FIG. 31-1. Some cellular relations in the vertebrate nervous system. (**Top**) Blood capillary perfusing choroid epithelium. Below the capillary are choroid epithelial cells. These cells, joined by tight junctions, secrete cerebrospinal fluid (CSF). Below the CSF are ependymal cells joined only by spot attachments at gap junctions. This allows free diffusion between the CSF and the intercellular clefts. Glial cells (*shaded areas*) are within the ependyma. The glial cells are joined by gap junctions. Presynaptic terminals contain synaptic vesicles. An oligodendrocyte (*1*) enwraps an axon to produce myelin. The major sites where astrocytes are exposed to substances released from neurons are along unmyelinated axons (*2*), at breaks in the myelin (*3*), and in the region of synapses (*4*). (**Bottom**) A brain capillary is surrounded by astrocyte endfeet with occasional gap junctions permitting diffusion from the extravascular space to the intercellular clefts. The endothelial cells (*5*) forming the capillary are joined by tight junctions and constitute the blood-brain barrier. [Modified from R. Orkand (1969), with permission.]

close apposition (cf. Chapter 51). Moreover, in a number of fiber tracts, there is a special anatomical relation between astrocyte processes and the node which makes the astrocyte part of a "paranodal apparatus" (Black and Waxman, 1988) and suggests a special functional relation at that site. Immunolocalization studies have demonstrated Na^{+} channels in these perinodal astrocytes (Black et al., 1991). However, the functional implications of this finding are not yet clear.

In at least one specific region of the nervous system, the pituitary pars intermedia, neurons form actual synaptic contacts with stellate cells, which have been identified as being glial because they stain positively for glial fibrillary acidic protein (GFAP). A calcium-dependent postsynaptic response consisting of a short (100 ms) depolarization followed by a more prolonged (45 to 75 s) hyperpolarization has been recorded from these glial cells (Mudrick-Donnon et al., 1993). The depolarization is mimicked by gamma-aminobutyric acid (GABA) and the hyperpolarization by dopamine. These experiments provide the first evidence for synaptic potentials in glial cells, and the results are consistent with this unusual anatomical arrangement.

NERVE IMPULSES DO NOT DIRECTLY AFFECT GLIAL CELLS

In the absence of such special anatomical relations, the question arises as to whether the flow of ionic current in the neurons might by itself exert an effect on the glial cells. There is no evidence that it does so. Kuffler and Potter (1964) recorded the membrane potential of packet glial cells in the leech while changing the membrane potential in the adjacent Retzius nerve cells. Neither massive neuronal discharge or prolonged potential changes produced by passing current in the neuron produced significant membrane potential changes across the glial membrane. R. Orkand et al. (1966) recorded the action potential with a microelectrode in the extracellular space of a mudpuppy optic nerve during a maximal nerve volley, advanced the electrode into a glial cell and again stimulated the axons. As shown in Figure 31-2, the action potential recorded by a microelectrode had the same form and amplitude when recorded with the electrode in the cell as it did when outside. This indicates that the recorded potential is the result of current flow in the extracellular space across the resistance of the extracellular fluid and does not produce a significant potential change across the glial membrane. The results can readily be explained by supposing that the extracellular space between the neurons and glia shunts the neuronal currents, that is, that the effective resistance of the glial membrane is much larger than that of the extracellular clefts.

NERVE IMPULSES ALTER THE GLIAL MICROENVIRONMENT

Ionic Changes Resulting from Impulse Activity

Potassium. The suggestion that nerve impulses cause changes in the ionic composition of the extracellular fluid and that these changes can have functional consequences was put forward by Barron and Matthews (1938) to explain negative dorsal root potentials and some other extracellular potentials recorded from

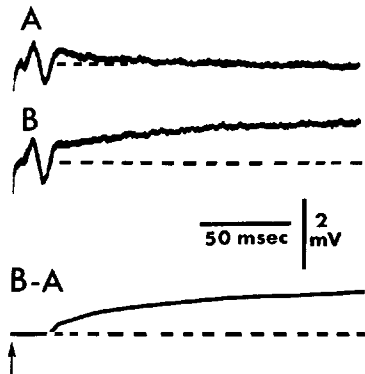

FIG. 31-2. Lack of effect of external current generated by nerve impulses on the glial membrane potential. (**A**) A recording microelectrode was placed in the extracellular space of an optic nerve of *Necturus* ($V_m = 0$) and the nerve was electrically stimulated. The triphasic potential is caused by current flow from the active axons across the resistance in the extracellular fluid between the microelectrode and the indifferent electrode in the bathing solution. (**B**) The electrode was advanced slightly and recorded a glial resting potential ($V_m = -84$ mV). Identical nerve stimulation sets up the same triphasic potential which, however, is followed by a slowly rising glial depolarization. *B − A*: Graphic subtraction of the two traces shows that the triphasic current from the stimulated axons did not produce a potential across the glial membrane. The remaining slow depolarization is the result of K^+ accumulation in the extracellular space following its efflux from the active axons primarily during the falling phase of the action potential. [Modified from R. Orkand et al. (1966), with permission.]

the spinal cord. In a study of afterpotentials in the squid giant axon, Frankenheuser and Hodgkin (1956) concluded that repetitive stimulation of the axon led to an accumulation of K^+ in the periaxonal space and that this change in the electrochemical driving force for K^+ (E_K) accounted quantitatively for the progressive reduction in hyperpolarizing afterpotentials and depolarization of the axon (Baylor and Nicholls, 1969; Astion et al., 1988). A similar mechanism was later suggested to explain the depolarization of glial cells in the amphibian optic nerve following axon stimulation (R. Orkand et al., 1966; see section—*Nerve Impulses Are Detected By Glial Cells*) and Figure 31-3). The development of ion-selective electrodes, especially those to measure K^+ in the extracellular space of the nervous system, has permitted extensive studies of the changes in this ion during normal and pathological nervous activity. These studies have been reviewed in this volume (see Chapters 26 and 47) and elsewhere (Sykova, 1983, 1992).

Sodium and Chloride. Sodium and chloride are the most abundant ions in the extracellular fluid and the movement of these ions across nerve membranes during activity does not produce large fractional changes in their extracellular concentration, and therefore they have little effect on their equilibrium potentials. Whereas a change of a few millimoles in extracellular K^+ produces relatively large membrane potential changes in glia (Kuffler et al., 1966; Kettenmann et al., 1983) and could affect glial activity, comparable changes in Na^+ or Cl^- concentrations do not have the same effect (Coles et al., 1989). However, during pathological situations, like spreading depression (Kraig and Nicholson, 1978), dramatic changes in Na^+ and Cl^- might have functional consequences for the glial cells.

Calcium. Calcium activity in the extracellular fluid is low ($1–5 \times 10^{-3}$ M) and much lower inside neurons ($<10^{-7}$ M). During activity, voltage-dependent Ca^{2+} channels, primarily in nerve terminals and dendrites but also along axons, open and Ca^{2+} enters neurons, thus decreasing the concentration in the extracellular space. With repetitive stimulation, Ca^{2+} may decrease to about 50% (Coles and Orkand, 1985;) or even increase by up to 80% under some conditions (Ziegler and Walz, 1989). In pathological states, such as seizures and ischemia, Ca^{2+} may fall to very low values (Heinemann et al., 1977; for review see Sykova, 1992).

Protons. The extracellular pH of the nervous system undergoes changes as a result of nervous activity, and these have been monitored with pH-sensitive microelectrodes (Chesler, 1990; Chapter 14, this volume). The changes may be monophasic, biphasic, and even triphasic. Recorded swings are about 0.2 pH units during normal activity and up to 0.8 pH units during anoxia or spreading depression (von Hanwehr et al., 1986; Sykova, 1992). Such changes can have measurable effects on the excitability of neurons and the permeability of ion channels (Konnerth et al., 1987), and can modify glutamate receptors (Traynellis and Cull-Candy, 1990; Vyklický Jr. et al., 1990).

A Variety of Substances Are Released from Active Neurons

The composition of the interstitial fluid separating neurons and glia is determined by the secretion of the capillaries that constitute the blood-brain barrier (Cserr, 1988), the secretion of cerebrospinal fluid by the choroid plexus (Neuvelt, 1989), and the metabolic and transport activities of the neurons and glia. Because the fluid is contained in narrow sheetlike spaces, only a few hundred Å wide, it is not easily sampled for analysis. The cerebrospinal fluid is in diffusion equilibrium with the interstitial fluid and

contains a large number of substances which could potentially function as a signal to the glial cells. These include, in addition to the ions discussed above, a wide variety of amino acids, hormones, peptides, catecholamines, organic acids, amines, purines, nucleosides, and metabolites of neurotransmitters and glucose (Siegel et al., 1989). There is some evidence that neurons release amino acids (Weinreich and Hammerschlag, 1975) and even ATP (Lloyd and Stone, 1983) at nonsynaptic regions, and these substances can have effects on glial cells. What is not known is which of these substances are released from active axons and reach the glial cells in sufficient concentration to serve as neuron-glial signals or affect glial activity. The production or release of growth factors responsible for proliferation of oligodendrocyte precursor cells by nerve impulses has been suggested in studies of the developing rat optic nerve (Barres and Raff, 1993). The particular anatomical relations (Figure 31-1) between glial cells and neurons in synaptic regions or at nodes of Ranvier provide loci for substances released from the neurons to react with glial receptors (see Section IV, *Receptors*). Such reactions are very likely to occur. However, in no case can we ascribe a specific physiological function to these receptor-mediated effects. For example, glutamate (100 μM) stimulates intercellular Ca^{2+} waves in cultured astrocytes (see Chapter 17), which propagate through glial gap junctions, and it has been suggested that such waves might originate in the region where astrocyte processes are close to glutamate synapses (Cornell-Bell et al., 1990). Their occurrence under physiological conditions and the functional role of these waves remain to be clarified.

NERVE IMPULSES ARE DETECTED BY GLIAL CELLS

Astrocytes Are Depolarized by Potassium Ion Accumulation Following Nerve Impulses

In the course of a study of electrical properties of spinal cord motor neurons, Coombs et al. (1955) occasionally recorded large resting potentials (−70 mV) from cells that could not be activated either synaptically or by depolarizing currents. They concluded that "the electrode may in these cases have become lodged in nonneuronal cells, possibly large neuroglial cells." Subsequently, it was found that these "idle" cells were depolarized during intense neuronal activity accompanying seizures caused by metrazol (Sugaya et al., 1964). A depolarization of glial cells by massive nerve stimulation in the optic nerve of amphibia (Figure 31-2) was observed by R. Orkand et al. (1966). As the optic nerve of *Necturus* consists only of one kind of ependymoglial cell and small unmyelinated axons, they suggested that the depolarization was recorded from the glial cells and confirmed this hypothesis by injecting a glial cell with aniline blue by electrophoresis through a microelectrode (Kuffler et al., 1966). Moreover, they demonstrated the K^+ electrode-like behavior of the glial membrane, and they further suggested, based on the known release of K^+ during the nerve impulses, that the glial depolarization was the result of K^+ accumulation in the narrow clefts that comprise the extracellular space (R. Orkand et al., 1966). Figure 31-3 illustrates the depolarization of optic nerve glial cells, which follows natural stimulation of the retina with light. The accumulation of K^+ in the extracellular space of the amphibian central nervous system was subsequently measured directly with K^+-selective electrodes (for review see Syková, 1983) and correlated with the glial depolarization (Syková and Orkand, 1980; Chapter 20, this volume). The original observation in 1966, of a depolarization, was extended by Ransom and Goldring (1973), who observed a hyperpolarization of glial cells in the mammalian cerebral cortex following high-frequency direct cortical stimulation. They attributed this effect to a decrease in extracellular K^+, resulting from activity of the neuronal Na^+ pump. This suggestion was supported by measurements with K^+ ion-selective electrodes of a delayed subnormal phase of extracellular K^+ following the initial accumulation (Kriz et al., 1975).

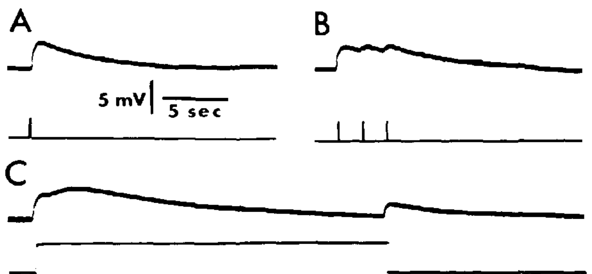

FIG. 31-3. Effect of "natural" nerve activity on the glial membrane potential. Light flashes were shone into the eye while recording from a glial cell in an anesthetized *Necturus*. (A) A single light flash of 100 ms sets up a transient depolarization. (B) The same flash repeated three times. (C) Light stimulus was maintained for 27 seconds. The initial glial depolarization declines due to adaptation of sensory receptors. When the light is turned off, an additional depolarization is produced. [From R. Orkand et al. (1966), with permission.]

Thus, there is good evidence that the membrane potential of glial cells follows changes in extracellular K^+ resulting from neuron activity (R. Orkand et al., 1966; Ransom and Goldring, 1973) or activation of the glial electrogenic Na^+ pump (Tang et

al., 1980). The latter hyperpolarizing effect can be demonstrated by loading the glial cells with Na^+, by bathing the cell in low K^+ solutions for a few minutes, and then increasing the extracellular K^+ to normal levels. On the other hand, there is no evidence that the glial membrane potential in the intact nervous system is affected by the release of other substances from neurons other than in the very special case of the pituitary pars intermedia (Mudrick-Donnon et al., 1993). As a large number of substances have been demonstrated to affect the glial membrane potential (see Chapters 21 to 25), it can be expected that such effects will be demonstrated as adequate techniques become available.

As shown in Figure 31-4, an increase in extracellular K^+ does have an effect on glial metabolism (P. Orkand et al., 1973; Salem et al., 1975) and has been regarded as a signal from active neurons to the surrounding glial cells (Pentreath, 1982; see also Chapter 52, this volume). These records of a decrease in glial cell fluorescence, resulting from a relatively modest increase in extracellular K^+, indicate a transient and reversible oxidation of NADH to NAD. This oxidation could come about as a result the activity of a variety of enzymes involved in brain glycolysis and could play a role in maintaining levels of ATP under anaerobic conditions (Siegel et al., 1989).

Changes in glial membrane potential represent only one indication of possible signal transfer. Neuron-glial signals, however, may result from interactions between substances released from neurons and glial receptors with a subsequent change in the metabolism of the glial cell which is not mediated or accompanied by a change in the ionic permeability pattern of the glial membrane.

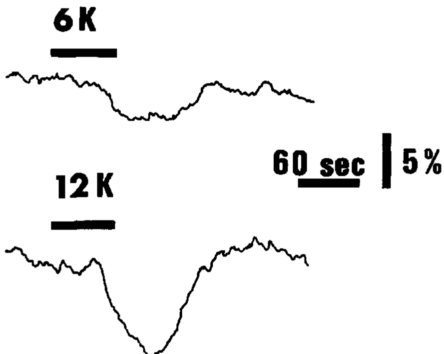

FIG. 31-4. Changes in glial metabolism produced by increased extracellular K^+. Two months after enucleation, the axons in the *Necturus* optic nerve are degenerated and the nerve consists solely of ependymoglia. When such a "glial" nerve was illuminated with light at 355 nM and the emitted light was recorded by a photomultiplier at 480 nM, the amount of light recorded is proportional to the level of reduced pyridine nucleotide (NADH) in the glial cells. Increasing extracellular K^+ from 3 mM to 6 or 12 mM produced a decrease in fluorescence suggesting an oxidation of NADH to NAD. [From P. Orkand et al. (1973), with permission.]

Nerve Impulses Facilitate Glial Voltage-Dependent Channels

In the frog optic nerve, a central nervous system tract that consists of 97% unmyelinated and 3% myelinated axons, oligodendrocytes, and astrocytes, a volley of nerve impulses facilitates voltage-dependent sodium channels in the superficial astrocytes (Marrero et al., 1989). The facilitation results from of a shift of the current voltage curve for activation of the inward sodium current to more hyperpolarizing potentials. Its maximum is about 50 ms after a volley and lasts for about a second. The facilitation is much briefer than the duration of K^+ depolarization, which results from K^+ lost from the axons following passage of the impulse (Figure 31-5). One possible explanation for the facilitation is that the nerve impulses alter the ionic composition of the extracellular fluid, for example, by producing a fall in extracellular calcium, and this ionic change shifts the current voltage curve for activation of the glial channels. This hypothesis suggests that the facilitation should be decreased in high calcium solutions or if calcium entry into the active axons is blocked by addition of calcium channel blockers. Recent studies suggest that, even though the facilitation is blocked by high calcium solutions, a decrease in extracellular calcium produced by axon impulses is not the cause of the facilitation (Marrero and Orkand, 1993). An alternative explanation is that some substance released from the active axons alters the function of the glial channels. Also intriguing, is the possible physiological role of nerve impulses in facilitating glial voltage-dependent channels. First, however, it will be necessary to ascribe some functional significance to the presence of these channels in glial cells (Chapter 12, this volume).

Axon-Schwann Cell Signaling in Squid

An effect of nerve impulses in the squid giant axon on the membrane potential of the surrounding Schwann cells was first reported more than 20 years ago (Villegas, 1972). Hyperpolarization, of the membrane, lasting about 10 minutes, was measured using a technique of repeated transient sampling with microelectrodes penetrating into the tessellated adaxonal Schwann cell, which has an average thickness of less than 2 μm. Using this technique, a complex picture of axon-Schwann cell interactions has evolved (Evans et

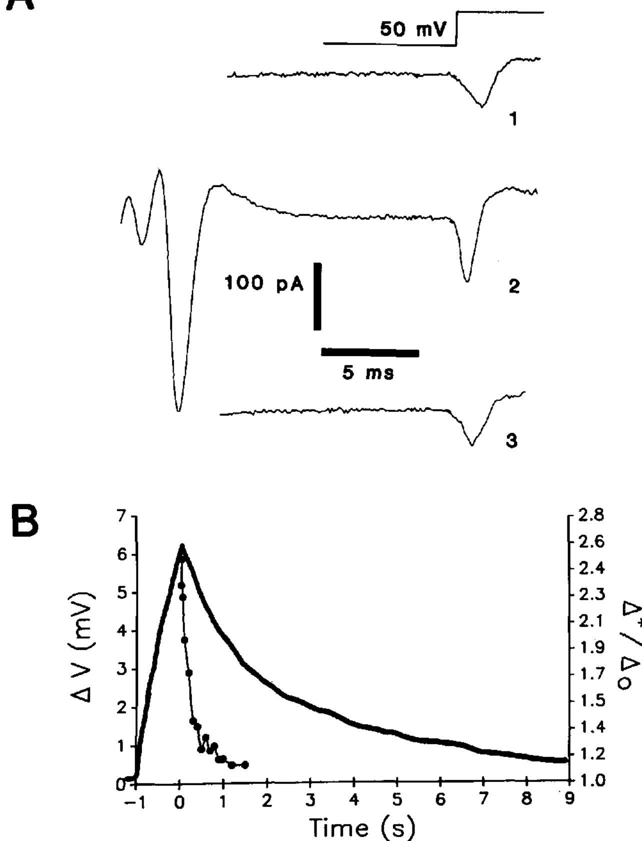

FIG. 31-5. Facilitation of voltage-gated ion channels in frog neuroglia by nerve impulses. (A) *Top*: Voltage-dependent current recorded via a loose-patch clamp electrode in response to a 50 mV depolarizing voltage step applied to the glial surface of a frog optic nerve. *Middle*: The axons of the optic nerve were stimulated 15 ms prior to the same voltage step and the axon action currents are recorded across the resistance of the bathing solution. The voltage-dependent currents from the glial surface are facilitated. *Bottom*: Control current 1 minute after the nerve stimulus was turned off. (B) Time-course of facilitation compared with the depolarization of the glial membrane produced by nerve impulses. The filled circles indicate the facilitation (ratio of facilitated to control response on right-hand scale) following a train of impulses at 10 Hz for 1 second. The heavy line is a record of the glial depolarization (left-hand scale) recorded from a glial cell with an intracellular electrode following an identical train of impulses in a separate experiment. The facilitation of voltage dependent currents recorded from the glial surface decays much more rapidly than the glial depolarization resulting from K^+ accumulation. [From Marrero et al. (1989), with permission.]

al., 1991). According to the proposed scheme, nerve impulses lead to the release of glutamate along the axon, which activates three distinct classes of glutamate receptors on the Schwann cell, that is, rapid and slow *N*-methyl-D-aspartate (NMDA)-type receptors and a quisqualate/kainate (Q/K)-type receptor. Activation of the Q/K receptor leads to corelease of acetylcholine and a vasoactive intestinal polypeptide (VIP)-like peptide from the Schwann cells. The effect of corelease is supposedly subject to modulation by octopamine. The role of NMDA receptor activation is still undefined. The entire scheme encompasses changes in Schwann cell calcium and cyclic AMP, which could alter the cell's behavior. However, the physiological role of this axon-Schwann cell interaction is not apparent. Hyperpolarization of the Schwann cell would favor the uptake of potassium into the cell and thereby aid in the proposed role of these cells to decrease the accumulation of potassium in the intercellular space following axon impulses (Lieberman, 1991). Newer electrophysiological techniques, including the use of patch-clamp electrodes, should provide more precise information concerning the time-course, mechanism, and significance of this axon-Schwann cell interaction.

Axon-Oligodendrocyte Signaling

There is at least one suggestion of a short-lived calcium- and potassium-dependent interaction, detected by voltage-sensitive dyes, between the axon and the oligodendrocyte in the region where the oligodendrocyte fingers are in close apposition to the axon membrane (Lev-Ram and Grinvald, 1986). Electrical stimulation of the axon has been shown to evoke a slow optical signal apparently reflecting a depolarization, lasting about 100 ms, of the oligodendrocytes in the paranodal or internodal region. The depolarization of the oligodendrocyte is suggested to result from a calcium-dependent increase in potassium conductance in the axon and the subsequent accumulation of potassium in a confined extracellular space (Berger et al., 1991).

Butt and Tutton (1992) have found that glutamate and GABA (both at 1 mM) depolarize some oligodendrocytes in the intact mouse optic nerve by a few millivolts. However, their study did not determine if the depolarization resulted from ligand-gated channels or electrogenic uptake of these neurotransmitters (Barbour et al., 1991). Moreover, there is no evidence that these transmitters are released in sufficient quantity and accumulate to a concentration that could depolarize glial cells in the intact nervous system. A possible role of these substances in axon-to-oligodendrocyte signaling at the nodes of Ranvier has to be further explored.

NERVE IMPULSES STIMULATE GLIAL TRANSPORT SYSTEMS

In this section, three established functions of glial cells in the homeostasis of the neuronal microenvi-

ronment are briefly outlined. The glial membrane transport systems involved in this regulation, like most homeostatic processes, are mostly reversible negative feedback systems. An increase above normal of K^+, H^+, or some amino acids leads to glial uptake or buffering, and a decrease below normal leads to glial release (Figure 31-6). It has also been suggested that positive feedback can play a role in a glial cell response to intense nervous activity and extracellular acidification (Chesler, 1990; Ransom, 1992). In effect, the systems are organized so that the substance being controlled represents the appropriate signal. The large glial membrane area forming the boundary of the narrow extracellular clefts provides an anatomical locus for the movement of ions and small molecules across the membrane, which enables glial cells to regulate the composition of the extracellular space. Since the glial cell volume is much greater than that of the extracellular space, movements of substances across the glial membrane may produce large changes in extracellular concentrations with relatively small changes in the glial cytoplasm.

Potassium Homeostasis

The accumulation of K^+ in the extracellular space is a normal consequence of electrical activity in neurons (see Chapters 18 and 47). Changes in extracellular K^+ affect the neuronal membrane potential and a variety of physiological behaviors such as the conduction velocity of the action potential, the amplitude of synaptic potentials and the frequency of rhythmic neuronal discharge. If excessive, the accumulation of K^+ can lead to a complete block of action potentials. The relatively high permeability of glial cells to K^+ and their syncytial nature suggested a role for them in K^+ homeostasis (Kuffler 1967), specifically, that glial cells buffer the rise in extracellular K^+. A rise in extracellular K^+ leads to the following glial response:

1. Glial depolarization and spread of depolarization through the glial syncytium. The resulting current leads to a more uniform distribution of the accumulated potassium (Orkand et al., 1966; Gardner-Medwin, 1983; Reichenbach, 1991). This is the so-called *spatial buffering* of potassium (Coles and Orkand, 1983; Karwoski et al., 1989; Chapter 47, this volume).
2. KCl uptake as a result of the requirements imposed by the Donnan equilibrium [the product of the activities of K^+ and Cl^- outside the cell is equal to their product inside the cell (Hodgkin and Horowicz, 1959; Coles et al., 1989)]. This passive KCl and water influx results in swelling of the glial cells (Wuttke, 1990).
3. K^+ and Cl^- uptake based on the driving force provided by the difference between the membrane potential and the equilibrium potential for the ions (Ritchie, 1991; see Chapter 11, this volume).
4. Additional K^+ uptake resulting from stimulation of the electrogenic Na/K-ATPase by a rise in external K^+ (Tang et al., 1980; Chapter 16, this volume).

FIG. 31-6. Some membrane transport systems in amphibian glial cells involved in the homeostasis of the neuronal microenvironment. Two of the systems, KCl uptake and Na/H exchange, are electroneutral. The remaining three, Na/K exchange pump (i.e., Na/K ATPase), Na-glutamate cotransporter, and Na^+-$2HCO_3^-$ cotransporter are electrogenic because more charge is transported in the direction of net transport (stoichiometries show direction of net charge movement and are imprecise). All the processes are entirely reversible depending on the membrane potential, the concentration gradients for the substances involved and the stoichiometry of the reaction. An increased outward movement of an ion has the same effect as a decreased inward movement of that ion. For example, a fall in extracellular pH will favor either (*1*) movement of HCO_3^- out of the cell or (*2*) less HCO_3^- movement into the cell. In either case, changes in cell pH can be countered by other transport mechanisms such as the Na/H exchanger. [From Orkand (1989), with permission.]

Hydrogen Ion Homeostasis

H^+ buffering minimizes changes in pH and provides for the constancy in the chemical composition of the environment necessary for normal brain function (see Chapter 14, this volume; Thomas et al., 1991). Intracellular pH in glial cells is above 7.0, far more alkaline than would be predicted if H^+ were passively distributed. This indicates that there is active regulation of H^+ across the glial membrane. Recent studies have provided evidence not only for intracellular pH regulation in glial cells but also that glial cells contribute to pH homeostasis in the extracellular fluid. Intracellular pH can be regulated in both neurons and glia by an amiloride-sensitive, bicarbonate-independent, neutral Na^+-H^+ antiport (Deitmer and Schlue, 1987; Astion et al., 1989). In addition, glial pH is regulated by an electrogenic Na^+-$nHCO_3^-$ cotransporter which is partially inhib-

ited by the stilbene derivatives SITS or DIDS (Astion et al., 1991; Deitmer, 1991). The stoichiometry is such that more HCO_3^- is transported than Na^+, so that there is a net transfer of negative charge. The result is that HCO_3^- can readily move in and out of glial cells to buffer changes in extracellular pH. Additional support for the hypothesis that glia play a role in the control of extracellular pH is provided by experiments that demonstrate that the buffering power in the extracellular space is decreased by the addition of the carbonic anhydrase inhibitor acetazolamide (Thomas et al., 1991). These results suggest that bicarbonate-dependent extracellular H^+ buffering is linked to Na^+-HCO_3^- cotransport across glial membranes.

A rise in extracellular H^+ leads to the following glial response:

The uptake of Na^+ and HCO_3^- by the electrogenic cotransporter is reduced or reversed so that HCO_3^- leaves the glial cells to buffer the decrease in extracellular pH (Deitmer, 1991, 1992). In effect, glial cells secrete HCO_3^- in response to an acidification of the extracellular fluid.

The ability of glia to buffer the extracellular pH is therefore a consequence of the basic properties of Na^+-dependent electrogenic transporters (Attwell et al., 1993). The activity, both rate and direction, of these transporters depends not only on the transmembrane gradients of the transported ions but also on the membrane potential. Depending on conditions, the glial cell can either increase or decrease the extracellular concentration of the charged species.

Interactions of Potassium and pH Homeostasis

A relatively large increase in extracellular K^+, such as might occur during intense nervous activity is accompanied by extracellular acidification (Kraig and Nicholson, 1978; Syková, 1992). In contrast, glial depolarization with K^+ (Boyarsky et al., 1988; Deitmer and Szatkowski, 1990) or neuronal activity (Chesler, 1990; Ransom, 1992) leads to a depolarization-induced alkalinization. This is because depolarization decreases the efflux of HCO_3^- from the glial cell via the electrogenic Na^+-HCO_3^- cotransporter (Deitmer and Szatkowski, 1990). Chesler (1990) and subsequently Ransom (1992) discussed the possibility that glial cells contribute to the extracellular acidification in a positive feedback manner to reduce neuronal excitability. On the other hand, in the leech ganglion, Deitmer has demonstrated that extracellular acidification *per se,* in the absence of an increase in K^+, leads to an intracellular acidification due to an increase in HCO_3^- efflux by the glial cells. He further suggests that glial cells tend to "muffle" that is, buffer changes in extracellular pH rather than to reinforce them. Thus, it appears that extracellular acid by itself leads to glial secretion of HCO_3^- to buffer the pH decrease, whereas in the event of intense neural activity leading to K^+ accumulation and acidification, the glial cells tend to contribute to the acidification and decrease neuronal excitability. This ability of glial cells to either buffer or contribute acidity reflects the stoichiometry of the Na^+-$n HCO_3^-$ cotransporter and its voltage dependence (Deitmer and Schlue, 1989; Deitmer and Szatkowski 1990, Astion and Orkand, 1989). This appears to be a special property of glial cells not shared by neurons (Thomas, 1988; Deitmer and Szatkowski, 1989).

The glial role in pH homeostasis appears to be directly related to the properties of the electrogenic Na^+-HCO_3^- cotransporter: (1) A decrease in extracellular pH causes the glial cell to secrete HCO_3^- and restore normal pH; (2) A decrease in extracellular pH accompanied by K^+ accumulation causes the glial cell to secrete acid and decrease neuronal excitability.

Amino Acid Homeostasis

Glial cells take up a variety of amino acids via a Na^+-dependent transport system, and these processes are believed to play a role in inactivation of neurotransmitters like GABA (P. Orkand and Kravitz, 1971) and glutamate (Brew and Attwell, 1987; see Chapters 15, 48, and 54, this volume). The glutamate uptake has been the best studied with electrophysiological techniques (Barbour et al., 1991; Wyllie et al., 1991). A picture is emerging whereby glutamate uptake into cells helps to terminate the action of this neurotransmitter and, in addition, keeps the concentration of glutamate in the extracellular space below neurotoxic levels. When glutamate is applied to glial cells, an inward current can be recorded that is abolished by removal of extracellular Na^+. The current is also evoked by glutamate analogues with the pharmacology of glutamate uptake, and it is presumed that the current reflects electrogenic glutamate uptake by a carrier that cotransports Na^+ into the cell.

A rise in extracellular glutamate or other amino acids leads to the following glial response (depending on the type of glial cell): Stimulation of electrogenic Na^+-dependent amino acid cotransport and or activation of glutamate-gated cationic channels (Wyllie et al., 1991). Figure 31-6 illustrates some glial

cell membrane transport processes which function in extracellular homeostasis.

SUMMARY

Nerve impulse activity has a number of effects on glial membrane transport systems that tend to maintain homeostasis in the neuronal microenvironment. In the case of increases in K^+, H^+, and some amino acids, glial membrane transport systems respond appropriately and reduce the concentration of these substances toward resting levels. These are well-established homeostatic functions of glial cells. In addition, intense neuronal activity leads to K^+ accumulation, and the glial cells contribute to an extracellular acidification that tends to reduce neuronal activity. The alkalinization and acidification of the extracellular fluid are consequences of the reversible voltage-dependent behavior of the glial electrogenic sodium-bicarbonate cotransporter. Voltage-dependent glial currents are facilitated by nerve impulses, but the mediator and significance of this effect are obscure. Furthermore, glial cells are exposed to a number of substances released from active neurons, including a variety of neurotransmitters and metabolites. The role of such substances in neuron-glial signaling and the physiological response of the glial cells to these substances needs clarification.

I thank Paula Orkand and Ladislav Vyklicky for helpful criticism of the manuscript.

32 Energy metabolism

BERND HAMPRECHT AND RALF DRINGEN

The indispensable major substrates of energy production in the mammalian brain are glucose and oxygen. Nevertheless, brain perfusion experiments have shown that the brain can do quite well without glucose or any other exogenous substrate for two hours, provided oxygen is offered at a sufficiently high concentration (Geiger, 1958). In this case the brain behaves like the legendary Canadian trapper in his log cabin who runs out of wood while surrounded by deep snow. In order to survive, the trapper burns the furniture in his cabin. Similarly, the brain uses up its stores of glycogen and amino acids and metabolizes protein and membrane lipids to generate energy.

This parable highlights what is meant by energy metabolism in this chapter: metabolic processes necessary for the generation of the energy-rich pyrophosphate bonds in adenosine triphosphate (ATP). Such processes include not only the ATP-synthesizing pathways of substrate chain phosphorylation (glycolysis and Krebs cycle) and oxidative phosphorylation but also the metabolism of the energy store glycogen and the generation, from precursors, of compounds suitable as fuel in the oxidative generation of ATP.

The ultimate fuel in the electron transport or respiratory chain is the most abstracted—in the word's original sense—form of reduction equivalents, the electrons. They end up becoming attached to dioxygen to form O^{2-} ions, which after combination with H^+ ions, are disposed of as water. Before being able to run through the cascade of the electron transport chain from the level of negative redox potential to the most positive one of O_2, the electrons need to be stripped of the atoms that accompany them in the fuel compounds. The sequence of stripping of atoms occurs in a hierarchical fashion. This can best be illustrated by the example of the amino acid alanine oxidatively metabolized as a fuel compound. First, the heteroatom N is eliminated. In this case the elimination is brought about by transamination. In other cases, for example, that of serine, well-known alternative mechanisms are used. At any rate, compounds emerge that consist only of carbon, oxygen, and hydrogen, such as pyruvate in our examples of alanine and serine. The subsequent processes, oxidative decarboxylation and the Krebs cycle, are primarily intramolecular redox reactions aimed at the simultaneous elimination of carbon and oxygen as CO_2. Since molecules such as pyruvate do not contain enough oxygen to allow the production of CO_2 by shear rearrangement, additional oxygen atoms need to be acquired from the solvent water. After the elimination of carbon and oxygen, only hydrogen is left in the form of hydride ions stabilized as NADH or $FADH_2$ for their existence in an aqueous environment. Finally, as the reduction equivalents enter the electron transport chain, the last packaging material, the proton, is stripped from the pair of electrons as an H^- ion.

There is no doubt that these metabolic processes are the same in the nervous system as in the rest of the body. However, in the nervous system it is less certain in which types of cells these processes take place. In fact, they may occur partially in one cell type, for example, the astrocyte, and be continued in another cell type, for example, the neuron or the oligodendrocyte. Such metabolic cooperation between adjacent cells, of course, would require intercellular transfer of metabolites. How little attention is still being paid to this aspect of glial function is exemplified by a recent overview article (Barres, 1991).

Those who are working in the field of neural energy metabolism cannot escape the feeling of just having scratched the surface of the underlying problems. The following questions indicate the state of our ignorance: Do some neurons or certain parts of them really lack hexokinase or cytochrome oxidase, and, if so, what are their physiological specialties that would allow such deficiencies? What is (are) the physiological function(s) of brain glycogen? How is the task to generate energy (and the corresponding metabolic pathways) divided up among the cell types of the central nervous system? What kind of signals switch the energy-generating systems from using glucose to using amino acids or fatty acids? What are the transport systems that allow transcellular transport of nutrients and waste products through the capillary endothelial cells and astrocytes?

Hypotheses about the cellular compartmentation of brain energy metabolism can be derived from the anatomical situation. Strategically speaking, astrocytes are located in a key position between the capillaries on the one side and the neurons and oligodendrocytes on the other side. Thus, all nutrients required for energy production such as glucose, oxygen, and amino acids may have to pass through these cells. In view of this and the presence of glycogen in these cells (Cataldo and Broadwell, 1986a), we consider astrocytes as putative storage and processing plants of energy metabolism.

GLYCOGEN

Glycogen Phosphorylase and Synthase

In brain, glycogen is reported to be found in astrocytes. Minor amounts of glycogen have been detected in neurons, choroid plexus epithelial cells, meningeal cells, capillary endothelial cells, and pericytes (Cataldo and Broadwell, 1986a, 1986b). Glycogen phosphorylase (GP), the activity of which determines the breakdown of glycogen, has been reported to be present in almost all cell types, most likely depending on the technique employed (Friede, 1956, 1959a, 1959b; Shimizu and Okada, 1957; Tewari and Bourne, 1962; Gentschev, 1967; Ohanian, 1972).

For obtaining more reliable results, an immunohistochemical method had to be developed. This required the purification of the brain isozyme of glycogen phosphorylase (Reinhart et al., 1990). Of the three isozymes known, the liver type L, the muscle type M, and the brain type B, the latter was the only one that had not yet been purified to apparent homogeneity. Mouse monoclonal antibodies raised against the B isozyme (Hamprecht et al., 1993) cross-reacted with the L and M isozymes.

The results of indirect immunofluorescence studies on astroglia-rich (Hamprecht and Löffler, 1985) and neuron-rich primary cultures derived from newborn and fetal rat brains, respectively, by using this antibody (Reinhart et al., 1990) are described in Chapter 33, which also discusses the immunocytochemical findings obtained with slices of adult rat brain (Ignacio et al., 1990; Pfeiffer et al., 1990, 1992, 1993). During development, appreciable GP activity appears in rat brain around embryonic day 16 and increases steadily thereafter until adult levels of activity are reached by the end of the third postnatal week (Pfeiffer et al., 1993). In addition to its permanent appearance in astroglial and ependymal cells, GP immunoreactivity is transiently expressed in the pia mater and in choroid plexus cells (Pfeiffer et al., 1993). The absence of GP from neurons of the brain areas mentioned above became the more striking, since the enzyme was strongly expressed in the magnocellular neurons of the mesencephalic trigeminal nucleus (Me5) (Pfeiffer et al., 1993).

Vital staining for GP enzyme activity after electrophoretic separation of brain proteins on "native" gels (Davis et al., 1967) demonstrated the presence of two or three bands, depending on the method and animal species used (Delain et al., 1973; Yonezawa and Hori, 1975; Sato et al., 1976; Richter et al., 1983; David and Crerar, 1986; Mayer and Letsch, 1991; Newgard et al., 1991). These bands are likely to correspond to the brain and muscle isozymes of GP. According to Northern blot analysis, rabbit brain contains predominantly the mRNA of the brain isozyme, transiently expresses the mRNA of the muscle isozyme, and has very little mRNA for the L isozyme (Newgard et al., 1989). The cell-type distribution in brain of these isozymes is unknown, with the exception that astrocytes of cerebral- and cerebellar cortex contain the B isozyme (Ignacio et al., 1990).

There is apparently only one report on the cellular localization in brain of the glycogen-forming enzyme glycogen synthase. According to Inoue et al. (1988) the enzyme appears to be present in all brain cells. This would only be compatible with the notion of cellular restriction of GP if one assumed an alternative pathway of degradation, for example by α-glucosidases (Newgard et al., 1991) in the cells lacking GP, that is, in oligodendrocytes and most neurons.

Glycogen Metabolism in Astroglial Cultures

We know close to nothing about the function of brain glycogen. It is conceivable that the functions of the polysaccharide may not be the same in astrocytes, ependymal cells, and neurons. Two theoretically possible functions are paradigmatically outlined by the situations in liver and skeletal muscle. The main purpose of glycogen storage in liver is to prevent the blood glucose level from falling below a certain threshold concentration. Thus, the glucosyl residues of glycogen are preferentially stored for the benefit of cells of tissues other than liver, and therefore need to be releasable as glucose. In contrast, muscle stores glycogen selfishly. All it may release at situations of high demand for energy is the lactic acid formed by glycolytic breakdown of the mobilized glucosyl residues of glycogen.

The unique capacity of liver to release glucose de-

rived from glycogen is due to the presence of glucose 6-phosphatase. The existence of this enzyme in brain is controversial (Nelson et al., 1985). By histochemical techniques such activity has been detected mainly in neurons (Stephens and Sandborn, 1976; Pertsch et al., 1988). Indeed, the first report on the isolation of the membrane-bound enzyme was using brain as a source rather than liver (Anchors and Karnovsky, 1975). However, it appeared disturbing that the glucose 6-phosphate translocase associated with the liver enzyme could not be found in brain (Fishman and Karnovsky, 1986). More recently, in an immunoblot analysis using antibodies against a subunit of the liver enzyme, immunoreactive material could not be detected in brain (Burchell and Waddell, 1991).

The complexity of brain with the intricately interwoven lamellar and neuritic cellular elements at the submicroscopic level does not allow assessment of the contribution of a certain cell type to a metabolic process by studying brain tissue. Such investigations need to be carried out in culture systems of reduced complexity. Ideally such culture consists of only one cell type. In the case of astroglial cells one may be dealing with astroglial-rich primary cultures derived from the brains of newborn rats or mice (Hamprecht and Löffler, 1985). Besides the numerically dominating astroglial cells they mainly contain oligodendroglial, microglial, and ependymal cells (Raff et al., 1979; Hamprecht, 1986; Reinhart et al., 1990). In the case of mouse primary astroglial cultures these accompanying cell types can be eliminated by culturing in a selective medium (Wiesinger et al., 1991).

The fate of the glycogen glucosyl residues was primarily studied in astroglial-rich cultures from mouse or rat brain. In such cultures the breakdown of glycogen can be induced by several hormones (Figure 32-1), among them also some that elevate the level of cyclic adenosine monophosphate (cyclic AMP) (Hamprecht, 1986). Such hormones are adenosine (Magistretti et al., 1986), norepinephrine (Quach et al., 1978; Rosenberg and Dichter, 1987; Cambray-Deakin et al., 1988; Subbarao and Hertz, 1990; Hamprecht et al., 1993), histamine (Quach et al., 1980; Arbones et al., 1990), serotonin (Quach et al., 1982), and vasoactive intestinal polypeptide (Magistretti et al., 1981). Glycogen degradation is also triggered by raising the concentration of Ca^{2+} in the cytosol (Hamprecht et al., 1993). The fact that elevation of the cytosolic levels of either cyclic AMP or Ca^{2+} triggers the catabolism of glycogen (Figure 32-1) points to an involvement of phosphorylase kinase. In addition, withdrawal of glucose (Dringen and Hamprecht, 1992a, 1993a) leads to loss of glycogen: On deprivation of glucose the glycogen content drops in a process exhibiting first-order kinetics with a half-life of 7 minutes (rat) or 15 minutes (mouse).

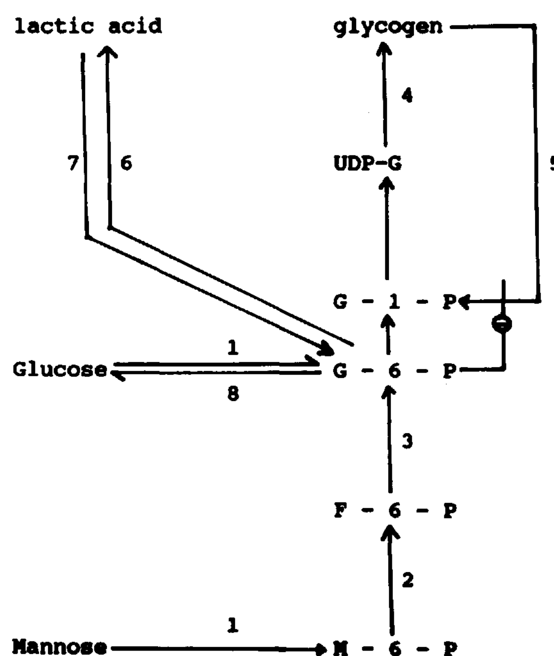

FIG. 32-1. Pathways of synthesis and degradation of glycogen in astroglial cells. *M-6-P*, mannose 6-phosphate; *F-6-P*, fructose 6-phosphate; *G-6-P*, glucose 6-phosphate. The numbers represent enzymes or pathways: *1*, hexokinase (EC 2.7.1.1); *2*, mannose-phosphate isomerase (EC 5.3.1.8); *3*, glucose phosphate isomerase (EC 5.3.1.9); *4*, glycogen synthase (EC 2.4.1.11); *5*, glycogen phosphorylase a (EC 2.4.1.1); *6*, glycolysis; *7*, gluconeogenesis; *8*, glucose 6-phosphatase (EC 3.1.3.9).

The degradation following deprivation of glucose is most likely a consequence of the loss of glucose 6-phosphate. This compound (Mayer and Letsch, 1989) and 2-deoxyglucose 6-phosphate (Dringen and Hamprecht, 1993b) block phosphorylase (Figure 32-1), whereas the unphosphorylated sugars do not. Feeding of 2-deoxyglucose to astroglial cells gives rise to the corresponding 6-phosphate, which is practically not metabolized and thus affords a permanent block of glycogenolysis (Dringen and Hamprecht, 1993b). The inhibitory action of deoxyglucose 6-phosphate on glycogen phosphorylase may also explain that deoxyglucose in the culture medium of astroglial cells elevates the cellular content of glycogen (Swanson et al., 1989). On the other hand, a similar effect of methionine sulfoximine on astroglial cells in brain (Folbergrová, 1973) and in culture (Swanson et al., 1989) remains unexplained, although an action on the level of glycogen phosphorylase has been suggested (Swanson et al., 1989). Also the molecular mechanism underlying similar effects of aspartate and glutamate (Swanson et al., 1990) are unknown. 1,5-Gluconolactone is another compound that can block glycogen phosphorylase

(Gold et al., 1971; Tu et al., 1971), and also blocks glycogen mobilization in astroglial cells (Dringen and Hamprecht, 1993b). Due to the spontaneous hydrolysis of the lactone and the lack of inhibitory capacity of the ensuing gluconate, the block exerted by the lactone is only transient. Both 2-deoxyglucose, as a precursor of deoxyglucose 6-phosphate, and gluconolactone may turn out as useful tools in the analysis of the glycogen metabolism in brain. Indeed, if glycogen degradation is blocked by 2-deoxyglucose or gluconolactone, the amount of lactate released from astroglial cells into the culture medium decreases by the amount expected to be generated from the glycogen present (Dringen and Hamprecht, 1992b).

After depletion by withdrawal of glucose, glycogen is restored in the astroglial cultures within 2 hours of repletion of glucose (Dringen and Hamprecht, 1992a). The maximal level of glycogen is twice as high if also serum, insulin or insulinlike growth factor I (IGF-I) is present. The latter is at least one order of magnitude more potent than insulin (Dringen and Hamprecht, 1992a). Therefore, and in view of the fact that brain contains a truncated variant of IGF-I (Carlsson-Skwirut et al., 1986), which binds more strongly to IGI-I receptors of brain membranes than IGF-I itself (Carlsson-Skwirut et al., 1989), it is safe to state that it is likely an IGF-I that would exert an elevation of glycogen levels in brain cells. This is especially interesting, since astroglial cells in culture produce IGF-I and express receptors for it (Ballotti et al., 1987), which would allow an autocrine effect. A report that insulin (1 μM) increases the incorporation of [^{14}C] glucose into cultured astroglial cells by 60% (Kum et al., 1992) is in accord with the results mentioned above (Dringen and Hamprecht, 1992a).

The mechanism by which insulinoids bring about an increased level of glycogen has been elucidated. The receptor tyrosine kinase phosphorylates the regulatory subunit of type-1 protein phosphatase, which enzyme, in turn, activates glycogen synthase by dephosphorylation (Dent et al., 1990).

Astroglial glycogen can not only be synthesized from glucose (Figure 32-1). Refeeding depleted cells with mannose instead of glucose leads to the same cellular concentration of glycogen as in glucose-fed cultures (Dringen et al., 1994a). Mannose is transported into the cells by the cytochalasin B-sensitive glucose transporter and is phosphorylated by hexokinase (Bergbauer et al., 1993). The ensuing mannose 6-phosphate is isomerized to fructose 6-phosphate by mannose-6-phosphate isomerase. With the further enzymatic isomerization to glucose 6-phosphate the carbohydrate moiety has entered the glycogenic pathway of glucose. Compatible with this notion is that the astroglia-rich cultures contain mannose 6-phosphate isomerase and can convert mannose to lactate (Bergbauer et al., 1993; Dringen et al., 1994a) (Figure 32-1).

Mannose is not normally a constituent of blood (Hawkins and Mans, 1983; Akazawa et al., 1986). Why then should astroglial cells contain mannose 6-phosphate isomerase? Possible they need the enzyme in the processes of synthesis and breakdown of glycoproteins. In this case it is expected, but not known, to be present in all cell types of the brain. On the other hand, the high specific activity of the enzyme in astroglia-rich cultures, higher than that of hexokinase (Dringen et al., 1993c), and the appreciable capacity of brain to metabolize mannose to lactate and CO_2 (Chain et al., 1969; Sloviter and Kamimoto, 1970) point to a metabolically more demanding function than would be required in the turnover of glycoproteins. In contrast to glucose or mannose, astroglial cells do not at all, or only slightly, accumulate glycogen if they are grown in the presence of galactose and fructose, respectively, instead of glucose (Dringen and Hamprecht, 1993a).

Astroglial Cells as a Lactic Acid Store

The most important aspect of glycogen degradation is the fate of the glucosyl residues. Surprisingly, the glucosyl residues do not appear as free glucose released into the surrounding incubation medium. Rather, the cells release lactic acid (Dringen and Hamprecht, 1992b; Dringen et al., 1993a) (Figure 32-1). If glucose had been excreted it would have been detected, as was the case with cultured hepatocytes.

The rapid degradation and repletion of glycogen, that is, the high turnover of the storage polysaccharide, can be analyzed by enzymatic determination of glycogen and can also be demonstrated by the use of radioactively labeled glucose (Hamprecht et al., 1993). As a consequence of a drop in the concentration of extracellular glucose or of an adequate hormonal stimulus, glycogen may be broken down locally. The glycolytic processing of the glucosyl residues benefits the astrocyte only to a small extent. The bulk of the free energy of combustion, however, is likely to be passed on to the neighboring neurons and oligodendrocytes within the lactic acid generated (Figure 32-2).

The appearance of lactate rather than glucose as a consequence of glycogen breakdown allows us to consider astroglial glycogen as a store of lactic acid rather than of glucose. The fact that the two lactic

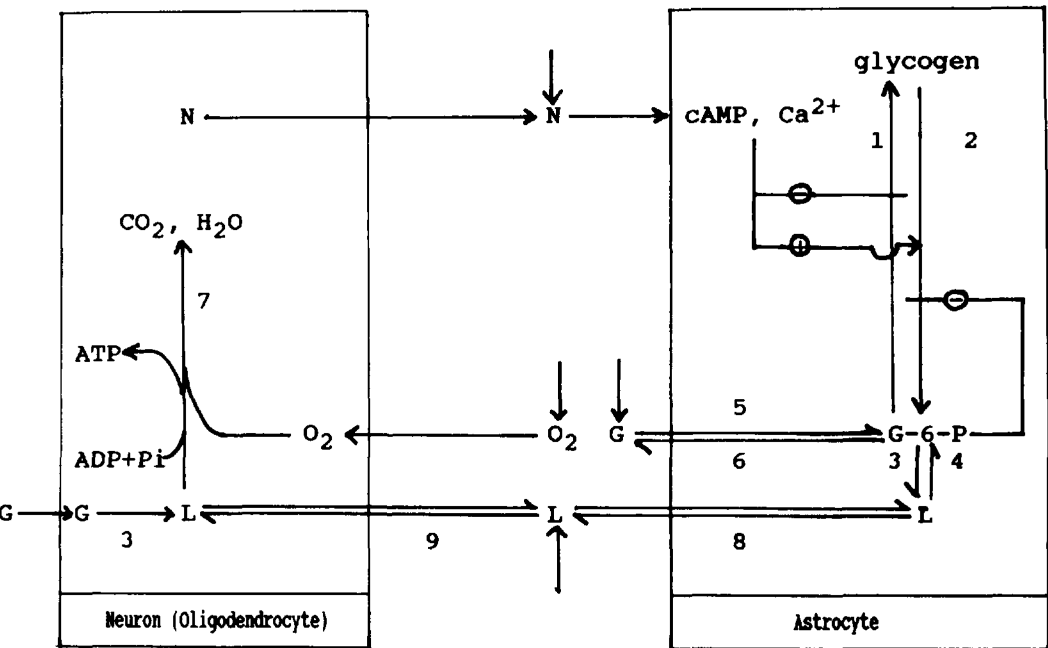

FIG. 32-2. Hypothetic scheme of metabolic interactions between brain cells due to dynamics of astroglial glycogen and lactate. *L*, lactic acid or lactate; *G*, glucose; *G-6-P*, glucose 6-phosphate; *N* neurohormone, neurotransmitter. The numbers represent pathways or enzymes: *1*, glycogenesis; *2*, glycogenolysis; *3*, glycolysis; *4*, gluconeogenesis; *5*, hexokinase; *6*, glucose 6-phosphatase; *7*, oxidative metabolism of lactate, including the tricarboxylic acid cycle and oxidative phosphorylation; *8* and *9*, astroglial and neuronal lactate transport, respectively. The *arrows* outside the cells indicate exogenous supply of a substance, either from outside the brain (or in the case of *N*, from another neighboring neuron). The production of ATP during glycolysis has been omitted for the sake of clarity. The interaction shown is between an astrocyte on the one side and a neuron or oligodendrocyte on the other side. In the case of an oligodendrocyte being the partner, it is not known whether it can release a neurohormone that could induce (second messenger-mediated) glycogenolysis in the astrocyte. If the concentration of extracellular glucose drops or if neurohormones emitted by neighboring neurons elevate the level of second messengers in the cytosol of the astrocyte, glycogen breakdown is initiated and glycogen synthesis is stopped. The *G-6-P* generated is used for glycolytic energy production. The lactate produced is released from the astrocyte and taken up into a neighboring neuron or oligodendrocyte (or even microglial cell?) to be used for energy production by oxidative metabolism. If the cell or part of it can also perform glycolysis, ATP can also be generated by using this pathway. Thus, if this neuron (or other neurons in the vicinity) is excited, the neurohormone released may be "understood" by the astrocyte as a "request" for delivering an energy substrate. Instead of lactate, other energy substrates such as pyruvate or ketone bodies might be generated and forwarded as well. It is conceivable that momentary local conditions can make lactic acid available to astrocytes from neighboring cells or their processes. The astrocytes might then dispose of the lactic acid by gluconeogenesis.

acid molecules are almost as valuable a fuel material in the oxidative pathways of generation of energy as the glucose they are derived from, is illustrated by the capacity of isolated rat brain cells (Vicario et al., 1991) or brain slices (Schurr et al., 1988) to use lactate as a source of energy. The observation that fetal sheep brain does not take up exogenously offered lactate (Harding and Charlton, 1990) may not be a contradiction, since some brain cells (neurons, oligodendrocytes) may well be using endogenous lactate produced by and released from their neighbors, for example, astrocytes. That such local production of lactate is a physiologically important phenomenon in the central nervous system has been clearly demonstrated by *in situ* microdialysis studies of the brain (Kuhr and Korf, 1988; Korf, 1989; De Bruin et al., 1990) and by work carried out on isolated retina (Ames et al., 1992). In culture the astroglial cells are taken out of the context of their physiological neighbors (neurons, oligodendrocytes, microglia). Thus, the lack of extracellular appearance of glucose on degradation of glycogen in cultured astroglial cells does not necessarily mean that this should also be the case in brain. *In situ* microdialysis studies are required to clarify this point.

Thus far, the most clear-cut example of metabolic cooperation between neural cells has been the interaction between glial and photoreceptor cells in the retina of the honeybee drone (Tsacopoulos et al., 1987, 1988). The glial cells store glycogen but lack mitochondria, whereas it is the other way around for the photoreceptor cells. On illumination, the glial cells receive from the photoreceptor cells a signal of hitherto unknown nature, upon which they degrade

their glycogen and provide the photoreceptor cells with a metabolic substrate that is neither glucose nor lactate or pyruvate. The photoreceptor cells use this compound and O_2 for the generation of energy. Such metabolic coupling is likely to exist also in the mammalian central nervous system. After all, oligodendrocytes (Kao-Jen and Wilson, 1980; Snyder and Wilson, 1983) and some neurons (Kao-Jen and Wilson, 1980; Simurda and Wilson, 1980; Katoh-Semba et al., 1988) contain hexokinase only at low activity and thus must widely rely on oxidative generation of energy. Important in this context is the protection granted by astroglial cells to neurons in culture during anoxia (Vibulsreth et al., 1987). With their stores of glycogen, astroglial cells in culture also enable neighboring neurons to survive a deprivation of glucose (Swanson and Choi, 1993).

Neural Transport and Utilization of Lactate

The concept that lactate released from astrocytes may be utilized by neurons implies the transport of lactate across the plasma membranes of these two cell types (Figure 32-2). It has been shown that the lactate produced by astroglial cells can not only be derived from glycogen but also from glucose (Pauwels et al., 1985; Walz and Mukerji, 1988a, 1988b). From studies of cellular release of lactate no data can be obtained that would allow conclusions as to the mechanism involved. Therefore, inward transport has to be investigated. According to the principle of the microscopic reversibility of chemical reactions, the data obtained should allow the construction of a mechanism also for the outward transport. The transport of lactate into cultured astroglial cells is quite rapid, even more so if the cells already contain lactate at the onset of the transport experiment and if the pH of the incubation medium is low (Dringen et al., 1994b; Tildon et al., 1993). Due to the rapidity of lactate uptake, using cells attached to culture dishes does not allow a reliable time resolution of the uptake process in the range below half a minute. This situation bars the determination of meaningful kinetic constants for the uptake process (Dringen et al., 1994b). Nevertheless, such constants have been published and the existence of a high-affinity/low-capacity and a low-affinity/high-capacity transport system has been postulated (Tildon et al., 1993). No such suitable carrier systems could be detected in another study, the data of which led to the conclusion that the rate of lactate uptake into astrolia-rich primary cultures derived from rat brain is proportional to the lactate concentration in the incubation medium (Dringen et al., 1994b). In other words, the transit of lactate, possibly as lactic acid, through the plasma membrane is facilitated by a nonsaturable pore or channel, analogous to that allowing the permeation of sorbitol (Stahl et al., 1989). Encouragement to accept this conclusion is lent by the notion that a widely employed inhibitor of lactate and pyruvate transport, α-cyano-4-hydroxycinnamate (Halestrap and Denton, 1974), fails to inhibit lactate uptake into astroglial cells (Dringen et al., 1994b).

If the lactate released from astrocytes is to be used as fuel material in neurons and oligodendrocytes (Figure 32-2), or in some regions of these cells, it must be taken up into them. Indeed, they can utilize lactate as energy source, at least in culture (Edmond et al., 1987). The uptake of lactate into neuron-rich cultures derived from fetal rat brains consists of two components, a saturable component and a nonsaturable component, of which only the former can be completely blocked by α-cyano-4-hydroxycinnamate (Dringen et al., 1993c). This contrasts with the lack of a saturable and inhibitable transport system in astroglial cells (see above; Dringen et al., 1994b) and resembles the situation of glucose transport in astroglial cells, in which only the saturable component would be inhibited by cytochalasin B (Stahl et al., 1989).

All cells that contain hexokinase should be able to generate ATP glycolytically, and all cells expressing cytochrome oxidase can be assumed to have the capacity of producing ATP by oxidative phosphorylation. Histochemical and activity studies of the distribution of these enzymes (Wilkin and Wilson, 1977; Kao-Jen and Wilson, 1980; Simurda and Wilson, 1980; Snyder and Wilson, 1980; Sandell, 1984; Aoki et al., 1987; Katoh-Semba et al., 1988; Borowsky and Collins, 1989; Hevner and Wong-Riley, 1989; Bilger and Nehlig, 1991; Burgess and Wilson, 1991; Gonzales-Lima and Garrosa, 1991; Griffin et al., 1992; Karmy et al., 1991) in the central nervous system revealed that their "territories" overlap only partially. This means that some cells rely on either the one or the other pathway of production of energy, whereas others have an alternative and, therefore, can more flexibly respond to a changing demand of energy. In the case of expression of both pathways in a cell type (e.g., astrocyte), the ratio of their maximal activities may vary with the stage of development and the anatomical location. Due to their juxtaposition to the capillaries, the astrocytes are closer to the source of glucose. In view of the normal abundance of glucose it would make sense (1) that astrocytes relied more strongly on glycolysis than on oxidative phosphorylation, and (2) that neurons and oligodendrocytes would preferentially pro-

duce their energy by oxidative phosphorylation. Their remote location in respect to the blood as a source of substrates for the production of energy requires a more efficient utilization of the energy substrate. This strategy is facilitated by the rapidity with which the very low molecular weight hydrophobic compound O_2 can diffuse transcellularly. The observation that astroglial cells are more dependent on glucose than neurons (Kauppinen et al., 1988) is compatible with this consideration. Those neurons that contain hexokinase can more rapidly generate ATP than would be possible by oxidative phosphorylation, and thus they would be able to respond more instantaneously to sudden demands for energy.

GLUCONEOGENESIS

Classical biochemistry has shown that in mammals gluconeogenesis is a privilege of liver and kidney. The term means generation of glucose from gluconeogenic substrates such as lactate, pyruvate, and a wide variety of amino acids including alanine, serine, threonine, aspartate, and glutamate. In the physiological practice of a starving animal the liver extracts such a substrate from the blood and, at the expenditure of 6 ATP (in the cases of alanine and lactate), synthesizes glucose from it, which is released into the bloodstream. For the reversal of lactic acid fermentation seven enzymes of glycolysis are used plus the four key enzymes of gluconeogenesis: pyruvate carboxylase (PC), phosphoenolpyruvate carboxykinase (PEPCK), fructose 1,6-bisphosphatase (FBPase) and glucose 6-phosphatase (G6Pase). However, it should be stressed that, probably with the exception of FBPase, these enzymes can be involved in other pathways as well. Thus, PC also acts as an anaplerotic enzyme, which—by catalizing the formation of oxaloacetate from pyruvate—replenishes the pool of Krebs cycle intermediates. By catalyzing the reverse reaction to its gluconeogenic activity, PEPCK may serve the same purpose as PC, that is, the formation of oxaloacetate from phosphoenolpyruvate and CO_2. In fact, PEPCK occurs in nongluconeogenic tissues, such as muscle, and may function anaplerotically (Schöttler and Wienhausen, 1981). G6Pase can play a role also in the last step of glycogenolysis. To our knowledge, only for FBPase has an alternative function thus far not been suggested.

The prerequisite for gluconeogenesis from lactate is the presence of all four key gluconeogenesis enzymes (Figure 32-3). Gluconeogenesis from amino acids that are degraded to Krebs cycle intermediates

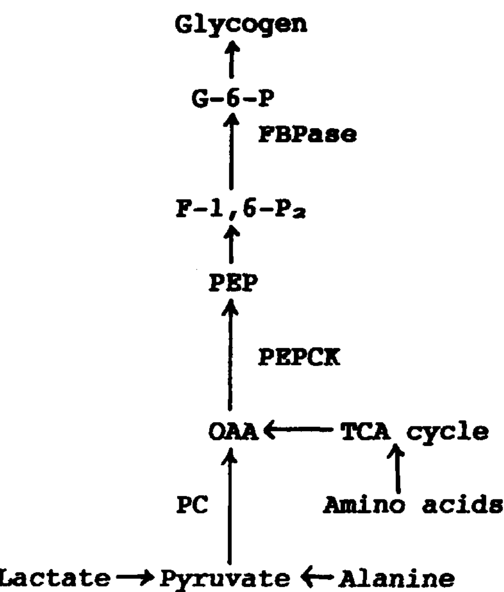

FIG. 32-3. Scheme of gluconeogenesis in astroglial cells. Numerous intermediate enzymatic steps have been omitted for the sake of clarity. *PC*, pyruvate carboxylase (EC 6.4.1.1); *TCA*, tricarboxylic acid; *OAA*, oxaloacetate; *PEP*, phosphoenolpyruvate; *PEPCK*, phosphoenolpyruvate carboxykinase (EC 4.1.1.32); *F-1,6-P$_2$*, fructose 1,6-bisphosphate; *G-6-P*, glucose 6-phosphate; *FBPase*, fructose 1,6-bisphosphatase.

does not require PC any more. Nevertheless, the occurrence of the four key gluconeogenic enzymes in an organism does not guarantee the occurrence of gluconeogenesis. It is a paradoxical situation that a blood-dwelling, parasitic helminth contains these enzymes, although it is living in the presence of an abundance of glucose in blood. Since the animal is unable to carry out gluconeogenesis (Tielens et al., 1991), this set of enzymes is in search of a function.

Two lines of evidence made it likely that gluconeogenesis could also occur in brain. One of these is the presence in brain of the gluconeogenic enzymes PC (Yu et al., 1983; Shank et al., 1985; Faff-Michalak and Albrecht, 1991), PEPCK (Zimmer and Magnuson, 1990), FBPase (Phillips and Coxon, 1975; Majumder and Eisenberg, 1977; Hevor and Gayet, 1978, 1981; Carter, 1983; Hevor et al., 1985; Chattoraj and Majumder, 1986; Liu and Fromm, 1988), and G6Pase (Anchors and Karnovsky, 1975). Also the fixation by astroglial cells of $^{14}CO_2$ in acid-stable products can be taken as support of the existence of PC in brain cells (Kaufman and Driscoll, 1992). In the case of PEPCK other authors (Wiese et al., 1991) have been unable to detect the enzyme in brain. The second line of evidence is dealing with the synthesis in tissue of the central nervous system of glycogen glucosyl residues from gluconeogenic precursors (Ide et al., 1969; Phelps, 1975; Phillips and Coxon, 1975; Goldman and Witkovsky, 1987; Goldman, 1988).

This creates a semantic problem with the definition of gluconeogenesis given above. We would have to redefine this term by specifying that we understand by gluconeogenesis the synthesis from gluconeogenic precursors (classically lactate) of glucosyl residues (rather than free glucose). The biochemical consequence of this change in semantics would be that G6Pase is not necessarily required any more for gluconeogenesis (Figure 32-3). Consequently, in this context we would no longer have to worry about the above-mentioned weak evidence for the existence of the enzyme in brain.

The occurrence of the key gluconeogenic enzymes in brain would not be sufficient to ensure gluconeogenesis. They would have to coexist in the same cell. This must be the case, since nervous tissue is apparently capable of incorporating label from radioactive precursor molecules into glycogen. Of the key enzymes only PC has been allocated with some certainty exclusively to one cell type, the astroglial cells (Shank et al., 1985; Yu et al., 1983; Cesar and Hamprecht, 1993a, 1993b). Therefore, we hypothesize that astroglial cells are the gluconeogenic cell type of the central nervous system. Indeed, sorbitol-selected (Wiesinger et al., 1991) pure astroglial cultures from mouse brain are capable of incorporating label from [^{14}C]lactate (Dringen et al., 1993b) or labeled alanine aspartate or glutamate (Schmoll and Hamprecht, 1993; Schmoll et al., 1993b) into glycogen. By taking advantage of the specificity of the three enzymes amyloglucosidase, hexokinase, and glucose 6-phosphate dehydrogenase it was proven that the label of lactate had indeed entered the glucosyl residues of astroglial glycogen rather than exclusively the protein accompanying the glycogen particles (Dringen et al., 1993b). It is important to point out that a demonstration of the incorporation of label from [^{14}C]lactate into glycogen was only possible in the presence of glucose. The depletion of glycogen in cells kept without glucose has already been described above. Under physiological conditions the concentration of extracellular glucose will always be well above zero, and gluconeogenesis will be taking place in the presence of glucose (Newgard et al., 1983, and literature cited therein).

With the exception of PC the activity of which is depressed by serum in the culture medium of glial cells (Lopes-Cardozo et al., 1989), the literature provides no insight into the regulation of the gluconeogenic enzymes in brain, not even for PEPCK, the hormonal induction of which in liver cells is quite well understood at the genome level (Granner et al., 1991). Recently it has been reported that PEPCK and FBPase activity in astroglial-rich primary cultures, but not in hepatocyte cultures, are inversely regulated by long-term withdrawal of glucose. In contrast to the strong rise of PEPCK activity elicited in hepatocytes by a cyclic AMP analogue and a glucocorticoid, no such response was encountered in astroglial cultures (Schmoll et al., 1993a). Apparently, gluconeogenesis is differently regulated in hepatocytes and astroglial cells.

The function of gluconeogenesis in the nervous system is enigmatic. The situation has to be explained that the same cells can generate lactic acid and use it for the synthesis of glycogen (Figure 32-1). It may well be that a given astrocyte in brain would rapidly switch between production and consumption of lactate, depending on the activities and needs of its neighboring neurons and the probably concomitant requirements of the adjacent oligodendrocytes. In situations of high rates of generation and release of lactic acid in their proximity, astrocytes could dispose of the deleterious acid by using it up in the gluconeogenic process. This would mean simultaneously serving three purposes, buffering and control of osmolarity of the extracellular fluid and recycling of the "waste product" generated by a neighboring cell during its (electrical) activity.

FATTY ACIDS AND KETONE BODIES

The facts that eicosanoids are also produced in brain and that they are derived from essential fatty acids that have to be supplied to the animal with the food already make clear that the brain must be able to take up such fatty acids (see Chapter 25, this volume). This is indeed the case (Dhopeshwarkar and Mead, 1969; Oldendorf, 1973; Kimes et al., 1983; Pardridge and Mietus, 1980; Rowley and Collins, 1985). Uptake is a prerequisite but not a sufficient criterion for the utilization of fatty acids of various sizes for the generation of energy. There is ample evidence that an exogenously applied radioactively labeled medium-chain fatty acid such as octanoic acid is rapidly metabolized in brain (Rowley and Collins, 1985). There, its carbon atoms quickly label the glutamate-glutamine pool, thus proving that oxidative metabolism has taken place (Cremer et al., 1977).

These results also demonstrate the participation of astrocytes in these events, since glutamine synthetase is predominantly expressed in astrocytes (see Chapter 33, this volume). In fact, cultured astroglial cells were shown to metabolize fatty acids (Bourre et al., 1983; Robert et al., 1983; Edmond et al., 1987). Auestad et al. (1991) have subsequently demonstrated that solely this cell type is capable of metabolizing octanoate and of generating ketone bodies, preferentially 3-hydroxybutyrate, from it. This result

again emphasizes the pivotal role of astrocytes as plants for the production of fuel molecules from exogenous raw material.

Which are the cells that can benefit from these astroglial activities and use the ketone bodies as fuel? Studies on the adult brain led to the conclusion that quantitatively seen, fatty acids are of little importance for energy metabolism of the adult mammalian brain (Carey, 1975; Miller et al., 1987). In contrast, the ketone body 3-hydroxybutyrate is rapidly utilized in the brain, although there exist enormous regional differences (Hawkins and Biebuyck, 1979). These authors consider ketone bodies as fuel supplement to glucose in the normally alimented animal. Under starvation, ketone bodies can become the dominant fuel of the brain (Owen et al., 1967). In cultured oligodendroglial cells, the ketone bodies acetoacetate and 3-hydroxybutyrate can be used as a fuel material for oxidative generation of energy (Sykes et al., 1986; Edmond et al., 1987). Cultured oligodendroglial cells strongly prefer ketone bodies to lactate as substrates for energy production (Sykes et al., 1986). If this held also for the adult brain, it would mean that lactate released from astrocytes would preferentially benefit neurons. Candidate users of lactate could also be microglial cells, the metabolic preferences of which are unknown. The notion that in most classes of brain cells energy substrates alternative to glucose can be utilized is supported by the fact that withdrawal of glucose does not affect the ATP level in cultured neurons and astroglial cells (Pauwels et al., 1985).

AMINO ACIDS

The experiment by Geiger (1958) mentioned earlier indicated that amino acids in free form and in proteins must also be considered fuel material for the brain. For example, leucine is taken up and metabolized by the brain (Cremer et al., 1977). It may well be used for the synthesis of ketone bodies.

Astroglial cells oxidize glutamate to CO_2 (Yu et al., 1982). The pathway is not via transamination to 2-ketoglutarate, since a transaminase inhibitor is without effect. This leaves as a possibility only usage of the alternative pathway via glutamate dehydrogenase (Yu et al., 1982). Since in brain this enzyme is localized in astrocytes, such a pathway of glutamate metabolism would have to be confined to them (Kaneko et al., 1987; Hussain et al., 1989; Würdig and Kugler, 1991). A rapid depletion from culture medium, even in the presence of glucose, of the branched-chain amino acids valine, leucine, and isoleucine has been observed in astroglia-rich cultures (Bixel et al., 1993).

The degradation in brain of amino acids (e.g., glutamate) to a member of the Krebs cycle would require also the activity of an enzyme that can permanently withdraw another member of the Krebs cycle. The most likely candidate for such an enzyme would be malic enzyme (Figure 32-4). Purification of the cytosolic isoform of the enzyme allowed the generation of monoclonal antibodies. In astroglia-rich cultures these antibodies stained GFAP-positive astroglial cells and myelin basic protein-positive oligodendroglial cells. The latter were the most intensively stained cells. Neurons in neuron-rich cultures were not stained (Kurz et al., 1993). This result is backed up by results from studies of enzyme activity in cell homogenates and by Western blot analysis of cell homogenates. The mitochondrial isoenzyme appears to be almost absent from the astroglia-rich cultures. In a previous immunocytochemical study of the cerebellum using antibodies of unknown specificity, the cytosolic malic enzyme was found associated with Bergmann glial cells (Martinez-Rodriguez et al., 1989).

These results are certainly compatible with the idea of astroglial cells as processing plants for the generation of fuel molecules. In the case of malic enzyme action the Krebs cycle intermediate malate would be transformed into pyruvate and CO_2, while NADP would be reduced. The pyruvate could be used locally in oxidative generation of ATP. Alternatively, it could be exported, either unchanged or reduced to lactate or alanine. It is known that alanine can be generated in astroglia-rich cultures from lactate (Dringen and Hamprecht, unpublished results) or pyruvate (Hamprecht and Dringen, 1994). The function of malic enzyme in oligodendrocytes would primarily have to be sought in the generation of NADPH that is required for the synthesis of myelin lipids.

Besides the C-3 compounds produced from amino acid-derived Krebs cycle intermediates with the aid of malic enzyme, these intermediates themselves could also be released by the astroglial cells (Sonnewald et al., 1991) for the benefit of neighboring cells, for example, neurons. The report that synaptosomes have a transport system for 2-ketoglutarate supports this view (Shank and Campbell, 1982).

CONCLUSIONS

The analysis of the widespread involvement of glial cells in the energy metabolism of the brain has generated new working hypotheses that should lead to

more detailed experimental approaches than were possible thus far. The concept emerged that astroglial cells are processing plants for the production of fuel material from fatty and amino acids that can be used by their neighboring cells. They may also remove "waste products," such as lactic acid, released from these neighbors during metabolic activity accompanying neuronal activity. In this context it appears most important that the enzymes characteristic of the various metabolic pathways be immunocytochemically localized in all areas of the central nervous system. This would allow the assignment of metabolic tasks with cell types and the examination of the general validity of such a separation of metabolic tasks among cell types, as far as development and regions of the central nervous system are concerned.

In a next step the *in situ* functioning of such pathways during physiological tasks will have to be analyzed by a combination of physiological, biochemical, and pharmacological investigations as they have been applied in a paradigmatic way by the groups of Tsacopoulos (1988) and Korf (1991). The *in vitro* studies allow us to find out the likely pathways used by certain cell types and thus enable us to ask more precise experimental questions to the brain itself than would be possible without the studies of cultured cells.

The plasticity of the metabolic facilities of the brain cells in response to developmental and acute changes of physiological situations needs to be found out. It is important to obtain information on the susceptibility of the alternative pathways for the generation of fuel molecules to the plethora of neurohormones (growth factors, neurotransmitters).

Much is also to be learned from inborn errors of metabolism and, thus, from collaboration with clinicians. We are presently experiencing a renaissance of interest in brain energy metabolism. This may be due to the fact that the dogmas that have been followed (such as glucose being the only fuel material of the brain) have not withstood the accumulating experimental results. This renaissance is certainly also elicited by the molecular information on the proteins involved that has become available through the techniques of modern molecular biology. It will certainly profit also from the enormous spatial resolution that is being brought about by confocal laser scanning microscopy. No single laboratory will have available all the equipment, expertise, and funds required for the multidisciplinary approach to understanding the functioning of the nervous system. Therefore collaboration will more than ever be the slogan of the future.

33 Glia-specific enzyme systems

HEINRICH WIESINGER

Enzymes form the basis of every cellular function, and particular pathways require particular enzyme systems. Accordingly, glia-specific functions may be reflected in glia-specific enzyme systems. However, it should be stated clearly that there are no glia-specific enzymes that do not occur in cells outside the nervous system, however little activity they may exhibit. Therefore, in this chapter the term "glia-specific" will refer to (1) enzymes that are found exclusively in glial cells rather than neurons within the nervous system, (2) enzymes that are highly enriched in glial cells compared with neurons, and (3) enzymes that exist in glia-specific isoforms. All three criteria can also be applied to particular glial populations and even subpopulations determined, for example, by regional heterogeneity.

With the restrictions given above, what are the means of identifying a glia-specific enzyme? Measurement of enzyme activity is only useful in pure cell populations, for example, glioma cell lines, whereas the results derived from brain slices or mixed glial primary cultures (although usually devoid of neurons) are not unequivocal. However, the introduction of pure cultures of a particular glial cell type (e.g., Besnard et al., 1989; Juurlink and Hertz, 1991; Wiesinger et al., 1991) and the improvement of enzyme histochemical methodology (Kugler, 1988, 1991a) will lead to new insights into glial enzymology.

Thus far, the only unequivocal way to assign an enzyme to a particular cell type is the proper use of immunological methods. However, a careful choice of cell markers and a thorough characterization of the antiserum antibody used are mandatory. In particular, monospecificity of the antibody and lack of cross-reactivity with closely related (iso)forms of the respective antigen have to be proven. More recently, *in situ* hybridization techniques have rendered possible the study of the synthesis of particular mRNAs with subcellular resolution. A critical evaluation of the results of enzyme histochemistry, immunocytochemistry and/or *in situ* hybridization may give strong indications of the differential expression of enzyme activity or protein in heterogeneous cell populations.

Particular care has to be taken to prove the absence of an enzyme from a given cell type. A number of enzymes have been assigned to a glial cell population in the first place but then have been demonstrated to exist in other cell types as well (see the following section). Neuronal localization of a few enzymes later shown to be glia-specific probably resulted from the improper use of immunological methods (see the following section). Notwithstanding, a variety of enzymes appear to be exclusively expressed or at least highly enriched in particular glial cells (see the section *Enzymes Specific for One Glial Cell Population*). Yet there are some unresolved controversies regarding enzyme localization (see the section *Points of Controversy*).

ENZYMES PRESENT IN MORE THAN ONE GLIAL CELL TYPE

Within the nervous system, a number of enzymes are found in more than one glial cell type but not in neurons. Glutamine synthetase and carbonic anhydrase were taken as enzymatic markers for astrocytes and oligodendrocytes, respectively, but more recently were shown to exist in other glial cell populations as well. Glycogen phosphorylase, cytosolic malic enzyme, and the enzymes of the sorbitol pathway are indicators of specific metabolic capacities of glial cells that are generally lacking in neurons.

Glutamine Synthetase

Glutamine synthetase (GS) [L-glutamate:ammonia ligase (adenosine diphosphate); EC 6.3.1.2] catalyzes the conversion of glutamate to glutamine in the presence of adenosine triphosphate (ATP) and ammonia and, therefore, is a pivotal enzyme in nitrogen metabolism (see Chapter 63, this volume). In the central nervous system (CNS), the enzyme has the dual function of (1) the disposal of the neurotoxic substances glutamate and ammonia and (2) providing glutamine as a substrate for neuronal glutaminase as well as for further utilization in protein synthesis and oxidative metabolism. GS modulates not only the activity of

glutamatergic neurons but also plays a role in the metabolism of the inhibitory transmitter gamma-aminobutyric acid the transamination of which furnishes, as one of the products, glutamate as well. A compartmentation of GS (glial cells) and glutaminase (neurons) with cycling of the respective substrates between the two cell types has been proposed (for review see Kvamme, 1983). In accordance with the latter hypothesis GS has been detected in glial cells of the CNS only, although the idea of an exclusive localization in astrocytes has to be abandoned. Molecular and catalytic properties of the liver enzyme, which appears to be identical with the enzyme isolated from brain, have been reviewed (Meister, 1985).

For a long time GS was considered as a marker enzyme of astroglial cells. GS has been localized in astrocytes in immunocytochemical electron microscopic studies on ultrathin sections of adult rat brain. No positive staining was observed in neurons, oligodendrocytes, or microglial cells (Norenberg and Martinez-Hernandez, 1979). Human GS immunoreactivity was also found in astrocytic cytoplasm and endfeet with an antiserum that appeared to be monospecific (Yamamoto et al., 1987). Accordingly, in the retina GS is localized exclusively in Müller glia cells (Linser and Moscona, 1979).

These findings had been corroborated by investigations in primary cultures derived from neonatal mouse brain. These cultures are highly enriched in astroglial cells many of which could be stained with antiserum against pig brain GS (Hallermayer et al., 1981). Treatment of the cultures with the glucocorticoid dexamethasone elevated GS specific activity about sixfold and increased strongly the number of cells with positive GS immunoreactivity (Hallermayer et al., 1981). Less pronounced effects of a glucocorticoid were seen when the cultures were grown in the presence of 20% horse serum instead of 10% fetal calf serum (Juurlink et al., 1981), presumably because of the already higher concentration of glucocorticoids in the horse serum. The concentration of astroglial translatable GS-mRNA also increased in the presence of glucocorticoids (Khelil et al., 1990). GS activity in cultured astrocytes has been demonstrated to be regulated by hormones other than glucocorticoids and growth factors (triiodothyronine, insulin, fibroblast growth factor, epidermal growth factor) (for references, see Fressinaud et al., 1991) and by the presence of neurons (Wu et al., 1988; Mearow et al., 1990). Particularly high GS activity was found in highly enriched type-2 astrocyte cultures (Juurlink and Hertz, 1991).

However, recently it became clear that GS is not confined to astroglial cells but can also be found in oligodendrocytes *in vitro* as well as *in vivo*. This was shown for the first time in oligodendrocyte-enriched cultures from 7-day-old rat brain in which GS activity was markedly lowered when the number of galactocerebroside-positive cells was decreased by complement-mediated lysis (Warringa et al., 1988). In addition, cellular coexistence of galactocerebroside and GS was demonstrated by immunocytochemical double-labeling experiments (Warringa et al., 1988). Subsequently, the presence of GS was demonstrated in oligodendroglial cells in heterogeneous mouse glial primary cultures (Wiesinger et al., 1991) and in cultured rat oligodendrocytes (Fressinaud et al., 1991) by immunocytochemistry. Pure oligodendrocytes also exhibited a pronounced regulation of GS by hormones (Fressinaud et al., 1991). Very recently, GS immunoreactivity as well as GS mRNA have been found in cultured ependymal cells (Graff et al., 1993).

Glutamine synthetase immunoreactivity has been reported *in vivo* in perineuronal gray matter oligodendrocytes of the cerebral cortex, cerebellum, brainstem, and spinal cord of the adult cat (D'Amelio et al., 1990). GS-immunoreactive oligodendrocytes exist in the white matter of rat and bovine brain as was confirmed on oligodendrocytes isolated from these species (Tansey et al., 1991). Electron microscopic evidence for the presence of GS in oligodendrocytes of mouse brain was obtained by Miyake and Kitamura (1992).

Glial GS may be involved in pathologic states of the brain. For example, GS appears to be impaired in ferric chloride-induced epileptic foci, which implicates improper regulation of the neuronal environment in seizure regulation (Tiffany-Castiglioni et al., 1989). The finding of increased GS immunoreactivity and enzymatic activity following cerebral ischemia (Petito et al., 1992) underlines the importance of glial cells in normalizing extracellular glutamate concentrations and thereby protecting brain from the neurotoxic effects of this amino acid.

In summary, one can conclude that GS should not be used as an immunological marker for astroglial cells without additional evidence for the nature of the GS-positive cells. Therefore, GS as an indicator of the phenotype of C6 glioma cells (e.g., Kentroti et al., 1991) may also be regarded with caution. However, absence of GS from neurons and presence in more than one population of glial cells underlines the importance of extraneuronal glutamine synthesis from glutamate and validates the proposed function of GS in the glutamate-glutamine-cycle. In addition, the results may indicate that perineuronal oligodendrocytes functionally resemble more astrocytes than myelinating oligodendrocytes (D'Amelio et al., 1990).

Glycogen Phosphorylase

Glycogen phosphorylase (GP) [α-1,4-D-glucan: orthophosphate D-glucosyltransferase; EC 2.4.1.1] catalyzes the formation of glucose-1-phosphate from the storage polysaccharide glycogen. Three homodimeric isozymes predominantly located in liver, muscle, and brain have been described. The brain isoform also occurs in fetal tissues, including liver and muscle (for references, see Reinhart et al., 1990). The brain isoform was purified from bovine brain and shown to have a subunit molecular mass of 97 kD (Reinhart et al., 1990).

Attempts to localize GP in cells of neural tissue with immunocytochemical methods had yielded ambiguous results probably due to the fact that the antibodies produced against the liver or muscle isoform reacted only poorly or not at all with the other isoforms. With the monoclonal antibodies raised against purified bovine brain GP no immunoreactivity could be detected in neurons in rat neuron-rich primary cultures (Reinhart et al., 1990). Examination of rat astroglia-rich primary cultures revealed a colocalization of GP with glial fibrillary acidic protein (GFAP) in many cells. GP immunoreactivity was also seen in GFAP-negative cells, which tentatively were identified as ependymal cells (Reinhart et al., 1990).

The suggestion derived from this study that GP is localized predominantly in glial (astroglial and ependymal) cells was substantiated by investigations with the same antibody in formaldehyde-fixed, paraffin-embedded slices from adult rat brain (Pfeiffer et al., 1990). GP immunoreactivity was found in cells, which, by morphological criteria, were classified as astrocytes, and in the ependymal cells of the ventricles (Pfeiffer et al., 1990). Immunofluorescence double-labeling and immunoenzyme double-staining methods finally demonstrated in these brain sections a strict coexpression of GP and GFAP as well as S-100 protein in cells of the cerebellum and hippocampus (Pfeiffer et al., 1992). In the cerebellum, both GP and GFAP were found in the fibrous astrocytes of the white matter, in astrocytes of the granule layer, and in the radial fibers of the Bergmann glia cells. Similar coincidence was shown for GP and S-100 protein in the same cell types. In the hippocampus, all GFAP-positive astrocytes exhibited a high level of GP immunoreactivity, with GP staining being particularly intense in the fine fibers of protoplasmic astrocytes surrounding neurons. In GFAP-negative ependymal cells, GP was colocalized with S-100 protein.

Immunohistochemical studies in human brain sections with antiserum against human brain-GP also revealed that the enzyme is present in astrocytes (Kato et al., 1989). Weak immunoreactivity was found in some neurons of the cerebral cortex and in the Golgi cells of the cerebellar cortex, whereas Purkinje and granule cells were devoid of GP (Kato et al., 1989). These findings are in large part in accordance with the results of an investigation that used antiserum against the epitope corresponding to the terminal 12 amino acids of the human brain GP on sections of macaque and rat cerebrum and cerebellum (Ignacio et al., 1990). The highest level of immunostaining was found in many of the fibrous astrocytes in white matter, which had processes ending on blood vessels. In addition, immunostaining was found in protoplasmic astrocytes of cerebral gray matter. No immunostaining was seen in Bergmann glia cells (Ignacio et al., 1990).

With the immunochemical methods described above GP was clearly demonstrated to be a glial enzyme located in astrocytes as well as in ependymal cells. The function of GP in these cells still has to be elucidated. Breakdown of glycogen in the ependymal cells may furnish the energy required for continuous beating of the cilia during states of reduced glucose supply, but release of glucose (or an equivalent compound) to the cerebrospinal fluid has also to be considered. The finding of GP being primarily localized in astrocytes points to the crucial role of this cell type in the energy metabolism of the brain (for a thorough discussion, see Chapter 32).

Malic Enzyme

Malic enzyme (ME) [L-malate:$NADP^+$ oxidoreductase (decarboxylating); EC 1.1.1.40] catalyzes the reversible formation of pyruvate, CO_2, and NADPH from malate and $NADP^+$ in the presence of the essential cofactors Mg^{2+} or Mn^{2+}. From rat and bovine brain two forms of the enzyme have been separated, a mitochondrial form and a cytosolic form, which can be distinguished by kinetic or electrophoretic properties. Cytosolic ME (cME) was purified from bovine brain and shown to be a homotetramer with a subunit molecular mass of 60 kD (Kurz et al., 1993). A previous immunocytochemical investigation had reported cME to be present in glial cells as well as in neurons of the cerebellum (Martínez-Rodríguez et al., 1989). However, this study was hampered by the fact that neither monospecificity nor cross-reactivity with cME from brain of the antiserum prepared against cME from chicken liver had been demonstrated. This is of particular importance, since Kurz et al. (1993) showed that rabbit polyclonal antiserum against cME from bovine brain reacted only weakly with cME purified from chicken liver. In contrast, a monoclonal anti-

body against cME from bovine brain was well suited for immunocytochemical investigations (Kurz et al., 1993). In rat glial primary cultures, cME immunoreactivity was found in GFAP-positive cells (astroglial cells), GFAP-negative cells (presumably ependymal cells) as well as in GFAP-negative, myelin basic protein- or galacto cerebroside-positive cells (oligodendroglial cells). The latter cell population exhibited particularly strong immunoreactivity, which may reflect a role of cME in NADPH production required for the lipid synthesis in myelinating cells. cME immunoreactivity was found neither in neurons in rat neuron-rich primary cultures (Kurz et al., 1993) nor in Purkinje cells and other neurons in adult rat brain slices. In these brain sections, however, cME could be detected in astrocytes and oligodendrocytes in the hippocampus and cerebellar white matter, and in Bergmann glia cells of the cerebellar cortex (G. Kurz, H. Wiesinger, and B. Hamprecht, unpublished observations).

In conclusion, cME can be considered a glia-specific enzyme present in astrocytes, oligodendrocytes, and ependymal cells. Since cME may be implicated in functions as diverse as glutamate metabolism or reduction of oxidized glutathione (Kurz et al., 1993), its presence in glial cells is a further example of the restriction of important metabolic processes to these cells within the CNS.

Carbonic Anhydrase

Carbonic anhydrase (CA) [carbonate hydrolyase; EC 4.2.1.1] catalyzes the reversible hydration of CO_2 yielding HCO_3^- and a proton. The CA gene family contains seven genes, each of which encodes an isoenzyme (CA I–CA VII) with distinct kinetic and, as far as determined, immunological properties (Tashian, 1989). To date, only CA II, with a molecular mass of 31 kD, has been detected in CNS parenchyma, whereas membrane-associated CA IV is expressed exclusively in brain capillary endothelial cells (Ghandour et al., 1992).

Increasing amounts of CA II appear in the particulate fraction of brain homogenates during postnatal development, and in the adult rodent as much as 50% of CA II was found to be bound to the plasma membrane, including myelin (Ghandour et al., 1980). Association of CA II with myelin was deduced from these studies, and, accordingly, CA enzyme activity and immunoreactivity were found in oligodendrocytes (Ghandour et al., 1989). *In situ* hybridization analysis detected the transcript for CA II only in cultured mouse oligodendrocytes (Ghandour and Skoff, 1991).

Nevertheless, CA was also detected in astroglial cells. Primary cultures derived from neonatal rat cerebral hemispheres exhibited CA activity, which could not be accounted for solely by the small percentage of oligodendrocytes in this astroglia-rich culture system (Kimelberg et al., 1982). In immunocytochemical experiments, the weak staining for CA observed in the cultured astroglial cells could be increased to an intensity equaling that of the oligodendrocytes after the cells had been treated with dibutyryl cAMP (Kimelberg et al., 1982). In the rodent brain, CA is expressed in some astrocytes of the gray matter, as demonstrated in double-labeling experiments with anti-CA antiserum and antibodies against GS and, more convincingly, GFAP (Cammer and Tansey, 1988). Enhanced expression of CA in astrocytes was also observed as a response to injury (Cammer et al., 1989b). Finally, CA immunoreactivity was found in vimentin-positive precursor cells in the rat forebrain as early as the first postnatal day (Cammer and Zhang, 1992).

In summary, it is clear that CA II is a glia-specific enzyme in the CNS, and it appears to be highly enriched in oligodendrocytes. The enzyme is lacking in neurons, although a CA-related peptide with unknown function has been detected in Purkinje cells (Kato, 1990). Besides its role in ion and pH homeostasis (see Chapter 14, this volume), consistent with a glial localization of CA in areas with a high rate of CO_2 production (Sapirstein, 1983), CA in the glial cells of the CNS may have additional functions. Double immunofluorescence staining showed CA and carbamoylphosphate synthetase II in the same astrocytes of rodent brain, which suggests that CA, together with GS detected in the same cells, could furnish the substrates bicarbonate and glutamine for pyrimidine synthesis (Cammer, 1991; see also the subsection *Multifunctional Protein CAD*). A similar colocalization of CA, acetyl-CoA carboxylase, and fatty acid synthetase may hint at a role of CA in another biosynthetic process (Cammer, 1991). An anaplerotic role of CA had already been suggested on the grounds of an astroglial coexpression of CA and pyruvate carboxylase that uses bicarbonate as substrate (Sapirstein, 1983).

Aldose Reductase and Sorbitol Dehydrogenase

Aldose reductase (AR) [alditol:NADP$^+$ 1-oxidoreductase; EC 1.1.1.21] and sorbitol dehydrogenase (SDH) [L-iditol:NAD$^+$ oxidoreductase; EC 1.1.1.14] constitute the so-called polyol (sorbitol) pathway, the activity of which results in the conversion of a variety of aldoses to the corresponding ketoses through a polyol intermediate. AR purified from hu-

man brain is a monomer with a molecular mass of 38 kD (Wermuth et al., 1982), whereas each subunit of homotetrameric SDH purified from bovine brain has a molecular mass of 39 kD and contains one zinc atom (Wiesinger and Hamprecht, 1989). Although a physiological function of the widely distributed sorbitol pathway is not known, accumulation of pathway substrates under hyperglycemic conditions has been implicated in the etiology of diabetic complications (Cohen, 1987). Since peripheral neuropathy is a major sequelae of long-lasting hyperglycemia, distribution of the sorbitol pathway enzymes in nervous tissue is of particular interest.

Early biochemical studies using Wallerian degeneration experiments on sciatic nerve had suggested that AR is confined to the Schwann cell, whereas SDH is localized in the axon (Gabbay and O'Sullivan, 1968). Later on, studies with antiserum against AR purified from seminal vesicles confirmed that AR is localized in the Schwann cell cytoplasm of rat sciatic and cranial nerves, and that axons are devoid of AR immunoreactivity (Ludvigson and Sorenson, 1980). Expression of AR as a function of differentiated or mature Schwann cells was also demonstrated recently (Wong et al., 1992). So far the restriction of SDH to the axon was not corroborated by immunocytochemical evidence. However, during studies on polyol pathway enzymes in cell cultures derived from rat central nervous system, AR as well as SDH enzyme activities were detected only in glial cells but not in neurons (Wiesinger et al., 1990). Moreover, with antiserum raised against purified bovine brain SDH, immunoreactivity was found in astroglial as well as in oligodendroglial cells of heterogeneous glial cultures derived from mouse brain (H. Wiesinger, unpublished observations). This finding is of interest, since the SDH-positive oligodendrocytes disappear from the culture after replacement of glucose in the growth medium by sorbitol, which is the basis of a convenient method to generate pure astroglia cultures of high cell density (Wiesinger et al., 1991). Although the functional significance of the restriction of AR and SDH to glial cells in the central and at least of AR to the Schwann cells in the peripheral nervous system is far from being clear, these findings demonstrate once more the metabolic versatility of glial cells.

ENZYMES SPECIFIC FOR ONE GLIAL CELL POPULATION

Oligodendrocytes and Schwann Cells

Since the major function of oligodendrocytes in the CNS as well as of Schwann cells in the peripheral nervous system (PNS) is the formation and maintenance of the myelin sheath, myelin-associated enzymes have to be considered as being specific to this class of neural cells. In addition, glycerol-3-phosphate dehydrogenase may be an enzymatic marker for oligodendrocytes.

Myelin-Specific Enzymes. Myelin-associated enzymes together with criteria defining myelin enzymes have been discussed expertly (Lees and Sapirstein, 1983; Vogel and Thompson, 1988; see Section VII, this volume). Therefore, only some recent findings will be presented in the following sections. Exclusively located in myelin, and therefore glia-specific within the nervous system, are only a few enzymes involved in lipid metabolism together with 2′,3′-cyclic nucleotide 3′-phosphodiesterase. Carbonic anhydrase has been localized in astroglial cells as well and is discussed in the preceding section *Carbonic Anhydrase.*

2′,3′-Cyclic nucleotide 3′-phosphodiesterase. 2′,3′-Cyclic nucleotide 3′-phosphodiesterase (CNP) [EC 3.1.4.37] hydrolyzes 2′,3′-cyclic nucleoside monophosphates with the release of 2′-phosphates. The former compounds are found only as intermediates in the reaction catalyzed by ribonuclease and may not represent the physiological substrates. Therefore, also the proper function of CNP remains an enigma. In a number of species, the enzyme is expressed in two isoforms with molecular masses of 46 and 48 kD (data from rat brain), which apparently are identical to the Wolfgram proteins and are the products of separate, alternatively spliced mRNAs (Bernier et al., 1987; Kurihara et al., 1990). A rabbit autoantibody specific for the 46 kD form was detected recently and might prove useful for distinguishing between the two CNP isoforms (Möller et al., 1992).

CNP has been detected in myelin of the CNS and PNS and in oligodendrocytes and Schwann cells that synthesize central and peripheral myelin, respectively. To a far lesser degree, CNP activity can also be found in nonneural tissues (for detailed discussion see Lees and Sapirstein, 1983, and Vogel and Thompson, 1988). CNP activity can be induced by cyclic AMP in cultured oligodendrocytes and C6 glioma cells, and it was shown, at least for the glioma cells, that the rate of synthesis of CNP is increased by cyclic AMP (McMorris et al., 1985). Other glial cell lines express CNP as well (Almazan and McKay, 1992). CNP mRNA was found exclusively in oligodendrocytes in the CNS (Trapp et al., 1988; Vogel et al., 1988). CNP may be a marker for oligodendrocyte differentiation, since it is enriched in a myelin fraction that is a transitional region between the oligodendroglial plasma membrane and mature multilamellar myelin (Trapp et al., 1988; Gil-

lespie et al., 1989). Association of CNP with the cytoskeleton in cultured oligodendrocytes was also reported (Dyer and Benjamins, 1989). Regulation of CNP gene expression in the PNS under normal and pathophysiological conditions was described recently (LeBlanc et al., 1992).

Cholesterol ester hydrolase. Of several enzymes involved in the modification of myelin lipids, a particular isoform of cholesterol ester hydrolase (CEH) [EC 3.1.1.13] appears to be enriched in myelin (Eto and Suzuki, 1973). The enzyme catalyzes the hydrolytic cleavage of cholesterol esters, yielding cholesterol and the free fatty acids. The myelin enzyme can be distinguished from a microsomal isoform by its pH optimum of activity (7.2 vs 6.0 of the microsomal enzyme) (Eto and Suzuki, 1973). Increase in CEH activity coincides with the period of active myelination (Lees and Sapirstein, 1983), and a physiological role for this enzyme in synthesis and maintenance of myelin has been inferred (Ghosh and Grogan, 1990). The role of CEH in experimental allergic encephalomyelitis has been discussed recently (Ghosh and Grogan, 1991).

UDP-galactose:ceramide galactosyltransferase. UDP-galactose:ceramide galactosyltransferase (CGalT) [EC 2.4.1.45] catalyzes the final step in the biosynthesis of galactosyl ceramide (cerebroside) by transferring a galactose moiety from the sugar nucleotide to ceramide. Since cerebroside is a lipid that occurs almost exclusively in myelin, CGalT may be considered a myelin-specific enzyme (Lees and Sapirstein, 1983). With immunocytochemical methods CGalT was localized in the outermost and innermost lamellae of the myelin sheath (Roussel et al., 1987), and expression of CGalT was demonstrated in cultured oligodendrocytes in a development-dependent manner (Nescovic et al., 1988). Levels of CGalT activity were comparable in homogenates from oligodendrocytes and the light myelin fractions (Saito et al., 1992), whereas CGalT activity was enriched 20-fold in purified rat oligodendrocytes as compared with brain homogenates, which led to the proposal that CGalT may be a proper enzyme marker for mature oligodendrocytes (Lubetzki et al., 1991).

Miscellaneous myelin-associated enzymes. Recently, a variety of enzymes have been described that appear to be enriched in oligodendrocytes and to be essential for the proper synthesis and function of myelin.

The RLM_6 form of cytochrome P-450 was localized immunocytochemically in oligodendrocytes of rat brain. A contribution of the enzyme to the energy supply in myelin through the utilization of ketone bodies was discussed (Cammer et al., 1991).

With *in situ* hybridization, the 80 kD isoform of diacylglycerol kinase was found to be expressed in oligodendrocytes of rat brain, and a role in myelin maturation was assigned to this enzyme (Goto et al., 1992).

The Y_p-subunit isoform of dimeric glutathione-*S*-transferase [EC 2.5.1.18] (see also the section *Isoforms of Miscellaneous Enzymes* below) was found exclusively in oligodendrocytes. The enzyme was suggested to remove toxic substances from the vicinity of the myelin sheath (Cammer et al., 1989a).

Plasma membrane-bound carboxypeptidase M [EC 3.4.17.12], which cleaves C-terminal basic amino acids of peptides was found closely associated with myelin and myelin-forming cells in the CNS as well as the PNS (Nagae et al., 1992).

Similarly, in the PNS, endopeptidase-24.11 [EC 3.4.24.11], an enzyme initiating the degradation of several peptide hormones, was found exclusively on Schwann cell membranes (Barnes et al., 1991).

Finally, glycerophosphorylcholine phosphocholine phosphodiesterase [EC 3.1.4.38] was found associated with purified rat brain myelin and in pure cultures of oligodendrocytes, but not in cultured neurons or astrocytes (Yuan et al., 1992).

Glycerol-3-Phosphate Dehydrogenase. L-Glycerol-3-phosphate dehydrogenase (GPDH) [L-glycerol-3-phosphate:NAD^+ oxidoreductase; EC 1.1.1.8] reduces dihydroxyacetone phosphate with the help of NADH to yield α-glycerol phosphate, and thus is part of the cyclic metabolic process which transfers reducing equivalents from the cytosol to the mitochondria. In paraformaldehyde-fixed sections of adult rat brain the enzyme was detected with immunoperoxidase staining procedures in oligodendrocytes exclusively (Leveille et al., 1980). Also in these cells, GPDH can be specifically induced by glucocorticoid hormones (Leveille et al., 1980). These findings may reflect the need of phospholipid synthesis in the myelinating cells, whereas a preference for the glycerol phosphate shuttle over the malate-aspartate shuttle (which yields an additional mole of ATP per mole of NADH) in the oligodendrocytes cannot be explained easily.

Astrocytes

In addition to the enzymes that astrocytes share with other glial cell types (see the section *Enzymes Present in More Than One Glial Cell Type* above), a variety of enzymes has been found in the CNS in astrocytes exclusively. In particular, enzymes catalyzing reactions involved in CO_2 fixation and the biosynthesis of the neurotransmitter glutamate, in the catabolism of neurotransmitters, or in detoxification of xenobiotics appear to be constituents of

astrocytes or are expressed in these cells in specific isoforms.

Pyruvate Carboxylase. Pyruvate carboxylase (PC) [pyruvate:CO_2 ligase (ADP); EC 6.4.1.1] is located in the mitochondrial matrix and catalyzes the formation of oxaloacetate from pyruvate and CO_2, which leads to a net synthesis of tricarboxylic acid cycle intermediates. Studies with antiserum against rat liver PC localized the enzyme in sections of adult mouse cerebellum in astrocytes exclusively (Shank et al., 1985). This finding is in accordance with an earlier report that PC enzymatic activity was present only in primary cultures of astrocytes but was detectable neither in cultured cerebral cortex neurons nor in cerebellar granule cells (Yu et al., 1983). These results implicate that the major CO_2-fixing cells of the brain are indeed the astrocytes being able to replenish constituents of the tricarboxylic acid cycle, which had been removed as precursors for the neurotransmitters glutamate and gamma-aminobutyric acid.

Glutamate Dehydrogenase. In the brain, mitochondrial NADH-dependent glutamate dehydrogenase (GDH) [L-glutamate:NAD^+ oxidoreductase; EC 1.4.1.2] catalyzes the reductive formation of glutamate from α-ketoglutarate and ammonia. Catalytic enzyme histochemistry was used to demonstrate that GDH is enriched in Bergmann glia cells and astrocytes in the rat hippocampus and cerebellar cortex (Kugler, 1991b; Würdig and Kugler, 1991). A similar preferential localization of GDH in astrocytes was suggested on the grounds of immunocytochemical investigations (Aoki et al., 1987; Wenthold et al., 1987). Therefore, α-ketoglutarate provided by the tricarboxylic acid cycle can be directly converted to glutamate within the astrocytes, which, thanks to this reaction, also have an additional means for the detoxification of ammonia.

1-Pyrroline-5-Carboxylate Dehydrogenase. 1-Pyrroline-5-carboxylate dehydrogenase [EC 1.5.1.12] catalyzes the NAD^+-dependent oxidation of 1-pyrroline-5-carboxylate (derived either from ornithine or proline) to glutamate. With histochemical staining methods, the enzyme was detected in Bergmann glia cells in the cerebellum and astrocytes in the hippocampus of the adult rat, but not in neurons (Thompson et al., 1985). Therefore, only glial cells possess this alternative route of glutamate production (Thompson et al., 1985).

