown in Fig. 18. A 5 m central blockage that is due to a focal cabin from which feeds are rotated into the focus was assumed in the calculations. The sidelobes of the measured pattern are filled in and are consistently of the same form for most beams, which indicates they may be due to effects not connected directly with the multibeam feed. Figure 19 shows the completed feed as it was lifted into position. Table 2 shows that the efficiency of the central beam is predicted to be 70.9 % relative to a uniformly illuminated aperture without including reflector surface errors. This efficiency decreases at the band edges to 68 % at 1.27 GHz and 66 % at 1.47 GHz. The efficiency of the most displaced feed (element 9) is 59.8 %, and the latter's coma sidelobe is −14 dB below the peak value. The spillover efficiency was estimated to

be $>$ 96 % for all beams, and this decreases slightly at lower frequencies due to broadening of the illumination. Overall, the cross coupling between beams is at a satisfactory level and has a maximum of -21 dB due to diffraction and mutual coupling in the array, but typically, it is < -35 dB while cross-polar isolation is $>$40 dB.

Australian SKA Pathfinder (ASKAP) PAF

The Australian Square Kilometre Array Pathfinder (ASKAP) is a 36-antenna interferometer radio telescope that has been developed and is currently being deployed by CSIRO at the Murchison Observatory in Western Australia. The specifications of the feed array for the ASKAP PAF application are listed in Table 3. Figure 20 shows the resulting connected array design that was developed to achieve these specifications.

As illustrated in Fig. 21, the PAF has conducting patches of similar form to the self-complementary array but also a parallel ground plane, used to give the array directivity and allow convenient placement of

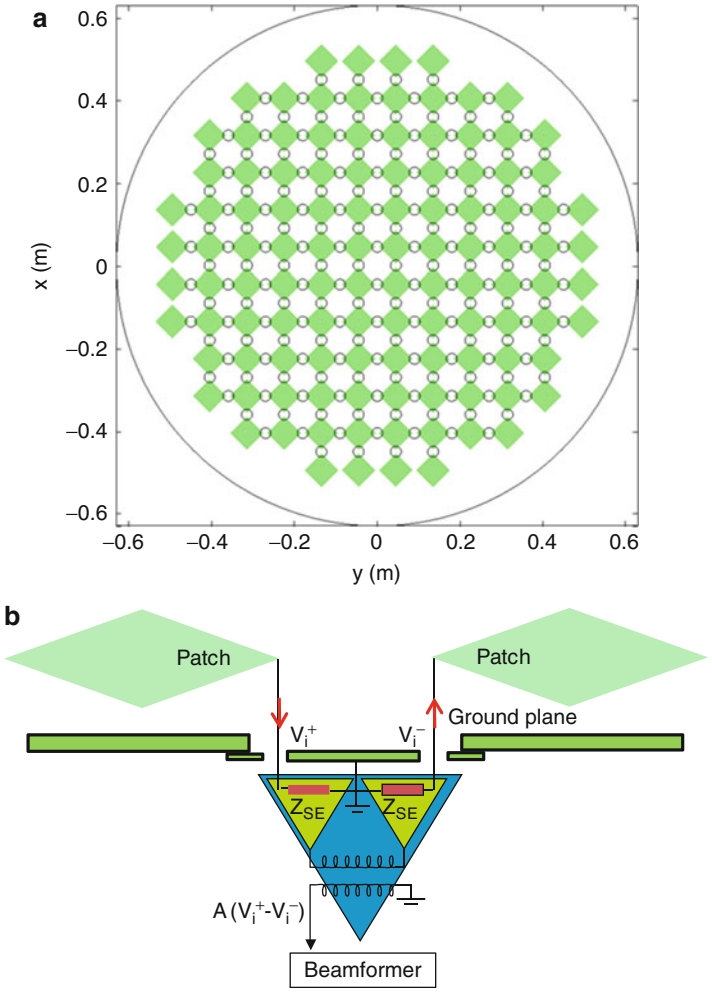

Fig. 21 One hundred and eighty eight-element connected array with ground plane (**a**) and schematic (**b**) of two-wire transmission lines diverting array currents to LNAs on the other side of the ground plane. The patches are 80 mm across the diagonal, and a 10 mm gap exists between neighboring patch corners, resulting in an array element spacing of 90 mm. The patches are 65 mm from the ground plane, which is 10 mm thick and has apertures 26 mm in diameter. The wires connecting the patch corners to the LNAs have a diameter of 0.86 mm

One key to solving the design challenges has been rigorous computational electromagnetic analysis of the array. This needs to account for the fine structure in the small array elements and also the mutual coupling across the entire array. An accurate and efficient technique was developed (Hay et al. 2011). This is an extension of the characteristic basis function method that accounts for the strong flow on conduction current between the connected array elements. The computational efficiency of the software allowed a study of the array effects, and, as a result, the new arrays were designed with improved performance including increased frequency range.

Another crucial development is a theory of the array operation in terms of common and differential modes of current on the two-wire transmission lines that divert the array currents to the LNAs behind the ground plane (Hay and O'Sullivan 2008). This has explained resonances that occur in the array with certain LNA configurations and led to an improved, resonance-free array/LNA design that is illustrated in Fig. 21.

A further important development has been the design and accurate experimental characterization of the LNAs (Shaw et al. 2012). Effective procedures have been developed for both the signal and noise

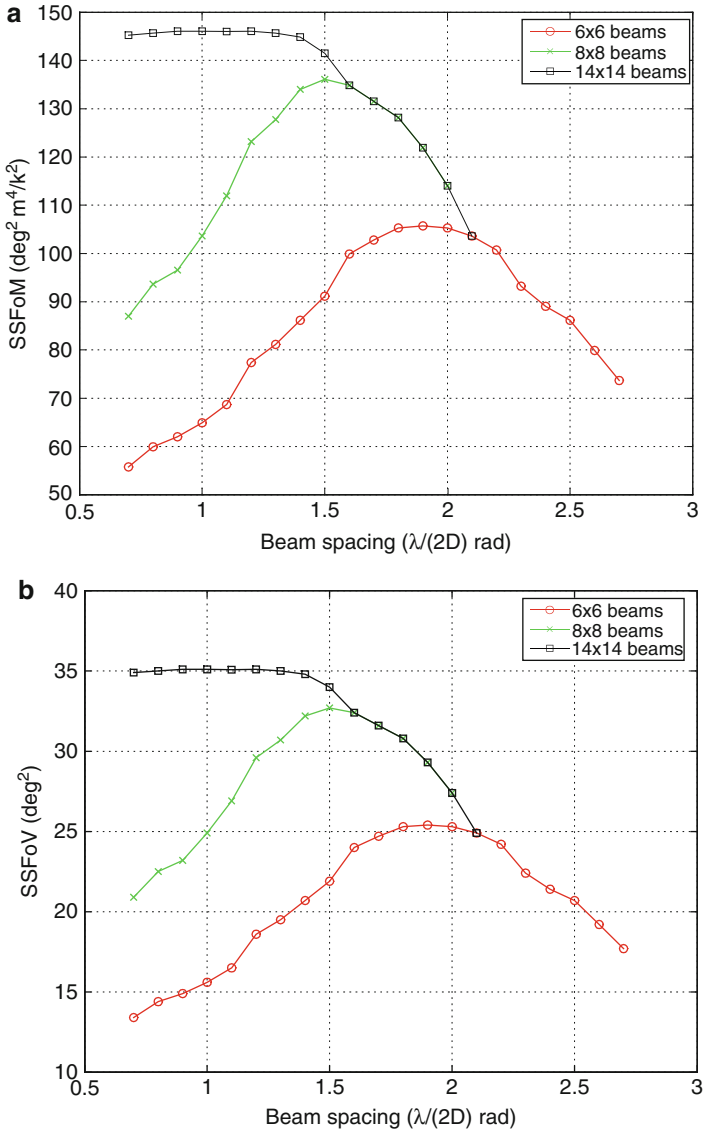

Fig. 22 Computed survey speed figure of merit (**a**, SSFoM, Eq. 83) and survey speed field of view (**b**, SSFoV, Eq. 82) for the 188-element ASKAP PAF at 1.3GHz as a function of the number and spacing of the beams. The LNA model is noise-matched to the array and has a minimum noise temperature Tmin of 30 K. The FoV is centered at zenith, and the assumed brightness temperature distribution is 5 K at zenith and transitions from this value to the ground temperature of 275 K between 80 and 120° from zenith

properties of the three-port LNAs, which have differential noise-match and input impedance of the order of 300 Ω.

An analysis of survey speed in section "Phased Array Feeds" provides a framework for optimizing the number and spacing of the PAF beams. Figure 22 shows the SSFoM and SSFoV at 1.3GHz for various beam numbers and spacings. Although performance is maximized with a beam spacing of λ/(2D), where D = 12 m is the aperture diameter of the ASKAP antennas, it is desirable in practice to use a larger beam spacing and smaller number of beams. This is because beamforming cost increases with the number of beams. For the ASKAP PAF, a 6 × 6 grid of beams was selected as a reasonable compromise between cost and performance. Figure 23 shows the computed SSFoM and SSFoV as a function of frequency. At each

DOI 10.1007/978-981-4560-75-7_97-1

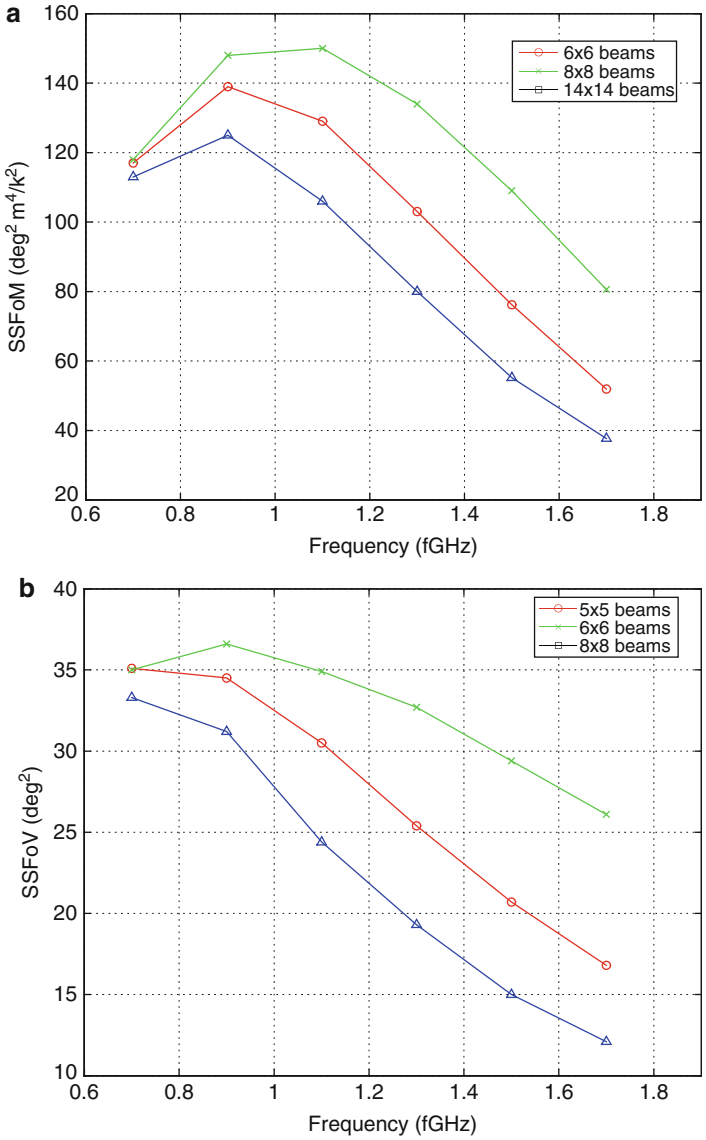

Fig. 23 Computed survey speed figure of merit (**a**, SSFoM, Eq. 83) and survey speed field of view (**b**, SSFoV, Eq. 82) for the 188-element ASKAP PAF as a function of frequency. The LNA model is noise-matched to the array and has a minimum noise temperature Tmin of 30 K. The FoV is centered at zenith, and the assumed brightness temperature distribution is 5 K at zenith and transitions from this value to the ground temperature of 275 K between 80 and 120° from zenith

frequency, the beam spacing has been optimized to maximize SSFoM. With a 6 × 6 beam, SSFoV is limited at low frequency mainly by the physical size of the PAF.

The development of the ASKAP PAFs has proceeded to a MKII design with a number of improvements including increased sensitivity. Figure 24 shows a 40-element prototype of the MKII PAFs. As illustrated in Fig. 25, the patch design is modified to allow improved matching of the array and LNAs. The overall geometry is similar to the original PAF, with the same element spacing of 90 mm and 10 mm of the wires in each of the two-wire transmission lines. The patches are reduced in size and are connected to the transmission lines via narrow strips in the same plane as the patches. This provides inductance that compensates for the ground plane at high frequency. Chip capacitors connect the strips to the patches, compensating also for the ground plane at low frequency. The diameter of the wires in the two-wire transmission lines is increased slightly to 1.6 mm.

Figure 26 compares measured and modeling results on a 5 × 4 prototype of the ASKAP MKII PAF. The results are for the beamformed receiver noise temperature

$$T_{\text{rec}} = T_0 \frac{\overline{\phi}^T G_{\text{rec}} \phi}{\overline{\phi}^T G_A \phi} \tag{85}$$

when tested as a directly receiving array pointed at zenith. The measured result is estimated from the measured Y-factor using the sky as the cold load and microwave absorber as the hot load (Chippendale et al. 2014). These results show good low noise performance across the 0.7–1.8 GHz frequency range required for ASKAP.

Conclusion

The area of phased array feeds has made significant progress through technology development and new applications. Advances are the large frequency range and digital beamforming, providing the ability to form multiple simultaneous antenna beams with highly controllable properties. The degree to which beam

DOI 10.1007/978-981-4560-75-7_97-1

properties can be controlled is increased over previous multibeam systems using horn feed arrays or arrays with analog beamforming networks. In both of these former systems, beam spacing is limited by the size of the feeds or by signal loss in analog beamforming networks. With digital beamforming, PAFs can produce beams with arbitrary spacing, without significant loss of signal. These features are of considerable interest for a range of applications in communications. These are:

1. Interference limited systems. The capacity of multiuser communication systems can be increased through frequency reuse using multiple simultaneous antenna beams at each frequency. The ability to closely control beam spacing, size, shape, sidelobes, and cross polarization should unlock the full potential of this approach. In addition, improved use of limited or expensive real estate will be possible. For example, as illustrated in Fig. 27, instead of multiple reflector apertures, each fed by horn-array feeds with limited spacing, a single reflector aperture with a PAF can produce a contiguous set of beams throughout the field of view.
2. Multiband systems. The large frequency range implies the ability to accommodate multiple frequency bands within the one receiving or transmitting aperture. For example, the satellite communication bands, or integration of the multiple bands used in wireless communications, in the base station antennas.
3. Cognitive systems. These systems are aware of the radio environment and adapt to make best use of the limited available resources of spectrum and power. This requires sensing the radio environment over a wide frequency range and then adapting antenna characteristics such as frequency, beam polarization, and radiation pattern.
4. Moving platforms. There is great interest in mobile platforms, including satellite systems for vehicles, ships, and aircraft. Also, in some systems, antennas are subject to perturbing motion of platforms, e.g., terrestrial point-to-point communication systems using towers that flex in the wind. The connected array offers correction for motion effects.
5. Spatial power combining. Transmitting systems can also be developed, allowing the power of multiple transmitters to be coherently combined. This is particularly attractive at high frequencies in mm-wave and THz frequency ranges, due to reduced power of electronic devices at these frequencies. Applications include very high throughput communications.

Radio astronomy has been a key driver including the requirement for high sensitivity obtained through integration of the array and low-noise amplifiers operating at ambient temperature. There exists good scope for further developments in this area. Wide FoV will continue to be a key area for development for radio astronomy. The benefits have been clearly illustrated by the various multibeam systems such as Parkes. Good progress has also been made in PAFs, e.g., ASKAP with further increased FoV and frequency range. There is significant interest in astronomy at higher frequencies including mm-wave and THz, evidenced by the recent development of the ALMA telescope, where wide FoV systems are a significant possibility and challenge for further development.

The ability to operate over a large frequency range with unprecedented beamforming accuracy and flexibility is likely to enable significant advances also in communications. Future developments will include extending the technology to higher frequency bands, where integration with electronic devices, signal transport, and array fabrication are key challenges.

MIMO Systems and Antennas for Terminals

Hui Li[a,b]* and Buon Kiong Lau[b]
[a]School of Electronic Information and Electrical Engineering, Dalian University of Technology, Dalian, China
[b]Department of Electrical and Information Technology, Lund University, Lund, Sweden

Abstract

MIMO technology has facilitated tremendous performance improvements in wireless communications, allowing the data rate to increase linearly with the number of antennas used, at no additional expense in transmit power or spectrum. However, the tremendous performance gain can only be achieved by multi-antenna designs that provide low coupling and correlation, as well as high total efficiency. Such design criteria are especially challenging for small terminal devices. The situation becomes even more complicated with increasing bandwidth requirements for terminals in existing and upcoming mobile communication standards. Beginning with the history of MIMO terminal antenna and its evaluation methods, this chapter is geared towards providing useful guidelines to researchers and practitioners alike on how to design efficient MIMO antennas for terminals. The focus is on decoupling and decorrelation techniques, including RF circuit level decoupling, antenna structure decoupling and characteristic mode based decoupling. Future directions in MIMO antenna design and some corresponding open problems are also described.

Keywords

MIMO systems; MIMO metrics; Channel capacity; Antenna correlation; Mutual coupling; Mobile communication; Characteristic mode; Parasitic element; Neutralization line; Defected ground plane

Introduction

The increasing popularity of smartphones, laptops and tablets is spurring the fast-growing demand for high speed mobile communications. This in turn leads to the widespread deployment of multiple-input multiple-output (MIMO) technology in wireless communication standards, where multiple antennas are employed at both base stations and terminals to enable linear increase in channel capacity (or ideal data transmission rate) with the number of antennas, without sacrificing additional frequency spectrum and transmitted power (Gesbert et al. 2003). However, the linear increase in channel capacity is the ideal case for MIMO. A lot of non-ideal factors, such as non-zero correlation between channels and antennas, imperfect antenna efficiency and finite power imbalance will deteriorate the link performance. To evaluate the MIMO performance of multiple antenna systems, figures of merits are introduced in this chapter and their effects on the data rate are illustrated.

From the antenna design perspective, MIMO technology greatly increases the complexity of antenna design in compact terminal devices, due to the requirement of implementing multi-antennas for single or multiple frequency bands within a limited space allocation. The closely spaced antennas can lead to high mutual coupling, which decreases the antenna efficiencies. At the same time, the close spacing can also increase the signal correlation between antennas, degrading the terminals' MIMO performances. Thus, it

*Email: hui.li@dlut.edu.cn

DOI 10.1007/978-981-4560-75-7_99-1

is important to decouple and de-correlate the antennas. The relationship between decoupling and decorrelation is discussed in the chapter. Generally, antenna design methods that are intended to achieve high isolation and low correlation are collectively called decoupling techniques. However, decoupling techniques are primarily aimed at increasing isolation and they do not ensure effective decorrelation in multi-antennas with moderate to low radiation efficiencies. The existing decoupling techniques based on various mechanisms are introduced in this chapter, including decoupling network, modified ground plane, neutralization/connecting line, characteristic modes, etc. Specifically, the characteristic mode based decoupling technique will be more systematically described, as it has been found to be effective for designing decoupled and decorrelated MIMO terminal antennas that offer good bandwidth performance.

In this chapter, the main metrics to characterize MIMO systems is first described. Then the discussions are focused on the design of multi-antennas for mobile terminals, since the same design principles herein apply to the larger form factors of tablet PCs, including phablets (phone-tablets) or mini-tablets. This is because the main challenges in multi-antenna design are related to the small physical sizes of the terminal in relation to the wavelength, which means that compact mobile terminals present the worst case. From another perspective, the design of multi-antenna elements for larger terminal devices than mobile handsets is equivalent to designing the antennas for mobile handsets for higher frequencies. For example, the electrical wavelength at the 700 MHz band is about three times longer than that at the 2 GHz band.

History of MIMO Terminal Antennas

MIMO technology is based on the use of multi-antennas. The term MIMO is commonly used in the context of spatial multiplexing, which is transferring multiple streams of data by applying multi-antennas at both the transmitter and receiver. However, the use of multi-antennas to improve wireless communications is not a new phenomenon. For example, multi-antennas were employed in the short-wave frequencies (3–30 MHz) to combat fading of radiotelegraph signals due to multipath propagation in the 1930s (Peterson et al. 1931). This fading mitigation approach is known as diversity reception, which relies on the received signals at different antennas having different signal strengths. Diversity reception has also been adopted in mobile communications when it is deployed in GSM base stations to improve signal quality. However, a common denominator of early adoptions of multi-antennas is that the multi-antennas are deployed at the base station rather than the user terminal, due to additional complexities required for processing the received signals as well as the cost of implementing the complexities. Moreover, in order for multi-antennas to yield signals that are sufficiently different (or decorrelated) from one another, one common approach is to implement antennas that are well separated in space, which is easier to achieve at the base station due to larger available space. The requirement of decorrelated antennas is critical for both diversity and spatial multiplexing techniques to work well, even though spatial multiplexing employs more advanced signal processing to enable transformation of the physical multipath propagation channel into independent transmission channels. The constraint of antenna spacing in the limited sizes of typical user terminals in relation to the signal wavelengths has made terminal multi-antenna design especially challenging.

The first attempt to deploy multi-antennas in mobile terminals was made for the Japanese Personal Digital Cellular (PDC) systems around the mid 1990s, based on antenna switched diversity (Kobayashi et al. 1994). A whip antenna (monopole) was used for both transmitting and receiving, whereas an internal planar inverted F-antenna (PIFA) was used for receiving. Multi-antenna diversity was also utilized to mitigate delay spread in the PDC systems, to reduce intersymbol interference (ISI) (Falconer et al. 1995). Notwithstanding, research and practical implementations of dual-antenna terminals predates the PDC systems, with the Japanese company NTT already proposing built-in (internal) two-PIFA based designs

for both shoulder-carry and handheld mobile terminals as far back as 1986 (Taga and Tsunekawa 1986; Taga and Tsunekawa 1987).

During the late 1990s, the MIMO technology that was first introduced in (Winters 1987) came out of obscurity and began to attract a lot of attention in the research community, due to its potential to drastically improve data rate without additional spectrum use. At a time when acquiring spectrum license has become a major expense of mobile operators, the idea of making far better use of existing spectrum was indeed timely. Nevertheless, extensive efforts were needed in the research and development of the technology before it was ready for commercial deployment. The first introduction of MIMO in mobile communications was for the High Speed Packet Access Evolution (HSPA+) system in 2007, corresponding to the Third-Generation Partnership Project (3GPP) Release 7 (Rao et al. 2009). HSPA+ employs spatial multiplexing with two data streams on the downlink to enable a data rate of up to 28 Mbits per second (Mbps), which effectively doubles the maximum data rate of its predecessor. At around the same time, MIMO also appeared on the market in the form of wireless local area network (WLAN) terminal devices that complied with the IEEE802.11n draft 2.0 specifications (Perahia 2008). Though limited in range to 70 m indoor and 230 m outdoor, IEEE802.11n systems can provide data rates of up to 600 Mbps, using 4×4 MIMO to support up to 4 data streams.

However, despite the enthusiastic adoption of MIMO technology in HSPA+ and IEEE802.11n, the MIMO feature remains optional in these standards. Hence, it is not compulsory to implement multi-antennas in their terminals. This situation changed with the deployment of Long Term Evolution (LTE) networks corresponding to 3GPP Release 8, since LTE mandates the implementation of two or more antennas in the terminals. The first LTE terminals were USB dongles that enable wireless broadband access for laptop computers. One example of such terminals is the Samsung LTE dongle (see Fig. 1), which was used in the world's first commercial LTE network deployed by the Nordic mobile operator Teliasonera on 14 Dec 2009. The LTE standard specifies up to four antennas for Category 5 User Equipment (UE), with maximum downlink and uplink data rates of 300 and 75 Mbps, respectively.

Evaluation of MIMO Systems

Ideally, spatial multiplexing can increase the channel capacity of a MIMO system linearly with the number of transmit-receive antenna pairs used. However, its realization depends on a lot of practical factors in both the antenna design and the propagation environment. This section introduces figures of merits that can be used to characterize MIMO system performance, focusing on the antenna and

DOI 10.1007/978-981-4560-75-7_99-1

propagation aspects. Moreover, the influence of mean effective gain, branch power imbalance and correlation on capacity and multiplexing efficiency will be discussed.

Mean Effective Gain

Mean effective gain (MEG), introduced by Taga in 1990 (Taga 1990), is defined as the average power received by the antenna to the total mean incident power in the real propagation channel. In spherical coordinates with azimuth angle ϕ and elevation angle θ, MEG is given by:

$$\mathrm{MEG} = \int_0^{2\pi}\int_0^{\pi}\left(\frac{XPR}{XPR+1}G_\theta(\theta,\phi)P_\theta(\theta,\phi)+\frac{1}{XPR+1}G_\phi(\theta,\phi)P_\phi(\theta,\phi)\right)\sin\theta d\theta d\phi, \tag{1}$$

where XPR is the ratio of the average power in the θ-polarized component to that of the ϕ-polarized component. $G_\theta(\theta,\phi) = |E_\theta(\theta,\phi)|^2$ and $G_\phi(\theta,\phi) = \left|E_\phi(\theta,\phi)\right|^2$ are the antenna gain patterns in the θ and ϕ components, respectively, with $E_\theta(\theta,\ \phi)$ and $E_\phi(\theta,\ \phi)$ being the θ- and ϕ-polarized electric far field pattern of the antenna, respectively. $P_\theta(\theta,\ \phi)$ and $P_\phi(\theta,\ \phi)$ are the angular power density functions in the θ and ϕ components, respectively. Different from total radiated power (TRP) of an antenna, MEG takes into consideration the full interaction between the antenna and the propagation channel, and represents the performance of an individual antenna in non-ideal environments. A high MEG indicates a good match between the antenna and the channel, such that the antenna can receive more signal power in the channel. Good MIMO performance requires that the individual antennas have high MEGs. For an ideal channel with uniform three dimensional (3D) angular power spectrum (APS), $XPR = 1$, $P_\theta = P_\phi = \frac{1}{4\pi}$.

Branch Power Imbalance

Aside from MEG, in order to achieve good MIMO performance, it is also required that the power levels of the signals received by the antennas should not vary significantly from one another. This is described by branch power imbalance, which is the minimum ratio of MEG between two branches (1 and 2):

$$k = \min\left(\frac{\mathrm{MEG}_1}{\mathrm{MEG}_2}, \frac{\mathrm{MEG}_2}{\mathrm{MEG}_1}\right). \tag{2}$$

For an ideal channel with uniform 3D APS, k is equal to the ratio of antenna efficiency or TRP between the two branches.

Correlation

Signal correlation is another metric critical to MIMO systems. The complex correlation coefficient between antenna element i and antenna element j, based on the far field patterns, is expressed as:

$$\rho_{c,ij} = \frac{\int_0^{2\pi}\int_0^{\pi} A_{ij}(\theta,\phi)\sin\theta d\theta d\phi}{\sqrt{\int_0^{2\pi}\int_0^{\pi} A_{ii}(\theta,\phi)\sin\theta d\theta d\phi \int_0^{2\pi}\int_0^{\pi} A_{jj}(\theta,\phi)\sin\theta d\theta d\phi}} \tag{3}$$

DOI 10.1007/978-981-4560-75-7_99-1

where $A_{ij} = XPR\ E_{\theta,i}(\theta,\phi)E^*_{\theta,j}(\theta,\phi)P_\theta(\theta,\phi) + E_{\phi,i}(\theta,\phi)E^*_{\phi,j}(\theta,\phi)P_\phi(\theta,\phi)$, $E_{\theta/\phi,i/j}(\theta,\phi)$ is the θ (or ϕ)-polarized electric far-field pattern of the antenna i (or j) in spherical coordinates. The (normalized) complex correlation matrix at the receiver for M_r antennas can be expressed as:

$$\overline{\mathbf{R}}_r = \begin{bmatrix} 1 & \rho_{c,12} & \cdots & \rho_{c,1M_r} \\ \rho_{c,21} & 1 & \cdots & \rho_{c,2M_r} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{c,M_r1} & \rho_{c,M_r2} & \cdots & 1 \end{bmatrix}. \tag{4}$$

In wireless communications, envelope correlation coefficient is often of interest due to signal envelope (magnitude) being easier to measure than complex signal with both magnitude and phase. It has been found empirically that envelope correlation coefficient (of antenna i and j) can be approximated by the square of the magnitude of the complex correlation:

$$\rho_{e,ij} \approx \left|\rho_{c,ij}\right|^2. \tag{5}$$

When the correlation is high, the MIMO performance will deteriorate, especially when the envelope correlation exceeds 0.5. This is because MIMO systems rely on the independence among the received signals to provide diversity and/or independent channels in spatial multiplexing.

Evaluation of Correlation

The evaluation of correlation is important in determining MIMO system performance. According to Eq. 3, signal correlation between two antennas is calculated from the full spherical radiation patterns of the antennas, which are obtained with both phase and polarization information. However, complete pattern measurement is both time-consuming and expensive, due to the need for specialized equipment and facilities.

Consequently, it is of significant interest to the antenna community to avoid using antenna patterns in calculating correlation. In 1962, the relationship between antenna patterns and scattering (or S) parameters in closed form was derived by Stein in (Stein 1962), with special emphasis on lossless and reciprocal cases. Though the work of Stein contains all the necessary building blocks, the explicit expression of signal correlation in terms of S parameters is attributed to (Blanch et al. 2003), in which the envelope correlation for two antennas is given by:

$$\rho_e \approx |\rho_c|^2 = \frac{\left|S^*_{11}S_{12} + S^*_{21}S_{22}\right|^2}{\left(1 - |S_{11}|^2 - |S_{21}|^2\right)\left(1 - |S_{22}|^2 - |S_{12}|^2\right)}, \tag{6}$$

where uniform 3D APS and 100 % antenna radiation efficiency are assumed. This S-parameter based correlation expression can be easily generalized to M-port antenna systems (Thaysen and Jakobsen 2006). The expression has been widely used in the evaluation of MIMO terminal antenna design (see e.g., Su 2010; Sonkki et al. 2012; Xiong et al. 2012), since it is far more convenient to measure S parameters with vector network analyzer (VNA) than to measure radiation patterns. Moreover, S parameters are important multi-antenna parameters to measure in their own right, which means no additional effort is required to obtain them. However, the accuracy of the method relies heavily on the assumption of 100 % radiation efficiency, and significant error can occur even for relatively high radiation efficiencies (Li et al. 2013a).

DOI 10.1007/978-981-4560-75-7_99-1

Unfortunately, this aspect is often overlooked in some open literature on MIMO terminal antenna evaluation, which employs Eq. 6 despite significant dielectric and conductive losses.

The accuracy of using Eq. 6 to calculate correlation due to antenna losses was first investigated in (Hallbjörner 2005). An improved method was proposed to calculate the upper bound of correlation (i.e., the worst case) for dual-antenna systems, and the relationship between antenna radiation efficiency and correlation uncertainty was presented. The upper bound (or "guaranteed" upper limit) of correlation in terms of S parameters as well as radiation efficiency η_{rad} is given by:

$$|\rho_c|_{\text{guaranteed}} = \frac{\left|2\text{Re}\left(S_{11}S_{21}^*\right)\right|}{\left(1-|S_{11}|^2-|S_{21}|^2\right)\eta_{\text{rad}}} + \frac{1}{\eta_{\text{rad}}} - 1, \tag{7}$$

where the two antennas are assumed to be identical. Re(•) denotes the real part of (•). This estimation of correlation coefficient is quite good for antennas with high radiation efficiencies, but it can be very conservative for antennas with low efficiencies. For example, when the radiation efficiency is lower than 50 %, which is not uncommon for mobile terminal antennas (especially in frequency bands below 1 GHz), the calculated upper bound is larger than unity regardless of the S parameters (Li et al. 2013a). More intuitively, the guaranteed correlation coefficients largely depend on the radiation efficiency of the antenna when the efficiency is low; however, the true correlation coefficients do not vary much with radiation efficiencies when materials with higher losses are introduced, since this will only cause slight changes in the antenna patterns.

In (Li et al. 2013a), equivalent circuits were used to estimate the signal correlation, where antenna losses were modeled as series resistance or parallel conductance depending on the antenna behavior. Given radiation efficiencies and S parameters, the loss resistance (or conductance) was calculated in order to isolate the lossy component from the original lossy antennas. For the dual-antenna case, the original lossy antenna array was decomposed into three parts: two resistors (one for each antenna) and one lossless two-element array. Then, the correlation coefficient of the original dual-antenna system can be calculated from the S parameters of the lossless array through matrix operations. Significantly better accuracy had been achieved using this method, relative to other S-parameter based methods.

It is worth noting that in practice, the calibration of the phases of the S parameters is very important in the measurement, since they are utilized in all S-parameter based calculation methods. In contrast, the phase of the coupling (or transmission) coefficient S_{21} (or S_{12}) is unimportant for conventional multi-antenna evaluation. Other approaches to estimate signal correlation can also be found in (Stjernman 2005, Salonen et al. 2005).

Relationship Between Decoupling and Decorrelation

By definition, decoupling means increasing isolation or decreasing coupling among the antenna ports, which leads to lower mismatch loss and higher total efficiency. On the other hand, de-correlation means making the complex radiation patterns of the antennas more orthogonal to one another, which leads to lower signal correlation.

To examine the relationship between decoupling and decorrelation, it is assumed that the antennas in a dual-antenna system are identical (e.g., identical antenna elements symmetrically distributed on a ground plane) and have 100 % radiation efficiency. Hence, Eq. 6 reduces to (Dossche et al. 2004):

$$\rho_e \approx \frac{\left|2\text{Re}\left(S_{11}S_{21}^*\right)\right|^2}{\left(1-|S_{11}|^2-|S_{21}|^2\right)^2}. \tag{8}$$

DOI 10.1007/978-981-4560-75-7_99-1

According to Eq. 8, if the antennas are well matched (i.e., $|S_{11}|$ is very small), the correlation between antennas will be low when the mutual coupling ($|S_{21}|$) is very small. Therefore, the antennas are automatically decorrelated when they are decoupled. Other than minimizing $|S_{11}|$ and $|S_{21}|$, another method to decorrelate the antennas is by causing S_{11} to be in quadrature with S_{21}, which can be achieved by using a coupled matching network (Dossche et al. 2004). However, low mutual coupling is not required in this case.

Based on these observations, it can be concluded that decoupling between antennas with high efficiencies can lead to decorrelation, whereas decorrelation does not necessarily mean decoupling. For antennas with low radiation efficiencies (e.g., terminal handset antennas at frequencies below 1 GHz), there exists no simple relationship between decoupling and decorrelation. Therefore, both metrics of coupling and correlation need to be considered and evaluated when designing antennas.

Channel Capacity

In MIMO systems with M_t transmit antennas and M_r receive antennas, the transmitted signals **s** and the received signals **y** can be represented in the baseband as:

$$\mathbf{s} = [s_1, s_2, \ldots s_{M_t}]^T, \tag{9}$$

$$\text{and} \qquad \mathbf{y} = [y_1, y_2, \ldots y_{M_r}]^T. \tag{10}$$

The input–output signal model of such a system is described as:

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n}, \tag{11}$$

where **n** is the AWGN noise at the receive antennas and the channel matrix **H** is given by:

$$\mathbf{H} = \begin{bmatrix} h_{11} & h_{12} & \cdots & h_{1M_t} \\ h_{21} & h_{22} & \cdots & h_{2M_t} \\ \vdots & \vdots & \ddots & \vdots \\ h_{M_r1} & h_{M_r2} & \cdots & h_{M_rM_t} \end{bmatrix}, \tag{12}$$

where h_{mn} is the complex transmission coefficient from the transmit antenna n to the receive antenna m. Then, the channel capacity (maximum achievable error-free data rate) for the MIMO system can be expressed as (Telatar 1999):

$$C = \max_{\mathrm{Tr}(\mathbf{R_{ss}})=M_t} \log_2 \det\left(\mathbf{I}_{M_r} + \frac{P_t}{M_t N_0}\mathbf{H}\mathbf{R_{ss}}\mathbf{H}^H\right), \tag{13}$$

where $\mathbf{I}_{M_r}$ is the $M_r \times M_r$ identity matrix, P_t is the transmit power and N_0 is the receiver noise power, and $(\bullet)^H$ denotes the Hermitian transpose operator. $\mathbf{R_{ss}}$ is the covariance matrix of **s** in Eq. 9 and must satisfy $\mathrm{Tr}(\mathbf{R_{ss}}) = M_t$ to constrain the total transmit power.

For antenna designers, the effect of non-ideal antennas on the channel capacity is an important design consideration. To study the impact of non-ideal behaviors, a simpler and more intuitive expression of Eq. 13 can be derived (Paulraj et al. 2003) using the Kronecker channel model (Kermoal et al. 2002), which has good accuracy for lower-order MIMO systems in non-line-of-sight scenarios with rich scattering and has been adopted in several IEEE standards

DOI 10.1007/978-981-4560-75-7_99-1

$$\mathbf{H} = \mathbf{R}_r^{1/2}\mathbf{H}_w\mathbf{R}_t^{1/2}, \tag{14}$$

where $\mathbf{R}_t \in C^{M_t \times M_t}$ and $\mathbf{R}_r \in C^{M_r \times M_r}$ are the transmit and receive antenna correlation matrices, respectively. $\mathbf{H}_w$ is the channel matrix for the independent and identically distributed (IID) Rayleigh channel. Substituting Eq. 14 into Eq. 13 for the case of equal power allocation (i.e., $\mathbf{R_{ss}} = \mathbf{I}_{M_t}$) gives

$$C = \log_2 \det\left(\mathbf{I}_{M_r} + \frac{P_t}{M_t N_0}\mathbf{R}_r^{1/2}\mathbf{H}_w\mathbf{R}_t\mathbf{H}_w^H\mathbf{R}_t^{H/2}\right). \tag{15}$$

Assuming $M_r = M_t = M$ and a high signal-to-noise ratio (SNR), the capacity of the correlated MIMO channel can be written as:

$$C \approx \log_2 \det\left(\frac{P_t}{M_t N_0}\mathbf{H}_w\mathbf{H}_w^H\right) + \log_2 \det(\mathbf{R}_r) + \log_2 \det(\mathbf{R}_t). \tag{16}$$

To focus on the antenna performance, the channel is assumed to be uniform 3D APS, then the correlation matrices can be expressed as $\mathbf{R}_t = \mathbf{\Lambda}^{1/2}\overline{\mathbf{R}}_t\mathbf{\Lambda}^{1/2}$ and $\mathbf{R}_r = \mathbf{\Lambda}^{1/2}\overline{\mathbf{R}}_r\mathbf{\Lambda}^{1/2}$ (Tian et al. 2011), where $\overline{\mathbf{R}}_t$ and $\overline{\mathbf{R}}_r$ are normalized correlation matrices similar to $\overline{\mathbf{R}}_r$ in Eq. 4, whereas $\mathbf{\Lambda}_t = \mathrm{diag}\left(\left[\eta_1, \ldots, \eta_{M_t}\right]\right)$ and $\mathbf{\Lambda}_r = \mathrm{diag}\left(\left[\eta_1, \ldots, \eta_{M_r}\right]\right)$ are diagonal matrices containing the total efficiencies of the antennas, with η_i being the total efficiency of the i^{th} antenna element.

In Eq. 16, $\log_2 \det(\mathbf{R}_r) \leq 0$ and $\log_2 \det(\mathbf{R}_t) \leq 0$, where the inequalities will occur for any non-ideal antenna behaviors in total efficiency, efficiency imbalance and correlation. This implies that non-ideal MIMO antennas will result in a capacity loss of $\log_2 \det(\mathbf{R}_r) + \log_2 \det(\mathbf{R}_t)$ bps/Hz. The effects of non-ideal behaviors on MIMO performance will be further explained in the next subsection using the metric of multiplexing efficiency.

Multiplexing Efficiency

Capacity is a very useful metric to describe MIMO performance at the system level, since it takes into account all antenna and propagation effects. However, expressing performance in data rates does not provide explicit information to antenna researchers and engineers regarding the impact of individual antenna design parameters. Moreover, antenna researchers and engineers are more accustomed to power based metrics such as total efficiency. Therefore, multiplexing efficiency was introduced as a new figure of merit to evaluate antenna performance in MIMO systems (Tian et al. 2011).

Multiplexing efficiency is defined as the power penalty of a non-ideal antenna system in achieving a given capacity, compared with an ideal antenna system with 100 % total antenna efficiencies and zero correlation among the antennas:

$$\eta_{\text{mux}} = P_0/P_t \leq 1. \tag{17}$$

In Eq. 17, P_0 and P_t are the transmit power (or SNR, if the same receiver noise is assumed) required by the ideal and the real antenna systems, respectively, to achieve the same capacity.

Following the procedure described in Tian et al. (2011), and assuming no correlation at the transmitter and the receive antennas being the MIMO antennas under test, the multiplexing efficiency for a $M \times M$ MIMO system can be derived as:

DOI 10.1007/978-981-4560-75-7_99-1

$$\eta_{\text{mux}} = \frac{\det(\mathbf{I}_M + \gamma_t \mathbf{R}_r)^{1/M} - 1}{\gamma_t} \quad [\text{dB}], \tag{18}$$

where $\mathbf{R}_r = \mathbf{\Lambda}^{1/2}\overline{\mathbf{R}}_r\mathbf{\Lambda}^{1/2}$ and $\gamma_t = P_T/N_0$. At high SNRs, the multiplexing efficiency can be well approximated by:

$$\eta_{\text{mux}} = \left(\prod_{i=1}^{M} \eta_i\right)^{\frac{1}{M}} \det\left(\overline{\mathbf{R}}_r\right)^{\frac{1}{M}}. \tag{19}$$

Equation 19 can be interpreted as a generalization of total efficiency of the single-antenna case to the multi-antenna case, where the extended form translates efficiency imbalance and correlation to an equivalent power loss in decibel (dB).

For the simple case with two antennas at both the transmitter and receiver, the multiplexing efficiency expression reduces to:

$$\eta_{\text{mux}} = \underbrace{\sqrt{\eta_1\eta_2}}_{\eta_g} \underbrace{\sqrt{\left(1 - |\rho_c|^2\right)}}_{\eta_c}. \tag{20}$$

In Eq. 20, η_g is the geometric mean (or arithmetic mean in dB) of the antenna efficiencies, which includes the effect of efficiency and efficiency imbalance, whereas η_c reveals the equivalent power loss caused by correlation. Equation 20 is useful for testing and comparing between different MIMO terminal antennas.

Decoupling Techniques for MIMO Terminals

As mentioned above, coupling is important in terms of its influence on total antenna efficiency, which together with correlation has significant impacts on MIMO capacity. In this section, existing decoupling techniques on both the circuit level and the antenna level for achieving low coupling and correlation are surveyed and discussed. Apart from the decoupling techniques covered in this section, it should be noted that polarization diversity can also be utilized to achieve low mutual coupling in multi-antennas (and multi-port antennas in general), with dual-polarized patch antenna being a classic example.

Decoupling Network

The purpose of a decoupling network is to reduce the mutual impedance or coupling coefficients among the antennas to zero, and at the same time retain the good impedance matching of each antenna element (Wallace and Jensen 2004). Therefore, it is also called decoupling and matching network (DMN) in the literature, (e.g., Volmer et al. 2008). Decoupling network is a circuit approach to achieve decoupled MIMO antennas.

One possible realization of decoupling network for dual-antennas is shown in Fig. 2 (Dossche et al. 2004). In this realization, the whole network consists of transmission lines, open-circuited stubs and a decoupling line. Firstly, the matching network is connected to the antennas to turn each reflection coefficient (S_{11} and S_{22}) into a real number and each coupling coefficient (S_{21} and S_{12}) into an imaginary number. According to Eq. 8, assuming the two antennas are identical, the correlation coefficient between the antennas is zero due to S_{11} being in quadrature with S_{21}. The imaginary S_{21} ensures that the mutual

DOI 10.1007/978-981-4560-75-7_99-1

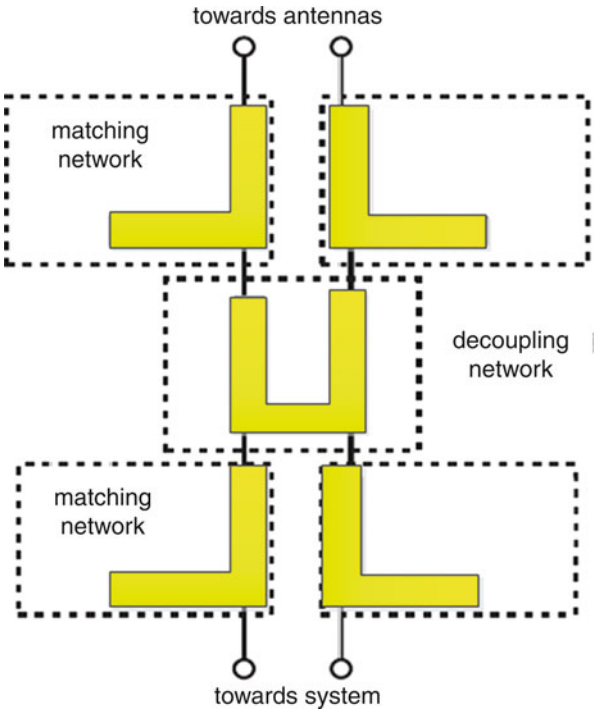

Fig. 2 Decoupling network for a two-port antenna system (Dossche et al. 2004)

impedance Z_{21} is imaginary, such that a lossless decoupling network can be employed to decouple the antennas by achieving $S_{21} = 0$. After that, a second matching network can be used to minimize S_{11} to ensure good impedance matching at the output ports. The dual-antenna system is then well matched and decoupled.

Other realizations of the decoupling network have been proposed based on a combination of lumped elements (including capacitors and inductors) (Chen et al. 2008), distributed elements (Dossche et al. 2005), the hybrid 180° coupler (Coetzee and Yu 2008b; Lin et al. 2012a; Volmer et al. 2008) or decoupler line (Dossche et al. 2005). Lumped elements are easier to tune and also conserve space on the PCB relative to distributed elements (Weber et al. 2006), yet at the same time when the number of lumped elements is increasing, the loss of the whole network increases, reducing the efficiency of the whole antenna system.

In order to enable multi-band and multi-mode operation for highly coupled terminal antennas, decoupling networks have also been designed to be tunable or work in multiple bands. One example of dual-band decoupling network has been illustrated in (Lin et al. 2012). A dual-mode 180° hybrid coupler is utilized to decouple the low band by creating orthogonal modes. In the high band, the shunt path between the upper and lower parts of the hybrid coupler is prohibited, and the coupler becomes only a pair of delay lines. Thus, the reactive elements, realized with standard matrix manipulation, take over to cancel the mutual coupling. The unusual dual mode 180° hybrid coupler, whose behavior differs at low band and high band, is realized by synthesized microstrip lines with additional LC tanks.

Modified Ground Plane

Modified ground plane is an antenna-level decoupling method, where the ground structure of the multi-antennas is modified (e.g., etched) in a certain way to change its electromagnetic properties, such as current distribution and surface wave. Due to the slow wave and stop-band characteristics of the Defected ground plane (DGS) (Ahn et al. 2001; Kin et al. 2002), it has been previously utilized to suppress

DOI 10.1007/978-981-4560-75-7_99-1

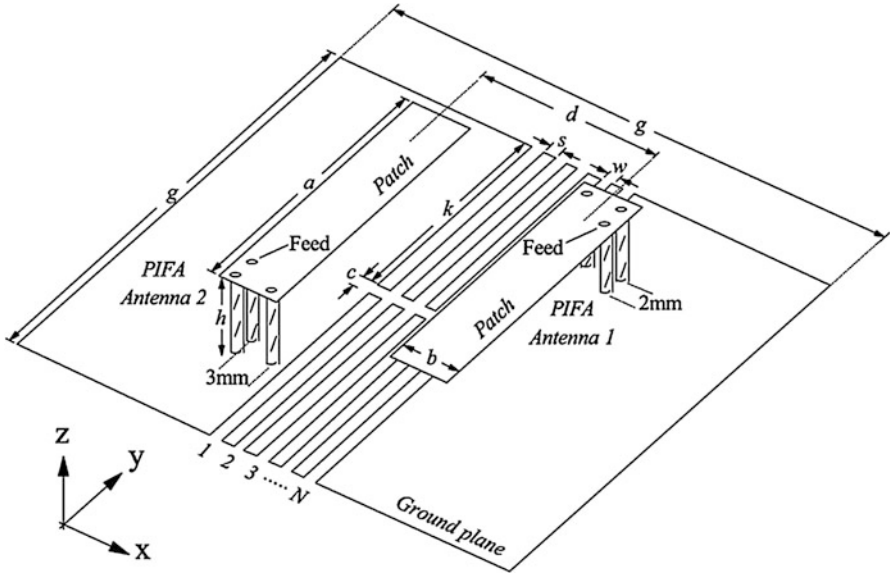

Fig. 3 Geometry of two closely-packed PIFAs with DGS (Chiu et al. 2007)

harmonics and cross polarization of a patch antenna in single-antenna design (Sung et al. 2003; Guha et al. 2005). For MIMO antennas, the effect of bandstop filter is employed to reduce the mutual coupling among the antenna elements. A common realization is to introduce multiple slits on the ground plane (Chiu et al. 2007; Li et al. 2009a; Huang and Lee 2009; Kokkinos et al. 2008; Zhu et al. 2009).

In the pioneering work of (Chiu et al. 2007), *N* pairs of slits were etched in the ground plane between two PIFA antennas, as presented in Fig. 3. The bandstop filter was built from slits interleaved with strips, where the capacitance comes from the strips, and the inductance is introduced along the central small connecting strip. The DGS part of the structure in Fig. 3 was extracted from the MIMO antennas and analyzed independently. Two transmission lines were connected to the DGS structure to test its reflection and coupling characteristics, which exhibit a stop-band from 2 to 3 GHz, i.e., most power is reflected back to the feeding port within the stop-band. Thus, when applied to MIMO antennas, most of electric current cannot flow from one antenna to the other, leading to improved isolation. The DGS approach was also successfully applied to other kind of antennas in (Chiu et al. 2007), including monopoles as non-planar radiating elements and patch antennas.

Following the same principles, different variations of DGS have been designed. Figure 4a shows an MIMO system with four quarter wavelength slots decoupled by a DGS between every two adjacent slot antennas (Li et al. 2010). Compared with the DGS in (Chiu et al. 2007), the required implementation space is halved and the terminal antennas can be more compact. In Fig. 4b, two coupled quarter wavelength slits with their openings on different edges of the ground plane are used (Kokkinos et al. 2008). Together with the ground plane, the two slots form an effective loop and resonate at a certain frequency. Thus, a transmission zero is introduced in the coupling path between the two antennas at the shorter edges, leading to high isolation of 50 dB. The shape of the DGS can also be different. For example, a simple ring shaped DGS was applied around a cylindrical dielectric resonator antenna (DRA) in (Guha et al. 2008), improving the isolation by 5 dB. The effect of different DGS structures, including dumb-bell shape, E shape and H shape were compared for closely packed microstrip patch antennas in (Elsheakh et al. 2010).

Apart from DGS, an electromagnetic band-gap (EBG) structure can also be used for decoupling. An EBG structure is constructed by arranging unit cells periodically on the ground plane (see Fig. 5). An EBG

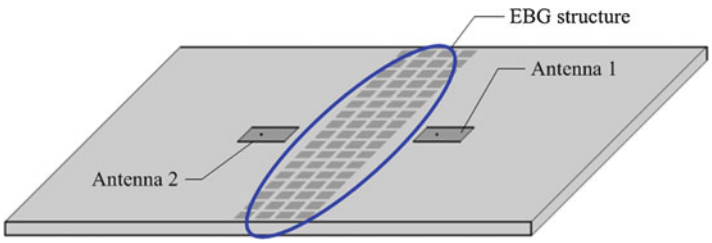

Fig. 5 The configuration of the EBG structure for decoupling (Yang and Rahmat-Samii 2003)

structrure behaves as a bandstop filter with a wide stop-band and high attenuation, which is well suited for decoupling multi-antennas (Yang and Rahmat-Samii 2003; Inclan-Sanchez et al. 2007). A typical EBG unit cell is a mushroom-like structure, consisting of a patch and a via connecting to the ground. By varying the dimensions of the unit cell and arranging them in two dimensions, the stop band can be achieved at different frequencies. In (Iglesias et al. 2008), using a 4-cell EBG structure, an isolation improvement of over 10 dB was achieved between two patch antennas at 2.8 GHz. However, restricted by the Bragg reflection condition, EBG structures are complicated and require a large implementation area, especially for low frequencies (Huang and Lee 2009).

Another similar decoupling technique is to use a soft surface in the modified ground plane, as shown in Fig. 6. Soft surface does the filtering in only one direction, so that it can have a smaller unit cell size when compared to EBG (Iglesias et al. 2009). With a soft surface, the isolation can normally be improved by around 10 dB. The use of more strips will result in higher isolation.

Neutralization/Connecting Line

Neutralization line approach is another antenna-level decoupling method. In general, a neutralization line is a conductive wire (or strip) that connects two antennas on a common ground plane to each other. Normally, the connection points are near the antenna feeds or shorting pins (if the antennas have shorting pins). In the beginning, the neutralization line is proposed to improve the isolation between two PIFAs whose resonating frequencies are very close to each other (Diallo et al. 2006). The technique was then

DOI 10.1007/978-981-4560-75-7_99-1

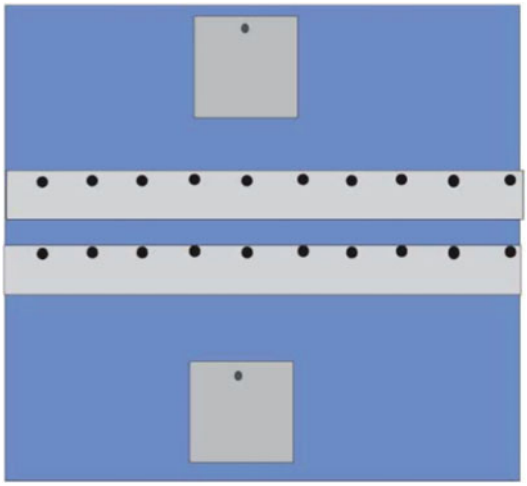

Fig. 6 Structure of soft surface to decouple two patch antennas (Iglesias et al. 2009)

applied to dual-antennas working at the same band, including different kinds of antennas, such as monopoles (Chung and Yoon 2007), patches (Ranvier et al. 2006) and PIFAs (Diallo et al. 2008). This technique is popular for designing MIMO antennas due to the simple design procedure and the relatively non-intrusive nature of the neutralization line structure.

The principle of the neutralization technique is to mitigate the existing electromagnetic coupling between the two antennas through introducing a direct connection (i.e., a new coupling path) via a suspended link. The design of PIFAs with the neutralization line between the feeding strips is shown in Fig. 7a. Strong current is observed on the connecting line at around 2 GHz, which cancels out the initial near field coupling and the coupling due to the shared ground plane. The effectiveness of the connecting line to achieve decoupling depends on the length and the width of the line, and a particular combination of the length and width of the line can lead to a better isolation level. Attributed to the connecting line, an isolation dip is achieved at around 2 GHz. The connecting line can also be placed between the shorting pins, which, unlike the connecting line between the feeding strips, can make the decoupling effect more frequency independent.

When the PIFAs are placed even closer to each other, as shown in Fig. 7b, there is insufficient space to accommodate the connecting line, which reduces its effectiveness. To decouple the antennas, one solution is to insert a folded line on the side of each PIFA, connecting the feeding strip to the ground plane (Chebihi et al. 2008). To obtain high isolation over multi-bands or a wide band, multiple neutralization lines of different lengths can be utilized (Wang and Du 2014), as shown in Fig. 8. Three neutralization lines operate at a center frequency of 1.81, 2.05 and 2.65 GHz, respectively, offering an isolation of over 15 dB from 1.7 to 2.7 GHz.

The neutralization line technique has also been analyzed from a generalized network perspective with a two-port model in (Shaker et al. 2008). Based on the model, the technique can be interpreted as a specific realization of the decoupling network in section "Decoupling Network", whereby the decoupling and matching network is built into the antenna by the use of neutralization line(s). Along the same line, another theoretical analysis of the neutralization lines was carried out in (Peng et al. 2013), where the neutralization lines were shown to be equivalent to 180° phase shifters and realized by feeding networks.

Parasitic Scatterer

In conventional single-antenna design, parasitic scatterers/elements are often used to create multi-resonances for bandwidth enhancement (Costa et al. 2007) or to obtain antenna pattern reconfigurability

DOI 10.1007/978-981-4560-75-7_99-1

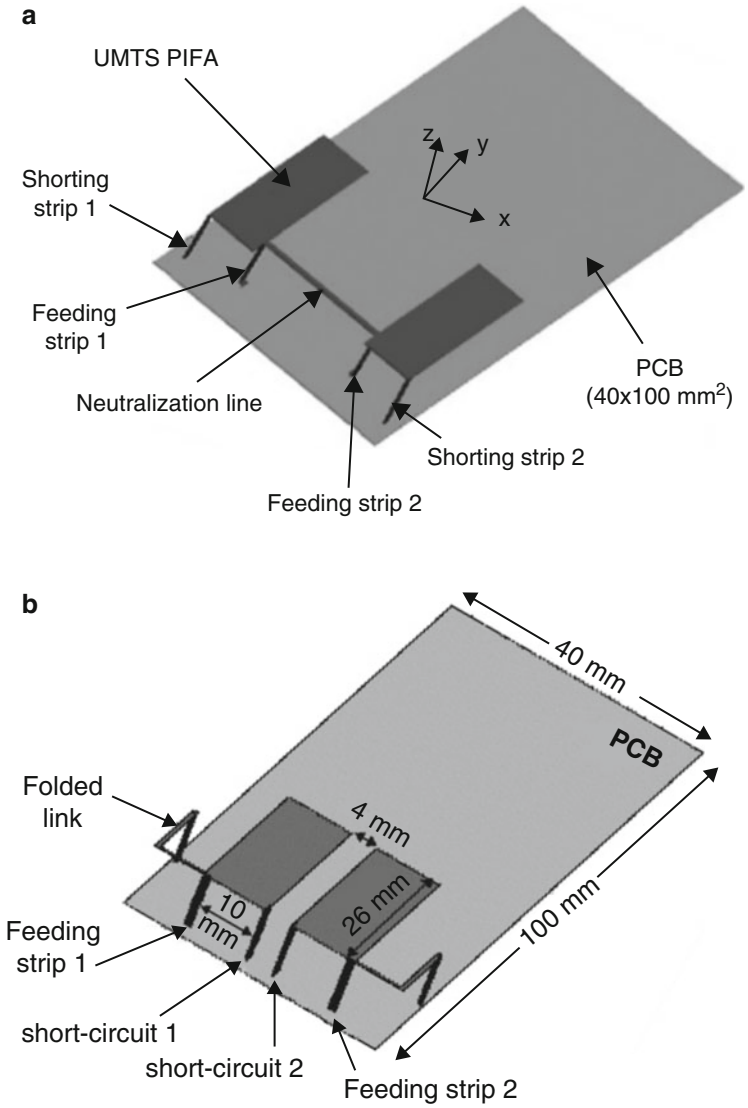

Fig. 7 (**a**) Two PIFA structure with the neutralization line between the feeding strips (Diallo et al. 2008); (**b**) two PIFA structure with the neutralization lines on the side (Chebihi et al. 2008)

(Lim and Ling 2010). In MIMO antenna design, it can also be added in between two radiating elements to reduce mutual coupling (Min et al. 2005; Lau and Andersen 2007; Mak et al. 2008; Minz and Garg 2010).

A parasitic scatterer artificially creates an additional coupling path between two antenna elements to reduce the coupling between them, which can be compared to a neutralization line adding a direct coupling path to achieve decoupling. By changing the configuration of the scatterer, the amplitude and phase of the coupling coefficient can be varied. A theoretical analysis of the parasitic scatterer can be found in (Lau and Andersen 2009, 2012). The principle of parasitic scatterer is illustrated with the setup in Fig. 9. In the "black box", a parasitic scatterer (port 2) is placed in between two antenna elements (ports 1 and 3). The parasitic scatterer is terminated by a load impedance Z_L, whereas the antenna elements are connected with matching circuits. A generalized three-port network can be used to analyze the setup, with which the voltage and current relationships between port 1 and port 3 can be obtained with the impedance of the antennas and the load Z_L. In order to decouple the antennas, it is required that the mutual impedance between port 1 and port 3 is zero. The load impedance of Z_L is then determined to fulfil the requirement. It

DOI 10.1007/978-981-4560-75-7_99-1

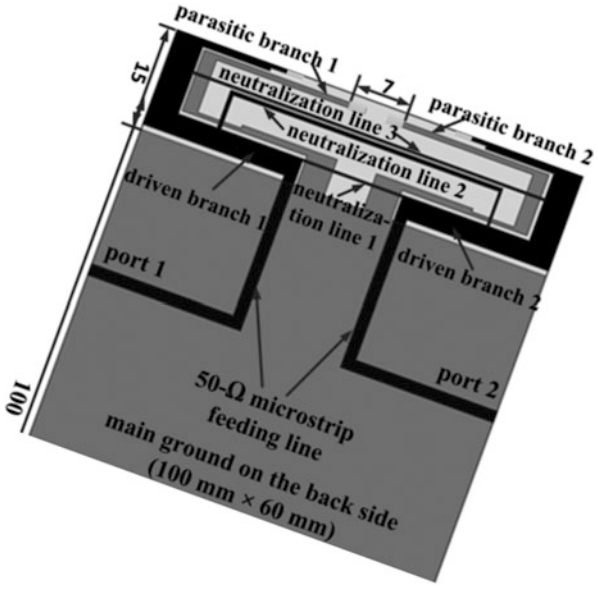

Fig. 8 A wideband dual-element MIMO antenna with good isolation achieved by using three neutralization lines (Wang and Du 2014)

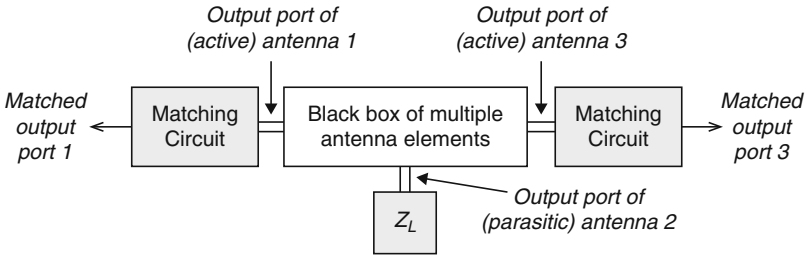

Fig. 9 Decoupling setup for a *black box* containing an arbitrary two-antenna structure (ports 1 and 3) and a parasitic scatterer (port 2) (Lau and Andersen 2012)

is worth noting that the closely coupled antenna and scatterer should be considered together as the radiating element. With the parasitic scatterer, a complete decoupling, i.e., zero coupling coefficient between antennas, can be achieved at the center frequency at the expense of bandwidth.

A more intuitive explanation of parasitic scatterer based on current distribution was provided in (Mak et al. 2008). Assuming a sinusoidal signal is fed into dipole antenna A, as seen in Fig. 10, a strong coupled current which is approximately 180° out of phase compared to the current in dipole A is then formed on dipole antenna B due to the close proximity of the two dipoles. When parasitic scatterer C, whose electrical length is around half wavelength, is inserted between the two dipoles, it creates another coupling path. The coupling starts from dipole A, goes through C and couples to dipole B. The current on Dipole B through this path is in phase with that on dipole A, because the scatterer C introduces an additional 180° phase. If coupling coefficient from A to B is denoted as α, and that from A to C is denoted as β, when β is properly optimized (e.g., using a capacitive load), the current on dipole B from the two coupling paths can cancel out each other, and decoupling is achieved.

Like the single-antenna counterpart, the parasitic scatterer has been successfully implemented on different dual-antenna structures. In Fig. 11a, a slotted meander line resonator is placed between two microstrip antennas (Alsath et al. 2013), improving the isolation by 10 dB. Though the parasitic scatterer

DOI 10.1007/978-981-4560-75-7_99-1

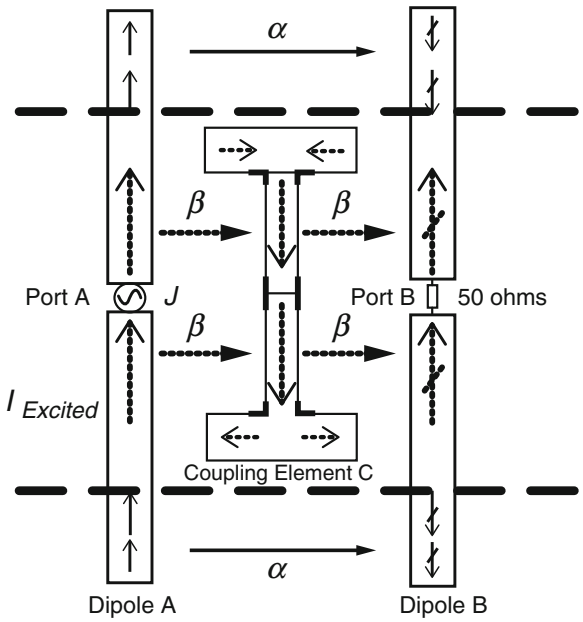

Fig. 10 Coupling between two dipoles with a parasitic scatterer (Mak et al. 2008)

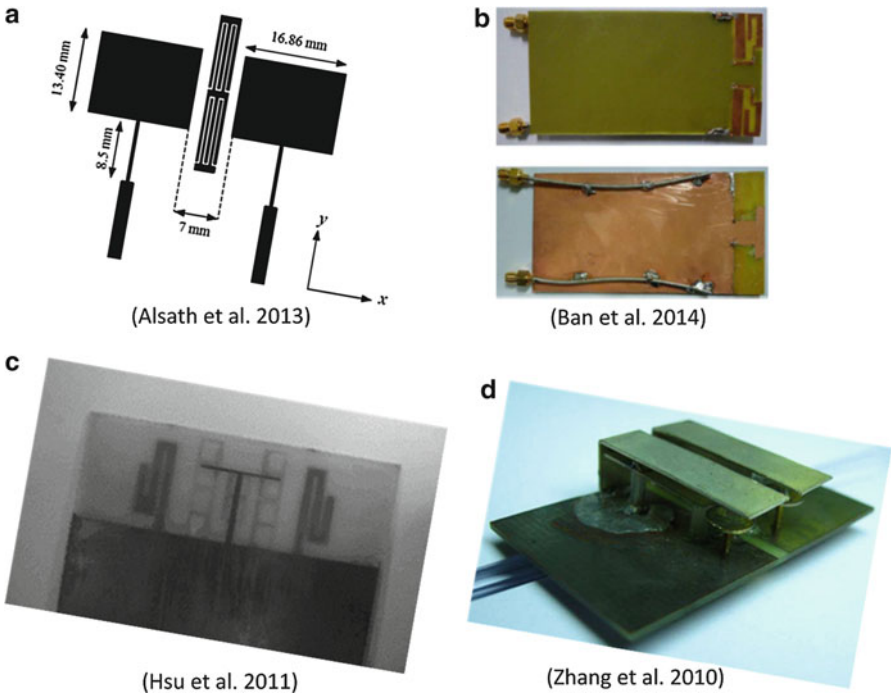

Fig. 11 Parasitic scatterers for isolation enhancement

in this case looks similar to the DGSs in section "Modified Ground Plane", the former DGS approach is based on the principle of stop-band filtering in choking out the coupling current, rather than introducing new coupling path(s). A popular implementation of parasitic scatterer is in the form of a grounded T-shaped structure (Ban et al. 2014; Lee et al. 2014; Hsu et al. 2011). The T structure as shown in Fig. 11b can also be utilized to accommodate some other electronic components, such as a USB port or a

DOI 10.1007/978-981-4560-75-7_99-1

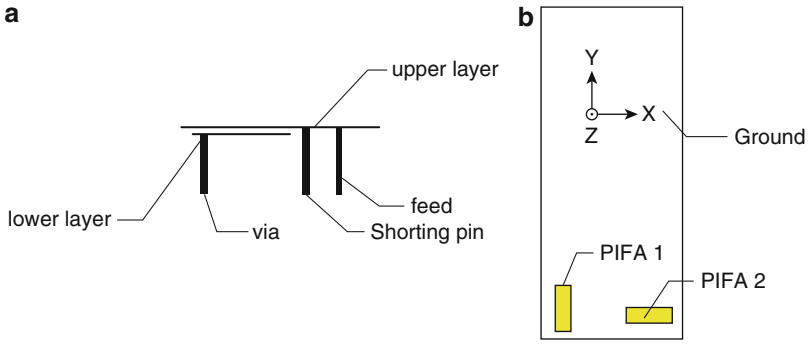

Fig. 12 Implementation of local ground plane to improve isolation (Li et al. 2009b)

loudspeaker. In Fig. 11c, the T-shaped branch is used together with an H-shaped metamaterial inspired insulator to achieve a 20 dB isolation bandwidth of about 12.8 %. Apart from adding a physical structure, the parasitic scatterer can also be formed opportunistically by placing two PIFAs side by side as illustrated in Fig. 11d, where the naturally formed slot in between the two PIFAs can be tuned to achieve decoupling (Zhang et al. 2010). This decoupling idea was further refined in (Zhang et al. 2012a) to allow for arbitrary ground plane size as well as dual-band operation.

Current Localization

As mentioned earlier, current flowing on the shared ground plane is a critical source of coupling for MIMO terminal antennas. The antenna-level decoupling techniques discussed so far in this chapter either create a new coupling path to cancel out the existed coupling or prevent the current flow by a bandstop filter. Different from these techniques, the technique of current localization aims to reduce the current on the shared ground plane through designing antennas that can better localize the current on the ground plane.

Adding a local ground plane is one way to realize current localization. As shown in Fig. 12 (Li et al. 2009b), a small local ground plane (lower layer) was inserted between PIFA and the main ground plane, so that the current is mostly confined to the lower patch underneath the PIFA. As a result, an isolation of over 20 dB was obtained. Another current localization method was proposed in (Gao et al. 2007).

Combination of Decoupling Techniques

Apart from the specific decoupling techniques described above, several decoupling techniques can be combined to further improve decoupling relative to the use of a single technique. In (Ling and Li 2011), good isolation is achieved for dual-band back-to-back monopoles by adding both a neutralization line and a parasitic scatterer between them, as shown in Fig. 13a. The neutralization line operates at the low band of 2.4 GHz, whereas the scatterer mainly takes effect at the high band of 5.8 GHz. Figure 13b shows a decoupling structure that consists of a grounded neutralization line and an ungrounded parasitic scatterer (Lee et al. 2009). The scatterer is a folded line with the electrical length of half wavelength. Another example of this decoupling approach is found in (Zhang et al. 2012b), where the parasitic scatterer that is formed from the gap between two ultra-wideband antennas further enhances the polarization diversity inherent to these antennas.

One common limitation for the decoupling techniques described in this section is that decoupling is normally achieved at the expense of bandwidth. This tradeoff can become a significant problem in frequencies below 1 GHz, since a given fractional bandwidth yields a lower absolute bandwidth for a lower center frequency, which can greatly complicate cellular band coverage. For example, 10 % bandwidth at 2.65 GHz (e.g., LTE Band 7) implies absolute bandwidth of 265 MHz, whereas 10 %

DOI 10.1007/978-981-4560-75-7_99-1

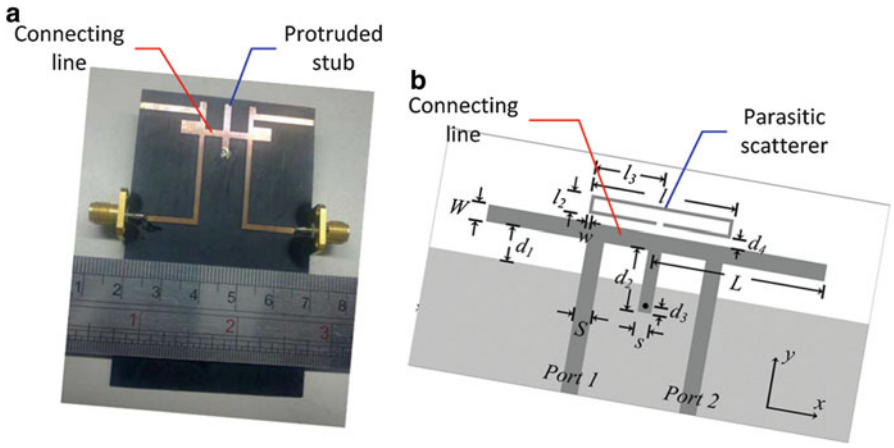

Fig. 13 (**a**) Combination method of connecting line and protruded stub (Ling and Li 2011) (**b**) Combination method of connecting line and parasitic scatterer (Lee et al. 2009)

bandwidth gives only 70 MHz absolute bandwidth at 700 MHz (e.g., LTE Band 13). Moreover, getting enough bandwidth is challenging at lower frequencies, even for single-antenna elements, due to decreasing electrical size of the mobile terminals. These problems can be addressed to some extent by the use of the Theory of Characteristic Modes (TCM) to design MIMO antennas, which is the subject of the following section.

Characteristic Mode Based Decoupling

In principle, the decoupling techniques in the previous section treat the ground plane of antennas as an electrically large structure, and hence the excitation of the ground plane (i.e., chassis) is not explicitly taken into consideration. However, for mobile terminal antennas, chassis radiation is critical for antenna design, especially for frequencies below 1 GHz. This is because at these frequencies, the largest dimension (i.e., length) of typical smartphone-type mobile terminals is around a third of a wavelength or less, with the antenna elements being even electrically smaller. Therefore, there is a large tendency for the chassis to be excited by the antenna elements to become the main radiator. Similar arguments apply for higher frequencies if terminals of smaller form factors are considered, such as USB dongles and smart watches. On the other hand, chassis radiation will become important for even lower frequencies if larger form factors are applied, including phablets and tablet PCs.

As will be further described in this section, chassis excitation complicates the design of decoupled and decorrelated MIMO antennas. Fortunately, recent results show that TCM can be used to significantly alleviate the design challenge. The main ideas of TCM are summarized below.

Theory of Characteristic Modes

Characteristic mode analysis is a method in electromagnetics, which gives insight into the potential resonant characteristics of a structure by finding and examining the inherent modes of the structure. Characteristic mode analysis is based on the Theory of Characteristic Modes (TCM), which was first introduced by Garbacz and Turpin (Garbacz 1968; Garbacz and Turpin 1971) and later refined by Harrington et al. (Harrington and Mautz 1971; Harrington et al. 1972).

Considering a conducting body with surface *S,* an incident or external (vector) electric field (or voltage) $\vec{E}^i$ can induce a surface current $\vec{J}$ on it. This surface current will further generate a scattered field $\vec{E}^s$.

DOI 10.1007/978-981-4560-75-7_99-1

According to electromagnetic boundary conditions, the tangential component on the surface of the conducting body satisfies the relation:

$$\left(\vec{E}^{i} + \vec{E}^{s}\right)_{\tan} = 0. \tag{21}$$

To relate the scattered electric field to the conductor surface current, an impedance operator of Z was defined, so that

$$Z\left(\vec{J}\right) = -\vec{E}^{s}_{\tan}, \tag{22}$$

where $Z\left(\vec{J}\right) = R\left(\vec{J}\right) + jX\left(\vec{J}\right)$, and R and X are the real and imaginary parts of Z, respectively.

The characteristic currents can be solved from the following eigenvalues equation:

$$X\left(\vec{J}_n\right) = \lambda_n R\left(\vec{J}_n\right), \tag{23}$$

where λ_n and $\vec{J}_n$ are the eigenvalues and eigenfunctions (eigencurrents), respectively, and both of them are real since R and X are real symmetric operators. Each eigenvalue represents the ratio of the modal stored reactive power (P_{stored}) to the radiated power (P_{rad}):

$$\lambda_n = \frac{P_{\text{stored}}}{P_{\text{rad}}} = \frac{\left\langle \vec{J}^{*}_n, R\vec{J}_n \right\rangle}{\left\langle \vec{J}^{*}_n, X\vec{J}_n \right\rangle}, \tag{24}$$

where $P_{\text{stored}} = \frac{1}{2}\left\langle \vec{J}^{*}_n, R\vec{J}_n \right\rangle, P_{\text{rad}} = \frac{1}{2}\left\langle \vec{J}^{*}_n, X\vec{J}_n \right\rangle$, and $\left\langle \vec{B}, \vec{C} \right\rangle = \oiint_S \vec{B} \cdot \vec{C}\ ds$.

Thus, the smaller the magnitude of λ_n, the more important the mode is for radiation, and $\lambda_n = 0$ corresponds to a resonant mode. One important property of the eigenvalue equation is that the characteristic currents and hence the modal electric far-fields are orthogonal, i.e.,

$$\left\langle \vec{J}^{*}_m, X\vec{J}_n \right\rangle = \frac{1}{\eta_0}\left\langle \vec{E}^{*}_m, \vec{E}_n \right\rangle = \delta_{mn}, \tag{25}$$

where η_0 is the free space wave impedance and δ_{mn} is a Kronecker delta function with $\delta_{mn} = 1$ for $m = n$, and $\delta_{mn} = 0$ for $m \neq n$. This property of orthogonal modes and patterns lends itself naturally to the design of multi-antennas for MIMO, which require low coupling and correlation between the antennas. With the above modal orthogonalities, any arbitrary surface current density can be expanded as a weighted sum of modal currents:

$$\vec{J} = \sum_n \alpha_n \vec{J}_n = \frac{\left\langle \vec{J}_n, \vec{E}^{i} \right\rangle}{1 + j\lambda_n} \vec{J}_n. \tag{26}$$

In this equation, λ_n and $\vec{J}_n$ depend solely on the structure and material of the conducting body, while α_n also depends on the excitation field $\vec{E}^{i}$, which is determined by the feeding method used. In antenna

DOI 10.1007/978-981-4560-75-7_99-1

design, α_n is decided by the number and location of the antenna ports, and also the amplitudes and phase of each excitation. In practice, one can excite mode n with a combination of inductive or capacitive feeds placed at appropriate location(s) on the conducting body (Martens et al. 2010).

Other than the conductor-only case, TCM was later extended to dielectric and magnetic bodies using a similar approach as for the conducting bodies, with the boundary condition in Eq. 21 replaced by the constitutive relationship (Harrington et al. 1972). For loss-free bodies, the current can still be expanded as a set of real characteristic functions, and the characteristic fields are orthogonal with each other. However for lossy materials, the characteristic far fields are no longer orthogonal. Most of the existing literature on TCM nowadays only treats the simple case of conducting bodies.

In the following, the TCM based MIMO antenna designs for frequencies above 1 GHz ("high frequencies") and below 1 GHz ("low frequencies") will be discussed separately. The two cases are treated differently because at high frequencies, the chassis readily offers multiple inherently orthogonal modes that can be excited to design decoupled and decorrelated MIMO antennas. However, at low frequencies, the chassis has only one resonant mode conventionally, and the single mode can become the main radiator that is shared by multi-antennas, which induces large coupling and correlation. Therefore, chassis excitation greatly complicates MIMO antenna design. To counteract this problem, different methods are used either to avoid the shared chassis radiation or to intentionally create more resonant modes for the same chassis form factor.

TCM Based MIMO Antenna Design for High Frequencies

For mobile terminals, the chassis plays a more important role than just being the ground plane of antenna elements. The impedance, bandwidth and radiation mode of an antenna element on a terminal ground plane is often defined by the location of the antenna and its feeding point on the ground plane (Best 2009). Efforts to apply TCM to terminal antenna design began around a decade ago and the topic has since been receiving increasing interest in the terminal antenna community. At the beginning, it was used to determine the optimum feeding arrangement to enhance the bandwidth of the antenna (Antonino-Daviu et al. 2004, 2005; Cabedo-Fabres et al. 2006; Schroeder et al. 2005, 2006). However, following the rise of MIMO technology, TCM is also employed to design MIMO terminal antennas. This is because TCM offers inherent orthogonal modes for a given structure, which is the ground plane in this case. The basic principle is that if the modes can be individually excited without affecting one other, ideal MIMO antennas with zero coupling and correlation can be obtained. In general, the orthogonal modes can be jointly excited to give multiple orthogonal antenna ports, as long as they are suitably combined in magnitude and phase to retain orthogonality at the antenna ports.

The eigenvalues of a candy-bar-type chassis with a size of 100 mm × 40 mm are shown in Fig. 14a. The figure shows four orthogonal modes which have closely spaced resonant frequencies at around 2.5 GHz. The current distributions of the four modes whose eigenvalues are close to zero are shown in Fig. 14b. The specific current distributions show sinusoidal behavior over the longer or shorter edges of the chassis. Each mode has its unique set of current maxima and minima at specific positions, which provide information on the location and type of feed to use. Through using four compact non-resonant capacitive couplers located at four vertices of the chassis and a feeding network composed of four 180° hybrid couplers, four orthogonal patterns are achieved with a small modification of the chassis. However, orthogonal patterns and good impedance matching cannot be achieved at the same time for all four antennas. It has been shown in (Ethier 2008) that for the 2.5 GHz band, the chassis of a typically mobile terminal is only capable of supporting at most three efficient radiating modes.

In addition to current distribution, near field distribution (including electric and magnetic fields) above the chassis is also important for mode excitation. The electric field and the current distribution will have a phase difference of 90°, i.e., the electric field distribution will have its minima at the maxima of the current

DOI 10.1007/978-981-4560-75-7_99-1

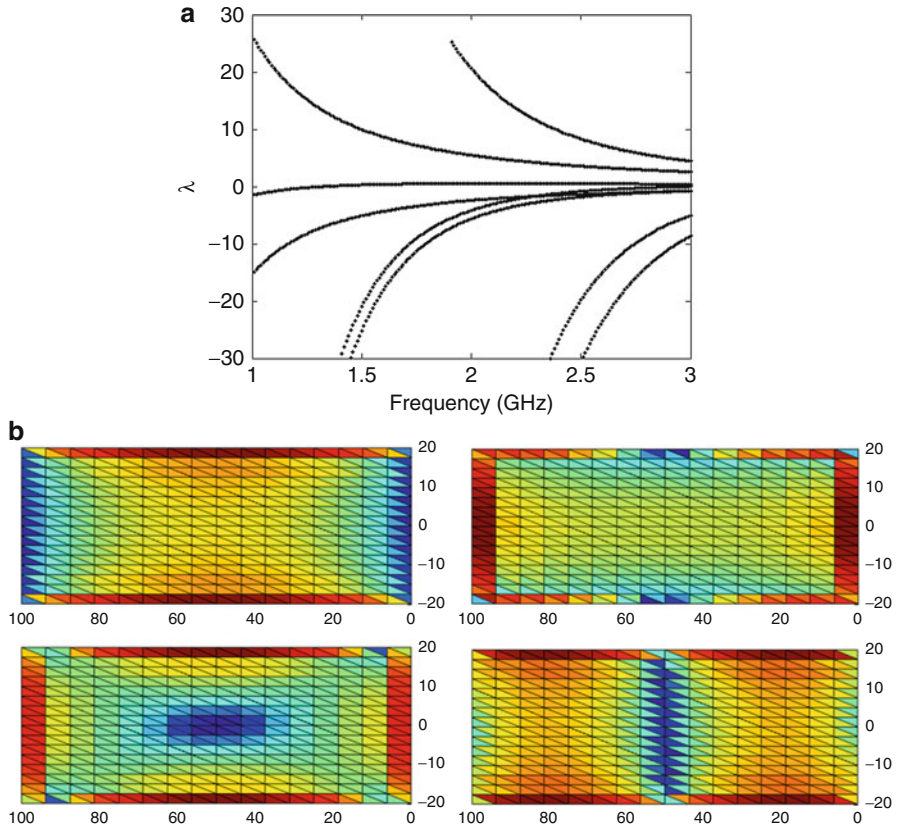

Fig. 14 (**a**) Characteristic eigenvalues over frequency for 100 × 40 mm chassis (**b**) Characteristic current distribution of the chassis. The chassis material is Perfect Electric Conductor (*PEC*)

distribution and vice versa. It means that if an inductive coupler is used, it should be located at one of the maxima in the current distribution. On the other hand, a capacitive coupler should be placed at one of the maxima in the electric field distribution.

In (Martens et al. 2010), inductive and capacitive feeds were used to selectively excite three modes of the chassis at 2.45 GHz. Each non-resonant inductive coupling elements (ICE) was created by a wire loop etched into one edge of the chassis, with its location corresponding to the location of one of the maxima in the current distribution of the desired mode, in order to excite a specific characteristic mode. The phase of each ICE was adjusted according to the requirement of the modes. For capacitive coupling, a small co-planar plate close to the main chassis was used as a non-resonant capacitive coupling element (CCE). Multiple CCEs were then located to excite the desire modes according to the locations of electric field maxima. In both cases of inductive and capacitive coupling, matching networks were needed to enhance the impedance bandwidth. A comparison between the inductive and capacitive coupling approaches is given in (Martens et al. 2010). For the inductive coupling approach, a three-port MIMO antenna was designed to achieve isolations of above 25 dB, and the correlations between all antenna pairs are lower than 0.02. However, one major drawback in this approach of using multiple non-resonant elements to excite any one of the desired modes is that the efficiency of the antennas is limited by the losses in the complicated matching network needed to properly excite the modes and to obtain good impedance bandwidth.

To improve coupling into the desired modes when fewer coupling elements are used, electrically larger coupling elements can be used, such as those shown in Fig. 15 (Kishor and Hum 2013). Different from using coupling elements as pure mode exciter, the complete antenna structure (ground plane and the exciters)

DOI 10.1007/978-981-4560-75-7_99-1

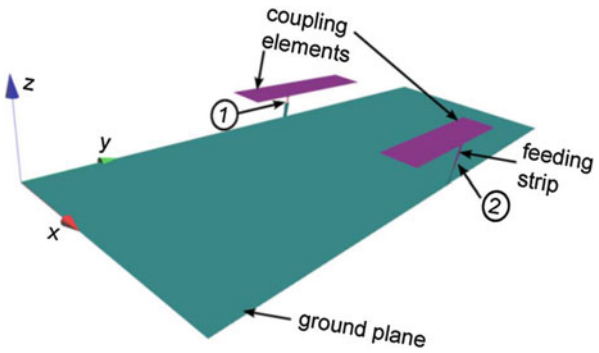

Fig. 15 Design of chassis mode based antenna with large exciters (Kishor and Hum 2013)

needs to be analyzed using TCM, because the eigenmodes and the radiation characteristics will change due to the increased electrical size of the coupling element. Moreover, unlike the MIMO antennas in (Martens et al. 2010), which rely on complicated matching networks with hybrid 180° couplers to excite non-overlapping sets of characteristic modes, only simple impedance matching is needed for the dual antenna system in Fig. 15 to excite two separate modes. Even though these two modes are simultaneously excited by both ports, the out-of-phase behavior between the ports ensures that pattern orthogonality is retained. As a result, the isolation of above 20 dB and the envelope correlation coefficient of below 0.1 are achieved.

In a separate study that accounts for the impact of larger coupling elements on characteristic modes, a two-port pattern reconfigurable MIMO antenna was designed using the method of port analysis (Kishor and Hum 2014). In this design, two coupling elements that were used as antenna ports were located at diagonally opposite corners of the chassis, where the electric field is at its maximum. The remaining two coupling elements were used as parasitic elements with reconfigurable impedance loads (i.e., Z_{L3}, Z_{L4}). Four orthogonal modes were selected and manipulated by TCM analysis to provide two sets of orthogonal patterns across the two ports. Each set of two orthogonal patterns, which represents one reconfigurable state, was obtained using different Z_{L3}, Z_{L4} selected based on port analysis. The design provides both low intra-state and inter-state correlations.

TCM Based MIMO Antenna Design for Low Frequencies

As explained earlier, a typical terminal chassis conventionally offers only one excitable mode at frequencies below 1 GHz. Moreover, multiple electrically small antenna elements tend to rely on this single mode as their dominant radiator. Hence, the problem of coupling is more severe at lower frequencies as compared to higher frequencies, and the isolation of MIMO terminal antennas with cellular band coverage is typically around 6 dB or less, e.g., (Plicanic et al. 2009).

To quantify this problem, the characteristic modes of a typical candy-bar-type chassis with a size of 100 mm × 40 mm are shown in Fig. 16. It is seen that there is only one mode that is excitable at around or less than 1 GHz. To further understand the single-mode problem, the normalized characteristic electric and magnetic fields on a plane 5 mm above the 100 mm × 40 mm chassis are shown for the single resonant mode at 1 GHz in Fig. 17a and b, respectively. The strong electric field at the chassis edges in Fig. 17a reveals that an electric antenna that is placed at either of the two shorter edges of the chassis can strongly excite the mode. Therefore, if two electric antennas are placed at the two chassis edges, both antennas will share the chassis as their main radiator, causing severe mutual coupling.