Multifunctional Protein CAD. A multifunctional polypeptide named "CAD" exhibits the enzymatic activities for carbamoyl phosphate synthetase II, aspartate transcarbamoylase, and dihydroorotase and thus furnishes, from glutamine, HCO_3^-, and ATP, dihydroorotate, the precursor of pyrimidines. With an antiserum against hamster CAD, the polypeptide was localized exclusively in astrocytes of normal hamster and rat brains and in the gliotic brains of myelin-deficient mutant rats (Cammer and Downing, 1991). In hamster brain, CAD was also found in Bergmann glia cells and tanycytes. Therefore, with the additional help of glutamine synthetase and carbonic anhydrase, which are also localized in astrocytes (see the sections *Glutamine Synthetase* and *Carbonic Anhydrase* above), these cells are able to perform the *de novo* synthesis of pyrimidines, which might be required in proliferating cells, besides the predominant salvage pathway.

Glycine Cleavage System. The glycine cleavage system, also called glycine synthase (GCS) [EC 2.1.2.10] catalyzes the degradation of glycine to yield methylenetetrahydrofolate, CO_2, and ammonia. It is located on the outer mitochondrial matrix, consists of four separate enzymes, and constitutes the major catabolic pathway for glycine in vertebrates (for references, see Sato et al., 1991). With antiserum against the P protein of GCS the multienzyme complex was detected in rat brain only in astrocytes and Bergmann glia cells, and in the retina only in Müller cells (Sato et al., 1991).

Isoforms of Miscellaneous Enzymes. The Y_b subunit of glutathione-*S*-transferase [EC 2.5.1.18] (see also the subsection *Miscellaneous Myelin-Associated Enzymes* above) was primarily found in astrocytes (and ependymal cells) in rat brain and appears to be absent from oligodendrocytes and neurons (Cammer et al., 1989a). In view of the anatomical position of astrocytes in the brain, these cells, therefore, may play a pivotal role in the brain's defense against toxic substances. A preferential astroglial localization of protein kinase C isoform III in human brain was postulated on the grounds of immunohistochemical studies (Todo et al., 1990). Similarly, phospholipase-δ appears to be the isoform that is enriched in astrocytes (Mizuguchi et al., 1991). Finally, astrocytes express predominantly the α_1-subunit of Na^+,K^+-ATPase that has low affinity for ouabain (Atterwill et al., 1984).

Microglial Cells

Only scarce data are available on enzymatic activities associated with microglial cells. Ectoenzymes are enzymes located on the plasma membrane, their active site being oriented toward the external surface

of the cell. Two such enzymes may be characteristic for microglial cells.

Ecto-NAD$^+$ glycohydrolase [EC 3.2.2.6] catalyzes the hydrolysis of pyridine dinucleotides present in the extracellular environment. The enzyme is a marker of phagocytic cells, since it is highly expressed in peritoneal macrophages or Kupffer cells of the liver. Ecto-NAD$^+$ glycohydrolase activity was also found on the surface of cultured brain microglial cells, and its activity increased with time in correlation with the increased phagocytic capacity of the cells during time in culture. Therefore, this enzyme was considered a marker of the functional state of cultured microglial cells (Bocchini et al., 1988).

Another ectoenzyme, 5′-nucleotidase [5′-ribonucleotide phosphohydrolase; EC 3.1.3.5] catalyzes the hydrolysis of 5′-phosphate esters of ribo- and deoxyribonucleotides. Besides bacteria and plants, the enzyme is also widely distributed in vertebrate tissues (Zimmermann, 1992). In the PNS the enzyme is found associated with the cell membrane of Schwann cells (Grondal et al., 1988; Nacimiento et al., 1991) and, in the CNS, on a variety of glial elements like Bergmann glia, astrocyte endfeet, and oligodendrocytes (Schoen et al., 1987). Therefore, 5′-nucleotidase appears not to be specific for a particular glial cell type and may be restricted to the glial cell population as a whole, since it was only occasionally located on neuronal surfaces in adult nervous tissue (e.g., Cunha et al., 1992; for discussion, Nacimiento et al., 1991; Zimmermann, 1992). However, 5′-nucleotidase immunoreactivity was found to be restricted to perineural microglia, at least as far as experiments were performed with the monoclonal antibody 5N4-2 (Schoen et al., 1992). This antibody may distinguish between structural variants of 5′-nucleotidases, and a function of the latter protein as an adhesion molecule on microglial cells participating in regeneration processes after axotomy has been discussed (Schoen et al., 1992).

POINTS OF CONTROVERSY

Controversial literature on cellular location exists on a few enzymes that are expressed in multiple forms or as genetically distinct isozymes. The most prominent examples are discussed. In addition, most recent literature sheds new light on the localization of cysteine sulfinate decarboxylase, the pivotal enzyme of taurine biosynthesis.

Hexokinase

Hexokinase (HK) [ATP:D-hexose 6-phosphotransferase; EC 2.7.1.1], the first enzyme of the glycolytic sequence, is of utmost importance in energy metabolism. Most of what is known about mammalian hexokinases is derived from studies on the brain enzyme, notably those done in the laboratory of J. E. Wilson. Brain HK is of isoform I type, and was cloned and sequenced recently (Schwab and Wilson, 1989). The enzyme is a monomer with a molecular mass of 100 kDa. HK exists as a soluble cytosolic form and a particulate one that is the same enzyme but is bound to the outer mitochondrial membrane with concomitant changes in the kinetic properties (Wilson, 1980). Based on regional differences in the activity of cytosolic HK, Bigl had already suggested a predominantly glial localization of the soluble form of HK (Bigl et al., 1971). Studies in cultured astrocytes derived from neonatal rat brain led to the conclusion that about 80% of the astroglial HK activity is due to the soluble form, and only 20% of astroglial HK is bound to mitochondria (Lusk et al., 1980). In agreement with Wilson's suggestion that predominance of cytosolic HK points to an important role of nonoxidative metabolism in a particular cell type (Wilson, 1980), astroglial energy metabolism may indeed be dominated by glycolysis (Lusk et al., 1980).

However, the studies described above required the disruption of the cells for biochemical analysis, and the data have been questioned recently on the grounds of a study using three-dimensional confocal microscopy, a method that can analyze the subcellular distribution of immunoreactivity (Lynch et al., 1991). About 70% of HK in cultured astrocytes was found to be associated with mitochondria under basal metabolic conditions, and the amount of HK bound to mitochondria varied with the metabolic state of the cells (Lynch et al., 1991).

Creatine Kinase

Creatine kinase (CK) [ATP:creatine phosphotransferase; EC 2.7.3.2] catalyzes the reversible formation of phosphocreatine from creatine and ATP, and thus participates in energy storage and transport within the cell (Wallimann et al., 1992). Besides several cytosolic isoforms, also genetically distinct mitochondrial CKs exist (Wallimann et al., 1992). The brain possesses a particular cytosolic isoenzyme, CK-BB which has been localized by immunohistochemical methods with a specific antiserum in astrocytes in the white matter of human cerebrum (Thompson et al., 1980). Immunocytochemical experiments detected CK-BB also, particularly in Bergmann glia cell bodies of chick cerebellum (Scalabrini et al., 1989), and the phosphocreatine circuit model was applied

to astrocytes (Wallimann et al., 1992). However, CK activity was found in cultured astrocytes and oligodendrocytes as well as neurons (Manos et al., 1991), and CK-mRNA was detected in cultured astrocytes, oligodendrocytes, and neurons, although at a low level in the latter cell type (Molloy et al., 1992). It was concluded that ATP regeneration is an important process in all types of glial cells but may be restricted to a particular set of neurons involved in specialized metabolic functions (Molloy et al., 1992).

Cysteine Sulfinate Decarboxylase

Cysteine sulfinate decarboxylase (CSD) [EC 4.1.1.29] catalyzes the decarboxylation of cysteine sulfinic acid to yield aminoethane sulfinic acid (hypotaurine), the immediate precursor of aminoethane sulfonic acid (taurine). Although this amino acid is abundant in the CNS, its role is far from being elucidated. In accordance with the proposal that taurine might be a neurotransmitter or -modulator, in an early study CSD was localized immunocytochemically in the cerebellum in Purkinje cells and other types of neurons (Chan-Palay et al., 1982). However, the antiserum used may not have possessed the specificity required for unambiguous immunostaining (Almarghini et al., 1991). With monospecific antiserum against purified CSD the enzyme was detected in glial cells, astrocytes as well as oligodendrocytes, in the rat cerebellum. No labeling was found in Purkinje cells or the stellate cells of the molecular layer (Almarghini et al., 1991). This suggests that taurine is indeed synthesized only by glial cells, and the function of taurine in the CNS has to be reconsidered.

34 Second-messenger systems

MARTHA L. SIMMONS AND SEAN MURPHY

As has been discussed in other chapters, glia have numerous cell-surface receptors (see Chapters 21 to 25, this volume). Responses to specific receptor activation in astrocytes are diverse, ranging from gross changes in morphology to glycogen metabolism and the release of neuroactive peptides and prostaglandins (see Murphy, 1993; see also Chapters 24 and 25). In contrast, receptors on microglia are only now beginning to be probed (Kettenmann et al., 1993). This chapter discusses some of the intracellular events that link receptors to the eventual responses of the glial cell. Such signal transduction can occur via receptors that are gated ion channels, receptors linked through G proteins to cyclases or phospholipases, or receptors with intrinsic enzyme activity (tyrosine kinase, guanylyl cyclase). For the sake of clarity, the focus here is on G protein-coupled receptors in astrocytes. Most studies to date have used primary cultures of astrocytes or astrocytoma-derived cell lines. General aspects of second-messenger systems will be presented first, followed by evidence for their expression and functional operation.

G PROTEIN-COUPLED RECEPTORS GENERATE A VARIETY OF SECOND MESSENGERS

Guanine nucleotide-binding proteins (G proteins) link some cell surface receptors with ion channels or enzyme systems (for reviews see Birnbaumer, 1990; Simon et al., 1991). These G proteins are heterotrimers comprising $\alpha\beta\gamma$ subunits, each of which exists as multiple isoforms. Upon interaction with an activated receptor, the subunits disassociate into an α subunit and a $\beta\gamma$ moiety, both of which are capable of activating an effector, although both are not necessarily active in any given receptor system. During this process the α subunit hydrolyzes guanosine triphosphate (GTP) to guanosine diphosphate (GDP), at which point it is again inactive. This system allows for amplification of a receptor signal, since each receptor can interact with more than one G protein, and each G protein can interact with more than one effector. The α subunits appear to be the most variable, with at least 15 isoforms identified. These can be specific for a given system (i.e., α_t, which links rhodopsin to cyclic guanosine monophosphate (GMP) phosphodiesterase in the visual system) or used by more than one receptor, as may be true for some of the α_i proteins. Some of these α subunits (α_s) are susceptible to ADP-ribosylation by cholera toxin, which causes a constitutive activation, while others (α_i) are ADP-ribosylated by pertussis toxin, which uncouples the G protein from associated receptors and hence prevents activation. Such toxins have proved useful tools for investigating the roles for various G proteins in a given system.

Phospholipases

Phospholipase C (PLC) hydrolyzes phospholipids to diacylglycerol (DAG) and the corresponding polar headgroup (see Figure 34-1). Of the inositol-specific PLCs the β, γ, and δ forms have been cloned (for review see Cockcroft and Thomas, 1992). PLCβ and PLCδ are generally linked to cell surface receptors via specific G proteins, while the γ form is regulated by receptor tyrosine kinases such as the platelet-derived growth factor receptor and the epidermal growth factor receptor.

The DAG formed by the hydrolysis of phospholipids activates protein kinase C, which then phosphorylates serine and threonine residues on target proteins. If the PLC acts upon phosphoinositide-4,5-bisphosphate (PIP_2), inositol-1,4,5-trisphosphate (IP_3) is concurrently released. IP_3 activates receptors located on organelles, such as the endoplasmic reticulum, causing the mobilization of calcium from these internal stores and raising intracellular free calcium $[Ca^{2+}]_i$. Both PKC activation and the rise in $[Ca^{2+}]_i$ are capable of modulating other second-messenger systems, as well as influencing more direct responses, such as Ca^{2+}/calmodulin activation of Ca^{2+}/calmodulin-dependent kinase II (CaM kinase II) and constitutive nitric oxide synthase, or phosphorylation of membrane receptors (see Figure 34-2).

In addition to PIP_2, a PLC can hydrolyze phosphatidylinositol (PI) or PIP leading to the production of IP or IP_2, and there is evidence that these reactions are more calcium-dependent than the PLC hydroly-

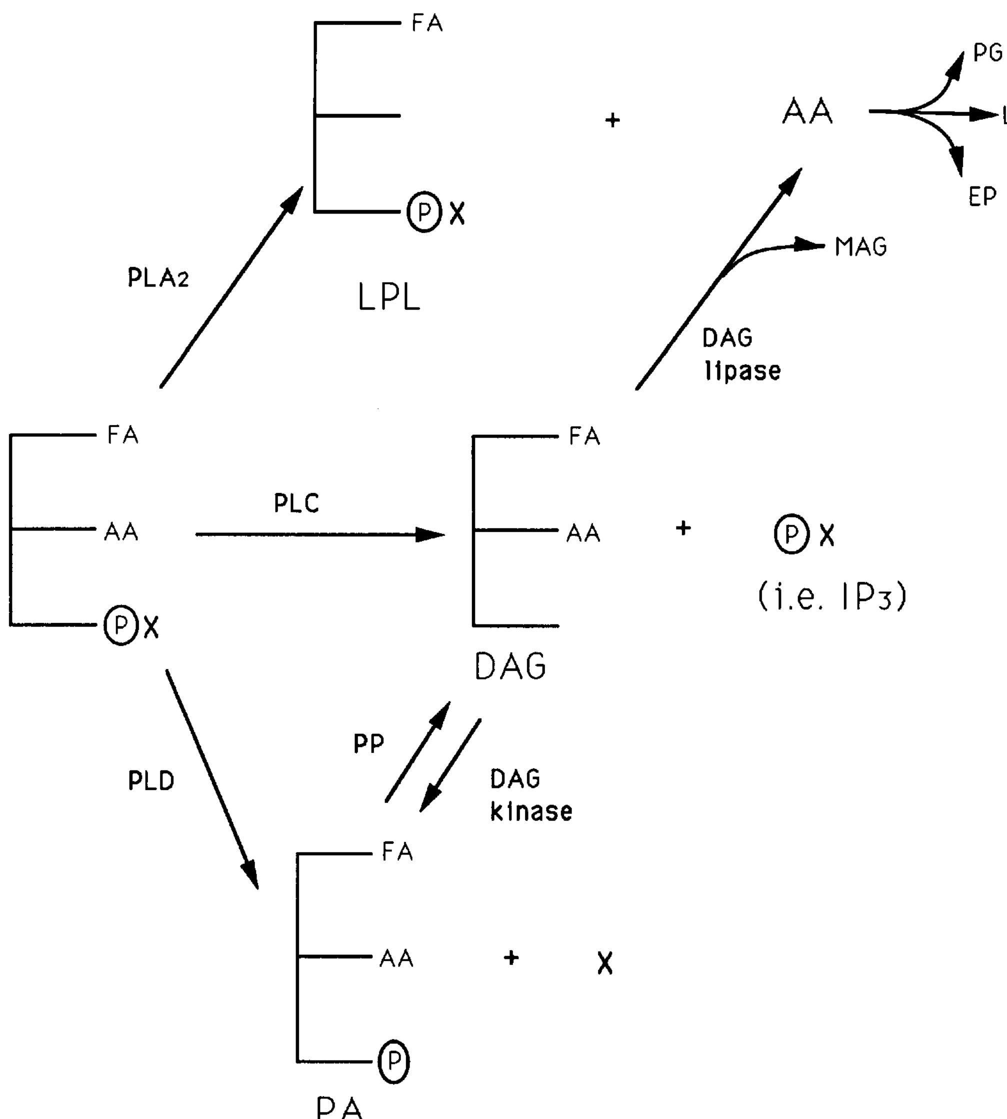

FIG. 34-1. Generation of second messengers by phospholipases. Phospholipase A_2 (*PLA_2*) cleaves arachidonic acid (*AA*) from the phospholipid leaving a lysophospholipid (*LPL*). AA can then be converted to prostaglandins (*PG*), leukotrienes (*LT*), or epoxyeicosatrienoic acids (*EP*). Actions of phospholipase C (*PLC*) results in the production of diacylglycerol (*DAG*) and a phosphorylated polar head group (e.g., inositol trisphosphate, IP_3). Phospholipase D cleaves off the polar head group (*X*) to form phosphatidic acid (*PA*). These products can be interchanged by the actions of phosphatidate phosphatase (*PP*), DAG kinase, and DAG lipase. See text for details.

sis of PIP_2 (Fain, 1990). The resulting inositol phosphates can also be interchanged by the actions of kinases and phosphatases, forming various isomers of IP_3 as well as IP_4 and IP_5. In some cases, this is simply a method of inactivation of the messenger, but there is evidence that IP_4, and possibly IP_5, may play a role in calcium signaling.

Phospholipase D (PLD) hydrolyzes phospholipids to yield phosphatidic acid and the corresponding base (for reviews see Shukla and Halenda, 1991, Thompson et al., 1991) (see Figure 34-1). Although the existence of the enzyme has long been recognized, only recently has it been implicated in signal transduction. Different forms of PLD may be activated by such compounds as carbachol, ATP, synthetic diacylglycerol, calcium ionophores, epidermal growth factor, protein kinase C, and vasopressin, some of these through the action of G proteins. Phosphatidic acid itself may have some second-messenger roles, or it can be further hydrolyzed to diacylglycerol by phosphatidate phosphatase. Protein kinase C activated via this method acts as a positive regulator of PLD, in contrast to the negative feedback on PLC, and may therefore provide a more long-term signal than can PLC (Shukla and Halenda, 1991). Conversely, diacylglycerol formed via PLC

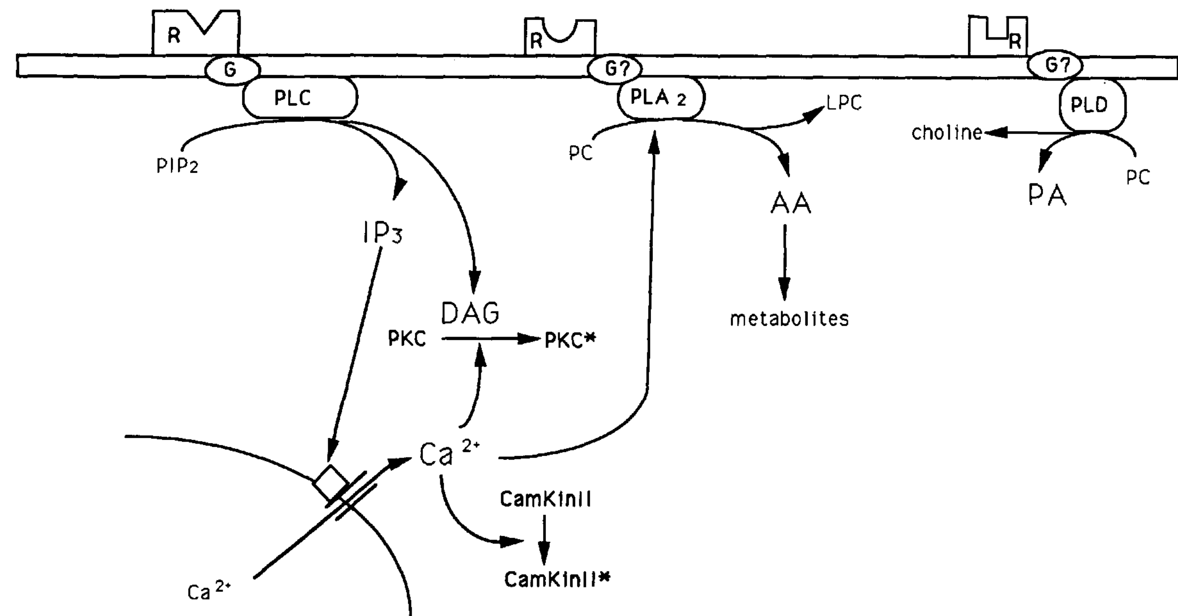

FIG. 34-2. Roles of phospholipases in intracellular signaling. Stimulation of G protein (*G*) coupled receptors (*R*) results in activation of phospholipases, which then generate a variety of second messengers. See text for details. *PKC*, protein kinase C; *PC*, phosphatidylcholine; *PIP_2*, phosphatidylinositol bisphosphate; *CamKinII*, calcium/calmodulin-dependent kinase II; *, activated kinase. For other abbreviations see legend to Figure 34-1.

can be phosphorylated by diacylglycerol kinase to form phosphatidic acid.

Phospholipase A_2 (PLA_2) hydrolyzes phospholipids to lysophospholipids and arachidonic acid (for review see Axelrod, 1990) (see Figure 34-1). The enzyme is calcium-sensitive and is activated by compounds such as angiotensin, α-adrenergic agonists, bradykinin, ATP, and arginine vasopressin—in some cases via the action of a G protein. In the visual system, the βγ subunits of the G protein activates PLA_2, but in other systems pertussis toxin-sensitive α subunits are the activators.

Arachidonic acid can also be produced by further reactions with the products of PLC and PLD. Diglyceride lipase can cleave arachidonic acid from PLC-produced diacylglycerol, while a PLA_2 can cleave arachidonic acid directly from phosphatidic acid. Arachidonic acid can be metabolized by cyclooxygenase to form prostaglandins, by lipoxygenases to form leukotrienes, hydroxyeicosatetraenoic acids (HETEs) and hepoxylins, or by epoxygenases to form epoxyeicosatrienoic acids. Many of these metabolites are neuro- and vasoactive. Arachidonic acid and some metabolites can increase $[Ca^{2+}]_i$ after diffusion to surface receptors on adjacent cells and others can modulate the formation of cyclic GMP or cyclic AMP. Lysophosphatidyl choline may also act as a second messenger, for example, by stimulating cyclic AMP phosphodiesterase, and, when acetylated, becomes platelet-activating factor.

Cyclases

The cyclic AMP cascade is the best-studied signal transduction system (for review see Kebabian, 1992). Cyclic AMP is formed by the enzyme adenylyl cyclase, which is linked to many different cell surface receptors via G proteins ($G\alpha_s$ as positive regulator, $G\alpha_i$ as a negative regulator). Cyclic AMP can then activate cyclic AMP-dependent protein kinase A (PKA), which phosphorylates specific proteins at serine and threonine residues. Cyclic AMP is broken down by cyclic nucleotide phosphodiesterases (CN-PDE).

There is considerable interaction between the phospholipid pathways and the cyclic AMP system. For example, the type I CN-PDE is activated by calcium and calmodulin, which would be available after IP_3-induced mobilization of intracellular calcium stores. Another PDE may be activated by lysophosphatidyl choline. Cyclic AMP signals may also be increased by arachidonic acid (Axelrod, 1990), and protein kinase A can decrease the activity of some forms of phospholipase C.

Cyclic GMP is also a second messenger, but its regulation is quite different from that of cyclic AMP. Cyclic GMP can be produced by activation of receptors with intrinsic guanylyl cyclase (GC) activity, for example, the receptors for atrial natriuretic peptides (for review see Chinkers and Garbers, 1991). These receptors have a single transmembrane region and intrinsic GC activity, often termed particulate GC.

Cyclic GMP can also be formed by a soluble GC (sGC), which is a heme-containing heterodimeric enzyme not associated with the membrane. Its main activators are nitric oxide (NO) and carbon monoxide (CO), which interact with the heme moiety. Nitric oxide can be formed in many cells expressing either a constitutive nitric oxide synthase (NOS) or an inducible NOS, and freely diffuses to adjacent cells where it can activate sGC (for review see Nathan, 1992). Carbon monoxide is produced by the activation of heme oxygenases (for review see Maines, 1993). Cyclic GMP activates protein kinase G (PKG), which, among other actions, phosphorylates a Ca^{2+} pump (Yoshida et al., 1991), permitting a decrease in $[Ca^{2+}]_i$, which mediates the relaxation of vascular smooth muscle in response to endothelium-derived NO (see Figure 34-3).

GENERATION OF SECOND MESSENGERS IN GLIAL CELLS

Phospholipase C

As demonstrated by immunohistochemistry, astrocytes in culture contain high levels of PLCδ and lower levels of PLCβ and γ, relative to oligodendrocytes or neurons (Mizuguchi et al., 1991), and this is consistent with the finding of PLCδ-positive astrocytes *in situ* (Choi et al., 1989). Developmentally, a small population of astrocytes in various regions of newborn rats, including cerebellar radial glia, show weak immunopositivity for PLCβ and -γ, while these forms are limited to white matter and hippocampus in adults. Cerebral astrocytes show PLCδ immunoreactivity beginning in the second postnatal week, which is distributed throughout the brain in the adult (Yamada et al., 1991). Since PLCγ is linked with growth factor receptors, these findings suggest that PLCγ may be involved in the proliferation of radial glia, which are thought to guide neurons in developing cerebellum. However, these cells switch to the PLCδ isoform in the adult, consistent with a role involving astrocyte responses to neurotransmitters via G protein-linked receptors.

A vast number of cell surface receptors have been linked to polyphosphoinositide hydrolysis in astrocytes. These include muscarinic cholinergic and α_1 adrenergic receptors (Pearce et al., 1985), as well as endothelin receptors (Chuang et al., 1991), bradykinin and vasopressin receptors (Cholewinski and

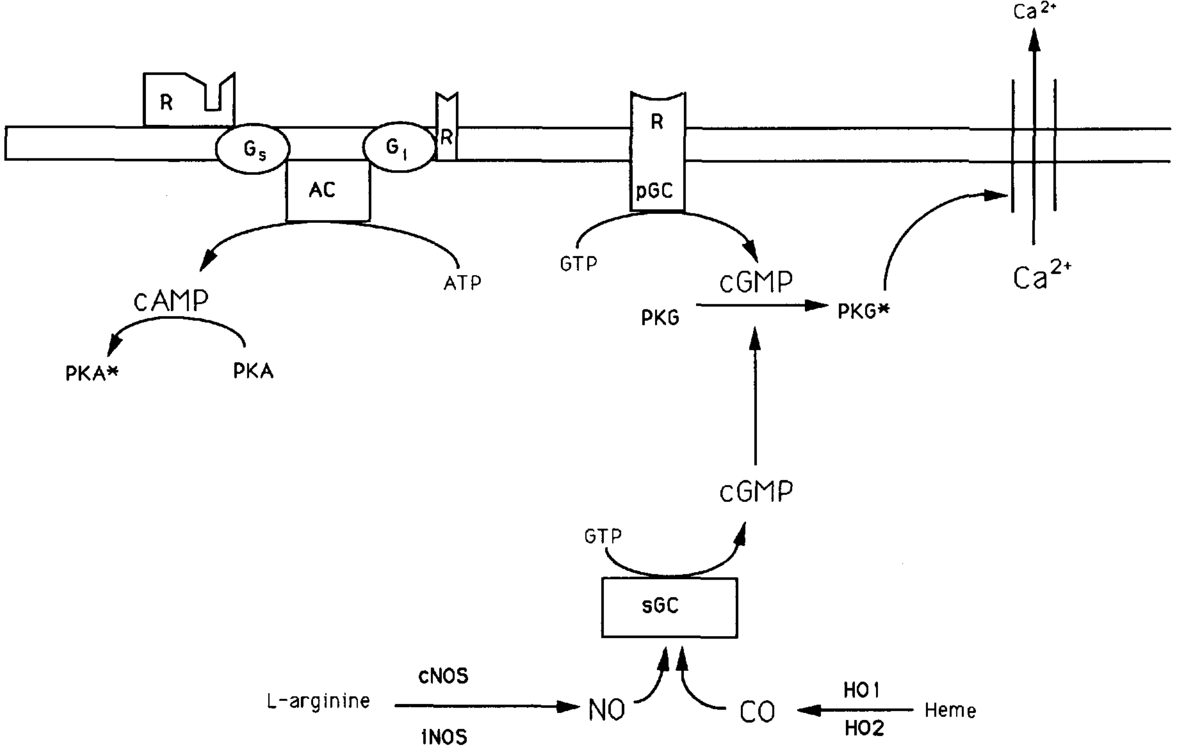

FIG. 34-3. Roles of cyclases in intracellular signaling. Adenylyl cyclase (*AC*) is under positive (G_s) or negative (G_i) control by G protein coupled receptors. The resulting cyclic AMP (*cAMP*) activates cAMP-dependent protein kinase (*PKA*). Particulate guanylyl cyclase (*pGC*) is receptor-associated, while soluble guanylyl cyclase (*sGC*) can be activated by nitric oxide (*NO*) produced by constitutive or inducible nitric oxide synthase (*cNOS, iNOS*) or by carbon monoxide (*CO*) produced by heme oxygenases (*HO*). Cyclic GMP (*cGMP*) produced by GCs activates cGMP-dependent protein kinase (*PKG*), which can influence calcium levels within the cell, possibly by phosphorylating a calcium transporter. See text for details.

Wilkin, 1988), prostaglandin $F_{2\alpha}$ receptors (Kitanaka et al., 1991), NK1 (substance P) receptors (Beaujouan et al., 1990), metabotropic glutamate receptors (Pearce et al., 1990), and P_{2y} purinergic receptors (Pearce et al., 1989). Calcium ionophores and histamine also evoke inositol phospholipid turnover in astrocyte cultures. Their effects are acutely sensitive to the presence of external calcium and may be due more to the hydrolysis of PI and PIP than PIP_2 (Pearce and Murphy, 1988).

As in other cells, there is crosstalk between second-messenger systems in glia. The polyphosphoinositide turnover induced by glutamate in astrocyte cultures can be inhibited by increases in cyclic AMP, which appears to be acting at or distal to a G protein, but not at the PLC itself (Robertson et al., 1990).

Phospholipase D and Phospholipase A_2

There is now evidence for PLD activity in astrocytes, although the endogenous regulation and consequences of its activation are not clear. Phorbol esters, which activate protein kinase C by mimicking diacylglycerol, activate PLD in cultured astrocytes (Bruner and Murphy, 1990b; Gustavsson and Hansson, 1990), as do calcium ionophore and thapsigargin that increase $[Ca^{2+}]_i$. Receptors linked to PLD in astrocytes have yet to be demonstrated conclusively. The calcium-induced PLD activity is inhibited by downregulation of PKC via long-term phorbol ester treatment, suggesting that the rise in $[Ca^{2+}]_i$ produced by these agents activates a PKC, which then activates PLD (Bruner and Murphy, 1990b).

There is also evidence for astrocyte PLA_2 activity, isoforms of which are under very diverse control. Activation of a P_{2y} purinergic receptor in primary astrocyte cultures leads to production of arachidonic acid and thromboxane (Bruner and Murphy, 1990a; Bruner and Murphy, 1993; Pearce et al., 1989). Initially, this was presumed to be via a pathway of calcium-activated PLA_2. The rise in $[Ca^{2+}]_i$ could be due either to PLC via IP_3-induced calcium mobilization from internal stores or through calcium influx induced by ATP (Neary et al., 1988b). However, Bruner and Murphy (1993) found that pertussis toxin, which at low concentrations completely inhibits ATP-stimulated thromboxane formation, only affects IP turnover at much higher concentrations, suggesting that the prostanoid production is not dependent on PLC activation but instead results from a direct linkage of the P_{2y} receptor with PLA_2. These results explain why only ATP and ADP evoke thromboxane release from astrocytes, although many other agonists also activate PLC. Additional evidence for the separation of ATP-induced PI turnover and AA production comes from the observation that serotonin inhibits ATP-stimulated AA production but actually increases ATP-evoked IP turnover (Murphy and Welk, 1990).

Despite a direct receptor linkage of PLA_2, the enzyme is still dependent on the presence of calcium. The interaction with a G protein simply seems to lessen the degree of calcium dependence when compared with ionophore-induced activation (Bruner and Murphy, 1993). Since phorbol esters also induce calcium-dependent prostaglandin production from astrocytes (Jeremy et al., 1987), PLA_2 appears also to be regulated by protein kinase C.

Expression of a secreted form of PLA_2 can be stimulated by inflammatory factors such as endotoxin (lipopolysaccharide), interleukin (IL-1), and tumor necrosis factor (TNF-α) in astrocyte cultures (Oka and Arita, 1991). These agents use different pathways of activation, since lipopolysaccharide induction is sensitive to dexamethasone and inhibition of protein kinase C, while the TNF-induced production is enhanced by increases in cyclic AMP. Additionally, in C_6 glioma cells that have astrocytic properties, there is evidence for a $GABA_A$ receptor linked to PLA_2. Activation of this PLA_2 can be enhanced by benzodiazepines but is not associated with a picrotoxin-sensitive chloride channel (Majewska and Chuang, 1985).

Adenylyl Cyclase

Adenylyl cyclase (AC) is under both positive and negative regulation in astrocytes. For example, isoprenaline or norepinephrine stimulates cyclic AMP production via interaction with β-adrenergic receptors, the classical AC linked receptor (Marin et al., 1990; Ruck et al., 1991). However, if these two agonists are used together, the α_2 activation by the nonspecific actions of norepinephrine actually attenuates the AC activation by the specific β-agonist isoprenaline (Ruck et al., 1991). Additionally, in cultures of mixed type I and type II rat astrocytes, high levels of isoprenaline resulted in a decrease in cyclic AMP production due to activation of α_1 receptors, but this effect was not seen in pure type I cultures (Ruck et al., 1991). By contrast, in mouse striatal astrocyte cultures, when α_2 and dopamine responses were blocked, α_1 activation by norepinephrine potentiated the β-induced cyclic AMP response, as did activation of α receptors with methoxamine. Such potentiation of the β response was dependent on external calcium (Marin et al., 1990). These obser-

vations again demonstrate the crosstalk between different second-messenger systems and illustrate how the second-messenger response induced by a particular agonist can be modulated by different signals received by the astrocyte concurrently.

Adenosine receptors also control AC in astrocytes. Cyclic AMP levels in primary astrocyte cultures are increased with adenosine analogues with a rank order of potency, suggesting activation of an A_2 receptor. Adenosine analogues can inhibit cyclic AMP production by isoproterenol with a rank order of potency, suggesting activation of an A_1 receptor (Murphy et al., 1991). Histamine also appears to activate AC via H_2 receptors in type I but not type II astrocytes in culture (Kubo et al., 1991).

Finally, astrocyte AC can be influenced by prostaglandins and opioids. Prostaglandin E_1 causes an increase in cyclic AMP in astrocyte cultures from embryonic rat striatum, cortex or brainstem. In each case cyclic AMP accumulation could be slightly attenuated by a δ opioid receptor agonist but not a μ receptor agonist, with the least effect in brainstem cultures (Eriksson et al., 1991). The AC/cyclic AMP appears to be under a multitude of controls, hence the response of an astrocyte to a particular AC stimulatory agonist will depend not only on what type of astrocyte it is, the anatomic location, and developmental stage, but also what other signals are being received by the cell concurrently.

Guanylyl Cyclases

As demonstrated by cytochemistry, astrocytes contain both guanylyl cyclase (GC) and cyclic nucleotide phosphodiesterase (Poeggel et al., 1991). The GC activity results from the presence of both particulate and soluble forms of the enzyme. Receptors for atrial natriuretic peptide, which contain intrinsic GC activity, cause cyclic GMP increases in cultures of astrocytes from neonatal rat hypothalamus and brainstem. The effectiveness of various peptides indicates that these receptors are primarily of the "A" type, which are most responsive to atrial and brain natriuretic peptides and less responsive to atriopeptin II (Sumners and Tang, 1992).

Astrocyte cultures respond to the nitric oxide donor sodium nitroprusside and to NO production from cerebellar granule cells with an increase in cyclic GMP (Kiedrowski et al., 1992). Both effects are presumably due to an activation of the soluble GC. Besides activation by exogenous NO, the soluble GC in astrocytes can also be activated by NO produced by the cells themselves (for review see Murphy et al., 1993). Agullo and Garcia (1992) have demonstrated that α_1 adrenergic, dopaminergic, bradykinin, vasoactive intestinal peptide, adenosine, and metabotropic glutamatergic receptors mediate cyclic GMP production in astrocytes, which is sensitive to inhibition by *N*-substituted analogues of L-arginine, indicating the production of NO by a calcium-dependent constitutive nitric oxide synthase. Additionally, long-term treatment with lipopolysaccharide and cytokines can induce a distinct nitric oxide synthase in astrocyte cultures and C_6 glioma cells (Galea et al., 1992), and in microglia (Banati et al., 1993). This calcium-independent nitric oxide synthase is also capable of increasing cyclic GMP levels in the cells in an arginine-dependent manner (Simmons and Murphy, 1992, 1993) via action on the soluble GC. Therefore, cyclic GMP levels in astrocytes can be modulated on a short-term basis via activation of atrial natriuretic peptide receptors, or soluble GC via NO from adjacent cells and astrocytes themselves. On a more long-term basis, induction of nitric oxide synthase by inflammatory mediators subsequently activates soluble GC.

TARGETS FOR SECOND MESSENGERS IN GLIAL CELLS

Evidence for a Nonneuronal Inositol Trisphosphate Receptor

Considerable evidence suggests that activation of receptors on astrocytes linked to PLC generates IP_3 and promotes mobilization of intracellular calcium (Finkbeiner, 1993; see Chapter 17, this volume). Thus, an IP_3 receptor must be present in these cells, and an autoradiographic study (Hösli and Hösli, 1991) has revealed binding of (^{3}H)IP_3 to astrocytes as well as to neurons. However, distribution of this homotetrameric receptor (subunit molecular weight of 260 kD) was described initially by autoradiography as being neuronal (Worley et al., 1989). The IP_3 receptor is one of the largest proteins to have been sequenced and is suggested to comprise eight transmembrane domains at the C terminus (for reviews see Berridge, 1993; Ferris and Snyder, 1992). However, through the use of the polymerase chain reaction, it is now recognized that there are distinct transcripts for the IP_3 receptor, probably derived by alternative splicing (Danoff et al., 1991; Meldolesi, 1992). A shorter nonneuronal form lacks a 120-nucleotide insert between the two protein kinase A phosphorylation consensus sequences. This form predominates in fetal brain and peripheral tissues, and is present in C6 glioma cells.

The IP_3 receptors share considerable homology in some of the transmembrane domains with the much

larger ryanodine receptors that mediate calcium-induced calcium release in neurons and in cardiac/skeletal muscle (Taylor and Marshall, 1992). While dantrolene, which blocks calcium-induced calcium release, inhibits calcium waves in glial cells (Charles et al., 1993), cytochemical evidence for ryanodine receptors is still wanting.

Protein Kinases Are Expressed in Glial Cells

Clearly, activation of phospholipase C in astrocytes liberates diacylglycerol. The observation that phorbol esters influence a range of astrocyte properties which include enzyme activity (Jeremy et al., 1987; Pearce and Murphy, 1988; Bruner and Murphy, 1990b; Gustavsson and Hansson, 1990), gap junction formation (Enkvist and McCarthy, 1992), expression of early response genes (Chapter 35, this volume), and volume regulation (Bender et al., 1992) implies the presence of protein kinase C (PKC), and the enzyme has been demonstrated both biochemically (Neary et al., 1988a) and by autoradiography (Hosli and Hosli, 1991). Ten subspecies of PKC have been described (Azzi et al., 1992; Hug and Sarre, 1993). Types I (γ), II (β), and III (α) are found in brain (Todo et al., 1990; Tanaka and Saito, 1992), and type III is almost exclusively localized in astrocytes and oligodendrocytes (Hidaka et al., 1988; Komoly et al., 1991) as revealed by immunocytochemistry.

The type II regulatory subunit of PKA is prominent in astrocytes (Loffler et al., 1985). Evidence for PKA function in these cells includes the effects of cyclic AMP on phosphorylation of glial fibrillary acidic protein (GFAP) and vimentin (McCarthy et al., 1985; Mobley and Combs, 1992), in the regulation of glycogen turnover (Cambray-Deakin et al., 1988) and membrane receptors (Robertson et al., 1990), and recently in the suppression of nitric oxide synthase induction (Feinstein et al., 1993).

Calmodulin-dependent kinase activity and calmodulin kinase II-like immunoreactivity have been described in astrocytes (Bronstein et al., 1988; Scholtz et al., 1988; Babcock-Atkinson et al., 1989). In neurons, calmodulin kinase phosphorylates proteins involved in neurotransmitter synthesis and release. In astrocytes, potential protein substrates include cyclic nucleotide phosphodiesterase, GFAP and vimentin, glycogen synthase, the IP_3 receptor, and PLA_2 (Schulman and Hanson, 1993). Recent evidence suggests involvement of this enzyme in the regulation of astrocytic volume that follows cell swelling (Bender et al., 1992).

Although cyclic GMP is known to have a variety of effects in cells of the nervous system, including modulation of ion channels and transmitter release (Garthwaite, 1991), the role of PKG in astrocytes has been little studied as compared with cardiac muscle or platelets (Butt et al., 1993). Clearly, with the observations that cyclic GMP levels in astrocytes are regulated both by peptides (Sumners and Tang, 1992) and by NO (Agullo and Garcia, 1992; Simmons and Murphy, 1992, 1993), this is an area that demands attention.

Second Messengers Can Reach Distant Targets

The actions of some second messengers may extend beyond the cell in which they are generated. This results from the fact that astrocytes may be coupled via gap junctions to each other or to neighboring cells, such as oligodendrocytes (see Chapter 19), and the best example is that of calcium moving through a syncytium of astrocytes (see Chapter 17). In addition, the chemical nature of a number of second messengers endows them with the ability to leave the cell of origin and enter neighboring cells. One obvious candidate is arachidonic acid, which is liberated by the activation of phospholipase A_2 and leaves astrocytes (and indeed all cells) in large amounts unmetabolized. Not only can this arachidonic acid serve as a substrate for metabolism through the various eicosanoid synthesis pathways in near-neighbor cells (neurons and cells of the vasculature), but it has been shown to directly modulate phospholipase C activity (Murphy and Welk, 1989).

Other diffusible messengers of particular note are NO and CO. The evidence for production of NO either by acute activation of a constitutive nitric oxide synthase or transcriptional induction of nitric oxide synthase in astrocytes has already been presented. The diffusibility of NO makes it likely that this messenger signals events to neighboring cells. Acute release of NO from perisynaptic astrocytes could result in modulation of synaptic transmission. Tonic release from astrocytes in which nitric oxide synthase has been induced could have profound and long-lasting effects on adjacent vasculature, modulating tone and permeability. Recently, the presence of a heat-shock-induced heme oxygenase (HO 1) in astrocytes has been reported (Ewing and Maines, 1991). Whether a constitutive form of the enzyme (HO 2) found in neurons is also present in glial cells remains an open question. Production of CO by HO, and of NO by NOS, could then activate soluble guanylyl cyclase locally in the cell of origin or in adjacent cells. In addition, via interactions with the array of heme-containing proteins found in cells, CO and NO can potentially modulate a variety of functions.

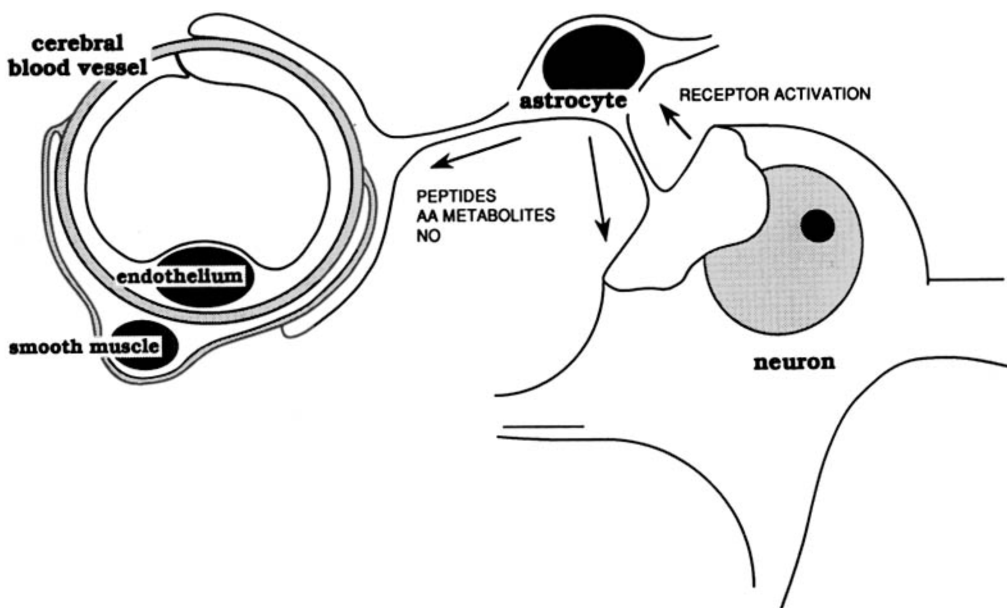

FIG. 34-4. Potential interactions between astrocytes, neurons, and the cerebral microvasculature. Signal molecules released from neurons activate specific receptors on adjacent astrocytes. Depending on the brain region and the receptor-activated second-messenger system, astrocytes release peptides (growth factors, endothelins, enkephalins, somatostatin), arachidonate (*AA*) metabolites (prostanoids, leukotrienes) or nitric oxide (*NO*). These signal molecules, in turn, can modulate functions of cells of the vessel wall (flow, permeability). In addition, the release of such agents from astrocytes can modulate neuronal metabolism and synaptic transmission.

SUMMARY

In the last few years the evidence for receptor-activated changes in glial cell metabolism has become incontrovertible. From the initial descriptions of binding sites for neurotransmitters on glial cells in culture we can now trace the signaling mechanisms by which particular agonists modulate specific glial cell functions. Through *in situ* autoradiography and now hybridization techniques we can also be assured that the expression of a particular receptor-effector pathway is not an artifact of the culture dish. The view of glial cells that emerges is that they have the capacity to function in a complex interaction with neurons and neighboring vessels (see Figure 34-4). The extent to which these proposed interactions occur *in vivo,* the degree to which classes of glial cells (e.g., astrocytes) are functionally heterogeneous, and the environmental signals that create and maintain this diversity—all this has yet to be revealed.

Work in the authors' laboratory is supported by grants from the National Institute of Neurological Disorders and Stroke (NIH). M.L.S. is supported by the Life and Health Insurance Medical Research Fund.

35 Early-response gene expression in glial cells

ALARIC ARENANDER AND JEAN DE VELLIS

For many years a gap existed in our understanding of the molecular mechanisms that mediated the transfer of short-duration extracellular signals into long-lasting phenotypic responses of glial cells. Most of these cellular responses were known in terms of events that appeared several hours after a cell was activated by a specific ligand. For example, one of the best studied genomic responses was the induction of the glycerol phosphate dehydrogenase (GPDH) gene and the subsequent increase in cytoplasmic enzyme activity (Kumar and de Vellis, 1988). GPDH induction occurs after treatment of oligodendrocytes or C6 glioma cells with glucocorticoids and/or activators of protein kinase A (PKA). Although both of these signaling pathways are activated within a short time, on the order of minutes, the increase in GPDH message and protein is seen only after several hours. A hint of the processes that occurred in this 1- to 2-hour gap came from experiments showing that ligand-mediated GPDH transcription was prevented by cycloheximide, an inhibitor of protein synthesis. Thus, the activation of GPDH required an early event coupled to the signaling pathway cascade that involved the synthesis of new protein. A number of other genes expressed in glial cells, such as transferrin, transin, myelin basic protein (MBP), and proteolipid protein (PLP), also share this property.

At about the same time, a set of genes was discovered that displayed very rapid expression kinetics. These are called early-response genes (ERGs) to distinguish them from the late-response genes (LRGs) such as GPDH. These genes are also called immediate early genes in analogy to viral expression patterns or primary response genes, since they precede the induction of secondary response genes (for review see Arenander and de Vellis, 1993; Arenander and Herschman, 1993). At the end of this first decade of study, these genes are regarded as key intermediaries in nearly every signaling cascade process and represent the molecular mechanism that bridges the gap. Their rapid and coordinated expression is required for the expression of many genes that code for phenotypic proteins and thus are considered necessary components in the expression of GPDH and a number of other glial-specific proteins in the nervous system. Their role in cellular responses is so widespread and complex that they are often referred to as the "third-messenger" system of signal transduction. In this chapter, we will review the research on ERG expression in glial cells during development and in the adult nervous system. The current focus of ERG research is how to integrate all the numerous ERG proteins into a coherent picture of the complex signaling process that leads to cell type-specific phenotypic response.

CLASSES OF EARLY-RESPONSE GENES

When a cell is exposed to an environmental agent, specific receptor-coupled signaling pathways are activated, which very quickly lead to altered processes in the cell nucleus. As a result, these pathways mediate the rapid onset of gene transcription. ERG mRNAs are then translated into proteins that are targeted to specific cellular locations and functions (see Figure 35-1). Four main types of ERG products are illustrated. Most of the ERG proteins discovered to date are transported to the nucleus and function as transcription factors. This chapter deals primarily with this class of genes that are part of the early response of the cell. As seen in Figure 35-1, the ERG proteins functioning as transcription factors coordinate the next or "late" round of genomic expression that contributes to a long-lasting phenotypic response. Of considerable interest are the types of ERG proteins that serve metabolic or structural roles in the cell or are integrated into the cell plasma membrane and serve as receptors for extracellular ligands that play important roles in glial development. A final type of ERG protein is secreted as a signal molecule to influence the behavior of neighboring cells. The different classes of protein encoded by ERGs are also listed in Table 35-1, based on message kinetics along with some examples.

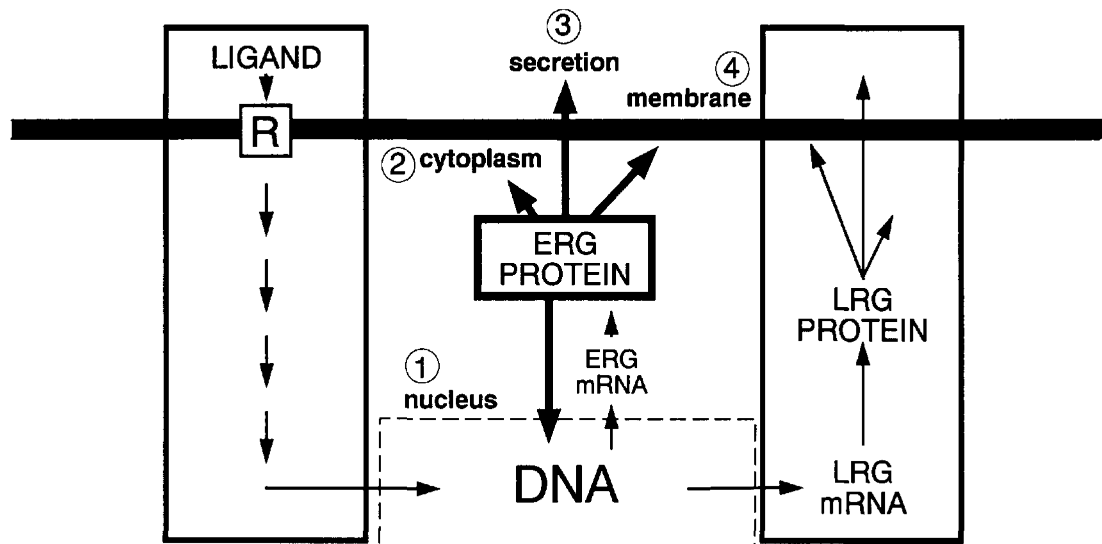

FIG. 35-1. Early-response genes (ERGs). These genes represent a new type of genomic program, acting as crucial intermediaries or "third-messenger" molecules, linking short-lasting extracellular signals to long-term gene expression and phenotypic change. The rapid expression of these genes lead to the appearance of proteins in many compartments of the cell. Shown here are the four main types of ERG products. Most of the ERGs discovered to date encode for proteins that return to the nucleus and function as transcription factors, regulating the kinetics of their own transcription and of the late-response genes (*LRGs*).

It is evident that the ERGs encoding for transcription factors demonstrate the most rapid and transient kinetics of both the message and protein and are termed class I ERGs. Two subtypes of ERGs can be delineated in this class of nuclear regulatory proteins: Class IA mRNA ERGs have very rapid expression kinetics with a very short half-life, while the expression of class IB mRNA is delayed somewhat, with a slightly longer half-life. The characteristic rapid induction kinetics and equally rapid kinetics of degradation of class I ERGs, yield very narrow windows of message accumulation and thus relatively short periods of protein accumulation, resulting in a temporally constrained period of transcriptional control of LRGs following an extracellular signal. These short, well-defined periods allow the cell to express a very powerful, but temporally limited, mode of communication to provide precise and specific control over its genetic programs. These ERG kinetics, therefore enable the cell to quickly "reset" its information gathering and processing programs and allows its genetic programs to remain sensitive to rapidly changing events in the environment. It also provides an extremely complex and efficient means of integrating the demands of the environment with the needs of numerous cellular

processes. Additional characteristics of ERG transcription factors are discussed below.

In contrast, the remaining classes of ERG proteins, encoding for cellular or membrane proteins, display generally slower kinetics, most likely appropriate for each of their functional roles in the cell specific response. The expression of the cytokine IL-6 has been extensively studied in glial and in immune cell types. The rapid kinetics of message induction, independent of protein synthesis, mark IL-6 as a class II ERG encoding secreted protein. Class III ERGs encoding membrane receptors include the expanding family of neurotrophin receptor proteins. Considerable work has been conducted in primary and clonal glial cells (Kumar et al., 1990, 1993) showing the ligand-dependent induction characteristics of the low-affinity (p75 NGFR) and the associated *trk* family of receptors (p140 *trk*A, B, C, see also Chapter 29). To date, only *trk*B and *trk*C have been found expressed in glial cells. Of the class IV ERGs, a ligand-inducible form of Prostaglandin synthetase II (PGS) (originally named TIS10) has been cloned and its expression studied in glial and other cell types (Arenander et al., 1989). Nitric oxide synthetase (NOS) also has an inducible form, and its kinetics and regulation are actively being examined (Bruner et al., 1993). Vimentin and actin are found in glia.

ENCODING TRANSCRIPTION FACTORS IN GLIAL CELLS

Many ERGs encode for transcription factors. Transcription factors, in general, can be classified based on the motifs of their protein domains that permit sequence-specific DNA binding and/or dimerization. Table 35-2 lists the main classes of transcription factors and some examples of each class. The number of classes, that is, unique motifs, is expected to increase over the next few years of research, as well as the membership of each family. At present, about 50 proteins have been examined for their genomic sequence, dimerization characteristics, DNA binding specificity, and transactivating potential (for review see He and Rosenfeld, 1991). Members of each of these classes, with a few exceptions, have been described in the nervous system, particularly in glial cells.

Three sets of research findings have influenced our efforts over the last few years (Arenander and de Vellis, 1993). *First,* it became apparent that many ERGs are induced when cultured glia are exposed to a ligand (Arenander and de Vellis, 1993). These results were consistent with the evidence rapidly accumulating for nonneural cell types that ERGs function in a combinatorial fashion to carry out their task as a third-messenger system. Although some cases of cell type-restricted expression have been reported (Herschman, 1991), these findings are an exception, rather than the rule, and the encoding of environmental information was not detected in differential patterns of restricted expression. Thus, nearly every member of every family is induced following ligand stimulation *in vitro*. Specificity of the encoded information therefore lay in the realm of differential ERG expression kinetics of message and protein and of posttranslational protein modification.

Second, the data from our laboratory and from a few published reports suggested that the expression pattern *in vivo* was highly restricted, in marked contrast to the cultured cells used in most research. This suggests ERG expression can be developmentally restricted and thus unique patterns of ERG expression may exert important influences on lineage decisions during glial development.

Third, an important issue that encourages multiple probing is the well-known variable dimerization characteristic of transcription factors. Research has demonstrated that a major mode of regulation of ERG transcription factor availability and promoter transactivation potential lies in heterodimer formation. Alternative binding partners can decide whether a factor is active and the degree of its transcriptional activation. The phenomenon becomes even more complex when one considers dimer formation not only within families but between families. Best known are the interactions among the *fos* and *jun* families. More recently, the HLH proteins have been shown to exhibit considerable heterodimerization with dramatic results (see below). For these reasons, we have expanded our ERG investigation to include members of five families of ERGs shown in Table 35-2.

LIGAND-MEDIATED TRANSCRIPTIONAL ACTIVATION OF EARLY-RESPONSE GENES

Research has examined how ERG proteins bind to specific regions of many late-response gene promoters, inducing the transcription of these genes. The mechanism responsible for the transcriptional activation of the ERGs themselves, however, until recently has remained unclear. *First,* many ERG genomic clones have been sequenced, indicating the nature of their promoter elements and configuration, indirectly suggesting specific modes of control. *Second,* some research has begun to examine the signaling cascade directly controlling the specific regulatory factors responsible for ERG promoter activation. The reason that ERGs, especially class I ERGs, display such rapid-onset kinetics is because preexisting, inactive ERG proteins located in the nucleus are quickly activated and turn on ERG transcription without much delay. Thus, ERG proteins are used to "kick-start" their own transcription activation.

The best understood example of control via post-translational modification of preexisting, inactive ERG proteins located in the nucleus is depicted in Figure 35-2. Under quiescent, basal conditions, the low levels of nuclear c-Jun possess a phosphorylation pattern that inhibits DNA-binding ability and hence prevents transcriptional activation. Exposure of the cell to ligand activates various intracellular signaling pathways leading to altered activity of various nuclear protein kinases and phosphatases. Activation of protein kinase C (PKC) by the phorbol ester (TPA) leads to activation of phosphatases that rapidly dephosphorylate two inhibitory C-terminal sites near the DNA-binding domain of c-Jun. This change in phosphorylated state permits efficient binding of c-Jun dimers to the TPA-responsive element within the promoter of c-Jun and other ERGs. c-Jun binds as a homodimer, since the initial lack of significant amount of c-*fos* disallows heterodimer formation.

Thus, the equilibrium between various nuclear kinases and phosphatases appears to be a major locus of control over the transactivating ability of c-Jun and, most likely, other ERG-encoded transcription factors. Thus, the ligand-induced shift in nuclear dominance from the constitutively expressed casein kinase II (CKII) to phosphatase and other kinases, alters the phosphorylated state of c-Jun and leads to strong induction of c-Jun responsive genes such as c-Jun itself, c-*fos,* and other ERGs.

The transient nature of transcriptional activation, characteristic of ERG expression, is due, in part to feedback control. For example, Fos is known to negatively regulate its own expression. Since c-Jun is a positive autoregulator (positive feedback), inhibitory control over c-Jun expression may depend upon an-

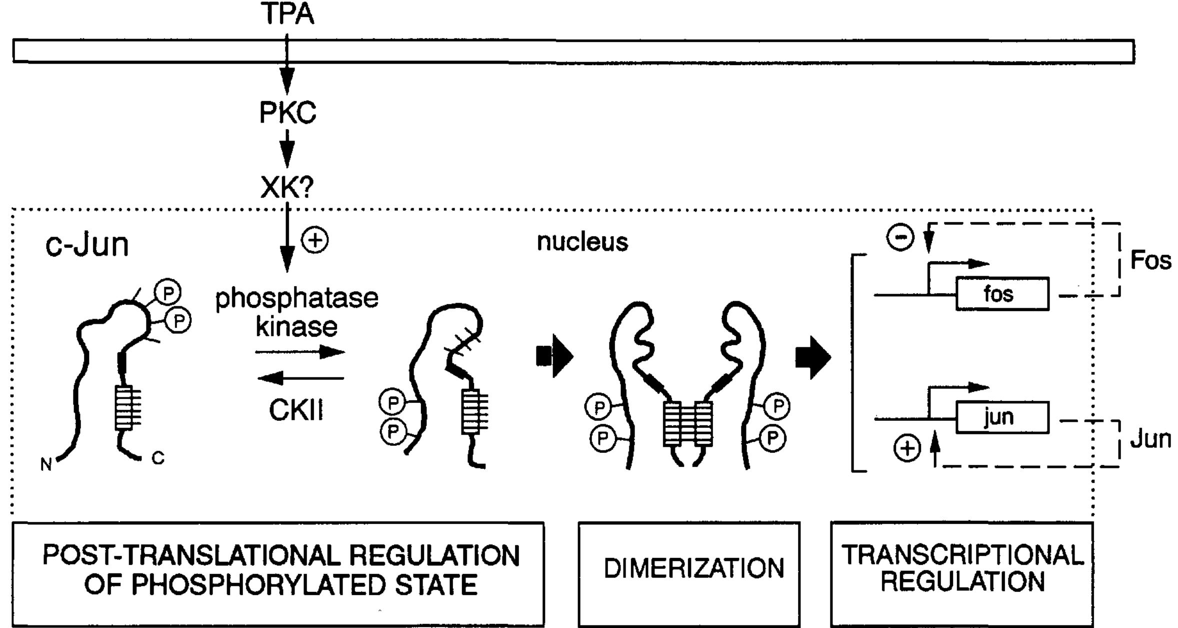

FIG. 35-2. Ligand-induced modification of ERG proteins and ERG transcription. The very rapid transcriptional induction of ERGs is due to the rapid modification of preexisting ERG proteins, which remain in an inactive state in the nucleus until the activation of the appropriate signaling pathway leads to an altered equilibrium between kinase and phosphatase activity. See text for details. The DNA-binding domain of c-Jun is shown as a stippled box. *CKII,* casein kinase II; *PKC,* protein kinase C.

other inhibitory protein which binds to the amino-terminal portion of c-Jun to reduce its ability to be a potent transcriptional activator. c-Jun can also be modified by phosphorylation of its two N-terminal sites by various transforming oncogene proteins. This leads to augumentation of the transactivating potential of the c-Jun, but not its DNA-binding ability.

COMBINATORIAL CONTROL OF TRANSCRIPTION

Another remarkable feature of ERG expression is that not only is it rapid for the reasons discussed above, but that many different signaling agents are capable of inducing transcription. For example, the transcription of *c-fos* can be detected within 5 minutes of cell exposure to ligands, such as serum, polypeptide growth factors, TPA, and cAMP. All these agents and their corresponding signaling pathways appear to converge on at least one region of the *c-fos* promoter, the serum response element (SRE). This approximately 40-base pair (bp) region is essential for transcriptional expression of c-Fos. The SRE contains a 20-bp dyad symmetry element (DSE) and a 22-bp c-Fos AP-1 site (FAP). Data from nonneural cells is depicted in Figure 35-3, which shows that at least eight different subfamilies of transcription factors, many of which are ERGs, bind to overlapping regulatory elements in the SRE. The helix-loop-helix protein rE12 and the C/EBP-related factor rNFIL-6 bind to neighboring sites within the c-Fos serum response element. Thus, multiple signaling pathways appear to interact at the level of the ERG promoter to provide a highly complex, yet precise, mode of combinatorial control over ERG transcription. Since not all transcription factors can physically bind at one time to specific, yet, overlapping recognition sequences, it is evident that some selection or competition process must take place to determine which factors will access the SRE sequence. Such selection undoubtably influences the mode of control exerted by the SRE on c-Fos transcription.

As the level of protein and the degree of posttranslational modification of ERG proteins rapidly increase following the onset of ligand-induced transcription, crosstalk is expected, that is, many ERG proteins will influence each others promoter activity. Thus, it is important to note that ERG proteins, in addition to serving as transcription factors regulating late gene expression, are also key regulators of their own expression kinetics and functional state.

EXPRESSION PATTERNS IN ASTROCYTES

Single-cell analysis of cultured astrocytes by *in situ* hybridization suggests that ligand responsiveness of a population of astrocytes can display considerable heterogeneity (Arenander and de Vellis, unpublished data). However, differential induction of ERG

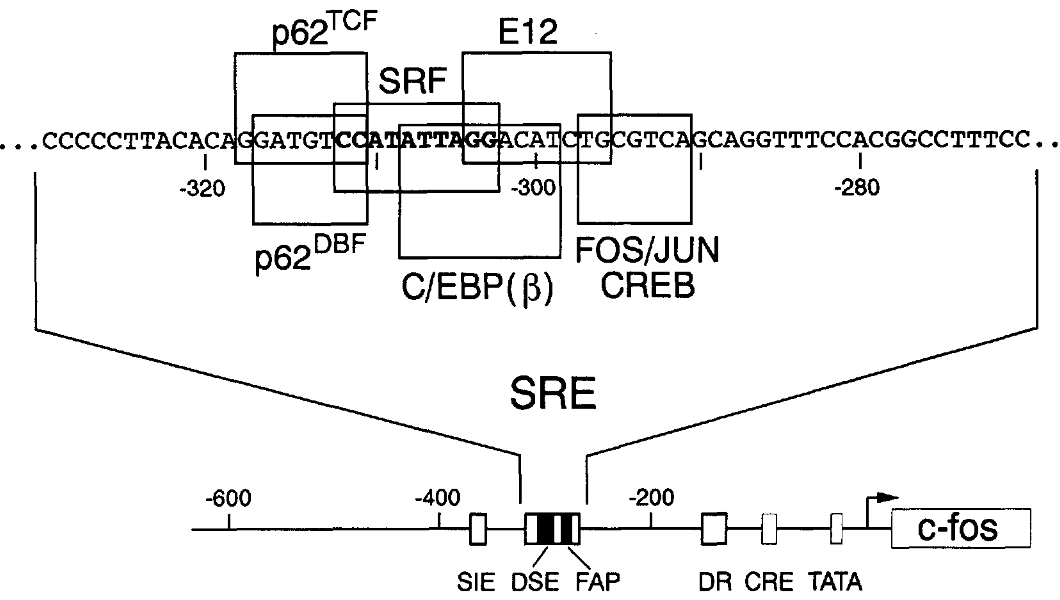

FIG. 35-3. ERG transcription factor interaction at the promoter: complexity of *c-fos* induction. The proximal part of the *c-fos* promoter is drawn below and the serum response element is enlarged above to the level of the nucleotide sequence. Note the sequence domains specific to each transcription factor overlap.

mRNA encoding transcription factors observed in cultured astrocytes appears due primarily to the variable degree of receptor expression in the cell population. In these types of experiments, TPA is used as a positive control, since all cells are expected to have PKC available for activation. Treatment of astrocytes with TPA induces both ERG mRNAs in nearly every cell. In contrast, stimulation by norepinephrine results in only about 60% of the cells expressing ERG mRNA. Since the TPA trials indicate the genes are inducible in all the cells, the response heterogeneity observed is most likely due to the known heterogeneity of nonadrenergic receptor expression in cultured astrocytes (Shao et al., 1993). Thus, ERG induction patterns represent an alternative, sensitive methodology for evaluating the cell type-specific expression pattern of functionally coupled receptors in astrocytes (Arenander and de Vellis, 1992).

Note that the mode of receptor-signalling pathway coupling to gene induction differs, however, among the ERGs. Whereas ligand-mediated *NGFIB* induction is completely suppressed by a β-blocker, propranolol, the induction of *egr*1 is only slightly effected, suggesting a more complex mode of signaling-coupled regulation of transcription of this latter ERG. Although not shown here, the results of control compounds are active ligands capable of activating the signaling pathways and altering cell phenotype (Arenander and de Vellis, 1993). These antagonists, in the absence of agonist, are capable of not only binding to the receptor, but also perturbing receptor coupling to intracellular signal pathways, so as to induce a genomic response and increase the levels of ERG mRNA.

In contrast to class I ERGs, some of the other classes of ERGs do show restricted expression patterns *in vitro*. For example, mRNA for PGSII (TIS10; Class IV ERG) is detectable after an initial delay of several hours in astrocytes as seen in Northern data (Arenander et al., 1989). *In situ* data from similar experiments suggest that the induction occurs in only a small, but varying, percentage of cultured astrocytes (unpublished observations). The clustered induction pattern suggest the ability to express this inducible form of PGSII is restricted to rarely occurring (or low proliferation and/or survival) specific expanded "clones" of astrocytes in culture.

EXPRESSION PATTERNS IN OLIGODENDROCYTES

Rat oligodendrocytes can be cultured from postnatal cerebral cortices and grown under relatively controlled conditions with definable cell phenotypes based on cell morphology and specific immunocytochemical staining profiles. Since many ligands are known to alter the proliferation and/or progression through specific developmental lineage stages, the question arises whether ERG expression is a necessary component of the ligand-induced transduction process leading to phenotypic response and control of differentiation. As an initial, correlative approach, the inducibility of a variety of ERGs by some for the key extracellular signaling agents was studied. Figure 35-4 shows the degree of ERG mRNA accumulation in oligodendrocyte cultures following treatment with different ligands. In this case, to ensure detectability of message induction, the cells were treated with ligand plus cycloheximide, the latter added to permit accumulation of very high levels of message in any cell capable of responding to the ligand. Note that *NGFIB,* a member of the steroid receptor superfamily of inducible transcription factors, displays very low basal levels of expression, a characteristic of most class I ERGs. Treatment with TPA plus cycloheximide (TX) to activate the PKC system leads to a very high level of message expression in most of the cells. In contrast, bFGF plus cycloheximide (FX) activates a much smaller portion of the cell population and with varying degrees of message accumulation per cell. The restricted expression of ERG mRNA in FX-treated cells is therefore due primarily to heterogeneous peptide receptor expression. Treatment with cycloheximide alone does not result in much message accumulation.

In order to detect unique profiles of ERG expression associated with differential responsiveness to important environmental ligands, we routinely compare the induction pattern of a number of ERGs in response to several ligands. Thus the data shown in Figure 35-4 are part of a larger experiment that allowed a detailed comparison of ERG inducibility in these developing oligodendrocytes for several inducing agents (see Figure 35-5). Scoring of these cultures shows that most ERGs are "well-behaved," exhibiting standard characteristics of class I ERGs: no detectable basal expression in the presence or absence of cycloheximide. *NGFIB* is an exception, displaying an expression pattern that differs significantly from the other ERGs, including *egr*1, a member of the same zinc-finger transcription factor family (but different family from *NGFIB,* see Figure 35-3). TPA is clearly the strongest inducing agent for all the genes, both in terms of percentage of cells positive and in the strength of the signal (level of probe per cell). Note, however, about 15% of the cells exhibit no response to TPA, even though it is assumed that all cells possess PKC. These results differ from the nearly homogeneous induction response observed for TPA-

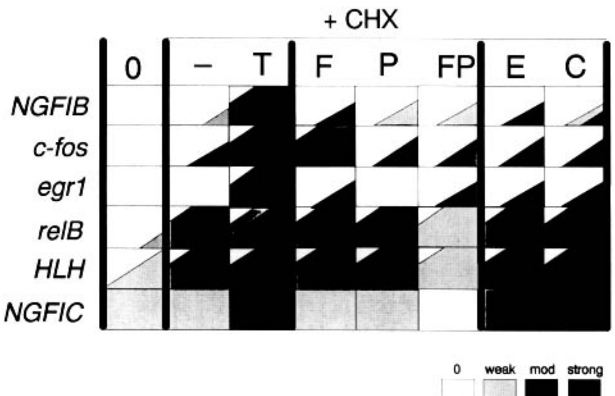

FIG. 35-5. ERG induction profile in developing oligodendrocytes. A number of agents known to influence oligodendrocyte development were tested for their effect on ERG mRNA induction as measured on the single cell level by *in situ* hybridization of oligodendrocyte progenitor cultures. This profile illustrates the unique pattern of ERG induction in these oligodendrocyte cultures. These data are derived from cell cultures shown in Figure 35-4 and from additional sister culture wells tested with other agents and examined for the expression of a number of different ERGs. Cell populations were scored for percentage positive cells for each condition and the degree of mRNA expression per cell based on a simple quantitative division into strong, moderate, weak or no level of mRNA expression. Conditions include two controls, no addition (O) or only cycloheximide (X). Cells were treated with inducing agent in the presence of X: *TPA(T)*, fibroblast growth factor (F), platelet-derived growth factor (*P*), epidermal growth factor (*EGF*), and carbachol (C).

treated cultured astrocytes. The induction levels by TPA across different genes varies considerably, suggesting the ERGs exhibit differential promoter control by TPA-activated pathways and/or oligodendrocytes can be heterogeneous with regard to PKC subtypes and hence respond differently to TPA treatment. Also note that EGF and carbachol induce high levels in some cells and that bFGF and PGDF are relatively weak inducers of ERGs in terms of amount of signal per cell and percentage of cells. It may be important that the addition of PDGF to bFGF-treated cultures actually results in a decreased level of expression in some ERG mRNAs.

ENCODING HELIX-LOOP-HELIX TRANSCRIPTION FACTORS

One of the most promising avenues of research into the genetic network of transcription factors that coordinate the spatial and temporal parameters of brain development has been the finding that helix-loop-helix proteins are expressed in the nervous system during development. The helix-loop-helix (HLH) (Table 35-3) motif is found in many proteins that act as either positive or negative regulators of gene expression and thus, exert remarkable control

TABLE 35-3. *HLH Transcription Factors in the Central Nervous System*

Class	Gene	Developmental Distribution
Class I: Basic-HLH		
IA	*E12/47*	Ubiquitous
IB	*MASH1*	Early neuronal
	MASH2	Early neuronal
IC	c-*myc*	ERG, ventricular, widespread
	L-*myc*	ERG, ventricular, early:wide, late:neuronal
	N-*myc*	ERG, ventricular, early:wide, late:glia
ID	*SCL*	Met/myelenceph ventricular zones
	NSCL1	Ventricular
	NSCL2	Ventricular
Class II: PROL-HLH

	Id2	Cortex, cerebellum, neuronal?
	Id3 (HLH462, heir1)	ERG, ventricular, 1/α N-*myc* in neuroblastoma

FIG. 35-4. *In situ* hybridization examination of ERG expression in developing oligodendrocyte cultures. Secondary cultures of oligodendrocytes were cultured for several days on Labtek Culture slides. Cultures contain predominantly O4-positive cells. Cells were then either left untreated (C) or treated for 6 hours with either cycloheximide (*X*) or TPA plus X (*TX*) or bFGF plus X (*FX*). The message (NGF1BmRNA) is detected by standard *in situ* hybridization techniques. The amount of mRNA can be correlated with the amount of radiolabeled riboprobe specifically bound and is observed as the number of white grains present in the photographic emulsion above each cell. See text for details and Figure 35-5 for summary analysis of these results.

over cell phenotype and cell fate. All the members listed in Table 35-3 are found expressed in the developing and/or adult nervous system. The members can be categorized based upon the type of protein domain adjacent to the HLH domain. Class I possess a DNA-binding basic domain (a number of basic amino acids grouped together) adjacent to the HLH dimerization domain, hence called BASIC-HLH. BASIC-HLH proteins are the positive-acting promoter regulators recognizing the E-box, the DNA consensus sequence —CANNTG—. Included in this category are the ubiquitous E12 family of HLH proteins that are common partners of all the remaining HLH proteins. E12 heterodimers generally exhibit greater transcription transactivation than do homodimers of the members of the positive regulator families listed, such as MASH (mammalian aschaete-scute homologues) (Johnson et al., 1992), *myc* and SCL.

The other classes are distinguished by the modification of the basic amino acid domain that prevents homodimers or heterodimers from binding to the promoter elements: Class II (PROL-HLH) have a proline substitution in the basic domain and Class III (HLH) possess no basic DNA binding region at all. Heterodimerization of class I proteins with either class II or III inhibits the positive acting BASIC-HLH proteins by sequestering these active regulatory molecules into inactive pools. This binding of class II and class III to members of class I is now considered a major mode of transcription factor control over cell differentiation. The most fully delineated system of HLH control over cell fate is in muscle cell development.

Since these HLH genes directly participate in the control of cell lineage progression, and since HLH mRNAs have been described in the nervous system with a notable degree of differential cell distribution, we have begun to study the developmental expression patterns of these HLH genes in glial cells. Several of these genes, especially members of the ligand-inducible inhibitory classes II and III can be classified as ERGs and may be coordinately expressed along with other classes of ERGs by peptide signals. *In situ* hybridization analysis of cultured cells and tissue sections demonstrate many of these HLH genes are expressed in glial cells and hence may play a role in glial cell lineage (Arenander and de Vellis, unpublished data). The expression of classes II and III inhibitory HLH mRNAs (Arenander and de Vellis, unpublished data) suggests the existence of a positive acting HLH target in glial progenitor cells analogous to the MyoD story. It is also encouraging to find the system of interacting control responsible for modulating MyoD activity in myocytes may also function in glia as they progress through the stages of lineage development. The various extracellular ligands and the corresponding intracellular signaling pathways that modulate the key regulator of muscle progenitor fate, MyoD (Figure 35-6), are similar to those found to regulate the fate of glial cell progenitors during development (Arenander and de Vellis, 1994). Thus, we expect that an "*OligoD*" gene will be found expressed during oligodendrocyte cell development and that the expression of the various inhibitory HLH ERGs will exhibit an inverse correlation with the stages of glial differentiation.

CONTROL OF GLIAL-SPECIFIC LATE GENE EXPRESSION

We showed that GPDH is expressed in the central nervous system in a ligand-specific, developmental stage-specific, and cell-type-specific fashion (for review see Kumar and de Vellis, 1988). What elements control the transcription of GPDH? As suggested in the introduction, ligand-induced expression of ERGs are important candidates to regulate GPDH transcription. Northern analysis of both ERG and LRG message levels can display a temporal sequence suggesting a possible dependence between the two events. The hydrocortisone-mediated induction of gene expression in C6 glioma cells suggests a close correlation between the appearance of several ERGs and the LRG, GPDH (Cheng and de Vellis, unpublished data). However, simple correlation is not sufficient to determine causality. In particular, because of the combinatorial modes of ERG control, induction may not depend upon only one or two ERGs. In addition, many of the ERGs are expressed in a nonspecific manner (i.e., induced by many agents). In the case of GPDH, many of the same ERGs are expressed by activators of PKA (by forskolin (FOR) treatment leading to GPDH induction) and PKC (by TPA treatment, inhibiting GPDH induction).

Which of these rapidly induced transcription factors are important for the transcription of GPDH? The question we are asking must be extended to consider more than just the appearance of message as the critical parameter. Posttranslational modification of ERG proteins is well-known. If it is differentially controlled by PKC and PKA, which is likely, then the same ERGs can be induced by TPA and forskolin but their activity may be very different leading to either induction or inhibition of GPDH gene expression.

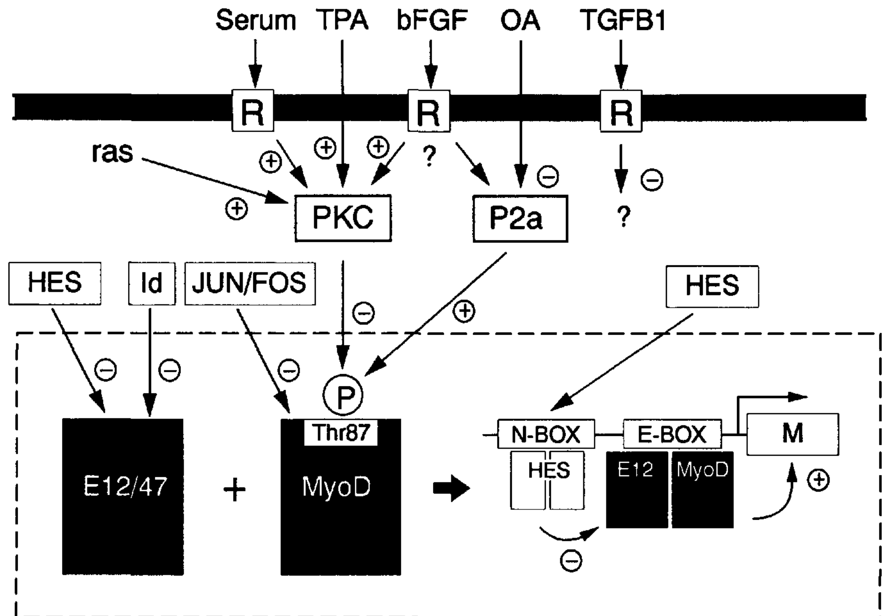

FIG. 35-6. Modulation of MyoD activity during muscle development. A number of agents control the development of myocytes. Note the analogy to oligodendrocyte developmental events. The agents in this figure all exert a negative influence on MyoD activity and thus inhibit myocyte differentiation. Note control is primarily exerted not at the level of MyoD expression, but rather at its activity as a positive regulator of muscle-specific gene expression (M in the gene box denotes muscle genes). Four levels of control are illustrated here. (*1*) HES dimers can bind to the N box in some muscle specific gene promoters which directly inhibits the activity of transactivating E-boxes. (*2*) HLH ERGs such as HES and Id can sequester E12 proteins into inactive pools. Lack of E12 proteins available for heterodimerization forces MyoD to form only homodimers, which are very weak transactivating factors of muscle-specific gene expression compared to heterodimers. The weakly active MyoD homodimers, however, are sufficient to continue to positively self-regulate MyoD gene expression. (*3*) The upregulation of JUN and FOS inhibit MyoD activity by directly binding to MyoD. (*4*) The threonine-87 residue in the basic region is a phosphorylation site that controls MyoD DNA binding activity. Agents shown converge on PKC, which then leads to phosphorylation of Thr-87. A parallel inhibition of phosphatase 2a (*P2a*), for example, by treatment with okadaic acid (*OA*), prevents dephosphorylation. The mode of inhibition of TGF β differs and remains unknown.

CONCLUSION: TRANSCRIPTION FACTOR NETWORKS FUNCTIONING IN GLIAL CELL DEVELOPMENT

Phenotypic progression of cells during development is by definition based on the expression of specific cellular proteins at each lineage stage. Since the expression of these proteins is a result of differential gene expression, the spectrum of transcription factors responsible for mediating the specific genomic programs represents a genetic control system or network (for review see Arenander and de Vellis, 1994). It is accepted that environmental agents control the fate of developing oligodendrocytes. Exposure of oligodendrocyte progenitor cells in culture to two of the main growth factors result in markedly different developmental end points (Figure 35-7). What is the difference in the genetic network that determines these different outcomes? It is possible that specific

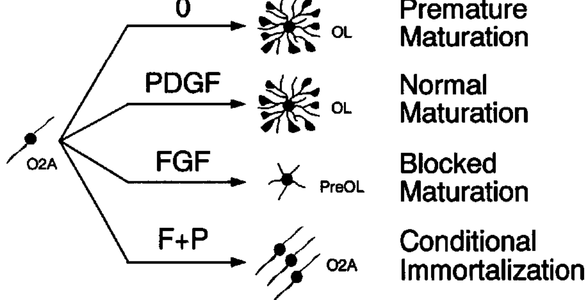

FIG. 35-7. Growth factor control of lineage decisions. Oligodendrocyte progenitor cells called oligodendroblasts (originally termed O-2A progenitor cells) will undergo four types of developmental processes depending upon the environmental signals present. Progenitor cells can become mature oligodendrocytes (*OL*) at two different rates, or enter and remain in a relatively undifferentiated stage (*Pre-OLs*) or continue indefinitely as early precursor cells.

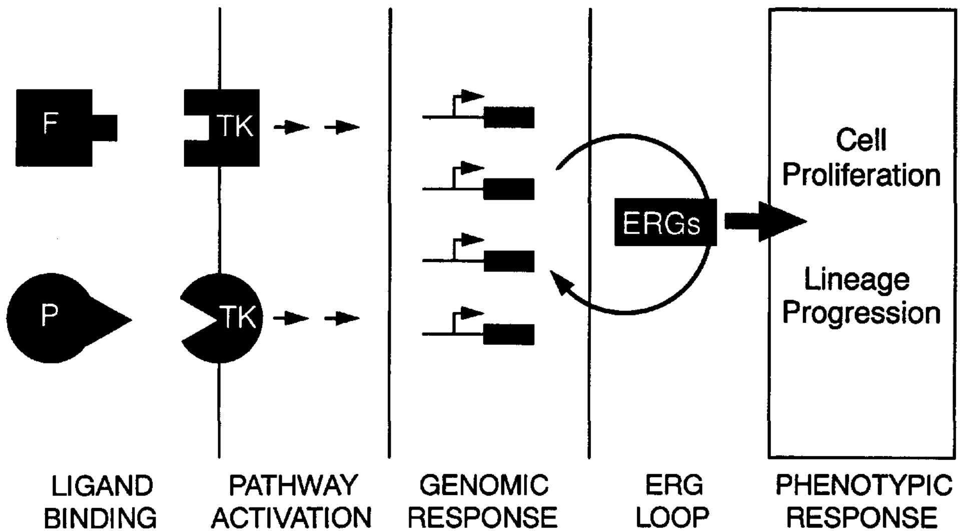

FIG. 35-8. ERGs mediating growth factor control of oligodendrocyte development. It is proposed that the differential expression of ERG encoding transcription factors in oligodendrocyte progenitor cells ("ERG loop") plays an important, possibly causal, role in determining cell response to extracellular signals (e.g., bFGF and/or PDGF) and hence glial cell fate during development.

FIG. 35-9. Transcriptional network control of glial cell lineage development. Four levels of transcription factor controls are depicted. Transcription factors can be responsible for different levels of control: (*1*) *lineage* (i.e., glia vs neuronal bifurcation), appearing in every early cell type), (*2*) *sublineage* (responsible for astrocyte vs oligodendrocyte decision), (*3*) *stage-specific* (responsible for stage progression and/or stabilization) and/or *process-specific* (i.e., proliferation) processes. In this hypothetical scheme, participation of transcription factors at each level of control is not mutually exclusive.

patterns of ERG expression play an important role in the network and contribute to the decision as to which genetic program to activate. Specifically, alternative patterns of growth factor-receptor coupling are encoded by differential ERG expression or "ERG-loops" as illustrated in Figure 35-8. These loops, in turn, coordinate the genetic expression required to carry out specific programs of proliferation and differentiation. Seen as a broader perspective, the transcriptional factor network composed of "constitutive" and induced proteins would assume different configurations depending upon the environmental signals that direct developmental decisions. Considering the whole of glial development, one can envision that present research efforts will eventually define the networks that encode for each major developmental decision. Toward that goal, we have outlined schematically alternative levels of network control over glial development (Figure 35-9).

Future research into the molecular mechanisms of ERG and LRG induction and their role in directing phenotypic development and cell function will benefit greatly from use of semiautomated injection into single cells of a side range of important reagents. Each cell in culture can now be manipulated as a complete *in vivo* system by injecting proteins, oligonucleotides, mRNA, DNA vectors, either individually or in combination and then examining the cell response over the period of minutes to days. Thus this approach provides a means to estimate the causal relationship of a particular process or molecule with a specific phenotypic response. Application of this technique permits more direct analysis than many current techniques that require either too much reagent or too many cells.

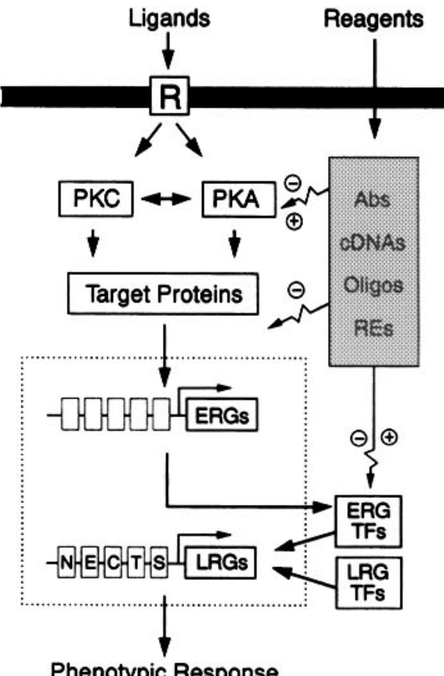

FIG. 35-10. Single-cell microinjection technology applied to the analysis of molecular mechanisms of glial development. The main signaling pathways leading to gene expression and phenotypic change are depicted. This technique permits injection into phenotypically defined cells of the glial lineage a variety of antibodies or antisense oligomers to block specific steps in the ligand-induced molecular cascade. One can also inject constitutive or inducible vectors to overexpress a specific RNA and/or protein to examine the influence on, for example, transcriptional control or to upregulate a particular step in the signaling cascade (i.e., kinase). TPs (Transcription factors). Dotted box is nucleus.

Microinjection modulation of ERGs will be valuable (see Figure 35-10). The work of R. Bravo and colleagues has demonstrated the potential inherent in the technique. Using highly purified reagents, they have been able to directly demonstrate the combinatorial control of ERGs over cell proliferation (Shuerman et al., 1989). Microinjection of antibodies with individual or pan specificity show the differential requirement for induction of each of the members of the *jun* and *fos* families in order to enable proliferation signals to function provides a model for investigating the causal mechanisms underlying similar processes during the various stages of glial lineage development. For example, injection of HLH vectors will permit upregulation of these key positively or negatively acting transcription factors and allow one to evaluated the predicted outcome in glial development. These data, in turn, can then be correlated with the results of *in vivo* distribution patterns of ERG expression during the development of the nervous system.

We thank Sharon Belkin and Carol Gray of the Mental Retardation Research Center for help in preparing the illustrations. Our research was supported by the Department of Energy contract DE-FC03-87ER-60615, NICHD grant 2P01-HD06576 and NIH grant 1RO1-NS29220-01.

36 Lipid metabolism

JULIAN N. KANFER

The lipid composition and lipid metabolism of oligodendroglia (Morell and Toews, 1984; Pleasure et al., 1984) and astrocytes (Kanfer, 1986) have been comprehensively described, and therefore will not be reviewed here. The basic characteristics were largely established during the 1960s, 1970s, and 1980s. This investigative activity was undoubtedly due to the development of procedures for both the bulk isolation and the successful maintenance of primary cultures of these cell types. The current general interest in the functional significance of membrane phospholipase hydrolysis of membrane phospholipid initiated by receptor occupancy (Dennis et al., 1991; Exton et al., 1991) applies also to neuroglial cells.

SPHINGOGLYCOLIPIDS

Cerebrosides

Galactosylceramide and its sulfated derivative, sulfatide, are enriched in the myelin membrane and in the oligodendroglia cell that elaborates this membrane. Therefore, these two sphingoglycolipids have been extensively investigated in oligodendroglia cells. The enzyme catalyzing the synthesis of galactosylceramide, UDPgalactose:ceramide galactosyltranferase, is usually assayed *in vitro* with both nonhydroxyfatty acid (NFA) and hydroxyfatty acid (HFA) containing ceramides. The distribution of this catalytic activity was determined in subcellular particles prepared from bulk-isolated oligodendroglia of 18- to 19-day-old rats. The specific activity for the HFA ceramide galactosyltransferase activity was greatest in fractions containing Golgi and endoplasmic reticulum. The specific activity for the NFA galactosyltransferase was greatest in the fractions containing endoplasmic reticulum (Sato et al., 1988). This suggests independent sites for the synthesis and the existence of independent enzymes for the formation of HFA- and NFA-containing cerebrosides. The activity of UDPgalactose:ceramide galactosyltransferase correlated with the increasing number of cells staining with an antigalactosylceramide antibody of primary oligodendrocyte cultures (Neskovic et al., 1988). Adult rat brain slices were exposed to an antibody prepared to a presumed purified UDPgalactose:ceramide galactosyltransferase. The innermost and the outermost loops of the myelin sheaths, as well as the cytoplasm and processes of oligodendrocytes were positively immunostained (Roussel et al., 1987).

The incorporation of [^{3}H]galactose into cerebroside and sulfatide was examined during the growth of primary oligodendrocytes in culture. The degree of labeling increased from 15 to 29 days in culture and then gradually decreased. The increase in numbers of cells stained with antisulfatide and anticerebroside antibodies and the increased mass of sulfatide and cerebroside had similar developmental patterns, plateauing at 30 DIC. This is reminiscent of the *in vivo* temporal course of appearance of these markers (Singh and Pfeiffer, 1985). Exposure of primary cultures of oligodendrocytes from 21-day-old rat brain for 2 days to dibutyl cyclic AMP increased [^{3}H]galactose labeling of cerebroside 2.5-fold (Pleasure et al., 1986). The $^{35}SO_4$ incorporation into sulfatide and the level of cyclic nucleotide phosphodiesterase (CNPase) activity are very low in oligodendrocytes in serum-free medium devoid of triiodothyronine (T_3) as compared to cells maintained in the presence of T_3 (Koper et al., 1986). The effect of several agents on the incorporation of [^{3}H]galactose into lipids by bulk-isolated oligodendrocytes from bovine brain and 15- to 20-day-old rat brains or by primary rat brain oligodendrocyte cultures was investigated. The bulk-isolated rat brain oligodendrocytes and the oligodendrocyte cultures had 20 to 24% of the total labeled lipids present in cerebroside, and this was increased in cells exposed to hydrocortisone, T_3, ketone bodies, and retinoic acid. About 76% of the total radioactivity present in cerebrosides of the bovine oligodendrocytes was unaffected by added agents. It is difficult to determine the metabolic events in the cells affected by these agents and manipulations (Poduslo et al., 1990). Primary oligodendrocyte cultures were subjected to hypoxic conditions for 6 hours or to 12 nM oligomycin, and the appearance of labeled precursor in cerebrosides was measured: The incorporation of [^{3}H]palmitate into cerebrosides decreased by 50 to 60%, but the incor-

poration into ceramides increased. By contrast, hypoxia increased the incorporation of [^{3}H]galactose into cerebroside without affecting the activity of UDPgalactose:ceramide galactosyltransferase. It was speculated that hypoxia interferes with the transport of newly synthesized ceramide to the site of galactosylation, but it does not hinder the galactosylation of preexisting ceramide (Kendler and Dawson, 1990). Oligodendrocytes from lamb brain were maintained in suspension culture or allowed to adhere to polylysine-coated dishes under conditions favoring morphological differentiation. The incorporation of individual labeled precursors into cerebroside, sulfatide, neutral lipid, and ethanolamine plasmalogen was greater in the adhering cultures than in the suspension cultures. It appears that adherence to a substratum favors activation of systems for myelin membrane production (Vartanian et al., 1992).

Astrocyte cultures from the neopallium of mice were exposed to various labeled compounds. [^{3}H]Glycerol and [^{14}C]acetate were taken up equally and labeled all the major phospholipids; the latter was also found in cholesterol. [^{3}H]Galactose was present in cerebroside, but [^{3}H]SO_4 was not incorporated into sulfatides. These cultures may have contained a 4% oligodendrocyte contamination based on the determination of CNPase activity (Yim et al., 1986).

Gangliosides

The value for ganglioside oligodendrocyte bulk isolates in humans is 0.35 μg sialic acid/mg protein, in bovine, 0.52, and in 60-day-old rats, 1.45. Although there are species differences, the major gangliosides are GD_{1b}, GD_{1a}, GD_3, GM_1, and GM_3 (Yu et al., 1989). The ganglioside sialic acid content of bulk-isolated astrocytes from 20-day-old rats is 2.8 μg sialic acid/mg protein, which is greater than that of the oligodendrocytes or the neurons from similar aged animals. The ganglioside distribution of the astrocytes is 35% as GD_{1a}, 18% to 27% as GT_{1b}, 10% as GD_{1b}, and 12% as GM_1. As determined densitometrically, 11% is GM_3; however, with [^{3}H]glucosamine labeling this represents only 2% of the total as GM_3. These investigators found low levels of UDP-*N*-acetylgalactosamine:GM_3 *N*-acetylgalactosaminyltransferase activity, which is the enzyme catalyzing the synthesis of GM_2 (Byrne et al., 1988). The ganglioside content of primary cultures of rat brain astrocytes is 2.4 to 3.4 μg sialic acid/mg protein, which is similar to that present in the bulk-isolated astrocytes. GM_3 represented 71 to 81% of the total gangliosides present, which is distinctly different from the bulk isolates. The activity of UDP-*N*-acetylgalactosamine:GM_3 *N*-acetylgalactosaminyltransferase was barely detectable in these astrocyte cultures. This probably explains the high GM_3 content of the cells because the biosynthetic enzyme leading to the more complex ganglioside species is nearly undetectable (Sbasching-Agler et al., 1988).

NEUTRAL LIPIDS

Fatty Acids

Oligodendroglia convert acetoacetate and glucose to fatty acids and cholesterol to a greater extent than do astrocytes (Koper et al., 1984). C6 glioma cell cultures have the capacity for both elongation and desaturation of $C_{18:3(n-3)}$ to $C_{20:5(n-3)}$, $C_{22:5(n-3)}$, and $C_{22:6(n-3)}$ fatty acids. This is the established pathway for this metabolic route of fatty acid conversion (Cook and Spence, 1987; Cook et al., 1991). Primary astrocyte cultures convert $C_{18:2(n-6)}$ to $C_{20:4(n-6)}$ and $C_{18:3(n-3)}$ to $C_{20:5(n-3)}$, $C_{22:5(n-3)}$, and $C_{22:6(n-3)}$ fatty acids. In contrast, cultured neurons possessed only the Δ-4 desaturase activity, but not the chain elongation activity. Docosahexanoic acid ($C_{22:6(n-3)}$) is a major fatty acid present in the lipids of excitable membranes; these results suggest that the astrocytes biosynthesize this fatty acid and may release it for neuronal uptake (Moore et al., 1991). Confluent astrocyte cultures can convert palmitate and octanoate to CO_2 and acetoacetate. This acetoacetate formation is not through the mitochondrial HMG-CoA cycle but either by 3-keto acid CoA transferase, or by acetoacetate CoA deacylase, or by a combination of these two possibilities (Auestad et al., 1991). Primary rat brain neuroglia cultures have demonstrable monoacylglycerol and diacylglycerol lipase activity, which does not change with time in culture (Farooqui et al., 1990).

Cholesterol

Neurosteroids denote steroids detectable in brain tissue that are at levels independent of their plasma concentrations. Some are produced *de novo* in brain, while others are cholesterol metabolites. The neurosteroids bind to membrane receptors and exert no genomic influence. Some neurosteroids bind to the GABA receptors, and some inhibit or enhance excitatory amino acid receptor responses (Paul and Purdy, 1992). Mitochondria prepared from bulk-isolated oligodendroglia of 21-day-old rats convert [^{3}H]cholesterol to the steroids [^{3}H]pregnenolone and [^{3}H]pregnene-3β,20α-diol (Hu, 1987). Primary cultures of neonatal forebrain initially contain 60% oligodendrocytes and 40% astrocytes. The oligodendrocytes stain both with sep-

arate antibodies directed toward galactosylcerebroside and cytochrome $P450_{SCC}$, a cofactor for cholesterol side chain cleavage. The conversion of [^{3}H]mevalonate to cholesterol, pregnenolone, and pregn-5-ene-3β20α-diol correlate with the numbers of oligodendrocytes in these cultures. If a cytochrome P450 inhibitor is present under these conditions, only cholesterol is produced (Jung-Testas et al., 1989a, 1989b). Membranes of astrocytes and oligodendrocytes primary cultures were electrophoresed and the membranes from both cell types immunoblotted with anti-low density lipoprotein (LDL) receptor antibodies. [^{3}H]Cholesterol oleate-loaded LDL was converted to cholesterol and pregnenolone by these cultures (Jung-Testas et al., 1992).

The activities of both a microsomal and a myelin-associated form of cholesterol ester hydrolase increased by 20 days in oligodendrocyte cultures (Bhat and Pfeiffer, 1985). The content of free and esterified forms of cholesterol in C6 cells increased until the cultures are about 50% confluent subsequently, and declined as the cell number increased. There are parallel changes in both HMG-CoA reductase and acylCoA cholesterol acyltransferase activities. These correlate with the growth rate of cells and are not dependent upon LDL receptors or diffusible cytosolic factors (Friedman et al., 1987). Primary cultures of mixed brain cells were grown in media containing lipoprotein-free serum or medium containing lipoprotein-free serum supplemented with total lipoprotein or LDL or high-density lipoprotein (HDL). The conversion of acetate to sterol and HMG-CoA reductase activity were increased in the lipoprotein-free serum-grown cells as compared to the other cells. This suggests that cholesterol biosynthesis in neuroglia cells is under the usual control mechanisms (Shah, 1988). Transfer of C6 cells or primary astrocyte cultures from a 10% fetal calf serum medium to 10% lipoprotein-poor serum increases both sterol synthesis and HMG-CoA reductase activity. This is prevented if LDL is also present in combination with the lipoprotein-poor serum. HDL supplementation to the lipoprotein-poor serum further increases both sterol and HMG-CoA reductase activity of the primary astrocytes but not C6 cells (Langan et al., 1987). The content and magnitude of labeling of the cholesterol esters of cultured chick glia cells was increased when the cells were maintained in serum-free medium (Saito et al., 1987). C6 cells produced cholesterol esters by the biosynthetic enzyme lecithin:cholesterol acetyltransferase. The appearance of [^{14}C]oleate in cholesterol oleate was reduced in a dose-dependent manner by the presence of U1866A, a hypocholesteremic agent. This compound has no effect on lecithin:cholesterol acetyltransferase activity as measured *in vitro* (Jeng et al., 1985).

PHOSPHOLIPIDS

Content

Astrocytes were maintained in a defined serum-free medium for 2 weeks, and then the cells were placed in a serum-containing medium. The protein and DNA content were identical under both growth conditions. The cells maintained in a serum-free medium displayed typical fatty degeneration. The phospholipid content of the cells in a serum-containing medium increased markedly compared to that of cells in the serum-free medium (Krause and Debuch, 1987). Mitochondria, microsomes, and plasma membranes were isolated from primary astrocytes at 16, 19, and 24 days in culture, and the fatty acid composition of the phospholipids were determined. The principal fatty acid of all the phospholipids was palmitic acid. There were no differences in the fatty acids present in phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine of the plasma membrane fractions. Docosahexanoic acid was absent from the phospholipids of the plasma membrane, but was present principally in the phosphatidylethanolamines of the other membranes (El-Achkar et al., 1987). The total phospholipid content, expressed as picomoles phosphate per cell, was found to progressively increase in bulk-isolated oligodendroglia isolated from rats at 18, 30, 60, and 100 days of age. There were equivalent increases in all classes of phospholipids (Kreda et al., 1992). The plasmalogen content of the plasma membrane prepared from C6 cells is 2.5-fold greater than that of the endoplasmic reticulum, but the phosphatidylcholine content of the endoplasmic reticulum is 2.5-fold greater than that of the plasma membrane (Thomas et al., 1992).

Metabolism

C6 glioma cells, NN transformed astrocytes, and primary astrocyte cultures were exposed to [^{14}C]glycerol for 24 hours. Approximately 50 to 60% of the radioactivity was present in phosphatidylcholine, 20% in phosphatidylethanolamine, and 10% in phosphatidylserine-phosphatidylinositol. Similar labeling patterns were seen with [^{14}C]acetate and $H_3\,{}^{32}PO_4$. However, the cellular turnover rates of the phospholipids labeled by these precursors were not identical. There was a greater turnover of acetate-labeled lipids with the tumors, a greater turnover rate of [^{32}P] labeled lipids in primary cultures, but the turnover of glyc-

erol-labeled lipids was equivalent in the tumors and in the primary cultures (Hugues et al., 1985). There was an increased CNPase activity, a presumptive myelin marker, and characteristic morphological changes when C6 cells are grown in serum-free medium. This CNPase increase is not observed if the growth medium contains either monomethyl- or dimethylethanolamine, but does occur if either ethanolamine or choline is present in the medium. There are no differences in cell growth between these groups or in Na^+/K^+ ATPase activity. Phosphatidylmethylethanolamine, which is normally absent, represented 50% of the total phospholipid at the expense of phosphatidylcholine in cells grown in the presence of monomethylethanolamine. The K_{ms} of CNPase activity of untreated and treated cells was the same, but the V_{max} of the treated cells was decreased. This suggests that the polar head groups of the membrane phospholipids and the membrane fluidity may influence the normal myelination process (Volpe et al., 1986).

In a classical pulse-chase paradigm, choline-prelabeled C6 cells were chased with nonradioactive choline. During this chase period there was a 20-fold increase in free choline, a 1.7-fold increase in glycerophosphorylcholine, but little change in phosphorylcholine. This suggested a catabolic pathway of phosphatidylcholine → lysophosphatidylcholine → glycerophosphorylcholine → choline (Morash et al., 1988). The fatty acid composition of endogenous phosphatidylcholine and lysophosphatidylcholine was determined. The endogenous lysophosphatidylcholine composition resembled the product of phospholipase A_2 hydrolysis of endogenous phosphatidylcholine rather than that of phospholipase A_1 hydrolysis. When presented to cells, 2-acyllysophosphatidylcholine was converted to phosphatidylcholine more effectively than 1-acyllysophosphatidylcholine, suggesting that phospholipase A_2 was the initial enzyme initiating this catabolic pathway (Morash et al., 1989). Electropermeabilized C6 cells were employed to introduce labeled intermediates of the *de novo* pathway of phosphatidylcholine synthesis directly into the intracellular compartment. The label from [^{3}H]choline was found in both phosphorylcholine and phosphatidylcholine, but little was found in either glycerophosphorylcholine or cytidine diphosphate (CDP) choline. In contrast, neither phosphocholine nor CDP choline electropermeabilized into the cells labeled phosphatidylcholine. The radioactivity from the choline-labeled phosphatidylcholine was reduced by choline, but not by phosphocholine or CDP choline. This suggests that the individual enzymatic reactions of the *de novo* biosynthetic pathway are functionally linked, and that these reaction intermediates do not equilibrate with existing intracellular pools (George et al., 1989). This channeling of these intermediates is dependent upon the presence of intracellular Ca^{2+} (George et al., 1991a). The appearance of radioactive [^{3}H]choline, presented to C6 cell cultures, in phosphatidylcholine and choline, but not that present in phosphorylcholine, was increased threefold by the simultaneous presence of phorbol myristate acetate (PMA). This PMA response was not observed with ethanolamine labeling of phosphatidylethanolamine (Cook et al., 1989). Cytochalasin B, a filament-disrupting agent, but not colchicine, a microtubule depolymerizer, prevented the incorporation of both choline and ethanolamine into their corresponding phospholipids. This response appears to be specific for these two phospholipids, since $H_3{}^{32}PO_4$ incorporation into other phospholipids was unaltered. Similar alterations were not seen with other cytochalasins tested, suggesting that the reduction of phospholipid labeling is not a result of altered states of cellular microfilaments. It was proposed that cytochalasins causes Ca^{2+} release from intracellular stores (George et al., 1991b). Maximal incorporation of [^{3}H]serine, supplied to C-6 cell cultures, into phosphatidylserine occurs by 4 to 8 hours and into non-plasminylphosphatidylethanolamine by 12 to 24 hours. Approximately 80% of the radioactivity present in phosphatidylserine and phosphatidylethanolamine is retained in the head groups portion (Xu et al., 1991). This conversion of phosphatidylserine to phosphatidylcholine presumably is catalyzed by combined activities of the constitutive phosphatidylserine decarboxylase and phospholipid *N*-methyltransferases. The platelet activating factor (PAF) phosphocholine transferase and the lyso-PAF acetyltransferase activities are both present in cultured glial cells (Francesangeli et al., 1993).

The base exchange enzymes catalyze a replacement by serine, or by ethanolamine or by choline of the polar head groups of a preexisting phospholipid yielding the corresponding phospholipid (Kanfer, 1989). The developmental profile, the activities and subcellular distribution of the ethanolamine base exchange enzyme activity and the ethanolamine phosphotransferase activity of primary astrocyte cultures were found to be different (Mersel et al., 1987). The ethanolamine base exchange enzyme activity of spontaneously transformed astrocytes was lower than that of primary astrocyte cultures. There was a transient elevation of this activity by dibutyl cAMP treatment but not that of either the choline base exchange enzyme or ethanolamine phosphotransferase activities (El-Achkar et al., 1988). The sole mechanism available for the biosynthesis of phosphatidylserine in mammals is catalyzed by the serine base exchange enzyme (Kanfer, 1989). C6

cells were incubated with [^{14}C]serine in the presence or absence of Ca^{2+}, with several agents capable of modulating intracellular Ca^{2+}. Glutamate, A23187, and thapsigargin elevated the intracellular Ca^{2+} content and reduced the incorporation of serine into phosphatidylserine. It was proposed that the site of Ca^{2+} release from intracellular stores also corresponds to the location of the serine base exchange enzyme. This enzyme requires Ca^{2+} for activity and depletion of this cation might be expected to reduce the activity of this enzyme (Czarny et al., 1992).

Phospholipase A_2

The general experimental approach for these types of investigations are identical. Cells usually are prelabeled with arachidonate acid ($C_{22:4}$), which is incorporated into cellular phospholipids. The appearance of unesterified arachidonate in response to agonists is regarded as an index of cellular phospholipase A_2 activation.

C6 cells were exposed to muscimol, a selective GABA agonist, and there was an increase in unesterified $C_{22:4}$ with a small decrease in radioactivity present both in phosphatidylcholine and in phosphatidylethanolamine (Majewska and Chuang, 1985). Acetylcholine stimulated the appearance of $C_{22:4}$ when added to C6-2B cells, and this release was blunted by atropine. Carbachol, but neither oxotremorine or pilocarpine, had a similar effect, suggesting that occupancy of muscarinic receptors on these cells activated phospholipase A_2. The Ca^{2+} ionophore A23187 also increased the free $C_{22:4}$ content (DeGeorge et al., 1986a). Norepinephrine and other adrenergic agonists presented to primary rat brain astroglia cultures caused a liberation of $C_{22:4}$. A combination of norepinephrine, acetylcholine, and histamine resulted in a greater release of $C_{22:4}$ than either agent alone. This suggests that each agonist activated phospholipase A_2 by independent mechanisms (DeGeorge et al., 1986b). The acetylcholine-provoked release of $C_{22:4}$ by C6-2B glioma cells was blocked by quinacrine, a phospholipase A_2 inhibitor, and also by dexamethasone. This observation suggests that glucocorticoids may interfere with phospholipase A_2 activations (DeGeorge et al., 1987b). The acetylcholine-stimulated release of free $C_{22:4}$ by C6-2B cells does not occur in Ca^{2+} free medium or in the presence of Ca^{2+} channel blockers, suggesting that phospholipase A_2 activation is coupled to Ca^{2+} influx (Brooks et al., 1989). Similarly, the complement complex C5b-9 provoked the release of $C_{22:4}$ by ROC-1 cells, a fusion product of rat oligodendrocytes + C6 glioma cells, was Ca^{2+}-dependent and blocked by phospholipase A_2 inhibitors (Shirază et al., 1989).

Phosphatidylinositol-Specific Phospholipase C

A general experimental approach has been adopted by most investigators for demonstrating phosphopinositide specific phospholipase C activation. Cells usually are prelabeled with [^{3}H]inositol for 24 to 48 hours, the labeling medium replaced with a solution containing $LiCl_2$ and the agent to be tested. The appearance of water-soluble inositol phosphates is regarded as an index of inositol-containing phospholipid hydrolysis. Frequently these metabolites are separated by anion exchange chromatography into mono-, di-, and triphosphoinositols. This format of investigation was designed to determine if particular receptors are linked to phospholipase C. The metabolites produced are regarded as lipid-derived second messengers. Diacylglyceride is proposed to be a protein kinase C activator and inositol triphosphate is proposed to liberate Ca^{2+} from intracellular stores (Dennis et al., 1991).

Immunohistochemical examination employing antibodies to phospholipase C (PLC) isoforms was undertaken with primary rat brain cultures. Oligodendrocytes stain more intensely than astrocytes for PLCβ and PLCα, but astrocytes stained more intensely than oligodendrocytes for PLCδ (Mizuguchi et al., 1991).

Examples of agonist-provoked phospholipase C activity of astroglia and oligodendroglia are provided in Table 36-1.

Phospholipase D

Phospholipase D activity is of current interest because of a hope that it may contribute to metabolic control regulatory mechanisms (Dennis et al., 1991). Primary astrocytes were exposed to [^{3}H]glycerol to prelabel the phospholipid pool. Phorbol myristate acetate and dioctanoate, protein kinase C (PKC) activators, stimulated the phospholipase D-catalyzed appearance of the expected hydrolysis products, perhaps by a PKC-mediated mechanisms (Gustavsson and Hansson, 1990). The phosphatidylethanolamines of astrocyte primary cultures, 02A glia and C6 glioma cells were prelabeled with radioactive ethanolamine. The presence of either 10% fetal calf serum or phorbol myristate acetate resulted in the appearance of free ethanolamine in the media. This may have occurred by an activation of phospholipase D (McNulty et al., 1992).

[^{3}H]Choline-prelabeled 1321N1 astrocytoma cells

TABLE 36-1. *Receptor-Linked Phosphoinositide Hydrolysis*

Agent[a]	Cells	Reference
Astroglia

Substance P	C6	Glanville et al. (1989)

[a]All the agents stimulated phosphoinositide hydrolysis.

were treated with carbachol, histamine, and bradykinin. These agents provoked the prompt release of phosphocholine into the culture medium, which preceded the release of choline. The intracellular source was not identified. In contrast, phorbol myristate acetate provoked choline release into the medium, but not the release of phosphocholine. Increased diacylglyceride was present in cells treated with either carbachol or phorbol myristate acetate. It was proposed that phosphatidylcholine hydrolysis by a phospholipase C was provoked by carbachol, but that phorbol myristate acetate provoked hydrolysis by phospholipase D (Martinson et al., 1989).

37 Biochemistry of myelin proteins and enzymes

SAMMYE NEWMAN, MEGUMI SAITO, AND ROBERT K. YU

Myelin is formed as an extension of the oligodendrocyte (central nervous system) or Schwann cell (peripheral nervous system) plasma membrane. During myelination, glial cell processes contact and wrap around axons in a "jelly roll" pattern until a tightly compacted, multilamellar structure has formed around the axon. The compact myelin sheath is a continuation of the parent glial cell. However, the biochemical composition of myelin is distinct from that of the oligodendrocyte or Schwann cell plasma membrane from which it is derived (Szuchet et al., 1988).

Although structurally complex, myelin is biochemically quite simple in that it is comprised of relatively few major components. Lipids make up 70 to 85% of the dry weight of compact myelin, depending on the species, with the remainder of the myelin sheath consisting of proteins (15 to 30%) and gangliosides (~0.5%) (Rumsby, 1987; Morell et al., 1989). The proteolipid protein (PLP) and the myelin basic proteins (MBPs) together make up about 80% of the total protein content of compact central nervous system myelin (Morell et al., 1989). In the peripheral nervous system the P0 protein represents more than 50% of the total myelin proteins, while P2 and the MBPs constitute a significant portion (15 to 20%) of the remaining protein content. It is in the multitude of minor myelin proteins, splice products, and posttranslationally modified protein isoforms that the biochemical complexity of myelin is revealed. A number of structural proteins, enzymes, receptors, and second messenger-related proteins are now known to be integral to myelin and are regarded as essential for the normal molecular architecture and function of the compact myelin sheath. The list of myelin-specific and myelin-associated proteins continues to expand as techniques for their detection become increasingly sensitive. This chapter attempts to give the reader an appreciation of the myelin sheath as a complex and dynamic structure that is biochemically quite unlike any other. Proteins that are thought to function primarily in assembly and maintenance of the myelin sheath will be discussed, followed by those demonstrated to have enzymatic activity, receptor activity, association with second-messenger/signal-transduction pathways, or mitogenic activity. Readers unfamiliar with the morphology and molecular architecture of the myelin sheath are encouraged to consult any of several excellent monographs (Braun, 1977; Raine, 1977; Morell et al., 1989; Kirschner and Blaurock, 1992) for detailed treatment of these topics (see also Chapters 40, 41, and 42).

STRUCTURAL PROTEINS

The major proteins of myelin were initially thought to be primarily structural in nature, although recent evidence points to additional roles for these proteins. The major proteins in both central and peripheral nervous systems are myelin-specific, and almost all are known to exist as multiple isoforms derived by alternative splicing (see Chapter 38). These proteins tend to be strongly conserved among the higher vertebrate species, suggesting essential roles in the formation and maintenance of myelin. The distribution and relative abundance of some well-characterized myelin proteins are shown in Table 37-1. Figures 37-1 and 37-2 show the proposed orientation and localization of the major central and peripheral nervous system proteins in myelin.

Myelin Basic Proteins

The MBPs are a group of related protein isoforms derived from alternative splicing of a single gene. The structure and expression of the gene are now known to be considerably more complex than previously thought, resulting in a number of MBP and MBP-related products whose expression is developmentally regulated and not necessarily myelin-specific (see Chapter 38 for detailed discussion). In this chapter we focus on the well-characterized group of myelin-specific MBPs that arise from alternative splicing of exons 2, 5, and 6 of the classical MBP gene (for review see Campagnoni, 1988).

TABLE 37–1. *Distribution and Abundance of Major Myelin Proteins*

Protein	CNS	PNS	References
MBP	30	18	Greenfield et al. (1980)

MOG	0.05	<0.01	Amiguet et al. (1992)

CNS, central nervous system; PNS, peripheral nervous system; MBP, myelin basic protein; PLP, proteolipid protein; MAG, myelin-associated glycoprotein; CNP, cyclic nucleotide phosphodiesterase; PMP22, peripheral myelin protein 22; MOG, myelin/oligodendrocyte glycoprotein.

Values correspond to the average percent of total myelin proteins in the adult mammalian nervous system. See text for localization of each component within myelin.

[a]mRNA encoding the specific protein has been detected, although neither the mRNA nor the protein is believed to exist in appreciable quantity in myelin.

As their name implies, the MBPs are a highly basic group of proteins, with isoelectric points above 10 (Smith, 1992). The diversity that results in this group from exon splicing is augmented by posttranslational modifications that sometimes confer charge heterogeneity. These modifications include loss of C-terminal arginine, *N*-acylation, glycosylation, phosphorylation, methylation, deamidation, and substitution of some arginine residues with citrulline (Toews and Morell, 1987; Morell et al., 1989; R. Smith, 1992). The MBPs are myelin-specific, extrinsic membrane proteins localized to the cytoplasmic

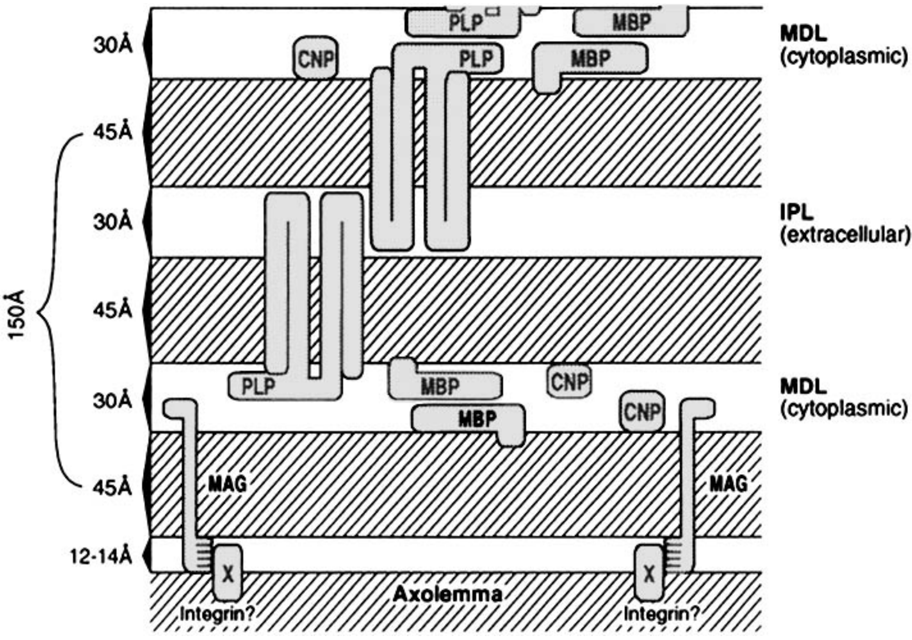

FIG. 37-1. Molecular architecture of central nervous system (CNS) myelin. The proposed orientation and localization of the major CNS myelin proteins are modeled after Lees and Bizzozero, 1992 (PLP); Smith, 1992 (MBP); Mendz, 1992 (MBP); Sprinkle, 1989 (CNP); Tsukada and Kurihara, 1992 (CNP); Salzer et al., 1990 (MAG); Trapp, 1990 (MAG); Quarles et al., 1992 (MAG). MAG is shown in the periaxonal myelin membrane, where it may mediate axon-glia adhesion through interaction with putative integrin receptor family molecules in the axolemma. CNP is concentrated in the inner mesaxon and periaxonal region of CNS myelin, as shown here, as well as in the paranodal compartments and noncompacted oligodendroglial ensheathments. The values for membrane spacing and periodicity are shown on the left and are averages for the CNS myelin of higher vertebrates (Kirschner and Blaurock, 1992). The *cross-hatched* sections represent the axolemma (lower section) or the extensions in the oligodendrocyte membrane (upper three sections). *MDL*, major dense line, *IPL*, intraperiod line; *PLP*, proteolipid protein; *MBP*, myelin basic protein; *CNP*, 2′,3′-cyclic nucleotide 3′-phosphodiesterase; *MAG*, myelin-associated glycoprotein.

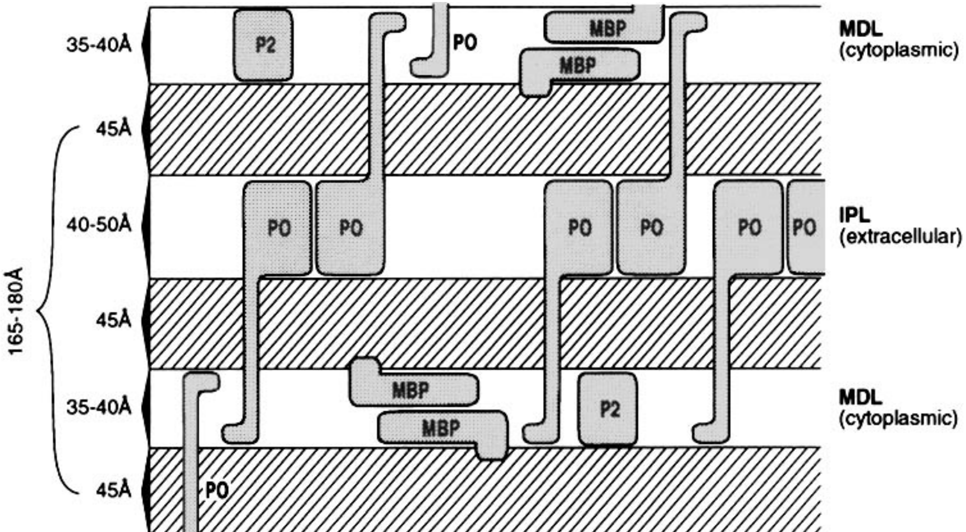

FIG. 37-2. Molecular architecture of peripheral nervous system (PNS) myelin. The proposed orientation and localization of the major PNS myelin proteins are modeled after Smith, 1992 (MBP); Mendz, 1992 (MBP); Kirschner and Blaurock, 1992 (P2 and P0); Colman et al., 1990 (P0); Filbin et al., 1990 (P0); Uyemura et al., 1992 (P0). MAG, not shown here due to its low abundance in PNS myelin, is thought to interact homotypically in the paranodal regions, mesaxon membranes, and Schmidt-Lantermann incisures in a manner similar to that presented here for P0 (see text). The values for membrane spacing and periodicity are shown on the left and are averages for the PNS myelin of higher vertebrates (Kirschner and Blaurock, 1992). The *cross-hatched* sections represent the extensions of the Schwann cell membrane. *MDL,* major dense line; *IPL,* intraperiod line; *MBP,* myelin basic protein.

membrane surface (major dense line) myelin of both the central and peripheral nervous system. The relative abundance of this class of proteins is greater in the central nervous system (~30% of rodent total myelin protein) than in the peripheral nervous system (~18% of rodent total myelin protein) (Greenfield et al., 1980). The abundance of MBPs in peripheral nervous system myelin is significant, suggesting an essential role for this class of proteins outside the central nervous system. However, data from dysmyelinating *shiverer* mutant mice would suggest otherwise. In the *shiverer* mouse, the majority of the MBP gene has been deleted, and MBPs are absent. Hypomyelination is the pathological hallmark of the *shiverer* central nervous system, with some myelin existing in an uncompacted state and lacking a major dense line (Readhead and Hood, 1990). In contrast, the peripheral nervous system of these mutants is relatively unaffected by the absence of MBP, implying that some other component(s), such as P0 or the basic P2 protein (see below), may substitute for MBP and be sufficient for formation of compact peripheral nervous system myelin. However, the relative abundance of MBPs in peripheral nervous system myelin implies a function that may be distinct from, and more subtle than, their role in the central nervous system.

Despite several decades of intense research, we still know relatively little about the precise structure of the MBPs in their native environment or the nature of their interactions with other biological molecules. Several recent reviews have discussed these topics and the problems inherent in their resolution in considerably more detail than can be presented here (Martenson, 1992; Mendz, 1992; Smith, 1992). MBPs appear to self-associate, and this association is promoted by lipids, implying that MBPs may exist as oligomers on the cytoplasmic surface of the myelin membrane (Smith, 1992). Up to one-third of the protein may penetrate between the lipid headgroups in the membrane (Smith, 1992; Mendz, 1992). The binding of a given MBP to an acidic lipid bilayer imposes more secondary structure on the protein than is seen in aqueous solution and also affects the organization of the lipid bilayer (Ong and Yu, 1984; Maggio and Yu, 1989, 1992; Mendz, 1992; Smith, 1992). There may be specific associations between MBPs and such acidic lipids as sulfatides and gangliosides, possibly resulting in stabilization and maintenance of the myelin structure (Ong and Yu, 1984; Maggio and Yu, 1989, 1992; Mendz, 1992). Biophysical studies support the idea that MBPs noncovalently cross-link apposed lipid bilayers in myelin and maintain the characteristic cytoplasmic spacing seen at the major dense line (Smith, 1992). Such studies have also provided clues regarding the possible significance of posttranslational modifications that introduce charge heterogeneity, such as phosphorylation, deamidation, and replacement of arginine residues with citrulline. The ability of the MBP

isomer to compact myelin is positively correlated with the net protein charge (Smith, 1992). Phosphorylation may serve to stabilize the functional ordered structure of the molecule, thus influencing its interaction with membrane lipids (Diebler et al., 1990).

Several models have been proposed for the secondary structure of MBPs (Stoner, 1984, 1990; Martenson, 1986, 1992). Historically, MBPs have not proven amenable to spectroscopic analyses or crystallization for x-ray diffraction studies. In fact, a recent study by Sedzik and Kirschner (1992) indicated that MBP does not possess any crystalline structure. Nonetheless, it has been possible to make predictions about conformation of the native molecule using algorithms that consider primary amino acid and cDNA sequences, the polycationic nature of the posttranslationally modified isomers, and evolutionary conservation of sequences and intron-exon structure (Stoner, 1984, 1990; Martenson, 1986, 1992). Although the details may vary somewhat, these models generally evoke a β-structure in which exon-intron junctions occur near the ends of predicted β-strands that are interrupted by large and small loops (Stoner, 1990). Hydrophobic residues in the large loop regions may mediate MBP insertion between the lipid head groups of the membrane bilayer (Martenson, 1992), while MBP self-association may contribute to myelin spiraling (Stoner, 1990).

Proteolipid Protein and DM20

The PLP is the most abundant protein in central nervous system myelin—about 50% in adult animals—and is absent from peripheral nervous system myelin. PLP is an integral membrane protein with several transmembrane domains. It has a high isoelectric point (>9) and a high content of cysteine residues, both as free thiols and as disulfide bonds (Lees and Bizzozero, 1992). Like many other myelin-specific proteins, the proteolipid proteins of myelin represent a class of proteins that are the products of alternative splicing of a single gene. The predominant isoform has an apparent molecular weight on SDS (sodium dodecyl sulfate) polyacrylamide gels of 25 kD and is commonly referred to as PLP. A second isoform, DM20, migrates during SDS polyacrylamide gel electrophoresis (SDS-PAGE) as a 20 kD band. Resolution of the primary sequences of PLP and DM20 has shown their authentic molecular weights to be 30 kD and 26 kD, respectively (Lees and Bizzozero, 1992; Macklin, 1992). DM20 is identical to PLP except for the deletion of amino acid residues 116–150 (Macklin, 1992). The high abundance of PLP in the myelin membrane and the striking evolutionary conservation of its amino acid sequence point to a critical role in the structure and function of central nervous system myelin.

PLP and DM20 are both acylated, containing covalently linked palmitic, oleic, and stearic acids as the major acyl groups (Toews and Morell, 1987; Lees and Bizzozero, 1992). Acylation appears to be a late posttranslational modification that takes place within myelin at a rapid turnover rate and requires fatty acyl-CoA as the acyl chain donor. The reaction occurs by an autocatalytic process, or autoacylation (Lees and Bizzozero, 1992). Deacylation is directed by a separate, myelin-associated protein fatty acylesterase (Bizzozero et al., 1992). The high content of acyl chains (2 to 2.4% by weight) may contribute to the interaction of PLP with the lipid bilayer of myelin (Toews and Morell, 1987).

The orientation of PLP in the myelin membrane has been examined using chemical and immunological approaches, but the data remain inconclusive. Different topographical models postulate from 2 to 4 membrane-spanning domains with extramembranous domains situated in both the cytoplasmic and extracellular spaces (Stoffel et al., 1984; Hudson et al., 1989; Lees and Bizzozero, 1992). The extracellular domains may be instrumental in stabilizing the intraperiod line of myelin (Morell et al., 1989). Functional studies using reconstituted membrane systems support an active role for PLP as an ion channel (Toews and Morell, 1987; Lees and Bizzozero, 1992). Clarification of the exact conformation of the protein in the intact myelin sheath will no doubt assist in defining its function.

DM20 is a relatively minor product of the PLP gene. However, recent studies have uncovered an intriguing pattern of DM20 developmental expression and tissue specificity. DM20 is expressed earlier in development than PLP and is in fact the major PLP gene product in the developing embryo (Macklin, 1992; Ikenaka et al., 1992; Timsit et al., 1992). Although neither gene product is readily detectable in peripheral nervous system myelin, both PLP and DM20 appear to be expressed in very low levels in Schwann cells in the peripheral nervous system (Puckett et al., 1987; Ikenaka et al., 1992). DM20 expression has been demonstrated in nonglial cell types as well (Campagnoni et al., 1992; Ikenaka et al., 1992). The appearance of DM20 in "premyelinating" glial cells and in cells outside the glial cell lineage suggests that this protein has a function(s) unrelated to myelination. Data from studies using dysmyelinating mutant animals point to a unique role for DM20 in glial cell differentiation (Macklin, 1992; Schneider et al., 1992). Almost all mutations identified in the PLP gene thus far are characterized

by hypomyelination as well as by oligodendrocyte degeneration and death (Hudson, 1990; Macklin, 1992). There is, however, a point mutation in the PLP gene of *rumpshaker* mice that results in hypomyelination without glial cell death (Schneider et al., 1992). Although sparse, some myelin sheaths subsist in the *rumpshaker* mutants and these showed selective immunostaining for DM20 using antibodies specific for PLP alone or PLP plus DM20 (Schneider et al., 1992). These findings suggest that DM20 may serve a critical purpose in glial cell development that is distinct from any function in myelin formation and maintenance.

Myelin-Associated Glycoproteins

The myelin-associated glycoproteins (MAGs) are heavily glycosylated and are specific to myelin sheaths. Although this class of proteins is relatively minor (1% of central nervous system/0.1% of peripheral nervous system myelin proteins) as compared to the MBP and PLP gene products, MAG is highly concentrated in the periaxonal regions of both central and peripheral nervous system myelin. In the peripheral nervous system, MAG immunostaining is also seen in glial membranes of the Schmidt-Lantermann incisures, paranodal loops, and mesaxons (Trapp, 1990). MAG is not seen within the compact myelin sheath in either the central nervous system or peripheral nervous system. This distribution pattern is consistent with the postulated role of MAG in membrane-membrane interactions during myelin formation and maintenance (Morell et al., 1989; Salzer et al., 1990; Quarles et al., 1992).

MAG derived from the central nervous system migrates as a single broad band of ~100 kD during SDS-PAGE. Enzymatic deglycosylation of the sample resolves this band into two equally intense bands with apparent molecular weights of 72 and 67 kD (Salzer et al., 1990; Quarles et al., 1992). Biochemical and molecular studies have revealed that the latter two bands represent two isoforms of MAG (L-MAG and S-MAG, respectively) that are derived by alternative splicing from a single gene. The MAGs have a carbohydrate content of ~30% (Quarles et al., 1992), with eight potential *N*-linked glycosylation sites predicted by the cDNA structure (Trapp, 1990). The complete structures of the carbohydrate side chains are unknown, but it is believed that they possess the HNK-1/L1 (or sulfated glucuronic acid [SGA]) epitope present in many cell adhesion molecules. The primary sequences of the MAGs predict a single transmembrane domain, a large extracellular domain that contains five IgG-like disulfide loop regions and the eight glycosylation sites, and C-terminal cytoplasmic domains with potential phosphorylation sites (Trapp, 1990; Quarles et al., 1992). The C-termini of L-MAG and S-MAG differ as a result of an earlier translation termination codon in S-MAG mRNA (Quarles et al., 1992). L-MAG is produced almost exclusively in the central nervous system, and is the predominant variant during early development and active myelination (Campagnoni, 1988; Trapp, 1990). S-MAG is the major isoform in the adult central nervous system and in the peripheral nervous system at all ages. Differences in phosphorylation and other posttranslational modification may be responsible for the differences observed in MAG distribution in central nervous system and peripheral nervous system, perhaps by mediating interaction with the cytoskeleton (Quarles et al., 1992; Trapp, 1990). Other posttranslational modifications of the MAGs include sulfation of oligosaccharide moieties and acylation of the transmembrane domain (Quarles et al., 1992).

The MAGs are members of the immunoglobulin superfamily by virtue of the extracellular immunoglobulin domains seen in both isoforms. Other members of the immunoglobulin superfamily include nervous system molecules that are involved in cell-cell adhesion, such as neural cell adhesion molecule (N-CAM) (Salzer et al., 1990; Trapp, 1990; Quarles et al., 1992). Another feature of the extracellular domain that is common to both L-MAG and S-MAG is the tripeptide sequence Arg-Gly-Asp (RGD) found in other cell recognition molecules as part of a binding site for the integrin receptor family (Salzer et al., 1990). All membranes that are enriched in MAG appose other membranes by a space of 12 to 14 nm (Trapp, 1990). The structure and localization of MAG thus strongly connote possible function in cell adhesion and membrane spacing (Trapp, 1990). Homotypic interaction may be operational in Schmidt-Lantermann incisures, paranodal loops, and mesaxon membranes in peripheral nervous system myelin, while heterotypic interactions with axolemmal constituents may mediate glia-axon adhesion (Salzer et al., 1990; Trapp, 1990; Quarles et al., 1992).

P0 Protein

The 28 kD P0 glycoprotein accounts for more than 50% of myelin protein in the peripheral nervous system, where it is an integral membrane protein expressed exclusively by myelinating Schwann cells (Kitamura et al., 1976; Uyemura and Kitamura,

1991; Uyemura et al., 1992). The location and abundance of P0 in peripheral nervous system myelin have led to speculation that P0 is the counterpart of PLP, even though the biochemical and physical characteristics of these two proteins are quite different. In contrast to other major myelin proteins, only one transcription product has been identified for the P0 gene.

Like MAG, P0 belongs to the immunoglobulin superfamily and is thought to play a role in adhesion between adjacent membranes. The predicted orientation of P0 in the myelin membrane resembles that postulated for MAG: a positively charged cytoplasmic C terminus is followed by a transmembrane domain and an extracellular glycosylated N-terminal region that bears a single immunoglobulinlike domain with a characteristic intradomain disulfide bond (Uyemura et al., 1992). In addition to glycosylation, the P0 protein undergoes phosphorylation, sulfation, and acylation (Uyemura and Kitamura, 1991; Uyemura et al., 1992). Unlike MAG, the P0 protein does not contain an RGD sequence and is found in compact myelin rather than localized to the axon-glia interface. These features point to a role for P0 in homotypic interactions across the intraperiod line.

Research using transfected cells that express P0 protein supports the idea that P0 serves as a homophilic adhesion molecule (Colman et al., 1990; Filbin et al., 1990). In this model, P0 molecules in adjacent layers of myelin would interact to bridge the extracellular space and form the intraperiod line. On the cytoplasmic membrane surface, the positively charged intracellular domain may interact with acidic membrane lipids to help form the major dense line (Uyemura and Kitamura, 1991; Uyemura et al., 1992). Recently, two groups independently demonstrated that mutation in the human P0 gene is associated with Charcot-Marie Tooth disease type 1B, an inherited peripheral nervous system neuropathy (Hayasaka et al., 1993; Kulkens et al., 1993).

P2 Protein

The P2 protein is a basic 14 kD peripheral membrane protein that is enriched in peripheral nervous system relative to central nervous system myelin (Uyemura and Kitamura, 1991). Despite the superficial similarity to the MBPs, there is no primary sequence homology between P2 and MBPs (Uyemura and Kitamura, 1991; Narayanan et al., 1988). However, the abundance of MBPs and P2 in peripheral nervous system myelin seem to be interdependent, in that the peripheral nervous system content of each protein varies among mammalian species, but the cumulative content of the MBPs plus P2 is relatively constant (Uyemura and Kitamura, 1991). This reciprocal relationship implies that the MBPs and P2 may be functionally related. P2 content ranges from less than 1% of peripheral nervous system myelin protein in rats and mice to approximately 15% of bovine peripheral nervous system myelin protein (Morell et al., 1989). Like the MBPs, P2 is localized to the cytoplasmic side of the myelin membrane and is thus a good candidate for a role in formation and maintenance of the major dense line (Morell et al., 1989; Uyemura and Kitamura, 1991; Martenson and Uyemura, 1992). There is, in fact, a direct correlation between the P2 content and the width of the cytoplasmic space in peripheral nervous system myelin in different species (Kirschner and Blaurock, 1992). The phylogenetic conservation of P2 is slightly higher than that of the MBPs (Uyemura and Kitamura, 1991; Martenson and Uyemura, 1992).

A distinct physiological role for P2 is suggested by its striking homology with the family of lipid-binding proteins that includes cellular retinoic acid-binding protein, cellular retinol-binding protein, and fatty acid-binding protein (Narayanan et al., 1988; Martenson and Uyemura, 1992). Indeed, high-affinity binding of bovine P2 with oleic acid, retinoic acid, and retinol has been observed (Uyemura et al., 1984). Thus, the P2 protein may be involved in solubilization and/or transport of fatty acids in myelin (Martenson and Uyemura, 1992).

PMP22/PASII

Kitamura and coworkers (1976) isolated an acid-insoluble peripheral nervous system-specific glycoprotein designated PASII, based on its electrophoretic properties and staining with periodic acid-Schiff reagent. The bovine PASII was characterized as an integral membrane protein containing glucosamine, mannose, galactose, fucose, and glucose and was further observed in peripheral nerve myelin from a number of species (Kitamura et al., 1976). More than a decade later, differential screening of cDNA libraries prepared from the distal stump of a crushed sciatic nerve and the normal contralateral nerve led to identification of a rat mRNA that is repressed in the injured nerve stump but present at high levels in naive rat sciatic nerve (De Leon et al., 1991). The protein encoded by this mRNA, designated PMP22 (peripheral myelin protein 22), is present in compact peripheral nervous system myelin as ~5 to 10% of total myelin protein (Snipes et al., 1992) and has been implicated in growth arrest (Welcher et al.,

1991; Suter et al., 1992). PMP22 and PASII are now known to be identical (Welcher et al., 1991; Snipes et al., 1992). The PMP22 mRNA sequence predicts an 18 kD protein with an *N*-linked glycosylation site that accounts for the observed molecular mass of 22 kD (Welcher et al., 1991). Although the mRNA has been detected in brain, no PMP22 protein has been observed in the central nervous system (Snipes et al., 1992). Mutation in the gene encoding this protein is responsible for the *trembler* mutation in mouse, which is characterized by severe hypomyelination and continuing Schwann cell proliferation throughout life (Suter et al., 1992). Mutation in the PMP22/PASII gene is also implicated in Charcot-Marie-Tooth disease type 1A (not to be confused with CMT type 1B, an apparent P0 protein-associated defect; see above) (Valentijn et al., 1992a, 1992b).

Myelin/Oligodendrocyte Glycoprotein

Myelin/oligodendrocyte glycoprotein (MOG) is a central nervous system-specific glycoprotein (Linington et al., 1984) representing ~0.05% of myelin proteins (Amiguet et al., 1992). SDS-PAGE of purified MOG reveals a doublet at 26 to 28 kD and a minor band at ~51 kD. Enzymatic deglycosylation results in a single band at ~25 kD, indicating that the 26 and 28 kD proteins represent differentially glycosylated products that may form dimers (Amiguet et al., 1992). Immunocytochemistry has localized MOG to the extracellular surface of myelin sheaths and oligodendrocytes (Brunner et al., 1989). The distribution pattern and the observation that MOG appears late in development relative to other myelin proteins (Matthieu and Amiguet, 1990) suggest that it might signal cessation of further myelination. The primary sequence of the rat mRNA encoding MOG has been determined (Gardinier et al., 1992). The deduced amino acid sequence places MOG in the immunoglobulin superfamily of proteins and predicts two transmembrane domains, unique among the immunoglobulin superfamily members, with a single immunoglobulinlike domain and *N*-linked glycosylation site on the extracellular membrane surface (Gardinier et al., 1992). MOG displays significant sequence homology with bovine butyrophilin, an acidic membrane glycoprotein that may serve as a lipid receptor. The sequence analysis thus connotes a potential recognition role for MOG in lipid interactions in myelin (Gardinier et al., 1992).

Myelin/Oligodendrocyte-Specific Protein

Like MOG and PLP, myelin/oligodendrocyte-specific protein (MOSP) is an integral membrane protein that is specific to central nervous system myelin. Monoclonal antibody studies show that MOSP, a 48 kD protein with a pI of 6.7, is abundantly expressed on the oligodendrocyte cell surface (Dyer et al., 1991). Moreover, specific antibody binding to cultured oligodendrocyte membrane sheets causes MOSP to redistribute directly over cytoplasmic microtubules to which cyclic nucleotide phosphodiesterase is colocalized (Dyer and Matthieu, 1993). MOSP is capable of transducing signals that result in an increase in microtubular structures within oligodendrocytes; this is the only surface membrane component known to date that has these signaling capabilities in oligodendrocytes (Dyer, 1993). Thus, MOSP may be critical to membrane-cytoskeleton interactions during assembly and maintenance of myelin (Dyer et al., 1991).

MYELIN-ASSOCIATED ENZYMES

In the past, myelin was believed to be metabolically inert and to function mainly as an electrical insulator that plays an important role in facilitating nerve conduction. This concept was derived from metabolic studies showing that myelin was the most stable component among brain subcellular fractions, and was consistent with initial reports demonstrating that isolated myelin preparations contained no enzyme activity except leucine aminopeptidase (Adams et al., 1966). However, since the discovery of 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNP) in purified myelin preparations (Kurihara and Tsukada, 1967), much attention has been directed toward enzymes intrinsic to myelin and their physiological significance. To date, the existence of more than 40 different enzyme activities in central nervous system myelin has been reported. The finding of this vast array of myelin-associated enzymes has forged the concept that myelin is not only an electrical insulator, but also may carry out active metabolism with its intrinsic enzyme activities. Indeed, it has been shown that lipid and protein components in myelin have measurable turnover rates and are subjected to metabolic turnover even after the period of active myelination (Smith, 1968; Horrocks, 1969; Benjamins and Smith, 1977; Miller et al., 1977; Ando et al., 1984). Recent studies have demonstrated that myelin membranes possess receptor and signal transduction activities, including high-affinity muscarinic cholinergic receptors (Larocca et al., 1987a) and G proteins (Bernier et al., 1989; Boulias and Moscarello, 1989; Braun et al., 1990b; Larocca et al., 1990, 1991), in addition to related enzyme activities such as adenyl cyclase, phospholipases, and enzymes involved in phosphoinositide

metabolism (see below). Evidence for the possible linkage between these receptors and formation of second messengers in myelin has also been presented. For example, treatment of myelin with effectors for cholinergic receptors caused the hydrolysis of phosphoinositide-4,5-bisphosphate (PIP_2) (Larocca et al., 1988) or G proteins (Golly et al., 1990). These findings imply that myelin membranes may respond to neurotransmitter and/or hormonal signals from the environment.

Table 37-2 summarizes the myelin-associated enzymes reported to date. In this section the localization, properties, developmental profiles, and physiological significance of these enzymes will be discussed. For further information, the reader is referred to several excellent reviews (Suzuki, 1980; Norton, 1981; Norton and Cammer, 1984; Ledeen, 1992).

2′,3′-Cyclic Nucleotide 3′-Phosphodiesterase

CNP is a myelin-associated enzyme that hydrolyzes 2′,3′-cyclic nucleotides to produce exclusively 2′-nucleotides (Sprinkle, 1989; Tsukada and Kurihara, 1992). However, no physiologically relevant substrate for CNP has yet been found in myelin, despite many frustrating searches. The current view is that the enzymatic activity may be vestigial and unrelated to the functional significance of the molecule in myelin (Braun et al., 1990a; Tsukada and Kurihara, 1992). For this reason, CNP may be considered with those myelin proteins thought to play primarily an architectural role, with the caveat that the authentic function of CNP in myelin is as yet unknown.

CNP is the principal component of the Wolfgram protein fraction of myelin, comprising ~4% of central nervous system myelin proteins. The enzyme is unique to oligodendrocytes in the central nervous system, but is found in peripheral nervous system myelin in lower abundance (~0.4%) and in other cell types outside the nervous system at very low levels of activity (Vogel and Thompson, 1988; Sprinkle, 1989; Tsukada and Kurihara, 1992). SDS-PAGE of purified CNP under reducing conditions resolves two bands with apparent molecular weights between 43 and 48 kD, depending on the species studied (Müller et al., 1981; Müller, 1982; Tsukada and Kurihara, 1992). These isoforms have been designated CNP1 and CNP2, respectively. The enzyme is posttranslationally modified by phosphorylation and by acylation of the N-terminal serine residue (Sprinkle, 1989). Molecular cloning studies have revealed that two rodent CNP mRNAs, differing in their 5′ ends, are derived by alternative splicing (Kurihara et al., 1990; 1992). CNP appears early in development, prior to myelination (Braun et al., 1990a), and is maintained at high levels throughout myelin formation and maintenance (Vogel and Thompson, 1988; Tsukada and Kurihara, 1992). Most studies suggest a cytoplasmic localization for CNP (Vogel and Thompson, 1988). Although CNP copurifies with myelin membranes, it is not observed in compact myelin (Sprinkle, 1989; Braun et al., 1990a; Tsukada and Kurihara, 1992). Instead, it is highly concentrated in the paranodal compartments, periaxonal membrane, inner mesaxon, and noncompacted oligodendroglial ensheathements (Sprinkle, 1989; Braun et al., 1990a). Although interspecies variation in CNP sequence is relatively low, there seems to be more evolutionary tolerance for mutation in CNP than in MBP or PLP (Tsukada and Kurihara, 1992).

A number of putative functions have been proposed for CNP, including a role in tRNA ligase reactions, cell adhesion, or kinase reactions (reviewed by Vogel and Thompson, 1988; Sprinkle, 1989; Tsukada and Kurihara, 1992). CNP has been shown to colocalize with cytoskeletal elements (Dyer and Benjamins, 1989; Braun et al., 1990a) and appears to self-associate in dimers or perhaps higher order oligomers (Vogel and Thompson, 1988; Braun et al., 1990a). These features are consistent with the notion that CNP may be a key component in an interactive protein network within the glial cell. A compelling line of evidence for a putative CNP function involves isoprenylation of CNP1 at a C-terminal cys-X-X-X-COOH site (Braun et al., 1991). Transfection studies have been performed using nonmyelinating mammalian cells and cDNAs encoding either wild-type CNP or a cys→ser mutant of CNP that cannot be isoprenylated. These studies have shown that only the wild-type protein causes these cells to extend filopodia and processes. Moreover, only the wild-type protein is localized to the cell membrane, whereas the cys→ser mutant CNP remains cytoplasmic (Gravel et al., 1993). These intriguing data suggest a possible role for CNP in oligodendrocyte process extension. Other proteins known to be isoprenylated at the C-terminus, such as *ras* proteins and some G protein subunits, are associated with signal transduction pathways (Braun et al., 1991). The presence in CNP of potential nucleotide-binding domains (Sprinkle, 1989) further strengthens the hypothesis that CNP may exert a regulatory influence on cellular events such as growth and differentiation by serving as part of a bridge between extracellular signals and intracellular effector molecules.

Cholesterol Ester Hydrolase

Eto and Suzuki (1973a) first reported that rat brain contained three different cholesterol ester hydrolase

TABLE 37–2. *Myelin-Associated Enzymes*

Enzyme	Reference
Unknown substrate	
2′,3′-Cyclic nucleotide-3-phosphodiesterase (CNPase)	Kurihara and Tsukada (1967); Sims and Carnegie (1978); Sprinkle et al. (1978, 1989); Wells and Sprinkle (1981); Vogel and Thompson (1988); Trapp et al. (1988); Agrawal et al. (1990)
Sterol metabolism	
Cholesterol ester hydrolase (cholesterol esterase)	Eto and Suzuki (1971, 1973a, 1973b); Johnson and Shah (1986)
Cholesterol ester synthetase (cholesterol acyltransferase)	Choi and Suzuki (1978); Jagannatha and Sastry (1981)
Testosterone 5α-reductase	Melcangi et al. (1988)
Glycolipid (or glycoprotein metabolism)	
UDP-galactose:ceramide galactosyltransferase	Nescovic et al. (1973); Costantino-Ceccarini and Suzuki (1975); Koul et al. (1980, 1981); Roussel et al. (1987)
Neuraminidase (sialidase)	Yohe et al. (1983, 1986); Saito and Yu (1986, 1992a, 1992b)
Phospholipid-synthesis	
Ethanolamine kinase	Kunishita et al. (1987b)
CTP:phosphoethanolaminecytidyltransferase	Kunishita and Ledeen (1984)
CDP-ethanolamine:1,2-diacylglycerol phosphoethanolamine transferase	Wu and Leeden (1980)
Choline kinase	Kunishita et al. (1987a)
CDP-choline:1,2-diacylglycerol phosphocholine transferase	Ledeen and Wu (1979)
Long-chain acyl-CoA synthase	Vaswani and Ledeen (1987)
Acyl-CoA:lysophospholipid acyltransferase	Vaswani and Ledeen (1989a)
ATP:1,2-diglycerol 3-phosphotransferase (diglyceride kinase)	Kahn and Moorell (1988)
Phospholipid catabolism	
Phosphatidate phosphatase (phosphatidic acid phosphatase)	Vaswani and Ledeen (1989b)
Phospholipase C toward phosphatidylcholine	Kanfer and McCartney (1989a, 1989b)
Phospholipase D toward phosphotidylcholine	Ledeen and Golly (1991)
Phosphoinositide metabolism	
ATP:phosphatidylinositol 4-phosphotransferase (PI kinase)	Deshmukh et al. (1978, 1981); Saltiel et al. (1987)
ATP:phosphatidylinositol-4-phosphate 5-phosphotransferase (PIP kinase)	Deshmukh et al. (1978, 1981)
Polyphosphoinositide phosphomonoesterases (PIP and PIP_2 phosphomonoesterases)	Deshmukh et al. (1982); Larocca et al. (1988); Palmer (1990)
Phospholipase C toward polyphosphoinositides	Deshmukh et al. (1982); Palmer (1990)
Membrane Transport	
Carbonic anhydrase	Cammer et al. (1976, 1977); Yandrasitz et al. (1976); Sapirstein and Lees (1978); Sapirstein et al. (1978)
Na^+,K^+-ATPase	Reiss et al. (1981); Zimmerman and Cammer (1982); Mrsuja et al. (1985)
5′-Nucleotidase	Kreutzberg et al. (1978); Cammer et al. (1980); Cammer and Zimmerman (1981); Heymann et al. (1984); Casado et al. (1988a, 1988b)
Protein metabolism	
Calcium-activated neutral protease (CANP or calpain)	Sato et al. (1982); Banik et al. (1985, 1991); Bertlet (1987); Yanagisawa et al. (1988); Chakrabarti et al. (1988, 1990a, 1990b)
Leucine aminopeptidase	Banik and Davidson (1969)
Acid protease	Bertlet et al. (1988)
Metalloproteinase	Chantry et al. (1989)
Protein kinase A	Johnson et al. (1971); Carnegie et al. (1973); Miyamoto and Kakiuchi (1974); Miyamoto (1975); Wu and Ahmad (1984); Bradbury et al. (1984)

(*Table continued on next page*)

TABLE 37–2. *Continued*

Enzyme	Reference
Protein kinase C	Turner et al. (1982, 1984); Kim et al. (1986); Murray and Steck (1986); Agrawal et al. (1990)
CA^{2+}-dependent, camodulin-stimulated kinase	Sulakhe et al. (1980a, 1980b); Endo and Hidaka (1980)
Myelin basic protein kinase	Yang (1986)
Ganglioside-stimulated kinase	Chan (1987)
Phosphorylated MBP phosphatase	Miyamoto and Kakiuchi (1974); MacNamara and Appel (1977); Wu et al. (1980); Yang et al. (1987)
Myelin basic protein (arginine) methyltransferase	Amur et al. (1986)
PLP fatty acyltransferase	Bizzozero et al. (1984); Konat et al. (1986); Ross and Braun (1988)
Acyl-proteolipid protein fatty esterase	Bizzozero et al. (1991, 1992)
Signal transduction-related	
Adenylate cyclase	Larocca et al. (1987a)
Phospholipases C and D	Kanfer and McCartney (1989a, 1989b); Ledeen and Golly (1991)
Others	
Esterase (nonspecific)	Rumsby et al. (1973); Tada et al. (1986)
Glutathione-*S*-transferase	Tansey and Cammer (1991)

activities: (1) lysosomal enzyme with lower optimal pH, (2) microsomal enzyme with optimal pH of 6.0, and (3) myelin-associated enzyme with an optimal activity at pH 7.2. The myelin enzyme was discriminated from the microsomal enzyme by their detergent requirement. The developmental profile of the myelin enzyme correlated with the accumulation of myelin (Eto and Suzuki, 1973b). Differing from most myelin-associated enzymes, cholesterol ester hydrolase activity in spinal cord myelin increases much more rapidly during early development and reaches the adult level three times higher as compared with that in brain myelin (Eto and Suzuki, 1973b). About 60 to 70% of the enzyme activity at pH 7.2 in whole brain was recovered in the myelin preparation with a 10-fold increase in relative specific enzyme activity. These results strongly suggest that cholesterol ester hydrolase is a specific marker enzyme for myelin. On the other hand, a recent study with rat, mouse, and human brains demonstrated that the enzyme activities in myelin and microsomes could not be distinguished from each other in respect to pH optimum and detergent and phospholipid requirement (Johnson and Shah, 1986). Thus, the specificity of the myelin enzyme remains to be determined.

UDP-Galactose:Ceramide Galactosyltransferase

UDP-galactose:ceramide galactosyltransferase is an enzyme that catalyzes the transfer of galactose to ceramide to synthesize galactosyl ceramide, one of the major lipid components in myelin. This enzyme activity was detected in myelin as well as microsomal fractions with similar specific activities (Nescovic et al., 1973; Constantino-Ceccarini and Suzuki, 1975). The presence of an intrinsic galactosyltransferase activity in myelin has been demonstrated by fractionation (Koul et al., 1980; Lees and Sapirstein, 1983) and immunocytochemical studies (Roussel et al., 1987). While both myelin and microsomal enzymes exhibited similar enzymatic properties, their developmental patterns differ from each other; the activity of myelin enzyme increases with active myelination and decreases thereafter to the adult level (Brenkert and Radin, 1972; Constantino-Ceccarini and Morell, 1972; Koul et al., 1980). The developmental profiles of the enzyme activity in different central nervous system regions appear to correspond with the timing of myelin deposition in these regions (Koul and Jungawala, 1986; Monge et al., 1988). Recently, it has been demonstrated that the enzyme activities directed toward HFA- and NFA-ceramides have different intracellular and myelin distribution in rat brain tissues, implying that these two activities may be catalyzed by different enzyme entities (Sato et al., 1988).

Neuraminidase (Sialidase)

Neuraminidase catalyzes the cleavage of terminal sialic acid residues from glycoconjugates such as sialoglycoproteins and gangliosides and plays a key role in the catabolism of these sialoglycoconjugates. The existence of an intrinsic neuraminidase activity in brain myelin was first suggested by Yohe et al. (1983) and, thereafter, characterized using a ganglio-

side (GM3) and nonganglioside substrates (*N*-acetylneuramin-lactitol) (Saito and Yu, 1986; Yohe et al., 1986). The enzyme activities directed toward these two substrates have been assumed to be catalyzed by a single enzyme (Saito and Yu, 1986). It is interesting that the enzyme can slowly hydrolyze GM1, which is usually resistant to most viral and bacterial neuraminidases. This finding is consistent with observations such as the slow turnover of GM1 in myelin (Suzuki, 1970; Ando et al., 1984) and the existence of asialo-GM1 in myelin (Kusunoki et al., 1986). The enzyme activities in myelin increase during active myelination, followed by a sharp decline to the adult level (Saito and Yu, 1992). Differing from central nervous system myelin, the neuraminidase is hardly detected in sciatic nerve myelin (Yohe et al., 1986). A study on the hydrolysis of membrane gangliosides by endogenous neuraminidase in myelin provided evidence that myelin-associated neuraminidase may play a critical role in the developmental changes in myelin gangliosides (Saito and Yu, 1992). It has also been suggested that the enzyme may function as a membrane adhesion molecule because a specific interaction exists between the enzyme and GM1 and there is a specific adhesion of oligodendroglial cells to GM1 (Saito and Yu, 1993). Thus, the myelin-associated neuraminidase not only plays a critical role in ganglioside metabolism in myelin, but also may be involved in the formation and maintenance of the myelin structure.

Phospholipid-Synthesizing Enzymes

Myelin contains a variety of enzymes involved in the synthesis and degradation of phospholipids. Regarding phospholipid-synthesizing enzymes, myelin has been shown to contain a set of enzyme activities that are required for the synthesis of phosphatidylethanolamine (PE). The first enzyme to be discovered was CDP-choline:1,2-diacylglycerol phosphoethanolamine transferase, which catalyzes the final step of PE synthesis (Wu and Ledeen, 1980). Additional enzymes required for PE synthesis are ethanolamine kinase and CTP:phosphoethanolaminecytidyltransferase, and both have been shown to be associated with the myelin membrane (Kunishita and Ledeen, 1984; Kunishita et al., 1987a). These findings suggest that PE can be synthesized *in situ* in central nervous system myelin. Myelin is also capable of carrying out the biosynthesis of phosphatidylcholine, as suggested by the existence of enzyme activities such as choline kinase (Kunishita et al., 1987b) and CDP-choline:1,2-diacylglycerol phosphocholine transferase (Ledeen and Wu, 1979).

Long-chain acyl-CoA synthetase is required for acylation in phospholipid synthesis and has been found in myelin (Vaswani and Ledeen, 1987). This enzyme can utilize oleic and arachidonic acids as the substrates. Acyl-CoA:lysophospholipid acyltransferase in myelin catalyzes the transfer of acyl chains to various type of lysophosphatidylphospholipids, especially lysophosphatidylcholine (Vaswani and Ledeen, 1989a). Regarding the metabolism of diglyceride, a metabolic study with ^{32}P-phosphate and ^{3}H-glycerol suggested the existence of ATP:1,2-diacylglycerol 3-phosphotransferase (diglyceride kinase) activity in myelin (Kahn and Morell, 1988). Evidence has been presented that the radiolabeled phosphatidic acid in myelin, an important metabolite in the phospholipid signal transduction pathway, may be generated mainly by phosphorylation of diglyceride, which is supplied through the breakdown of polyphosphoinositides by phospholipase C. This hypothesis is supported by the finding that addition of acetylcholine stimulates the formation of phosphatidic acid (Kahn and Morell, 1988).

Phospholipid-Catabolizing Enzymes

Phosphatidic acid phosphatase plays a key role in phospholipid metabolism in that it provides diacylglycerol (diglyceride), which is an essential intermediate in the synthesis of phospholipids. The activity of this enzyme has been found in rat brain myelin (Vaswani and Ledeen, 1989b). Myelin also contains a phospholipase C activity that hydrolyzes phosphatidylcholine, generating diacylglycerol and phosphorylcholine. The specific activity of this enzyme was about threefold higher than that in brain homogenate (Kanfer and McCartney, 1989a, 1989b). The existence of phospholipase D activity directed toward phosphatidylcholine has also been reported recently (Ledeen and Golly, 1991).

Phosphoinositide-Metabolizing Enzymes

Myelin contains a relatively high level of polyphosphoinositides (Hauser et al., 1971; Eichberg and Hauser, 1973). The distribution of phosphoinositides in the myelin sheath may be different for the various phosphoinositide species; phosphatidylinositol is distributed evenly in three myelin subfractions, while phosphatidylinositol-4-phosphate (PIP) and phosphatidylinositol-4,5-bisphosphate (PIP_2) are concentrated in the light myelin fraction (Deshmukh et al., 1980). Metabolic studies with ^{32}P-phosphate have indicated that the phosphate groups of phosphoinositides in myelin undergo rapid turnover

(Deshmukh et al., 1981; Kahn and Morell, 1988). These findings suggest the existence of synthetic and degradative activities for phosphoinositides in myelin. Phosphatidylinositol and phosphatidylinositol-4-phosphate (PIP) kinase activities, which catalyze the formation of PIP and PIP_2, respectively, have been detected in purified myelin (Schacht, 1976); both kinase activities are highest in the heavy myelin fraction although appreciable levels are also present in other subfractions (Deshmukh et al., 1978). Phosphatidylinositol kinase has recently been purified from bovine brain (Saltiel et al., 1987).

As for enzyme activities responsible for the degradation of phosphoinositides, relatively high levels of PIP and PIP_2 phosphomonoesterase activities have been detected in myelin (Deshmukh et al., 1982). The activities directed toward PIP and PIP_2 show different developmental profiles, suggesting that they may be ascribed to distinct enzyme entities (Palmer, 1990). Myelin contains both activities of phospholipase C directed toward PIP and PIP_2, generating inositol 1,4-phosphate (IP_2) and inositol 1,4,5-triphosphate (IP_3), respectively (Keough and Thompson, 1970; Deshmukh et al., 1982). These activities may play an important role in signal transduction in myelin.

Transport-Related Enzymes

It has been suggested that ion transport is an important process in the myelin membrane and may be involved in many physiological functions of the membrane. The myelin membrane has been shown to possess ion transport mechanisms (de Cozar et al., 1987; Robertson et al., 1989) including K^+-channels (Morell et al., 1990). Of several components of myelin, proteolipid proteins may function as ionophores and may be involved in the ion transport processes (Ting-Beall et al., 1979; Helynck et al., 1983). Lees and Sapirstein (1983) have proposed that carbonic anhydrase and Na^+,K^+-ATPase may play an important role in controlling K^+ levels at the node of Ranvier. It has also been demonstrated that these two enzymes are involved in transmembrane movement of fluid in many cells. This may be the case for myelin, as suggested by a recent study demonstrating that acetazolamide, an inhibitor of carbonic anhydrase, improves edema-induced vacuolar degeneration of brain myelin induced by triethytin (Yanagisawa et al., 1990).

Carbonic anhydrase is an enzyme that catalyzes formation of carbonic acid (H_2CO_3) from CO_2 and H_2O. Since neurons are practically devoid of this enzyme activity, the myelin enzyme may play a role in the removal of CO_2 that is produced in excess during elevated neuronal activity. The generated carbonic acid is dissociated into bicarbonate (HCO_3^-) and proton (H^+) at physiological pH, forming the proton gradient across the membrane (Giacobini, 1987). In brain tissues, carbonic anhydrase exists in both soluble and membrane-bound forms (Sapirstein et al., 1978). The enzyme is located in myelin (Cammer et al., 1976, 1977; Sapirstein and Lees, 1978) in addition to astroglial and oligodendroglial cells (Ghandour et al., 1979; Kumpulainen and Korhonen, 1982; Cammer and Tansey, 1988a, 1988b). Among myelin subfractions, the medium and heavy myelin are more enriched with the enzyme activity (Sapirstein et al., 1978). Myelin-associated carbonic anhydrase having an apparent molecular weight of 30 kD has enzymatic and immunological properties similar to the type C isoenzyme isolated from erythrocytes.

Na^+,K^+-ATPase plays a crucial role in the Na^+-K^+ pump mechanism. While previous studies have detected a Na^+,K^+-ATPase activity in isolated myelin, this activity has been attributed to contaminating membranes mainly because of the low recovery of the activity in myelin and relatively low specific activity (Norton and Poduslo, 1973; DeVries et al., 1978; Danks and Matthieu, 1979). Thereafter, evidence has been accumulated suggesting that this enzyme activity is intrinsic to myelin (Zimmermann and Cammer, 1982). Na^+,K^+-ATPase activity in myelin could be distinguished from that in microsomes in respect to effects of detergent, discontinuous temperature for activity, and affinity to strophantidin (Reiss et al., 1981). A discrepancy between developmental profiles of the enzyme activities in myelin and brain homogenates also supports the existence of the enzyme activity intrinsic to myelin (Zimmermann and Cammer, 1982). These results are strongly supported by an immunocytochemical study demonstrating the presence of K^+-dependent *p*-nitrophenylphosphatase (K^+-NPPase) activity, a component of the Na^+,K^+-ATPase complex, in myelin (Mrsulja et al., 1985). The enrichment of K^+-NPPase activity in the paranodal region as compared to compact myelin supports the hypothesis that this region may be the main site for ion transport (Mackenzie et al., 1984).

5′-Nucleotidase hydrolyzes 5′-AMP to produce adenosine, which functions as a neuromodulator through its effects on Ca^{2+}-transport and adenyl cyclase activity (McCarthy and DeVellis, 1980; Phillis and Wu, 1981). While this enzyme is widely distributed to plasma membranes of different cell types, it is also an integral enzyme of the myelin membrane (Cammer et al., 1980). The highest specific activity

of 5′-nucleotidase is found in heavy myelin subfractions (Cammer and Zimmermann, 1981; Casado et al., 1988a, 1988b). Immunocytochemical studies have demonstrated the presence of the enzyme at the surface of the myelin sheath, between the axolemmae and innermost myelin lamellae, and within the myelin lamellae as well as glial plasma membranes (Kreutzberg et al., 1978; Heymann et al., 1984; Casado et al., 1988a, 1988b). The activity of 5′-nucleotidase in rat brain myelin increases almost fourfold during the developmental period from 20 to 90 days of age, while the activities of CNPase and carbonic anhydrase are relatively constant (Cammer and Zimmermann, 1981). Consequently, the recovery of 5′-nucleotidase in myelin (21%) resembles that of cyclic nucleotide phosphodiesterase (28%), suggesting that myelin may be the predominant, although not exclusive, locus of 5′-nucleotidase in adult brain.

The π form of glutathione-*S*-transferase (GST) has recently been demonstrated to be intrinsic to central nervous system myelin, as well as to oligodendrocytes (Tansey and Cammer, 1991). The GSTs function in intracellular transport of hormones and removal of toxins from cells (Tansey and Cammer, 1991), and may thus represent a protective mechanism for the myelin sheath.

Calcium-Activated Neutral Protease and Other Proteases

The presence of protease activities in central nervous system myelin was initially suggested some time ago (Marks et al., 1976; Smith, 1977). Of the protease activities, calcium-activated neutral protease (CANP, calpain) has drawn much attention because of its possible involvement in demyelinating diseases (Banik et al., 1992). The existence of intrinsic CANP activity has been demonstrated by autodigestion of myelin proteins during incubation of myelin membranes in the presence of Ca^{2+}. Both MBP and MAG appear to be good substrates for the enzyme (Sato and Miyatake, 1982; Sato et al., 1982; Banik et al., 1985). While PLP or Wolfgram proteins are fairly resistant to the protease action, the addition of Triton X-100 and EGTA (no Ca^{2+}) causes preferential degradation of PLP relative to MBP implying the involvement of a noncalcium-dependent protease(s) for the degradation of PLP (Banik et al., 1985). More recently, the presence of CANP in purified myelin has been confirmed using an anti-chicken CANP antibody (Yanagisawa et al., 1988). Partially purified CANP from myelin is activated by Ca^{2+} in the millimolar range (mCANP or calpain II). Since the intracellular Ca^{2+} concentration is much lower than this level, this enzyme may be autolyzed into a more sensitive μM form (μCANP), which is more active *in vivo*. A recent observation that myelin mCANP can be activated by gangliosides may also be of some interest for considering the regulatory mechanism of the enzyme activity (Chakrabarti et al., 1990a, 1990b).

In addition to CANP, aminopeptidase (Banik and Davison, 1969), acid protease (Berlet et al., 1988), and metalloproteinase (Chantry et al., 1989) have been shown to be associated with myelin. The activity of acid protease is assumed to be due to cathepsin D-like endopeptidase, whereas the metalloprotease cleaves many bonds in MBP, producing only trichloroacetic acid-precipitable peptides.

Protein Kinases and Phosphatase-Related Enzymes

Phosphorylation and dephosphorylation are the major reactions in protein metabolism in myelin. Myelin proteins, especially MBPs, have been shown to be radiolabeled rapidly after injection of ^{32}P-phosphate into rats (Carnegie et al., 1974; Miyamoto and Kakiuchi, 1974; Miyamoto et al., 1974; Kim et al., 1986). The phosphate groups of MBPs are metabolized with half-lives of minutes, contrasting to their polypeptide backbones, which have turnover rates on the order of months (Fisher and Morell, 1974; McNamara and Appel, 1977; Shapira et al., 1981; DesJardins and Morell, 1983). The phosphorylation reaction has been observed even in regions of compact myelin (DesJardins and Morell, 1983). These findings suggest the presence of protein kinase and phosphatase activities in myelin.

To date, different types of protein kinase activities have been found in myelin, including cAMP-dependent kinase (protein kinase A) (Carnegie et al., 1973; Miyamoto, 1975; Wu and Ahmad; 1984), Ca^{2+}-dependent, calmodulin-stimulated kinase (Sulakhe et al., 1980a, 1980b; Endo and Hidaka, 1980), and Ca^{2+}-dependent, phospholipid-stimulated kinase (protein kinase C) (Turner et al., 1982, 1984; Kim et al., 1986; Murray and Steck, 1986). Activity of protein kinase A appears to be associated loosely with myelin membranes and shows properties similar to those seen in microsomes (Miyamoto et al., 1978; Wu and Ahmad, 1984). A MBP-specific kinase has been shown to function as an activator for ATP,Mg^{2+}-dependent protein phosphatase (Yang, 1986). Ganglioside-stimulated kinase does not phosphorylate MBP preferentially (Chan, 1987).

Intrinsic activity of protein phosphatase in myelin has also been shown (Miyamoto and Kakiuchi, 1975; MacNamara and Appel, 1977). An enzyme

with an apparent molecular weight of 46 kD has been purified and its substrate specificity characterized (Wu et al., 1980). A recent study suggests that an inactive/latent phosphatase with a molecular weight of 350 kD (designated LP-2) is the most predominant protein phosphatase responsible for the dephosphorylation of brain myelin (Yang et al., 1987).

The physiological significance of these enzyme activities in myelin has been strengthened by the finding that myelin contains various types of control systems for the activities. Myelin possesses an intrinsic adenylate cyclase activity that is responsible for the production of cyclic AMP, an activator for protein kinase A (Larocca et al., 1987a).

Receptors, Second-Messenger Systems, and Mitogenic Activity

The traditional view of myelin as an insulating membrane has been forced to undergo expansion and revision by reports in recent years of myelin-intrinsic signal transduction systems. A number of substrates and enzymes known to be linked to such systems have been known to exist in myelin for some time. For example, phosphoinositides had been observed in isolated myelin prior to their implication in the signal transduction pathway involving phospholipase C hydrolysis to produce second messengers (Kahn and Morell, 1988). Studies from several laboratories intimate that muscarinic receptors are intrinsic to myelin and that these receptors are linked to formation of second messengers (reviewed by Ledeen, 1992). Binding of ligand to these receptors can activate adenylate cyclase with subsequent activation of protein kinase A; alternatively, receptor stimulation may lead to phospholipase C hydrolysis of phosphoinositides to produce diacylglycerol, which leads to stimulation of protein kinase C, and inositol 1,4,5-triphosphate, which acts to mobilize calcium (Larocca et al., 1987b; Kahn and Morell, 1988; Eichberg et al., 1989). The GTP-binding family of proteins seems an obvious candidate for a common denominator in all of these pathways. In fact, several laboratories have now reported the presence of a number of G proteins associated with myelin (Braun et al., 1990b; Larocca et al., 1991), thus providing a mechanism for transmitting signals from receptor to intracellular effector molecules. The *in vivo* source of extracellular acetylcholine or other cholinergic agonist has yet to be resolved.

A series of studies have demonstrated that a myelin-enriched fraction isolated from either the peripheral or central nervous system contains an intrinsic mitogenic activity (reviewed by Baichwal and De Vries, 1992). This mitogenic activity is directed toward Schwann cells and mediated by phagocytosis of the myelin membrane by macrophages. Evidence has been presented that the mitogen itself is a polypeptide related to MBP (Baichwal and De Vries, 1989). The mitogen characterized in these studies is postulated to be responsible for the Schwann cell proliferation associated with Wallerian degeneration *in vivo* (Baichwal and De Vries, 1992).

CONCLUDING REMARKS

Our understanding of myelin biochemistry has been greatly facilitated by the development by William Norton and his collaborators in the 1970s of a convenient procedure for isolating highly purified myelin preparations. Most of the early studies were directed toward defining the chemical composition of myelin. These early studies reinforced the long-held notion that the major function of myelin is to facilitate nerve conduction. More recent research has given rise to the idea that myelin is not only an inert insulator, but is actually metabolically active with many myelin-associated enzymes and voltage-dependent ion transport systems. With the advent of contemporary molecular biological techniques, great strides have been made in determining the structure and function of myelin genes as well as in delineating mutations involved in a variety of genetic disorders affecting myelination and the maintenance of myelin structure. Despite the recent triumphs of molecular genetics and molecular biology, the regulatory mechanisms for myelin synthesis and assembly remain obscure. Moreover, the biological and physiological functions of many myelin proteins and lipids are still not fully understood. The future of myelin research undoubtedly lies in addressing such problems.

We wish to thank Drs. George De Vries, Charissa Dyer, Minnetta Gardinier, and Marjorie Lees for critical reading of the manuscript. This work was supported, in part, by research grants NS11853, NS23102, NS26994 from the NIH and IN-105R from the MCV/VCU Massey Cancer Center.

38 Molecular biology of myelination

ANTHONY T. CAMPAGNONI

Myelination is a developmentally regulated event that begins postnatally in the rat and mouse brain and within the third fetal trimester in the human spinal cord. The expression of the myelin protein genes and the synthesis and assembly of these proteins into myelin represent one of the most intriguing aspects of modern molecular neurobiology. The genes encoding a number of myelin proteins have now been isolated and their structures have been determined. Table 38-1 lists myelin proteins for which the genes have been cloned and some of the characteristics of these proteins. Table 38-2 lists characteristics of the myelin protein genes that have been examined to date.

The synthesis and assembly of myelin proteins into the membrane is a complex event involving a number of steps. Research over the past decade indicates that regulation of the expression of these genes occurs at a number of different levels, including (1) promoter choice, (2) transcription, (3) splicing, (4) mRNA stability, (5) translation, and (6) posttranslational processing. This chapter briefly examines the molecular biology of myelination from the perspective of the myelin protein genes, their expression into mRNA and protein, and the assembly of their protein products into myelin. Since a number of reviews have appeared since 1988 (Campagnoni, 1988; Campagnoni and Macklin, 1988; Lemke, 1988; Nave and Milner, 1989; Ikenaka et al., 1991; Mikoshiba et al., 1991), this chapter emphasizes the most recent findings in this area. The reader is encouraged to consult these reviews for information on earlier studies.

From a historical perspective, the myelin basic protein and proteolipid protein were among the first nervous system proteins to be isolated and characterized biochemically because of their relatively high abundance in nervous tissue. It is not surprising, then, that they also were among the first cDNAs to be isolated from brain cDNA libraries. In the case of myelin basic protein (MBP) cDNAs, degenerate DNA probes, based on the known protein sequence, were used to isolate cDNAs from brain libraries (Roach et al., 1983; Zeller et al., 1984). One of the first proteolipid protein (PLP) cDNAs to be isolated occurred as part of a screen for "brain-specific" clones (Milner et al., 1985) and its high abundance in adult rat brain resulted in its isolation.

Figures 38-1, 38-3, 38-4, and 38-5 diagram the structures of the myelin protein genes along with the RNA splice products that have been identified to date. The genes of many of the myelin proteins located in the central nervous system have been found to be alternatively spliced to produce at least two polypeptide isoforms. For several of the myelin proteins [MBP, PLP, 2′,3′cyclic nucleotide 3′phosphodiesterase (CNPase), and myelin-associated glycoprotein (MAG)] the proportions of the individual isoforms expressed changes with development, thus the splicing patterns of the genes are developmentally regulated.

Golli-mbp GENE

Structure

The structure of the *MBP* gene was the first of the myelin protein genes to be elucidated. The "classic" *MBP* gene consists of seven exons distributed over a 32 kb stretch of chromosome 18 in mouse (Roach et al., 1985). The gene maps to human chromosome 18 (Sparkes et al., 1987) and rat chromosome 1 (Koizumi et al., 1991). At least six transcripts are expressed from this gene in the mouse through alternative splicing of three exons. The alternatively spliced MBP mRNAs encode MBP isoforms that range in molecular mass between 14 and 21 kD. The splicing of the transcripts is developmentally regulated. For example, those containing exon 2 (i.e., encoding the 17 and 21.5 kD isoforms) appear early in myelination and decline with development.

Recently, the *MBP* gene has been found to be included in a larger transcription unit, called the *Golli-mbp* gene (Campagnoni et al., 1993; Pribyl et al., 1993). The exons and promoter region comprising the MBP gene are included within the *Golli-mbp* transcription unit, which is approximately 105 kb in length in the mouse (Figure 38-1). A 36 kb region of the *Golli-mbp* gene that contains the MBP-encod-

TABLE 38-1. *Myelin Proteins for Which cDNAs Have Been Cloned*

Protein	CNS/PNS	Mass (kDa)	Characteristics	References[a]
CNPase	CNS and PNS	44–48	No known function. Found in myelin and oligodendrocyte plasma membranes. Early marker of oligodendrocytes	Sprinkle, 1989; Tsukada and Kurihara, 1992
MAG	CNS and PNS	~100 (glycosylated) 67/72 (apoproteins)	Principal glycoprotein of the CNS. Believed to be an adhesion molecule involved in the interaction between the axon and the myelin sheath. Implicated in some peripheral neuropathies	Mendell et al., 1985; Quarles et al., 1992; Tatum, 1993
MBPs	CNS and PNS	14–21.5	Located at major dense line. Peripheral membrane protein. Encephalitogenic, autoimmunogenic. pI > 10.5	Campagnoni, 1988; Campagnoni and Macklin, 1988
MOG	CNS	26–28	Located at external surfaces of myelin sheath and oligodendrocytes. May be involved in autoimmune demyelinating events.	Bernard and Kerlero de Rosbo, 1991
OMgp	CNS	120	Glycosylated protein. Located in oligodendrocyte membranes and at paranodal region of myelin sheath.	Mikol and Stefansson, 1988; Mikol et al., 1990b
P_0 protein	PNS	28	Major glycoprotein of the PNS. Integral membrane protein, probably important in myelin compaction through homotypic interactions between lamellae.	D'Urso et al., 1990; Filbin et al., 1990; Uyemura et al., 1992
P_2 protein	PNS and CNS (minor)	~15	A basic protein that binds fatty acids and retinoids. An autoimmunogen that induces experimental allergic neuritis.	Martenson and Uyemura, 1992; Narayanan et al., 1988; Veerkamp et al., 1991
PMP-22/PAS II	PNS	18	Minor glycoprotein of PNS myelin.	Snipes et al., 1992; Spreyer et al., 1991
PLP/DM20	CNS and PNS	25 (DM20) 30 (PLP)	Very hydrophobic integral membrane protein. Highly conserved amino acid sequence. Encephalitogenic.	Lees and Bizzozero, 1992; Nave and Milner, 1989

ing exons 5B-11 can function as an independent transcription unit. It can be introduced into transgenic mice and expressed within oligodendrocytes of the central nervous system with appropriate developmental specificity. It also can be introduced into *shi* mice (which have a deletion of exons 7–11), with a subsequent reduction in the clinical signs of the neurological disorder caused by the mutation (Readhead et al., 1987). Sequences up to 4 kb upstream of *Golli-mbp* exon 5B can be used to drive the expression of oncogenes (Hayes et al., 1992), MHC (major histocompatibility complex) molecules (Turnley et al., 1991), and reporter genes (Gow et al., 1992; Miskimins et al., 1992) in transgenic mice. Exon 5A of the *Golli-mbp* gene also can drive the expression of reporter genes in transfected cells (Miura et al., 1989; Devine-Beach et al., 1990). Thus, the *MBP* gene is part of a rather complex genetic locus, and is an example of a "gene within a gene." In this respect, the *Golli-mbp* gene is similar to the neurofibromatosis gene in that they are both large transcription units that encompass smaller genes (Viskochil et al., 1991). However, they are distinctly different in that the smaller MBP portion of

the *Golli-mbp* gene is not simply included within an intron of the larger transcription unit, but shares alternatively spliced exons in common.

The splicing pattern of *Golli-mbp* is very complex, both with respect to the numbers of products expressed and their developmental regulation. In the mouse, the gene contains three transcription start sites (at exons 1, 4, and 5B in Figure 38-1) each of which becomes active at different times during pre- and postnatal brain development. Transcription start site 1 expresses several *Golli* RNA splice products that contain exons 1, 2, and 3 of the gene spliced

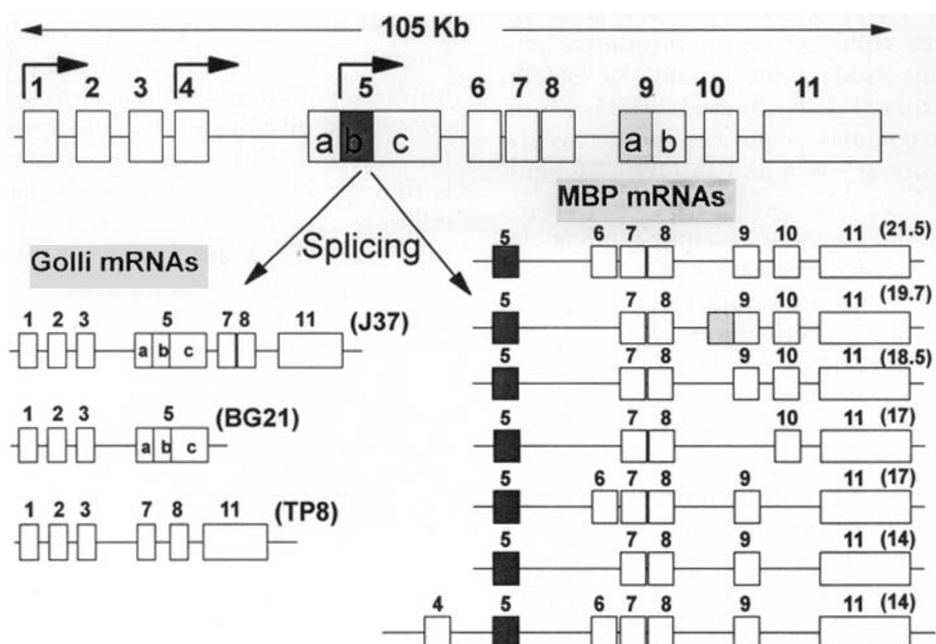

FIG. 38-1. Illustration of the structure and splicing pattern of the *Golli-mbp* gene. The names of the Golli mRNA products (*in parentheses*) are taken after those published by Campagnoni et al., 1993. The individual MBP mRNAs are identified (*in parentheses*) by the MBP isoform they encode. The three *arrows* above the gene indicate the three transcription start sites of the gene.

into MBP-encoding exons (see Figure 38-1). The second start site at exon 4 (Kitamura et al., 1990) and the third transcription start site at exon 5B express MBP mRNAs. The expression of at least six alternatively spliced forms of MBP mRNAs generated from the major (third) transcription start site has been well documented (see Aruga et al., 1991).

Recently, the human gene has been cloned and its organization is similar to that of the mouse gene except that it is much larger, approximately 179 kb (Pribyl et al., 1993). It also expresses alternatively spliced products, some of which are similar but not identical in structure to the mouse products.

Transcriptional Regulation

Identification of the *cis* genetic elements and the *trans*-acting factors regulating the tissue, cell, and developmental specificity of the *MBP* gene has drawn the attention of several laboratories in recent years. It has generally been felt that the regulation of the gene is complex, involving multiple sites within the region upstream of the MBP transcription start site and encompassing exon 5A of the *Golli-mbp* gene, where *trans*-acting factors that bind to different parts of the promoter interact to regulate the activity of the MBP transcription unit (Mikoshiba et al., 1991). Accordingly, this region has been isolated, analyzed, and used to define putative regulatory elements. The MBP promoter does not contain conventional TATA or CAAT boxes, that is, regulatory sequences common to all promoters and believed to be involved in the binding of general transcription factors (Takahashi et al., 1985; Miura et al., 1989). It contains sequences similar to the SV40 enhancer core at −648 and an NFI/CTF binding site at −125.

Recently, a thyroid hormone receptor binding element has been identified between −163 and −186 nt upstream of the transcription start site (Farsetti et al., 1991). Mikoshiba and coworkers (Mikoshiba et al., 1991) and Khalili and coworkers (Devine-Beach et al., 1990, 1992) have defined two regions of the promoter they call the "proximal" (i.e., +60 to ~ −50) and "distal" (i.e., ~ −50 to ~ −300) regions. Within each of these regions a number of sequences have been reported to confer either tissue or cellular specificity to the expression of the gene (Tamura et al., 1989, 1991; Devine-Beach et al., 1990, 1992). The focus of most of these studies has been on a region 1.3 kb upstream of the *MBP* gene, primarily within the +60 to −300 nt region of the gene and its upstream region. In another approach to defining elements important in the tissue-specific regulation of *MBP* gene expression, Gow et al. (1992) have recently reported that, in transgenic mice, the 1.3 kb upstream region of the *MBP* gene does not contain the information necessary to permit expression of the gene in the peripheral nervous system.

Posttranscriptional Regulation

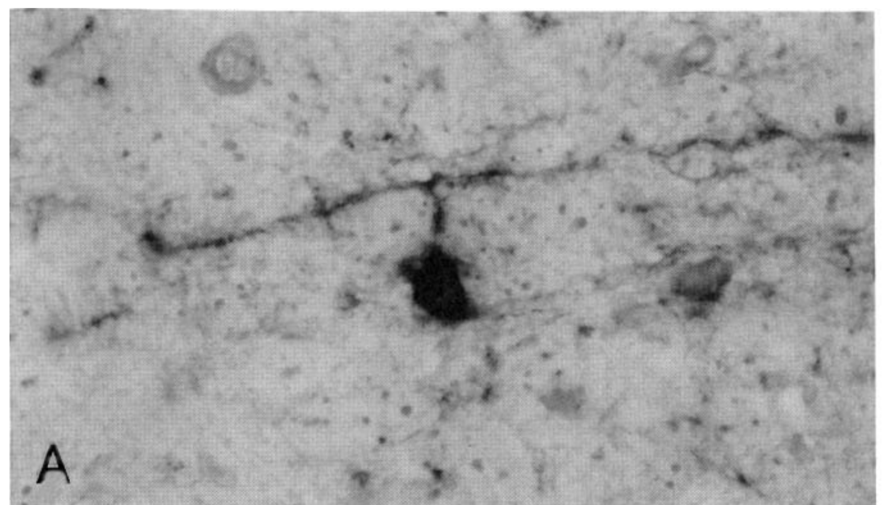
There is growing evidence that expression of the MBP transcription unit may be regulated at the posttranscriptional level. Several groups have reported posttranscriptional regulation by steroids or thyroid hormone by mechanisms including MBP mRNA stabilization or direct effects on translation rates (Kumar et al., 1989; Verdi and Campagnoni, 1990; Cabacungan et al., 1991).

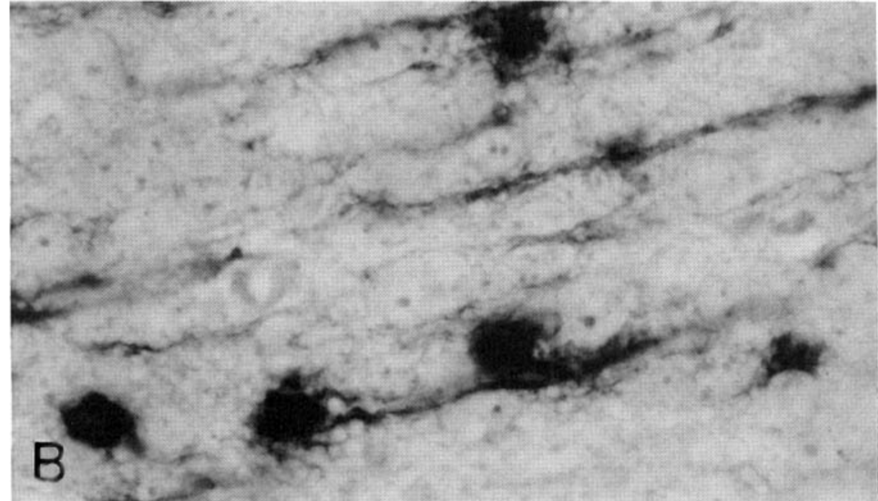
One of the most interesting features of posttranscriptional events of *MBP* gene expression is the well-documented phenomenon of MBP mRNA translocation. The MBPs are highly cationic polypeptides that can interact with virtually any negatively charged molecule. Therefore, a mechanism is required for targeting MBPs to the oligodendrocyte processes without inappropriate interactions of MBP polypeptides with other cellular components. This appears to be accomplished through the translocation of MBP mRNAs from the cell somas to the oligodendrocyte processes and channels that infiltrate the myelin sheath. This has been observed in many studies both *in vivo* (Trapp et al., 1987; Verity and Campagnoni, 1988) and *in vitro* (Amur-Umarjee et al., 1990b). Figure 38-2 shows an *in situ* hybridization result, which clearly localizes the MBP mRNAs within oligodendrocyte cell bodies, processes, and myelin sheaths. The myelin sheaths stain for MBP mRNA because the messages are localized within the cytoplasmic channels that surround and infiltrate the sheath. The extensive dispersion of MBP mRNAs within these cytoplasmic channels, recognized by the probes, provides an *in situ* hybridization result that looks very much like results obtained by injection of oligodendrocytes with horseradish peroxidase (Ransom et al., 1991). Very recently, Ainger et al. (1993) have demonstrated the existence of two sites within the 3′UT region of the MBP mRNA that are involved in targeting these messages to oligodendrocyte somas or processes.

MYELIN PROTEOLIPID PROTEIN (*PLP/DM20*) GENE

Structure and Localization

The myelin proteolipid proteins, PLP and DM-20, constitute about 50% of the protein in the myelin





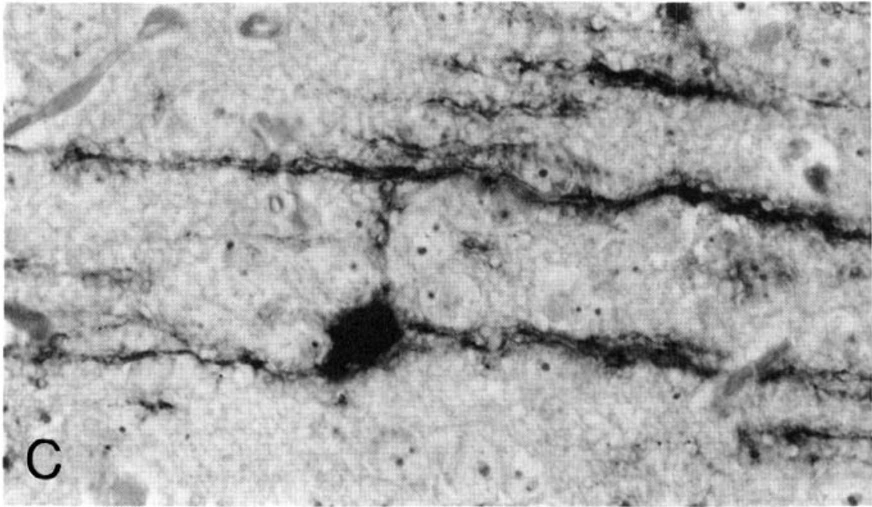


FIG. 38-2. A montage of three areas of mouse midbrain showing the *in situ* hybridization histochemical localization of MBP mRNA using digoxigenin-labeled riboprobes. (A) MBP mRNA within a single oligodendrocyte extending a process to a myelinated fiber that also contains MBP mRNA. (B and C) Several regions of myelinated fibers that contain MBP mRNA, presumably evident because of their localization within the cytoplasmic channels coursing through the sheath. In addition, they show several oligodendrocyte cell bodies also filled with MBP mRNA. In some cases the bodies are connected to the myelinated fibers through MBP mRNA-containing processes. In Figure C the oligodendrocyte appears to possess MBP mRNA-containing processes connected to at least two MBP mRNA-containing myelinated fibers. [Photomicrographs courtesy of Dr. Charles F. Landry.]

sheath and, as such, are among the most abundant proteins in the central nervous system. The amino acid sequences of the PLPs have been deduced from their corresponding cDNAs in many species, and their strong conservation among species has been noted by many investigators (for reviews see Nave and Milner, 1989; Hudson and Nadon, 1992; Macklin, 1992).

The *PLP/DM20* gene, located on the X chromosome in mouse, rat, and man, is ~17 kb in length

and consists of 7 exons (Figure 38-3). The myelin PLP was thought to be the only proteolipid in myelin until the early 1970s when a second proteolipid, called DM20, was identified and characterized by Agrawal et al. (1972). On the basis of peptide mapping studies of the purified polypeptides, Trifilieff et al. (1985) proposed that DM20 differed from PLP by an internal deletion of ~40 amino acids. Molecular biological studies subsequently established the location of a 35-amino acid deletion in the protein (Nave et al., 1987). This region is encoded in exon 3B of the gene.

The *PLP/DM20* gene is alternatively spliced to produce two mRNA products that encode the PLP and DM20 polypeptides. The gene also possesses three polyadenylation signals within the last exon encoding the 3′ untranslated region of the mRNA. The utilization of any or all of these sites generates a family of PLP/DM20 mRNAs of ~1.6, ~2.4, and ~3.2 kb. The proportions of these size classes of mRNAs varies considerably among species (Campagnoni and Macklin, 1988). All three size classes appear to contain mRNAs encoding both PLP and DM20 polypeptides (LeVine et al., 1990).

Expression

The *PLP/DM20* gene expresses two alternatively spliced mRNAs that encode a 30 kD (PLP) and a 25 kD (DM20) protein. In the brain, the splicing of the *PLP/DM20* gene primary transcript appears to be developmentally regulated. The developmental appearance of the DM20 protein precedes that of the myelin PLP in several species (Kronquist et al., 1987; Gardinier and Macklin, 1988; LeVine et al., 1990; Schindler et al., 1990). During the early stages of myelination the expression of the DM20 splice product predominates and it gradually declines with development. At later stages, the PLP splice product becomes the major form that is expressed.

The biological role of the DM20 protein has been unclear since its discovery over 20 years ago (Agrawal et al., 1972). Evidence that products of the *PLP/DM20* gene may be involved in processes other than myelination first came from cell biological studies on *jimpy*, a mutation in a splice site of exon 5 of the *PLP/DM20* gene (see review in Chapter 39, this volume). This *PLP/DM20* gene mutation results in a number of developmental abnormalities that occur prior to the active synthesis of myelin and which are, therefore, difficult to reconcile with a single structural role for PLP and/or DM20 in myelin.

It is becoming apparent that the expression of the *PLP/DM20* gene is not confined to oligodendrocytes in the central nervous system. To date, the expression of the gene has been reported in myelinating cells such as the oligodendrocyte in the central nervous system and the Schwann cell in the peripheral

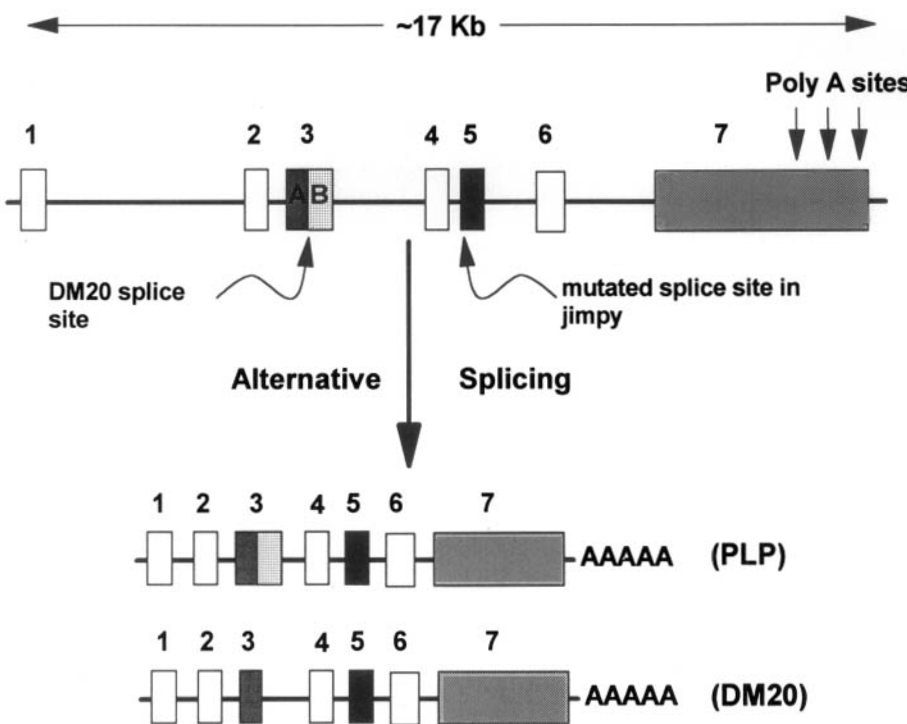

FIG. 38-3. The PLP/DM20 gene showing the alternative splicing pattern that gives rise to the PLP and DM20 mRNAs.

nervous system, although it appears that the PLP and DM20 proteins produced are not incorporated into myelin (Puckett et al., 1987; Kamholz et al., 1992). The gene is also expressed in nonmyelinating cells, such as myocardial cells in the heart (Campagnoni et al., 1992) and in cells of the embryonic nervous system (Ikenaka et al., 1992; Timsit et al., 1992), although in these cases the the DM20 mRNAs are the predominant forms of the gene that are expressed. Myocardial cells express DM20 mRNA in a postnatal developmental pattern that is roughly similar to that occurring in the brain, but these cells produce very little, if any, PLP mRNA, implying tissue-specific regulation of the splicing of the *PLP/DM20* gene primary gene product. Taken together, these results indicate that the products of the *PLP/DM20* gene play some additional role in the cell beyond that of structural proteins of the myelin sheath. It is interesting that ion channel, pore-forming properties have been ascribed to PLP-related proteins on the basis of their structure (Kitagawa et al., 1993) and that the PLP/DM20 proteins bear some homologies to ATPase (Laursen et al., 1983). These activities are consistent with the finding that DM20 mRNAs are expressed in the heart since this tissue, like the brain, contains substantial quantities of proteolipids, many of which are associated with mitochondrial function and energy transduction (Terzi et al., 1990; Hekman and Hatefi, 1991). Perhaps the role of DM20 is related to these cellular activities, but that remains to be determined.

Transcriptional Regulation

Several laboratories have attempted to analyze *cis*-acting elements and *trans*-acting factors that might regulate the activity of the *PLP/DM20* gene (Nave and Lemke, 1991; Berndt et al., 1992; Cook et al., 1992; Kim and Hudson, 1992). In studies with the rat upstream promoter region Nave and Lemke (1991) were able to identify a number of positive and negative *cis*-regulatory elements that also bound protein factors as assessed by gel retardation assays. Using the human promoter region, Berndt et al. (1992) also identified a number of elements that bound protein factors. Unfortunately, the elements identified in the two studies were not in complete agreement. In a general sense, however, both studies found that the region proximal to the transcription start site (i.e., −300 to −400 bp) was rich in *cis* elements. Both groups also found sequence motifs common to the promoter regions of many of the myelin protein genes, but these motifs were not always conserved within the same gene throughout species or among all the myelin protein genes. It seems unlikely that there is a myelin protein gene regulatory element-equivalent of the muscle-specific gene elements that bind MyoD (Weintraub et al., 1991). Recent studies by Macklin and coworkers suggest that positive regulatory elements may also reside within the first intron of the *PLP/DM20* gene (W. B. Macklin, personal communication).

2′,3′-CYCLIC NUCLEOTIDE-3′-PHOSPHODIESTERASE

CNPase activity is found in many tissues but it is particularly active in the central nervous system (reviewed by Sprinkle, 1989; Takahashi, 1992). The enzyme is localized within oligodendrocytes in the central nervous system and within Schwann cells in the peripheral nervous system. It is one of the earliest markers of cells in the oligodendrocyte lineage (Amur-Umarjee et al., 1990a), and it is widely used in cell biological studies for this purpose. Two CNPase mRNAs have been identified in rat brain and a CNPase mRNA of a different size has been identified in rat thymus (Bernier et al., 1987). Two *CNPase* genetic loci, which hybridize to the rat CNPase cDNA probes, have been reported on mouse chromosomes 3 and 11 (Bernier et al., 1988). These authors reported that the *CNPase* locus on chromosome 11 appeared to contain all the DNA sequences necessary to encode alternatively spliced CNPase mRNAs. However, it is not yet clear if both genetic loci give rise to CNPase mRNAs (perhaps in different tissues) or if the chromosome 3 locus is a pseudogene. The human gene maps to chromosome 17 (Douglas et al., 1992).

cDNAs from several different species have been isolated (Bernier et al., 1987; Vogel and Thompson, 1987; Kurihara et al., 1988) and the structures of the mouse and human *CNPase* genes have been determined (Kurihara et al., 1990; Douglas et al., 1992). They are ~6 kb and ~9 kb in length, respectively, and each consists of four exons (Figure 38-4). The mouse gene contains two transcription start sites at the beginning of the first (i.e., exon 0) and second exons (i.e., exon 1) that appear to be responsible for giving rise to two CNPase mRNAs. The mRNA produced from the upstream transcription start site (at the first exon) is smaller than the one produced from the downstream start site (at the second exon), and each encodes a separate isoform of the enzyme (Kurihara et al., 1990). The first exon splices into the interior of the second exon to produce the smaller CNPase mRNA (see Figure 38-4).

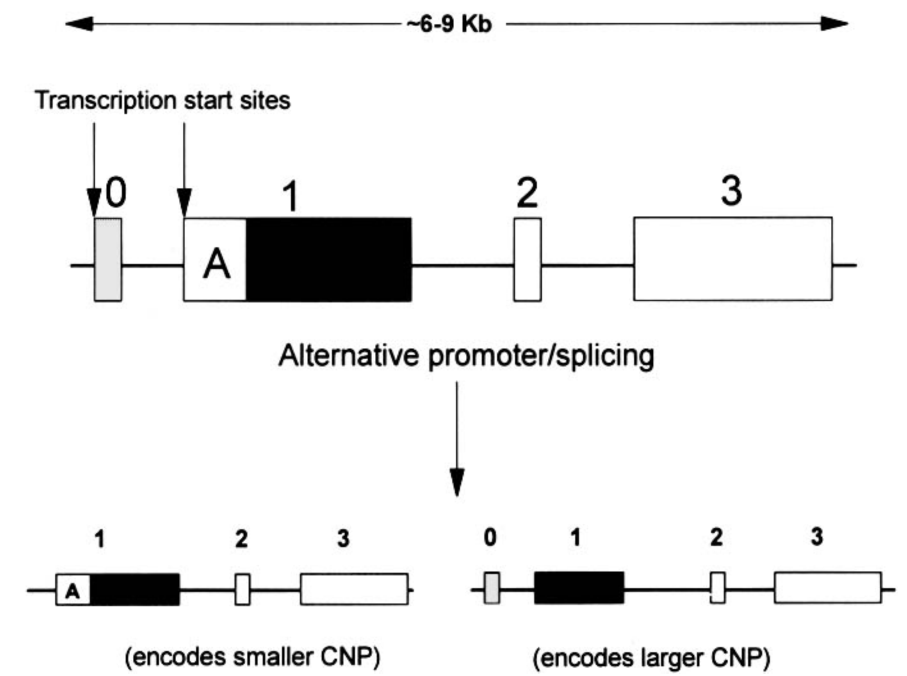

FIG. 38-4. The CNPase gene indicating the two transcription start sites at the first (exon 0) and second (exon 1) exons and the alternative splicing pattern that gives rise to two CNP mRNAs.

It has been observed that four electrophoretically separable CNPase polypeptides are expressed in the mouse (Kurihara et al., 1992). The relationship of these polypeptides to the CNPase mRNAs and the gene(s) that encode them still remains to be established.

MYELIN-ASSOCIATED GLYCOPROTEIN

MAG is the principal glycoprotein of central nervous system myelin (for recent reviews see Milner et al., 1990; and Quarles et al., 1992). The polypeptide portion of MAG consists of two isoforms with apparent molecular masses of 67 and 72 kD. On SDS gels the fully glycosylated polypeptides exhibit a molecular mass of ~100 kD. Theoretical analysis of the amino acid sequence data generated from cDNA clones indicate that MAG is a member of the immunoglobulin gene superfamily (Sutcliffe et al., 1983; Lai et al., 1987; Salzer et al., 1987). The extracellular, N-terminal domain of both MAG isoforms can be divided into five domains, ~80–90 residues in length, that have structural features similar to immunoglobulin domains, that is, a pair of cysteine residues separated by 43–62 residues (Milner et al., 1990). The data suggest that MAG is most closely related to the cell adhesion molecules N-CAM, L1, and contactin. It is generally believed that MAG is involved in some aspect of adhesion of the myelin sheath to the axonal plasmalemma. MAG has also been implicated in peripheral neuropathies in humans (Mendell et al., 1985) and in animal models (Tatum, 1993).

As shown in Figure 38-5 the MAG gene consists of 13 exons distributed over ~16 kb in the rat and has a similar structure in the mouse (Nakano et al., 1991). The gene maps to chromosome 7 in the mouse (Barton et al., 1987) and chromosome 19 in humans (Barton et al., 1987; Spagnol et al., 1989). Exons 2 and 12 are alternatively spliced to produce the two MAG mRNAs in the rat (Arquint et al., 1987; Lai et al., 1987; Salzer et al., 1987). Exons 1–4 of the gene encode 5′ untranslated region, and exons 5–9 each encode one immunoglobulin (Ig) domain, a feature common with genes of the Ig superfamily (Milner et al., 1990). The mRNA encoding the 72 kD MAG polypeptide is composed of all the exons of the gene except exon 12, and the mRNA encoding the 67 kD MAG is composed of all the exons of the gene except exon 2 (see Figure 38-5). Exon 12 contains a termination signal that creates a shorter coding region in the mRNA than would be present in its absence, thereby encoding the smaller, 67 kD MAG polypeptide. The absence of exon 2 (encoding 5′ UT region) has no effect on the size of the protein.

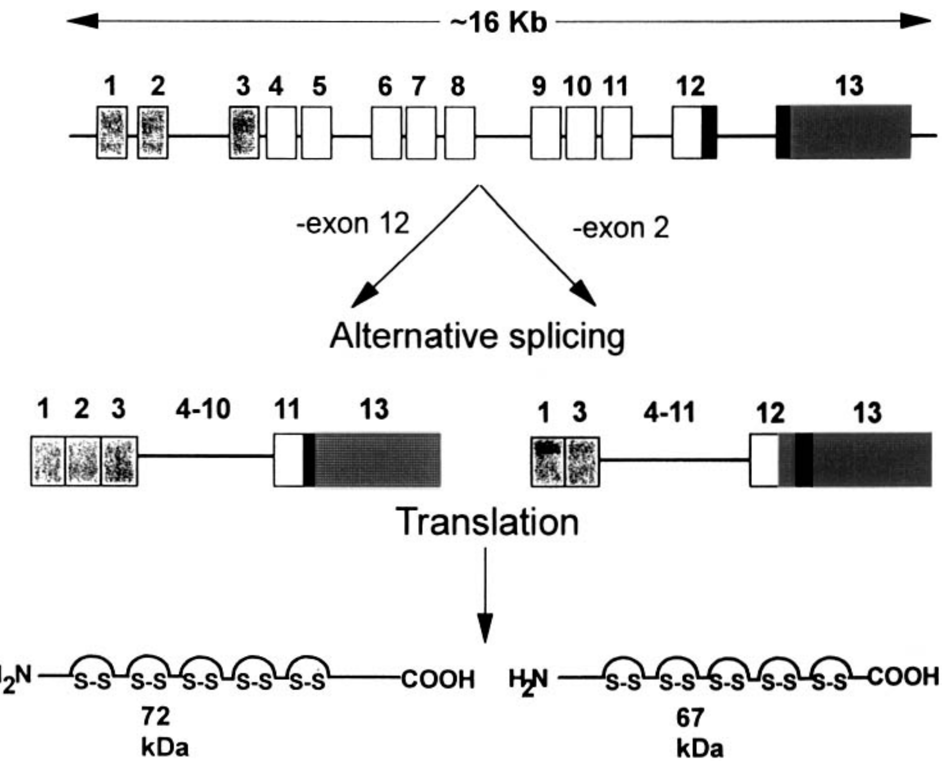

FIG. 38-5. The MAG gene showing alternative splicing to produce two mRNAs and two MAG protein isoforms. The protein diagrams emphasize the immunoglobulin domains within their structure.

MYELIN/OLIGODENDROCYTE GLYCOPROTEIN

MOG was first observed with an anonymous monoclonal antibody raised against rat cerebellar glycoproteins (Linington et al., 1984). Initially, it was thought that the smaller of the two bands (of 51 and 26 to 28 kD) recognized by the monoclonal was a breakdown product. Subsequently, however, this monoclonal was used to clone a cDNA encoding the MOG protein with a predicted size of 25 kD (Gardinier et al., 1992). On SDS-PAGE immunoblots MOG runs as a 26 to 28 kD doublet (Matthieu and Amiguet, 1990), which, on deglycosylation, runs as a single 25 kD polypeptide, leading to the conclusion that MOG polypeptides undergo at least two different types of glycosylation to give rise to two posttranslationally modified forms of the protein (Amiguet et al., 1992).

Although expression of MOG is developmentally regulated, and it appears generally with the onset of myelination, it is one of the last myelin protein genes to be expressed (Scolding et al., 1989), making it a marker of mature oligodendrocytes. A rat cDNA for MOG has been cloned, and it encodes a protein containing a signal peptide of 27 amino acids followed by a mature polypeptide of 218 amino acids (Gardinier et al., 1992). The MOG mRNA is ~1.6 kb in length. On the basis of an analysis of its predicted structure the protein contains a single glycosylation site at asn^{31} and some features that suggest it may be a member of the immunoglobulin gene superfamily (Gardinier et al., 1992).

MOG has received considerable attention because of its potential role in autoimmune-mediated demyelinating events. The protein is localized primarily at the external surfaces of the myelin sheath and oligodendrocytes, and anti-MOG antibodies can cause demyelination *in vivo* (Schluesener et al., 1987) and *in vitro* (Kerlero de Rosbo et al., 1990). Several lines of evidence suggest that MOG may be a pathogenetically important target in demyelinating conditions such as experimental autoimmune encephalomyelitis (EAE) and Multiple Sclerosis (Gunn et al., 1989; Bernard and Kerlero de Rosbo, 1991). In this regard, the M2 autoantigen described by Lebar et al. (1986), is probably MOG as assessed by their similarity in immunological cross-reactivities, cellular localization, and molecular weight (Bernard and Kerlero de Rosbo, 1991).

OLIGODENDROCYTE-MYELIN GLYCOPROTEIN

OMgp was initially discovered and isolated from the human central nervous system as a 120 kD glycoprotein that bound to peanut agglutinin (Mikol and Stefansson, 1988). OMgp is one of the "minor" protein components of myelin that appears in the central nervous system during the period of myelination. It is highly glycosylated and it appears to be specific to oligodendrocyte and myelin membranes in the central nervous system, since it was not found in Schwann cells or peripheral nervous system myelin (Mikol and Stefansson, 1988). The protein is anchored to the membrane through a glycosylphosphatidylinositol intermediate. A subpopulation of OMgp molecules from human brain appear to contain the HNK-1 carbohydrate (Mikol et al., 1990a), which has been implicated in mediating cell-cell interactions in the nervous system. A human cDNA corresponding to the OMgp mRNA has been isolated from a human fetal spinal cord library, and the primary structure of the protein has been deduced (Mikol et al., 1990b). The cDNA predicts a polypeptide sequence of 433 amino acids, including a 17-amino acid leader sequence. The size of the nascent polypeptide backbone with the leader removed is predicted to be 46 kD. Analysis of the predicted protein structure suggests the presence of four domains that includes a series of tandem leucine repeats that have been implicated in adhesive processes in other proteins. The presence of the HNK-1 carbohydrate in a subpopulation of OMgp molecules, the presence of a tandem leucine repeat domain in the predicted polypeptide sequence, and the apparent presence of OMgp at the paranodal regions of the myelin sheath have led Mikol et al. (1990b) to speculate that it functions as an adhesion molecule.