To avoid the excitation of the shared chassis by more than one antenna, the simplest method is to optimize the position of the second antenna to effectively reduce chassis excitation for that antenna (Li et al. 2012a). The dual-antenna design with PIFA and slot monopole elements as shown in Fig. 18a

DOI 10.1007/978-981-4560-75-7_99-1

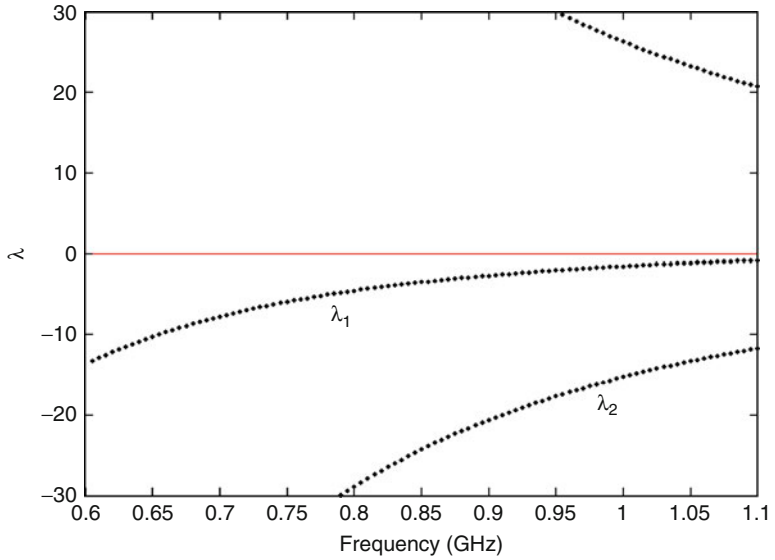

Fig. 16 Characteristic eigenvalues over frequency for 100 × 40 mm chassis (Li et al. 2012a). The chassis material is Perfect Electric Conductor (*PEC*)

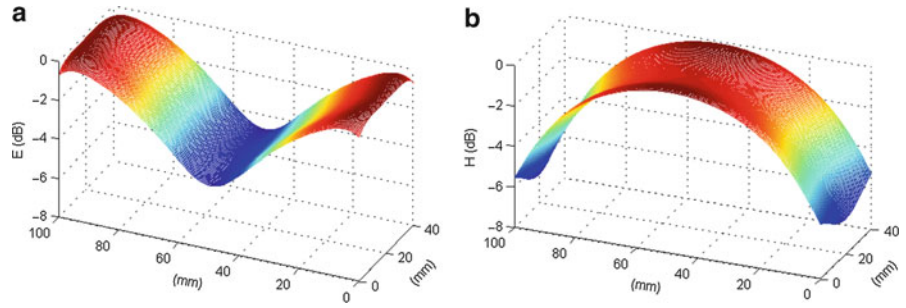

Fig. 17 The normalized magnitude of (**a**) the total electric field and (**b**) the total magnetic field for the first mode of the chassis (chassis size: 100 × 40 mm) (Li et al. 2012a)

was used to demonstrate this design principle (Li et al. 2012a). To optimize the antenna location, the first antenna, which is a slot monopole, was kept at one edge of the chassis (to excite the single chassis mode), whereas the second antenna, which is a PIFA, was moved from the edge of the chassis towards the center position (to avoid exciting the mode). As a result, the isolation was enhanced from below 4 to 10 dB and the capacity for equal power condition was increased from 5.5 to 7.5 bps/Hz when averaged over a bandwidth of 30 MHz. It is interesting to note that the significant isolation improvement occur even though the distance between antenna elements is halved. Therefore, this simple example also reveals that chassis coupling dominates over other coupling mechanisms, which should increase with the smaller inter-element distance.

Another solution to the chassis induced coupling problem is to utilize magnetic antenna instead of electric antenna for one of the two antennas (Li et al. 2012b). As opposed to an electric antenna, a magnetic antenna stores mainly magnetic energy (rather than electric energy) in the near field. According to Fig. 17b, the magnetic field of the chassis mode is quite weak at the shorter edges. Thus, if a magnetic antenna is placed at a shorter edge, the chassis will not be excited. This means that an electric antenna, if placed on the opposite shorter edge to excite the chassis, will be relatively unaffected by the magnetic antenna, resulting in high isolation. Following this principle, a coupled fed loop antenna that radiates like

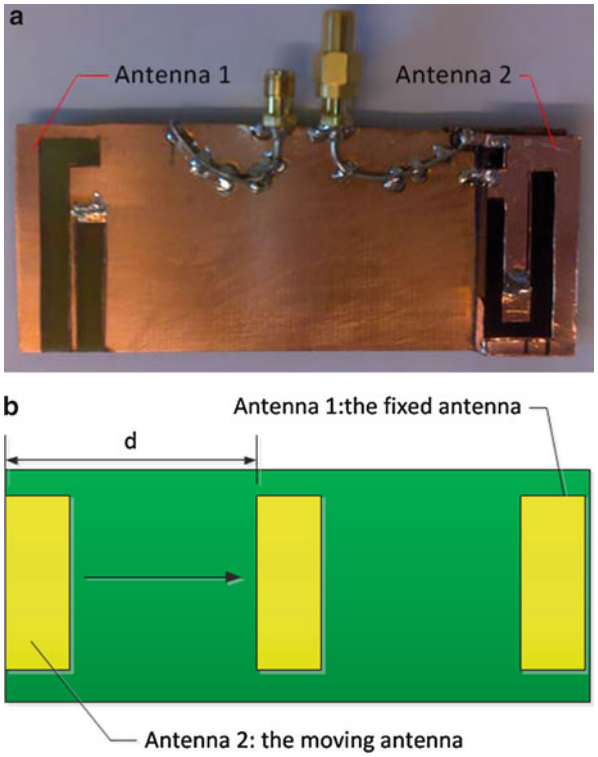

Fig. 18 (**a**) Prototype when the PIFA is at the short edge; (**b**) the study of MIMO performance for different positions of the PIFA (Li et al. 2012a)

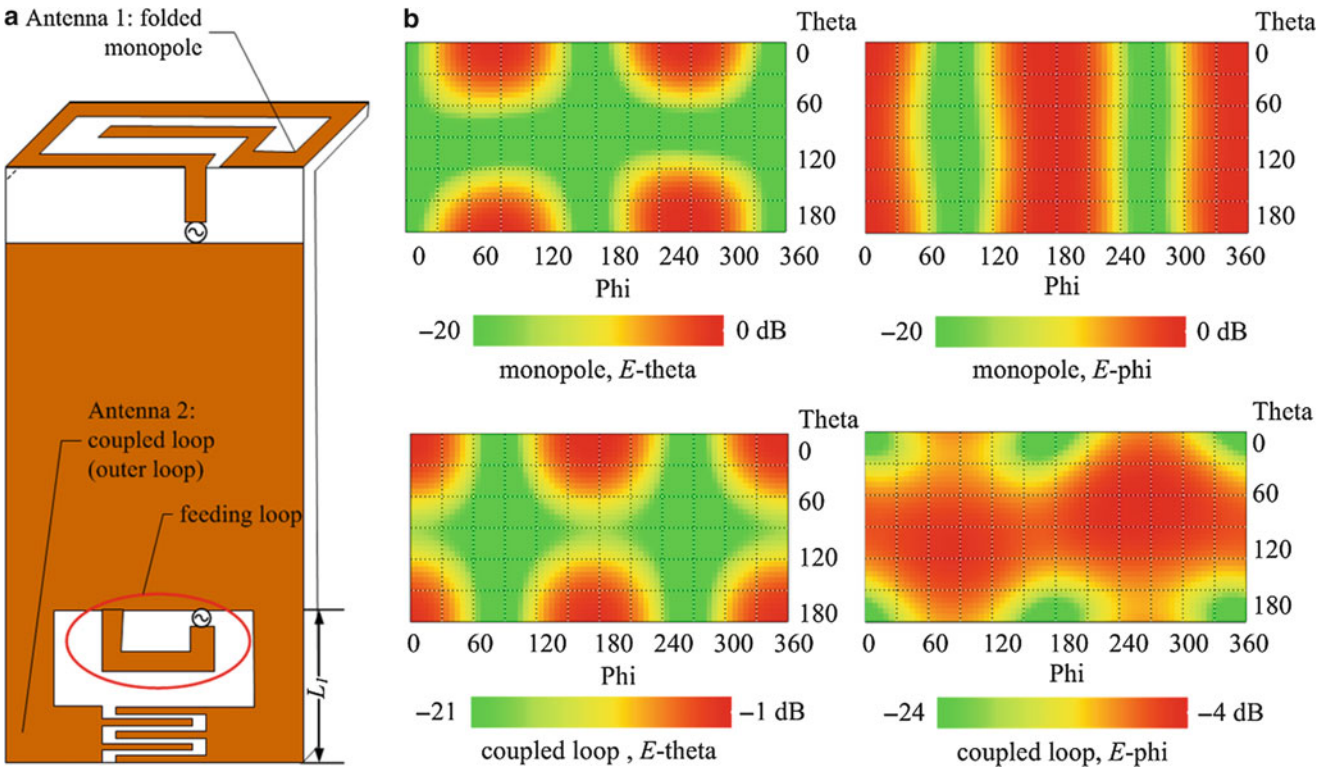

Fig. 19 Orthogonal dual-antenna design using monopole and coupled loop. (**a**) Antenna structure; (**b**) far field patterns (Li et al. 2012b)

DOI 10.1007/978-981-4560-75-7_99-1

a magnetic dipole was designed at one shorter edge, as shown in Fig. 19a. The small half loop inside is used to match the outer loop to 50 Ω. On the other shorter egde, a folded monopole is used to excite the chassis mode and create an electric dipole like pattern. Thus, the polarizations of the antennas are different and the patterns are orthogonal to each other, as shown in Fig. 19b. The isolation between the antennas is above 30 dB in simulation. With some modifications, the two antennas can be co-located at the same edge of the chassis to save more space on the PCB.

The main drawback of the two above decoupling methods is that the bandwidth of the non-chassis-exciting antenna is usually limited due to it being electrically small and not making use of the electrically larger chassis to radiate. Therefore, it is difficult to obtain low mutual coupling and correlation as well as adequate antenna bandwidth at the same time.

To solve the problem of limited bandwidth, an entirely different decoupling approach has been proposed. In particular, minor modifications of the chassis can be used to generate multiple resonant modes at low frequencies (i.e., lower than 1 GHz). Once multiple modes are achieved, they can be exploited in a similar manner as was described in the previous section for the case of higher frequencies.

The first example of chassis modification is to load the chassis with a metal bezel along its periphery, with the bezel connected to the center of one shorter chassis edge through a shorting pin (Li et al. 2013b). The geometries of the bezel-loaded chassis are shown in Fig. 20a. It is easy to practically integrate the bezel and the shorting pin onto the mobile casing. In fact, it should be noted that metal bezel is a design feature of some existing smartphone models, including Apple iPhone 4, which means that an existing structure of these phones can be used opportunistically to implement this decoupling technique. The eigenvalues of the bezel-loaded chassis are presented in Fig. 20b. At frequencies below 1 GHz, it can be seen that apart from the fundamental mode that was found earlier (denoted by λ_2), a new bezel mode (λ_1) is generated. The eigenvalue of this new mode is close to zero at frequencies around 0.81 GHz. The two

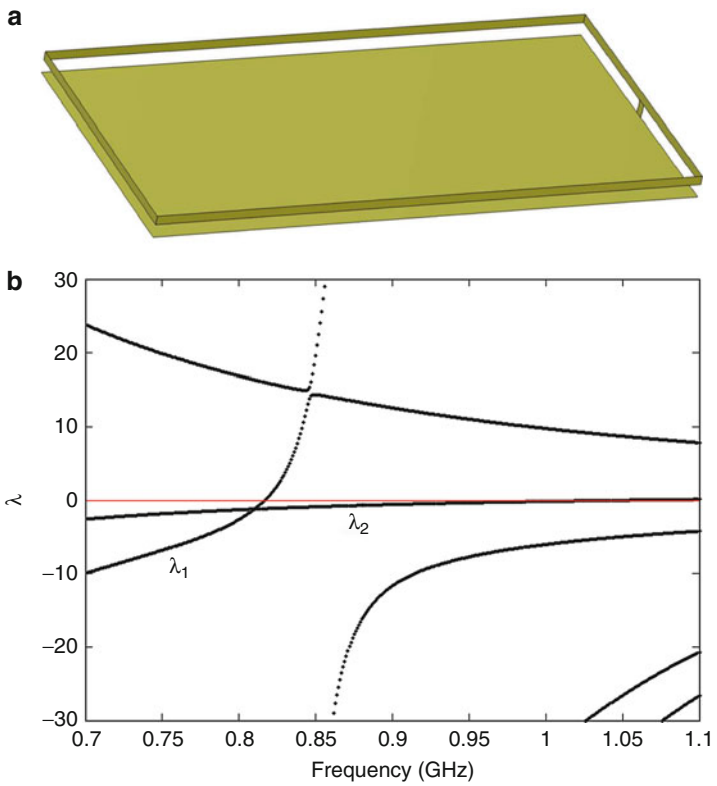

Fig. 20 (**a**) Geometries of the bezel-loaded chassis. (**b**) Eigenvalues of the bezel-loaded chassis (Li et al. 2013b)

DOI 10.1007/978-981-4560-75-7_99-1

orthogonal resonant modes at the same frequency can be used to design uncorrelated dual-element MIMO antennas through proper excitations. Detailed current distributions and characteristic patterns of the two modes are given in (Li et al. 2013b). High isolation of over 20 dB is achieved for the designed antennas. The eigenvalue curve also indicates that the fundamental mode has a large bandwidth, whereas the bandwidth of the bezel mode is relatively narrow. This is because a given mode becomes harder to excite as the eigenvalue increases, and a steeper slope in the eigenvalue around its resonant frequency indicates that modal excitation is fundamentally limited to a smaller bandwidth (termed as smaller "bandwidth potential" in the literature).

Another example of practical chassis modification is to load the chassis with T-strips along the longer edges (Li et al. 2014). The geometries of the T-strip loaded chassis are shown in Fig. 21a. Two metal strips along the length of the chassis are connected to the chassis through shorting pins at the center of each strip. The eigenvalues in Fig. 21b show that there are three resonant modes at frequencies below 1 GHz. Mode 1, which corresponds to the T-strip mode, and mode 3, which is the chassis' fundamental mode, are exploited to radiate due to their larger bandwidth potential (i.e., more gentle slopes around the resonant frequencies).

Through analyzing the characteristic electric and magnetic fields of the T-strip loaded chassis for modes 1 and 3, the feeding methods of both modes are determined. As shown in Fig. 22, a small narrow plate parallel to the chassis is used to create capacitive coupling to excite the T-mode, whereas a conventional coupled fed monopole is used to excite the fundamental mode. The detailed description on how to implement the feeds can be founded in (Li et al. 2014). The measured results show that both antennas cover LTE Band 8 with an isolation of above 10 dB. The envelope correlation between the two antennas in

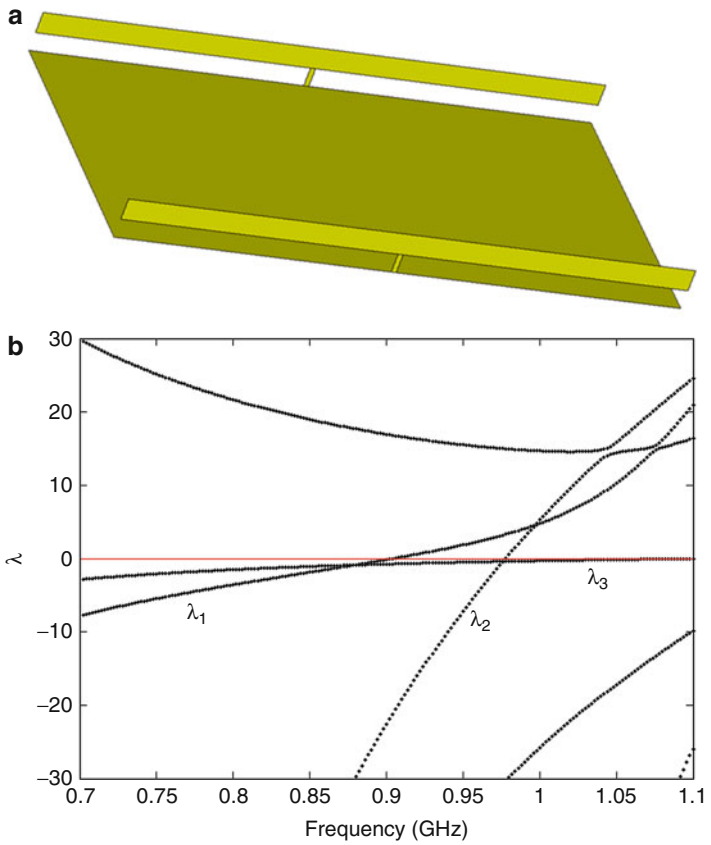

Fig. 21 (**a**) Geometries of the T-strip loaded chassis; (**b**) Eigenvalues of the T-strip loaded chassis (Li et al. 2014)

DOI 10.1007/978-981-4560-75-7_99-1

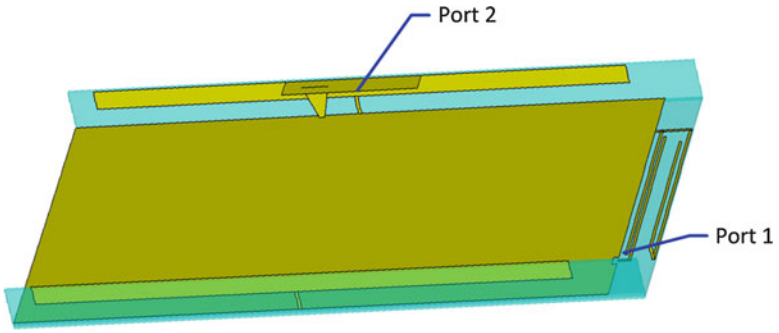

Fig. 22 Geometries of the T-strip loaded antenna system (Li et al. 2014)

free space is below 0.1 over the operating band. Due to the above reasons, a higher capacity was achieved, relative to existing designs. Another advantage of the antenna is that the S parameters and the envelope correlation coefficients were found in full-wave simulations to be only marginally influenced by the hands and the mobile casing.

The design of characteristic mode based MIMO antennas has been developed further to enhance the bandwidth and to allow multiband operation, two aspects which are critical for mobile terminal applications (Miers et al. 2013). The design framework is based on the correlation of characteristic currents (or characteristic near fields) between different modes. The correlation is used to identify if there are other modes having similar current characteristics in the vicinity of existing feed locations. By making opportunistic use of existing feeds to excite additional mode(s) at a different but close-by frequency, the bandwidth of the antenna can be enhanced due to multimode resonances. Multi-band operation is achieved if the chosen frequency is far away from the existing frequency band. In most cases, further (but minor) chassis modifications are needed.

For example, the eigenvalues of the T-strip loaded chassis were modified (as shown by the solid lines in Fig. 23a) when the two original shorting pins were displaced rotationally by 22 mm from the center. The chassis with the displaced shorting pins is shown Fig. 23b. The characteristic currents for mode 1 and mode 2 were highly correlated at the shorting pins, though their currents and near fields were significantly decorrelated across the remaining parts of the chassis. Consequently, simultaneous excitation of both λ_1 and λ_2 is possible through locating a single gap feed at one of the two shorting pins. This step extended the structure's bandwidth potential for the resonance below 1 GHz. For multi-band operation, cross-correlation was carried out between the currents around the shorting pins at the resonances of λ_1 and λ_2 and the characteristic currents of all the significant modes from 1.3 to 2.0 GHz. As a result, λ_2 and λ_4 showed significantly high correlation with the feed currents in the low band. However, neither of the two modes was resonant near 1.8 GHz, as can be seen in Fig. 23a. Thus, some structural modification was needed. Through shortening the shorter ends of the T-strips, the eigenvalues are modified as shown by the dashed lines ("Adapted modes") in Fig. 23a, where λ_2 and λ_4 are now close to zero (i.e., modal resonance) at the frequencies around 1.8 GHz. Thus, multiple bands have been achieved, along with enhanced bandwidth at the lower band. Following similar principles, multi-band operation of the bezel loaded antenna was also obtained, and the details can be found in (Miers et al. 2014).

DOI 10.1007/978-981-4560-75-7_99-1

Adapted modes were formed through shortening the shorter ends of the capacitive strips by 10 mm; (**b**) T-strip loaded structure with shorting pins at 22 mm rotationally symmetric offset (Miers et al. 2013)

Future Directions and Open Problems

As detailed in this chapter, significant progress has been made in addressing the challenging problem of designing efficient multi-antennas for MIMO terminals. Apart from useful metrics that have been devised to better quantify MIMO performance, a number of decoupling and decorrelation techniques have been proposed to counteract the problem of limited implementation space in small terminals. In particular, the recently proposed approach of applying TCM analysis for designing MIMO terminal antennas has been shown to be very effective, since the characteristic modes have the desirable property that their farfield patterns are inherent orthogonal. Furthermore, since TCM analysis takes the entire terminal chassis into account, it can also provide decorrelated multi-antenna solutions with larger bandwidths than other existing methods.

Table 1 provides a quick overview of the different decoupling techniques described in this chapter, including their mechanisms, advantages and disadvantages. The concise information in the table can serve as guidelines for antenna designers on available options in designing decoupled and decorrelated MIMO terminal antennas.

Notwithstanding, the terminal antenna research community is facing even tougher challenges on the horizon. For example, nearly 40 cellular bands that range from 700 to 3.8 MHz have now been specified (3GPP TS36.101 2014). Even if simultaneous coverage of all bands is beyond reach, operators are demanding multi-antenna solutions with much larger bandwidths than those achieved today. Recent results have demonstrated that a tunable, chassis-exciting antenna solution can provide continuous

DOI 10.1007/978-981-4560-75-7_99-1

Table 1 Overview of different decoupling techniques

Decoupling techniques	Decoupling mechanisms	Advantages	Disadvantages
Decoupling network	Mitigation of mutual impedance or coupling coefficients using a coupled network	Decoupling of antenna ports without changing the antenna structure	Loss in the network; can be physically large if distributed elements used; can be hard to implement the network
Modified ground plane	Choking of coupling current by means of bandstop filter	Applicable to various kinds of ground plane based antennas; can be simple to implement	Change in the ground plane structure required
Neutralization line	Creation of an additional (direct) decoupling path through the line to cancel out existing coupling	Intuitive and simple to implement	Change in the antenna structure needed
Parasitic scatterer	Creation of an additional coupling path between two antenna elements through a scatterer	Simple to implement; high total efficiency demonstrated	A scatterer must be added between the coupled antennas
Current localization	Localization of the current to the near proximity of the excited antennas	Simple to implement; no additional structure needed	The decoupling method is antenna-specific
Characteristic mode	Excitation of different orthogonal modes of an antenna structure to achieve very low correlation	Systematical design method providing information on feeding method and location; larger bandwidth than other methods by exploiting the ground plane	Minor modification of the antenna structure (including ground plane) may be needed

coverage over the entire frequency range from 750 to 2500 MHz (Valkonen et al. 2013). However, this solution relies on the excitation of the relatively wideband fundamental mode of the chassis, especially at the lower frequency end. It will be very challenging to design a second antenna based on mode(s) that can be excited as well as being orthogonal to the first antenna.

To further complicate the design problem, the carrier aggregation (CA) feature in LTE requires simultaneous coverage across two cellular bands that can be very widely spaced. For example, inter-band CA is specified for LTE Band 1 (1920–2170 MHz) and Band 5 (824–894 MHz). This means that any tunable or frequency reconfigurable solutions should allow for simultaneous coverage even across large frequency spacings.

Furthermore, as LTE-Advanced (or "true 4G") with even higher data rates than LTE (up to 1 Gbits per second) is starting to appear on the market, terminal antenna designers will also need to take into account the coverage of both uplink and downlink frequencies for each band, as it allows for uplink MIMO transmissions. On top of even higher bandwidth requirements than LTE, LTE-Advanced also provides for up to 8×8 MIMO and 4×4 MIMO on the downlink and uplink, respectively.

Other major future tasks for the terminal antenna research community include the need to provide intelligent antenna solutions that will optimize the antennas to the immediate environment, which includes the user as well as the propagation channel. For example, measurement results indicate that reconfigurable radiations pattern can enable up to 30 % improvement in capacity in an interference-limited outdoor macrocellular environment (Plicanic et al. 2012).

Antennas in Handheld Devices

Cyril Luxey* and Aykut Cihangir
Laboratoire Electronique pour Objets Connectés, Université Nice Sophia Antipolis, Sophia Antipolis, France

Abstract

This chapter gives a general overview of the antennas used in mobile phones for wireless cellular communications. The evolution of the antenna structures is discussed in combination with the evolution of cellular communication standards. Some common antenna types widely used in mobile terminals are presented, some of them being examples from commercial products. The antenna design techniques that are used to achieve broader operating bandwidths with smaller antenna dimensions are addressed. Tunable and reconfigurable antennas are mentioned and their advantages and disadvantages versus passive antennas explained. The most important metrics that quantize antenna performance in mobile phones are presented. Some simulation and measurement results as well as data from previously published papers are used to support the claims and information in the chapter. The chapter is finalized with some forecast for the future cellular standards, and some challenges that antenna designers might face for the fifth generation are mentioned.

Keywords

Mobile phone; Handheld terminal; Antenna; PIFA; Multi-band; Matching networks; Reconfigurable; SAR; LTE; 4G; Cellular communication; Wireless communication

Introduction

This chapter is dedicated to the antennas used in handheld devices. As known, there is a very wide variety of electronic handheld devices, used for communication purposes. This chapter will confine itself to mobile phones (also referred to as mobile terminals in the text) and will aim to inform the user about the antennas used in mobile phones.

For this purpose, first a summary of the cellular communication standards, starting from the first generation of analog systems until the fourth generation, will be done. Concerning this evolution in the communication standards, the changes and improvements on the terminal antennas will be discussed, starting with external antennas. The migration to internal antennas will then be presented and the challenges faced for internal antenna design explained. Some common antenna types will be explained and some examples of antenna from commercial mobile phones given.

Some techniques used to obtain broadband antennas and to miniaturize them will then be presented with some emphasis on matching networks. Some tunable/reconfigurable antenna topologies will be mentioned, with their advantages/disadvantages over passive prototypes.

Interactions between the antenna and the user will then be given. Both, the effects of the user on the antenna performance and the radiation hazard risk on the user's head, will be discussed. Possibility of

DOI 10.1007/978-981-4560-75-7_100-1

utilizing antennas with multiple feeds and the advantages/disadvantages compared to single-feed antennas will be presented in the next section.

Finally, some problems that might occur during mobile phone antenna measurements will be discussed, some important metrics that should be measured in a commercial product antenna will be explained, and some common antenna manufacturing techniques will be presented. The chapter will be finalized with a conclusion section.

It should be noted, at this point, that MIMO and diversity antenna configurations are out of the scope of this chapter since they are discussed in different chapters dedicated for them. Multiantenna systems for mobile phones will only be mentioned as multifeed antennas that operate at different frequency bands and not in a MIMO configuration.

Evolution of Cellular Communications

Wireless communication is an indispensible benefit of technology used in every part of the modern life, with a wide range of applications like navigation, voice communication, urgency communication, air traffic, etc. Probably the most common wireless communication method in the consumer sense is the cellular mobile communication, which was once launched to give the users the freedom to make voice calls in a wireless sense. However, it now enables a diversity of applications like high-speed Internet access, video calls, video/audio streaming, etc.

In a typical cellular communication network, the land that will be serviced is divided into a number of cells and at least one transmitter (a base station) located to serve the users in each cell. The user can move between different cells, and the handover from cell to cell is automatically handled, transparent to the user. In general sense, a cellular communication system is composed of three layers: the core, the edge, and the access subsystems as stated in Toh (2011). The core is the layer handling the voice calls, doing the traffic control and user authentication, as well as keeping track of the usage/charges. The edge layer is the air interface between the core and access layers. The access layer (also called Node B or base station) is then responsible to establish the wireless link between the base station and the user's mobile phone and also to monitor the link parameters.

The wireless cellular communication requires a two-way link, meaning the user needs to both receive and send information. The transmission of information from the user to the base station is named "uplink," whereas the reverse direction is called "downlink." To enable this two-way communication, duplexing schemes are necessary, which can be either in time or frequency domain. In time division duplexing (TDD), the user transmits and receives in the same frequency band but in different time slots allocated. On the contrary, in frequency division duplexing (FDD) transmit and receive functions occur using different carrier frequencies for uplink and downlink. In order to serve multiple users from a base station, multiple access schemes (like frequency division multiple access or time division multiple access) are used as well.

As also mentioned in Akyildiz et al. (2010), Jaloun and Guennoun (2010), and Kumar et al. (2010), the cellular mobile communication has undergone several improvements since the first-generation (1G) technology was introduced in 1979 in Tokyo, followed by Europe in 1981 and USA in 1982 (Fig. 1). The 1G cellular networks were totally analog, able to deliver only voice through frequency modulation. Both 450 MHz and 900 MHz frequencies were used in Europe whereas the AMPS (Advanced Mobile Phone System) was used in USA at 850 MHz with a 40 MHz bandwidth. Each user was assigned a specific carrier frequency resulting in FDMA. The major disadvantage of the first-generation systems was the lack of interoperability between countries, resulting in a mobile terminal that could be used in that specific country only.

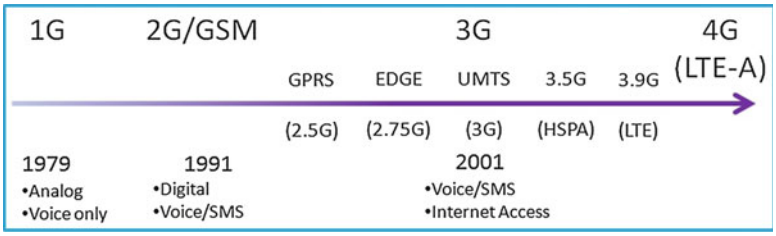

Fig. 1 Evolution of cellular communication technologies

Approximately 10 years later, the second generation of cellular mobile communications was launched in Finland. The most common 2G technologies are GSM (Global System for Mobile Communications, used globally), cdmaOne (mostly used in USA), iDen (mostly used in USA), and PDC (mostly used in Japan). These technologies used either TDMA or CDMA modulation schemes to handle multiple users. Among these technologies, GSM is the most commonly used, with a high market share. The biggest difference of this second generation compared to the first is the modulation schemes, which are completely digital like GMSK (Gaussian minimum shift keying) used in GSM technology, for instance. This led the way to higher spectral efficiency and better quality of services. In addition to the voice, the second generation allowed the user to receive/send text messages with the short message service (SMS), which can be counted as low-speed data transfer. Global roaming was also made possible, where the same phone number can be used in different countries, by means of the newly introduced subscriber identity module (SIM) cards. The GSM technology uses FDD as the duplexing scheme and both TDMA and FDMA to serve multiple users, where eight users share the same time frame. The channel bandwidth allocated for each user is 25 kHz. There were two main evolutions based on the GSM technology to supply users' higher data rates. Among these, GPRS (general packet radio service) is a technology that is referred to as 2.5G, increasing the maximum data rate up to 150 kbps. With GPRS technology, the circuit-switched data transmission was changed to packet-based type. To further increase the maximum data rate, EDGE (Enhanced Data rate for GSM Evolution) technology referred to as 2.75G was introduced, allowing up to 384 kbps in optimum conditions. One of the main reasons to increase the data rate was the utilization of 8-PSK (instead of GMSK) as the digital modulation technique.

The requirements for the third-generation cellular communication were determined by the 3GPP (3rd Generation Partnership Project) in Release 99 in the year 2000 in scope of the IMT-2000 project. In 2001, the first deployment of 3G was started in Japan, followed by South Korea in 2002 and Europe and USA in 2003. There are mainly two dominating technologies: UMTS (called also W-CDMA) used in Europe and CDMA2000 used in USA. The main target of 3G technologies was to propose to the user high data rate enabling video calls, high-quality video/audio streaming, and high-speed Internet benefiting also the introduction of smartphones with touchscreens. New frequency bands were allocated for the 3G communications in addition to the previously existing bands between 1990 and 2170 MHz. The maximum bandwidth for a user was increased to 5 with W-CDMA technology whereas CDMA2000 uses one or more available 1.25 MHz channels. A further improvement to the 3G was done with the introduction of HSPA (High-Speed Packet Access), called 3.5G and increasing the data rate to 14.4 Mbps and even higher with HSPA+ (21 Mbps, 42 Mbps in dual-carrier mode and 84 Mbps in dual-carrier mode + 2 $\times$ 2 MIMO).

In accordance with the improvements through 4G, 3GPP announced Release 8 through the end of 2008, describing the first LTE (Long-Term Evolution) specifications. The target peak data rate for LTE technology is 100 Mbps for downlink in a full-IP network. Since LTE standard could not reach the data rate levels necessary for 4G as strictly defined by the International Telecommunication Union, LTE is generally referred to as 3.9G. In this technology, various modulation techniques (like QPSK, 16QAM,

64QAM) can be used for downlink, depending on the channel conditions. The OFDM (orthogonal frequency-division multiplexing)-type waveforms are utilized to improve link performance in urban multipath environments and the maximum channel bandwidth increased to 20 MHz. In MIMO (multiple-input–multiple-output) techniques, up to four transmit and four receive antennas are also proposed to reach the 100 Mbps maximum data rate. Both TDD and FDD duplexing schemes can be used as duplexing methods. Table 1 and 2 present the frequency bands, their region of utilization, and the available channel bandwidths for FDD and TDD LTE respectively. It can be seen that two new frequency bands have been introduced with LTE (in addition to existing UMTS bands), between 698 and 824 MHz in the low-band and between 2.5 and 2.69 GHz in the high-band.

To fulfill the requirements of 4G cellular communications, 3GPP published Release 10 in the beginning of 2011, named as LTE-A (LTE Advanced), which is the "real" 4G technology. The maximum data rate is targeted as 1 Gbps for low-mobility users (slow-moving like pedestrians) and 100 Mbps for high-mobility users (as in a car). The MIMO utilization is increased up to eight transmit and eight receive antennas. As mentioned before, the maximum single-channel bandwidth is up to 20 MHz for higher carrier frequencies and up to 10 MHz for lower carrier frequencies. The usable channel bandwidth can be increased up to

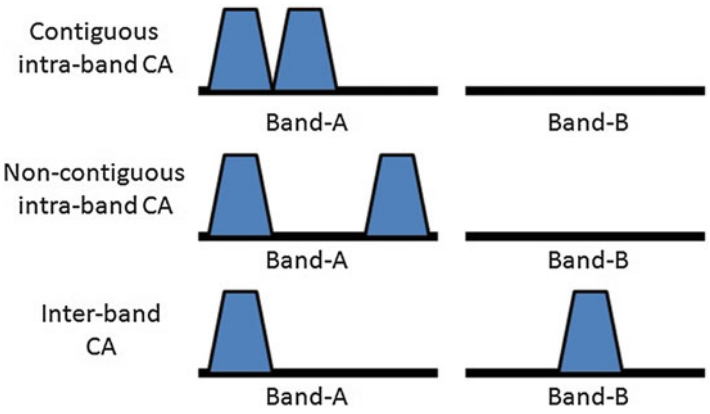

Fig. 2 Different carrier aggregation scenarios

100 MHz, using multiples of 20 MHz channels, defined as carrier aggregation (CA). Different CA scenarios are possible as presented in Fig. 2. When two adjacent frequency channels are assigned to a single user, it is named as contiguous intraband CA, whereas it is called noncontiguous if the two channels are separated in the same band. Likewise, depending on the frequency licenses the operator possesses, a user can be assigned a channel from one band and simultaneously another channel from a different band. This scenario is then called interband CA.

During the evolution of mobile cellular communications since the 2G, new frequency bands were introduced to the existing ones (as shown in Fig. 3). For example, the frequency interval of 1.71–1.99 GHz was introduced to the 2G frequency bands with the UMTS technology. Likewise with LTE, two new bands 698–824 MHz and 2.5–2.69 GHz were added. These newly added frequency bands form a key aspect from the antenna design point of view because they increase the design challenges of the implementation of broader-frequency antennas within a limited space (mainly reduced height). The possibility of using CA techniques is also of high importance from the antenna side, since they might need to cover simultaneously two or more frequency bands which might not be possible with

DOI 10.1007/978-981-4560-75-7_100-1

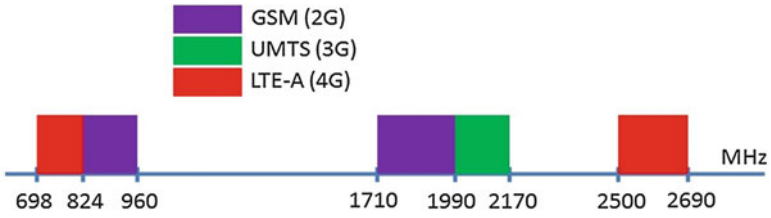

Fig. 3 Frequency bands used since 2G

band-switching reconfigurable antenna topologies. Finally, MIMO scenarios should also be considered in the design phase in order to situate the multiple numbers of antennas in a limited space with reasonable isolation.

Through the rest of this chapter, the frequency intervals of 698–960 MHz and 1.71–2.69 GHz will be called as 4G communication bands, the former referred to as low-band (LB) and the latter referred to as high-band (HB). In summary, the 698–824 MHz band will be called low-LTE band, 824–960 MHz as GSM band, 1.71–1.99 GHz as DCS/PCS band, 1.99–2.17 GHz as UMTS band, and 2.5–2.69 GHz as high-LTE band.

Evolution of Mobile Phone Antennas

The advancements on the cellular communication standards since 35 years had an absolute effect on the terminal antennas, as well as the other mobile phone components. The evolution of the mobile phone antennas was generally driven by two major forces. The first one is the user demand, which is mainly composed of aesthetical and ergonomic issues. This effect can be seen from the domination of the market by the mobile phones with internal antennas soon after the first internal antenna phone models were released. Mobile phones incorporating internal antennas had better appearances, were smaller in size, and thus were easier to carry so that the customer demand was immediately adhered to regardless of considering any disadvantages in antenna performance. The second major driving force on the antenna evolution is of course the newly added frequency bands with the introduction of new standard generations. This necessity put harder requirements on the antenna bandwidth in a limited volume, leading to different antenna design methodologies and different antenna layouts.

External Antennas

The mobile phones that were manufactured for the first generation and also in the beginning of the second generation had an external antenna placed on the top corner of the handset. Some examples of such antennas can be seen in Fig. 4. The most commonly used external antenna types are whip (monopole) and helical antennas. Some designs were made of both types in a proper combination arrangement.

Whip Antennas

Whip antennas were the most common type of antenna in the first mobile terminals. This type of antennas has a length close to quarter wavelength in the frequency of operation. They are fed similar to dipoles where the PCB ground plane is connected to one pole of the feed and the antenna is fed from the other pole. These kinds of antennas are very efficient radiators, especially when the phone has a metal chassis with a length close to quarter wavelength forming a full-structure dipole both with the whip antenna. For the ease of utilization, some whip antennas had the opportunity to be retracted into the phone when not in use, of course affecting the antenna performance due to the changing environment.

DOI 10.1007/978-981-4560-75-7_100-1

Fig. 4 External antenna examples for mobile phones

Helical Antennas

Helical antennas can achieve the coverage of the same frequency band with a shorter antenna element compared to whip antennas. This enables decreasing the total size of the device where they are used. For this reason, helical antennas have been largely used in many commercial mobile phones. In the normal mode (physical length smaller than one wavelength), helical antennas have a radiation pattern similar to a monopole element, mainly in the transversal direction with a null in normal (main axis) direction. It was possible to make helical antennas dual band as described in Ying (2000), Nevermann and Pan (2002). In Ying (2000), multiband behavior was achieved by using the total length of the helical antenna for low-band resonance and using nonuniform diameter and/or pitch angle for a resonance at higher frequencies. Another alternative to obtain multiband response was proposed in Haapala and Vainikainen (1996) by using two helical antennas on the two top corners of the mobile terminal. One of the antennas was tuned to operate in DCS/PCS frequency bands (1.7–2 GHz) and the other to UMTS frequency bands (2–2.2 GHz).

Combination of Whip and Helical Antennas

Common types of external antennas for mobile terminals were combinations of whip and helixes, enabling multiband coverage. A whip, which is placed in the vertical axis of a helix, is presented in Saldell (1997): the helical antenna is placed on the top corner of the device, and the whip is passing through the central axis and can be retracted when not in talk mode. Similarly, two helical antennas with different radii have been placed on the same axis, achieving dual-band response (Haapala and Vainikainen 1996).

The external antennas generally had a high efficiency and broadband matching despite making the total device bigger. One major disadvantage was the high SAR (specific absorption rate) due to the high efficiency of the antenna and the proximity of the radiating element to the user. With the introduction of mobile phones with internal antenna elements, external antennas started to disappear from the market and cannot be found in any major commercial phone anymore.

Internal Antennas

With the market trend toward internal antennas for mobile terminals, the space restriction about antenna placement started to be one of the main concerns from the antenna design point of view. Dealing with newer standards, another requirement was to obtain more broadband antennas in this limited space.

DOI 10.1007/978-981-4560-75-7_100-1

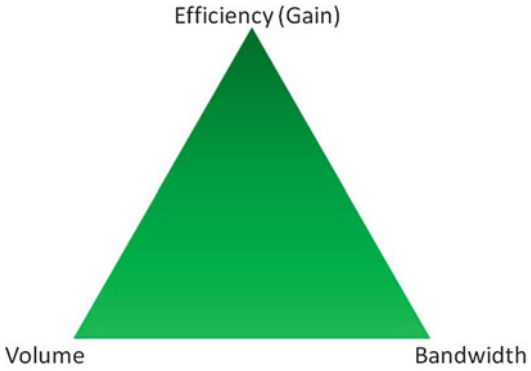

Fig. 5 Antenna efficiency, volume, and bandwidth trade-off

With the market trend to shrink the mobile phones as small as possible around 2000, this space limitation became even more challenging. With the introduction and the rise of smartphones, the device sizes started to increase, so did the space reserved for the antenna. But with the current trend of larger touchscreens and thinner smartphones, the antennas again need to be shrunk not really in terms of size but rather of height. This current constraint results in electrically small antennas mainly because of low LTE, though causing challenges in terms of antenna design (Fig. 5).

Electrically Small Antenna Challenges

The typical space allocated to the antenna in a 2G mobile phone or a smartphone is small compared to its free-space wavelength of operation. Equation 1 is the general formula to define an electrically small antenna, where r is the radius of the smallest sphere that can enclose this antenna.

$$\frac{2\pi r}{\lambda} \ll 1 \tag{1}$$

Considering a spherical volume having a maximum dimension of 60 mm ($r = 30$ mm) allocated to an antenna to operate at 900 MHz ($\lambda_0 = 333$ mm), the above inequality will be true. So, the antennas operating in GSM frequencies in a typical mobile phone can be considered as electrically small. It is known that for any antenna, the product of efficiency (or gain), volume, and bandwidth is a constant number which basically means for profiting one of the aforementioned parameters, the other two needing to be sacrificed. For example, to increase the bandwidth of an antenna, either a lower efficiency needs to be accepted or the volume of the antenna shall be increased. In the electrically small antenna case, since the antenna volume is limited, an optimum condition for the bandwidth and efficiency should be found. The main disadvantage of an electrically small antenna is the low radiation efficiency and the low real part of the input impedance which make a broadband input matching (to the front-end module or more generally to a fictitious 50 Ω source) hard and cause the antenna to be narrowband. Electrically small antennas and their fundamental properties or limitations have been studied in the literature (Chu 1948; Wheeler 1947; Collin and Rothschild 1964; Hansen 1981; McLean 1996; Yaghjian and Best 2005).

One of the most important figures of merit for an electrically small antenna is its quality factor (Q). This value is defined as the ratio of 2π times the energy stored in the near fields excited by the antenna to the energy radiated plus the energy dissipated per cycle. It is inversely proportional to the bandwidth potential. So Q should be minimized to maximize the matching bandwidth of an antenna. The lowest obtainable quality factor (also known as the Chu limit) for a linearly polarized antenna radiating in only one mode (the transverse electric or the transverse magnetic mode) can be calculated using Eq. 2.

DOI 10.1007/978-981-4560-75-7_100-1

$$Q = \frac{1}{(ka)^3} + \frac{1}{(ka)} \tag{2}$$

where k is the wavenumber and a is the radius of the smallest sphere that can enclose the antenna. It should be emphasized that this Q value is a theoretical low-bound scalar which is very optimistic to even get close in practice, even with complicated antenna structures. A formula to obtain the Q-factor of an antenna at any frequency using its input impedance was proposed in Yaghijan and Best (2005), given in Eq. 3.

$$Q(\omega) = \frac{\omega}{2R(\omega)} \sqrt{[R'(\omega)]^2 + \left[X'(\omega) + \frac{|X(\omega)|}{\omega}\right]^2} \tag{3}$$

where ω represents the angular frequency point, $R(\omega)$ and $X(\omega)$ stand for the real and imaginary parts of the input impedance at angular frequency ω, and $R'(\omega)$ and $X'(\omega)$ are the first derivates of $R(\omega)$ and $X(\omega)$ according to the frequency. This formula proposes, under some assumptions, a very fast and reliable calculation method, without the need for computing the stored energy and radiated energy of the antenna: it is valid for a single resonant antenna, close to its resonance frequency.

Using these Q-factor values, the obtainable frequency bandwidth could be calculated from Eq. 4 as also presented in Holopainen (2011), where S is the maximum VSWR target and T is the coupling coefficient as given in Pues and Capelle (1989).

$$FBW = \frac{1}{Q} \sqrt{\frac{(TS-1)(S-T)}{S}} \tag{4}$$

For a value of $T = 1$, Eq. 5 reduces to

$$BW_{cc} = \frac{1}{Q} \frac{(S-1)}{\sqrt{S}} \tag{5}$$

The bandwidth calculated by equating $T = 1$ is the critical coupling case, where the input impedance of the antenna at the center frequency is matched exactly to 50 Ω, ending in an infinitely small reflection coefficient. The bandwidth in this case is thus the frequency interval having a reflection coefficient below a predefined limit (generally −6 dB for mobile terminal antennas) around the center frequency. To illustrate the situation better, the input impedance of a critically coupled antenna is shown with red curves in Fig. 6 in a Smith chart (plotted between 0.6 and 1.1 GHz) as well as the reflection coefficient in dB form on right. It can be seen that for critical coupling case, the antenna has a very low reflection coefficient at a single frequency point and the impedance curve passes through the center of the Smith chart at this frequency. If −6 dB is chosen as limit, the antenna has a bandwidth of 100 MHz (between 740 and 840 MHz). An alternative coupling scheme to obtain more broadband antennas is the optimal overcoupling case where the antenna is matched with a worse reflection coefficient (still under the threshold) but in a broader bandwidth. The blue curve in Fig. 6 represents the optimally overcoupled case, where the bandwidth for −6 dB reflection coefficient is increased to 320 MHz, although the reflection coefficient is not as low as critical coupling case. Some examples of using a matching network to obtain optimally overcoupled antennas are presented in Antoniades and Eleftheriades (2010)and Selvanayagam and Eleftheriades (2010).

Considering the 4G-LTE frequency bands coverage in a typical recent smartphone, the antenna shall be able to cover between 700–960 MHz and 1.7–2.7 GHz with a profile generally smaller than 60 × 15 × 5 mm^3. It is obvious that the antenna will behave as an electrically small antenna in the low-band

DOI 10.1007/978-981-4560-75-7_100-1

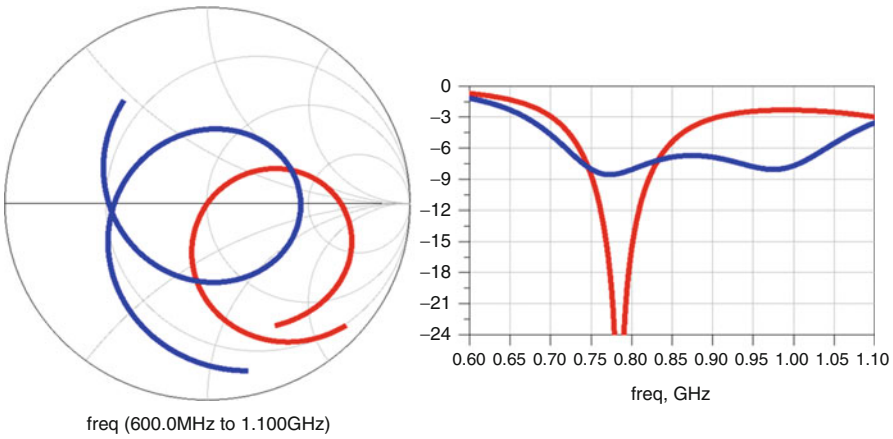

Fig. 6 Critical coupling and optimally overcoupled matching

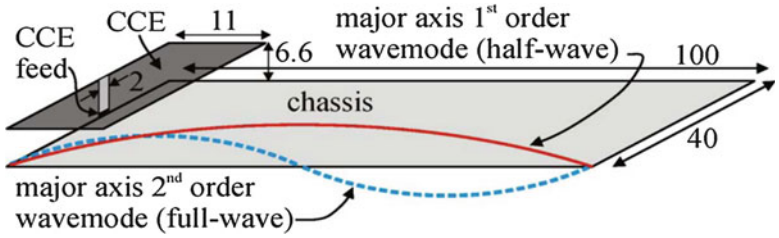

Fig. 7 First- and second-order wavemodes of a typical mobile phone's ground plane (© [2010] IEEE. Reprinted, with permission, from Holopainen et al. 2010)

(LB) especially around 700 MHz. Therefore, it is almost impossible to obtain the 30 % bandwidth coverage needed in the LB using only an electrically small radiating structure integrated in this volume. It was shown in Vainikainen et al. (2000, 2002, 2004)and Villanen et al. (2006) that the ground plane of the device plays a major role in the antenna performance in the LB and a minor role in HB. In fact, 90 % of the total radiation comes from the ground plane at 900 MHz (Villanen et al. 2006), regardless of the antenna type which is used. This is also evident from the dipole-type radiation shape of mobile terminal antennas in the LB, for almost all antenna types. So, the main role of the antenna in the LB is actually to excite electric currents on the system ground plane that will further compose the dominant part of total radiation in LB. Due to the large size of the ground plane which is not an electrically small structure anymore (thick rectangular conducting body), low-Q properties and thick dipole-type radiation can be obtained in the LB. This antenna-ground plane radiating structure can have a lower Q-factor if the ground plane is strongly excited. Therefore, the antenna element alone is not really an antenna in the LB but rather a coupling element for the ground plane. The obtained low Q-factor leads to higher bandwidth potential around the frequency region where the excitation is strong. Around the frequency corresponding to the $\lambda_0/2$ resonance of the ground plane, higher excitation and higher bandwidth potential can be observed if the coupling element efficiently excites the resonant mode of the ground plane. The length of typical ground planes in today's mobile terminals vary between 100 and 130 mm, which correspond approximately to $\lambda_0/2$ in LB. So, in a particular LB frequency, the first-order wavemode shown in Fig. 7, taken from Holopainen et al. (2010), can be strongly excited, depending on the orientation and type of the antenna coupling element. This excitation can increase the bandwidth potential of the antenna considerably, enabling the coverage of the 30 % bandwidth in LB. It should be noted that a matching network is needed to obtain the desired input impedance.

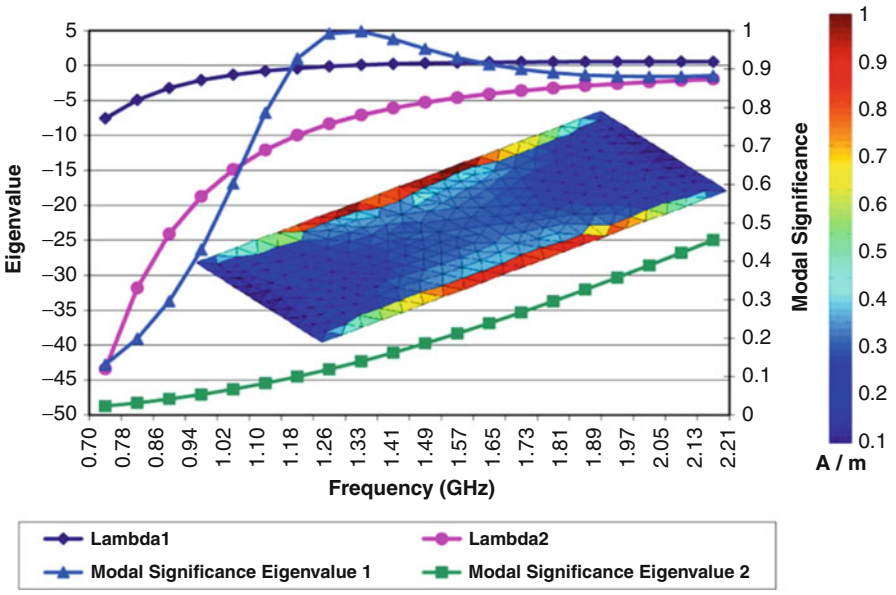

Fig. 8 Characteristic mode analysis of a 100 × 40 mm^2 (© [2011] IEEE. Reprinted, with permission, from Andujar et al. 2011)

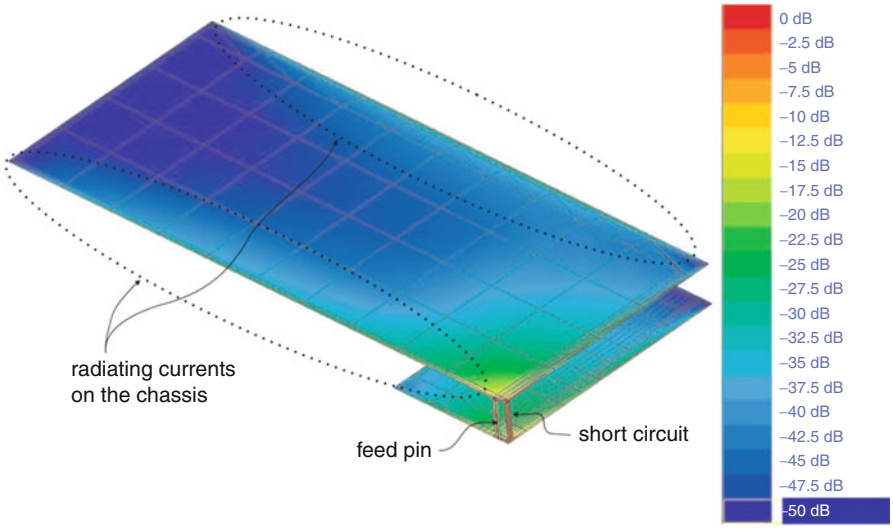

Fig. 9 Currents on the ground plane for a PIFA from Holopainen (2008)

For example, the characteristic mode analysis of a 100 × 40 mm^2 ground plane has been carried out in Andujar et al. (2011). As seen in Fig. 8, the first wavemode of this ground plane occurs around 1.25 GHz. At 892 MHz, the plotted currents are stronger through the long edges and weaker on the short edges of the ground plane which gives some guidelines for the design of an efficient coupling element.

A similar behavior was also presented in Holopainen (2008) for a PIFA (Planar Inverted-F antenna) placed over a mobile phone ground plane at 900 MHz (Fig. 9). The currents induced on the ground plane are concentrated on the long edges, forming the first wavemode.

DOI 10.1007/978-981-4560-75-7_100-1

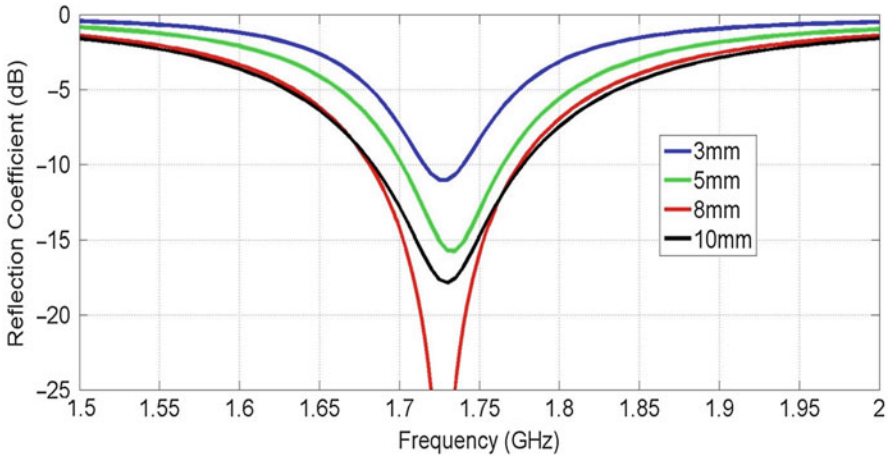

Fig. 10 Effect of the height of the PIFA on the antenna bandwidth

Common Antenna Types Used in Mobile Terminals

Planar Inverted-F Antennas (PIFAs)

PIFAs have been one of the most commonly used internal antennas in the mobile phone market. A PIFA is basically a quarter-wavelength patch antenna over a ground plane, having also one or more inductive ground connections, generally close to its feed. This ground connection acts as a shunt inductor and cancels out the high capacitance between the PIFA element and ground plane, at particular frequencies. This makes them resonant and narrowband antennas as a disadvantage. On the other hand, PIFAs are easy to manufacture, low profile, and might be low cost. Another main advantage is the ease of matching (if a narrow bandwidth is sufficient) by tuning the shorting strip and the feed distance, as well as tuning the thickness of the shorting pin.

In a mobile phone, the matching bandwidth of the PIFA is naturally increased in the LB (and not narrowband anymore) as the PIFA is also acting as a coupling element to excite the currents of the ground plane. Therefore, the bandwidth of the PIFA–ground plane combination depends heavily on the volume (and thus the height) of the antenna and the length of the ground plane. Figure 10 shows the effect of the antenna height (changing between 3 and 10 mm) on the bandwidth of a PIFA (tuned to the same resonance frequency at each height). The bandwidth for a reflection coefficient lower than −6 dB is 75 MHz for a 3 mm height and rises to 175 MHz for a 10 mm height.

PIFA antennas can be made multiband with various techniques like

- Etching slots on the antenna element to create alternative current paths of different lengths
- Adding resonant strips
- Usage of parasitic elements, either connected to ground plane or floating
- Adding multiple grounding strips

For example, a PIFA design with multiple radiating strips realized by etching slots is given in Korva (2007). A parasitic strip (connected to ground plane) is also used in this design to obtain multiband behavior. Another PIFA with three slots and two grounding strips to cover 880–980 MHz and 1.88–3 GHz is presented in Bhatti et al. (2008). The antenna in Ciais et al. (2004) utilizes a combination of these techniques to achieve multiband and wideband coverage (Fig. 11).

It is also of high importance to minimize the antenna dimension with negligible performance trade-off, as the area reserved for the antenna has generally a shrinking trend. To achieve this in a PIFA-type

DOI 10.1007/978-981-4560-75-7_100-1

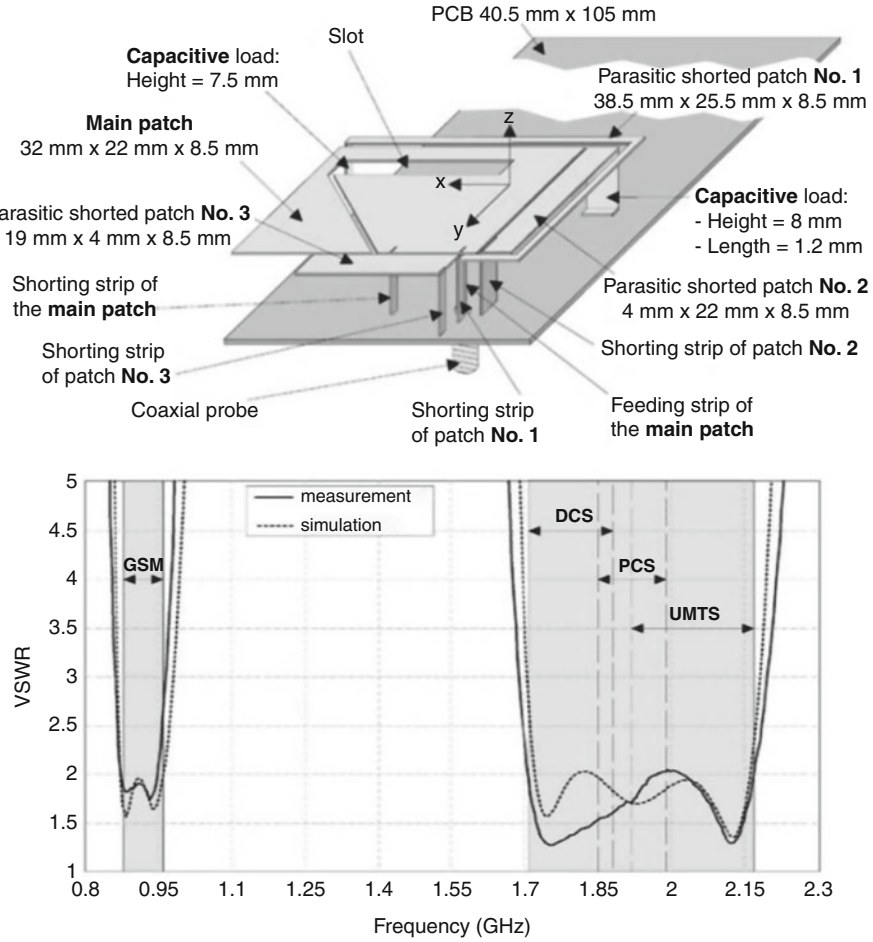

Fig. 11 An example of multiband PIFA design and associated VSWR performance (© [2004] IEEE. Reprinted, with permission, from Ciais et al. 2004)

antenna, techniques like etching slots (or meandering the main strip) and capacitive loading are used. For example, the antenna in Zaid et al. (1998) is shrunk in size by etching a slot and creating a longer path for the currents, although it is not exactly a PIFA. The capacitive loading technique was used in Guo et al. (2003)and Rowell and Murch (1997), where the main patch of the PIFA was extended down close to the ground plane to create a strong capacitance. In this way, the resonance frequency of the antenna could be decreased without increasing its size, at the expense of a reduced bandwidth.

To enlarge the operating bandwidth of a PIFA in a mobile terminal, the techniques used to obtain multiband antennas (described above) can be used. Another popular method for broader bandwidth is to etch slots on the ground plane. In this way, the wavemodes of the ground plane are pulled to lower frequency bands, and the length, width, and position of the slot can be arranged to set the wavemode of the ground plane to the frequency of interest: in fact, it lowers the Q-factor and increases the bandwidth potential at a specific frequency. Such a study on the slot parameters was carried out in Zhang and Zhao (2009) for a multiband PIFA. Slots on the ground plane of a PIFA were proposed also in Villanueva et al. (2013), Cabedo et al. (2009), andZhang (2013a, b) to obtain wideband and multiband performance. Slotted ground plane antennas could not get popular in the industrial sense due to practical manufacturing reasons. For example, components of high importance like the touchscreen or battery of a mobile terminal might need to fit over the slot and change completely the antenna behavior.

DOI 10.1007/978-981-4560-75-7_100-1

Monopole-Like Antennas

Another most commonly used antenna type in commercial mobile phones is the monopole-like antenna. The term *monopole* is used here to indicate that there is a ground clearance region under the monopole element and the driven strip of the antenna does not have a direct ground connection. Designs having also a ground connection forming a loop are also possible, so one pole of the feed port is connected to the strip, whereas the other pole is connected to the ground plane, to excite the antenna. Those types of antennas started to gain popularity especially after new frequency bands were added with 3G and 4G since they offer broader bandwidth when compared to PIFAs. One of the disadvantages for monopole-like antennas is the higher SAR (compared to PIFAs) due to the lack of shielding ground plane beneath the antenna. So, the possibility of locating the antenna at the bottom corner of the device also helped these antennas to be more popular as the SAR in this configuration is lower than the case of a top-corner monopole where the SAR might exceed the authorized limits.

To miniaturize monopole-like structures, the most popular and easiest method is meandering, to shift the resonance to lower frequencies within the same antenna volume (at the expense of a bandwidth reduction). Therefore, the bandwidth enhancement for this type of antennas can be achieved using multiple resonant arms or inserting capacitively excited parasitic elements. For example, in Wong and Chen (2010), the antenna element was formed from two metal strips connected together through an inductor to achieve dual-band coverage for the GSM and DCS/PCS/UMTS bands. Multiple resonant arms were used in combination with slots in the ground plane to achieve GSM/DCS/PCS/UMTS coverage in Liu et al. (2010). Parasitic elements (connected to ground plane or floating) excited by monopoles are commonly proposed in the literature to achieve wideband operation in mobile terminals. For this type of antennas, the main methodology is to capacitively excite a longer metal strip connected to the ground plane through a shorter driven strip. The lower frequency coverage is generally achieved by the excitation of the parasitic element and the higher frequency bands covered by the monopole together with the higher-order resonances of the parasitic. In Lin and Wong (2007), slots were etched on the ground plane to form two parasitic strips, excited by a monopole. In Chu and Wong (2012)and Yang et al. (2011), a monopole-driven strip is used to excite a longer parasitic element connected to the ground plane on one of its edge. The parasitic strip can also be connected to the ground plane on both edges (forming a loop) as in Chen et al. (2012)and Chiu et al. (2010). The loop structure was meandered to increase its electrical length and shift the resonance frequency down. In the antennas proposed in Chen and Wong (2010, 2011), Chu and Wong (2011), andLee and Wong (2010), monopole antennas with parasitic elements were proposed, taking into account a dielectric casing for the antenna (Fig. 12). In Cihangir et al. (2013), a parasitic element was exploited to cover low-LTE/GSM frequency bands (700–960 MHz) with a short ground plane (Fig. 13).

Capacitive Coupling Elements

The role of the system ground plane on the radiation and matching characteristics of a mobile terminal antenna was previously mentioned. Capacitive coupling elements (CEs) are inherently nonresonant structures that are designed and located with the purpose of exciting the wavemodes of the ground plane in a systematic manner (Vainikainen et al. 2002; Villanen et al. 2006; Holopainen et al. 2010). This way, the antenna system has a low Q-factor and thus high bandwidth potential especially close to the resonance frequency of the ground plane. The feeding mechanism of the CE is similar to one of a monopole with no inductive contact (or ground return) to the PCB ground plane. Since these structures are inherently nonresonant, they initially have poor matching, but the antenna can easily be tuned to the desired frequency band using a matching network (MN).

A typical CE configuration, its input impedance without any MN and the corresponding Q-factor can be seen in Fig. 14 taken from Holopainen (2011). It is worthwhile to note that in this figure, the CE is situated

DOI 10.1007/978-981-4560-75-7_100-1

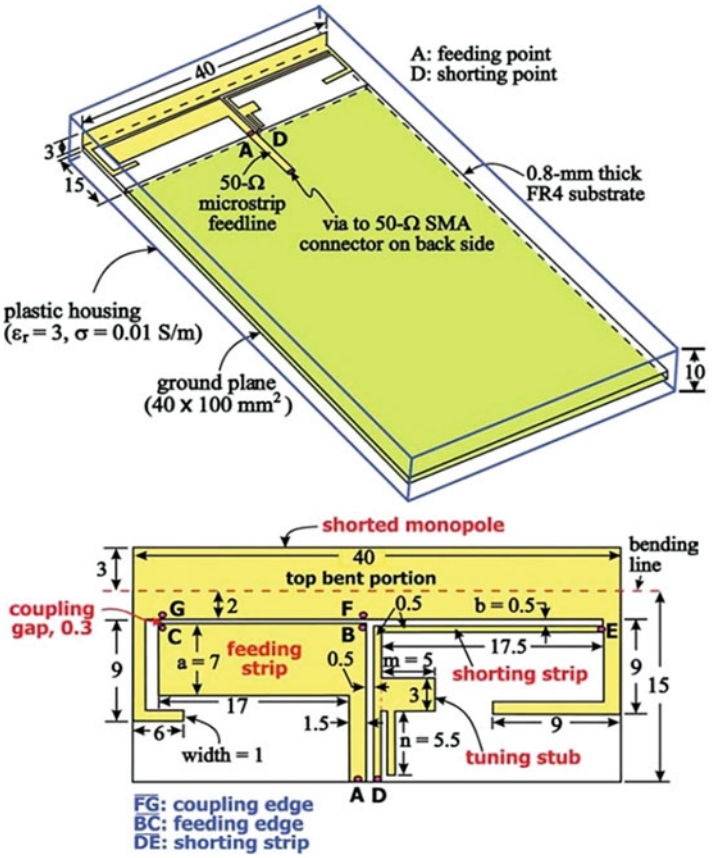

Fig. 12 Monopole antenna with parasitic element for 4G coverage from Chen and Wong (2010)

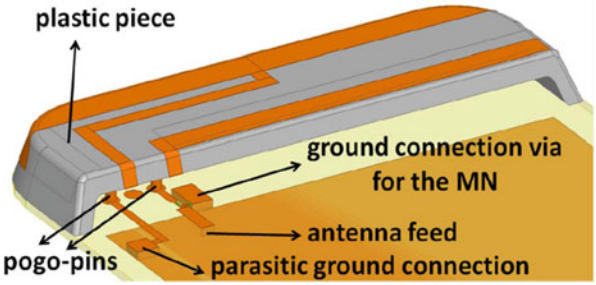

Fig. 13 Monopole antenna for low-LTE coverage from (Cihangir et al. 2013)

over the ground plane, which is not the common way in very recent publications. It was shown with later publications that leaving a ground clearance region under the CE leads to lower Q-factor and higher bandwidth potential (BP). The CE is fed similar to a monopole without any ground connection and excites the surface currents of the ground plane through capacitive coupling from the edges and corners, especially in lower frequencies. From Fig. 14, it is observed that the first wavemode of the ground plane occurs at 1.17 GHz, where the rate of change of the impedance (around this frequency) is slower compared to other frequencies. This effect can also be observed from the Q-factor, making a local minimum around 1.17 GHz. This phenomenon is beneficial especially for the low frequencies where the CE antenna element is itself electrically small. By benefiting from the currents on the ground plane, both the radiation efficiency and bandwidth potential are increased.

DOI 10.1007/978-981-4560-75-7_100-1

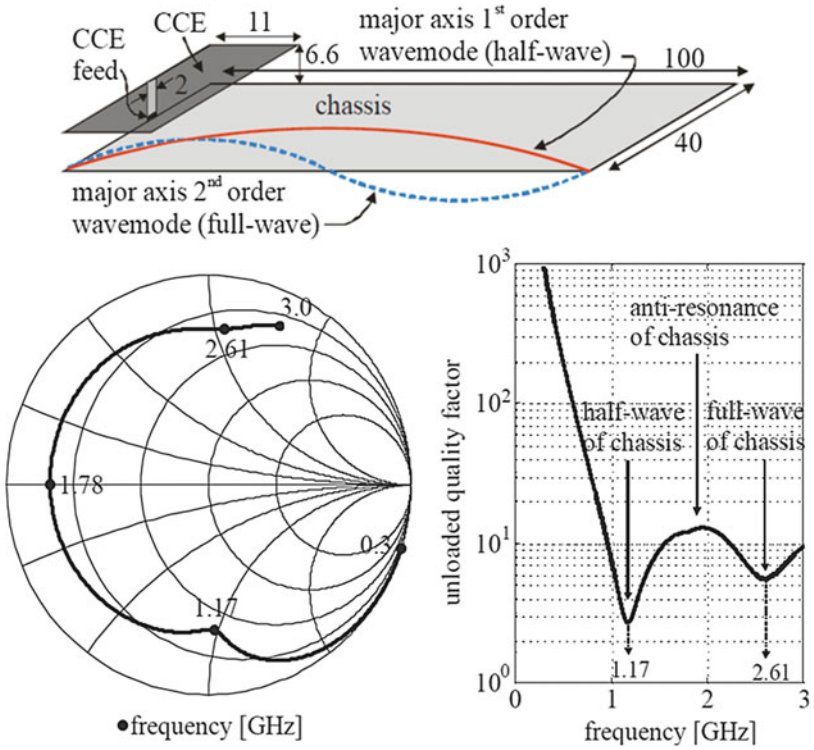

Fig. 14 Capacitive coupling element antenna and behavior from Holopainen (2011)

Antennas using capacitive CEs for mobile terminals have been widely proposed in the literature. In Villanen et al. (2007a), two capacitive CEs were placed on the two corners of the short edge of the PCB (as in Fig. 15), one covering the GSM frequency band (824–960 MHz) and the other the DCS/PCS bands (1.71–1.99 GHz). A matching network branch was designed for the feed of each CE and special attention given to make each branch behave as open circuit relative to the other branch. This way, the two branches could be connected into a single feed at the end. A similar strategy was used in Andujar et al. (2011) to use two CEs while the MN branches were connected together using notch filters.

In Valkonen et al. (2012), three different CEs were proposed, having different dimensions and orientations to investigate the effect of the user's hand on the matching and efficiency. The antennas were able to cover the low LTE (700–960 MHz) and DCS/PCS/UMTS bands (1.7–2.2 GHz) with a two-branch MN (nine SMD components with inductors and capacitors) connected to a single feed (Fig. 16).

An antenna system using a CE (and ground plane) to cover the LTE frequency bands (700–960 MHz and 1.7–2.7 GHz) was presented in Valkonen et al. (2013a). This antenna is like a dual-feed structure where the low-band feed uses the radiating element as a CE, whereas the high-band feed has an offset in the excitation region, using also the resonant properties of the radiating element (Fig. 17). These two feeds are combined together in a single feed after introducing a two-branch MN (eight lumped components) where each branch behaves as an open circuit at the operating frequency of the other.

Another design methodology using a CE to cover the LTE frequency bands was proposed in Cihangir et al. (2014). This design is a combination of a nonresonant CE with a resonant monopole antenna. The antenna is a dual-feed structure where one of the feeds is responsible for low-band (700–960 MHz) coverage and the other feed responsible for high-band (1.7–2.7 GHz) coverage. The LB feed is connected to a CE which is made hollow by removing the metal region inside, to be more space efficient. There is a MN of four lumped elements at the feed of the coupling element. The monopole, responsible for HB

DOI 10.1007/978-981-4560-75-7_100-1

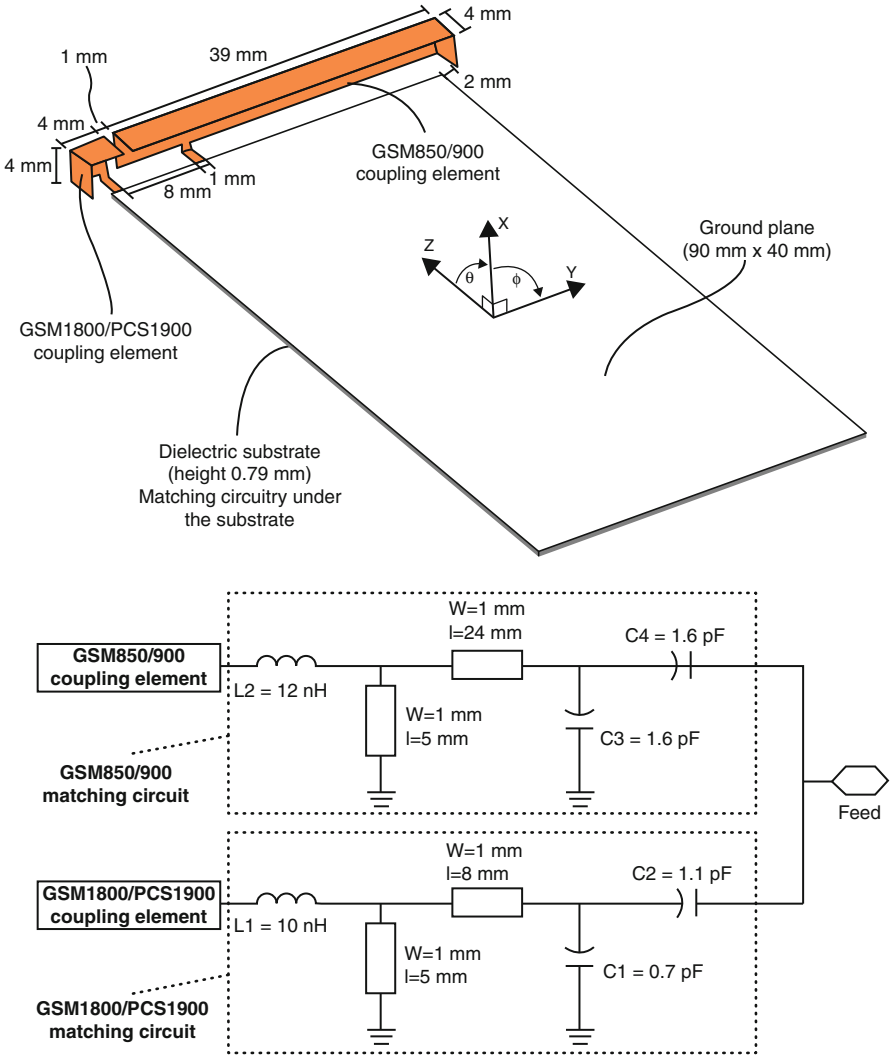

Fig. 15 Quad-band CE antenna structure (From Villanen et al. (2007a), with permission from John Wiley and Sons)

coverage, can be situated inside this available space (hollow CE) without perturbing the structure. However, it was printed on the substrate in this study for mechanical stability. The coverage of both bands was achieved with reasonable isolation between the feeds and with considerably lower number of MN components (Fig. 18).

The main advantage of using a CE-type antenna is the excellent bandwidth potential characteristics and the resulting broadband antennas that one can easily achieve. However, the absolute necessity of a MN at the feed is a disadvantage compared to other antenna types, in terms of cost. The disadvantage is more severe if a multiband antenna is targeted with a single antenna feed. In this situation, special attention shall be given to the MN design to be able to combine them into a single feed. Also the total number of SMD components in the MN will be high for this case, increasing the power losses in the components, the cost of the overall system, and the complexity of the MN that might cause unexpected measurement results considering the tolerance values of the lumped components (inductance or capacitance).

Examples of Commercial Antennas

Since their introduction, mobile phones have gone under significant changes in terms of both size/shape and functionalities. The functionalities expected from the mobile terminals have always been in an increasing trend. For the size, until the release of smartphones, the general aim was to shrink them in

DOI 10.1007/978-981-4560-75-7_100-1

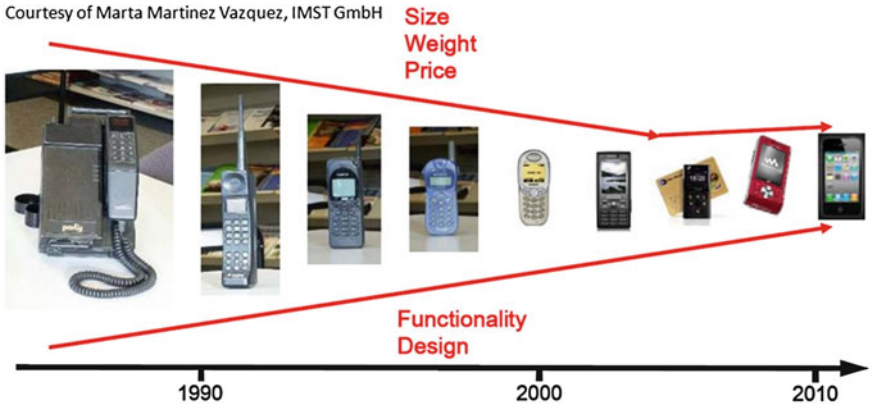

Fig. 19 The change in the size and functionality of mobile phones

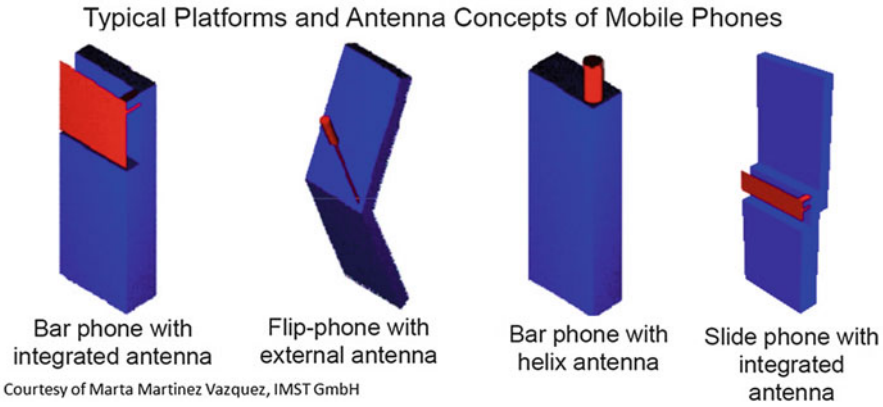

Fig. 20 CAD models for different mobile phone form factors

size for the ease of mobility. This returned to the antenna designer with the challenge of broadband antennas in a smaller volume. With the smartphone concept where a large touchscreen is the main component for device functionalities, the handheld size has more or less increased due to the touchscreen covering most of the device, but the space reserved for the antenna was not increased (Fig. 19). These kinds of constraints have led the antenna designers to look for new techniques and geometries to achieve antennas with broader bandwidth in limited volumes. Comprehensive studies about the evolution of mobile antennas were done in Ying (2005, 2012)and Rowell and Lam (2012). This section presents some examples of antennas integrated in commercial phones, together with some information about the most common device form factors.

Mobile Phone Form Factors

There are mainly three form factors that were widely used in commercial mobile phones as bar-type, flip-type, and slide-type (Fig. 20).

In the bar-type form factor, the device is formed by a rectangular prism without any movable part. Generally the keypad and the screen (or just the touchscreen) of the device are on the same face as seen in Fig. 21. Since the layout of the main components (like battery, screen, keypad, etc.) is stable and does not change, the antenna design for this form factor is more straightforward compared to other two form factors.

DOI 10.1007/978-981-4560-75-7_100-1

Fig. 21 Bar-type mobile phones

Fig. 22 Various flip-type mobile phones

For the flip-type phones, the device is formed by two sections that are connected to each other through hinges (Fig. 22). Those sections can be fairly modeled by full ground plane rectangles. When the device is in closed state, the total size shrinks into half, making it more ergonomic. Generally, the keypad and the screen are located in these two different sections and not visible when the phone is not opened. The antenna design for phone form factor is more tricky since the orientations of the main components relative to the antenna can be subject to change, depending on if the phone is open or closed. Moreover, the effective length of the chassis in the closed state is very short regarding the operating wavelength, and even the Q factor of this superposed state of PCBs is not low and could not lead to enough bandwidth potential at LTE LB. In Villanen et al. (2007b), the antenna performance for a flip-type phone was investigated, and it was shown that the radiation efficiency can decrease significantly when the phone is

DOI 10.1007/978-981-4560-75-7_100-1

Fig. 23 Various slide-type mobile phones

closed. In fact, in this situation, the currents excited on the two parts of the ground plane (strong especially in the lower frequencies) are in reverse direction and physically very close to each other that tend to cancel each other and not produce radiation in far field. This also affects the input impedance of the antenna decreasing the bandwidth potential as explained before. A reconfigurable matching network topology was suggested in the same study that will switch the matching network between two alternatives, one to match the antenna when the phone is closed and the other matching the antenna in open state.

The third common form factor is slide-type, whose examples are shown in Fig. 23. The device is again composed of two sections, but now, these sections can slide over each other on rails. Generally, one section that is in the front hosts the screen and the other the keypad. Also, special care should be taken in the antenna design for this form factor since the two conditions of the device may be different in terms of the surroundings of the antenna. The most important effect is probably the length of the ground plane and the wavemodes that can be excited on it, depending on the state. It can easily be told that almost the same design problems encountered with flip-type mobile phones exist for slide types, especially considering the closed state of the mobile phone.

Examples of Commercial Phones

The first generation of analog mobile phones used to have an external antenna placed on the top corner of the device. The preliminary models that were first released to the market used to have a whip antenna that is approximately a quarter wavelength long in the band of operation like the phone on left in Fig. 24. Some of the later models utilized retractable monopole antennas that were more ergonomic for the user (Fig. 24 on right).

External antennas continued to be used also in the former models of the 2G. The long-whip antennas switched to more user-friendly configurations like the retractable antenna. With dual-band operation being necessary, different design techniques were also used like inserting the retractable whip antenna in the center of a helical antenna or using a helical antenna with different pitch angles. The length of these antennas was considerably reduced by switching from whip antennas to helical antennas which also enabled shrinking the device form factors (Fig. 25).

The first commercial mobile phone with an internal antenna was the Hagenuk Global Handy, which was released in 1996. This antenna can be seen in Fig. 26, together with a CAD model taken from Rowell and Lam (2012). It is a slot antenna etched into the RF shielding operating at GSM900 band.

DOI 10.1007/978-981-4560-75-7_100-1

Fig. 24 Pictures of first generation of mobile phone antennas

Fig. 25 Pictures of external antenna examples

The internal antennas started quickly to become very popular due to both ergonomic and aestheticl reasons, with a lot of manufacturers switching to internal antennas in the newer models. Figure 27 shows three antenna models from the same manufacturer released in 3 consecutive years.

The detail of the internal antennas for the two mobile phones mentioned above can be observed in Fig. 28. The antenna on the left is a single-band antenna which uses a slot to increase the electrical length and achieve miniaturization. The antenna on the right is dual-band antenna placed on the top of the device, using a slot to obtain two patch sections and dual-band behavior.

One of the most common antenna types used in the 2G/3G mobile phones was the PIFA, with two examples shown in Fig. 29, taken from Rowell and Lam (2012). The antenna on the left is composed of two parts, the larger part responsible for GSM/DCS/PCS coverage and the smaller part responsible for UMTS coverage. Slots are used on the antenna elements to alter the current paths and enable both miniaturization and multiband coverage. The antenna on the right is a triband antenna (GSM/DCS/PCS), using a parasitic element which is capacitively excited by the main PIFA.

DOI 10.1007/978-981-4560-75-7_100-1

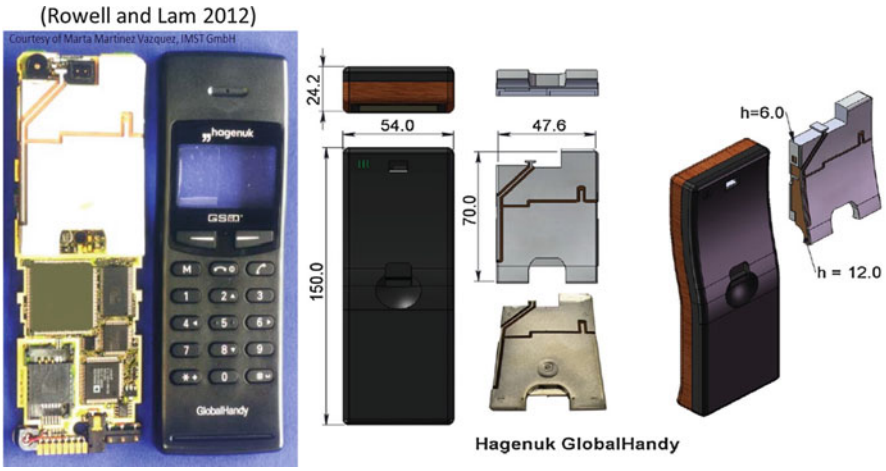

Fig. 26 First internal antenna in a mobile terminal (partially from Rowell and Lam (2012))

Fig. 27 Example of the transition from external to internal antennas during 3 years for the same manufacturer

Two other mobile phone models and their antennas are shown in Fig. 30. These antennas have no ground plane underneath them which make them behave as monopole-like antennas. In the model on the left, the antenna is placed at the bottom of the slide-type device, whereas it is placed in the middle (close to the hinge) for the flip-type phone on the right.

In the 4GS iPhone, the metallic portions of the phone casing (metallic frame) are used as CE to the PCB and also radiating structures. For this purpose, the metallic frame is split in two parts, the longer one forming the GSM/UMTS antenna and the shorter one forming the Bluetooth/Wi-Fi/GPS antenna. Very soon, it was revealed that this antenna was very sensitive to the user's hand (Antennagate), which degraded the received signal strength considerably when the finger is placed on the region separating the two metal frame portions (Fig. 31).

As the final of this section, the antennas used in Samsung Galaxy SII can be observed in Fig. 32. The main antenna responsible for GSM/UMTS coverage is placed at the bottom of the device. This layout typically decreases the SAR significantly since the antenna is usually set further away from the user

(tissue) when compared to an antenna placed on top. A second antenna for Bluetooth/WiFi is also placed at the bottom of the phone. The GPS antenna, working in the receive mode only, is situated at the top of this device, just above the camera.