The structure and chromosomal localization of the OMgp gene has been determined (Mikol et al., 1990a). The human gene is small (~3 kb), consisting of two exons, and it maps to human chromosome 17 q11-12. An unusual feature of the OMgp gene is that it is included, along with two other unrelated genes of similar simple structure, within an intron of the neurofibromatosis type 1 gene (Viskochil et al., 1991). Interestingly, all three of these genes have a transcriptional orientation *opposite* to that of the neurofibromatosis gene (i.e., they are transcribed off the opposite strand.) At the present time, there are only a few examples in mammals of "genes within genes." It is particularly interesting that of the handful of genes that fall within this category, two are myelin protein genes, that is, *OMgp* and *MBP*.

PERIPHERAL MYELIN PROTEIN ZERO

P_0 protein accounts for over 50% of the protein in peripheral nerve myelin (Ishaque et al., 1980). The sequence has been deduced by conventional protein sequencing techniques for the bovine protein (Sakamoto et al., 1987) and from the cDNAs isolated from many species including man (Hayasaka et al., 1992), rat (Lemke and Axel, 1985), chicken (Barbu, 1990), and shark (Saavedra et al., 1989). The protein is synthesized with a signal sequence and undergoes posttranslational glycosylation. It is a transmembrane protein with a glycosylated extracellular domain, a single membrane spanning region, and a highly basic intracellular domain (Lemke and Axel, 1985). The P_0 extracellular domain has received considerable attention and analysis. It is generally thought to play an important role in the compaction of myelin through the homotypic interaction of molecules on adjacent myelin lamellae (Lemke, 1988). This notion is supported by transfection studies of P_0 cDNA constructs into cells in culture (D'Urso et al., 1990; Filbin et al., 1990). The extracellular domain is similar to an immunoglobulin variable region domain and is encoded by two exons (Lemke et al., 1988). Because most immunoglobulin-related domains in proteins within this superfamily have been found to be encoded by a single exon, it has been suggested that this partitioning between two exons is evidence for the evolution of immunoglobulin-related domains from an ancestral half-domain (Lemke et al., 1988).

The P_0 gene consists of six exons distributed over 7 kb in rats and mice (Lemke et al., 1988; You et al., 1991) and the gene maps to mouse chromosome 1 (Kuhn et al., 1990; You et al., 1991). Expression of the P_0 gene is highly restricted to Schwann cells, unlike many of the other myelin protein genes (e.g., *MBP, PLP, MAG*) that are expressed in both oligodendrocytes and Schwann cells, as well as other cell types. The elements regulating this expression appear to reside within a 1.1 kb 5′ flanking region of the gene based upon transgenic experiments (Messing et al., 1992).

SCIP

Studies on myelin protein gene expression in Schwann cells have led to the discovery of a POU domain gene, called *SCIP* (for suppressed *c*AMP-*i*nducible *P*OU), which has been proposed to act as a transcriptional repressor of myelin-specific genes (Monuki et al., 1989; Kuhn et al., 1991). *SCIP* is expressed transiently during glial development in the

central and peripheral nervous systems. In Schwann cell progenitors *SCIP* expression appears to be high at a time when expression of the P_0 and *MBP* genes is low. In contrast, when these myelin protein genes are expressed maximally, *SCIP* expression is substantially reduced. In cultured Schwann cells, agents that increase cAMP levels also induce *SCIP* expression. The *SCIP* gene has recently been isolated (Kuhn et al., 1991). It appears to be a single copy, intronless gene of approximately 3 kb in length, and it has the general features of an expressed retroposon. The gene produces a 3.1 kb mRNA that encodes a 451-amino acid, 45 to 47 kD protein, which has been localized to Schwann cell nuclear extracts by Western blot analysis (Kuhn et al., 1991).

PERIPHERAL NERVE P_2 PROTEIN

In peripheral nerve, the major proteins are P_0, MBP (referred to as P_1 in the older literature) and P_2, a basic protein distinct from the myelin basic protein. The P_2 protein was first isolated from bovine nerve roots (London, 1971) and the protein sequenced from many species (Kitamura et al., 1980; Ishaque et al., 1982; Suzuki et al., 1982). The P_2 protein has been of immunological interest because it induces experimental allergic neuritis, a demyelinating disease of the peripheral nervous system, in animals (Kadlubowski et al., 1980). The P_2 protein bears sequence homology to cellular retinol and retinoic acid-binding proteins (Crabb and Saari, 1981; Eriksson et al., 1981) and fatty acid-binding proteins (FABPs) (Veerkamp et al., 1991) and it has been shown to have a high affinity for oleic acid, retinoic acid, and retinol (Uyemura et al., 1984). cDNAs encoding the P_2 protein have been isolated and characterized from rabbit sciatic nerve (Narayanan et al., 1988) and human fetal spinal cord (Hayasaka et al., 1991) cDNA libraries. The P_2 mRNA has been detected in rabbit sciatic nerve, spinal cord, and, to a lesser extent, in brain (Narayanan et al., 1988). P_2 mRNA levels parallel myelination during development as well as the levels of microsomal enzymes involved in fatty acid elongation. These results have prompted the suggestion that the P_2 protein may be involved in fatty acid elongation, or in the transport of very long-chain fatty acids to myelin (Narayanan et al., 1988).

The structure of the mouse P_2 gene has been determined (Narayanan et al., 1991), and it appears to be similar to other members of the FABP family of genes. The P_2 gene is rather small (~4.5 kb) and consists of four exons. Phylogenetic studies suggest that the P_2 protein gene belongs to an ancient family of FABPs that diverged into two major subfamilies: one comprising the genes for mammalian liver FABP and gastrotropin, and a second comprising the genes for the retinol-binding proteins, cellular retinoic acid-binding protein, the adipocyte and heart FABPs and the P_2 protein (Medzihradszky et al., 1992). The P_2 gene is similar to the PLP/DM20 gene in that they are both members of an ancient family of proteins that have been highly conserved through evolution (Kitagawa et al., 1993).

PERIPHERAL NERVOUS SYSTEM MYELIN PROTEIN: PMP-22/PASII/SR13

Early studies indicated the existence of several glycoproteins in myelin isolated from mammalian peripheral nerve. Some of these were identified as the myelin-associated glycoprotein (Sternberger et al., 1979) and the P_0 protein (Kitamura et al., 1976). In addition to these, a very large glycoprotein of 170 kD has been described (Shuman et al., 1986) as well as low molecular weight proteins in the 19 to 23 kD range (Kitamura et al., 1976; Smith and Perret, 1986). Initially, these 19 to 23 kD glycoproteins were thought to be breakdown products of the P_0 protein (Ishaque et al., 1980) until Smith and Perret (1986) showed that a 19 kD band was not related to the P_0 glycoprotein and probably corresponded to the PAS II protein described by Kitamura et al. (1976).

Recently, two groups (Spreyer et al., 1991; Welcher et al., 1991; Snipes et al., 1992) independently cloned cDNAs from rat sciatic nerve with high homology to the growth arrest-specific mRNA, *gas 3*, and PAS II glycoprotein. The polypeptide encoded by this cDNA has been named PMP-22 and corresponds to PAS II. A human PMP-22 cDNA has also been isolated (Hayasaka et al., 1992). Like the other peripheral myelin protein genes, the expression of PMP-22 mRNA is downregulated after the nerve is crushed or transected, a fact that Spreyer et al. (1991) took advantage of to isolate their clone through differential screening techniques. The rat PMP-22 mRNA is ~1.8 kb in length and its analysis indicates that it encodes a polypeptide of 160 amino acid residues with a predicted molecular mass of ~18 kD. The polypeptide also contains a predicted leader sequence of 26 residues at its N terminus. It has four hydrophobic regions that could represent membrane-spanning domains in the molecule.

The *PMP-22* gene maps to mouse chromosome 11 and a point mutation in this gene is apparently responsible for the autosomal, dominant mutation, Trembler (*Tr*) (Suter et al., 1992a,b). In humans

the gene maps to chromosome 17 and in Charcot-Marie-Tooth 1A patients it is duplicated, thereby making it a candidate for the gene defect in these patients (Patel et al., 1992; Timmerman et al., 1992; Valentijn et al., 1992).

The rat *PMP-22* gene is developmentally regulated in the Schwann cell, its expression coinciding with myelination (Snipes et al., 1992; Spreyer et al., 1991). Its expression appears to be largely confined to the peripheral nervous system, although low levels of expression (0.1 to 0.01) can be detected in the lung, brain, and colon.

CONCLUSION

As a reading of this short review should indicate, there has been an explosion of work within the past few years on the molecular biology of myelin protein genes. The work has shown that some of the genes, such as the *MBP* and *OMgp* genes, are part of larger and more complex genetic loci. In the case of the *Golli-mbp* gene, portions of the gene are expressed in tissues outside the nervous system, including the immune system. This should encourage us to reevaluate our current concepts concerning the immunology of the myelin basic protein and the mechanisms governing its autoimmunogenicity as well as tolerance to the protein. An impressive amount of evidence has been gathered, indicating that genes we thought were prototypically nervous system-specific, for example, *MBP* and *PLP/DM20* (since myelination only occurs in the nervous system), are, in fact, expressed outside the nervous system. In the case of *PLP/DM20*, the products of the gene undoubtedly have functions completely unrelated to those of myelin structural elements, and it will be of great interest to learn what these functions are when they are elucidated. Almost all the genes encoding the "minor" myelin proteins have been cloned and molecular defects in at least one (PMP-22/PAS II) appears to result in the *Trembler* phenotype in mouse and is a strong candidate for the Charcot-Marie-Tooth 1A gene defect. The cultured Schwann cell has certainly emerged as an extremely useful cellular and molecular biological tool with which to study the regulation of myelin protein genes in the PNS. Even though the last five years have been a period of enormous growth in our understanding of the molecular mechanisms governing the expression of myelin protein genes and myelination, with all the molecular and cellular tools now available I suspect the next five years hold even more promise.

I wish to thank Sheila Bagsby, Vilma Schonmann, and Karen Park for their invaluable assistance in assembling this manuscript. I would also like to thank Dr. Charles Landry for providing the data shown in Figure 38-2. This work was supported, in part, by research grants NS23022, NS23322, HD25831 from the NIH and grant RG 2233A1 from the National Multiple Sclerosis Society.

39 Neurological mouse mutants: a molecular-genetic analysis of myelin proteins

KLAUS-ARMIN NAVE

FROM GENOTYPE TO PHENOTYPE

Genetics provides a powerful tool to dissect mechanisms of development—from genes that encode structural or regulatory proteins to complex cellular interactions. For studying mammalian development genetically, laboratory mice have become the preferred model system with their short gestation period (19 days) and generation cycle (3 months). Numerous defects of neural development have been associated with single genes in neurological mutant mice (Sidman, 1965; Hogan and Greenfield, 1984) and contributed to our knowledge of normal development. However, among the many "classical" neurological mouse mutants that occurred spontaneously, only a few have been molecularly identified, and most of these affect myelin formation. Today, the ability to experimentally generate mutations in transgenic mice of virtually any cloned gene (Mansour et al., 1988) predicts that the catalog of neurological mouse mutants will be quickly growing.

Spontaneous mutants provide the outcome of a "natural" experiment in which normal development is specifically altered. The analysis of a developmental defect such as hypomyelination, the subject of this chapter, must reach from the molecular level to the morphological and behavioral levels before a final conclusion about the defect can be made. Assuming that a neurological mouse mutant differs in only one gene function (e.g., not by a large genomic alteration that affects several genes at once), all developmental differences detectable between the normal and the mutant should be associated directly or indirectly with the normal action of the gene. However, the phenotype does not "show" the gene's normal function (or the loss of it) directly, but demonstrates how the animal develops in the absence of a specific gene function. Most organisms can respond to the deprivation of a gene function in many ways throughout development, which causes a pleiotropic phenotype by the time the observations are made.

In the simplest case, the mutation has inactivated a gene and the loss of function affects only the homozygous animal. Most genetic defects in the catalog of neurological mutant mice belong to this group of recessive mutations. In some specific cases, the mutation may have enhanced or modified the normal property of a gene in a way that the encoded protein has an altered function which also disturbs development ("gain-of-function" mutation). Heterozygous mutant mice may present a dominant or semidominant (intermediate) phenotype when one wild-type copy of the gene is not sufficient for normal development ("haploinsufficiency"). Finally, a mutant protein may have lost its own function but interferes with the activity of the wild-type protein when present in the same cell ("dominant-negative" action). When heterozygous mice with dominant mutations survive for at least 4 months and are not too handicapped to breed, these mutations can also be propagated to subsequent generations.

The identification and molecular cloning of the defective gene is a major goal but also a hurdle in the final analysis of a mutant mouse, and has been more often determined by coincidence than by the application of "reverse genetic" techniques. Once the mutation has been established at the nucleotide level, one can begin to causally link information about the wild-type gene product and its expression to the developmental processes that appear abnormal. The final conclusion of the gene's normal function is usually more difficult than anticipated due to either extensive pleiotropic action of the gene defect or to the functional redundancy built into the system. Most current research on the genetics of myelin genes focuses on this link between genotype and phenotype in myelin-deficient mouse mutants.

MUTATIONS AFFECTING MYELIN FORMATION

Myelination provides the electrical insulation of the axon by a multilayered sheath of membrane and is

the physical basis for rapid saltatory impulse conduction in the nervous system, as detailed in Section VII. The physiological requirement for myelinated axons has been met independently by the glial cells of the central and peripheral nervous system. A morphologically very similar structure, the compacted myelin sheath, is assembled by oligodendrocytes and Schwann cells, utilizing two different but overlapping sets of myelin proteins, some of which are shown schematically in Figure 39-1. This provides the opportunity to compare central and peripheral myelination in these mutants and to assess the contribution of each protein to myelin assembly.

In rodents, terminal differentiation of myelin-forming glial cells occurs largely after birth, at a time when the basic wiring pattern of the nervous system has been established. Mutations that affect myelin formation can therefore be identified by characteristic behavioral abnormalities such as shivering, ataxia, and, frequently, seizures. These signs begin when normal mice assemble large amounts of myelin, which gradually becomes a requirement for motor control and normal brain function. The specific phenotype of myelin-deficient mice necessitates also that the mutant gene is cell-type specifically expressed in Schwann cells and/or oligodendrocytes, which holds true for most (but not all) of the structural myelin protein genes (Lemke, 1988). Numerous other important molecules (cytoskeletal proteins, ion channels, cell adhesion molecules) are critical not only for myelin-forming glial cells but also other neural cell types that differentiate much earlier in embryonic development. Structural defects of these genes may have escaped detection in viable neurological mouse mutants.

Under laboratory conditions myelin is a temporarily dispensable structure. The inability of glial cells to assemble normal myelin is not immediately lethal for the animal. In fact, most mutant mice survive for several weeks after birth, which allows to compare, over a long period of time, the differentiation of normal and mutant glial cells *in vivo*. The frequently used term "*dys*myelination" denotes, in this chapter, the primary inability of the glial cell to assemble qualitative or quantitative normal myelin (the term "*de*myelination" should be reserved for the secondary loss of myelin, usually in the course of a degenerative disease such as multiple sclerosis). Most neurological mutations cause dysmyelination, but also nongenetic factors (malnutrition, poisoning) may cause dysmyelination. Conversely, some late-onset genetic disorders may present a clinical picture that includes demyelination, as in some human neuropathies of the peripheral nervous system.

In the following paragraphs, an overview is given of the molecular-genetic analysis of specific mutations in the mouse, which has improved our understanding of myelin protein function in the central and peripheral nervous system (Table 39-1). Some of these findings are directly applicable to human genetic diseases.

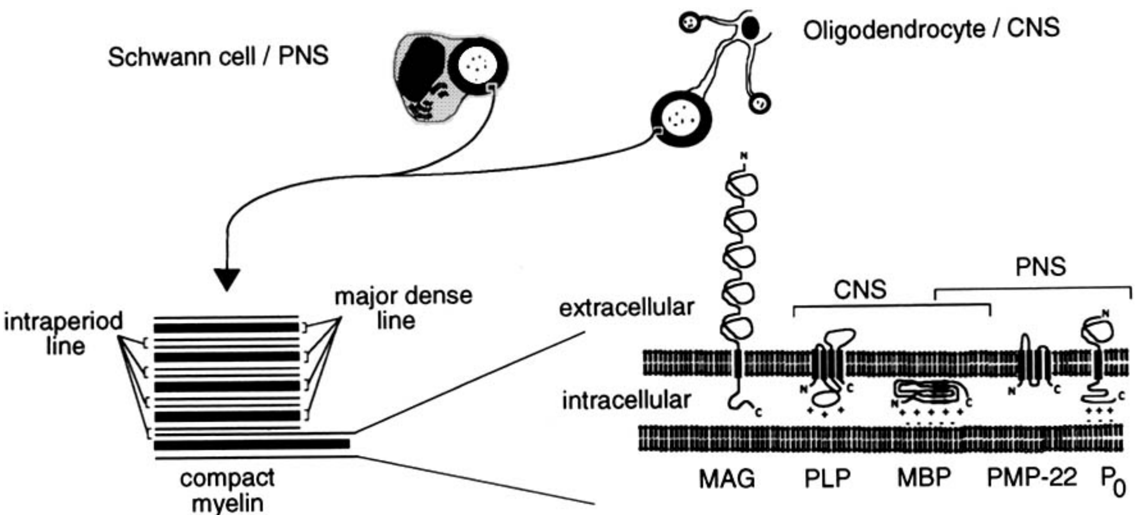

FIG. 39-1. Myelin-forming glial cells, the ultrastructure of myelin, and major proteins of the compacted membrane. Schwann cells and oligodendrocytes utilize overlapping but distinct sets of proteins to assemble myelin. Indicated are only gene products that have been implicated in the molecular defect of dysmyelinating mouse mutants: *PLP*, proteolipid protein (*jimpy*); *MBP*, myelin basic protein (*shiverer*); *PMP-22*, peripheral myelin protein (*trembler*); and P_0. In myelin of wild-type mice, the myelin-associated glycoprotein (*MAG*) is restricted to the innermost membrane facing the neuronal axon. Not shown are isoforms of PLP, MBP, and MAG derived by alternative RNA splicing.

MYELIN BASIC PROTEIN: ABNORMAL MYELIN COMPACTION IN *SHIVERER* MICE

Myelin basic protein (MBP) comprises a complex family of related proteins, which together constitute at least 30% of the protein mass in central nervous system myelin and about 10% of peripheral nervous system myelin protein. The molecular mass of the major isoforms is 14 kD, 17 kD, 18.5 kD, 20 kD, and 21.5 kD. As described in detail in Chapter 38, the relationship of these structural proteins has been resolved by cloning of their respective cDNAs. All MBP isoforms arise by alternative RNA splicing of a primary transcript from the MBP structural gene. Inclusion of all seven exons generates the largest MBP isoform (21.5 kD), whereas the selective exclusion of exons 2, 5, and/or 6 generates the smaller isoforms (de Ferra et al., 1985; Takahashi et al., 1985). The functional difference between these proteins, however, is not known. The "myelin-specific" transcription unit of the *MBP* gene (Figure 39-2) is itself part of the considerably larger *golli-MBP* gene complex (for *g*ene in the *ol*igodendrocyte *li*neage). The upstream *golli*-specific exons encode the aminoterminal portion of MBP-like isoforms, which are expressed also outside the nervous system and which may serve functions completely unrelated to myelination (Campagnoni et al., 1993).

MBPs are positively charged membrane-associated proteins of myelin and located at the cytoplasmic surface ("major dense line") of the glial process. The function that MBP contributes to the assembly of compact myelin has been studied in the myelination defect of the *shiverer* mouse. *Shiverer* mice (genetic symbol: *shi,* mouse chromosome 18) lack any detectable MBP and were the first neurological mouse mutants successfully studied at the molecular-genetic level (Roach et al., 1983). Affected homozygous mutants fail to make normal myelin in the central nervous system and display a behavioral defect that is characteristic for *shiverer* and other myelin-deficient mice; these are best described by their given names. In the second postnatal week, *shiverer* mice develop a general body tremor, which is most pronounced when the animals initiate voluntary movements (Biddle et al., 1973; Chernoff, 1981). The shivering, which reflects a loss of spinal motor and reflex control, increases with age and is followed by seizures in the adult. Most *shiverer* mice die prematurely at about 6 months of age.

Histologically, the mutants are dysmyelinated throughout the central nervous system, whereas their peripheral myelin appears completely normal (Privat et al., 1979; Kirschner and Ganser, 1980; Rosenbluth, 1980). The ultrastructure of myelinated fibers in brain and spinal cord reveals a characteristic lack of myelin, and myelinlike structures—where present—are loosely wrapped around the axon. The intracellular adhesion zone of the extended cell process which normally forms the "major dense line" of myelin cannot be discerned. *Shiverer* oligodendrocytes appear nevertheless normally differentiated.

Biochemically, the dysmyelination is reflected in a dramatic reduction of all major myelin proteins, specifically in the complete lack of the MBPs. The latter is the primary defect of the mutant and results from a 20 kb large genomic deletion encompassing exons 3–7 of the *MBP* gene (or exons 7–11 of the larger *golli-MBP* gene) as summarized in Figure 39-2. Thus, *shiverer* mice have no coding capacity for any of the MBP isoforms (Roach et al., 1985; Molineaux et al., 1986).

FIG. 39-2. Genomic structure of the myelin basic protein locus which is partially deleted in *shiverer* mice and duplicated in the *shiverer-mld* mutant. The exons of the myelin-specific MBP transcription unit (*black boxes*) are numbered on top and the equivalent numbers of the larger *golli-MBP* gene complex are indicated below (for details see Chapter 38, this volume). The position of a genomic deletion in *shiverer* mice is indicated by a *dashed line*. Normal and antisense-containing MBP transcripts are shown by *arrows*. An inverted segment (x–x) within the duplicated *MBP* gene of *shiverer-mld* mutant is labeled *MBP-antisense*. Exon sizes are not drawn to scale.

The definitive proof that the lack of MBP itself is responsible for the dysmyelinating phenotype utilized transgenic mice. When the entire wild-type MBP gene was reintroduced into the germ line of *shiverer* mice, the tremoring phenotype dissappeared as a function of regained MBP expression (up to 25% of wild-type level) so that the mutation was phenotypically "cured" (Readhead et al., 1987). In fact, raising MBP expression levels by increasing the transgeni gene copy number in *shi/shi, shi/+,* and shi^{mld} mice resulted in myelin compaction (the formation of a major dense line) and the proportional increase in myelin thickness (Popko et al., 1987; Shine et al., 1990). This demonstrates that the amount of MBP available to oligodendrocytes is a rate-limiting step in the assembly of central nervous system myelin (Figure 39-3).

What is the functional difference of the MBP isoforms? The alternatively spliced mRNAs appear individually regulated throughout brain development, suggesting isoform-specific functions (Barbarese et al., 1978). On the other hand, it has been possible to phenotypically "cure" transgenic *shiverer* mice by reintroducing an MBP "minigene," which encodes only the smallest (14 kD) MBP (Kimura et al., 1989). Thus, the major structural function in myelin appears common to all MBP isoforms.

A *shiverer*-like phenotype has also been generated in normal mice by specifically downregulating the amount of MBP mRNA available for protein synthesis (Katsuki et al., 1988). This has been achieved by transgenic expression of the MBP gene in "antisense" orientation under the control of its cognate MBP promotor (the antisense RNA hybridizes to MBP transcripts, forming RNA duplex molecules that are degraded in the cell). Using the same technique, it may be possible to target other antisense RNAs into oligodendrocytes (or Schwann cells) of transgenic mice. This will allow to study the glial-specific function of those genes that are expressed in a variety of cell types.

The formation of antisense MBP RNA is the presumed primary defect of the mouse mutant *myelin-deficient* (symbol: shi^{mld}), an allele of the *shiverer* mutation on chromosome 18 (Doolittle and Schweikart, 1977). Here, a tandem duplication of the entire *MBP* gene, with the inversion of exons 3–7, creates a second transcription unit immediately upstream of the intact *MBP* gene (Figure 39-2), transcribing RNA that is in part complementary to the normal MBP transcript (Popko et al., 1988). The presence of this antisense RNA most likely reduces and dysregulates the amount of normal MBP mRNA toward a level insufficient for myelin formation (Fremeau

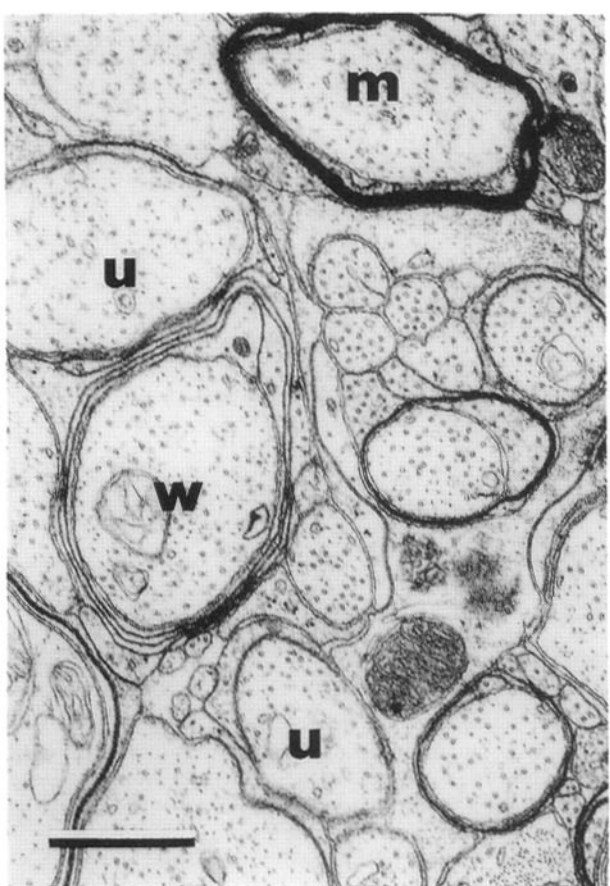

FIG. 39-3. Electron micrograph of partially myelinated fibers in the optic nerve of *shiverer* mice (*shi/shi*) transgenic for the myelin basic protein (*MBP*) gene (see Readhead et al., 1987). Whereas some axons remain unmyelinated (*u*) or loosely wrapped (*w*), more axons become ensheathed by compacted myelin (*m*) as the level of regained MBP expression increases in MBP-transgenic *shiverer* mice (here 12.5% of normal). Bar = 0.5 μm.

and Popko, 1990; Tosic et al., 1990). Morphologically, dysmyelination of shi^{mld}/shi^{mld} mice is less severe than of *shi/shi* mice. Interestingly, the genomic inversion occurred in the same region that has been deleted in *shiverer* mice, suggesting a "hot spot" of recombination in this part of the mouse *MBP* gene.

A puzzling observation in *shiverer* and its *mld* allele is the formation of functional myelin in the peripheral nervous system, including the formation of a normal "major dense line," despite the lack of MBP, which constitutes about 10% of the myelin protein made by normal Schwann cells (Privat et al., 1979; Kirschner and Ganser, 1980). Most likely, the structural function of MBP is substituted in *shiverer* by P_0, the major integral myelin protein of the peripheral nervous system (Lemke and Axel, 1985). The amino terminus of P_0 forms a "basic" domain located at the inside of the myelin membrane, which may be sufficient for the formation of a *major dense line*. Apparently, this "basic" structural function of MBP is redundant in the peripheral nervous system, even though MBP and P_0 share no obvious sequence homology (Martini et al., 1995).

PROTEOLIPID PROTEIN: DYSMYELINATION AND GLIAL CELL DEATH IN *jimpy* MICE

Proteolipid protein (PLP) is the most abundant integral membrane protein of myelin in the central nervous system, constituting roughly 50% of its protein mass. Two isoforms of PLP, the 30 kD major form (PLP apoprotein or lipophilin) and the 26 kD DM20 protein, are generated by alternative RNA splicing (Nave et al., 1987a), a recurrent feature of myelin genes. Several aspects of PLP are unusual and relevant to genetic defects associated with this gene. PLP appears relatively late in evolution as a central nervous system myelin protein of tetrapodes (Waehnelt et al., 1986), but DM20-related mRNAs exist in the central nervous system of lower vertebrates (Kitagawa et al., 1993). In higher vertebrates, PLP is specific to the compact myelin assembled by oligodendrocytes. The gene is also expressed at a low level in Schwann cells, but its function in the peripheral nervous system remains unclear. A second remarkable feature of PLP is its structural conservation in mammalian evolution. The PLP primary structure (276 amino acids) is 100% identical between mouse, rat, and humans, suggesting that PLP engages in multiple protein interactions, and, possibly, multiple cellular functions. PLP is an unusually strong hydrophobic protein with four predicted membrane-embedded domains (Figure 39-4). Alternative topological models have been proposed for PLP, but most evidence and theoretical considerations support a model with four α-helical domains and the amino- and carboxy termini oriented toward the cytoplasm, and the major dense line (Popot et al., 1991; Weimbs and Stoffel, 1992). It is likely that the membrane-associated domains of PLP interact in the lipid bilayer, possibly by forming a homooligomeric complex.

The mammalian *PLP* gene is linked to the X-chromosome, which has helped to identify its involvement in neurological defects of the mouse and in the human Pelizaeus-Merzbacher disease. These mutations have provided an unexpected glimpse at the complex function of PLP in oligodendrocyte development and myelin assembly.

In mice, three mutations of the *PLP* gene have been morphologically and genetically characterized:

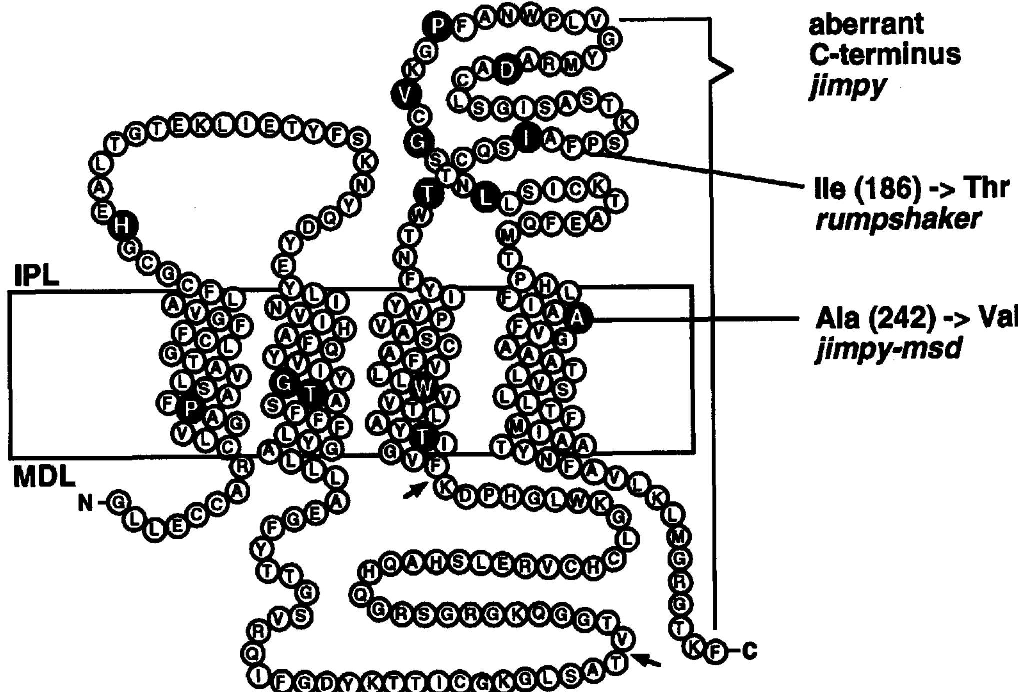

FIG. 39-4. Topological model of myelin proteolipid protein (PLP) depicted as a 4-helix bundle protein (see Popot et al., 1991) with the amino and carboxy termini oriented to the cytoplasmic surface of the lipid bilayer (*MDL,* major dense line; *IPL,* intraperiod line). The position of residues 116–150, absent from the DM20 isoform of PLP, is indicated by two *arrows.* The effect of three mutations in the mouse PLP gene (*jimpy, rumpshaker,* and *myelin-synthesis deficient*) is shown to the right. In *jimpy,* residues 207–276 are deleted and replaced by an aberrant carboxyterminus of 36 amino acids. Also indicated are the positions of single substitutions (*circles*) underlying lethal dysmyelinations in other species including the md rat (Thr74→Pro), *shaking pup* (His36→Pro), and human patients with Pelizaeus-Merzbacher disease (Pro14→Leu; Gly73→Arg; Thr155→Ile; Trp162→Arg; Thr181→Pro; Asp202→His; Pro215→Ser; Val218→Phe; Gly220→Cys; Leu223→Pro). For references see text.

jimpy (jp), myelin synthesis-deficient (*jp^{msd}*), and *rumpshaker (rsh).* All of them are point mutations that alter the structure of the encoded protein, as summarized in Figure 39-4. Each mutation results in a characteristic dysmyelinating phenotype, which is, assuming a complete loss of function in *jimpy,* more severe than the hypomyelination caused by MBP deficiency in the *shiverer* mouse.

In *jimpy* mice, the mutation is a single nucleotide change in the *PLP* gene, which inactivates the splice-acceptor site of intron 4 (the *PLP* gene spans 7 exons and is approximately 17 kb in length). This causes the loss of exon 5 from the fully spliced *jimpy* PLP mRNA with a deletion of 74 nucleotides and a shift in the normal open reading frame (Morello et al., 1986; Nave et al., 1986; Hudson et al., 1987; Macklin et al., 1987; Nave et al., 1987b). As a consequence, the encoded *jimpy* PLP lacks the last α-helical transmembrane domain, which is replaced by an aberrant carboxy terminus. The abnormally folded protein is degraded in the endoplasmic reticulum shortly after its synthesis and thus fails to reach the Golgi apparatus (Roussel et al., 1987). No immunoreactive PLP accumulates in *jimpy* oligodendrocytes and myelin membranes.

Morphologically, the central nervous system of the *jimpy* mouse is nearly completely myelin-deficient, whereas the peripheral nervous system myelin appears ultrastructurally intact (Sidman et al., 1964; Herschkowitz et al., 1971). Less than 1% of the axons normally myelinated in brain and spinal cord are ensheathed. Where present, "islands of myelin" in the mutant contain little more than a few layers of abnormally thin myelin. This myelin may consist of uncompacted whorls of membrane or display a compacted but abnormal ultrastructure: the double *intraperiod line* is fused to a single electron-dense structure, which has been attributed directly to the absence of a PLP domain from the extracellular space (Duncan et al., 1989).

The major and primary cause of dysmyelination in *jimpy,* however, is the well-documented lack of differentiated oligodendrocytes. Whereas in other myelin-deficient mutants, such as *shiverer,* oligodendrocytes are morphologically normal, in *jimpy* they remain immature. In fact, the proliferation rate of

oligodendrocyte precursor cells is increased, but an abnormal rate of apoptotic cell death eliminates most of the maturating oligodendrocytes (Farkas-Bargeton et al., 1972; Skoff, 1982; Knapp et al., 1986). It appears that the normal program of oligodendrocyte differentiation comes to a halt for the vast majority of cells before myelination has started. The degeneration of *jimpy* glial cells begins even before PLP becomes immunodetectable in normal mice (Vermeesch et al., 1990). Morphologically, dying oligodendrocytes in *jimpy* show typical features of programmed cell death (apoptosis), which is part of normal glial development (Barres et al., 1992), but in the PLP mutant mice at a vastly enhanced rate (Figure 39-5A). Only few oligodendrocytes escape degeneration and developmental arrest, producing scattered "islands" of myelinated fibers. Phenotypically, *jimpy* mice are most severely affected with a general body tremor and ataxia beginning at 2 weeks of age. They remain strikingly reduced in body weight and die from seizures and convulsions in the fourth week after birth. Heterozygous *jimpy* females, which are mosaics with respect to the X-linked *PLP* gene are behaviorally normal.

The phenotype of the allelic mouse mutant *jimpy*^{msd} (for myelin synthesis-deficient) is very similar to *jimpy*. Compared to *jimpy*, about twice as many glial cells escape premature degeneration and form visible myelin structures with a similar ultrastructural defect (Billings-Gagliardi et al., 1980). Remarkably, the molecular defect of *jimpy*^{msd} is a conservative amino acid substitution (Ala^{242}→Val) within the last transmembrane domain of PLP (Gencic and Hudson, 1990). This mutant protein is apparently also unstable, as very little of it is incorporated into myelin (Nussbaum and Mandel, 1973). It is unclear in which way this subtle structural change causes a dramatic loss of protein function, but it points again to critical protein interactions of PLP in the plane of the membrane.

A novel mutation of the *PLP* gene presents the mouse mutant *rumpshaker* (Schneider et al., 1992). Like the allelic mutants *jimpy* and *jimpy*^{msd}, the molecular defect is a single amino acid substitution of PLP (Ile^{186}→Thr); however, the phenotype of the mouse is different. *Rumpshaker* mice have more myelin than other dysmyelinated mutants and the degree of dysmyelination varies more strikingly between central nervous system regions than in other PLP mutants. Early myelinated spinal cord axons are nearly normally ensheathed, whereas late myelinated areas, such as the optic nerve, remain severely hypomyelinated. Ultrastructurally, oligodendrocytes appear differentiated and, most importantly, most of them escape apoptotic cell death. Thus, *rumpshaker* mice have a normal complement of mature oligodendrocytes (Griffiths et al., 1990). The mutant DM20 isoform (but not PLP itself) can be readily detected in the myelin membrane with site-specific antibodies (Schneider et al., 1992). This suggests that the *rumpshaker* mutation interferes with the oligodendrocytes ability to deposit PLP in the myelin membrane, and that the surface expression of DM20 may be sufficient to allow oligodendrocytes to survive (Figure 39-5b). *Rumpshaker* mice are viable, live without seizure activity, and have a normal life span.

In several other mammalian species, mutations of the *PLP* gene have been identified, and most of them result in a structurally altered form of PLP and DM20 (Figure 39-4). In a myelin-deficient strain of the rat (*md*), a point mutation changes Thr^{74}→Pro in the second transmembrane domain of PLP (Boison and Stoffel, 1989). A single base change in the canine *shaking pup* causes the substitution His^{219}→Pro close to the first transmembrane domain of PLP (Nadon et al., 1990). Ultrastructurally, the oligodendrocytes in both mutants show unusual intracellular vacuoles, presumably caused by aberrantly folded PLP unable to exit the endoplasmic reticulum. Mutations of the human *PLP* gene, including the complete deletion of the locus, have been identified in several patients with Pelizaeus-Merzbacher disease (Pham-Dinh et al., 1991).

When the entire normal *PLP* gene was reintroduced into *jimpy* mice as an autosomal transgene (in an attempt to restore myelination), the wild-type *PLP* transgene was normally expressed but the dysmyelinated phenotype of the *jimpy* mice did not change. Thus, in experimentally created "heterozygous" oligodendrocytes (normal heterozygous *jimpy* females are mosaic with respect to the X-linked *PLP* gene), the *jimpy* allele acts in a dominant-negative fashion (Schneider et al., 1995). This may reflect that normal and mutant proteins interact in the endoplasmic reticulum, form aberrantly folded complexes, and are, in part, jointly degraded by resident proteases. Surprisingly, PLP-transgenic wild-type mice which overexpress the normal *PLP* gene more than twofold become themselves myelin-deficient with tremors, seizures, and premature death (Kagawa et al., 1994; Readhead et al., 1994). The extent of dysmyelination in the PLP transgenic mice and their survival time is determined by the degree of PLP overexpression (e.g., the transgene copynumber). Thus, both PLP overexpression and structural mutations interfere in a similar way with myelin formation; however, the mechanisms that make oligodendrocytes so vulnerable to and dependent on PLP function are not understood.

PROTEIN ZERO: AN ADHESION MOLECULE OF SCHWANN CELLS AND P_0-DEFICIENT MICE

In myelin of the peripheral nervous system, the major protein component—approximately 50% by mass—is protein zero (P_0), a glycosylated membrane protein of 219 amino acids (molecular weight: 30 kD). With a single transmembrane domain and one immunoglobulin (Ig)-like extracellular domain, P_0 is an ancestral member of the Ig superfamily of proteins (Lemke and Axel, 1985; Lemke et al., 1988).

The presence of ultrastructurally normal peripheral nervous system myelin in the myelin basic protein-deficient *shiverer* mouse had provided indirect evidence that P_0 serves at least one function related to that of myelin basic protein in the central nervous system: mediating the intracellular adhesion of two apposed myelin membranes with formation of the major dense line. This redundancy in function with myelin basic protein would be accomplished by the basic intracellular domain of P_0. The second and presumably major function of the protein concerns its extracellular Ig domain oriented toward the intraperiod line of myelin. Here, the direct implication of P_0 as a homophilic cell adhesion molecule resulted from transfection studies and ectopic surface expression of P_0 in nonglial cells: P_0 mediates both the formation of junction structures between cells in a monolayer and the aggregation of cells in suspension (D'Urso et al., 1990; Filbin et al., 1990; Schneider-Schaulies et al., 1990). That P_0 is essential for the formation of peripheral myelin was first demonstrated by the expression of P_0 antisense RNA in cultured Schwann cells (Owens and Boyd, 1991), which interfered with the normal assembly of myelin. Without a known spontaneous mutation of the P_0 gene (located on mouse chromosome 1), the *in vivo* analysis of P_0 function had to await the targeted disruption of the gene in transgenic mice.

P_0-deficient mice have been generated by homologous recombination of the P_0 gene in mouse embryonic stem cells with the cloned gene (interrupted by the neomycin resistance gene in exon 1) and subsequent generation of germline chimeric mice (Giese et al., 1992). Heterozygous animals lacking one functional copy of the P_0 gene in the F1 generation are phenotypically normal, but homozygous P_0-deficient mice (P_0-/P_0-) develop a novel behavioral phenotype shortly after the second postnatal week: a body tremor and dragging movements of the hindlimbs. Seizures and paralysis are absent, however, and the mutants have a normal life span. As predicted, the underlying defect is the inability of Schwann cells to assemble a multilayered normally compacted myelin sheath. The events preceding myelin formation, including the association of Schwann cells with single axons in a 1:1 ratio are not disturbed. Interestingly, Schwann cells in one and the same mutant animal differ considerably in the degree of dysmyelination, even though they are genetically identical. It is thus likely that the complete loss of P_0 function is, at least in part, masked by other variables, in particular, some cell adhesion molecules (myelin-associated glycoprotein; N-CAM), which are abnormally abundant in the myelinlike ensheathements of P_0-deficient mice. Even PLP, which is normally expressed at a very low level in Schwann cells and which is excluded from peripheral myelin, becomes a prominent myelin protein in the absence of P_0. Future experiments will define the direct and indirect effects of this novel mutation, including the intriguing finding of many degenerating axons engulfed by P_0-deficient Schwann cells.

It is interesting to compare the loss of P_0 in mutants with the ablation of Schwann cells in transgenic mice when coupled to the onset of P_0 expression. Using the promoter and regulatory region of the P_0 gene in a fusion gene construct, a bacterial toxin has been experimentally expressed in Schwann cells of transgenic mice (a few molecules of the diphtheria toxin A peptide are sufficient to kill a cell). This dominant "mutation" in mice causes the physical loss of the majority of myelin-forming Schwann cells, which begin to express P_0 after associating in a 1:1 ratio with axons (Messing et al., 1992). The behavioral phenotype of the Schwann cell-ablated mice closely resembles that of P_0-/P_0- mutants. Indirect effects of this lesion include the proliferation of non-myelin-forming Schwann cells, presumably triggered by the myelin-deficient local milieu, and skeletal muscle atrophy. The abnormal degeneration of large caliber axons, noted in the peripheral nervous system of P_0-deficient mice, is less prominent.

FIG. 39-5. (A) Electron micrograph of a dying oligodendrocyte in the spinal cord of a 3-week-old *jimpy* mouse carrying a mutation in the proteolipid protein gene. Note the chromatin condensations characteristic of apoptosis (programmed cell death) and the complete absence of myelin from surrounding axons (*G*, Golgi apparatus; *ER*, endoplasmatic reticulum). (B) Hypomyelination in the spinal cord of *rumpshaker* mice. This mutation is allelic to *jimpy* but differs by the survival rate and number of mature oligodendrocytes. The proximity of myelinated and dysmyelinated large-caliber axons is striking and indicates a defect in terminal oligodendrocyte differentiation rather than a structural defect of PLP-dependent myelin assembly.

The "mutant" mice die at 3 to 4 months of age, but the exact cause of death has not been determined.

PMP-22: A SCHWANN CELL GROWTH DEFECT IN *trembler* MUTANT MICE

A second integral membrane protein specific to Schwann cells is the glycoprotein PMP-22 (for 22 kD peripheral myelin protein). Only recently discovered as a gene product that is differentially regulated in Schwann cells proximal and distal to a peripheral nerve cut, PMP-22 has been quickly recognized as a myelin protein, which is important for normal Schwann cell development (Spreyer et al., 1991; Welcher et al., 1991).

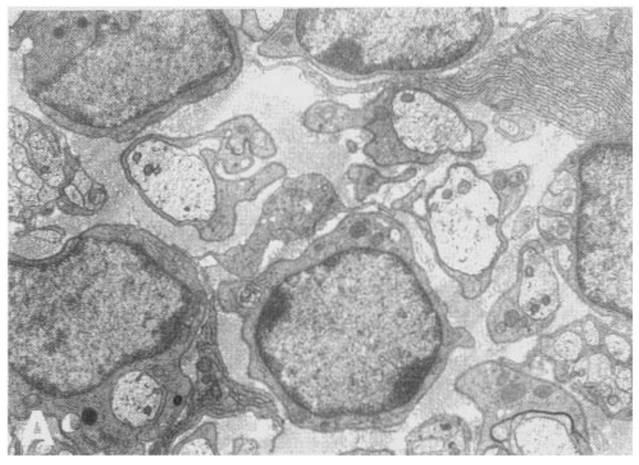
The primary structure of the 160-residue PMP-22 protein is well conserved between rodents and human (87%), in particular within the four predicted transmembrane domains. PMP-22 is identical to the gas-3 protein, which was identified first as a growth arrest-specific gene transcript in NIH3T3 cells (the reason for the expression of this myelin gene in a fibroblast cell line is unclear). The glial protein is incorporated into compacted myelin and is coregulated with the major myelin genes of the peripheral nervous system in both development and, after injury, in the regenerating nerve. PMP-22 could be a structural component of myelin, but a nonstructural role in Schwann cells is also likely, for example, in maintaining the quiescent state, but this has not been shown experimentally. Some insight into PMP-22 function came from two neurological mouse mutants and the involvement of the *PMP-22* gene in a human peripheral neuropathy (see the subsection *Charcot-Marie-Tooth Disease* this chapter).

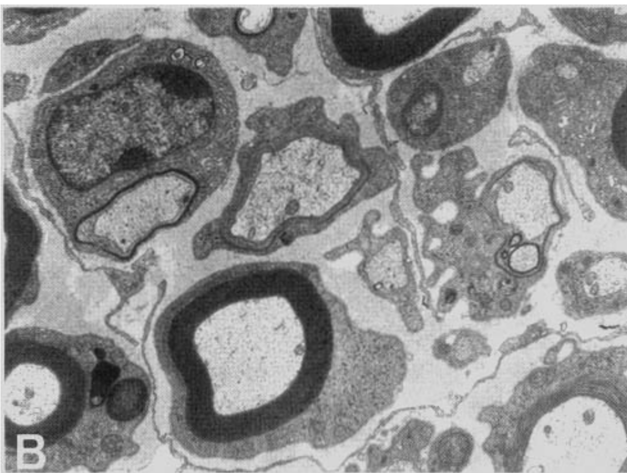
A mutation of the *PMP-22* gene is the primary cause of dysmyelination in the *trembler* mouse (Tr; mouse chromosome 11), which has a myelination defect restricted to the peripheral nervous system (Falconer, 1951). A point mutation has been identified that causes a nonconservative amino acid substitution (Gly^{150}→Asp) within the predicted fourth transmembrane domain of PMP-22 (Suter et al., 1992a). Most likely the mutant protein is abnormally folded and nonfunctional. The *trembler* mutation is semidominant, which implies that either a 50% reduction of functional PMP-22 is not tolerated (haploinsufficiency) or that the mutant protein exerts a dominant-negative effect on the normal protein (as observed in PLP-transgenic *jimpy* mice).

Two aspects of the *trembler* phenotype are important to the normal cellular PMP-22 function. First, the majority of large caliber axons in the sciatic nerve remains completely naked (up to 70% in Tr/+ mice instead of 1% in normal mice), and the myelin sheaths, where present, are abnormally thin and compacted (Henry and Sidman, 1988). Second, myelination is arrested in affected Schwann cells at the promyelin stage when they have segregated with axons in a 1:1 ratio. At the same time, the total number of Schwann cells in the *trembler* peripheral nerve is dramatically increased relative to normal. This could be either the primary defect (in a growth-arrest function of PMP-22) or a less specific secondary response to dysmyelination (as seen in Schwann cell-deficient mice). Older *trembler* mice show signs of both dysmyelination and demyelination with characteristic "onion bulb" formations, a sign of Schwann cell hypertrophy related to the pathology of peripheral nerves in patients with Charcot-Marie-Tooth disease.

Homozygous *trembler* mice (*Tr/Tr*) assemble virtually no peripheral myelin. The behavioral phenotype of hypomyelinated *Tr/+* and myelin-deficient *Tr/Tr* mice is nevertheless the same: a coarse action tremor that begins at the end of the second postnatal week and results in moderate quadriparesis and an overall waddling gate. Interestingly, *trembler* mutant Schwann cells exert secondary effects on the engulfed nerve axons: their diameter is significantly decreased, the axonal transport is slowed down, and neuronal filaments are abnormally phosphorylated; however, the nature of this glial-neuronal interaction is not understood (Aguayo et al., 1977; de Waegh et al., 1992). Remarkably, all *trembler* mice, including the homozygous, are fully viable and long-lived, suggesting that under the artificial living conditions of the laboratory cage, a mouse can survive in the complete absence of peripheral myelin (Henry and Sidman, 1988). This contrasts with the lethal phenotype of a second *trembler* allele and the limited life span of Schwann cell-deficient mice.

The second mutation of the PMP-22 gene was identified in *trembler-J* (Tr^J) mice. In this allele, a nonconservative substitution (Leu^{16}→Pro) alters the first transmembrane domain of PMP-22 (Suter et al., 1992b). As in *Tr*, the mutant protein is presumably nonfunctional and aberrantly folded. The phenotype of heterozygous $Tr^J/+$ mice is similar to the original *Tr* allele; however, the expression is more clearly semidominant: a marked decrease of peripheral myelination is associated with a wide spectrum of Schwann cell differentiation, many cells being arrested at the "promyelin" stage (Figure 39-6). Tr^J/Tr^J mice, with a complete lack of peripheral myelin, are clinically more severely affected (than the viable *Tr/Tr*) with quadriparesis and premature death at about 3 weeks of age. The latter is surprising, considering that the homozygous animals of both *trembler* alleles appear equally myelin-deficient, but only





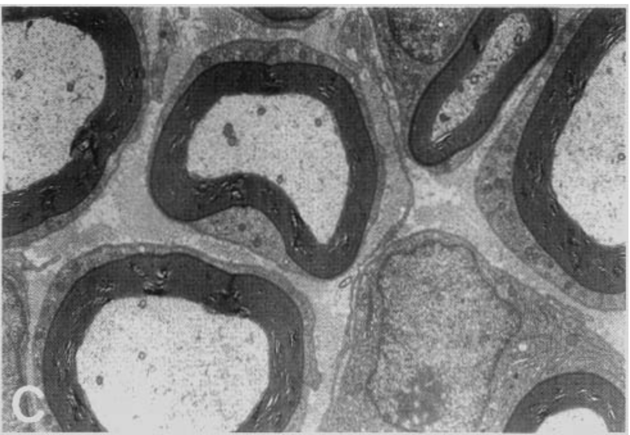


FIG. 39-6. Transverse section of sciatic nerves from 13-day-old *trembler*^{J} mice with a point mutation in the gene encoding PMP22. (A) In homozygous animals (Tr^J/Tr^J), myelin is completely lacking, but individual axons have been engulfed by mutant Schwann cells in a 1:1 ratio. (B) In heterozygous mice ($Tr^J/+$), many cells are arrested at the "promyelin" stage, but there is a wide range of Schwann cell differentiation (C) when compared to sciatic nerves from unaffected littermates. [Adapted from Henry and Sidman (1983), with permission.]

trembler^J mice succumb to it. In fact, when the amount of MBP in sciatic nerve extracts is taken as a measure of dysmyelination, mice of the lethal *trembler-J* allele are better myelinated than the viable *trembler* allele (Fryxel, 1983). This paradox could result from a different genetic background of the two mutations or relate to the expression of PMP-22 in other parts of the nervous system. Whether the increased proliferation of Schwann cells in either *trembler* mutant prevents normal myelination or, vice versa, is a response to dysmyelination is not known. Experiments involving transgenic mice and ectopic PMP-22 expression in cultured cells may help to define the function of this protein during growth and differentiation.

OTHER MYELIN GENES

Several neural genes which have been molecularly cloned qualify as "myelin genes" because they either encode structural proteins of the myelin sheath or myelin-associated regulatory molecules, such as transcription factors. Intensively studied proteins in this group include the myelin-associated glycoprotein (MAG), myelin-oligodendrocyte glycoprotein (MOG), the enzyme 2′,3′-cyclic nucleotide 3′-phosphohydrolase (CNPase), or the POU-homeobox protein SCIP (suppresed *c*AMP-inducible *POU*). So far, these proteins have not been correlated with existing neurological mutations in the mouse. However, it will be possible to study all of these genes as a loss-of-function mutation in the near future. Possibly, some of these engineered mutations may not simply reveal the proteins normal function, as the phenotype is too complex, embryonically lethal, or because there is no detectable phenotype at all (if other genes serve redundant functions). There are multiple examples for each scenario in other systems. The second group of "myelin genes" is at present only genetically defined with a phenotype that affects primarily myelination. A well-studied gene in this group is *quaking* (*qk*), a recessive mutation on mouse chromosome 17 (Sidman et al., 1964). Homozygous mice carrying the viable *quaking* allele (qk^v/qk^v) show the typical behavioral signs of dysmyelination, but rarely seizures, and have a normal life span. The myelin deficiency of the central nervous system is more severe than the dysmyelination of the peripheral nervous system, suggesting (but not proving) that the *qk* protein is predominantly expressed in brain and spinal cord. Axons are thinly myelinated, but rarely naked. In peripheral myelin of *quaking*, a lack of normal compaction and enlarged "intraperiod line" of some myelinated fibers has been noted (Trapp, 1988). My-

elin-associated glycoprotein (MAG), which is normaly restricted to the innermost myelin layer facing the axon is distributed throughout the compact myelin sheath of *quaking* mice. Such an ultrastructural defect may be caused by a dysregulation of the alternative MAG mRNA splicing, whereas the *MAG* gene itself (mapped to mouse chromosome 7) cannot be the site of the mutation. Homozygous male mutants are sterile (caused by a sperm defect), which indicates that the *qk* gene serves a second function in testes or that the viable qk^v mutation affects more than one gene. The latter is supported by the generation of several *qk*-allelic point mutations by saturation mutagenesis—some of which are embryonically lethal. The recent finding of a large genomic deletion associated with chromosome 17 of qk^v mice (Ebersole et al., 1992) suggests that the *quaking* gene will soon be identified.

IMPLICATIONS FOR HUMAN GENETIC DISEASES

Neurological mouse mutants may provide true animal models for human neurological diseases. Three myelin genes have been specifically implicated in homologous genetic disorders in man and mouse: the *PLP* gene in patients with Pelizaeus-Merzbacher disease, the *PMP-22* gene in patients with Charcot-Marie-Tooth disease type 1a, and the P_0 gene in patients with Charcot-Marie-Tooth disease type 1b. In two cases the neurological mouse mutants (*jimpy, trembler*) were instrumental as models for the identification of the human gene defects.

Pelizaeus-Merzbacher Disease

Pelizaeus-Merzbacher disease (McKusick No. 312080) is a lethal X-chromosome-linked disorder characterized by the lack of myelin formation in the central nervous system. Based on the degree of myelin deficiency and the onset of clinical symptoms, several subtypes of Pelizaeus-Merzbacher disease have been defined. Clinically, Pelizaeus-Merzbacher disease is diagnosed when male infants (*connatal* type) or young boys (*classical* type) develop a severe defect of motor control (nystagmus, spasticity, ataxia) and often psychomotor retardation as a result of a generalized myelin deficiency of the central nervous system (as diagnosed by magnetic resonance imaging). The homology of this genetic disease with the dysmyelinating phenotype of the X-chromosome-linked mouse mutants (Koeppen et al., 1987) and the identification of point mutations in the rodent *PLP* gene prompted the detailed analysis of the human gene in Pelizaeus-Merzbacher disease patients (Hudson et al., 1989). As of today, more than thirty different mutations of the *PLP* gene have been associated with Pelizaeus-Merzbacher disease (Figure 39-4), including the complete deletion of the *PLP* locus (Gencic et al., 1989; Troffater et al., 1989; Pham-Dinh et al., 1991; Raskind et al., 1991; Iwaki et al., 1993). Most of the *PLP* gene mutations are single-base changes that cause amino acid substitutions of the protein. As in the mouse models of Pelizaeus-Merzbacher disease, it is likely that the onset of the disease and its clinical course is determined by the specific functional defect of the mutant PLP. The abnormal regulation of the *PLP* gene may also cause Pelizaeus-Merzbacher disease, because an interstitial duplication of the human X chromosome which includes the *PLP* locus results clinically in Pelizaeus-Merzbacher disease (Cremers et al., 1987), and a mere twofold overexpression of the normal *PLP* gene causes dysmyelination in transgenic mice (Readhead et al., 1994).

Charcot-Marie-Tooth Disease

Among the human motor-sensory neuropathies, Charcot-Marie-Tooth disease type 1a (Charcot-Marie-Tooth1a or human motor-sensory neuropathy1) is the most common inherited peripheral neuropathy, linked to human chromosome 17 (autosomal-dominant). Clinically, nerve conduction velocities are decreased and associated with sensory losses and muscle weakness as the first signs of the disease. Schwann cells are hypertrophic with ultrastructural signs of dys- and demyelination ("onion-bulb formation"). As in Pelizaeus-Merzbacher disease, mutations affecting the structure of the protein and those affecting expression level cause a very similar disease. Cytogenetic evidence indicated that in several families Charcot-Marie-Tooth1A is associated with an interstitial duplication on the short arm of chomosome 17. Human chromosome 17 is, to a large extent, syntenic to mouse chromosome 11 which encodes the peripheral myelin protein PMP-22. The human *PMP-22* gene is contained within the duplicated part of chromosome 17 (Patel et al., 1992; Timmerman et al., 1992) suggesting that 50% overexpression of the *PMP-22* gene causes Charcot-Marie-Tooth1A. Other families were identified with point mutations in the *PMP-22* gene. In fact, the identical mutation identified first in the mouse mutant *trembler-J* ($Leu^{16} \rightarrow Pro$) was found in a human patient with Charcot-Marie-Tooth1a (Valentijn et al., 1992). This also demonstrates that the clinical picture of the same molecular defect can be quite different between a short-lived mouse and a human patient. A partial deletion of chromosome 17 (the reciprocal meiotic loss of the

interstitial duplication in Charcot-Marie-Tooth1a patients) was identified in families with the peripheral myelin disease hereditary neuropathy with liability to pressure palsies (McKusick 162500) (Chance et al., 1993). This latter disease affects young adults and is defined by a recurrent demyelinating condition of peripheral nerves following minor traumas, most likely caused by haploinsufficiency of the human *PMP-22* gene. The pathomechanisms, however, remains to be determined. A second familial form of Charcot-Marie-Tooth disease (type 1B) is linked to human chromosome 1 and most likely caused by mutations in the gene for P_0 (Hayasaka et al., 1993; Kulkens et al., 1993). The autosomal-dominant mode of inheritance contrasts, at first glance, with the previous observation that heterozygous P_0- mice are normally myelinated, but may be explained with a dominant-negative function of mutant P_0 in compacted myelin. A complete loss of P_0 or PMP-22 function may underlie the rare Déjerine-Sottas neuropathy.

CONCLUSIONS

The combination of classical and molecular genetic techniques has provided insight into the *in vivo* function of the major myelin protein genes. Most dysmyelinating mouse mutants have been studied in detail without prior knowledge of the underlying primary genetic defect which allowed an "unbiased" analysis of each phenotype. In general, the developmental abnormality of the mutant mice is in good agreement with the predicted role of the major structural myelin proteins in assembly and maintaining the multilayered compacted sheath. A certain degree of redundancy between functionally related proteins may mask the full loss of function of a single gene. For some myelin proteins, a more complex phenotype has provided a glimpse at cellular functions of myelin proteins, which may exceed that of simple structural components. It is possible that these myelin proteins have been recruited as structural components from a primary function in glial cells, which is yet unrelated to myelin assembly. In the near future, the number of available myelin mutants will increase as more genes have been molecularly cloned and are used to generate transgenic mouse mutants. Further unraveling of the myelination process may soon come to illustrate that mammalian brain development can be dissected with the tools of genetics.

For providing original electron micrographs, I am indebted to Drs. David Shine (Figure 39-3), Pamela Knapp and Robert Skoff (Figure 39-5a), Ian Griffiths (Figure 39-5b), and Richard Sidman (Figure 39-6). I also thank Drs. Kazuhiro Ikenaka, Greg Lemke, Robert Milner, Carol Readhead, Melitta Schachner, Armin Schneider, and Greg Sutcliffe for helpful discussions. My work was supported by a grant from the Bundesministerium für Forschung und Technologie (BMFT 0316000A).

Note added in proof: Target inactivation of the mouse MAG gene has now been reported by Montag et al. (1994) and Li et al. (1994).

40 Axoglial interactions at the cellular and molecular levels in central nervous system myelinated fibers

STEPHEN G. WAXMAN AND JOEL A. BLACK

It is now clear that myelinated fibers and nodes of Ranvier in the central nervous system are complex structures where the axon, the oligodendrocyte, and the perinodal astrocyte interact in a highly coordinated manner. In this chapter we discuss the interaction of axons, oligodendrocytes, and astrocytes in the maturation of the central myelinated fibers and node of Ranvier. In examining the collaboration between these three cell types in myelinated central nervous system axons, we focus on three fundamental questions.

First, what are the factors that control the development of the myelinated fiber at the *cellular* level and the mechanisms that determine the structure of the myelin sheath (and thus of its component spiral of oligodendroglial membrane? In most myelinated tracts the internodes have properties that optimize a number of axonal functions (Rushton, 1951). One example is provided by the thickness of the myelin sheath. Conduction velocity scales linearly with diameter in myelinated fibers and is maximized when myelin thickness has a value such that the g ratio (diameter of axon within myelin sheath: outer diameter of myelin sheath) is close to 0.6. The number of myelin lamellae in most central nervous system myelinated fibers is matched to axon diameter so that g ratios fall close to this optimal value over a wide range of diameters (Waxman and Bennett, 1972). A second example is provided by the internode distance, or distance between the nodes of Ranvier. Physiological studies show that there is an optimal ratio of internode distance to fiber diameter (approximately 100 to 200), which maximizes conduction velocity (Brill et al., 1977). In many white matter tracts [excluding "delay line" tracts where axons interpose specific time-delays (Waxman, 1971) and preterminal axons where short myelin internodes mediate impedance matching (Waxman and Brill, 1978)], the measured values for internode distance are close to those predicted for maximization of conduction velocity (Hess and Young, 1952; McDonald and Ohlrich, 1971). This optimization, in terms of the structure of the myelinated internodes, focuses attention on the interactions between axons and glial cells that regulate parameters such as the number of lamellae in the myelin sheath and the length of the oligodendroglial wrapping, which determines internode distance.

Second, what is the *molecular* architecture of central nervous system myelinated fibers, how are the ion channels distributed in the axon membrane, and how do glial-axonal interactions localize channels at specific sites? The voltage-gated Na^+ channels that underlie the depolarization phase of the action potential are not distributed at random along the myelinated axon but, on the contrary, are clustered in high densities in the axon membrane at the node of Ranvier, precisely where they are required for action potential electrogenesis (Ritchie and Rogart, 1977; Waxman, 1977). "Fast" K^+ channels, in contrast, are localized in the axon membrane under the myelin in the paranodal and/or internodal regions (Chiu and Ritchie, 1981b; Kocsis et al., 1982). A detailed account of the distribution and function of these, and other, ion channels and other active molecules in the membrane of the myelinated fiber, can be found in Waxman and Ritchie (1993). The clustering of ion channels at specific sites in the axon membrane, precisely correlated with the location of the myelin sheath and the node of Ranvier, raises the question of how interactions with glial cells modulate the molecular structure of the axon membrane.

Third, what is the relationship between perinodal astrocyte processes and the node of Ranvier? Perinodal astrocytes, as well as axons and oligodendrocytes, are major components of central nervous system white matter tracts. Suzuki and Raisman (1992) have proposed a model in which longitudinally oriented oligodendrocyte processes and radially oriented astrocyte processes interdigitate in a stereotyped manner within central nervous system white matter. Electron microscopy has, in fact, demon-

strated a highly specific relationship between astrocyte processes and the node of Ranvier in the central nervous system.

The node of Ranvier in the central nervous system comprises three cell types: the axon, the oligodendrocyte, and the astrocyte. In this discussion of central nervous system myelinated fibers, we examine interactions not only between the oligodendrocyte and the axon, but also with the astrocyte.

LOCAL AXON-OLIGODENDROCYTE INTERACTIONS REGULATE MYELIN FORMATION

Oligodendrocytes are the cells of origin of central nervous system myelin sheaths (Bunge et al., 1961; Hirano, 1968; Waxman and Sims, 1984). At early stages of development the axon is loosely ensheathed by processes arising from immature, relatively undifferentiated glial cells (Figure 40-1). This early ensheathement soon gives way to a spiral wrapping of the axon by oligodendroglial processes that form compact myelin. In some tracts the immature myelin sheaths are initially close to the oligodendroglial cell body (Remahl and Hildebrand, 1990), but, as maturation proceeds, the sheaths appear to be displaced radially; thus, in many mature white matter tracts, the myelin sheaths remain connected only by thin cytoplasmic bridges to the oligodendroglial cell bodies from which they originate. This morphological arrangement is illustrated at the light microscopic level in Figure 40-2, which shows a dye-filled image of a presumed oligodendrocyte from the intact rat optic nerve (Butt and Ransom, 1989). The number of axons, myelinated by a single oligodendrocyte, ranges from less than five for some oligodendrocytes to dozens for others (Butt and Ransom, 1989; Bjartmar et al., 1994).

Figure 40-3 is an electron micrograph showing a maturing oligodendrocyte, together with myelin sheaths that originate from it. Two myelinated axons, the oligodendroglial cell of origin of their myelin sheaths and the thin cytoplasmic processes connecting the oligodendrocyte to the myelin sheaths, are shown. In Figure 40-3 (inset) the thin bridge of oligodendroglial cytoplasm, connecting the myelin sheath to its cell of origin, can be seen at higher magnification.

Figure 40-3 illustrates several important features of oligodendroglial organization, and of the relationship between the oligodendrocyte and myelin sheaths. As noted by Waxman and Sims (1984) and confirmed by Remahl and Hildebrand (1990), the myelin sheaths originating from each oligodendrocyte rotate in random directions, some extending clockwise and the others counterclockwise from their oligodendrocytic stalks. Thus, the myelin circles clockwise around axon A_1 and counterclockwise around axon A_2. The random polarities of the myelin sheaths, despite their origin from the same oligodendrocyte, indicates that the myelin spirals cannot be formed by rotation of the glial cell body around the outer edge of the myelin. On the contrary, the myelin must grow by addition of membrane at, or near, the leading edge of the oligodendroglial processes. This suggests that membrane biosynthesis during myelination is a *local* process, occurring in distal parts of the oligodendroglial process close to the myelin or within the myelin sheath itself.

The myelin sheath is formed by an elaboration of the membrane of the oligodendrocyte, and myelination involves a marked increase in membrane area. The machinery necessary for myelin membrane biosynthesis, in fact, is distributed distally, so that it is located close to the forming myelin sheaths. As shown in Figure 40-3 (inset), polyribosomes and cisternae of ribosome-studded endoplasmic reticulum are present, during development, in distal parts of the oligodendroglial processes, close to the developing myelin sheaths (Waxman and Sims, 1984). A similar proliferation of ribosome-studded endoplasmic reticulum in Schwann cells during myelination in the peripheral nervous system was observed by Robertson (1961), who suggested that this reflects increased membrane biosynthesis during myelination. Transient elaboration of intracytoplasmic membranes, within paranodal oligodendroglial loops associated with maturing myelin sheaths in the central nervous system of developing animals, has also been observed (Waxman et al., 1988). These membranes form tubulovesicular profiles which are most prominent in paranodal loops closest to the node, that is, in parts of the oligodendroglial cytoplasm corresponding to the outermost myelin lamellae, which were probably formed most recently. The presence of these membrane profiles during myelination appears to reflect increased membrane turnover in paranodal oligodendroglial loops, close to the axon. These observations demonstrate a substrate for protein biosynthesis and an intracytoplasmic pool of membrane within distal oligodendroglial processes at sites close to the axon during myelination in the central nervous system. They thus support the hypothesis (Waxman and Sims, 1984) of local membrane assembly within the oligodendroglial processes during myelination.

It appears likely that localized axoglial interactions also participate in the control of myelin sheath characteristics. Myelin formation by a given oligodendrocyte is not stereotyped; it is not, for example, limited to axons of a single diameter. On the con-

trary, single oligodendrocytes can myelinate axons of various diameters in their vicinity. Moreover, a single oligodendrocyte can form myelin sheaths of different thickness around axons of differing diameter. Despite their origin from the same oligodendroglial cell, the myelin sheaths are thicker for larger axons (Waxman and Sims, 1984). The thickness of the myelin sheaths is thus not preprogrammed for each oligodendrocyte but, on the contrary, depends on *local regulation,* by the axon, of myelination.

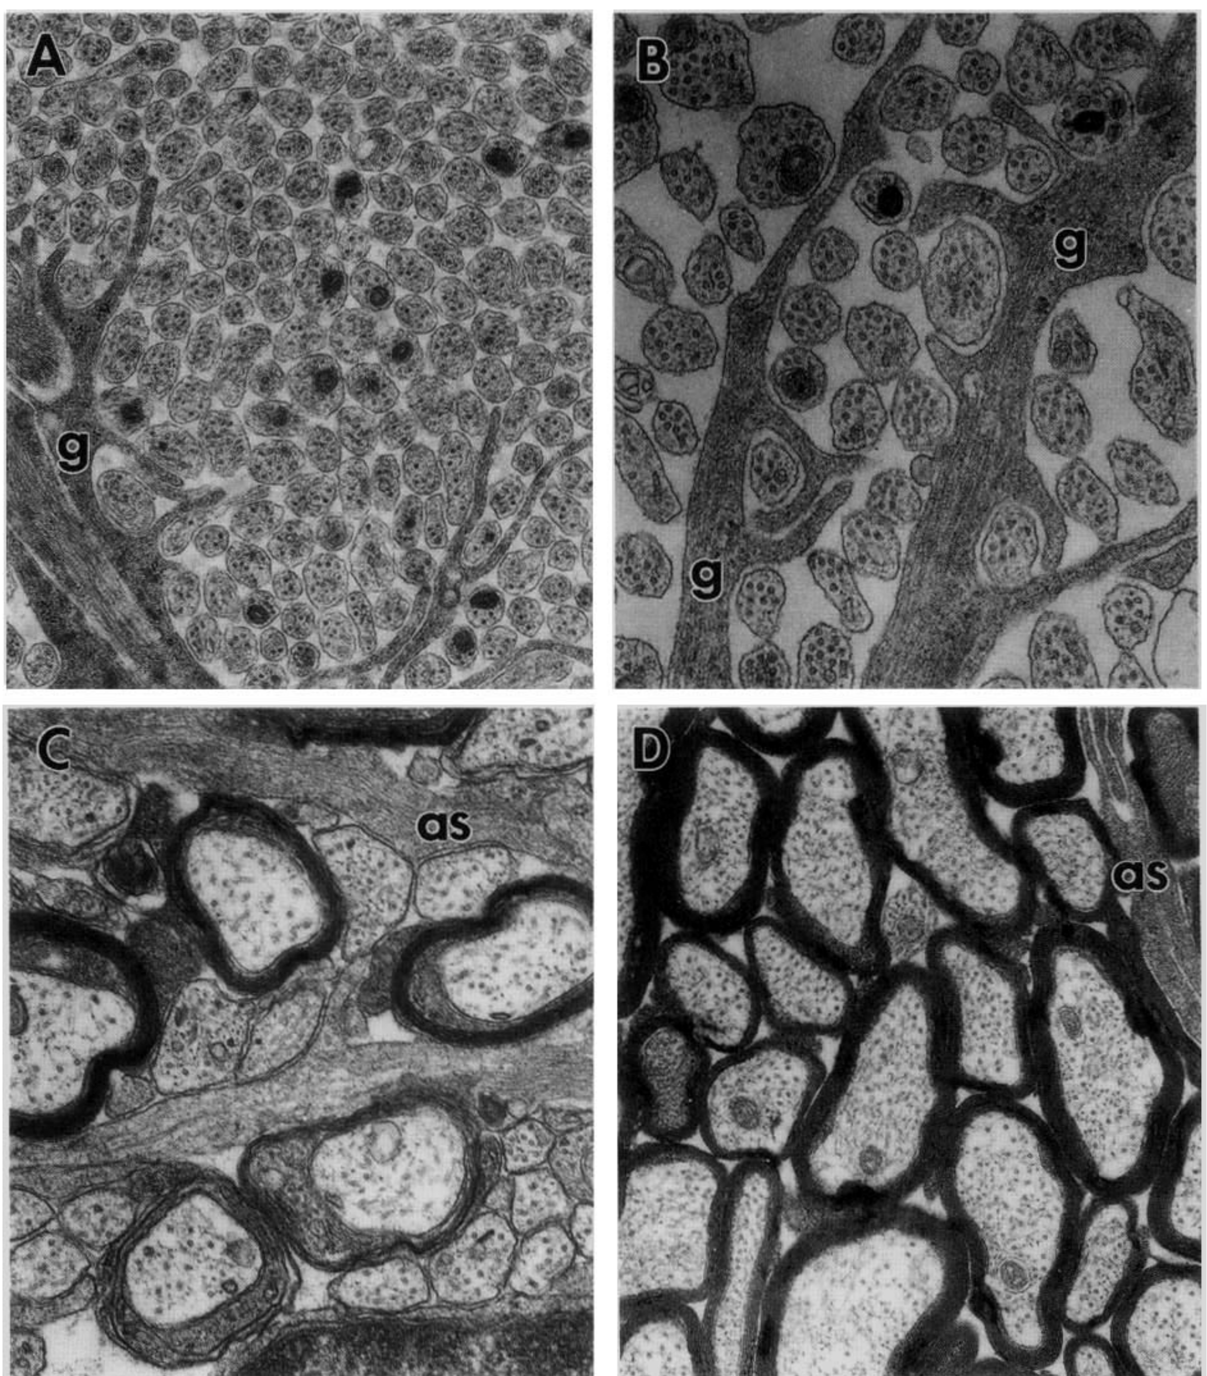

FIG. 40-1. Development of myelinated axons in rat optic nerve, as seen by electron microscopy in transverse section. (A) 2 days postnatal. Occasional septae composed of primitive glial cell processes (*g*) divide the fiber tract into bundles, but most of the premyelinated axons are not yet ensheathed. ×20,000. (B) 8 days old. Occasional axons are loosely ensheathed by primitive, undifferentiated glial cells, but myelin is not yet present. ×40,000. (C) 16 days old. Approximately 20% of the axons are surrounded by compact myelin. ×20,000. (D) Adult. The optic nerve is fully myelinated. ×20,000.

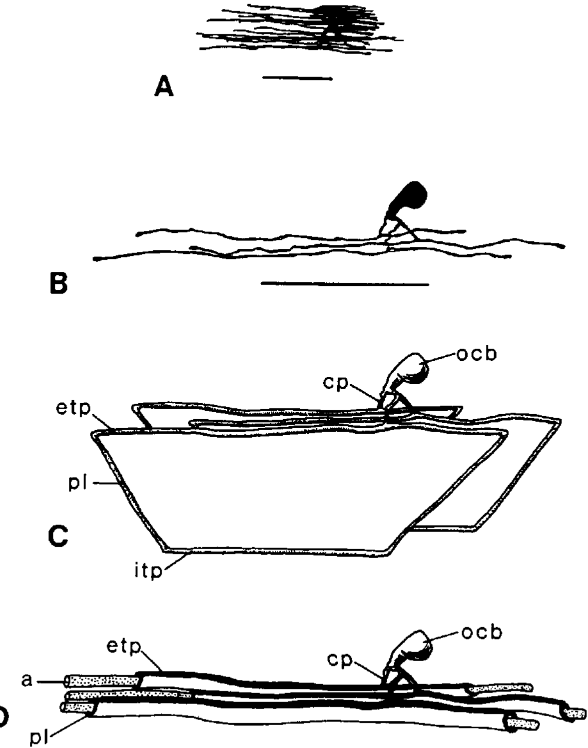

FIG. 40-2. Dye-filled image of a presumed oligodendrocyte. (A) Camera lucida drawing of HRP-filled oligodendrocyte from rat optic nerve (*P12*). Scale bar = 100 μm. (B) Camera lucida drawing of A at higher power (×1250); only the cell body and three selected longitudinal processes have been drawn. Scale bar = 100 μm. (C) Schematic interpretation of the light microscopic morphology of the oligodendrocyte. If the myelin sheaths could be unwrapped they would appear as trapezoid sheets with ridges of cytoplasm along their edges corresponding to the internal and external tongue processes and the paranodal loops; these edges are in cytoplasmic continuity with the cell body. (D) Reconstruction of the oligodendrocyte with its myelin sheaths wrapped around axons. *a,* axon; *ocb,* oligodendrocyte cell body; *cp,* connecting process; *etp,* external tongue process; *itp,* internal tongue process; *pl,* paranodal loop. [Modified from Butt and Ransom (1989), with permission.]

Internode distance along the central nervous system is also matched to fiber diameter (Hess and Young, 1952). The internode distance:diameter ratio is different for fibers in different tracts. Moreover, some central nervous system myelinated fibers exhibit, at specific sites, nonmyelinated zones much larger than normal nodes (Waxman and Bennett, 1972). Thus, it is probable that *localized axoglial interactions* specify the domains of an axon that should, and should not, be myelinated.

Although the molecular mechanisms that control myelination are not yet fully understood, some clues about these mechanisms have been provided by studies of developing central nervous system axons. It is now well established that the axon specifies whether or not a myelin sheath will be formed around it (Aguayo et al., 1976; Weinberg and Spencer, 1976). Freeze-fracture studies have demonstrated a significant increase in intramembranous particle (IMP) density in the protoplasmic face (P-face) of the axon membrane that occurs in association with glial ensheathement in developing white matter tracts (Black et al., 1982). An example is shown in Figure 40-4, which shows a premyelinated axon located adjacent to an ensheathed axon in the developing rat optic nerve. A markedly increased density of P-face IMPs, which correspond to membrane-intercalated protein or glycoprotein molecules, can be seen in the membrane of the ensheathed axon, compared to the bare adjacent axon. The increase in axolemmal P-faced IMP density occurs even in axons that have been experimentally deprived of glial ensheathement (Black and Waxman, 1986), demonstrating that incorporation of new P-face IMPs into the axon membrane does not represent a response to glial contact, but rather reflects an inherent change in axon membrane composition, which occurs at the developmental stage when myelination is usually initiated. The expression of the new axon membrane IMPs occurs only in axons that have achieved the diameter that is associated with myelination, at the time when myelination begins.

Although early hypotheses suggested that myelination was triggered when a developing axon reached a "critical diameter," it is now well established that myelination occurs over a range of diameters (Fraher, 1972), even along single axons (Waxman et al., 1972; Waxman, 1985). The signal for myelination appears to be specific for particular axons or particular domains along axons. The axon membrane contains molecules that trigger mitogenesis in Schwann cells and oligodendrocytes (Salzer et al., 1980a; 1980b; DeVries et al., 1983; Chen and DeVries, 1989). Similarly, the axon membrane appears to express molecules that regulate the rate, and/or degree, of myelin formation. We have hypothesized (Black et al., 1986; Waxman 1987a, 1987b) that incorporation of new axon membrane P-face IMPs reflects the expression of "recognition molecules" in the axon membrane, which initiate myelination. Increased metabolic activity of high molecular weight proteins is observed in Schwann cell membranes following demyelination with lysophosphatidylcholine for several days prior to remyelination (Smith et al., 1983a), consistent with the idea that complementary recognition molecules are synthesized and expressed by myelin-forming cells as myelin production is initiated. The expression in the axon membrane, of a signal that controls myelin formation by nearby glial cells, would provide an explanation for the specific patterns of myelination

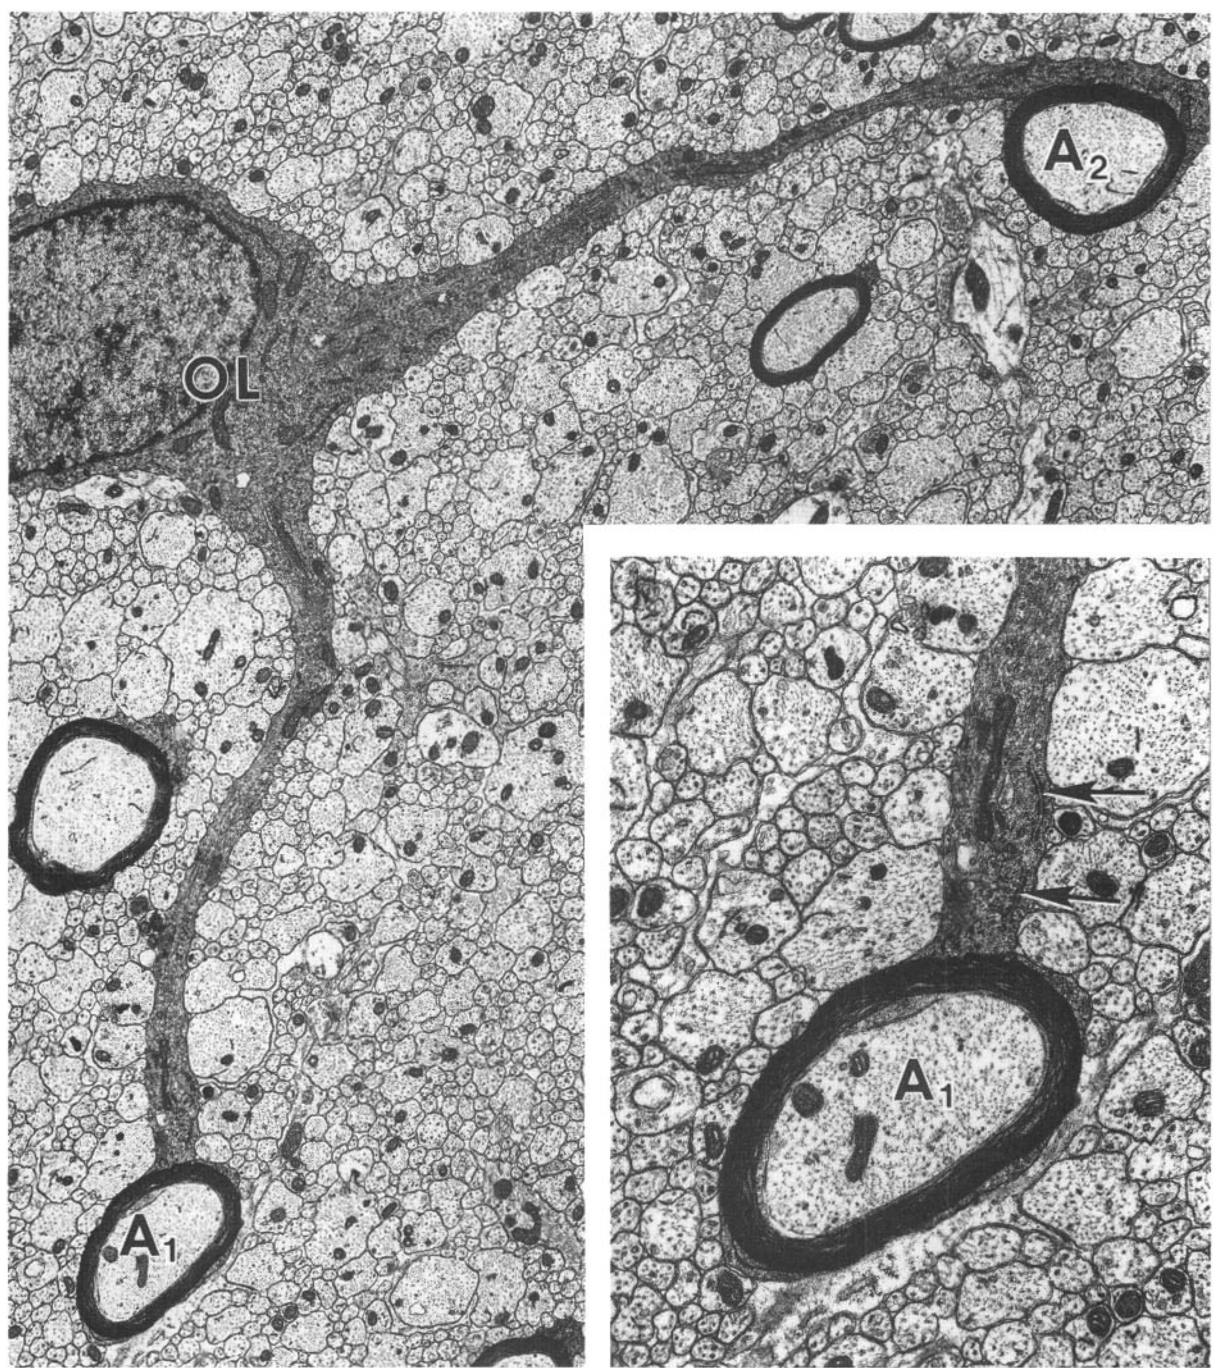

FIG. 40-3. Oligodendrocyte (*OL*) in ventral funiculus of the spinal cord of a 13-day-old rat. Connections can be seen to two myelin sheaths, surrounding axons A_1 and A_2. The myelin sheaths surrounding these two axons have opposite rotational polarities. ×8500. *Inset:* Axon A_1 shown at higher magnification. Note the ribosome-studded endoplasmic reticulum in the oligodendrocyte cytoplasm (arrows) close to the forming myelin sheaths. ×16,000. [Modified from Waxman and Sims (1984), with permission.]

that are observed in the central nervous system (Waxman, 1978). If P-face IMPs, of the type shown in Figure 40-4, represent recognition molecules in the axon membrane that control myelination, the number of axonal recognition molecules per unit axon length would be expected to scale positively with diameter so that the number of axonal recognition molecules presented to a given oligodendrocyte would be greater for axons of larger diameter. According to this scheme, the strength of the axo-

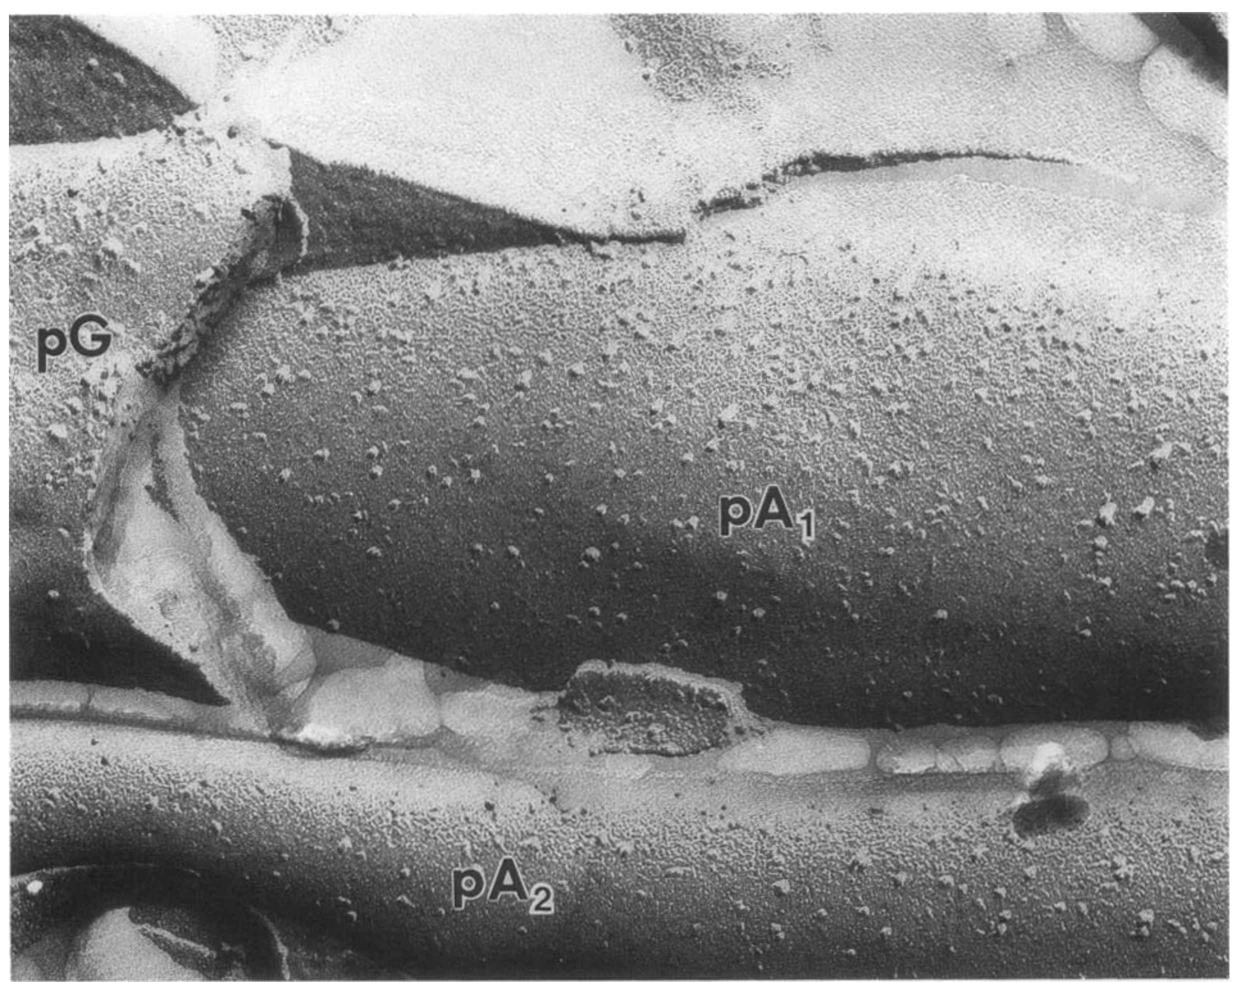

FIG. 40-4. New molecules are incorporated into the axon membrane prior to myelination. This freeze-fracture electron micrograph shows the P-faces of the axon membranes of two adjacent axons from rat optic nerve during the period of myelination. One axon (pA_1) is ensheathed by a glial process whose P-face can be seen (pG). This ensheathed axon expresses a higher density of P-face intramembranous particles than the adjacent premyelinated axon (pA_2) which has not yet elicited ensheathment. ×160,000. [Modified from Black et al. (1982), with permission.]

glial signal would be dependent on diameter, and could thus regulate the thickness of the myelin sheath. The differentiation of the axon membrane might also provide localized signals demarcating single internodes, or larger domains that should or should not be myelinated, since differentiation of the axon membrane into nodal regions (Waxman and Foster, 1980; Waxman et al., 1972) and longer domains destined to remain nonmyelinated (Waxman and Anderson, 1980) occurs prior to the formation of compact myelin.

ASTROCYTE PROCESSES ARE COMPONENTS OF THE NODE OF RANVIER

The early electron microscopic studies of Hildebrand (1971a, 1971b) on feline spinal cord established the presence of perinodal astrocytic processes at nodes of Ranvier in the central nervous system. The ubiquity of perinodal astrocytic processes prompted Hildebrand to suggest that they might participate in essential functions, such as metabolism of the node, the regulation of ion concentrations in the perinodal extracellular microenvironment, or the production of the nodal gap substance. Subsequent studies have demonstrated perinodal astrocyte processes in the rabbit corpus callosum (Waxman and Swadlow, 1976), rat optic nerve (Hildebrand and Waxman, 1984; Waxman and Black, 1984), and guinea pig (Raine, 1984) and rat (Sims et al., 1985) spinal cord. Perinodal astrocyte processes have also been observed at nodes of Ranvier in inframammalian species (Bodega et al., 1987), and the origin of perinodal processes from radial glia has been described (Sims et al., 1991).

Perinodal astrocyte processes usually have sheetlike or fingerlike configurations when reconstructed in three dimensions, and meander or arc through the neuropil for tens of μm, to contact the Na^+ channel-rich membrane at the node of Ranvier. The relationship between the perinodal astrocyte and the neighboring axon is well displayed in freeze-fracture electron micrographs (Figure 40-5), which expose large domains of astrocyte membrane (Waxman and Black, 1984). Perinodal astrocyte processes are closely associated with the axon membrane at the node, approaching within 10 nm of it, but special-

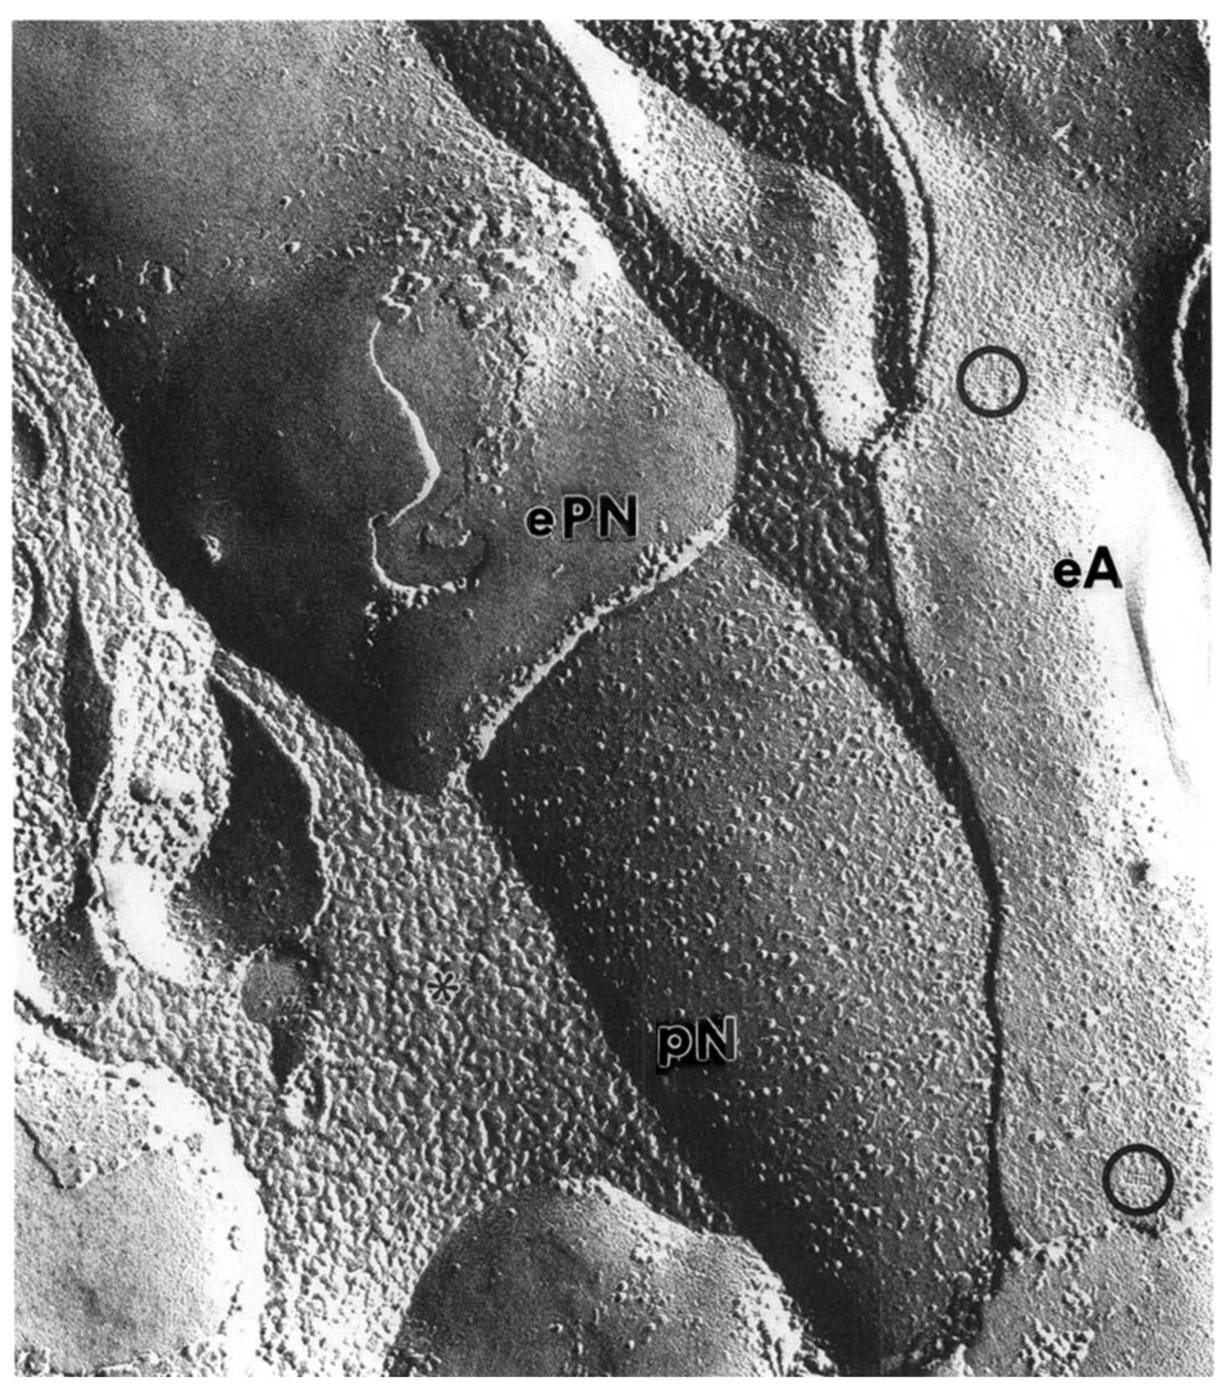

FIG. 40-5. Freeze-fracture electron micrograph showing myelinated axon from rat optic nerve (*pN,* P-face of axon membrane at a node of Ranvier; *ePN,* E-face of paranodal part of oligodendrocyte). A perinodal astrocyte (*eA*), whose E-face is displayed, runs through the neuropil to contact the node. Orthogonal arrays, characteristic of astrocytic membrane, are *circled.* *, extracellular space. ×85,000. [Modified from Waxman and Black (1984), with permission.]

ized membrane junctions, such as gap junctions, tight junctions, and so on, are not present between the perinodal astrocyte and the axon. Gap junctions are present between perinodal astrocytes and the oligodendrocytes bounding the node of Ranvier (Figure 40-6), although the functions of these junctions are not understood (Massa and Mugnaini, 1982; Waxman and Black, 1984).

Astrocyte processes are also associated with Na^+ channel-rich zones of the axon membrane that are not located at nodes of Ranvier. For example, they are associated with patches of node-like membrane that are expressed by specialized nonmyelinated axons such as the nonmyelinated portions of ganglion cell axons within the retinal nerve fiber layer in the rat. These retinal ganglion cell axons are myelinated distally in the optic nerve. Closer to their cell bodies within the retinal nerve fiber layer, these axons are nonmyelinated, but nevertheless express small islands of node-like membrane, which appear to be "hot spots" at which Na^+ channels are clustered (Hildebrand and Waxman, 1983; Black et al., 1984). Radially oriented processes of retinal astrocytes and Müller cells (which are usually considered to be members of the astroglial family) are colocalized with these patches of node-like membrane, and often form a corona around them. The location of the Müller glial processes coincides precisely with that of the node-like axon membrane "hot spots" (Figure 40-7). These nonmyelinated axons thus provide a second example, in addition to the node of Ranvier, of the close relationship between the differentiation of clusters of Na^+ channels in the axon membrane, and abutment of the axon by astroglial processes.

Studies on pathological models have revealed a similar relationship between the astrocyte contact and node-like regions along demyelinated axons. Some of these studies have examined the rat spinal cord irradiated during the period of gliogenesis (at 3 days postnatal) using methods developed by Gilmore (1963, 1966). Since the densities of oligodendrocytes and astrocytes are reduced following irradiation, random neuroglial interactions are minimized, facilitating the study of specific axoglial relationships (Sims et al., 1985). Even though myelin is initially absent in this tissue, small zones of node-

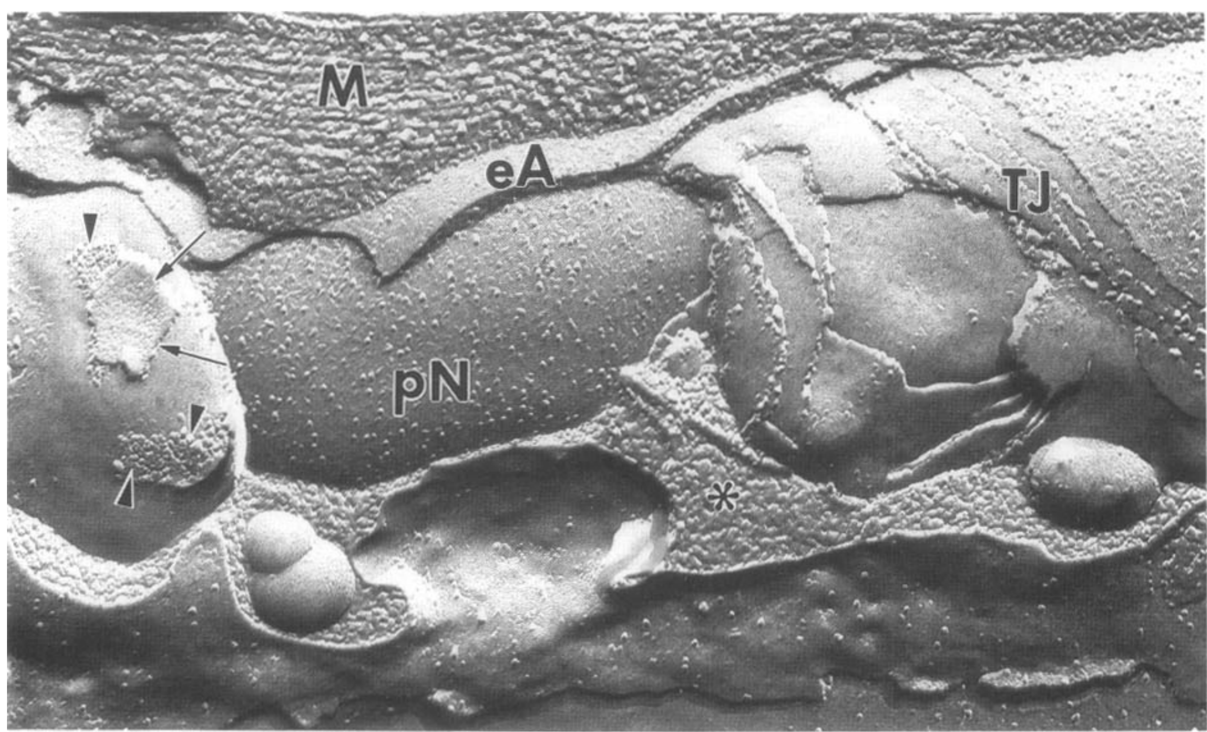

FIG. 40-6. Freeze-fracture electron micrograph showing glial relationships at node of Ranvier from rat optic nerve. The E-face of a perinodal astrocyte process (*eA*) wraps around the P-face of the node (*pN*). Tight junctions (*TJ*) can be seen between oligodendroglial layers in the myelin segment to the right of the node. To the left of the node, the P-face of the outer terminal oligodendrocyte loop is exposed, and two gap junctions are present. The gap junction is formed between the P-face (*arrowheads*) and the E-face (*arrows*) of an adjacent cell. These gap junctions usually connect oligodendrocytes and perinodal astrocytes. *M*, myelin surrounding nearby axon; *, extracellular space. ×58,000. [Modified from Waxman and Black (1984), with permission.]

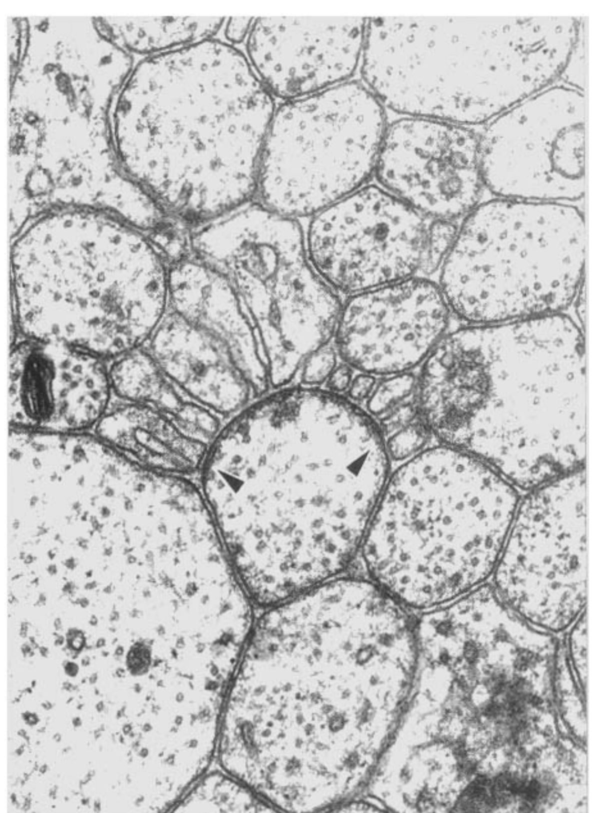

FIG. 40-7. Island of nodelike membrane (*between arrowheads*) in a nonmyelinated axon from retinal nerve fiber layer of adult rat. Note the corona of radially oriented Müller cell processes whose distribution precisely matches that of the nodelike membrane. ×40,000. [Modified from Hildebrand and Waxman (1983), with permission.]