Antenna Feeding and Matching Methods

This section starts with the discussion of the two antenna feeding methods with their advantages or disadvantages. Next, the exploitation of parasitic elements is briefly introduced, with examples from literature. Information about the most common antenna matching methodology, namely, the utilization of

DOI 10.1007/978-981-4560-75-7_100-1

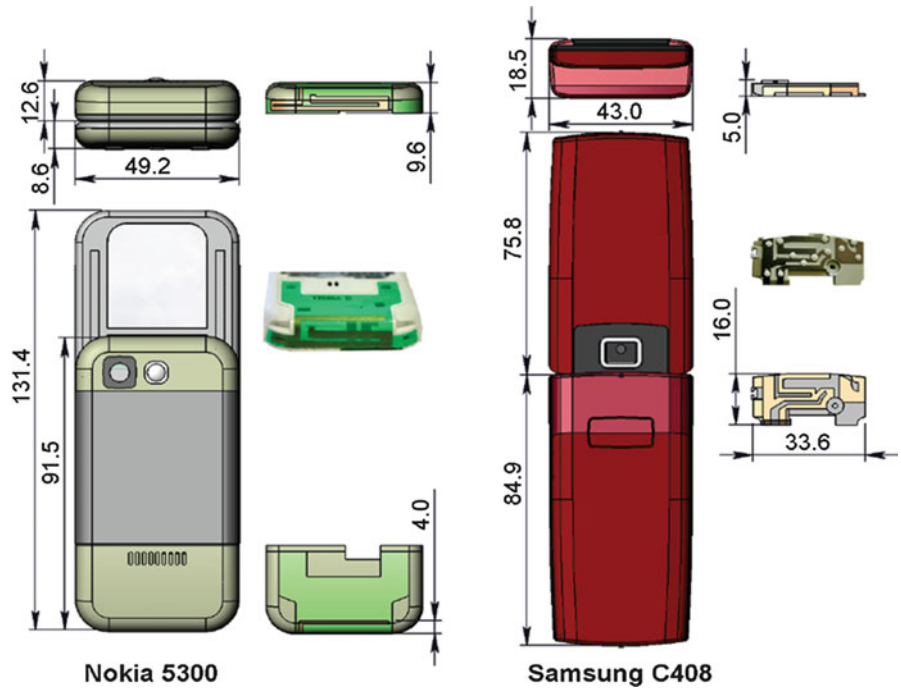

Fig. 30 Examples of monopole-like antennas from commercial phones from Rowell and Lam (2012)

Fig. 31 Coupling element-type antenna for a smartphone (iPhone 4S)

matching networks, is also given in this section with some basic topologies for different possible input impedances.

Antenna Feeding Methods

Inductive Feeding

In this feeding scheme, the power is coupled to the main radiating element through a direct metallic (galvanic) contact between the output of the front-end module (FEM) and the antenna. Examples can be any form of striplines, meander lines, or pogo pins.

DOI 10.1007/978-981-4560-75-7_100-1

Fig. 32 Picture of the antennas used in Samsung Galaxy SII

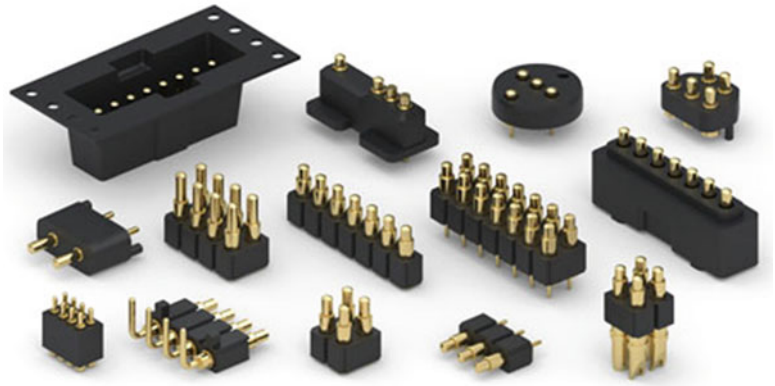

Fig. 33 Pictures of various pogo pins

Pogo pins are common inductive contacts. Since the mobile phone antennas generally have a height over the system PCB (rather than being directly printed on the PCB) for better bandwidth, the power transmission is necessary to/from the FEM. Pogo pins ensure good connection through spring-loaded pins (Fig. 33).

Meander lines are also an inductive feeding method that is commonly employed in mobile phone antennas to miniaturize the antenna element and still get the same operating (resonance) frequency. To illustrate this, simulations were performed with a monopole element, printed directly on an FR4 substrate as seen in Fig. 34. The resonance (defined here as the frequency having minimum reflection coefficient) of the monopole antenna (without any meanders) occurs at 1.8 GHz (Fig. 35) for a monopole length of 24 mm (PCB is 100 $\times$ 50 mm^2). The same resonance frequency can be obtained with a 14 mm monopole element when using meander lines, enabling approximately 50 % shrinkage in length. The main disadvantage is the lower real part of the input impedance of the antenna as seen in a Smith chart,

DOI 10.1007/978-981-4560-75-7_100-1

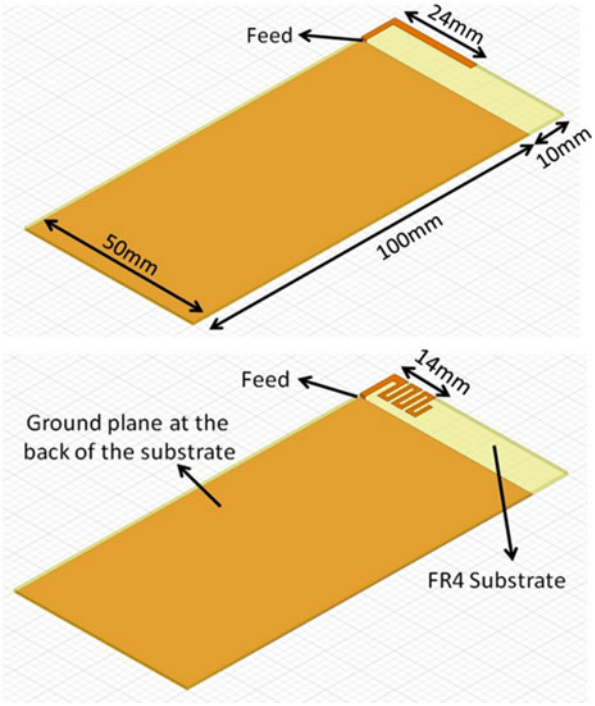

Fig. 34 Utilization of meander lines (geometry)

resulting in a worse reflection coefficient performance and less bandwidth potential compared to without meanders.

Capacitive Feeding

In the capacitive feeding scheme, the main radiating element is excited capacitively (with no direct metallic contact) through another driven element. This driven element is generally shorter and may cause some higher band resonances for the overall antenna. For a comparison between inductive excitation and capacitive excitation, the models shown in Fig. 36 are used. A monopole antenna printed on FR4 substrate has a 24 mm length. It is fed by inductive excitation (shown on left). This antenna is compared with a capacitively excited monopole, connected to ground plane on one end (shown on right). To excite this grounded monopole, a shorter feed is used close to the other end, which is left open. This last antenna has a total length of 20 mm.

The input impedances of these two antennas (plotted between 1.5 and 3 GHz) are presented in Fig. 37. It can be seen that a loop is formed in the Smith chart for the capacitive feed configuration. The bandwidth potentials calculated using a commercial software for a reflection coefficient below −6 dB are also given below for the two feeding methods. For this antenna layout, the capacitive excitation gives approximately double bandwidth potential around 2.3 GHz when compared to the inductive excitation, with a smaller profile.

Parasitic Elements to Increase the Bandwidth Potential

Utilization of parasitic elements to enhance the matching bandwidth is a popular technique in mobile terminal antenna design, since the antenna is electrically small especially in lower frequencies. Some antenna examples from the literature and from commercial phones that contain parasitic elements for bandwidth enhancement were presented in this chapter so they will not be repeated in this section. The effect of the parasitic element on bandwidth potential will be discussed here with an example.

DOI 10.1007/978-981-4560-75-7_100-1

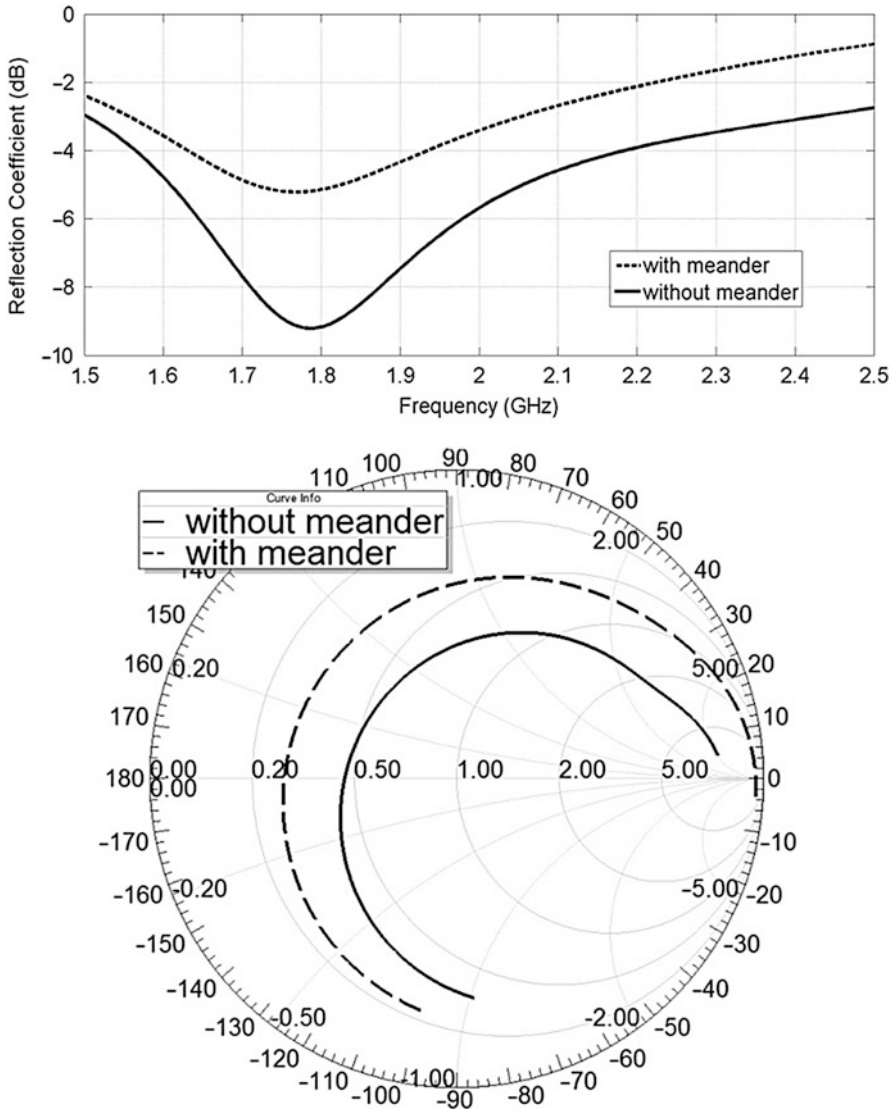

Fig. 35 Utilization of meander lines (reflection coefficient)

An antenna design that operates in the low-LTE/GSM frequency band (700–960 MHz) was presented in Cihangir et al. (2013). The design challenge in the study was the use of a short ground plane (75 mm) for the device. Longer ground planes (like 100 mm) have their first wavemode around 1.1 GHz; however, this resonance shifts up to around 1.4 GHz if this length is 75 mm. Keeping in mind the role of the ground plane wavemodes on the antenna bandwidth potential in the lower frequency bands, the bandwidth potential coming from this short ground plane will be very narrow between 700 and 960 MHz. For this reason, a parasitic element was used in combination with a monopole-like driven strip. The model of the antenna is presented in Fig. 38. The antenna rests on a plastic piece and is composed of two strips. The first strip is the driven strip where the antenna feed is connected. This strip capacitively excites a longer parasitic strip connected to the ground plane on one end. Pogo pins are used under the plastic piece for the connection of the antenna and the PCB.

The simulation results of this antenna with and without the parasitic strip are presented in Fig. 39. A new resonance that does not exist without the parasitic strip is seen to be created around 750 MHz with the introduction of this parasitic strip. When the input impedance in a Smith chart is observed, a loop is

DOI 10.1007/978-981-4560-75-7_100-1

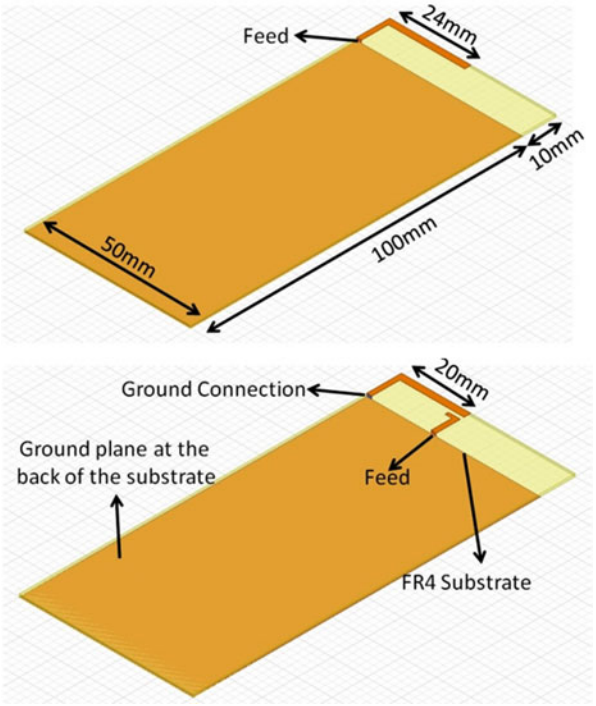

Fig. 36 Utilization of capacitive excitation (geometry)

seen in the presence of the parasitic strip which considerably increases the real part of the input impedance. To tune the antenna behavior, several design parameters can be changed. For example, increasing the length of the parasitic strip will lower the resonance frequency coming from it. Another parameter can be the coupling distance between the strips and/or the orientation of the two strips (affecting the coupling strength) that will change the shape of the loop in the Smith chart and in turn affect the bandwidth potential.

The simulated bandwidth potential with/without parasitic element can be seen in Fig. 40. To cover the target band (700–960 MHz), a bandwidth potential of nearly 260 MHz is necessary at 830 MHz (center frequency of this band). The bandwidth potential at this frequency is less than 50 MHz without the parasitic element. A significant increase in the bandwidth potential is observed with the introduction of the parasitic element, rising up to more than 200 MHz.

Utilization of Matching Networks for Impedance Matching

As mobile terminal antennas had to shrink due to available space and also due to the necessity of more broadband antennas, the usage of matching networks has come forward. These matching networks (MNs) can be placed at the antenna input, as well as distributed through the antenna like an inductor placed at the center of a metallic strip to increase its electrical length and decrease the resonance frequency. The MN can contain both lossless and lossy components, but the existence of lossy components will have a negative effect on the antenna efficiency so they are not widely preferred. For this reason, the MNs are generally composed of lumped inductors and capacitors. Figure 41 presents how the input impedance location in a Smith chart changes when a shunt/series inductor/capacitor is used at the antenna feed. Arrow-1 shows how the impedance moves in a Smith chart when the value of a series capacitor is decreased at the antenna input. On the contrary, increasing the inductance value of a series inductor will move the impedance in the direction of arrow-2. It should be noted that the components connected in series move the impedance on the “constant impedance circles” in the Smith chart. Arrow-3 shows

DOI 10.1007/978-981-4560-75-7_100-1

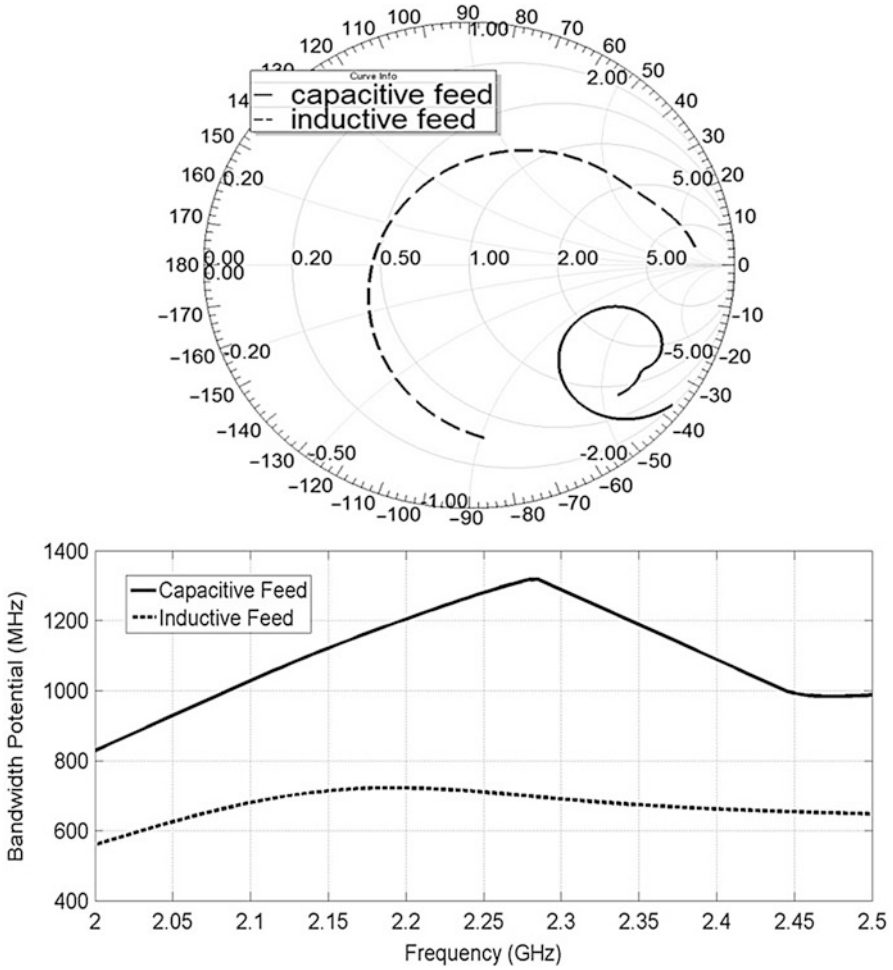

Fig. 37 Utilization of capacitive excitation (impedance and bandwidth potential)

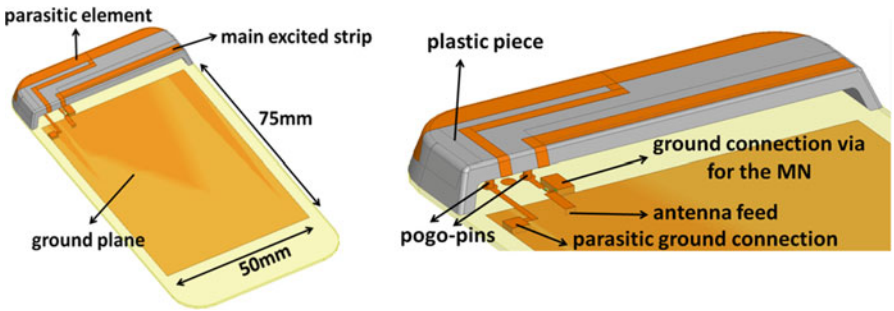

Fig. 38 Low-LTE/GSM antenna using a parasitic element from Cihangir et al. (2013)

the impedance behavior when the inductance of a shunt inductor is decreased, and arrow-4 presents the change when the capacitance of a shunt capacitor is increased. The impedance changes occur on the "constant admittance circles" when shunt elements are used.

One of the simplest MN topologies is L-type, placed at the input of the antenna. These types of MNs are composed of two lumped components, one of which is in series configuration and the other in shunt configuration. The eight possible L-type MN layouts are presented in Fig. 42. These different topologies

DOI 10.1007/978-981-4560-75-7_100-1

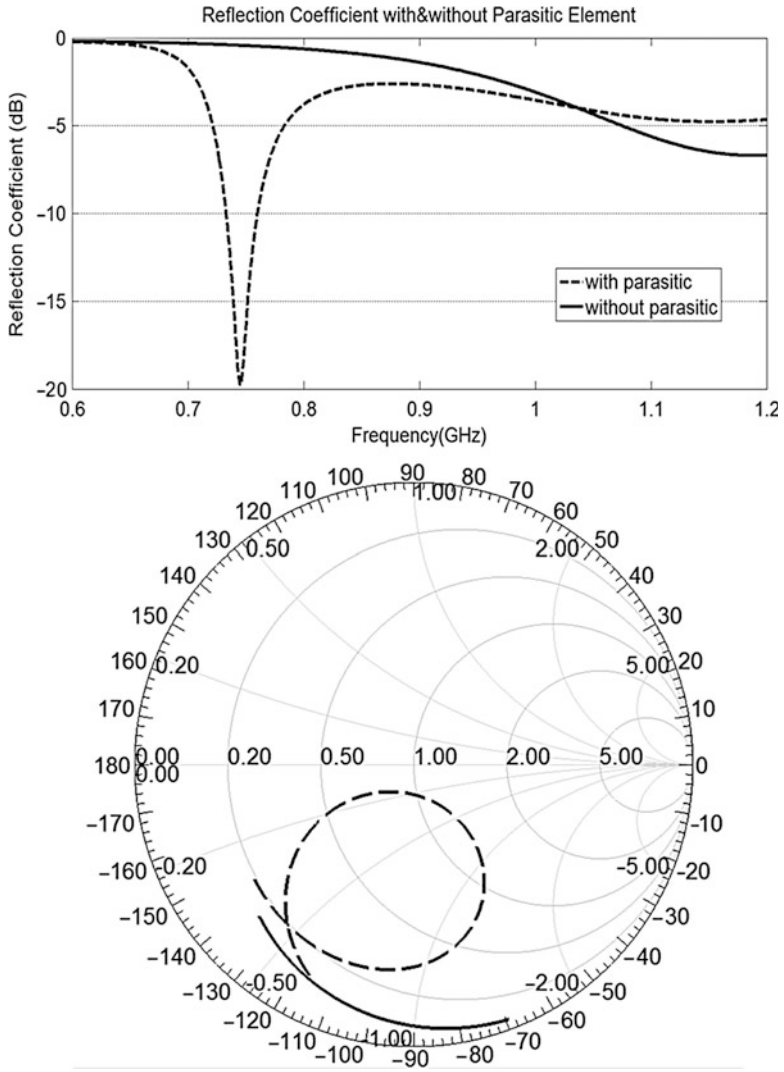

Fig. 39 Simulations of the effect of the parasitic element on the input impedance of the antenna from Cihangir et al. (2013)

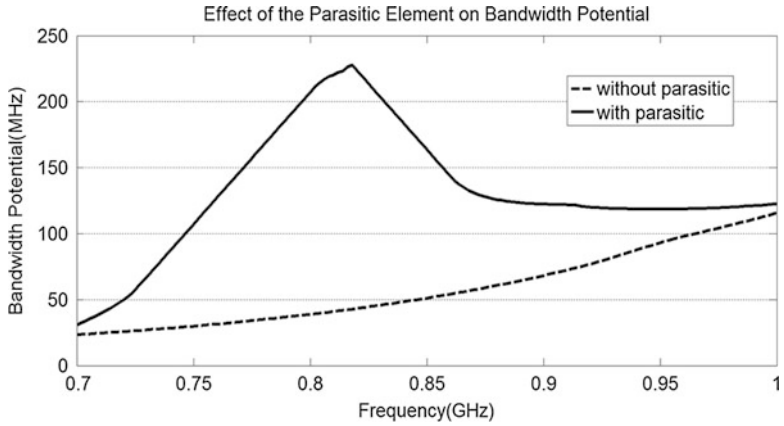

Fig. 40 Simulation of the effect of the parasitic element on bandwidth potential from Cihangir et al. (2013)

DOI 10.1007/978-981-4560-75-7_100-1

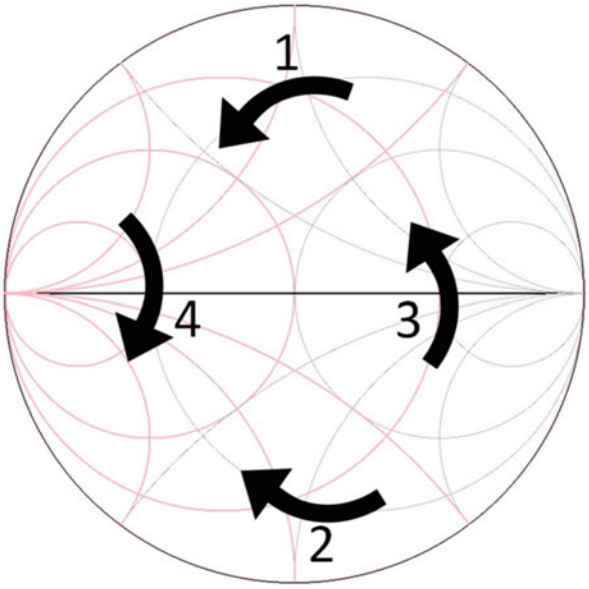

Fig. 41 Lumped inductor and capacitor effects on the antenna impedance

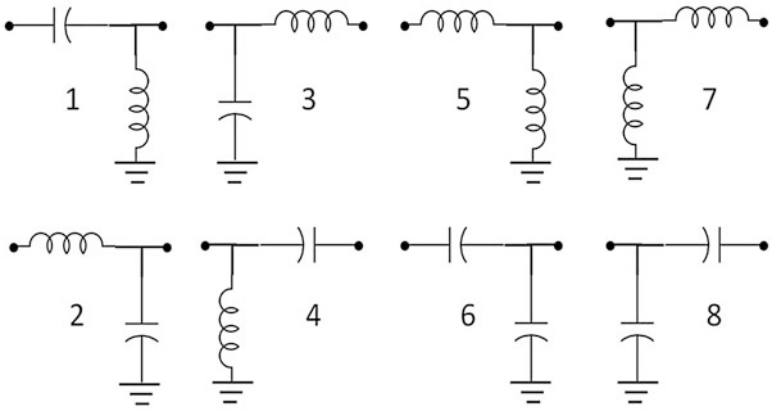

Fig. 42 L-type MN topologies

can be used to bring any input impedance to the center of the Smith chart, to obtain a good matching and low reflection coefficient. However, specific topologies can be used to match the impedances on specific regions of the Smith chart as shown in Fig. 43.

To further illustrate, two different MN topologies were used to match the same antenna in Figs. 44 and 45. The impedance of the antenna without any MN plotted between 1.7 and 2.2 GHz is shown with the red curve. Since the original impedance is in the lower hemisphere of the Smith chart, topology types 1, 3, 5, and 7 can be used (Fig. 43) to match this antenna. In Fig. 44, topology-3 was used. Using first the series inductor, the impedance is moved in clockwise direction on the constant impedance circle (black curve). Then using the shunt capacitance, the impedance is moved in clockwise direction on the constant admittance circle.

In Fig. 45, topology-5 was used to match the same antenna. Using the shunt inductor, the original antenna impedance is moved in counterclockwise direction along the constant admittance circle. Then

DOI 10.1007/978-981-4560-75-7_100-1

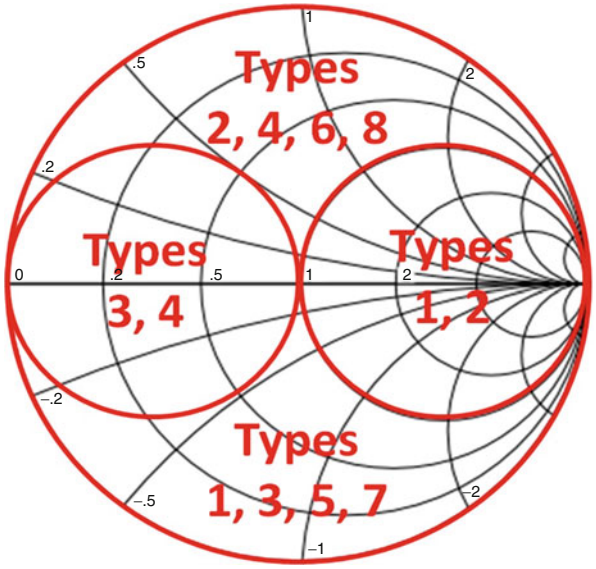

Fig. 43 Regions on Smith chart, according to the usable L-type MN topologies

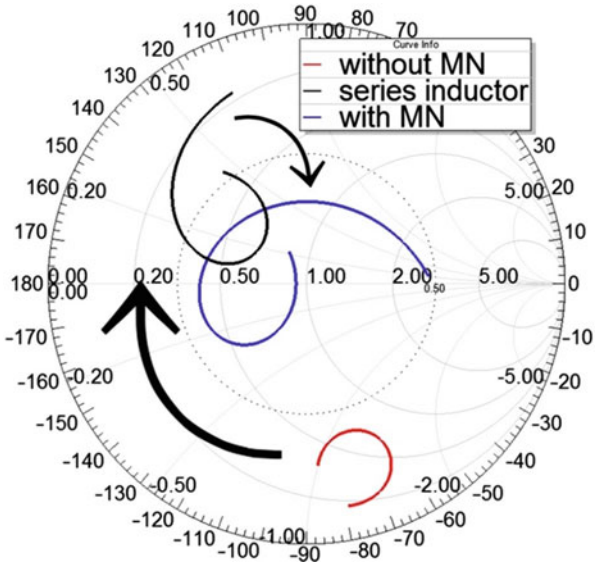

Fig. 44 Matching an antenna using L-type topology-3

using the series inductor, the antenna is matched by moving in clockwise direction on the constant impedance circle. Figure 46 presents the reflection coefficients for these three cases (without MN, with topology-3, with topology-5).

Tunable/Reconfigurable Antennas in Mobile Terminals

Tunability or reconfigurability is used for a wide variety of purposes in antennas like changing the radiation direction, the polarization, beamwidth, or even the operating frequency. For mobile phone antennas, it is by itself a big challenge to obtain acceptable level of matching like −6 dB in free space, but

DOI 10.1007/978-981-4560-75-7_100-1

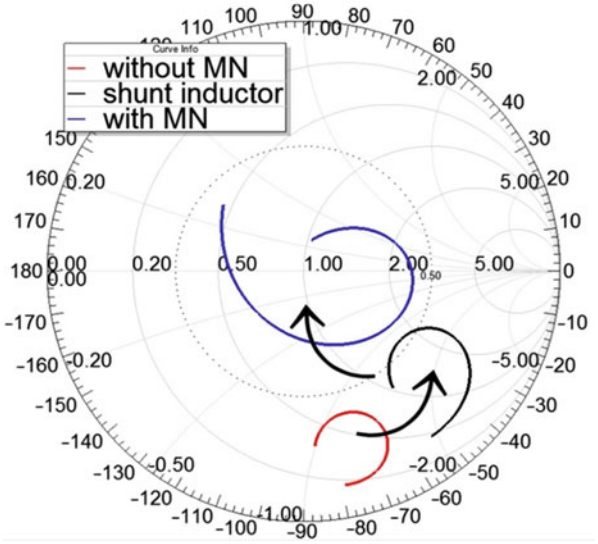

Fig. 45 Matching an antenna using L-type topology-5

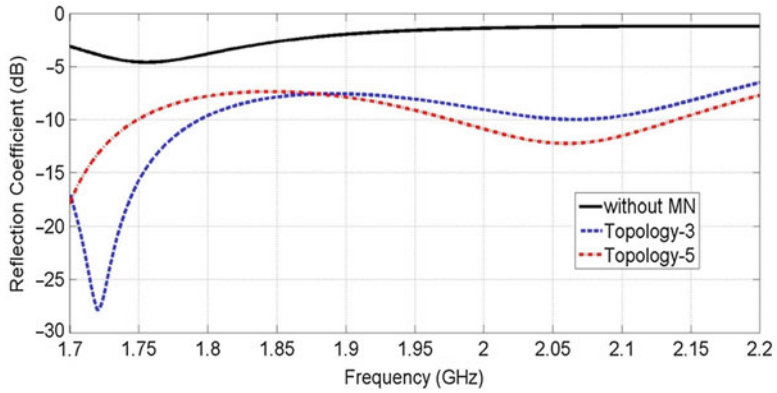

Fig. 46 Reflection coefficients for different MN topologies

if −10 dB is needed, the tunable/reconfigurable topologies have been already proposed to overcome the matching problem and decrease the reflection coefficient in a wider band.

A variety of tunable components are available for reconfigurable antennas. Switches that operate in the RF frequencies (like HEMT, pin diodes, or MEMS) are mainly used for matching an antenna in predefined frequency bands. On the other hand, tunable components (BST capacitors, MEMS variable capacitors, varicap diodes) are generally utilized to achieve a continuous but narrowband matching that can be swept through the target frequencies by changing the component values.

In Valkonen et al. (2007, 2010), matching networks (MNs) composed of multiple branches are used at the antenna feed. The active MN branch that feeds the antenna is changed using MEMS switches. For example, in Valkonen et al. (2010), a CE is placed on one edge of the PCB and excited through the MN seen in Fig. 47. According to the positions of the two switches, one of the two MN branches excites the antenna which tunes it to either the lower-frequency GSM band or the higher-frequency DCS/PCS band.

In Yamagajo and Koga (2011), a MN with switches is used again at the antenna feed. The antenna without MN covers the frequency ranges higher than 2 GHz but has poor matching below 2 GHz. The MN contains three switches which are connected to different shunt inductors. According to ON/OFF states of

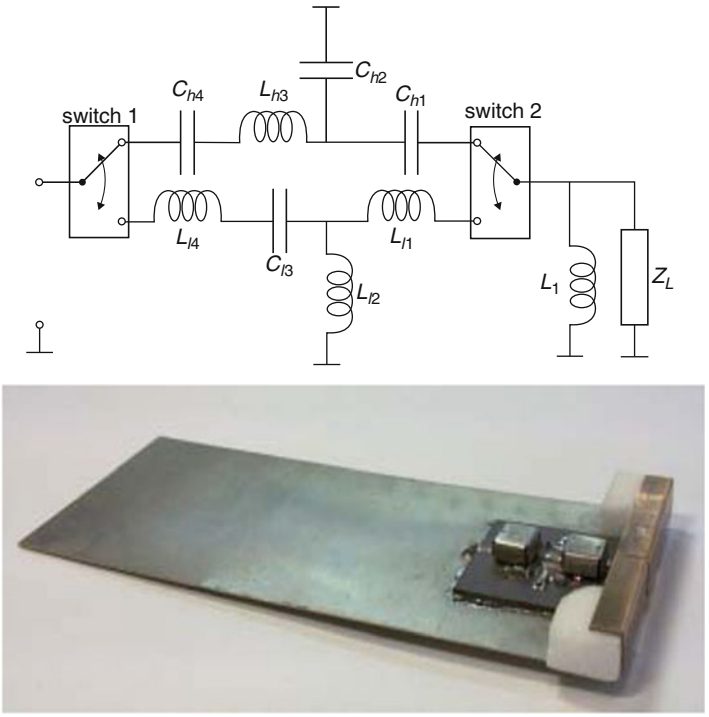

Fig. 47 MN and antenna topology for a tunable antenna using switches from Valkonen et al. (2010)

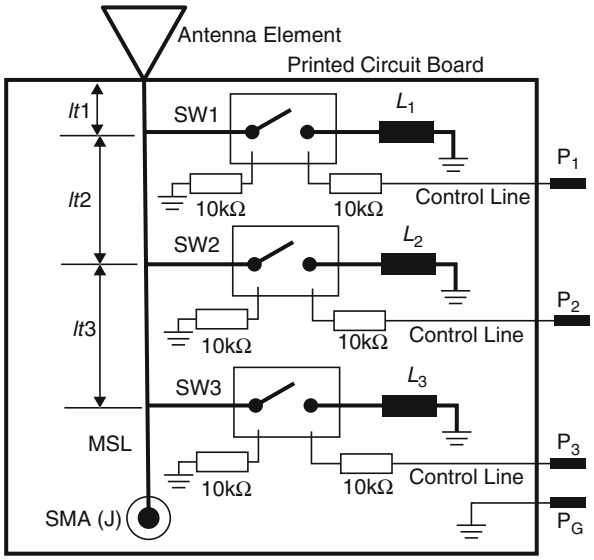

Fig. 48 MN composed of switchable shunt inductors (© [2011] IEEE. Reprinted, with permission, from Yamagajo and Koga 2011)

the switches, the overall shunt inductor value of the MN is changed and tunes the antenna to different operating bands between 640 MHz and 5.85 GHz (Fig. 48).

The tunable components are distributed through the antenna rather than placed at the feed in Mak et al. (2007) and Park and Sung (2012). For example, in Mak et al. (2007), two different topologies are evaluated, named as "switched feed design" and "switched ground design." In switched feed design, the feed of the antenna is either done from one end of a slotted strip or changed to the other end. In this way,

DOI 10.1007/978-981-4560-75-7_100-1

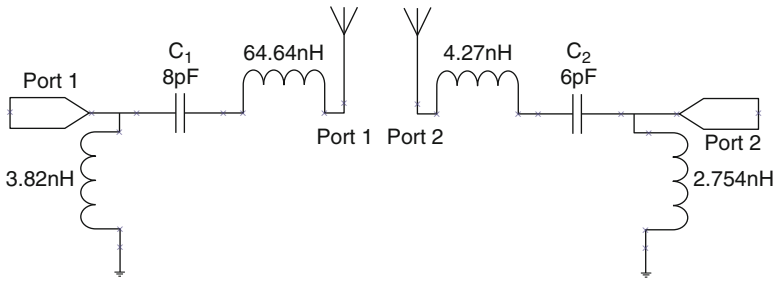

Fig. 49 Tunable MN with variable capacitors from Hu et al. (2010)

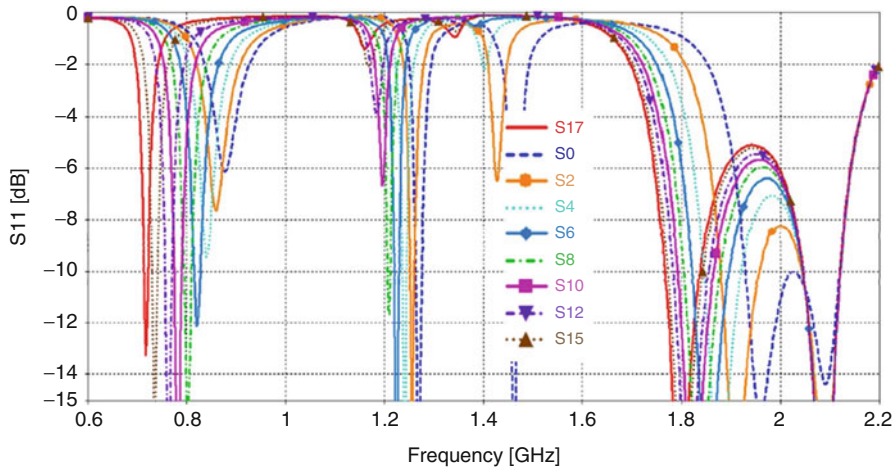

Fig. 50 Reflection coefficient for different capacitance values (© [2013] IEEE. Reprinted, with permission, from Ramachandran et al. 2013)

the reflection coefficient of the antenna operates in two states, the difference between the states being more in the higher band around 2 GHz. In switched ground state for the same antenna, one end of the metal strip is fed and the other end is either shorted to ground plane (forming a loop) or left open, according to the switch state.

In Park and Sung (2012), two pin diodes are used between the feed point and grounding point of a PIFA. According to the DC modes of the pin diodes, the antenna operates whether in PIFA mode or in loop mode to cover either the low-frequency GSM or DCS/PCS/UMTS bands.

Apart from these frequency switching antennas, tunable components can also be used to match continuously and instantaneously narrowband intervals for broader frequency bands. In Hu et al. (2010), two coupling elements are used with their own matching networks (Fig. 49). The MNs each consists of two lumped inductors and a variable capacitor. By changing the capacitance values between 0.2 and 8 pF, the first CE is tuned between 450 and 1360 MHz and the other one between 1660 and 2750 MHz.

In Boyle and Steeneken (2007) and Ramachandran et al. (2013), MEMS tunable capacitors are exploited at the ground connections of PIFAs to achieve tenability. Figure 50 displays the reflection coefficient for the antenna in Ramachandran et al. (2013) plotted for different capacitance levels of the tunable capacitor.

In Manteuffel and Arnold (2008), both switches and tunable components were used to obtain better matching with a simple CE, in a very wide frequency range going down to FM radio (100 MHz), DVB-H, GSM, and up to UMTS frequencies. Different MNs were used in different frequency bands, and these

DOI 10.1007/978-981-4560-75-7_100-1

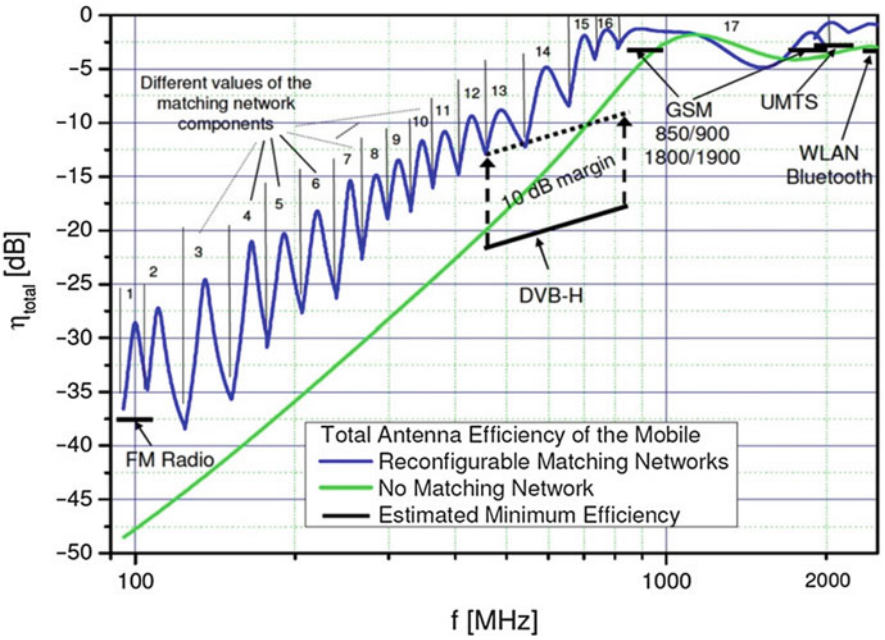

Fig. 51 Total efficiency for different MN states (© [2008] IEEE. Reprinted, with permission, from Manteuffel and Arnold 2008)

sub-MNs also contained tunable elements that enabled better matching in the sub-bands of interest. Figure 51 presents the total efficiency obtained from this antenna between 100 MHz and 2.2 GHz.

Tunable antennas have the advantage of enabling wider frequency coverage with a simpler antenna when compared to passive antennas. Tunable MNs can also be used to miniaturize antennas to obtain acceptable reflection coefficient and sufficient total efficiency. Another major advantage is the detuning effects (like the effect of the hand of the user covering the mobile phone) that can be compensated to some extent by adjusting dynamically the component values in a tunable MN. However, tunable/reconfigurable antennas also have some disadvantages compared to passive antenna layouts. The first and maybe the most significant one are the losses coming from the tunable components that will decrease the total efficiency of the antenna. Also, a real-time monitoring (closed-loop system) can be necessary to follow the healthy operation of the antenna and tunable components which increases both the complexity and the cost of the antenna parts of the mobile phone.

Antenna-User Interaction in Mobile Terminals

The interaction between a mobile phone antenna and the user can be categorized in two ways: the effects of the user on the antenna and the effects of the antenna on the user.

Effects of the User on the Antenna

In mobile phone antennas, the scenario which has the strongest interaction between the user and the antenna is the talk position. In this position, the antenna is held by the user's hand close to the cheek of the user. So, it can be told that the effect of the user on the antenna is limited by the hand and head of the user.

Practically, two effects of the user on the antenna can be mentioned. First is the detuning due to dielectric loading by the hand and head, since these tissues have high dielectric permittivity values. The second effect is the absorption of the radiation by the hand and head, due to their lossy characteristics. The

DOI 10.1007/978-981-4560-75-7_100-1

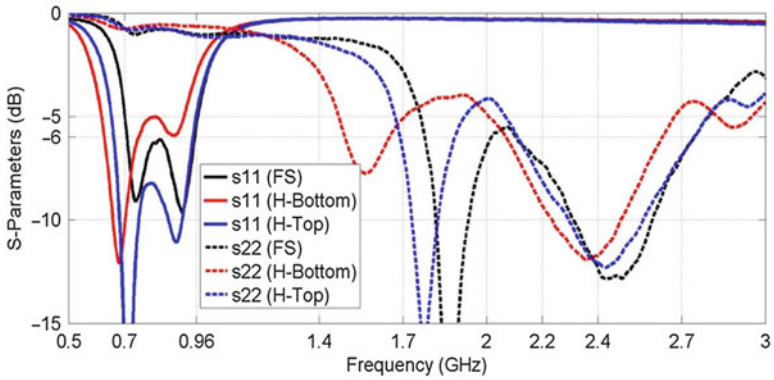

Fig. 52 Measured S-parameters with the user effects for the dual-feed antenna from Cihangir (2014)

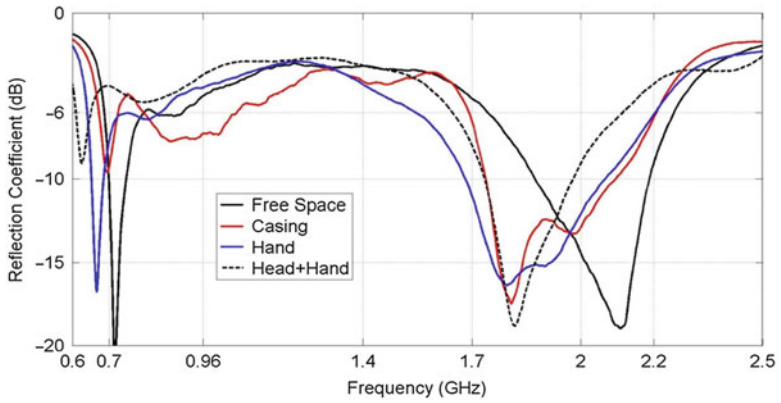

Fig. 53 Measured S-parameters with the user effects for the single-feed antenna from Cihangir (2014)

first effect can be observed from the reflection coefficient of the antenna whereas the second effect results in reduced total efficiency.

Detuning of the Antenna Due to User

The detuning of the antenna in the presence of the user's hand and head occurs due to the dielectric loading, by shifting the resonance frequency of the structure to lower frequencies. The effect of the user's hand was demonstrated with measurements with a dual-feed antenna in Cihangir (2014). The measured s-parameters of this study for three configurations are shown in Fig. 52. These three configurations are free-space, with hand when the antenna is placed on top of the PCB (facing the index finger), and with hand when the antenna is placed at the bottom of the PCB (facing the palm). In the hand-top configuration, a resonance shift toward lower frequencies is observed in both the lower and higher bands, but the shift is not as severe to cause a significant band detuning. When the antenna is placed at the bottom of the PCB with the hand, the resonance shift is stronger so the antenna gets detuned around 830 MHz and 1.9 GHz. It is expected to see a stronger detuning when the antenna is at the bottom of the PCB since the antenna in this position is totally covered by the lossy palm. However, when it is positioned on top, the antenna only faces the index finger which does not totally cover the antenna.

Another study about the user effect was done in Cihangir (2014), this time with a single-feed antenna and in four configurations as free space, with a dielectric casing, with hand, and with hand and head. In all

DOI 10.1007/978-981-4560-75-7_100-1

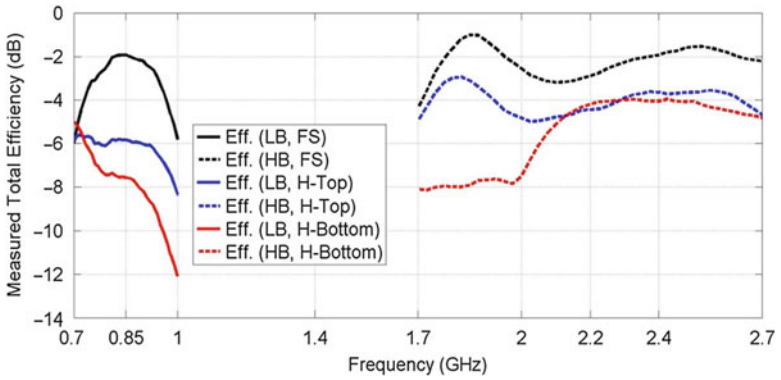

Fig. 54 Measured total efficiency with the user effects for the dual-feed antenna from Cihangir (2014)

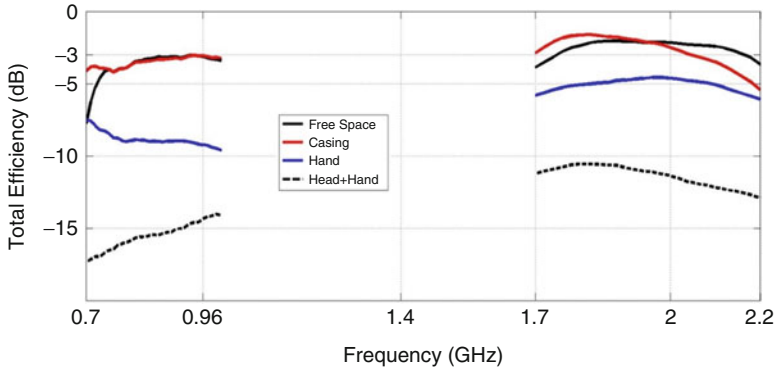

Fig. 55 Measured total efficiency with the user effects for the single-feed antenna from (Cihangir 2014)

these configurations, the antenna is placed at the bottom of the PCB, facing the palm. Figure 53 shows the measurement results from this study. The same behavior as before can be observed also here, with the resonance frequency shifting to lower frequencies with the presence of the casing, hand, and head. In this antenna, the detuning in the lower frequency band is more severe whereas the high-band detuning is less significant.

Total Efficiency Reduction Due to User

As also mentioned previously, the second major effect of the user on the antenna is the reduction of its total efficiency. The total efficiency can be reduced both due to the detuning (and thus higher return loss) and the absorption of the hand and head (that reduces the radiation efficiency). The total efficiency measurements for the two antennas presented above are given in Figs. 54 and 55. For the dual-feed antenna, the efficiency drops to around −6 dB and −8 dB in the low band for respectively "antenna on top" and "antenna on bottom" configurations. The efficiency in the high band is less affected compared to low band. Comparing, for example, the free-space (FS) and antenna on top with hand (H-top) configurations, there is a significant efficiency drop with the hand, although the reflection coefficient is not disadvantageous in Fig. 52. This suggests the decrease of the radiation efficiency owing to the lossy nature of the hand. As expected, the efficiency when the antenna is at the bottom is the least among all configurations.

DOI 10.1007/978-981-4560-75-7_100-1

Similar conclusions can be drawn from Fig. 55, representing the measured total efficiency for the single-feed antenna mentioned before. The efficiency with the hand is approximately around −9 dB in low band and around −5 dB in HB. The efficiency with also the head further decreases as expected.

The effect of the user on the antenna parameters was also investigated in a number of studies in literature. In Ilvonen et al. (2012), a shielding structure was proposed that minimizes the interaction between the hand and the antenna. Efficiency when the antenna is on top of the PCB in presence of the hand and head was measured to be −10 dB in lower band and −7.5 dB in higher band. In Valkonen et al. (2012, 2013b), antenna structures that were designed on purpose of preventing detuning when the antenna is on top of the PCB were proposed. The efficiency drop in the presence of the hand, compared to free space case, was around 7 dB for these antennas. The user effect on a narrowband PIFA was investigated in Pelosi et al. (2009), showing efficiency drop of 11 dB at 900 MHz and 8.5 dB at 1800 MHz in the presence of hand and head.

Effects of the Antenna on the User (Specific Absorption Rate)

It is a well-known fact that electromagnetic radiation can cause serious health risks for the human body. For the higher portions of the frequency spectrum (ultraviolet, X-rays, Gamma rays), the waves carry enough energy to ionize the atoms or molecules in the human tissues so they are called ionizing radiation. However for the microwave frequencies which mobile phones also use, the waves are categorized as nonionizing type. The main effect is thus confined to thermal that can cause damage through excessive heating of the tissues due to being exposed to radiation.

Specific absorption rate (SAR) is a quantity to calculate the RF power absorbed by the body. It is the accepted metric to quantize the potential risk on the user from the mobile terminal. The unit for SAR is (W/kg). It can be calculated through Eq. 6.

$$\mathrm{SAR} = \int \frac{\sigma(r)|E(r)|^2}{\rho(r)} dr \tag{6}$$

where σ is the conductivity of the tissue, $E(r)$ is the electric field amplitude, ρ is the mass density, and the integration is done over the volume where the SAR is measured.

It can be told that the SAR of a mobile phone antenna depends on the wave properties like frequency and polarization, the body characteristics like the shape and electrical properties of the tissue, the distance between the antenna and the tissue, and last but not least the antenna concept.

The SAR can be defined as full-body SAR or local SAR. For mobile phones, the only part of the body in close interaction with the antenna in talk mode is the head, so the local SAR in the head is used to characterize mobile phones. Two limit values were set by two standards (IEEE 2003), defining the limit in USA and (IEC 2005) in Europe. The US limit sets a maximum local SAR of 1.6 W/kg averaged over 1 g of tissue. The European limit is less strict compared to the US limit, being 2 W/kg averaged over 10 g of tissue. It can be told that a mobile phone compliant with the US SAR limit is almost always automatically compliant with the European SAR limit. Any mobile phones that exceed these limits are not authorized to be released on the market.

Different talk positions like cheek or tilt positions are defined for the simulation and measurement of the SAR. After the mobile phone is positioned in talk mode, the SAR is the maximum value seen in the head, after being averaged over 1 g (or 10 g) of tissue.

DOI 10.1007/978-981-4560-75-7_100-1

Multifeed Antenna Systems

A lot of current mobile phones use a single-feed antenna that can cover all the required frequency bands for communication. This antenna connects to different front ends for different communication standards through a single-pole multithrow (SPMT) switch. According to the communication standard used at the instant, the antenna switch position is changed accordingly, to route the signal to/from the front end from/to the antenna. With the introduction of the LTE Advanced technology, it will be needed to receive and transmit data over two different frequency bands to achieve interband carrier aggregation. For example, a service provider can select offering the user an interband carrier aggregation scenario of aggregating LTE Band-4 (1.71–2.15 GHz) and LTE Band-12 (698–746 MHz). This means that the antenna should be able to operate in these two distinct frequency bands simultaneously and transmit/receive the RF signal to the two front ends for these two bands. This is not possible with the topology previously discussed since the SPMT switch will let the system transmit/receive only from a single band at a single instant. To overcome the problem, a switch that has logic to enable two or more inputs/outputs at an instant should be used. An alternative could be using a diplexer just before the antenna that will direct the higher and lower frequency portions of the carrier-aggregated signal to corresponding front ends. However, this will increase losses in the front end.

An alternative is to use multiple-feed antenna systems. Such topologies are composed of two or more antenna elements with their corresponding feeds covering narrower (compared to single-feed) different frequency bands. In this way, the constraints of a single-feed antenna are relaxed, and it enables the utilization of simpler switches. The major drawback is the challenge of minimizing the isolation between the different port-to-port antennas since it will degrade the total efficiency of the used antenna through coupling from one port to the other (if the isolation is not high enough).

An antenna of this kind for mobile terminals is presented in Ikonen et al. (2012), also shown in Fig. 56. Three monopole-like antennas are used, one to cover 700–960 MHz, one for 1.7–2.2 GHz, and one for 2.5–2.7 GHz. A matching network is used at the feed of each antenna. The S-parameter of the antenna system is presented in Fig. 57.

A similar strategy was applied to achieve LTE band coverage with multiple feeds in mobile terminals in Cihangir (2014). This time, only two antenna elements were used with a dual-feed configuration, one antenna to cover 700–960 MHz (larger antenna in Fig. 58) and the other (smaller one) to cover 1.7–2.7 GHz. The matching network used at the feed of the low-band antenna has a low-pass topology, and similarly the matching network at the feed of the high-band antenna has a high-pass topology. This configuration helps achieve higher isolation between the two antennas, although they are physically very close to each other. As seen in Fig. 59, the target bands can be covered with a reflection coefficient below −6 dB with a high isolation of more than 23 dB through the whole target band.

From the antenna design perspective, the main advantage of using multiple-feed antennas is the relaxed constraint on the bandwidth. Instead of targeting dual-band or triple-band behavior from a single antenna (meaning wider frequency band coverage), a single antenna element in a multifeed system shall only cover a smaller portion of the frequency band. This will ease the design of the antenna, help miniaturization, and also decrease the matching network complexity and hence the losses associated to them. Of course the main drawback is to get acceptable isolation between the multiple elements, especially at lower frequencies, using both antenna placement which complicates the antenna design and using band-reject matching networks at the feeds which complicates the MN design.

Handheld Device Antenna Measurements

This section includes some topics related to the measurement of mobile terminal antennas that have not been mentioned in the chapter before but deserve being mentioned. First, the effects of the feed cable on the S-parameter and efficiency measurements are discussed. The Wheeler Cap method which is a simple and easy method the measure the antenna efficiency is then mentioned. Finally, the definitions of TRP (total radiated power) and TIS (total *sotropic* power) are given with basic information about how they can be measured.

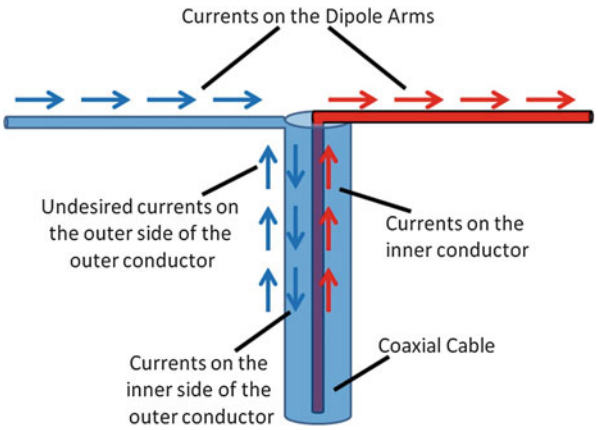

Fig. 60 Currents flowing on the feed cable of a dipole antenna

Effect of the Feeding Cable on Measurements

In most of the electromagnetic simulation tools where the mobile phone antennas are modeled and simulated, the antenna feed is modeled as a voltage difference between the feed point and the ground plane. However, in the manufactured prototype, generally an SMA connector is integrated to the prototype and the antenna fed through the inner conductor of this connector. The outer conductor of the SMA is then connected to the ground plane of the PCB. This difference between the feeding schemes in simulations and measurements causes some discrepancies between simulated and measured reflection coefficients, efficiency, and patterns. This situation has been investigated also in the literature as in Liu et al. (2012) and Chen et al. (2005).

The main problem causing this difference between simulations and measurements is the currents that flow on the outer face of the outer conducting part of the coaxial cable. This undesired effect can be explained for a dipole antenna as in Fig. 60. For the inner conductor of the feed cable, the current has nowhere else to go except the dipole arm. However for the outer conductor, the currents may flow both on the inner side or the outer side. The undesired currents that flow on the outer side of the outer conductor can be excited in two ways for mobile terminal antennas. First is due to the currents that are excited on the ground plane of the PCB and flow through the outer side of the cable. The other possible way is by the fields radiated from the antenna that excite surface currents on the cable without direct connection.

These currents can significantly change the input impedance of the antenna, causing errors in the measured reflection coefficient depending on the cable length. They also affect the antenna radiation pattern (and total efficiency), by creating ripples and nulls that normally should not occur. This phenomenon is more or less pronounced depending on the antenna concept which is measured, and it is very hard to predict if the undesired currents are going to be strongly excited or not before any measurement. A good trick to have an idea if a lot of currents are flowing on the outer part of the cable is to simply move your finger along the feeding cable during a VNA measurement and check if the reflection coefficient is strongly affected or not during these moves.

Some methods to minimize the disadvantages of this situation were also proposed. The first solution is to use quarter-wavelength long sleeve baluns on the outer face of the outer conductor. The balun is short circuited to the outer conductor on the balun's end so it presents an open circuit in the end of the cable owing to quarter-wavelength length. However, this technique blocks the currents in a limited bandwidth since the electrical length of the balun will change with frequency. Another alternative is to use EMI suppressant materials or place some ferrites on the outside of the cable. The ferrites operate well up to

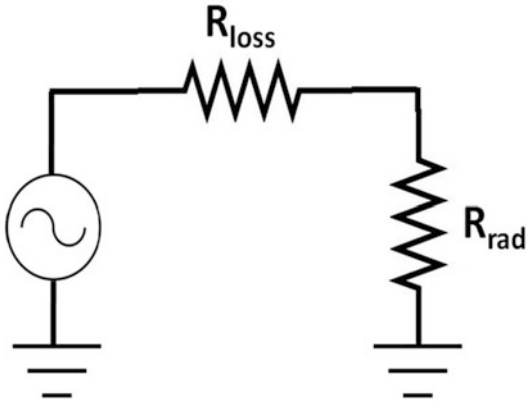

Fig. 61 Loss mechanism in the radiation of an antenna for Wheeler cap method

1 GHz, but their effectiveness is limited in the higher bands. These two solutions (EMI suppressant and ferrites) both suffer from reducing the efficiency of the antenna, since lossy materials are placed in its near field.

Wheeler Cap Method

The Wheeler cap method is the easiest and fastest way to measure the total efficiency of an antenna (Wheeler 1947). This method consists of placing the antenna under test inside a metallic cap (which can be spherical or cylindrical) and measuring the antenna reflection coefficient in free space and with this cap. If the metallic cap that encapsulates the antenna is well connected to the ground plane, it should reflect all the radiation from the antenna back to it, increasing the reflection coefficient. Figure 61 shows the radiation and loss mechanisms in a simple circuit representation. The first resistance R_{loss} stands for the radiation losses of the antenna at resonance which decreases its efficiency. R_{rad} is the radiation resistance of the antenna.

Hence the antenna efficiency (radiation efficiency) can be written as Eq. 7.

$$\eta = \frac{R_{rad}}{R_{rad} + R_{loss}} \tag{7}$$

When the reflection coefficient is measured with the antenna enclosed by the metallic cap, all the radiation will be reflected back and so $R_{rad} = 0$. Calculating R_{loss} from this measurement and R_{rad} from free space reflection coefficient, the antenna efficiency can be calculated without the need of any anechoic chamber or complex equipment. However, this method only gives information about the total efficiency and can't predict about the radiation pattern of the antenna. It can only be achieved in the prototype stage of the antenna. Several methods exist to extract the radiation efficiency from those two measurements. To the best of the authors' knowledge, the McKinzie method is a very accurate and reliable method (McKinzie 1997).

TRP/TIS

TRP (total radiated power) and TIS (otal isotropic sensitivity) are two metrics used to evaluate the radiation characteristics of a mobile phone when hardware is available. Indeed, the manufacturers need to evaluate compliance of their models with the standard values before releasing a phone on the market. Among these two definitions, TRP is related to the transmit characteristics of the phone, whereas TIS is related to receive characteristics.

TRP is the measure of the radiated power, when the transmitter, antenna, power amplifier, and their interconnections are in final state as the commercial phone. TRP measurements are active measurements,

DOI 10.1007/978-981-4560-75-7_100-1

where all the phone components shall run almost in final configuration, powered by the battery. For calculating the TRP, the EIRP (effective isotropic radiated power) shall be measured in all spherical directions. EIRP is basically the amount of equivalent input power that an isotropic antenna would need to have the same field strength as the device under test. To calculate the TRP, the time-averaged EIRP measured in all directions shall be integrated over the sphere.

TIS can be explained as the sensitivity of the receiver averaged over a 3D sphere in the basic sense. It is the integration of the EIS (effective isotropic sensitivity) over entire measurement sphere. The EIS is measured for a signal coming from a specific direction with a specific polarization and defines the minimum power level to resolve the data with a BER (bit error rate) lower than a predefined threshold. For this measurement, the mobile phone is placed in an anechoic chamber to obtain a measurement setup free from interferences: the phone uses a test SIM card and is linked to a base-station emulator. The power output level of the chamber antenna is decreased until the BER threshold is violated. In addition, broadband test antennas, positioning equipment, base station emulator, and head phantoms are also necessary.

Antenna Manufacturing Technologies

This section very briefly discusses some of the techniques used to manufacture mobile phone antennas. It is indeed difficult to describe every antenna manufacturing technology as the fabrication techniques evolve very quickly due to cost issues.

Metal Stamping

Metal stamping is the easiest and cheapest mobile phone antenna manufacturing technique. In this technique, the desired shape is given to a sheet of metal by stamping. The stamped metal is then integrated on a plastic piece, for example, by gluing. This technique does not offer the designer a lot of design freedom due to possible error sources like the placement of the metal piece on the plastic and the tolerance fabrication of the metal sheet.

Molded Interconnect Device (MID)

MID is a process that enables plastic parts that are selectively metallized. It allows integrating both electrical and mechanical elements enabling closely packed components.

One common technique is the two-shot molding, which uses two kinds of plastic materials molded together, differently from single-shot molding. For this technique, two resins are utilized, one of which is nonplatable and the other is platable. The platable material doped with catalyst is molded to the nonplatable material. This platable material shape also defines the traces of the metallization, intended to manufacture. The metallic traces are then realized with electroless plating.

Another technique used to obtain MID structures is the Laser Direct Structuring (LDS). This technology offers a lot of design freedom enabling the efficiency utilization of the available space. A thermoplastic material, which is doped with metal additives, is activated by laser according to the metal traces intended on it. In this way, a microscopically rough surface is created, forming the nuclei for the metallization step. This laser-activated material is then put into electroless copper baths to give it the final form. Using this technology, a high degree of freedom is obtained in terms of the metallization shape. An antenna manufactured using LDS technology can be seen in Fig. 62. Some thermoplastic material can also be chosen to allow reflow soldering which enables the possibility of directly integrating the MN into the plastic piece.

DOI 10.1007/978-981-4560-75-7_100-1

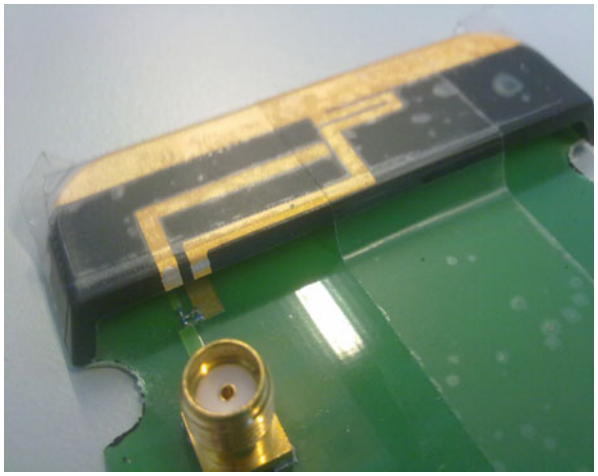

Fig. 62 An antenna realized using LDS technology from Cihangir (2014)

Future Directions and Open Problems

Antennas used in handheld mobile terminals were mentioned in this chapter.

General information about cellular communication standards and their evolution through time was summarized first. Through this evolution, some challenges arose for the antenna designer. With the announcement of each new generation, the antennas were needed to operate in broader frequency bands with generally smaller space dedicated to them.

In parallel to this evolution, the mobile terminal antennas have also undergone several changes, as explained in the second section. The initial antennas in former communication standards were external antennas, being generally of whip type, helical type, or a combination of these two. With the appearance of internal antennas in the market, there was a fast switch from external antennas to internal. Concerning this, different antenna types were investigated and used in the commercial products (some examples given in section "Examples of Commercial Antennas"), each having their own advantages and disadvantages over the other types.

As the internal antennas needed to be more broadband in a smaller size, some techniques have been used to make the antennas more broadband and miniaturized. Section "Antenna Feeding And Matching Methods" presented some of these methods. Different antenna feeding methods and the utilization of matching networks were discussed.

Active/reconfigurable antennas are also evaluated in industry and in academy to be used as mobile terminal antennas. These antennas can have some tunable components or switches at the antenna feed, as well as distributed over the antenna geometry. Some examples were given and their advantages/disadvantages over passive antennas discussed in section "Tunable/Reconfigurable Antennas in Mobile Terminals."

Section "Antenna-User Interaction in Mobile Terminals" was dedicated to the interaction between the user and the antenna of the handheld device. This interaction can occur in both ways. The user affects the antenna by detuning its reflection coefficient through dielectric loading and decreasing the total efficiency by absorption. The antenna has also effects on the user, launching electromagnetic fields on the tissues of the head, quantized by SAR.

The antenna topologies designed for use in mobile terminals can be single-feed or multifeed designs. Some multifeed design concepts with its advantages/disadvantages over single-feed antennas were mentioned in section "Multi-Feed Antenna Systems."

Section "Handheld Device Antenna Measurements" addressed some definitions and issues used in the measurements for mobile terminal antennas that were not discussed before in the chapter. One of the major problems in the reflection coefficient and efficiency measurements is the effect of the feeding cable that does not exist in a real-case scenario since the antenna is fed directly by a microstrip from the transceiver. Wheeler cap method was mentioned briefly as the simplest method to measure the efficiency. Definitions about TRP/TIS were also explained in this section.

The chapter was finalized with section "Antenna Manufacturing Technologies" mentioning the antenna manufacturing methods, commonly used in mobile terminal antennas.

Satellite Antennas on Vehicles

Stefan Lindenmeier* and Simon Senega
Institute of High Frequency Technology and Mobile Communication, Universität der Bundeswehr München, Neubiberg, Germany

Abstract

The mobile reception of satellite services on vehicles places high demands on the antennas in many regards. Due to the high path loss because of the great distances, low signal levels are experienced on the ground.

The following chapter gives an overview on antennas which can be used for the mobile reception on vehicles. The main areas of application in this regard are systems for global positioning and for satellite radio services. At first an overview of the requirements on the antennas imposed by the different services is given. Thereafter some basic antenna types are discussed regarding their advantages and disadvantages as far as the reception of satellite services are concerned including dipole and ring structures. More advanced antenna designs are also presented which are specifically optimized for different satellite systems.

In reception scenarios with severe signal impairments like multipath propagation resulting in deep signal fades, a single antenna is not sufficient for satellite reception. The mechanisms which lead to these scenarios are shortly introduced followed by a discussion of antenna diversity techniques which are an effective means to reduce these impairments. Special consideration is given to scan-phase diversity which efficiently combines the advantages of a simple system design with high signal quality improvements. Measurements obtained in real fading scenarios are presented for single antenna as well as scan-phase diversity systems. They show that antenna diversity can significantly improve the audio availability in adverse reception scenarios compared to single antenna systems. Furthermore, diversity can even allow for using antenna mounting positions which are unsuitable for single antennas like the dashboard or single side mirrors while still outperforming a rooftop mounted standard antenna.

GNSS; Satellite radio; Ring antenna; Dipole; Scarabeus antenna; Multipath fading; Antenna diversity

Introduction

In this chapter an overview on car antennas and antenna diversity technologies for mobile reception of satellite radio signals is given. The special requirements for the design of satellite reception antennas on a vehicle are discussed in general and in detail for the very common satellite services for navigation and radio broadcast. Basic antenna types are discussed in comparison with each other with respect to meeting the requirements for mobile satellite radio reception on vehicles. Together with the well-known common structures, for example, patch antennas, new ring types of receiving antennas are explained leading to an improved reception quality and enabling a lean efficient design. Applications are shown for the examples

DOI 10.1007/978-981-4560-75-7_101-1

of navigation and satellite radio services. Furthermore, ways of optimizing the reception quality of satellite radio significantly via antenna diversity are shown. This includes the discussion of appropriate diversity circuits and antenna structures which may be located together in one mounting volume which is as compact as former single antenna solutions. In real scenarios it is shown by experiment that in critical fading scenarios the number of mutes is reduced by more than one order of magnitude. The diversity technology enables the choice of new antenna mounting positions, which would not be chosen for a single antenna because of the strong decrease of reception quality. By means of diversity technology, successful reception of high quality is shown even for the use of inferior antenna positions like in side mirrors or on the dashboard.

General Requirements on Car Antennas for Satellite Reception

For satellite radio reception in cars, high demands are placed on the antennas with respect to gain, efficiency, volume requirements, and mounting conditions as well as reliable reception in critical reception scenarios like fading environment. Carrier frequencies to be considered are settled in the L-band and in the S-band. Since the wavelengths at these frequency bands are considerably shorter than those of the terrestrial radio reception services, only small antenna elements with a footprint of around 5 cm by 5 cm (2″ by 2″) and a height of less than 2.5 cm (1″) are needed. In the following, the main requirements for mobile satellite receiving antennas on vehicles are listed:

- Low mounting volume (typical footprint area: around 5 cm by 5 cm (2″ by 2″); typical height: $<$2.5 cm (1″))
- Low losses (typically 1.5 dB or less), high efficiency
- Power matching to 50 Ω
- Omnidirectional behavior with respect to azimuth
- Radiation pattern in elevation tailored to the satellite position to be expected from point of view of the receiver
- Easy fabrication and high reproducibility
- Circular polarization and high axial ratio
- Sufficient bandwidth (order of magnitude in MHz between 1 and 10 in case of navigation services and between 10 and 100 in case of satellite radio and mobile communication)
- Mounting position of low influence on the radiation pattern by the car's structure
- Low influence on the antenna performance when placing antennas for other services in close proximity

The angle ranges, in which certain gain values are required, differ very much with the satellite system. At LEO (low Earth orbit) and MEO (medium Earth orbit) systems, there is only a low height of the satellite above the sea level in comparison with the orbit radius, which means that the direction, in which the satellite might be expected from point of view of the receiving antenna, could be nearly arbitrary. With that, the radiation pattern of such systems should cover the complete upper half-space. In contrast in systems using a geostationary orbit (GEO) satellite, this satellite can be expected most probably in a range of diagonal elevation angles from point of view of the receiving antenna. HEO satellite systems use satellites where the transmission is active while its direction is of high elevation angle above the horizon. This means that the radiation pattern for such systems should have high gain values around the zenith. Additionally, there is often the requirement for reception of signals in very low elevation since terrestrial repeaters often support satellite services in urban regions where shadowing of high buildings might harm the satellite reception. As very common examples for satellite services are using orbits of MEO, GEO, and

DOI 10.1007/978-981-4560-75-7_101-1

HEO type, the following sections focus more closely on the requirements of navigation services and especially on the different aspects of requirements for satellite digital audio radio services (SDARS).

Antenna Requirements for Mobile Reception of Navigation Signals

For navigation, mobile satellite services such as GPS, GLONASS, and GALILEO are nowadays part of a typical equipment of vehicles for civil and military use. For these services the L-band is used with a center frequency of 1.575 GHz for GPS and Galileo, 1.65 GHz for GLONASS, and additional possible center frequencies at 1.23 GHz and 1.18 GHz for GPS as well as 1.19 GHz and 1.28 GHz for Galileo, each with a bandwidth of less than 10 MHz, typically 2–5 MHz (Hegarty and Chatre 2008).

Since the satellite orbits of the navigation systems are MEOs, the angle range of reception antennas for positioning services is very wide between zenith with theta = 0° and low elevation over ground with theta = 70°. In this angle range a constant gain is required. Often, a requirement for a certain axial ratio is reported. In some cases an axial ratio of less than 6 dB helps in fact to prevent first-order reflections of the radio waves in the environment since with the reflection the polarization is inverted. The problem is that for low elevation angles above the ground, only a high axial ratio is possible since in the horizontal plane above a very well conducting ground, an electromagnetic wave can only have a vertical polarization. In vertical direction a first-order reflection is only possible on the ground. In such a case it is more of interest how large the back lobe of the antenna is after being mounted onto a car. So the only case where a low axial ratio helps to prevent interference by reflections at high buildings is an elevation angle around 45°.

For these requirements, cheap patch antennas with a footprint area of less than 2.5 cm by 2.5 cm (1″ by 1″) have been commonly used. Nowadays other structures are considered too which also ensure easy fabrication combined with high efficiency and well covering of the required angle ranges.

Antenna Requirements for Mobile Reception of Satellite Digital Audio Radio Systems

In the last years, satellite radio systems gained more and more importance also for broadcast reception in the USA (Davarian 2002). Also for Europe, there have been plans to establish new satellite radio services in the S-band (Reding 2007) to follow an earlier system called WorldSpace which operated in L-band (Sallam et al. 2008).

In contrast to terrestrial systems, satellite radio services use satellites to broadcast the radio signals to a huge area of reception. By using satellites for transmission in satellite radio services, the reception area is extended to cover almost the complete continental USA as well as large parts of southern Canada. The frequencies usable in such a system are limited by the available transmission power as well as transmitting antenna size (and of course regulatory restrictions). American SDARS work in a frequency range from 2,320 to 2,345 MHz with a bandwidth of 25 MHz (Briskman and Prevaux 2004; Patsiokas 2001). While currently no European SDARS are commercially available, the frequency band between 2,170 and 2,200 MHz has been dedicated to this purpose (Reding 2007) and was auctioned to two buyers (Reding 2009). In contrast to the US systems, these will use a signal coding that is part of the DVB family and was standardized as DVB-SH by ETSI (ETSI 2010a, b, c).

An overview of the setup of a satellite radio system is depicted in Fig. 1. The broadcast signal is encoded in the broadcast center using all desired audio and data channels as well as supplementary information. After modulation and up-conversion in frequency, it is transmitted to the satellites. The satellites amplify and down-convert the signal to the desired frequency band and retransmit it after further

DOI 10.1007/978-981-4560-75-7_101-1

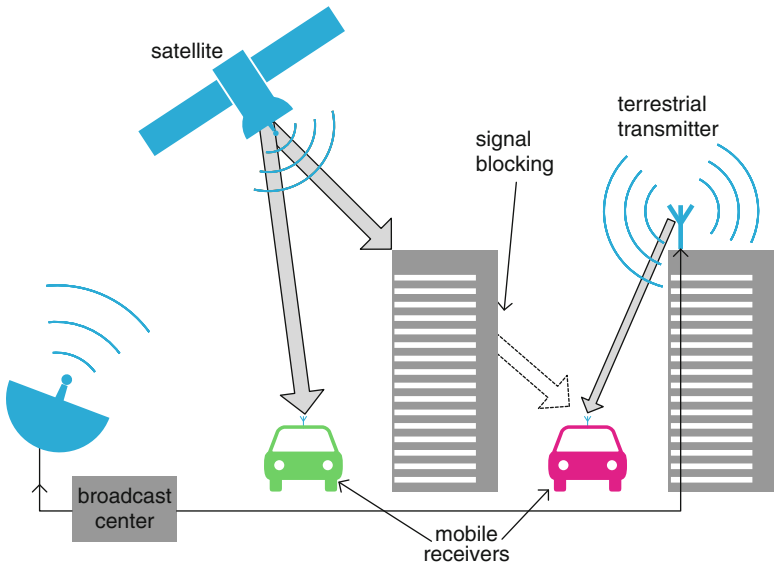

Fig. 1 SDARS system overview and signal paths (Senega 2013)

amplification (Briskman and Prevaux 2004). Mobile (and also stationary) receivers can then decode the transmitted information. In areas where a direct signal from the satellite is not available due to signal blocking – which can be the case due to natural or man-made attenuators in the signal path – supplementary terrestrial transmitters can be used. Of course these increase the overall system cost and are thus only sparsely used in areas with high numbers of service subscribers (e.g., in big cities).

Different satellite constellations are used by the (formerly two and now one) service provider(s) of US SDARS. One service started with (and still uses) two GEO satellites, while the other complemented its initial three HEO satellites with an additional GEO satellite. The HEOs' ground track – which describes the position of a satellite projected to Earth's surface over the course of one revolution – is a lemniscate. The ground tracks of three HEO and two GEO US SDARS satellites are depicted in Fig. 2. The GEO satellites always stand on the same position in the sky and therefore have an elevation angle that is almost constant unless the receiving antenna moves over great distances north or south. In most of the continental USA, the elevation angle of a GEO satellite is in the range of 30–45° above the horizon. The elevation angle of a HEO satellite strongly changes over time even for a stationary receiver. It can even have negative values when the satellite is below the horizon. Therefore at least three satellites are needed in order to ensure sufficiently high availabilities at any given time. The advantage of such a configuration is that one of the satellites is usually visible in very high elevation angles over ground of 60–90° (e.g., the red dot in Fig. 2) thus lowering the probability of a blocked signal path compared to a GEO transmitter. In Fig. 3 the elevation angles of the US SDARS satellites are plotted for a receiver located in a major US city over a time of 24 h.

The distance of the satellites to Earth is of course much higher than the distance between terrestrial transmitters and receivers. Due to propagation in the vastness of space, the free-space path loss of the transmission link gives a very convenient estimation of the attenuation that can be expected between the satellite and a receiver in line-of-sight (LOS) conditions. Free-space path loss a is calculated according to the following.

$$a = \left(\frac{\lambda_0}{4\pi d}\right)^2 \tag{1}$$

DOI 10.1007/978-981-4560-75-7_101-1

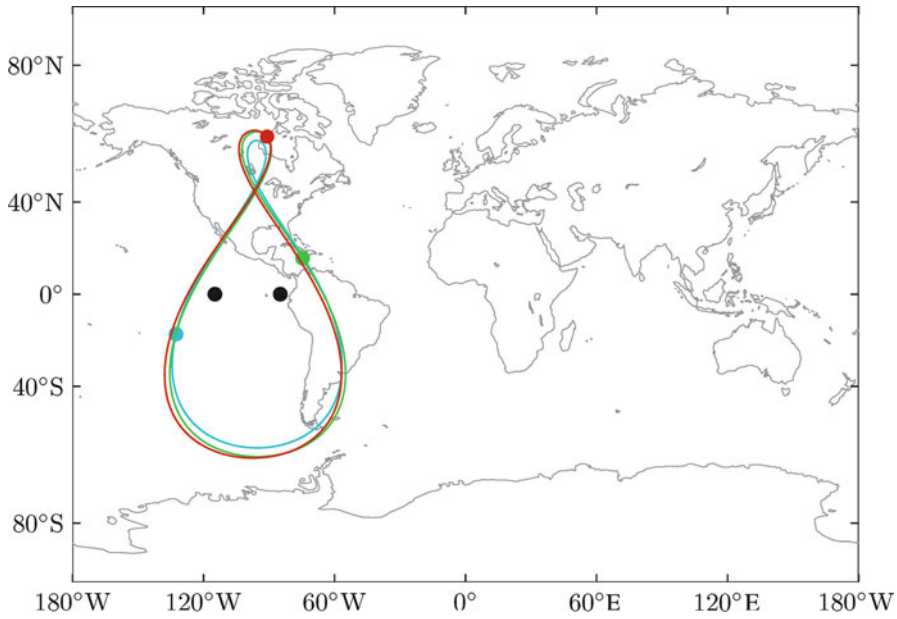

Fig. 2 Ground track of the satellites of XM Satellite Radio (GEO, *black dots*) and Sirius Satellite Radio (HEO, *blue*, *green,* and *red* lemniscate, GEO not depicted) (Müller 2010)

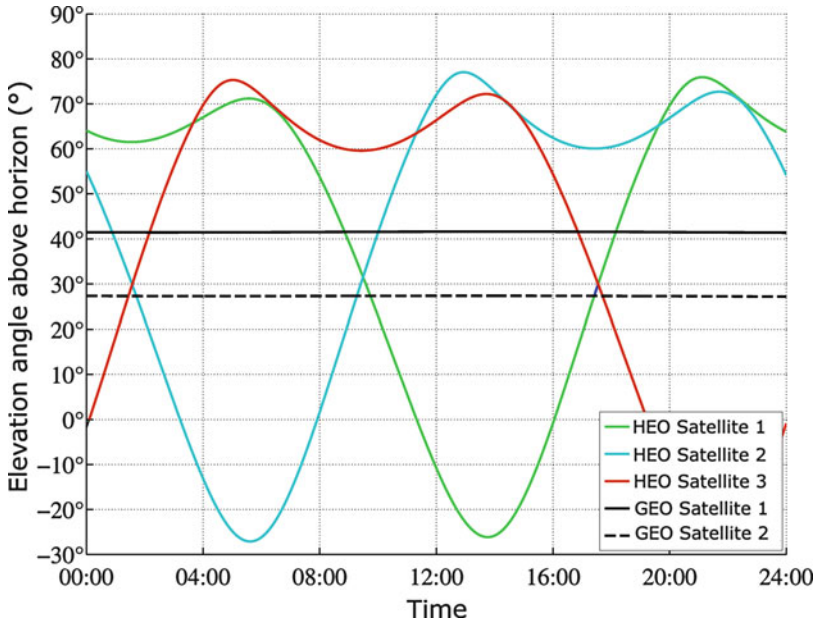

Fig. 3 Elevation angles over ground of GEO and HEO satellites over New York City, NY, USA, over a time period of 24 h (Müller 2010)

where λ_0 is the free-space wavelength and d is the distance between transmitter and receiver.

Due to the elliptical orbit, changes occur not only in the elevation angle but also in the distance of the satellite to the receiver. This means that the varying free-space path loss leads to signal levels that are dependent on the satellites position. A calculation of the free-space path loss of the signals from GEO and HEO using Eq. 1 and values given in Briskman and Prevaux (2004) leads to an attenuation in the range of −190 to −193 dB depending on orbit position as it is given in Table 1 (neglecting further attenuation due to atmosphere, weather, etc.).

DOI 10.1007/978-981-4560-75-7_101-1

Table 1 Free-space path loss from an SDARS satellite to Earth for different orbital positions

	Distance to Earth (km)	Free-space path loss (dB)
Perigee	24,469	(−187.55)
HEO 35° elevation	32,750	−190.09
Apogee	47,102	−193.24
GEO	38,192	−191.42

The modulation and digital coding of the satellite signals comprise a number of means to ensure high service availability in most reception scenarios (Briskman and Prevaux 2004). Of course any included redundant information for error correction or avoidance reduces the available number of information channels or the audio quality due to the limited frequency and power resources. Therefore the implemented measures are always a compromise between service variety, quality, and availability. While frequency, time, and spatial diversity as well as forward error correction schemes ensure high audio availabilities in many reception scenarios, they cannot avoid all signal outages, for example, in severe multipath fading scenarios.

The measure for quality of reception is the SNR at the receiver. If the SNR falls below a certain value – e.g., 5 dB – the decoding of the signal will suddenly be almost impossible due to bit errors. The exact value of the critical SNR is highly dependent on several parameters which among others include the modulation scheme, the number of bits per symbol, the method and parameters of the forward error correction, the influence of noise and disturbances on the transmission path and the receiver, etc. A critical decision during the design of communication systems is that of the link margin in typical reception scenarios. The link margin describes the typical difference between the signal level at the receiver and its sensitivity limit (the lowest signal power that it can decode quasi error free). In this regard the free-space path loss needs to be considered when the minimum transmit power of the satellites is specified. Any additional attenuation in the transmission path due to obstacles, weather, or multipath propagation will then reduce the remaining signal power until the SNR falls below the threshold, and decoding of the signal becomes impossible.

Special requirements on the radiation characteristics are made for SDARS signal reception (Haller 2001). Regarding the reception of US SDARS signals transmitted by HEO satellites, an angle range between zenith direction at theta = 0° and lower elevation at theta = 35° can be expected. In the last years transmission via GEO satellites gained more and more importance, so currently antennas are required which are appropriate for both the reception of signals from high elevation angles of HEO satellites and signals of medium elevation angles of GEO satellites. For GEO satellites the relevant angle range can be expected between low elevation at theta = 70° for northern regions and high elevation at theta = 45° for southern regions up to higher elevations at theta = 37° in a small area at the south border toward Mexico (if the receiver position's longitude is close to that of the GEO satellite). Each of the antennas still has to fulfill additional requirements for reception of terrestrial signals also at very low elevation angles. In parallel to this development, new ring type antennas have been created which can be made of panel without using lossy dielectric material. This results in a very high efficiency and hence to a strong improvement in signal to noise ratio.

Basic Antenna Structures for Mobile Satellite Signal Reception

In the following basic antenna structures are considered which are capable for the reception of satellite signals. All of these structures enable omnidirectional reception with respect to azimuth and a circular polarized field with a vertical main beam direction for HEO satellite signal reception or a diagonal main

DOI 10.1007/978-981-4560-75-7_101-1

beam direction for GEO satellite signal reception. All the structures considered fulfill the common requirement of a low antenna height in order to allow for easy integration underneath flat antenna radomes. In literature (e.g., Balanis 2005) there can be found a large number of other structures, for example, helical structures, which require a large antenna height or a large diameter with respect to the wavelength, so that normally such structures cannot be considered for integration in the small mounting volumes given in cars.

Crossed Dipole Antennas

A first very basic and well-known structure consists of crossed horizontal dipoles (Balanis 2005) which are positioned in a distance *d* above the ground plane. Figure 4 shows such a structure where the bold black lines represent the dipoles, while the gray structures represent the feeding network. If the distance *d* is one fourth of the wavelength, the reflection at the ground plane yields additional 3 dB in Gain in vertical direction, since a positive superposition of the waves propagating directly in vertical direction together with the waves which are reflected by the ground plane arises. For $\lambda/2$ dipoles the sinusoidal current distributions which are shown above the dipoles in the figure are obtained. In order to excite a circular polarized wave with vertical main beam direction, the two horizontal dipoles are connected with the feed with 90° of phase difference. This means that in one moment only the current distribution along one dipole is developed as shown in solid lines, while in one fourth of the time period, only the current distribution along other dipole is developed as shown in dashed lines.