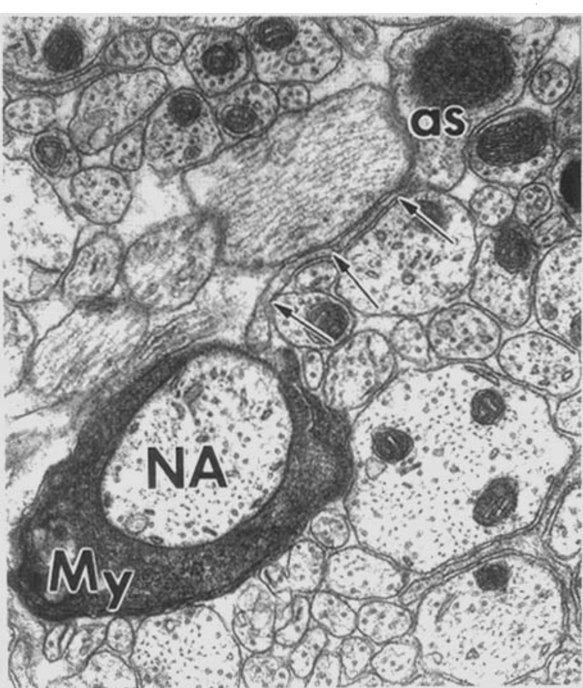

FIG. 40-8. Despite the paucity of glial cells in the dorsal columns of the rat following x-irradiation during gliogenesis, occasional axons are myelinated. This electron micrograph includes a tangential section through a node of Ranvier (*NA*, nodal axon; *My*, myelin). A thin extension (*arrowheads*) runs through the neuropil from an astrocyte process (as) to contact the axon membrane at the node. ×24,000. [Modified from Sims et al. (1985), with permission.]

like membrane develop (at the postnatal age when myelination normally occurs) along some of the unensheathed axons; these zones of node-like membrane are always apposed by astrocyte processes (Black et al., 1985a). Later, following protracted postirradiation intervals, myelination occurs around a small number of axons in the irradiated spinal cord. Despite the paucity of astrocytes in this tissue, astrocyte processes are closely associated with the nodes that do form (Sims et al., 1985). These astrocyte processes can extend for considerable distances through the neuropil to contact the axon at the node (Figure 40-8). The mechanisms that guide the astrocyte processes to their nodal targets and anchor them there are not understood, but clearly there is a high degree of specificity in the astrocyte-axon relationship at the node, both in the normal central nervous system and in glial cell-deprived systems. The Na^+ channel is heavily glyosylated (Trimmer and Agnew, 1989), and it is possible that sialic acid residues, on the extracellular dome of the channel bind, in a manner similar to cell adhesion molecules, to extracellular matrix molecules on the astrocyte surface (Waxman, 1993b). Binding of this type could anchor Na^+ channels at the node, or stabilize the astrocyte-axon contact at nodes of Ranvier.

SODIUM CHANNELS ARE CLUSTERED IN THE NODAL AXON MEMBRANE IN MATURE MYELINATED FIBERS

Voltage-sensitive Na^+ channels are distributed in a highly nonuniform pattern in the axon membrane of mature myelinated fibers. This membrane heterogeneity has been studied using a variety of pharmacological and physiological methods, including saxitoxin (STX) binding (Ritchie et al., 1976), nodal voltage-clamp (Brismar, 1980; Chiu and Ritchie, 1981a; Schwarz et al., 1991), and loose (Shrager, 1987) and gigaseal–patch-clamp methods (Jonas et al., 1989). These methods reveal a high Na^+ channel density (~1,000/μm^2) in the axon membrane at the node of Ranvier (Ritchie and Rogart, 1977; Waxman, 1977; Shrager, 1989) and a much lower density (<25/μm^2) in the internodal axon membrane.

Morphological studies on Na^+ channel distribu-

tion in central nervous system axons have utilized two techniques: freeze-fracture and ultrastructural immunocytochemistry. The freeze-fracture method provides *en face* views of the membrane lipid monolayer closest to the extracellular compartment (E-face), or the lipid monolayer closest to the protoplasm (P-face), and displays intramembranous particles (IMPs), which are thought to represent membrane-associated protein and/or glycoprotein molecules (Branton, 1966; Bullivant, 1977), in the lipid bilayers that partition with either fracture face. The freeze-fracture technique has the advantage of revealing large expanses of the membrane which can be examined *en face*, and it permits quantitative examination of membrane structure with high spatial resolution. Rosenbluth (1976) and Kristol et al. (1977) have presented evidence which suggests that large E-face IMPs are related to voltage-sensitive Na^+ channels. A freeze-fracture electron micrograph showing the E-face of a mature node of Ranvier is shown in Figure 40-9. The nodal part of the axon membrane exhibits a characteristic structure and contains a much higher density of large E-face IMPs than the paranodal and internodal parts of the axon membrane. Even in the absence of definitive identification of the IMPs (if any) that represent Na^+ channels, freeze-fracture permits the visualization of membrane with node-like properties, since the very high density of E-face IMPs makes the nodal membrane morphologically unique.

Immunoelectron microscopic methods, which permit the localization of clusters of Na^+ channels at the electron microscopic level, have recently been developed (Black et al., 1989a, 1989b). These techniques utilize polyclonal antibodies generated against the rat brain Na^+ channel (Elmer et al., 1990) and facilitate the localization of clusters of Na^+ channels. These methods do not, however, permit quantitation of the number of channels (or their density) in a cluster. Moreover, the threshold for staining is not known; it is probably higher than $100/\mu m^2$, since unmyelinated C-fibers, which display Na^+ channel densities of around $200/\mu m^2$ (Pellegrino and Ritchie, 1984), do not display Na^+ channel immunoreactivity with these methods. Figure 40-10 is an electron micrograph, which shows a mature node of Ranvier, immunostained with antibody 7493. This electron micrograph illustrates the dense staining of the axon membrane with antibodies generated against Na^+ channels that is characteristic of the node of Ranvier, in contrast to the internodal and paranodal axon membrane and the oligodendrocyte membrane, which do not stain. The complex structure of the mature node of Ranvier, as shown in Figures 40-9 and 40-10, can be considered the endpoint of development in central nervous system white matter tracts.

THE AXON MEMBRANE HAS A HOMOGENEOUS STRUCTURE PRIOR TO GLIAL ENSHEATHEMENT

The premyelinated axon membrane appears to contain a relatively low density of Na^+ channels, which are distributed uniformly prior to loose wrapping by glial cells. For example, in premyelinated axons of the optic nerve in the neonatal rat, STX-binding experiments demonstrate an Na^+ channel density of approximately $2/\mu m^2$; surprisingly, this low density of Na^+ channels is sufficient to support action potential electrogenesis, probably due to the high input resistance (which is proportional to diameter $^{-3/2}$) in these small-diameter axons (Waxman, et al., 1989). As seen in Figure 40-11, E-face IMP density in these premyelinated axons is quite low and, at early stages of development when glial wrapping is not present, the IMPs are distributed uniformly along the axons and are not clustered (Black et al., 1982). Na^+ channel immunoreactivity is not seen along these immature, bare axons. Thus, prior to glial ensheathement, premyelinated axons do not appear to be regionally specialized. It is likely that Na^+ channels are uniformly distributed along premyelinated axons at early stages prior to glial ensheathement.

As we have discussed above, the mature node of Ranvier is a highly complex structure involving three cell-types and displaying a high degree of axon membrane differentiation. The development of the node, from premyelinated precursor axons, raises four important questions:

1. Does axon membrane differentiation reflect a preprogrammed sequence of events that occurs intrinsically within the neuron, irrespective of association with glial cells?
2. Alternatively, does axon membrane development depend on glioaxonal interactions?
3. How do the oligodendrocyte, astrocyte, and axon collaborate in the differentiation of the mature myelinated fiber?
4. How, and when, do Na^+ channels cluster in the nodal axon membrane, and how does the low internodal Na^+ channel density develop?

We will now examine the complex interactions between the triad of cell types that constitute the central nervous system myelinated fiber—the axon, the oligodendrocyte, and the astrocyte—and will explore the events that regulate axon membrane differentiation during the development of central nervous system white matter.

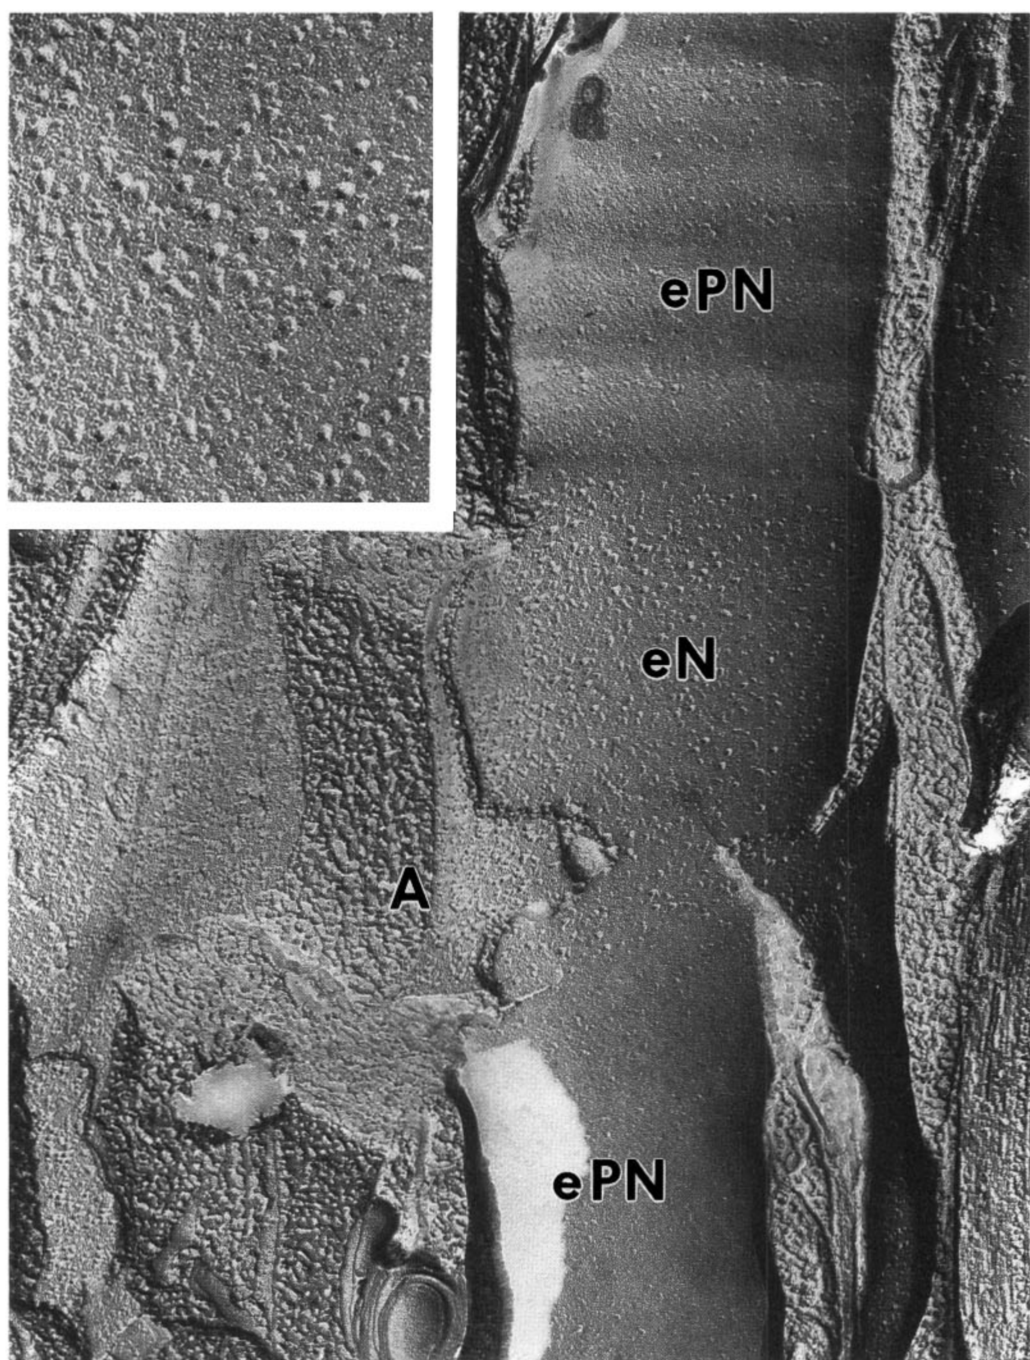

FIG. 40-9. Freeze-fracture electron micrograph showing the differentiated structure of the axon membrane at the node of Ranvier (adult rat, optic nerve-retina junction). The fracture plane exposes the E-face of the axon membrane. Note the difference in the structure of the axon membrane at the node (*eN*), compared with that at the flanking paranodes (*ePN*). A perinodal astrocyte process, which partially encircles the node, is marked *A*. ×70,000. *Inset:* The increased IMP density in the nodal membrane E-face can be more clearly seen at higher magnification. ×175,000.

INSERTION OF SODIUM CHANNELS IN THE DEVELOPING NODAL MEMBRANE IS NOT DEPENDENT ON MYELIN FORMATION

Early studies on developing peripheral nervous system axons used cytochemical and freeze-fracture methods to examine the differentiation of nodal membrane, and demonstrated that the first foci of node-like membrane develop at the time of ensheathment of the axon by loose (noncompact) Schwann cell processes (Waxman and Foster, 1980; Wiley-Livingston and Ellisman, 1980). These node-like

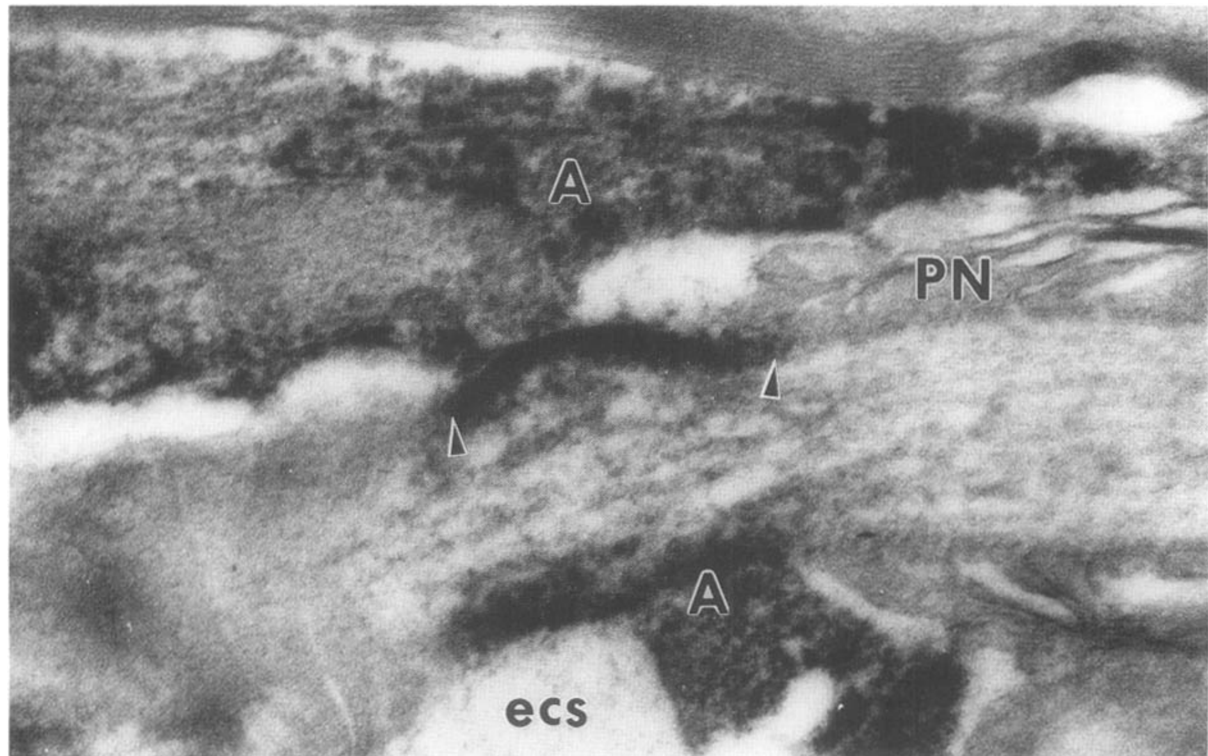

FIG. 40-10. Immunoelectron micrograph showing node of Ranvier from rat optic nerve following staining with antibody 7493 directed against Na^+ channels. There is dense Na^+ channel immunoreactivity of the axon membrane at the node (*between arrowheads*). In contrast, the paranodal axon membrane, beneath the terminating myelin loops (*PN*) is not stained. Dense Na^+ channel immunoreactivity can also be seen within the cytoplasm of an adjacent perinodal astrocyte (*A*). *ecs*, extracellular space. ×60,000. [Modified from Black et al. (1989a), with permission.]

membrane specializations are observed prior to the formation of compact myelin or mature axoglial paranodal junctions, demonstrating that myelination is not a prerequisite for the formation of node-like membrane in peripheral nervous system axons.

A similar sequence of events has been observed in developing central nervous system white matter. Loose glial ensheathement of axons is seen in the rat optic nerve beginning at about 6 days postnatal (Figure 40-1B). The first clusters of large E-face IMPs, similar to those in the nodal axon membrane, appear at the time of loose glial ensheathement. These membrane specializations develop at the edges of ensheathing glial processes (Figure 40-12), and consist of aggregates of IMPs with a higher particle density than found over other parts of the axon membrane. These IMP aggregates contain a high percentage of large IMPs, similar to those seen at nodes of Ranvier. The specialized membrane patches usually extend for 1 to 2 μm along the length of the axon, that is, several times the length of a normal node. The morphology of these IMP clusters suggests that they are primitive Na^+ channel clusters at the precursors of nodes of Ranvier (Black et al., 1982; Waxman et al., 1982).

Glial cell-deficient systems, including the central nervous system of the myelin-deficient *md* rat (Csiza and De LaHunta, 1979; Dentinger et al., 1982) and the dorsal funiculus in the rat spinal cord after x-irradiation (Black et al., 1985a; Sims et al., 1985) have provided additional information about the formation of nodes of Ranvier. In the *md* rat, myelin is absent due to an abnormality in the biosynthesis of proteolipid protein (Duncan et al., 1987; Hudson et al., 1987). To examine the role of myelinating cells in the regulation of Na^+ channel expression, Oaklander et al. (1984) examined the binding of labeled STX, which acts as a marker for Na^+ channels, in 6-day-old and 21-day-old *md* rats, and in normal controls. These ages were chosen because they encompass both the period of active myelination, and the period of development of symptoms in the affected animals. As expected, these workers found a significant, large increase in STX binding capacity of the tissue from 21-day-old normal rats compared to the corresponding tissue from 6-day-old normal animals. However, there was no significant difference in STX binding capacity of *md* and normal brain, spinal cord, or sciatic nerves. Similarly, STX-binding studies on the hypomyelinated murine mutant *shiv-*

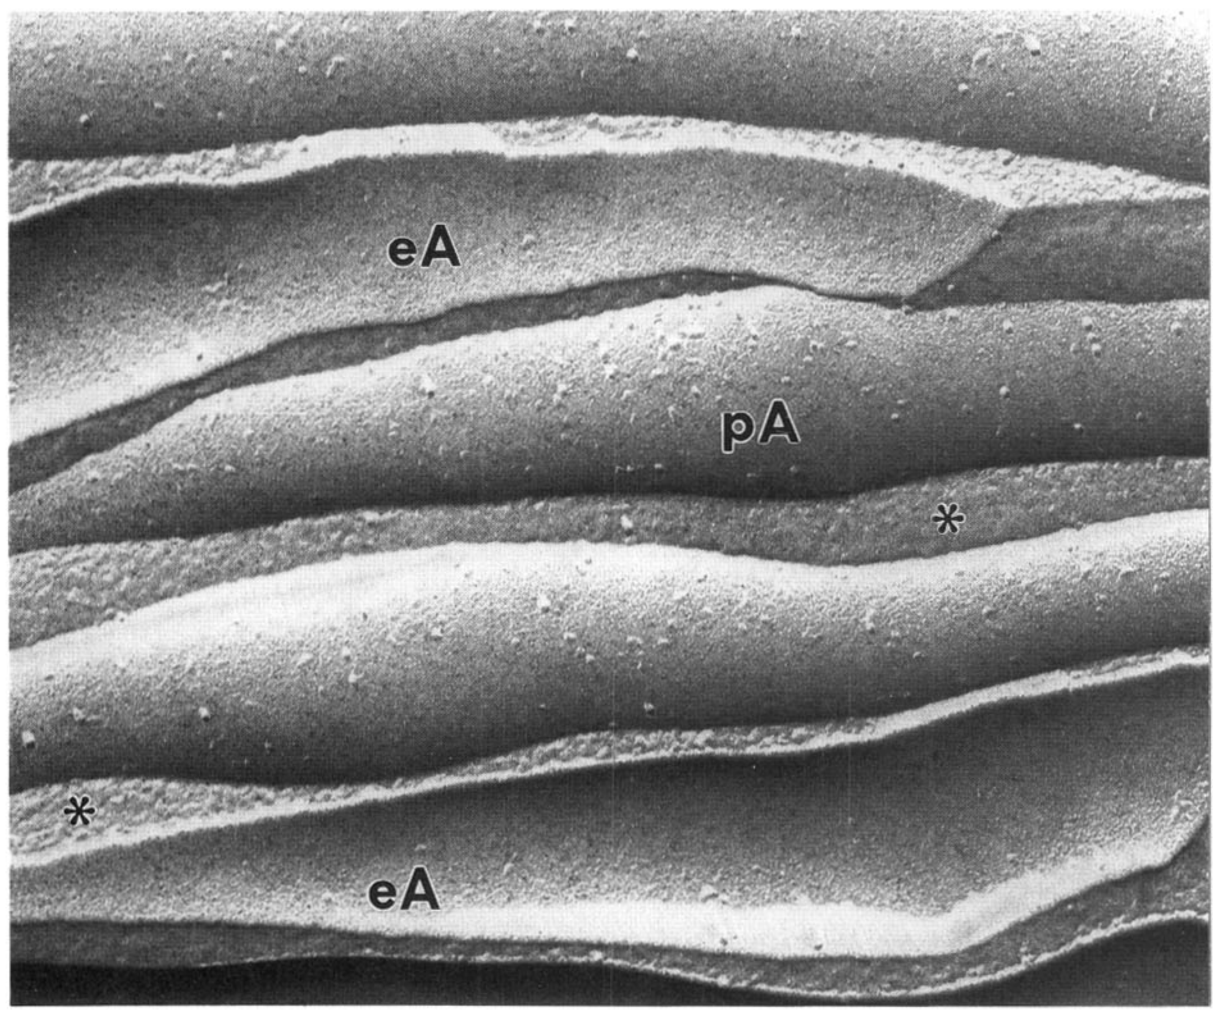

FIG. 40-11. Freeze-fracture ultrastructure of premyelinated axons from 2-day-old rat optic nerve (corresponding to the axons shown in Figure 40-1A). E-faces (*eA*) and P-faces (*pA*) of the premyelinated axons are shown. The E-face intramembranous particle density is low, and regional heterogeneity has not yet developed. ×150,000. erer have demonstrated an excess of Na^+ channels compared to control myelinated axons (Noebels et al., 1991). These ligand-binding results do not provide information about the spatial distribution of Na^+ channels; however, they do provide evidence which suggests that, even in the absence of myelination, Na^+ channels are deployed along axons in these hypomyelinated tissues.

Freeze-fracture studies on the x-irradiated spinal cord have provided evidence for the insertion of Na^+ channels in clusters, at sites where nodes of Ranvier would normally develop along white matter axons, irrespective of whether myelination has occurred. Since the number of glial cells is markedly reduced in this model so that most axons are not ensheathed (Gilmore et al., 1982; Sims and Gilmore, 1983), this model permits an examination of axon membrane differentiation in a glial cell-deprived milieu. Black et al. (1985a) observed the development of foci of increased E-face IMP density in spinal cord axons within the irradiated, glial cell-deprived spinal cord at the same ages as in controls, even though axonal ensheathement by myelin-forming cells had not occurred (Figure 40-13). These regions of high E-face particle density extend 1 to 2 μm along the axis of some axons, and up to 5 μm (i.e., about five times the length of a normal node) in others (Black et al., 1985a). These specialized foci contain a high percentage of large (>10 nm) IMPs similar to those at nodes of Ranvier. The total number of IMPs within

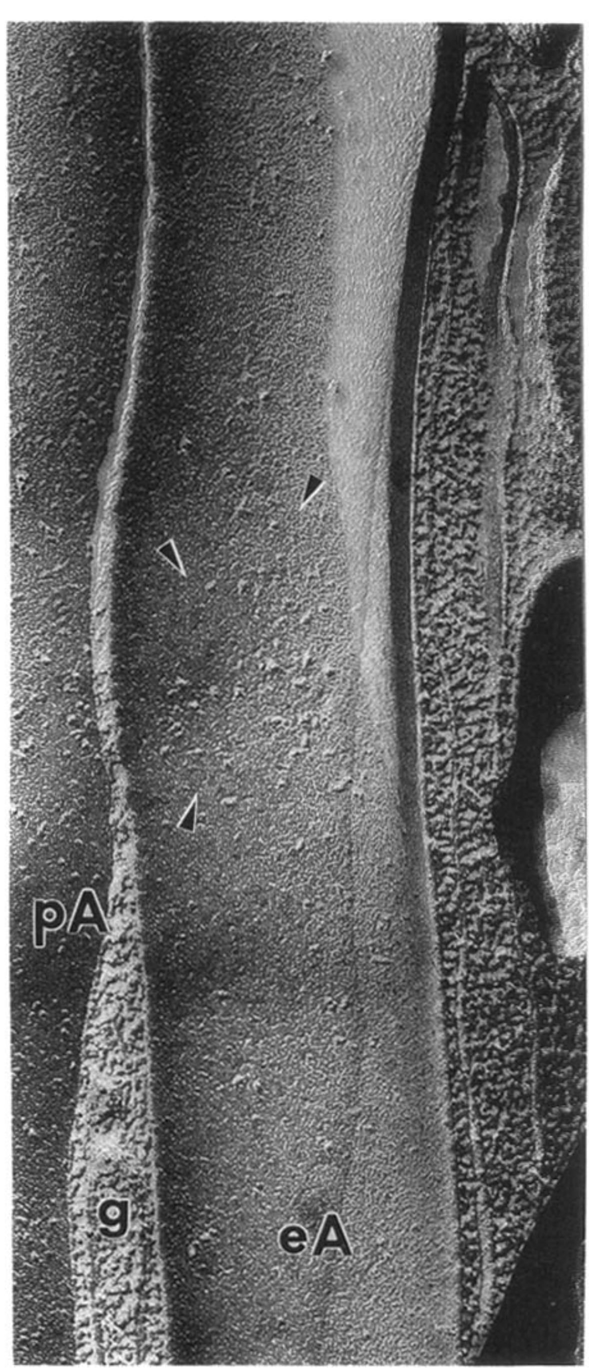

FIG. 40-12. Cluster of E-face intramembranous particles (IMPs) (*between arrowheads*) in the membrane (*eA*) of an axon from 16-day-old rat. This cluster of IMPs probably represents an early concentration of Na^+ channels at a developing node of Ranvier, and is located at the edge of a glial cell process (*g*), which has not yet formed compact myelin. The P-face of an adjacent axon (*pA*) can also be seen. ×100,000. [Modified from Waxman et al. (1982), with permission.]

these regions is similar to that at mature nodes. Thus, even though myelin has failed to develop, foci of node-like membrane are expressed along these axons. Interestingly, these axonal E-face IMP clusters are usually contacted by astrocytes. These foci of axon membrane specialization are likely to be Na^+ channel clusters, and appear to represent the precursors of nodes of Ranvier.

SUBMICRON LOCALIZATION OF NODAL SODIUM CHANNELS IS MODULATED BY INTERACTIONS WITH MYELIN-FORMING CELLS

Although the results described above suggest that Na^+ channels, destined for the nodes of Ranvier, can be inserted into the axon membrane independently of myelination, oligodendrocytes may nevertheless participate in the localization of Na^+ channels in the developing axon membrane. It has been suggested that the formation of a discrete annulus of axon membrane, with high E-face IMP density, may be facilitated by the development of paranodal axoglial junctions between the axon and myelin-forming cells. Rosenbluth (1976) proposed that the paranodal axoglial junctions, between terminating oligodendroglial loops and the axon membrane, might function as barriers that limit the movement of Na^+ channels within the plane of the axon membrane.

Observations on ectopic oligodendroglial processes have provided support for the idea that oligodendrocyte-axon contact modulates the placement of Na^+ channels in the axon membrane (Black et al., 1985b). These observations suggest that at regions where ectopic oligodendroglial processes contact the nodal membrane, there is a focal suppression of Na^+ channels in the axon membrane. Figure 40-14 is a freeze-fracture electron micrograph that shows an aberrant oligodendroglial process, which extends over the axon membrane at a node of Ranvier. The axon membrane has developed a specialized morphology similar to that at the paranodal junctions at the zone of contact between the oligodendrocyte and the axon. In the part of the axon membrane that is contacted by the oligodendrocyte, there is a highly localized reduction in the density of E-face IMPs. The reduction in IMP density is especially significant, since it occurs within the nodal part of the axon membrane where these IMPs are usually expressed with a high density. Since this kind of alteration in axon membrane structure is coextensive with the zone of contact by the oligodendroglial process, this interaction appears to involve a *focal* modulation, by the glial process, of axon membrane

structure. Thus, superimposed upon the inherent differentiation of the axon membrane, contact-mediated interactions with glial cells appear to result in focal alterations in Na^+ channel expression in the axon membrane. These glial-axonal interactions, in the paranodal region, may modulate the structure of the axon membrane during development, so that, at the end of myelination, there is a sharp border that demarcates the axon membrane into nodal and paranodal domains.

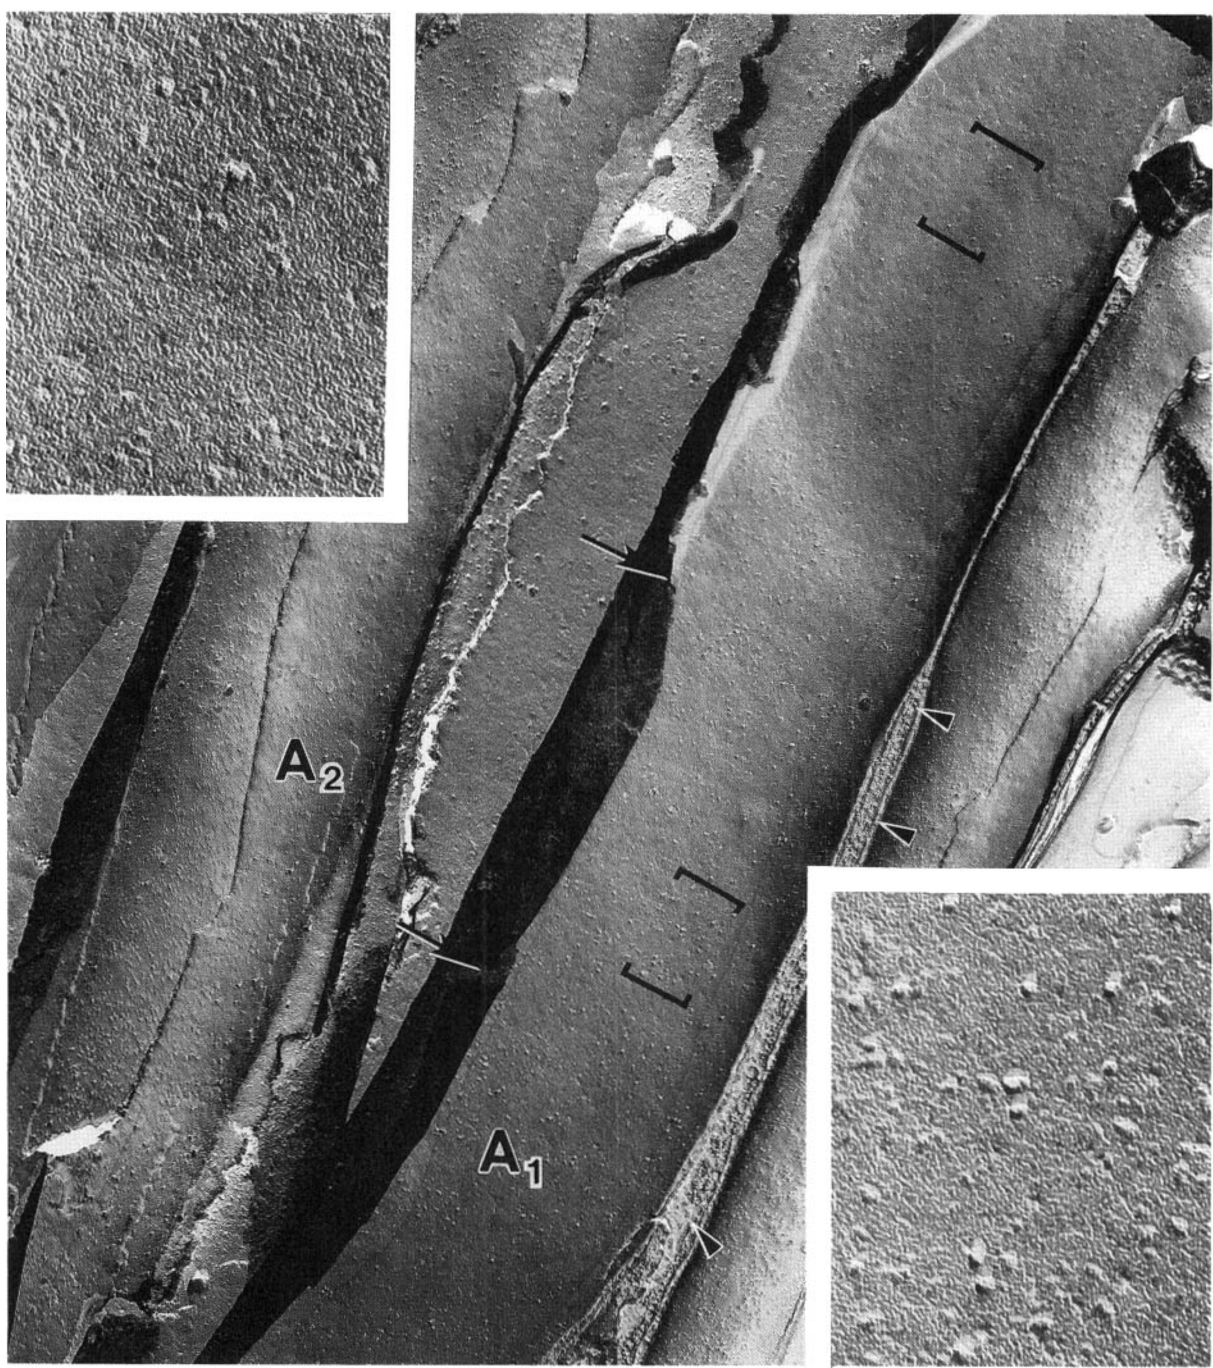

FIG. 40-13. Freeze-fracture electron micrograph showing cluster of E-face intramembranous particles (*between lower brackets*) in an axon (A_1) without myelin in the spinal cord of 19-day-old rat that had been irradiated during gliogenesis. The cluster of E-face intramembranous particles occurs in a region contacted by an astrocyte (*arrowheads*). An adjacent axon (A_2) is not contacted by astrocytes, and does not display clustering of E-face intramembranous particles. ×25,000. *Insets* show the areas in brackets at higher magnification. ×175,000. [Modified from Black et al. (1985a), with permission.]

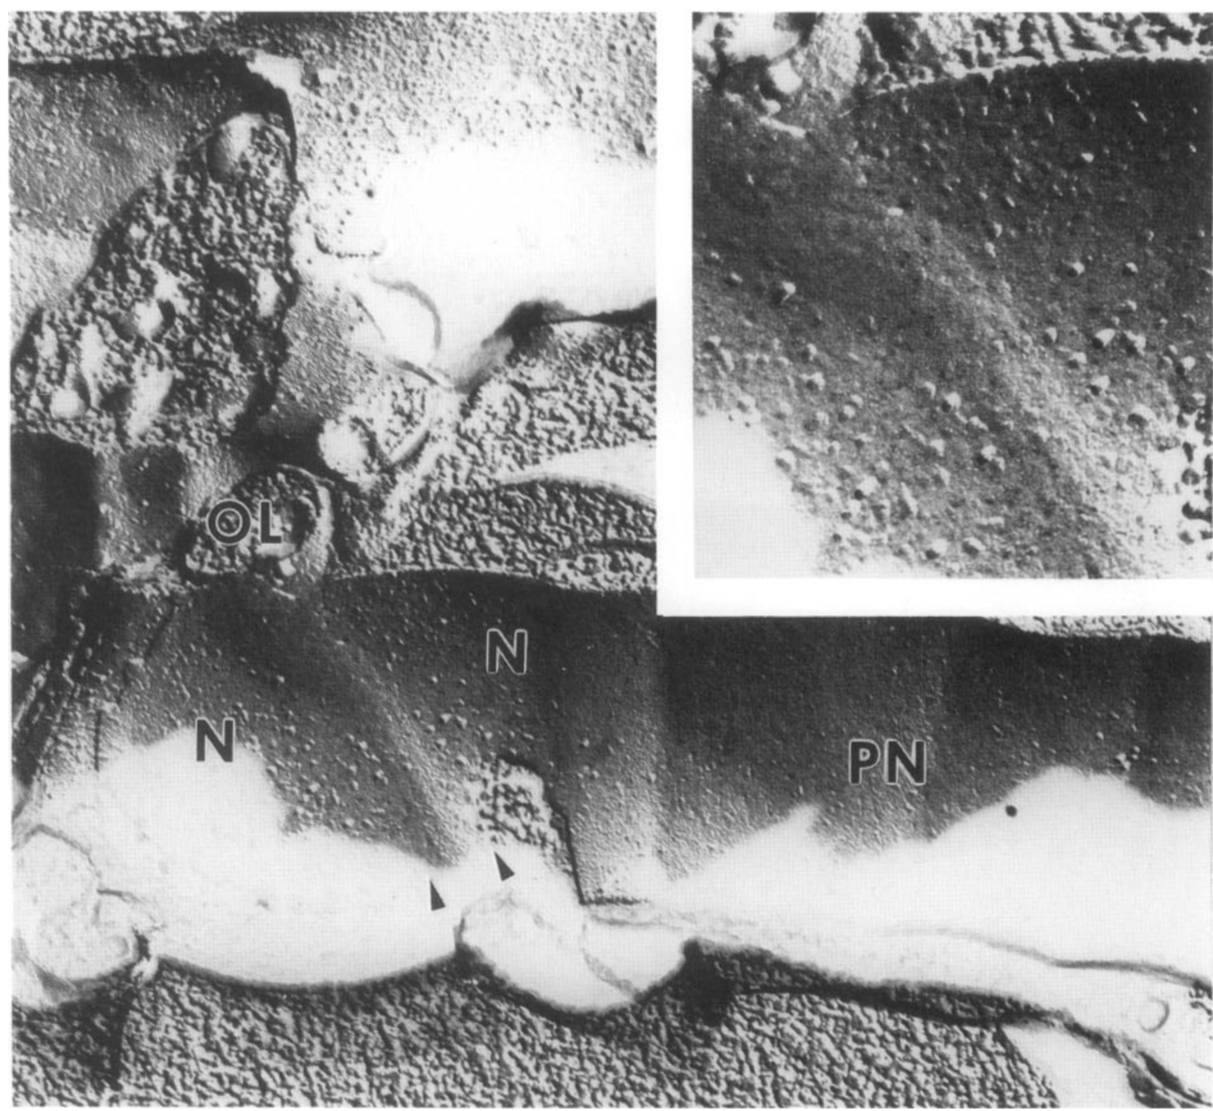

FIG. 40-14. Focal alteration in axon membrane structure at the site of contact with an oligodendrocyte process (*OL*). This freeze-fracture electron micrograph shows the E-face of an axon from the retina-optic nerve junction of rat. Nodal (*N*) and paranodal (*PN*) regions can be seen. An aberrant oligodendroglial process (seen in cross-fracture, *OL*) runs obliquely over the axon membrane (*between arrowheads*). Note the reduction in axon membrane E-face intramembranous particle expression at the zone of oligodendrocyte contact. ×70,000. *Inset:* ×150,000. [Modified from Black et al. (1985b), with permission.]

SUPPRESSION OF INTERNODAL SODIUM CHANNELS FOLLOWS ENSHEATHEMENT BY MYELIN-FORMING CELLS

The development of the axon membrane at the node of Ranvier is described above. A parallel sequence of events occurs as the *internode* develops and becomes myelinated. As described above, in mature myelinated fibers the internodal axon membrane contains a low density of Na^+ channels and may not be excitable (Ritchie and Rogart, 1977; Waxman, 1977; Shrager, 1989). On the other hand, the premyelinated axon (including regions destined to develop into the internodal membrane) is electrically excitable (Foster et al., 1982; Waxman et al., 1989). These observations raise the question of when, and how, the internodal axon membrane becomes inexcitable.

If axon membrane development and myelination were not tightly coupled, developing internodes might become inexcitable prior to myelin formation, so that a transient period of conduction block would occur during development. It might be expected on functional grounds that the internodal axon membrane would maintain its excitability until at least several layers of compact myelin have been

formed, so as to ensure the development of a shield against capacitative current loss and subsequent conduction block. Evidence that loss of excitability in the internodal axon membrane is not a preprogrammed event, but rather involves an active suppression of Na^+ channels by the overlying oligodendrocyte or myelin sheaths, has in fact been provided by studies on glial cell-deprived central nervous system axons (Black et al., 1985a, 1986). E-face IMP density in the unensheathed axon membrane of glial cell-deprived fibers is significantly higher than in age-matched control myelinated (internodal) axon membrane (Figure 40-15). In the dorsal columns of normal rats at 3 days postnatal, the E-face IMP density of premyelinated axons is approximately 300/μm^2. This probably represents a density of Na^+

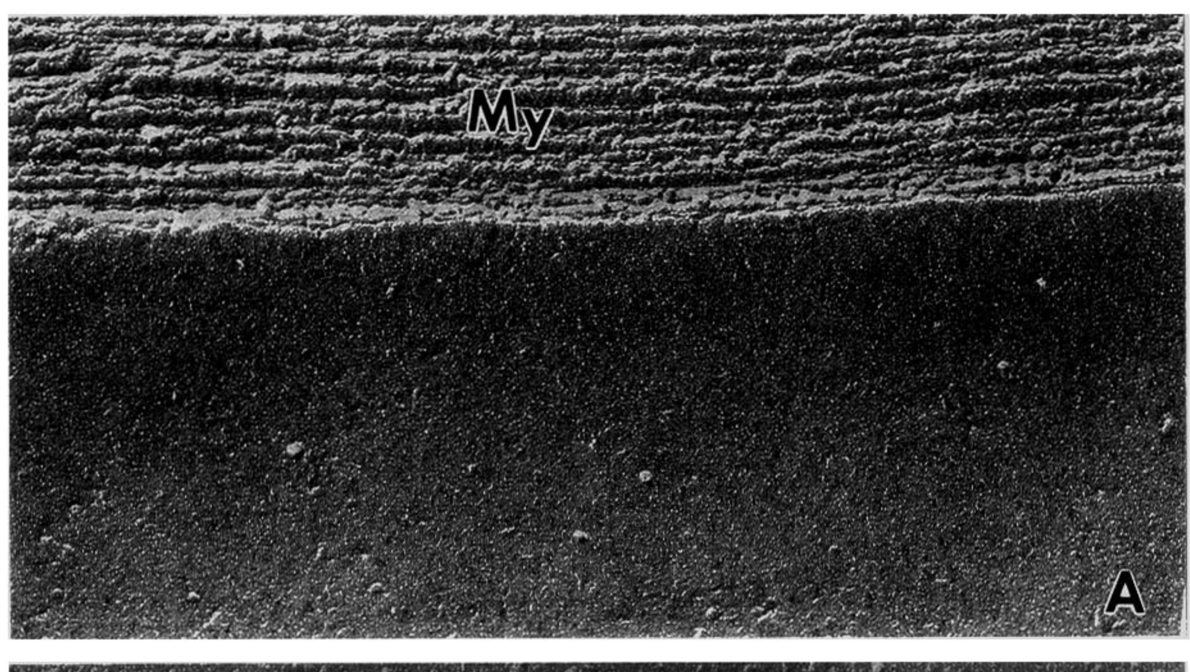

FIG. 40-15. Suppression of E-face intramembranous particles, which may correspond to Na^+ channels, in the internodal axon membrane following myelination. This freeze-fracture electron micrograph shows the axon membrane of myelinated axon (*My*, myelin) from dorsal funiculus of 19-day-old rat (control, *A*), and from glial cell-deprived dorsal funiculus of rat that had been irradiated during gliogenesis (*B*). In the absence of glial ensheathment, E-face IMP density remains high, consistent with a relatively high Na^+ channel density. ×150,000.

channels similar to that in nonmyelinated axons. During normal development, the density of E-face IMPs in the axon membrane is reduced as the axon is myelinated, falling to approximately 180/μm^2 in the internodal axon membrane in 19-day-old myelinated axons. The reduction in E-face IMPs appears to be related to the development of inexcitability of the internodal part of the axon.

Formation of myelin around the axon appears to be a prerequisite for the reduction in Na^+ channel expression in the internodal axon membrane; if myelination is delayed, the loss of Na^+ channels does not occur. Thus, in unensheathed axons in the spinal cord of the 19-day-old x-irradiated rat (which, on the basis of diameter, would normally have been myelinated), there is not a reduction in the E-face IMP density (Figure 40-15B). On the contrary, E-face IMP density in these glial cell-deprived axons increases slightly, to approximately 440/μm^2. This value is similar to that observed in unmyelinated fibers in the 19-day control spinal cord (approximately 450/μm^2), and it suggests that a density of Na^+ channels similar to that in unmyelinated axons (and therefore sufficient to support conduction) is retained when myelination is prevented (Black et al., 1985a). Behavioral observations provide evidence for maintenance of conduction in the glial cell-deprived axons since paraplegia is not observed in developing rats after x-irradiation.

The maintenance of Na^+ channel densities, at levels higher than in the internode, in glial cell-deprived axons raises the important question: What are the mechanisms that downregulate Na^+ channel density in the axon membrane after myelination? One possibility is that myelination provides a signal that results in a suppression of Na^+ channel expression. There is precedent for downregulation of Na^+ channel expression via cell-cell interactions; Na^+ channel expression in spinal cord astrocytes is decreased when these cells are cocultured together with dorsal root ganglion cells (Thio et al., 1993). If excitability is lost in the internodal axon via suppression of Na^+ channels as a result of myelination, it would be predicted that, even if myelination occurred in a delayed manner, it would be accompanied by a decrease in axon membrane E-face IMP density. In the irradiated spinal cord, some axons are, in fact, myelinated after a delay of several weeks by either oligodendrocytes or Schwann cells. When spinal cord axons are examined after delayed myelination, they display a significant reduction in E-face IMP density, which falls to approximately 150/μm^2 (a value similar to that of normal internodal membrane) in the newly formed internodal axon membrane (Black et al., 1986). The reduction in E-face IMP density is seen with both oligodendrocyte- and Schwann cell-mediated myelination. Since, in neighboring axons that had not been myelinated, E-face IMP densities are maintained at high levels (approximately 400/μm^2) the change in axon membrane structure is related to myelination, and is not a generalized systemic change (Black et al., 1986).

On the basis of these observations, we have proposed that normal axonal maturation involves a *suppression of internodal* Na^+ *channel expression,* which occurs as a result of ensheathment by myelin-forming cells (Waxman, 1987a, 1987b). The mechanism underlying the suppression of Na^+ channels is unclear. Since Na^+ channels are heavily glyosylated (Trimmer and Agnew, 1989), cell-cell interactions involving binding between glial cell-associated molecules and Na^+ channels could modulate their channel expression or localization (Waxman, 1993b). Alternatively, the decreased transmembrane voltage gradient due to the voltage drop through the overlying myelin could affect channel turnover and result in a reduced Na^+ channel density in the internodal axon membrane. Although the half-life of Na^+ channels in myelinated axons is not known (and may be different for premyelinated, nodal, and internodal Na^+ channels), the half-life of Na^+ channels in neuroblastoma cells and Schwann cells is 26 hours and 2.2 days, respectively (Waechter et al., 1983; Ritchie, 1988). If myelination were to be followed by a structural alteration which reduced the rate of insertion of Na^+ channels in the underlying axon membrane, there would be a decrease in the density of Na^+ channels in the internodal membrane over the next several days due to channel turnover and lack of replenishment.

ASTROCYTES ARE INVOLVED IN THE CLUSTERING OF SODIUM CHANNELS IN THE AXON MEMBRANE

Following early patch-clamp studies that demonstrated Na^+ channels in cultured astrocytes (Bevan et al., 1985; Gray and Ritchie, 1985), it has been shown in a number of studies that mammalian astrocytes *in vitro* can express Na^+ channels (Nowak et al., 1987; Barres et al., 1988; Sontheimer et al., 1991a, 1991b, 1992; Sontheimer and Waxman, 1992). Moreover, some mammalian astrocytes can express Na^+ channels with biophysical properties similar to Na^+ channels expressed by neurons (Barres et al., 1989; Sontheimer and Waxman 1992; Sontheimer et al., 1991a, 1991b). Using *in situ* hybridization, Black et al. (1994a) detected the expression of mRNA for Na^+

channel subtypes II and III, as well as the putative glial cell-specific Na^+ channel NaG (Gautron et al., 1992) in cultured astrocytes. The possibility that astrocytic Na^+ channel expression is an artifact of culture was ruled out by immunoultrastructural studies which used polyclonal antibodies directed against Na^+ channels (Black et al., 1994b) to demonstrate that Na^+ channels are present within perinodal astrocytes *in situ* within the mammalian central nervous system. In addition, RT-PCR (reverse transcriptase polymerase chain reaction) amplifies the mRNAs for Na^+ channel α-subunit subtypes I, II, and III from rat optic nerve, which does not contain neuronal cell bodies but does contain astrocytes (Oh et al., 1994), and also amplifies the Na^+ channel $\beta1$ subunit (Oh and Waxman 1994; Oh et al., 1994).

The distribution of Na^+ channels within astrocytes in the optic nerve is nonuniform; immunoreactivity with antibodies generated against Na^+ channels is more intense in perinodal astrocyte processes, close to nodes of Ranvier, than in astrocyte cell bodies or endfeet surrounding blood vessels or near the glia limitans (Black et al., 1989b). The subcellular localization of Na^+ channels is different, moreover, in astrocytes and axons. Within myelinated axons, immunoreactivity with antibodies generated against Na^+ channels is most intense in the axon membrane at the node of Ranvier, and there is only moderate immunoreactivity within the axoplasm. In contrast, in astrocytes the Na^+ channel immunoreactivity is distributed throughout the cytoplasm (Black et al., 1989a, 1989b). These results suggest that, within astrocytes, there is a cytoplasmic pool of Na^+ channels or channel precursors. Although STX-binding studies have not yet been carried out on astrocytes to determine the magnitude of the cytoplasmic pool of Na^+ channels, STX-binding studies have been carried out on Schwann cells (which also exhibit Na^+ immunoreactivity within the cytoplasm). These binding studies have demonstrated that approximately 50% of saturable STX-binding sites are located within the cytoplasmic compartment of Schwann cells (Ritchie et al., 1990). Differences in the equilibrium dissociation constant K_D between the cytoplasmic and membrane-associated pools of Na^+ channels suggest a precursor-product relationship, as has been observed in axonal growth cones (Wood et al., 1989). This is consistent with the idea that the cytoplasmic pool contains Na^+ channel precursors (Ritchie et al., 1990). The presence of a similar intracytoplasmic pool of Na^+ channels in astrocytes *in situ* is suggested by the observation of immunoreactivity with antibodies generated against Na^+ channels within the cytoplasm of astrocytes in the optic nerve (Black et al., 1989a, 1989b).

While Na^+ channels are present within the membranes of most astrocytes that have been studied, they are apparently distributed with a density ($<1/\mu m^2$) (Sontheimer et al., 1991a, 1991b) that is too low to support electrogenesis [an exception is observed in spinal cord cultures, where some astrocytes can transiently express high Na^+ channel densities, up to 8 to $10/\mu m^2$ during the second week *in vitro*, although action potential generation does not occur, since these cells have a low resting potential so that most channels are inactivated at rest (Sontheimer and Waxman, 1992; Sontheimer et al., 1992)]. Moreover, astrocytes typically have significantly greater K^+ conductances than Na^+ conductances; the large P_K:P_{Na} ratio stabilizes membrane potential close to E_K and thus inhibits excitability (Sontheimer et al., 1992). In addition, electrical coupling between astrocytes (Gutnick et al., 1981) will tend to clamp each cell close to a common value for the population, impeding the rapid regenerative responses necessary for action potential electrogenesis.

The possibility that astrocytes might function as subsidiary sites for the synthesis of Na^+ channels which are transferred to the axon membrane has been suggested by Ritchie and his colleagues (Bevan et al., 1985; Gray and Ritchie, 1985). Cell-to-cell transfer of ion channels has not been demonstrated to date, and this hypothesis thus remains speculative. Nevertheless, the available evidence suggests that glial cells participate in the development of Na^+ channel clusters as the axon develops. The earliest foci of node-like membrane develop along premyelinated axons at a time when they have become associated with glial cells (Black et al., 1982; Waxman et al., 1982; Tao-Cheng and Rosenbluth, 1983). Moreover, preliminary observations suggest that, even at early stages in the development of Na^+ channel clusters along premyelinated axons (i.e., at early stages in the development of nodes of Ranvier), the axon is associated with glial cells that contain Na^+ channels. Figure 40-16 is an electron micrograph, showing a longitudinal section through the optic nerve of a 10-day-old rat. The tissue has been immunostained with an antibody directed against the rat brain Na^+ channel. Although compact myelin has not yet been formed, one axon expresses a small zone of Na^+ channel immunoreactivity, which extends approximately 1.5 μm along the length of the fiber, a distance that is slightly longer than the length of a mature node of Ranvier. This "hot-spot" of Na^+ channel immunoreactivity appears to be the precursor of a node of Ranvier (see Waxman et al., 1982). Flanking this part of the axon, two cellular processes, containing dense Na^+ channel immunoreactivity, are present. The location and orientation of

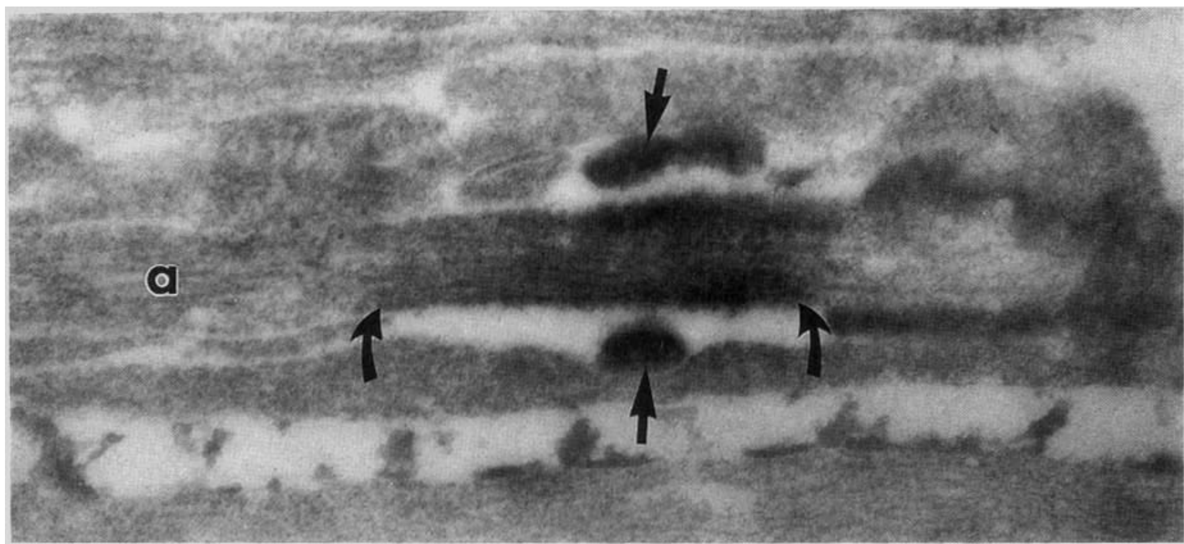

FIG. 40-16. Perinodal astrocytes appear to be present even at early stages of nodal development. This electron micrograph shows, in longitudinal section, the premyelinated optic nerve from a 10-day-old rat, immunostained with antibody 7493. An island of dense Na^+ channel immunoreactivity (*between curved arrows*) is present along a premyelinated axon, at a region where a node of Ranvier will presumably develop. This hot spot of axonal Na^+ channel immunoreactivity is flanked by two glial processes (*straight arrows*), which also express Na^+ channel immunoreactivity. The orientation and size of these glial processes, as well as their location, are similar to those of perinodal astrocytes. ×40,000.

these processes are similar to that of perinodal astrocytes. While, in the absence of double staining for GFAP (glial fibrillary acidic protein) or another cellular marker for astrocytes, it is impossible to definitively identify these processes as astrocytic, these preliminary results suggest that, even at early stages of maturation, astrocytes containing Na^+ channels are associated with developing nodes of Ranvier.

ASTROCYTES ARE INVOLVED IN AXONAL REORGANIZATION AFTER DEMYELINATION

Astrocyte processes, and their Schwann cell counterparts in the peripheral nervous system, may also play a role in Na^+ channel reorganization along demyelinated axons. Smith et al. (1983b) studied demyelinated axons in peripheral nerve following injection of lysophosphatidylcholine, and observed that, prior to remyelination, discontinuous conduction was supported by "phi-nodes," which presumably correspond to clusters of Na^+ channels. In an electron microscopic study, Blakemore and Smith (1983) observed a possible morphological counterpart for phi-nodes, that is, islands of axon membrane that were associated with a dense undercoating, similar to the nodes of Ranvier. These specialized regions of the axon membrane were always contacted by Schwann cell processes. Within the spinal cord, chronically demyelinated axons also exhibit zones of node-like specialization. These are invariably abutted by astrocyte processes (Rosenbluth and Blakemore, 1984; Black et al., 1991). In an immunoultrastructural study on Na^+ channel localization along dorsal column axons following ethidium bromide irradiation in the rat, Black et al. (1991) demonstrated that, by 4 weeks following demyelination, immunoreactivity with antibodies generated against Na^+ channels develops along some demyelinated spinal cord axons. The Na^+ channel-rich membrane is only seen in axons following contact by glial cells.

There is a remarkable degree of overlap between the region of Na^+ channel clustering and the zone of glial contact along demyelinated axons (Black et al., 1991). Some chronically demyelinated axons express discrete "islands" where Na^+ channels are clustered in high density. Whenever such clusters of Na^+ channels are observed, they are abutted by glial cell processes whose extent very closely matches the distribution of the Na^+ channel-rich axon membrane (Figure 40-17). Precise overlap, between astrocyte-axon contact and development of nodelike properties in the axon membrane following demyelination, suggests that astrocyte-axon interactions play a role in reorganization of the axon membrane following demyelination. Thus, during both normal development (see Figure 40-16) and following demyelination (Figure 40-17), there appears to be a close relationship between astrocyte-axon contact and increased expression of Na^+ channels in the axon membrane.

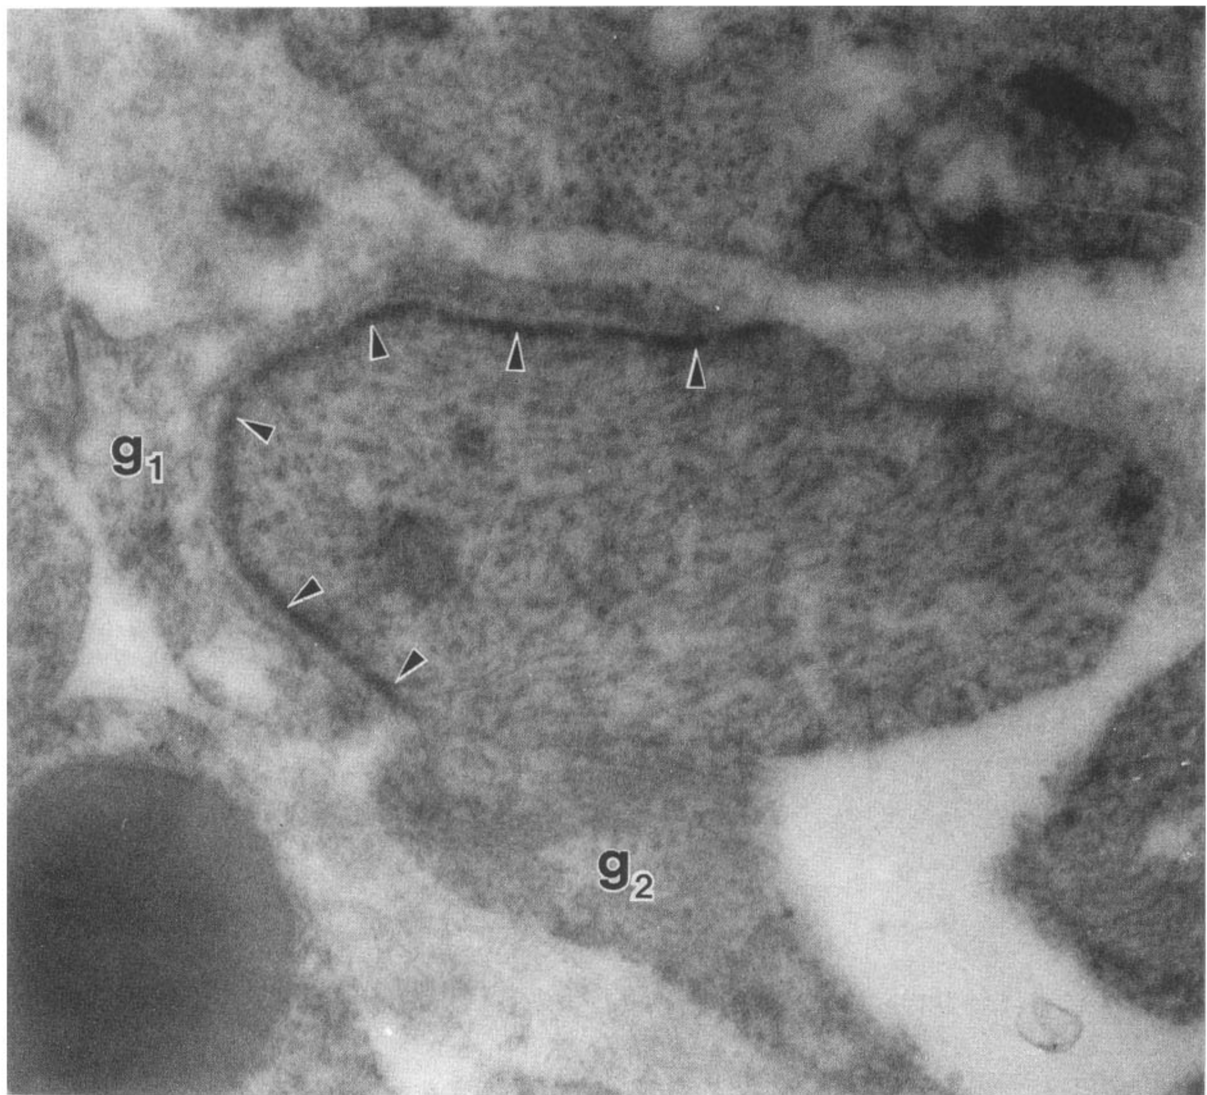

FIG. 40-17. Glial processes are present at hot spots of Na^+ channels along demyelinated axons. This immunoelectron micrograph shows Na^+ channel expression in axons in the spinal cord (dorsal column) of a rat that had been demyelinated with ethidium bromide 30 days previously. An island of Na^+ channel immunoreactivity (*arrowheads*) is present in part of the axon membrane, and is abutted by a glial process (g_1). The axon membrane contacted by a second glial process (g_2) does not express Na^+ channel immunoreactivity. ×50,000. [Modified from Black et al. (1991), with permission.]

Gliosis has classically been considered as a *negative* response to injury, that is, a response that inhibits recovery of function. Classical pathologists, for example, proposed that astrocytes inhibit central nervous system regeneration and remyelination. It is now clear that astrocytes also exhibit a number of *positive* roles, which may promote recovery of function, following injury to the brain and spinal cord. This conclusion has important implications for a number of disorders, including multiple sclerosis and spinal cord injury. For example, under some circumstances astrocytes may promote the regrowth of central nervous system axons (Liesi and Silver, 1988; Schwab and Caroni, 1988). Similarly, as discussed above, astrocytes may participate in the reorganization of Na^+ channels in demyelinated axons (Waxman, 1993a). The astrocyte is clearly emerging as a complex cell, which is intimately related to the axon, both in the normal central nervous system and following various pathological insults. It may be simplistic to think that functional recovery can be promoted simply by muting the astrocytic response to injury. In fact, the complexity of the astrocyte's role, both in normal development and following central nervous system injury, suggests that it might be therapeutically advantageous to enhance some aspects of the astrocytic response to injury of the brain and spinal cord.

Work in our laboratories has been supported in part by the Medical Research Service, U.S. Department of Veterans Affairs, and by Grants from the National Institutes of Health and the National Multiple Sclerosis Society. Support from the Allen Charitable Trust, the Daniel Heumann Fund, and the Folger Foundation is also gratefully acknowledged.

41 Glial membranes and axoglial junctions

JACK ROSENBLUTH

This chapter is concerned primarily with the plasma membranes of macroglia and their interactions at specialized interglial and axoglial contacts. The functional significance of specific surface structures and junctions are considered. Most of the discussion will be devoted to myelin-forming cells; astrocytes are reviewed extensively elsewhere (Chapters 19, 27, 28, and 40).

SIZE AND SHAPE OF MYELIN-FORMING CELLS

Classically, myelin-forming glial cells are depicted without their attached myelin sheaths, and the misleading impression has thus been fostered by neurohistological studies that oligodendrocytes, in particular, are small cells that give rise to few processes. In the light of more recent work, including dye injection studies (Butt and Ransom, 1989), however, it is clear that these cells, far from being small, are among the largest known by virtue of their gigantic membranous appendages, the myelin sheaths, which presumably remain attached to the cell body under normal circumstances. Myelin-forming cells rival neurons with respect to surface area, which is orders of magnitude greater than that of typical epithelial cells having perikarya of comparable size. This enormous surface is divided into distinct domains with regard to the distribution of both cytoplasmic and plasma membrane components.

A Schwann cell produces a single myelin sheath around one axonal segment ~100 to 1000 μm in length. Oligodendrocytes, in contrast, may generate multiple myelin segments around different axons. However, the size of the fibers and the thickness of the sheaths are very different in the peripheral and central nervous systems, and, as a result, the overall surface area of myelin generated by an oligodendrocyte around multiple axons may be no larger than that formed by a Schwann cell around a single internode.

For example, the total surface area of a myelin-forming Schwann cell, based on an internodal length of 500 μm, an axon diameter of 8 μm, and 50 myelin lamellae, would approximate 0.6 mm^2, ~96% of it in the domain of the compact myelin lamellae. An oligodendrocyte that forms myelin around 10 axons, each 2 μm in diameter with an internodal length of 500 μm and 20 layers in each sheath, would also have a total surface area of ~0.6 mm^2. In contrast, a cuboidal epithelial cell 10 μm wide would have a total surface area of <0.005 mm^2, that is, more than two orders of magnitude less.

A neuron with an axon 2 μm in diameter and 10 cm long would have an overall surface membrane area approximating 0.6 mm^2 as well. However, such a neuron would have a correspondingly large cytoplasmic volume to support, while the myelin-forming cell would not; the glial plasma membrane is thus disproportionately large, and the cell body supporting it is presumably involved primarily in the maintenance of that membrane.

The cell surface area of myelin-forming cells is so large as to suggest the need for specialized structures and mechanisms for transporting components between the perikaryon and the remote extensions. Microtubules, which are conspicuous in the cytoplasm-containing portions of myelin-forming cells, may subserve the directional movement of organelles within glial cells, as they do in axons. Post-Golgi vesicles transported in this way could be involved in the growth, turnover, or modification of compact myelin at distant sites.

Autoradiographic studies of turnover do indeed demonstrate involvement of the superficial cytoplasmic channels of Schwann cells in the synthesis and distribution of myelin components to the sheath. Choline lipids spread rapidly inward through the compact myelin, while proteins and glycoproteins tend to remain more superficial. The role of the paranodal loops and the Schmidt-Lanterman clefts is uncertain. They could be involved in signaling from the axon to the perinuclear portion of the Schwann cell (Gould, 1990) as well as in the transport of cytoplasmic organelles from the Schwann cell perikaryon to its periphery.

SUBCELLULAR DOMAINS

Typical epithelial cells are surrounded by a plasma membrane that is divided into discrete domains, the

apical surface bearing channels, carriers, and other membrane proteins distinct from those along the basolateral surface. The respective domains are separated by the junctional complex, including a girdle of tight junctions situated along the lateral portion of the cell close to the luminal surface, which serves as a barrier to movement of proteins and lipids within the plane of the membrane from one domain to the other (Alberts et al., 1989).

Not only are the membrane proteins different in these domains, but so also are the subapical cytoskeletal structures, condensed into a "terminal web" apposed to the apical membrane. There may be other distinctive morphological specializations peculiar to the apex as well, including microvilli and cilia, and these too are associated with cytoplasmic cytoskeletal elements.

Traffic from the Golgi apparatus within the cell is also polarized with respect to the apical and basal membrane domains, some vesicles moving only to the apex and others only to the basolateral region. Individual vesicles are addressed specifically to one or the other domain; that is, the traffic is not stochastic but depends, rather, on specific targeting signals (Rodriguez-Boulan and Powell, 1992).

Although not as simple as that seen in typical epithelial cells, regional differentiation also occurs in myelin-forming cells. The pattern here is less straightforward. In a mature myelin-forming cell whose sheath is "unrolled," there is no simple apex and base and no symmetric band-like junctional complex formed with neighboring glial cells. Indeed, individual myelin-forming cells are not interconnected by any kind of cell-cell junction. Rather, myelin-forming cells form conspicuous tight junctions and, to some extent, adhesive junctions between different portions of the *same* cell, and they also form asymmetric band-like junctions with the underlying axon (Livingston et al., 1973; Dermietzel, 1974a; Schnapp and Mugnaini, 1975).

This axoglial junctional region appears as a narrow strip, the "lateral belt," ~0.1 to 0.2 μm wide, along both lateral edges of the glial cell (Figures 41-1 to 41-9). The junction clearly divides the axolemma into domains (see below), but it does not divide the myelin-forming cell itself into domains, since these junctions occur only at the extreme edges of the sheath. The tight junctions on either side of the axoglial junctional strip (Figures 41-1, 41-7, and 41-8) may isolate the strip from the remaining glial membrane, however.

Subdivision of a cell into domains can be accomplished by other mechanisms as well and does not necessarily require tight junctions, as has been shown in neurons (Rodriguez-Boulan and Powell,

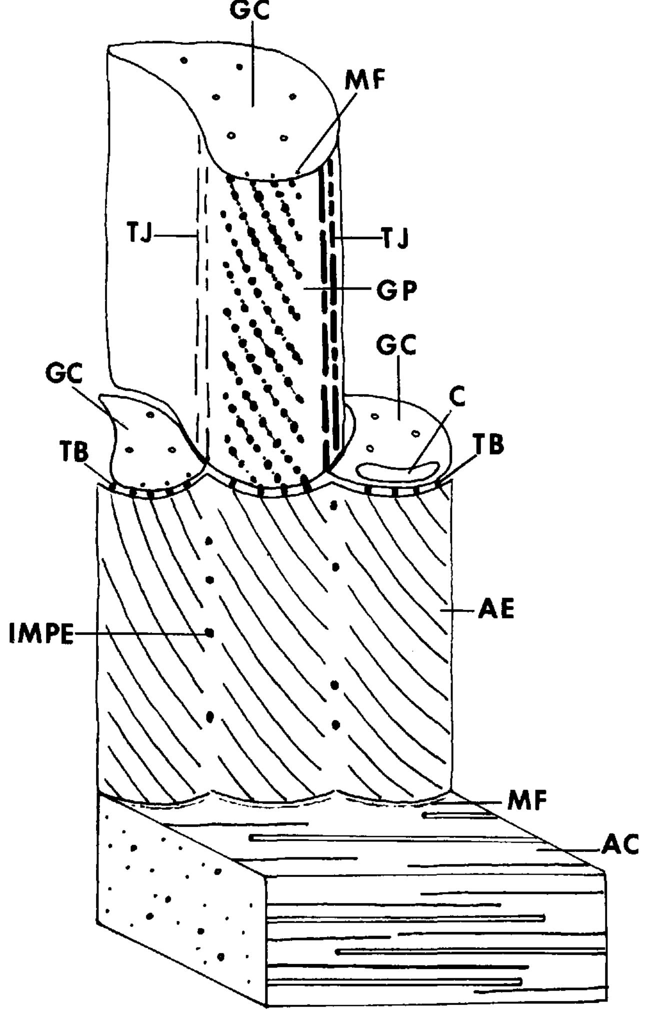

FIG. 41-1. Diagram of paranodal axoglial junction. The axonal axis is horizontal, with the nodal region toward the right (*not shown*) and the internode toward the left. Three "terminal loops" of glial cytoplasm (*GC*), containing circumferentially oriented microtubules, are shown. The P fracture face of the membrane of the middle loop displays diagonal rows of intramembranous particles between tight junctions (*TJ*). The intercellular junctional cleft of 2 to 4 nm is occupied by periodic ridges, the "transverse bands" (*TB*), which impress a diagonal pattern on the E fracture face of the axolemma (*AE*). Node-like intramembranous particles (*IMPE*) occupy rows in the axolemmal E fracture face between the indented strips of junctional membrane. The axonal cytoplasm (*AC*) contains axially oriented microtubules and neurofilaments as well as microfilaments (*MF*) immediately adjacent to the junctional membrane. The cytoplasm in two of the glial loops contains orthogonally oriented cytoskeletal filaments, seen as dots (cf. Figure 41-6) immediately adjacent to the junctional membrane (*MF*). The loop nearest the node contains a membranous cisterna (*C*) apposed to the junctional membrane.

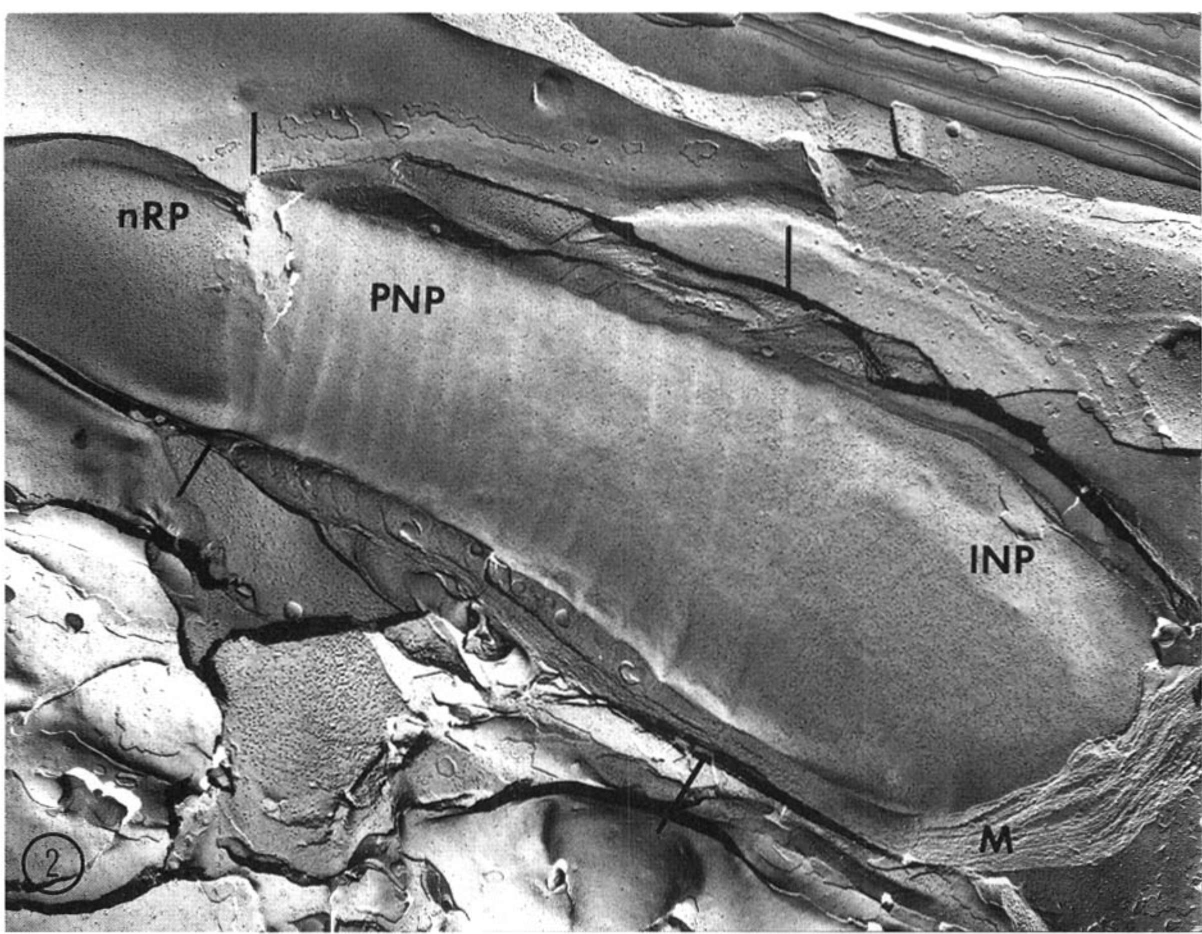

FIG. 41-2. Freeze-fracture replica of axon showing the inner leaflet (P fracture face) of the axolemma. The nodal membrane (*nRP*) is comparable to the internodal membrane (*INP*) in this fracture face. The paranodal region (*NP*) is marked by 17 strip-like indentations imposed by the apposed "terminal loops" of myelin lamellae. The loops themselves have been cross-fractured and are visible above and below the axolemma (*between bars*). *M*, compact myelin.

1992). In the case of myelin-forming Schwann cells, the outermost portion of the cell is enveloped by a basal lamina, which bridges across the node of Ranvier to the myelin segments on either side (Figure 41-8). Although the presence of a basal lamina would seem to identify the outermost layer of the Schwann cell as the base, the perinodal region of the cell gives rise to microvillous projections comparable to those normally arising from the apical domain in epithelial cells (Figures 41-8 and 41-9).

The innermost Schwann cell lamella and the "outer" perinuclear portions of the cell are separated by the great expanse of the intervening compact myelin. The enormous distance between the respective regions would seem to isolate them from each other at least partially. However, cytoplasmic "rivers," or channels, traverse the compact myelin and interconnect the innermost and outermost layers of the sheath (Gould, 1990). The most conspicuous, and consistent, of these transverse interconnections is represented by the *terminal loops,* which constitute the lateral margins of the sheath spiraling around the axon in the paranodal regions (Figures 41-1, 41-4, 41-6, 41-7, and 41-8). Other such channels, corresponding to *Schmidt-Lanterman incisures,* follow a similar spiral path at irregular intervals within the internodal myelin sheath. These various pathways serve as a potential route for movement of cytoplasmic components, including organelles and even mRNA (Colman et al., 1982; Trapp et al., 1987).

Although these pathways are extensive in peripheral myelin formed by Schwann cells, they are much more restricted in oligodendrocyte myelin in the central nervous system. Cytoplasm-containing channels corresponding to Schmidt-Lanterman incisures, occur in large-caliber sheaths (Hildebrand et al., 1993), but not in small-caliber sheaths. In all sheaths, however, regardless of size, the paranodal loops form a cytoplasmic channel along the lateral edges of each

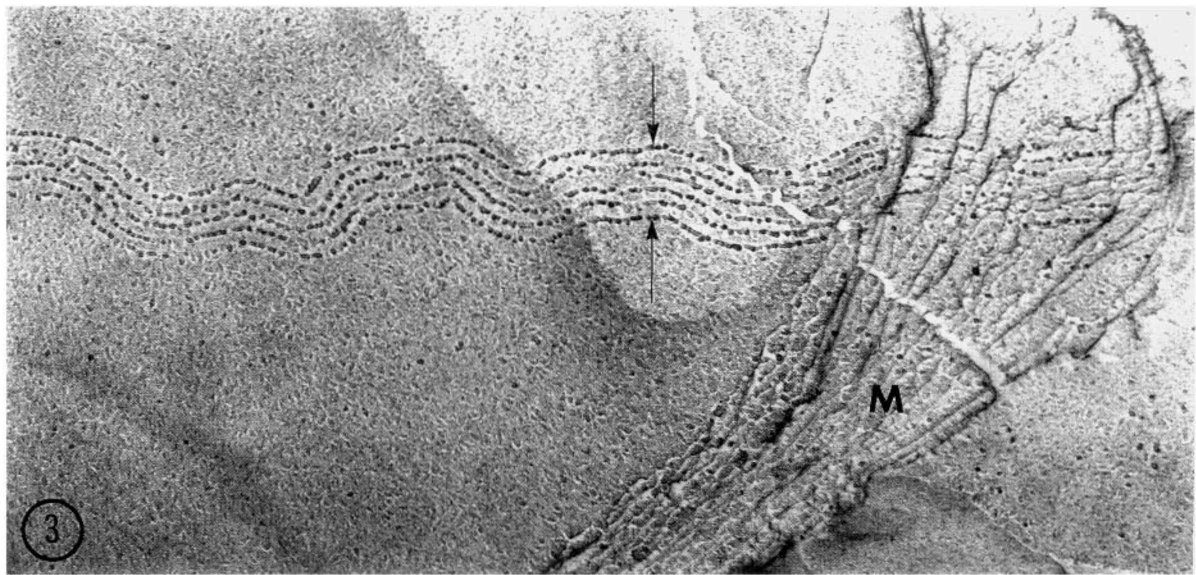

FIG. 41-3. The fracture face of a compact myelin lamella (left and center) contains five meandering "radial component" strands (*between arrows*). At right, the fracture steps through ~10 myelin lamellae, all of which display equivalent strands in register with those at left.

myelin segment continuous with the cytoplasm-containing innermost and outermost layers of the sheath. In some cases the outermost layer includes the oligodendrocyte cell body, and in other cases it is interconnected with the cell body by a narrow cytoplasmic process (Remahl and Hildebrand, 1990a; Peters et al., 1991).

Thus, even in the absence of zonular tight junction barriers, both peripheral and central myelin-forming cells can be roughly divided into the compact region of the myelin sheath, whose structure and biochemical composition are distinctive, and the cytoplasm-containing borders, which are continuous around the cell periphery, together with the transverse channels connected to them. Even within these regions, there appear to be subdomains. The lateral borders bear the paranodal axoglial junctional strips, flanked by tight junctions. The protein MAG (myelin-asso-

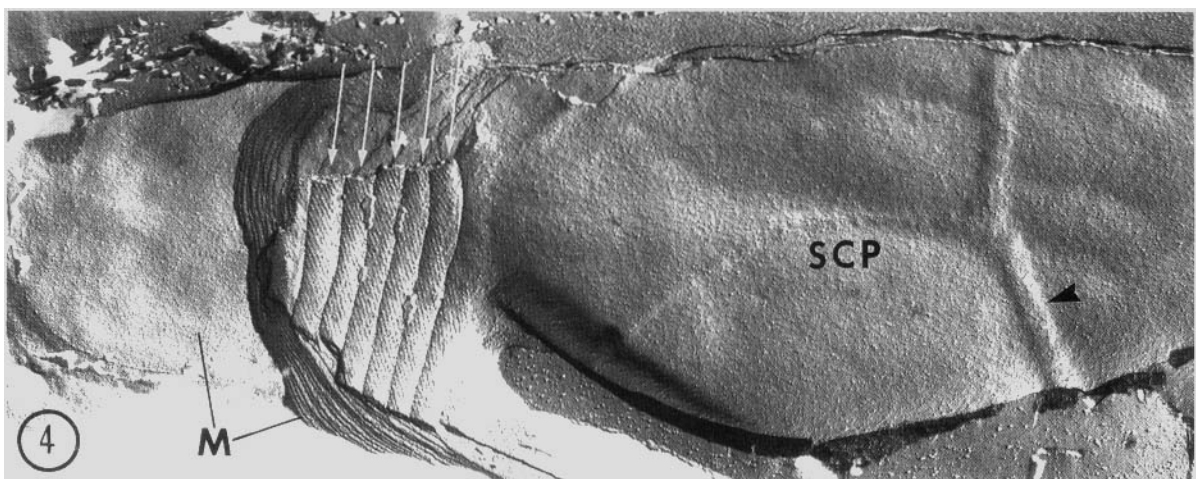

FIG. 41-4. Peripheral myelinated nerve fiber fractured to reveal the P-face of paranodal "terminal loops" (*arrows*) containing highly regular, diagonal rows of particles. The loop closest to the center of the figure is continuous with a myelin lamella (*SCP*), extending toward the right. Particles in the latter membrane are comparable to those in the loops, but are not organized into the same paracrystalline array. *Arrow* indicates the location of a cytoplasmic "channel" corresponding to a Schmidt-Lanterman incisure. Endoneurial connective tissue is visible at the upper left. *M*, additional myelin lamellae.

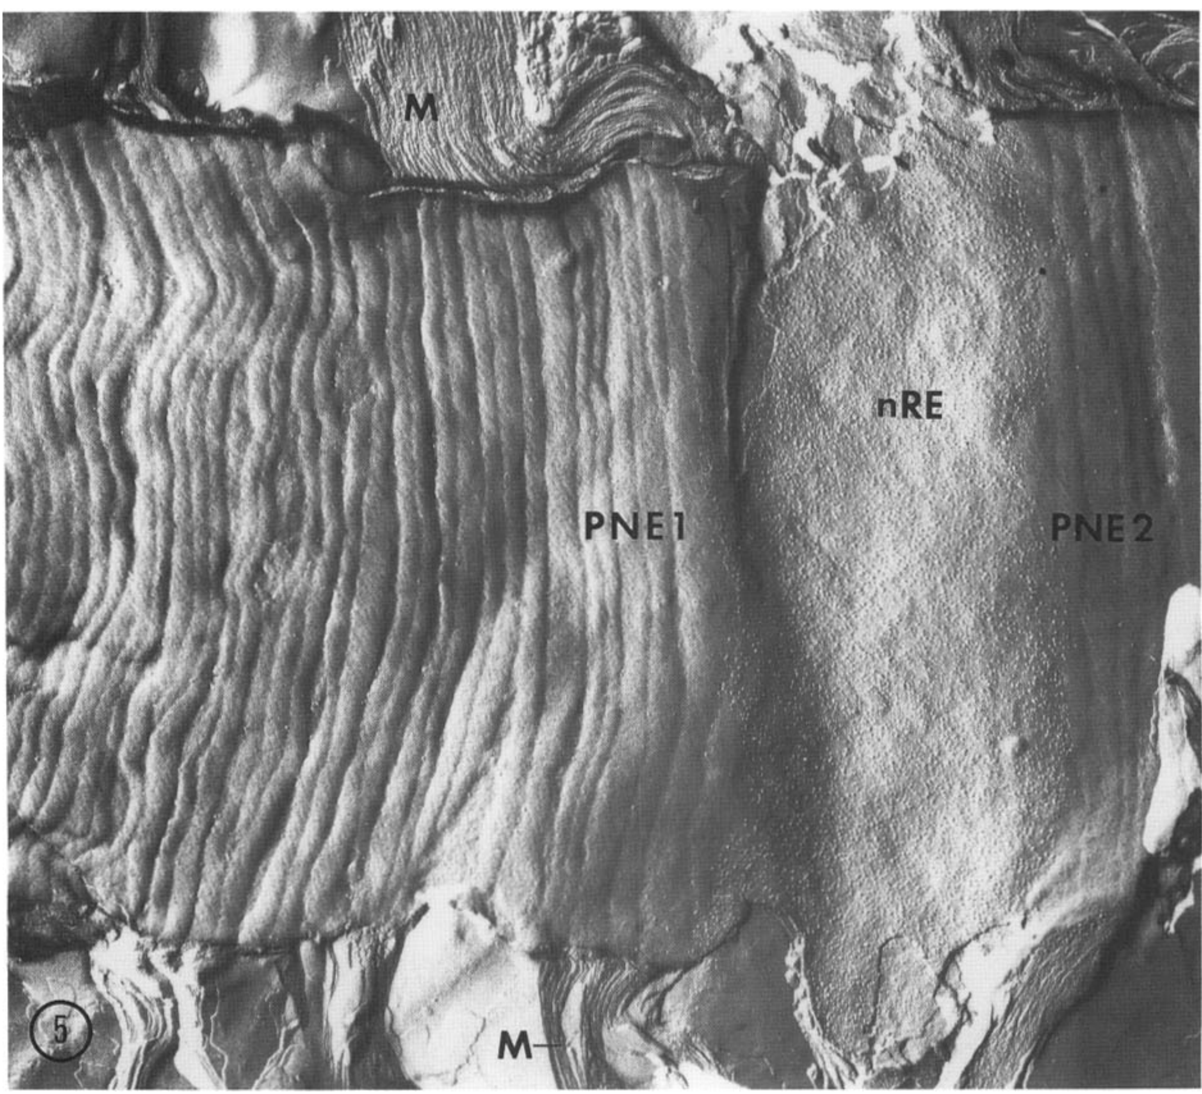

FIG. 41-5. Peripheral myelinated axon fractured to reveal the outer leaflet of the axolemma (E fracture face). The node of Ranvier (*nRE*) contains large numbers of membrane particles, in contrast to the internodal axolemma (*not shown*), which in this fracture face contains very few. The nodal particles are sharply demarcated by the paranodal regions on either side (*PNE1* and *PNE2*), which display multiple strip-like indentations bearing a diagonal pattern and few membrane particles, except within "grooves" (upper right). There are ~33 indentations in PNE1, representing junctions with terminal loops such as those shown in Figure 41-4. *M*, compact myelin.

ciated glycoprotein) appears primarily in association with the innermost border, corresponding to the first layer of the sheath, adjacent to the enclosed axon, plus, in Schwann cells, the Schmidt-Lanterman incisures and paranodal terminal loops (Trapp, 1990).

The extent to which membrane components are able to move from one domain to the next within the plane of the membrane is unknown. Nor is it clear how turnover of compact myelin components is accomplished. One can only speculate that membrane elements diffuse laterally within the plane of the membrane to the nearest cytoplasmic channel, where "packages" of new components transported from the perikaryon via cytoplasmic vesicles are available for replacement of old components, which are then transported back to the perikaryon. The possibility remains that the myelin sheath "grows" continuously from the outer edge, nearest the perikaryon, and is sloughed continuously from the innermost edge. This conflicts with the observation that different components of myelin turn over at different rates, however (Norton, 1981). Some components may also be able to move transversely across lamellae, and some may be synthesized by enzymes resident within compact myelin (Ledeen, 1984).

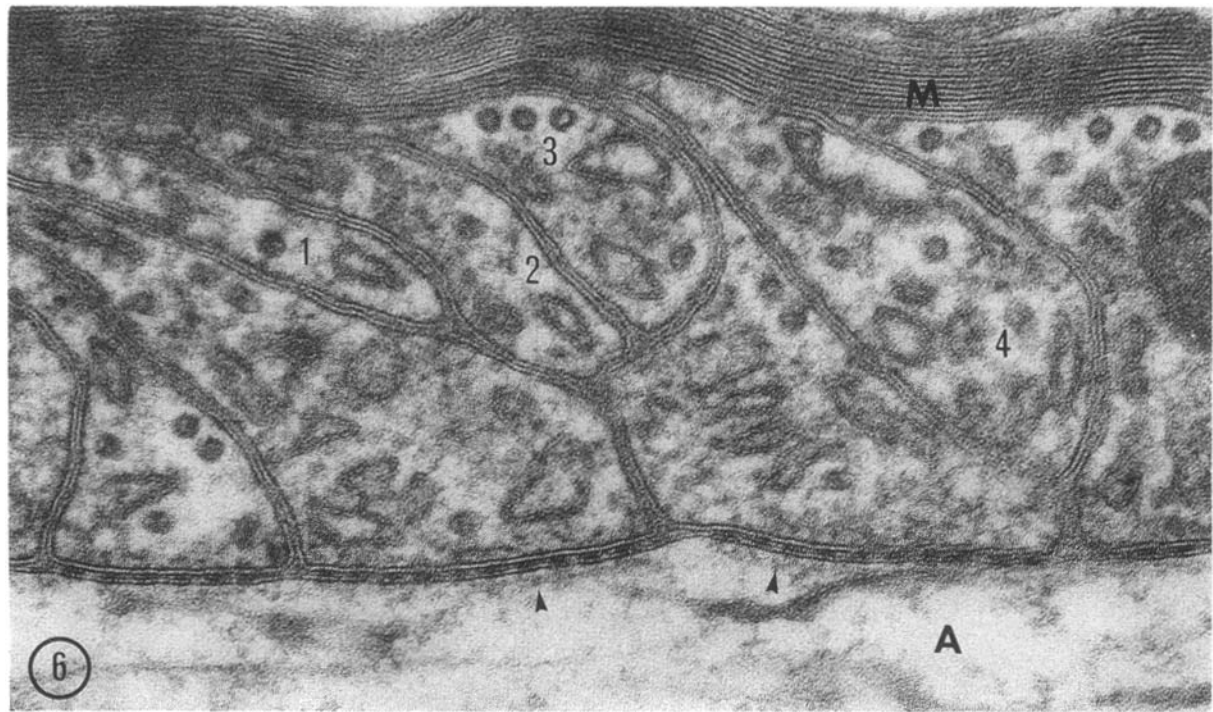

FIG. 41-6. Thin section of paranodal region. Compact myelin lamellae (*M*) split to form tear-drop-shaped "terminal loops" that extend toward the axon (*A*). Some of the loops form junctions with the axolemma, marked by periodic densities, the "transverse bands." In the axoplasm just beneath each junction, microfilaments (*arrowheads*) run parallel to the axolemma. Fine dots in the terminal loop cytoplasm just adjacent to the junctional membrane represent orthogonal microfilaments cut transversely. The terminal loops contain membranous cisternae and microtubules. Four of the loops (1 to 4) do not reach the axolemma and display no junctional specializations. Tight junctions are evident between terminal loop membranes.

GLIA-GLIA JUNCTIONS

Although in typical epithelial cells the subapical junctional complex between adjacent cells appears to constitute a dividing line between apical and basolateral domains, myelin-forming cells, as pointed out above, have no equivalent junction with their immediately adjacent fellows. At the extreme ends of each internode in the peripheral nervous system, adjacent Schwann cells abut each other, but they do so in a spray of microvillous processes that intermingle and approach each other closely, but do not, so far as is known, form junctions with each other (Figures 41-8 and 41-9). The Schwann cell-Schwann cell interaction at the node of Ranvier is thus distinct from the epithelial cell-epithelial cell junction at the junctional complex.

The latter junction, in addition to separating apical from basolateral domains within each cell, serves to isolate the extracellular fluid surrounding the apices of the cells from that surrounding their bases, which may be very different in composition. In the case of a myelinated axon, however, the fluid bathing the outside of the myelin sheath is directly continuous with that bathing the node of Ranvier. Only a basal lamina separates the two. Indeed, saltatory conduction requires a low-resistance pathway extending from the nodal axolemma to the extracellular space surrounding the internode. Any barrier to current flow here would undoubtedly disrupt saltatory conduction.

Within the central nervous system, myelin-forming oligodendrocytes do not form microvilli over the node of Ranvier. The equivalent structures in this case are either absent or are formed by astrocytes (Hildebrand, 1971), again with no high-resistance barrier between the axonal surface at the node and the remainder of the extracellular space.

In contrast to the lack of specialized junctions between neighboring myelin-forming cells, myelin lamellae within a single internode, derived from the same cell, form very conspicuous tight junctions between successive terminal loops in the paranodal regions (Figures 41-1 and 41-6). These junctions serve to isolate the minute paranodal periaxonal space from the narrow aqueous space between successive layers of the sheath. Similarly, the internal mesaxon, which constitutes a potential pathway interconnecting the internodal periaxonal space with the extracellular space within the sheath, is also

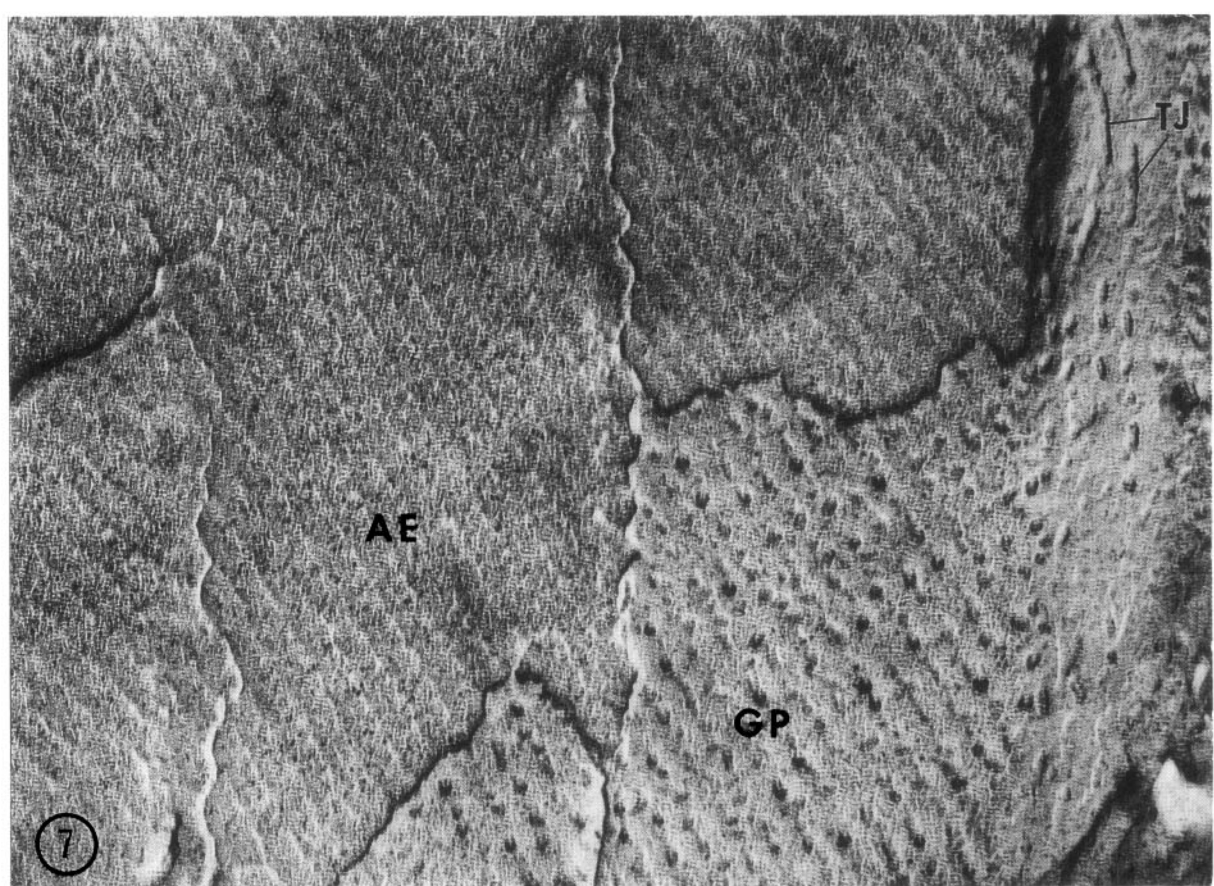

FIG. 41-7. Freeze-etched specimen showing the external leaflet of the paranodal axolemma (*AE*) dried down against "terminal loops," whose cytoplasmic leaflet (*GP*) displays paracrystalline rows of membrane particles having the same orientation and repeat period as the pattern in the axolemma. The junctional face of the terminal loop membrane is flanked by tight junction strands (*TJ*).

sealed closed by tight junctions (Figure 41-8), as is the external mesaxon formed between the outermost layer of the sheath and the one just internal to it (Tetzlaff, 1978; Dermietzel et al., 1980; Shinowara et al., 1980), thus apparently isolating the extracellular space within the sheath from that outside. The disposition of these tight junctions is such that the compact region of the myelin sheath is ringed by tight junctions, laterally, internally, and externally. Presumably, the seal is effective over the brief duration of an action potential, although it can be penetrated over longer time periods by cations or hypo-osmolar media (Ropte et al., 1990) and by antibodies (Raine et al., 1978).

To what extent the tight junctions extend further, into the compact region, is uncertain. Particle strands (Figure 41-3) associated with the *radial component* (Kosaras and Kirschner, 1990) extend across multiple myelin lamellae, primarily in the quadrant that includes the inner and outer mesaxons (Peters et al., 1991). It is not known whether these have the same significance as tight junctions in restricting movement through the extracellular compartment within the myelin sheath, either circumferentially or longitudinally. Nor is it clear whether the radial component strands serve to divide the compact membrane domain by restricting movement of membrane components within the plane of the myelin membrane.

Adhesive junctions are also seen sometimes between successive terminal loops, that is, between different portions of the same cell membrane, but not between different myelin-forming cells at adjacent internodes. Typically, the adhesive junctions are found adjacent to the tight junctions on the side away from the axolemma in a position corresponding to that of the girdle-like adherent junctions at epithelial junctional complexes. Presumably, they serve to anchor the respective terminal loops together mechanically and to prevent slippage between successive layers of the sheath in the paranodal region. In the unrolled state, these adherent junctions

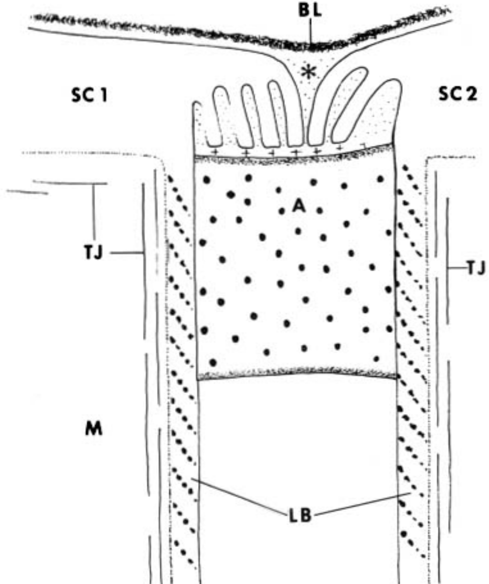

FIG. 41-8. Diagram of nodal junction between "unwrapped" Schwann cells (*SC1* and *SC2*) and an axon (*A*) displaying a typical "undercoating" of the nodal axolemma. A basal lamina (*BL*) bridges across the nodal gap, which contains a proteoglycan "gap substance" and many slender processes arising from the adjacent Schwann cells. The processes stabilize at a constant separation of ~20 to 25 nm from the axolemma; this space contains both transverse and parallel junctional filamentous structures. Adjacent to the node, the unwrapped lateral belt of each Schwann cell is marked by diagonal particle arrays, which form the paranodal axoglial junction (*not shown;* see Figure 41-1). Tight junctions (*TJ*) are present between the compact myelin (*M*) and lateral belts and between the Schwann cell cytoplasm and outermost layer of compact myelin.

would appear intermittently in the membrane of the terminal loops adjacent to the tight junction strands.

A recent confocal microscopy study of peripheral nerve fibers has demonstrated E-cadherin associated with the plaque-like adhesive junctions, aligned in register between successive paranodal loops of myelin, as well as with the internal and external mesaxons and Schmidt-Lanterman incisures. This protein colocalizes with β-catenin and F-actin, suggesting that the complexes thus formed may serve not only to maintain the integrity of the cytoplasmic channels within the myelin sheath and the organized structure of the sheath, but also to transmit signals across myelin lamellae (Fannon et al., 1995).

Although oligodendrocyte processes of the same cell are known to form tight junctions with each other, tight junctions between astrocytes and oligodendrocytes have not been reported (Mugnaini, 1986). Rather, gap junctions form between the respective cells. These are macular structures that do not encircle membrane domains or isolate extracellular spaces. If the perinodal astrocyte is indeed involved in the regulation of extracellular ion composition, as has been proposed, coupling to oligodendrocytes by way of gap junctions might serve to redistribute ions intracellularly within oligodendrocytes as well as astrocytes. Mechanical adhesion might also be postulated, that is, a mechanism for immobilizing and retaining astrocytes at the perinodal locus. In addition, the passage of small molecules involved in signaling, for example, cAMP, could couple the respective cells into a *metabolic syncytium* and serve to coordinate their behavior (Ransom and Kettenmann, 1990; Chapter 19, this volume).

PARANODAL AXOGLIAL JUNCTIONS

More striking than the gap and tight junctions formed by myelin-forming cells are the "close" axoglial junctions, which are formed by the lateral edges of the sheath as it winds around the axon (Livingston et al., 1973; Dermietzel, 1974a; Schnapp and Mugnaini, 1975). The winding pattern is distinctive. In the case of a roll of paper, all the layers are coextensive, and only the innermost one is in contact with the core. In the case of the myelin sheath, however, successive layers are slightly shorter, moving from the outside of the sheath inward, and, as a result, the edge of *each* turn of the sheath is in contact with the axolemma (Figures 41-4 and 41-12). Hence the total area of contact between the sheath and the axon is enormous, the amount increasing with the number of turns and the diameter of the axon.

Since the width of each junctional strip is ~0.1 to 0.2 μm, 20 adjacent strips at a single central nervous system paranode would extend up to 4 μm in the axial direction (Figure 41-12). For an axon 2 μm in diameter, the total surface area of one such paranodal junction would approach ~24 μm^2. Since there are two such regions for each myelin segment, the total area of axoglial junction in this segment would be almost 50 μm^2. In the case of peripheral nervous system fibers (Figure 41-5), the number of turns of the myelin sheath can be much greater, and the diameter of the axon in the paranodal region may be greater as well, resulting in an increase in junctional area, although in the case of very thick sheaths, not all terminal loops reach the axon (Figure 41-6). Nevertheless, the paranodal axoglial junction is surely the largest intercellular junction known and presumably subserves one or more important functions.