If the branches of the dipoles were to be connected each with the same single-ended feed, it is obvious that a complicated network of phase shifters, power combiners, and baluns is necessary. In Fig. 4 an example of such a network is shown, where different phase shifters for each of the four branches yield a phase at these branches which is increasing in 90°steps in circular direction around the phase center.

For wideband applications such an antenna is advantageous since it can be expanded to a wideband crossed butterfly antenna structure as shown in Fig. 5. The wideband capabilities enable a use for several satellite services. Depending on the phase shifting and matching circuit, for different frequencies, LHCP and RHCP wave reception is possible at the same time. In Lindenmeier et al. (2001, 2002b), multifunctional antenna structures have been presented for different satellite services and terrestrial services. While for the satellite services the four vertical lines together with the horizontal elements act like a crossed butterfly antenna structure, they act in a common phase like a monopole with roof capacitor for terrestrial services.

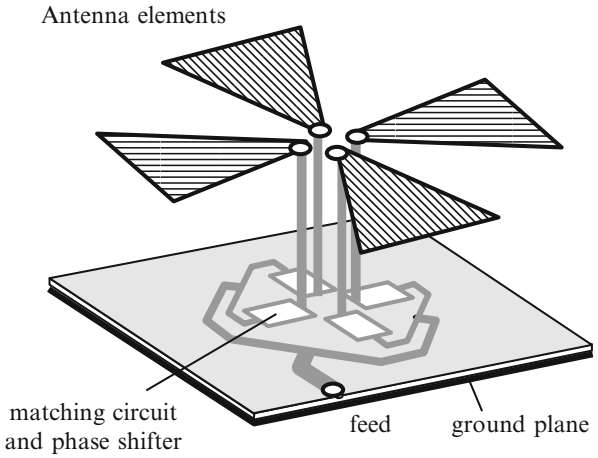

Fig. 5 Multifunctional crossed dipole structure

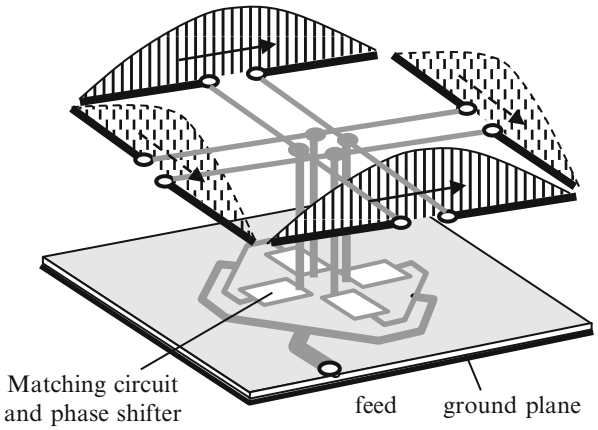

Fig. 6 Crossed pairs of dipoles

If further gain in the vertical direction is needed, the crossed horizontal dipoles can be expanded to two antenna arrays (Balanis 2005) as it is shown in Fig. 6. Off course, the up to 3 dB higher gain yields also a lower beam width which makes this structure more capable to reception of GEO satellite signals in southern regions. Since this structure is rather large, there is a strong requirement to shorten this structure. If the structure should be used for only one service, there is an unnecessary hardware effort to be paid for the feeding structure, which additionally decreases the antenna efficiency because of its circuit losses.

Patch Antennas

A very similar current distribution is occurring at the well-known patch antennas. Due to their small size, patch antennas are very common for mobile satellite signal reception and have been described in a large number of variations in literature, as, for example, in Sharma and Gupta (1983), Herscovici et al. (2003), Nasimuddin et al. (2007), and Pozar and Duffy (1997). As it is well known patch antennas represent a microstrip waveguide with an effective length of half of the wavelength for the first resonance mode. At such a short microstrip waveguide, there occurs a current distribution of a sinusoidal standing wave which has got maximum values along the opposite side edges of the microstrip line.

Patch antennas for a circularly polarized field are of roughly squared shape where the squared patch can be seen as a microstrip waveguide along two orthogonal horizontal directions. Hence, two orthogonal

DOI 10.1007/978-981-4560-75-7_101-1

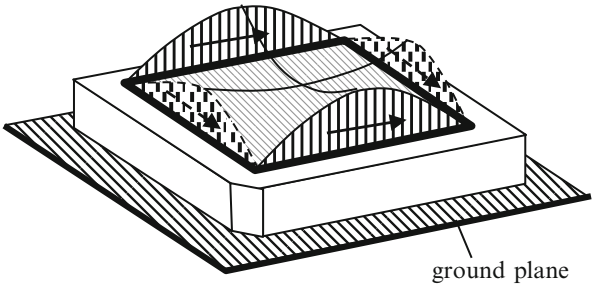

Fig. 7 Patch antenna

modes of resonance can be excited for the two orthogonal horizontal directions. In Fig. 7 a patch antenna is shown with the current distribution along the opposite edges of the patch. In between, the current distribution forms a saddle function with a minimum in the center of the patch.

If the two orthogonal resonant modes are excited with a phase distance of 90° between each other, current distributions are obtained at the edges of the patch which are similar to those of the pairs of crossed dipoles. The current distributions on opposite sides which are in phase with each other yield a strong gain in vertical direction, acting similar to a pair of λ/2 dipoles. On the other hand, the length of the edges is smaller than the length of the λ/2 dipole of Fig. 6 because of the shortening effect of the dielectric substrate. If ceramics substrate with high permittivity is used, the patch concept enables a small antenna size and hence an easy integration of the antenna in small mounting volumes.

The resonant modes can be coupled with each other via chamfered corners of the metal patch or the dielectric plate or a slightly rectangular shape together with an asymmetric feed, so that no phase shift circuit is needed and an easy fabrication is possible. This is why patch antennas are widely used for reception of GPS signals. The relative bandwidth of patch antennas, which is in a rather low range of a few percent, can be increased by the use of additional structures like stacking or insertion of slots in the patch (Herscovici et al. 2003; Nasimuddin et al. 2007; Pozar and Duffy 1997).

For the reception of satellite radio signals, patch antennas are often used either. Though the metal patch is oriented in horizontal plane, the substrate enables weak reception of a vertical field component at very low elevation which can be used for reception of signals of terrestrial repeaters.

Because of the relatively high gain in vertical direction, a patch antenna is not capable very well for reception of GEO satellite signals at the lower elevation angles. A general disadvantage of patch antennas is the loss in the dielectric material which decreases the signal to noise ratio of the received signal.

Crossed Frame Antenna

In order to obtain a radiation pattern which can be used for lower elevation angles, a crossed frame antenna has been introduced in Lindenmeier et al. (2002a). In the same way as a crossed dipole structure has been realized via phase shifters, two vertical frame antennas are crossed and excited with a phase distance of 90° to each other.

The basic principle is shown in Fig. 8 together with a sketch of the current distribution. Due to the vertical parts of the frame antennas, a considerable share of vertical polarized waves is received in horizontal plane and at low elevation angles. This enables also the reception of GEO satellite signals. Due to series capacitors being inserted in the frame antennas, the antennas are set into resonance and the radiation pattern can be adapted to special requirements. In Fig. 9 an example of such an antenna is shown together with its matching and phase-shift circuit. Like for the crossed dipole structure, the matching and phase-shift circuit required means an additional hardware effort, harming also the efficiency of the antenna. Nevertheless, due to its capability also for lower elevation angle ranges, this antenna has been used successfully for SDARS reception and in particular for GEO satellite reception.

Loop Antennas

In the following a very efficient antenna concept is shown for satellite signal reception. If a horizontal loop antenna has got a circumference equal to the wavelength, it is a resonant structure. It can be considered like an electromagnetic waveguide where the wave is guided in a circle. As long as such a wave is excited only for propagation in one direction, there will occur a current distribution which moves along the closed loop in positive direction as shown in Fig. 10. This current distribution yields a very pure circular polarization of the antenna structure. In Fig. 11 a radiation pattern for ideal conditions is shown for the left-hand and right-hand circular polarized field (LHCP and RHCP). While for the LHCP a gain of 8 dB in vertical direction is obtained, only a gain of −11 dB is occurring for RHCP.

An antenna design which is tailored to high efficiency, a wide angle range, and a small size is the "Scarabeus" antenna (Kammerer and Lindenmeier 2011), which is depicted in Fig. 12. It consists of a loop antenna which is connected to vertical elements. These vertical elements are connected to ground via capacitors. Due to the vertical elements, two advantageous effects occur: At first, the structure is even smaller than the loop structure of Fig. 10 because of a shortening effect of the capacitive vertical elements. Secondly, the current distribution along the vertical elements yields a nearly omnidirectional vertically polarized field in horizontal plane. In Fig. 13 the radiation pattern in the vertical plane is shown for the co-polarization LHCP and the cross-polarization RHCP. In Fig. 14 the radiation pattern is shown in the horizontal plane for ideal conditions.

DOI 10.1007/978-981-4560-75-7_101-1

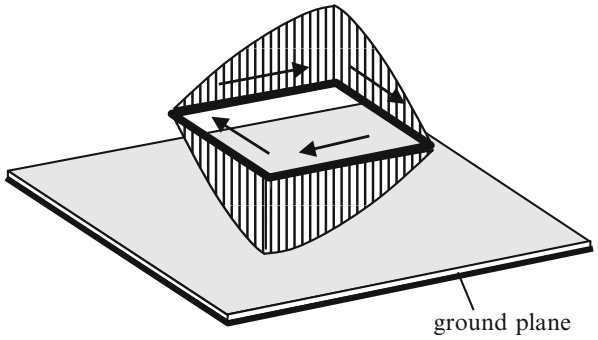

Fig. 10 Horizontal loop antenna

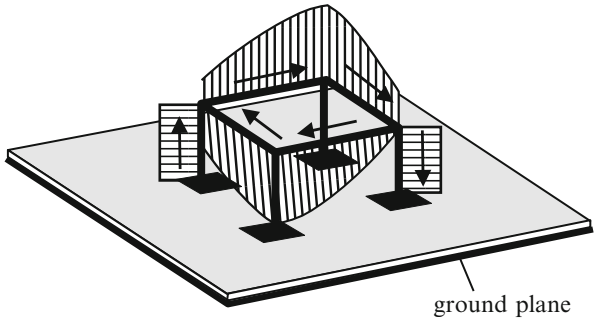

Fig. 11 Scarabeus antenna

Since manufacturing of these antenna structures is easy – the conducting structures are realized in panel and since dielectric material can be prevented – these structures have a very high efficiency with losses of only 0.5 dB. This is why even for a simple realization, as shown in hardware samples in Figs. 15 and 16, an antenna characteristic is achieved, which is very close to the ideal case, as is shown in the measured diagrams in Figs. 17 and 18.

As the radiation diagrams show, the antenna offers an omnidirectional behavior with respect to azimuth and a wide beam width in elevation of more than 90° which enables to use the concept for SDARS services with HEO and GEO satellites as well as for navigation services. Special characteristics of this antenna type are as follows:

- High efficiency and low losses of only 0.5 dB since the antenna structure can be realized by panel without the need to lead the electric field through material of high permittivity as it is necessary for patch antennas.
- Low footprint area of around 13 % of the wavelength.
- High axial ratio of more than 15 dB in zenith.
- Easy combination with terrestrial antennas which can be positioned in the phase center of the Scarabeus antenna.
- The wide bandwidth enables its use both for GPS and for GLONASS global positioning service.

Especially for situations where satellite antennas should be hidden invisibly, it might be necessary to embed the antenna into the skin of the car in a way that the antenna is not sticking out of the surrounding metal surface. This leads to an increased focus of the radiation pattern to higher elevation angles, which might harm its application for GEO satellite signal reception. In case of the Scarabeus antenna, the high

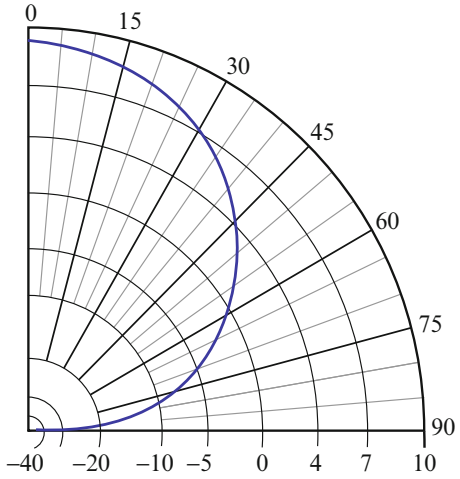

Fig. 12 Radiation pattern of loop antenna (*blue*: LHCP, RHCP not visible)

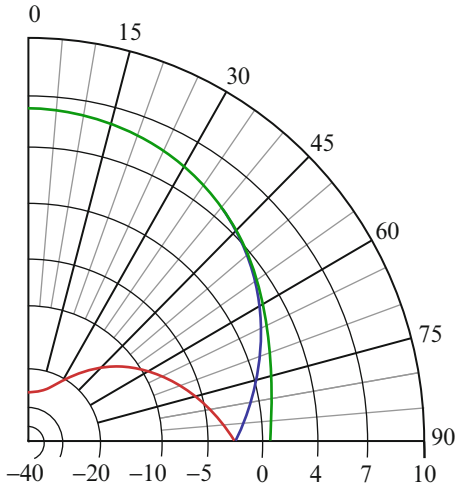

Fig. 13 Radiation pattern of Scarabeus antenna (*blue*: LHCP; *red*: RHCP, *green*: total)

efficiency nonetheless yields a sufficient reception quality even for SDARS signals as has been shown in Kammerer and Lindenmeier (2013b, a) even for an antenna combination of SDARS and GPS, hidden invisibly in a squared cavity of $40 \times 40 \times 10\ \text{mm}^3$. In numerous test drives in real reception scenarios, the Scarabeus antenna has proven a significantly larger reception quality due to its high efficiency together with an antenna characteristic which is tailored to the needs of GEO satellite signal reception while still enabling as well the reception of HEO satellite signals.

Due to its ring shape, Scarabeus antennas can be combined with each other for different services at different carrier frequencies (Kammerer and Lindenmeier 2012, 2013a). The design allows also easy combination with antennas for terrestrial signal reception as, for example, mobile phone antennas or even antennas for AM, FM, and DAB broadcast reception, which can be placed in the center of the Scarabeus antenna (Kammerer et al. 2012).

Circular Polarized Homogenous Field Loop Antenna

In the following an antenna structure will be considered which is useful for the reception of circularly polarized signals transmitted via GEO satellites (Saala et al. 2009, 2010; Saala and Lindenmeier 2010).

DOI 10.1007/978-981-4560-75-7_101-1

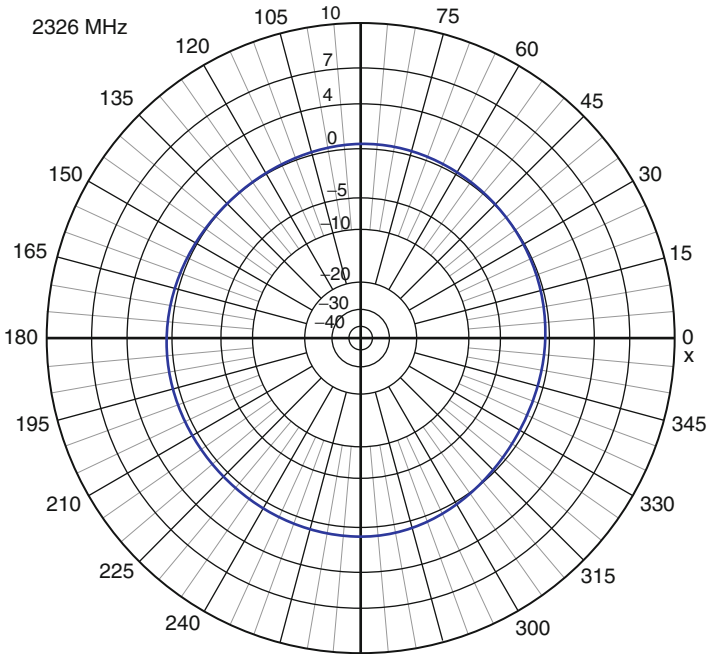

Fig. 14 Radiation pattern in the horizontal plane at 2.3 GHz (total field in vertical polarization)

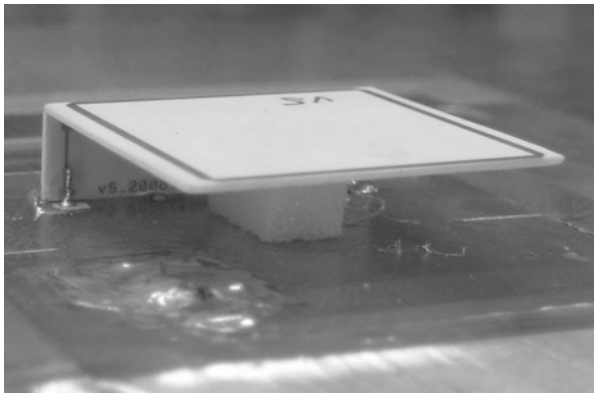

Fig. 15 Hardware sample of a loop antenna for 2.3 GHz; length and width: 34 mm; height: 10 mm

This structure consists of a ring structure which is combined with a vertically polarized monopole structure, as shown in Fig. 19.

In contrast to all the other antenna concepts shown here, the current distribution of this antenna is homogenous with respect to azimuth. While the current distribution of the monopole with its vertical direction is independent from azimuth anyway, an omnidirectional current distribution on the loop is achieved via insertion of series capacitors.

The monopole yields a vertically polarized field (theta direction) with omnidirectional characteristics and constant phase in azimuth and a horizontal main beam direction, as shown in Fig. 20a in blue. The loop antenna yields a horizontal polarized field (phi direction) also with omnidirectional characteristics and constant phase in azimuth and a main beam direction close to 45° in elevation, as shown in Fig. 20a in red.

DOI 10.1007/978-981-4560-75-7_101-1

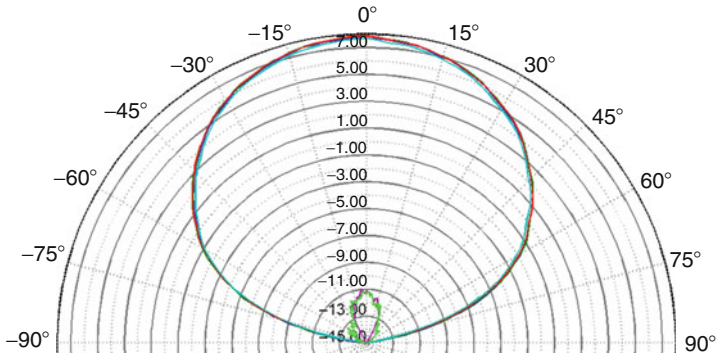

Fig. 17 Measured rad. pattern of loop antenna (LHCP and RHCP)

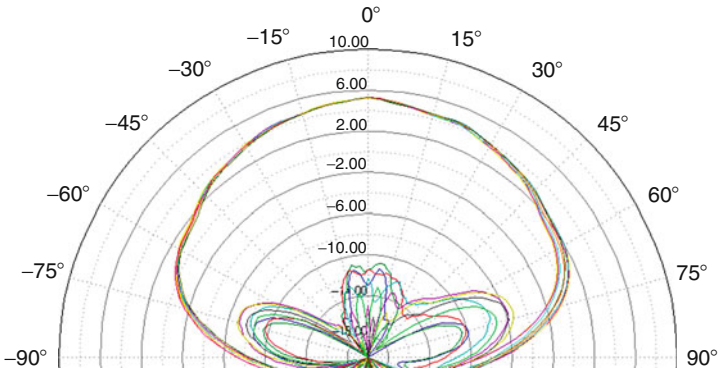

Fig. 18 Measured rad. pattern of Scarabeus (LHCP and RHCP)

Exciting the monopole and the loop antenna together with a chosen weighting and a phase distance of 90° to each other, a weighted and phased superposition of its characteristics is obtained. The resulting characteristics of a circularly polarized field are shown in the radiation patterns of Fig. 20b. The circular co-polarization (co-pol) of the complete antenna is shown in red, while the cross polarization (x-pol) is shown in blue. It can be seen that the cross-polarization ratio is dependent on the elevation angle. Depending on the power distribution between the horizontal loop and the vertical monopole, a minimum

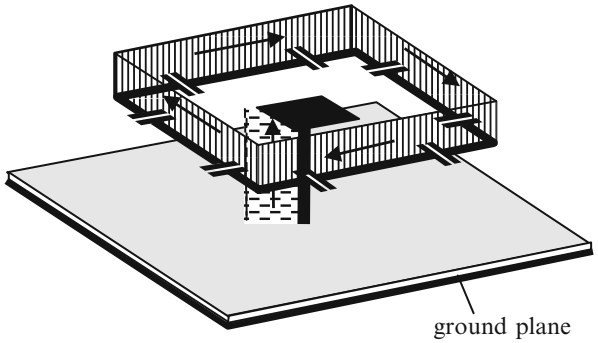

Fig. 19 Circular polarized homogenous field loop antenna

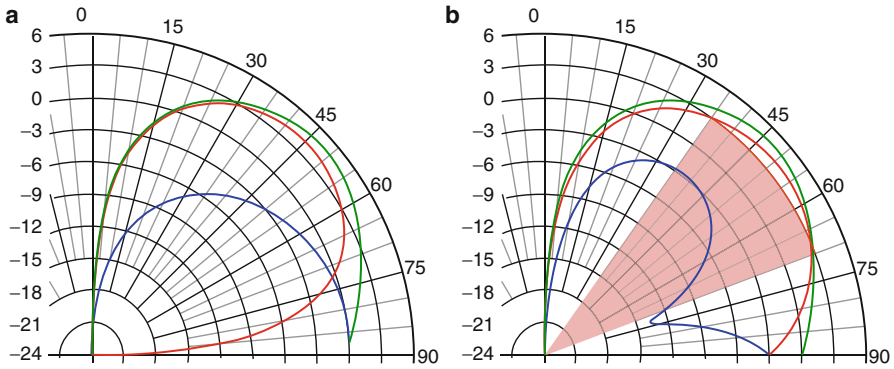

Fig. 20 Vertical radiation pattern of circularly polarized field loop antenna; (**a**) linear polarization vertical (*red*), horizontal (*blue*); (**b**) circular co-polarization (*red*), x-polarization (*blue*); total gain (*green*)

in cross polarization can be shifted to an elevation angle of choice. While in vertical direction there is no reception possible, for the circular co-polarization this antenna structure achieves an especially high gain for diagonal elevation angles around 45°.

Hence, this structure is ideally tailored to the reception of signals transmitted via GEO satellites. Within the required elevation angle range between theta = 65° and theta is 70°, a gain of more than 3 dB can be achieved in ideal conditions by the combination of those two antennas.

For real hardware structures, the efficiency is depending on the quality of the capacitors. For air-filled capacitors, which can be realized in an air slot technology, losses of less than 0.8 dB are achieved. In Fig. 21 a hardware sample of a circular polarized field loop antenna is shown. A typical measured radiation pattern is shown in Fig. 22. The 10 dB bandwidth achieved is 28 MHz and its efficiency is 1.5 dB.

According to the principle of duality, the abovementioned antennas can also be realized as slotted structures. Dual to the crossed dipole there, one can also have a crossed slot structure in the upper surface of a cavity (Balanis 2005). This realization is as well applicable to the ring structure in the form of a slot ring. Even the combination of dipoles and slots is possible as the next example will show.

Narrow Slot Dipole Antenna

In the following the combination of a slot antenna with a dipole antenna for mobile reception of circularly polarized waves is shown, as has been introduced in Müller et al. (2009). The structure is especially advantageous in mounting situations where the antenna has to be integrated into a very narrow finlike radome on the roof of a car.

DOI 10.1007/978-981-4560-75-7_101-1

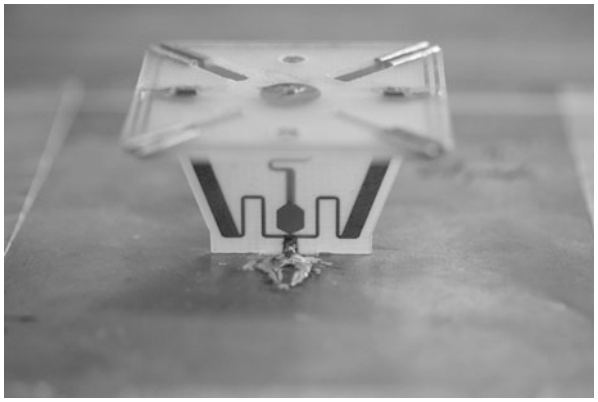

Fig. 21 Hardware sample of homogenous field loop antenna (length and width: 32 mm; height: 20 mm)

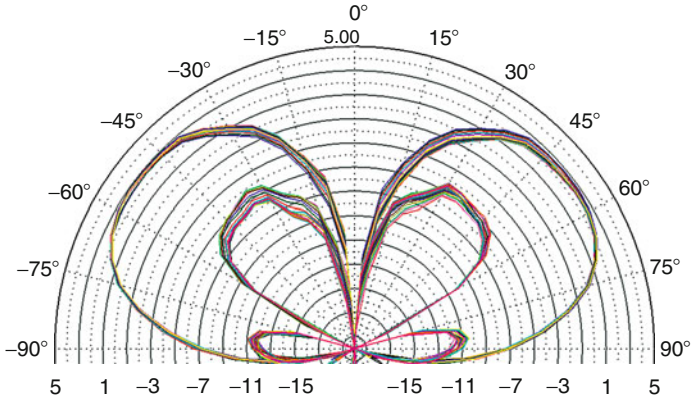

Fig. 22 Gain in dBic of the homogenous field loop antenna

The basic concept is shown in Fig. 23. Like at a crossed dipole structure, two antenna parts yield two shares of the field with linear polarization which are orthogonal to each other having a phase distance of 90° to each other. While in the common crossed dipole structure (see Fig. 4), two dipoles are contributing these linear polarizations, this is done here by a monopole and a slot antenna. While the dipole yields a current distribution corresponding to a field which is polarized in the same direction as the dipole, the slot antenna corresponds to a field with a polarization which is orthogonal to the slot direction. In order to obtain the required phase distance between the excitation of the two orthogonal field shares, the dipole is fed with that phase delay via a feed line with a length of λ/4.

In Fig. 24 a hardware sample of this antenna is shown for SDARS at 2.3 GHz with a height of around λ/4 (32 mm), a similar length of 30 mm, and a thickness of 1.5 mm. Figure 25 depicts a typical radiation pattern achieved by this structure.

For the first applications in SDARS signal reception, crossed frame antennas and patch antennas have been commonly used. Especially for the transmission via HEO satellites, patch antennas have proven to fulfill the requirements quite well. This led to the situation that the most common antennas for this application were patch antennas which have been used in different variations. For combined GEO and HEO satellite systems, loop antennas like the Scarabeus antenna are increasingly used because of its high efficiency in combination with an easy fabrication. This is also true for the positioning services where these antennas offer a wide bandwidth, which offers its use for more than one service, as, for example, GPS and GLONASS, being covered by the same antenna.

Environmental and Mounting Aspects, Antenna Combinations, and Multifunctional Structures

In the following the environment of satellite reception antennas is considered with respect to common integration technologies, common packaging and housing of multiple antennas and front-end parts, integration into narrow environments, and the investigation of coupling effects. In mobile applications the close integration of front-end modules and antennas in a narrow environment with a variety of possible electric and electromagnetic interferences is of high challenge. The small size of microwave antennas with low directivity enables a common integration and close packaging of antennas and circuitry for amplification of antenna signals or signal processing of multiple antenna signals in antenna diversity and smart antenna systems. In Fig. 26 a typical antenna combination is shown, in which terrestrial antennas for AM and FM broadcast and cell phone are combined with satellite antennas for SDARS and GPS signal reception underneath one common roof radome.

Coupling effects are prevented by inserting band-stop filters into a cell phone antenna. If terrestrial antennas can be positioned in the phase center of a satellite antenna, the modes of oscillation are

DOI 10.1007/978-981-4560-75-7_101-1

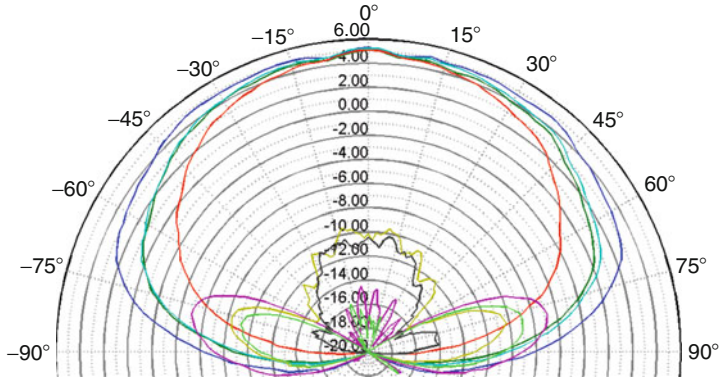

Fig. 25 Measured radiation pattern of the slot dipole antenna

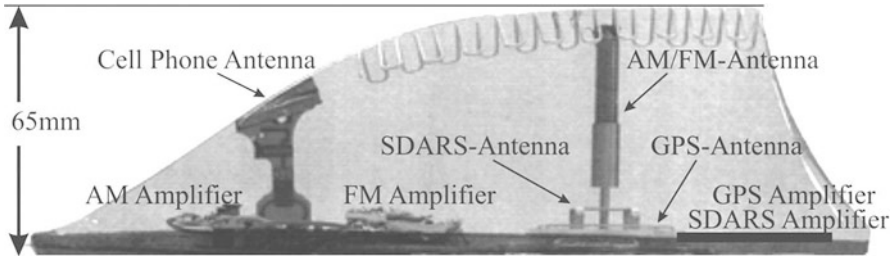

Fig. 26 Antenna combination of satellite antennas for SDARS and GPS with terrestrial antennas for AM, FM broadcast, and phone underneath one common roof radome (Kammerer et al. 2012)

decoupled from each other. This is possible with the Scarabeus loop antenna. As has been shown in Kammerer et al. (2012) even for the combination of Fig. 26, the radiation characteristics of two Scarabeus antennas – one for SDARS and one for GPS – whose phase centers are coincident with the phase center of a large AM-FM antenna are not harmed.

If a satellite antenna is integrated into plastic parts where no large ground plane is available and only a small plate can be added with a diameter of 7.5–10 cm (3″ to 4″), a ripple will occur in the vertical radiation diagram, as can be seen for different examples in Fig. 27. While the dashed line shows the diagram for a large ground plane in the solid blue lines, a superimposed ripple is observed whose envelope is mainly depending on the diameter of the ground plate. The number of ripples is depending on the height of the antenna position over ground.

In Fig. 28 a result is shown for a small ground plate with diameter of only 65 mm with a high ripple, leading to deviations from required gain by around 3–4 dB. Since the demands on the antenna gain are very close to that which is achievable for a large ground plane, it is obvious that in a situation with a small ground plate, the antenna will not be capable any more for SDARS satellite signal reception.

A similarly inferior situation where a single antenna would not fulfill the gain requirements in the regarded angle ranges also occurs if a satellite antenna is integrated in mounting positions, for example, inside the side mirror or on the dashboard of a car. In Fig. 29 the radiation pattern of an antenna is shown which is integrated in one side mirror. Not even on the right side of the diagram the required gain is fulfilled in all the angle ranges since values of gain below 0 dB at an elevation of theta = 60° are not acceptable. Because of shadowing and reflection effects, the gain is even further decreased on the left side of the diagram in the direction toward the car.

Generally spoken in situations of special mounting positions – where the antenna cannot be mounted on top of a large metallic plane – there are problems to keep the required reception quality of a single antenna.

DOI 10.1007/978-981-4560-75-7_101-1

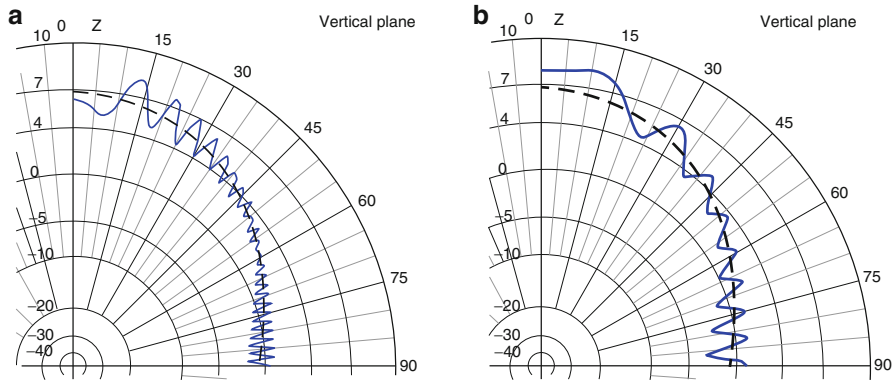

Fig. 27 Vertical radiation diagram of SDARS satellite antenna with small ground plane of 85 mm diameter for different height h over ground: (**a**) h = 1,5 m, (**b**) h = 0.5 m

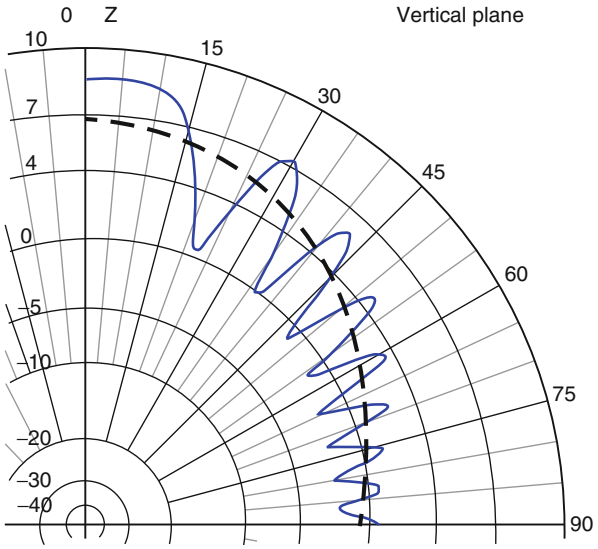

Fig. 28 Vertical radiation diagram of SDARS satellite antenna with small ground plane of 65 mm diameter at 0.5 m height over ground

In this case the use of antenna diversity is of great help, where critical mounting positions and changing environmental conditions can be treated by the use of alternative antennas in an adaptive way. In the next section antenna diversity for satellite radio reception is explained, which enables to keep a high reception quality also in critical mounting situations and also for critical environmental situations around the car.

Antenna Diversity for Mobile Satellite Reception

The reception of satellite radio signals using single antennas generally works flawless in conditions with an LOS propagation path from the satellite transmitter to a stationary or mobile receiver. Still it can be severely impaired in non-LOS scenarios (Parsons et al. 1975). The reasons for these impairments are a combination of attenuation due to signal shadowing and reflection, refraction, and scattering caused by objects in and close to the direct transmission path. This leads to a received signal which is a superposition of a multitude of waves with different directions, levels, as well as phases and causes statistically

DOI 10.1007/978-981-4560-75-7_101-1

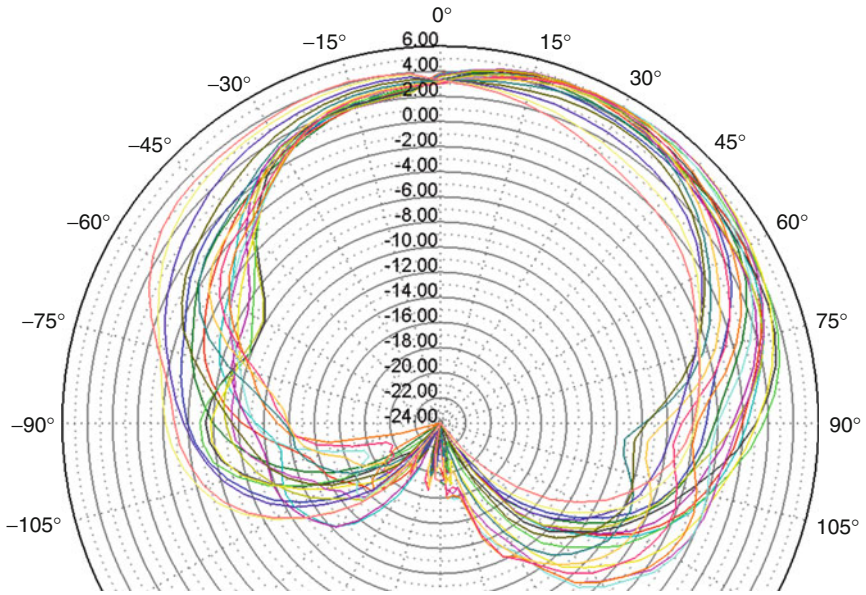

Fig. 29 Vertical radiation diagram of SDARS satellite antenna with small ground plane of 65 mm diameter at 0.5 m height over ground

distributed deep signal fades along the driving paths (Parsons et al. 1975; Brennan 1959). An example of such a scenario and the resulting signal levels is depicted in Fig. 30.

The probability of the deep fades is lower with a strong LOS component and increases with increasing attenuation of the direct signal. A very high probability of deep fades exists in the absence of an LOS signal component. Mathematically the probability distribution in a fading scenario can be described with a Rice distribution where an LOS component is present. In non-LOS conditions this reduces to a Rayleigh distribution with a much higher probability of low signal levels. The Rayleigh distribution of the probability f_R of signal amplitudes r in such a scenario can be described as

$$f_R(r,\Omega) = \frac{2r}{\Omega} \cdot e^{-\frac{r^2}{\Omega}}$$

where Ω denotes the total power of the signal. The resulting distribution in dependence of the signal power Ω is displayed in Fig. 31. The area below the probability distribution is 1 in all cases. When the total signal power is high ($\Omega = 4$), the probability distribution is flat meaning that a broad variety of signal amplitudes is experienced at the receiver. With smaller total signal power (e.g., $\Omega = 0.5$), the probability of high signal amplitudes is very low, whereas small amplitudes are very common. Assuming a signal outage when the amplitude is below r_{crit} (and amplitudes in the positive range including 0), the probability for outages is calculated using the cumulative distribution function

$$p_{r \le r_{crit}} = \int_0^{r_{crit}} f_R(r,\Omega)\, df = 1 - e^{-\frac{r_{crit}^2}{\Omega}}$$

Resulting values for $p_{r \le 0.5}$ for different values of Ω are given in Table 2.

Every single antenna will experience such a distribution of signal levels, and thus, deep signal fades along a driving path through this kind of fading scenario. This can be seen in Fig. 32 which shows two recorded antenna signal levels relative to the LOS level in a Rayleigh fading scenario. The signals have been recorded during test drives in a real fading scenario in the USA.

DOI 10.1007/978-981-4560-75-7_101-1

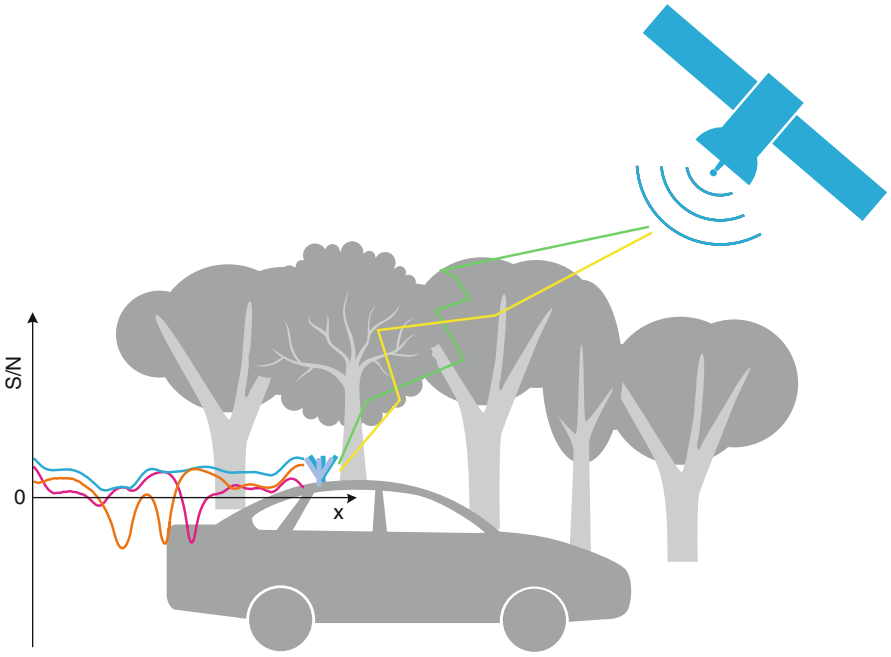

Fig. 30 Signal reception in multipath fading scenarios; *red* and *orange*: reception signals of two diversity antennas; *blue*: improved signal level with diversity

A possibility to avoid the deep fades and therefore increase the reception quality significantly is given by antenna diversity systems (Brennan 1959; Parsons et al. 1975). Assuming two antennas are completely uncorrelated and both show a mute probability of p_m, then the probability of a mute on both antennas simultaneously can be calculated as p_m^2. Therefore if each single antenna has a mute probability of 0.1, this means that two independent antennas have a mute probability of 0.01 and three antennas only have 0.001. Of course the reduction of the probability of mutes with an increasing number of antennas also increases the cost and mounting volume of the system so that a compromise has to be made.

The complexity of antenna diversity systems ranges from a lean switching diversity to the most complex form which is given by a maximum ratio combining diversity system. All systems have in common that their effectivity increases with antenna signals that are less correlated. This decorrelation can, for example, be ensured by a significant dislocation of the antennas' phase centers (Parsons et al. 1975). In practical applications it is much preferred to ensure decorrelated signals by using different polarizations, antenna patterns, or other means that do not necessitate in multiple mounting positions to be used.

Antenna Diversity Basic Concepts

Switching or scanning diversity simply avoids deep fades by switching between the available antenna signals (Barié et al. 2010; Lindenmeier et al. 2007; Lindenmeier 2007). A block diagram is depicted in Fig. 33. Switching is either initiated if the signal level of the currently selected antenna falls below a threshold or if another signal level is higher. In the case where always the best signal is selected, the diversity signal follows the highest of all input signal levels as it is depicted in Fig. 37.

Due to the phase modulation of the satellite radio signals and the decorrelation of the received antenna signals phase, differences occur between the antennas. Without further measures this would lead to bit errors and thus audio mutes after switching. In order to avoid these impairments, switching needs to be

4	6.1

synchronized to the phase reference symbols that are transmitted regularly (Barié et al. 2010). These are made to inform the receiver of the current absolute phase of the received signal thus allowing for the correct decoding of the transmitted information.

Overall, switching diversity can be realized in a quite lean diversity system, as it is shown in Fig. 33. Due to the frequency dependence of the transmission path, a channel-selective level detection circuitry is necessary. The signal does not need to be decoded in order to achieve this information; thus, a simple local

DOI 10.1007/978-981-4560-75-7_101-1

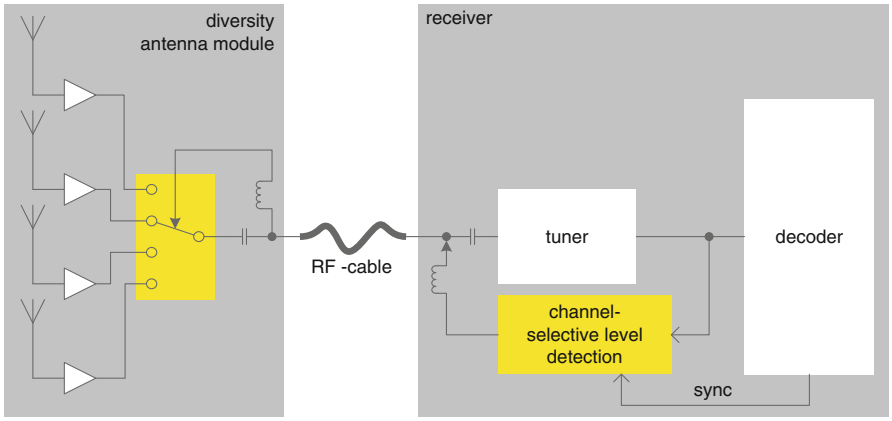

Fig. 33 Switching diversity system

oscillator suffices without the need of phase and frequency locking to the signal carrier. But due to the necessity of synchronizing the switching activity to the phase reference symbol, a cooperative receiver must deliver the respective timing information.

The ability of the diversity circuit to select another antenna if one of the antennas is in a deep fading leads to the prevention of the main adverse effect of Rayleigh fading. This is why without a phase alignment and superposition of antenna signals, the pure switching between the antenna signals and choosing the best antenna signal in each moment yield a considerable improvement in reception quality, as it has been shown in Lindenmeier et al. (2007), Lindenmeier (2007), and Barié et al. (2010).

Another diversity concept which is well known is phase diversity (or equal gain diversity), where there is no selection of antenna signals. Instead they are continuously superimposed after phase alignment. A block diagram is depicted in Fig. 34. Phase shifters in all antenna paths are needed to allow for the superposition of the signals. Also a channel-selective phase detection must be done for each path separately. Due to the complexity of this component, it is commonly situated in the receiver. Therefore separate RF cables and tuners are necessary for each antenna. Due to this restriction not more than two antennas have been usually considered for such a radio reception system. In cases where two input antenna signals have equal levels (in signal and noise, respectively), a phase diversity system allows for an improvement of the SNR of 3 dB. Lower improvements are achievable with signal levels differing stronger. A disadvantage of such a system is that the SNR of the combined signal can even be lower than that of the better input signal if the other signal has a very low signal level but a similar noise level (e.g., in a deep fade). This means that despite the very high effort to realize such a system, the improvement is statistically not better than the one of a switching diversity, which will be shown by example of signal levels depicted in Fig. 37.

A phase diversity system with maximum ratio combining phase-aligns the antenna signals before superimposing them. A (continuously valued) weighting factor is applied to each signal which is derived from its SNR. A block diagram is depicted in Fig. 35. By using phase alignment as well as signal weighting, negative contributions to the combined SNR by input signals with a low SNR are avoided. This allows for the highest possible SNR of the combined signal using the given input signals and explains the name of this system. Figure 37 shows signal levels of single antennas as well as of several diversity systems one of which is an MRC system. The signal levels of an (ideal) MRC diversity system are the highest to be achievable.

Nevertheless, the difference between the results of MRC and the other diversity systems is very low in critical moments of fading at an antenna. This means that the effect of improvement of reception quality is not much higher than the one of the other diversity concepts.

DOI 10.1007/978-981-4560-75-7_101-1

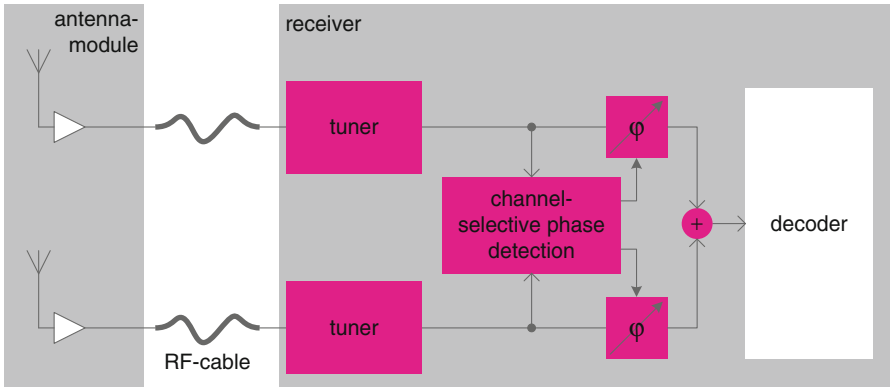

Fig. 34 Equal gain phase diversity system

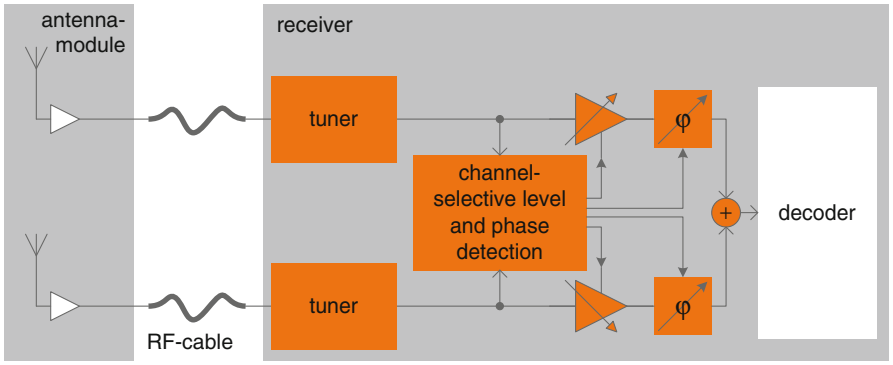

Fig. 35 Maximum ratio combining diversity system

On the other hand, a great disadvantage of this system is its very high complexity. Phase shifters as well as variable gain or attenuation stages are needed in every signal path. Also a complex SNR as well as phase measurement is needed for each signal independently. This leads to separate RF cables and tuners as well as an increased requirement in signal processing power in such systems.

A scan-phase diversity system combines the advantages of a simple switching diversity with the capabilities of a phase diversity (Lindenmeier et al. 2008; Barié 2008). This combination almost reaches the performance of an MRC diversity but with a much reduced hardware effort. The block diagram is given in Fig. 36. It shows the phase shifters and switches as well as the signal combining. In contrast to the MRC system, simple switches deactivate signals with a negative contribution to the SNR of the combined signal. Also phase shifters with discreet phase steps are sufficient due to the low order of the satellite signal's PSK modulation (usually QPSK is used) (Senega et al. 2010). Only a minor degradation of performance results from these steps that on the other hand significantly decrease the overall system complexity. The selection of antenna signals and the calculation of phase differences can be based on signal levels to further reduce the complexity of the detection circuitry by avoiding SNR and phase measurements.

The overall complexity is low enough to allow for the implementation of the complete system in the antenna module itself (Senega and Lindenmeier 2012). Only a single RF cable connects the antenna diversity module to the receiver. The diversity circuit is run independently of the receiver, requiring no further cooperation. Hence, regarding the interface to an SDARS receiver, it behaves like a single standard antenna. Therefore any receiver can be connected to such an antenna system without adaptation in order to improve the reception quality significantly compared to a single antenna.

DOI 10.1007/978-981-4560-75-7_101-1

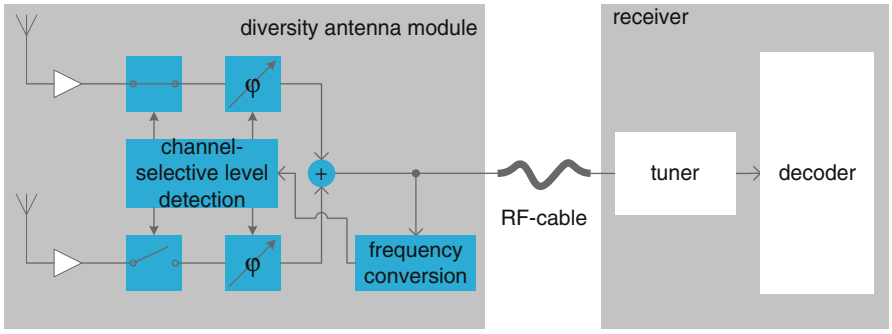

Fig. 36 Scan-phase diversity system

Signal levels of two single antennas as well as of a scan-phase diversity system are depicted in Fig. 37. The signal levels achieved with the scan-phase diversity system are approximately of the same values like those of an MRC diversity system with a very little average deviation of less than 0.4 dB.

Comparison of Diversity Systems

The antenna diversity systems described above show significant differences in their complexity. Table 3 gives a short summary of some of the most important and complex subcircuits which are needed in the different antenna diversity systems.

Regarding the improvements of signal reception which are possible using the presented diversity systems, Fig. 37 shows a short level history of recorded antenna signals as well as of simulated signal levels of the diversity systems. All of them avoid most of the deep signal fades because they use more than one antenna. Only in cases where all antennas experience a deep signal fade at the same time a deep fade in the diversity signal occurs.

Scanning diversity always shows the signal level of the best single antenna. Deep fades are avoided unless all input antenna signals fade at the same time (a total signal blockage). Due to phase differences of the uncorrelated antenna signals, a synchronization to the transmitted reference phase is mandatory in such a system which necessitates in a modified SDARS receiver. In contrast to a scanning diversity system, equal gain diversity can improve the signal level up to 3 dB above that of the two input signals if they show similar levels (e.g., around sample 10,150 in Fig. 37). But due to the lack of signal weighting, the SNR is lower than that of the best input signal in cases where one signal level is much lower than the other. In these cases an equal gain diversity shows worse output SNR than even a simple switching diversity system (e.g., around sample 10,125 in Fig. 37).

An ideal MRC system of course shows the highest improvement of all diversity systems – as it can be seen in Fig. 37 – due to its ability to weight the antenna signals before their phase-aligned combination. But although the hardware complexity of an MRC diversity is much higher, the improved signal quality of the scan-phase diversity system is comparable to that of an MRC diversity system. An analysis of recorded signal levels with calculated ideal diversity systems shows only a small deviation of less than 0.4 dB in average between the MRC system and a scan-phase diversity system (Lindenmeier et al. 2013).

While the results shown in Fig. 37 are true for the simulated diversity systems in reality, the described systems react to changing signal conditions on very different time scales. While switching and scan-phase diversity provide almost immediate responses to deep fades, the phase and SNR estimation invoked in equal gain and MRC diversity usually take much longer and therefore impede fast reaction times. This becomes increasingly problematic when higher driving speeds are considered. Investigations on switching speed and the resulting diversity efficiency show the importance of fast reaction times (Barié et al. 2010). Figure 38 shows the degradation of the effective number of antennas for switching time

periods in the range of 137 μs to 2.2 ms. Up to a time period of 275 μs, almost constant numbers of effective antennas are achieved, while for 2.2 ms the diversity system shows no improvement of reception quality at all. This investigation was done for a speed of 104.6 km/h (65 mph) so that a distance of λ at SDARS frequencies is covered in 4.4 ms. Therefore reaction times equivalent to distances of less than λ/8 at the highest driving speed considered are necessary to ensure sufficient efficiency of diversity reception systems.

The necessity of fast reaction times to changing signal conditions is obvious from the signal level history depicted in Fig. 37 as well as by the effective number of antennas depicted in Fig. 38. A logical consequence of this fact is that slow beam steering of an antenna combination will not yield noteworthy improvements of signal levels in a fading scenario. The maximum gain which is possible by such a measure of course is 3 dB. While this might seem like a huge improvement at first glance, the fast-changing phases of the individual signals in such a scenario prohibit the combination of the antennas with slow reaction times so that the combined antenna will itself behave like a single antenna and experience deep signal fades which by far are much worse than the 3 dB gained by combination.

In contrast to a slow combination, the fast selection and superposition of antenna signals that is done in a scan-phase diversity system will significantly increase the SNR of the combined signal even in fading scenarios. While this gain in SNR could be seen as a bonus that improves the audio availability, another possibility is that such a gain could be considered in the system design because it is equivalent to an increased link margin of the transmission path. This increased link margin allows for the reduction of other error-correcting redundancies in the signal so that more information could be transmitted instead. Users would then benefit in the form of additional audio channels or higher audio quality.

Satellite Antenna Structures for Diversity

In the following concepts for compact antenna, diversity structures are considered, in which the RF signal processing units and antennas structures are integrated together in a common mounting volume at one single position at the vehicle. Particular attention has to be paid to the decorrelation of the antenna signals. In the following examples for antenna, diversity structures are shown, which are advantageous for a phased superposition of their antenna signals with an optimized signal to noise ratio in order to increase the reception quality significantly in comparison to a common single antenna.

New fabrication technologies enable the integration of three antenna structures in one part in a mounting volume of $29 \times 29 \times 17$ mm^3 as shown in Fig. 39. The three antennas which are printed onto a common carrier consist of a horizontal loop antenna type together with a circular polarized homogenous field loop antenna and a vertically polarized monopole structure which yield radiation patterns being orthogonal to each other.

Such a set of three antennas being also presented in Müller et al. (2010a) provides three highly decorrelated reception signals for the diversity processor. After phase alignment of the antenna signals and superposition, a combined radiation pattern of the three antenna array (blue line) can be seen in Fig. 40 in comparison to the gain of a standard patch antenna (dashed black line). It shows that in LOS situations the three antennas together yield a gain which is overall around 2–3 dB higher than the one of a common patch antenna.

In a Rayleigh fading scenario, this additional gain would not help to increase the SNR if the main beam direction of the common antenna pattern would be only directed toward the satellite. Together with the diversity circuits shown above, the alternative antenna signals are combined in a way that even in a deep fading scenario – which is most critical for reception quality – the fading can be prevented. This is only possible if the antenna signals are strongly decorrelated, so that fading effects would not occur at the same time at all the alternative antennas of the diversity set. The radiation patterns of the different antennas show a sufficient orthogonality to each other, and hence, the antennas are decoupled from each other by values of more than 25 dB.

Similar values have been achieved with an antenna diversity structure as it is presented in Müller et al. (2010b) requiring a mounting volume of only $29 \times 29 \times 11$ mm^3 and consisting of a circular polarized homogenous field loop antenna together with a patch antenna. In Fig. 41 this antenna set is

shown in a mounting position on the dashboard of a car. Figure 42 shows the measured radiation pattern of the combined diversity antennas in LOS conditions, which occurs depending on the phase constellation between the two antennas. The blue line shows the main lobe which can be steered onto any angle in azimuth via the phase distance between the two diversity antennas.

Measurements of Scan-Phase Diversity in Fading Scenarios

Test drives have been done in Rayleigh fading scenarios in the USA in order to assess the functionality of the scan-phase diversity system. For these test drives a hardware demonstrator was created and connected to a multitude of different antenna diversity sets located in various mounting positions. Also the reception of HEO and GEO satellites has been evaluated separately in order to show that both can benefit from such a diversity reception system. Pictures of two of the demonstrators used in these measurements are shown in Fig. 43.

Measurement results using a diversity antenna set to receive GEO satellite signals on the rooftop of a car show that the scan-phase diversity system with two antennas significantly improves the availability of the audio signal compared to a single standard patch antenna. Recorded audio levels of a typical result are depicted in Fig. 44. During a test time of 430 s, the mute time of 67.1 s with the single antenna is reduced to only 5.1 s using the scan-phase diversity system. Longer test drives over a duration of 15 min even show mute times as low as 10.9 s resulting in an availability of 99.1 % (Senega and Lindenmeier 2011).

DOI 10.1007/978-981-4560-75-7_101-1

Fig. 41 Diversity antenna function demonstrator in a mounting volume of 29 × 29 × 11 mm^3 on dashboard of a test car

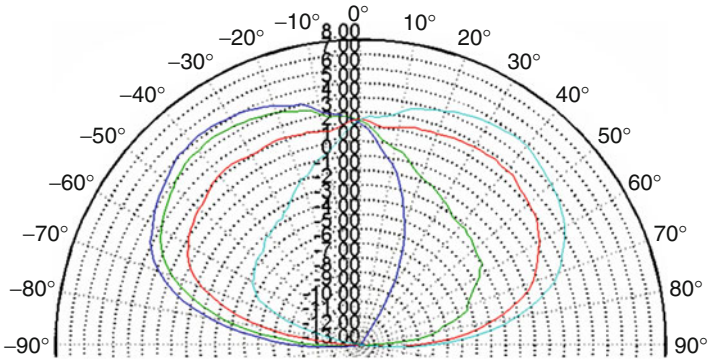

Fig. 42 Measured radiation pattern of combined diversity antennas; *blue line*: main lobe which can be steered onto any angle in azimuth via the phase distance between the two diversity antennas

Measurements of a single HEO satellite show an improvement of availability from 86.8 % with a single antenna to 97.8 % with diversity (Senega et al. 2009).

Apart from the significant improvement of audio availability when rooftop mounting is considered, diversity allows for the consideration of mounting positions that would be unthinkable of using a single antenna. A typical application of such mounting positions would be in convertibles (where rooftop mounting is impossible) or cars where the rooftop mounting space is otherwise restricted or unavailable. Test drives with a diversity set mounted on the dashboard of a car (see Fig. 41) show that diversity can even outperform a rooftop mounted single antenna. The availability is improved from 84 % with the single antenna to 86 % although the reference antenna was placed on the metallic roof of the same test car (Senega and Lindenmeier 2012).

Even mounting the antenna set in a single automotive side mirror has been investigated showing again even better results than a rooftop mounted reference antenna in the reception of a GEO satellite. The test drives have been conducted on a straight road in both directions east to west and west to east so that also in this test drive, the shadowing of the satellite by the car itself has been considered. The availability is improved from 96.7 % with the single antenna to 98.7 % with the diversity system (Senega et al. 2014).

Conclusion

Together with classical antenna concepts, new antenna types for reception of signals of HEO, MEO, and GEO satellite systems have been explained which yield high efficiency, low mounting volume, tailored radiation patterns, and easy manufacturing to meet the special requirements for satellite signal reception in a vehicle. Especially, loop antennas like the Scarabeus antenna yield an easy combination with terrestrial antennas in close proximity, which can be set into its phase center. For satellite digital radio services, where gain requirements are relatively high, diversity concepts have been shown which help to improve the reception quality in critical reception scenarios considerably. This is especially achieved with a concept of a scan-phase diversity which can be realized easily and which has got a simple interface to the radio which is equivalent to one of a common single antenna. Within a similar mounting volume as it is already used for single satellite reception antennas and its amplifiers, the complete diversity system can be integrated, consisting of up to three antennas and the diversity circuit. The use of diversity systems also enables the use of inferior mounting positions in the car, where no single antenna could achieve the required reception quality.

Smart Antennas for Satellite Communications

Qi Luo* and Steven Gao
School of Engineering and Digital Arts, University of Kent, Canterbury, UK

Abstract

Smart antennas are important for satellite communications because they can increase the channel capacity, spectrum efficiency, and coverage range of the communication systems. This chapter reviews the technology for smart array antenna design with examples. Applications of smart antennas for satellite ground stations and direct broadcast satellite systems are also presented in this chapter. A detailed list of references is given in the end of this chapter.

Keywords

Smart antenna; Satellite communication; Array antenna; Beam forming

Introduction

Smart antennas are antenna arrays incorporated with active microwave circuits, a beam-forming network and signal process units. Beam forming can be performed by controlling the complex weight of each array element or each subarray. If the direction of arrival (DOA) algorithm is used, the beam of the smart antenna can be adaptively adjusted by calculating the beam-forming vectors to form a beam in the desired direction and form nulls at any undesired directions; thus, the interference levels are reduced, and the system capacity is improved. In some literatures, smart antennas are also mentioned as adaptive array antennas or intelligent antennas (Bachman 1996; Chryssomallis 2000).

High data rate and seamless coverage have become the trend of the nowadays wireless communications. With the increasing number of wireless users, to maximize the system efficiency and avoid the co-channel interferences, smart antennas are used to replace the conventional antenna systems. With a smart antenna, a communication system can have better signal-to-noise ratio and cover much larger area than the system using a conventional array, especially in high-interference environments (Chryssomallis 2000). In addition, smart antennas can increase the overall capacity in a mobile communication network. Meanwhile, for satellite communications (SatCom), where conventional reflector antennas are deployed for the ground stations, there is also a trend to employ smart antennas. One smart antenna can be used to communicate with several satellites almost simultaneously instead of having several reflector antennas which are usually bulky and can only track the satellites through mechanical steering.

Depending on how the beams of the smart antennas are steered, generally speaking, the smart antennas can be categorized as beam-switching smart antenna and adaptive beam-steering smart antenna. If the complex weights of the array element are predefined and the antenna system has limited number of fixed beam patterns, the smart antenna is called beam-switching smart antenna. On the another hand, if the complex weight of each array element can be adjusted adaptively and the shaped beam of the smart antenna can be steered continuously within certain angular range, then such a system is called adaptive

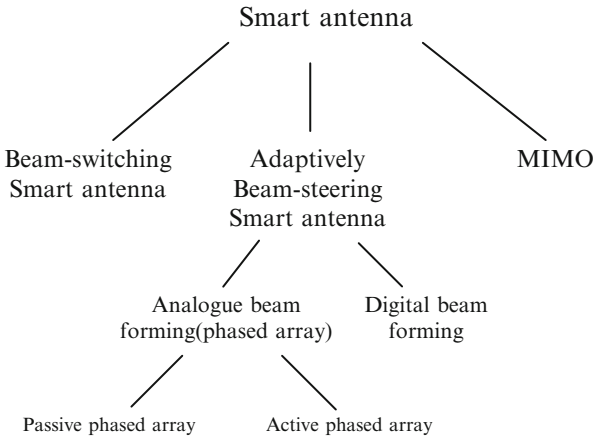

Fig. 1 Classification of smart antennas

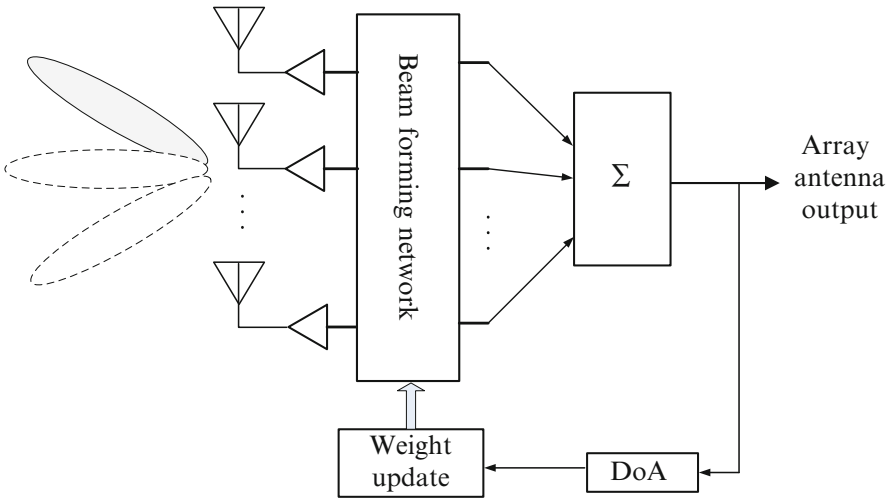

Fig. 2 The generic architecture of a smart antenna

beam-steering smart antenna. For both types of smart antenna, either analogue beam forming or digital beam forming can be employed. Multiple-input and multiple-output (MIMO) antenna is also a form of smart antenna. It utilizes the space diversity to achieve increased data throughput, and there is no dedicated beam forming required for such system. Figure 1 shows a classification for smart antennas. As can be seen, adaptive beam-steering smart antennas with analogue beam forming can be divided into passive phased arrays and active phased arrays. The active phased array refers to the antenna array that each of the radiating elements has its own transmit/receive (T/R) module and the active circuitry is integrated with the passive antenna element (Jenshan and Itoh 1994). In this chapter, only the beam-switching and beam-steering smart antenna will be discussed. For readers who are interested in MIMO antennas, they can refer to Kalis et al. (2014) for more details.

Key Parameters of a Smart Antenna

Figure 2 shows a general structure of a smart antenna. A smart antenna usually consists of an antenna array with a beam-forming network formed by microwave circuitry. Applying advanced signal processing

DOI 10.1007/978-981-4560-75-7_103-1

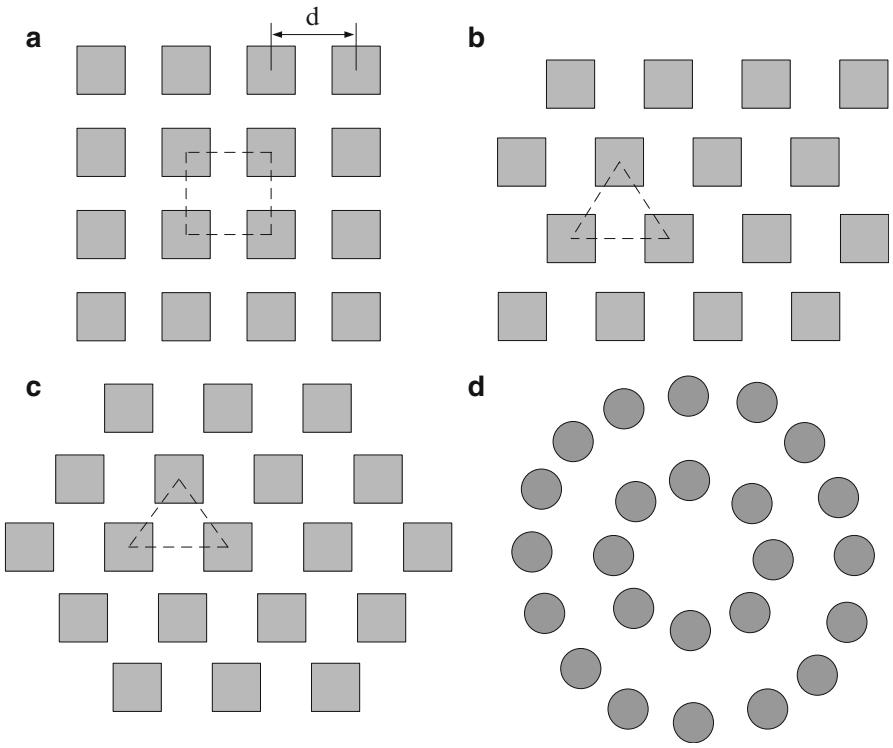

Fig. 3 Three typical topologies of the planar array antenna: (**a**) rectangular lattice, (**b**) triangular lattice, (**c**) hexagonal lattice (**c**) concentric circular array

algorithms to the digital baseband signals of all single antenna elements of the array, the radiation pattern of an array can be shaped even in real time.

The array antenna is a critical component for the smart antenna. It determines the beam-steering performance (e.g., largest beam-scanning angle), directivity, and radiation efficiency of the antenna system. The beam-forming network and the microwave circuit determine the beam-steering or beam-switching capability of the phased array antenna. Therefore, the key parameters of the smart antenna can be described from two aspects: the array antenna and the microwave circuit. Since this chapter is more focused on the designing of antennas and it is not feasible to cover the parameters of circuitry design, so the parameters presented below are only related to the performance of the array antenna.

The antenna array can be either a linear or planar array, depending on the requirements of the specific applications. In general, planar array is preferred for the design of smart antennas so it can benefit from the advanced beam-forming network and signal processing algorithm. Figure 3 shows four typical topologies of the planar array antenna.

The radiation pattern of an array antenna can be expressed as the product of the array factor (AF) times the radiation pattern of a single radiating element:

$$E_{\text{total}} = E_{\text{single\_antenna}} \times AF \tag{1}$$

where E_{total} represents the total electrical field of the array and $E_{\text{single\_antenna}}$ is the electrical field of a single array element. For a two-dimensional planar array with M elements placed in the X-direction and N elements placed on the Y-direction, the array factor can be expressed as (Balanis 2005):

$$AF = S_{xm} \times S_{yn} \tag{2}$$

DOI 10.1007/978-981-4560-75-7_103-1

where:

$$S_{xm} = \sum_{n=1}^{M} I_{m1} e^{j(m-1)(kd_x \sin\theta \cos\varphi + \beta_x)} \tag{3}$$

$$S_{yn} = \sum_{n=1}^{N} I_{1n} e^{j(n-1)\left(kd_y \sin\theta \cos\varphi + \beta_y\right)} \tag{4}$$

The β is the progressive phase in X- or Y-direction, and the (Θ, φ) present the angle of the beam in the elevation and azimuth planes, respectively. k is the propagation constant, and I is the excitation coefficient of each element. To avoid the grating lobes, with a rectangular lattice planar array, the space (d) between the array elements is required to be:

$$d \leq \frac{\lambda_0}{1 + \sin\theta_{\text{Max}}} \tag{5}$$

where θ_{Max} is the maximum scan angle of the array and λ_0 is the free space wavelength at the frequency of interest. When hexagonal or triangular lattice is employed, with the same requirement for grating lobe free scan angle range, the distance d can be larger, and the number of radiating element can be reduced by about 15 % (Hansen 2009).

The directivity (D) of the array antenna is decided by the number of radiating elements when the distance between each array element is fixed (Mailloux 2005):

$$D = \frac{4\pi A}{\lambda^2} \varepsilon_A \cos\theta \tag{6}$$

where A is the size of the radiating aperture, and ε_A is the aperture efficiency of the array. If the beam has a symmetrical pattern in both E- and H-planes, the 3-dB beamwidth of the array antenna in radian with uniform illumination taper can be estimated by (Mailloux 2005):

$$\theta_{3dB} = \sqrt{4\pi 0.866^2 / D} \tag{7}$$

The beam angle of the array antenna is determined by the complex weight on each array elements, which is controlled by the vector modulator when analogue beam forming is used. The vector modulator can perform the phase shifting and control the amplitude of the RF signal through variable attenuators. In case of digital beam forming, there is a digital to analogue converter for each radiating element, and there is no need of using any phase shifters.

It is desirable to have continuous phase control over 360° and continuous amplitude control. Figure 4 shows the amplitude and phase response of an ideal vector modulator.

However, practically the phase can only be provided discretely, and the phase quantization errors are related to the bits of phase shifters. For example, with a 6-bit phase shifter, 64 sets of phase can be provided with 5.625° level differences. Moreover, random phase and amplitude errors also exist. With the phase and amplitude errors, there will be pointing error, increased sidelobe level, and directivity decrease. When phase and amplitude errors are present, the directivity of a smart antenna and the variance of beam pointing deviation can be estimated by (Mailloux 2005):

DOI 10.1007/978-981-4560-75-7_103-1

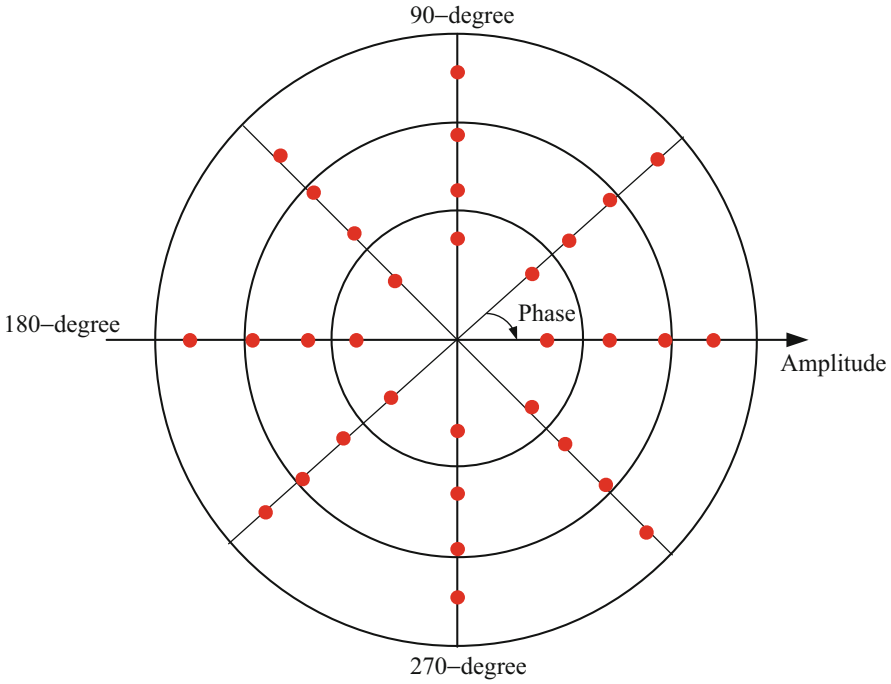

Fig. 4 The amplitude and phase response diagram of an idea vector modulator

$$\frac{D}{D_0} = \frac{P}{1 + \overline{\delta}^2 + \overline{\Phi}^2} \tag{8}$$

$$\overline{\Delta}^2 = \overline{\Phi}^2 \frac{\sum I_i{}^2 x_i{}^2}{\left(\sum I_i x_i^2\right)^2} \tag{9}$$

where D is the directivity of the array with errors, D_0 is the directivity of the array without any phase/amplitude errors, Φ is the phase error, δ is the amplitude error, $\overline{\Delta}^2$ is the variance of beam pointing deviation, I_i is the amplitude of ith element excitation, and x_i is the element position divided by element spacing d. Due to the existence of these errors, a smart antenna with analogue beam forming is required to perform calibrations before it is equipped on the communication system.

Review on the Smart Antenna Design

Beam-Switching Smart Antennas

Beam-switching smart antennas form a limited number of fixed beams in predefined directions. Different beams can be switched by employing a multi-port beam-switching network or introducing RF switches on the feed network. The multi-port beam-switching network can be realized by using the Butler matrix, which can be designed by cascading several branch couplers with RF crossover structure. Many beam-switching antenna arrays using the Butler matrix as the feed network have been reported, including the design of one-dimensional array with either linearly polarization (LP) (Han et al. 2012) or circularly polarization (CP) (Chao-Hsiung et al. 2008; Elhefnawy and Ismail 2009; Changrong et al. 2011). In Elhefnawy and Ismail (2009), a planar microstrip antenna array with a Butler matrix is designed to operate

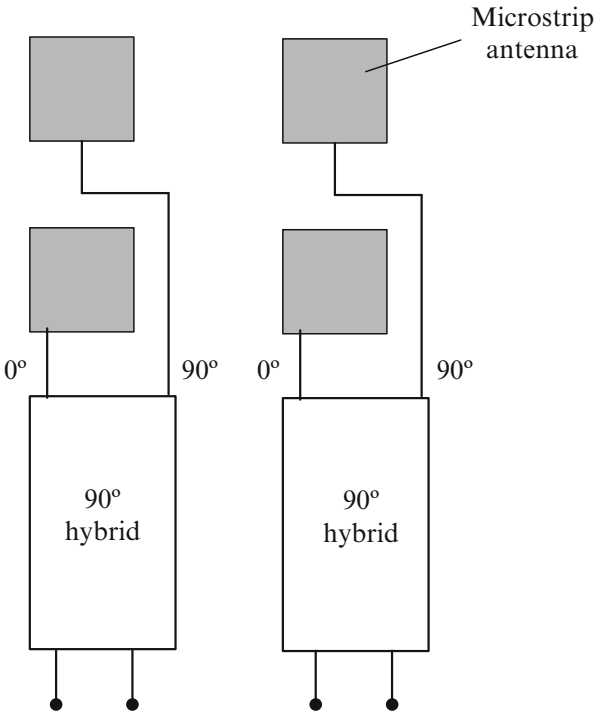

Fig. 5 Demonstration of using 90° hybrid to feed the array element in the same column as presented in Moulder et al. (2010)

at 2.4 GHz for indoor wireless dynamic environments. The CP radiation is achieved by employing one microstrip antenna array consists of four sequentially rotated inset-fed rectangular patch antennas.

A 60-GHz beam-switching smart antenna receiver subsystem based on substrate integrated wave (SIW) guide technology is presented in Fan Fan et al. (2012). Conventional 4 × 4 Butler matrix was used, and SIW bends were used to provide required phase delays. In this design, there is a high-density integration of front-end components into one single substrate, including the 4 × 4 slot array antenna, Butler matrix, band-pass filter, mixer, and local oscillator (LO). It is shown in Fan Fan et al. (2012) that four beams can be realized with the largest scan angle to 45°. Another integrated solution is presented in Patterson et al. (2012), where a 60-GHz active receiving switched-beam antenna array with integrated Butler matrix and gallium arsenide (GaAs) low-noise amplifiers is demonstrated. In this design, the beam of a 4 × 1 active array is controlled by GaAs single-pole-double-throw (SPDT) switches that incorporate with the Butler matrix. The antenna array consists of four quasi-Yagi dipole and can scan the beam up to 40°. The active receiving switched-beam array is printed on the liquid crystal polymer (LCP) substrate, and the measured results show that peak active gain of 27.5 dB is achieved.

While most of these designs can only switch the beam in one plane, a modified planar beam-switching network based on Butler matrix is presented in Moulder et al. (2010). This beam-switching array antenna is designed for 60-GHz short-range communication and is able to switch the beam two-dimensionally. The beam-switching array is comprised of a 2 × 4 planar array and a feeding network that includes two 4 × 4 Butler matrices and four hybrid couplers. Each of the hybrid couplers provides 90° phase shift between its two outputs which feeds the two antennas at the same column, as shown in Fig. 5. With this feed network, eight directional beams in the upper hemisphere can be obtained.

A hybrid solution, which introduces adaptive control in the beam-switching network, is developed in Chia-Chan et al. (2010), where an 8-way Butler matrix was used to feed a 1 × 8 printed patch array. The feeding network is realized by striplines, and the overall system has a multilayered structure. Different from the conventional design, phase shifters were introduced in the feed network, as demonstrated in

DOI 10.1007/978-981-4560-75-7_103-1

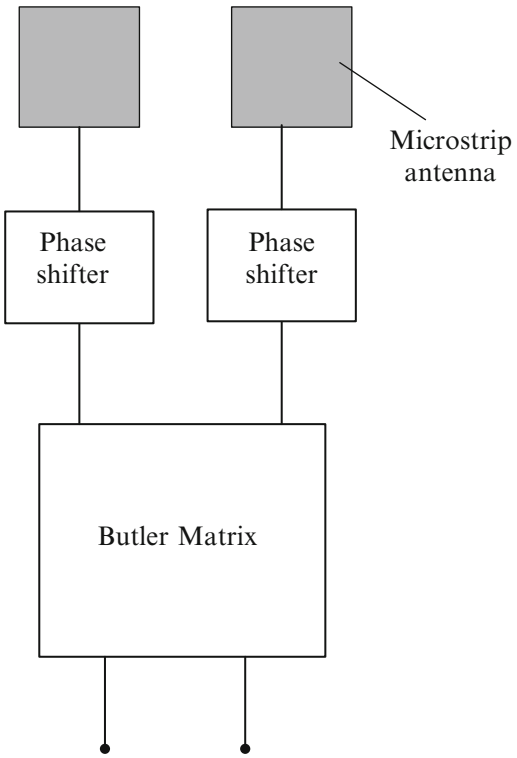

Fig. 6 Demonstration of introducing phase shifter in the Butler matrix as proposed in Chia-Chan et al. (2010)

Fig. 6. The beam of the array is initially switched to a certain direction through choosing the corresponding port of the Butler matrix, and then it can be slightly adjusted by controlling the phase shifters. Thus, the focused beam can be steered to cover more scan angles.

Recent progresses in the beam-switching smart antenna design with RF switches include employing RF PIN switches or RF MEMS switches on the feed network to provide a limited number of fixed beams up to 40° (Bayraktar et al. 2007; Jun 2011). However, this usually leads to a complicated feed network as the result of introducing additional DC biasing network, which limits its application in compact design especially when the number of radiating element is large.

Adaptive Beam-Steering Smart Antennas

The main disadvantage for the beam-switching smart antenna is that it can only provide limited number of fixed beams. Instead, the adaptive beam-steering antennas are able to continuously steer the beam to the desired directions and shape the beam to maximize the link budget with sophisticated signal processing algorithms. In order to adaptively shape the beam, an adaptive beam-forming network is required, which can be either an analogue beam forming (ABF) or digital beam forming (DBF). The ABF requires employing a large number of phase shifters and attenuators to provide complex weights to the array elements. The summed signals need to be down convert to baseband signal and then pass to the analogue/digital (A/D) converter before sending to the signal processing unit. Most of the beam-switching smart arrays steer the beam by controlling the input phase of the array elements only, and they belong to analogue beam forming. Instead of using large amount of microwave phase shifters, which are expensive and lossy, DBF uses A/D converter and digital down converter (DDC) on each array element, and then the beam forming can be realized digitally. However, DBF requires a large amount of A/D converters, which have high power consumptions and need real-time signal processing. To realize the adaptive beam forming, there are several well-defined algorithms available such as the least mean square (LMS)

DOI 10.1007/978-981-4560-75-7_103-1

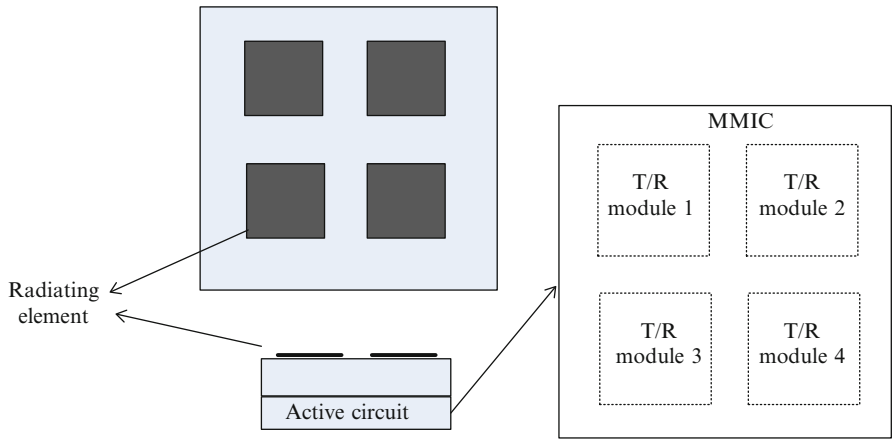

Fig. 7 Demonstration of using one MMIC integrated with four T/R modules to control four antenna elements as presented in Chaloun et al. (2014)

algorithm, the recursive least squares (RLS) algorithm, and the constant modulus (CM) algorithm. Reader can refer to Balanis and Ioannides (2007) for more details on these algorithms.

For mobile satellite applications, the smart antenna is required to scan the beam within large angle range with high efficiency. For such systems, one of the key components is an array antenna with large beam-scanning angles. Designing antenna arrays with large scan angles is challenging and has been attracted much research interest in recent year. Recent progresses in this field include using slot antenna (Zhang et al. 2012), patch (Zhou et al.), and stacked patch (Chaloun et al. 2014) as the array element, and the wide scan angle range is achieved by suppressing the surface waves and reducing the mutual coupling between adjacent elements. One state-of-the-art design in the field of smart antennas using ABF is reported in Chaloun et al. (2014), where a highly integrated Ka-band transmit/receive reflectarray (Pilz and Menzel 1998) with wide scan angle is presented. The reflectarray has 108 antenna elements, and the array can scan its beam to $\pm 60^{\circ}$ in the upper hemisphere. Plated through holes were introduced to suppress the surface waves and thus reduce the mutual coupling between adjacent elements. Because of the small size of the array element, which is 5 mm $\times$ 5 mm ($0.5\lambda_{30GHz} \times 0.5\lambda_{30GHz}$), four T/R modules are integrated on one Monolithic Microwave Integrated Circuit (MMIC), as shown in Fig. 7.

Recent development in the smart antennas with DBF includes electronically steerable receive and transmit antennas for satellite communications at Ka-band reported in Stark et al. (2009). In this work, the smart antenna is a highly integrated antenna with 15-layer low-temperature co-fired ceramic (LTCC) tiles and combines the antenna elements, the calibration network, the RF circuitry, and the cooling system. The architecture of this DBF smart antenna is shown in Fig. 8.

Since smart antenna is a complicated system especially for the adaptively beam-steering smart antenna, it is impossible to cover all the details for the design of each component including the RF circuit design in this chapter. Instead, this chapter will focus more on the design of the array antenna and its corresponding feed network. For the design of the RF circuits, readers can refer to Li (2012) for more details. This chapter is organized as follows. In section "Smart Antenna Design," the design techniques of array antennas for beam-switching and adaptive beam-steering smart antenna are demonstrated with examples. Then, in section "Application of Smart Antennas in SatCom," the applications of smart antennas in the field of satellite ground station and mobile direct broadcasting satellite systems are presented.

Smart Antenna Design

As introduced in section "Introduction," smart antennas can be categorized into two main types: beam-switching smart antennas and adaptive beam-steering smart antennas. A beam-switching smart antenna has a beam-forming network that provides fixed phase shift to form shaped beams in predefined directions. After introducing either the RF switches or using couplers with multiple ports, the beam can be switched discretely. This leads to a low-cost solution because there is no need of using any phase shifters and amplitude attenuators. Due to the complexity of the feed network, most of the beam-switching smart antennas are only able to switch the beam in one direction.

In contrast to the beam-switching smart antenna, the adaptive beam-steering smart antenna is able to continuously steer the beam to the desired directions and shape the beam to maximize the link budget with sophisticated signal processing algorithms. The accurate control of the input phase and amplitude to each radiating elements increases the system complexity; thus, adaptive smart antennas exhibit higher cost.

Beam-Switching Smart Antenna

Beam-switching smart antennas provide a low-cost and low power consumption solution if the continuous beam steering is not required. It does not need to employ any phase shifters, and in most cases analogue beam forming is used. A beam-switching smart antenna has a beam-forming network that provides a set of fixed phase shifts to the array elements, and shaped beams in predefined directions can be formed. Thus, the beam-forming network is the most critical component of the beam-switching smart antenna.

Theory

Figure 9 shows the generic architecture of a beam-switching array. To realize a beam-switching feed network, multiple ports are usually employed, and the beams can be switched by selecting the corresponding RF port.

One technique for realizing such a beam-forming feed network is to introduce RF switches on the feed network. Figure 10 shows one example of introducing RF switches on the feed network of a one-dimensional microstrip patch transmitting array with four radiating elements.

As can be seen from Figure 10, two RF switches are mounted on the input of the microstrip feed lines, and by controlling the states of the RF switches, the patches can be fed by RF signals with two different phase delays. This is equivalent to a two-port beam-forming feed network. Introducing more RF switches increases the number of different phase delays for each radiating element, and then more radiation patterns can be obtained. One of the most common and cost-effective RF switches is the RF PIN diode. RF PIN

DOI 10.1007/978-981-4560-75-7_103-1

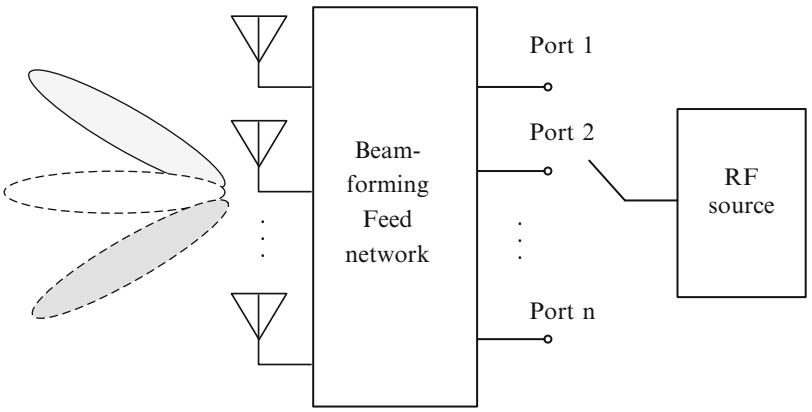

Fig. 9 The generic architecture of a beam-switching smart antenna

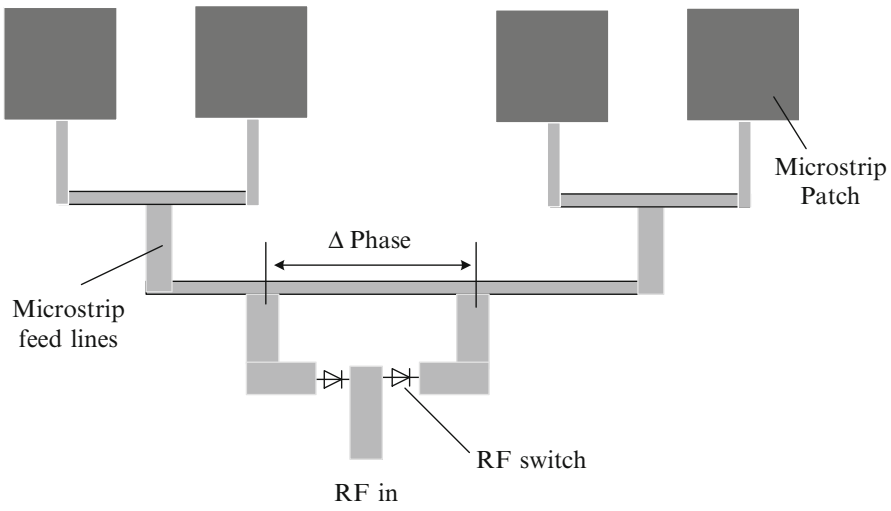

Fig. 10 Example of introducing RF switches on the feed network of an array antenna

diodes exhibit fast switching time with reasonable insertion loss and isolation. A RF MEMS (microelectromechanical system) exhibits a better performance with respect to low insertion loss and high operation frequency (e.g., millimeter wave frequencies) but with higher fabrication cost and assembly complexity.

A biasing circuit is required in the feed network in order to control the ON and OFF states of the RF switches. The biasing circuit must ensure that there is a high RF/DC isolation at both the RF port and the DC power source, while there is low insertion loss and impedance mismatch caused by the lumped elements introduced. Figure 11 presents a circuit model of the biasing circuit for an antenna application. The capacitor is employed to block the DC power, while the inductor is used to block the RF signals (RF chock). For printed microstrip antenna design, the DC bias line can be realized by microstrip lines of narrow width, which exhibits high impedance at RF frequencies. To ensure proper impedance matching, the capacitor needs to have a small reactance at the lowest microwave frequency of interest, and its self-resonant frequency must be much higher than the highest frequency of interest (AVX Corporation). A microstrip line of a quarter wavelength and radial stubs can be used to improve the impedance matching of the feed network.

Another well-known approach to design a beam-switching feed network is to use a Butler matrix (Butler and Lowe 1961). The Butler matrix has N input ports and N output ports, where:

DOI 10.1007/978-981-4560-75-7_103-1

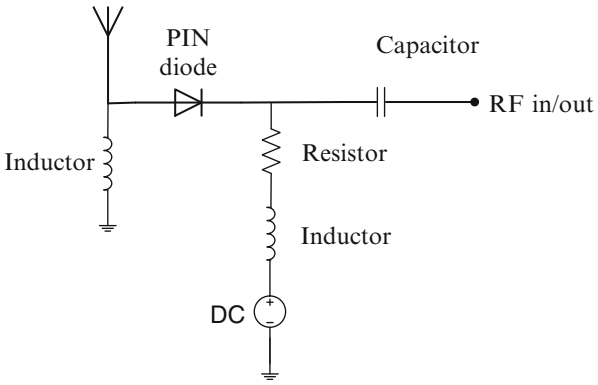

Fig. 11 A circuit model of the biasing circuit for RF switches in antenna application

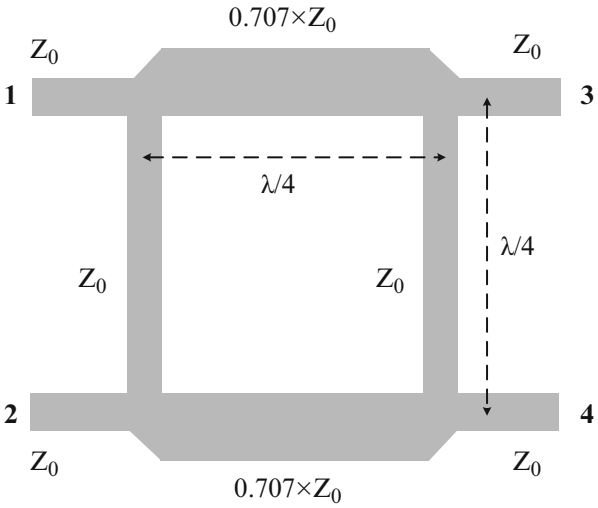

Fig. 12 A four-port branch-line couplers

$$N = 4n, \quad n = 1, 2, 3, \ldots$$

Figure 12 shows the layout of a four-port Butler matrix realized by the branch-line coupler. As shown in Figure 12, each transmission line is a quarter wavelength long at the frequency of interest, and the horizontal microstrip lines have impedance of $0.707 \times Z_0$.

With a four-port Butler matrix, the scattering matrix can be expressed as:

$$\begin{bmatrix} Output\ 1 \\ Output\ 2 \\ Output\ 3 \\ Output\ 4 \end{bmatrix} = B \times \begin{bmatrix} Input\ 1 \\ Input\ 2 \\ Input\ 3 \\ Input\ 4 \end{bmatrix} \tag{10}$$

where

DOI 10.1007/978-981-4560-75-7_103-1

$$B = \frac{1}{\sqrt{2}} \times \begin{bmatrix} 0 & 0 & 1 & -j \\ 0 & 0 & -j & 1 \\ 1 & -j & 0 & 0 \\ -j & 1 & 0 & 0 \end{bmatrix} \tag{11}$$

Assuming the port 1 (as indicated in Figure 12) is the input port with voltage of V_{in}, which means:

$$\begin{bmatrix} Input\ 1 \\ Input\ 2 \\ Input\ 3 \\ Input\ 4 \end{bmatrix} = \begin{bmatrix} Vin \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{12}$$

Solving the above equations, it can be derived that:

$$Output\ 1 = 0$$

$$Output\ 2 = 0$$

$$Output\ 3 = \frac{Vin}{\sqrt{2}} \times \exp(\varphi)$$

$$Output\ 4 = \frac{Vin}{\sqrt{2}} \times \exp\left(\varphi - \frac{\pi}{2}\right) \tag{13}$$

This means that 90° phase difference is obtained at the ports 3 and 4, and port 2 is isolated. By changing the input port from port 1 to port 2, the output phase of the ports 3 and 4 is swapped.

Design Examples

Figure 13 shows the schematic diagram of using branch-line couplers and power dividers to form a feeding network for a beam-switching array. As presented in Figure 12, the branch-line coupler can split the input RF signal with equal amplitude and 90° phase difference. Then, microstrip power dividers can be introduced to the output ports of the branch-line couplers. Microstrip lines of varied length can be used at the outputs of the power dividers to introduce the true time delays and thus control the input phases for each radiating elements.

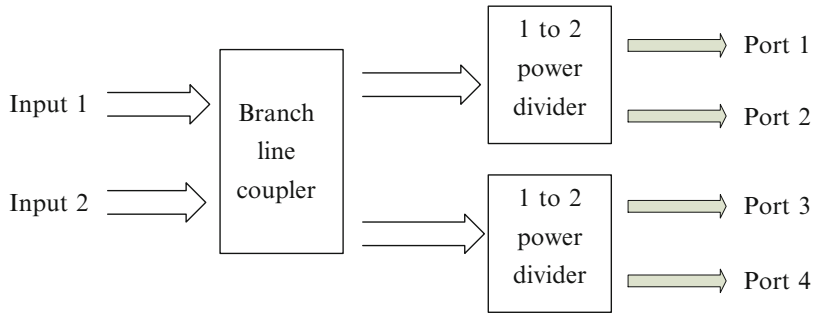

Fig. 13 The schematic diagram of using branch-line couplers and power dividers to design a feed network for a beam-switching array

DOI 10.1007/978-981-4560-75-7_103-1

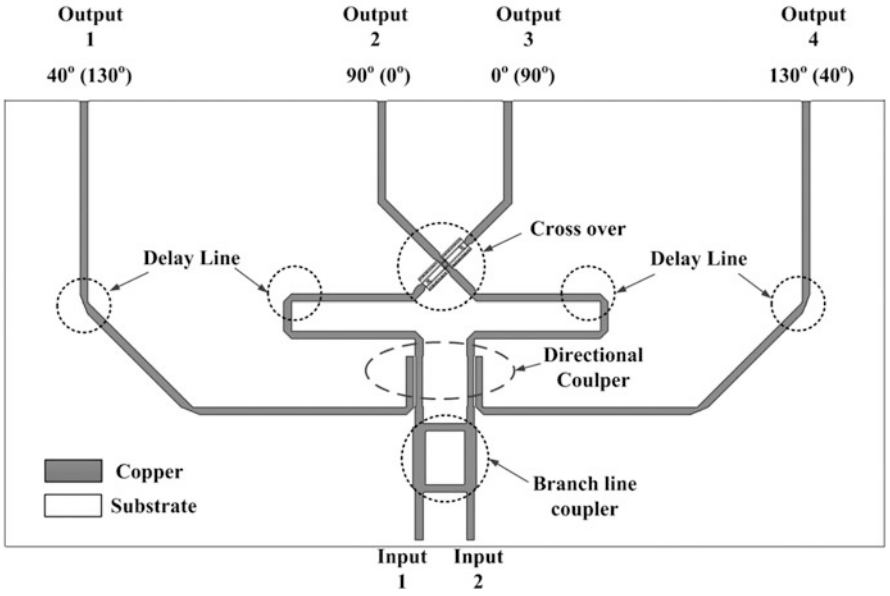

Fig. 14 The configuration of the feeding network presented in Han et al. (2012)

As an example, Figure 14 shows one feeding network based on the branch-line coupler presented in Han et al. (2012). This feeding network is designed for a beam-switching array that consists of four patch elements that operates at 5.1–5.3 GHz. A branch-line coupler is employed at the first stage of the feed network, and then the two coupled lines are introduced to split the power into four outputs, where the microstrip patch is fed by probe feeding. The length of the microstrip lines after the power divider can be varied to produce different phase delays, which is determined by the required beam-switching angle. The radiating elements are fed with two different sets of phase distributions when the RF signals are input from port 1 or port 2. The corresponding phases of each radiating element are indicated in Figure 14. Thus, the beam of this array can be switched by selecting different input ports.

Figure 15 shows the measured radiation patterns of this beam-switching array when port 1 and port 2 are selected. As seen, when port 1 is selected as the input port, this linear array has its beam pointing at 22.5° while the beam is switched to −22.5° when port 2 is excited. This design is a very classic example of applying branch-line coupler and power dividers to obtain a beam-switching feed network. In this example, the beam can only be switched between two different angles. More beam-switching angles can be obtained by cascading more couplers, and then the number of input port is also increased.

Besides using a Butler matrix, another approach for designing a beam-switching array is to introduce RF switches on the feeding lines. Figure 16 shows the layout of a feeding network with PIN diode switches embedded on the feed lines for the array antenna in Maqsood et al. (2014). The DC biasing network is required to provide proper DC bias for the PIN diode switches. To ensure that there is high isolation between DC and RF source, inductors of 100 nH are used as the RF chocking and capacitors of 10 μF are used as the shunt capacitors at the biasing points.

As shown in Figure 16, the feed network has four output states, which means that the phase of each radiating element can be adjusted with four different sets of phase; thus, the beam of the array can be switched to four different angles. Four dual-band circularly polarized stacked annular ring antennas are used in this array, and the resonating frequencies are designed to be 2.454 and 3.15 GHz. Figure 17 shows the measured radiation pattern of this beam-switching array with four different sets of phase distributions when different RF switches were forwarded biased. It is observed that at both frequencies, the beam of the array can be switched to ±25° with moderate gain and low sidelobes.

DOI 10.1007/978-981-4560-75-7_103-1

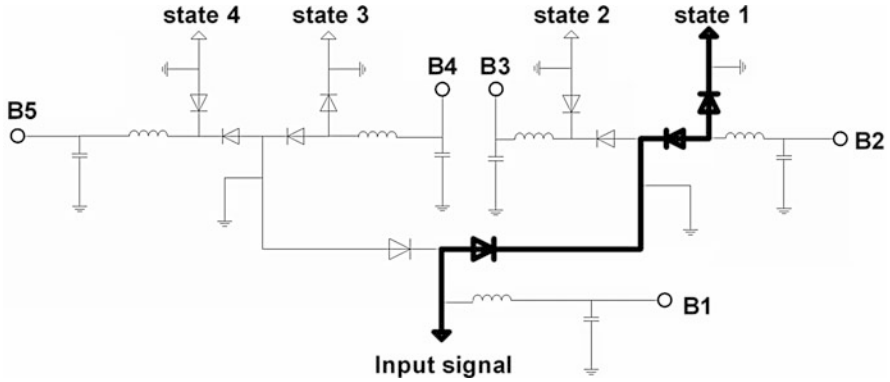

Fig. 16 The layout of the feeding network with PIN diode switches (Maqsood et al. 2014)

From these two design examples, it can be seen that with a Butler matrix, the beam switching of an array can be realized by selecting the corresponding input ports. The number of the ports increases with increasing number of antennas. The array is a multiple-input and multiple-output system and can also be

DOI 10.1007/978-981-4560-75-7_103-1

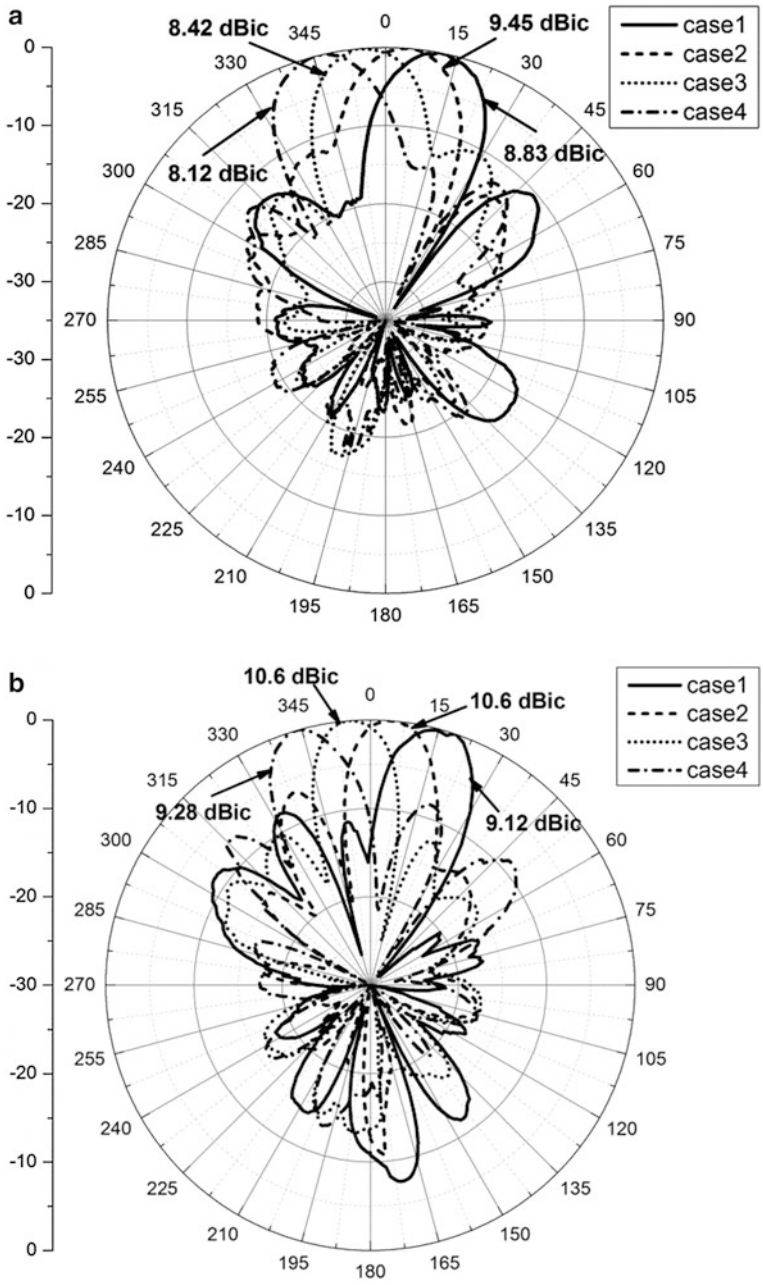

Fig. 17 The measured radiation patterns of the dual-band CP array at (**a**) 2.454GHz and (**b**) 3.15GHz (Maqsood et al. 2014)

applied to the multi-beam applications. With the second approach, which is introducing RF switches on the feeding lines, the phase distribution of the array can be adjusted by controlling the states of the RF switches, and only one input port is required. However, additional DC-biased circuitry is required to control the RF switches, which increases the overall system complexity and reduces the efficiency of the antenna system (due to the loss of the RF switches) if a large number of RF switches are employed.

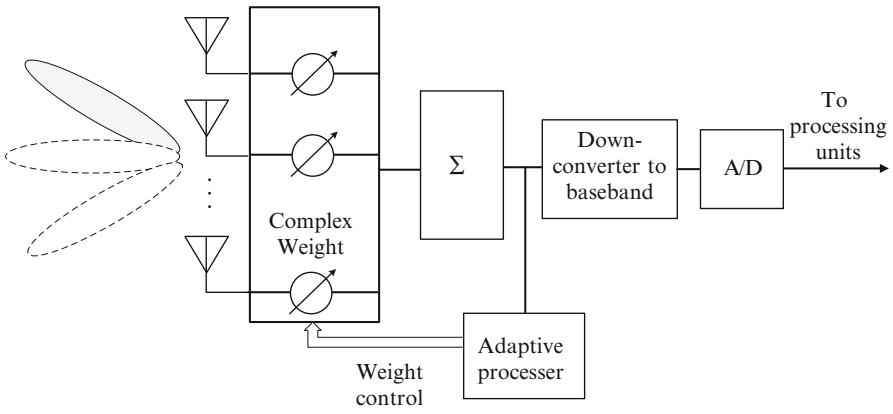

Fig. 18 The general architecture of a smart antenna with analogue beam forming

Beam-Steering Smart Antenna

Theory

Adaptive beam-steering smart antennas are able to continuously steer the beam to the desired directions and shape the beam to maximize the link budget with sophisticated signal processing algorithms. This makes it more attractive compared to the beam-switching smart antennas, which can only provide limited number of beams. For mobile satellite applications such as SatCom on the move, the adaptive beam-steering smart antenna is required to scan the beam within large angle ranges with high efficiency.

The beam forming of the adaptive smart array antennas can be achieved by employing a phased array with controllable amplitude and phase. Figure 18 shows the general architecture of a smart antenna with analogue beam forming (Luo et al. 2014).

A two-dimensional antenna array with large scan angle is usually required to be equipped on an adaptive smart antenna. When the size of the array is large, the radiating elements in the central region have similar characteristics as an element in an infinite array. Then, the array can be analyzed by using the Floquet modes with the assumption that the array has an infinite size. With Floquet modes, an antenna array with infinite sources can be represented as a superposition of Floquet modal functions, instead of solving Maxwell's equations with infinite source excitation functions. It has been proven that using the results from the infinite array, the performance of a finite array (e.g., mutual coupling, active reflection coefficients) can be determined with good accuracy (Bhattacharyya 2006).

When the array elements are excited with uniform amplitudes and linearly progressed phase, using the Floquet modal function, the impedance of an array element can be calculated by (Bhattacharyya 2006):

$$\frac{Z^{FL}\left(k_{x0},\ k_{y0}\right) = -<\vec{E},\ \vec{I}>}{I_0^2} \tag{14}$$

where k_{x0} is the phase constants in X-direction, k_{y0} is the phase constants in Y-direction, I_0 is the input current, $\vec{E}$ is the electric field at the current source location, $\vec{I}$ is the current distribution function, and $<\vec{E}\ ,\ \vec{I}>$ is the self-reaction of the current source in the unit cell and is given by:

$$<\vec{E}\ ,\ \vec{I}>=\iint \vec{E}\times\ \vec{I}\ dx\ dy \tag{15}$$

DOI 10.1007/978-981-4560-75-7_103-1

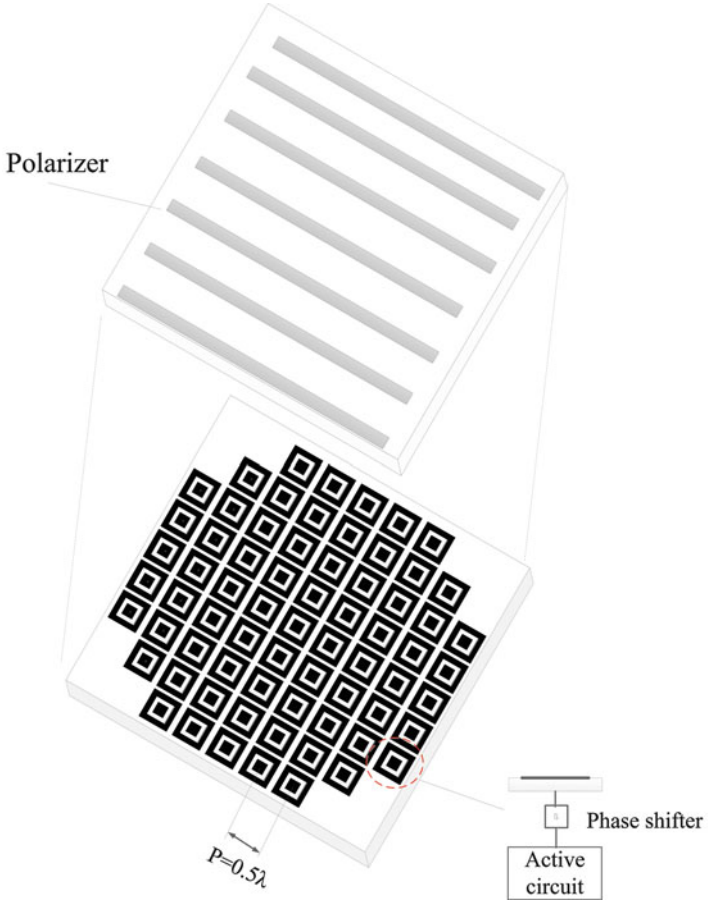

Fig. 19 The configuration of the folded reflectarray presented in Luo et al. (2013)

After computing the Floquet impedance of the array element with different scan angles, the scan blindness angle can be identified by locating the angle where the input impedance of the antenna exhibits a large value (poor impedance matching). At the scan blindness angle, the antenna array does not radiate, and almost all of the input RF energy is reflected back.

Design Example

One Ka-band folded reflectarray with large scan angle for SatCom on the move has recently been presented in Luo et al. (2013). This reflectarray can scan its beam to ±60° in the hemisphere with an appropriate active microwave circuitry. The configuration of this folded reflectarray is shown in Figure 19. As seen, this reflectarray consists of a planar microstrip slot antenna array and a dielectric polarizer. Behind each radiating element, its interface allows it to incorporate the transmit/receive unit with phase/amplitude control.

The unit cell of this reflectarray is based on a dual-polarized square-ring slot antenna fed by striplines, as shown in Figure 20a. The dual linear polarized array unit cell is used to rotate the E-field of the reradiated waves from the slot antenna by 90°, as required for the folded reflectarray design (Menzel and Kessler 2009). In order to integrate with the MMIC that lies below each of the radiating element, the RF signal is transmitted through a stripline to coaxial-like structure with shielding vias. For the purpose of characterizing the array elements, passive prototypes were developed, and stripline to microstrip line transitions are introduced, as shown in Figure 20b.

DOI 10.1007/978-981-4560-75-7_103-1

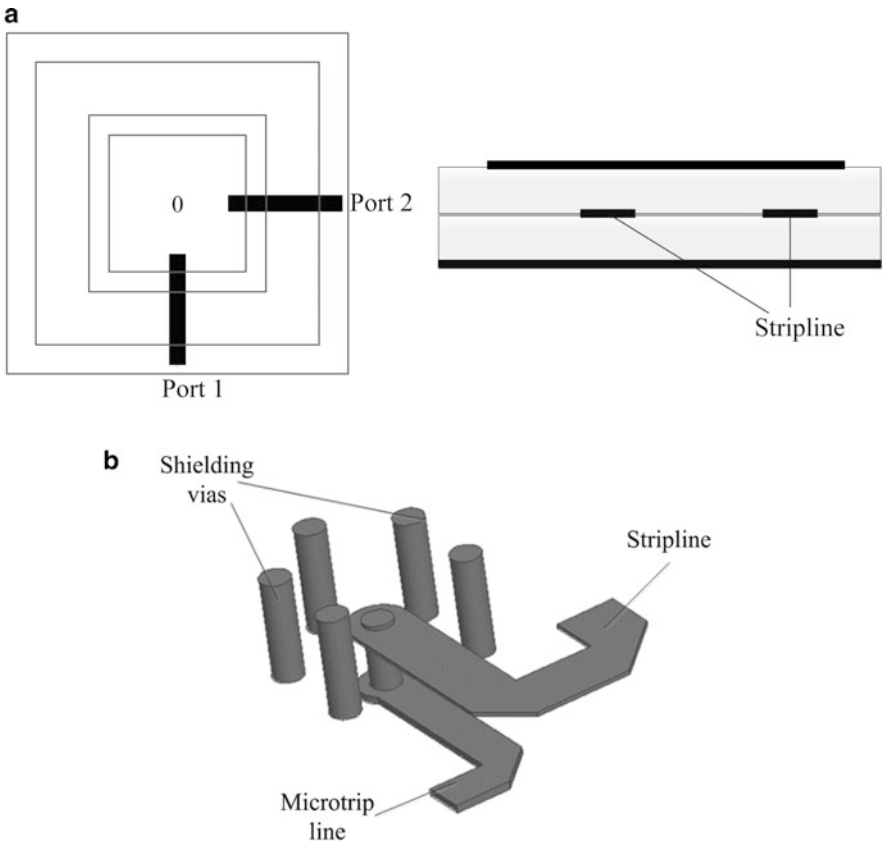

Fig. 20 (**a**) The top and side view of the reflectarray unit cell; (**b**) the stripline to microstrip line transition (Luo et al. 2013)

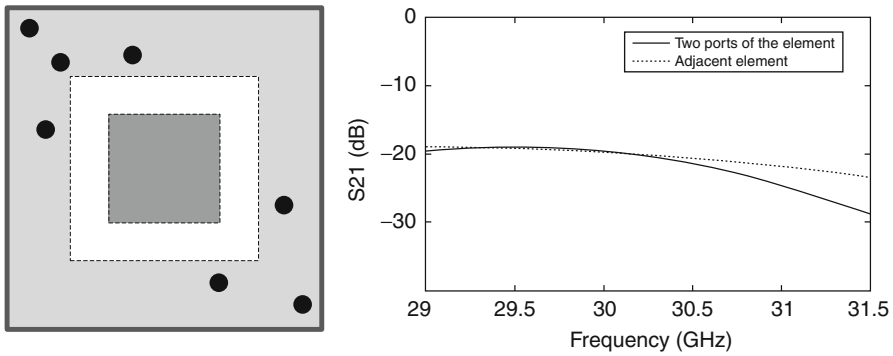

Fig. 21 The positions of the via on the array element and the simulated isolation between the two ports of the antenna as well as the lowest isolation between two adjacent elements in an infinite size array

The distance between each unit cell is kept to half of its free space wavelength at 30 GHz, in order to avoid the grating lobes during the beam scanning. Meanwhile, to make sure the array can steer the beam to large angles, it is important to suppress the propagation of the surface wave and keep a high isolation between the two input ports of the array element as well as the ports between the adjacent radiating element. To achieve this, vias were introduced near the radiating slots. Figure 21 shows the positions of the vias on the radiating element and the simulated isolation between the two ports of the array unit cell as well as the isolation between adjacent antenna elements analyzed by using the Floquet modes. As can be seen, the isolation between the two ports of the antenna is always higher than 20 dB, and the lowest

DOI 10.1007/978-981-4560-75-7_103-1

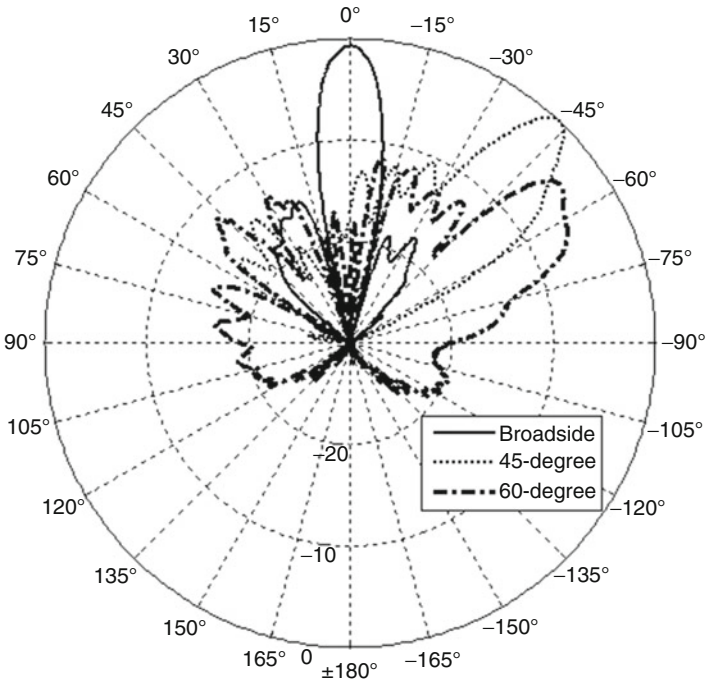

Fig. 22 The measured radiation patterns of the folded reflectarray with beam pointing at 0°, 45°, and 60° in E-plane

isolation between two adjacent elements is higher than 19 dB. These high isolations ensure that this array can scan its beam to large angles without any scan blindness.

The required phase for each radiating element in order to have its focused beam steered to certain angle is calculated by using the formula (Huang and Encinar 2007):

$$\Phi_R = k_0(d_i - (x_i \cos\varphi_b + y_i \sin\varphi_b)\sin\theta_b)$$

where Φ_R is the phase of the reflection coefficient of the antenna element i, k_0 is the phase constant in vacuum, (x_i, y_i) are the coordinates of the array element i, d_i is the distance from the phase center of the feed to the antenna unit cell, and (θ_b, φ_b) is the expected scan angle of the beam in the spherical coordinate system.

Several passive demonstrators were fabricated. The measured radiation patterns of the passive reflectarray at 30GHz with fixed beam steered to different angles are shown in Figure 22. As can be seen from these measurement results, the radiation performances of the passive reflectarray demonstrators exhibit low sidelobes with frozen beam pointing at different scan angles up to 60°. The measured maximum gain at broadside is 21.7 dBi, which represents 42 % aperture efficiency. Because of having a symmetrical structure, similar results were observed for the measured radiation patterns in H-plane.

To achieve an active phased array, it is important to incorporate the active microwave circuit with beam-forming network. MMIC devices are normally employed for such applications. Due to the small size of the Ka-band array element, which is only 5 mm × 5 mm, it requires combining several transmit/receive (T/R) modules on one chip. It is impossible to address the details of the microwave circuit design in this chapter, but readers can refer to Valenta et al. (2012) for more information.

From this example, it can be seen that the complexity of designing an adaptive beam-steerable smart antenna is high, for both the array antenna and the microwave circuit design. Since a large number of radiating elements are usually employed for such application, using Floquet modal functions provides an

Application of Smart Antennas in SatCom

Smart Antennas for Satellite Earth Station Systems

Satellites can be categorized as geostationary and non-geostationary satellites according to the orbits that they are operating. The geostationary satellites, which are in a circular orbit directly above the equator of the earth, have positions in the sky that remains the same for the ground station stationary observer on earth. In this case, the antenna for the ground station does not need to track the satellites, and the beam steering for the satellite ground station is not required as the satellites are in relative fixed locations. For such application, conventional reflector antennas can provide a low-cost solution with promising radiation performance. For the non-geostationary satellites, such as satellites in elliptical geosynchronous orbits or in low Earth orbit (LEO), it is required that the antenna systems for the ground stations are able to track the satellites.

Therefore, the antennas for the satellite earth station application are usually required to satisfy the following technique specification:

1. Have high gain with low sidelobes: to ensure good data connection and minimize the unwanted interference
2. Be able to track the non-geostationary satellites and provide wide angular coverage
3. Use circularly polarized antenna

Table 1 lists some of the frequency bands that have been defined for the satellite communication.

Table 2 summarizes the characteristics of some non-geostationary satellite systems.

Intelsat has defined many standards for the satellite earth stations. Each standard corresponds to different types of services provided by the earth station. Some of the Intelsat Earth Station Standards (IESS) are listed in Table 3. More standards with detailed definitions can be found in Intelsat (2005, 2006).

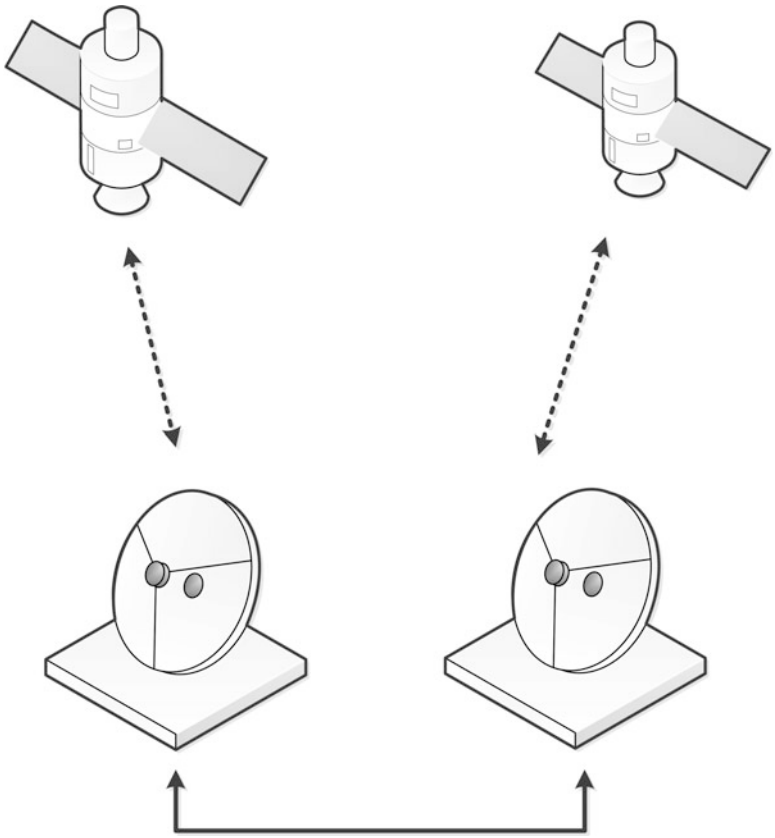

Fig. 23 Using multiple reflector antennas to communicate with multiple satellites

Conventionally, reflector antennas are employed for the satellite earth station, as its advantages of high gain, broad operation bandwidth, and low cost. However, they are always bulky and can only track the satellites by mechanical movement, which makes it impossible for them to communicate with multiple satellites simultaneously or perform seamless handover unless more than one reflector are employed, as shown in Figure 23.

Compared to the reflector antennas, smart antennas have the capability to scan the beam electronically with high pointing accuracy. The beam of the array can be steered in microseconds; thus, with only one smart antenna, different satellites can be tracked, and the handover can be done seamlessly. Figure 24 illustrates the scenario that uses one smart antenna array to communicate with multiple satellites.

It is known that with a planar phased array, the gain of the array decreases at larger scan angles in the elevation plane, as the results of the reduction in the effective radiation aperture, and it cannot cover the

DOI 10.1007/978-981-4560-75-7_103-1

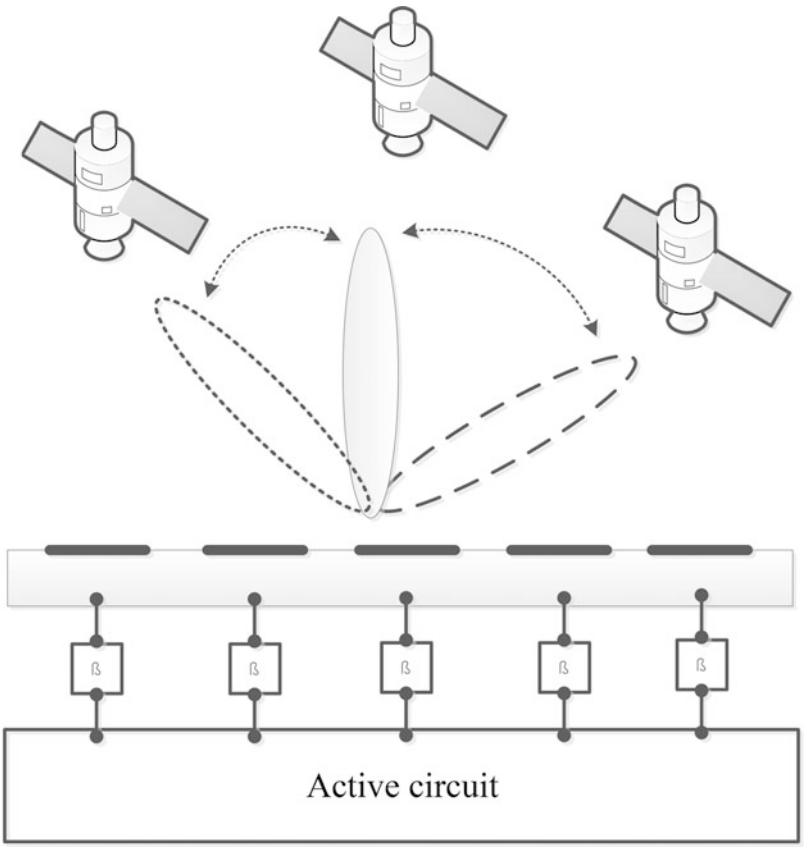

Fig. 24 Illustration of one smart antenna array communicates with multiple satellites

entire azimuth plane. Therefore, in order to have a smart antenna that can steer the beam in the entire hemisphere, faceted array and hemispherical array can be employed (Josefsson and Persson 2006). The advantage of using such arrays is that the array facets can be selected in order to enhance the antenna performance in certain parts of the overall coverage region. For either the hemisphere array or the faceted array, the number of active radiating elements can be controlled so the array with different beamwidth and directivity can be formed based on the needs of the mission. Narrower beamwidth can be achieved at small elevation angles because more radiating elements can be activated due to the geometrical configuration. Figure 25 shows the calculated radiation patterns of a hemisphere array and a faceted array with beam pointing at different elevation angles (Yao et al. 2012). It can be seen that a hemisphere array and a faceted array can steer the beam over large angle ranges with similar radiation patterns. The beam steering of the array is achieved by taking advantage of its physical geometry. During the beam steering, only a small number of the antenna elements are radiating, and the rest of array elements are deactivated, which results in low aperture efficiency of the array antenna.

One important issue associated with the fully electronic beam-steering smart array antenna is the complexity of the RF circuit, especially when the number of the radiating element is large. Besides the complexity in the circuit design, the use of large amount phase shifters, the size of the feed network, and effective system thermal dissipation can increase the cost and reduce the radiation efficiency of the overall antenna system. Thus, until now there are few available commercial products equipped with a fully electronic beam-steering smart array antenna.

To reduce the cost while maintaining reasonable system efficiency, a hybrid system provides a compromised solution. Figure 26 shows the configuration of an m × n microstrip antenna array. Instead of incorporating one phase shifter for each of the antenna element, the array is divided into *m* linear

DOI 10.1007/978-981-4560-75-7_103-1

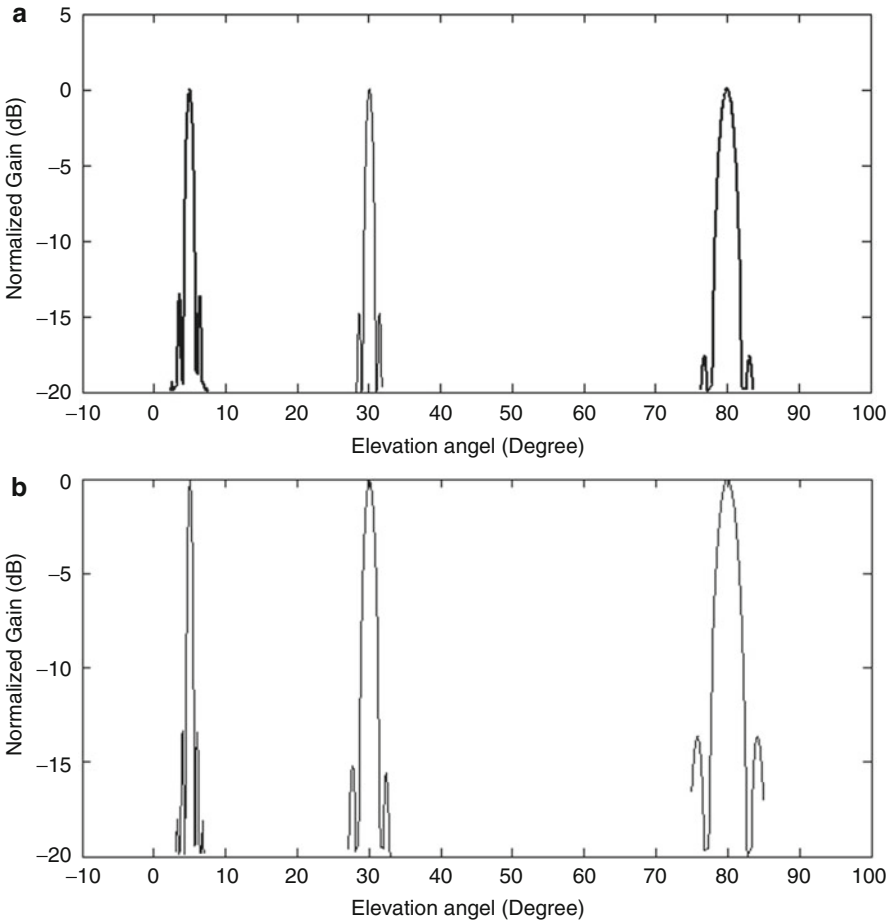

Fig. 25 The calculated radiation patterns of the (**a**) hemisphere array and (**b**) facet array with beam pointing at 10°, 30°, and 50°. There are totally 82,177 radiating elements in the hemisphere array and 40,100 radiating elements in the facet array (Yao et al. 2012)

subarray arrays, and the phase shifting is implemented at the subarray level. Thus, the amount of the phase shifters is reduced from $m \times n$ to m. However, with this configuration the array is only able to scan in one direction. By introducing a mechanical steerable platform, beam scanning within the entire hemisphere would be possible.

In the applications where fast tracking is not required, using mechanically beam-steerable smart antenna provides the most economical solution. Figure 27 demonstrates one planar array placed at a platform that can be rotated in both azimuth and elevation plane. In this configuration, there is no need of using any phase shifters, and the beam steering is controlled by the corresponding motors.

Figure 28 shows a photo of the commercial available terminal for the aero mobile applications. This array is designed for Ka-band application, and dual-polarized (RHCP and LHCP) waveguide horn is used as the radiating element. It operates at 28.1 to 30.0 GHz for transmission and 18.3 to 20.2 GHz for receiving. The antenna system consists of an antenna array, control unit, and programmable servomotors that can be used for azimuth and elevation position controlling. It is reported that this antenna has elevation coverage from 0° to 75° and 360° continuous coverage in azimuth plane. More than 2,500 radiating elements are used, and the antenna array has EIRP (equivalent isotropically radiated power) of 43.5 dBW after taking account of the radome loss.

Smart Antennas for Mobile Direct Broadcast Satellite Systems

The International Telecommunication Union (ITU) authorized the use of high-power Ku-band for the satellite-to-home video program during 1979 and 1989. These services are the so-called direct broadcast satellite (DBS) services (Meadows 2008). DBS provides high-powered broadcast services, including television and radio services, to users in large geographic areas (Thorburn 2012). Figure 29 shows the scenario of the direct broadcasting satellite system, where one broadcast center uplinks signals to the satellite and then the satellite retransmits the signals to multiple users in the areas covered by the satellite

DOI 10.1007/978-981-4560-75-7_103-1

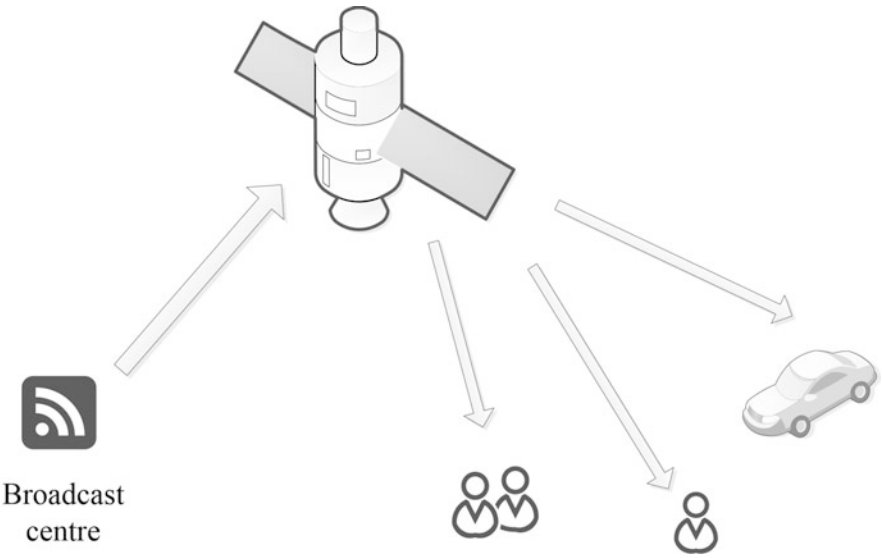

Fig. 29 Illustration of the direct broadcasting satellite system

antenna system. The frequency bands allocated for the DBS are 11.7–12.2 GHz in ITU Region 3 (Asia and Australia), 10.7–12.75 GHz in ITU Region 1 (Europe, Russia, and Africa), and 12.2–12.7 GHz in ITU Region 2 (North and South America).

To ensure good reception from the broadcasting satellites, the DBS antenna is required to have a gain of more than 21dBi and have a beam with a certain title angle (Hirokawa et al. 1995; Watanabe et al. 1996) in the elevation plane. For mobile users, such as moving vehicles, the antenna system is also required to be able to track the DBS satellites.

To reduce the system complexity, the antenna array can be designed to exhibit relatively broad beamwidth in the elevation plane and place the array with certain inclination angle (Soon-Ik et al. 2000). The beam steering in the azimuth plane can be realized by rotating the array mechanically (e.g., by a motor), as demonstrated in Figure 30. It is reported that with a beamwidth of about 12°, even without the beam steering, promising reception can still be reached in Japan (Hirokawa et al. 1995; Watanabe et al. 1996).

Mechanical steering is a low-cost solution, but it suffers from the low tracking speed. For the system presented above, to track the broadcasting satellite, about 2 s are needed (Hirokawa et al. 1995). It is shown that for the real-time road tests, the turning speed of a medium size car can be as fast as 60°/s with an angular acceleration of up to 85°/s^2 (Mousavi et al. 2009). Thus, more accurate tracking of the satellite

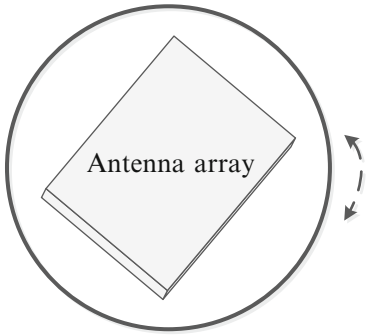

Fig. 30 Employing a planar array on a rotating base that steers the beam in the azimuth plane

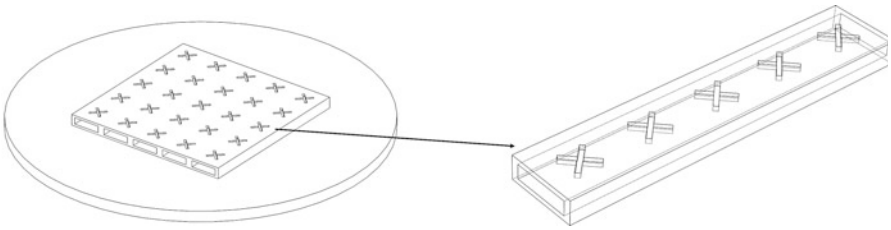

Fig. 31 Configuration of the smart antenna for DBS consists of wave guide slot array presented in Wang and Winters (2004)

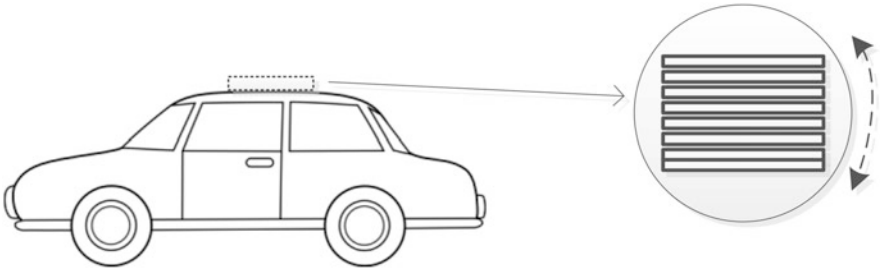

Fig. 32 Demonstration of mounting of the smart antenna presented in Wang and Winters (2004) on the roof of the car

is needed for better services. In this case, electronic beam steering is desired. However, similar to the smart antenna for ground station, a full electronic beam-steering array can lead to a complex and high-cost system. Therefore, the hybrid design that combines both the electronic and mechanical beam steering provides a relatively low-cost solution with improved system performance.

A vehicle-mounted satellite antenna for mobile DBS application is described in Wang and Winters (2004). The look angle of the antenna is set to about 40° in the elevation plane, and the beams can be electronically steered by ±15°. In the azimuth plane, mechanical steering is employed. There are two reasons for such configuration. Firstly, the tracking accuracy needs to be higher in elevation than azimuth plane. Secondly, it can keep a low profile for the overall antenna system, so it is suitable for mounting on the roof of the vehicle. This antenna consists of ridge waveguides, on which cross-shaped slots were uniformly spaced, as shown in Figure 31. By optimizing the positions and the length of the cross-shaped slot, circularly polarized radiation can be achieved. As a waveguide slot array, it can radiate different polarized waves in forward and backward direction (Gao et al. 2014). Thus, either LHCP or RHCP can be obtained.

Figure 32 demonstrates the mounting of this DBS smart antenna on the roof the car. This smart antenna has a low profile with height of less than 76 mm.

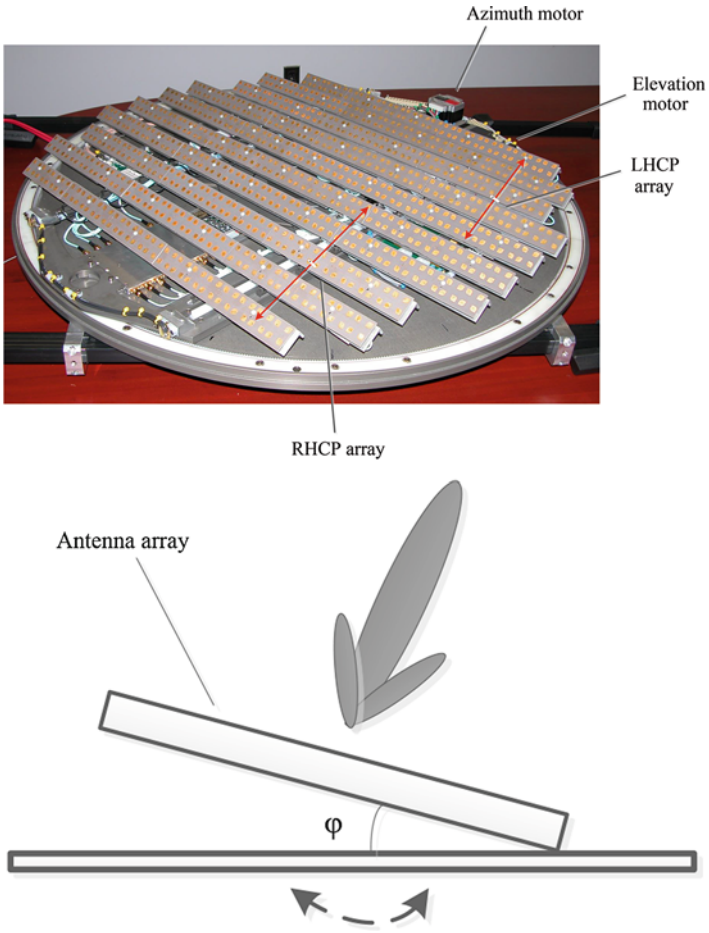

Fig. 33 The phased array antenna for DBS application reported in Mousavi et al. (2010) (Courtesy of Centre for Intelligent Antenna and Radio Systems (CIARS), Canada)

Recently, a smart antenna array based on microstrip printed antenna and subarray technique has been presented in Mousavi et al. (2008, 2010). Mechanical rotation at both azimuth and elevation planes is employed, while the array can additionally scan the beam electronically in the elevation plane. Thus, this smart antenna can provide a wide-angle reception for the DBS satellite reception. 2×2 linearly polarized patch was arranged in a sequentially rotated position to generate the CP radiation. There are 17 subarrays used for either RHCP or LHCP operation, and for each polarization, the antenna arrays are placed in five consecutive panels with certain tilt angle, as shown in Figure 33. Since the array antenna is fabricated by using PCB techniques, it exhibits lighter weight with less fabrication complexity compared to the waveguide-based arrays.

Figure 34 shows the system configuration of this smart antenna system. There are two motors that can be controlled to mechanically rotate the antenna array in both azimuth and elevation planes. Each subarray is connected to a voltage-controlled analogue phase shifter via an LNA and low-loss cable. The phase shifters can be controlled by the voltages, which can be adjusted by the beam-forming algorithm, applied through the digital to analogue converter (DAC) board. For either LHCP or RHCP polarization, a power combiner is used to combine the outputs of the phase shifters. Novel model-free beam-forming algorithms (Fakharzadeh et al. 2009) are employed to track the desired satellite and compensate the inaccuracy from the fabrication errors. It is reported in Mousavi et al. (2010) that with these algorithms, this smart antenna can maintain the received power level above the 90 % in any road test circumstances.

Future Directions and Open Problems

Smart antennas are important for satellite communications. They can increase channel capacity, track satellites electronically, and avoid interference signals. These advantages over conventional antennas make them attract much research interest. In this chapter, a review on smart antenna technologies and design examples, including one beam-switching CP array and one reflectarray with large scan angle range, are presented. The beam-switching smart array provides a low-cost solution with a limited number of fixed beams, while the adaptive smart array can steer the beam continuously with higher system complexity and cost. The applications of smart antennas for satellite ground stations and mobile direct broadcast services are also introduced in this chapter. Different solutions with design examples as well as commercial applications are discussed and presented.

The future work for the smart antenna design involves the design of fully electronically scanned smart array antenna for satellite communications at Q-band (33–50 GHz), V-band (50–75 GHz), and W-band (75–110 GHz), as the need for more spectrum and satisfying the growing communication capacity requirements (Acosta 2012). Although 60-GHz antenna arrays with multilayered configuration and fabricated by using low-temperature co-fired ceramic (LTCC) technology have been reported recently (Hucheng et al. 2013; Lei et al. 2013), these presented arrays cannot perform beam scanning. The challenge at these higher frequency bands is the following: In order to keep the beam-scanning capability and maximize the largest scan angle of the smart antenna without any grating lobes and scan blindness, the maximum dimension of the array element is approximately half the free space wavelength at the frequency of interest. In order to make the array antenna be scalable, it is desirable to have an independent MMIC below each array element. Thus, each radiating element can be treated as an intelligent pixel. This also gives challenges to the MMIC and beam-forming network design as the size of the MMIC is constrained by the size of the radiating element. Moreover, the integration of the overall system and the heat dissipation need to be addressed as well.

Terahertz antennas also attract much research interests in recent years, and antenna array for operation at terahertz frequency is anticipated. Electronically controllable phase shifters operating at THz frequencies are critical components for a terahertz phased antenna array. Terahertz antenna phase shifter designs, including using electrically driven THz metamaterials (Chen et al. 2009) and integrally gated graphene transmission lines (Pai-Yen et al. 2013), have been investigated. Since terahertz frequencies are between

DOI 10.1007/978-981-4560-75-7_103-1

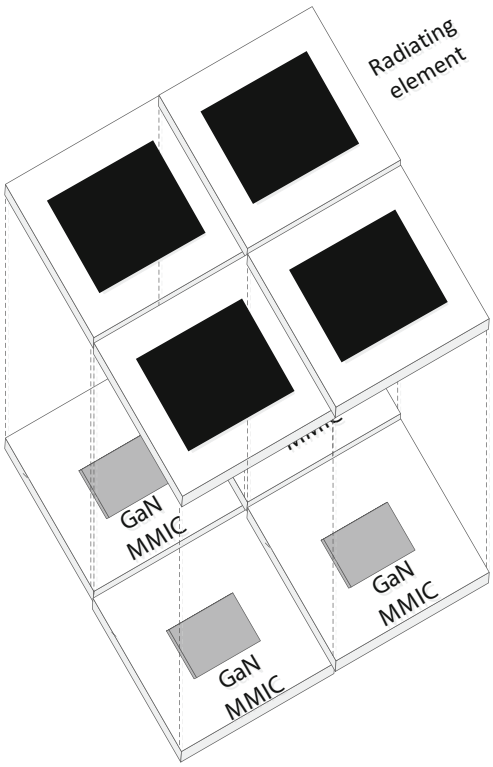

Fig. 35 The concept of the intelligent pixel with GaN-based MMIC

the microwave and optical frequencies, efficient fabrication techniques with low antenna loss need to be further explored, especially when many radiating elements are required to form a high-gain array antenna.

Another direction for the future work is to incorporate gallium nitride (GaN)-based MMIC with high power amplifiers (HPA) under each radiating element, and then the power of amplifiers can be combined in space by the smart array antenna, as shown in Figure 35. The material properties of GaN exhibit revolutionary performance for millimeter wave power amplifiers in many aspects compared to conventional gallium arsenide (GaAs) technology, including the output power, power-added efficiency (PAE), operation bandwidth, signal linearity, gain flatness, and noise level (Oki et al. 2013). In term of applying the GaN technology in the smart antenna design, one of the challenges for this concept is how to efficiently dissipate the heat generated by all the HPAs.

Using new materials, such as graphene/carbon nanotube (Wu et al. 2014) brings new perspectives to the future antenna and antenna array designs. One antenna-enhanced optoelectronic microscopy study on nanoscale devices has been presented recently (Mauser et al. 2014), but there are few works in using these new materials to design smart array antennas up to now. Thus, more investigations are expected in this new field.

Antennas in Access Points of WLAN/WiFi

Hiroyuki Arai*
Yokohama National University, Yokohama, Kanagawa, Japan

Abstract

This chapter presents antennas used in access points of WLAN/WiFi systems. The frequency spectrum for these systems based on the standards is described first. Antenna parameters to understand the WLAN/WiFi antennas are also explained. The antennas are classified into outdoor, indoor, and built-in antennas in this chapter, which are presented in detail.

Keywords

WLAN; WiFi diversity; MIMO; Access point; Yagi-Uda array; Reflector antenna; Microstrip antenna; Collinear array; Sleeve antenna; Dipole antenna; Monopole antenna; L-shaped antenna; Inverted-F antenna

Introduction

This chapter presents antennas in access points of WLAN and WiFi. The antenna specifications, frequency and antenna gain, are summarized in the following section, and the definitions of antenna parameters are also described. Recent high-speed wireless terminal use MIMO (multiple input and multiple output) system and then its evaluation factors are also defined. Section "WLAN/WiFi Antennas" describes antennas used in WLAN and WiFi systems, classified into outdoor, indoor, and built-in antennas.

Specifications of WLAN/WiFi Antennas

Wireless local area network (LAN) is designated as WLAN, the local area network systems provided by electromagnetic waves. The WLAN specifications are created and maintained by IEEE LAN/MAN standards committee (IEEE802.org), so-called IEEE802 since 1997. WiFi is a name of nonprofit organization, Wi-Fi Alliance, to promote wireless LAN products and devices. This section presents major frequency spectrums of WLAN and antenna specification in use and the antenna parameters to find the definition of technical terms.

Frequency Spectrum Allocations

Major frequency bands for WLAN are 2.4 (2.417–2.497) GHz and 5 (5.15–5.35, 5.475–5.725) GHz. For a point to point wireless communication, 25 (24.77–25.23)-GHz band is also used for outdoor applications. Millimeter frequency band of 60 (59.0–66.0) GHz is released to provide high-speed data transmission protocols up to 7 GHz bps. This standard is designated as WiGig (Wireless Gigabit). The WLAN

*Email: arai@ynu.ac.jp

DOI 10.1007/978-981-4560-75-7_106-1

access points often require several antennas to mitigate multipath fading for the IEEE 802.11b/g at 2.45 GHz and 802.11a at 5 GHz. This scheme is called as diversity antenna utilizing two reception antennas and more. To increase the data transmission speed, MIMO (multiple input and multiple output) scheme is also used in WLAN systems. The number of MIMO streams, channels to transmit different data, is 4 (802.11n) and 8 (802.11ac), which is given by the product of the number of transmitting and receiving antennas $N_t \times N_r$.

Antenna Parameters: Bandwidth, Directivity, Half-Power Beam Width, and EIRP

Required frequency bandwidth of WLAN antennas is determined by voltage standing wave ratio (VSWR) at the antenna feeding point. The VSWR is defined by a transmission line impedance Z_o and an antenna impedance Z_i as follows:

$$\mathrm{VSWR} = \frac{1 + |\Gamma|}{1 - |\Gamma|}, \Gamma = \frac{Z_i - Z_o}{Z_i + Z_o} \tag{1}$$

where Γ is the reflection coefficient at the antenna input port and the Z_o is usually 50Ω for the matching with output or input impedance of transceivers. Examples of typical VSWR value for WLAN antennas are $\mathrm{VSWR} \leq 2$ or $\mathrm{VSWR} \leq 3$. Radiated power from the antenna given by $1 - |\Gamma|^2$ is 89 % of input power for $\mathrm{VSWR} = 2$ and 75 % for $\mathrm{VSWR} = 3$.

The antenna radiation performance is evaluated by antenna gains, which are directive gain and absolute gain. The directive gain does not include losses inside the antenna and input impedance mismatch. It defines the spatial distribution of radiated energy power into space from the antenna. The absolute antenna gain G_s including all the antenna loss factors specifies the transmission power in real operating environments. The absolute gain G_s is measured by comparing the received electric field strength between the standard gain antenna and the antenna under test (AUT). The absolute gain of a standard antenna is $G_s = 2.15$ dBi for a half wavelength dipole antenna.

The antenna pattern is also characterized by half power beam width and front to back (FB) ratio. The half power beam width H_b is the angle between the half power points of the main beam as shown in Fig. 1. The FB ratio is the directivity ratio between the front and back of antenna pattern. The front ($\theta = 0°$) is the maximum radiation direction and back one is taken as an angle of the maximum radiation level within the range of $\theta = 120(180 - 60)°$ to $240(180 + 60)°$ as shown in Fig. 1.

The antenna radiation level of WLAN antennas is generally defined by effective isotropic radiated power (EIRP). It is the amount of power for an isotropic antenna, which needs to radiate the same power level for a given angle of directive antenna. To keep this specification, the input power level of directive antenna should be decreased.

Diversity and MIMO

To reduce the fading effect in the real propagation environment, diversity reception is used for wireless systems to compensate for very weak signal reception caused by multipath fading. Antenna diversity techniques are classified into space, polarization, and pattern diversity. The space diversity uses several independent signals from different antennas spaced apart, and the polarization diversity is given by receiving the normal and cross-polarization components at the same position. In addition, the antenna pattern diversity utilizes the signals from antennas with nonoverlapping antenna radiation patterns.

The evaluation factor of diversity antenna is the correlation coefficient between different outputs of the antenna. When there are two outputs for a diversity antenna, the correlation coefficient of the detected signal envelope of e_1 and e_2 is defined as

DOI 10.1007/978-981-4560-75-7_106-1

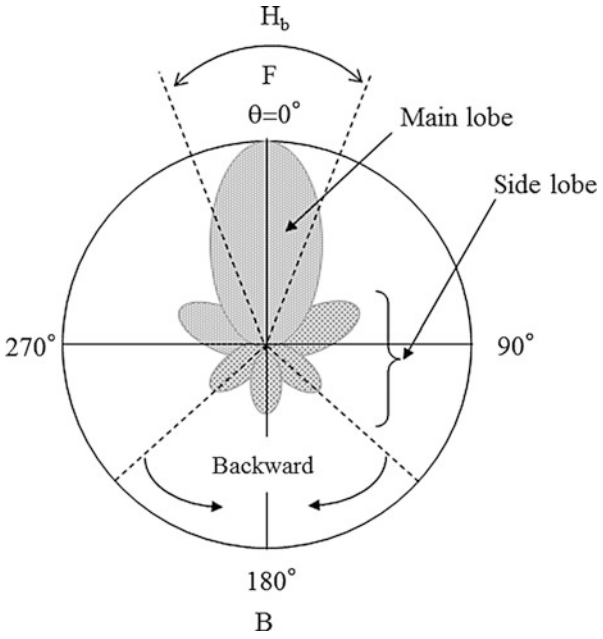

Fig. 1 Antenna pattern parameters

$$\rho = \frac{\frac{1}{2}\langle (e_1 - \langle e_1 \rangle)^* (e_2 - \langle e_2 \rangle) \rangle}{\frac{1}{2}\sqrt{\left\langle (e_1 - \langle e_1 \rangle)^2 (e_2 - \langle e_2 \rangle)^2 \right\rangle}} \tag{2}$$

where <x> denotes the mean value of parameter x and (y)* denotes the complex conjugate of the difference parameter (y). The correlation for antenna with low loss is calculated using S-parameters as follows (Thaysen and Jakobsen 2006):

$$\rho = \frac{\left| S_{11}^* S_{12} + S_{12}^* S_{22} \right|^2}{\left(1 - |S_{11}|^2 - |S_{21}|^2\right)\left(1 - |S_{12}|^2 - |S_{22}|^2\right)} \tag{3}$$

The correlation is also evaluated by complex radiation patterns of diversity antennas, which is time consuming by measuring patterns in the whole angles along azimuth and elevation coordinates. Then Eq. 3 is widely used to evaluate the diversity antennas.

The diversity performance is determined by the envelope correlation which is approximated by $\rho_e \cong \rho^2$. Small ρ_e increases the diversity gain, and its recommended critical value is $\rho_e = 0.6$ for effective diversity antenna design (Yamada et al. 1991).

MIMO performance characterized by channel capacity is approximated by McNamara et al. (2000)

$$C \cong C_{SNR} + C_{COR} = N_r log_2\left(\frac{\rho}{N_t}\right) + log_2\left\{det\left(\boldsymbol{H_n H_n^H}\right)\right\} \tag{4}$$

where N_t and N_r denote the number of the transmitting and receiving antennas and ρ is the averaged signal-to-noise ratio (SNR) at each receiving antenna. $\boldsymbol{H_n}$ is a normalized channel matrix and the superscript H represents a complex conjugate transpose. The above equation indicates that channel

DOI 10.1007/978-981-4560-75-7_106-1

capacity contains elements depending on SNR (C_{SNR}) and correlation (C_{COR}). The channel matrix characterized as det($\boldsymbol{H_n H_n}^{\boldsymbol{H}}$) is dominated by the spatial correlation coefficient γ_s and small γ_s enhances the channel capacity. To satisfy this requirement, high gains with low correlated radiation patterns are required in access point antenna designs. The channel capacity of 2×2 MIMO is saturated for $|\gamma_s| < 0.7$, and this is the critical value to evaluate the correlation (Uchida and Arai 2013).

WLAN/WiFi Antennas

This section presents WLAN antennas used in actual use. The antennas are classified into outdoor, external, and built-in antennas in this section. The antennas of WLAN/WiFi terminal antennas are discussed and terminal ones are not included.

Outdoor Antennas

The WLAN outdoor antennas are high gain and used for the point-to point wireless data communication systems. Typical high-gain antennas are Yagi-Uda array and parabolic reflector antenna. Yagi-Uda array consists of a radiating element, a reflector, and director elements as shown in Fig. 2. Its directivity gain is enhanced by increasing the number of director elements. The range of antenna gain of 2.4 GHz outdoor Yagi-Uda array is 10–19 dBi. The highest gain antennas for outdoor applications are provided by parabolic reflector antennas consisting of a grid reflector and a primary feeder as shown in Fig. 3. The grid reflector is used to reduce the load by wind pressure. The antenna gain is 24–30 dBi at 2.4 GHz and 5 GHz WLAN systems.

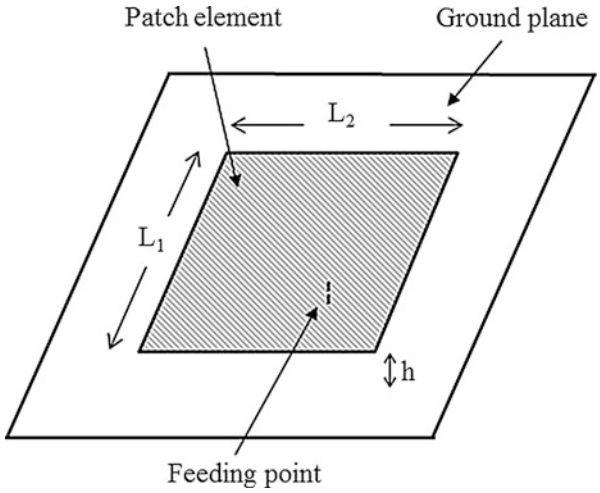

Fig. 4 Microstrip antenna

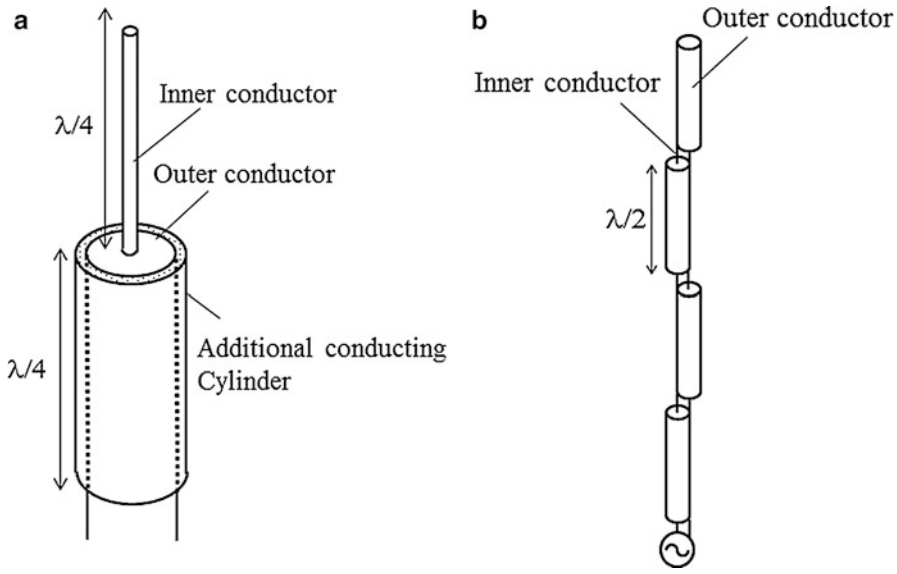

Fig. 5 Sleeve and collinear array, (**a**) sleeve antenna, (**b**) collinear array

For the multipoint WLAN applications, sector-shaped patterns and omnidirectional patterns in horizontal plane are used. The sector pattern is given by a microstrip (patch) antenna as shown in Fig. 4 and the gain range is 5–10 dBi. The omnidirectional pattern is provided by a sleeve antenna and collinear array as shown in Fig. 5. The sleeve antenna is a kind of a half wavelength dipole antenna involving the balun transformer which converts an unbalanced feeding cable like the coaxial line to a balanced feeding antenna. The collinear array is made up by several half-wavelength coaxial cables connecting the inner conductor of the lower element to the upper outer one to change the phase alternatively at the edge. The antenna gain of sleeve antenna is 2.15 dBi and that of collinear array is 5–10 dBi.

DOI 10.1007/978-981-4560-75-7_106-1

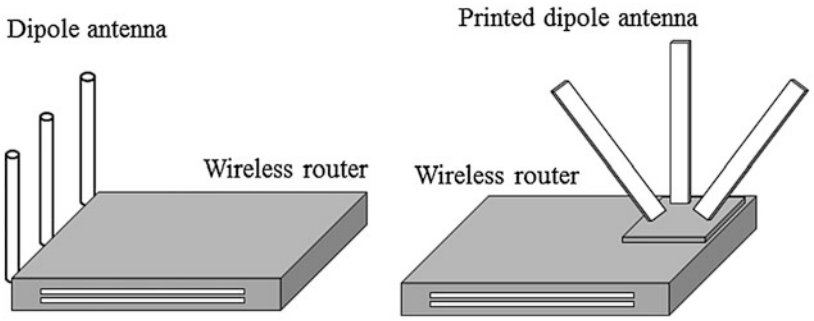

Fig. 6 External antennas

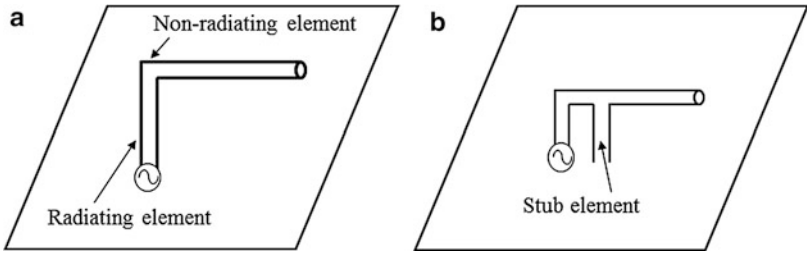

Fig. 7 Bent monopole antenna

External Antennas

The external WLAN antennas described in this section are the antennas protruding from the access point body. Most of the antennas are half-wavelength dipole antennas consisting of conducting pole or dielectric substrate as shown in Fig. 6. A dual-band printed antenna involves 2.4 GHz and 5 GHz dipoles etched on a dielectric substrate, and each antenna is fed by a thin coaxial cable. These antennas require balanced feeding, and then the balun like the sleeve antenna is built in at the feeding pint. A whip antenna is also used for the external antenna. It is a quarter-wavelength monopole antenna on a finite-sized ground plane given by a part of access point body.

Two external antennas are used for 2 × 2 MIMO access point; however, another one is often added for the diversity reception. Two antennas are used to reduce the fading effect at the reception, which is equivalent to select a pair of low-correlated antennas. MIMO channel capacity is also enhanced by low-correlated antennas, and the diversity reception by three antennas is useful for WLAN access point antennas.

Built-In Antennas

The external antennas are replaced with built-in antennas due to the miniaturization of access point and good outside appearance. A bent monopole antenna and an inverted-F antenna are often used for built-in antenna.

The bent monopole antenna is called as L-shaped antenna as shown in Fig. 7. A vertical part to the ground plane is radiating element and a horizontal one is called as a non-radiating element. Low profile L-shaped antenna with short radiating element is not easy to match the antenna input impedance with that of transmission line. Another vertical element to connect non-radiating one with ground plane is a stub element, which is used for impedance matching of the antenna. This antenna is called as inverted-F

DOI 10.1007/978-981-4560-75-7_106-1

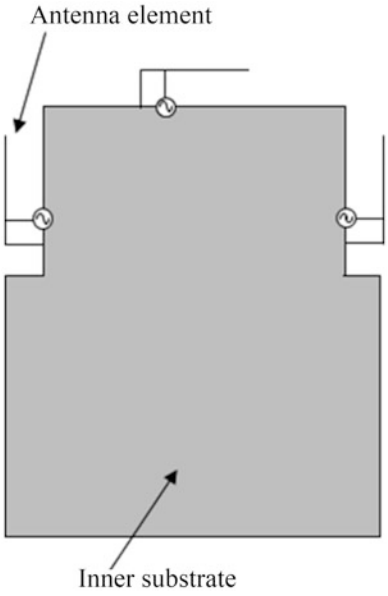

Fig. 8 Built-in antennas

antenna and is widely used for built-in antennas. Three inverted-F antennas are attached at the edge of internal substrate as shown in Fig. 8 for the MIMO system.

The integrated antenna is one of built-in antennas used in millimeter frequency band. A short wavelength in this band needs to remove transmission line and to integrate antennas into device package. These antennas are called as antennas in package. The aperture-coupled microstrip line-fed antennas are embedded on low-temperature cofired ceramic (LTCC) substrate operating in the 60-GHz frequency band. Air cavities processed inside the LTCC substrate are used to improve the bandwidth and gain of the antennas (Lamminen et al. 2008). Another antenna-in-package with high efficient radiation and high shielding effectiveness to electromagnetic noises is composed of U-shaped slots cut on the shielded ball grid array package. The measured antenna gain of the fabricated antenna is from 2.9 to 5.2 dBi in the 60 GHz band (Hashimoto et al. 2014). A multilayer parasitic microstrip antenna array on a multilayer Teflon substrate for millimeter wave is also proposed for system-on-package modules. This antenna achieves a radiation efficiency of greater than 91 % and antenna gain of 11.1 dBi at 60 GHz (Seki et al. 2005). The integrated WiGig antennas are still under development and high efficient and high gain antennas are required.

Summary

This chapter presented antennas used in access points of WLAN/WiFi systems. The antennas classified into three types were explained by showing example antennas. High-gain antennas like Yagi-Uda array and reflector antennas are often used to point-point wireless communication systems, and dipole antennas are major ones for the external access point antennas. As the built-in antennas, L-shaped antenna and inverted-F antenna are also explained. Further miniaturization of wireless devices and the use of millimeter wave need to develop another high efficient antennas for WLAN/WiFi systems.

Abstract

This chapter concentrates on embroidered textile antennas for body-centric wireless identification and sensing systems. Methods for modeling and characterization of embroidered UHF RFID tag antennas, creating totally embroidered wearable patch-type antennas, and co-designing textile-based transmit antenna and mm-size implant antenna for challenging wireless brain-machine interface systems will be presented. Wireless body-centric identification and sensing systems hold an enormous potential to revolutionize wearable intelligence by extending the functionality of advanced garments. There are several specific requirements for on-body and implant antennas and their communication: on-body antennas have to be lightweight, conformal, easy to integrate into clothing, and as immune as possible to the performance-degrading effects of human body. When implanted systems are considered, communication link between the on-body and implant antennas has to be as efficient as possible, but at the same time SAR regulations must be obeyed. Moreover, implants and thereby implant antennas are intended to be as small as possible, and therefore the on-body textile antennas have to be able to efficiently communicate with mm-size implant antennas. Approaches to solve these challenges are presented in this chapter. Additionally a comprehensive and organized list of references is provided to assist the readers in identifying most pertinent publications about this very important and timely subject.

Introduction

Wireless body-centric identification and sensing systems hold an enormous potential to revolutionize wearable intelligence by extending the functionality of advanced garments. Wireless sensor networks integrated with garments allow inexpensive and continuous health state and environment monitoring. These sensor networks incorporate physiological sensors, low-power integrated circuits and computing devices, and wireless communication antennas for transmission and reception of recorded data. This relatively new interdisciplinary technology can be considered as a breakthrough technology in personal healthcare domain, ultimately making concepts such as telemedicine to become reality (Wang et al. 2013; Yang et al. 2008; Occhiuzzi et al. 2010; Vena et al. 2013). Antennas are one of the paramount components defining the reliability and efficiency of the wireless communication link between the body-worn electronic systems and the surrounding environment. Wearable passive ultrahigh (UHF) frequency

radio-frequency identification (RFID) tag antennas, operating in the 860–960-MHz band, are of particular interest due to providing a predictable verification platform. They provide an invaluable contribution in the development toward an intelligent environment, where low-cost tag antennas are seamlessly integrated with daily garments to enable wireless body-centric communication everywhere and at any time (Polívka et al. 2009; Marrocco 2010; Koski et al. 2013a). Figure 1 presents various embroidered antenna structures, which are discussed in this chapter.

Biomedicine and personal healthcare systems demand information about sensed or measured biological parameters to be reliably and quickly sent over a wireless communication link for analysis purposes. Further, the communication system must be totally maintenance-free, comfortable to wear, low cost, and low power in order to meet widespread use and to provide an independent life for patients. Wireless body-centric communication sensing systems are promising candidates for the realization of such systems incorporating mobile control units and wearable and implantable antennas. Seamlessly integrated wearable and miniaturized implantable antennas have thus the potential to revolutionize the everyday life of people and contribute to independent living. Body-centric wireless communication is considered as an important part of the fourth-generation mobile communication systems and is expected to be part of the future convergence and personalization of the personal area networks (PANs) and body area networks (BANs) (Hall and Hao 2006).

The wireless brain-machine interface (BMI) system is a challenging future application in the field of body-centric communication systems. Real-time wireless interfaces between the human brain and mechanical prosthetics are highly desirable for patients suffering from severely disabling neurological conditions as these would allow them to use prosthetic limbs in the same manner as biological limbs. As a groundbreaking example, one can envision a technology that would convert a thought into action and let a person control a device just by thinking about it (Carmena 2012), or even further, one can imagine tiny brain-implantable devices which would restore the motor, sensing, or cognitive skills of an injured person. This system requires neural sensors transferring neural data to an external device to be decoded and used to control artificial actuators (Nicolelis 2001; Rabaey 2011). Thanks to the plasticity of the brain, the implanted BMI quickly becomes a seamless part of the brain allowing the direct brain control of smart prosthetics and computers (Nicolelis 2001; Koralek et al. 2012).

Currently, communication between the neural sensor and the computer is established via wires, which increases the infection risk of the patient and limits the usability of the system only to clinic environments

DOI 10.1007/978-981-4560-75-7_108-1

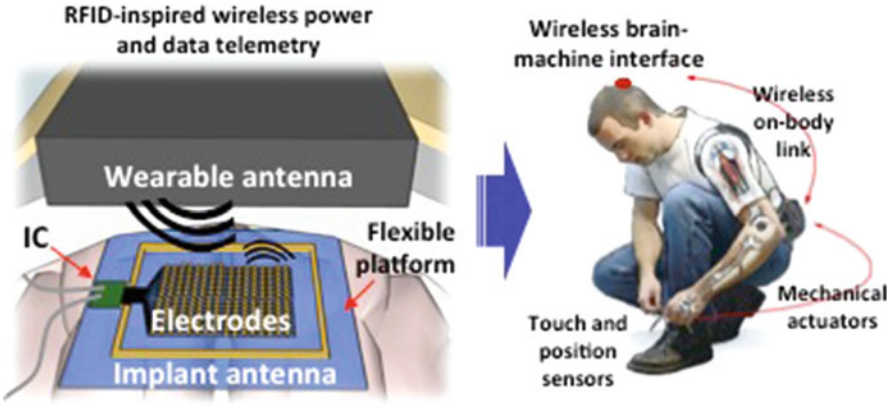

Fig. 2 Backscattering-based approach for wireless communication in brain-machine interface systems

(Collinger et al. 2013). Hence, to have a mobile BMI system and to be able to use the system in everyday life, data and power telemetry to the implanted neural sensor should be implemented wirelessly. There are two main challenges to reliably and accurately control prosthetic devices for long time periods: to realize viable neural interfaces that last a lifetime and to control the prosthetic devices in a naturalistic way (Carmena 2013). For this purpose, the neural implant must be biocompatible and minimally invasive to reduce tissue damages. Thus, it should be wirelessly powered, need minimum power, and support bidirectional data flow, i.e., "reading" and "writing" from/to the brain (Yakovlev et al. 2012).

The neural implant requires a transmitting antenna outside the human body to establish the wireless body-centric communication link. Figure 2 presents the backscattering-based approach for wireless BMI systems. This antenna should be comfortable to wear, low profile, and optimized for strongest possible coupling to the implant antenna. In this chapter, the feasibility of using flexible electro-textiles in the realization of transmitting loop antennas for wireless BMI systems is explained. For this purpose, both embroidered and commercially available textiles will be presented.

Design Considerations

Wearable antennas face many requirements. They should be comfortable to wear, lightweight, totally maintenance-free, and inexpensive for their widespread use to become reality (Koski et al. 2013a; Kellomäki and Ukkonen 2010; Bayram et al. 2010). Considering identification systems, RFID chip impedances typically have capacitive input impedance. To ensure proper impedance matching and thereby maximum power transfer at antenna-chip interface, the input impedance of the tag antenna has to provide the corresponding inductive component. Efficient impedance matching is particularly important in passive RFID systems, where all tag antenna available power comes from the remote reader unit (Marrocco 2008). Additionally, wearable antennas should show high immunity to the human body interaction, which otherwise may drastically detune the antenna input impedance and degrade the radiation efficiency. These issues are also common to the design of antennas operating in close proximity of metal objects (Ukkonen et al. 2005). In the UHF RFID band, the human body represents a high-loss dielectric object with a relative permittivity $\varepsilon_r \approx 50 - 60$ and loss tangent $\tan\delta \approx 0.5 - 1.2$ (Polívka et al. 2009). It is commonly known that in case of omnidirectional radiators, such as the dipole antennas, the presence of the human body causes considerable input impedance detuning and absorption of the received or radiated RF energy (Foster and Burberry 1999; Raumonen et al. 2003). As a result, the antenna radiation efficiency is degraded, and the identification distance becomes shorter.

DOI 10.1007/978-981-4560-75-7_108-1

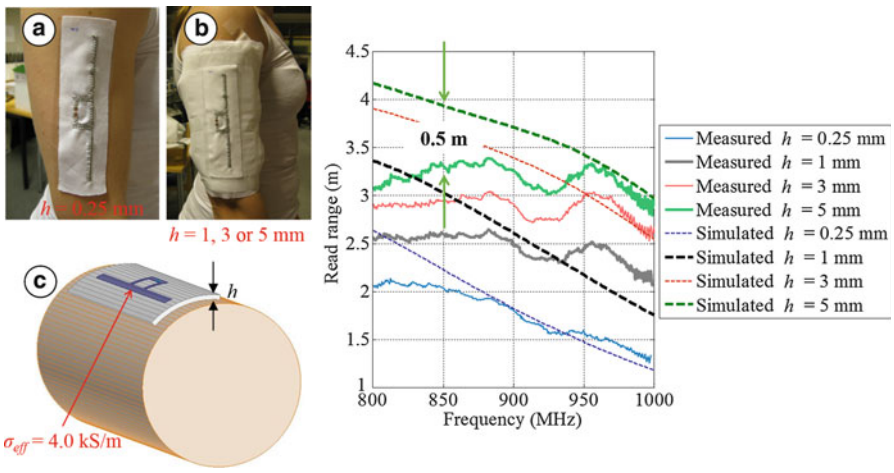

Fig. 3 Measured (*M*) and simulated (*S*) on-body read ranges of embroidered dipole antenna with different insulation layer thicknesses (*h*). (**a**) Embroidered antenna on the arm with 0.25-mm insulation. (**b**) Embroidered antenna on the arm with 1-, 3-, or 5-mm insulation. (**c**) Modeling approach with simplified arm model

However, reasonable read ranges can be achieved with embroidered dipole-type antennas, when they are attached on human body. Figure 3 presents a case study with a dipole RFID tag antenna embroidered utilizing conductive silver thread. The antenna has also been modeled utilizing an arm model (Koski et al. 2014a), and simulation and measurement results have been compared. Different thicknesses of insulating cotton fabric (0.25–5 mm) were placed between the antenna and human body. It can be observed that at around 900 MHz, the on-body read range varies between 1.5 m and 3.5 m, depending on the thickness of insulating layer, which is sufficient for short-range wireless identification and sensing applications.