This junction is not only extraordinary in size, but also unique in form, with no clear counterpart in other tissues. Its distinctive characteristics include the following:

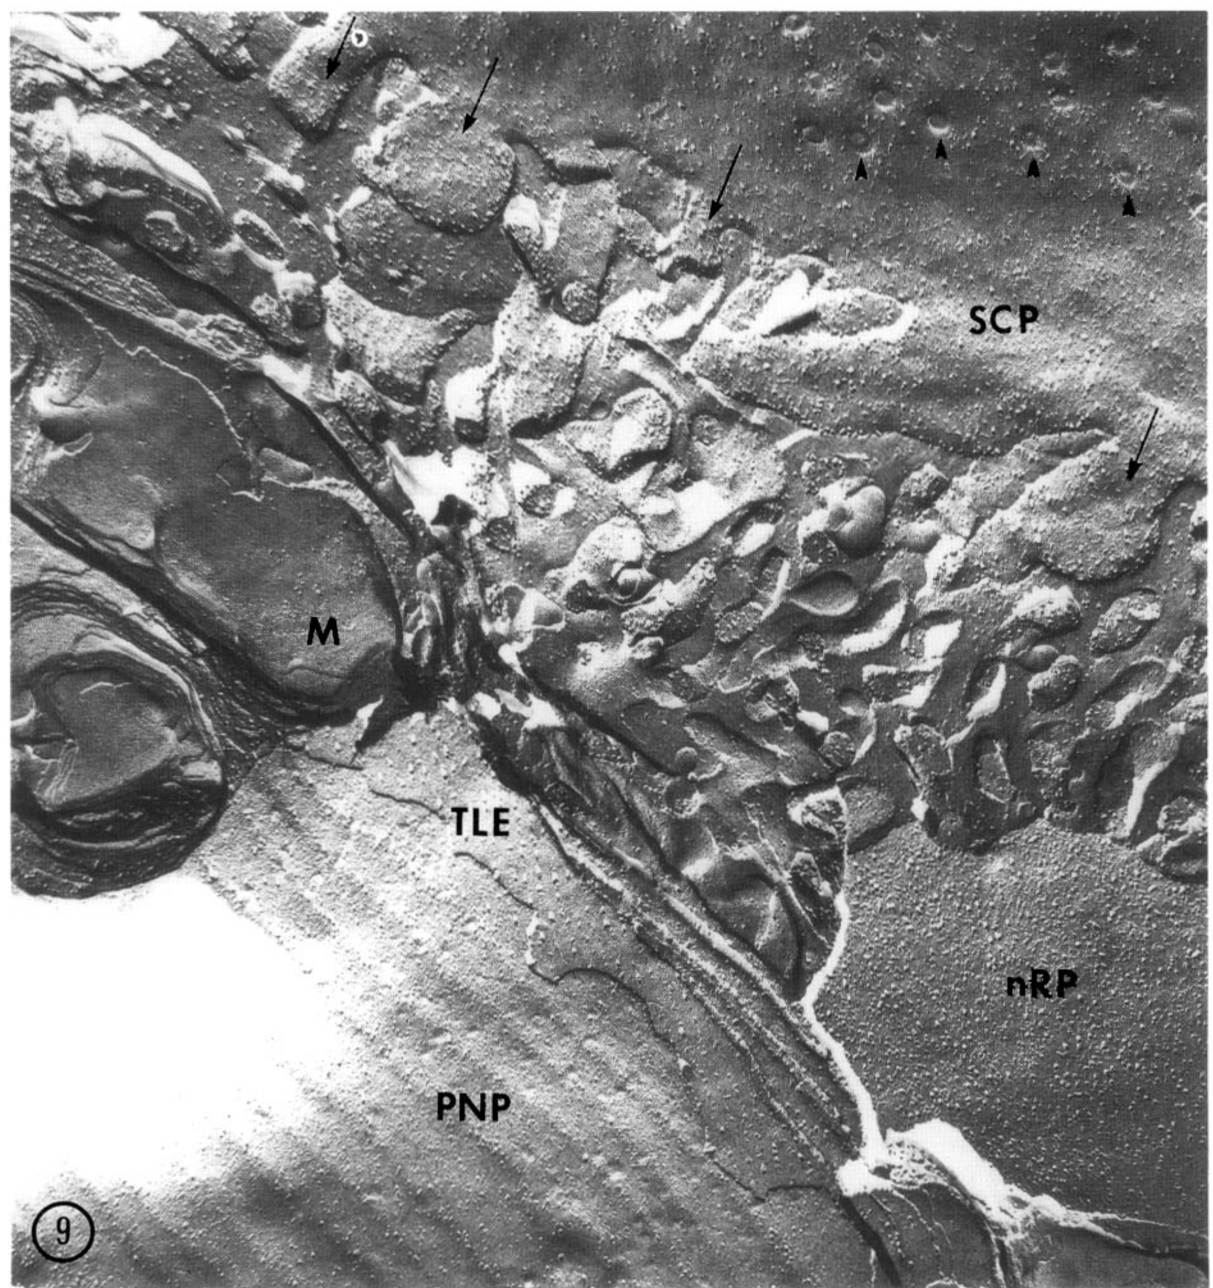

FIG. 41-9. Freeze-fracture replica of peripheral node of Ranvier. The P fracture face of the paranodal axolemma (*PNP*) containing strip-like junctional indentations is shown at the lower left. It is partly covered by terminal loop membrane (*TLE*), which in the E fracture face displays few particles, but has a faint diagonal pattern. The P face of the node (*nRP*) is covered by a profusion of microvilli within the perinodal space in the center of the figure. Some of these can be seen to arise from the adjacent Schwann cell (*SCP*) at *arrows*. *Arrowheads*, pinocytotic pits. *M*, myelin.

1. Exceptionally close apposition (2 to 4 nm separation) between the axolemma and the apposed terminal loop membranes (Figure 41-6), comparable to the membrane spacing at gap junctions (Livingston et al., 1973)
2. Indentation of the axolemma (Figures 41-2, 41-5, 41-6, and 41-9) by the terminal loops (Robertson, 1959)
3. Ordered, oblique arrays (Figures 41-1, 41-4, and 41-7) of membrane particles within the junctional membrane of the terminal loop (Livingston et al., 1973; Rosenbluth, 1984)
4. Oblique intercellular ridges (Figures 41-1 and 41-6), the *transverse bands* (Hirano and Dembitzer, 1982), corresponding in orientation and period to the terminal loop particle arrays

5. Filamentous cytoskeletal elements (Figures 41-1 and 41-6) in both axon and terminal loop cytoplasm (Rosenbluth, 1984, 1990; Ichimura and Ellisman, 1991). In addition, membranous cisternae (Figure 41-1) occur commonly in the terminal loops in close apposition to the junctional membrane (Rosenbluth, 1984), but these are not consistent, and in the central nervous system they are uncommon.

The axoglial junction is exclusively heterophilic; that is, Schwann and glial cells never form such junctions between their own processes or with adjacent cells of like kind. "Floating" terminal loops that do not reach the axon show no sign of junctional or hemijunctional structure (Figure 41-6). Nor do axons form such junctions with other neuronal processes. Presumably, neither myelin-forming cells nor neurons are capable of producing all the components necessary for assembly of this junction. Indeed, only the axonal portion of the neuron appears capable of forming this junction.

Although the prodigious size of this junction suggests that it subserves one or more important functional roles, what those roles are is still uncertain. Several possibilities seem likely.

Anchorage of the Myelin Sheath. The junction may serve to anchor the myelin sheath to the axon; that is, transmembrane components may attach the cortical cytoskeleton of the axon to that of the glial cell in the paranodal region, thus maintaining the nodal gap at a fixed length regardless of extraneous mechanical stresses. This would be of most importance in the peripheral nervous system, in view of the considerable lengthening and shortening of nerves associated with skeletal movements. Clearly, changes in nodal area would have serious effects on nodal capacitance and safety factor and could cause conduction failure.

Electrical Isolation. The junction may serve to isolate the perinodal space between myelin segments from the periaxonal space underneath the myelin sheaths electrically (Rosenbluth, 1976, 1983). The action currents generated at the node flow axially within the axon and longitudinally outside the myelin sheath, forming circuits completed at adjacent nodes of Ranvier. If a substantial part of that current were to be short-circuited underneath the myelin sheath, the effectiveness of saltatory conduction would be compromised. Thus, it is essential that the paranodal myelin sheath be sealed to the axon in such a way as to impose a high resistance to current flowing longitudinally along the external surface of the axon.

The simplest biological device to meet this need would be a tight junction between the glial terminal loops and the axolemma. In fact, this does not occur. Tracer molecules are able to follow this pathway (Feder et al., 1969; Hirano and Dembitzer, 1969), and, in addition, some current flow has been reported through this pathway after completion of action potentials, apparently representing the discharge of internodal capacitance (Barrett and Barrett, 1982). Thus, the characteristics of this junction appear to be such that the high-frequency current flows that accompany the action potential are not significantly short-circuited, while at the same time, slower time-course currents associated with afterpotentials are able to flow.

Perhaps more important, there may be sufficient electrical continuity through the junction so that internodal potassium channels are able to establish the resting potential for both the nodal and internodal axolemma (Chiu and Ritchie, 1982), since there may be relatively few potassium channels in the nodal membrane itself.

Differentiation of the Axolemma. Freeze-fracture studies of unmyelinated axons show the axolemma to be a relatively uniform structure containing randomly scattered particles without obvious regional differentiation (Figure 41-12 bottom). Myelinated fibers, in contrast (Figures 41-5 and 41-12 top) are differentiated in a highly distinctive manner with respect to the distribution of membrane particles in the external leaflet of the axolemma (Rosenbluth, 1976). Typically, the nodal axolemma, which has the form of a cylinder or barrel, depending on its curvature, contains large numbers of large particles, sharply demarcated by the collar of paranodal junctions on either side of the node. The paranodal axolemma is serially indented by the helically wound lateral edge of the myelin sheath, successive turns of which are closely apposed to each other (Figures 41-4 and 41-12 top).

In contrast to the nodal axolemma, the paranodal axolemma contains only small numbers of node-like particles, and those present occur primarily within the narrow "grooves" between junctional strips. Occasionally, especially in that portion of the paranode furthest from the node, the strips are less tightly packed, and the grooves between them widen into "lakes," which contain larger numbers of node-like particles. Such particles occur as well in the juxtaparanodal portion of the internodal axolemma (JPI) immediately adjacent to the paranode. The particles here are sharply demarcated by the last junctional strip of the paranode, their concentration declining gradually with distance in the direction of the internode to a baseline level of ~$100/\mu m^2$ (Tao-Cheng and Rosenbluth, 1984).

The E-face of the paranodal junctional axolemma often displays a paracrystalline pattern (Figures 41-5 and 41-7), especially in specimens that have been etched, that is, those in which the water between the axolemma and apposed glial membrane has sublimed, resulting in collapse of the outer leaflet of the axolemma against the intercellular, ridgelike transverse bands (Rosenbluth, 1984). The result is that the image of the transverse bands becomes embossed on the junctional axolemma, resulting in the appearance of a diagonal pattern within the strips. In some preparations, the inner leaflet of the paranodal axolemma displays a complementary pattern, which could also have been embossed by the transverse bands prior to fracture. This pattern has been ascribed, alternatively, to arrays of particles intrinsic to the paranodal axolemma (Wiley and Ellisman, 1980). However, the absence of such a pattern in acutely demyelinated axons does not support that interpretation.

It is clear that the angle formed by the paranodal transverse bands in mammalian nerves approaches 90 degrees with respect to the axonal axis, but in amphibian (Rosenbluth, 1976; Tao-Cheng and Rosenbluth, 1980) and reptile nerves (Schnapp and Mugnaini, 1975) the angle is obviously smaller. Presumably, the orientation of the particles in the junctional glial membrane determines this angle.

Intercellular Transfer. The great length of the axon has suggested that this appendage, particularly where it is most remote from the parent neuronal perikaryon, may depend on the investing glia for some sort of "nutrition" or "support." Most recently, this hypothesis has taken the form of suggestions that voltage-gated sodium channels may be generated in glial or Schwann cells and subsequently transferred to axons by way of the nodal microvilli (Shrager et al., 1985). The paranodal junction would be another possible site for transfer in view of its size, the much closer proximity of the axon and glial membranes to each other here, and the strategic location of the junction with respect to the node of Ranvier.

Although provocative, the hypothesis that glial channels are transferred to axons has not yet received direct support, however. Indeed, recent data (see *Pathology* below) suggest that axolemmal sodium channels in the central nervous system of the myelin-deficient rat, which is virtually devoid of myelin, as well as the *shiverer* mouse, are not reduced. On the contrary, evidence from both freeze-fracture studies and saxitoxin-labeling experiments suggests that myelin deficiency results in an overall *increase* in axonal sodium channels, with higher-than-normal concentrations in the axolemma.

The converse possibility, that the paranodal junction is a site of signaling from the axon to the myelin-forming cell, remains open, although it must be pointed out that the junction has not yet formed during the early stages of myelination, but appears only later (Tao-Cheng and Rosenbluth, 1983). Nevertheless, the junction could be the site at which the mature myelin-forming cell "reads" the state of the enclosed axon. The junction could thus underlie phenomena such as Wallerian degeneration, in which myelin segments far from the site of an axonal injury begin to degenerate, even though they have not been directly damaged by the trauma (Ishise and Rosenbluth, 1986).

NODAL AXOGLIAL JUNCTIONS

The nodal axolemma also bears a characteristic relation to the surrounding Schwann or glial cell processes, which is distinctly different from that in the paranodal region and is sufficiently specialized in structure to justify calling it a junction. The essential character of this junction can be seen not only at normal nodes of Ranvier in both the peripheral nervous system (Figure 41-8) and central nervous system (Figure 41-12), but also, and in some cases to better advantage, in abnormal fibers (see *Pathology* below).

The essential features of the nodal junction include, on the axonal side, a distinct "undercoating" (Peters et al., 1991) of the plasma membrane by cytoskeletal elements (Figures 41-1, 41-8, 41-10, and 41-11). An isoform of ankyrin has been localized to this site (Kordeli et al., 1990). The external surface of the nodal axolemma is separated from the surrounding glial processes by a space having a consistent width of ~20 to 25 nm (Figures 41-10 and 41-11), that is, ~5 to 10 times the width of the paranodal gap. This space is reminiscent of that at desmosomes or adhesive junctions between epithelial cells not only in size but also with respect to the presence of a dense lamina within the cleft and irregular interconnections between the axonal and glial membranes (Figures 41-8, 41-10, and 41-11). These fine filamentous interconnections are visible both in thin sections (Rosenbluth, 1983) and in etched preparations (Ichimura and Ellisman, 1991).

In those cases where the external glial component of the junction is missing, the axonal components are nevertheless present, and the complex resembles the *hemidesmosomes* that link intracellular cytoskeletal elements to extracellular fibrous components, as

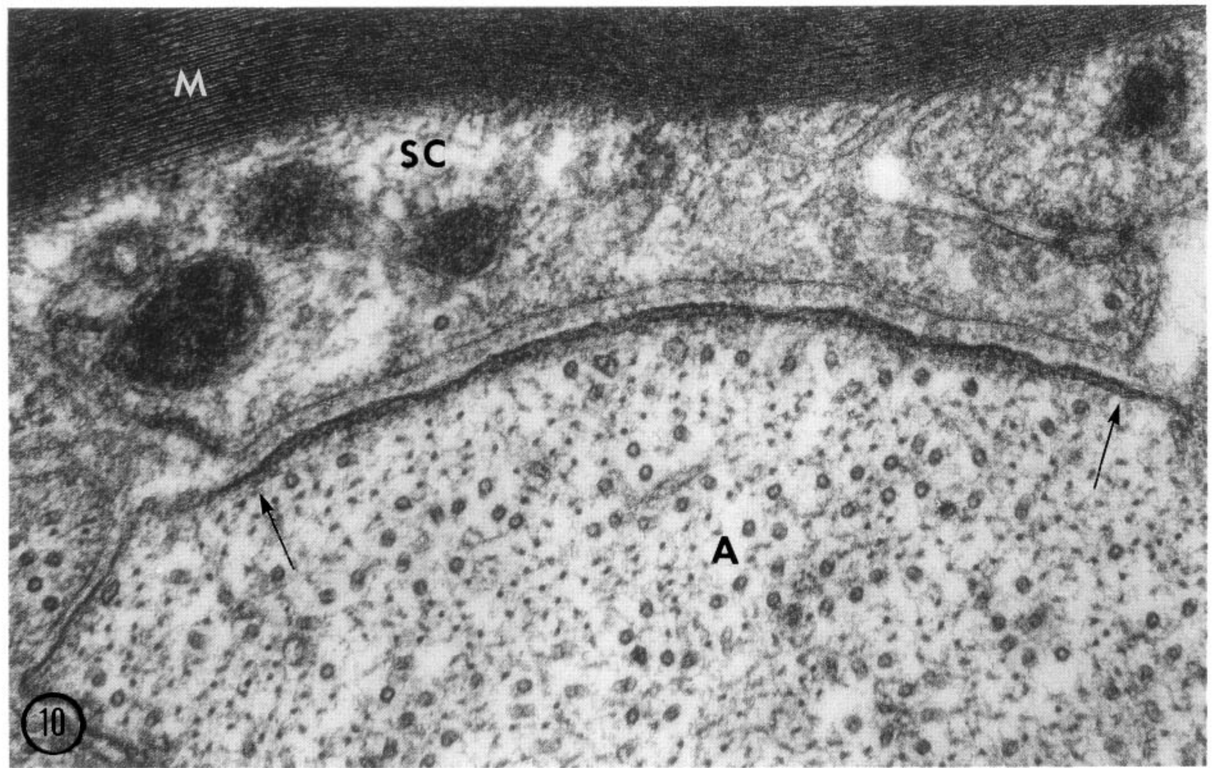

FIG. 41-10. Dystrophic mouse spinal root axon (*A*) forming an aberrant node-like junction (*between arrows*) with a Schwann cell (*SC*), which has formed a compact myelin sheath (*M*) around another axon (*not shown*). The junction is marked by an axoplasmic undercoating and cross-shaped filaments in the intercellular junctional space. The respective membranes follow each other closely at a separation of ~20 to 25 nm.

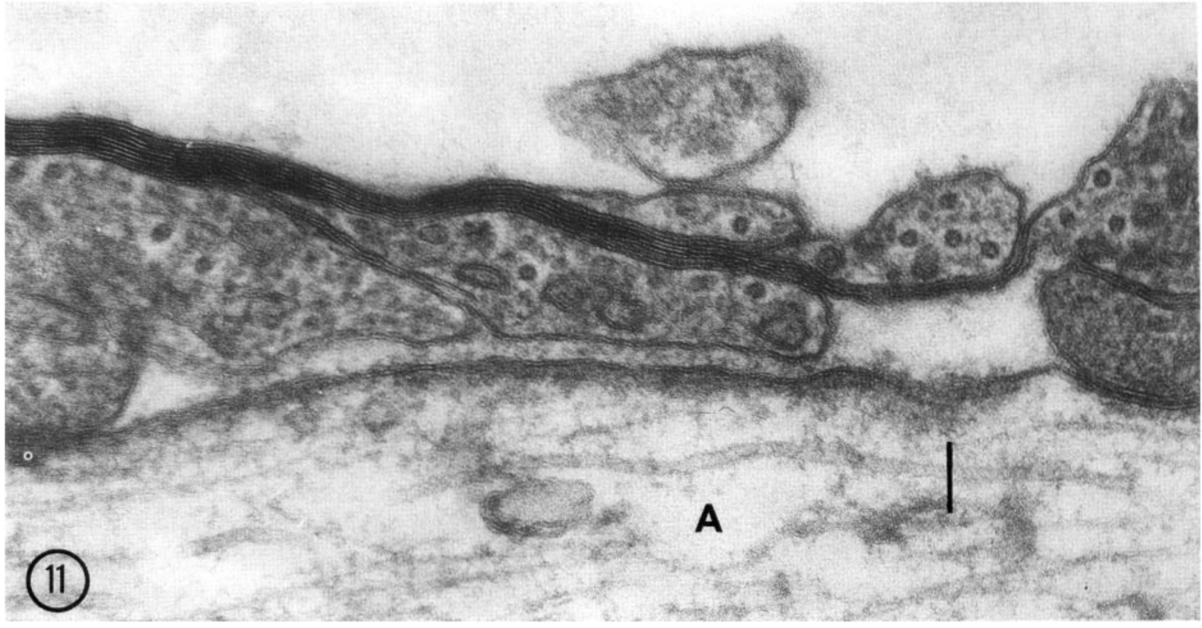

FIG. 41-11. Axoglial junctions formed between transplanted oligodendrocytes and spinal cord axon (*A*). To the right of the bar, and at the extreme left of the figure, the junctions are of the close paranodal type. To the left of the bar, the junctions are node-like, with an axolemmal undercoating and a wide gap containing intercellular filamentous material.

in the case of epithelial cells facing a basal lamina adjacent to a connective tissue matrix, or muscle cells at a myotendinous junction.

In the peripheral nervous system the nodal junction is formed by the same Schwann cells that form the adjacent myelin segments, but nodal junctions in the central nervous system are typically formed by astrocyte processes, not oligodendrocytes (Hildebrand, 1971). Occasional oligodendrocyte-axon junctions may nevertheless be seen at central nervous system nodes of Ranvier. These too show the typical wide but uniform separation of membranes, intercellular density, and axolemmal undercoating (Figure 41-11).

The functions of the nodal junction are uncertain. Adhesion is obviously one, especially in view of the localization of adhesion molecules to that site (Waxman, 1986; Salzer, 1995). In addition, a role for the perinodal glial processes in nodal differentiation has been postulated, although it is not difficult to find central nervous system nodes with little or no astrocytic investment, both during myelinogenesis and in adults. In the latter case, the undercoated nodal membrane faces a widened extracellular space containing just the extracellular proteoglycan matrix.

Observations made on glial cell-deficient spinal cord, in which both oligodendrocytes and astrocytes are sparse, suggest that the nodal axolemma (or elements in its vicinity) *induces* astrocytes to extend processes toward the perinodal region, but leave open the converse possibility, that is, that astrocyte processes may be involved in *determining* nodal sites (Sims et al., 1985). Even if the nodal axoglial junction proves not to be involved in the initial differentiation of the nodal axolemma, it may nevertheless play a significant role in the *subsequent* stabilization and maintenance of the differentiated nodal axolemmal structure (see below).

Node-like junctions also form in the nonmyelinated portion of the retina between retinal ganglion cell axons and Müller cell processes. Here, partial node-like specializations, including an axolemmal undercoating that extends part way around the axonal circumference (Hildebrand and Waxman, 1983), and node-like membrane particle patches of aberrant shape (Black et al., 1984) develop in the axons in the absence of myelin or myelin-forming cells. Similar observations have also been made in fibers lacking myelin as a result of pathological processes (see *Pathology* below). In all these cases, it is clearly impossible to invoke the paranodal junction or myelin-forming cell as an essential factor in nodal differentiation, since the perinodal glial component of the nodal junctional complex alone is associated with the differentiated state of the membrane. In nerve fibers lacking glia entirely, however—for example, at the center of an ethidium bromide lesion (see below)—there is no convincing evidence that any new node-like specializations form or that those previously formed are permanently maintained (Rosenbluth et al., 1985).

POSSIBLE MECHANISMS OF GLIAL INFLUENCE ON AXOLEMMAL STRUCTURE

The paranodal axoglial junction divides the axolemma into discrete nodal and internodal domains, which differ markedly in structure and ion channel distribution. Figure 41-12 illustrates the characteristic distribution of E-face particles in the axolemma of a myelinated fiber at and around the node of Ranvier.

Several means can be proposed by which glial association could bring about nodal specialization. The structure of some integral membrane protein molecules, including the sodium channel, is such that they project substantially beyond the external surface of the axolemmal bilayer (Barchi et al., 1981). At close axoglial junctions of the paranodal type, apposition of glial processes to only 2 nm from the axolemma may obstruct insertion of such molecules into that region of the axolemma. In addition, close apposition of glial membranes to the external surface of the axolemma may sterically prevent membrane proteins of this kind in adjacent, *non*-junctional regions from moving laterally within the plane of the membrane through the junctional region. Thus, sodium channels could become "trapped" at a presumptive node flanked by close axoglial junctions. Ionic currents generated by small clusters of such trapped channels could in turn lead to the recruitment of new channels to the same site (Rosenbluth, 1984). The original cluster may thereby "nucleate" the development of a full-blown node.

Nodal integral membrane protein molecules could also become "trapped" through linkage to perinodal glial processes externally, although it is not clear that perinodal glial processes are consistently present during the earliest stages of nodal development. In addition, they could form clusters by becoming bound to each other and thus immobilized. However, freeze-fracture studies show nodal particles to be randomly distributed with no evidence of close packing or crystalline arrays. Finally, nodal particles could become bound to preexisting axonal cytoskeletal elements. However, particle clusters would then be expected even in the absence of interaction with glial cells, and, as discussed above, there is no con-

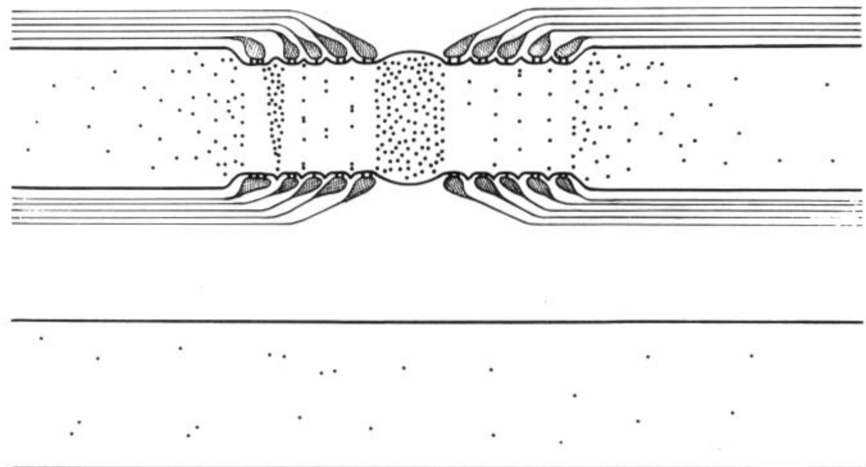

FIG. 41-12. **Top:** Diagram of nodal and paranodal regions of a myelinated axon in the central nervous system. The nodal particles characteristic of the axolemma, which are thought to represent sodium channels, are indicated by *black dots*. These are highly concentrated and randomly distributed at the node, in the center. They are also present in linear strings between junctional indentations in the paranodal regions, on either side of the node, and, in larger numbers, in an occasional "lake" (*left*) where the junctional indentations separate. Particle concentration in the juxtaparanodal region of the internode (*JPI*) is highest adjacent to the paranode and diminishes gradually in the lateral direction. In three dimensions, the paranodal particle "strings" are part of a continuous helical strip interconnecting the node with the JPI and represent a potential route for addition or removal of nodal sodium channels (see Rosenbluth, 1976). **Bottom:** Sparse, randomly scattered membrane particles in an unmyelinated axon. [From Rosenbluth (1989), with permission.]

vincing evidence that completely naked axons display node-like axolemmal specializations.

The essential role of glia in nodal differentiation has been confirmed in recent studies of cultured neurons showing a random distribution of axolemmal sodium channels, in the absence of Schwann cells, and clustering of sodium channels after addition of Schwann cells to the culture. This effect was independent of the distribution of the axonal cytoskeletal elements ankyrin and spectrin (Joe and Angelides, 1992).

In remyelination as well, sodium channel aggregates form initially at the edges of redeveloping myelin sheaths, then shift with those edges along the axon, as remyelination proceeds, until reaching their ultimate position, where they are still bordered by Schwann cell edges. In some cases, two neighboring aggregates in the same axon appear to be "pushed" toward each other by the growing edges of the adjacent internodal segments and eventually fuse to form a single node between the two internodes (Dugandzija-Novakovic et al., 1995).

Whether or not nodal-type junctions or cytoskeletal interactions play a role in the *formation* of nodes, they may play a significant role in the *maintenance* of nodes, once formed, in the same way that extracellular elements are thought to anchor transmembrane receptors at synapses (McMahan, 1990). In the latter case, interaction with agrin is thought to result in phosphorylation of the receptors and aggregation. A similar mechanism could operate at nodes of Ranvier, in view of the presence of agrin there (Reist et al., 1987), although recent attempts to induce sodium channel aggregation by agrin in cultured myotubes have not succeeded (Lupa et al., 1991).

Steric hinderence due to closely applied paranodal junctions could also maintain nodal differentiation, while still allowing for turnover of nodal membrane components. A continuous helical line of axonal membrane winds through the paranodal region between the junctions formed by the glial loops. Node-like particles are visible within this linear path, as well as aggregates of them in "lakes" where the glial loops are not directly adjacent to each other (Figure 41-12). Particles within this helical channel are evidently not sterically hindered and could be en route, within the plane of the bilayer, to or from the nodal axolemma.

FUNCTIONAL SIGNIFICANCE OF AXOGLIAL INTERACTION IN NODAL AND PARANODAL REGIONS

Unlike the paranodal junctional regions, the nodal axolemma reveals no evidence of a paracrystalline pattern and contains, instead, large numbers of large particles, primarily in the E fracture face, where they are sharply demarcated on both sides by the paran-

odal junctions (Figures 41-5 and 41-12). The overall particle concentration in the E fracture face of the nodal axolemma is ~1000 to 1500 particles/μm^2 in both cold-blooded vertebrates (Rosenbluth, 1976; Tao-Cheng and Rosenbluth, 1980) and mammals (Kristol et al., 1978). The nodal channel density is at least an order of magnitude greater than that of the internodal axolemma, except in the juxtaparanodal region (Tao-Cheng and Rosenbluth, 1984) (Figure 41-12).

The characteristic nodal particles have attracted considerable attention, since they correspond to the voltage-gated sodium channels, known to be concentrated at the node, with respect to location, size, and concentration, and it has been hypothesized (Rosenbluth, 1976, 1981) that each particle represents one sodium channel, a glycoprotein of high molecular weight. This proposal has been further supported by freeze-fracture studies of purified sodium channels in artificial membranes (Ellisman et al., 1983), which show particles comparable in size and appearance to those at normal nodes of Ranvier. Thus, the distribution of the particles may correspond to the distribution of sodium channels within the axolemma, including those in regions that cannot be readily detected by electrophysiological methods.

The hypothesis was originally questioned in view of saxitoxin-binding studies suggesting a nodal particle density tenfold higher than that of the particles (Ritchie and Rogart, 1977). However, the saxitoxin studies were undoubtedly measuring sodium channels not only in the nodal axolemma but also in Schwann cells (Shrager et al., 1985) and perhaps also in the internodal axolemma, which is now known to contain far more sodium channels than the node itself, albeit at much lower concentration (Grissmer, 1986; Chiu and Schwarz, 1987). Data from a variety of sources (e.g., Chiu, 1980) have now established that nodal sodium channel density corresponds closely to that originally predicted by the E-face particle density (Rosenbluth, 1976).

Further support has been obtained from studies of the electric organ in *Sternarchus*, which consists of modified nerve fibers containing both excitable and inexcitable nodes (Waxman et al., 1972). Here too, membrane particle concentration has been shown to be high at the excitable nodes but low at the inexcitable ones (Kristol et al., 1977). Clearly the nodal E-face particles cannot represent voltage-gated potassium channels, since the latter have the converse distribution; that is, they are more concentrated in the internodal axolemma than at the node of Ranvier (Chiu and Ritchie, 1980; Kocsis and Waxman, 1980; Sherratt et al., 1980).

Thus, these membrane particles may represent sodium channels but are unlikely to represent potassium channels. On this basis, their distribution may be useful in inferring the electrical characteristics of axonal membranes under experimental or pathological conditions. For example, studies of nerve fibers from diabetic animals show no significant change in nodal particle density, suggesting no diminution in nodal sodium channels, but point, rather, to paranodal abnormalities as a basis for conduction slowing (Shirasaki and Rosenbluth, 1991). Conversely, the marked increase in axonal particle density in the axons of myelin-deficient rats probably reflects an abnormally high concentration of axonal sodium channels that underlies the spontaneous activity seen in these animals (Rosenbluth, 1990).

PATHOLOGY: EFFECTS OF MYELIN ABNORMALITIES ON AXOLEMMAL STRUCTURE AND FUNCTION

An extensive series of studies has produced clear evidence that the concentration and distribution of particles within the axolemma is markedly affected by the investing myelin sheath (Rosenbluth, 1981, 1988), and numerous studies have shown consistently that the distinctive pattern illustrated in Figure 41-12 occurs only in the axolemma of fibers invested by normal myelin sheaths.

In cases where myelin of aberrant form is laid down, some semblance of the normal nodal and paranodal membrane structure may be seen, the distortions in axolemmal particle distribution corresponding to the aberrations in the form of the overlying sheath. In cases where myelin is absent, the typical cylindrical, sharply demarcated axolemmal membrane specializations are also absent, although aberrant noncircumferential specializations may occur in association with glial processes.

For example, some differentiation of the axolemma has been shown in thin sections of demyelinated axons associated with astrocyte processes (Blakemore and Smith, 1983), and in freeze-fracture replicas of the periphery of ethidium bromide lesions, it has also been possible to find node-like particle accumulations corresponding to such axon-astrocyte junctions (Rosenbluth et al., 1985). It is clear, however, that such particle accumulations, in the absence of normal myelin sheaths, never develop the typical sharply defined 1μm cylindrical form shown in Figure 41-12. Rather, the particle patches tend to appear in elongated form and do not completely encircle the axon; that is, the nodal domain is not clearly separated from the internodal domain. Thus, contact with astrocyte processes

alone is associated with only partial differentiation of the axolemma. The fully differentiated pattern requires that the axon be normally myelinated as well. Although aberrant nodal and paranodal junctions occur at the periphery of the lesions, where astrocyte and oligodendrocyte processes are present, they do not occur in the core of the lesion, where glial processes are absent.

Similarly, in the peripheral nervous system, the amyelinated bundles that occur in the spinal roots of the dystrophic mouse mutant display aberrant nodal (Figure 41-5) and paranodal axolemmal specializations only at the periphery, where limited contact with Schwann cells occurs, but not in the glia-free interior of the bundles (Rosenbluth, 1979). Thus, in the absence of all glial contact, the axolemma shows no significant focal particle accumulations.

These studies indicate that differentiation of the axon depends on contact with glial elements—the myelin sheath and the perinodal processes. Once myelin has formed, however, and the axon has already become differentiated, does it retain that differentiated structure even if the investing myelin sheath is lost or altered? Several experimental studies bear on this question.

In the ethidium bromide model of demyelination, referred to above, the toxin affects all exposed cell bodies, including both oligodendrocytes and astrocytes, but not the axons passing through the lesion, whose cell bodies are remote. The glia and the myelin sheaths attached to them disintegrate, resulting in a focal glia-free region, which remains stable for many weeks. As described above, aberrant axoglial junctions occur at the periphery of such lesions, but examination of the core shows an abundance of apparently normal axons closely applied to each other with no evidence, thus far, of any nodal or paranodal axolemmal specializations. Since the spinal cord was fully myelinated at the time of the injection, this finding implies that whatever differentiated structures were associated with the original nodal and paranodal complexes must have disappeared; that is, the axons have dedifferentiated in this region in the absence of continuing glial contact. Equivalent results have been seen in the peripheral nervous system after antibody-mediated demyelination (Rosenbluth, 1981).

Thus, contact with glial cells appears necessary not only for the initial *development* of the differentiated form of the axolemma, but also for long-term *maintenance* of the differentiated structure of the axolemma. Accordingly, although the pre-existing axolemmal sodium channel distribution may persist temporarily following demyelination, it can be expected to change eventually, as the axon dedifferentiates, or to reorganize if reensheathement occurs.

In addition to its effect on the regional differentiation of the axolemma and sodium channel distribution, interaction with myelin-forming cells also appears to affect the overall number of axolemmal sodium channels. Particle counts suggest that the sodium channel density in the normal internodal axolemma is at least an order of magnitude lower than that in the nodal axolemma (Tao-Cheng and Rosenbluth, 1984). Nevertheless, the total surface area of the internode is so large that the total number of internodal channels is probably at least an order of magnitude greater than that at the node.

In a normal fiber, the internodal channels are presumably inactive, and only the nodal channels are involved in ion exchange. Nerve fibers that lack myelin sheaths, however, such as those seen in the myelin-deficient rat spinal cord, in some cases develop much larger concentrations of node-like membrane particles than are ever seen in normal internodes, suggesting higher-than-normal sodium channel densities (Rosenbluth, 1990). These regions, which may be extensive, appear in animals more than 3 weeks old, in which generalized seizures are manifest, but not in younger animals, before the development of seizures (Rosenbluth, 1990).

Recent saxitoxin-binding studies of the shiverer mouse mutant came to the same conclusion, that is, that the dysmyelinated fibers in that mutant also develop abnormally high sodium channel densities (Noebels et al., 1991). This effect was attributed specifically to myelin basic protein deficiency, though it is more likely to be a feature of myelin deficiency from any cause.

Thus, the presence of myelin appears to govern not only the distribution of sodium channels, but also their overall density. Specifically, myelination of an axon segment appears to downregulate insertion of sodium channels into the internodal axolemma of that segment.

Elimination of this regulatory factor might be beneficial or detrimental. If, in the case of a demyelinated axon, the sodium channel concentration in the bare, formerly internodal, region of an axon were to rise gradually, continuous conduction might be restored to an otherwise blocked fiber. Although reversal of conduction block by this means is desirable, and may underlie much of the functional return after acute attacks of multiple sclerosis, continuing increase of axolemmal sodium channel concentration could result in spontaneous activity due either to direct activation of low-threshold fibers by action currents generated in neighboring fibers or by spontaneous depolarization due to potassium accumula-

tion in the narrow interstitial spaces. These mechanisms may underlie the paroxysmal activity often seen in multiple sclerosis or in peripheral demyelinating conditions.

It is of interest too that the initial segment of spinal ganglion cells, which is ensheathed but not myelinated, also displays a much higher density of node-like membrane particles than that seen in the internodal axolemma of the same axon more distally (Matsumoto and Rosenbluth, 1985), suggesting that the same mechanism may regulate regional sodium channel density in normal fibers as well.

ASTROCYTES

Although the astrocyte is much less conspicuously divided into domains than the myelin-forming cells, its surface is nevertheless distinctly nonuniform with respect to the distribution of membrane components and junctions. In the case of astrocytes that form the glia limitans, the cell as a whole assumes a clearly polarized form that includes a region peripherally corresponding to the "base" of a classical epithelial cell.

Such astrocytes extend processes to the pia-glial junction where their apposed terminal expansions form both gap junctions and punctate adherent junctions. That portion of the cell facing the pia corresponds to the base of the cell in that it is covered by a basal lamina. Similarly, astrocytes extend processes toward capillaries that form incomplete sheaths around the vessels. Here too, that portion of each cell facing the capillary is covered by a basal lamina. Although goldfish astrocytes have been reported to form enormous networks of tight junctions and to be interconnected by desmosomes (Wolburg et al., 1983), neither of these specialized junctions has been seen at contacts between mammalian astrocytes (Mugnaini, 1986). Thus, the extent to which the membrane components of mammalian astrocyte domains remain segregated.

Another differentiated region of the cell consists of the microvillous processes that sometimes surround nodes of Ranvier forming the nodal axoglial junctions in the central nervous system corresponding to the junctions formed by the perinodal Schwann cell "fingers" in the peripheral nervous system. There is no basal lamina associated with the astrocyte microvilli, but an ill-defined extracellular matrix material occupies the perinodal extracellular space. In the peripheral nervous system, there is a clear separation between the perinodal matrix, which lies deep to the Schwann cell basal lamina, and the endoneurial extracellular space external to the basal lamina (Figure 41-12). The latter contains collagen and other obvious formed elements, while the perinodal matrix is amorphous. Histochemical studies suggest that the perinodal matrix is a proteoglycan, presumably secreted by the perinodal glial processes, which has ion exchange properties that serve to buffer the perinodal region with respect to sodium and potassium (Langley, 1979). In lower vertebrates, a similar matrix, distinct from the endoneurium, also surrounds the axon hillock and initial segment of spinal ganglion cells (Pannese, 1981; Matsumoto and Rosenbluth, 1986) and sympathetic ganglion cells (Taxi, 1976).

Astrocytes clearly form gap junctions (Figure 41-13) with each other and with oligodendrocytes as well (Mugnaini, 1986), thus coupling the macroglia into a functional syncytium capable of redistributing extracellular ions, especially potassium, and thereby maintaining the constancy of extracellular pH and ionic composition (Orkand et al., 1966). Many additional functions have been proposed for astrocytes, including isolation and sequestration of neurotransmitters and secretion of growth factors and other cytokines. The recently demonstrated calcium waves in astrocyte networks in response to exogenous glutamate or to nerve stimulation *in vivo* (Dani et al., 1992) may depend on gap junction coupling and may thus represent a signaling mechanism that serves to coordinate astrocyte behavior over broad areas. As discussed above, the passage of cAMP or other small molecules through gap junctions may subserve this purpose as well (see Chapter 21, this volume.)

The most intriguing astrocyte membrane specialization (Figure 41-13) consists of tetrads or orthogonal arrays of membrane particles known as *assemblies* (Dermietzel, 1974b; Landis and Reese, 1974). These occur also in the satellite cells of peripheral ganglia (Pannese, 1981) and have been found in muscle and other cells as well (for review see Landis, 1986). Although their morphology and distribution have been studied extensively, the function of these distinctive structures is still uncertain.

In view of the role that has been ascribed to astrocytes in regulating extracellular potassium and other ions, it has been proposed that the assemblies are involved in ion transport, perhaps representing channels that permit efflux of potassium taken up by astrocytes into pericapillary and subarachnoid regions, where the excess can be carried off by either the blood or the spinal fluid innocuously without altering the resting potential of neuronal processes. Of great interest is the fact that the concentration of assemblies on the astrocyte surface is greater in the pericapillary processes and at the pia-glial junctional

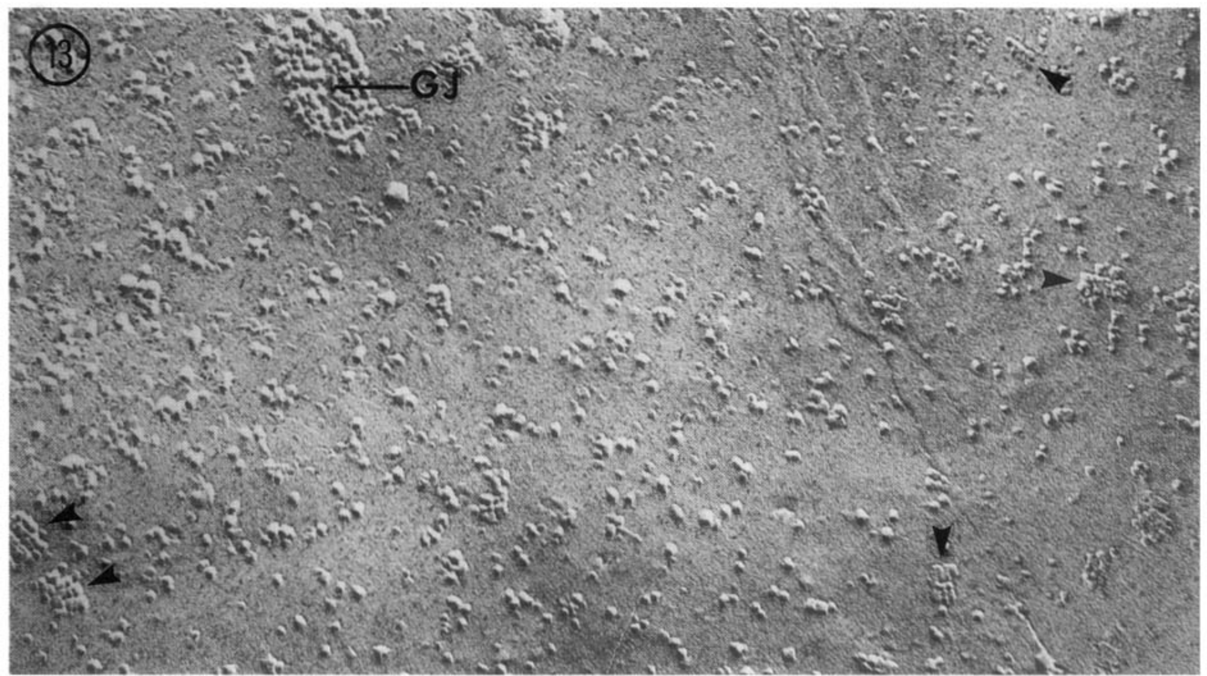

FIG. 41-13. Freeze-fractured astrocyte membrane (*P-face*) showing a patch of gap junction particles (*GJ*) and scattered rectangular "assemblies" (*arrows*).

endfeet than elsewhere, that is, precisely at the site where correlative physiological studies (Newman, 1986a) have shown potassium conductance to be tenfold higher than elsewhere along the astrocyte surface! Equivalent observations have been made on Müller cells, the counterparts of astrocytes in the retina (Newman, 1986b; Wolburg and Berg, 1988. See also Chapters 4 and 50).

The mechanisms that govern synthesis, formation, and distribution of the "assemblies" remain uncertain. Coculture of astrocytes with endothelial cells induces their appearance along the astrocyte membrane facing the endothelial cells (Tao-Cheng et al., 1990). Thus, in this case, it appears that the regional differentiation of the astrocyte membrane is under the influence of adjacent cells. The mechanism of this interaction is not known, however. Moreover, no one has succeeded in isolating assemblies in subcellular fractions or characterizing them biochemically. Nor are any mutations known in which these structures are absent. Surprisingly, although they are abundant in mammalian astrocytes, they have not been seen in amphibian or fish astrocytes; yet, they are present in the Müller cells of all three classes (Berg-von der Emde and Wolburg, 1989).

SUMMARY

Oligodendrocytes, astrocytes and Schwann cells are divided into subcellular domains that display distinctive surface structures as well as specialized junctions between the glial cells themselves and between glial cells and axons. The axoglial junctions are of two types, nodal and paranodal, both of which affect the structural differentiation of the axolemma and the distribution of ion channels within it. The relevance of these various structures to the behavior of both the glia and the axons, under normal and pathological conditions, is discussed.

42 Cytoskeletal organization of myelinating Schwann cells

GRAHAME J. KIDD AND BRUCE D. TRAPP

In 1954, Geren demonstrated with the electron microscope that the myelin sheath is an elaborate specialization of the Schwann cell plasma membrane, which is spirally wrapped around and separate from the axon. Although our knowledge of the biochemistry, cell biology, and molecular biology of myelin and myelination has increased tremendously since then (see Chapters 38 and 39), many questions about basic mechanisms of myelination remain unanswered. Very little is known about how spiral growth of the myelin internode occurs, how axons regulate myelination, or how myelin molecules are targeted to different sites millimeters away from their point of synthesis. Because the cytoskeleton is integral to membrane growth and intracellular transport, understanding the organization and specializations of the Schwann cell cytoskeleton will help elucidate many of the basic mechanisms of Schwann cell myelination.

The cytoskeleton consists of three morphologically and biochemically distinct networks: *microfilaments* (MFs), *microtubules* (MTs), and *intermediate filaments* (IFs). This chapter focuses on the distribution and organization of these networks and their potential functions during myelination. The cytoskeleton is a dynamic and versatile organelle system that is essential for many cellular functions. *Actin, tubulin,* and *vimentin* provide the structural framework for MFs, MTs, and IFs in myelinating Schwann cells, and their distributions have been described (Trapp et al., 1989; Zimmerman and Vogt, 1989; Kobayashi and Suzuki, 1990; Kordeli et al., 1990; Kidd et al., 1993; Trapp et al., 1993). Molecules that bind to F-actin, tubulin, or vimentin endow the cytoskeleton with specialized functions. The identification and distribution of these molecules in myelinating Schwann cells are largely unknown. It is tempting to speculate that Schwann cells express unique cytoskeletal molecules that have evolved to help mediate the membrane expansion and protein targeting that is required during myelination.

THE PERIPHERAL NERVOUS SYSTEM MYELIN INTERNODE

Before discussing the distribution and organization of the Schwann cell cytoskeleton, and its roles in myelination, it is important to understand the size and complexity of myelin internodes in the peripheral nervous system. Myelinating Schwann cells develop from small, relatively undifferentiated cells into myelin internodes that can be as much as 2 mm long and contain 5 mm of myelin spiral (Friede and Bischhausen, 1980). This tremendous expansion of the Schwann cell plasma membrane occurs within a few postnatal weeks and is a highly ordered process. The ultimate extent of myelin growth is determined by the axon.

As illustrated in Figure 42-1, the myelin internode is more than a simple extension of the Schwann cell plasma membrane. It contains several ultrastructurally and biochemically distinct membrane domains that include the outer plasma membrane of the Schwann cell, compact myelin, the Schmidt-Lanterman incisures, paranodal loops, nodal microvilli, the periaxonal membrane, and the membranes of the outer and inner mesaxons. These membranes contain different structural proteins (Figure 42-2). The P_0 glycoprotein (P_0), peripheral myelin protein 22, and myelin basic protein are enriched in compact myelin (Trapp et al., 1981; Omlin et al., 1982). The myelin-associated glycoprotein is concentrated in membranes of the paranodal loops, Schmidt-Lanterman incisures, periaxonal membranes, and inner and outer mesaxons (Figure 42-2) (Trapp et al., 1984). Laminin, an extracellular matrix component, is secreted from and attached to the Schwann cell plasma membrane (Cornbrooks et al., 1983). The subdivision of the myelin membranes requires elaborate pathways for protein transport and targeting. For instance, P_0, myelin-associated glycoprotein, and laminin are synthesized in the rough endoplasmic reticulum and Golgi membranes that are concentrated in the perinuclear cytoplasm. These proteins are sorted into different carrier vesicles as they exit the

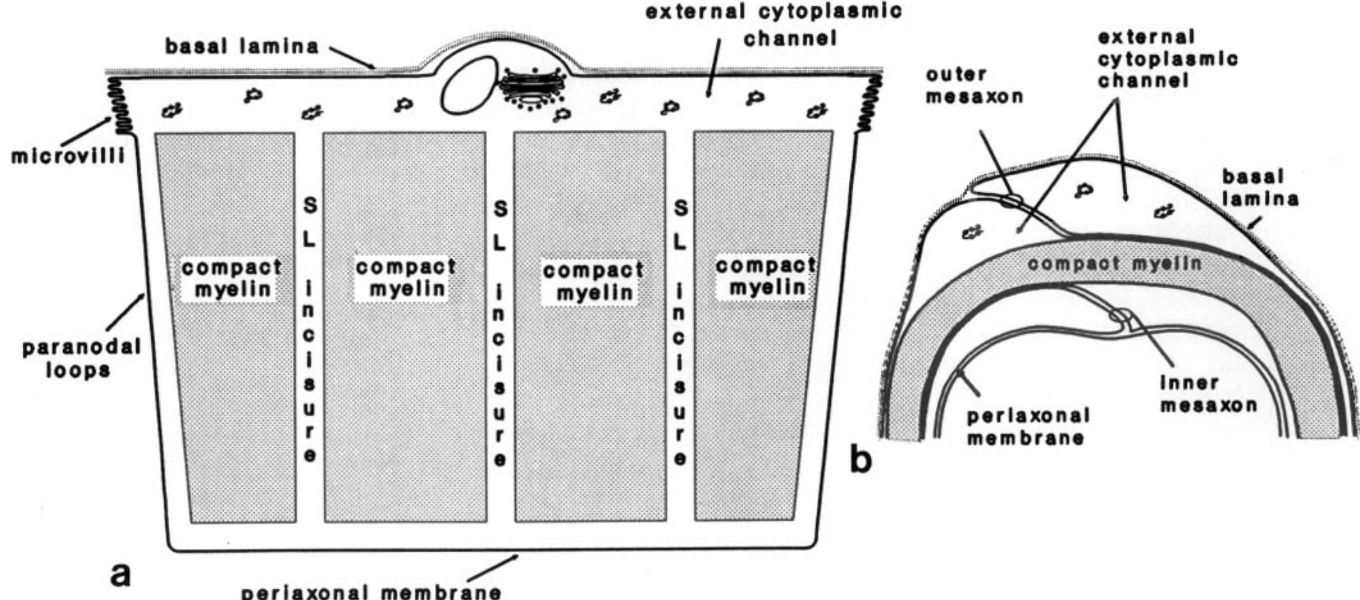

FIG. 42-1. Membrane domains and cytoplasmic compartments of peripheral nervous system myelin internodes. (A) A Schwann cell and its "unrolled" myelin internode. Most of the internode consists of compact myelin. Schmidt-Lanterman (*SL*) incisures are cytoplasmic channels that extend through regions of compact myelin. At either end of the myelin internode, the sheath terminates in cytoplasmic channels that form the paranodal loops. Microvilli extend from the Schwann cell to cover the nodal axolemma. (B) A partial cross section through a myelin sheath illustrates the outer and inner mesaxons. The Schwann cell plasma membrane is surrounded by a basal lamina.

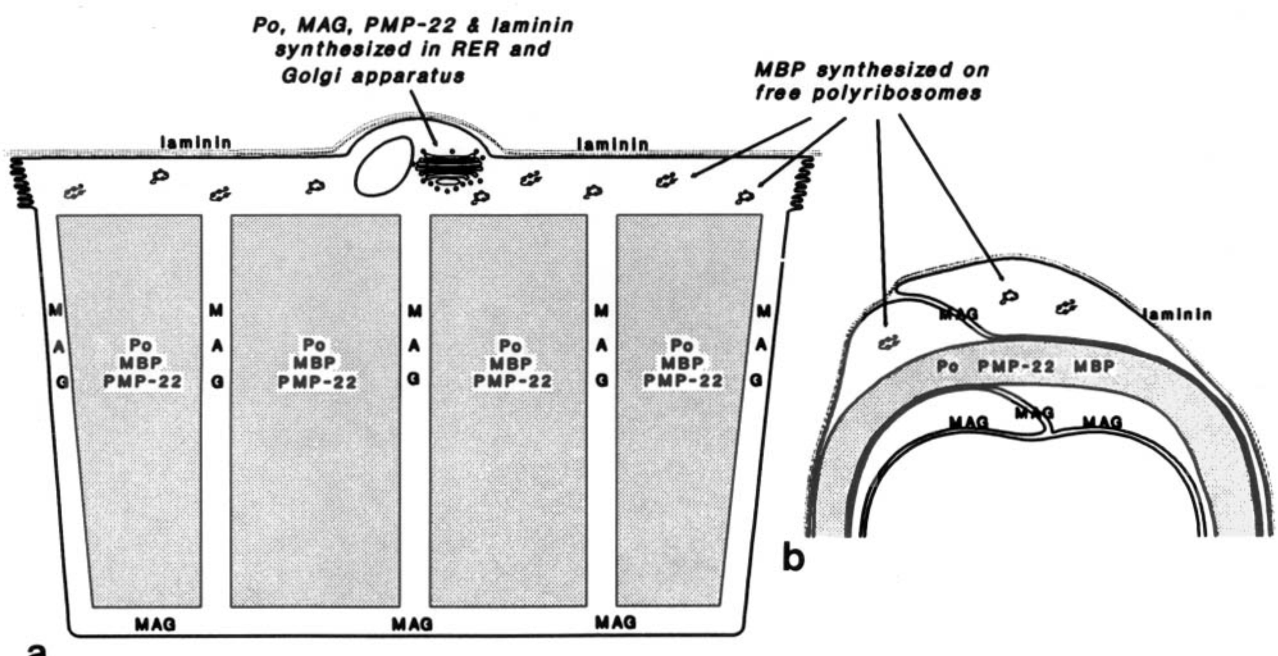

FIG. 42-2. Distribution and sites of synthesis of myelin proteins in (A) an "unrolled" myelin internode and (B) partial cross section. P_0, peripheral myelin protein 22 (PMP-22), and myelin basic protein (MBP) are enriched in compact myelin membranes (*stippled*). Myelin-associated glycoprotein (MAG) is enriched in membranes of the Schmidt-Lanterman incisures, paranodal loops, periaxonal region, and outer and inner mesaxons. The basal lamina component, laminin, is secreted from the outer (abaxonal) plasma membrane (see also Figure 42-4). P_0, PMP-22, MAG, and laminin are all glycoproteins that are synthesized in the perinuclear cytoplasm. MBP mRNA is transported within the external cytoplasmic channels and translated on free polyribosomes at sites along the myelin internode.

trans Golgi network (Trapp et al., 1993), transported over millimeter distances, and then inserted into different surface membranes. P_0 and myelin basic protein are both enriched in compact myelin but are transported very differently: P_0 by vesicular transport and myelin basic protein by translocation of its mRNA (Colman et al., 1982; Trapp et al., 1987; Griffiths et al., 1989). The cytoskeleton plays essential roles in membrane assembly, movement, and growth, and participates in protein and mRNA transport and the organization of synthetic organelles. It is not surprising that the cytoskeleton of myelinating Schwann cells is dynamic, complex, and modulated by axonal influences.

MICROFILAMENTS

MFs, which are the smallest of the cytoskeletal filaments (6 to 8 nm in diameter), consist of helical assemblies of actin monomers. They are polarized structures, in that they elongate by preferentially adding monomers to one end, termed the (+) or *barbed* end. Actin can be removed from MFs from the (−) or *pointed* end. Monomer addition is dependent on adenosine triphosphate (ATP) hydrolysis, and assembly and disassembly are dynamically regulated by a number of accessory proteins and by other factors, such as pH and ionic conditions (Pollard, 1990). Microfilament networks are organized by a large number of actin-binding molecules (see reviews by Carraway and Carraway, 1989; Heintzelman and Mooseker, 1992; Stossel, 1993) that promote or inhibit MF growth, cross-link MFs, sever MFs, or attach them to cell surface molecules and organelles. Elongation, contraction, and disassembly of MFs provide the force behind membrane movements that are required for cell growth and motility. Myosins serve as MF motors; they contract the MF network by sliding the filaments past one another and providing movement of membranes and membrane organelles on MFs.

There are two types of MF assemblies in nonmuscle cells. One is attached to the plasma membrane, forming the cell cortex, and is characterized by a nonparallel MF organization. Microfilaments may also be bundled into parallel arrays that form stress fibers and microvilli (Carraway and Carraway, 1989; Heintzelman and Mooseker, 1992). In myelinating Schwann cells, MFs are enriched beneath the membranes of the Schmidt-Lanterman incisures, the paranodal loops, the periaxonal membrane, the outer and inner mesaxons, and portions of the outermost compact myelin lamella and Schwann cell plasma membrane (Trapp et al., 1989; Zimmerman and Vogt, 1989; Kordeli et al., 1990) (Figures 42-3 and 42-4). These distributions were determined by phallicidin labeling of filamentous actin (Trapp et al., 1989; Zimmerman and Vogt, 1989). *Spectrin,* an MF cross-linking protein, and *ankyrin,* which binds spectrin to integral membrane proteins (Branton et al., 1981; Low, 1986; Carraway and Carraway, 1989), colocalize with filamentous actin in Schwann cells (Trapp et al., 1989). Together these three components form the framework for MFs beneath plasma membranes. The spatial arrangement of MFs in the cortex of the Schwann cell is unknown. In electron micrographs, the cortical MF network typically appears as a thin layer of largely amorphous material undercoating the Schwann cell plasma membrane (e.g., see Peters et al., 1991). This appearance may belie a highly organized submembranous MF network, however; in other cells, MFs form latticeworks beneath the plasma membrane that restrict movement of membrane-associated molecules and promote their interaction (see Edidin, 1992). The only consistently observed MF bundles in myelinating Schwann cells form the core of nodal microvilli (Landon and Williams, 1963; Raine, 1982); occasional accumulations of actin filaments have been observed in periaxonal cytoplasm (Jacobs and Cavanagh, 1972), but their organization and functional significance are unclear.

Functions of Microfilaments in Myelinating Schwann Cells

Membrane Movement. A phenotypic hallmark of myelinating Schwann cells is membrane expansion and membrane movement. During formation of the myelin internode, the periaxonal membrane ensheathes the axon and the outer or inner mesaxons or both must rotate to increase the number of myelin lamellae. Schmidt-Lanterman incisures are believed to migrate along the myelin sheath (Mugnaini et al., 1977), and paranodal loops retract to internodal locations in response to axonal swelling (Griffin et al., 1987). Because MFs are concentrated beneath all of these membranes (Figure 42-4), and because myosin is present in all cytoplasmic compartments of the myelin internode (Unsicker et al., 1978; Zimmerman and Vogt, 1989), it is reasonable to suggest that MFs drive membrane movement in myelinating Schwann cells as they do in other cells (see Stossel, 1993).

For membrane movement to occur, MFs must be attached to a membrane components. Because rotational growth is a unique feature of myelination, it is likely to involve a molecule specific to myelin-forming cells. It has been proposed that an interaction between myelin-associated glycoprotein (MAG)

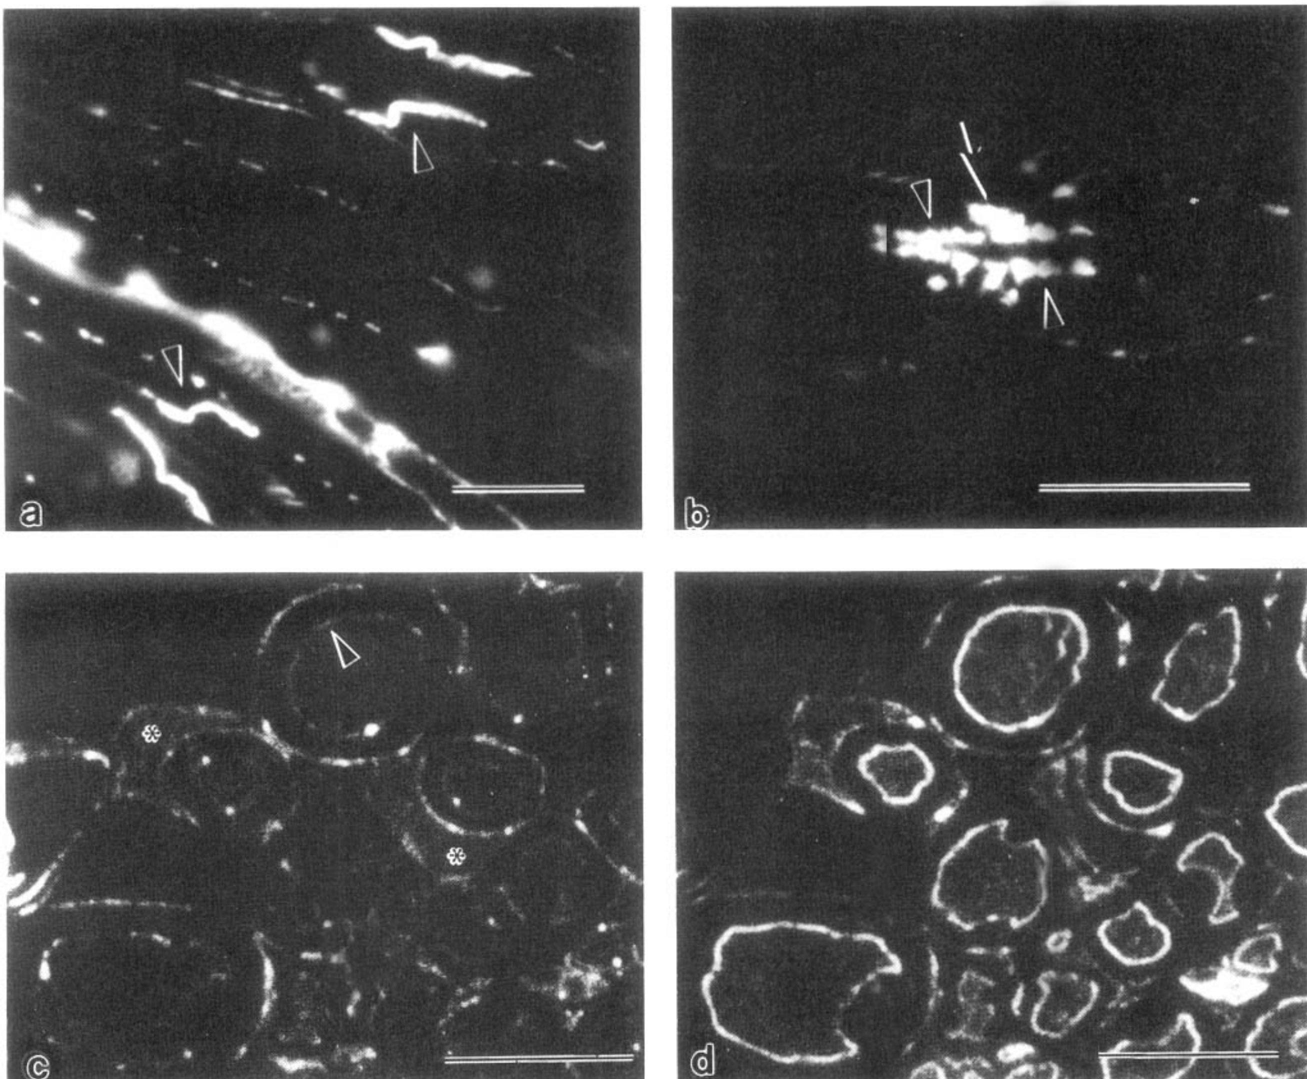

FIG. 42-3. Cryosections of adult rat sciatic nerve (1 μm): (A,B) stained for F-actin (rhodamine-phallicidin), and (C,D) double-labeled for F-actin and spectrin. F-actin is enriched in Schmidt-Lanterman incisures (Figure A, *arrowheads*) and also within the paranodal loops (Figure B, *arrowheads*) and nodal microvilli (*arrow*). In transverse sections, F-actin is present beneath periaxonal (Figure C, *arrowhead*) and abaxonal plasma membrane, and also adjacent to the outer compact lamella (*asterisks* denote external cytoplasmic channels). Spectrin (Figure D) colocalizes with F-actin at all locations, although staining intensities differ. Scale bars = 10 μm. [From Trapp et al. (1989), with permission.]

and MFs may play a role in membrane motility during myelination (Trapp and Quarles, 1982; Trapp et al., 1984; Martini and Schachner, 1986; Salzer et al., 1987). MAG is a member of the immunoglobulin gene superfamily and consists of a large extracellular domain that contains six IgG-like regions, a single transmembrane domain, and a cytoplasmic domain (Arquint et al., 1987; Lai et al., 1987; Salzer et al., 1987). MAG colocalizes with MFs (Figure 42-3) at membranes that move during internodal growth (Trapp et al., 1989). When MAG-containing membranes move, they use another membrane as a substrate and appose this membrane by a 12- to 14-nm gap. A number of studies indicate that MAG is responsible for maintaining this gap by acting as an adhesion molecule or a membrane spacer (Trapp and Quarles, 1982; Trapp et al., 1984; Martini and Schachner, 1986; Salzer et al., 1987). Transfection of additional copies of MAG into myelinating Schwann cells induces precocious spiral wrapping (Owens et al., 1990), whereas spiral wrapping is impaired or completely prevented in Schwann cells in which MAG expression is reduced or eliminated (Owens and Bunge, 1991). MAG, therefore, is a prime candidate for mediating movement of membranes in myelinating Schwann cells, either as part

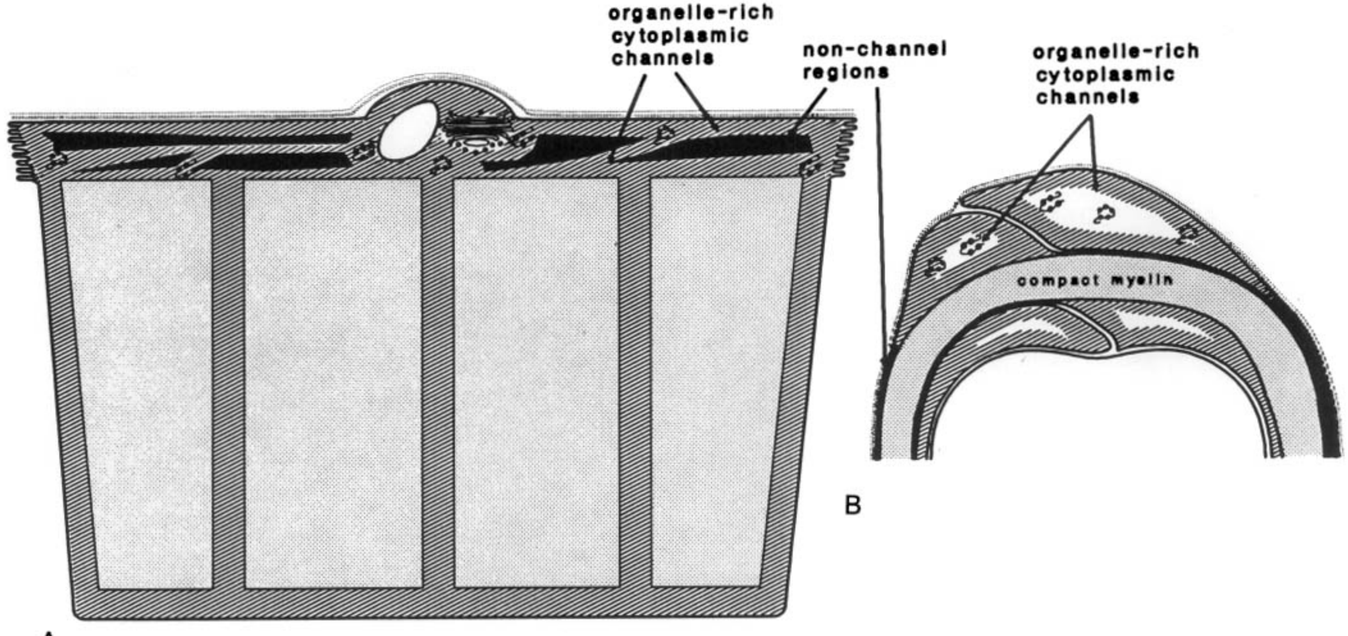

FIG. 42-4. Distribution of microfilaments in peripheral nervous system myelin internodes in (A) an "unrolled" internode and (B) a partial cross section. Microfilaments (*cross-hatching*) are enriched beneath the periaxonal membrane and the membranes of Schmidt-Lanterman incisures, paranodal loops, outer and inner mesaxons, and nodal microvilli. The cytoplasm at the outer margins of the myelin internode is normally subdivided into organelle-rich channel regions that are demarcated by microfilaments and nonchannel regions (*black*) that are devoid of organelles or detectable submembranous microfilaments.

of the motor attached to MFs or as an anchor that permits MF-mediated movement. A dynamic interaction between MFs and the cytoplasmic domain of MAG could explain how MAG-containing membranes are associated with stable membrane interactions in mature sheaths and with membrane movement during myelin formation.

Maintaining Cytoplasmic Channels. The size and geometry of the myelin internode necessitates an elaborate network of cytoplasmic channels that surround and traverse compact myelin (Mugnaini et al., 1977; Peters et al., 1991). These channels, which contain organelles, are important to formation and maintenance of the myelin internode and to intracellular transport of myelin components. They include the external cytoplasmic channels, Schmidt-Lanterman incisures, paranodal loops, and periaxonal cytoplasm (Figures 42-1 and 42-4). Microfilaments are associated with the membranes that demarcate these channels. The outer perimeter of the myelin internode is divided into organelle-rich channel regions and organelle-free nonchannel regions (Figure 42-4). Microfilaments are concentrated beneath the membranes of the organelle-rich channel regions. Because MFs demarcate the organelle-rich cytoplasmic domains of the myelin internode, it is reasonable to suggest that they help maintain these domains.

Membrane Interaction with Axons and Extracellular Environment. Similar to polarized epithelial cells, myelinating Schwann cells have two major surfaces. The abaxonal plasma membrane apposes the external endoneurial environment and the adaxonal periaxonal membrane apposes the axon. The microfilaments are enriched beneath both of these membranes (Trapp et al., 1989; Zimmerman and Vogt, 1989). Microfilaments associated with these plasma membranes are likely to have multiple functions dealing with the external environment. Microfilaments participate in endocytosis (Blok et al., 1982), pinocytosis (Phaire-Washington et al., 1980), and exocytosis (John et al., 1983; Koffer et al., 1990) and may mediate or regulate processes such as endocytosis of cholesterol (Boyles et al., 1989; Rothe and Müller, 1991) and exocytosis of extracellular matrix components (Cornbrooks et al., 1983). Cortical MFs can also provide resistance to externally applied stresses and transmit them to other cytoskeletal components (Wang et al., 1993). Stress resistance may be particularly important in Schwann cells, which are frequently subjected to compressive and traumatic events.

Several transmembrane molecules may anchor and organize the MF network beneath the Schwann cell plasma membrane. The abaxonal membrane is attached to a basal lamina, the formation of which

is a prerequisite for Schwann cell myelination to occur (Bunge et al., 1990). Schwann cells interact with the basal lamina through integrins, a family of transmembrane glycoproteins with a cytoplasmic domain that can be anchored to MFs by actin-binding proteins (Buck and Horwitz, 1987; Hynes, 1987; Wang et al., 1993). The α2-β1 integrin isoform has been identified on the surface of myelinating Schwann cells from human nerves (Hsiao et al., 1991). Schwann cells may also interact with the basal lamina through heparan sulfate-containing proteoglycans, which bind to extracellular matrix components (Hynes and Yamada, 1982). One membrane-spanning proteoglycan (Mehta et al., 1985; Carey and Todd, 1986) is exposed on the Schwann cell surface and is bound to an actin/spectrin/vimentin-rich cytoskeleton (Carey and Todd, 1986). The basal lamina surrounds the entire external surface of myelinating Schwann cells, but MFs appear to be enriched beneath the plasma membrane only where cytoplasmic channels are present. This raises two possibilities: integrins and other extracellular matrix receptors in the nonchannel regions are not attached to MFs, or MFs are present in the nonchannel regions at nondetectable concentrations. At the adaxonal surface of myelinating Schwann cells, MFs may be attached to adhesion molecules such as MAG (Trapp et al., 1989; Trapp, 1990).

Paranodal Membrane Specialization. The main function of myelin is to insulate the axons so that propagation of the action potential can occur by saltatory conduction (Funch and Faber, 1984). Current flow or ion exchange associated with the action potential does not occur through axolemma covered by myelin. Instead, current flow occurs at nodes of Ranvier, where the axolemma contains a high concentration of voltage-sensitive sodium channels. The paranodal loops and nodal microvilli are believed to serve an important role in buffering and maintaining the nodal environment (Landon and Williams, 1963; Thomas et al., 1993). Microfilaments form the structural core of the microvilli (Raine, 1982), which extend from the outer paranodal loops to surround the nodal axolemma. Microvilli increase the absorption/secretion surface area of membranes at nodes and therefore also the buffering power of these membranes (Thomas et al., 1993).

An isoform of ankyrin, ankyrin R, is selectively enriched in paranodal regions of peripheral nervous system myelin internodes (Kordeli et al., 1990). Microvilli and paranodal membranes also contain Na^+/K^+ ATPases (Ariyasu and Ellisman, 1987) and sodium channels (Ritchie et al., 1990). Ankyrin R can bind to both molecules (Koob et al., 1987; Nelson and Veshnock, 1987; Srinivasan et al., 1988), raising the possibility that ankyrin R plays a role in stabilizing and/or targeting sodium channels and Na^+/K^+ ATPases to specific regions of the myelin internode. These studies have provided the first evidence for selective enrichment of MF components in specialized regions of myelinating Schwann cells.

Myelin Protein Insertion. Another Schwann cell membrane in which MFs may have special functions is the outer compact myelin lamella in regions of the organelle-rich cytoplasmic channels. This membrane is unique in that its extracellular leaflet forms an intraperiod line with the underlying compact myelin sheath, while its cytoplasmic leaflet is associated with MFs. Autoradiographic studies implicate this membrane as the principal site for addition of myelin proteins during growth of the myelin sheath (Gould, 1977). Addition of P_0 to compact myelin most likely occurs by fusion of carrier vesicles, and may involve a specialized fusion receptor (Trapp et al., 1993). Microfilaments could potentially aid in this fusion or exert control over fusion sites by determining the distribution and/or properties of putative receptors. Microfilaments associated with this outermost compact myelin lamella may also contribute to myelin basic protein (MBP) synthesis and the targeting of MBP to compact myelin. Myelin basic protein is a heavily charged molecule that binds nonspecifically to many lipids (Smith, 1977; Boggs and Moscarello, 1978). Translation of MBP close to the site of incorporation into myelin assures its association with myelin and prevents binding to other organelles. Microfilaments participate in localization of mRNA and ribosomes in other cells (Singer et al., 1989; Yisraeli et al., 1990; Sundell and Singer, 1991), and may bind and stabilize MBP mRNA in the Schwann cell periphery. Microfilaments associated with the outer compact myelin lamella may selectively bind MBP mRNA-containing polyribosomes and thus ensure immediate association of newly synthesized MBP with compact myelin.

MICROTUBULES

MTs, the largest of the cytoskeletal filaments, provide dynamic substrates for the trafficking and structural organization of most organelles (for reviews, see Dustin, 1984; Kirschner and Mitchison, 1986; Schroer and Sheetz, 1991). Microtubules are cylindrical filaments that have an external diameter of about 25 nm. They are constructed of heterodimers of α and β tubulins, which polymerize in a guanosine triphosphate (GTP)-dependent process into fila-

ments that may reach 700 μm in length (Tsukita and Ishikawa, 1981). Microtubule growth is asymmetric; subunits are preferentially added and removed at the (+) or "fast-growing" end. Subunit addition at the (−) end is slow, and *in vivo*, the (−) end is frequently bound to an MT-nucleating structure, such as the centrosome. Microtubule asymmetry is important to MT-based transport, because the MT motors that transport organelles move preferentially toward either the (+) or (−) end of the MT. The factors that regulate motor direction, motor activity, and motor interactions with organelles remain poorly understood.

The size and complex geometry of the peripheral nervous system myelin internode (Figure 42-1) requires special mechanisms for synthesis, sorting, site-specific targeting, and stabilization of myelin proteins to the appropriate membrane domains (Figure 42-2). Microtubules have a well-established role in intracellular transport (Dustin, 1984; Schroer and Sheetz, 1991) and specialized MT configurations can mediate site-specific targeting (Hugon et al., 1987; Achler et al., 1989; Bre et al., 1990; Gilbert et al., 1991). In myelinating Schwann cells, the distribution and organization of MTs (Kidd et al., 1993) and studies of MT disruption (Hansson and Sjostrand, 1971; Jacobs et al., 1972; Roytta et al., 1984; Trapp et al., 1993) demonstrate that MTs are crucial to transport of myelin proteins and organelles. The transport and structural functions of MTs are governed by their orientation and organization, which in Schwann cells are influenced by axons (Kidd et al., 1993). Although the precise molecular interactions involved in transport of myelin proteins remain uncertain, MT disruption studies have provided insight into mechanisms mediating sorting and transport of myelin proteins (Trapp et al., 1993).

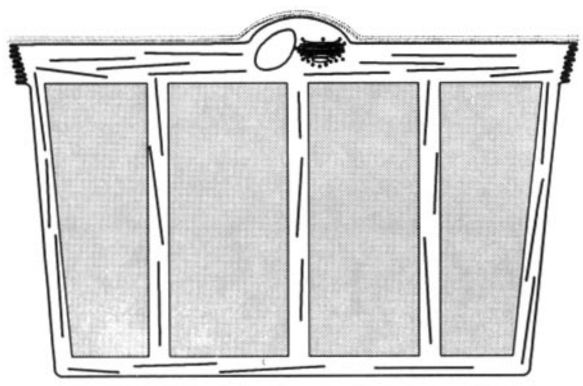

FIG. 42-5. In myelinating Schwann cells, microtubules are numerous in the outer cytoplasmic channels and perinuclear cytoplasm. Fewer microtubules are present in Schmidt-Lanterman incisures, paranodal loops, and periaxonal cytoplasm.

Distribution and Organization of Microtubules

MTs are present in all major cytoplasmic compartments of the myelin internode, but are excluded from compact myelin (Figure 42-5) (Peters et al., 1991). Thus, MTs have the potential to transport vesicles and organelles within all major cytoplasmic regions of the internode. They are numerous in the perinuclear region and in the cytoplasmic channels that lie external to the outer margin of the compact sheath (Peters et al., 1991). Microtubules are also present in Schmidt-Lanterman incisures, paranodal loops, and the periaxonal cytoplasm (Peters et al., 1991).

The organization of MTs is determined in part by their site of nucleation, which fixes, at least initially, the location of the MT (−) end. In many cells such as fibroblast, MTs are nucleated from a filamentous material concentrated around the centrosome (Dustin, 1984), forming an MT-organizing center. Myelinating Schwann cells have a more complex arrangement in which MTs extend from many sites scattered throughout the perinuclear cytoplasm and not from the centrosome (Figure 42-6) (Kidd et al., 1993). Microtubule-nucleating sites have not been detected at other internodal locations. Thus, there are no MT-organizing centers along the internode that may have served as specific (−)-end transport sites, analogous to the apical surface of epithelial cells (Hugon et al., 1987; Achler et al., 1989; Bre et al., 1990; Gilbert et al., 1991).

Although MT-nucleating sites are restricted to perinuclear cytoplasm, MT polarity in the external cytoplasmic channels is mixed (Figure 42-7) (Kidd et al., 1993), providing an MT network in which both (+)-end-directed and (−)-end-directed transport may move organelles from the perinuclear region. About 75% of MTs have their (−) ends toward the nucleus (Figure 42-7), whereas 25% have (−) ends away from the nucleus; this (+)-end to (−)-end ratio is maintained along the internode. Myelinating Schwann cells, therefore, are probably nucleated in the perinuclear cytoplasm, then detached from these nucleating sites, and transported along the internode (Figure 42-8). A similar mechanism has been proposed for axonal MTs (Hoffman and Lasek, 1975; Black and Lasek, 1980; Baas and Ahmad, 1992). Microtubules with their (−) ends directed away from the perinuclear region could be generated in two ways. First, some may be transported from the perinuclear cytoplasm in that orientation, for instance, by (−)-end-directed MT sliding, as occurs in flagella (Dustin, 1984). Alternatively, all MTs may

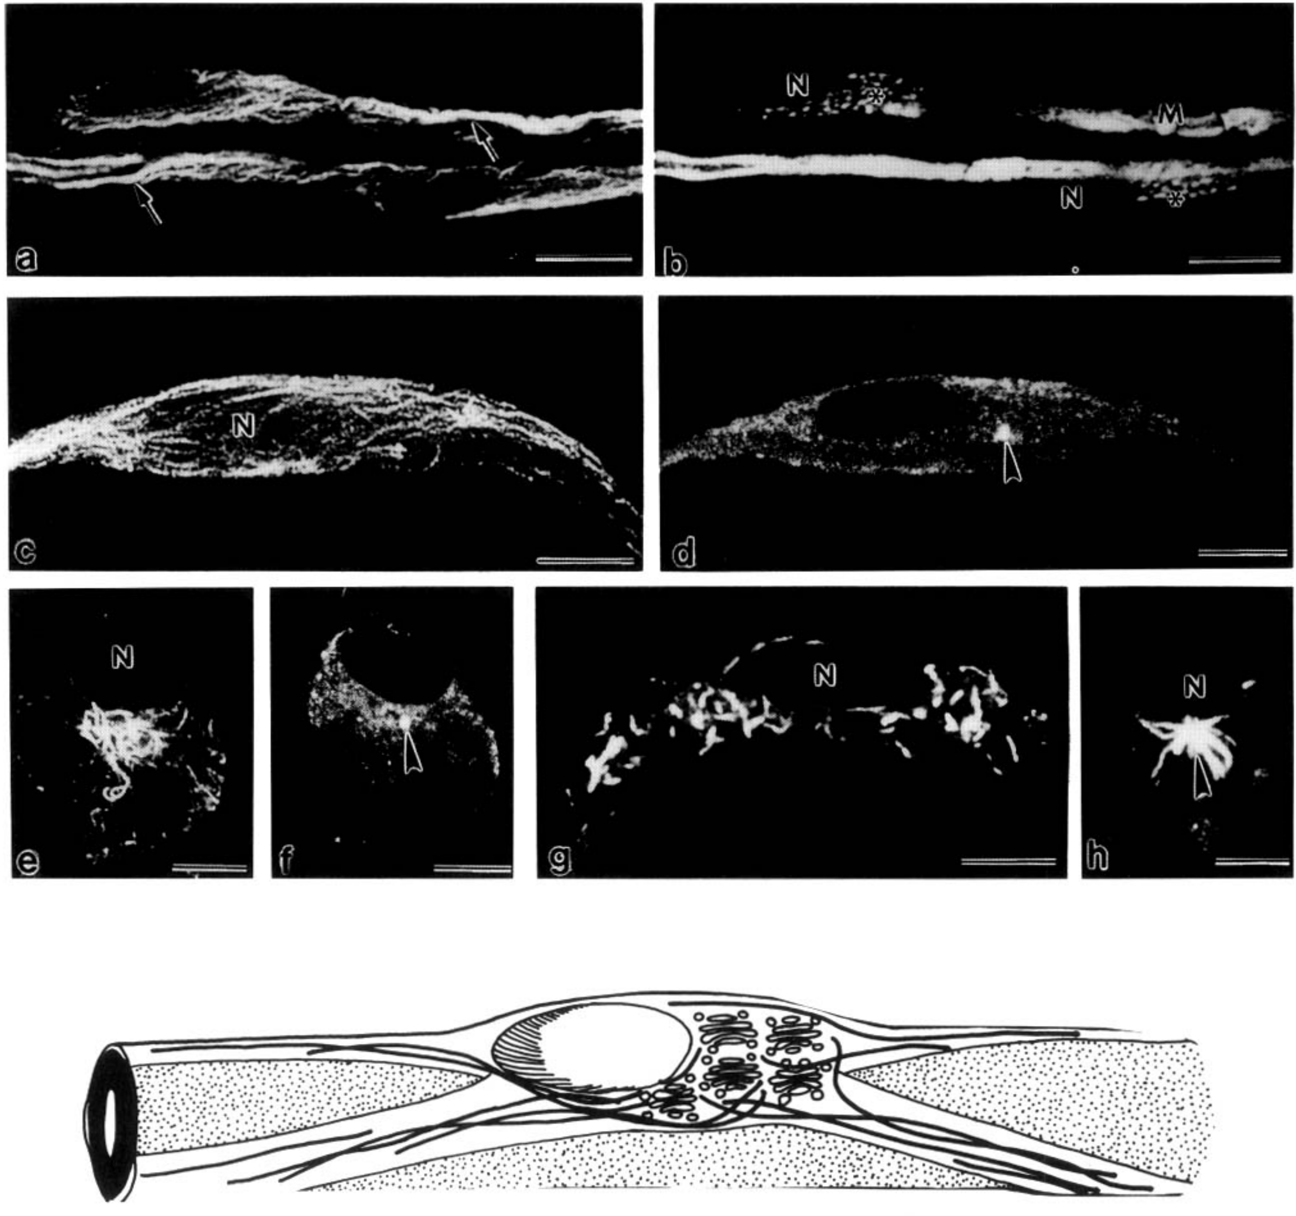

FIG. 42-6. Confocal fluorescence micrographs of myelinating Schwann cells (*a–d, g*) and perineurial cells (*e, f, h*) from rat sciatic nerve after immunostaining for microtubules (acetylated α-tubulin; *a–c, d, g, h*), the Golgi apparatus (P_0 antibody; *b*), and the centrosome (pericentrin; *d, f*). In developing internodes (*a, b*) microtubules are concentrated in the perinuclear region and extend into the external cytoplasmic channels (*arrows*). There is no discrete microtubule-organizing center (*c, d*), and Golgi profiles (*) are scattered throughout the cytoplasm at one longitudinal end of the nucleus (*N*). In contrast, perineurial cells from the same tissue (*e, f*) have a prominent centrosomal microtubule-organizing center. After colchicine-induced microtubule depolymerization, microtubules repolymerize at numerous sites within the perinuclear region (*g*), and not at a single aster, unlike fibroblasts (*h, arrow*). The organization of microtubules is summarized in (i). Scale bars = 10 μm. [From Kidd et al. (1993), with permission.]

initially be transported with (−) ends toward the perinuclear region (Figure 42-8), as proposed in axons (Baas and Ahmad, 1992). Later, the normal cycles of catastrophic depolymerization and repolymerization reduce MT length and permit 180 degrees rotation. Microtubules subsequently elongate with (+) ends pointed toward the perinuclear region. In either scenario, other factors must limit (−)-end-directed transport or MT rotation to only 25% of the total MT population.

In addition to MT nucleation sites and MT transport, stabilization can also modulate MT function.

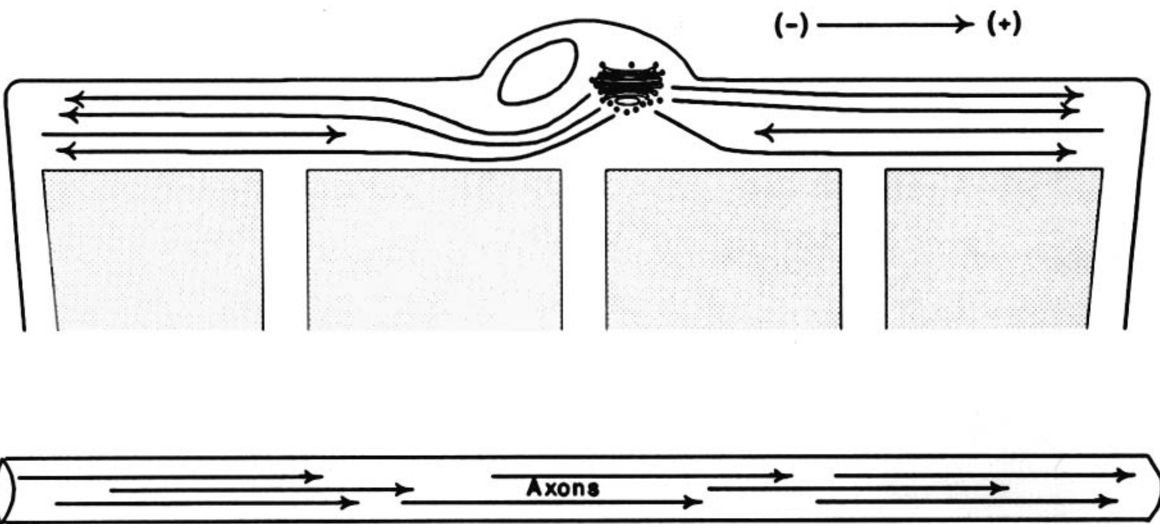

FIG. 42-7. Microtubule polarity in myelinating Schwann cells was determined by using the hook method. Seventy-five percent of Schwann cell microtubules had (+) ends away from the perinuclear region, whereas the remainder had the opposite polarity. In contrast, 95% of axonal microtubules had a uniform polarity.

Microtubules are inherently unstable and oscillate between phases of elongation and collapse (Dustin, 1984; Kirschner and Mitchison, 1986). The extent of MT depolymerization and repolymerization is determined by complex assembly/disassembly kinetics and can be influenced by modifications such as binding of MT-associated proteins (MAPs) (Sloboda et al., 1976; Pryer et al., 1992). Myelinating Schwann cell MTs are enriched in acetylated α-tubulin epitopes (Kidd et al., 1993), a posttranslational modification characteristic of MTs with long half-lives (Cambray-Deakin and Burgoyne, 1987; Piperno et al., 1987). Myelinating Schwann cells also contain MAP1a, MAP1b, and tau (Kidd et al., 1993), which could participate in stabilization of MTs. Stabilization increases MT density without the metabolic burden of producing and transporting many more labile MTs, and is particularly important in cells with long processes, such as Schwann cells and axons.

Microtubule Functions in Myelinating Schwann Cells

Protein Transport. Microtubules provide a substrate for rapid transport of organelles, which is mediated by molecular motors in an energy-dependent manner. These motors bind to both the MT and the organelle being transported, and different motors preferentially translocate material toward either the (+) or (−) end of MTs (Vale et al., 1985; Paschal and Vallee, 1987; Paschal et al., 1987; Schroer et al., 1989). The involvement of MTs in transporting and targeting P_0 protein, MAG, and laminin to different surface membranes has been investigated (Trapp et al., 1993). All three proteins are synthesized in rough endoplasmic reticulum and Golgi and transported to surface membranes as part of membrane carrier vesicles that bud from the *trans*-Golgi network. Microtubule disassembly causes marked accumulation of P_0, MAG, and laminin in the perinuclear cytoplasm of myelinating Schwann cells (Trapp et al., 1993) (Figure 42-9), indicating that MTs translocate carrier vesicles enriched in these molecules from the perinuclear cytoplasm to sites along the myelin internode. Both (+)-end- and (−)-end-directed MT motors could potentially mediate transport from the perinuclear region (Kidd et al., 1993), but since most MTs have their (+) ends directed away from the perinuclear cytoplasm, it seems likely that most vesicles are delivered to myelin by (+)-end

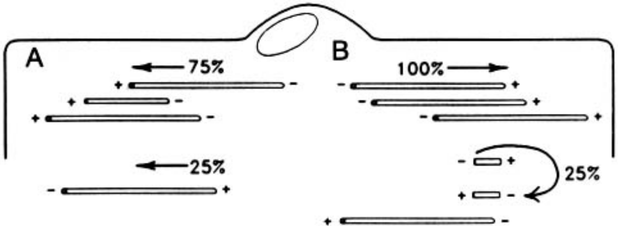

FIG. 42-8. Two possible mechanisms may generate microtubules of mixed polarity in the external cytoplasmic channels. (A) Microtubules may be transported in both orientations from the perinuclear region, although not in equal numbers. (B) Alternatively, microtubules may be initially transported from the perinuclear region with a uniform polarity, then depolymerize. About 25% become sufficiently short to rotate, and these subsequently elongate with their (+) ends toward the perinuclear region.

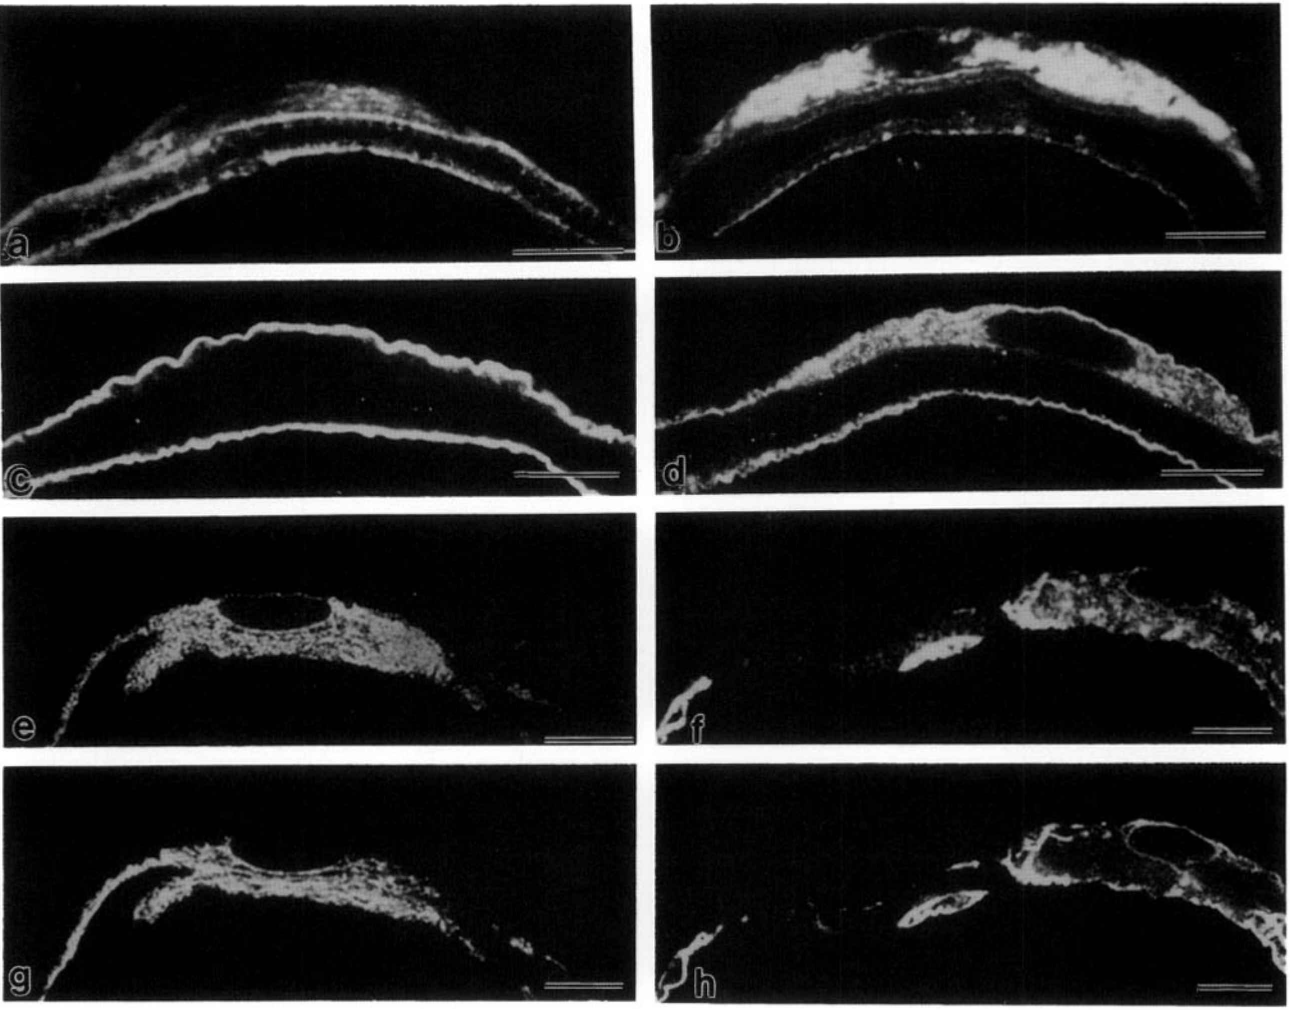

FIG. 42-9. Confocal fluorescence micrographs of myelinated nerve fibers from rat sciatic nerve, illustrating the effects of colchicine treatment on P_0 (*a, b*), laminin (*c, d*), endoplasmic reticulum (*e,f*), and vimentin (*g,h*) distributions (left panels, saline treated, right panels, 24-hour colchicine treatment). (*e,g*) and (*f,h*) show double-labeling of the same fibers. Note the islands of smooth endoplasmic reticulum that are surrounded by vimentin immunostaining after colchicine treatment (*arrows*). Scale bars = 10 μm. [From Trapp et al. (1993), with permission.]

MT motors. If so, what could be the function of MTs that have their (−) ends pointed toward the periphery? Translocation of mRNA and ribosomes has been attributed to (−)-end-directed transport in dendrites (Baas et al., 1988; Baas and Black, 1990), oocytes (Stebbings and Hunt, 1983; Yisraeli et al., 1990), and myelinating cells (Kidd et al., 1993). Translocation of MBP mRNA along the myelin internode is the chief means of delivering MBP to the myelin sheaths (Colman et al., 1982; Trapp et al., 1987; Griffiths et al., 1989) and previous studies have demonstrated that ribosomal RNA is transported from the nucleus to points along the peripheral nervous system myelin internode at a rate of 0.1 to 0.3 mm per day (Gould and Mattingly, 1990). Whether MBP mRNA is transported with ribosomes is unknown. Estimates of mRNA transport in other cells (0.1 to 0.5 mm per day; Yisraeli et al., 1990) suggest that cotransport is possible. If MBP mRNAs are transported attached to ribosomes, they must be very stable, with half-lives of days, or else they would be degraded before reaching the paranodes.

Do Schwann cell MTs play a role in targeting myelin proteins to distinct membranes of the myelin internode? Ultrastructural immunocytochemical studies indicate that P_0 and MAG are segregated into separate carrier vesicles as they exit from the *trans*-Golgi network (Trapp et al., 1993). The fate of these P_0- and MAG-rich carrier vesicles after MT disassembly has provided clues to the mechanisms of their targeting. Following MT disassembly, P_0-rich carrier vesicles fused with each other to form compact myelin-

like membrane whorls, while MAG carrier vesicles fused with each other to form membrane whorls distinct from those rich in P_0 protein. P_0 and MAG were not mistargeted to Schwann cell surface membranes after MT disassembly, suggesting that MTs do not play an essential role in directing these molecules specifically to compact myelin or the outer mesaxon. These data imply that each class of carrier vesicles contains signals that only permit their fusion with the correct surface membrane.

Organelle Distribution. The effects of MT disassembly demonstrate that MTs organize the distribution of Golgi membranes, endoplasmic reticulum, and intermediate filaments in myelinating Schwann cells (Hansson and Sjostrand, 1971; Jacobs et al., 1972; Roytta et al., 1984; Trapp et al., 1993) (Figure 42-9). Disruption of Golgi membranes after MT disassembly is consistent with similar studies in other cell types (Kreis, 1990; Karecla and Kreis, 1992) and indicates that MTs organize the Golgi apparatus by transport toward their (−) end. After MT disassembly, organelles aggregated at discrete sites within the cytoplasmic channels at the outer perimeter of the myelin internode. The organelle-rich regions consisted of a central core of smooth endoplasmic reticulum membrane surrounded by intermediate filaments. Other organelles were embedded in the intermediate filament-rich zone and excluded from the smooth endoplasmic reticulum-rich zone. These results indicate that MTs help organize independent networks of endoplasmic reticulum and intermediate filaments that extend from the perinuclear cytoplasm to the paranodal cytoplasm. Previous studies have demonstrated that certain lipids are synthesized in the smooth endoplasmic reticulum located in the outer cytoplasmic channels of the myelin internode (Gould and Sinatra, 1981; Gould et al., 1987). The interdependence between MTs and smooth endoplasmic reticulum extension (Trapp et al., 1993) may help coordinate the addition of lipids and proteins into compact myelin.

Axonal Modulation of Microtubule Organization in Myelinating and Degenerating Internodes

Schwann cells can display several phenotypes that are governed by axonal influences (Aguayo et al., 1976; Weinberg and Spencer, 1976). Physical contact with an appropriate axon induces expression of myelin protein genes (Lemke, 1986), whereas loss of axonal contact causes a rapid decrease in transcription of these genes (Trapp et al., 1988). Cell-cell contact influences the organization of cytoskeletal components in a variety of cell types (e.g., Bacallao et al., 1989), including Schwann cells (Kidd et al., 1993) (Figure 42-10).

In explant cultures of neonatal dorsal root ganglia, Schwann cells that have not yet myelinated and lack axonal contact radiate MTs from a single MT-organizing center that contains the centrosome (Kidd et al., 1993) (Figure 42-10). Thus, most MTs

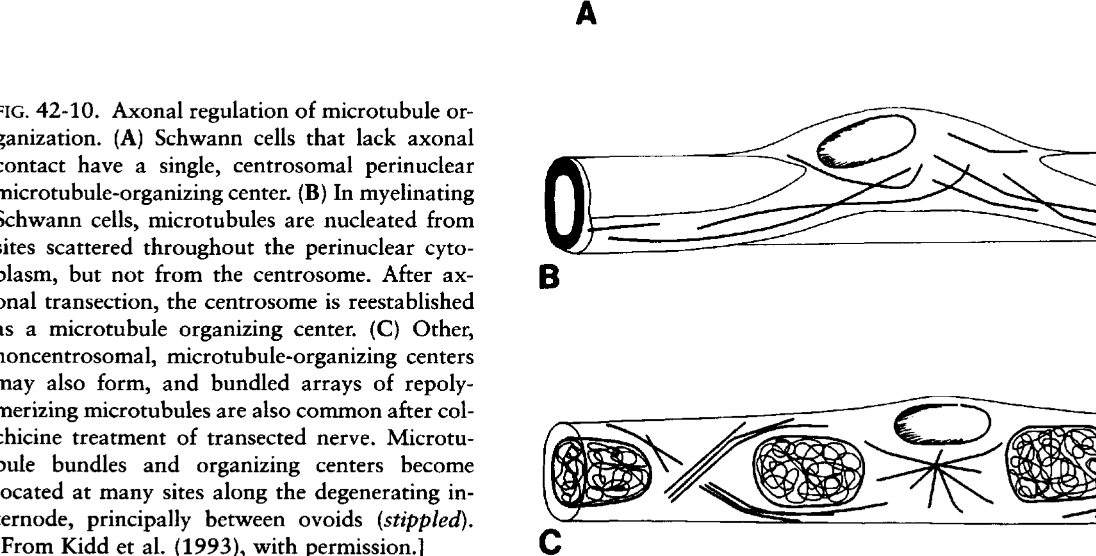

FIG. 42-10. Axonal regulation of microtubule organization. (A) Schwann cells that lack axonal contact have a single, centrosomal perinuclear microtubule-organizing center. (B) In myelinating Schwann cells, microtubules are nucleated from sites scattered throughout the perinuclear cytoplasm, but not from the centrosome. After axonal transection, the centrosome is reestablished as a microtubule organizing center. (C) Other, noncentrosomal, microtubule-organizing centers may also form, and bundled arrays of repolymerizing microtubules are also common after colchicine treatment of transected nerve. Microtubule bundles and organizing centers become located at many sites along the degenerating internode, principally between ovoids (*stippled*). [From Kidd et al. (1993), with permission.]

have their (+) ends oriented toward the cell periphery and their (−) ends at the center of the cell. This MT arrangement provides the Schwann cell with a simple transport system in which the Golgi apparatus and other (−)-end-tethered organelles are concentrated at the cell center, and transport to the cell surface is mediated by (+)-end-directed motors. MT-organizing centers were not observed in Schwann cells cultured from adult nerve or Schwann cells passaged many times, underscoring the dynamic nature of the Schwann cell MT network in different environments.

Contact with a myelin-inducing axon results in a more complex MT organization (Kidd et al., 1993) (Figures 42-6 and 42-10). As described above, the MT network in myelinating Schwann cells is formed from nucleating sites scattered through the perinuclear cytoplasm, and not from centrosome. A network of MTs with mixed polarity is generated in the external cytoplasmic channels, and most MTs are enriched in acetylated α-tubulin epitopes, a characteristic of stable MTs.

The dynamic nature of Schwann cell MTs and the influence of axonal contact on MT organization are further demonstrated by the pattern of MT organization during Wallerian degeneration (Kidd et al., 1993) (Figure 42-10). By 24 hours after axonal transection, Schwann cells in the distal stump form multiple MT-organizing centers and MT bundles. One perinuclear MT-organizing center contains the centrosome, while other MT-organizing centers and bundles of parallel MTs appear along the internode and are located between degenerating myelin ovoids. The MT-organizing centers and MT bundles are initially observed in perinuclear cytoplasm and later identified at sites along the internode, raising the possibility that axonal transection induces the transcription and peripheral transport of MT-nucleating materials. This MT organization occurs transiently and only occurs for 1 to 3 days after axonal transection. By 4 days after transection, Schwann cells disassemble their cytoplasmic MTs as they undergo mitosis. The observation that new MT organizing centers are produced in degenerating internodes and positioned between myelin ovoids (Kidd et al., 1993) provides evidence that Schwann cells participate in the early events of myelin degeneration. This MT distribution concentrates lysosomes and endosomes in periovoidal cytoplasm (Kidd and Trapp, unpublished observations), through their association with MT (−) ends (Matteoni and Kreis, 1987). These organelles may contribute hydrolytic enzymes to the degenerating myelin ovoids, and are likely to be involved in processing the products of myelin degeneration.

INTERMEDIATE FILAMENTS

IFs are polymers of one or more IF proteins and have a diameter of ~10 nm in electron micrographs. The IF proteins form six groups of structurally related proteins (for reviews, see Klymkowsky et al., 1989; Skalli and Goldman, 1991). In myelinating Schwann cells, the predominant IF protein is vimentin (Dahl et al., 1982; Schachner et al., 1984; Kobayashi and Suzuki, 1990). Several authors have reported glial fibrillary acidic protein in nonmyelinating (Remak) Schwann cells (Dahl et al., 1982; Jessen et al., 1984; Schachner et al., 1984; Fields and Yen, 1985; Kobayashi and Suzuki, 1990) indicating that axons mediate IF composition in Schwann cells. Neurofilament mRNAs and proteins have also been reported in Schwann cells (Kelly et al., 1992; Roberson et al., 1992). Although neurofilament proteins may coassemble with vimentin (Gill et al., 1990), they are not a major constituent of the cytoskeleton in normal myelinating Schwann cells. Recent studies in other cells have implicated phosphorylation of vimentin in the regulation of IF assembly and disassembly (Chou et al., 1989; Chou et al., 1990) and a vimentin-specific kinase has been identified (Chou et al., 1990). Little is known about the kinetics of IF assembly or disassembly in myelinating Schwann cells.

Intermediate filaments constitute a substantial component of the Schwann cell cytoskeleton (Kobayashi and Suzuki, 1990; Peters et al., 1991), but their organization and functions remain poorly understood. In myelinating Schwann cell, electron microscopy and immunocytochemical studies have identified IFs in the perinuclear cytoplasm and external cytoplasmic channels (Kobayashi and Suzuki, 1990; Peters et al., 1991; Trapp et al., 1993) (see Figure 42-9g). In the external cytoplasmic channels, IFs are oriented parallel to the axon and follow a sinuous course similar to MTs. While IFs in nonmyelinating Schwann cells appear bundled, those in myelinating cells are more widely spaced. This difference has been attributed to the presence of glial fibrillary acidic protein in nonmyelinating cells (Kobayashi and Suzuki, 1990). Intermediate filaments are generally considered to have a structural role in mechanically maintaining cell shape against externally applied forces (Klymkowsky et al., 1989; Skalli and Goldman, 1991). Vimentin IFs may interact with MF-associated molecules such as integrins (Wang et al., 1993) and ankyrin (Georgatos and Marchesi, 1985), and with MTs in resisting stress (Wang et al., 1993).

Are IFs essential for myelination? Because myelinating Schwann cells contain abundant IFs, and IF

composition between myelinating and nonmyelinating Schwann cells may vary, it is likely that IFs are important. Oligodendrocytes, however, make numerous myelin sheaths but have few, if any, IFs, suggesting that the presence of IFs is not a fundamental requirement of myelination. Both of these views may be correct, if the primary role of IFs is to support the Schwann cell against external stresses. Oligodendrocytes would not need IFs, since they are sheltered from external forces by the skull and vertebrae and by IF-rich astrocytes. Peripheral nerves, on the other hand, are frequently subjected to compression during limb movement and external trauma. While some of these forces are mitigated by the epineurium, perineurium, and the endoneurial collagen fibrils, an intracellular apparatus for maintaining cell shape and resisting external stress may also be necessary.

CONCLUSIONS

This chapter has reviewed the general distribution of microfilaments, microtubules, and intermediate filaments in myelinating Schwann cells and some of the effects of MT disassembly on the distribution of organelles and transport of myelin proteins. Myelinating Schwann cells offer many advantages for elucidating the role of (1) MFs in membrane movement and stabilization, (2) MTs in intracellular transport and organelle distribution, and (3) IFs in resisting external stress. The major challenge of the immediate future is to identify and characterize the molecules that are critical to cytoskeletal functions, such as MT motors or MF-binding proteins. Many of these molecules are likely to be expressed by other cell types and already characterized; immunocytochemical studies of Schwann cells with use of antibodies against known cytoskeletal components should be both productive and informative. Some cytoskeletal molecules, however, are likely to be Schwann cell-specific or at least specialized isoforms of known cytoskeletal protein families. The use of polymerase chain reaction technology may help identify and characterize molecules that have sequence homology to cytoskeletal molecules. The identification of unique molecules will require a dedicated search and a considerable amount of luck. Ultimately, successful application of transgenic technology and homologous recombination should elucidate the specific functions of the Schwann cell cytoskeleton and define the mechanisms responsible for spiral wrapping of myelin membranes and site-specific targeting of myelin proteins.

We wish to thank Dr. Pamela Talalay for helpful discussions and Rod Graham for preparing and editing the manuscript. 43 | Intermediate filaments in astrocytes

LAWRENCE F. ENG AND YUEN LING LEE

The cytoskeleton is composed of three major filamentous components; microfilaments (mainly actin), microtubules (mainly tubulins), and intermediate filaments (IFs). During the past ten years the chemistry, biology, and structure of the cytoskeleton and associated proteins have been described in numerous publications (Traub, 1985; Schliwa, 1986; Goldman and Steinert, 1990). Originally, five distinct classes of IF proteins were defined on the basis of the cell type or specific tissue from which the filaments were isolated and characterized: keratin in epithelial cells, vimentin in cells of mesenchymal origin, desmin in muscle cells, glial fibrillary acidic protein (GFAP) in astrocytes, and neurofilaments in neurons. Molecular biological studies based on amino acid homologies now show that all IF-forming proteins possess a central α-helix rod domain of closely conserved length and secondary structure, but with specific differences, which permit classification into distinct sequence types. At present, the IF proteins are divided into five types (Goldman and Steinert, 1990):

Type I: acidic keratins
Type II: neutral-basic keratins
Type III: includes vimentin, desmin, GFAP, and/or 57 kD neuronal IF protein
Type IV: classical neurofilaments
Type V: nuclear lamins

Vimentin, desmin, and GFAP are highly homologous throughout their rod and C-terminal domains.

This chapter focuses on the two principal IF proteins in astrocytes: vimentin and GFAP. The expression of vimentin and GFAP in developing and mature, differentiated astrocytes and following injury will be discussed. Since GFAP is the major IF protein in mature cerebral astrocytes, we have described *in vitro* and *in vivo* studies relating to GFAP metabolism, phosphorylation, assembly, immunocytochemistry, and molecular biology. The role of GFAP in gliosis and in brain tumor diagnosis has also been included. The chapter is intended to provide an overall summary of the various aspects of GFAP biology as it relates to astrocytes. Since an enormous amount of work has been done in this area, it has been impossible to include every relevant reference.

VIMENTIN

Vimentin was first demonstrated in chicken fibroblasts as the major subunit of filaments and is mainly expressed in cells of mesenchymal origin (Brown et al., 1976; Franke et al., 1979). Immunohistology showed that vimentin was present in a variety of cultured cells and permanent cell lines from other tissues. Cells of different embryologic origin produce vimentin when grown *in vitro*. Vimentin is also expressed sequentially during the differentiation of various cell lineages. Most cells *in situ* express only one type of IF. Exceptions include some glial cells, aortic smooth muscle cells, and neurons. For example, vimentin coexists with GFAP in immature astrocyte, in Bergmann glia and tanycyte processes (Shaw et al., 1981) and in Müller fibers of degenerating retinae (Shaw and Weber, 1983). It is thought that expression of vimentin is correlated with a less differentiated state. By immunofluorescence and electron microscopy, vimentin IFs occur as single filaments or gently curving, loose bundles. The genomes of various vertebrate cell types are known to have a single copy of a gene for vimentin (Quax et al., 1983) but this gene appears to make at least two mRNA species (Zehner and Paterson, 1983).

Vimentin in Central Nervous System Development and Reactive Astrogliosis

Developmental expression of cytoskeletal IFs has been studied in a number of experimental models. In the developing chick embryo, vimentin is present in virtually all of the replicating neuroepithelial cells in the early neural tube. As the cells mature, neurofilaments replace vimentin in the postmitotic neuron, and GFAP replaces vimentin in the mature astrocyte (Schnitzer et al., 1981; Tapscott et al., 1981). GFAP increases and vimentin decreases in differentiating rodent glial cells (Schnitzer et al., 1981). Vimentin and GFAP have been reported to coexist in varying proportions in cultured astrocytes (Schnitzer et al., 1981; Chiu and Goldman, 1984; Eng et al.,

1986a; Goldman and Chiu, 1984a) and in Bergmann radial glial fibers of the adult cerebellum (Schnitzer et al., 1981; Bovolenta et al., 1984). IF heteropolymers consisting of alternating GFAP and vimentin monomers have been demonstrated by immunoelectron microscopy in human glial tumors (Sharp et al., 1982; Wang et al., 1984) and cultured mouse astrocytes (Abd-El Basset et al., 1992). Studies by Dahl and coworkers (1982) have shown an increase of vimentin in the rat optic nerve undergoing Wallerian degeneration. Whether this increase is due entirely to activated and fibrous astrocytes or to other vimentin-containing cells, such as activated endothelial cells, macrophages, and lymphocytes, remains to be determined.

Schiffer et al. (1986) have studied astrocytic reactions to injury under two experimental conditions in the rat central nervous system: brains injured by laser irradiation and brain tumors induced with the chemical carcinogen, ethylnitrosourea. After immunostaining with antibodies to GFAP and vimentin, GFAP antibodies labeled all the reactive astrocytes, whereas vimentin antibody staining was found in astrocytes at the periphery of the lesion. The authors suggested that vimentin was expressed only in the astrocytes undergoing proliferation. Using the experimental allergic encephalomyelitis (EAE) model in the Lewis rat, we were unable to demonstrate the colocalization of GFAP and vimentin in the activated astrocytes, except possibly for a few proliferating astrocytes adjacent to perivascular lesions (Eng et al., 1986b). Under these conditions nonglial cells such as endothelial cells, macrophages, and lymphocytes were heavily immunostained for vimentin in freeze-substituted EAE rat spinal cord (L. Eng, M. Gibbs, and M. Smith, unpublished data). Proliferating astrocytes at the site of a stab wound in the brain or spinal cord contusion also immunostain for GFAP and vimentin (Calvo et al., 1991; L. Eng, unpublished observations).

GLIAL FIBRILLARY ACIDIC PROTEIN

GFAP studies originated from our research on multiple sclerosis, a demyelinating disease of the central nervous system that is characterized by intense reactive astrogliosis and scar formation. The term glial fibrillary acidic (GFA) protein evolved from "plaque" protein (Eng et al., 1970), glial fibrillary protein (Eng et al., 1971) to GFAP or GFA protein (Uyeda et al., 1972; Bignami et al., 1972). In the special issue of the *Journal of Neuroimmunology* (Vol. 8, No. 4–6) on GFAP Cedric Raine stated in his editorial that "this protein has become a prototype antigen in nervous tissue identification and a standard marker for fundamental and applied research at an interdisciplinary level" (Raine, 1985). Other protein preparations containing GFAP or its proteolytic degradation products are astroprotein (Mori and Morimoto, 1975) and alpha-albumin (Gheuens et al., 1984). A detailed discussion regarding GFAP-related proteins has been reported elsewhere (Eng, 1980). GFAP, first isolated from multiple sclerosis (MS) plaques (Eng et al., 1970, 1971), is the protein subunit of glial intermediate filaments, which form packed bundles within the cell bodies and cytoplasmic processes of differentiated astrocytes. In the past, considerable confusion existed regarding the chemical and immunologic relationships between the glial filament, neurofilament, and neurotubule proteins. Neurotubules had been reported to have similar chemical properties to glial filaments and GFAP (Johnson and Sinex, 1974; Dahl, 1976a, 1976b: Dahl and Bignami, 1976b; Chan et al., 1977). Neurotubules had also been reported to share common properties with neurofilaments (Wisniewski et al., 1968, 1971; Gaskin and Shelanski, 1976; Dahl and Bignami, 1977; Iqbal et al., 1977). Still other studies had suggested that neurofilament proteins had similar chemical and immunologic properties with GFAP and glial filaments (Davison, 1975; Dahl and Bignami, 1976a; Yen et al., 1976; Davison and Hong, 1977; Day, 1977; Lee et al., 1977; Goldman et al., 1978). Our early reports (De Vries et al., 1976; Eng et al., 1976b) indicating that GFAP from astrocytes was not related to neurofilaments were challenged but subsequently were confirmed by many studies (Bignami and Dahl, 1977; Liem et al., 1978; Schachner et al., 1978; Dahl and Bignami, 1979; Schlaepfer et al., 1979; Chiu et al., 1980). We direct those requiring more comprehensive treatment of the subject to the following reviews and books: Eng and Bigbee, 1978; Bignami and Dahl, 1979; Eng, 1979, 1980, 1985; Eng and DeArmond, 1982, 1983; DeArmond and Eng, 1984; Traub, 1985; Dahl et al., 1986; Schliwa, 1986; Eng and Shiurba, 1988.

Biochemical properties of GFAP that have impeded its characterization are insolubility in aqueous solvents, tendency to aggregate or polymerize, and susceptibility to neutral proteases. Only a very small pool of aqueous soluble GFAP could be detected at any age in development of the rat brain (Malloch et al., 1987), in cultured astrocytes (Chiu and Goldman, 1984), and in rat spinal cord (Aquino et al., 1988). Early reports of a soluble GFAP fraction utilized human postmortem tissue and animal tissue where the time between death and homogenization of the tissue was not controlled. The low molecular

weight soluble forms in these cases are probably due to a calcium-activated neutral proteinase, which has a high substrate specificity for vimentin and desmin (Schlaepfer and Zimmerman, 1981; Bigbee et al., 1983b; DeArmond et al., 1983a; Nelson and Traub, 1983; Ciesielski-Treska et al., 1984). Routine biochemical procedures are now available for isolating homogeneous preparations of GFAP from spinal cord homogenates in sufficient quantities for chemical, immunological, and metabolic studies (Chiu et al., 1980; Liem, 1982; Eng and DeArmond, 1983; Fukuyama et al., 1991). GFAP shows species-specific amino acid sequence heterogeneity, and its molecular weight ranges from 48,000 to 51,000 kD (Eng, 1980; DeArmond et al., 1983a), that is, 48,000 kD for mouse, 49,000 kD for human, 50,000 kD for bovine, and 51,000 for rat.

Metabolism

Metabolic studies with rodent astrocyte cultures have shown that the rate of GFAP monomer synthesis and cytoplasmic accumulation of glial filaments can be experimentally modulated (Chiu and Goldman, 1985). Goldman and Chiu (1984a) were able to alter the morphology of neonatal rat cortical astrocytes by varying the initial seeding densities. Astrocytes in low-density cultures were flat and polygonal in shape, and they contained large amounts of actin relative to IF proteins. In contrast, astrocytes in high-density cultures appeared morphologically differentiated, often were stellate in shape, and had delicate, branching cytoplasmic processes. Astrocytes at high density contained relatively less actin but more IF proteins than astrocytes in low-density cultures. Chiu and Goldman (1984) did not detect any influence of growth rate on the pattern of IF protein synthesis, and they found that the turnover of GFAP revealed both a fast-decaying pool (half-life: 18 hours) and a more stable form (half-life: 8 days). These authors (Goldman and Chiu, 1984b) reported that the intracellular content of GFAP could be doubled by exposing cultured astrocytes to dibutyryl-cyclic AMP (cAMP) for 2 weeks. The increase in GFAP content also was correlated with a reduction in cytoskeletal actin and morphological transformation of the flat, polygonal astrocyte to the stellate form. cAMP (Sensenbrenner et al., 1980), beta-adrenergic agonists such as isoproterenol (McCarthy et al., 1985; Pollenz and McCarthy, 1986), and agents such as phorbol esters that activate protein kinase C (PKC) (Mobley et al., 1986; Mobley and Harrison, 1991) also have been found to transform the flat, polygonal astrocyte to the stellate form. Morrison et al. (1985) observed that growth factors and hormones regulate the expression of GFAP *in vitro*. Induction of GFAP synthesis in secondary rat astrocyte cultures grown in chemically defined medium increased GFAP content 2- to 4-fold in the presence of insulin, hydrocortisone, putrescine, prostaglandin $F_{2\alpha}$, and pituitary fibroblast growth factor. Increase in the specific rate of GFAP synthesis was maintained for up to 3 weeks after the cells were exposed to chemically defined medium. The resultant elevation in GFAP content accompanied the morphological maturation of astrocytes from the flat, polygonal to the stellate form. The half-life for GFAP was determined by two independent methods to be 7.5 days. Conversion of the cultured cells to chemically defined medium did not result in an increase in intracellular levels of cAMP (Wu et al., 1985). Astrocytes cultured in serum-containing medium grow to confluence, stop producing GFAP, and remain morphologically undifferentiated as flat cells with few processes. If these cells are grown in serum, but on a nitrocellulose membrane, at confluence they continue to differentiate into fibrous process-bearing astrocytes, which continue to increase in GFAP content. This suggests that, in addition to growth and matrix factors, there is a physical component that can induce astrocyte differentiation (Eng et al., 1986a).

In contrast, GFAP turnover *in vivo* in mouse spinal cord (DeArmond et al., 1986) was much slower than that reported for astrocytes in culture (Chiu and Goldman, 1984; Morrison et al., 1985). At 9 weeks after intravenous injection of [guanido ^{14}C]arginine, 40% of the radioactivity incorporated into spinal cord cytoskeletal GFAP was still present, indicating that a significant proportion of glial filaments is degraded relatively slowly *in vivo* (DeArmond et al., 1983b, 1986). In addition, study of short-term *in vitro* uptake of [^{3}H] amino acids into rat spinal cord IF proteins showed that GFAP had a slower rate of turnover than any of the neurofilament proteins (Smith et al., 1984b). The relatively slow turnover rate for GFAP is consistent with a possible structural role for glial filaments.

Phosphorylation

Posttranslational phosphorylation may account for the charge heterogeneity of GFAP observed following isoelectric focusing by polyacrylamide gel electrophoresis. *In vitro* translation of GFAP mRNAs from normal and mutant rodent central nervous system and from a human glioma-derived cell line grown in culture and as a solid tumor yielded single

molecular weight polypeptides, which showed ionic charge differences among two to three spots with an isoelectric pH range of 5.7 to 5.9 (Bigbee and Eng, 1982). Norephinephrine treatment of C6 glioma cells induced the phosphorylation of a number of intracellular proteins, including vimentin and GFAP (Browning and Ruina, 1984). All receptor agonists that have been shown to increase cAMP levels increase phosphorylation of GFAP and vimentin in cultured astrocytes (McCarthy et al., 1985). While cAMP treatment of astrocytes induces a morphological change from the flat to process-bearing cell (Sensenbrenner et al., 1980), phosphorylation of GFAP and vimentin is independent of the morphological change (Pollenz and McCarthy, 1986).

Phorbol ester-induced changes in astrocyte morphology and GFAP and vimentin phosphorylation produce a shift in PKC from the cytosol to the membrane (Harrison and Mobley, 1990). Both the PKC activator, phorbol 12-myristate 13-acetate (PMA), and the cAMP-dependent protein kinase (PKA) activator, 8 bromo-cyclic AMP, phosphorylates several regions of GFAP and vimentin (Harrison and Mobley, 1991). ATP-evoked calcium signal stimulates protein phosphorylation/dephosphorylation in cultured astrocytes. The phosphorylation of a 52 kD protein, which comigrates with GFAP in sodium dodecyl sulfate polyacrylamide gel electrophoresis, supports the premise that calcium-dependent protein kinases and phosphatases are transducing elements for calcium signal brought about by activation of P2 purinergic receptors in astrocytes (Neary et al., 1991). PMA and inhibitors of PKC have been shown to alter GFAP mRNA (Sharma et al., 1991). A cytoskeletal-associated protein activity has been identified that phosphorylates GFAP and vimentin and is distinct from PKC and PKA (Harrison and Mobley, 1992).

Monoclonal antibodies to two synthetic peptides were produced, which react to phosphorylated GFAP. pG1 reacted to the serine in residues 3-13 and pG2 reacted to residues 29-39. The phosphorylation of these two serine residues on intact GFAP induced disassembly of glial filaments *in vitro* (Inagaki et al., 1990). These two antibodies react specifically with mitotic astroglial cells. The authors suggest that increased phosphorylation during mitosis may directly influence intracellular organization of glial filaments (Nishizawa et al., 1991; Matsuoka et al., 1992).

GFAP was found to be phosphorylated *in vivo* after intracerebral injection of ^{32}P-orthophosphate, in brain slices and in a cell-free system. In both systems, the GFAP was phosphorylated at the serine and threonine residues. Incubation of brain slices with ^{32}P and the PKC activator, PMA, or an activator of cAMP-dependent protein kinase, forskolin, stimulated phosphorylation of GFAP. Phosphorylation of GFAP was also enhanced by calcium/phosphatidylserine/diolein and by exogenous cAMP-dependent kinase in a cell-free system. These findings indicate that PKC and cAMP-dependent kinase may play physiological roles in the *in situ* phosphorylation of GFAP. In cytoskeletal preparations incubated with [γ^{32}P]ATP, GFAP was phosphorylated *in vitro* by two additional protein kinases, a Ca^{2+}/calmodulin-dependent and an effector-independent kinase. These data suggest that phosphorylation of GFAP may be regulated by multiple second-message pathways (Noetzel, 1990a). A brain slice preparation was also employed to study GFAP synthesis and phosphorylation. The results indicate that the increase of GFAP during the first month of life cannot be ascribed solely to the rate of GFAP synthesis. The findings are consistent with the hypothesis that during later stages of astrocytic development the accumulation of GFAP may be due to a low rate of protein degradation. The pattern of GFAP phosphorylation in the developing rat brain differed from that observed for the incorporation of [^{3}H]amino acids into GFAP. The peak incorporation of ^{32}P into GFAP occurred on postnatal day 10 at a time when synthesis of the protein had declined by 43%. These results suggest that during GFAP development, phosphorylation of GFAP is mediated by factors different from those directing its synthesis (Noetzel, 1990b).

Assembly

A number of *in vitro* assembly studies of GFAP have reported that cations, pH, ionic strength, and ATP influence assembly (Rueger et al., 1979; Lucas et al., 1980a, 1980b; Yang et al., 1988; Yang and Babitch, 1988; Quinlan et al., 1989; Steward et al., 1989). A recent report employing a fluorescence energy transfer assay method suggests that GFAP filaments appear to be in dynamic equilibrium with subunits *in vitro* (Nakamura et al., 1991). These authors conclude that factors other than pH, ionic strength, or metal ions modulate the assembly state of GFAP *in vivo*, one of the factors being phosphorylation. As mentioned previously, all IF proteins share a common subunit organization consisting of a non-α-helical N-terminal head domain, a central α-helical rod domain, and a C-terminal tail domain (Weber and Geisler, 1985). The *in vitro* assembly process of IFs seems to consist of several association steps that involve different protein domains. Dimer and tetramer formation depend solely on the α-helical rod domain (Kaufmann et al., 1985). Assembly of filaments from

tetramers requires the presence of the head domain (Traub and Vorgias, 1983; Kaufmann et al., 1985). The head domain of the different IFs are variable in size and amino acid sequence; however, they are positively charged, because of a series of arginine residues, and contain serine residues available for phosphorylation by PKA, PKC, and cdc2 kinase (Inagaki et al., 1988). *In vitro* studies suggest that phosphorylation of vimentin (Inagaki et al., 1987; Evans, 1988), desmin (Geisler and Weber, 1988; Inagaki et al., 1988), and GFAP (Inagaki et al., 1990) inhibit IF assembly. It has been proposed that phosphorylation could participate in the regulatory processes in assembly and turnover of IFs (Geisler and Weber, 1988).

Molecular Biology

A clone encoding mouse GFAP was initially reported by Lewis et al. (1984). The mouse GFAP gene was first located on chromosome 11 by Bernier et al. (1988) and more recently confirmed by Boyer et al. (1991) and Brownell et al. (1991). The chromosomal location of the human GFAP gene was located on chromosome 17q21 by Bongcam-Rudloff et al. (1991) and also confirmed by Brownell et al. (1991) and Kumanishi et al. (1992). cDNA clones encoding rat GFAP were isolated from rat astrocyte and Schwann cell cultures. Nucleotide sequences from astrocytes and Schwann cells contained identical coding, however the 5′ untranslated region from the Schwann cell line indicated that the start site for peripheral nervous system GFAP mRNA lies 169 bases upstream from that used in the central nervous system. The data suggest that structural differences between GFAP in these two cell types occur at the nucleic acid and protein level (Feinstein et al., 1992).

The studies of promoter and enhancer elements of GFAP gene provide an understanding of GFAP regulation in glial development and glial response to injury. cDNA clones encoding human GFAP were isolated which contain the complete GFAP coding region (Reeves et al., 1989; Brenner et al., 1990). *In vitro* transcription analysis showed that the basal level expression of GFAP is controlled by two elements: a TATA box located about 25 base pairs (bp) upstream from the transcription start site, and another element located between +11 and +50 bp downstream from the start site (Nakatani et al., 1990a, 1990b). Miura et al. (1990) found that the *cis* element for astrocyte-specific expression was located within 256 bp from the transcription startpoint. They further defined three *trans*-acting factor binding sites: AP-2, NFI, and cAMP-responsive element motifs, which explains upregulation of GFAP in response to various kinds of injury. Transient transfection studies with a chloramphenicol acetyl transferase reporter gene were used to identify three regions (A, B, and D) responsible for GFAP gene expression (Besnard et al., 1991). The D region is located near the basal promoter, which is similar to the finding of Miura et al. (1990), while A and B are next to each other about 1500 bp further upstream. Employing site-directed mutgenesis of the 124-bp B region, the same group from Brenner's laboratory showed that there are multiple active sites in this region. Activation of GFAP transcription in astrocytes involves interaction among factors binding to these sites. The most crucial sequence has been shown to be a consensus AP-1 binding site. This is the first demonstration for a function of a specific transcription site in astrocytes, since polyclonal antibodies to c-Fos and c-Jun recognize proteins binding this site (Masood et al., 1993). Sarkar and Cowan (1991) found two similar positive elements, one is located −1.631 to −1.479 bp and another one located −97 to −80 bp; however, they also found a negative element that is located within the first intron of the GFAP gene. More recently, Kaneko and Sueoka (1993) found two negative regulatory regions: GDR1 is in a 2.7-kb region extending from the first intron through the fifth exon, and GDR2 is within 1.7 kb 3′ of the polyadenylation site. GDR1 alone inhibit GFAP expression in nonneuronal tissues, while both GDR1 and GDR2 inhibit the GFAP expression in neuronal cells.

GFAP In Development

In situ hybridization with a GFAP cDNA probe applied to the developing mouse brain has shown that mRNA levels with the astrocytes vary by a large amount depending on their location. In the adult brain, the astrocytes in the glial limitans contain the highest amount of GFAP mRNA with a decreasing amount localized to the white matter and gray matter (Lewis and Cowan, 1985). Employing Northern blot analysis with a GFAP cDNA probe (Lewis and Cowan, 1985), Landry et al. (1990) found that GFAP mRNA expression followed a caudal to rostral gradient, consistent with overall brain development. In a recent transcriptional study with a cDNA probe to GFAP, during mouse brain maturation, GFAP-mRNA occurred in a two-step developmental expression. It increased between birth and day 15 and then decreased until day 55 (Tardy et al., 1989; Riol et al., 1992). In a combined immunocytochemical and *in situ* hybridization study of the GFAP and

GFAP mRNA in the developing mouse retina, it was found that Müller cells do not express or contain low amounts of GFAP. GFAP-containing cells were found only in the ganglion cell and nerve fiber layers after postnatal day 1 and continue to form until P-10. GFAP-mRNA levels were high in the first week of birth and declined rapidly as the animal developed. During normal retinal development, GFAP and GFAP-mRNA were present only in astrocytes (Sarthy et al., 1991). A recent study by Erickson et al. (1992) reported that by RNA blotting analysis, normal cat retina expressed a low basal level of GFAP mRNA, which was induced 500% within 3 days of retinal detachment. Electron microscopic *in situ* hybridization analysis detected GFAP mRNA in detached retinas, but not in normal retinas. GFAP mRNA was readily detected in retinal astrocytes.

Developmental expression of GFAP mRNA has been reported in a number of astrocyte culture studies. During astroglial proliferation in culture (7 to 18 days), GFAP mRNA increased. A decrease followed with marked changes in cell shape, cell process outgrowth, and the accumulation of glial filaments (Charriere-Bertrand et al., 1989; Tardy et al., 1989); cAMP-stimulating agents increase GFAP levels (Hertz et al., 1978; Sensenbrenner et al., 1980; Goldman and Chiu, 1984b), while short-term treatment with cAMP-induced cell shape changes and no increase in GFAP. Increase in GFAP mRNA occurred only with long-term treatment (Le Prince et al., 1991). cAMP-dependent kinase and PKC may be regulating roles in determining GFAP mRNA levels (Shafit-Zagardo et al., 1988; Messens and Slegers, 1992).

GFAP In Reactive Gliosis

A timely, excellent review on the molecular profile of the reactive astrocyte documents the broad and continuing interest in astrogliosis. The numerous *in vitro* and *in vivo* studies of molecules, which are upregulated during astrocyte activation, illustrates their complex and varied responses (Eddleston and Mucke, 1993). Reactive astrogliosis is a prominent feature of astrocytes adjacent to and extending far beyond the site of injury. It occurs in central nervous system demyelination such as in MS and in degenerative diseases such as Alzheimer's disease, Creutzfeldt-Jakob's disease, and Huntington's disease. Gliosis is characterized by astrocyte proliferation and extensive hypertrophy of the cell body and cytoplasmic processes. Activated, reactive astrocytes exhibit cytological, biochemical, and histochemical transformations which include increases in nuclear diameter, elevated DNA levels, heightened oxidoreductive enzyme activity, and increased synthesis of GFAP, vimentin, glutamine synthetase, and glycogen (Eng and Shiurba, 1988). However, the biochemical events that precede and trigger astrocyte activation are unknown, and the proposed inhibitory effects of glial scarring on central nervous system repair, including neuronal regeneration and remyelination, remain unexplained at the molecular level.

Astrogliosis is thought to play a role in the healing phase following central nervous system injury by actively monitoring and controlling the molecular and ionic contents of the extracellular space of the central nervous system. Important extracellular constituents that may be regulated by reactive astrocytes include potassium ions, neurotransmitters, trophic factors, nutrients, and metabolic waste products. (For reviews, see Kimelberg and Ransom, 1986; Manthrope et al., 1986; Reier, 1986). Astrocytes participate in the removal of myelin and neuronal debris from injured areas. They also encapsulate regions of the central nervous system that are exposed to non-central nervous system tissue environments following trauma. In contrast to a role in healing central nervous system injury, gliosis may produce pathological effects by interfering with the function of residual neuronal circuits, by preventing remyelination, or by inhibiting axonal regeneration (Reier et al., 1983; Reier, 1986). It is therefore important to identify the essential molecular mechanisms that activate alternative metabolic responses in astrocytes in order to understand the pathogenesis of neuropathological lesions. These signals may result from anoxia due to disruption of the blood supply; dilution of inhibitory "chalones" around the injury site due to edema; changes in the ionic and molecular composition of the central nervous system extracellular fluid after disruption of the blood-brain barrier; release of growth factors and cytokines from non-central nervous system cells such as macrophages, T and B cells that may infiltrate the lesion; and loss of ionic coupling and release from cell density-dependent inhibition of growth due to increase in extracellular space. The signals also include factors from activated endothelial cells and microglia at the site of the lesion and secretion of mitogenic and trophic factors from degenerating neurons and oligodendroglia.

Astrogliosis is characterized by rapid synthesis of GFAP intermediate filaments and by hypertrophy of the astrocytic cytoplasmic processes. One can only speculate about the functional significance for this increase in IFs. Evidence from studies with rat optic nerve astrocyte cultures suggests that content and

subcellular distribution of IFs are important for cytoplasmic process formation and for structural stability of astrocytes. As mentioned previously, the relatively slow metabolic turnover rate for GFAP is consistent with such a structural role (DeArmond et al., 1983b, 1986; Smith et al., 1984b). Ultrastructural and immunocytochemical studies of astrocytic differentiation *in vitro* show that the flat, polygonal astroblast contains abundant microtubules and actin stress fibers; however, these elements progressively decrease, while GFAP increases during the change in shape of this astroblast to a stellate cell having slender, unbranched processes (Ciesielski-Treska et al., 1982a, 1982b; Trimmer et al., 1982).

Increased protein content or immunostaining of GFAP has been found in experimental models involving gliosis, such as the cryogenic lesion (Amaducci et al., 1981), stab wounds (Latov et al., 1979; Mathewson and Berry, 1985; Takamiya et al., 1986, 1988; Jeneczko, 1988; Miyake et al., 1988; Topp et al., 1989; Hozumi et al., 1990b; Vijayan et al., 1990), toxic lesions (Brock and O'Callaghan, 1987; Reinhard et al., 1988; Rataboul et al., 1989), and experimental allergic encephalomyelitis (EAE) (Smith et al., 1983, 1984a; Goldmuntz et al., 1986; Aquino et al., 1988).

Increase of GFAP-mRNA has been found in brains infected with scrapie and Alzheimer's disease (Wietgrefe et al., 1985); Creutzfeldt-Jakob disease (Manuelidis et al., 1987); in 6-hydroxydopamine lesion of the substantia nigra in the rat (Rataboul et al., 1988, 1989), in a mechanical lesion to rat cerebral cortex (Condorelli et al., 1990; Hozumi et al., 1990a; Landry et al., 1992); in entorhinal cortex lesions (Poirier et al., 1991); corticospinal axotomy (Kost-Mikucki and Olbinger, 1991), in EAE (Aquino et al., 1990), and in the lesioned dentate gyrus (Steward et al., 1990).

Transgenes

A transgenic vector containing almost the entire GFAP gene plus 5′ and 3′ flanking regions was fused to the *E. coli lacZ* structural gene. Injection of the GFAP-*lacZ* hybrid gene into the germline of mice yielded six different lines of transgenic mice. The expression of *lacZ* was astrocyte-specific. Upmodulation of transgene expression showed that induction of GFAP-*lacZ* expression was detectable within 1 hour after a focal mechanical lesion (Mucke et al., 1991). In a recent study, transgenic mice carrying the *lacZ* reporter gene linked to a 2.2 kb 5′ flanking sequence derived from the human GFAP gene were produced. This promoter directed expression to astrocytes and was also upregulated following injury to the brain. This approach can now be used to target expression of other heterologous genes to astrocytes *in vivo,* and to study the mechanism for reactive gliosis at the DNA level (Brenner et al., 1993). Cultured astrocytes prepared from GFAP *lacZ* transgenic pups implanted into brains of nontransgenic mice migrated to specific regions of the host brains and expressed the GFAP *lacZ* fusion gene for at least a year. Graft-derived astrocytes responded to focal injuries in these regions, but did not invade neural lesions in other areas. Their predictable migration and prolonged injury-responsive expression of GFAP driven transgenes should make these astrocytes potent vehicles for delivery of therapeutic agents (Mucke and Rockenstein, 1993).

Immunochemistry

GFAP and the other IFs share some chemical properties and common intramolecular polypeptide domains, however, GFAP also has some unique, highly immunogenic epitopes. We have produced specific GFAP antibodies in a rabbit immunized with MS plaque tissue that had been fixed in formalin for several years. These GFAP-specific epitopes are detected by high-affinity polyclonal antisera and monoclonal antibodies prepared from human and bovine GFAP. GFAP immunoreactivity in the mature central nervous system is restricted to glial filaments within protoplasmic astrocytes in gray matter, fibrous astrocytes in white matter, and radial glia in the cerebellum (Bergmann glia) and subependymal astrocytes adjacent to the cerebral ventricles. At the surface of the brain, GFAP immunoreactivity is especially concentrated in astrocytes which form the outer limiting membrane, the glia limitans. Polyclonal and monoclonal antibodies to GFAP have been extensively used for immunochemical and immunocytochemical studies (for reviews and discussions see Eng and Bigbee, 1978; Eng, 1979, 1980; Bignami and Dahl, 1979; Eng and DeArmond, 1983; Dahl and Bignami, 1983, 1985; Eng, 1985; Dahl et al., 1986; Eng et al., 1987.)

Mild tissue processing methods (i.e., unfixed, frozen, or freeze-substituted sections) and more sensitive detection procedures (immunogold labeling) have demonstrated GFAP-like immunoreactivity in regenerating teleost spinal cord, in Schwann cells, glialike cells in the myenteric plexus, Kupffer cells of the liver, salivary tumors, a pineal astrocytoma, and cells in the pineal gland. GFAP immunoreactivity has also been demonstrated in epiglottic cartilage, pituicytes and pituitary adenomas, immature oligo-

dendrocytes, papillary meningiomas, and metastasizing renal carcinomas. Mouse lens epithelium reacts with both polyclonal and monoclonal anti-GFAP antibodies.

Immunochemical application of GFAP antiserum has been used to quantitate GFAP in a variety of immunoassays. These include quantitative immunoelectrophoresis, competitive radioimmune assays, 2-site immunoradiometric assays, and enzyme-linked immunoassays (ELISA). Anti-GFAP antisera have been employed to isolate translated GFAP *in vitro* (Beguin et al., 1980), to immunostain and identify GFAP in transblots, and to identify reassembled GFAP fibers *in vitro* (Eng and Shiurba, 1988).

GFAP antibodies have been used extensively to identify astrocytes in normal, pathological, and experimental tissue. One must be cautious in interpreting immunocytochemical results. While positive staining may identify an astrocyte in the central nervous system, a negative result may be false. It is important to remember that this morphological technique is only indirect evidence for the presence of an antigen. The method of tissue processing is a very important factor. For example, the protoplasmic astrocyte in normal gray matter has a low content of GFAP and does not stain for GFAP when fixed in formaldehyde for an extended period of time. However, pretreatment of the formaldehyde-fixed tissue section with trypsin exposes more GFAP epitopes, which then can be detected by immunostaining. This has been confirmed on freeze-substituted brain tissue (see discussion in DeArmond and Eng, 1984). A much larger number of astrocytes immunostain for GFAP in the granule cell layer and white matter of the normal mouse cerebellum when the tissue is fixed by freeze-substitution instead of aldehyde (Figure 43-1). Monoclonal antibodies to GFAP have been generated that are specific and others that bind to both GFAP and vimentin (Eng, 1985; Pegram et al., 1985).

The intensity of GFAP immunostaining does not always correlate with GFAP content. Two examples are the rapid increase in GFAP staining seen 30 minutes after a cryogenic lesion of the rat brain (Amaducci et al., 1981) and that seen in the early stages of experimental allergic encephalomyelitis (EAE) (Smith et al., 1983). EAE is a cell-mediated autoimmune disease, which has been the principal experimental model for studying the etiology and pathogenesis of MS (Smith et al., 1984a; Eng et al., 1986b; Smith et al., 1987; Smith and Eng, 1988; Smith et al., 1988). Astrocyte proliferation and hypertrophy of cell processes appear very early in this model, coincidentally with the first inflammatory foci and is apparent by an increase in immunostaining of the astrocytes with GFAP antibodies without an increase in GFAP content (Smith et al., 1983; Goldmuntz et al., 1986). Aquino et al. (1988) have shown that this increase in GFAP immunoreactivity of the astrocytes without a corresponding increase in GFAP content is not due to an increase in GFAP epitopes resulting from limited proteolysis, to glial filament dissociation yielding an aqueous soluble fraction, or to differences in the avidity of a number of different antibody preparations tested. In acute EAE, the increase in GFAP immunostaining of the astrocytes is widespread and not confined to lesion sites (Smith et al., 1983). The reason for astrocyte hypertrophy and increased immunostaining for GFAP without a demonstrable increase in GFAP content is unknown. The onset of edema due to disruption of the blood-brain barrier and leakage of bloodborne substances into the central nervous system (Cutler et al., 1967; Juhler et al., 1984) may contribute to this phenomenon. Swollen astrocytic processes filled with disrupted bundles of glial filaments and glycogen particles have been shown by electron microscopy in edematous brain tissue (Kimelberg et al., 1982).

Recently we examined the early EAE lesion by electron microscopy and obtained results similar to that reported by Kimelberg et al. (1982). The astroglial processes contained many glycogen particles. The glial filaments were arranged in small bundles or loose thin filaments adjacent to the bundles. The glial filaments that normally appear as tight bundles expanded and appeared less dense (Figures 43-2 and 43-3). The general picture indicated that the first stages of EAE are pathogenetically related to an abnormal blood-brain barrier permeability. The "watery" cytoplasm of astrocytes at this early stage of EAE is most likely expressing a "partial" breakdown of the blood-brain barrier, resulting in intracellular (astrocytic) edematous fluid (Lee, 1982; Miquel et al., 1982). We have suggested that the increase in GFAP immunostaining, without an increase in GFAP content, is due primarily to the disruption of the blood-brain barrier. The resulting edema allows the tight bundles of glial filaments to dissociate and thus expose more antigenic sites (epitopes) to GFAP antibodies (Eng et al., 1989). GFAP intermediate filament dissociation can also explain the rapid increase in GFAP staining following cryogenic lesion of the rat brain without an increase in GFAP content (Amaducci et al., 1981).

Clinical Studies

Since the initial reports describing the use of GFAP antiserum for tumor diagnosis (Deck et al., 1976;

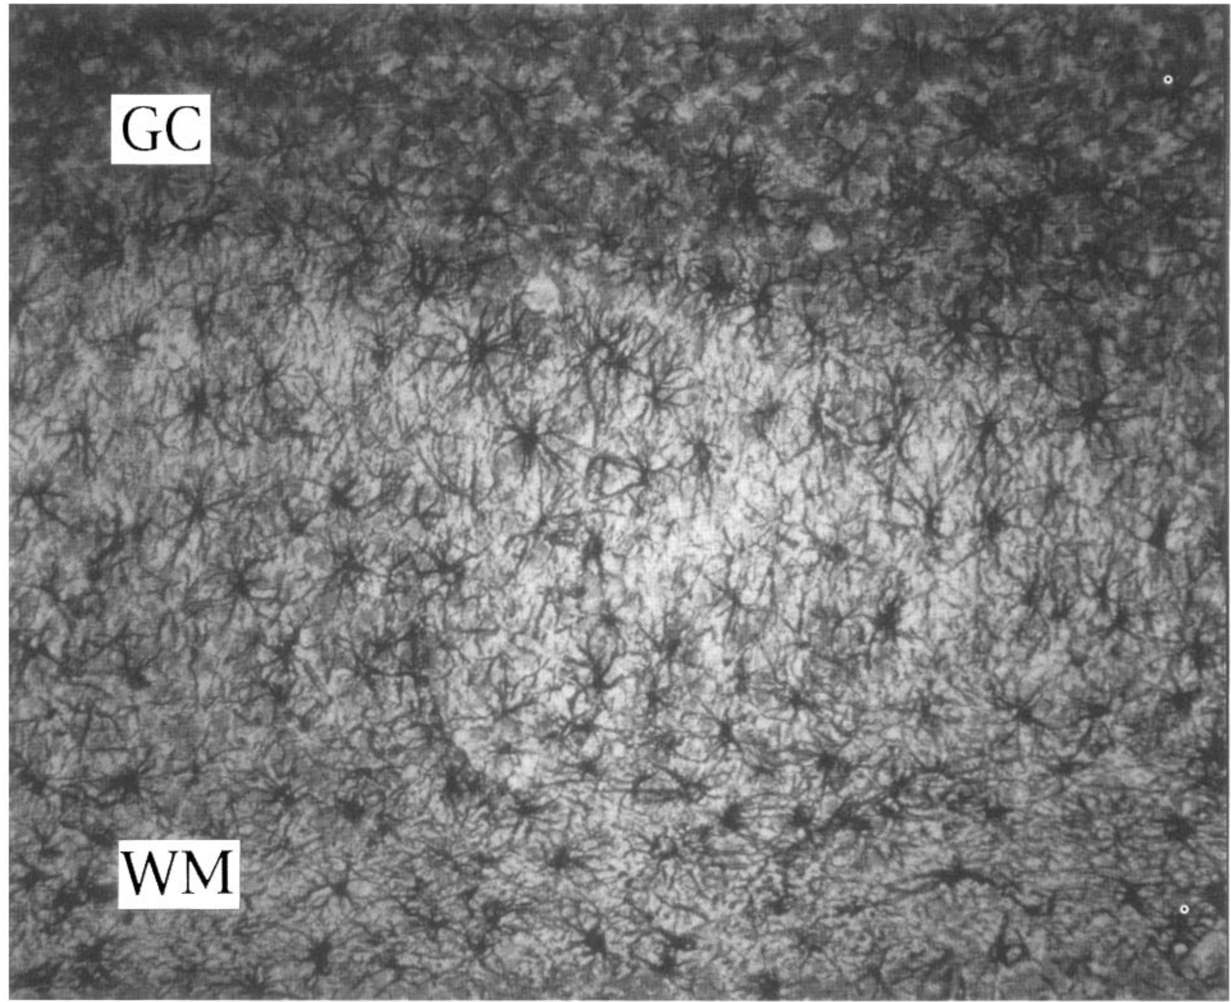

FIG. 43-1. A segment of mouse cerebellum was freeze-substituted in a mixture of chloroform, methanol, and acetone; the tissue was embedded in paraffin; a 5- to 6-μm section was immunostained with a polyclonal antiserum to human GFAP; and the GFAP visualized with the colloidal gold-silver enhancement technique. Note the dark silver-stained astrocytes in the granule cell layer (*GC*) and white matter (*WM*).

Duffy et al., 1977; Deck et al., 1978; Eng and Rubinstein, 1978), numerous reviews have appeared (DeArmond et al., 1980; Eng, 1980; DeArmond and Eng, 1984). Polyclonal and monoclonal antibodies to GFAP are used routinely in medical centers throughout the world to assist in the diagnosis of human neoplasms. It is always better to use a specific polyclonal antibody than a single monoclonal antibody for tumor diagnosis. A cocktail of three different monoclonal antibodies has been used successfully for identifying GFAP-containing tumor cells (McLendon et al., 1986).

Immunocytochemical assays, radioimmunoassays, and ELISA have been used to examine cerebrospinal fluid and body fluids from patients with MS, brain tumors, stroke, Alzheimer's disease, and other neurological diseases. GFAP has become an immunohistochemical marker for determining glial origin of many human brain tumors, and it may also provide a clinically useful tool for studying nonneoplastic central nervous system disorders.

FUTURE PROSPECTS

Morphological and metabolic studies indicate that GFAP may function by providing structural stability to the astrocyte and its processes. Other possible roles have not been demonstrated; however, many possible factors and biochemical mechanisms that may induce astrocyte activation are being studied. This reflects the availability of *in vitro* models, highly sensitive and specific analytical methods, monospecific antibodies, and cDNA probes. These

(**B**) The center of the picture is occupied by an extremely swollen astrocytic process with dispersed glial filaments (*arrows*) and scattered membranous structures. Figure A: ×12,150; Figure B: ×18,750. [From Eng et al. (1989), with permission.]

new tools have permitted the study of molecular mechanisms of GFAP synthesis and degradation, phosphorylation/dephosphorylation, and glial filament assembly.

What are the consequences of astrocyte activation and induction of GFAP synthesis in disease and central nervous system injury? Is this a beneficial or detrimental response to central nervous system injury? How can one modulate astrogliosis to promote healing and functional recovery of damaged neuronal pathways? Our working hypothesis is that control of astrocyte activation and astrogliosis may be linked to GFAP synthesis. For example, inhibition of GFAP synthesis immediately following injury may delay astrogliosis and allow neurons time to regenerate and oligodendrocytes time to proliferate and remyelinate. In addition, activation of GFAP synthesis in astrocyte tumors may induce terminal differentiation and mitotic arrest. Our investigations of the biological function of GFAP employ a correlated morphological and biochemical approach to understanding gliosis. We have developed an *in vitro* model of astrogliosis in which astrocyte cultures are mechanically damaged (Yu et al., 1993). Current molecular biological techniques allow us to modulate GFAP synthesis in this injury model. GFAP can be detected by quantitative polymerase chain reaction (Galea and Feinstein, 1992). A quantitative polymerase chain reaction method has been developed which permits the identification of rare mRNAs and the quantitation of small and large changes following activation (Murphy et al., 1993). We have utilized antisense GFAP oligonucleotides to inhibit its synthesis in response to cAMP in normal (Yu et al., 1991) and injured astrocyte cultures (Yu et al., 1993). When specific GFAP enhancer sequences are identified, retroviral antisense constructs could be synthesized and might be used to inhibit GFAP transcription. With the *in vitro* mechanical injury model, we can systematically test hormones, growth factors, and other chemical mediators that promote or inhibit astrogliosis. Additional factors include mitogens, neurotransmitters, neurotoxic chemicals, extracts of degenerating neural tissue, and adhesion molecules as well as phorbol esters and other activators of protein kinases. New information obtained from *in vitro* experiments can be tested with *in vivo* models. With this information, we may be able to identify the cellular source of each factor and whether each response is beneficial or detrimental to central nervous system regeneration. This may allow us to design specific treatments to promote regeneration and function in the injured central nervous system. These treatments could employ antisense oligonucleotides, antibodies, growth factors, enzymes, pharmaceutical drugs, and gene therapies.

We thank Donna L. Buckley for preparation of the manuscript and Drs. Jianxin Bao and Roopa Ghirnikar for providing valuable comments on the manuscript. This study was supported in part by the Department of Veterans Affairs Medical Research Service and NIH grant NS-11632 (Javits Neuroscience Investigator Award to L.F.E.).

IX Glia as Part of the Immune System

This page intentionally left blank

44 Microglia and neuronal dysfunction

DANA GIULIAN

Microglia are a class of mononuclear phagocytes intrinsic to the central nervous system and are the principal immune effector elements of the brain (Giulian, 1987). Although microglia do not cause disease, they react to it and ultimately help to determine the pattern and degree of central nervous system recovery of function (Giulian, 1992b) through the secretion of bioactive agents including cytotoxins (Giulian, 1990). These cells, moreover, are closely associated with such diverse clinical problems as Alzheimer's disease, trauma, stroke, epilepsy, and acquired immunodeficiency syndrome (AIDS) (Giulian, 1992a). As argued here, future strategies to treat neurologic disorders will need to mitigate microglial disruption of neuronal function.

HISTORY

Rio Hortega (1932) described microglia as argentophilic cells with two or more "wavy, branched processes beset with spines." These ramified microglia were thought to make up at least 20% of the total glial population in normal, mature central nervous system. Further investigation showed that "ameboid" microglia emerged during embryonic development with such macrophagic properties as migratory capacity and phagocytosis. During central nervous system injury, ramified microglia retracted processes, became more ameboid-like, and transformed into a third form, the reactive microglia (Figure 44-1).

What is the origin of microglia? This question remains unanswered in part because of the lack of cell-specific markers suitable for study of early embryonic development (see Chapters 5 and 10). Rio Hortega (1932) felt that microglia arose from the mesoderm, first appearing as "roundish cells with pseudopodia." At present, most investigators agree that microglia arise during early embryonic development from blood precursor elements and later proliferate *in situ*. The bone-marrow chimera studies of Hickey and Kimura (1988) also indicate that perivascular central nervous system mononuclear phagocytes, but not parenchymal microglia, are exchanged with blood monocytes throughout normal adult life. In pathological situations, the origin of activated brain mononuclear phagocytes becomes more complicated. Invading blood-borne macrophages as well as reactive microglia were found after penetrating wounds (Giulian et al., 1989) or at sites of inflammatory-mediated demyelination (Hickey, 1991a). By contrast, microglia, but not invading macrophages, reacted to axotomy of the facial nucleus (Graeber et al., 1988). As noted by Rio Hortega, reactive microglia eventually take part in every type of inflammatory or necrotizing process in the brain.

MICROGLIA AS A DISTINCT CLASS OF MONONUCLEAR PHAGOCYTES

In vitro studies have been used to compare ameboid microglia with such other classes of mononuclear phagocytes as peritoneal macrophages, splenic macrophages, blood monocytes, and bone marrow progenitor cells (promonoblasts and monoblasts) (Metcalf, 1984). When grown under identical conditions in chemically defined culture medium, all mononuclear phagocytes possessed scavenger receptors that could be identified using a fluorescently labeled acetylated low-density lipoprotein (ac-LDL) (Figure 44-2). Microglia and macrophage were active phagocytes with very little response noted in marrow cells. Ameboid microglia and macrophages displayed chemotaxis. Spontaneous proliferation was noted for microglia, but not macrophages or monocytes; marrow cells would proliferate but only in the presence of growth factors. Ameboid microglia developed long, thin projections (up to several hundred microns in length), which resembled the branches of ramified microglia in tissue (Figure 44-3), while neither macrophages (short, stubby processes, if any) nor marrow cells (round or oval) displayed similar patterns of morphologic differentiation.

In another line of investigation, Kettenmann and coworkers (1991) have shown that membrane channel properties in microglia can be distinguished from

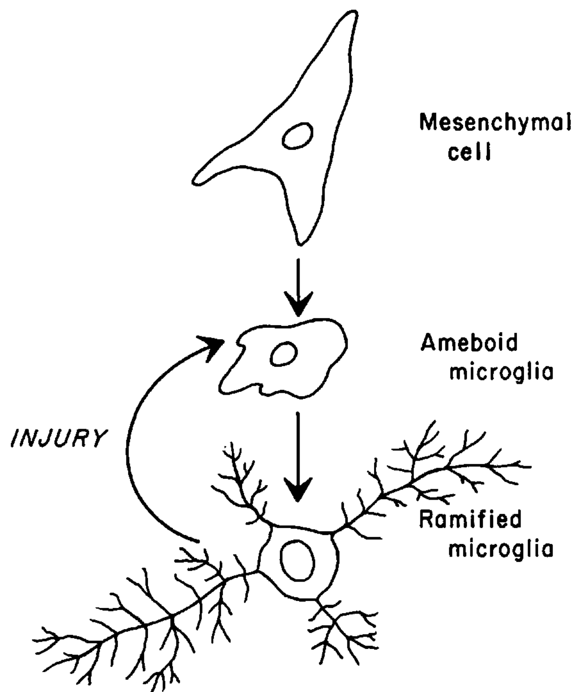

FIG. 44-1. The current view of microglial development. During early embryogenesis, mesenchymal cells migrate into the central nervous system. The earliest form of microglia are ameboid cells that show such macrophage properties as phagocytosis, release of cytokines, and scavenger receptors. During the postnatal period, microglia undergo differentiation to become ramified cells. These process-bearing cells lack macrophage properties and have no known function. However, at times of injury reactivation of the quiescent ramified cells occurs with retraction of processes and reappearance of macrophage functions.

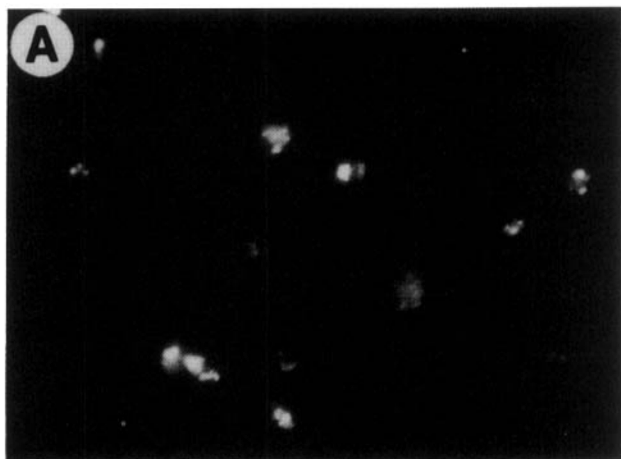

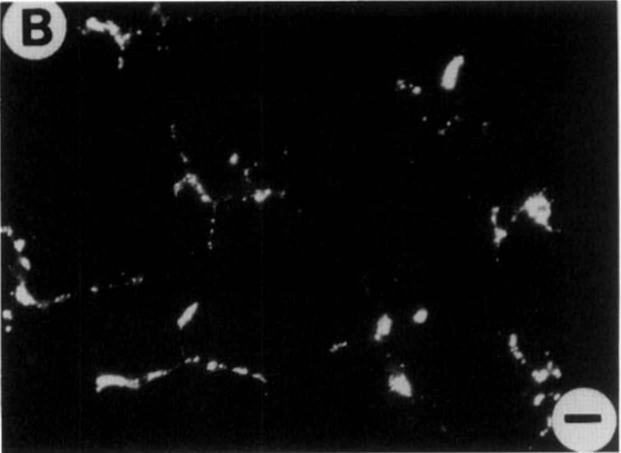

FIG. 44-2. Fluorescence photomicrographs showing cultures of rat peritoneal (A) macrophages or (B) microglia after 30 days *in vitro*. In chemically defined medium, macrophages take on a condensed, ameboid form with short, stubby processes. In contrast, microglia project thin processes that extend over hundreds of microns. The process-bearing microglia eventually lose macrophage properties and resemble ramified microglia found in tissues. Cells are labeled with a fluorescent probe for the ac-LDL receptor. Bar = 20 μm.

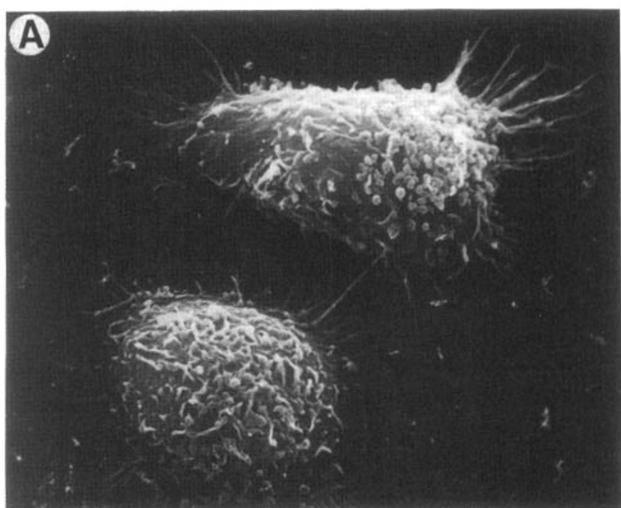
those in macrophages and blood monocytes. Using patch-clamp techniques, they found both ramified and ameboid microglia to contain large inward-directed rectifying currents dependent on K^+ (as indicated by reversal potentials and sensitivity to channel blockers). In contrast, macrophages displayed both a large outward rectifier current and a small inward one, while a subpopulation of bone marrow precursor cells had an inward-directed rectifying currents similar to that of microglia (Banati et al., 1991).

Present evidence, therefore, suggests microglia to be a distinctive class of mononuclear phagocytes that persist within the central nervous system after the perinatal period. In the ameboid form, microglia showed some properties common to tissue macrophages (surface markers, production of cytokines and cytotoxins) but displayed other features associated with bone marrow progenitor cells (proliferative capacity, response to colony-stimulating factors, and similarities in membrane current properties). It seems that these brain glia express a wide spectrum of features, ranging from those found in the more primitive as well as in the highly differentiated forms of mononuclear phagocytes. The overall pattern suggests a unique set of qualities that may have arisen during adaptation to the central nervous system (Giulian, 1992b).

REGULATORS OF MICROGLIAL REACTIVITY

Microglia found in the mature central nervous system are quiescent, ramified cells with no recognized function (Rio Hortega, 1932; Giulian, 1987; Giulian, 1992). Within days after central nervous system insult, ramified microglia expressed scavenger recep-

tors, retracted processes, migrated to areas of tissue debris, and engaged in vigorous phagocytosis. Membrane receptor densities often increased very rapidly and were among the first changes seen in reactive cells (Giulian et al., 1989). For example, microglia abutting damaged neurons displayed complement receptors within hours after axotomy of the facial nerve (Graeber et al., 1988). This precise pattern of cell activation suggested the early presence of a short-range signal (perhaps an unstable soluble factor or a contact-mediated event) to rouse close neighbors. In general, the range of microglial responses to central nervous system damage varied widely, with some cells showing only surface membrane changes or altered morphology, while others displayed full-blown phagocytic and secretory activities. For example, rod cells and lamellar cells (altered shapes) were associated with chronic infections such as rabies or tertiary syphilis, while rapidly appearing fat granule cells (active phagocytes) engulfed necrotic tissue (Rio Hortega and Penfield, 1927). Although signaling mechanisms doubtlessly vary with neuropathic conditions, the activation of microglia is a response common to all inflammatory and necrotizing processes in the brain. Thus, strategies to block microglial activation may prove effective in suppressing central nervous system inflammation.



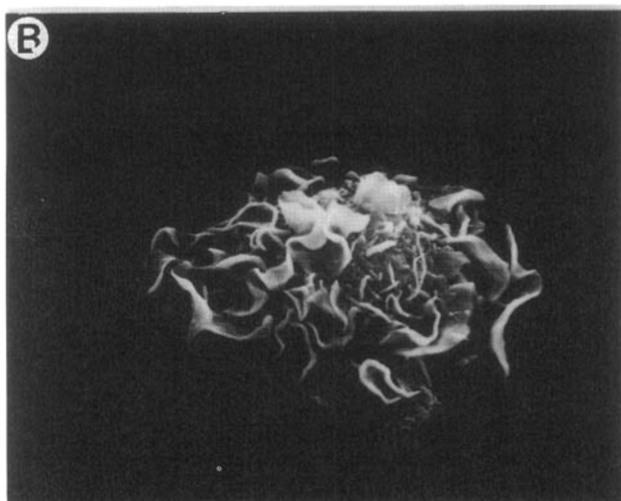


FIG. 44-3. (**A**) Cultured ameboid microglia have a surface morphology that can be distinguished from that of (**B**) tissue macrophages, using scanning electron microscopy. The characteristic spiny projections of microglia remind one of comments from Rio Hortega. [From Giulian and Baker (1986), with permission.]

What specific signals drive microglia to a reactive state? Rio Hortega (1932) has suggested that neuronal debris, blood clots, and dead cells are among the most potent signals to elicit reactive microgliosis. In culture systems, phagocytic signals (yeast wall particles or zymosan; fixed bacteria such as *Staphylococcus aureus*), cytokines, including interferon γ, and a variety of other immunoactivators (lectins, lipopolysaccharides, and phorbel esters) as scavenger receptor ligands and gp120, the coat glycoprotein of human immunodeficiency virus-1, have been used to elicit microglial secretion, changes in shape, appearance of surface markers, or chemotaxis responses (Giulian and Baker, 1986; Giulian, 1987; Giulian et al., 1991; Giulian et al., 1993b) (Table 44-1).

Immunomodulators have also been implicated as microglial activators *in vivo*. Hickey (1991b), for example, finds that systemic injections of tumor necrosis factor alpha (TNFα) elicit microglial major histocompatibility complex (MHC) class II receptors. Perhaps systemic immune responses, which generated cytokine release, initiate a reactive state within the brain. Granulocyte macrophage colony-stimulating factor (GM-CSF) has been found to expand microglial populations after infusion into brain tissues

TABLE 44-1. *Signals That Activate Microglia in Culture*[a]

Lipopolysaccharide
Phagocytic signals
Stimulation of neurotoxin release
Zymosan A
gp120 Viral protein
Scavenger receptor ligands

[a] *In vitro* studies show that a variety of agents promote microglial proliferation or secretory activity. Lipopolysaccharides stimulate release of such cytokines as interleukin-1 and tumor necrosis factor but not of neurotoxins. In contrast, the viral protein gp120 elicits neuron-killing factors but not cytokine secretion. These differential effects of activators suggest that cytokine and cytotoxin secretory mechanisms are independently regulated and point to discrete events that govern particular immune responses in the central nervous system.

(Giulian and Ingeman, 1988), and a GM-CSF-like factor has been recovered from injured brain (Giulian et al., 1991). Microglial sensitivity to immunoregulatory signals represents, therefore, an important link between immune and neural tissues.

MICROGLIA, ASTROGLIA, AND NEURONAL INJURY

Mononuclear phagocytes secrete cytotoxic factors (Adams, 1980; Khoo et al., 1981; Colton and Gilbert, 1987), which can be classified as short-lived (i.e., nitric oxide, hydrogen peroxide, or superoxide anion) or long-lived cell poisons (cytokines and enzymes; Table 44-2). Because cytotoxins have been implicated in various neurologic disorders, it was likely that brain inflammatory cells were important sources of these neuron-killing factors (Giulian, 1990; Giulian et al., 1990). In cell culture, microglia from newborn brain secreted neuron-killing factors, while astroglia released neuronal growth factors (Figure 44-4). The astroglial factors were found to be large molecules (>10 kD) (Vaca and Wendt, 1992; Giulian et al., 1993a), and the secreted microglial factors were heat-stable toxins of low molecular mass (Table 44-3). The astroglia-derived growth factors were proteins, sensitive to proteases and heat. Although not further characterized, these proteins probably included such astroglia-derived growth factors as neurotrophin-3, brain-derived growth factor, and ciliary neurotrophic factor (Ferrara et al., 1988; Manthorpe et al., 1989; Stockli et al., 1989). The microglia-derived neuron-killing factors were toxic to chick ciliary neurons and rat hippocampal and spinal cord neurons, but not to brain glia (Giulian et al., 1993a). Phagocytic signals (zymosan, fixed *S. aureus*) or scavenger receptor ligands were required to drive microglia from newborn brain to discharge neurotoxins (Table 44-1). The fact that lipopolysaccharide, a commonly used stimulant for cytokine release, did not elicit significant neuron-killing activity (Giulian et al., 1993b) suggests separate control mechanisms for release of cytokines and cytotoxins.

[a]Examples of molecules secreted by mononuclear phagocytes that have cytotoxic properties. Target cell sensitivities and conditions under which these factors act as poisons vary considerably. However, the large molecules tend to be proteins with long-lived activity, while the small molecules are nonproteinaceous with short-lived actions. The unidentified microglial neurotoxins, in contrast, are small molecules with long-lived action.

MICROGLIAL-DERIVED NEUROTOXINS

The neurotoxic activity recovered from mononuclear phagocytes was stable in storage at −80°C and resistant to boiling (Table 44-3). Although brain mononuclear phagocytes were known to produce free radical intermediates with cytotoxic actions (Table 44-2), such highly reactive molecules would be heat-sensitive, and, therefore, not be responsible for the neuron-killing effects observed here. The inflammatory cell-derived neurotoxic activity was also resistant to proteinase K (100 μg/ml for 60 minutes at 37°C), ruling out protein cytokines and large peptides as toxic agents. Gel filtration chromatography showed that neuron-killing activities from all sources were small molecules, <500 Daltons.

Excitatory amino acids and their metabolites (as small, heat-stable, protease-insensitive agents) can serve as neurotoxins in the mammalian brain by acting through the *N*-methyl-D-aspartate (NMDA) class of glutamate receptor (Dingledine, 1986; Honore, 1989). The selective NMDA antagonist 2-amino-5-phosphopentanoic acid (AP5) and NMDA-receptor ion channel blocker MK801 protected against the neurotoxicity secreted by mononuclear phagocytes, while the antagonists to non-NMDA-type glutamate receptors [2-amino-3-phosphonopropanoic acid (AP3), 6-cyano-7-nitroquinoxoline-2,3-dione (CNQX) and gamma-D-glutamylaminomethylsulfonic acid (GAMS)] did not do so (Table 44-3). The microglia-derived neurotoxins could be separated from such NMDA agonists as excitatory amino acids, quinolinic acid, and polyamines by ion exchange chromatography and reverse-phase high-performance liquid chromatography (Giulian et al., 1993a). In addition, partially purified neurotoxins showed very low concentrations of the excitatory amino acids glutamate and aspartate (<100 pM), or quinolinic acid (<2 nM), which were all below the toxic range for cultured ciliary neurons (Giulian et al., 1993a). Microglia, therefore, released a class of small, stable neuron poisons with actions mediated

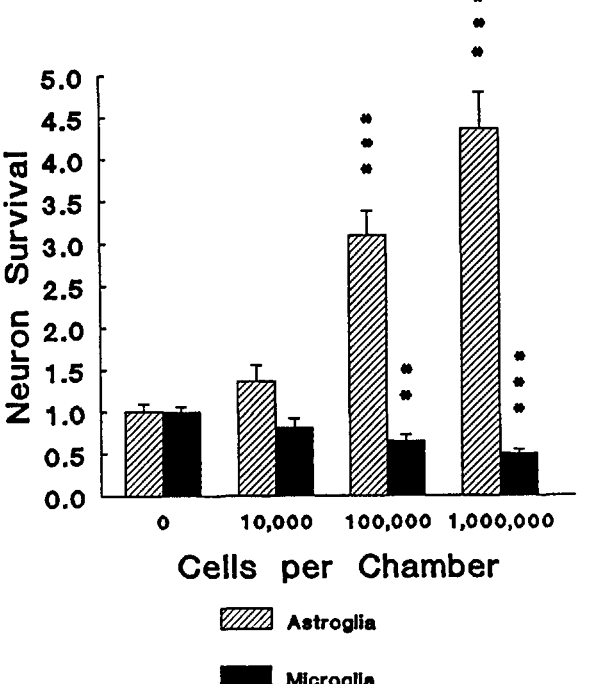

FIG. 44-4. Microglia secrete neurotoxins and astroglia release neuron survival-promoting factors. Isolated DiI-ac-LDL(+) microglia (>98% homogeneity) or GFAP(+) astroglia (>99% homogeneous population) were seeded at the densities indicated and placed in MilliCell-CM chambers. The chambers were then placed into wells (12 well plates; 3.8 cm^2 per well) and cocultured for 48 hours with approximately 8000 chick ciliary neurons per well grown on poly-L-lysine-coated glass coverslips. Both microglia and astroglia were incubated with zymosan A particles. Viable neurons were identified by phase contrast microscopy at ×200 magnification. Neuron survival scores (neurons per field in treated group/neurons per field in the untreated control group) are presented as mean values ± standard error. Each value was obtained from 18 fields per coverslip, using at least 4 coverslips per group. Zymosan A particles placed in the MilliCell-CM chambers alone did not affect neuronal survival. Significant differences among controls and microglia or astroglia cocultures are noted at 100,000 and at 1,000,000 cell concentrations using Student's *t* test ($^{**}p < .001$; $^{***}p < .0001$) with a confidence level for 6 comparisons estimated at $p < .008$ using the Bonferroni method.

by NMDA receptors that could be distinguished from known brain-derived NMDA agonists.

Since our initial observations, the concept of activated microglia as a source of neurotoxic factors has been confirmed by other investigators in a number of different settings. During the past few years, Pulliam et al. (1991) and Piani et al. (1991) have described microglial release of neurotoxins in different cell culture systems. There has also been extensive work on microglial secretion of free radicals in the laboratories of Colton and Gilbert (1987) and Thery et al. (1991). More recently, *in vivo* experiments from Thanos et al. (1993) have suggested mononuclear phagocyte-mediated damage of neurons. Thus, the release of microglia-derived cytotoxins appears to be a common pathway in many neuropathological processes.

MICROGLIA AND TRAUMATIC BRAIN INJURY

Cell culture experiments demonstrated that astroglia or microglia could regulate neuron survival through the actions of secretion products. By combining glial secretion products, it was apparent that increasing amounts of astroglial-conditioned medium attenuated the toxic effects of microglia (Figure 44-5). This *in vitro* competition between glial populations suggested that opposing secretory mechanisms might influence *in vivo* tissue viability. To test such a hypothesis, different types of central nervous system injury were monitored for tissue production of neuron-promoting or neuron-killing factors.

Penetrating trauma to the rat neocortex elicits an inflammatory response marked by the appearance of both reactive microglia and invading macrophages which bear scavenger receptors within 5 to 8 hours after injury (Giulian et al., 1989). The greatest number of these inflammatory cells appear at 2 days after injury (Figure 44-6A; from Giulian et al., 1993a). To monitor the presence of neurotoxins during the course of central nervous system injury, punch microdissections of wound sites (recovered 12 hours to 7 days after trauma) were incubated in culture medium and tested for effects upon ciliary neuron assay. Although little cytotoxic activity was detected before or after the peak of inflammation, nearly 50% of neurons were destroyed when incubated with tissue-derived factors isolated 2 days after trauma (Figure 44-6C). These neurotoxic factors were of low molecular mass (<1 kD), were blocked by the NMDA antagonist AP5, and appeared identical in action to those toxins derived from isolated microglia (Table 44-2). Further study showed that media conditioned by injured tissue also contained neuron-promoting factors (Figure 44-6B) as noted by other investigators (Needels et al., 1987). These factors were trypsin-sensitive growth-promoting molecules (>10 kD), present in undamaged tissues (Table 44-3), and similar to proteins derived from cultured astroglia (Giulian et al., 1993a; see also Chapter 30).

MICROGLIA AND CENTRAL NERVOUS SYSTEM ISCHEMIA

Ischemia to the central nervous system can produce a delayed decline in neurologic function that occurs

TABLE 44-3. *Cell Types and Release of Neuron Growth-Regulating Factors*[a]

	Microglia	Astroglia	Reactive Phagocytes
Promotes neuron survival	No	Yes	No

NMDA, *N*-methyl-D-aspartate; AP5, 2-amino-5-phosphopentanoic acid; GAMS, gamma-D-glutamylaminomethylsulfonic acid; CNQX, 6-cyano-7-nitroquinoxoline-2,3-diones.
[a]Properties of molecules released by microglia and astroglia isolated from neonatal brain or from reactive mononuclear phagocytes isolated from adult brain damaged by ischemia. Conditioned media were heated by boiling for 10 minutes at pH 7.4. Protease treatments for factors from microglia and reactive cells involved proteinase K (1 μg/ml) for 2 hours at 37°C and stopped by ultrafiltration. Astroglial factors were incubated with trypsin (1 μg/ml) for 2 hours at 37°C and then inhibited with soybean trypsin inhibitor (2 μg/ml). Toxic activities from microglia and reactive phagocytes were associated with small, stable, nonproteinaceous molecules mediated through NMDA receptors. In contrast, astroglia released growth-promoting proteins whose actions involve calcium L-channels.

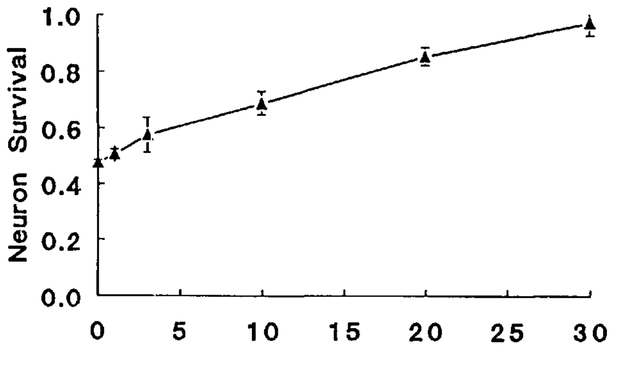

FIG. 44-5. Opposing effects of glial secretion products upon neuronal survival. Ciliary neurons were treated with microglial toxic activity (20% conditioned medium by volume from 10^6 cells activated with zymosan for 48 hours) in the presence of growth factors found in equal volume of medium conditioned by astroglia (from 10^6 cells incubated with zymosan). As shown, astroglial factors attenuated the microglial toxins. Such observations suggest that different glial populations have competing actions upon the survival of neurons. Neuron survival scores (neurons per field in treated group/neurons per field in the untreated control group) are presented as mean values ± standard error. Significant differences were noted between astroglia and other treatment groups using the Student's *t* test ($**p < .001$).

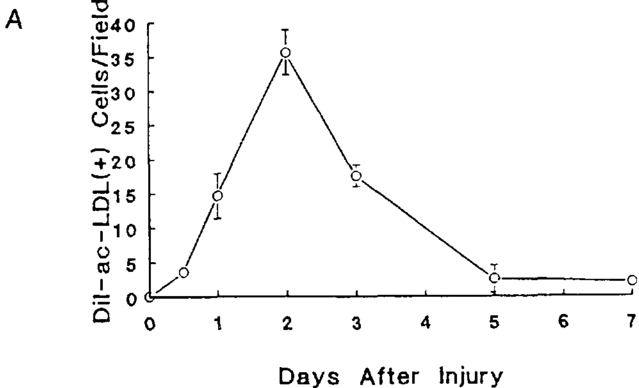
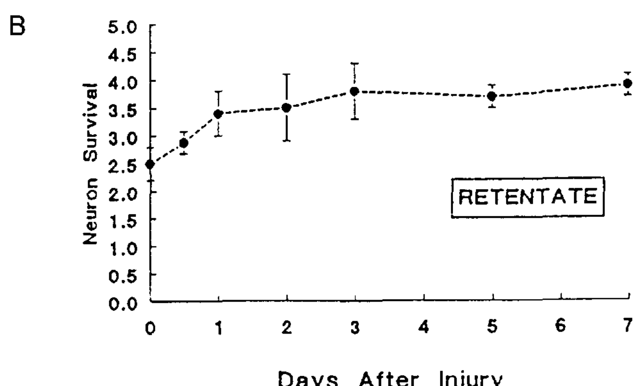
within the first several days after injury. Transient occlusion of the rabbit abdominal aorta (20-minute occlusion) caused ischemic damage in the spinal cord with a striking inflammatory response seen within the first 24 hours (Giulian and Robertson, 1990), particularly at sites of neuronal damage in the lower lumbar cord. Serial sections of spinal cord (extending from the lower thoracic to upper sacral) were placed in culture dishes containing neurons and after a 24-hour coculture period, punch microdissections of grey matter were taken of the tissue sections to monitor the presence of DiI-ac-LDL(+) mononuclear phagocytes. Spinal cord tissue from a normal rabbit contained astroglia with glial fibrillary acidic protein (GFAP), lacked DiI-ac-LDL(+) mononuclear phagocytes, and released growth-promoting factors that increased neuronal survival by 2- to 3-fold (Figure 44-7A). In general, the spinal cord damaged by ischemia was less supportive of neuronal growth with some contiguous sections of tissue showing significant release of neuron-killing activity (Giulian and Vaca, 1993) (Figure 44-7B). Importantly, tissues taken from a region of the lower lumbar cord both produced a striking reduction in neuron survival and





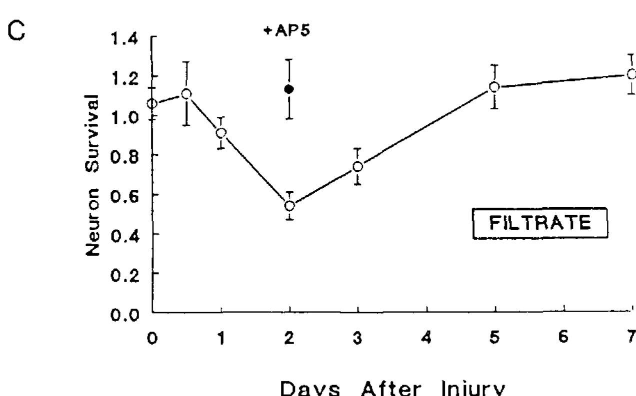


FIG. 44-6. Traumatic injury to the neocortex of adult rat elicits tissue production of neurotoxins. (A) Time course of inflammation at the site of a penetrating wound placed 1.0 mm from the surface of the brain. The peak number of DiI-ac-LDL(+) mononuclear phagocytes occurs at about 2 days after injury. Data represent mean values ± standard error taken from at least 10 fields per punch microdissection when viewed at ×200 magnification. Ultrafiltration of media conditioned by wound site tissues showed the presence of both (B) neuron-promoting factors (retentate >3 kD) and (C) neurotoxins (filtrate <3 kD). The neurotoxic effects for tissue-derived toxins were blocked by 10 μM AP5 as noted for microglia-derived cell poisons ($p < .01$ by Student's t test). The greatest concentrations of neurotoxic activity were recovered at 2 days after injury or the peak of the inflammatory response. Values are expressed as mean neuronal survival score ± standard error with conditioned media tested at concentrations of 20% by volume.

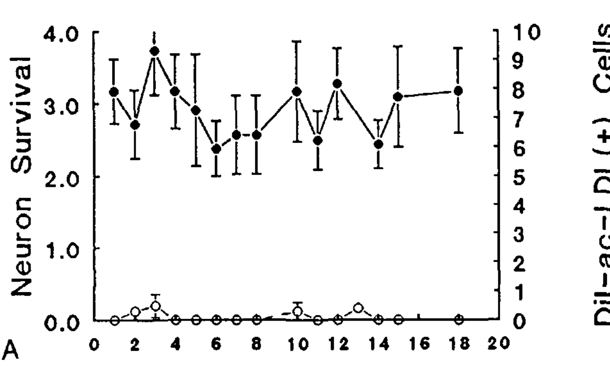
held the largest population of DiI-ac-LDL(+) cells (Figure 44-7B). Tissues most heavily infiltrated with activated mononuclear phagocytes were, therefore, the greatest source of neuron-killing activity.

To confirm the cellular sources of the neurotoxic activity within damaged spinal cord, central nervous system mononuclear phagocytes were isolated by selective adherence to plastic. More than 90% of cells



Ischemic Injury

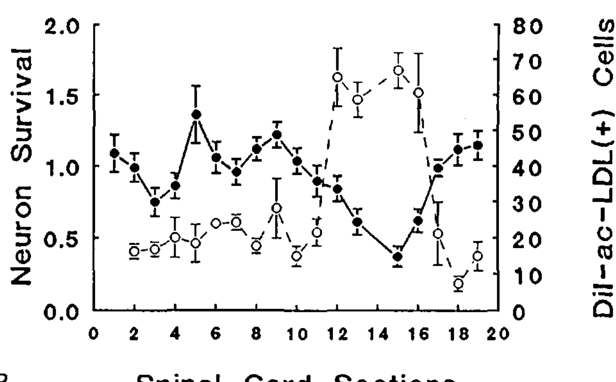


FIG. 44-7. The spinal cord of rabbit releases neurotoxins when damaged by ischemia. (A) Serial sections (1 cm thick) obtained from the lumbar spinal cord of a normal rabbit were coincubated with ciliary neuron cultures for 24 hours. In the presence of normal rabbit tissue, neuron survival was increased by about threefold. Undamaged tissue showed no evidence of reactive mononuclear phagocytes as determined by labeling with DiI-ac-LDL. (B) In contrast, serial sections obtained 2 days after ischemic injury showed inflammatory cells throughout the lumbar spinal cord with heavily inflamed tissue noted in lower region of the cord. These same sections (sections 12 through 16) showed the greatest production of neuron-killing factors demonstrated by the decline in ciliary cell survival. These observations point to a close association between central nervous system inflammation and the release of neurotoxins. Assays were performed upon coded, randomized samples with values expressed as mean survival scores ± standard error. Mononuclear phagocytes in spinal cord sections were viable as demonstrated by the ability to endocytose DiI-ac-LDL.

recovered from rabbit spinal cord were DiI-ac-LDL(+) macrophagelike phagocytes laden with debris. These cultured cells released a neurotoxin of low molecular mass that was sensitive to AP5 blockade (Giulian and Vaca, 1993). In contrast, nonadherent, DiI-ac-LDL(−) cell populations (containing >75% GFAP(+) astroglia) produced factors promoting neuronal growth. These results further supported the idea that reactive microglia were a source of neuronal poisons, while neighboring astroglia sustained neuron survival.

IMMUNOSUPPRESSION AS TREATMENT FOR ISCHEMIC INJURY

Time course studies have suggested that reactive mononuclear phagocytes migrate to the site of injury and engulf debris prior to the release of cytotoxic factors (Figure 44-6; Giulian, 1992). Suppression of such initial cellular events, therefore, might offer some clinical benefit by preventing subsequent production of neuron poisons. Drugs, known to inhibit endocytosis, phagocytosis, and secretory function in mononuclear phagocytes have been tested as potential suppressants of central nervous system inflammation (Giulian et al., 1989; Giulian and Robertson, 1990). Chloroquine and colchicine, when given by intraperitoneal injection at 60 minutes after ischemic injury, reduced the numbers of these scavenger receptor bearing cells by about 75% at the site of infarction. A similar inhibition was noted when comparing factors released from 2-day-old infarcts with factors recovered from lesions 1 day after injury (prior to the appearance of most activated mononuclear phagocytes) or from drug-treated animals 2 days after injury. Tissues damaged by ischemia, but containing few inflammatory cells, released no measurable neurotoxic activity, whereas inflamed tissues released factors that killed neurons. Thus, in the absence of an inflammatory reaction, severely damaged neural tissues did not produce significant amounts of neurotoxic activity. However, animals that received chloroquine plus colchicine at the time of middle cerebral artery occlusion also showed no reduction in the volume of infarcted tissue. Thus, it was not likely that the direct tissue injury brought on by ischemia (which rapidly destroyed both neurons and glia at the site of infarction) was under immune control. Although quiescent brain mononuclear phagocytes did not effect neuronal sensitivity to acute ischemic insult, reactive phagocytes did influence neuronal survival, but at a later period.

Does immunosuppression alter functional recovery after injury? As noted earlier, a moderate degree of ischemia elicited a large number of reactive mononuclear phagocytes in the rabbit spinal cord. The close association between the appearance of activated mononuclear phagocytes and deterioration in hindlimb function suggested an immune-mediated loss of function (Giulian and Robertson, 1990). To test this hypothesis, chloroquine and colchicine were given at 6 hours after injury and continued for a total of 3 days. Transverse sections of the lumbar spinal cord showed that the gray matter of control animals have massive invasions of phagocytes whereas drug-treatment led to a substantial reduction of inflammation (Table 44-4). Importantly, far more surviving neurons were found in the anterior horn of animals receiving chloroquine and colchicine than in control animals (Table 44-4). Control animals typically have a decline in hindlimb function by 24 to 36 hours after injury. In contrast, chloroquine-colchicine-treated animals either maintained a high level of function or showed improvement from the baseline examination obtained prior to treatment (Table 44-4). This level of hindlimb strength remained stable for at least 7 days after injury as did bladder function. Thus, early control of central ner-

TABLE 44-4. *Effects of Immunosuppression After Ischemic Damage to Rabbit Spinal Cord*

	Control	Chloroquine /colchicine
Histologic findings		
Reactive mononuclear phagocytes (cells per field)	58 ± 6	5 ± 3
Motor neuron survival (%)	28 ± 6	77 ± 10

Following occlusion of the abdominal aorta for 20 minutes, rabbits were treated with chloroquine + colchicine (1.0 mg/kg and 0.2 mg/kg, respectively) per day for 3 days. The numbers of DiI-ac-LDL(+) mononuclear phagocytes found in gray matter of lumbar spinal cord at 3 days postinjury were significantly reduced by drug treatment when compared to untreated controls ($p<.001$ by Student's t test). Values are expressed as mean number of cells ± standard error per field (×200 magnification).

Reduction in the inflammatory response by chloroquine plus colchicine is correlated to an increase in motoneuron survival ($p<.005$ by Student's t test). Values are expressed as mean percent motor neuron survival (number of neurons in treated group/number of neurons in normal animals) ± standard error. Scoring used coded cresyl violet-stained sections (20 μm thick) of spinal cord at the level of L5. Normal animals showed 18.1 ± 0.5 large neurons per field of the anterior horn when viewed (×200 magnification).

	Control	Chloroquine /colchicine
Functional outcome		
Hopping behavior	0/6	4/6
Bladder control	1/6	5/6

Immunosuppression began at 6 hours after injury with one intravenous dose of 1 mg/kg chloroquine plus 2.5 mg/kg per day of chloroquine intramuscularly and 0.2 mg/kg per day colchicine intravenously. Identical daily doses of intramuscular chloroquine and intravenous colchicine were given for 3 days. Motor and bladder examinations were performed every 6 to 8 hours for 7 days.

vous system inflammation improved long-term recovery of neurologic function.

MICROGLIA AND EPILEPSY

Although trauma, meningitis, and encephalitis have been associated with the onset of seizures, the mechanisms by which these pathologic conditions produced aberrant electrical discharges are unknown. One feature common to these diverse central nervous system injuries was the presence of brain inflammation. Since blood-borne invading macrophages and reactive microglia secreted a complex mixture of substances, including arachidonic acid metabolites, cytokines, amino acids, and cytotoxins, it seemed reasonable that inflammatory cells might also secrete factors that alter electrical activity within the central nervous system.

The hippocampus has a propensity for epileptiform activity (Alger, 1984) and can be a site of origin for complex partial seizures. Moreover, the cellular organization of the CA3 region in the hippocampus consists of many local circuits capable of synchronous bursting, the hallmark of epileptiform activity (Johnston et al., 1986). For these reasons, factors secreted by activated mononuclear phagocytes were examined for effects upon electrical activity in the CA3 region of the hippocampal slice preparation (Rutecki et al., 1985). Brief exposure to microglial or macrophagic secretion products induced a series of epileptiform discharges in tissue slices (D. Giulian and P. Rutecki, unpublished observations).

The observation that inflammatory cells release neuroexcitants opens a new area of investigation about immune-mediated mechanisms of seizure disorders. The data indicate that reactive mononuclear phagocytes secreted agents that both damaged central nervous system tissues as well as induced seizures. Moreover, preliminary study has shown that inflammatory cells excite neighboring neurons in such a way as to induce electrical activity that persisted long after resolution of the inflammation. Perhaps "immunokindling" is an important early event in types of epilepsy associated with infection or trauma. See also Chapter 62, this volume.

MICROGLIA AND ALZHEIMER'S DISEASE

Alzheimer's disease is a neurodegenerative dementia associated with loss of neurons, accumulation of paired helical filaments, and the deposit of amyloid in senile plaques and vessel walls (Terry, 1985). Although Bolsi (1927) long ago noted argentophilic reactive cells surrounding senile plaques, the significance of reactive microglia in Alzheimer's disease has only recently received much attention (Cras et al., 1990; Styren et al., 1990). Using the histocompatibility marker HLA-DR as an indicator of activation, McGeer et al. (1988) have described numerous reactive microglia within the corona of senile plaques. Moreover, Griffin et al. (1989) have found interleukin-1 production in microglia surrounding amyloid plaques. Although it seemed unlikely that microglial abnormalities were a primary cause of senile dementia, these cells could influence secondary events, which have been identified as important pathologic features of Alzheimer's disease. For example, contact between microglial membranes and amyloid deposits implied an intimate link to microglial function. Perhaps reactive cells provided a necessary element in the plaque-forming process. Alternatively, core material found in plaques of Alzheimer's disease has been noted to be very resistant to chemical attack (Nikaido et al., 1971) and could, therefore, subvert the debris-clearing capacities of microglia. In this way, the plaques could serve as stable irritants that hold the central nervous system in a chronic state of inflammation. Activated microglia might, in turn, influence the disease course by accelerating the rate of neuron death. While these issues remain to be clarified, it is clear that chronic brain inflammation might further impair cognitive abilities of patients with Alzheimer's disease. See also Chapter 68, this volume.

MICROGLIA AND AIDS

Acquired immunodeficiency syndrome produces a devastating effect upon the brain and spinal cord, with more than 70% of all patients showing loss of memory, paralysis, seizures, sensory deficits, or global dementia (McArthur, 1987). Human immunodeficiency virus-1 (HIV-1) has been isolated from the central nervous system of AIDS patients and identified in several classes of central nervous system mononuclear phagocytes, for example, microglia, macrophages, and multinucleated macrophage-like cells (Budka et al., 1989). At autopsy, the brains of AIDS patients with dementia showed cortical atrophy and loss of cortical neurons (Navia et al., 1986). Although direct viral infection of neurons in brain tissue has not been demonstrated by immunohistology or by *in situ* hybridization (Koenig et al., 1986; Wiley et al., 1986), recent ultrastructural study had

shown extensive neuronal damage (Wiley et al., 1991). Thus, neurologic disorders of AIDS appear to be an indirect effect of retrovirus infection and might be the result of neurotoxic factors.

Several specific types of neurotoxic mechanisms have been put forth to account for neuron death associated with HIV-1 infection. Brenneman et al. (1988) and Dreyer et al. (1990) have reported the viral coat glycoprotein gp120 to be a neuron poison. A second hypothesis, and the one favored by my laboratory (Giulian et al., 1990; Pulliam et al., 1991; Giulian et al., 1993c), has been that *inflammatory* cells infected with HIV-1 release neuron-killing factors. Alternatively, the neurotoxin quinolinic acid (Schwarcz et al., 1983) might be a toxic factor in AIDS dementia, since elevated quinolinic acid concentrations were found in the cerebrospinal fluid of patients suffering from AIDS encephalopathy (Heyes et al., 1989).

A coculture system was used to test whether HIV-1-infected cells release neurotoxic factors. Test cells, with or without HIV-1 infection, were placed in filtered chambers (pore size <0.4 μm) and then cocultured with target neurons grown atop glass coverslips. Using this approach, factors secreted by viral human cells could be examined for effects upon cultures of chick ciliary ganglion, rat embryonic spinal cord neurons, or rat embryonic hippocampal neurons (Giulian et al., 1990). The human CD4(+) cell lines that were tested had been constitutively infected with HIV-1 and included the lymphoid cell line H9, promonocytic cell line U937, and the monocytoid cell line THP-1. After 48 hours, neurons were quite robust-looking, both in control cultures or in cocultures involving uninfected CD4(+) cells. However, coculture with infected monocytoid cells brought about dramatic neuronal losses (Figure 44-8). This pattern of cell killing could also be observed for neurofilament(+) rat spinal cord neurons. In contrast, the lymphoid cell line H9 with or without HIV-1 infection did not produce neurotoxins. Since H9 cells released significant quantities of virions and viral proteins (as much as 10-fold higher than observed for media incubated with monocytoid cells), it appeared that HIV-1 or its constituents were not toxic to cultured neurons. Direct experiments confirmed that recombinant proteins from HIV-1, including the structural protein gag, enzymes such as HIV-1 protease and reverse transcriptase, or gp120, had no direct toxic effects upon chick ciliary neurons, rat spinal cord neurons, or rat hippocampal cells (Giulian et al., 1993c). To determine whether an indirect neuron-damaging mechanism was involved, human blood lymphocytes and monocytes, or the cell lines THP-1, H9, and U937, were incubated with recombinant HIV-1 proteins. Only gp120 stimulated monocytoid cells to elicit neurotoxic activity (Figure 44-9). There was no release of neuron-killing molecules from lymphocytes or H9 cells exposed to gp120 or the other recombinant proteins.

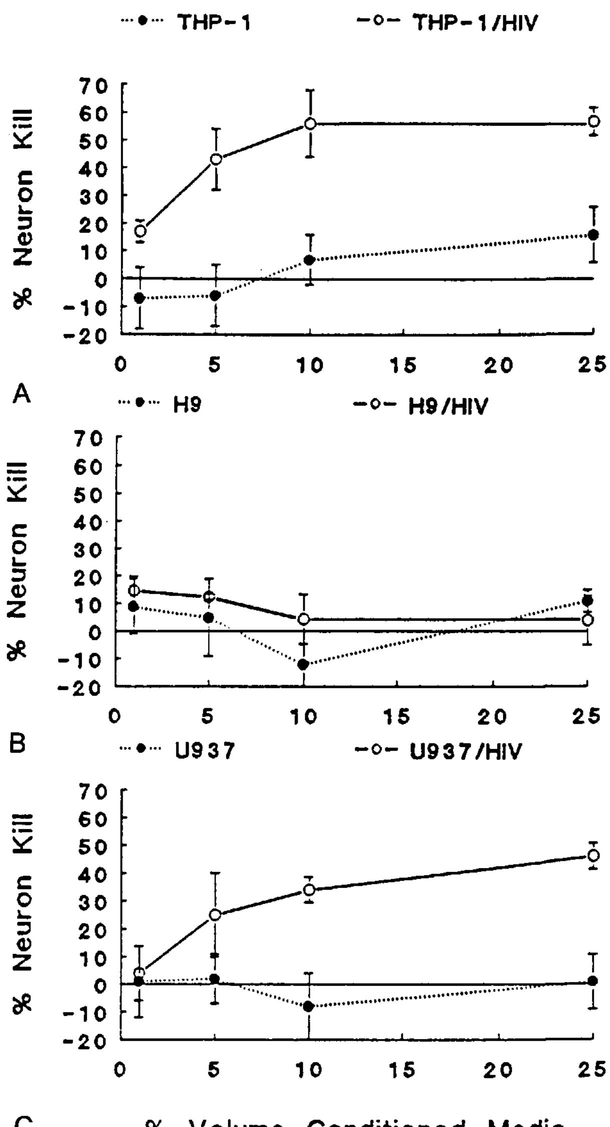

FIG. 44-8. The percent neuron kill for each experiment was expressed as mean number of neurons per field for a treated culture/mean number of neurons per field for untreated control cultures. Every value, expressed as mean% neuron kill + standard error, was obtained from at least three cultures. The uninfected (*open bars*) or HIV-infected (*filled bars*) cell lines were plated at the indicated densities in Millicell-CM chambers. The chambers were then transferred to 3.8 cm^2 wells, each containing 10,000 neurons and incubated for 48 hours prior to fixation. (A) THP-1 monocytoid cells. (B) H9 lymphoid cells. (C) U937 promonocytoid cells. [From Giulian et al. (1990), with permission.]

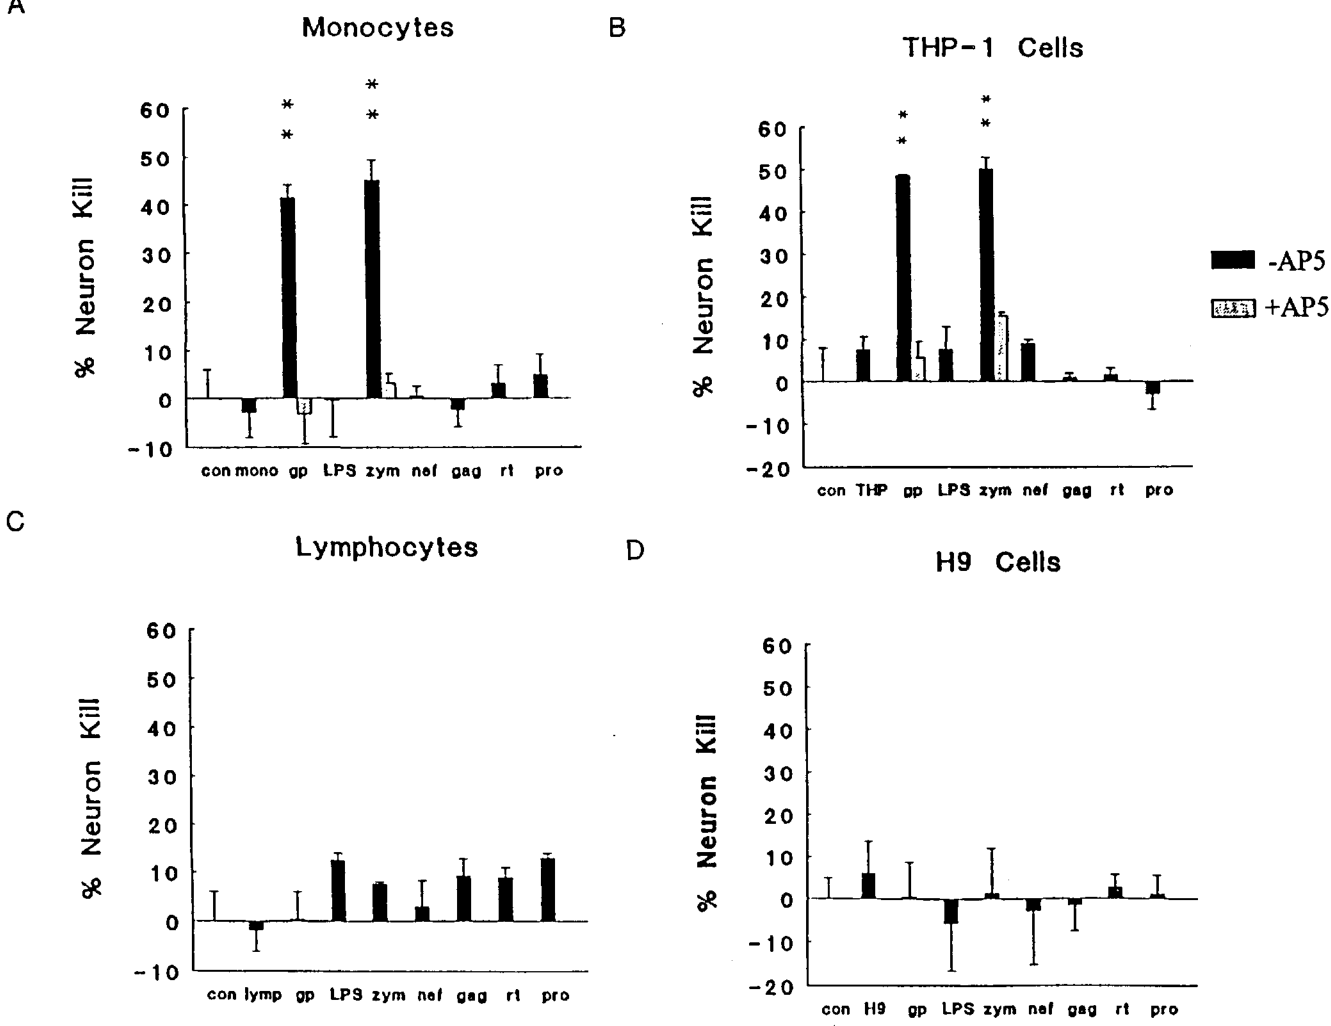

FIG. 44-9. Indirect toxicity of gp120 on ciliary neurons. (A) Isolated human blood monocytes, (B) the monocytoid human cell line THP-1, (C) isolated human blood lymphocytes, or (D) the lymphoid human cell line H-9 were incubated for 48 hours in the presence of 10 nM of various recombinant-derived HIV-1 proteins. Media from the treated cells were then assayed at a final concentration of 20% volume on ciliary neurons for the presence of neurotoxicity. As shown, only gp120 (gp)-stimulated monocytes (Figure A) or THP-1 cells (Figure B) released factors that were toxic to ciliary neurons. These effects were significantly elevated above the untreated control cultures (*con*) using the Student's t test ($^{**}p < .001$) with a confidence level of $p < .006$ by the Bonferroni method for 8 comparisons. Importantly, this toxic activity could be attenuated by 10 μM of the NMDA antagonist AP5 (Figures A and B). Zymosan A particles (*zym*), but not LPS, also elicit neurotoxin release in the monocytoid cells (Figures A and B) but not in lymphoid cells (Figures C and D). Media from unstimulated monocytes (*mono*), THP-1 cells (*THP*), lymphocytes (*lymp*), or H-9 cells (*H9*) did not produce neuron-killing factors (Figures A–D). HIV-1 protease (*pro*), reverse transcriptase (*rt*), p25/24 gag (*gag*). [From Giulian et al. (1993c), with permission.]

As sources of neurotoxic factors, brain mononuclear phagocytes, therefore, might create a persistantly disruptive influence upon neurologic function in HIV-1-infected individuals. The neurotoxins released by HIV-1-infected or gp120-stimulated monocytoid cells consisted of small molecules, which were heat-stable, protease-resistant, and acted via the NMDA receptor. As noted for reactive microglia, the HIV-1-associated neurotoxic activity was not quinolinic acid or any of the excitatory amino acids. See also Chapter 67, this volume.

CONCLUSIONS

Although reactive gliosis has long been thought to impair recovery of neurologic function (Aguayo et al., 1981; Reier, 1983), it remains unclear whether astroglia or microglia were responsible for such impairment. As noted by other laboratories, astroglia produced proteins which stimulate the outgrowth and survival of neurons in culture (Manthorpe et al., 1986; Ferrara et al., 1988; Manthorpe et al., 1989; Vaca and Wendt, 1992). Such astroglia-derived fac-

tors were found within normal neural tissues and within damaged tissues neighboring sites of trauma (Needels et al., 1987) and might include ciliary neurotrophic factor, brain-derived growth factor, and neurotrophic factor-3 all which are produced by astroglia (Vaca and Wendt, 1992). In contrast, brain inflammatory cells were a source both of short-lived free radicals which participated in contact-mediated killing of neurons and of long-lived neurotoxic factors that appeared after traumatic and ischemic injury. The release of long-lived inflammatory cytotoxins was a delayed process and not detected until a peak of cellular reactivity was reached, often by the second day after injury. The unopposed effects of neurotoxins from microglia and macrophages (see also Chapter 29) during the acute phase of inflammation might limit survival or function of neurons. This neuron-killing action could, in turn, be balanced by growth factors released from astroglia at a later phase of wound repair so that recovery of neuronal function would depend to a degree upon the location and numbers of reactive glia. Destruction of neurons neighboring sites of injury might be an important mechanism by which reactive microglia quell the spread of neurologic dysfunction (Giulian, 1992). As noted by Rio-Hortega (1932), necrotic tissue or hemorrhage elicit striking brain inflammatory reactions. As a potent stimuli for reactive microgliosis, tissue debris might continue to drive local production of neuron-killing factors in response to a variety of central nervous system injuries (Giulian, 1992) and, therefore, influence neuronal survival well beyond the period of initial tissue insult.

Microglia-derived neurotoxins were heat-stable protease-resistant molecules <500 Daltons with actions blocked by *N*-methyl-D-aspartate (NMDA) receptor antagonists. These molecules were distinguished from free radical intermediates and separated from excitatory amino acids and from the NMDA receptor-mediated toxin quinolinic acid by ion exchange and reverse-phase chromatography. In addition, the neurotoxic activities released from microglia or macrophages were small molecules with long-lived action and could be distinguished from a number of secreted cell poisons. Purification of microglia-derived neurotoxins will be necessary to uncover their precise mechanisms of action and to determine their relationships to NMDA agonists.

Five lines of evidence now support the idea that microglia-derived neurotoxins have an important role during neural tissue damage (Giulian, 1992).