Fabrication and Characterization of Embroidered RFID Tag Antennas

Fabrication and characterization of embroidered RFID tag antennas requires taking into account specific aspects, such as methods for modeling these antennas utilizing computational electromagnetic modeling methods and taking into account the physical behavior of current flows in the antenna structure. Different types of wearable RFID tags have been designed and explored in Choi et al. (2008), Yeonho et al. (2007), and Goojo et al. (2008). Authors of these studies have sewed the geometry of the tag antenna on textile with a computer-aided sewing machine using conductive threads. These studies explore the performance of sewed tag antennas and investigate the factors affecting the conductivity of the sewed antennas. According to the measurement results, the conductivity of sewed antenna improves by using highly conductive threads, increasing stitch and thread density, and also by choosing a sewing pattern that consists of sewed lines along the direction of the current flow. However, presented next is another approach to model and analyze the conductivity and performance of embroidered RFID tag antennas.

Fabrication and Read Range Performance

In designing an embroidery tag antenna with electromagnetic modeling tools, the complex embroidery pattern can be treated as a uniform conductive material layer when the pattern is sewed densely. Hence, it is the conductivity of an embroidery pattern that is the decisive factor in the simulation model of an embroidery antenna. This chapter focuses on wearable embroidered dipole-type UHF RFID tag antennas. The objectives of this chapter are to explain an estimation technique for the conductivity of embroidered RFID tag antennas and also to further investigate the factors affecting the conductivity and performance of sewed dipole-type tag antennas.

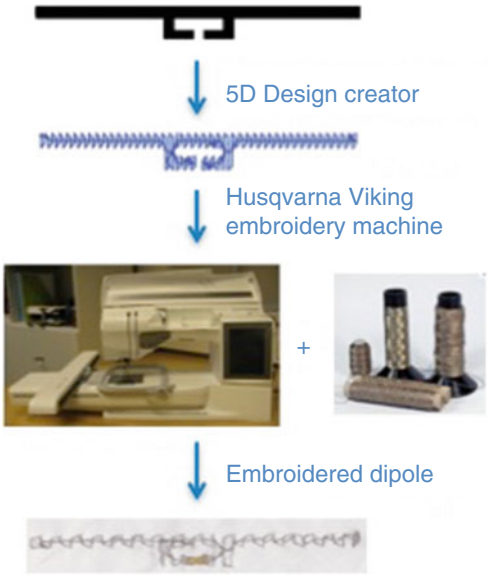

Fig. 4 Process of creating the embroidered antenna

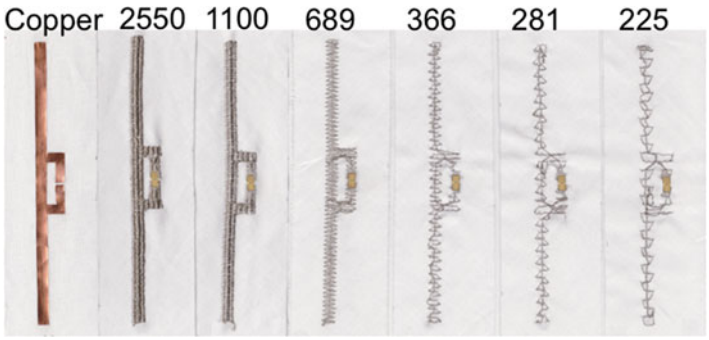

Fig. 5 Embroidered tags with different stitch densities and a copper reference tag. Numbers above the antennas refer to the number of stitches used to create the antenna

As presented in Fig. 4, the embroidery antennas are sewed with HUSQVARNA VIKING computer-aided sewing machine, using electric thread 110f34 dtex 2-ply HC. The thread has a weight of 110 dtex (dtex = g/10,000 m) raw yarn twisted with a second 110 dtex raw yarn to make a yarn of 220 dtex. Then the yarn is plated with silver to gain a weight of 275 dtex. The DC lineal resistivity of the thread is 500 ± 100 Ω/m, and the diameter is approximately 0.16 mm. The thread consists of 34 filaments in a yarn. The sewing pattern is created with 5D Embroidery System software. The software enables to control the stitching techniques and the stitching density when creating the sewing pattern. The file containing the created pattern is then transferred to the embroidery machine to be embroidered on cotton automatically. Figure 5 presents the embroidered dipole antennas. The created sewing pattern consists of a horizontal line along the length of the dipole and zigzags sewed vertically on it. The dipole with 2550 stitches has the highest zigzag density, and the dipole with 225 stitches has the lowest zigzag density. The rightmost tag is the copper-based reference.

The effect of the stitch and zigzag density on the performance of the antenna is investigated by embroidering six dipoles with different zigzag densities and measuring their performance in an anechoic chamber. The fully assembled tags are shown in Fig. 5 with the amount of stitches of each sewed tag written on top of it.

DOI 10.1007/978-981-4560-75-7_108-1

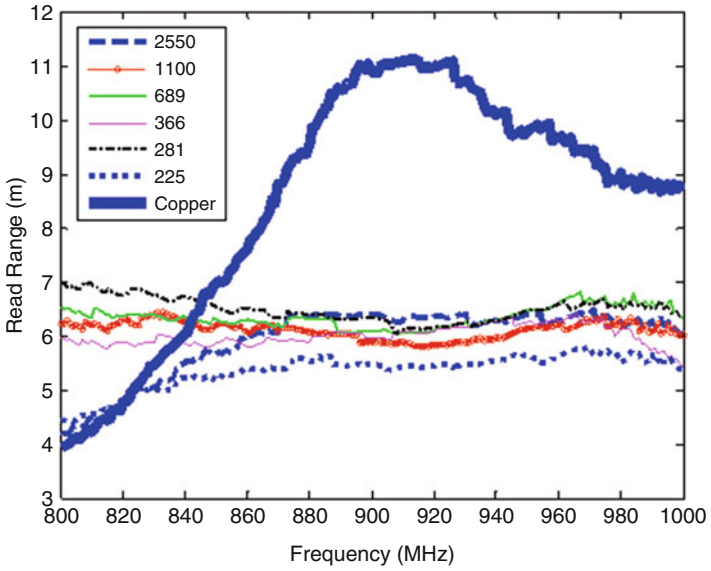

Fig. 6 Measured forward read range graphs of embroidered dipoles with different stitch densities

To characterize the performance of the embroidered dipoles, the maximum achievable read range (r_{max}) of the fully assembled tags using Voyantic Tagformance RFID measurement system was measured. In practice, the read range r_{max} is attained when the tag is located in the main beam of a reader antenna, which has its polarization perfectly aligned with the tag and is transmitting the maximum power allowed by the regulations. In this measurement configuration, the achievable read range is calculated based on Friis transmission equation as (Dobkin 2007)

$$r_{max} = \frac{\lambda}{4\pi}\sqrt{\frac{EIRP}{L_{fwd}P_{th}}}, \tag{1}$$

where λ is the wavelength, L_{fwd} is the measured linkloss factor from the output port of the generator to the input of a hypothetic isotropic radiator placed at the tag's location, P_{th} is the minimum transmitted power required to turn the tag IC on, and $EIRP$ is the regulated effective isotropic radiated power (EIRP). By definition, $EIRP$ is the amount of power that would be needed to put into an isotropic antenna to produce the same power density in the radiation field as was observed in the main beam of the directional antenna. In the European RFID band (865.7–867.6 MHz) $EIRP = 3.28$ W.

Figure 6 shows the measured read ranges of the tags in air shown in Fig. 5. Comparing the read ranges graph of the copper dipole with the corresponding graphs of sewed dipoles, it can be observed that in the case of sewed dipoles the frequency bandwidth is greatly increased. This is mainly due to the reduction of conductivity and quality factor of the sewed antennas. The achieved read ranges of the sewed tags range from 5.5 m to 7 m. This is competitive against the results reported in Choi et al. (2008), Yeonho et al. (2007), and Goojo et al. (2008) and without a doubt sufficient in many applications.

According to Fig. 6, the performance of sewed tags is fairly similar regardless of the zigzag density, and only when the amount of stitches is as low as 225, the performance starts to change noticeably. Thus, it can be deduced that antennas can be sewed sparsely to save materials and still achieve nearly as good performance as with antennas sewed with a high stitch and zigzag density.

Simulation Model and Effective Conductivity

For modeling the embroidery tag antennas, the effective conductivity of the embroidery pattern needs to be known. In this way the antenna can be modeled as a uniform conductor layer, and its performance can be optimized in a well-founded manner. This chapter presents a technique to evaluate the conductivity of sewed antennas based on the comparison between simulation and measurement results. This enables the design of antennas optimized for a given stitch pattern.

In order to find the conductivity of the embroidered antennas, the measured realized gain graphs of the embroidered antennas are compared with simulation results of the dipole with different conductivity values and thicknesses. The realized gain of the tag antennas can also be calculated based on link loss factor L_{iso}, IC sensitivity (i.e., the minimum input power required to activate the IC) $P_{ic,0}$, and the measured threshold power P_{th} results (Ukkonen et al. 2012):

$$G_{r,tag} = \frac{P_{ic,0}}{L_{iso}P_{th}}. \tag{2}$$

Realized gain takes into account the radiation efficiency of the antenna and power reflection coefficient, i.e., impedance matching with the RFID IC.

The thickness of embroidered antennas changes as a function of stitch density. When the amount of stitches and the thread density are high enough, in a sense that the sewed structure resembles a flat pattern, the thickness of the sewed structure can be talked about. But, when the sewed pattern is sparse, it is not convenient to talk about the thickness of it because the sewed structure is not flat and solid. Still, in simulator it is needed to define a thickness for the antenna material. Thus, the thickness of the sewed structure on the upper face of each tag is measured, and it is defined as the thickness of the conductive part of the antenna in ANSYS HFSS simulator. The measured thicknesses of the embroidered planar dipoles are listed in Table 1.

As illustrated in Fig. 6, the read range graphs of embroidered dipoles are located closely to each other. This might lead to a conclusion that the conductivities of embroidered antennas are almost the same too. However, when the varying thickness of the embroidered structure is considered, different conductivity values for each of them are achieved.

As illustrated in Fig. 7a, the simulated realized gain of the dipole with a thickness of 0.425 mm and conductivity of 2000 S/m matches with the measured realized gain of the sewed dipole with 2550 stitches. Thus, it can be deduced that the conductivity of this sewed dipole is 2000 S/m. Similarly, Fig. 7b shows simulated realized gain of the dipole with different conductivities and measured realized gain of sewed dipoles with 1100 and 689 stitches. In this case, in simulations, the thickness of the dipoles is set to 0.2 mm. According to Fig. 7b, the conductivity of sewed dipoles with 1100 and 689 stitches varies from 3000 S/m to 5000 S/m. Figure 7c shows simulation results and measurement results of sewed tag antennas with 366, 281, and 255 stitches. In this case, in HFSS model, the thickness of the dipole is 0.1 mm, which causes higher conductivity values than before. According to this figure, the conductivity of these tag antennas varies from 6000 S/m to 9000 S/m.

According to these results, the effective conductivity of the embroidered dipoles decreases as the thread density and the thickness of the sewed pattern increases. There is only a little performance deviation between the embroidered dipoles with 281–2550 stitches, while they have different thicknesses. Thus, the

Selected Case Studies

Embroidered Patch-Type Textile Antennas in Wireless Body-Centric Applications

Performance of dipole-type antennas is relatively sensitive to the presence of human body, due to absorption of electromagnetic energy by biological tissue (Ukkonen et al. 2012). Patch-type antennas with ground plane offer an alternative with less sensitivity to the materials the antennas are mounted on (Hall and Yang 2012; Ziai and Batchelor 2010). Moreover, utilization of different electro-textile approaches provides novel ways to construct flexible, garment-integrated antennas. Electro-textiles are becoming widely used in body-centric sensing systems as wearable antenna materials, thanks to their suitable radio-frequency (RF) performance, flexibility, and durability (Wang et al. 2013; Ouyang and Chappell 2008; Bayram et al. 2010). Electro-textiles typically refer to a group of electrically conductive textiles. These are created either by using conductive sewing threads in a computer-assisted embroidery machine (Ouyang and Chappell 2008; Koski et al. 2012; Wang et al. 2012) or by plating or interpolating a nonconductive fabric surface with an alloy of metals or with pure metal (Locher et al. 2006). The embroidered textile always results in an anisotropic pattern, in which the conductivity is strongly dependent on the direction of the current flow in the pattern, pattern geometry, and stitching density of the pattern (Koski et al. 2013a; Moradi et al. 2012). The different types of electro-textile ground planes for wearable patch antennas are presented in Fig. 8.

Electro-Textile Ground Plane and Top Radiating Patch Characterization

An efficient and proper ground plane provides important antenna-to-body isolation and reduces the body effects on the antenna performance (Hall and Yang 2012). A patch-type tag will concentrate its radiated energy away from the ground plane, and hence, less energy is lost in the human body and the overall radiation efficiency is enhanced. Therefore, a patch antenna is a potential choice for wearable antenna applications.

As new unconventional materials for wearable antennas are emerging, it is of paramount importance to characterize their applicability as antenna ground plane and top patch structures. From the modeling point of view, all electro-textiles may be considered as infinitely thin dissipative dielectric materials and characterized with the complex sheet impedance parameter $Z_S = R_S + jX_S$. Depending on the

DOI 10.1007/978-981-4560-75-7_108-1

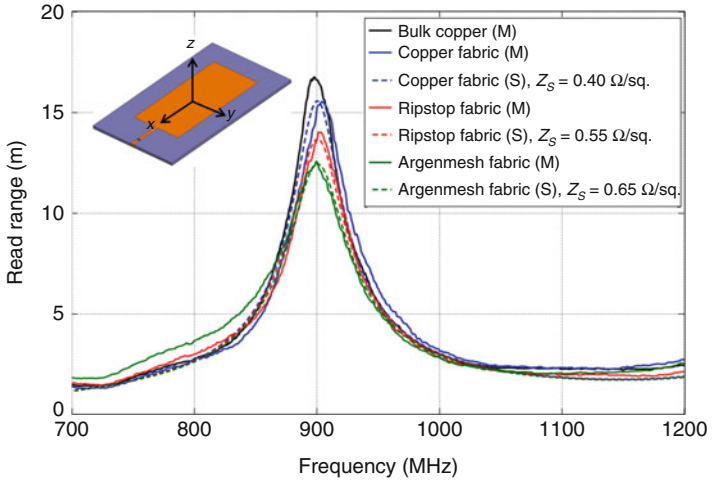

Fig. 9 Measured (*M*) and simulated (*S*) read range in air in + *z* direction for a patch tag antenna with conductive fabric ground plane. No impedance detuning is encountered; the conductive fabrics may be approximated as conductors whose sheet impedance is purely real. Also, the measured E-plane power patterns show low antenna back lobe levels for the conductive fabrics

electro-textile structure and on the implementation of the metallization, the sheet impedance is either purely real or complex. When the electro-textile does not affect the antenna input impedance, the sheet impedance imaginary part is negligible. This is the case for pure conductors and most conductive fabrics (e.g., the copper and silver fabrics in Fig. 1). As Fig. 9 shows, the copper and silver fabrics (ripstop and argenmesh) do not cause any impedance detuning compared to a bulk copper, and hence, their sheet impedance is purely real.

For embroidered structures, the sheet impedance is always complex. The imaginary part accounts for the increased antenna electrical length, which results from the increased current path length in the embroidery. Therefore, the embroidered structure increases the antenna input inductance, and as a consequence, the antenna resonance is shifted toward lower frequencies compared to a bulk copper antenna. The magnitude of the imaginary part is determined by the embroidered structure shape, size, and density. In Figs. 10 and 11, the sheet impedance for different embroidered ground planes and top patches, respectively, are determined.

When the embroidered structure shape and size are fixed, the imaginary part of the sheet impedance is directly proportional to the embroidery density. In Fig. 12, this relation is evidenced for the embroidered ground planes G1–G3 and top patches T1–T2.

When the current path length in the embroidered ground plane structure becomes long, the amount of back radiation is increased. This is demonstrated in Fig. 13.

Realizing Fully Wearable Embroidered Patch Antenna

The electro-textile sheet impedance is required in the design and optimization of wearable antenna to properly account for the electromagnetic effects induced by the material. In Fig. 14, a fully wearable embroidered antenna is implemented using the G6 and T2 embroideries. The bandwidth of the regularly shaped patch antenna is directly proportional to the substrate thickness and inversely proportional to the square root of its dielectric constant (Kumar and Ray 2003). Therefore, a thicker substrate with a low dielectric constant is generally preferred. For better radiation efficiency, a low-loss dielectric substrate is desired. The 3-mm-thick EPDM (ethylene propylene diene monomer) foam serves as a suitable wearable antenna platform.

DOI 10.1007/978-981-4560-75-7_108-1

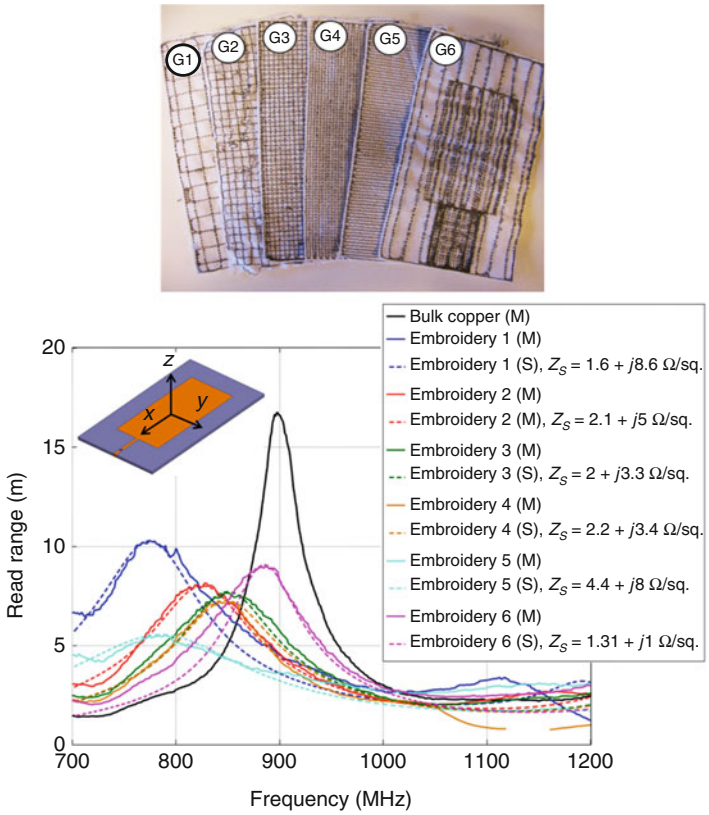

Fig. 10 Measured (*M*) and simulated (*S*) copper tag antenna read range in air in + *z* direction with embroidered ground plane. When the current path length in the ground plane is long, the impedance detuning becomes significant, and the electro-textile sheet reactance becomes large. The electro-textile sheet resistance and reactance values are minimized by optimizing the thread density according to the simulated surface current density in the copper tag antenna ground plane (embroidery 6)

The performance of the wearable embroidered antenna is presented in Fig. 15. The read range is relatively stable over the observed frequency range. At 900 MHz, the antenna achieves 3-m read range in air. When the antenna is operated near the human body, the high-permittivity human tissues are expected to shift the resonance back to the RFID band. The antenna achieves extremely low back lobe level, which is required for a good antenna-to-body isolation. Most importantly, Fig. 15 provides a strong indication that a complex sheet impedance is required to properly account for the electromagnetic effects induced by the conductive fibers.

In the future, embroidery techniques enable seamless and robust integration of antennas with clothing, which promote the industrial and public acceptance of the technology.

Wearable Embroidered Patch Antenna Performance in Close Vicinity of the Human Body

The desired wearable antenna performance must be guaranteed in close vicinity of the human body. Therefore, every design process of a wearable antenna should involve a verification step in which the antenna is measured on the human body. The embroidered antenna was measured on the human arm (Koski et al. 2014b). The antenna was separated from the arm with a 0.7-mm-thin tight shirt. The body effects are more prominent when the antenna-to-body separation is small. A thin shirt was chosen to evaluate a worst case scenario.

Comparing the performances in Figs. 15 and 16, it is evident that the antenna features inherently excellent antenna-to-body isolation. Further, the relatively flat read range response points out that the antenna's input impedance is not critically affected by the human body. At 900 MHz, the antenna's

on-body read range exceeds 3 m, which sets a benchmark for future wearable embroidered antenna designs.

Embroidered On-Body Antenna for Communication with mm-Size Implants

In this section, the feasibility of using flexible electro-textiles in the realization of transmitting loop antennas for wireless brain-machine interface (BMI) systems is explored. For this purpose, both embroidered and commercially available textiles are considered. The neural implant requires a transmitting

antenna outside the human body to establish the wireless body-centric communication link. This antenna should be comfortable to wear, low profile, and optimized for strongest possible coupling to the implant antenna. These requirements are addressed in this section.

Modeling of Antennas and Wireless Link

Powering and communicating with mm-size battery-free cortical implants require transmitting antennas achieving high link power efficiency without violating SAR limits. In addition, the on-body transmit antenna should fulfill the requirements of wearable antennas, having compact size and being flexible, lightweight, and even washable. Electro-textile materials provide compelling means for conformal wearable antennas. Neural implants require a transmitting antenna outside the human body to establish the wireless body-centric communication link. This antenna should be comfortable to wear, low profile, and optimized for strongest possible coupling to the implant antenna. The feasibility of using flexible electro-textiles in the realization of transmitting loop antennas for wireless BMI systems is explored and explained in this section. For this purpose, both embroidered and commercially available conductive textiles will be considered.

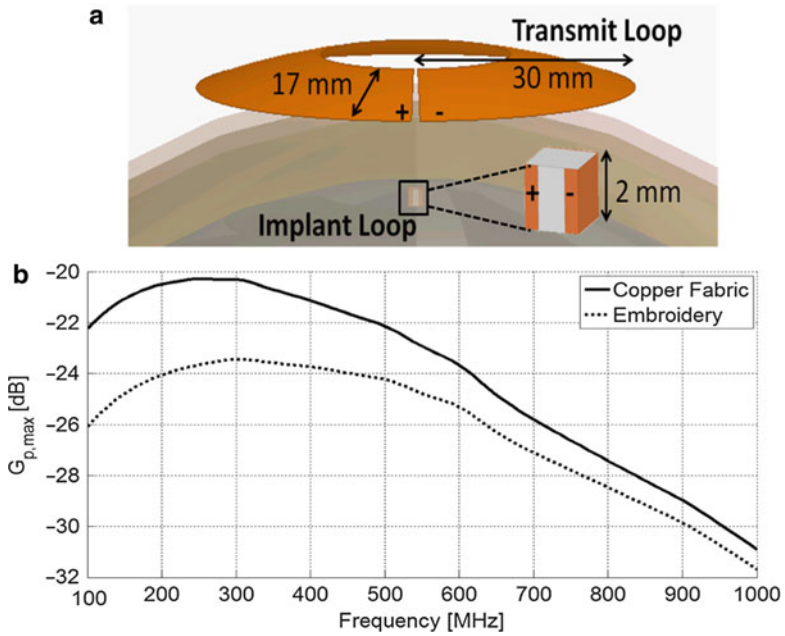

Fig. 17 (**a**) Conformal model of the electro-textile transmit antenna coupled to a mm-size cubic loop. The wireless channel model consists of four spherical layers of tissues. (**b**) Simulated maximum operating power gain of both electro-textile transmit antennas coupled to the SMMDF101 cored $2 \times 2 \times 2$ mm^3 implant antenna

Small mm-sized loop antennas are capable of coupling to an external transmitting loop efficiently through an inductive link in frequencies ranging from hundreds of megahertz to low gigahertz. Analyzing the inductive link as a two-port network allows us to compute the link power efficiency as the maximum operating power gain of the two-port system:

$$G_{p,\,max} = \frac{|Z_{12}|^2}{S + \sqrt{S^2 - |Z_{12}Z_{21}|^2}}, \tag{2}$$

$$S = Re(Z_{11})Re(Z_{22}) - Re(Z_{12}Z_{21}),$$

where $G_{p,max}$ is the maximum operating power gain and Z_{xy} are the two-port system Z-parameters (Moradi et al. 2013). This is the ratio of the power received by the implant IC to the power transmitted by the transmit antenna.

In practice, for the user's comfort, the low-profile transmitting loop needs to be flexible and wearable. Therefore, transmitting loops made of electro-textiles were designed. Copper fabric and an embroidered structure were considered. The electro-textile-transmitting loops were modeled as infinitely thin conductors having the sheet resistance as the only material parameter. The copper fabric and the embroidered pattern were assigned sheet resistance values of $R_S = 0.4\ \Omega/\square$ and $R_S = 1.25\ \Omega/\square$, respectively. These values were determined through wireless reflectometry measurement (Koski et al. 2013b). A flexible cotton fabric ($\varepsilon_r = 2.2$, $\tan\delta = 0.08$) was chosen as the substrate material for both wearable antennas.

Conformal transmitting loops were designed for coupling with a $2 \times 2 \times 2$-mm^3 copper cubic loop with a magnetodieletric core (SMMDF101, $\varepsilon_r = 18$, $\mu_r = 17.5$, $\tan\,\delta_{magn} = 0.15$, $\tan\,\delta_{diel} = 0.02$ at 300 MHz). In simulations, a spherical human-head model (Fig. 17a) with an outer diameter of 9.2 cm was used. The spherical model consisted of 2-mm skin, 2-mm fat, 7-mm bone, and brain layers. Previous studies have shown that small mm-size loop antennas are capable of coupling to an external transmitting

loop efficiently through an inductive link in frequencies ranging from hundreds of MHz to low GHz (Yakovlev et al. 2012). Simulations showed that at 300 MHz, the optimized dimensions of the transmit loop with both sheet resistances are the same. The optimized inner radius was 13 mm and the trace width was 17 mm. The simulated wireless link performance is shown in Fig. 17b. At 300 MHz, the peak $G_{p,max}$ of copper fabric (−20 dB) is approximately 3 dB higher compared to that of the embroidered pattern (−23 dB). It is worth noticing that the link power efficiency achieved by the wearable transmit antennas is lower than that achieved by an optimized bulk copper antenna made on solid substrate ($G_{p,max} = -15.6$ dB) (Moradi et al. 2013). However, when using wearable antennas, the received power P_L is in the same order as using a copper transmit antenna. It means that the wearable loop antennas can provide similar powering performance as the bulk copper loop at the expense of a bigger size and higher energy consumption. As presented in Fig. 16, at 300 MHz, the link power efficiency of embroidered transmit antenna is approximately 3 dB lower than that of the copper fabric antenna.

DOI 10.1007/978-981-4560-75-7_108-1

Fabrication and Measurements

The electro-textile antennas were fabricated and experimentally characterized. As the conductive fabric, the commercial conductive textile from LessEMF, pure copper taffeta fabric (35 % copper), was chosen. The embroidered antenna was sewed with HUSQVARNA VIKING computer-aided sewing machine using the conductive thread Shieldex 110f34 dtex 2-ply HC. The embroidered pattern is composed of circular lines of conductive thread sewn along the loop. The stitching density along the loop radius was set equal to 1 line/mm to achieve a sheet resistance of 1.25 Ω/□. The implant antenna was a $2 \times 2 \times 2$ mm^3 SMMDF101 cored cubic loop. It was fabricated using a 50-μm-thick copper tape. The accuracy of VNA is best around 50 Ω, which is the characteristic impedance of its ports. Therefore, additional circuit board fixtures to impedance-match the designed antennas to 50 Ω were fabricated. Figure 18 presents the fabricated components.

Both in-air and in-liquid measurements were conducted. In the latter case, the implant antenna was immersed in human-head equivalent liquid phantom provided by SATIMO. The liquid phantom had similar dielectric properties to those of human head at 300 MHz, following the IEEE standards ($\varepsilon_r = 44.32$, $\sigma = 0.83$ S/m). The implant loop was measured in air with both electro-textile transmit loops at a fixed distances of 16 ± 1 mm. In the *in-liquid* measurements, the implant was placed 11 ± 1 mm beneath the liquid surface, and the transmit loop was 5 ± 1 mm above the liquid surface. These distances were chosen to match with the distances used in the layered human-head model (2-mm skin + 2-mm fat + 7-mm bone = 11 mm). The link power efficiencies between the antennas were computed based on the measured *S*-parameters. Results of both *in-air* and *in-liquid* measurement setup are shown in Fig. 18. In all cases, the peak $G_{p,max}$ is achieved at 305 MHz, near the predicted matched frequency. The link power efficiency of the copper fabric transmit loop at 305 MHz was −9.62 dB and −14.6 dB when the implant was placed in air and in liquid, respectively. Concerning the embroidered prototype, a 3-dB lower peak value of $G_{p,max}$ was measured (−12.3 dB in air, −17.1 dB in liquid), thus confirming the previous simulation results (Fig. 18). Around the matched frequency, simulations are in good agreement with measurements. The maximum difference between the peak values is less than 1.4 dB. This is likely due to the fabrication tolerance and the variability of the discrete components (e.g., capacitors with 5 % tolerance). Overall, the achieved results clearly demonstrate the ability to accurately predict the coupling between the two antennas. The measured peak values of $G_{p,max}$ were significantly higher than those computed by considering only the antennas. This means that the presence of the test boards created an additional coupling mechanism. Hence, the proposed full model enables to evaluate, compensate, and eventually remove the measurement artifacts introduced by the test boards in order to estimate the power that can be delivered to the neural IC in real applications.

Conclusion

Wireless body-centric identification and sensing systems hold an enormous potential to revolutionize wearable intelligence by extending the functionality of advanced garments. Groundbreaking application systems include wireless brain-machine interfaces, which have the potential to revolutionize the treatment of severe neurological conditions, such as paralysis and epilepsy. There are several specific requirements for on-body and implant antennas and their communication: on-body antennas have to be lightweight, conformal, easy to integrate into clothing, and as immune as possible to the performance-degrading effects of human body. When implanted systems are considered, communication link between the on-body and implant antennas has to be as efficient as possible, but at the same time power transmission regulations must be obeyed. Moreover, implants and thereby implant antennas are intended to be as small as possible, and therefore the on-body textile antennas have to be able to efficiently communicate with

DOI 10.1007/978-981-4560-75-7_108-1

mm-size implant antennas. Electro-textiles are becoming widely used in body-centric sensing systems as wearable antenna materials thanks to their suitable RF performance, flexibility, and durability. Electro-textiles typically refer to a group of electrically conductive textiles. These are created either by using conductive sewing threads in a computer-assisted embroidery machine or by plating or interpolating a nonconductive fabric surface with an alloy of metals or with pure metal. In this chapter, the above challenges have been addressed by presenting methods for modeling and characterization of embroidered UHF RFID tag antennas, creating totally embroidered wearable patch-type antennas and co-designing textile-based transmit antenna and mm-size implant antenna for challenging wireless brain-machine interface systems.

Three-Dimensionally Printed/Additive Manufactured Antennas

Min Liang* and Hao Xin
Department of Electrical and Computer Engineering, University of Arizona, Tucson, AZ, USA

Abstract

Additive manufacturing (AM), or often referred to as three-dimensional (3D) printing, is an important emerging research area which has received much attention recently. It allows 3D objects with arbitrary geometry to be printed automatically layer by layer from bottom to top. This technology offers several advantages compared to conventional manufacturing techniques including the capability of more flexible design, prototyping time and cost reduction, less human interaction, and faster product development cycle. 3D printing techniques have been applied in many different sectors including mechanical engineering, electrical engineering, biomedical engineering, art, architecture, and landscaping. This chapter reviews state-of-the-art 3D printed antennas from microwave to THz frequencies and offers practical and futuristic perspectives on the challenges and potentials of 3D printed antennas. An overview of various 3D printing techniques relevant to antenna applications is presented first. A number of 3D printed antenna examples categorized by different AM methods are then described. Finally, technical challenges and possible solutions of 3D printing technology specific to antenna application, as well as new and revolutionary antenna design/realization concepts enabled by 3D printing technology, are discussed.

Keywords

Additive manufacturing; 3D printing; Computer-aided design; Automatic fabrication

Introduction

Additive manufacturing (AM), often called “3D printing” or “rapid prototyping”, is an automated fabrication technology to make a three-dimensional physical object directly from digital data. Contrary to the subtractive manufacturing which realizes a product by subtracting a material from a larger piece of material such as cutting out a screw from a piece of metal, it makes a product layer by layer additively.

AM was originated in the United States and was first commercialized in the late 1980s. At that time, it was called “rapid prototyping (RP)” or “generative manufacturing” (Gebhardt 2012), and these terms are still occasionally in use presently. In the early 1990s, several different AM processes including laser sintering (LS) (Agarwala et al. 1995) and fused deposition modeling (FDM) (Griffin and McMillin 1995) were developed and became available commercially. In the mid-1990s, another 3D printing process which creates an object by jetting a liquid binder onto a bed of powder and doing post-processing to solidify the whole structure was invented (Bak 2003). After that, through the rest of the 1990s, further research and development were mainly focused on materials such as various thermoplastics (Kambour 1973) and elastomeric polymers (Kornbluh et al. 2000) in different forms to enable AM techniques to be used in more applications. As the new century begins, the focus was shifted back to improving the AM technology by developing new printing processes. New techniques such as the laser melting (LM) and

Handbook of Antenna Technologies
DOI 10.1007/978-981-4560-75-7_109-1

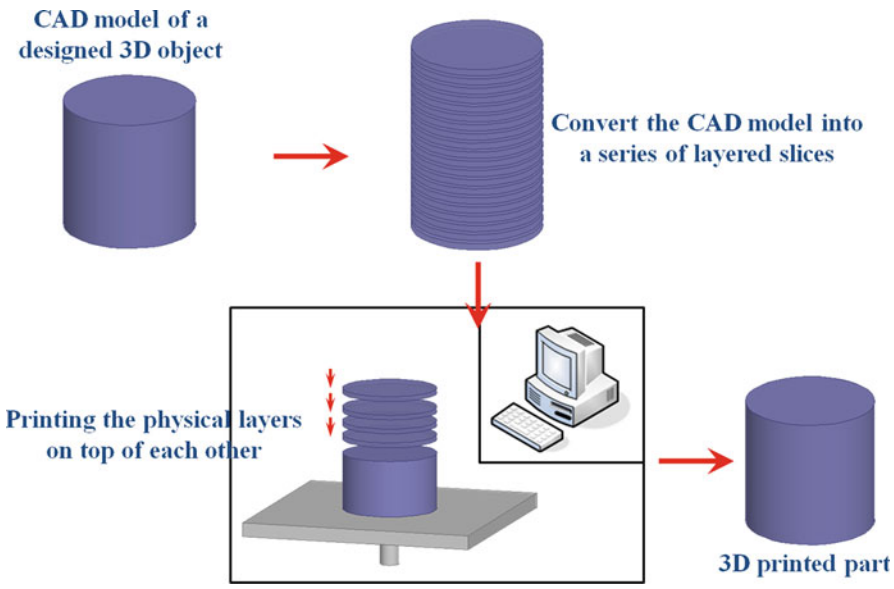

Fig. 1 Schematic illustration of a typical AM process

electron beam melting (EBM) processes were developed. These techniques allow various alloyed materials to become available in the AM process. Over subsequent years, more and more AM companies are founded from all over the world and starting to develop their own printable materials and AM systems. Many new types of materials and systems become available as the demand for AM increases. It is realized that these techniques are not just for rapid prototyping; instead, they can be developed and applied as a new form of manufacturing technology. Therefore, from then on, the name "additive manufacturing" has been coined. Recently, AM has received much attention with impressive demonstrations ranging from musical instruments, to vehicles, to housing components or even entire buildings. Many different structural materials such as metal, polymer, ceramics, concrete, and even biocompatible materials have been incorporated in various 3D printing technologies. Due to its ability to realize desired structures with arbitrarily designed spatial distribution, 3D printing technology has been argued to be the future of manufacturing as it offers huge potentials to revolutionize both the design and manufacturing procedures.

The technical realization of AM is based on layer-by-layer processes, and therefore it is called "layer-based technology" or "layer-oriented technology." The working principle of the layer-based techniques is to create a 3D physical structure from many slices with the same thickness. Each slice is fabricated according to the information from the corresponding 3D model and placed on top of the pervious layer. A schematic illustration of a typical AM procedure is shown in Fig. 1. The process starts with a 3D computer-aided design (CAD) model which represents the 3D object to be printed. This CAD model can be created directly from CAD software or by digital 3D scanning of a real structure. After the CAD model is obtained, specialized software is used to slice the model into layer-by-layer cross sections. As a result, a series of layered slices with equal thickness are generated. The information of these slices including position, layer thickness, and layer number is sent to a machine that could print each layer and bond it to the previous one. The printing and bonding of the layers can be done in many ways based on different physical phenomena. By printing the object layer by layer, the entire structure is built from bottom up.

These basic steps are the same for almost all varieties of AM equipment available today. The differences of different equipment are how they generate the layers, how the adjacent layers are joined together to form the final part, and the corresponding built materials.

Compared to conventional manufacturing methods (such as injection molding, casting, stamping, and machining), the AM approach has the following advantages.

DOI 10.1007/978-981-4560-75-7_109-1

Arbitrary Complexity

AM approach has the ability to create 3D objects with arbitrary shape and complexity. The cost of the 3D printed components is only related to the volume of the parts; there is no additional cost or lead time for making the structure more complex. Also, with multiple printing heads, it is possible to cohesively integrate different materials at the same location simultaneously. Therefore, AM may revolutionize product designs because of the much more flexible object geometry and material property distribution it offers. For example, 3D structures with arbitrary EM property distribution can be printed relatively easily.

Digital Manufacturing

After an object is designed, the whole 3D printing process is accurately controlled by a computer with very little human interaction needed to realize the design. This automatic 3D printing process means that the time between design iterations can be dramatically reduced compared to conventional manufacturing methods.

Waste Reduction

The 3D printed component is created bottom up via layer-by-layer processes so that only materials needed for the design are used. Therefore, material waste in AM process will be much less than conventional subtractive manufacturing techniques.

Various 3D printed antennas have been reported taking advantages of the AM technology. Antennas of different structures such as horn antennas (Huang et al. 2005), patch antennas (Liang et al. 2014a), meander line antennas (Adams et al. 2011), gradient index (GRIN) lens antennas (Liang et al. 2014a), and reflect-array antennas (Nayeri et al. 2014), made of different materials such as all-dielectric antenna (Wu et al. 2012), all-metal antenna (Garcia et al. 2013), and dielectric-metal combined antenna (Liang et al. 2014; Adams et al. 2011; Nayeri et al. 2014), working at different frequencies from GHz to THz, have been realized using different 3D printing techniques. In the next section, an overview of various AM techniques relevant to antenna application is provided, and the pros and cons for each are discussed.

Overview of 3D Printing Techniques

At the present time, there are many kinds of 3D printing techniques, all of which follow the basic steps of AM discussed in the previous section, for example, generating individual physical layers and combining them together. Various materials such as metal, plastic, ceramics, or even biocompatible materials can be used in the generation of the physical layers. According to the methods of generating physical layers and bonding adjacent layers together to form an object, five basic categories of AM processes are commercially available (Gebhardt 2012), including selective sintering and melting, powder binder bonding, polymerization, extrusion, and layer laminate manufacturing (LLM). Key aspects of these five processes are discussed and some commercially available 3D printers as well as printed examples are reviewed.

Selective Sintering and Melting

The 3D printing technique using a laser to selectively sinter or melt powdered material is called selective laser sintering (SLS) (Agarwala et al. 1995) or selective laser melting (SLM) (Kruth et al. 2004). If an electron beam is used instead of laser, the process is called electron beam melting (EBM) (Cline and Anthony 1977).

An SLS printer usually includes a building chamber to be filled with powdered built material and a laser beam on top that can be scanned precisely in the XY (horizontal) plane. The bottom of the chamber is

DOI 10.1007/978-981-4560-75-7_109-1

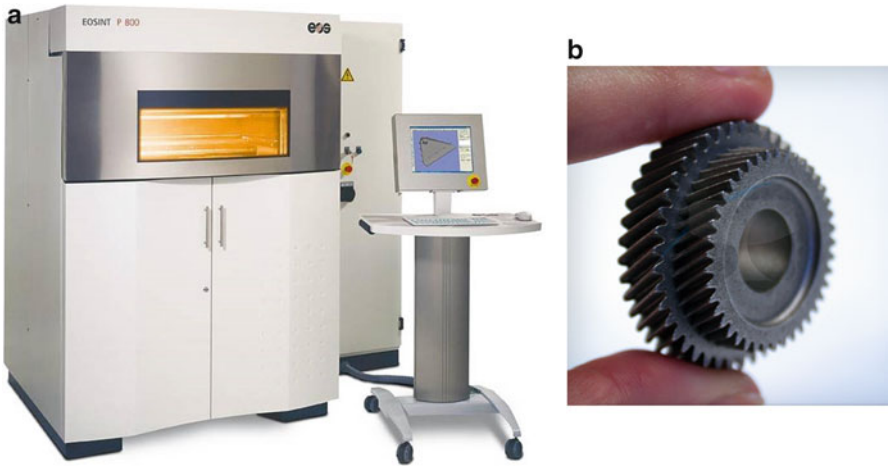

Fig. 2 (**a**) Photo of a selective laser sintering printer (*SLS*) (model EOS P800; size: 2.25 m × 1.55 m × 2.1 m). (**b**) An SLS printed metallic object

moveable in the Z (vertical) direction. During the printing process, the entire chamber is heated to a high temperature close to the melting point of powder so that they are at an optimal temperature for melting. To prevent oxidation, the chamber is often filled with shielding gas (e.g., nitrogen). The scanning laser beam is then used to fuse the powders at designated locations. As the laser beam travels in the XY plane, the melted powders cool down and solidify. After the scanning of an entire layer at designated positions, a solid layer with designed pattern is achieved. After one layer is printed, the powder bed is lowered by the amount of one layer thickness and an automated roller adds a new layer of powdered built material on the top of the previous layer. Then the selective melting process repeats until the entire object is printed. The remaining unsolidified powders are then removed after printing. The SLS technique is quite versatile since it can be used to print several classes of materials, including plastics, metals, and ceramics.

Typically, SLS-fabricated metal parts such as steel and titanium are dense. They may be post-processed by cutting or welding, depending on specific materials involved. Plastic parts such as nylon and polystyrene fabricated using SLS have properties similar to those made by plastic injection molding. As an example, Fig. 2 shows an SLS printer (EOS P800) and a metallic part made by using SLS.

Selective laser melting (SLM) is developed in particular to process metal parts that need to be very dense (>99 %). In this case, the laser beam melts the metal powders completely into liquid phase which results in a close to 100 % density part after resolidification. SLM can be used to print many metals including stainless steel, carbon steel, CoCr, titanium, aluminum, gold, and a large variety of alloys.

EBM is a similar 3D printing process in which metal powders are melted or fused by applying an electron beam under a high voltage (typically in the range of 30 ∼ 60 KV) instead of a laser beam. To avoid oxidation, the process is performed in a high-vacuum chamber. Because the electron beam penetrates much deeper than a laser beam, EBM allows a higher scanning speed. In addition, deeper penetration can be used for powder preheating so that the printing process works at elevated temperatures compared to the laser case. As a result, the mechanical stress and distortion of printed objects are reduced and greater strength can be achieved. Figure 3 shows an example of an EBM 3D printer and a 3D printed object using EBM technique.

Sintering and melting processes are very suitable for applications requiring high strength and/or high temperature. Antennas printed by SLS or EBM can be very dense, void-free, and very strong. The disadvantages of selective sintering and melting techniques are that the printing resolution is limited by the size of the powders (i.e., tens of microns) and a high-vacuum chamber or shielding gas is needed to avoid oxidation (Kruth et al. 2003).

Powder Binder Bonding

Powder binder bonding is another 3D printing technique that implements layer-by-layer bonding of powdered materials by selectively injecting a liquid binder onto the powder bed. This process was first developed in the mid-1990s. Currently, various materials such as plastics, metals, and ceramics can be printed using this technique.

A typical powder binder bonding printer is very similar to a selective laser sintering printer with a piston at the bottom of chamber to adjust the height and a roller to recoat the powders. The printing process starts with depositing small drops of liquid binder onto a layer of built material powders at designated locations. The powders forming the designed structure are bounded together while the surrounding loose powders support the next layer of the structure to be printed. The printing process is then repeated for each layer until the entire structure is completed. Compared to the sintering or melting process, this process is performed at much lower temperature. Therefore, no preheating, shielding gas, or vacuum chamber is needed.

At the end of the printing process, the residual powders are removed and an infiltration process may be performed for enhanced durability. For plastic parts, wax or epoxy resin can be used in the infiltration process. If this technique is used to print a metallic antenna (Lopez et al. 2013), a subsequent high-temperature process is needed to provide strength and durability. For example, to print a bronze object, the

DOI 10.1007/978-981-4560-75-7_109-1

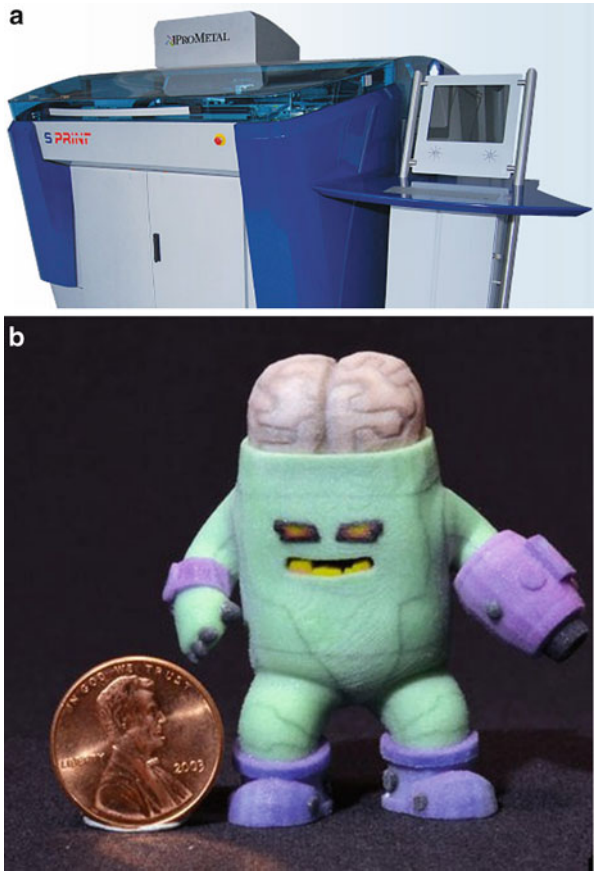

Fig. 4 (**a**) Photo of a powder binder bonding 3D printer (model ProMetal S15; size: 3.1 m × 3.4 m × 2.2 m). (**b**) An example printed using the powder binder bonding technique

printed part needs to be infused into bronze powder and heated up to more than 1,000 °C to replace the binder with bronze (Lipkea et al. 2010). This process can also be used to print alloy materials by changing the sintering temperature and time during the infiltration process (Kruth et al. 2005). Figure 4 shows a powder binder bonding 3D printer and an example printed using this technique. Similar to the sintering and melting processes, the resolution of this technique is also limited by the size of the powders. For the currently available printer on the market, the minimum feature size is 0.1 mm.

Polymerization

Polymerization is a process that selectively solidifies liquid resin using ultraviolet radiation or other power sources. Typically, photosensitive polymers are used as built material. There are several kinds of AM methods based on the polymerization process. Their differences are mainly in how the photon energy is applied and how the layers are created.

Stereolithography is the most accurate polymerization process which employs an ultraviolet laser to solidify a liquid ultraviolet curable polymer. To print each layer, a laser beam scans over the surface of a liquid polymer reservoir to cure the cross section according to the designed pattern. The curing thickness can be adjusted by the laser power and laser scanning speed. After one layer is printed, the building stage descends a distance of one layer thickness. Then, a blade sweeps across the surface of the printed part, recoating it with fresh liquid polymer before the next layer is printed on top. It is possible to incorporate different materials in the printing process, thus achieving multiple material stereolithography (Gebhardt 2012). In this case, the resin needs to be drained and replaced by the new material. After an object is

DOI 10.1007/978-981-4560-75-7_109-1

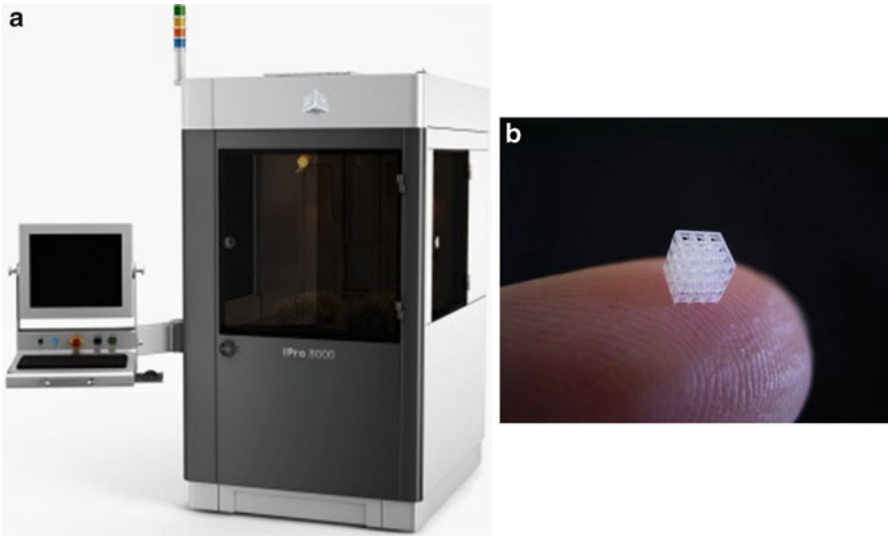

Fig. 5 (**a**) Photo of a laser stereolithography 3D printer (model systems iPro™ 8000; size: 1.26 m × 2.2 m × 2.28 m). (**b**) A sample fabricated using stereolithography technique

printed, it is cleaned and moved into a UV chamber for a final post-curing process to make it more stable. Figure 5 shows a stereolithography 3D printer example and an object realized by stereolithography. Compared to other AM techniques for 3D printing of antennas, the stereolithography process can achieve a very good surface smoothness and finer resolution. In fact, a two-photon stereolithography process has been reported to obtain a submicron printing resolution (http://www.nanoscribe.de/en/). However, the strength of a 3D printed part by stereolithography is weaker than other techniques such as sintering, melting, or powder binder bonding.

If a photosensitive polymer is applied by printer heads, the AM process is called polymer jetting. During printing, the printer head deposits photosensitive polymers onto a stage with designed patterns. Upon jetting, the printed photosensitive polymers are immediately cured by an ultraviolet lamp on the printer head and unlike stereolithography, no post-curing process is needed. The thickness of each layer of this process can be on the order of 20 μm, which provides a very smooth surface. Moreover, multiple types of polymers can be printed simultaneously using multiple printer heads. A gel type of polymer can be used as support material to print overhanging structures and released (e.g., water-soluble support materials can be washed away) after the printing process. A schematic drawing of the polymer jetting procedure is shown in Fig. 6. The polymer jetting method can only be applied to print polymers, limiting its applications to all-dielectric antennas. An additional metallization process would be required to incorporate the conductor part. It has a better resolution than sintering and powder binder bonding techniques. However, similar to stereolithography, parts printed by polymer jetting are not as strong as some of the other AM techniques.

Extrusion

Extrusion, often called fused deposition modeling (FDM), is an AM process that prints an object by extruding thermoplastics through a heated nozzle. A FDM printer includes a feeding roll, a heated extrusion head, and a building platform. The building materials are usually thin thermoplastic filaments which are wound up and stored in a cartridge. The thin thermoplastic filament is guided into the extrusion head by the feeding roll. During the printing process, the heated extrusion head melts down the filament

DOI 10.1007/978-981-4560-75-7_109-1

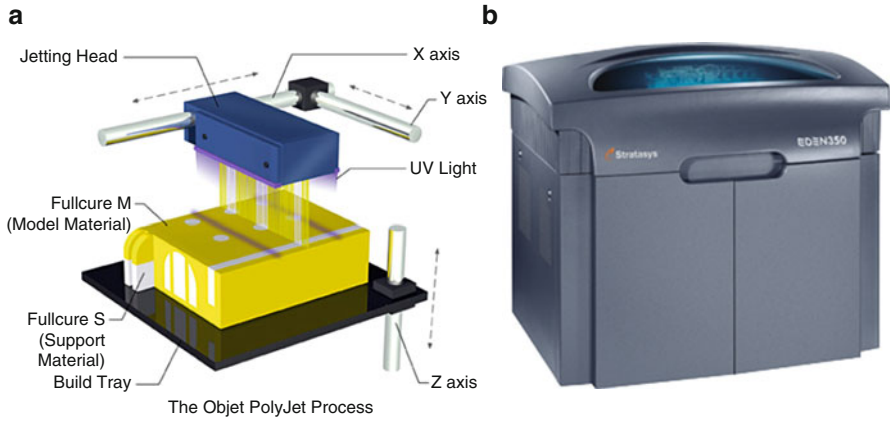

Fig. 6 (**a**) Schematic picture of the polymer jetting technique. (**b**) Photo of a polymer jetting 3D printer (model Stratasys Eden350V; size: 1.3 m × 1 m × 1.2 m)

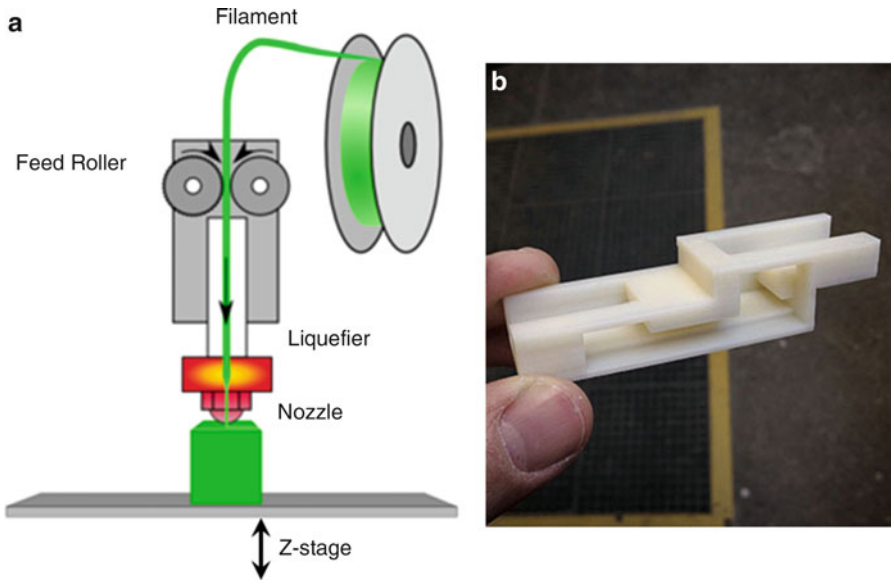

Fig. 7 (**a**) Schematic of FDM. (**b**) An example printed using FDM

and extrudes it through the nozzle at designated locations on the building platform. When the extruded thermoplastic reaches the building platform, it cools down and hardens. After one layer is completed, the platform lowers down by one layer thickness and is ready for printing of the next layer. Figure 7 shows the schematic of an FDM printer and a printed example.

There are a number of available built materials for FDM including polycarbonate (PC), acrylonitrile butadiene styrene (ABS), polyphenylsulfone (PPSF), etc. The advantages of using this technique to print antennas are the relatively simpler processing (i.e., no post-processing needed) and lower printer cost compared to other AM techniques. The disadvantage of FDM is lower resolution (about 0.25 mm (Wong and Hernandez 2012)).

Layer-by-Layer Bonding

Layer-by-layer bonding is an AM technique that creates a 3D structure by cutting a prefabricated sheet or foil into a designed contour and subsequently bonding a number of layers together. It is often called

DOI 10.1007/978-981-4560-75-7_109-1

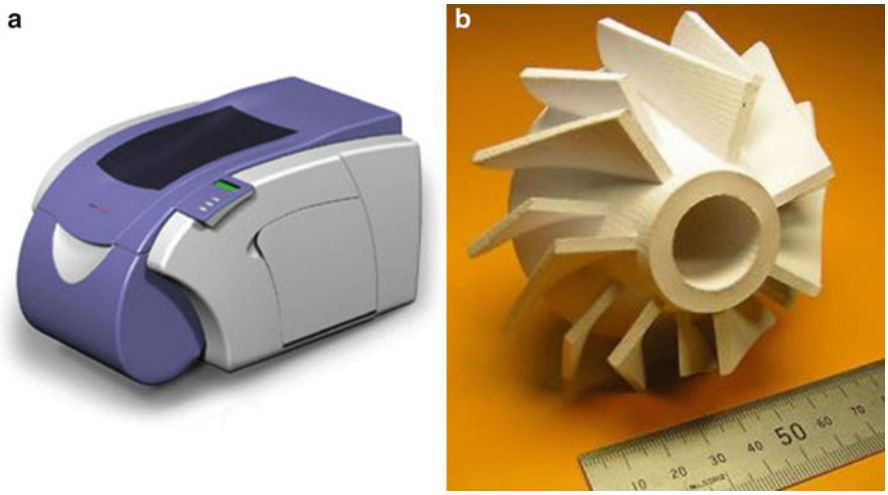

Fig. 8 (**a**) Photo of a LOM 3D printer (model Solidimension SD300; size: 450 mm × 725 mm × 415 mm). (**b**) An object made of paper printed using the LOM method

laminate object manufacturing (LOM). A LOM printer consists of a building platform that can move in the z-direction, a foil supply system to supply and position the foil, and a cutting device to create the contour. The LOM procedure is as follows: First, the foil is positioned and adhered to the building platform by a heated roller. Second, the cutting tool scans on the foil to create the designed contour and perform crosscutting on the non-model area to make it into small pieces for easier removal after printing. After one layer is printed, the platform moves down and the roller positions the next layer of foil on top of the previous layer. Then the platform moves up into position to receive the next layer and the process repeats until the entire 3D object is printed completely. A photo of a LOM 3D printer using paper material is shown in Fig. 8 together with a 3D printed example.

The foil built materials for the LOM technique can be paper, plastic, or metal (Gebhardt 2012). The cutting tool can be a scanning laser, a knife, or a milling machine. To bond adjacent layers, different methods such as gluing, soldering, and ultrasonic or diffusion welding can be used depending on the material properties. Compared to other AM techniques, the advantages for using the LOM in antenna printing include lower material cost and faster building speed for large objects. The disadvantages are less accuracy (e.g., 0.3 mm for the Solidimension SD300 3D printer shown in Fig. 8) and some material waste depending on the geometry.

AM Technique Summary

Most of the AM processes currently available can be classified by the abovementioned five basic categories. Table 1 summarizes the key features of these techniques.

3D Printed Antennas

AM technology enables the flexible and rapid realization of structures with arbitrary shapes and complexity. It has been successfully applied in many scientific and industrial areas such as biomedical, aerospace, and toy industry, architecture, and landscaping (Gebhardt 2012). In the following sections, applications of AM techniques for realizing 3D printed antennas are reviewed. A number of antenna examples printed by different AM techniques including electron beam melting, powder binder bonding, stereolithography, polymer jetting, conductive ink printing, and fused deposition modeling are presented.

DOI 10.1007/978-981-4560-75-7_109-1

Table 1 Summary of key characteristics of the five basic categories of AM processes

Classification	Available material	Process temperature	Resolution	Strength	Can print overhanging structure?	Print multiple materials
Sintering and melting	Polymer, metal and ceramic	High temperature	Low	Strong	Yes	No
Powder binder bonding	Polymer, metal and ceramic	Depending material	Moderate	Moderate	Yes	No
Polymerization	Polymer	Room temperature	High	Moderate	Need support material	Yes
Extrusion	Polymer	200–300 °C	Low	Strong	Need support structure	Yes
Layer by Layer bonding	Paper, plastic and metal	Depending on material	Low	Moderate	Yes	No

(**b**) EBM printed horn antenna with a dimension of 145.1 mm × 52.8 mm × 66.2 mm. (**c**) EBM printed horn antenna with a dimension 131.9 mm × 47.3 mm × 55.2 mm (Garcia et al. 2013)

Antenna Printed Using Sintering and Melting

As mentioned in section "Overview of 3D Printing Techniques," sintering and melting is an AM technique which uses laser or electron beam to selectively melt powder material and build 3D structures. In Garcia (2013), two horn antennas operating at Ku-band are printed by employing the EBM technique. Figure 9a is a commercial standard gain horn antenna manufactured conventionally as the reference, while Fig. 9b, c are two 3D printed horns with different dimensions. The RMS (root mean square) surface roughness of the 3D printed horns is measured to be 25.9 μm and 39.7 μm for the antennas in Fig. 9b, c, respectively. The simulated antenna gains without considering surface roughness are compared with measured results at 15 GHz, as shown in Table 2. One can see that the measured antenna gains agree very well with the simulated results for the reference horn antenna and the 3D printed horn antenna in Fig. 9b. For the 3D printed horn antenna in Fig. 9c, the measured antenna gain is about 0.6 dB lower than the simulated result which is attributed to the relatively worse surface roughness.

Table 2 Comparison of simulated and measured gains at 15 GHz for the reference and EBM printed horn antennas shown in Fig. 9 (Garcia et al. 2013)

Name	Simulated gain (dBi)	Measured gain (dBi)
Reference horn	19.56	20.00
3D printed horn 1	18.98	19.02
3D printed horn 2	18.42	17.78

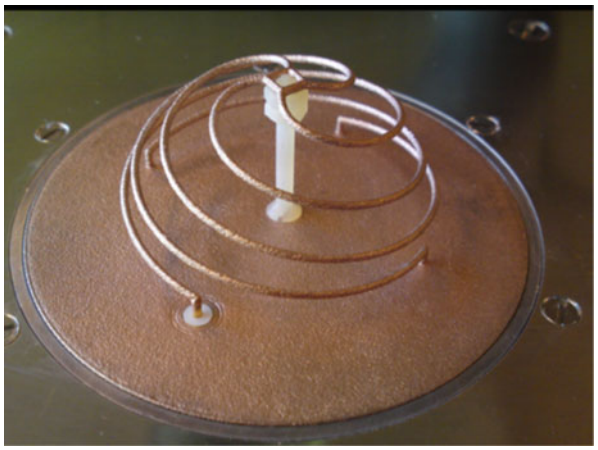

Fig. 10 SLS printed spherical helix antenna with several layers of copper painting (Kim 2013)

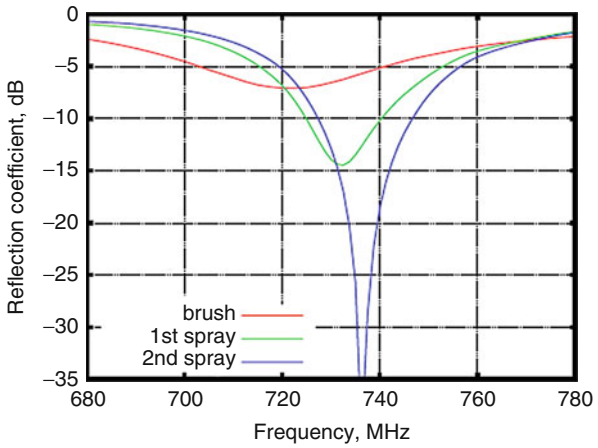

Fig. 11 Measured reflection coefficients of the SLS printed spherical helix antenna during painting process (Kim 2013)

In Kim (2013), an SLS technique is also applied to print an electrically small spherical helix antenna. The antenna is first printed with nylon using an SLS technique and then coated with several layers of conductive paint to make it conductive. A photo of the antenna is shown in Fig. 10. This helix antenna is fed by a SMA connector from the bottom. Figure 11 plots the measured reflection coefficients at different painting steps. The measured resonance frequency is at 736.3 MHz, which is lower than the expected 750 MHz. The reason is attributed to the gravity-induced deformation of the helix arms. The measured

DOI 10.1007/978-981-4560-75-7_109-1

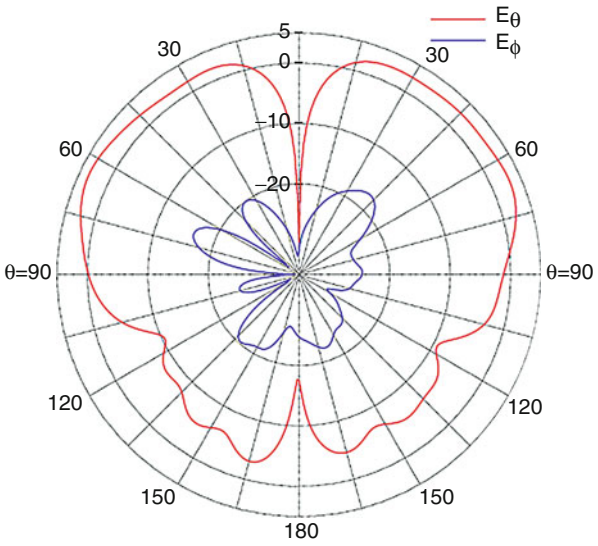

Fig. 12 Measured radiation pattern of the 3D printed spherical helix antenna at 737 MHz (Kim 2013)

radiation efficiency is 80 % compared to the simulated result of 97 % based on solid copper. The discrepancy is from the conductive loss of the copper paint. The measured radiation pattern of the antenna in the elevation plane is plotted in Fig. 12 and it is close to omnidirectional with a null in the broadside direction.

In summary, microwave horn antennas printed by EBM and SLS methods have been successfully demonstrated. It is observed that the surface roughness of 3D printing methods can influence the antenna performance such as gain. This issue will be more severe for higher-frequency bands such as mmW and THz. Moreover, the relatively coarse printing resolution that can be achieved by EBM, SLS, and SLM may also limit their applications for those higher-frequency bands.

Antenna Printed Using Powder Binder Bonding

Another 3D printing technique that is capable of printing pure metallic structures, the powder binder bonding technique, is utilized to realize a 3D volcano smoke antenna (Lopez et al. 2013) for ultrawideband (UWB) applications. The antenna is built using steel material. However, due to the low conductivity of steel, two methods to improve the antenna performance are applied. One method is covering the 3D printed prototype with copper tape. The other method is electroplating the prototype with copper. The antenna geometry and a photo of the 3D printed antenna prototype are shown in Fig. 13. The measured antenna reflection coefficients for both methods are plotted in Fig. 14 together with the simulated result. For the copper tape-covered case, the discrepancy between the measured and simulated results is believed to be due to the glue on the copper tape which would introduce an air gap between the steel and copper. For the electroplating case, the difference between simulation and measurement may come from the insufficient plating of copper layer at some part of the antenna. Nevertheless, the reflection coefficients of the 3D printed antennas show a broadband behavior for both cases.

Antenna Printed Using Stereolithography (SL)

Stereolithography is one of the most accurate AM techniques. It has also been applied in the realization of microwave antennas. An example using stereolithography and electroplating approach to build horn antennas at Ku-band is reported in Huang et al. (2005). Two horn antenna prototypes are first printed using polymer. Then, the stereolithography printed parts are coated by conductive silver ink as a seed layer and electroplated with copper. Figure 15 shows the schematic of the horn and a photo of the antenna after the

stereolithography printing process. The measured reflection coefficients of two printed horn antennas with different dimensions are plotted in Fig. 16 together with the simulation results. It can be clearly seen that the measured reflection coefficients of both antennas are quite good and they agree reasonably with the simulation results. The measured radiation patterns of the 3D printed horn antennas are plotted in Fig. 17, and the results are also very close to the simulated patterns. The measured and simulated antenna gains of the two printed horns are compared in Table 3.

In Chieh et al. (2014), a Ku-band corrugated conical horn antenna made via the stereolithography technique is also reported. This antenna is printed using acrylonitrile butadiene styrene (ABS) and then coated with conductive aerosol paint. Figure 18 shows the photos of the 3D printed horn antenna before and after the conductive aerosol paint process. The total time in printing the antenna is about 8 h. The surface coating of the antenna is Super Shield 841 which is a conductive spray typically used for EM interference (EMI) reduction. A total DC resistance of 2 Ω is measured across the length of the antenna after final coating. The measured and simulated reflection coefficients are compared in Fig. 19. It can be seen that the measured results agree well with simulation from 11 to 18 GHz. The spike around 18 GHz is believed to be caused by the excitation of the TE_{01} mode from the rectangular-to-circular waveguide transition. The measured co- and cross-polarization patterns at 14 and 16 GHz are plotted in Fig. 20. It is observed

Table 3 Measured and simulated gain and efficiency of the stereolithography printed horn antennas

	Size($a \times b \times h$)	Measured gain	Simulated gain	Efficiency
Horn antenna I	$40.2 \times 29.3 \times 51.0$ mm^3	14.58 dB	14.52 dB	100 %
Horn antenna II	$23.7 \times 117.3 \times 40.9$ mm^3	10.15 dB	10.35 dB	95.5 %

that the measured main beam agrees with the simulated results well and the cross-polarization level is at least 20 dB lower.

These works show successful examples of using stereolithography printing and metallic coating to fabricate microwave antennas at Ku-band. Because of the high resolution of the stereolithography technique, it can be applied in the realization of a finer structure than other AM techniques and therefore achieved at a higher operating frequency. Nevertheless, the required separate metallization process could be cumbersome and nonideal.

Antenna Printed Using Polymer Jetting

Polymer jetting is another kind of AM technique based on polymerization. Nayeri et al. (2014) report an example using polymer jetting technique to print dielectric reflect arrays as high-gain antennas operating at W-band (75–110 GHz). A reflect-array antenna is a class of antennas that uses one or a number of driving elements in front of a designed flat reflecting surface to produce a high directional beam. In Nayeri et al. (2014), the phase control of the reflect-array elements is achieved by varying the thickness (height) of the dielectric slab in each unit cell, and the designed structure of the reflect-array antenna is printed using a polymer jetting printer (Objet Eden350). There are 400 unit cells in the reflect arrays. After the polymer structure is printed, a thin layer of gold with thickness of about 100 nm is sputtered on the back of

DOI 10.1007/978-981-4560-75-7_109-1

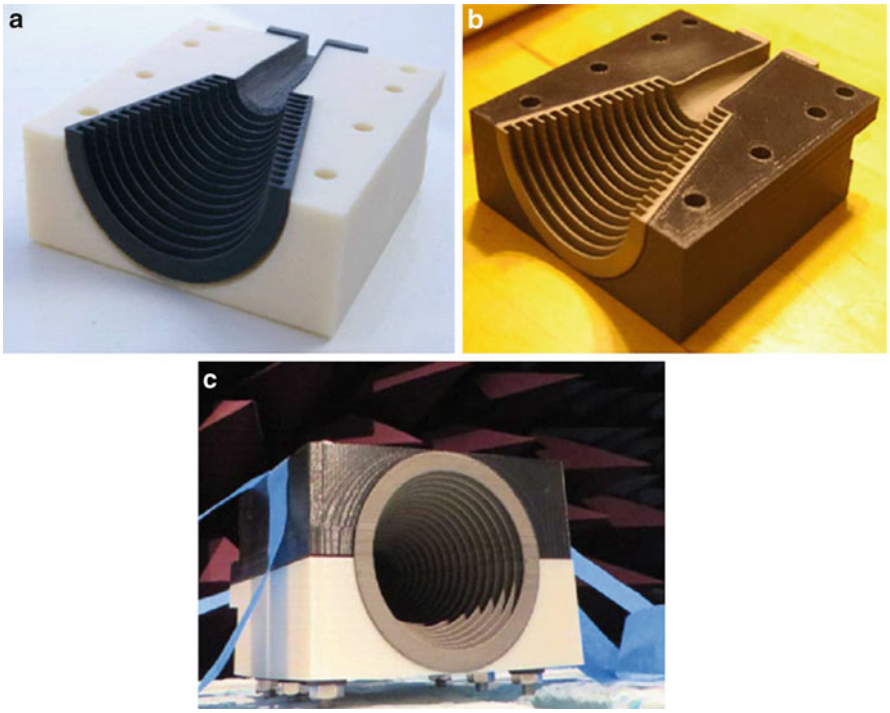

Fig. 18 A 3D printed Ku-band corrugated conical horn antenna using stereolithography before and after conductive aerosol paint (Chieh et al. 2014). (**a**) Half of the printed horn antenna before painting. (**b**) Half of the printed horn antenna after painting. (**c**) The complete final antenna

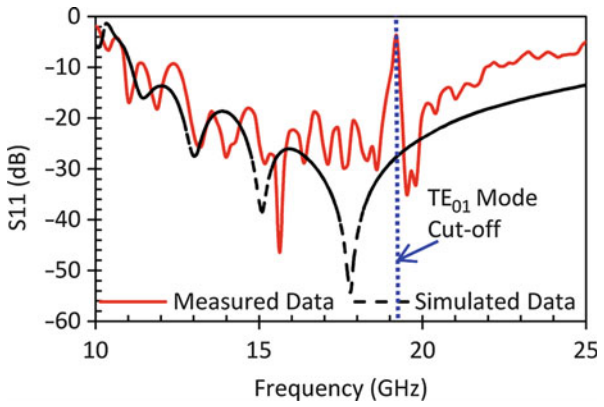

Fig. 19 Measured reflection coefficients of the 3D printed corrugated conical horn antenna compared with simulation (Chieh et al. 2014). The discrepancy around 18 GHz is due to the excitation of the TE_{01} mode from the rectangular-to-circular waveguide transition

the polymer structure as a seed layer. Then, electroplating process is applied to metalize the backside of the reflect array. Photos of the printed reflect-array antennas are shown in Fig. 21. A W-band pyramidal horn placed 22.5 mm away from the reflect-array aperture with a tilted angle of 25° is used as the feed. Figure 22 shows the measured and simulated radiation patterns of the first design in Fig. 21. It can be seen that the measured results agree well with simulation. The measured gain of these three designs at 100 GHz is 22.5 dB, 22.9 dB, and 18.9 dB, respectively. This work shows that the polymer jetting printed dielectric reflect array is a promising approach of realizing a high-gain antenna at a submillimeter frequency.

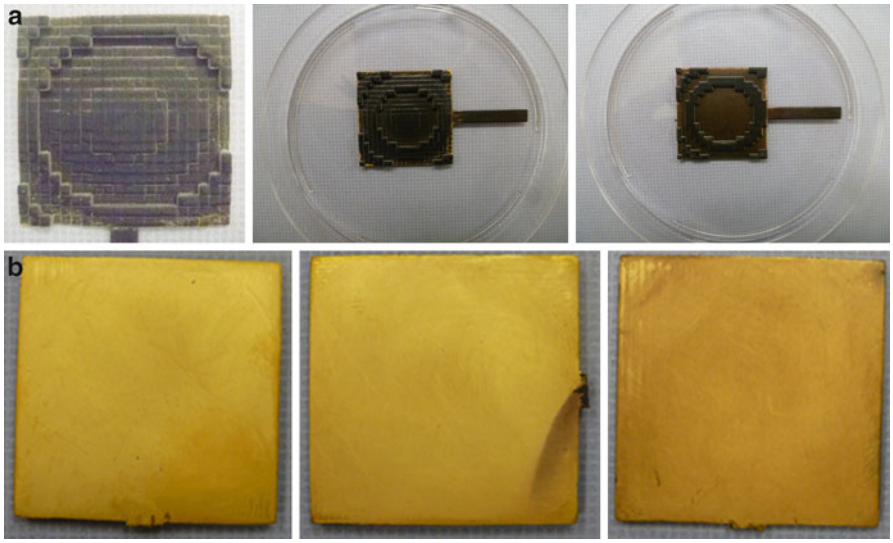

Fig. 21 (**a**) Top view and (**b**) bottom view of the dielectric reflect-array antennas printed using polymer jetting technique and electroplating (Nayeri et al. 2014)

An all-dielectric antenna operating in the mmW/THz frequency range has also been realized by the polymer jetting 3D printing technique. In Wu et al. (2012), a 3D printed electromagnetic crystal (EMXT)-based all-dielectric THz horn antenna is reported. The EMXT structure exhibits electromagnetic band gaps in certain frequency bands due to its periodicity. Within these band gaps, EM wave propagation is prohibited and therefore a hollow channel in the crystal structure will be able to confine and guide wave propagation along the channel. Photo images of the 3D printed EMXT horn antenna are shown in Fig. 23. Because of the band gap structure, in certain frequency bands, the wave propagation will be confined in the horn-shaped hollow core, and the antenna would work similarly like a regular horn antenna. These frequency bands are termed as the passbands of this EMXT horn antenna.

DOI 10.1007/978-981-4560-75-7_109-1

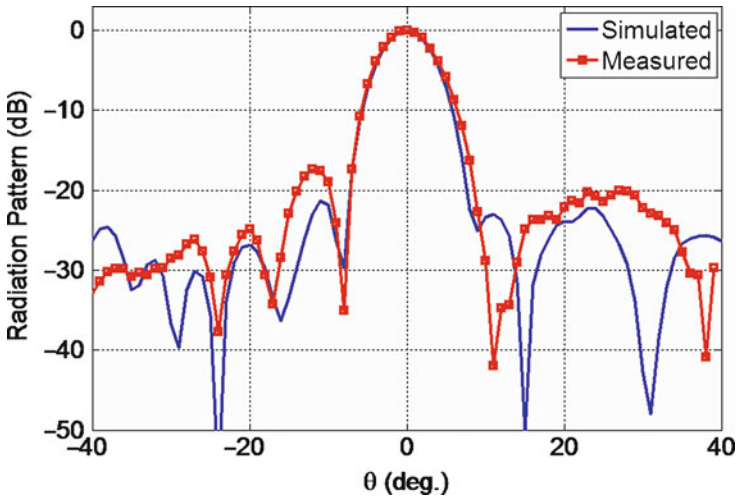

Fig. 22 Simulated and measured radiation patterns of the first reflect array in Fig. 21 at 100 GHz (Nayeri et al. 2014)

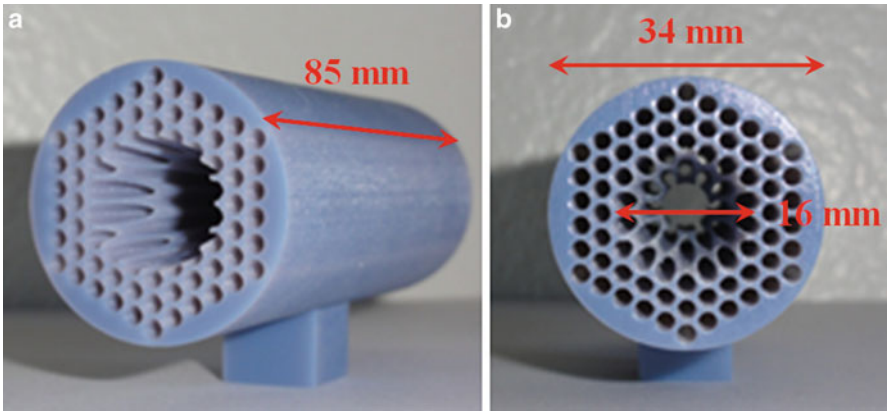

Fig. 23 Photos of the polymer jetting printed THz EMXT horn antenna. (**a**) Side view. (**b**) Front view. The total size of the antenna is 85 mm for length and 34 mm for diameter and the flare angle of the horn is 12.4° (Wu et al. 2012)

This all-dielectric EMXT horn antenna is experimentally characterized by a THz time domain spectroscopy system. Figure 24 plots the measured and simulated radiation patterns of the antenna for the first (105 GHz) and third (146 GHz) passbands. It can be seen that the measured results agree well with simulation. This printed all-dielectric horn antenna demonstrates comparable or better radiation performance compared to a copper horn antenna with the same geometry (Wu et al. 2012). Moreover, as an important free-space coupling component, the demonstration of the all-dielectric antenna may lead to potential integrated THz systems that can be manufactured by the polymer jetting technique.

Another example using polymer jetting technology to print an all-dielectric microwave lens antenna is reported in Liang et al. (2014) in which a broadband 3D Luneburg lens antenna (Luneburg 1964) operating from X to Ku-band is printed by employing the polymer jetting technique. The Luneburg lens is an attractive gradient index device used as an antenna for wide-angle radiation scanning because of its broadband behavior, high gain, and the ability to form multiple beams. Every point on the surface of an ideal Luneburg lens is the focal point of a plane wave incident from the opposite side. The refraction index n distribution of a spherical Luneburg lens is given by equation $n(r)^2 = \varepsilon_r(r) = 2 - (r/R)^2$, where ε_r is the relative permittivity, R is the radius of the lens, and r is the distance from the point to the center of the

DOI 10.1007/978-981-4560-75-7_109-1

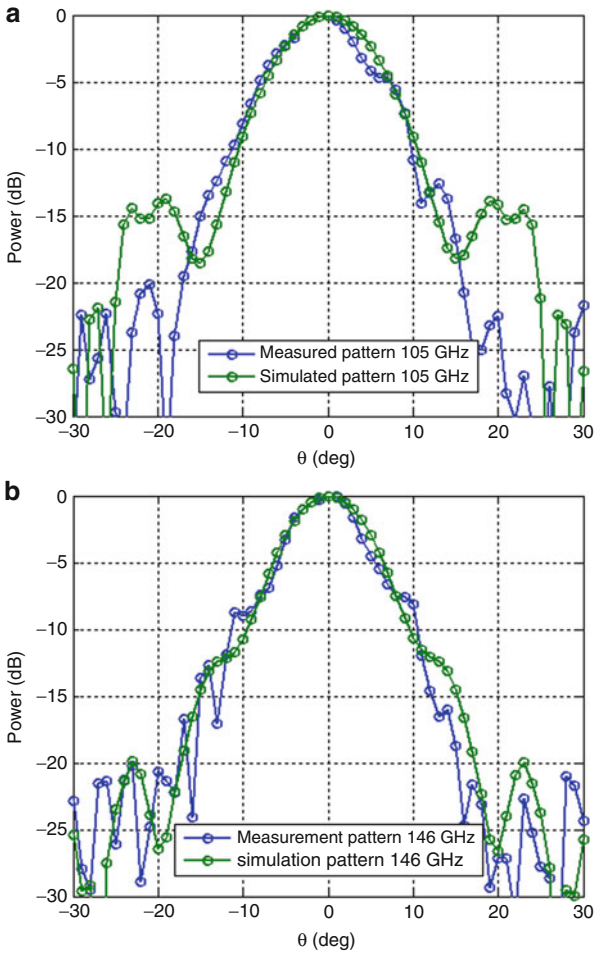

Fig. 24 Measured and simulated radiation patterns of the polymer jetting printed EMXT horn antenna at (**a**) 105 GHz and (**b**) 146 GHz (Wu et al. 2012)

sphere. In Liang et al. (2014), the required gradient index distribution of Luneburg lens is realized by controlling the filling ratio of a polymer-/air-based unit cell and therefore changes the effective permittivity at different locations. For example, at the center part of lens, a larger required effective permittivity will need a larger polymer filling ratio. At the edge of lens, a smaller required effective permittivity will need a smaller polymer filling ratio. One important thing to note is that the unit cell size needs to be small enough to guarantee the effective medium assumption of the design. Figure 25 shows three examples of 3D printed Luneburg lens: the first one has a diameter of 12 cm, the second one is a larger version of the lens with a diameter of 24 cm, and the third one is a Luneburg lens working at Ka- and Q-band with much smaller unit cell size. In the measurement, the feed of the Luneburg lens antenna is either a rectangular waveguide or a coaxial probe mounted on the surface of the lens. Figure 26 plots the simulated and measured radiation patterns of the 12-cm-diameter lens antenna at 10 GHz using a waveguide feed. All the radiation patterns from 8.2 GHz to 20 GHz show a highly directional beam and good agreement between experiment and simulation is obtained. The gain of this lens antenna using a waveguide feed is measured to be from 17.3 dB (at 8.2 GHz) to 24 dB (at 19.8 GHz). The side lobe is measured to be about 25 dB lower than the main beam in the H-plane and about 20 dB lower than the main beam in the E-plane. The difference is due to the asymmetry of the waveguide feed. Compared to traditional Luneburg lens fabrication techniques, the polymer jetting technique has a much lower cost, and the fabrication process is more precise, convenient, and faster.

DOI 10.1007/978-981-4560-75-7_109-1

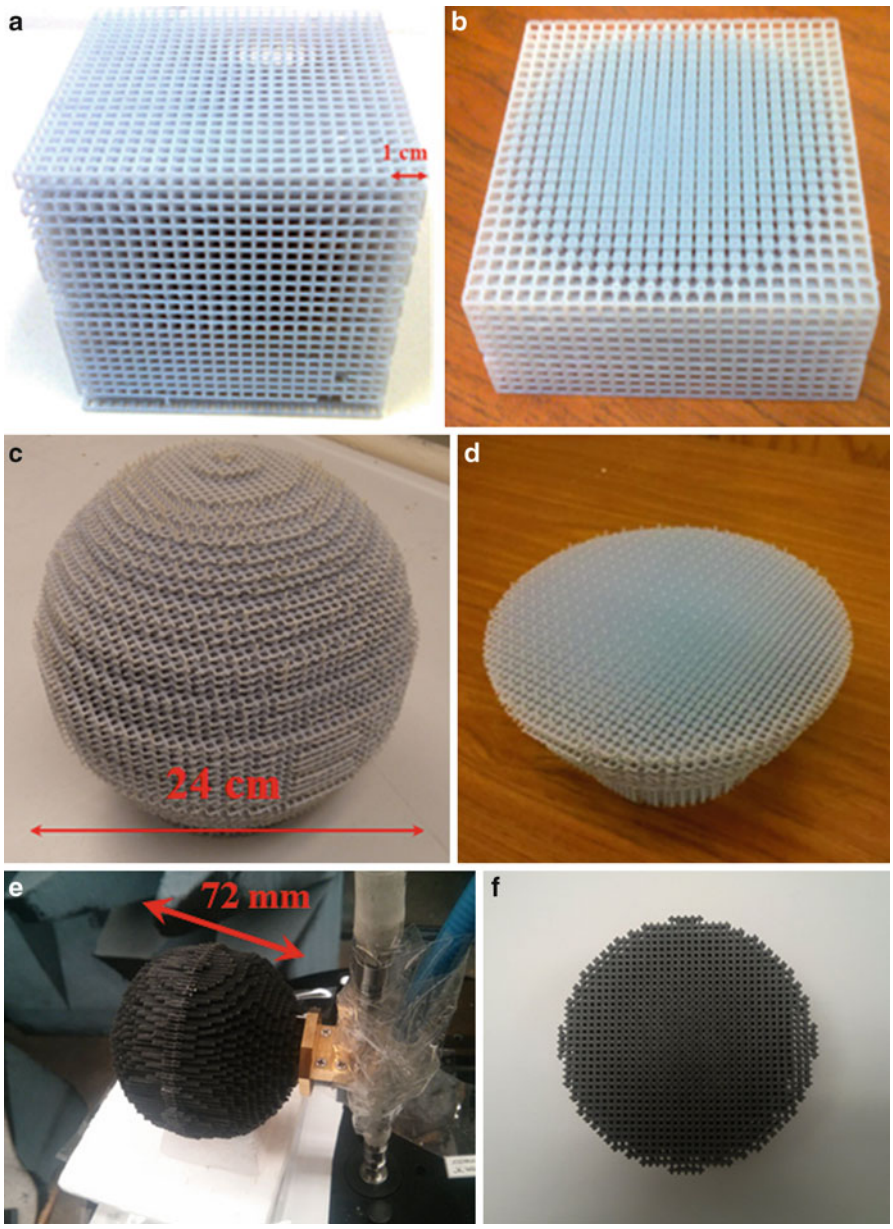

Fig. 25 Photos of the polymer jetting printed Luneburg lenses. (**a**) A lens with a 12 cm diameter. (**b**) The cross-section cut through the center of the 12-cm-diameter lens. (**c**) A larger lens with a 24 cm diameter. (**d**) Cross-section cut of the 24-cm-diameter lens. (**e**) A Luneburg lens working at Ka- and Q-band. (**f**) Cross-section cut of the Ka- and Q-band Luneburg lens (Liang et al. 2014; Gbele et al. 2014)

The above mentioned antenna examples show that the polymer jetting technique is a very good candidate in realizing 3D printed antennas, even up to THz frequency. Some of the complicated structures of these antennas would be very difficult or even impossible to fabricate using conventional manufacturing process. Moreover, compared to the conventional method, the polymer jetting technique will have a lower cost, and the fabrication process is more precise, convenient, and faster.

Antenna Printed Using Direct Printing of Conductive Ink

Direct printing refers to any technology that has the ability to deposit a variety of materials onto a surface in a designed pattern (Lopes et al. 2012). The surface to be printed on can be either flat or curved. Silver

DOI 10.1007/978-981-4560-75-7_109-1

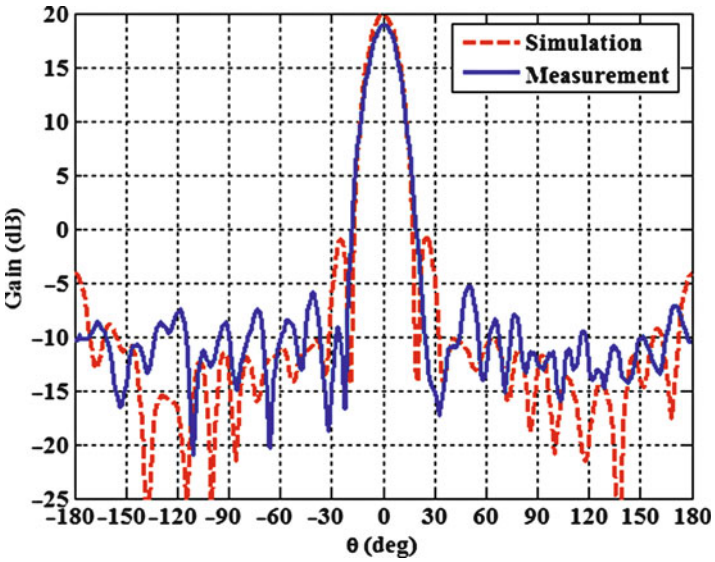

Fig. 26 Simulated and measured H-plane radiation patterns of the polymer jetting printed 12-cm-diameter Luneburg lens antenna at 10 GHz (Liang et al. 2014)

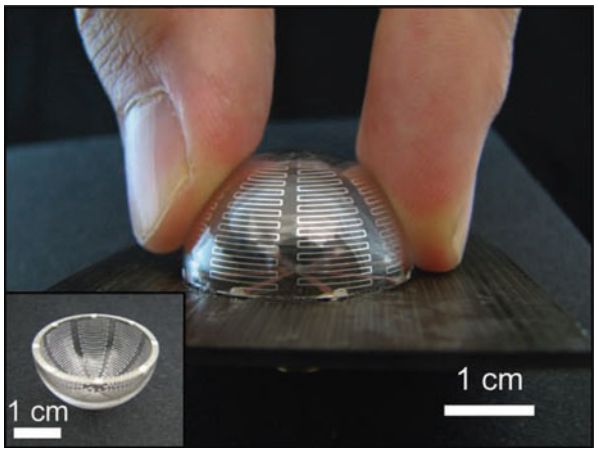

Fig. 27 Photos of the meander line antenna printed using conductive ink before (*inset*) and after connecting to feed lines (Adams et al. 2011)

conductive ink is a commonly used material in direct printing to realize the conductive surface of microwave antennas. After a post-printing annealing process, the conductivity of the printed ink may be on the same order of the conductivity of pure metal.

An example using direct printing technology to implement an electrically small antenna is reported in Adams et al. (2011) in which conductive meander lines are printed through a tapered cylindrical nozzle onto a hemispherical glass substrate to realize the antenna (Ahn et al. 2009). A post-annealing process at 550 °C is applied for 3 h. The printed meander line shows a DC conductivity of 2×10^7 S/m, which is within a factor of 3 compared to the conductivity of pure silver. Photos of the direct printed antenna before and after connecting to the feed lines are shown in Fig. 27. Figure 28 plots the measured VSWR as a function of frequency for one of the printed antennas together with the simulation results. The measured center frequency is at 1.7 GHz with a bandwidth of 12.6 %, indicating a good performance approaching the Chu limit of this electrically small antenna (Chu 1948).

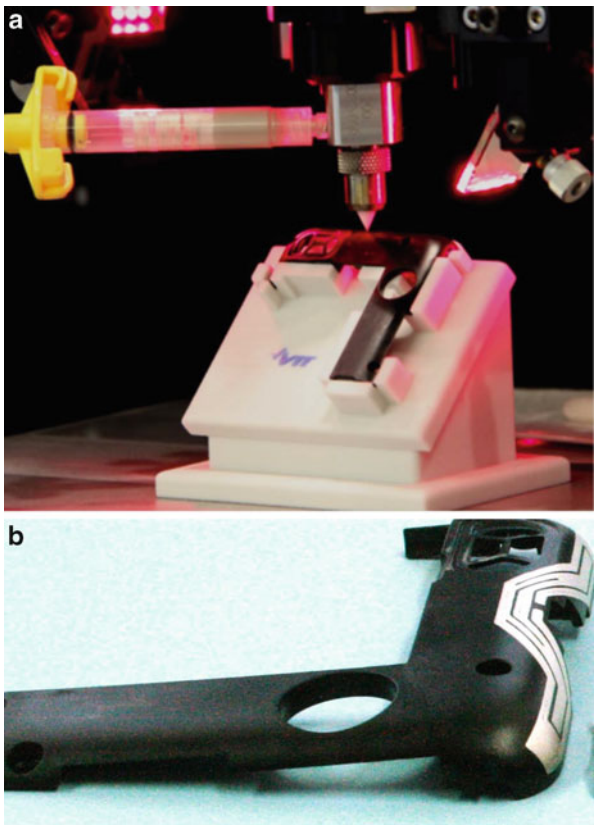

Fig. 29 (**a**) A photo shows a handset antenna during the direct printing process. (**b**) The handset antenna after printing (Salonen et al. 2013)

Salonen et al. (2013) also report a printed antenna using the direct printing technique on a 3D surface. The antenna is realized using the nScrypt@ nozzle dispensing tool (http://www.nscrypt.com/). A photo of the handset antenna during the printing process is illustrated in Fig. 29a, b which shows the antenna after

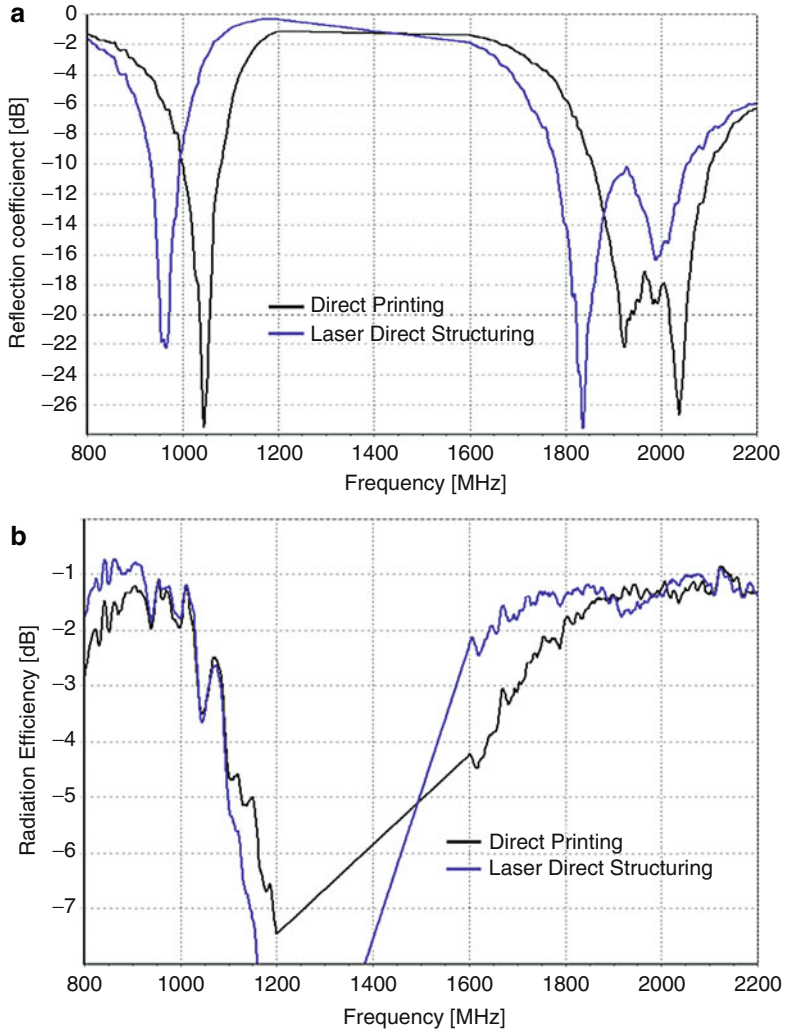

Fig. 30 Measured (**a**) reflection coefficient and (**b**) radiation efficiency of a handset antenna printed using direct printing technique compared to the same antenna made by the laser direct structuring (*LDS*) technique (Salonen et al. 2013)

printing. In the printing process, the conductive silver paste is extruded through a nozzle and deposited onto the substrate. The nozzle position is controlled by a 3-axis motion system and the material flow is adjusted by a precision pump. After printing, the silver paste is heat treated at 120 °C for 10 min to increase the conductivity. 120 °C is selected because a higher temperature causes some deformation of the plastic substrate. Figure 30 plots the measured reflection coefficient and the radiation efficiency of the direct printed antenna compared to those of the standard laser direct structuring (LDS) technique-fabricated antenna. The results show that these two antennas have similar performance in terms of reflection coefficient. The radiation efficiency of the direct printed antenna is 0.5 dB lower at the lower band and nearly equal at the higher band, compared to the LDS antenna. The slightly lower efficiency is believed to be caused by the skin effect which is more dominant at the lower band due to the smaller conductivity of the ink.

Antenna Printed Using Fused Deposition Modeling (FDM)

The FDM technique has the ability to print a large number of thermoplastic materials. In Ahmadloo and Mousavi (2013), a 3D meander line dipole antenna is printed on a V-shaped substrate using the FDM technique. The conductive part of the antenna is realized using a printed conductive ink. The curing

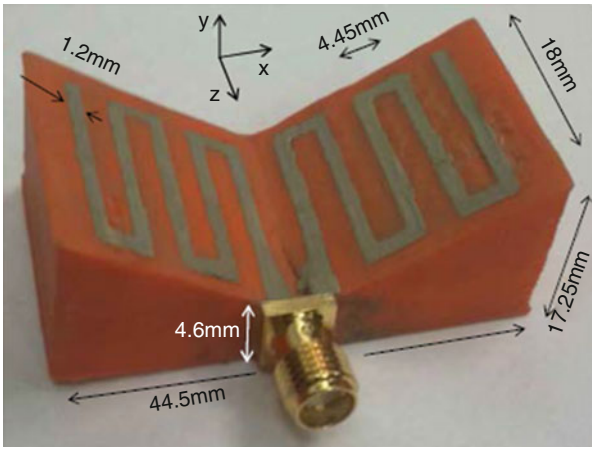

Fig. 31 FDM printed meander line dipole antenna on V-shaped substrate (Ahmadloo and Mousavi 2013)

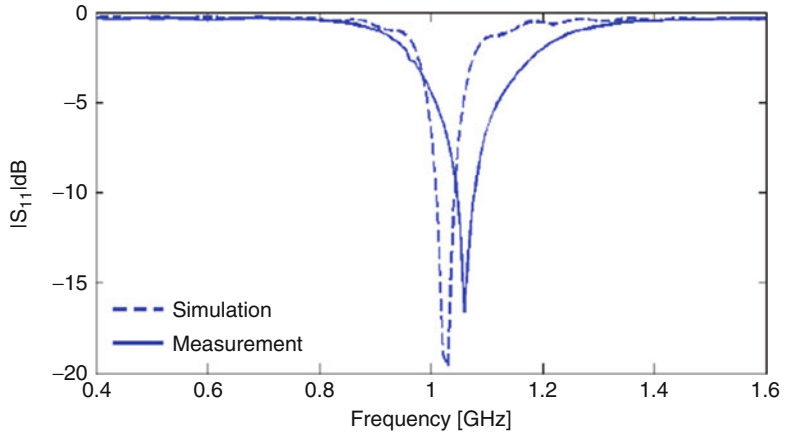

Fig. 32 Measured and simulated reflection coefficients of the FDM printed meander line dipole antenna (Ahmadloo and Mousavi 2013)

process of the printed conductive ink is at 85 °C for 15 min to reduce the resistivity. After curing, the conductivity of the silver ink is measured to be 1.5×10^6 S/m. A higher curing temperature can achieve a higher conductivity. However, to avoid the substrate deformation during the curing time, 85 °C is selected. A photo of the printed antenna is shown in Fig. 31. The meander line dipole is fed by a SMA connector. Figures 32 and 33 compare the measured and simulated reflection coefficients and radiation patterns of this antenna. It can be seen that the measured results agree well with the simulation results.

As a potential solution for integrating dielectric and conductor printing while maintaining high quality for each material, a microwave patch antenna is realized by FDM and an ultrasonic wire mesh embedding process (Liang et al. 2014). The substrate of the patch antenna is created using an FDM 3D printer and the conductive part of the antenna is realized using an ultrasonic machine which has the ability to embed copper wires on a 3D surface. Compared to the conductive ink approach, the ultrasonic wire embedding technique is performed at room temperature and therefore will not influence the thermoplastic substrate. In addition, since pure metal wire is used, the conductivity of the material is much larger than that of the conductive ink. The schematic design of the patch antenna and a photo of the 3D printed patch antenna are shown in Fig. 34. The feed of this antenna is a SMA probe from the back of the patch. The measured reflection coefficient and radiation pattern compared to simulation results using wire mesh and ideal

DOI 10.1007/978-981-4560-75-7_109-1

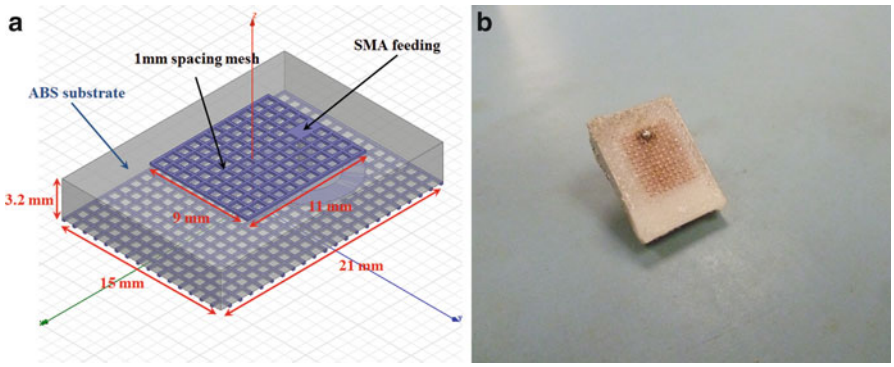

Fig. 34 Schematic of a microwave patch antenna made of FDM printed substrate and ultrasonically embedded wire mesh (*left*) and a photo of the patch antenna printed using FDM and wire mesh embedding technique (Liang et al. 2014)

conductor are illustrated in Fig. 35. It can be seen that the wire mesh structure works as well as a regular conductor sheet at microwave frequency and the measurement agrees well with simulation.

This example successfully demonstrated 3D printing of a microwave patch antenna by combining the FDM method with ultrasonic metal wire mesh embedding. No metal sintering or any other high-temperature conductor printing process is needed, and the printed metal wire mesh works as well as a regular metal sheet at a microwave frequency. The demonstrated 3D printing process of both dielectric and conductor can be applied to the other more sophisticated EM structures such as vertically integrated phased arrays. The disadvantage of this wire mesh embedding technique is the lower resolution compared to other AM techniques due to the minimum diameter of the metal wire (50 μm). This will limit the maximum operating frequency of components printed using the wire mesh embedding technique.

Challenges and Potential Solutions

It has been argued that 3D printing could be the future of manufacturing due to its ability to print structures with more flexible design than conventional methods. Recently, rapid progress has been made in the 3D printing area. However, a number of challenges still need to be resolved before advanced functional antennas can be printed in a 3D fashion robustly.

Surface Roughness

Surface roughness is an important parameter for manufacturing of antennas, especially for higher-frequency ranges such as mmW and THz. A rough surface can seriously degrade the EM performance

DOI 10.1007/978-981-4560-75-7_109-1

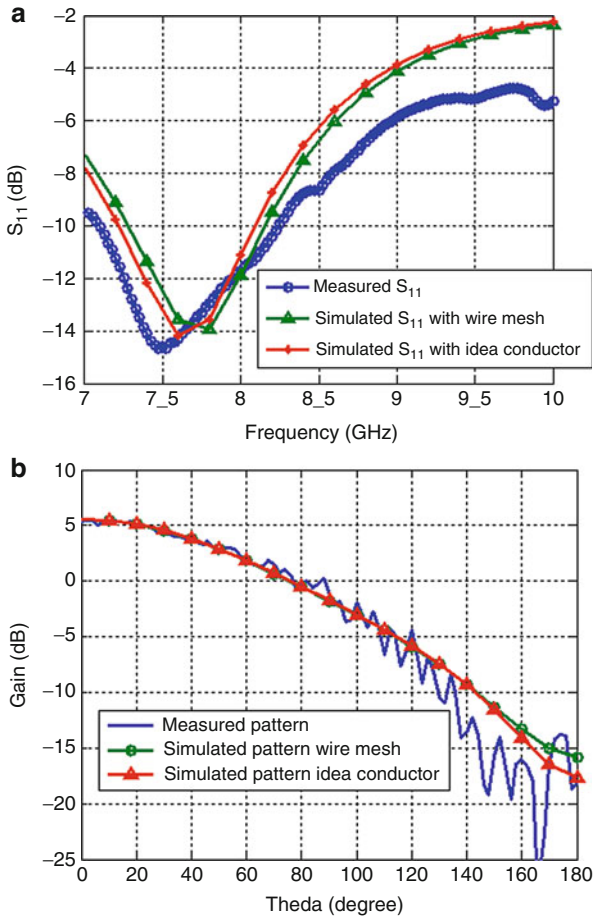

Fig. 35 Measured and simulated (**a**) reflection coefficients and (**b**) radiation patterns of the patch antenna printed using FDM and wire mesh embedding technique (Liang et al. 2014)

in terms of increased conductor loss. Currently, a drawback of many 3D printing techniques is the rough surface finish. For example, the EBM technique has a surface roughness on the order of tens of microns (Garcia et al. 2013). The FDM method has a surface roughness from 10 to 50 μm (Ahn et al. 2008). A post-polishing step often needs to take place after the printing process if fine surface roughness is required. However, for some of the complicated parts, it is inconvenient or even impossible to polish the inner part of the structure. Therefore, improving the surface roughness is one of the challenges in AM for high-frequency antenna applications.

Resolution

The printing resolution is also a challenge for AM technology, especially for those components working at high frequencies (e.g., mmW or THz). A higher resolution means a more accurate structure which is necessary for higher-frequency applications. Currently, most of the 3D printing techniques have a resolution no better than 20 μm with the exception of a two-photon polymerization stereolithography technique which has a sub-micrometer resolution. However, there is always a trade-off between printing resolution, printable size, and printing speed. For example, it is difficult to print large-size components (e.g., >1 cm) using the two-photon polymerization technique because of the printing speed. The long-term solution lies in the integration of multi-scale 3D printing techniques so that high-resolution or high-volume/high-speed techniques can be seamlessly integrated and applied when necessary.

DOI 10.1007/978-981-4560-75-7_109-1

Limited Electromagnetic (EM) Property Range

Another issue for 3D AM of antennas is the lack of available printable materials with desired EM properties (i.e., permittivity ε and permeability μ). At the present time, most of the commercially available materials used in 3D printing technologies are designed or selected with only the mechanical property in mind, and none of the material is designed for the EM applications. The lack of 3D printable materials with desired EM properties restricts their applicability to microwave components. For example, most of the existing printable polymers have a permittivity from 2 to 3. However, a higher dielectric constant is often desired for a microwave circuit and antenna for miniaturization purpose. Therefore, research and development in new printable materials with flexible EM properties would be necessary. A potential solution is using a polymer matrix composite method which mixes a 3D printable polymer with nanoparticles (Liang et al. 2014). By employing this method, novel materials with a wider range of EM properties (i.e., ε and μ) may be realized.

Performance of Printed Conductor

As discussed previously, the incorporation of a high-quality conductor with 3D printed dielectrics is also a challenge. Printing conductive inks on a dielectric substrate is one of the most popular methods to realize 3D spatial control of conducting material. However, to achieve high conductivity, high-temperature curing processes, which are usually not compatible to 3D printing techniques such as thermoplastic extrusion and photopolymerization, are necessary. With the limit of low curing temperature, the conductive inks tend to have relatively poor conductivity which leads to higher loss and could be detrimental to antenna performance, especially at a high frequency. Using the ultrasonic wire embedding technique in Liang et al. (2014) to realize the conductive part of the microwave antenna is an attractive alternative since this method guarantees a high conductivity (σ) at room temperature. Nevertheless, the resolution of the wire mesh embedding technique is lower than other AM techniques. Therefore, developing methods to realize the printing of a high-conductivity material at room temperature with arbitrary geometry will be critical to advance the state-of-the-art 3D printing of electronics including antennas.

Multiple Scales and Multiple Materials

Another desired capability in AM technology is multiple-scale printing. Currently, for most of the commercially available 3D printers, their printer heads only have one resolution which means it would take a long time to print a large object if a small part of the object needs a fine resolution. To address this problem, a multi-scale printer which has the ability to print some part of the object with fine resolution and print other parts of the object with coarse resolution is necessary.

A 3D AM technology capable of printing multiple materials is also highly desirable. Being able to efficiently realize arbitrary 3D spatial distribution of EM (ε, μ, and σ) is the holy grail of 3D printing technology for antenna applications. It will enable many new design possibilities which may lead to revolutionary antenna configurations having unprecedented advantages. An antenna structure with artificially controlled EM properties (ε, μ, and σ) in arbitrary 3D spatial distribution, novel 3D gradient index (GRIN) metamaterial-based lens antenna, and 3D printed vertically integrated phased array system are just some of the examples. If printable materials with time-dependent and/or nonlinear EM properties (i.e., 3D printed semiconductors (Ahn et al. 2006)) become available, AM technology may be used to achieve advanced fully functional systems.

DOI 10.1007/978-981-4560-75-7_109-1

Summary

In this chapter, the working principles and processes for various 3D AM techniques that are relevant to antenna design and implementation are described. Recent progresses and challenges for 3D printing of antennas are reviewed and discussed. The reported experiments demonstrate a number of successful antenna examples printed by various AM techniques. There are still substantial challenges that need to be overcome before complete and fully functional antennas and microwave systems can be truly realized via AM. However, further investigation and development of 3D printing technology in the areas of mechanical engineering, material science and engineering, and electrical engineering will no doubt lead to a new paradigm of 3D printed antennas and other microwave components and systems.

Antennas and EM Issues in Medical Diagnosis and Treatment Systems

Kazuyuki Saito* and Koichi Ito
Center for Frontier Medical Engineering, Chiba University, Chiba, Japan

Abstract

In recent years, various types of medical applications of electromagnetic techniques have been investigated. We have also been studying several medical applications of microwave techniques, which can be classified into diagnosis techniques and therapeutic systems. In this chapter, radio frequency techniques in magnetic resonance imaging (MRI) are discussed from the point of view of biomedical electromagnetic compatibility as an example of medical diagnostic devices. Moreover, therapeutic systems that employ the microwave thermal effect of biological tissue are also introduced. These systems are the thermal treatment of cancer and surgical devices using high-power microwave energy.

Keywords

Medical application; Diagnosis; MRI; Thermal therapy; Hyperthermia; Surgical device; SAR; Temperature elevation

Introduction

In recent years, the quality of life of patients has become increasingly important. Therefore, it is an established fact that medical applications of microwave techniques are important (Sterzer 2002) because these applications are effective in reducing the mental and physical burden of patients (Ito 1996). These applications can be classified as follows:

1. Information gathering and diagnostic techniques inside the human body that use microwave, such as computerized tomography (CT) and magnetic resonance imaging (MRI).
2. Thermal treatments, which use microwave energy as a heating source.
3. Transmission of patients' medical information.

Transmission of patients' medical information [point (3) above] is considered to be an extension of communication technologies (Shimizu et al. 1995) and has been described by many papers and books. Therefore, this chapter only focuses on specific aspects of the medical applications of electromagnetic (EM) waves [points (1) and (2) above].

Microwave Techniques in Magnetic Resonance Imaging (MRI)

Diagnostic Devices Using an Electromagnetic (EM) Field

Diagnoses inside the human body using X-ray, ultrasound, and magnetic fields have been well-studied and widely employed. In recent years, researchers have also tried using microwave techniques, although compared to X-ray CT, microwave CT is less popular. However, microwave CT for detection of breast cancer has been actively studied in recent years (Hagness et al. 1999; Bond et al. 2003). Moreover, MRI might be one of the diagnostic devices that use an EM field with the most success at the moment. There are many papers and books describing the principles and improvement of MRI devices; therefore, in this chapter, after briefly describing the structure of the MRI, the biomedical EM compatibility (EMC) of the device is introduced.

Structure of the MRI

During an MRI , the subject undergoing testing is placed in a high-strength static magnetic field and is radiated with EM wave pulses called radio frequency (RF) pulses. As a result, the spin of the atomic nuclei inside the test subject generate nuclear magnetic resonance (NMR) signals. By receiving the NMR signals and adapting the image reconstruction processing, various anatomical information from inside the object can be obtained. Figure 1 shows a normal tomographic image of the head and an image of blood vessels in the brain (magnetic resonance angiography). Various types of images inside the subject under test can be obtained by changing the parameters of the RF pulses. Figure 2 shows the basic configuration of the MRI device. The main magnet generates a high-strength static magnetic field which brings the spin of the atomic nuclei inside the test subject into line. The gradient coil creates a gradient magnetic field to determine the position of the image. In addition, the RF coil radiates the RF pulses to the test subject and receives the NMR signals from the test subject. Therefore, the RF coil is not a "coil" but rather an "antenna." For a detailed description of the structure of the MRI system, see, for example, Jin (1998). Figure 3 shows the various RF coils for imaging.

Biomedical EM Compatibility During MRI

In this section we describe the biomedical EMC of the human body during MRI, which is caused by the RF pulse radiation from the RF coil. Several kinds of RF coils have now been developed and can be selected according to the imaging portion of the body. During the MRI, the RF coil radiates pulsing EM waves (RF pulses) to the body and in response receives the NMR signals emitted from the nuclei, which constitute the body. Here, according to the shape of the RF pulses, various types of images inside the body

DOI 10.1007/978-981-4560-75-7_112-1

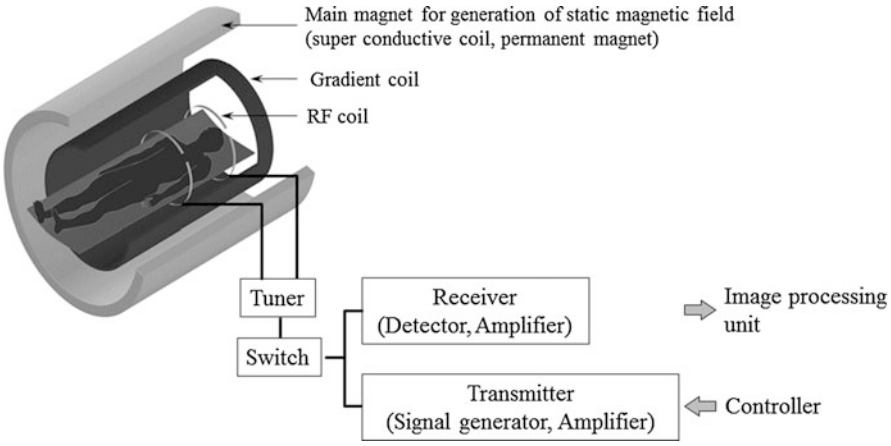

Fig. 2 Basic configuration of a magnetic resonance imaging device

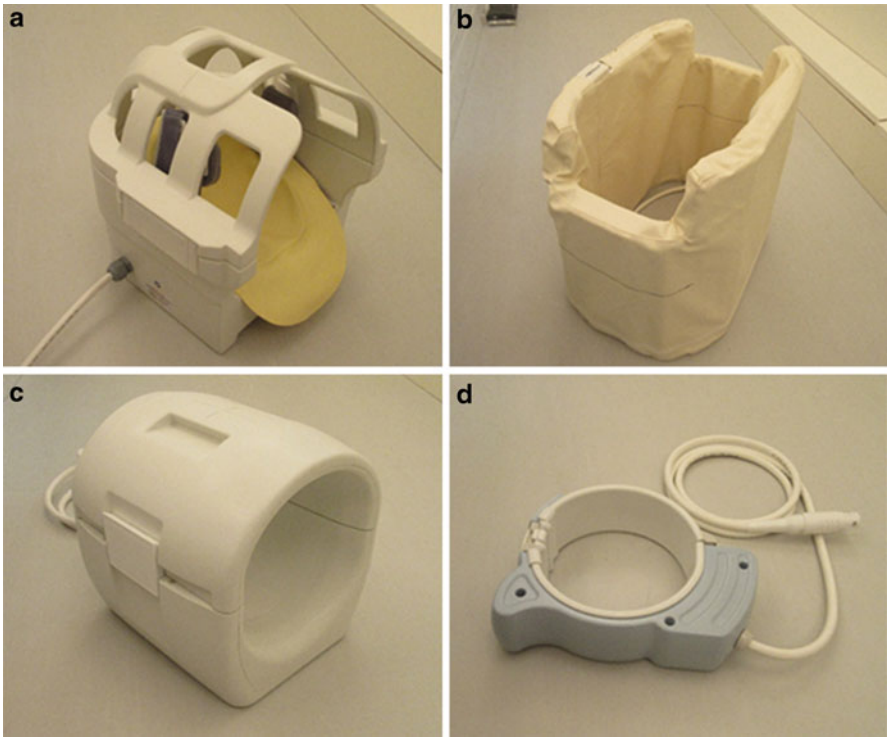

Fig. 3 Various radio frequency coils: (**a**) head coil; (**b**) chest coil; (**c**) knee coil; and (**d**) joint coil

can be obtained, as indicated in Fig. 1. In general, although the widths of the RF pulses are narrow, the amplitudes are not so low. Therefore, it is necessary to estimate the specific absorption rate (SAR) in the human body due to the radiated EM energy from the RF coils.

Until now, evaluation of the SAR in the human head has been studied during MRI (Angelone et al. 2004; Chen et al. 1998; Nguyen et al. 2004; Simunic et al. 1996; Collins et al. 2004), and restriction of the SAR for the safety of patients has been established as the International Electrotechnical Commission (IEC) standard (IEC Standard 2002). However, recently, MRI has been employed not only for the head but also for various other portions of the body. Moreover, MRIs tend to generate high-quality images and reduce the imaging time. In this chapter, the SAR distributions in a pregnant woman and her fetus are

DOI 10.1007/978-981-4560-75-7_112-1

investigated. In general, an ultrasound diagnostic system is used for the medical examination of pregnant women. However, an MRI is sometimes chosen for medical reasons, such as when the diagnosis of a fetal anomaly is unclear via ultrasound (Hubbald et al. 1999; Amin et al. 1999; Levine 2004).

The SAR distributions in a pregnant woman and her fetus exposed to the EM waves from the RF coil were calculated employing the two different types of pregnancy stage high-resolution whole-body pregnant woman models. In addition, two types of birdcage coil were employed for these calculations.

Numerical Calculation Method and Calculation Models

Calculation Method

In the numerical calculation, the electric field in and around the RF coil is analyzed by the finite difference time domain (FDTD) method (Yee 1966) and the EM energy absorption rate (SAR), which is one of the most important indices for evaluation on thermal effect of biological tissue, is calculated from the following equation (Eq. 1):

$$\mathrm{SAR} = \frac{\sigma}{\rho} E^2 [\mathrm{W/kg}] \tag{1}$$

where σ is the conductivity of the tissue [S/m], ρ is the density of the tissue [kg/m^3], and E is the electric field (rms) [V/m]. The SAR takes a value proportional to the square of the electric field around the antennas and is equivalent to the heating source generated by the electric field in the tissue.

Female Models

In this section, the SAR distributions on two types of realistic female models are calculated. Here, the realistic high-resolution whole-body voxel model of an adult Japanese female average figure, developed at the National Institute of Information and Communications Technology, Japan (NICT) (Nagaoka et al. 2004) is used for the calculation of the SAR of a pregnant woman in the early period (Model A). The size of the fetus (embryo) in the early period is very small, and hence it is difficult to confirm pregnancy status. Therefore, it is considered that the person who does not notice her own pregnancy state uses MRI. Moreover, the 26th gestational week pregnant woman model (Model B) (Nagaoka et al. 2004; Saito et al. 2006a; Togashi et al. 2008) is employed as one example of late pregnancy stages. In order to develop this model, the fetus model was first developed from the MR images of a pregnant woman in the 26th gestational week. The fetus model consists of six organs: fetal body, fetal brain, fetal eyes, amniotic fluid, placenta, and uterus wall. Next, the abdomen of the woman in Model A was expanded following the standard shape and structure of the pregnant woman. Finally, these two models were combined and adjusted following comments from medical doctors. More detailed explanation regarding the development of the pregnant woman models are described in Nagaoka et al. (2007).

Figures 4a, 4b show Models A and B, respectively. These high-resolution models are composed of a $2 \times 2 \times 2$ mm cubical voxel. The physical properties of these models were determined from previous publications (Hand et al. 2006; Gabriel 1996; Duck 1990; Van Den Berg et al. 1983). Table 1 summarizes some of the parameters regarding the abdomen of the pregnant woman and her fetus.

Calculation Models for Radio Frequency (RF) Coils

A birdcage coil is employed as one of the most fundamental RF coils for MRI systems. The birdcage coil is often used for both the transmission of the RF pulse and reception of the NMR signal, and is categorized into two types by the different position of the loaded capacitors: a highpass birdcage coil, and a lowpass birdcage coil (Jin 1998). Figures 5a, 5b show the highpass and lowpass birdcage coils, respectively.

DOI 10.1007/978-981-4560-75-7_112-1

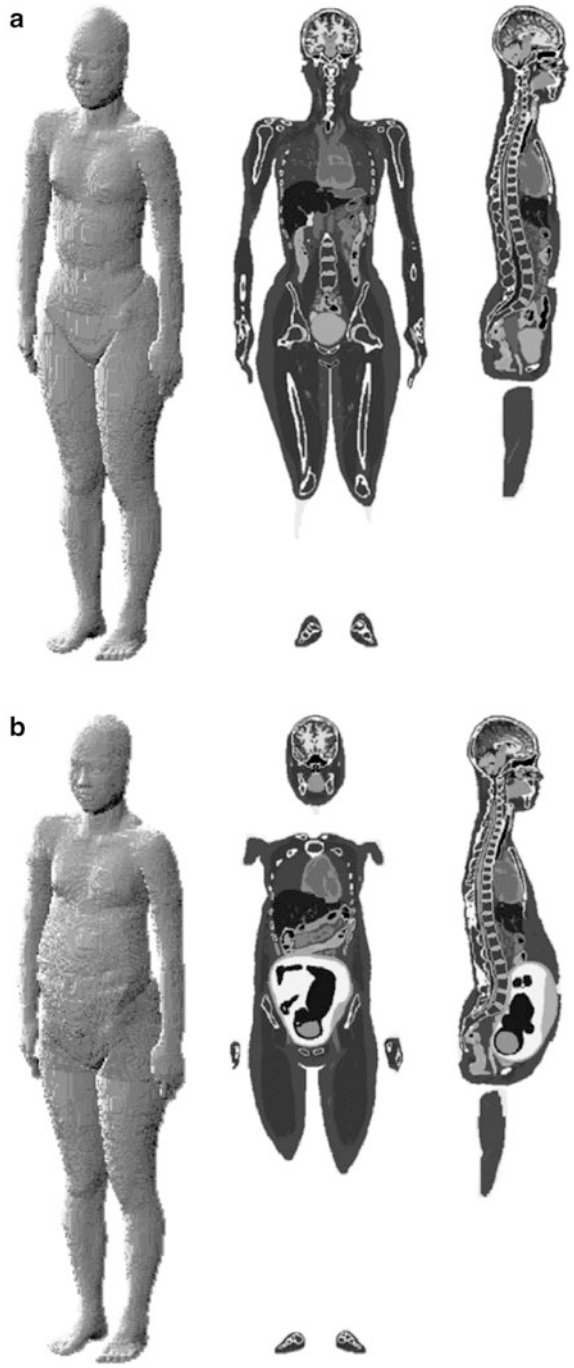

Fig. 4 Realistic female models: (**a**) Model A (pregnant woman model in early period); and (**b**) Model B (pregnant woman model in 26th gestational week)

The operating frequency of the coil is around 64 MHz in both cases, which is used in the generic 1.5 T MRI systems to excite the nuclei in the human body for imaging. These coils consist of two end rings and eight legs, the widths of which are 10 mm, and are modelled as perfect electric conductors for calculations. The diameter and the length of the coil are 600 and 700 mm, respectively, allowing the realistic female model to be used. In order to reduce radiation of RF energy to outside of the coil, the coils are surrounded by an RF shield that is also modeled as a perfect electric conductor. A cylindrical RF shield, with an

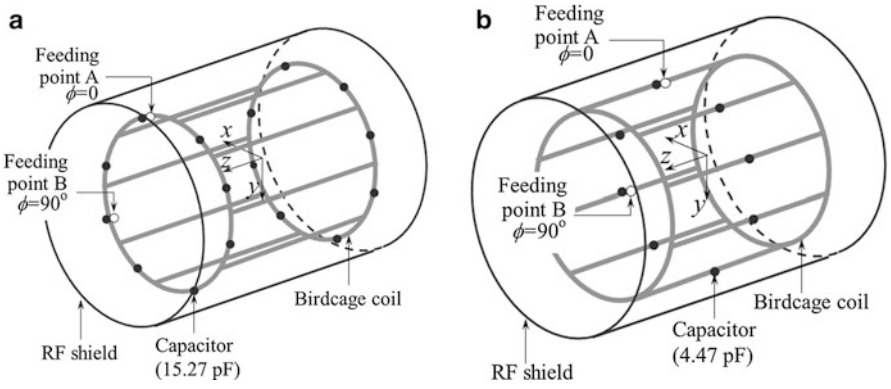

Fig. 5 Two types of birdcage coils: (**a**) highpass type; and (**b**) lowpass type

internal diameter of 740 mm and a length of 1260 mm, was located lateral to the coil. The dimensions of the coil and the RF shield were determined based on previous publications (Hand et al. 2006; Wu et al. 2006; Ochi et al. 1993).

The capacitors were loaded into the end rings on the highpass birdcage coil in Fig. 5a, and into the legs on the lowpass birdcage coil in Fig. 5b. In order to determine the capacitances, a "birdcage builder" (Chin et al. 1998), which calculates the resonance frequency of the birdcage coil using the equivalent electrical circuit model, was employed. Values for capacitors to resonate both coils at 64 MHz were 15.27 pF for the highpass birdcage coil and 4.47 pF for the lowpass birdcage coil. In addition, two feeding points were employed in these calculations and the phase difference between two ports is 90°. This excitation method is called "quadrature excitation" and can generate clear MRI images using a circular polarized field (Jin 1998).

Numerical Calculation Model

Figure 6 shows the FDTD calculation model including the realistic female model. As an example of the model, Model B is inserted into the highpass birdcage coil. There are several possibilities for the coil position, because it is considered that the position of the coil is not the same for each type of imaging. Previously, the relationships of several positions of the RF coil with the SAR were calculated (Kikuchi et al. 2007). However, here, the coil was placed in the center of the uterus in Model A, and placed at the center of the fetal brain in Model B. In order to calculate the whole-body female models, a large analytical region was required and a super technical server (Hitachi SR11000) in the Institute of Media and Information Technology, Chiba University (Chiba, Japan) was employed. In the numerical calculations, the uniform grid size inside the shield including the female model is 2.0 mm. The non-uniform mesh is used for the outside of the shield, because most of the EM waves are not emitted outward by the shield.

The parameters used in the FDTD calculations are listed in Table 2. In addition, steady-state analysis is performed by enforcing a continuous sinusoidal wave of electric field on the feeding gaps to calculate the SAR distribution in the model. Moreover, the coordinate origin is the center of the calculation model. The effectiveness of the calculation technique is confirmed by comparison with an experimental result (Saito et al. 2006b).

SAR Distributions in the Abdomen of Pregnant Woman Models

In the actual MRI system, the various pulse sequences are employed according to the imaging region and type. However, the SARs in the pregnant woman and her fetus were calculated by exciting the continuous sinusoidal wave at the feeding point, because the radiation power of each pulse sequence was not clear. Here, in order to simplify conversion of radiation power, the SAR values are normalized by 1.0 W

DOI 10.1007/978-981-4560-75-7_112-1

radiation power from the coil in all cases. In addition, the radiation power was calculated by a surface integral of the Poynting vector on the closed surface surrounding the coil.

Comparison of the SAR Distributions in Model A with the Two Types of RF Coils

Figures 7a–7h show the calculated SAR distributions inside Model A by employing the highpass and lowpass birdcage coil. The observation planes are the sagittal plane (*yz*-plane) including the uterus, and the coronal plane (*xz*-plane) around the center of the uterus. Moreover, positions of observation line A–A′, B–B′, C–C′, and D–D′ are indicated in the Figs. 7a–7d. Here, Model A (the non-pregnant woman model) is assumed as the early period of pregnancy, when the fetus or embryo is very small. Therefore, the SAR inside the uterus and ovary were observed in place of fetal tissue (Dimbylow 2006).

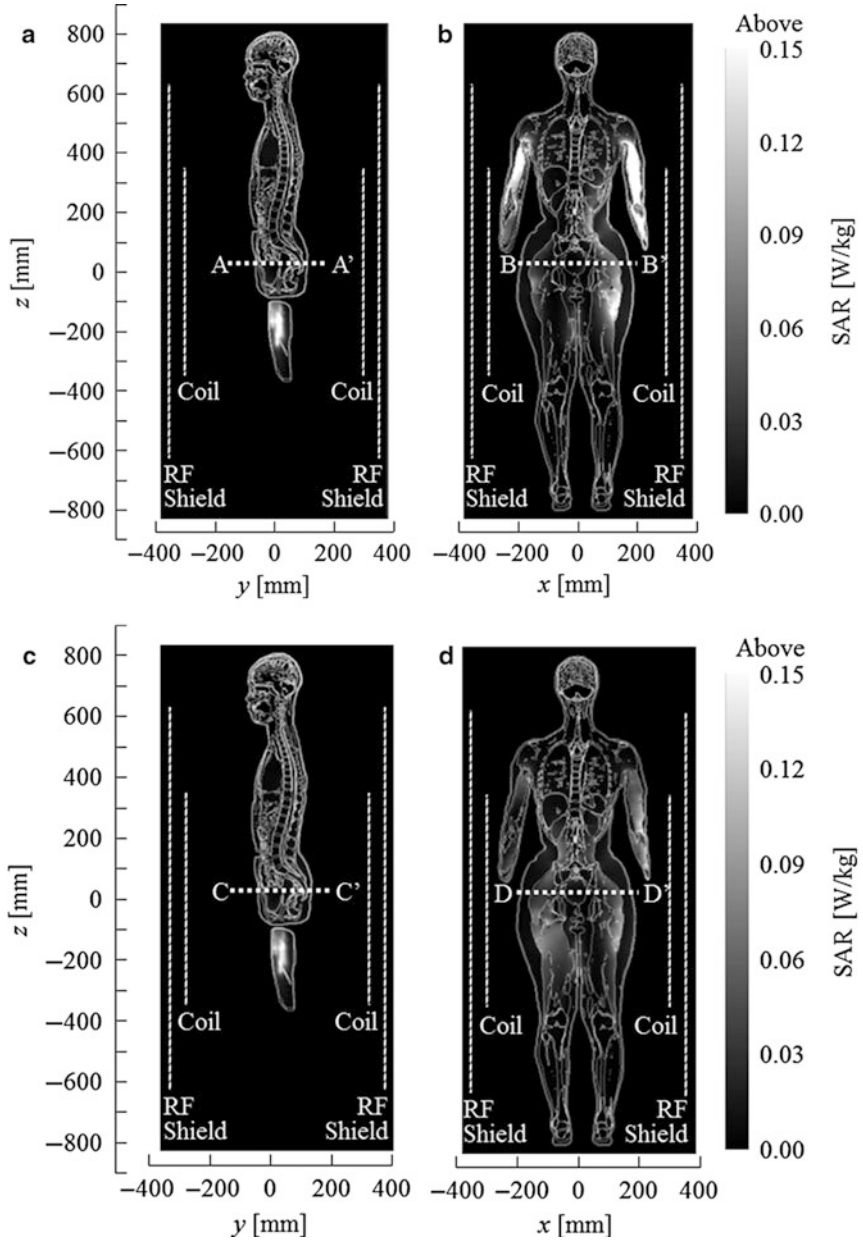

Fig. 7 (continued)

DOI 10.1007/978-981-4560-75-7_112-1

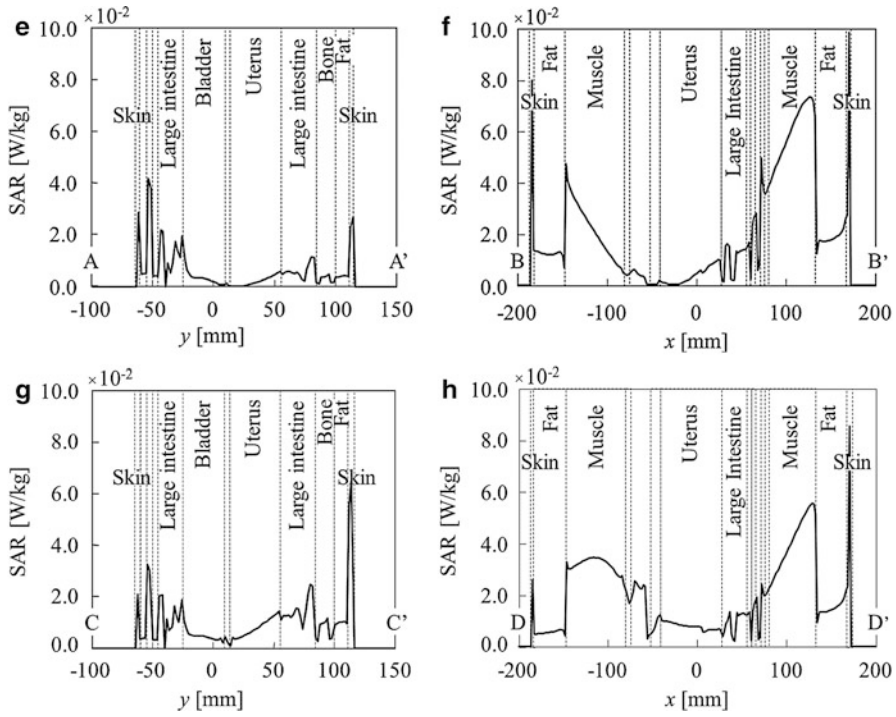

Fig. 7 Calculated specific absorption rate distributions inside Model A due to radiated electromagnetic waves from two types of birdcage coils: (**a**) sagittal plane (highpass birdcage coil); (**b**) coronal plane (highpass birdcage coil); (**c**) sagittal plane (lowpass birdcage coil); (**d**) coronal plane (lowpass birdcage coil); (**e**) A–A′ in sagittal plane (highpass birdcage coil); (**f**) B–B′ in coronal plane (highpass birdcage coil); (**g**) A–A′ in sagittal plane (lowpass birdcage coil); and (**h**) B–B′ in coronal plane (lowpass birdcage coil)

As shown in Figs. 7b, 7d, the SAR distributions on the coronal plane are observed as having an unsymmetrical tendency in comparison with the left side (-225 mm $< x < 0$) and right side ($0 < x <$ 225 mm). Moreover, it was confirmed that the tendency of the SAR distributions depends on their position in the body. Because it was considered that the tendency is influenced by two points of feeding, a symmetry of SAR distributions was confirmed in the case of one point of feeding model. Moreover, from Fig. 7a–7d, relatively high SAR values are observed around the skin, muscle, etc., which have a high electrical conductivity and are located close to the surface of the maternal body. The tendency can be confirmed in Fig. 7e–7h, except for fat tissue which has low electrical conductivity. Moreover, high SAR values are observed inside the thigh ($x = 0$, $-100 < z < -300$ mm in Fig. 7b, 7d) and armpit ($x = \pm 200$ mm, $z = 400$ mm in Fig. 7b, 7d). This is due to the concentrated electric field at those narrow gaps. In comparison with the SAR distributions due to the EM energy from the highpass and lowpass birdcage coil, comparatively high SAR values are observed in the vicinity of each position of feeding points and loaded capacitors. Here, according to the result that confirmed all SAR distributions, it was found that this phenomenon is dependent on whether an electric field concentrates on an existing gap of the human body and a coil.

Meanwhile, the SAR in the uterus and the ovary (around $15 < y < 60$ mm, $-50 < z < 50$ mm in Fig. 7a, 7c, and around $-40 < x < 25$ mm, $-50 < z < 50$ mm in Fig. 7b, 7d) are low compared to the maternal surface of skin and muscle tissue. In addition, a low SAR value is observed at the uterus (around $15 < y <$ 60 mm in Fig. 7e, 7g, and around $-40 < x < 25$ mm in Fig. 7f, 7h) due to the attenuation of EM energy in the muscle tissue. Moreover, it is observed that there is very little difference between the SAR in the uterus and the ovary by different coil types. From these results, it has been confirmed that the SARs in the uterus and the ovary are low, because these areas are located in deep regions of the body.

DOI 10.1007/978-981-4560-75-7_112-1

Comparison of the SAR Distributions in Model B with the Two Types of RF Coils

Figures 8a–8h show the calculated SAR distributions in Model B using the highpass and lowpass birdcage coil. The observation planes are the sagittal plane (*yz*-plane) including the center of the fetal head, and the coronal plane (*xz*-plane) around the center of the fetal body. Positions of the observation line A–A′, B–B′, C–C′, and D–D′ are indicated in Fig. 8a–8d.

As shown in Fig. 8, relatively high SAR values are observed around the maternal surface and unsymmetrical tendencies are observed in the same results as SAR distributions in Model A. Moreover, it is observed that the SAR at the amniotic fluid is also relatively high. In particular, relatively high SAR

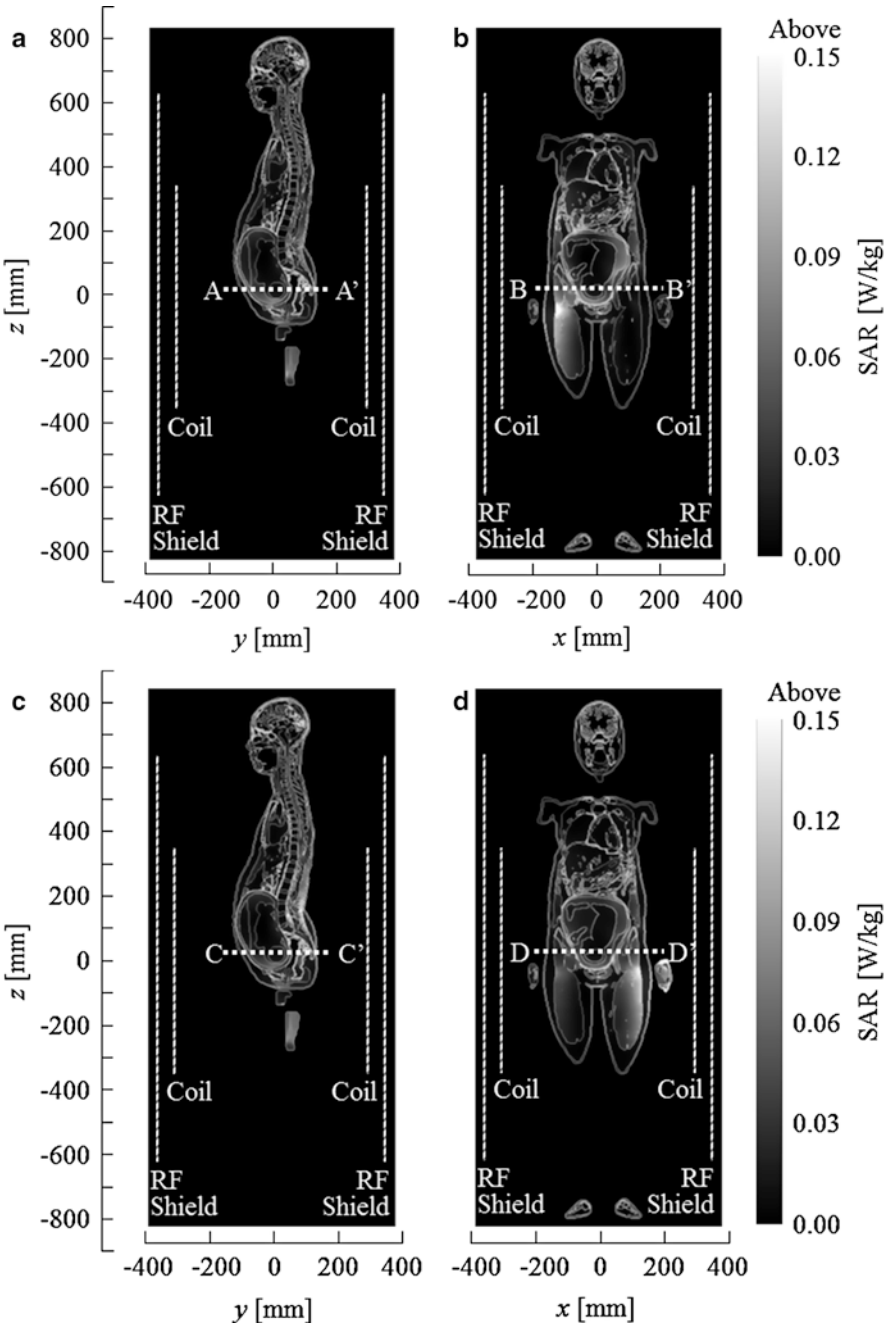

Fig. 8 (continued)

DOI 10.1007/978-981-4560-75-7_112-1

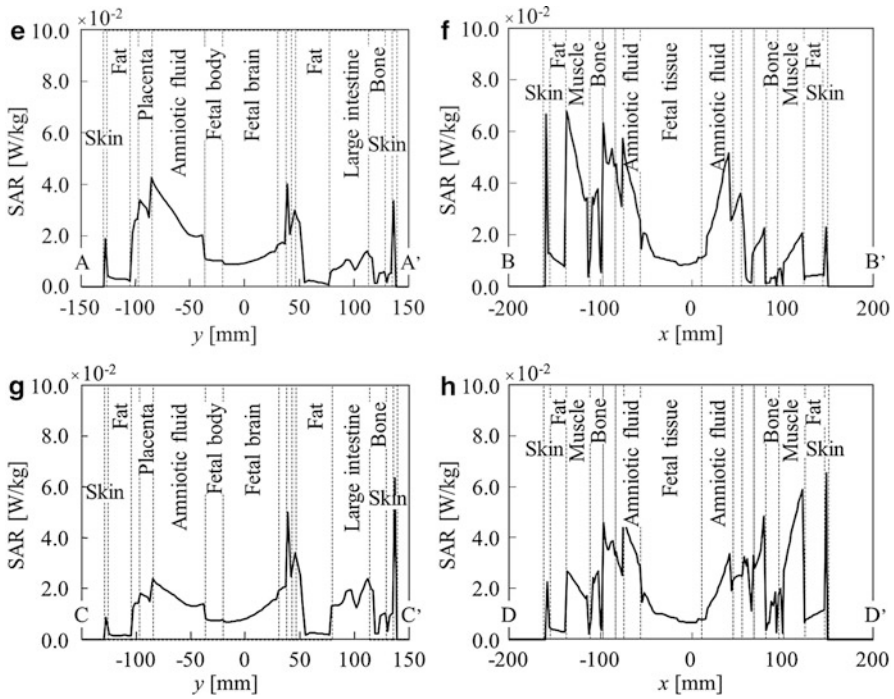

Fig. 8 Calculated specific absorption rate distributions inside Model B due to radiated electromagnetic waves from two types of birdcage coils: (**a**) sagittal plane (highpass birdcage coil); (**b**) coronal plane (highpass birdcage coil); (**c**) sagittal plane (lowpass birdcage coil); (**d**) coronal plane (lowpass birdcage coil); (**e**) A–A′ in sagittal plane (highpass birdcage coil); (**f**) B–B′ in coronal plane (highpass birdcage coil); (**g**) A–A′ in sagittal plane (lowpass birdcage coil); and (**h**) B–B′ in coronal plane (lowpass birdcage coil)

values are observed at the upper and lower portions of amniotic fluid (around $y = -100, z = -50, 150$ mm in Fig. 8a, 8c, and around $x = 0$, $z = -50$ mm and $x = 100$ mm, $50 < z < 200$ mm in Fig. 8b, 8d). In addition, as Fig. 8e–8h indicate, it has been found that the SAR in the amniotic fluid near the fetal tissue is relatively high. This is because the electrical conductivity of amniotic fluid is almost 1.5–2.0 times higher than other tissues, as listed in Table 1. In addition, the SAR distributions around the boundary of each tissue were precipitously varied due to the heterogeneous structure.

However, the SAR in the fetus (around $-20 < y < 50$ mm in Fig. 8e, 8g, and around $-50 < x < 15$ mm in Fig. 8f, 8h) is low compared with the values of the maternal body. Moreover, the maximum SAR value within the fetus is less than 1.0 % of that of the maternal body. From these results, it has been confirmed that the SAR in the fetus is attributed to the attenuation of EM energy in the amniotic fluid which has high conductivity.

Summary

Here, we introduced the SAR calculations of pregnant women during MRI. Deeper analyses of the SAR values are discussed in Kikuchi et al. (2009) and there have been several papers published on SAR analyses for MRI (De Wilde et al. 2005). SAR reduction during MRI via improvement of RF coil structure is also one of the important study themes.

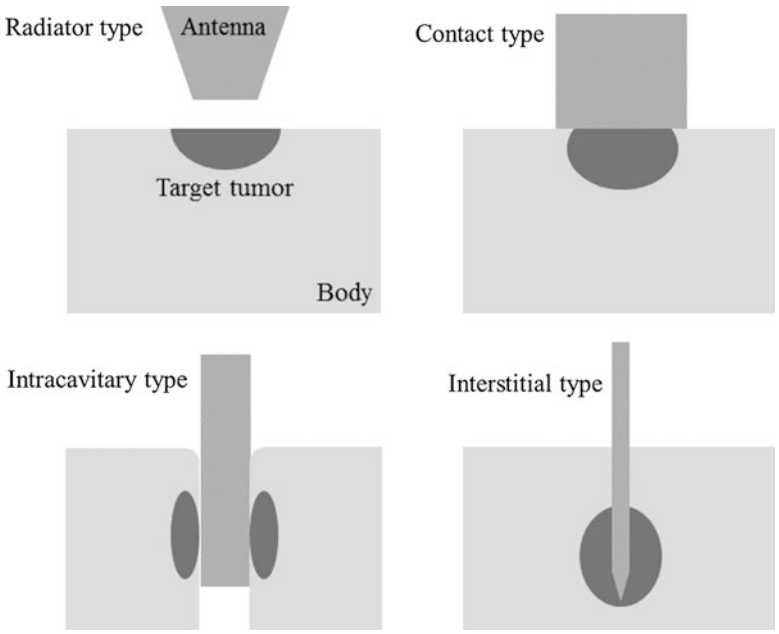

Fig. 9 Various types of antennas for microwave heating

Thermal Treatment of Cancer by Microwave Energy

Classification of Heating Scheme

There are several different methods of cancer treatment, including surgical operations, radiation therapy, chemotherapy, gene therapy, immunotherapy, ablation, and hyperthermia. Two or more different ways are sometimes combined for clinical use. Hyperthermia is one of the promising modalities for cancer treatment, utilizing the difference in the thermal sensitivity between tumors and normal tissue, and is one of the most effective medical applications of microwave techniques. In this treatment, the tumor is heated up to the therapeutic temperature, between 42 °C and 45 °C, without overheating the surrounding normal tissues (Seegenschmiedt et al. 1995). Moreover, the effect of other cancer treatments such as radiotherapy and chemotherapy can be enhanced by using them together with hyperthermia.

There are several energy sources used for heating the tumor, such as hot water, ultrasound, EM wave, etc. Microwave energy is one of the heating sources used for localized hyperthermia (Tsukiyama et al. 1991). The frequency for microwave hyperthermia ranges from several hundred to several thousand MHz (i.e., up to several GHz). For hyperthermia treatments, heating devices using 430 MHz, 915 MHz, and 2.45 GHz have been commercially developed.

The size and shape of the target tumors also vary. Therefore, it is impossible to treat many different types of tumors with a single unique type of antenna (Ito 2006). Figure 9 shows four different types of microwave antennas for hyperthermia treatment. The “radiator type” and the “contact type” are classified into “external antennas,” and the “intracavitary type” and the “interstitial type” are called “internal antennas.” Here, we introduce some topics regarding internal antennas.

Interstitial Microwave Hyperthermia

Interstitial microwave hyperthermia can be applied for a localized tumor. With this technique, thin microwave antennas are inserted into the tumor and radiate microwave energy directly into the target (Tsukiyama et al. 1991; Lin and Wang 1987), permitting effective and reliable heating of the tumor.

DOI 10.1007/978-981-4560-75-7_112-1

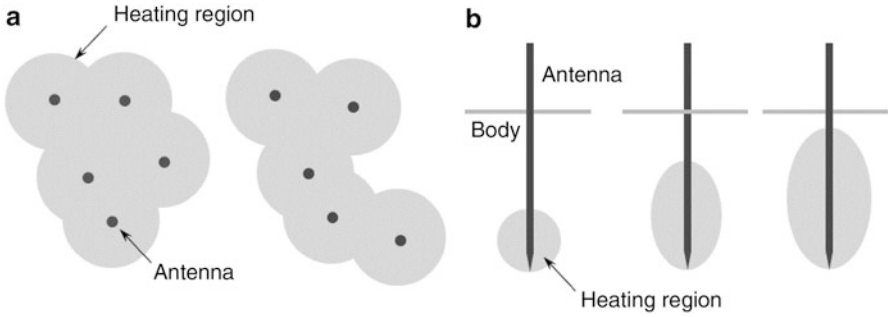

Fig. 10 Heating patterns generated by thin microwave antennas: (**a**) perpendicular to antenna axis; and (**b**) parallel to antenna axis

In this technique, it is possible to change the heating pattern in the perpendicular direction of the antenna axis by varying the number of elements and their insertion points (Fig. 10a). However, control of the heating pattern in the longitudinal direction of the antenna axis is realized by changing the structure of the antenna elements while keeping the thin structure (Fig. 10b). In the following sections, we describe the heating characteristics of the thin microwave antennas, which generate the controllable heating patterns in the longitudinal direction of the antenna axis. Moreover, arbitrary shape heating patterns by an array applicator composed of the developed antennas are also outlined.

Antenna Configuration

In order to generate a controllable heating region in the longitudinal direction, a coaxial-dipole antenna is employed. This antenna was developed for generation of a localized heating region around only the antenna tip (Kikuchi et al. 2006; Saito et al. 2008). Here, we attempt to explain advanced heating pattern control by the coaxial-dipole antenna.

Figure 11 shows the basic configuration of the coaxial-dipole antenna. The operating frequency of the antenna is 2.45 GHz, which is one of the industrial, scientific, and medical (ISM) frequencies in Japan. This antenna is composed of a thin, semi-rigid coaxial cable. A ring slot is cut on the outer conductor of the thin coaxial cable and the tip of the cable is short-circuited. Here, L_{ts} is the length from the shorted point to the center of the slot and is set to 10 mm for impedance matching (Kikuchi et al. 2006). In addition, two conductive sleeves, whose lengths (L_{ld} and L_{ud}) affect the shape of the heating region, are connected to both sides of the slot. The antenna is inserted to a catheter for hygiene. In addition, although the antenna insertion depth depends on the position of the target tumor, it is set 70 mm in this chapter.

SAR Distributions of a Single Antenna

In order to estimate the heating pattern around the antennas, the SAR around the antennas is calculated. Figure 12 and Table 3 show the calculation model of the coaxial-dipole antenna and parameters for the calculations, respectively.

Figure 13 shows the measured and calculated SAR distributions around the antenna. The SAR observation line is parallel to the antenna axis and is 3.0 mm away from the center of the antenna (shown in Fig. 12). Here, the SAR distributions are measured using the thermographic method; details of the measurement are described in Saito et al. (2013a).

The length of the lower sleeve, L_{ld}, is changed from 10.0 to 30.0 mm when L_{ud} is set to 20.0 mm. In these results, the length of the high SAR region in the longitudinal direction is almost the same as the length of $L_{ld} + L_{ud}$ from the tip (the gray region in Fig. 13). Moreover, in all cases, good agreements are observed between the calculations and the measurements except at the slot position. The SAR value at the

DOI 10.1007/978-981-4560-75-7_112-1

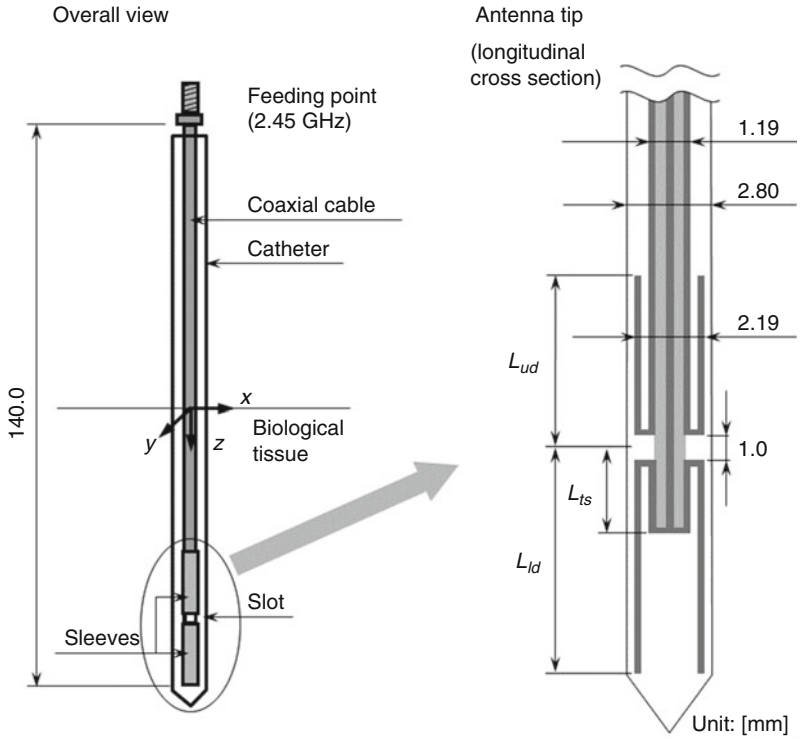

Fig. 11 Basic configuration of the coaxial-dipole antenna

slot is extremely high compared to other positions. In such a case, heat transfer at the peak point cannot be ignored in the thermographic method and the measured SAR value is lower than the calculation.

From these results, it can be said that the coaxial-dipole antennas generate the controllable heating regions in the longitudinal direction. In addition, according to preliminary investigations, the length of the sleeve (L_{ld} or L_{ud}) should be less than 30 mm for generating controllable heating patterns.

Moreover, if an antenna with enough lower sleeve length is prepared, the size of the longitudinal heating region can be adjusted easily by cutting the lower sleeve. In Fig. 13, the minimum length of the lower sleeve L_{ld} is 10 mm, which is the same as L_{ts}.

Generation of Arbitrary Shape Heating Patterns by Array Applicator

The controllable heating patterns in the longitudinal direction of the antenna axis could be generated by use of the coaxial-dipole antennas. Here, generation of three-dimensional arbitrary heating patterns is considered to be by array applicators. (The term "applicator" indicates the part of the heating system that is directly applied on the human body. On this basis, an antenna is an applicator. However, the "applicator" is used only for an array antenna and is not used for a single antenna element conventionally). In this chapter, heating patterns of the array applicators composed of four coaxial-dipole antennas are investigated. Figure 14 shows a calculation model of the array applicator. All of the antenna elements are fed by the same amplitude and in phase.

According to a previous study (Saito et al. 2004), 20 mm array spacing (intervals of antenna elements) was suitable for actual treatment. Therefore, this array spacing is complied with. In addition, antenna insertion depths of all antenna elements of 70 mm are the same.

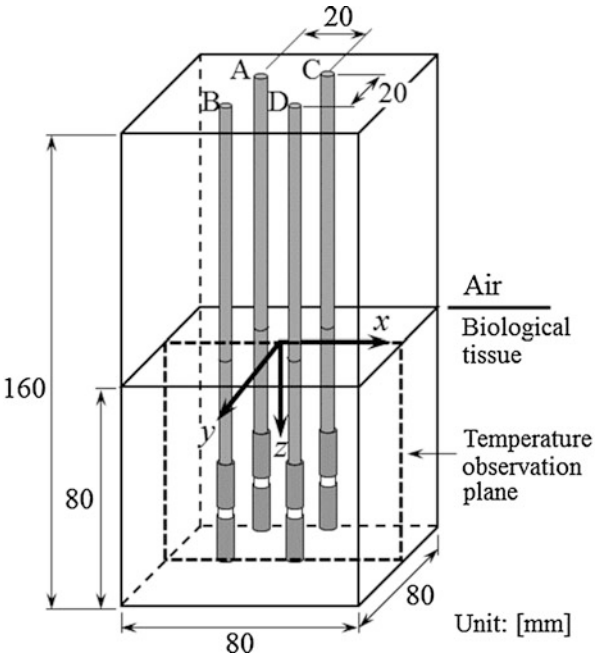

Fig. 14 Calculation model for the array applicator composed of four coaxial-dipole antennas

Here, heating patterns of the array applicators are evaluated by temperature distributions. The temperature distributions inside biological tissue can be calculated by solving a bioheat transfer equation (Penns 1948) (Eq. 2) numerically. The detail of the calculation scheme is the same as Saito et al. (2006c). In addition, electrical and thermal parameters for the calculations are listed in Table 4 (Van Den Berg et al. 1983; Johnson and Guy 1972).

$$\rho c \frac{\partial T}{\partial t} = \kappa \nabla^2 T - \rho \rho_b c_b F (T - T_b) + \rho \cdot \mathrm{SAR} \tag{2}$$

where T is the temperature [°C], t is the time [s], ρ is the density of the tissue [kg/m^3], c is the specific heat of the tissue [J/kg K], κ is the thermal conductivity of the tissue [W/m K], ρ_b is the density of the blood

DOI 10.1007/978-981-4560-75-7_112-1

Initial temperature [°C]	37.0
Blood temperature [°C]	37.0

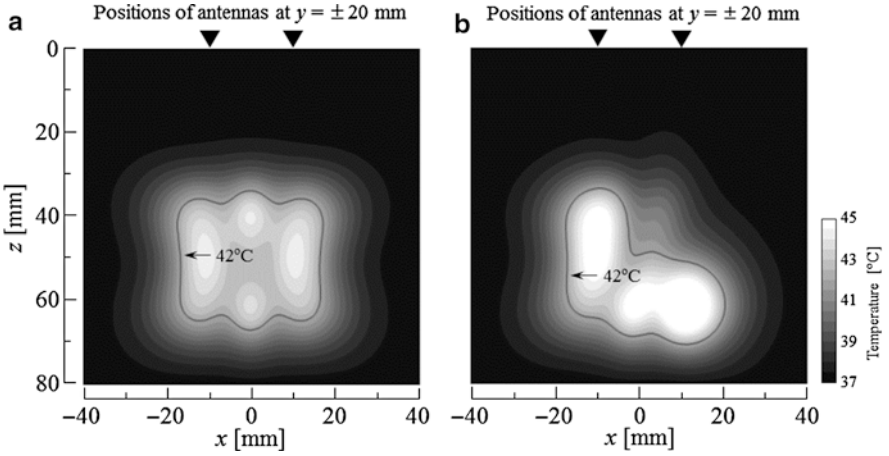

Fig. 15 Calculated temperature distributions by two types of array applicators. (**a**) All antenna elements have the same parameters. (**b**) Two sleeve parameters

[kg/m^3], c_b is the specific heat of the blood [J/kg K], T_b is the temperature of the blood [°C], and F is the blood flow rate [m^3/kg s].

Figure 15 shows the calculated temperature distributions. The temperature observation plane is defined in Fig. 14 and the black solid line indicates the region more than 42 °C, which is the lowest temperature for the treatment (effective heating region). Radiation power from the whole array is 20 W. Even in the array applicator, it is preferable that the size of the effective heating region in z direction is same as the length of $L_{ld} + L_{ud}$ for heating pattern control.

As shown in Fig. 15a, when all antenna elements have the same parameters, the size of the effective heating region in the longitudinal direction (z direction at $x = \pm 10$ mm) is approximately 27 mm. In this case, the length of $L_{ld} + L_{ud}$ is 40 mm. Therefore, the size of effective heating region decreases by 33 %.

On the other hand, as shown in Fig. 15b, in the case of using two kinds of sleeve parameters, the sizes of the longitudinal heating regions depend on the sleeve length. Therefore, the length of the effective heating region in z direction close to the elements A and B (at $x = -10$ mm) is approximately 29 mm, even though the length of $L_{ld} + L_{ud}$ is 40 mm. It decline by 28 %. In addition, the length in z direction around the elements C and D (at $x = +10$ mm) is 19 mm. This is almost the same as $L_{ld} + L_{ud}$.

DOI 10.1007/978-981-4560-75-7_112-1

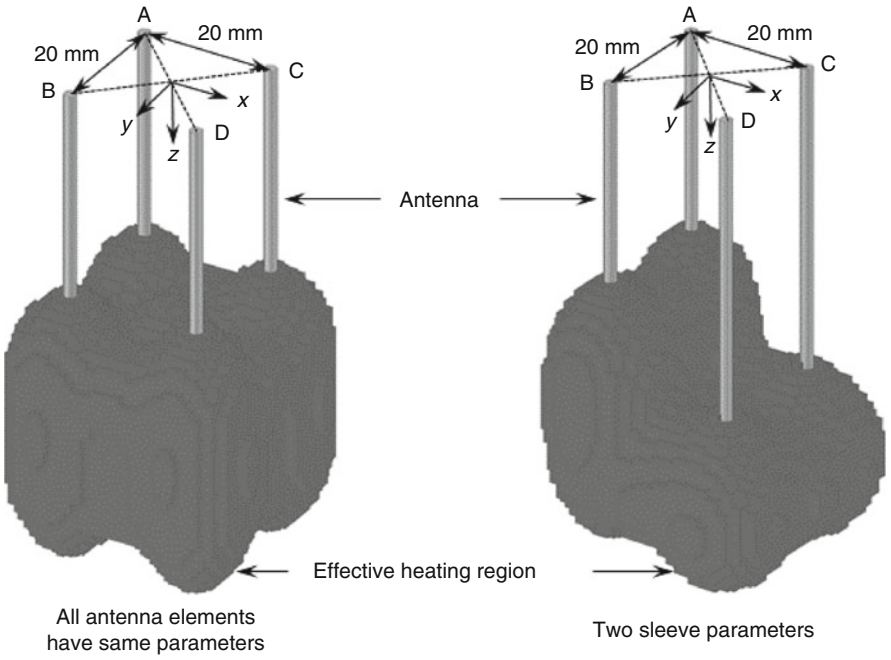

Fig. 16 Three-dimensional calculated temperature distributions

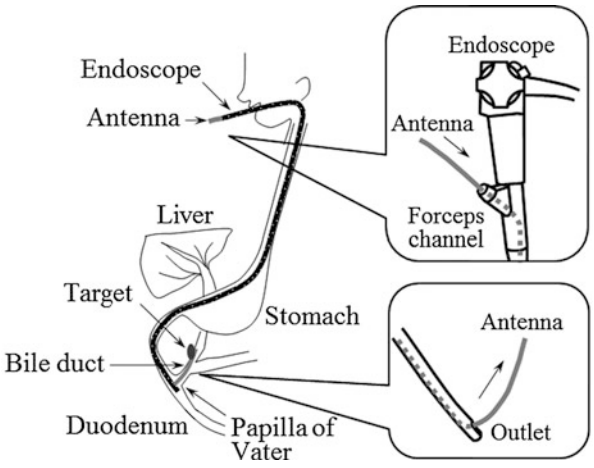

Fig. 17 Scheme of intracavitary microwave hyperthermia for bile duct carcinoma

From these results, it can be said that the heating pattern depends on the sleeve length in the array applicator. This can be clearly seen in Fig. 16, which shows the three-dimension effective heating region.

Intracavitary Microwave Hyperthermia

Microwave antennas can be used for intracavitary microwave hyperthermia if the target tumor is located close to an abdominal cavity, such as the esophagus, large intestine, urethra, etc. We have been studying the microwave antenna with endoscope for intracavitary microwave hyperthermia of bile duct carcinomas, and the scheme of the treatment is shown in Fig. 17. In this treatment, an endoscope is firstly inserted into the duodenum, and a long, thin, flexible microwave antenna is inserted into the forceps channel of the endoscope. Finally, the antenna is guided to the bile duct through the papilla of

DOI 10.1007/978-981-4560-75-7_112-1

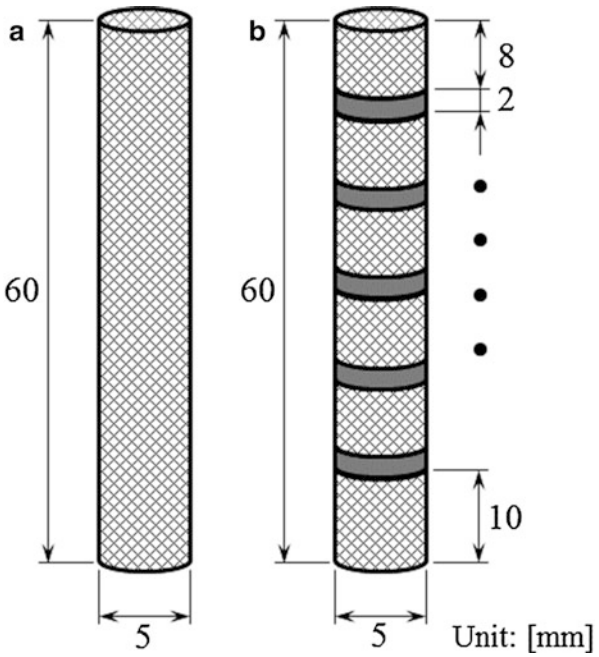

Fig. 18 Structure of biliary stents: (**a**) conventional stent; and (**b**) proposed stent

Vater, which is located in the duodenum. This non-invasive treatment is effective for treating unresectable bile duct carcinoma. Therefore, it is expected to be useful for treating various types and locations of carcinomas.

It should be noted that placement of self-expandable metallic stents is the current standard of care for patients with malignant obstructive jaundice caused by the bile duct carcinoma. However, in less than 50 % of patients with metallic stents, a stent blockage develops within 6–8 months (Loew et al. 2009) by explosive growth of cancer cells. Moreover, according to a previous study, the metallic stent will be shielded from microwave energy from the antenna inserted into it (Saito et al. 2010). Therefore, the authors introduced a new biliary stent compatible with microwave hyperthermia of bile duct carcinoma involving the use of an endoscopic coaxial antenna for intracavitary treatment.

Structure of the Biliary Stent

Figure 18 shows the structure of the two different biliary stent models: the conventional metallic stent (Fig. 18a) and the proposed stent (Fig. 18b) (Itakura et al. 2012). The proposed stent is composed of six metallic stents and five plastic stents of 2 mm in length. Taking the previous study into account, the arrangement of plastic stents at regular intervals could generate extensive heating outside of the stent. Moreover, if the distance between the plastic stents is narrowed to some extent, microwave energy cannot be radiated from plastic stents efficiently. Therefore, plastic stents (relative permittivity: 2.1) are arranged at regular intervals of 8 mm. The length and diameter of the stent, which were determined taking into account a previous study (Püspök et al. 2005), are 60 and 5 mm, respectively. In order to adjust for the length of the stent, a metallic part at the bottom of the proposed stent is set to 10 mm in length. Although stents generally have a mesh structure, a solid cylindrical structure is used in the calculation because the reticulation of a stent mesh is small enough in comparison with the wave length of the feeding EM wave.

Structure of the Coaxial Antenna

Figure 19 shows the structure of the coaxial antenna for feeding. The antenna is composed of a thin, flexible coaxial cable that can be inserted into the endoscope. The diameter of the coaxial antenna is

DOI 10.1007/978-981-4560-75-7_112-1

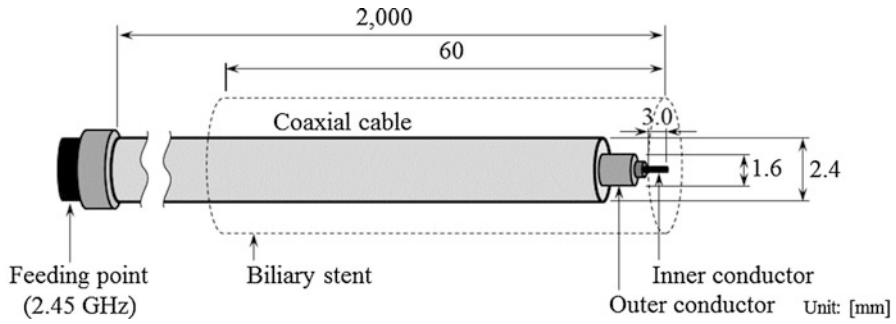

Fig. 19 Structure of feeding coaxial antenna

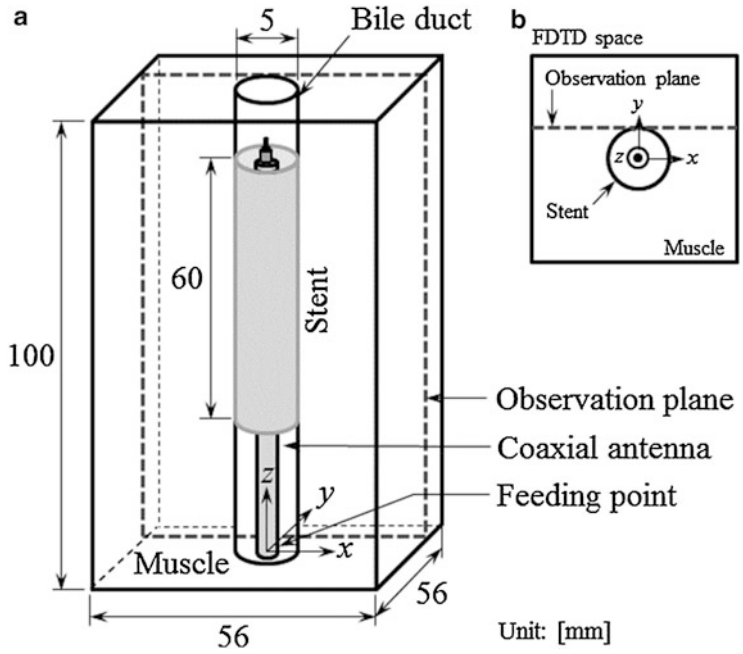

Fig. 20 Finite difference time domain space for the biliary stent and coaxial antenna: (**a**) over view; and (**b**) top view

2.4 mm. An inner conductor of the antenna sticks away 3 mm from the tip of the cable. A feeding point is set at the end of the cable. In this treatment, the whole antenna is placed at the center of the stent, and the antenna passes through the stent end at approximately 1 mm. Therefore, none of the antenna has contact with the stent. Thus, this feeding method utilizing EM coupling is able to be carried out in situations where the biliary stent has been covered with tissues or tumors due to restenosis.

Calculation Model

Figure 20 shows the FDTD calculation model for the biliary stent and the coaxial antenna and observation plane. The stent model is placed in the bile duct filled with the bile, and the bile duct is in the muscle. Moreover, assuming restenosis due to tumors, the inside of the stent is filled with muscle from the viewpoint of their electrical properties. The operating frequency of the antenna is 2.45 GHz. The parameters used in the FDTD calculations and the properties of the biological tissues are listed in Table 5 (Duck 1990; Van Den Berg et al. 1983).

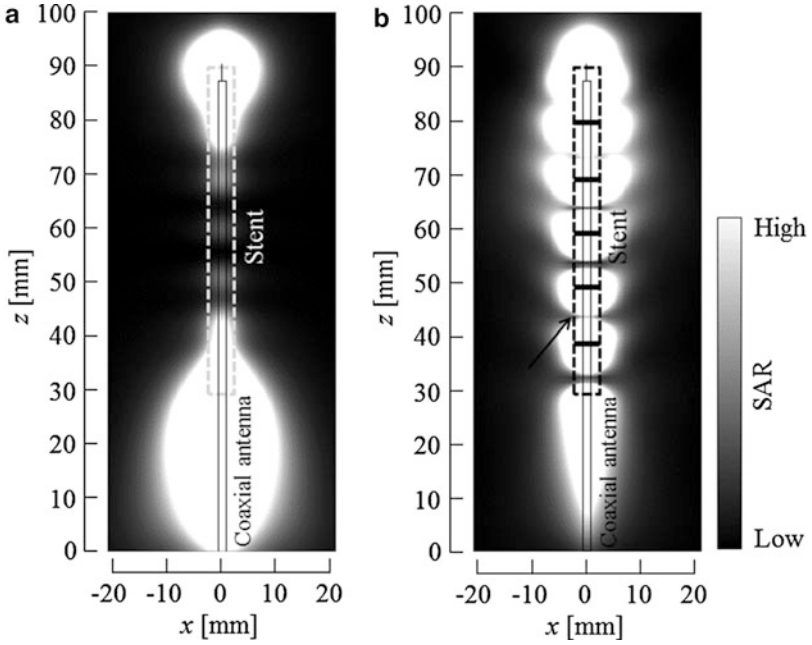

Fig. 21 Calculated specific absorption rate distributions: (**a**) conventional stent; and (**b**) proposed stent

Calculated Results

Figure 21 shows the calculated SAR distributions around the conventional and proposed metallic stent. The observation plane is defined in Fig. 20. In the conventional metallic stent, a lower SAR around the central part of the stent ($40 < z < 70$ mm) than around both edges of the stent ($10 < z < 30$, and $85 < z < 95$ mm) is observed. This is due to the shielding effect by the metallic stent. The target carcinoma should be located at near or around the central part of the stent; thus, this result means that the conventional metallic stent is unsuitable for the treatment. Besides, in the proposed metallic stent, the higher SAR region appears around the whole of the stent ($30 < z < 90$ mm). It is considered that the microwave energy can leak to the outside from the plastic parts of the stent. From the above, it can be said that the proposed stent can have significant heat around it, where the target carcinoma should exist.

Experimental Evaluations

Figure 22 shows the experimental system used in SAR measurements. Figures 23a, 23b show trial manufacture of the biliary stent and the endoscopic coaxial antenna. First, the trial-manufactured proposed and conventional metallic stents are put between the muscle-equivalent solid phantoms (Figs. 23c, 23d). Next, the antenna passes through the stent end at 1 mm and supplies it with microwave energy. The probe is connected to a microwave generator. The input power and the radiation time for the probe are set at 50 W and 60 s, respectively. The measured temperature rise distributions by an infrared camera are converted to the SAR distributions (Okano et al. 2000). The observation plane of the experiment is the same as the calculations shown in Fig. 20.

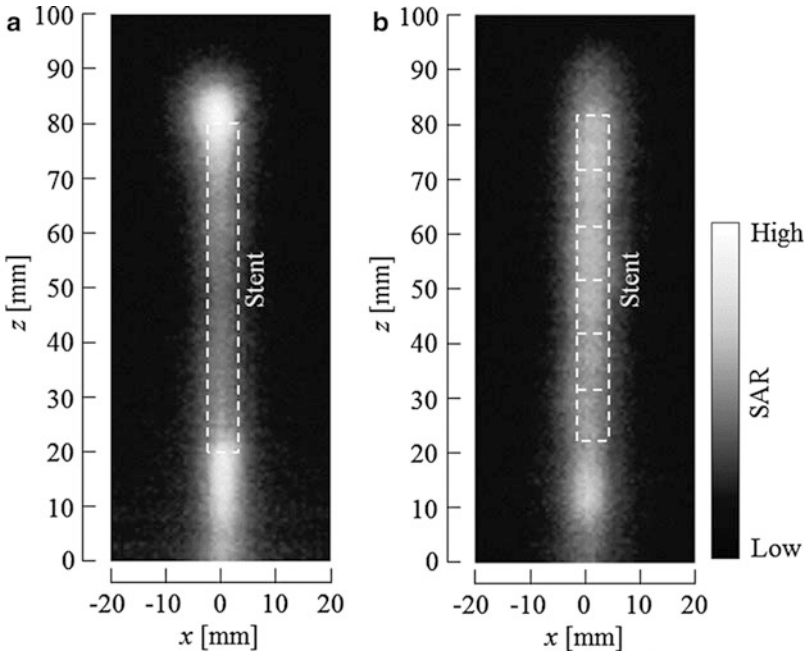

Fig. 24 Measured specific absorption rate distributions: (**a**) conventional stent; and (**b**) proposed stent

Figures 24a, 24b show the SAR distribution around the conventional and proposed metallic stent. In the conventional metallic stent, a lower SAR region around the central part of the stent ($40 < z < 70$ mm) than at both edges of the stent ($20 < z < 30$ mm, and $80 < z < 90$ mm) is observed. Besides, in the proposed stent, the higher SAR region around the whole of the proposed stent can be observed due to the microwave energy leaked to the outside from each plastic part of the stent. From these results, it is confirmed that the proposed stent could generate extensive heating regions around it in the longitudinal direction of up to 60 mm.

Summary

In this section we have introduced the heating characteristics of the microwave antenna for interstitial and intracavitary heating. Not only the development of practical devices but also the treatment protocol should be investigated in further studies.

Surgical Devices Using Microwave Energy

We have also investigated development of surgical devices using the thermal effect of microwave energy. Generally, the electrical scalpel has been widely used for surgical operations. It uses the RF current (from several hundred kHz to several MHz) and can realize both tissue coagulation and dissection. However, this device has some problems. First, it requires an external electrode which sometimes causes burn injuries around it. Moreover, the RF current may flow through an unexpected part, and causing involuntary muscle movement. In addition, since the device generates an extremely high temperature, the biological tissue is carbonized. As a result, fog is be generated. This is a serious problem, especially in laparoscopic surgery. Ultrasonically activated scalpels are also used in surgical operations. In this case, bodily fluid may be splashed by the device, causing the fog that is undesirable in laparoscopic surgery.

DOI 10.1007/978-981-4560-75-7_112-1

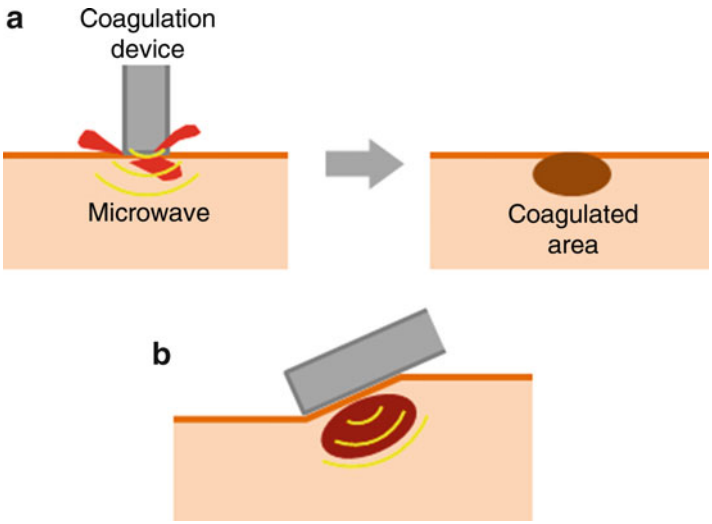

Fig. 25 Microwave tissue coagulation device: (**a**) hemostasis; and (**b**) generation of side coagulated region

It should be noted that massive bleeding during a surgical operation is a danger for the patient. In particular, laparoscopic surgery cannot be continued if there is significant bleeding because the view of the laparoscope is reduced. Therefore, hemostasis is one of the most important treatments (Fig. 25a). Saito et al. (2013b) have studied the tissue coagulation device based on a microwave small-loop antenna and confirmed its effectiveness using numerical calculations and some experiments. However, there is a problem that should be improved: the developed device can generate a coagulated region only around the bottom of it, whereas a coagulated region around the side region of the device is important in some cases (Fig. 25b). Therefore, in the following sections we introduce a tissue coagulation device for hemostasis that can generate coagulated regions around the bottom and the side of it.

Structure of the Device

In our study, a helical structure is employed for the coagulation device shown in Fig. 26. The number of helices is 11 and the pitch of the wire is 2.0 mm. Moreover, the whole helical part is covered by polytetrafluoroethylene (PTFE) material for prevention of tissue adhesion. The operating frequency of the antenna is 2.45 GHz.

Figure 27 shows the FDTD calculation models. The antenna contacts muscle tissue in two ways, and is fed by a coaxial cable. In addition, the entire device is placed in a saline solution that assumes the same properties as bodily fluid.

Heating Characteristics

The heating performance of the device is evaluated by numerical calculations and experiments using a biological tissue. The procedure of the calculation is the same as in section "Thermal Treatment of Cancer by Microwave Energy." First, SAR distribution around the antenna is calculated. After that, temperature distribution in muscle tissue is calculated by solving the bioheat transfer equation numerically. The physical properties of muscle tissue are listed in Table 6.

Figure 28 shows the calculated temperature distributions. The observation planes are a *yz*-plane of $x = -1.7$ mm for Model A and *xy*-plane of $z = -1.0$ mm for Model B. The input power and heating time are 80 W and 20 s, respectively. The maximum sizes of the coagulated region in these planes (a region more than 60 °C) are approximately 13 × 33 mm (*yz*) in Model A and 5 × 4 mm (*xy*) in Model B.

Specific heat (c) [J/kg K]	3600
Thermal conductivity (κ) [W/m K]	0.50
Density (ρ) [kg/m^3]	1020
Blood flow rate (F) [m^3/kg s]	8.3×10^{-6}
Initial temperature [°C]	37.0

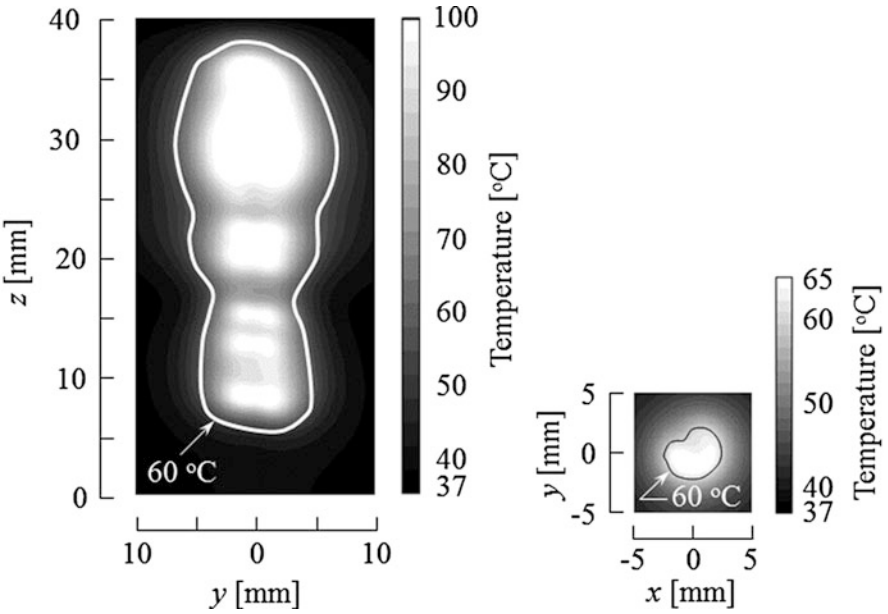

Fig. 28 Calculated temperature distributions

The validity of the device is confirmed by experiments using the removed biological tissue. Figure 29 is photograph of the experiment. Here, the radiation power from the device and radiation time are approximately 25 W and 10 s, respectively. In addition, this experiment was performed without saline water because this was a fundamental investigation.

From Fig. 29, the coagulated region can be confirmed around the side and bottom of the device. Therefore, it can be said that the developed device generates two coagulated regions using one device.

Summary

Prototype devices, which can be used for actual surgical treatment, will be developed in a further study. However, the effectiveness of the device must be confirmed in living animals before its use in actual treatments.

Holographic Antennas

Christian Rusch*
Institut für Hochfrequenztechnik und Elektronik, Karlsruhe Institute of Technology, Karlsruhe, Germany

Abstract

The holographic theory known from optics can also be used to describe the functionality of a special kind of leaky-wave antennas. Within the so-called holographic antenna, a hologram builds the radiating aperture, which is fed by surface-wave modes traveling on thin substrates. The hologram can be described as the interference pattern of the superposition of the traveling surface wave and the radiated plane wave. Therefore, it is possible to control the beam direction and beam shape of the holographic antenna by a modification of the hologram form. Compared to other kinds of leaky-wave antennas, the holographic antennas have also advantages in manufacturing and system integration, which make them to be a very promising antenna type for different millimeter-wave applications, e.g., radar systems.

Keywords

Holographic antenna; Leaky-wave antenna; Traveling-wave antenna; Beam scanning; Millimeter-wave antenna; Millimeter-wave radar

Introduction

Mostly known leaky-wave antennas are slotted waveguides or similar antennas realized as substrate-integrated waveguides (SIW). For high frequencies the manufacturing of waveguides is expensive and complex. SIW technology is easier to manufacture, also at low millimeter-wave frequencies, but at sub-THz range the necessary via distance to guide the waveguide mode with low leakage through the sidewalls should not be more than a few micrometers. This recommendation cannot be reached by commercial printed-circuit-board (PCB) processes, which are available today.

Holographic antennas do not need vias and can be realized with different kinds of technologies as etching processes or with thin-film process. Therefore, a manufacturing also for systems working at D or J band is possible. The idea of the holographic antenna was already published in 1968 by P. Checcacci. Due to the low aperture efficiency of that antenna type and the used difficult feeding by an external horn antenna then, the research was nearly stopped for many years. Just in the last century, some groups worked again on this field as they also see the holographic antenna due to the low complexity and the good integration skills in spite of the large aperture as promising candidate for millimeter-wave radars.

Within this chapter the theory of the holographic antenna with its analogy to the optical holography is explained and recommendations for the antenna design are made.

Concrete designs with feeding structures for creating the traveling surface-wave mode are presented. A novel combination with a feeding array also allows the beam scanning within two dimensions. The millimeter-wave radar with integrated holographic antenna is presented at the end of this chapter as an application that extremely benefits from the integration properties and the beam-scanning functionality.

Theory

The holographic antennas belong to the group of leaky-wave antennas. Their distinctive feature is that the theory from the optical holography is used to calculate the geometry of the radiating aperture in contrast to other antenna types described in (see chapter on Jackson, "► Traveling-Wave Antennas (Including Leaky Wave and Surface Wave Antennas"), e.g., the slotted waveguide antennas.

After describing the theory of optical holography, this theory is transferred to the antenna design process in section "Using the Holographic Theory for Antenna Designs." Due to the usage of surface-wave modes in the context with holographic antennas, their propagation is theoretically explained in section "Propagating Surface Waves as Reference Waves." Also, possibilities creating these modes are shown in the following section. Due to the fact that holographic antennas are kind of periodic leaky-wave antennas, the relation to this group is pointed out in section "Properties of Leaky-Wave Antennas."

A Short Description of Optical Holography

The optical holography was invented and described the first time in 1948 from the Hungarian engineer Dénes Gábor. This method is used to record the spatial image of an object and allows the three-dimensional reconstruction (Gabor 1948). The term "holography" includes the Greek designations "holos" and "graphein." A translation of these Greek terms means "complete image." This completeness is achieved by recording not only intensity values but also values, which describe the different heights of the object. An explanation follows with a comparison between photography and holography.

During the recording process of photography, an image of the object is built on a photographic film by using an objective. An illumination of the object is necessary. The intensity values of the light, which is reflected by the object, are recorded on the film or today's usually used light sensor. The phase information of the light waves is not recorded and therefore is lost by this method. For the observer results a two-dimensional image of the object.

The method of holography consists of the two-process steps "recording" and "reconstruction." During the recording, the object and the photo film are illuminated with a coherent light source as shown in Fig. 1 on the left. A non-flat object will produce reflected waves with phase variations among each other depending on the positions of the individual reflecting points on the object's surface. These so-called object waves with different phase values interfere with the directly illuminating reference wave (plane wave) on the photographic film. The resulting interference pattern is called "hologram" and contains both the intensity information as brightness contrast (similar to the photography) and the height information (phase) as distance variation between the interference lines.

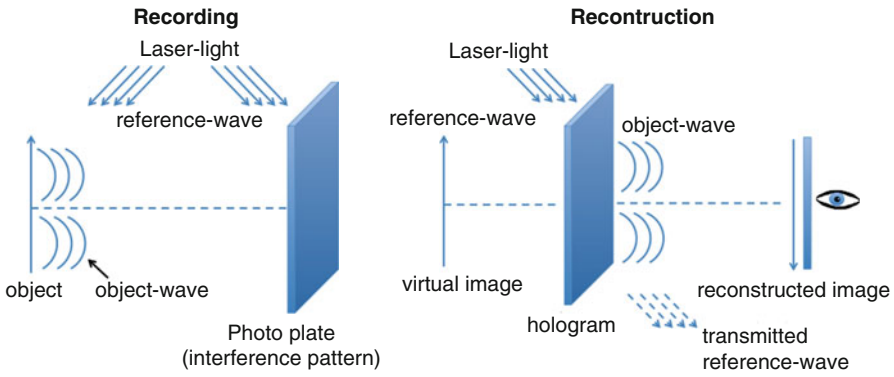

Fig. 1 Process steps of the optical holography

DOI 10.1007/978-981-4560-75-7_113-1

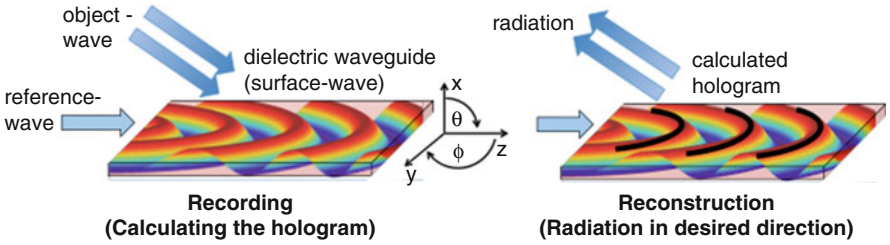

Fig. 2 Schematic illustration of the holographic antenna concept

Illuminating the hologram with the reference light source, which was also used during the recording, does the following reconstruction of the object. The superposition of the light with the interference pattern (hologram) creates a three-dimensional image of the recorded object (see. Fig. 1, right side). This theoretical approach can be used to describe the function of special types of leaky-wave antennas.

Using the Holographic Theory for Antenna Designs

For holographic antennas, the explained theory of the optical holography process is used to calculate the geometry of the radiating aperture. As a photographic film cannot be used as radiating aperture, the recording process is only a theoretical approach to calculate the necessary interference pattern. A schematic representation of the two-process steps transferred to the antenna design is shown in Fig. 2.

The holographic antenna consists of an antenna substrate, which is used as dielectric waveguide for a surface-wave mode propagating in z-direction with its wave number β_0. In relation to the optical holography, this surface wave builds the reference wave. An excitation of this mode type can be done by illuminating the substrate edge with horn antennas (Iizuka et al. 1975; Sooriyadevan et al. 2007; ElSherbiny et al. 2004) or by implementing planar end-fire antennas as surface-wave launchers directly on the substrate surface (Podilchak et al. 2008; Hammad et al. 2003). Within an area with small distance to the source, a traveling wave with circular phase front arises. By using a point source within the substrate, the electric field of the propagating surface wave in a lossless medium can be described as follows (for Cartesian coordinates):

$$\vec{E}_{\mathrm{ref}_{z,\,y}} = E_{\mathrm{ref}_r} \cdot e^{-j\beta_0 r} \tag{1}$$

with

$$z = r \cdot \cos(\phi)$$

$$y = r \cdot \sin(\phi)$$

The surface wave propagates from the source spherically and uniformly within the substrate plane (see. Fig. 2, left side). The parameter r describes the radial distance of the wave to the source. $\vec{E}_{\mathrm{ref}_z}$ and $\vec{E}_{\mathrm{ref}_y}$ are the electric-field components. For ideal circular propagation the amplitude and phase of the electric field are constant at a radial distance to the source. The amplitude at distance r to the surface-wave launcher is called E_{ref_r}.

DOI 10.1007/978-981-4560-75-7_113-1

The radiated TEM wave is defined as object wave, but for calculating the hologram a superposition of this TEM object wave with the reference wave on the substrate surface is assumed. The direction of the incoming object wave, which determines the resulting main-lobe direction of the antenna, is defined by the angles θ_0 and ϕ_0 (see Fig. 2). The electric-field components illuminating the substrate surface ($x = 0$) are described as a function of the angular direction.

$$\vec{E}_{\mathrm{obj}_{z,y}} = E_{\mathrm{obj}_{z,y}} \cdot e^{jk_0 \cdot \sin(\theta_0) \cdot \cos(\phi_0) \cdot z} \cdot e^{jk_0 \cdot \sin(\phi_0) \cdot y} \tag{2}$$

$E_{\mathrm{obj}z,y}$ describes the amplitude of the field components and k_0 is the propagation constant of the TEM wave in free space.

Samples for calculated phase fronts of a reference wave propagating as surface wave within the substrate and of an object wave with $\theta_0 = -45°$ and $\phi_0 = 0°$ at the substrate surface are shown in Fig. 3a, b. For the calculation of the interference pattern, it is assumed that the object wave is not radiated but illuminates the substrate surface and builds a superposition with the circular reference wave. Figure 3c shows the resulting interference pattern. The cylindrical geometry is a result of the spherical phase front of the propagating reference wave close to the surface-wave launcher. To build the hologram on the substrate surface, metallic stripes are used. These stripes shorten the electric-field lines of the surface-wave mode at their positions and therefore build the roots of the interference pattern. Therefore, the created hologram in Fig. 3d builds an interference pattern with reduced phase information. By using this method the remaining phase information is lost.

Nevertheless the feeding of this type of hologram with the reference wave shows a radiation with the previously defined main-lobe direction.

Propagating Surface Waves as Reference Waves

The easy way of integrating holographic antennas to millimeter-wave systems is a result of using surface-wave modes to feed the hologram as radiating aperture. For calculating the hologram geometry of a predefined radiation characteristic, the knowledge about the wave number β_0 of the propagating mode is necessary. To calculate β_0 of the different propagable modes on a substrate as shown in Fig. 4 and plotting mode charts as shown in Fig. 5 following assumptions are made.

- The substrate is infinitely extended in y- and z-direction.
- The substrate is lossless.
- The surface-wave propagation direction is $+z \rightarrow e^{-j\beta_0 z}$.
- All electromagnetic fields in y-direction are constant $\left(\frac{\delta}{\delta y} = 0\right)$.
- Continuity of the tangential field components at the air-dielectric transition → no inconstancy of the fields at the boundary.

As described in (Beer 2013), the following four transversal field components for the symmetrical case depending on the longitudinal components exist:

$$E_x\left(\frac{\omega^2}{c^2} - \beta_0^2\right) = -j\beta_0 \frac{\partial E_z}{\partial x} \tag{3}$$

DOI 10.1007/978-981-4560-75-7_113-1

Table 1 Mode equations of the TE and TM surface waves

	Mode equation	Cutoff frequency
Even TM with $n = 0, 2, 4,\ldots$	$\frac{k_c}{k_0}\tan\left(\frac{k_c}{k_0}2\pi\frac{d}{\lambda_0}\right) = \varepsilon_r\sqrt{(\varepsilon_r-1)} - \frac{k_c^2}{k_0^2}$	$f_c = \frac{nc_0}{n4d\sqrt{\varepsilon_r-1}}$
Odd TM with $n = 1, 3, 5,\ldots$	$-\frac{k_c}{k_0}\cot\left(\frac{k_c}{k_0}2\pi\frac{d}{\lambda_0}\right) = \varepsilon_r\sqrt{(\varepsilon_r-1)} - \frac{k_c^2}{k_0^2}$	$f_c = \frac{nc_0}{n4d\sqrt{\varepsilon_r-1}}$
Even TE with $n = 0, 2, 4,\ldots$	$\frac{k_c}{k_0}\tan\left(\frac{k_c}{k_0}2\pi\frac{d}{\lambda_0}\right) = \sqrt{(\varepsilon_r-1)} - \frac{k_c^2}{k_0^2}$	$f_c = \frac{nc_0}{n4d\sqrt{\varepsilon_r-1}}$
Odd TE with $n = 1, 3, 5,\ldots$	$-\frac{k_c}{k_0}\cot\left(\frac{k_c}{k_0}2\pi\frac{d}{\lambda_0}\right) = \sqrt{(\varepsilon_r-1)} - \frac{k_c^2}{k_0^2}$	$f_c = \frac{nc_0}{n4d\sqrt{\varepsilon_r-1}}$

$$E_y\left(\frac{\omega^2}{c^2} - \beta_0^2\right) = j\omega\mu_0\mu_r\frac{\partial H_z}{\partial x} \tag{4}$$

$$H_x\left(\frac{\omega^2}{c^2} - \beta_0^2\right) = -j\beta_0\frac{\partial H_z}{\partial x} \tag{5}$$

$$H_y\left(\frac{\omega^2}{c^2} - \beta_0^2\right) = -j\omega\varepsilon_0\varepsilon_r\frac{\partial E_z}{\partial x} \tag{6}$$

Due to the inhomogeneous medium perpendicular to the z-direction, the propagation of transversal-electromagnetic waves (TEM waves) is not possible. Therefore, the propagable TE and TM modes can be described with the general field components (see Eqs. 3, 4, 5, and 6). The results are summarized in Table 1. The parameters k_c and h build the cutoff wave numbers for the regions within the substrate or vacuum:

$$k_c^2 = \varepsilon_r k_0^2 - \beta_0^2 \text{ for } 0 \le |x| \le d$$

$$h^2 = \beta_0^2 - k_0^2 \text{ for } d \le |x| \le \infty$$

The equations for the single modes in Table 1 can be solved numerically to plot the mode diagrams and to determine the wave number β_0 of the propagating wave. It can be seen that the propagation of the modes TE_0 and TM_0 is already possible on very thin substrates, because there is no cutoff frequency for these two modes. By adding a continuous metallization on one substrate surface (top or bottom layer), the propagation of TE modes with even mode numbers ($n = 0, 2, 4,\ldots$) and TM modes with odd mode numbers ($n = 1, 3, 5,\ldots$) is suppressed. The reason is that the electrical field lines of these modes would be parallel to the metallization.

TE_0 on substrates without metallization plane and TM_0 modes on substrates with metallization are the two modes mostly used as reference waves for holographic antennas, because high mode purity can be guaranteed. The propagation of further modes could create other unwanted radiating main lobes.

Surface-Wave Launchers

During the history of holographic antennas, several ways to create the desired surface-wave mode have been developed. Today especially the planar feeds directly printed on circuit boards are interesting, because they allow the design of compact and easy-to-integrate holographic antennas up to very high frequencies. Since the hologram builds the radiating aperture, the influence of the surface-wave launcher on the radiation pattern is low, as long as the launcher works stable within the desired frequency range and

DOI 10.1007/978-981-4560-75-7_113-1

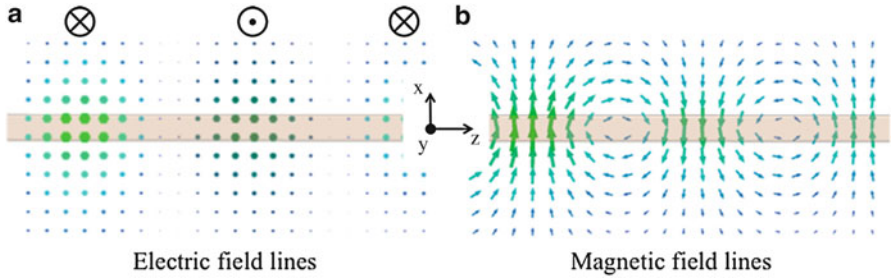

Fig. 6 Field distribution of a TE_0 surface wave propagating in $+z$-direction

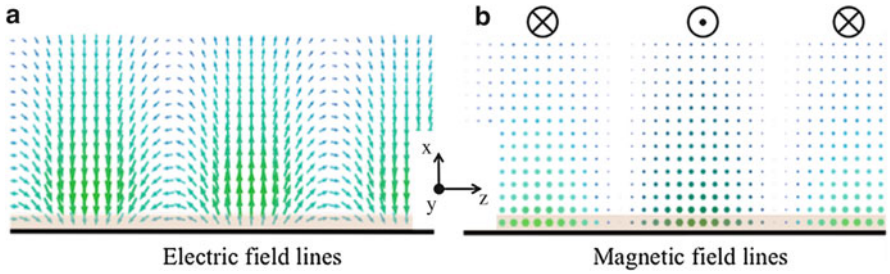

Fig. 7 Field distribution of a TM_0 surface wave propagating in $+z$-direction

illuminates the complete hologram area. There are different possibilities to create the desired mode and because of the low effect to the radiation pattern, the choice can be made on other properties, e.g., the integration level or the feeding line technology of the surface-wave launcher.

A view to the field lines of the two modes, TE_0 on substrates without metallization plane (Fig. 6) and TM_0 on substrates with metallization on one substrate side (Fig. 7), helps to investigate possible surface-wave launchers. With the electric-field perpendicular and the magnetic field lines parallel to the propagation direction, the field distribution of TE_0 waves is similar to a slot-line mode. For this reason tapered slot antennas are advisable to be used as surface-wave launchers for TE_0 modes on substrates without metallization. Different variations of these surface-wave launchers are possible, e.g., the planar Vivaldi antenna with feeding slot line or an antipodal version with microstrip feeding line (Bai et al. 2011).

For TM_0 reference waves Podilchak published a slotted quasi-Yagi-Uda feed (Podilchak et al. 2009). Another possibility is an integrated horn antenna realized in SIW technology. The disadvantage is the need of a high number of vias in small distance to each other, which means high requirements for the manufacturing at high frequencies.

An overview of different surface-wave launchers will follow (see chapter on Rusch, "► Holographic Antennas", section "Propagating Surface Waves as Reference Waves.").

Properties of Leaky-Wave Antennas

After designing the hologram with the calculated β_0 of the propagating reference wave and the desired main-lobe direction at a certain frequency, the antenna's radiation characteristic can be described with leaky-wave antenna theory (see chapter on Jackson, "► Traveling-Wave Antennas (Including Leaky Wave and Surface Wave Antennas"). Figure 8 shows the longitudinal section of the antenna. The surface-wave launcher creates the reference wave, which feeds the periodic single elements of the hologram serially. Due to this point of view, the antenna can be described as periodic leaky-wave antenna. For this

DOI 10.1007/978-981-4560-75-7_113-1

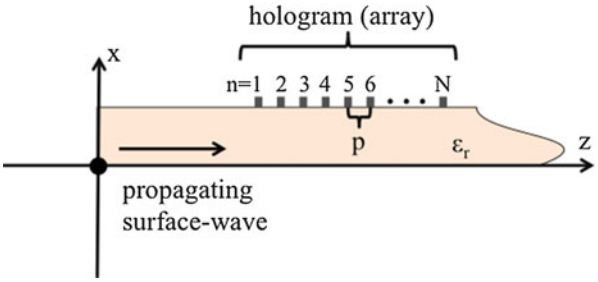

Fig. 8 Side view of the holographic antenna

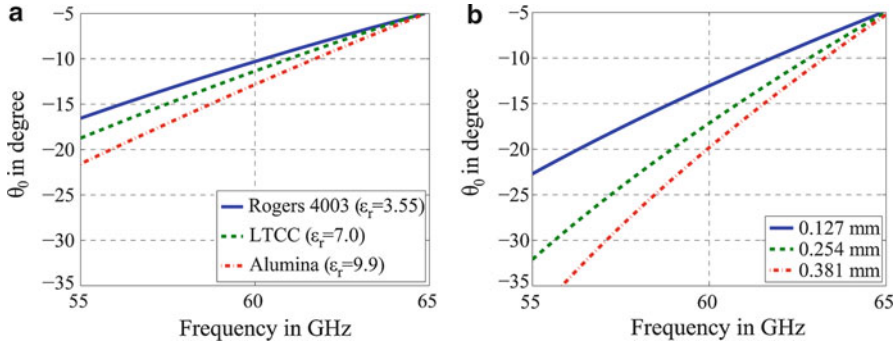

Fig. 9 Influence of material properties on the frequency-dependent scanning range

antenna type, radiation is done by the $n = -1$ spatial harmonic (Oliner 1993), due to the fact that the propagating surface-wave mode with $n = 0$ is a "slow wave" and therefore non-radiating.

With the known β_0 of the slow reference wave and the periodicity p of the hologram, the wave number of the different space harmonics can be calculated with the following equation:

$$\beta_n = \beta_0 + \frac{2\pi}{p} n. \tag{7}$$

The requirement for the radiation of a space harmonic is given by Eq. 8:

$$-k_0 < \beta_n < +k_0. \tag{8}$$

Here k_0 is the propagation constant of a TEM wave in free space. If this condition is met for a space harmonic, this wave is called "fast wave." The main-lobe direction of the antenna using a fast wave with β_n is given by Eq. 9:

$$\sin(\theta_0) \approx \frac{\beta_n}{k_0} \tag{9}$$

With Eq. 9 and the β_0 calculation from (see chapter on Rusch, "▶ Holographic Antennas," section "Propagating Surface Waves as Reference Waves"), the frequency-dependent main-lobe direction can be calculated. Figure 9 shows the scanning range of the antenna for different materials and depending on the substrate thickness. This results show that thick substrates with a high dielectric constant improve the scanning range of the antenna.

DOI 10.1007/978-981-4560-75-7_113-1

Design

With the theory from (see chapter on Rusch, "► Holographic Antennas," section "Theory"), the hologram shape for a holographic antenna radiating in a desired direction can be calculated. Also the effect of the material properties on the frequency-dependent scanning range was explained. Now we will see how the holographic antenna can be integrated within an RF front end. Also the usage of a surface-wave launcher array to build a 2D-scanning holographic antenna will be described. In the end of this chapter, two example designs of 1D- and 2D-scanning holographic antennas are presented.

Multilayer-Substrate Structure

The scanning range of holographic antennas with feeding surface waves is improved by thick antenna substrates with high dielectric constants. To enable interconnects to a front end with transmission-line technology, planar surface-wave launchers are used. Within a front end with signals transmitted via transmission lines (e.g., microstrip lines), the propagation of surface waves can decrease the efficiency of the transmission (Collier and White 1976). Therefore, at this area of the front end, it is advantageous to use thinner substrates to avoid the surface-wave propagation.

To avoid this, a trade-off in (Rusch et al. 2013a) a multilayer substrate is used for the radar front end with integrated holographic antenna (see Fig. 10). The "low-temperature cofired ceramic (LTCC)" has a complete thickness of 0.42 mm and a dielectric constant of $\varepsilon_r = 7.1$. Below the radar circuit, which is realized in microstrip technology, the ground plane (GND) is on the second metal layer. Due to this effective thin substrate (0.127 mm), the propagation of surface waves is avoided within this area and the microstrip lines have a high transmission factor. The GND plane is interrupted close to the surface wave launcher. The effective substrate thickness below the hologram is therefore 0.42 mm. With that value the propagation of surface waves is supported and the frequency-dependent scanning range is improved (see chapter on Rusch, "► Holographic Antennas," section "Properties of Leaky-Wave Antennas"). The simulated gain of this antenna is shown in Fig. 11. Within the frequency range of 55–65 GHz, the main-lobe direction changes by 41°.

Circular Holograms with Single Surface-Wave Launchers

Due to the holographic theory and the planar phase front of the radiated object wave, the hologram shape represents the phase front of the propagating reference wave. Due to the circular phase front created by a single surface-wave launcher, the single radiating elements are concentric semicircles with distance p to each other. The main lobe radiated within in the plane perpendicular to the substrate and the radiation angle depends on the distance p and the frequency. By changing the periodicity of the hologram, the radiation angle at a desired frequency can be changed (see Fig. 12a, b). Changing the main-lobe direction also within the second plane (xy) results in a hologram shape shown Fig. 12c. The circles are not concentric for this radiation characteristic. Therefore, controlling the main-lobe direction within two planes can only be done by an interchange of the hologram. One possibility is published in Rusch et al. (2013b). Here, the hologram is manufactured on a thin polyamide foil. The planar feed is realized directly on an empty ceramic substrate. By putting the foil on top of the substrate, a feeding of the hologram is possible and radiation in the desired direction is created. Since the foil is not fixed on top of the substrate, an interchange of the hologram allows changing the main-lobe direction of the antenna. The interchange of the hologram may be done by a mechanical solution.

Linear Holograms with Surface-Wave Launcher Arrays

By using a surface-wave launcher array, the propagating surface wave shows a planar phase front instead of a circular one (see Fig. 13). Due to this fact the single hologram elements also change their shape from circular to linear. As can be seen in Fig. 14, a simple rotation of this hologram with linear stripes means a beam forming of the radiation within the second plane. This effect can be used to build systems with the capability to control the main-lobe direction electronically within two planes.

Such a system is shown in Rusch et al. (2013c). Here, a phased array as surface-wave launcher is combined with the frequency-scanning capability of the holographic antenna. If the tilted propagating reference wave, created by the phase difference between the single launchers, impinges on the hologram, the effect on the main-lobe direction is similar to the rotation of the hologram itself. In Rusch et al. (2013c) a Rotman lens is used to realize the different propagation angles of the reference wave (for more information see chapter on Rusch, "► Holographic Antennas," section "Example I: 2D-Scannable

DOI 10.1007/978-981-4560-75-7_113-1

Holographic Antenna"). Also other phase-control feeding networks, i.e., the Butler matrix, or the usage of single MMIC phase shifters in front of every surface-wave launcher could be used.

Surface-Wave Launcher Designs

Depending on the desired mode of the reference wave, different types of surface-wave launchers can be used. In general the surface-wave launcher should satisfy the following conditions to get a holographic antenna with high efficiency and low cross polarization:

- Creating a surface-wave mode with high mode purity
- Low antenna mismatch
- Radiation within the substrate plane with high directivity to the hologram direction
- Frequency-independent radiation characteristic

For creating the desired mode, planar end-fire antennas can be used as surface-wave launchers. It has to be noticed that the launcher dimensions have to be matched to the wavelength of the propagating surface wave. Four examples of surface-wave launchers are shown in the following subsections.

Yagi-Uda -Feed

Planar dipoles or folded dipoles are often published surface-wave launchers. Adding a reflector and one or more directors improves the directivity of the launcher and results in a more efficient feeding of the hologram. The relative dimensions and distances of the single antenna elements can be copied from recommended values for Yagi-Uda antennas in air (Rothammel and Krischke 1995) but have to be adapted to the wavelength of the surface-wave mode. A fine adjustment should than be done via full-wave simulation. An integrated balun (see Fig. 15) can be used to feed the launcher with a coplanar waveguide (CPW), which also includes the reflector (Ma et al. 1999). With this balun the holographic antenna can be directly connected to single-ended ICs and also the measurements on a probe-based antenna setup are possible. Due to the resonant launcher type, the antenna matching is narrow band compared to other surface-wave launchers.

Planar Vivaldi Feed

Vivaldi antennas, as shown in Fig. 16, belong to the group of broadband antennas. Due to their broadband antenna matching and frequency-stable radiation characteristic, they are often used for ultra-wideband (UWB) applications (Pancera et al. 2011; Adamiuk et al. 2008). The taper shape and length of slot antennas are analyzed in different publications (Frayne and Leggetter 1991; Yngvesson et al. 1989). Mostly exponential tapers are used, which result in a broadband antenna matching and a high directivity. Due to the strong component of the electric field perpendicular to the propagation direction of the slot-line mode, this antenna type is very well suited to launch a TE_0 surface wave. The layout can be expanded by corrugations to suppress returning currents on the two wings and improve the antenna matching at center

DOI 10.1007/978-981-4560-75-7_113-1

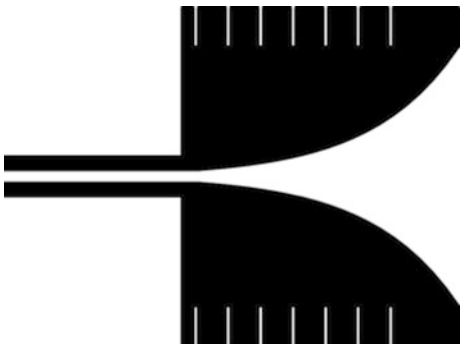

Fig. 16 Vivaldi antenna used as surface-wave launcher with slot-line feed

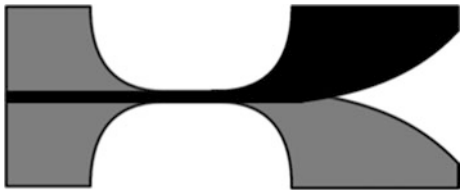

Fig. 17 Antipodal Vivaldi antenna as surface-wave launcher for TE_0 modes

frequency. One disadvantage is the variation of the phase center depending on the frequency. Therefore, it is not guaranteed for a very large bandwidth that the phase center is positioned within the center of the circular hologram. This effect can decrease the antenna efficiency. Due to the feeding slot line, this surface-wave launcher is especially suitable in combination with ICs with differential output ports. To connect with single-ended ICs or for probe-based antenna measurements, the balun from (see chapter on Rusch, "► Holographic Antennas," section "Yagi-Uda-Feed") could also be used.

Antipodal Vivaldi Feed

Also an antipodal version of the Vivaldi feed can be realized. In this case the two antenna wings are positioned on different substrate layers (see Fig. 17; Bai et al. 2011; Hood et al. 2008). The advantage is the feeding with microstrip line technology, which is often used in millimeter-wave front ends. To implement the feed within a microstrip front end, no transition between different transmission-line technologies is necessary and a very high bandwidth can be reached. The effects of taper shape and length are similar to that of the planar Vivaldi antenna. In addition the transition of the feeding microstip line to the strip-line mode between the antipodal wings has to be optimized with respect to the bandwidth and the radiation characteristic, which could have a tilted main-lobe direction, due to the influence of the substrate.

Example I: 2D-Scannable Holographic Antenna

There are different possibilities to control the phase of the surface-wave launcher array (see chapter on Rusch, "► Holographic Antennas," section "Linear Holograms with Surface-Wave Launcher Arrays"). Integrated phase shifters have the advantage to control the phase of every single launcher element stepless and independent of each other (Yun and Chang 2001). The disadvantage is the complex system integration of this kind of phase shifters due to the necessary biasing. Passive phase-control feeding networks like Butler matrix and Rotman lens are easy to implement but have only a limited number of phase shifts dependent on the number of input ports. Compared to the Butler matrix, the Rotman lens

DOI 10.1007/978-981-4560-75-7_113-1

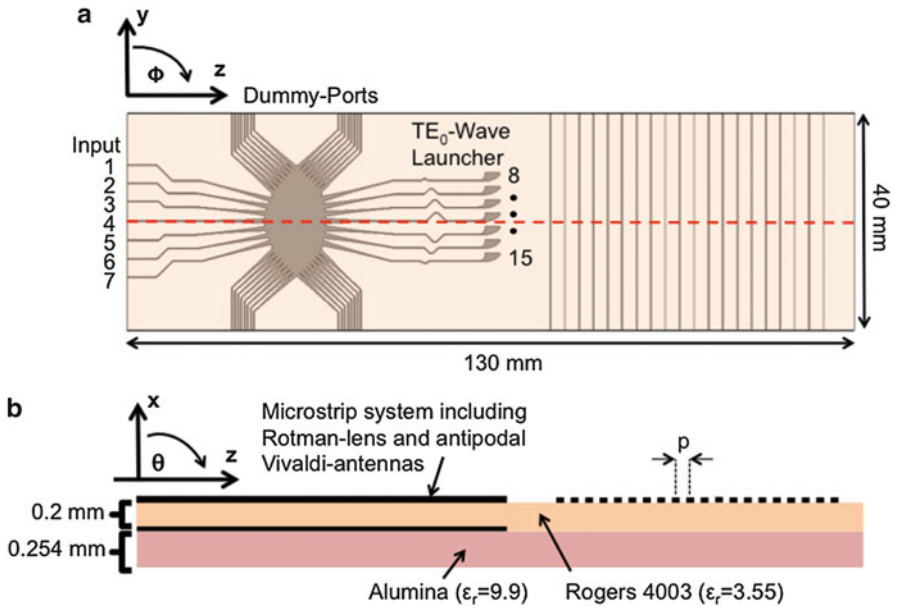

Fig. 18 Layout of the 2D-scannable holographic antenna with Rotman lens (Rusch et al. 2014)

allows more design variances to choose the phase-shift range and the step size within this range. Different kinds of design instructions can be found in the literature, starting with the original paper by Rotman (Rotman and Turner 1963). For the design process in the following example, the description from (Lambrecht et al. 2010) has been used.

Figure 18a shows the top view of the presented antenna. The hologram builds the radiating aperture and consists of linear metal stripes. As described in detail in (see chapter on Rusch, "► Holographic Antennas," section "Using the Holographic Theory for Antenna Designs"), the metal stripes are periodically positioned at the roots of the interference pattern, which results from the superposition of a propagating surface wave (reference wave) and the radiated plane wave (object wave). The surface wave is created by the antipodal Vivaldi array (surface-wave launcher) and propagates as TE_0 mode with planar phase front on the dielectric slab without the ground plane.

The fed input port of the Rotman lens controls the phase difference between the antipodal Vivaldi surface-wave launchers and therefore the propagation direction of the TE_0 surface wave. This results in a change of the main-beam direction in free space within the *xy*-plane (Rusch et al. 2013c). The Rotman lens, the surface-wave launchers, and the hologram are positioned on a dielectric slab of Rogers 4003 ($\varepsilon_r = 3.55$) with a thickness of 0.2 mm. As shown in the layer stack up in Fig. 18b, at the position of the Rotman lens and part of the surface-wave launchers, a GND plane exists at the bottom of the RO layer. This GND plane ends where the surface-wave launchers end. At this point the TE_0 surface wave propagates in the high-permittivity alumina layer below the Rogers substrate. The alumina dielectric sheet with a thickness of 0.254 mm is added to improve the propagation of the surface wave and to increase the frequency-scanning range due to the high ε_r of the material (as described in see chapter on Rusch, "► Holographic Antennas," section "Properties of Leaky-Wave Antennas"). The multilayer stack up allows the suppression of surface waves in the area of the microstrip transmission-line system due to the low dielectric constant of Rogers 4003 and on the other hand increases the frequency-scanning range and promotes the TE_0 surface-mode propagation in the area of the holographic antenna due to the alumina substrate with the high ε_r. This layer stack up can be done with a standard PCB process and is commercially available.

DOI 10.1007/978-981-4560-75-7_113-1

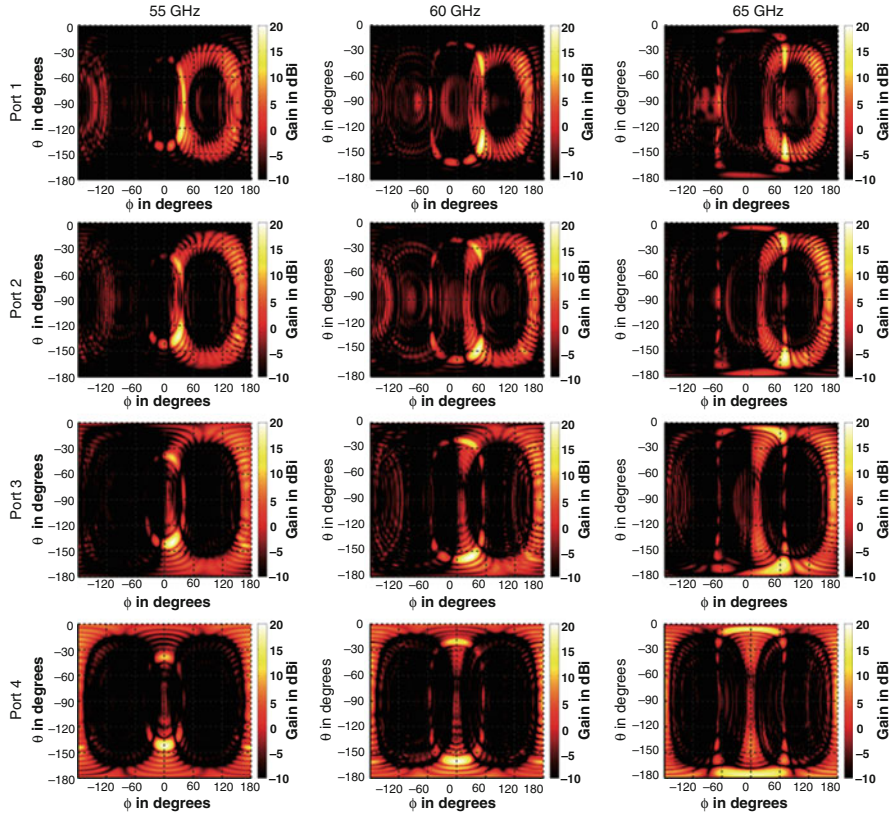

Fig. 19 Simulated radiation patterns of the holographic antenna combined with Rotman lens (Rusch et al. 2014)

Figure 19 shows the simulated radiation patterns for the first four input ports of the Rotman lens. The patterns with feeding at the other ports are not shown, because of the symmetry of the antenna design. The beam-scanning ranges in the two planes meet the expectations. Due to the usage of a dielectric slab without GND plane, there is a second main lobe visible that is mirrored at the symmetry plane. This second beam could be avoided by using reflectors or a volume-type hologram (Iizuka et al. 1975). With the presented concept, a scanning range of $5^\circ < \theta_0 < 40^\circ$ and $-70^\circ < \varphi_0 < +70^\circ$ with a maximum antenna gain of 19.1 dBi was reached.

Example II: Holographic Antenna with TM_0 Surface Wave at 60 GHz

There are limited possibilities of surface-wave launchers for creating the TM_0 mode. A well-working surface-wave launcher for TM_0 modes with good integration properties is a horn antenna built with substrate-integrated waveguide (SIW) technology (Tsao et al. 2012). With its closely spaced vias forming the sidewalls, the manufacturing for mmW frequencies gets difficult. Therefore, this feed can be used only at frequencies up to W band with technology available today. For higher frequency ranges, real planar antennas like the slotted dipole can be used. Podilchak already published a slotted quasi-Yagi-Uda surface-wave launcher (Podilchak et al. 2009) and a scaled version is used here (see Fig. 20). Due to the resonant feed, the bandwidth of the TM_0 antenna is more limited compared to the TE_0 antenna with Vivaldi feed. The feeding line is a coplanar waveguide (CPW), which fits very well to the probe-based measurement system, which was used for measuring the radiation patterns of the holographic antennas (Beer and Zwick 2010).

Since a symmetrical beam forming around broadside is advantageous for most radar applications, a periodicity of the hologram with $p = 3.45$ mm is used to get a main-lobe direction of $\theta_0 = 0^\circ$ at the

Fig. 20 Slotted quasi-Yagi-Uda feed as surface-wave launcher (similar to Podilchak et al. 2009)

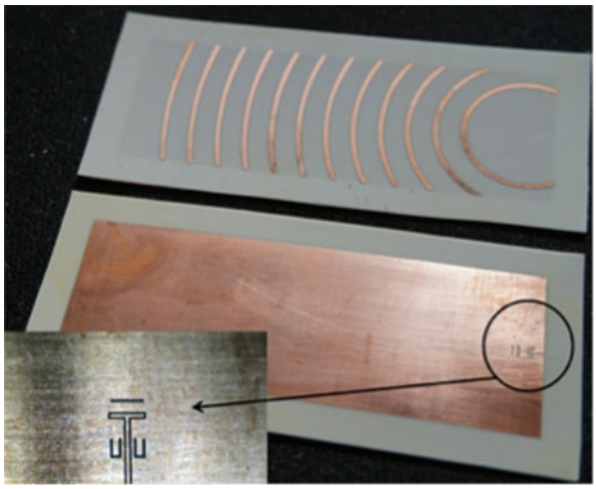

Fig. 21 Manufactured holographic antenna with TM_0 reference wave and slotted quasi-Yagi-Uda surface-wave launcher

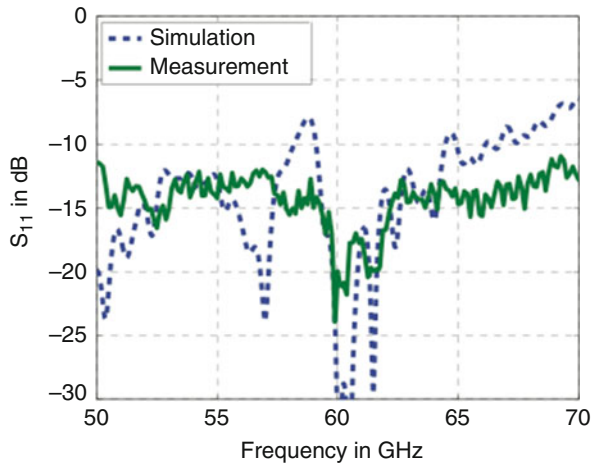

Fig. 22 Reflection coefficient

center frequency $f_c = 60$ GHz. The manufactured structure is shown in Fig. 21. The complete antenna size with its hologram with $N = 12$ elements is 5×2 cm^2. The S parameters for the complete holographic antenna including the feed in Fig. 22 show a good agreement between simulation and measurement. The simulation shows a peak at 58 GHz, which is caused by the stop band close to broadside radiation (Oliner 1993). This is a usual effect of periodic leaky-wave antennas, but its influence

DOI 10.1007/978-981-4560-75-7_113-1

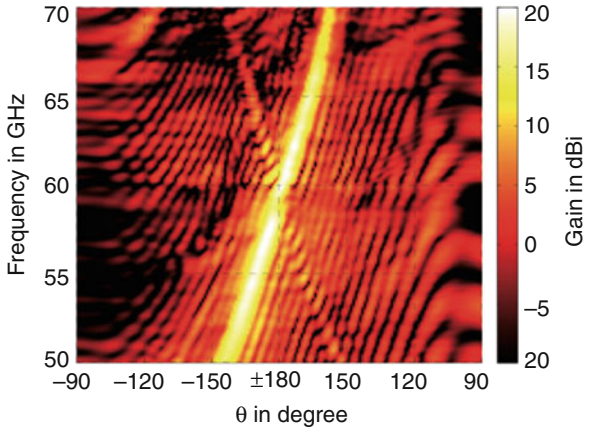

Fig. 23 Simulated antenna gain of the holographic antenna with TM_0 mode and slotted surface-wave launcher

on the radiation depends of the hologram configuration. Although the stop band exists for TM_0 antennas at mmW frequencies as well, the influence on the radiation is lower than for the concepts with TE_0 mode. The reason is that the wave impedance variation caused by the metal stripes with TM_0 mode is decreased. At this frequency and in the range higher than 64 GHz, the agreement between simulation and measurement decreases. The manufactured feed shows a little over-etching which caused a lower directivity than the simulated feed. Therefore, the power of the reference wave, which propagates to the substrate edges perpendicular to the desired propagation direction, does not interact with the hologram and radiates parallel to the substrate plane. This power loss causes a gain decrease and pretends a good antenna matching since it is not coupled back into the surface-wave feed.

With the continuous metal plane there is no bidirectional radiation. The simulated pattern in Fig. 23 shows that the configuration allows the symmetrical beam scanning around broadside. A gain decrease of 3.4 dB due to the stop band is also recognized but is much lower than for similar configurations, i.e., with TE_0-surface waves. The beam-forming range is limited to $\pm 12°$ for a bandwidth of 10 GHz. Due to the asin function in Eq. 9 with the lowest gradient around zero, periodic leaky-wave antennas have the lowest beam-forming range to bandwidth ratio around broadside radiation (Oliner 1993).

Related Planar Periodic Leaky-Wave Antenna Structures

As the holographic antenna is a type of periodic leaky-wave antennas, other radiating structures based on microstrip transmission lines or waveguides with periodic slots have similar radiation characteristics and can be described by the theory approaches explained in (see chapter on Rusch, "► Holographic Antennas," section "Properties of Leaky-Wave Antennas"). In this chapter alternative antenna designs are described that were published in the past and also show the high interest in frequency-scanning antennas.

Most periodic leaky-wave antennas published in literature and used in different applications for radar or communication are realized in waveguide technology or as surface-integrated waveguide to get a planar antenna. Waveguides have the advantage of high robustness against temperature and environmental influences and can therefore be found in space or military applications. The high effort in manufacturing can be reduced by using the SIW technology. The possibilities to feed leaky-wave antennas in SIW technologies with microstrip transmission lines (Martinez-Ros et al. 2011) or coaxial cables (Gandini et al. 2012) facilitate the integration to millimeter-wave RF front ends. By using the fundamental-mode TE_{10}, both slot arrangements transversal (Liu et al. 2011) and parallel to the propagation direction (Gandini et al. 2012) can be used. Transversal-arranged slots influence the currents on the waveguide surface strongly and the resulting stop band prohibits the radiation in broadside direction. Methods have been found by different groups to reduce this stop-band effect and antennas with frequency-scanning

DOI 10.1007/978-981-4560-75-7_113-1

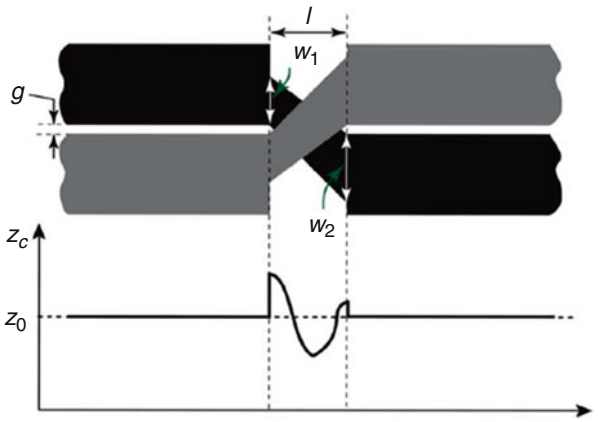

Fig. 24 Unit cell of the periodic leaky-wave antenna based on microstrip transmission-line technology (Yang et al. 2010)

main-lobe directions around the broadband are presented (Dong and Itoh 2011). In Guntupalli and Wu (2012) an easy-to-implement but effective method is presented by using unit cells with transversal-arranged double slots. The slot pairs within a unit cell with a distance of a quarter wavelength at broadside radiation frequency cause a cancelation of the reflected waves and therefore suppress the stop-band effect and allow a continuous frequency-scanning main-beam direction around broadside. Complex systems are published that allow a combination of phased arrays and frequency-scanning antennas and therefore show the possibility of changing the main-beam direction in two dimensions and different spatial directions (Guntupalli and Wu 2013).

By using slots that are arranged parallel to propagation direction, the stop band is not as strong as for the transversal slots due to the lower influence on the traveling wave, but a disadvantage of this configuration is a lower leakage rate of the single unit cells. That means that a higher number of periods are necessary to get an efficient antenna. For a short antenna with a lower number of unit cells, a wave with a high-power level transmits to the end of the antenna which is usually matched to the antenna impedance to avoid the creation of standing waves. In Schuhler et al. (2010) a technique is presented to recycle the power transmitted to the antenna end by guiding it to the antenna feeding port with a meander line to get an in-phase superposition of the waves.

Leaky-wave antennas based on periodic transmission-line structures have the advantage compared to SIW antennas that a high number of vias with very close distance to each other are not necessary. These vias make the SIW antennas expensive in manufacturing and also limit their frequency range of operation. Compared to SIW antennas periodic stubs on a microstrip transmission line are a simple and cheap method to build planar leaky-wave antennas, but also a high number of periods are necessary to get a high antenna efficiency. Also for this type of realization, a method to decrease the stop-band effect at broadside radiation was found by using matching circuits in front of the periodic discontinuities (Paulotto et al. 2009). In Yang et al. (2010), Ke Wu and his group presented the structure shown in Fig. 24. The crossed transmission lines show only a small influence on the traveling wave. Therefore, the stop band at broadside radiation is negligible without using additional techniques and a continuous frequency-scanning main lobe around broadside with an angle range of more than 100° for a frequency sweep from 16 to 39 GHz is presented.

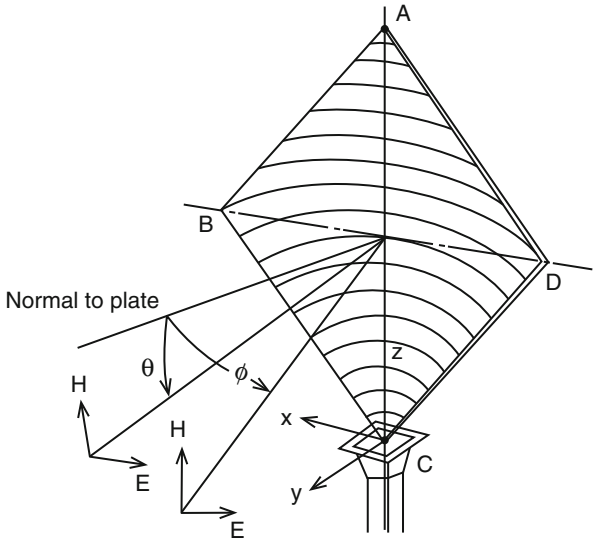

Fig. 25 Structure and geometry of a holographic antenna (Iizuka et al. 1975)

Applications

History of Holographic Antenna Design

The idea to transfer the holographic theory from optics to antenna design was published at first by P. Checcacci et al. (1970). Checcacci created an interference pattern by a superposition of two coherent waves from two different antennas (a horn antenna and a parabolic reflector). In the second step the resulting hologram was illuminated by the horn antenna, which was already used during the recording process. Therefore, the reconstructed antenna pattern of the parabolic reflector was created. Checcacci described his hologram as a pattern consisting of metallic stripes, which represent the roots of the interference pattern. He was the first one who showed that this interference pattern with reduced phase information is sufficient to get the desired main-lobe direction of the holographic antenna. With his antennas Checcacci coined the term holographic antenna.

K. Iizuka (Iizuka et al. 1975) enhanced this technology based on Checcacci's work, which was very important for the practical usage for the millimeter-wave technology. Iizuka rearranged the concept and placed the reference wave and the interference pattern into the same plane, so that both the feed and hologram could be realized on one printed circuit board (see Fig. 25). The radiation perpendicular to this plane built the reconstructed object wave. Iizuka used antenna substrates without a continuous metal plane on top or bottom. The spacing between the metal strips was one wavelength of free space, rather than one wavelength of the surface wave, which should also exist on the interface between the dielectric of the printed circuit board and air. By illuminating the substrate edge with a parallel-arranged rectangular horn antenna, the hologram was fed by the reference wave. Due to the lack of a continuous metallization on one substrate surface, this antenna showed a bidirectional radiation pattern. For that reason another novelty was published the first time in this paper. The authors proposed a way to create a unidirectional radiation by a suitable arrangement of two holographic plates. The two plates were spaced a quarter wavelength apart and the radii of the rings of the second hologram were always a quarter wavelength shorter. Thus, the reconstructed waves interfered constructively in one direction and destructively in the other direction and hereby a unidirectional plane wave was created. They formed the hologram by etching a printed circuit board, which was 12 wavelengths long and wide and used a horn antenna as feed element at the substrate edge. A measured gain was not published, but a unidirectional narrow beam was achieved with a front-to-back ratio of about 20 dB.

DOI 10.1007/978-981-4560-75-7_113-1

In 1980 the idea of dynamically steering an antenna beam based on the concept of holography was mentioned for the first time (Farhat 1980). In this case it was proposed to use semiconductor panels whose charge carrier concentration could be controlled. Thus, changes in the transmission and reflection coefficients of the panel could be realized locally to dynamically create different interference patterns that created a steered beam together with a reference wave. In the presented concept the illuminating antenna did not lie in the same plane as the interference hologram.

Later, the holographic principle was mainly used for antenna measurements. In this case a reference antenna illuminated an interference pattern and synthesized a plane wave that was necessary for the antenna measurements. Especially the measurement of large reflector antennas for satellite communications was eased by the holographic measurement method (Hirvonen et al. 1997; Sazonov 1999).

From 2001 onward, the amount of research on holographic antennas has increased again. Fathy et al. from Sarnoff Corporation published their works performed during their Reconfigurable Aperture Program (ElSherbiny et al. 2004; Fathy et al. 2001, 2003a, (b). Presented is their concept for reconfiguration based on metallic-like conductive plasma islands that are driven by a DC current. These plasma islands could be precisely formed and controlled on silicon substrates. Thus, metallic patterns could dynamically be formed on a silicon wafer (Fathy et al. 2001, 2003b). Holographic antennas were mentioned as one possible application of this concept. Using the DC-driven plasma islands, a dynamically changed interference pattern or hologram could be formed on the silicon wafer that, together with a reference wave, was used for beam steering. To prove their concept, a 35 GHz holographic antenna was realized, however by using simple etching technology instead of the plasma island technology (ElSherbiny et al. 2004; Fathy et al. 2003a). The antenna was realized on a layered substrate of alumina and TMM-4 and consists of the etched concentric rings that form the hologram and a feed antenna in form of an open-ended waveguide. In a distance of a quarter wavelength apart from the substrate, a ground plane was attached that acts as a reflector and creates a unidirectional beam; see Fig. 26. The novelty in their design mainly laid in the fact that a surface wave was used as reference wave rather than a space wave. The surface wave that travels inside the layered material had a shorter wavelength compared to the space wave and thus the hologram could be created denser. They in fact realized several 35 GHz antennas with different holograms to create beams in different angular directions. The hologram dimensions were about 92 $\times$ 92 mm and a gain of about 25 dBi was achieved.

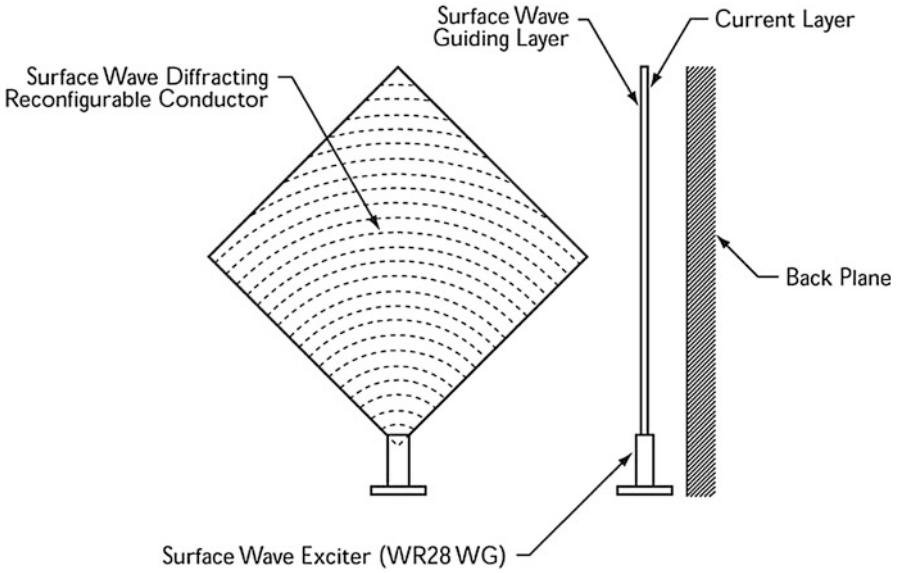

Fig. 26 Holographic surface-wave antenna (ElSherbiny et al. 2004)

DOI 10.1007/978-981-4560-75-7_113-1

The method with rectangular horn antenna as feed was still used in current publications (Sooriyadevan et al. 2007). Although this feeding concept was not suitable for systems with high integration level, the idea using planar end-fire antennas as surface-wave launchers was published a long time after the first mention of holographic antennas (Petosa et al. 2004; Sutinjo et al. 2010). With these types of surface-wave launchers for different kinds of surface-wave modes (Podilchak et al. 2009, 2011), an integration of the holographic antenna in millimeter-wave systems up to very high frequencies (>100 GHz) was possible. In addition to end-fire antennas like Yagi-Uda radiators or tapered slot antennas (Thingvold et al. 2003), also dipoles (Li et al. 2011) or patch antennas (Sutinjo et al. 2010) were published as solutions for creating the surface-wave mode.

With these possibilities holographic antennas had the advantage compared to other types of leaky-wave antennas, e.g., slotted waveguides in "substrate-integrated waveguide (SIW)" technology, that a manufacturing without vias became possible. Therefore, thin, ceramic substrates with high dielectric constants could be used which are favored for thin-film technology to build antennas at very high frequency ranges.

Example: The Frequency-Scanning Millimeter-Wave Radar

Using leaky-wave antennas due to their frequency-scanning properties in frequency-modulated continuous-wave (FMCW) radars can be a cheap solution with low complexity to measure distance, and the angle of a target position has been shown by different groups. A large system bandwidth is necessary to get sufficient resolution for both measurement dimensions. That is the reason why the usage of this antenna type is especially interesting for integrated millimeter-wave radars, and at high center frequencies, the antennas become small enough to make packaging solutions similar to the one presented in Beer et al. (2013) possible.

General Principle of Operation

Radar systems with frequency-scanning antennas have the advantage that range and cross range of targets in one plane can be measured at the same time. Therefore, a combination with frequency-modulated continuous-wave (FMCW) radars is useful. This approach is discussed in Mayer et al. (2003) and Alvarez-Lopez et al. (2012) and allows a system with lower complexity compared to radars with phased-array or mechanically scanning antennas. In the case of frequency scanning, no mechanical movement of components or of the entire antenna is needed, which reduces the complexity of the design and reduces the risk of failure due to material fatigue. By sending a frequency chirp with a desired bandwidth B, the main-lobe direction of the holographic antenna scans over the measurable angle range. The back-reflected wave from a target is mixed with the transmitted chirp signal, as it has also been done in traditional FMCW radars, so that an intermediate frequency is generated which includes the range information of the illuminated target.

$$R = \frac{c_0}{2B} f_{IF} t_{\mathrm{mod}} \tag{10}$$

Smaller targets at different angular positions to the radar will reflect only parts of the frequency chirp back to the radar depending on the time of illumination. This results in a modulation of the received signal power. After mixing transmit and receive signal, this power modulation is still included within the intermediate baseband signal. By analyzing this power modulation, the cross range of targets can be measured.

DOI 10.1007/978-981-4560-75-7_113-1

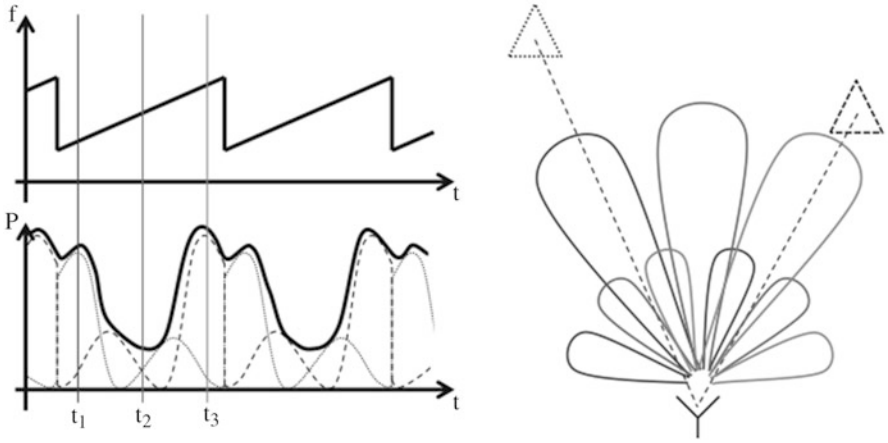

Fig. 27 Scheme of the radar principle with frequency-scanning antenna

Figure 27 shows this in a schematic diagram. The curve on the top-left corner shows the transmitted frequency-modulated signal. The example scenario with two targets is shown on the right side, in which also the antenna characteristics for different time points are indicated. The second graph shows three curves. The two dashed curves represent the echo signals created by the individual targets. The bold line is the superposition of these echoes, which is received by the radar. Depending on the configuration of the transmitted frequency chirp, the main-lobe direction at different times varies. At the beginning of the sending process at the time t_1, the main beam illuminates the first object; thereby a strong echo signal is received (short-dashed line). At the time t_2 the main lobe points to an empty range without target, which results in a low receiver signal. At the third time t_3, the received power increases again because the antenna now illuminates the second target (long dashed).

Range Measurement

The maximum range resolution $\Delta R_{\max}$ of an FMCW radar is described by Eq. 11 and therefore is inversely proportional to the system bandwidth B and proportional to the propagation velocity of the wave c.

$$\Delta R_{\max} = \frac{c}{2B} \tag{11}$$

If a leaky-wave antenna with frequency-scanning main-lobe direction is combined with this radar type, not the complete bandwidth B is available at the receiver. Due to the fact that the antenna illuminates the individual target just within a shorter time range, the new bandwidth B' that was transmitted during this time determines the resolution. If a constant beam width θ_{3dB} and a linear slope of the frequency-dependent main-lobe direction $\frac{\delta\theta}{\delta f}$ are assumed, the decreased distance resolution can be calculated by the relation of scanning range θ_S and beam width θ_{3dB} (Mayer et al. 2003):

$$\Delta R = \frac{c}{2B'} = \frac{c}{2B}\frac{B}{B'} = \frac{c}{2B}\frac{\theta_S}{\theta_{3dB}}. \tag{12}$$

In general the range information is given by the proportionality of the intermediate frequency f_{IF} and the target distance as known from the traditional FMCW radar. Due to the different angle ranges, illuminated by the antenna at different times during the modulation time t_{mod}, the maximum measurable target range becomes dependent from the target's cross range. This is shown in Fig. 28. For an FMCW radar the echo

DOI 10.1007/978-981-4560-75-7_113-1

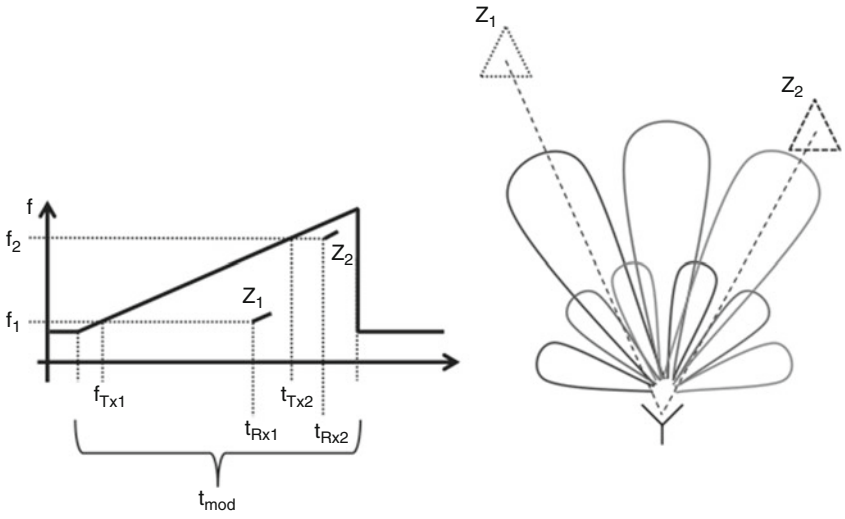

Fig. 28 Decreasing of range resolution and maximum range by the usage of frequency-scanning antennas

of a faraway positioned target should be received within the modulation time t_{mod} due to the mixing process of T_x and R_x chirp (for a real FMCW radar: $t_{\mathrm{Rxn}} << t_{\mathrm{mod}}$).

For the following example the simplified approach $t_{\mathrm{Rxn}} \leq t_{\mathrm{mod}}$ applies. If there is a target Z_1 within the angle range, which is illuminated at the beginning of the transmitted chirp, the transmitted and reflected signal can travel a longer way within the remaining modulation time without violating the condition than for the target Z_2, which is illuminated later. A simple calculation will illustrate this circumference. For the frequency-scanning radar, a modulation with bandwidth $B = 10$ GHz and modulation time $t_{\mathrm{mod}} = 10$ ms is used. Target Z_1 is illuminated by a signal with frequency f_1, which was transmitted at the time $t_{Tx1} = 1$ ms and received as echo at t_{Rx1}. Accordingly target Z_2 is illuminated by a signal with frequency f_2, which was transmitted later at $t_{Tx2} = 9$ ms and received due to the propagation time at t_{Rx2}. To satisfy the condition that the last received echo is within the modulation time, the maximum distance results:

$$R_{\max} = \frac{c_0}{2}(t_{\mathrm{mod}} - t_{\mathrm{Txn}}), \tag{13}$$

For the described scenario this means maximum distances of the two targets with $R_{\max 1} = 1,350$ km and $R_{\max 2} = 150$ km. The values show that this effect is only important for very fast frequency sweeps or large target distances.

Cross Range Measurement

For measuring the cross range of a target, the amplitude modulation of the received power signal is analyzed. The echo signal of a point target at angle position θ_Z includes the frequency-dependent antenna radiation characteristic of the radar. Due to the fact that the relation between time and transmitted signal frequency is known, the cross range information can be extracted. This requires synchronization between the transmitter and receiver for an exact knowledge of the transmitted signal frequency at the time, when the echo was received (see Fig. 27). To get a high-quality convergence of the antenna characteristic, the IF frequency should not be too low. If there are only a small number of periods within the IF signal, there is an undersampling of envelope power and results in a lack of measurement accuracy (Chan and Judah 1998). This limit depends on the scenario and on the desired resolution. A practical approach to move this limitation is the usage of meander lines to create higher IF frequencies for equal target distances

DOI 10.1007/978-981-4560-75-7_113-1

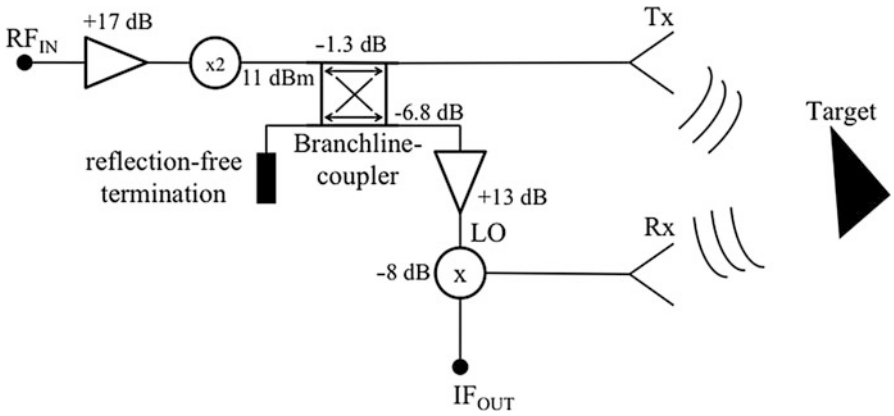

Fig. 29 Equivalent circuit of the radar front end in LTCC

(Mayer et al. 2003). To get a high accuracy of the cross range measurements, the time-shift caused by the propagating velocity of the signal has to be noticed. This time-shift causes a measurement inaccuracy due to the lack of synchronization between transmit chirp and power modulation at the receiver. The inaccuracy can be corrected by measuring the range with Eq. 10 in a first step. If the range is known, the resulting time-shift can be calculated and therefore used for the calibration of the cross range measurement.

The cross range resolution is defined by the 3 dB beam width θ_{3dB} of the antenna main lobe (Skolnik 1990). If the targets are in a closer distance to each other, a reliable separation is not guaranteed.

Cross Range/Distance Trade-Off

As described in (see chapter on Rusch, "► Holographic Antennas," section "Range Measurement"), a wide antenna beam width is necessary to get a high-range resolution. This is in contrast to the condition of a small beam width for a high cross range resolution as described in (see chapter on Rusch, "► Holographic Antennas," section "Cross Range Measurement"). This trade-off is a principal characteristic of the combination of FMCW radar and frequency-scanning antenna. With Eq. 14 the uncertainty relation can be defined.

$$\Delta R \cdot \Delta\theta = \frac{c}{2B}\theta_S \tag{14}$$

With this equation, the limit of one parameter can be calculated if the other parameter is known (Solbach and Schneider 1999).

Implementation: Radar Front End in LTCC with Integrated Holographic Antenna at 60 GHz

This chapter presents a radar front-end prototype with integrated holographic antenna. Test-measurement results in laboratory environment are shown to clarify the operating principle and the requirements of FMCW radars with frequency-scanning antennas.

Measurement Setup

For test measurements the radar front end is positioned on the antenna measurement setup described in Beer and Zwick (2010). The movable arm, which holds the reference horn antenna during antenna gain measurements, is used to align radar and target. Figures 29 and 30 show an equivalent circuit of the front end and the measurement setup with all used instruments.

DOI 10.1007/978-981-4560-75-7_113-1

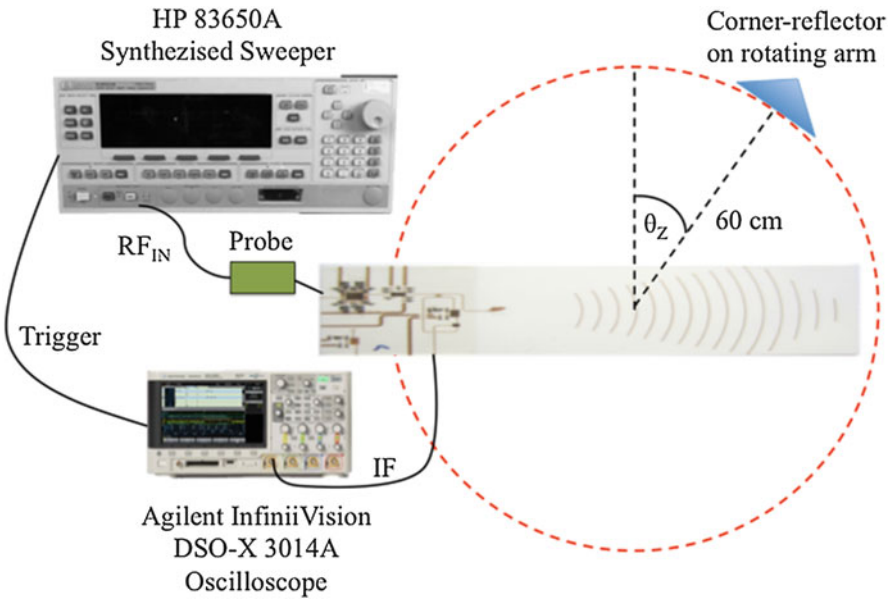

Fig. 30 Test-measurement setup of the radar front end with integrated holographic antenna

The radar input RF_{in} is fed by ground-signal-ground(GSG) probes. With the signal generator HP 83650A, the frequency chirp with a bandwidth of 6 GHz is created around the center frequency 31.5 GHz. With the implemented frequency multiplier ($x2$), the transmit signal has a bandwidth of 12 GHz with a center frequency of 63 GHz. The used frequency range is adapted to the measured characteristics of the manufactured antenna, which are slightly different to the simulation results, due to tolerances of the material parameters and manufacturing process. The minimum available sweep time $t_{\mathrm{mod}} = 20$ ms has been chosen, to get IF frequencies as high as possible. The movable arm rotates in a distance of approximately 70 cm around the radar. With Eq. 15 an IF frequency of $f_{IF} = 2.8$ kHZ is expected, if the signal propagation time within the front end is neglected.

$$f_{IF} = \Delta f \frac{\Delta t}{t_{\mathrm{mod}}} = \frac{\Delta f^2 r / c_0}{t_{\mathrm{mod}}} \tag{15}$$

(with r as distance between radar and target in m, c_0 as wave velocity in air, and t_{mod} as sweep time)

The sampling of the IF signal is done with the oscilloscope Agilent InfiniiVision DSO-X 3014A. The oscilloscope and signal generator are synchronized by a trigger signal. This synchronization is necessary to get the relation between the transmitted frequency at the time when the target was illuminated and the main-lobe direction of the antenna. A corner reflector is used as target to get a high radar cross section. In Fig. 30, the target is placed above the radar. This has been done within the illustration to have the same angle definition for θ and θ_Z as in previous figures. For the measurements the target is placed beyond the substrate ($\theta_Z > 180°$), because of the higher radiation of the antenna within the lower hemisphere. The approximate target distance of 60 cm, which results by the measurement setup, meets the far-field condition from (Balanis 1997).

Short-Time Fourier Transform

The short-time Fourier transform (STFT) is one of the mostly used time-frequency analyzers. The function is based on the discrete Fourier transform (DFT). Instead of windowing the complete signal, a short window is used and moved from sample to sample. Therefore, a time resolution of the analyzed

DOI 10.1007/978-981-4560-75-7_113-1

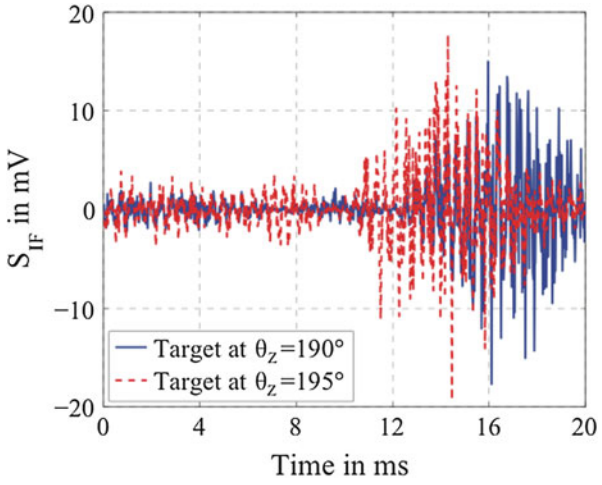

Fig. 31 Measured IF signals for two different angular positions of the corner reflector

signal results and a higher number of individual DFTs are created, which include the information about the signal spectrum at different times. A sequence of these single DFTs results in a STFT. The generated spectrogram as square of the absolute STFT shows the power of the analyzed signal as a function of time and frequency. To get a high temporal resolution, a short window function should be used. Accordingly a short window decreases the frequency resolution. Therefore, an accurate choice of the window parameters is important to get high-quality measurement results. By using the STFT the following four parameters should be considered with reference to the resolution and the computing time:

- The number of samples in frequency domain determines the length of the DFT (possible increase by using "zero padding" (Skolnik 1990)).
- The number of samples in time domain determines the number of DFTs, which must be calculated.
- The shape of the window influences the intenseness of the spectral leakage.
- The length of the window determines the trade-off between time and frequency resolution.

Depending on the significance of the two parameters' time and frequency resolution, the window length should be adapted.

Measurement Results

Two measurement examples with a corner-reflector target at two different angular positions within the described measurement scenario are shown in Fig. 31. To eliminate effects of antenna mismatch or coupling between transmit and receive path, the signals are corrected via subtraction with a reference measurement within the empty scenario. With a constant distance the change of the angular position is clearly visible, due to the amplitude maximum at different times.

Due to the synchronization between FMCW sweep generator and oscilloscope, the transmitted signal frequency at every time step is known. To get the main-lobe direction of the antenna at the time of the maximum received amplitude, the measured antenna gain should be used for the signal processing. The range and angular position resolution can be configured with the definition of the window length (here, Hamming window) for the STFT. Figure 32 clarifies this trade-off.

This figure shows the STFT of two different measurements with the same corner reflector. The corner reflector is mounted to the movable arm. The distance to the radar is reduced to approximately 60 cm. The two defined angular positions are $\theta_Z = 190°$ and $\theta_Z = 200°$. The STFT implementation in Matlab

DOI 10.1007/978-981-4560-75-7_113-1

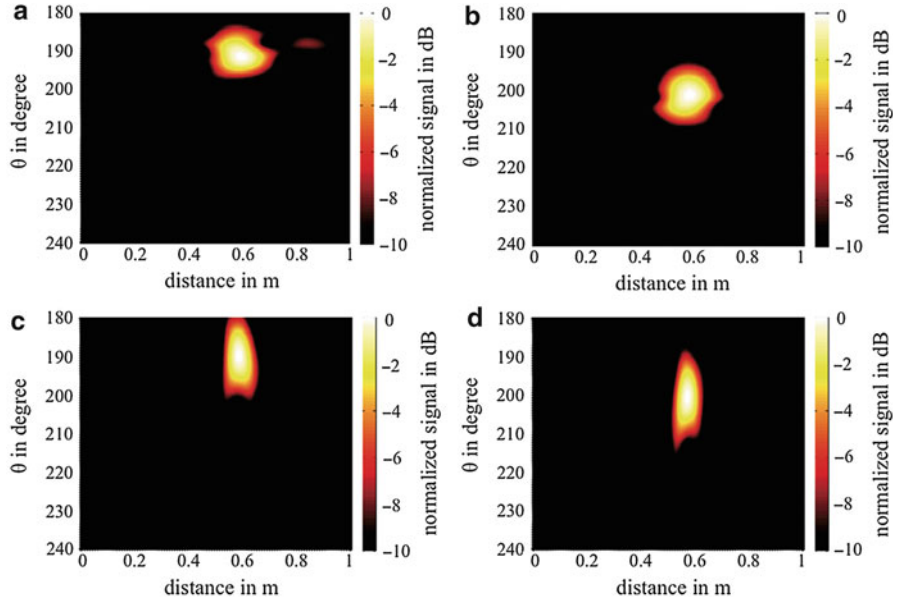

Fig. 32 Measurement results in a 1-target scenario; (**a**) $\boldsymbol{\theta_Z} = 190°$, $\boldsymbol{N_W} =$ 101 samples; (**b**) $\boldsymbol{\theta_Z} = 200°$, $\boldsymbol{N_W} =$ 101 samples; (**c**) $\boldsymbol{\theta_Z} = 190°$, $\boldsymbol{N_W} =$ 401 samples; (**d**) $\boldsymbol{\theta_Z} = 200°$, $\boldsymbol{N_W} =$ 401 samples

allows defining the window function with its length and window type. Due to the knowledge of the measured antenna pattern and the wave velocity, the time and frequency axes can be replaced with range and angular position. The complete signal has a length of $N_S = 2,001$ samples.

A longer window ($N_W = 401$ samples) narrows the measured signal within the range axes, which results in a higher range resolution. The same effect can be seen on the angular position axes by using a shorter window ($N_W = 101$ samples). A maximum resolution should be reached by using a Dirac for maximum angular position resolution or a rectangular window with a length according to the complete number of samples for the maximum range resolution. The intermediate frequency is measured within the complete sampled time range. This effect is caused by the nonideal antenna pattern, which illuminates the target also with its side lobes. Therefore, a longer window increases the signal-to-noise ratio as well. To decrease the effect of spectral leakage, a Hamming window with length N_W was used for the shown measurements. During the post-processing, two different window lengths are applied to every measurement to get high accurate results of both measured variables. Furthermore, the sample number is increased by zero padding to $N_S = 4,096$. In the first processing step, the Hamming window with length $N_W = N_S$ is applied. From the calculated spectrum the intermediate frequency is determined. No temporal resolution is available during this first step, but the range is determined with the maximum accuracy. To get the angular position of the target, the STFT is applied to the data with a shorter Hamming window. A length of $N_W = 1$ should result in a maximum angular position resolution, but it means the determination of the maximum amplitude of the signal in time domain. This amplitude is strongly influenced by environmental effects or noise. Therefore, a short window length with $N_W = 101$ samples has been selected to get a good temporal resolution on the one hand and to decrease the effects from noise on the amplitude on the other hand.

The corner reflector is positioned on the movable arm and rotated with $-5°$ steps started at $\theta_Z = 220°$ around the radar. The center of rotation is aligned with the hologram. Figure 33 shows the measurement results. The distance values are calculated with the determined intermediate frequency and the wave velocities within the dielectric waveguide and air. The second y-axis shows the transmit frequency at the time of the maximum measured echo signal. A linear FMCW chirp after triggering the sweep generator is

DOI 10.1007/978-981-4560-75-7_113-1

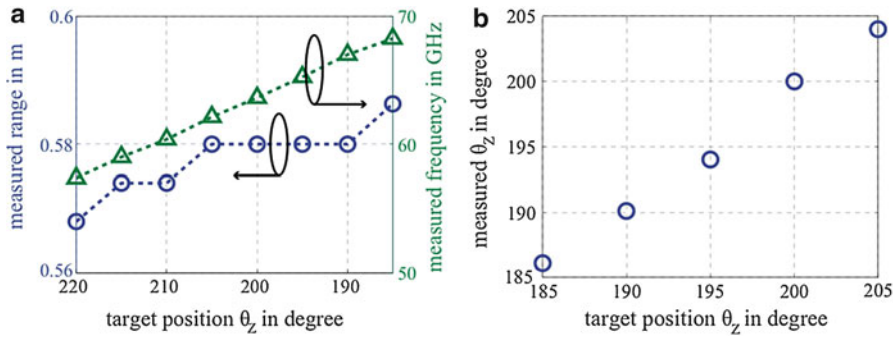

Fig. 33 Radar measurement results for the 1-target scenario

assumed. With the available measured antenna pattern, these axes can be interchanged with the measured angular positions of the target (Fig. 33b). The measurement error is only $\pm 1°$ and the limitation in this case is given by the resolution of the measured antenna pattern. For the antenna pattern measurement, a step width of 2° has been used to move the reference horn around the AUT.

The deviation of the distance measurement at smaller position angles is explained by a nonconstant phase-center position of the antenna, due to its large longitudinal expansion and the nonconstant amplitudes of the single hologram elements.

Conclusion

It has been shown that the usage of planar holographic antennas on dielectric substrates within has several advantages, which makes them to be promising candidates for millimeter-wave systems. Due to the usage of surface waves as feeding modes, the manufacturing of holographic antennas is possible up to very high frequencies (e.g., D and J band) also with standard PCB technology.

In the previous chapter, the theory of holographic antennas and their analogy to the optical holography were explained. Concrete relations between material parameters and antenna properties as the frequency-dependent beam-scanning angle were shown.

The deviation of the propagation properties of different surface-wave modes on grounded and ungrounded dielectric slabs served as background for the followed investigations. Three feeding structures, in literature often called surface-wave launchers, realized as planar feeds similar to the Vivaldi antenna and the Yagi-Uda antenna in two different layouts were presented.

Building an array of these surface-wave launchers causes the propagation of surface waves with linear phase fronts and therefore influences the hologram shape. This novel structure allows the realization of systems with beam-scanning functionalities in two dimensions.

An FMCW radar as one of the most interesting applications of holographic antennas was explained. A possible implementation with LTCC technology allows a compact RF front end, which measures range and angular position of targets within a scenario simultaneously.