1. Neurotoxins were only detected in tissues heavily infiltrated with reactive microglia or macrophages. The levels of neurotoxic activity found in central nervous system injured by either trauma or ischemia correlated to the number of mononuclear phagocytes at the lesion sites. Importantly, no toxic activity was detected in neighboring noninflamed tissues or in normal animals.
2. Drugs that reduced inflammatory cell numbers also reduced the amount of neuron-killing activity released by damaged tissues.
3. Active mononuclear phagocytes appeared at a time of a delayed loss of neurons and deterioration in neurological function (Giulian and Robertson, 1990).
4. Suppression of central nervous system inflammation both improved motor neuron survival and preserved motor function (Giulian and Robertson, 1990).
5. Isolation of specific cell populations confirmed that reactive mononuclear phagocytes were the principal source of neuron-killing factors found in the damaged central nervous system (Giulian et al., 1993b).

Reactive microglia appear in almost every type of central nervous system disorder, including infection, trauma, stroke, degeneration, and demyelination. These inflammatory cells are the major source of central nervous system-derived cytokines, help to regulate wound healing in neural tissues, and serve as an important link between systemic immune responses and the central nervous system. Moreover, microglia produce a wide spectrum of cytotoxic agents, some of which demonstrate potent neurotoxic effects. I suggest that inflammatory cell production of neuron-killing factors is a significant pathogenic mechanism common to a variety of central nervous system insults. Inhibition of inflammatory cell-derived toxins may help to preserve neurons near sites of tissue injury and, thus, improve recovery of function.

45 Antigen presentation by central nervous system glia

HARTMUT WEKERLE

Skin tissue transplanted to the skin of an unrelated recipient is unavoidably rejected within a predictable time of about 7 to 10 days. The same transplant grafted onto the *brain* surface, however, may well survive for unlimited times (Barker and Billingham, 1977). Over many years, this led to the conclusion that the central nervous system is exempt from the mechanisms of immune surveillance that are responsible for identifying and reacting against foreign structures that have invaded the organism.

Several anatomical peculiarities are responsible for the immunoprivileged status of the central nervous system. These include lack of lymphatic drainage, a dense endothelial barrier secluding the brain tissue from blood circulation, and the lack of antigen-presenting cells within the brain (Wekerle et al., 1986).

Yet the brain cannot be completely deprived of immune protection. As in other tissues, there must be ways to control central nervous system infection and neoplastic transformation. Indeed, these pathological lesions are commonly associated with marked infiltrations of inflammatory cells. How do these cells enter the central nervous system, and how do they function there?

Answers to these questions have come from studies of experimental autoimmune reactions involving autoimmune T lymphocytes attacking myelin structures of the brain. This work indicates that the central nervous system *is* controlled and protected by the immune system. Some, though not all, immune cells can pass into the central nervous system, and a considerable number of glial cells can be induced to act as antigen-presenting cells.

EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS: A MODEL FOR CENTRAL NERVOUS SYSTEM IMMUNE REACTIVITY

Experimental autoimmune encephalomyelitis (EAE) is an inducible, myelin-specific autoimmune disease that is commonly considered a valid model for the initial stages of the autoimmune pathogenesis of multiple sclerosis (Lassmann, 1983; Raine, 1984; Wekerle et al., 1986).

EAE lesions are characterized by mononuclear cell infiltrates, which are concentrated around postcapillary microvessels of the central nervous system white matter but also invade the surrounding tissue. These infiltrates are predominantly composed of monocytes and $CD4^+$ T lymphocytes. Typically, the endothelial blood-brain barrier is broken. The results are vasogenic edemas and fibrin deposition. Then local glia cells are highly activated. Astrocytes produce increased amounts of cytoskeletal glial fibrillary acidic protein (GFAP), and microglial cells express major histocompatibility complex (MHC) class I and class II antigens.

In fully developed EAE, the inflammatory lesions are concentrated within the myelinated parts of the central nervous system. It should be noted, however, that, at least in the Lewis rat, the earliest and most severe inflammatory signs are localized within the leptomeninges (Traugott and Raine, 1979; Kitz et al., 1981). In fact, weak EAE may be recognized solely by meningeal infiltration.

Time-course and tissue distribution of EAE are very predictable. Both in actively induced and in passively transferred EAE of the Lewis rats, development of the disease follows a remarkably strict scenario. All models of EAE show a characteristic interval between induction of EAE and the development of clinical manifestations. In actively induced EAE, neurological and histological signs appear 7 to 14 days after immunization. In T line-transferred EAE, the lag phase separating T cell transfer and onset of disease is usually 3 to 4 days (Ben-Nun and Cohen, 1984).

In "classical" EAE of the Lewis rat, the inflammatory process starts in the lumbar spinal cord and then migrates rostrally. The forebrain is attacked only in the most severe cases and in late stages of the disease (Lassmann et al., 1988). The cellular basis of this particular pattern of disease development is uncertain. It has been suggested that in the normal

central nervous system, the number of MHC class II-expressing glial cells is highest in the lumbar spinal cord (Vass and Lassmann, 1990).

T cell-transferred EAE of the Lewis rat, like most other EAE models, is a self-limited monophasic disease (Ben-Nun and Cohen, 1984). Spontaneous remissions are observed not only in normal recipients but even in rats immunosuppressed by heavy irradiation (Sedgwick et al., 1987; Wekerle et al., 1987).

The particular spatial and temporal development of clinical and histological EAE is probably controlled by factors within the central nervous system target tissue. There must be local regulatory mechanisms that define when, where, and how the pathogenic potential of infiltrating T cells is manifested. As discussed below, glial cells interacting with the T lymphocytes appear to be the most probable actors in this interplay.

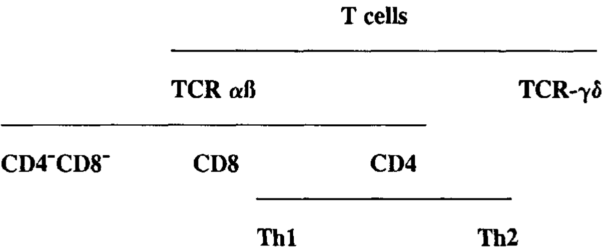

FIG. 45-1. Pedigree of T lymphocytes. The two main classes of T cells are distinguished by their differential usage of T cell receptor genes. The large majority uses the $\alpha\beta$ type, whereas a minor set uses $\gamma\delta$ type of receptors. Among the TCR $\alpha\beta^+$ T cells, cytotoxic T cells express the CD8 membrane marker, while T cells involved in B cell help and delayed type hypersensitivity express the CD4 marker; a third category of unknown physiological function expresses neither CD4 nor CD8. Among the $CD4^+$ T-helper subset, upon activation the Th1 population preferentially secretes the cytokines IL-2 and interferon-γ, whereas, in contrast, Th2 lymphocytes secrete IL-4 and IL-5.

ACTIVATED $CD4^+$ T CELLS CAUSE AUTOIMMUNE EFFECTS IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS AND EXPERIMENTAL AUTOIMMUNE NEURITIS

EAE was the first autoimmune disease to be unequivocally transferred by immune cells rather than autoantibodies. This was done first in outbred rats (Koprowski et al., 1960; Paterson, 1960) and subsequently in inbred Lewis rats (Paterson and Bell, 1962).

The T cell nature of the pathogenic, encephalitogenic lymphocytes was revealed by several approaches. First, it was observed that, depleting rats (Gonatas and Howard, 1974) or mice (Bernard et al., 1976) of T lymphocytes rendered them resistant to active induction of EAE using conventional immunization protocols. Reconstitution of T cells restored inducibility of EAE (Ortiz-Ortiz et al., 1976; Stohl and Gonatas, 1980).

More detailed identification of the pathogenic T cells was achieved by combining T cell transfers with monoclonal antibodies binding to T cell subset markers (Fig. 45-1). Transfer of unseparated, *in vivo*-primed lymphocytes, which had been reactivated *in vitro* by confrontation with the encephalitogen myelin basic protein (MBP) showed that the pathogenic potential was associated with T cells carrying markers of the $CD4^+$ subset [high expression of Lyt-1 in the mouse (Pettinelli and McFarlin, 1981) and W3/25 in the rat (Holda and Swanborg, 1982)]. The ultimate proof of the effector function of $CD4^+$ T cells was provided by Ben-Nun et al. (1981) who succeeded in isolating permanent T cell lines that were exclusively specific for MBP. These T cell lines were derived from Lewis rats that had been undergoing EAE after immunization with MBP in Freund's complete adjuvant. They recognized their target epitope in the molecular context of MHC class II antigens, and uniformly expressed the $CD4^+CD8^-$ membrane phenotype (Ben-Nun and Cohen, 1982).

The key role of $CD4^+$ autoaggressive T cells in the pathogenesis of EAE was fully confirmed by therapeutic experiments designed to influence clinical EAE by transferring monoclonal antibodies against different T cell markers. Anti-CD4 antibodies efficiently reduced EAE in rats (Brostoff and Mason, 1984; Brinkman et al., 1985), mice (Waldor et al., 1985), and primates (Rose et al., 1987; Van Lambalgen and Jonker, 1987).

The first successful transfers of EAE used high numbers of lymphocytes freshly isolated from freshly primed immune organs (Paterson, 1960). Soon, however, it became clear that the encephalitogenic potential of MBP-primed T cells could be significantly enhanced by *in vitro* activation with mitogens (Panitch and McFarlin, 1977) and, even more so, by presentation of the specific autoantigen (Richert et al., 1979; Holda et al., 1980).

The definite proof that only activated, but not resting, MBP-specific T cells are able to mediate EAE came again from studies of MBP-specific T cell lines. MBP-specific T cell lines are capable of transferring EAE at extremely low cell numbers, provided they were preactivated *in vitro* by immunospecific presentation of MBP, or, even by polyclonal mitogen. In the *resting* state, however, the same T cell line would

not even induce EAE in 100-fold increased cell numbers (Naparstek et al., 1983).

Activation of autoaggressive T cells is produced in experimental autoimmune disease either *in vivo,* by immunization with strong adjuvants or, in transfer models, by activation *in vitro.* "Spontaneous" autoimmune disease is thought to be the result of T cell activation via reaction of autoimmune T cells with microbial epitopes (Fujinami and Oldstone, 1985). Interestingly, transgenic mice expressing an MBP-specific T cell receptor on all T cells developed "spontaneous" EAE under conventional, but not germ-free, conditions (Goverman et al., 1993). Also T cell activation by (bacterial) superantigens could play a role in parainfectious autoimmunity. Superantigens specific for T cell receptor isotypes common to a particular class of autoimmune T cells could trigger an autoimmune disease by antigen-independent activation (Herman et al., 1991). In fact, this pathway was directly confirmed by recent experiments activating the encephalitogenic potential of MBP-specific T cells by staphylococcal exotoxin (Rott et al., 1992).

Thus, cell activation is critically required to convert the harmless resting autoreactive T cells contained within the normal immune repertoire to pathogenic cells that attack the body's own tissues. Prevention of activation must be one way to ensure self-tolerance.

INTERACTION OF AUTOIMMUNE T CELLS WITH THE ENDOTHELIAL BLOOD-BRAIN BARRIER

In all models of EAE, the pathogenic, myelin-specific T cells must be activated outside the central nervous system, and then have to reach their target tissue via blood. How can these circulating T cells reach the brain tissue that is separated from the circulation by the hermetically closed endothelial blood-brain barrier (BBB)?

The endothelium of the BBB differs from most other endothelia by a number of subcellular specializations (Dermietzel and Krause, 1991) that exclude bloodborne macromolecules and cells from the central nervous system parenchyme. Most important for T cell migration is the network of tight junctions that interconnects adjacent BBB endothelial cells (Brightman and Reese, 1969). These junctions are most elaborated in small postcapillary venules (Nagy et al., 1984).

Until a few years ago, one assumed that the BBB is impermeable for all circulating lymphocytes (Barker and Billingham, 1977). More recently, our own work (Wekerle et al., 1986) and results from others (Hickey et al., 1991) showed that *activated* T line lymphocytes can cross through the BBB, irrespective of their antigen specificity. In contrast, the BBB is indeed completely impermeable to *resting* T cells.

The migration pattern of activated T lymphocytes differs fundamentally from that of resting T cells. Activated T cells, for example, have a propensity to "home" to the thymus (Naparstek et al., 1982) and to perithymic lymph nodes (Klinkert, 1987). In contrast, resting T cells adhere preferentially to high endothelial venules of immune organs, gut or skin (Butcher, 1990).

It seems that distinct profiles of cell adhesion molecules account for the differential migration of activated and resting T cells (Butcher, 1990; Shimizu et al., 1992), although the exact nature of these determinants remains obscure to date.

It should be stressed that the events described so far concern exclusively the *first* contacts between autoimmune T cells and the *naive,* resting BBB endothelium. In the course of the ongoing autoimmune inflammation of the central nervous system, a multitude of cytokines and other inflammatory factors are produced, which activate the local BBB endothelium. The BBB becomes leaky, and plasma macromolecules and blood cells enter to produce edema. The rupture of the BBB, together with chemotactic cytokines, pave the way for cellular infiltrations (Cross et al., 1991).

Identification of the endothelial signals leading to the entry of activated (auto-) immune T cells into the central nervous system will be of high clinical importance. Blocking of these structures would be desirable in treating central nervous system autoimmune disease, whereas their induction or enhancement could have a beneficial effect in infection and neoplasia. Indeed, very recently, monoclonal antibodies against the endothelial $\alpha4\beta1$ integrin were found to interfere with development of EAE in mice (Yednock et al., 1992).

T CELL INTERACTION WITH ASTROGLIA

The tissue-specific autoimmune T cells mediate disease that is quite strictly limited to the relevant target tissue. MBP-specific T cells, for example, attack almost exclusively central nervous system white matter (Raine, 1985), but ignore peripheral nerves. Conversely, T cells recognizing peripheral myelin protein, P2, cause disease only in peripheral nerves (Izumo et al., 1985). Furthermore, T cells recognizing retinal S antigen (Kalsow and Wacker, 1978) or the interphotoreceptor protein (Chan et al., 1987) cause inflammation only in the retina (and in the

pineal gland, which also expresses these two autoantigens).

How can the autoimmune T lymphocytes recognize their target organ so clearly? The most probable explanation should be presentation and recognition of specific autoantigenic epitopes within the tissue. In the case of EAE, this would require the existence of local antigen presenting cells within the central nervous system, a situation clearly negated by the conventional dogma of immune privilege.

It is clear at present that antigen-presenting cells are not only present within the central nervous system, but a considerable proportion of all brain glial cells can function at least partially as competent antigen-presenting cells. Astrocytes were the first glial cells identified as brain cells inducible to MHC products. This was done using brain cultures from neonatal mice. The cells of these cultures did not express any demonstrable class II material. Upon treatment with interferon-γ, however, at least some of the astrocytes became strongly class II-positive (Hirsch et al., 1983; Wong et al., 1984). In addition to MHC products, proinflammatory cytokines induce a variety of cell adhesion molecules on astrocytes. For example, interferon-γ, tumor necrosis factor-α (TNF-α), and interleukin-1 (IL-1) trigger the expression of intercellular adhesion molecule-1 (ICAM-1) (Frohman et al., 1989), lumphocyte function associated antigen-3 (LFA-3), vascular cell adhesion molecule (VCAM), and very late antigen (VLA) (Aloisi et al., 1992; Hurwitz et al., 1992). MHC inducibility on astrocytes by cytokines strongly varies between species and even strains. EAE-susceptible mice and rats often show a higher response to interferon-γ than resistant animals (Massa et al., 1987b), but this association is not complete (Barish and Raissdana, 1990).

MHC class II products and cell adhesion molecules are not only induced in astrocytes by T cell-derived cytokines, but also by certain viruses. Lewis rat astrocyte cultures infected with coronavirus express both high doses of MHC class II antigens (Massa et al., 1986) and ICAM-1 (Kraus et al., 1992). This induction is further enhanced by treatment with TNF-α (Massa et al., 1987a). In the mouse, flaviviruses were reported to induce MHC class II in astrocytes (Liu et al., 1989), and HTLV-I (human T cell leukemia virus) in human astrocytes (Hirayama et al., 1988).

Several agents are known to reduce, or even suppress MHC class II expression on astrocytes. Interferon-β interferes with MHC class II induction on neoplastic (Joseph et al., 1988) and untransformed human astrocytes, presumably acting on transcriptional level (Ransohoff et al., 1991). Transforming growth factor-beta (TGF-β) (discussed in more detail below) is another cytokine reducing astrocytic MHC expression (Schluesener, 1990). Downregulation of MHC in astrocytes has been observed, using β-adrenergic agents like norepinephrine (Frohman et al., 1988b), the neuropeptides vasoactive intestinal peptide (VIP) (Frohman et al., 1988a), glutamate (Lee et al., 1992), potassium channel blockers (Ohira et al., 1991), and, in general, agents that interfere with the function of second messengers (Sasaki et al., 1990). Although the concentrations used in some of these studies seem higher than possibly reached *in situ,* neurotransmitters may have a role in physiological regulation of MHC expression. In experiments culturing cerebellar neurons with astrocytes, glial MHC induction was significantly reduced (Aloisi and Wekerle, 1990).

Expression of MHC products is necessary, but not sufficient for a cell to act as an antigen-presenting cell. Activation of astrocytes by interferon-γ clearly equips the glial cells with the capacity of efficiently presenting protein antigens to specific T lymphocytes (Fig. 45-2). This was first shown in a culture system composed of astrocytes from neonatal Lewis rat brains, and monospecific syngeneic T cell lines (Fontana et al., 1984). In the absence of antigen, the T lymphocytes do not form any particular cellular complexes with the astrocytes. After addition of specific protein (auto-)antigen, however, the T cells start to firmly adhere to the astrocytes, transform to large lymphoblasts and proliferate. This activation reflects recognition of antigen presented by astrocytes, because it depends on the dose of antigen added and on the induction of MHC class II antigens on the astrocytes. The reaction can be completely blocked by monoclonal antibodies binding to the proper MHC class II determinants, but not class I products (Fontana et al., 1984; Fierz et al., 1985). Although astrocytes are good antigen-presenting cells *in vitro,* it should be stressed that they do not possess the *full* functional spectrum of a professional antigen-presenting cell. Astrocytes present antigen optimally only to *primed,* memory T cells, but not to *naive* T cells (Sedgwick et al., 1991a). They seem to lack proper costimulatory factors, such as the B7 molecule required to trigger the full activation program of naive T lymphocytes (Linsley and Ledbetter, 1993).

The interaction between T cells and antigen-presenting astrocytes is by no means unidirectional. Astrocytes act on T cells by presenting antigen. Activated T cells, in turn, affect astrocytes, either via soluble cytokines, or by direct contact. They secrete proinflammatory cytokines (e.g., interferon-γ or TNF-α), which may promote, in addition to the in-

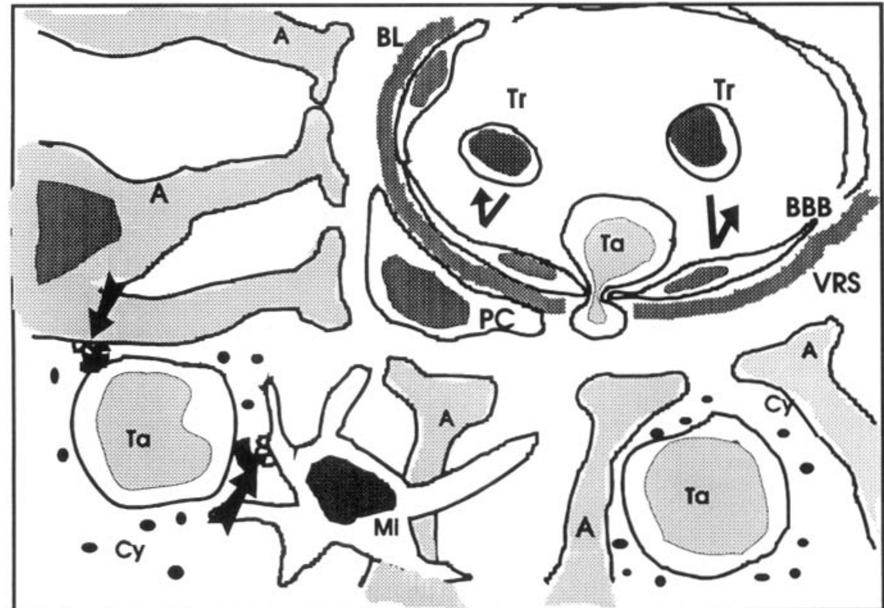

FIG. 45-2. Immunosurveillance of the central nervous system. Activated (Ta), but not resting T cells (Tr) pass through the endothelial blood-brain barrier (BBB) irrespective of their antigen specificity. They break through the microvascular basal lamina (BL), and enter the Virchow-Robin space (VRS) passing by perivascular cells (PC). Some activated T cells penetrate the perivascular glia limitans formed by astrocytic endfeet (A) and microglia (Mi). Proinflammatory cytokines (Cy) released by the migratory activated T cells induce MHC antigens in local glial cells, thus creating the structural basis for antigen presentation to the T cells (arrows).

duction of MHC and cell adhesion molecule expression, glial proliferation, and fibrosis (Selmaj et al., 1991; Yong et al., 1991).

Direct cell-to-cell contact is required for cytotoxic interaction between encephalitogenic T cells and MBP-presenting astrocytes. Studying the coculture system of Lewis rat T cell lines and astrocytes, Sun and his colleagues observed that T cell activation following recognition of the MBP epitope 68-88 resulted in the complete destruction of the antigen-presenting astrocyte monolayers (Sun and Wekerle, 1986). Like T cell activation, target cell lysis depends on the antigen dose (requiring somewhat higher protein concentrations than triggering of proliferation), depends on MHC class II induction on the target cells, and can be completely blocked by relevant monoclonal antibodies. Encephalitogenic T cells not only kill antigen-presenting astrocytes, but all antigen-presenting cells presenting MBP in recognizable molecular context, for example, macrophages, as well. Furthermore, at least in the Lewis rats, cytotoxicity is a property of encephalitogenic T cells. All encephalitogenic T cells have a cytotoxic potential, whereas many nonencephalitogenic T cells are nonlytic (Sun and Wekerle, 1986). Similar observations have been made in murine (Fallis and McFarlin, 1989) and human (Dhib-Jalbut et al., 1990) culture systems, although human $CD4^+$ T cells seem to have a tendency to kill astrocytes even in the absence of nominal antigen (Ruijs et al., 1993).

The previous findings establish that the central nervous system does contain large numbers of autochthonous cells that can be induced to present (auto-)antigens to T cells. Activated MBP-specific T cells that may have crossed the BBB, may interact with local glial cells *in situ* as they have been shown to do *in vitro*. They may induce MHC products and trigger the antigen-presenting potential of astrocytes. Recognition of the appropriate peptide epitope in context of the proper class II product would then result in cytokine production and a cytotoxic attack by T cells against the local autoantigen presenting cells (Sun and Wekerle, 1986).

Although macrophages are presumably required to produce the full pathogenic program of EAE (Brosnan et al., 1981; Huitinga et al., 1990), successful transfer of encephalitogenic T cells into immunosuppressed recipients indicates the autonomous pathogenic potential of the autoaggressive lymphocytes (Sedgwick et al., 1987).

Class II expression on astrocytes *in vivo* is not demonstrable in all cases (Matsumoto et al., 1989), and certainly is lower than on microglial cells (see below). In a careful study combining immunocytochemistry with electron microscopy, Vass and Lassmann (1990) demonstrated interferon-γ-induced class II products on astrocytes. Intriguingly, these molecules were concentrated on the perivascular processes (Vass and Lassmann, 1990). Class II-positive astrocytes have been described in human multiple sclerosis tissues as well (Lee et al., 1990).

CENTRAL ROLE OF MICROGLIA AS ANTIGEN-PRESENTING CELLS

It is now clear, however, that astrocytes are not the only, and perhaps not even the "best," inducible

antigen-presenting cells within the central nervous system. There is good evidence suggesting that microglia cells count among the most efficient antigen-presenting cells of the brain parenchyme. First, Frei and colleagues (1987) showed directly how efficiently microglial cells process and present protein antigens to syngeneic T cells *in vitro*. Resting microglia cells isolated mechanically from mixed glial cultures of newborn mouse brain readily take up particulate material and express receptors for immunoglobulin Fc parts, but no MHC antigens. Interferon-γ treatment leads to the expression of MHC class II products (Frei et al., 1987; Suzumura et al., 1987), and to the capacity of presenting protein antigens to MHC-compatible T cells (Frei et al., 1987). Similar findings were made in rat cultures (Woodroofe et al., 1989).

Microglia are the most prominent MHC-expressing central nervous system cells *in vivo*. Intravenous infusion of recombinant interferon-γ into rats preferentially induces MHC antigens in microglia in some (Steiniger and Van der Meide, 1988), but not in other studies (Momburg et al., 1986). Clearly, however, profound changes in membrane antigen expression on glial cells are caused by direct, intrathecal injection of cytokines. Vass and Lassmann found that infusion of recombinant mouse interferon-γ into the subarachnoidal space of Sprague-Dawley rats resulted in typical patterns of MHC induction. The first cells to be induced were perivascular dendritic cells and parenchymal microglia. At higher doses and at later stages only astrocytes and ependymal cells became MHC-positive (Vass and Lassmann, 1990).

Microglial MHC expression can be triggered by multiple pathways. Immunocytochemical analyses of MHC class II induction in central nervous system parenchymal cells established that microglial cells exhibit the strongest class II expression in autoimmune inflammation (Matsumoto et al., 1986; Konno et al., 1989; Sedgwick et al., 1991b). As discussed above, most of this induction seems to be due to the local release of proinflammatory cytokines from autoimmune infiltrate cells (Kennedy et al., 1992; Merrill et al., 1992).

There are, however, additional noninflammatory pathways to induce MHC antigens in microglial cells. Cell degeneration in general leads to preferential induction of MHC products in central nervous system glial cells, preferentially in microglial cells. In 1966 Kreutzberg demonstrated that dissection of a rat facial nerve is followed by the activation of perineuronal microglial cells positioned within the central nervous system motor nuclei. The microglial reaction was noted only ipsilaterally, but not on the contralateral nucleus, with an intact peripheral nerve. Microglia activation is reflected by proliferation and by the increased expression of complement receptors (Graeber et al., 1988). Most important, however, the activated microglial cells are induced to express MHC class I (Maehlen et al., 1988) and class II determinants (Streit et al., 1989b). Very similar effects have been observed after transection of sciatic nerves (Maehlen et al., 1988; Gehrmann et al., 1991).

The molecular basis for microglial activation and MHC induction has remained uncertain. Immunocytochemistry suggested that the lesioned neurons start to produce mediators related to interferon-γ (Olsson et al., 1989). This could not be confirmed in a more detailed subsequent study. Western and Northern blot analyses failed to demonstrate interferon-γ (Kiefer et al., 1991).

Remote activation of central nervous system microglia has been achieved by peripheral axotomy, but it also is seen by neuronal poisoning following retrograde transport of ricin (Streit et al., 1989a), and ischemia (Gehrmann et al., 1992a). Perhaps most surprisingly, microglial cells in the *central nervous system* are activated during autoimmune attacks against *peripheral* nerves. Gehrmann and coworkers induced experimental autoimmune neuritis in the Lewis rat by transferring neuritogenic T cell lines recognizing peripheral myelin protein, P2 (Gehrmann et al., 1992b). As mentioned, inflammation in this disease is strictly confined to the peripheral nervous system, sparing completely the central nervous system (Izumo et al., 1985), and follows an equally rigid time schedule. Infiltration and neurological deficits start on the fourth day after cell transfer (Heininger et al., 1986). Two days *before* development of experimental autoimmune neuritis, microglial cells around central nervous system motor neurons become activated, expressing MHC antigens. The activation gradually intensifies and spreads rostrally, finally to reach nuclei gracilis and cuneatus (Gehrmann et al., 1992b).

OTHER ANTIGEN-PRESENTING CELLS IN THE CENTRAL NERVOUS SYSTEM?

Among all central nervous system cell lineages, neurons are least inducible to induction of MHC antigens. Neurons are resistant to activation by interferon-γ in culture, under conditions, where all other cell types express at least class I determinants (Wong et al., 1984). In fact, this lack of MHC expression seems to be responsible for persistence of neurotropic viruses within the central nervous system. Neurons harboring lymphocytic choriomeningitis virus are resistant

against the cytotoxic effects of virus-specific $CD8^+$ killer T cells. They are efficiently lysed, however, after transfection with suitable MHC class I determinants (Joly et al., 1991).

The immunological status of oligodendrocytes is more complex. *In vitro,* MHC class I, but not class II antigens are inducible on rodent oligodendrocytes by interferon-γ. In most of these studies, membrane markers like galactocerebroside (GalC) were used as markers of cell maturity (Lisak et al., 1984; Wong et al., 1984). Induction of MHC class I is accompanied by the appearance of cell adhesion molecules (Satoh et al., 1991). Also within multiple sclerosis plaques, residual oligodendrocytes failed to bind class II-specific antibodies (Lee and Raine, 1989).

Interferon-γ inducibility of class II seems to be lost during rodent oligodendrocyte differentiation. In contrast to mature oligodendrocytes, bipotential O-2A glia progenitor cells are still inducible in culture (Calder et al., 1988). According to a recent report, class II induction can be restored in GalC- and proteolipid protein-positive rat oligodendrocyte cultures by glucocorticoids (Bergsteinsdottir et al., 1992).

At present, it appears that neurons are incapable of presenting antigen to any T lymphocyte class. In contrast, oligodendrocytes fulfil the criteria for presenting peptides in MHC class I context, and thus to interact with $CD8^+$ cytotoxic T cells. Whether they are able to interact with $CD4^+$ T cells under regular conditions remains to be proven.

ANTIGEN PRESENTATION *IN VIVO*

Are the class II-induced glial cells indeed involved in the *in vivo* presentation of (auto-)antigens to specific T lymphocytes? Maehlen et al. (1989) showed that this is probably the case. Inducing EAE in facial nerve axotomized Lewis rats by active immunization with MBP in complete Freund's adjuvant they found mononuclear infiltration in the lesioned facial nucleus, but not in the normal, contralateral area (Maehlen et al., 1989). Others extended these findings using optic tract lesions and passive T cell transfer EAE (Konno et al., 1990).

Less clear is the situation with cytokine-activated glia. Billiau and colleagues (1988) were the first to show that systemic treatment of SJL/J mice with interferon-γ did by no means enhance active induction of EAE, but rather decreased development of disease. Monoclonal antibodies against interferon-γ also enhanced chronic relapsing EAE in SJL/J mice after active or passive induction (Duong et al., 1992). A similar paradoxical effect of interferon-γ (and of antiinterferon antibodies) was noted in Lewis rats after intraventricular cytokine instillation, although in the same studies intravenous treatment preceding the onset of disease aggravated EAE (Voorthuis et al., 1990). These observations are not easy to explain. Observations in related autoimmune models emphasize the diversity of effects potentially exerted by interferon-γ (Hartung et al., 1990). Considering the pleiotropic effects of interferon-γ, many factors affecting EAE development may be altered: T cell activation outside the central nervous system, migration through the BBB and, finally, interaction with parenchymal target cells. Some of these effects may neutralize each other. Thus, timing and dosaging of cytokine treatment crucially determines the outcome of the treatment. However, most importantly, treatment of patients with interferon-γ provoked a rate of relapses, which cogently demonstrated the proinflammatory effect of the cytokine in a human central nervous system disease with putative autoimmune pathogenesis (Panitch et al., 1987).

Activation of glial cells by degenerative events which may occur within the central nervous system, or even outside, is certainly of importance to understand human disease. That similar events do take place in human brains has been demonstrated under various pathological conditions. In multiple sclerosis lesions, for example, MHC class II induction extends into non-infiltrated "healthy" parenchyme areas surrounding actual lesions (Woodroofe et al., 1986; Boyle and McGeer, 1990). Further, MHC-positive glial cells are characteristic for degenerative disorders as diverse as Huntington's chorea, Parkinson's and Alzheimer's disease (McGeer et al., 1988; Sobel and Ames, 1988; Styren et al., 1990; Perlmutter et al., 1992).

WHICH ARE THE MOST IMPORTANT NEURAL ANTIGEN-PRESENTING CELLS?

As pointed out above, Vass and Lassmann demonstrated a hierarchic sequence of glial class II induction following intrathecal treatment with interferon-γ. They found that in a first stage of the response, perivascular cells and microglia are induced, and that only later astrocytes and ependymal cells follow with MHC class II expression (Vass and Lassmann, 1990).

Intriguing information on the role of antigen-presenting cells in generation of EAE came from studies using bone-marrow reconstituted irradiation chimeras. Studies of chimeric rats established that most *parenchymal* microglial cells were of recipient

origin. In MHC disparate rat chimeras, bone-marrow derived MHC class I determinants were not found within the parenchyme (Matsumoto and Fujiwara, 1987), and similar findings were made using mouse chimeras with a transgenic bone-marrow marker (De Groot et al., 1992). These observations leave it open, whether they are due to the neuroectodermal origin of most parenchymal microglial cells, or to their extremely slow turn over.

On the other hand, similar studies led to the identification of a new, bone-marrow derived perivascular glia population. Perivascular microglial cells extend processes between astrocytic endfeet to form local glia limitans. They are highly susceptible to bloodborne interferon-γ (Lassmann et al., 1991). Interestingly the same cells are activated in areas close to neuronal degeneration (Streit et al., 1989a). Their active role in antigen presentation *in situ* has been established in transfers of parental MBP specific T cells to rat chimeras. MHC compatibility of the transferred encephalitogenic T cells with the chimeras' bone marrow was necessary and sufficient to produce clinical and histological EAE (Hinrichs et al., 1987; Hickey and Kimura, 1988; Matsumoto and Fujiwara, 1988). Since, obviously, astrocytes and most resident microglial cells would lack suitable MHC class II products to present myelin to the transferred T cells, the bone marrow-derived perivascular glial cells remain as the most probable candidate antigen-presenting cells to produce EAE in these animals.

Together the data suggest that, in principle, several intracerebral antigen-presenting cells may have an active role in the development of EAE. While resting endothelial cells do not seem to provide antigen-specific signals to circulating activated T cells, antigen may be presented by perivascular glial cells. Their high sensitivity to MHC inductive stimuli and their strategic location close to the BBB predestine these bone marrow-derived glial cells to control the very first steps in immunosurveillance and autoimmunity of the central nervous system parenchyme. When inflammation develops, additional antigen-presenting cells may be recruited, including bone marrow-independent parenchymal microglia, and finally astrocytes. At present it is uncertain, whether oligodendrocytes can also be induced to act as antigen-presenting cells *in vivo*. Antigen presentation by astrocytes may well occur only in late stages of the autoimmune inflammatory process. In view of the crucial physiological roles of astrocytes, cytotoxic effects by encephalitogenic T cells against these cells would be especially disastrous, and could result in severe clinical deficits.

SUPPRESSOR ASTROCYTES-T CELL APOPTOSIS

Not all astrocytes are fully efficient antigen-presenting cells. As discussed above, the genetically determined variation in astrocytic MHC class II inducibility is considerable. However, even astrocytes from animals with high MHC inducibility vary in their antigen presenting capacity. Screening a series of Lewis rat-derived cloned astrocyte lines, we found that many of these lines triggered antigen-specific T cell proliferation. Other astrocyte clones, however, did not present productively protein antigens, although they expressed cytokine-induced MHC class II determinants. In most cases this was not due to "simple" inability to process the proteins, but reflected active suppression of T cell proliferation. These suppressive astrocytes vigorously suppressed even T cell responses elicited by "professional" antigen-presenting cells (dendritic cells) derived from peripheral immune organs (Wekerle et al., 1987). Similar cell dose-dependent suppression had been recorded in a related rat (Matsumoto et al., 1992), and mouse systems (Takiguchi and Frelinger, 1986), and more recently with human astrocytes and T cells (E. Meinl, personal communication).

Suppressive control of T cell activation is not a function limited to cerebral astrocytes, but similar activities were described in antigen presentation within the eye. Retinal Müller cells (Caspi et al., 1987), and ciliary body cells (Helbig et al., 1990) also have been shown to suppress antigen presentation to T cells.

The molecular mechanism of astroglial suppression of T cell activation remain to be elucidated. Astrocytes may act on T cells either directly by cell-to-cell contacts, or via suppressive mediators. In principle, any astrocyte product with known immunosuppressive activity could be involved in the process.

Early studies indicated apolipoprotein E (ApoE) as a possible immunosuppressive agent of astrocytes. ApoE, a plasma protein involved in lipid transport and metabolism, suppresses cellular immune responses, though at relatively high concentrations (Mahley, 1988). ApoE is constitutively expressed in astrocytes *in vivo* (Boyles et al., 1985), and *in vitro* (Oropeza et al., 1987). The molecule is involved in nerve de- and regeneration (Ignatius et al., 1986; Snipes et al., 1986). In astrocyte cultures its expression is further enhanced by interferon-γ treatment (Oropeza et al., 1987).

More recently, members of the transforming growth factor-β (TGF-β) family have attracted attention as possible downregulators of central nervous system immune reactivity. Glial TGF-β was discovered in analyses of a soluble immunosuppressive

mediator released by transformed human glioblastoma cells (Schwyzer and Fontana, 1985). Its molecular identity as TGF-β2 was revealed by protein sequencing and by cloning of its gene (De Martin et al., 1987). While original studies suggested that TGF-β2 is exclusively released from glioma tissue, later at least the latent form of TGF-β2 was demonstrated in cultures of normal astrocytes (Saad et al., 1991; Constam et al., 1992). TGF-β, whose production seems to involve autocrine regulation (Saad et al., 1991), has profound effects on central nervous system differentiation and function. For example, TGF-β1 enhances nerve growth factor production (Lindholm et al., 1990), and cell adhesion molecule expression (Saad et al., 1991) in rat astrocytes. It is induced in astrocytes by trauma (Lindholm et al., 1992).

Most important in our context, TGF-β2, like other isoforms of TGF-β, is a powerful immunosuppressive agent (Schwyzer and Fontana, 1985; Schluesener and Lider, 1989) that acts on several levels. TGF-β reduces MHC class inducibility of glial cells (Schluesener, 1990), and suppresses T cell activation and proliferation (Siepl et al., 1988; Wahl et al., 1988). Interestingly, TGF-β may act as a mediator of post-EAE suppressor T cells (Karpus and Swanborg, 1991), and may downregulate autoimmune T cell responses after oral tolerization (Kuruvilla et al., 1991; Khoury et al., 1992). Finally, TGF-β expression is enhanced in the spontaneous recovery phase of EAE, further emphasizing its potential role as a downregulatory agent (Khoury et al., 1992).

TGF-β thus looks like an ideal drug to treat T cell-mediated autoimmune diseases. Indeed there are numerous reports on successful treatment of EAE (Johns et al., 1991; Kuruvilla et al., 1991; Racke et al., 1991) and other central nervous system inflammations (Stitz et al., 1991).

Nevertheless, TGF-β is by no means a completely reliable antiinflammatory drug, and this is due to several undesirable properties. TGF-β displays marked and broad chemotactic activity. It attracts monocytes (Wahl et al., 1987), polymorphonuclear leukocytes (Reibman et al., 1991), and T lymphocytes (Adams et al., 1991). It may hence not surprise that under certain conditions, treatment with TGF-β may not result in suppression of an (autoimmune) inflammation, but rather in its exacerbation (Drake and Issekutz, 1993). Furthermore, TGF-β induces preferential immunoglobulin isotype production by B lymphocytes (in the mouse IgA (Coffman et al., 1989), and IgG2b (McIntyre et al., 1993)), which may be deleterious under specific conditions.

Most recently, IL-10 has raised attention as a potential downregulatory cytokine of the central nervous system. Predominant among the many effects of IL-10 are efficient inhibition of cytokine production by monocytes (De Waal Malefijt et al., 1991), and functional suppression of T cells, especially the Th1 subset (Del Prete et al., 1993), which is involved in EAE mediation. Like TGF-β, IL-10 expression comes up in the late, recovery stages of SJL/J mouse EAE (Kennedy et al., 1992). This and the recent demonstration of IL-10 in human astrocyte cultures (E. Meinl, personal communication), make this cytokine an additional possible mediator of astrocyte-dependent immunosuppression.

Recent work raised the possibility that many of the activated T cells entering the central nervous system may not leave that tissue, but rather will perish there. Ohmori et al. (1992), for example, found that T cells having entered the central nervous system do not persist for a long time in their state of activation and proliferation. Moreover, a morphological study of EAE lesions in rat brains indicated that numerous round cells undergo apoptosis. Pender et al. (1991) concluded that most of these cells were of oligodendrocytic origin. Combining immunocytochemistry, electron microscopy, and *in situ* nick translation of apoptotic DNA (Gold et al., 1993), Lassmann and colleagues identified most of the apoptotic cells in EAE as degenerating T cells (Schmied et al., 1993). These findings might explain the remarkably low frequency of autoantigen specific T cells recoverable from EAE brains. Furthermore, similar patterns of cell death have been observed in active infiltrations of multiple sclerosis brain lesions (H. Lassmann, personal communication). These findings certainly have to be considered in interpreting T cell receptor sequences amplified by polymerase chain reaction from multiple sclerosis brain tissue (Oksenberg et al., 1993). Apoptosis of activated, myelin specific T cells may lead to a profound distortion of the T cell repertoire in brain infiltrates, with a relative underrepresentation of the pathogenic T cells among unspecific infiltrate lymphocytes. Further, it will remain to be established, whether related processes are involved in "determinant spreading" described by Lehmann et al. (1992).

There is evidence that T cell suppression by astrocytes is not just a tissue culture artifact, but may have a "real" function *in vivo*. Equivalent mechanisms may be responsible for the unexpectedly low proliferation rate noted for intraparenchymal infiltrating T cells in transfer EAE (Ohmori et al., 1992).

The central nervous system parenchyme is a microenvironment, which can be induced to interact positively with transmigrating T lymphocytes. Glial cells, especially microglia, but also certain astrocytes can be induced to present protein (auto-)antigens in

MHC class II context to specific T cells. T cell activation is under tight control, with regulatory mechanisms making sure that it is limited both in duration and in intensity.

CONCLUSION

All experimental evidence indicates that the central nervous system is subject to active immune surveillance. The surveillant immune cells are activated, that is, they must have been recently primed by encountering "their" antigen. Within the central nervous system parenchyme, several glial cell types are able to present protein antigen to T cells. Microglial cells appear to be the most promptly inducible and efficient central nervous system antigen-presenting cells. In addition, at least some astrocytes can be recruited to positively interact with T cells. Many astrocytes seem, however, to be involved in downregulation of immune responses. They produce mediators that suppress topical MHC induction and reduce activity of T cells. Further, astrocytes are capable of causing apoptosis, preferentially in activated T cells that interact with locally presented (auto-)antigen.

The complex and tight control of immune reactivity within the central nervous system may well have developed to maximally reduce bystander damage to the sensitive neural cells.

46 | Cytokine production

ETTY N. BENVENISTE

This chapter emphasizes the expression and action of a select group of cytokines, namely, those implicated in contributing to inflammatory and immune responses within the central nervous system. These cytokines include interferon-gamma (IFN-γ), interleukin-1 (IL-1), tumor necrosis factor alpha and beta (TNF-α/TNF-β), interleukin-6 (IL-6), transforming growth factor beta (TGF-β), the colony stimulating factors (CsFs), and the chemoattractant cytokines called chemokines. The chapter's main focus is on how glial cells both respond to and synthesize cytokines, and how these changes in gene expression and function may contribute to various neurologic disease states such as multiple sclerosis, experimental allergic encephalomyelitis (EAE), and AIDS dementia complex.

BACKGROUND

The central nervous system is generally regarded as an "immunologically privileged site" for two reasons: (1) the central nervous system is for the most part devoid of a lymphatic system that captures potential antigens, and (2) the central nervous system is protected from circulating blood by the blood-brain barrier, a specialized vasculature consisting of endothelial cells with tight junctions, which is impermeable to immunoglobulins and cytokines and which acts to restrict the migration of lymphoid cells into the central nervous system. Additionally, cells of the central nervous system (neurons, astrocytes, oligodendrocytes, microglia) constitutively express very low levels of class I and II major histocompatibility complex (MHC) antigens, which play a fundamental role in the induction and regulation of immune responses (Wong et al., 1984a. See Chapter 45). Pathological events within the central nervous system often result in a breakdown of the blood-brain barrier, which permits cells of the peripheral immune system access to this site. In human diseases such as multiple sclerosis (Hauser et al., 1983) and AIDS dementia complex (Navia et al., 1986) and in animal models of central nervous system disease such as EAE (Raine, 1984), inflammatory infiltrates composed of varying ratios of activated T cells, B cells, and macrophages are found in the brain.

Studies have addressed the question whether factors from immune cells contribute to astrogliosis. Astrogliosis is the result of astrocyte proliferation, hypertrophy, and the increased synthesis of glial fibrillary acidic protein (GFAP), an astrocyte-specific protein that eventually produces dense glial scars in the central nervous system. Astrogliosis is often associated with inflammatory infiltrates in the central nervous system and is one of the characteristic hallmarks of the diseases multiple sclerosis and AIDS dementia complex. Because of the close proximity of astrocytes and activated lymphocytes in the central nervous system, the question arose as to whether lymphocytes might contribute to the process of astrogliosis. To test this hypothesis, Fontana et al. (1982a, 1982c) examined the ability of lymphocytes to produce soluble products that might stimulate astrocyte proliferation. Supernatants from activated rat lymphocytes were shown to enhance both RNA and DNA synthesis in rat astrocyte cultures (Fontana et al., 1982a). Merrill et al. (1984) demonstrated that both rat astrocytes and oligodendrocytes could respond by increased proliferation to supernatants from activated human T cells, and these supernatants also enhanced maturation of oligodendrocytes as assessed by the increased expression of myelin basic protein (MBP) (Benveniste et al., 1985).

Since soluble factors from activated lymphoid cells could enhance the growth of glial cells, investigators were interested in determining whether the reciprocal could occur, that is, whether glial cells might secrete soluble products that would affect lymphoid cells and/or macrophages. Fontana et al. (1982b) discovered that cultured murine astrocytes, upon stimulation with lipopolysaccharide, secreted significant amounts of prostaglandin and an IL-1 like factor, and that human glioblastoma cell lines constitutively secreted an IL-1 like molecule. These early studies provided evidence that glial cells and lymphocytes could communicate via soluble mediators.

CYTOKINES: GENERAL FEATURES

Cytokines play a major role in the initiation, propagation, regulation, and suppression of immune and inflammatory responses. Although cytokines comprise a diverse group of proteins, they share a number of general properties. Cytokines are low molecular weight proteins produced during the effector phases of immunity. Most cells do not constitutively produce cytokines; instead, an activation event results in cytokine gene transcription. Cytokines generally are secreted, but can also be expressed on the cell surface. An individual cytokine can be produced by many different cell types and have multiple biological effects on different cell types. Cytokines have also been shown to have redundant functions, that is, several cytokines can mediate a common event. Thus, the cytokine system displays pleiotropism and redundancy. Cytokines often influence both the synthesis and function of other cytokines, resulting in complex "cytokine cascades." Cytokines act locally and initiate their action by binding to specific cell surface receptors on target cells. These receptors show high affinities for their ligands, with dissociation constants in the range of 10^{-10} to 10^{-12} M, suggesting that very low amounts of a cytokine can elicit a biological response.

INTERFERON-GAMMA AND GLIAL CELLS

Interferon-gamma (IFN-γ), a pleiotropic cytokine with antiviral activity, antiproliferative effects, and immunomodulatory effects, is produced predominantly by activated T cells (for review see Farrar and Schreiber, 1993). These immune effects include the ability to enhance the functional activity of macrophages, promotion of T- and B-cell differentiation, and the modulation of both class I and class II major histocompatibility complex (MHC) expression on a wide variety of cells.

Biological Action on Glial Cells

IFN-γ is present in the central nervous system only in disease states in which the blood-brain barrier has been disrupted, and activated T-cells have infiltrated into that site. IFN-γ is a potent modulator of MHC antigen expression in a number of cell types, including astrocytes, oligodendrocytes, and microglia. The preceding chapter provides a comprehensive overview of MHC antigen expression on the astrocyte, so the effect of IFN-γ on glial cell MHC expression will be just briefly discussed here.

Cells in the brain normally express extremely low levels of class I MHC antigens, which have a critical role in the regulation of immune responses. IFN-γ induces an increase in the expression of class I MHC antigens on astrocytes, oligodendrocytes, and microglia both *in vitro* and *in vivo* (Wong et al., 1984a, 1984b; Suzumura et al., 1986). The implication of enhanced class I MHC expression on these cells is that they can be rendered susceptible to lysis by class I-restricted cytotoxic T lymphocytes (Skias et al., 1987).

Class II MHC molecules have a key role in regulating the immune response by presenting antigen to T-helper cells, resulting in their activation and differentiation (for review see Benoist and Mathis, 1990). Astrocytes and microglia do not constitutively express class II MHC antigens; however, IFN-γ can induce class II molecules on these cells *in vitro* (Wong et al., 1984a; Fierz et al., 1985; Suzumura et al., 1987). *In vitro,* class II MHC-positive astrocytes and microglia can present antigen to T cells in an MHC-restricted manner, resulting in T-cell activation (Fierz et al., 1985; Frei et al., 1987). The implication of class II expression on both astrocytes and microglia is that these cells may stimulate the development of aberrant immune responses within the central nervous system.

Recent studies from our laboratory have focused on understanding the intracellular and molecular events involved in IFN-γ induction of class II MHC expression by primary rat astrocytes. Our results indicate that both IFN-γ-induced protein kinase C activity and enhanced sodium influx (via the Na^+/H^+ antiporter) are required for class II MHC gene expression in the astrocyte (Benveniste et al., 1991). Additionally, IFN-γ-induced tyrosine kinase activity is also necessary for class II MHC expression (Lee et al., 1995). The cloning and sequencing of class II MHC genes have led to the identification of conserved sequences located between 50 and 160 base pairs upstream of the transcriptional start site of all class II promoters. Three elements have been described: from 3′ to 5′, they are the Y, X, and W boxes, respectively (for review see Benoist and Mathis, 1990). These conserved elements are necessary for constitutive and IFN-γ-mediated expression of class II MHC in various cell lines. Studies on primary rat astrocytes indicate that IFN-γ acts at the transcriptional level to induce class II expression in these cells, and that the W, X, and Y elements are all essential for IFN-γ inducibility of the class II gene. We have identified a IFN-γ-induced DNA binding protein with specificity for the X element that is produced by astrocytes, named IFNEX (Moses et al., 1992). We believe IFNEX is involved

in IFN-γ induced transcription of the class II MHC gene.

Role in Neurologic Diseases

Due to its ability to modulate expression of MHC antigens on glial cells, and activate macrophages, IFN-γ has been proposed to contribute to the pathogenesis of multiple sclerosis. In clinical trials, administration of IFN-γ to relapsing-remitting multiple sclerosis patients caused exacerbation of disease (Panitch et al., 1987), suggesting that IFN-γ has a role in disease progression. In multiple sclerosis patients, IFN-γ positive cells have been localized to the plaque region, and these cells have been identified as astrocytes (Hofman et al., 1991).

The best characterized experimental model for central nervous system autoimmune disease is EAE. This disease is induced by injection of spinal cord components such as MBP or proteolipid protein (PLP) with adjuvant, injection of MBP or PLP peptides, or transfer of encephalitogenic MBP or PLP-specific T cells to naive recipients. EAE is characterized by an inflammatory infiltration of the central nervous system by activated T cells and macrophages, demyelination, and acute, chronic, or chronic-relapsing paralysis. The mediators of this disease are MBP or PLP-reactive $CD4^+$ T helper cells that are class II MHC-restricted (for review see Zamvil and Steinman, 1990). Interestingly, in mice with EAE, treatment with neutralizing antibody against IFN-γ caused an increase in disease severity and mortality (Billiau et al., 1988; Duong et al., 1992), while treatment with IFN-γ itself resulted in reduced morbidity and mortality (Billiau et al., 1988). These results suggest that IFN-γ exerts an inhibitory effect on the development of EAE, which is different than that which was observed in multiple sclerosis clinical trials, in which IFN-γ led to an exacerbation of disease (Panitch et al., 1987). IFN-γ is found in the central nervous system of mice with EAE (Kennedy et al., 1992; Merrill et al., 1992) and persists into the early chronic/remission stage (Kennedy et al., 1992). The reasons for the contradictory actions of IFN-γ in EAE compared to multiple sclerosis are unknown at this time.

INTERLEUKIN-1 AND GLIAL CELLS

Interleukin-1 (IL-1) is a 17,000 Dalton cytokine produced predominantly by activated macrophages, although other cell types, such as endothelial cells, B cells, keratinocytes, microglia, and astrocytes, can also secrete IL-1 upon stimulation (for review see Arai et al., 1990). IL-1 is responsible for mediating a variety of processes in the host response to microbial and inflammatory diseases. IL-1 is expressed in two major forms, IL-1α and IL-1β, which are the products of two different genes. Although these two forms of IL-1 have less than 30% homology between their amino acid sequences, they both bind to identical receptors and have similar biologic activities. IL-1 is the major costimulator for T-helper cell activation via the augmentation of both IL-2 and IL-2 receptor expression. IL-1 is a principal participant in inflammatory reactions through its induction of other inflammatory metabolites, such as prostaglandin, collagenase, and phospholipase A2. IL-1 acts on endothelial cells to promote leukocyte adhesion and induces the production of various cytokines, such as IL-6, tumor necrosis factor-alpha, colony-stimulating factors, and IL-1 itself.

Biological Action on Glial Cells

Purified IL-1 was shown to have a mitogenic effect on astrocyte growth *in vitro* (Giulian and Lachman, 1985), while IL-1 directly injected into the brain can stimulate astrogliosis (Giulian et al., 1988). These results suggest that IL-1 may contribute to astroglial scarring. Both activated astrocytes and microglia have been shown to secrete IL-1 *in vitro* (see below); thus these cells would provide an endogenous brain source of IL-1.

A variety of central nervous system cells have been shown to produce cytokines in response to IL-1. IL-1 stimulation of primary rat astrocytes primes them for the secretion of tumor necrosis factor-alpha (TNF-α) (Chung and Benveniste, 1990), and induces IL-6 (Frei et al., 1989; Benveniste et al., 1990; Norris et al., 1994) and transforming growth factor-beta (TGF-β) production (da Cunha and Vitkovic, 1992), and primary human astrocytes produce IL-6 and colony-stimulating factors in response to IL-1 (Aloisi et al., 1992; Lee et al., 1993). With respect to microglia and oligodendrocytes, IL-1 induces TGF-β expression by these cells (da Cunha et al., 1993). These are all cytokines involved in mediating immune reactions and inflammatory responses; thus their production by resident brain cells can contribute to these processes within the central nervous system.

Studies from our laboratory have been directed toward understanding the molecular and intracellular signaling events involved in TNF-α gene expression. IL-1 induced TNF-α gene expression in astroglioma cells is dependent on protein kinase C (PKC) activation in that two PKC inhibitors, H7 and staurosporine, abrogate IL-1-induced TNF-α expression,

and depletion of PKC activity by prolonged treatment with a high concentration of phorbol ester (phorbol myristate acetate) renders the astroglioma cells incapable of producing TNF-α in response to IL-1 (Bethea et al., 1992b). We have determined that PKC activity is also required for IFN-γ/IL-1β induction of TNF-α gene expression in rat astrocytes, and that PKC activity is needed for transcriptional activation of the TNF-α gene (Chung et al., 1992).

Expression by Glial Cells

IL-1 production by glial cells of the central nervous system was originally suggested by a study in which cultured murine astrocytes, upon stimulation with lipopolysaccharide (LPS), secreted an IL-1-like factor (Fontana et al., 1982b). This finding was later confirmed using astrocyte cultures of >95% purity, and observing that LPS-stimulated murine astrocytes expressed mRNA for both IL-1α and IL-1β (Malipiero et al., 1990). Additionally, primary cultures of human fetal astrocytes produce IL-1 upon stimulation with LPS (Velasco et al., 1991). Both rat and murine microglia produce IL-1 in response to LPS stimulation (Giulian et al., 1986; Malipiero et al., 1990; Chao et al., 1992). There has been some controversy as to whether primary cultures of astrocytes do in fact produce IL-1, the concern being that contaminating microglia in these cultures may be the source of IL-1. The use of double labeling immunohistochemistry to positively identify cells *in vivo* expressing IL-1 has demonstrated that both astrocytes and microglia express IL-1, but that astrocytes are the more frequent producer of this cytokine in diseased brain (da Cunha et al., 1993). Oligodendrocytes also are capable of producing IL-1 in that human oligodendroglioma cell lines produce IL-1 (Merrill and Matsushima, 1988), and oligodendrocytes in diseased brain stain positively for IL-1 (da Cunha et al., 1993). These data indicate that there are three endogenous sources of IL-1 within the central nervous system: astrocytes, microglia, and oligodendrocytes.

Role in Neurological Diseases

Because of the known inflammatory effects of IL-1 and the fact that glial cells can produce IL-1 within the central nervous system, there has been interest in the role of IL-1 in EAE. Jacobs et al. (1991) demonstrated that *in vivo* administration of IL-1α enhanced the severity and chronicity of clinical paralysis associated with EAE, whereas treatment of animals with soluble mouse IL-1 receptor (an IL-1 antagonist) significantly delayed the onset of EAE, reduced the severity of paralysis, and reduced the duration of disease. A study by Kennedy et al. (1992), examining EAE induced in SJL/J mice by adoptive transfer of MBP-sensitized cells, demonstrated that mRNA for IL-1 was detected in the acute phase of disease and remained elevated during the early chronic state. mRNA for other cytokines such as IL-2, IL-4, IL-6, IL-10, and IFN-γ were also detected in this model of EAE. In a separate study, IL-1 protein expression was detected in the central nervous system of Lewis rats 10 days after immunization with spinal cord homogenate. The number of lesions with IL-1-positive cells increased during full-blown EAE, and declined during remission. Based on microscopic analysis, IL-1 immunoreactivity was detected in macrophages and microglia (Bauer et al., 1993). In contrast, Merrill et al. (1992) did not detect IL-1 in the brains of SJL/J and B10.PL mice that were immunized with MBP peptides. This would suggest that the method of immunization by which EAE is induced may influence cytokine expression in the brain.

TUMOR NECROSIS FACTORS ALPHA AND BETA AND GLIAL CELLS

TNF-α, a 17,000 Dalton peptide, is the principal mediator of the host response to gram-negative bacteria (for review see Vilcek and Lee, 1991). Activated macrophages are the major cellular source for TNF-α, although other cell types such as T cells, mast cells, microglia, and astrocytes can be stimulated to secrete TNF-α. TNF-α is an active participant in inflammatory responses and can alter vascular endothelial cell function by enhancing the permeability and adhesive properties of these cells. TNF-α can modulate immune responses by affecting the expression of class I and class II MHC molecules on a variety of cell types and can stimulate many cell types to produce numerous cytokines, including IL-1, IL-6, colony-stimulating factors, and TNF-α itself.

TNF-β (also known as lymphotoxin) is genetically related to TNF-α, but is produced primarily by antigen-activated T cells (for review see Paul and Ruddle, 1988). TNF-α and TNF-β share approximately 30% amino acid residue homology, bind to the same receptors, and produce similar, but not identical, biological effects.

Biological Effects on Glial Cells

TNF-α has a diverse range of functions in the central nervous system because of its direct effects on oligodendrocytes and astrocytes. Most relevant to cen-

tral nervous system disease is the ability of TNF-α to mediate myelin and oligodendrocyte damage *in vitro* (Selmaj and Raine, 1988) and its ability to kill rat oligodendrocytes *in vitro* (Robbins et al., 1987). TNF-β exerts a more potent cytotoxic effect toward oligodendrocytes than does TNF-α, and mediates its effect by apoptosis (Selmaj et al., 1991c). This aspect of TNF-α and TNF-β activity may contribute directly to myelin damage and/or the demyelination process observed in diseases such as multiple sclerosis, EAE, and AIDS dementia complex.

TNF-α has multiple noncytotoxic effects on the astrocyte, and it may function in an autocrine fashion as astrocytes express high affinity receptors for TNF-α and secrete TNF-α upon activation (Lieberman et al., 1989; Chung and Benveniste, 1990; Velasco et al., 1991; Bethea et al., 1992a). TNF-α alone has no effect on class II MHC expression by astrocytes, but acts to enhance expression initially induced by either IFN-γ or virus (Massa et al., 1987; Vidovic et al., 1990). TNF-α acts by increasing IFN-γ-induced transcription of the class II gene, but does not affect class II mRNA stability (Vidovic et al., 1990; Panek et al., 1992). Elements within the W, X, and Y sequences of the class II MHC promoter are critical for TNF-α enhancement of IFN-γ-induced class II gene expression. TNF-α alone does not induce any nuclear proteins that bind to the class II promoter; however, combined treatment of astrocytes with both IFN-γ and TNF-α induces a DNA protein complex designated as TIC-X (TNF-α-induced complex X), which is distinct from the IFN-γ-induced nuclear protein IFNEX (Moses et al., 1992; Panek et al., 1992; Panek et al., 1994). We believe that expression of TIC-X contributes to the ability of TNF-α to enhance IFN-γ-induced class II expression in astrocytes. TNF-α has also been shown to induce proliferation of both primary bovine astrocytes (Selmaj et al., 1990) and human astroglioma cell lines (Bethea et al., 1990), thereby contributing to astrogliosis.

TNF-α is a potent inducer of cytokine production in astrocytes. Primary astrocytes and human astroglioma cell lines produce three CsFs upon stimulation with TNF-α; granulocyte-macrophage (GM)-CsF, G-CsF, and M-CsF (Malipiero et al., 1990; Aloisi et al., 1992; Lee et al., 1993). CsFs can augment inflammatory responses due to their leukocyte chemotactic properties, which would promote migration of granulocytes and macrophages to inflammatory sites within the central nervous system. TNF-α also induces IL-6 expression by both primary rat and human astrocytes (Frei et al., 1989; Aloisi et al., 1992; Norris et al., 1994). Finally, TNF-α induces expression of its own gene in rat astrocytes, suggesting a positive feedback loop for TNF-α expression (Benveniste et al., 1994).

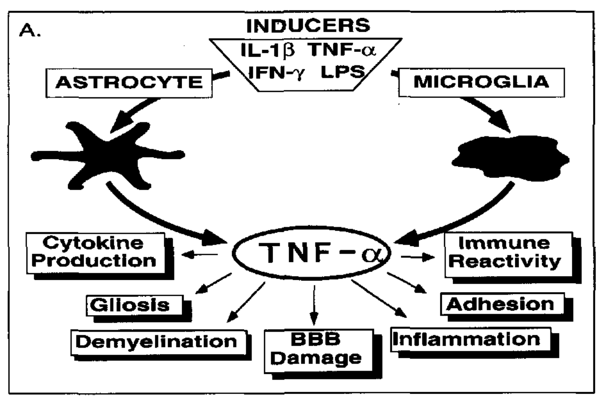
Expression by Glial Cells

Glial cells are capable of producing TNF-α upon exposure to multiple stimuli. Rat astrocytes express TNF-α in response to treatment with lipopolysaccharide (Robbins et al., 1987; Lieberman et al., 1989; Chung and Benveniste, 1990), exposure to the cytokines IFN-γ and IL-1β (Chung and Benveniste, 1990) and exposure to the neurotropic virus, Newcastle disease virus (Lieberman et al., 1989). Primary human astrocytes produce TNF-α in response to LPS (Velasco et al., 1991), and human astroglioma cell lines are capable of expressing TNF-α upon stimulation with LPS (Velasco et al., 1991) and IL-1β (Bethea et al., 1992a). Mouse microglia secrete TNF-α in response to LPS (Frei et al., 1987, Chao et al., 1992) and IFN-γ (Frei et al., 1987). These data indicate that both activated astrocytes and microglia can produce TNF-α within the central nervous system (see Figure 46-1A).

Role in Neurologic Diseases

Several groups have demonstrated that antibody to TNF-α/TNF-β can prevent the transfer of EAE by encephalitogenic T-cells in SJL/J mice (Ruddle et al., 1990; Selmaj et al., 1991b). In contrast, the disease course of EAE in SJL/J mice actively immunized with spinal cord homogenate was not affected by treatment with antibody against TNF (Teuschler et al., 1990). These differences may be due to the route of EAE induction. The above findings indicate that under certain conditions, TNF-α and TNF-β play an important role in EAE. Adding to these observations are the findings by Chung et al. (1991) that astrocytes from EAE-susceptible and -resistant rat strains differ in their ability to express TNF-α protein. Astrocytes from Lewis rats (susceptible) produce TNF-α in response to IFN-γ/IL-1β, while astrocytes from Brown Norway rats (resistant) do not. The capacity for TNF-α production by Lewis astrocytes, especially in response to disease-related cytokines such as IFN-γ and IL-1, may contribute to disease susceptibility and to the inflammation and demyelination associated with EAE.

In vivo studies suggest that TNF-α/TNF-β may be involved in multiple sclerosis. TNF-α-positive astrocytes and macrophages have been identified in the brains of multiple sclerosis patients, particularly in the plaque region (Hofman et al., 1989). Selmaj et al. (1991a) have determined that both TNF-α and



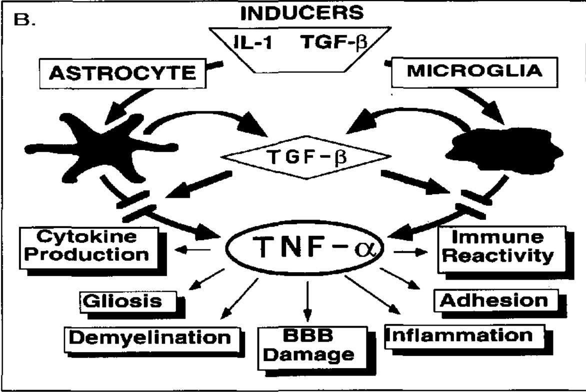


FIG. 46-1. (A) Effects of TNF-α within the central nervous system (CNS). TNF-α can be produced by both astrocytes and microglia in response to various inducers (IL-1, IFN-γ, TNF-α, LPS), and has a number of effects on glial cells, endothelial cells, and immune cells found both within the CNS and/or the CNS vasculature. (B) Effects of TGF-β within the CNS. TGF-β can be produced by activated astrocytes, microglia, and oligodendrocytes (*not shown*) in response to various inducers, including IL-1 and TGF-β. TGF-β can act in an autocrine or paracrine manner to inhibit TNF-α production, gliosis, demyelination, and inflammation within the CNS.

TNF-β are present in multiple sclerosis plaque regions, and that TNF-α is localized within astrocytes, whereas TNF-β is associated with microglia and T cells. Increased cerebrospinal fluid levels of TNF-α have been documented in patients with multiple sclerosis (Maimone et al., 1991; Sharief et al., 1991). Sharief et al. (1993, 1992) then went on to demonstrate that a strong correlation exists between cerebrospinal fluid levels of TNF-α, disruption of the blood-brain barrier, cerebrospinal fluid pleocytosis, and increased levels of circulating intercellular adhesion molecules-1 in both the serum and cerebrospinal fluid of patients with active multiple sclerosis. Other studies have failed to demonstrate TNF-α in the cerebrospinal fluid of multiple sclerosis patients (Gallo et al., 1989). The failure to detect TNF-α may be due to differences in the patients examined, or to the instability of TNF-α in cerebrospinal fluid if not treated with a protease inhibitor. Additionally, TNF-α may only be present locally in the central nervous system during different stages of multiple sclerosis and not detectable in cerebrospinal fluid.

Elevated levels of TNF-α have been demonstrated in the cerebrospinal fluid of AIDS patients, and TNF-α staining in brains from AIDS patients localizes with some endothelial cells and astrocytes, but mostly with macrophages/microglia (Tyor et al., 1992). TNF-α has been shown to activate and enhance HIV-1 replication in macrophages (Poli et al., 1990b), and thus may contribute to the pathogenesis of AIDS dementia complex. Astrocytes and microglia have a direct role in this process, as TNF-α produced by these cells induces the expression of HIV-1 in macrophages (Vitkovic et al., 1990; Peterson et al., 1992).

INTERLEUKIN-6 AND GLIAL CELLS

IL-6, similar to IL-1 and TNF-α, is a pleiotropic cytokine involved in the regulation of inflammatory and immunologic responses (for review see van Snick, 1990). IL-6, a 26,000 Dalton molecule, is secreted by a wide range of activated cells, including fibroblasts, monocytes, B cells, endothelial cells, T cells, microglia, and astrocytes. The two best described functions of IL-6 are on hepatocytes and B cells. IL-6 stimulates hepatocytes to synthesize several plasma proteins, such as fibrinogen and C-reactive protein, which contribute to the acute phase response. IL-6 serves as the principal cytokine for inducing terminal differentiation of activated B cells into immunoglobulin-secreting plasma cells.

Biological Action on Glial Cells

IL-6 has a mitogenic effect on bovine astrocytes (Selmaj et al., 1990), which may contribute to astrogliosis. Astrocytes respond to IL-6 by secreting nerve growth factor, which induces neural differentiation (Frei et al., 1989). IL-6 has been demonstrated to inhibit TNF-α production by monocytes (Aderka et al., 1989). Since astrocytes can secrete TNF-α, and TNF-α induces IL-6 production by astrocytes (see below), IL-6 may be involved in the negative regulation of TNF-α expression in the central nervous system.

Expression by Glial Cells

IL-6 is produced within the central nervous system by both astrocytes and microglia. Primary human, mur-

ine, and rat astrocytes can secrete IL-6 in response to a number of stimuli, including virus, IL-1, TNF-α, IFN-γ plus IL-1, lipopolysaccharide, calcium ionophore, and norepinephrine (Frei et al., 1989; Lieberman et al., 1989; Benveniste et al., 1990; Aloisi et al., 1992; Norris and Benveniste, 1993). Mouse microglia secrete IL-6 upon infection with virus or stimulation with the cytokine macrophage colony-stimulating factor (Frei et al., 1989), and rat microglia express IL-6 upon stimulation with lipopolysaccharide (Norris and Benveniste, 1993).

The molecular mechanism(s) by which IL-1β and TNF-α activate IL-6 expression have been examined by transient transfection of the IL-6 promoter linked to a reporter gene in primary rat astrocytes. Both IL-1β and TNF-α act at the transcriptional level to induce IL-6 gene expression, and use of deletion mutants revealed that the nuclear factor-kappa B (NF-κB)-like binding site is required for cytokine induction of IL-6 promoter activity (Sparacio et al., 1992). Nuclear proteins isolated from IL-1β- or TNF-α-treated astrocytes are specific for the NF-κB-like binding site within the IL-6 promoter, and it appears that the action of IL-1β and TNF-α is mediated by post-translational activation of preexisting cytoplasmic NF-κB.

Role in Neurologic Diseases

Increased IL-6 levels have been found in the cerebrospinal fluid of mice suffering acute EAE, and Gijbels et al. (1990) suggest that local production of IL-6 is responsible, since serum levels of IL-6 were not elevated. IL-6 mRNA levels increase rapidly during acute EAE in SJL/J mice, and decline when clinical symptoms resolve (Kennedy et al., 1992). In contrast, IL-6 protein is not found in the central nervous system of SJL/J mice which acquire EAE through MBP peptide immunization (Merrill et al., 1992). Again, the different methods of immunization and analysis may account for the conflicting results.

One of the hallmarks of multiple sclerosis is intrathecal B cell activation as evidenced by elevation of the cerebrospinal fluid IgG index and the presence of oligoclonal IgG bands in the cerebrospinal fluid (Tourtellotte and Ma, 1978). Since IL-6 is involved in differentiation of B cells into immunoglobulin-secreting plasma cells, there has been interest in determining whether elevated IL-6 levels could be responsible for local B-cell responses within the central nervous system. Results have been conflicting; two groups report that IL-6 is not detected in multiple sclerosis cerebrospinal fluid (Frei et al., 1988; Houssiau et al., 1988), while two more recent studies suggest that IL-6 is elevated in multiple sclerosis cerebrospinal fluid (Maimone et al., 1991), and multiple sclerosis plasma (Frei et al., 1991). These latter findings suggest that there is a heightened systemic B-cell response in multiple sclerosis.

Elevated central nervous system IL-6 levels have been documented in AIDS dementia complex patients (Tyor et al., 1992). IL-6 has been shown to upregulate production of HIV in infected cells of the monocytic lineage, and to act synergistically with TNF-α (Poli et al., 1990a). IL-6 produced by human astrocytes can stimulate HIV-1 expression in a promonocyte cell line (Vitkovic et al., 1991), thus, intracerebral production of IL-6 by astrocytes may contribute to HIV replication within the central nervous system.

COLONY-STIMULATING FACTORS AND GLIAL CELLS

The group of cytokines that have potent stimulatory effects on the growth and differentiation of bone marrow progenitor cells are collectively called CsFs. By stimulating the growth and differentiation of bone marrow cells, CsFs act to provide inflammatory leukocytes (for review see Golde and Gasson, 1988). Interleukin-3 (IL-3), also known as multi-CsF, is produced by T-helper cells, and acts on the most immature bone marrow progenitors to induce the expansion of cells that differentiate into all known mature cell types. Granulocyte-macrophage colony-stimulating factor (GM-CsF) is produced by a number of activated cells, including T cells, macrophages, endothelial cells, fibroblasts, and astrocytes. GM-CsF acts on bone marrow progenitor cells already committed to differentiate into granulocytes and monocytes. GM-CsF can also interact with various mononuclear phagocytes, including microglia, to induce their activation. Macrophage colony-stimulating factor (M-CsF), also called CsF-1, is made by macrophages, endothelial cells, and fibroblasts. M-CsF acts primarily on progenitor cells already committed to develop into monocytes; these progenitor cells are more mature than the targets for GM-CsF. Granulocyte colony-stimulating factor (G-CsF) is made by the same cells that produce GM-CsF, and acts primarily on bone marrow progenitors already committed to develop into granulocytes.

Biological Action on Glial Cells

As activation of microglia, the macrophage of the brain, is an important early response to brain

trauma, there has been interest in how the activation and differentiation of microglia is induced. Frei et al. (1987) demonstrated that both IL-3 and GM-CsF induced murine microglia to proliferate. Further *in vitro* studies by Giulian and Ingeman (1988) also showed that rat microglia could proliferate in response to IL-3, GM-CsF, and M-CsF, and that both IL-3 and GM-CsF induced more rapid phagocytosis by microglia. They also performed *in vivo* experiments in which recombinant GM-CsF, IL-3, M-CsF, or G-CsF was infused into the cerebral cortex of rats. Both GM-CsF and IL-3 stimulated the appearance of microglia at the site of injection, and the phagocytic capability of these cells. M-CsF has also been shown to induce microglia to produce IL-6 (Frei et al., 1989), and inhibits both basal and IFN-γ-induced class II MHC expression on microglia (Lee et al., 1993). These findings indicate that some of the CsFs can enhance inflammatory responses within the central nervous system by activation of microglia.

Expression by Glial Cells

Astrocytes appear to be the major source of CsFs within the brain. Unstimulated astrocytes do not constitutively express GM-CsF and G-CsF, but are induced to by both TNF-α and LPS (Malipiero et al., 1990; Ohno et al., 1990). Primary human astrocytes were recently shown to produce GM-CsF, M-CsF, and G-CsF in response to both IL-1 and TNF-α (Aloisi et al., 1992; Lee et al., 1993). Unstimulated human astrocytes constitutively expressed mRNA for M-CsF, but had to be induced by IL-1 or TNF-α to express transcripts for GM-CsF or G-CsF. Similar observations have been made for murine astrocytes (Hao et al., 1990; Thery et al., 1990). Microglia can be induced to express mRNA for both M-CsF and G-CsF upon stimulation with LPS (Malipiero et al., 1990; Thery et al., 1990), and human fetal microglia constitutively express M-CsF mRNA and protein, which is enhanced by LPS (Lee et al., 1993).

TRANSFORMING GROWTH FACTOR-BETA AND GLIAL CELLS

TGF-β is a dimeric protein of approximately 28,000 Daltons that is synthesized by almost all cell types. It is normally secreted in a latent form that must be activated by proteases (for review see Massague, 1990). The TGF-β family is comprised of five different isoforms encoded by separate genes, which have high amino acid sequence homology. The actions of TGF-β are highly pleiotropic and include inhibiting the proliferation of many cell types (epithelial, endothelial, lymphoid, and hematopoietic cells), promoting the growth of new blood vessels (angiogenesis), serving as a chemotactic factor for macrophages, and inhibiting immune and inflammatory responses. TGF-β has been demonstrated to inhibit the production of numerous cytokines and is thought to function as a negative regulator of immune responses.

Biological Action on Glial Cells

TGF-β can modulate the activity of astrocytes, microglia, and oligodendrocytes. TGF-β1 and TGF-β2 can inhibit IFN-γ-induced class II MHC expression on rat astrocytes (Schluesener, 1990), inhibit proliferation of rat astrocytes (Lindholm et al., 1992; Morganti-Kossmann et al., 1992), and can act as chemotactic agents for both rat astrocytes and microglia (Yao et al., 1990; Morganti-Kossmann et al., 1992). TGF-β inhibits TNF-α production by microglia (Suzumura et al., 1993), and astrocytes (Benveniste et al., 1994). TGF-β affects oligodendrocytes by promoting differentiation of these cells (McKinnon et al., 1993). Since TGF-β is produced by glial cells (see below), locally produced TGF-β may contribute to the recruitment and activation of glial cells (both astrocytes and microglia) at local inflammatory sites within the central nervous system.

Expression by Glial Cells

Primary rat astrocytes, upon exposure to exogenous TGF-β, secrete TGF-β (Wahl et al., 1991). This same group later demonstrated that rat astrocytes constitutively express mRNA for TGF-β1, which is increased upon exposure to exogenous TGF-β1, indicating that TGF-β1 levels can be regulated in an autocrine manner (Morganti-Kossmann et al., 1992). da Cunha and Vitkovic (1992) have also shown that primary rat astrocytes constitutively express mRNA for TGF-β1, but do not constitutively secrete TGF-β1 protein. However, upon stimulation with IL-1, the astrocytes secrete TGF-β1. Further work from the Vitkovic laboratory has demonstrated that both primary rat oligodendrocytes and microglia can secrete TGF-β1 upon stimulation with IL-1α (da Cunha et al., 1993). Taken together, the above studies indicate that all three glial cell types, astrocytes, oligodendrocytes, and microglia, are capable of secreting TGF-β. As TGF-β exerts many immunosuppressive effects,

TGF-β produced by glial cells may act to restrict and/or downregulate inflammatory processes within the central nervous system. Additionally, TGF-β may exert beneficial effects on oligodendrocytes by inducing differentiation of these cells.

Role in Neurologic Diseases

Several studies have demonstrated that TGF-β improves the clinical course of EAE in SJL/J mice (Johns et al., 1991; Kuruvilla et al., 1991; Racke et al., 1991). Injection of TGF-β1 could delay development of EAE, and prevent the incidence of relapse in these mice (Kuruvilla et al., 1991). Racke et al. (1991) demonstrated that TGF-β1 inhibited the activation of MBP-specific lymph node cells *in vitro,* which reduced that capacity of these cells to transfer EAE. Additionally, injection of TGF-β1 resulted in an improved clinical course, even when administered during ongoing disease. Johns et al. (1991), showed that *in vivo* injection of TGF-β1 reduced the incidence of clinical disease, as well as the severity of inflammation and demyelination within the central nervous system. In addition, TGF-β1, -β2, and -β3 were present in inflammatory lesions within the brain. Santambrogio et al. (1993) examined the mechanism(s) by which TGF-β modulates the disease course of EAE. Their results demonstrated that TGF-β treatment prevented the accumulation of myelin-sensitized T cells in brain and spinal cord, indicating the protective effect of TGF-β is exerted at the level of the central nervous system and/or its vascular endothelium. It was further suggested that TGF-β may act by inhibiting both the production of TNF-α and its effects within the central nervous system, including the involvement of TNF-α in inflammatory processes (see Figure 46-1B).

TGF-β1 has been identified in the brains of patients with AIDS, but not in control brain tissue (Wahl et al., 1991). The TGF-β staining was localized to macrophages, microglia, and astrocytes, especially in areas of diseased brain. Moreover, HIV-1-infected monocytes secreted a factor that induced cultured astrocytes to secrete TGF-β, which in all likelihood is TGF-β itself. TGF-β has bifunctional effects on HIV expression, either inhibiting or enhancing replication, depending on the time of exposure (Lazdins et al., 1991; Poli et al., 1991). Thus, HIV-1-induced TGF-β production by macrophages may act in an autocrine manner to modulate HIV replication, or in a paracrine fashion to induce astrocytes to produce TGF-β. By either pathway, TGF-β may play an important role as a regulator of HIV expression in infected macrophages/microglia.

CHEMOATTRACTANT CYTOKINES AND GLIAL CELLS

A family consisting of at least 10 distinct novel 8000 to 10,000 Dalton cytokines has been described recently. Collectively designated as "chemokines" or "intercrines," these cytokines are the product of two related gene families, members of which exhibit sequence homology and structural similarities (for review see Oppenheim et al., 1991). These cytokines are expressed locally in response to inflammatory stimuli, and act to recruit inflammatory cells via their chemoattractant properties. In the mouse, representative chemokines include JE/MCP-1 and IP-10.

A recent study by Ransohoff et al. (1993) investigated chemokine production in the central nervous system during EAE to identify factors potentially governing inflammatory cell accumulation during immune-mediated demyelination. EAE was induced in SJL/J mice using PLP peptides, and expression of JE/MCP-1 and IP-10 mRNA was examined by RT-PCR and *in situ* hybridization. Astrocytes were the only cells in the central nervous system that expressed mRNA transcripts for JE/MCP-1 and IP-10, and expression correlated with the appearance of clinical and histologic EAE. *In vitro* studies support this finding, since the human astroglioma cell line U-105MG constitutively secretes high amounts of JE/MCP-1 (Yoshimura et al., 1989), and human astrocytic cells express IP-10 mRNA following exposure to IFN-γ and TNF-α (Ransohoff et al., 1993). These findings suggest that astrocytes play a significant role in the accumulation of inflammatory cells within the central nervous system due to their ability to secrete "chemokines."

SUMMARY

This chapter has summarized studies showing that cells of the immune system and glial cells of the central nervous system use many of the same cytokines as communication signals. Activated astrocytes and microglia are the principal sources of these cytokines (IL-1, IL-6, TNF-α, CsFs, TGF-β, chemokines), although oligodendrocytes are capable of expressing IL-1 and TGF-β. The glial cells respond to these cytokines by changes which include the following (see Table 46-1 for summary):

1. Regulation of proliferation and differentiation
2. Induction, enhancement, and inhibition of the expression of cell surface antigens (class I MHC, class II MHC)
3. Stimulation of the secretion of other cytokines

TABLE 46–1. *Cytokines in the Central Nervous System*

Glial Cell Type	Cytokines Produced	Response to Cytokines							
		IFN-γ	IL-1	TNF-α/β	IL-6	GM-CsF	M-CsF	IL-3	TGF-β
Astrocyte	IL-1 TNF-α IL-6 M-CsF G-CsF GM-CsF TGF-β Chemokines	Increases class I MHC Induces class II MHC Increases TNF-α receptors Primes cells for TNF-α, IL-6 production	Proliferation IL-6 production TNF-α production G-CsF, M-CsF, GM-CsF production TGF-β production	Increases class I MHC Enhances class II MHC Proliferation IL-6 production G-CsF, M-CsF, GM-CsF production TNF-α production	Proliferation NGF production	?	No effect; do not have M-CsF receptors	?	Chemotactic Inhibits proliferation Inhibits class II MHC Inhibits GM-CsF production
Microglia	IL-1 TNF-α IL-6 M-CsF G-CsF TGF-β	Increases class I MHC Induces class II MHC TNF-α production	TGF-β production	Inhibits class II MHC	?	Proliferation Increases phagocytosis	Proliferation Morphological changes IL-6 production Inhibits class II MHC	Proliferation Increases phagocytosis Morphological changes	Chemotactic
Oligodendrocyte	IL-1 TGF-β	Increases class I MHC	TGF-β production	Cell death Myelin damage	?	?	?	?	Differentiation of cells

This is by no means a complete listing since cytokines affect the expression of other genes by glial cells such as complement components, ICAM-1, and Fc receptors, which were not discussed in this chapter. There is a complex circuitry of interactions mediated by cytokines, especially in the event of blood-brain barrier damage and lymphoid/mononuclear cell infiltration into the central nervous system. The secretion of IFN-γ by infiltrating activated T cells may be the initiating signal for glial cell activation by inducing astrocytes and microglia to express class I and II MHC antigens, and priming these cells for subsequent cytokine production. In addition, infiltrating activated macrophages produce cytokines such as IL-1, TNF-α, and IL-6, which in concert with IFN-γ would trigger glial cells to produce their own cytokines. The activation of astrocytes and microglia to secrete cytokines may contribute to the propagation of intracerebral immune and inflammatory responses initiated by immune cells. The cytokine cascades ongoing in the central nervous system could ultimately be downregulated due to the presence of immunosuppressive cytokines such as TGF-β and IFN-β, or perpetuated, leading to disease progression. Whether immune and inflammatory responses within the central nervous system are propagated or suppressed depends on a number of parameters including:

1. The activational status of these cells
2. Cytokine receptor levels on glial and immune cells
3. The concentration and location of cytokines in the central nervous system
4. The temporal sequence in which a particular cell is exposed to numerous cytokines

Many of the studies cited in this chapter reflect the capacity of cultured primary murine, rodent, and human cells or human glial cell lines to function *in vitro*. These studies provide important information on how these cells can respond to a variety of stimuli, and provide useful working models for further understanding the nature of the second messenger signals utilized by glial cells, delineating *cis*-acting DNA regulatory elements and nuclear proteins involved with MHC and cytokine expression by glial cells, and characterizing the types of cytokine receptors found on glial cells. The *in vitro* studies suffer, however, from the fact that the cells have been taken out of their natural microenvironment. *In vivo* studies can address the capacity of cells to express cytokines or surface antigens in their normal setting, or in the case of EAE or multiple sclerosis during ongoing disease. Many of the *in vivo* studies have demonstrated that particular glial cells can express certain genes, which correlate with *in vitro* results. However, there still is controversy in the literature regarding production of cytokines by astrocytes, oligodendrocytes, and microglia. Some of the *in vivo* studies suggest that microglia are the predominant source of some cytokines such as IL-1 and TNF-α. One of the problems has been that most of the *in vivo* studies have examined cytokine *protein* expression within the central ner-

vous system. These studies cannot distinguish between cells producing cytokines or binding them via specific receptors. *In situ* hybridization to examine cytokine mRNA expression coupled with immunohistochemistry to identify the cell type producing the cytokine will definitively address the issue of which endogenous glial cells produce cytokines *in vivo*. Thus, the combined use of both *in vitro* and *in vivo* systems, and extrapolation between the two, will provide an understanding of the mechanism(s) by which cytokines influence glial cell function.

I thank Ms. Sue Wade for superb secretarial and editorial assistance in preparing this manuscript.

47 Glial cell regulation of extracellular potassium

ERIC A. NEWMAN

Neurons in the central nervous system are maintained in a highly regulated environment. The blood-brain barrier provides an effective shield that isolates the brain from variations in blood levels of organic and inorganic molecules. This isolation is essential as neurons are extremely sensitive to such common ions as K^+ and Ca^{2+} and to amino acids, including glutamate and γ-aminobutyric acid (GABA). The blood-brain barrier by itself cannot ensure a stable extracellular environment, however. Neuronal activity results in the release of neurotransmitters and in extracellular pH shifts, both of which modify neuronal function.

Neuronal activity also results in the release of K^+ and its accumulation within extracellular space. Activity-dependent increases in extracellular K^+ concentration ($[K^+]_o$) would rapidly lead to substantial changes in neuronal behavior if these increases were not buffered. The central nervous system possesses several homeostatic mechanisms that help to regulate activity-dependent $[K^+]_o$ variations. Glial cells play a major role in this regulatory process.

Although the discussion of K^+ regulatory mechanisms in this chapter is limited to vertebrate species, glial cells of invertebrates also help regulate $[K^+]_o$ (Coles and Tsacopoulos, 1979; Gardner-Medwin et al., 1981; Coles, 1989; Wuttke, 1990).

ACTIVITY-DEPENDENT VARIATIONS IN $[K^+]_o$

The resting level of $[K^+]_o$ in extracellular space is low, approximately 3 mM. Thus, the release of even small amounts of K^+ from active neurons leads to a substantial percentage increase in $[K^+]_o$ (Adelman and Fitzhugh, 1975; Coles and Poulain, 1991). Neurons at rest release little K^+. Potassium efflux increases greatly, however, when neurons depolarize, due to the increased electrical driving force on K^+ and to the opening of voltage-gated K^+ channels.

Ion-Selective Microelectrode Measurements of $[K^+]_o$ Variations

Cerebral Cortex. Activity-dependent variations in $[K^+]_o$ in the central nervous system have been measured directly with ion-selective microelectrodes. Measurements reveal that normal physiological stimuli result in modest $[K^+]_o$ increases in the cortex, which rarely exceed 1 mM (Figure 47-1A; (Kelly and Van Essen, 1974; Singer and Lux, 1975). Much larger increases are seen, however, under pathological conditions. Increases to 8 to 12 mM are seen during episodes of epileptic discharge (Lux, 1974; Lothman et al., 1975), while electrical stimulation results in $[K^+]_o$ increases, which can rise as high as 12 mM (Somjen, 1979) (Figure 47-2). An intriguing aspect of these $[K^+]_o$ increases is that $[K^+]_o$ does not (usually) exceed a ceiling level of ~12 mM, no matter how intense the electrical stimulation or the epileptic activity (Heinemann and Lux, 1977). A ceiling level of ~10 mM is also seen in the optic nerve, a white matter tract (Connors et al., 1982). The existence of this ceiling $[K^+]_o$ level is direct evidence that the central nervous system possesses powerful mechanisms for removing K^+ from extracellular space.

Retina. Activity-dependent variations in $[K^+]_o$ have been extensively characterized in the vertebrate retina (Figure 47-1B). Light stimulation results in $[K^+]_o$ increases in the two synaptic layers of the retina, an increase of less than 1 mM in the inner plexiform layer, and a smaller more transient increase in the outer plexiform layer (Karwoski and Proenza, 1977; Dick and Miller, 1985; Karwoski et al., 1985). In addition, photoreceptor hyperpolarization generates a large light-evoked $[K^+]_o$ decrease in the distal retina, which can reach several millimolar under optimal conditions (Oakley and Green, 1976).

Effect of $[K^+]_o$ Variations on Neuronal Function

The resting membrane potential of neurons reflects, in large part, the K^+ equilibrium (Nernst) potential

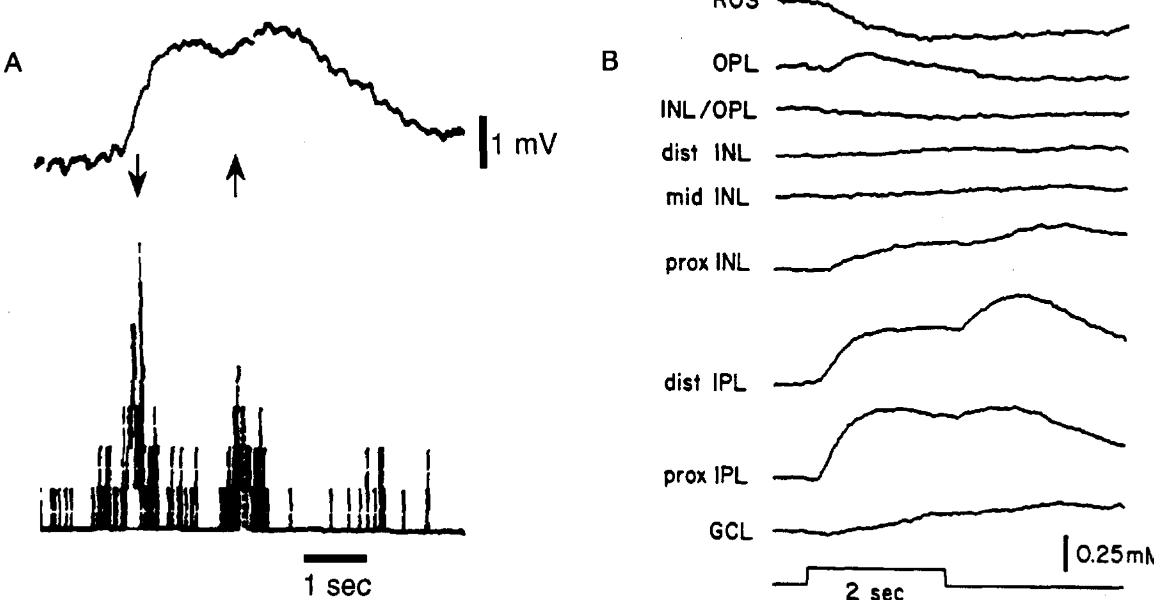

FIG. 47-1. Variations in $[K^+]_o$ within the central nervous system evoked by sensory stimuli. (**A**) *Upper trace:* $[K^+]_o$ variations in the cat visual cortex evoked by movement of a bar down (↓) and then up (↑) through the receptive field of a hypercomplex cell. *Lower trace:* Activity of an adjacent neuron, recorded with the reference barrel of the double-barreled ion selective microelectrode. The 1-mV calibration bar for $[K^+]_o$ corresponds to ~0.17 mM. [Modified from Singer and Lux (1975) with permission.] (**B**) $[K^+]_o$ variations in the frog retina (retinal slice preparation) evoked by a diffuse 2-second light flash. $[K^+]_o$ increases occur in the inner plexiform layer (*IPL*) and the outer plexiform layer (*OPL*), while a $[K^+]_o$ decrease occurs in the subretinal space (rod outer segment layer, *ROS*). [From Karwoski et al. (1985), with permission.]

which, in turn, is determined by the K^+ concentration gradient across the cell membrane. Physiological increases in $[K^+]_o$ result in small but significant cell depolarizations which can influence neuronal function in many ways, including modification of the threshold for action potential initiation and modulation of voltage-sensitive receptor processes (e.g., the *N*-methyl-D-aspartate (NMDA) receptor). Synaptic transmission is particularly sensitive to $[K^+]_o$ variations. An increase in $[K^+]_o$ beyond 5 mM in hippocampal slices, for instance, leads to a reduction in the efficacy of synaptic transmission (Rausche et al., 1990).

Variations in $[K^+]_o$ as Possible Signals

Activity-dependent variations in $[K^+]_o$ are normally viewed as perturbations of the neuronal microenvi-

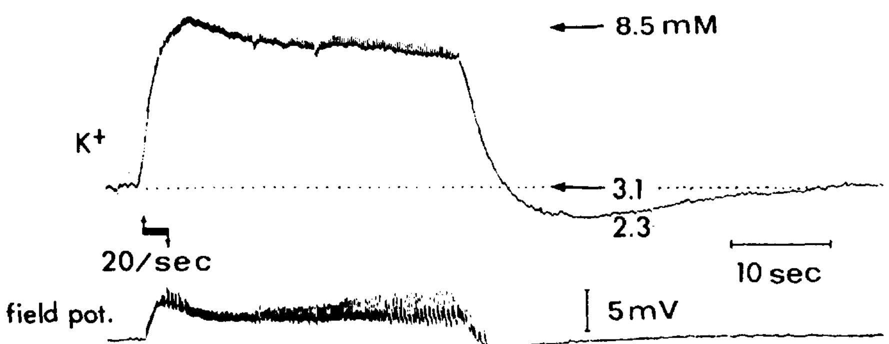

FIG. 47-2. Variations in $[K^+]_o$ in the cat cerebral cortex evoked by electrical stimulation of the cortical surface. *Upper trace:* $[K^+]_o$. *Lower trace:* The field potential (recorded with the reference barrel of the ion-selective microelectrode, negative upward). The brief electrical stimulus (*horizontal bar between traces*) triggers a prolonged epileptiform discharge and $[K^+]_o$ increase. The electrical stimulation ends before the peak of the $[K^+]_o$ response. Note that $[K^+]_o$ drops below control level (*dotted line*) following the end of the neuronal activity. [From Lux (1974), with permission.]

ronment which must be minimized in order to preserve normal brain function. It is possible, however, that variations in $[K^+]_o$ also serve as signals between neurons or between neurons and other cells (Orkand et al., 1966). The magnitude of a $[K^+]_o$ increase is a good index of overall neuronal activity, and thus conveys important information. Increases in $[K^+]_o$ may serve as signals mobilizing energy sources for neurons, perhaps from glial cells (see Chapter 52). Potassium variations may also constitute a signal which couples increases in neuronal activity to localized increases in blood flow (Paulson and Newman, 1987).

OVERVIEW OF POTASSIUM REGULATORY MECHANISMS

There are several mechanisms which aid in the regulation of activity-dependent variations in $[K^+]_o$ (Figure 47-3). The simplest of these is diffusion of K^+ through extracellular space. Extracellular $[K^+]$ can also be regulated by K^+ uptake into cells, either neurons or glial cells. Both active uptake, mediated by Na^+/K^+ ATPases, or passive uptake, mediated by flux through transporters or channels, operate to reduce $[K^+]_o$ increases. Glial cells accumulate K^+ at a far higher rate than do neurons (Walz and Hertz, 1982), indicating the importance of these cells to K^+ regulation.

Variations in $[K^+]_o$ can also be regulated by K^+ transport via current flow through glial cells (Orkand et al., 1966). This process, termed "K^+ spatial buffering," leads to the transfer of extracellular K^+ from regions where $[K^+]_o$ is higher to regions where K^+ is lower. See also Chapter 26. In a specialized form of spatial buffering, termed "K^+ siphoning" (Newman et al., 1984), K^+ currents are selectively directed out from the endfeet of glial cells.

DIFFUSION

Activity-dependent increases in $[K^+]_o$ are dissipated, in part, by simple diffusion of K^+ through extracellular space. The movement of ions, including K^+, in extracellular space is accurately described by diffusion with the ion diffusion coefficient, D (~$2 \cdot 10^{-5}$ $cm^2\ s^{-1}$ for K^+) reduced by a factor λ^2, where λ is the tortuosity of the diffusional path through extra-

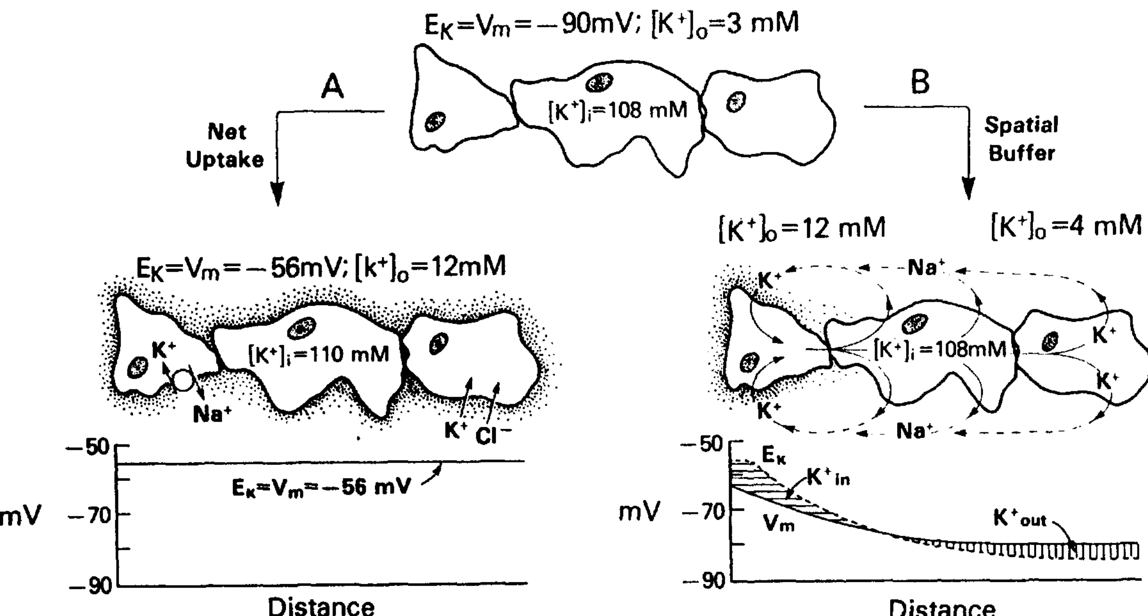

FIG. 47-3. Overview of glial cell K^+ regulatory mechanisms. Top: Three glial cells, coupled by gap junctions. Left: Net K^+ accumulation. When $[K^+]_o$ is raised uniformly (*shaded area surrounding cells*) uptake mechanisms lead to K^+ accumulation and to an increase in $[K^+]_i$ in the glial cells. Uptake occurs by active pumping (*left cell*) and by passive uptake (*right cell;* $Na^+/K^+/2Cl^-$ transport or $K^+ + Cl^-$ flux driven by Donnan forces). Increased $[K^+]_o$ results in cell depolarization (*shown in graph below cells*). **Right:** K^+ transfer via spatial buffer current. When $[K^+]_o$ is raised locally (*shaded area surrounding left cell*) a current flow is established with K^+ entering the left cell and K^+ leaving the other two cells. This current results in the transfer of K^+ from the shaded region where $[K^+]_o$ is raised to regions where $[K^+]_o$ is lower. The graph below the cells illustrates that the transmembrane K^+ fluxes are driven by the difference between the cell membrane potential (V_m) and the K^+ equilibrium potential (E_K). K^+ influx occurs when E_K is positive to V_m (*left cell*). K^+ efflux occurs when V_m is positive to E_K (*middle and right cells*). Although *not illustrated,* net K^+ accumulation would also occur in the left cell. [From Orkand (1986), with permission.]

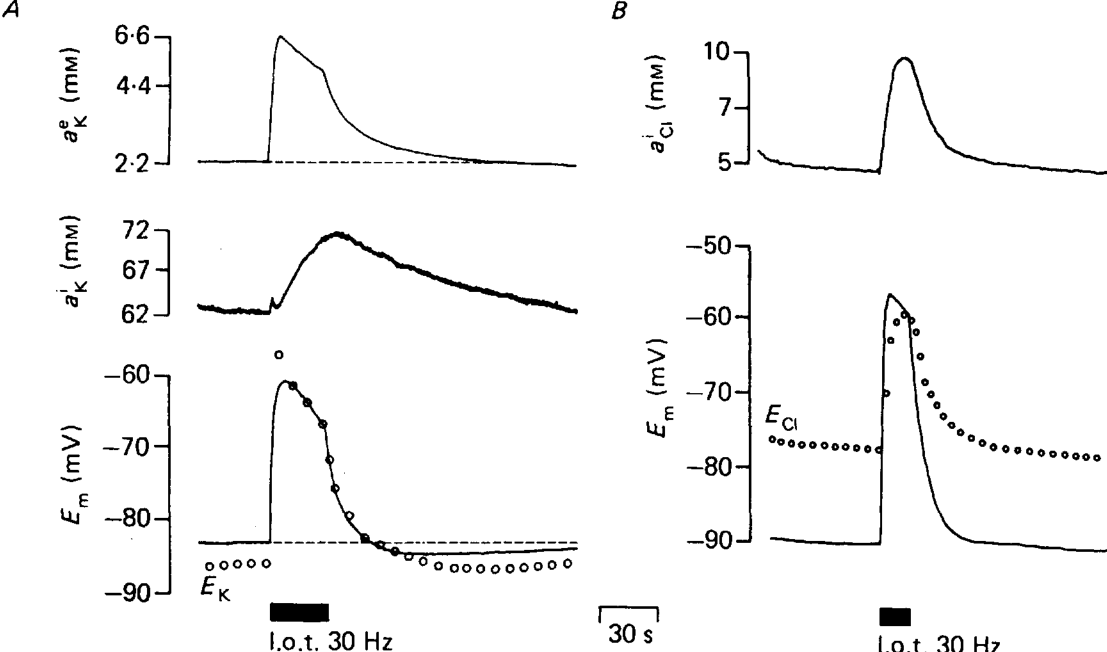

FIG. 47-4. Accumulation of K^+ and Cl^- in glial cells of the guinea pig olfactory cortex (slice preparation). (A) Electrical stimulation of the lateral olfactory tract (*l.o.t.*) results in an increase in $[K^+]_o$ (*top*), an increase in $[K^+]_i$ (*middle*), and to cell depolarization (*bottom*). (B) Stimulation also results in an increase in $[Cl^-]_i$ (*top*). The K^+ accumulation shown in Figure A was due partially to a Ba^{2+}-sensitive $K^+ + Cl^-$ influx and partially to ouabain-sensitive active uptake. Ion activities, rather than concentrations, are shown and were measured with intracellular ion selective microelectrodes. [From Ballanyi et al. (1987), with permission.]

cellular space (Chapter 26, this volume; Nicholson and Phillips, 1981). The effective diffusion coefficient, D/λ^2, equals ~$8 \cdot 10^{-6}$ cm^2 s^{-1} for K^+.

ACTIVE POTASSIUM UPTAKE

Potassium Accumulation

Activity-dependent $[K^+]_o$ increases are regulated by active K^+ uptake into cells (Figure 47-3A). All the K^+ released by active neurons must eventually be returned to these cells. This uptake occurs primarily by the action of the neuronal Na^+/K^+ ATPase (Ballanyi et al., 1984; see also Chapters 16 and 18). Evidence suggests that uptake occurs slowly in neurons, over minutes following tetanic stimulation (Heinemann and Lux, 1975; Ballanyi et al., 1984). Thus, active uptake by neurons is not sufficient to buffer rapid $[K^+]_o$ increases. This conclusion is underlined by the results of a study on cultured cells, which demonstrated that active uptake in neurons was fivefold lower than was uptake in glial cells (Walz and Hertz, 1982).

Glial cells also possess a Na^+/K^+ ATPase that is believed to play an important role in removing excess K^+ from extracellular space. The properties of the glial Na^+ pump differ from those of the neuronal pump in its activation by external K^+ (see Chapter 16). Whereas the neuronal pump saturates as $[K^+]_o$ reaches 3 to 5 mM, the activity of the glial pump continues to rise until $[K^+]_o$ reaches 18 to 20 mM (Franck et al., 1983). Thus, the glial Na^+/K^+ ATPase is well suited to maintaining $[K^+]_o$ near 3 mM and will operate efficiently to pump K^+ when $[K^+]_o$ is raised to abnormally high levels (Franck et al., 1983; Reichenbach et al., 1987).

Active glial cell uptake of K^+ has been demonstrated directly in ion-selective microelectrode experiments on guinea pig olfactory cortical slices (Ballanyi et al., 1987) (Figure 47-4). Following electrical stimulation, the intracellular K^+ concentration ($[K^+]_i$) of glial cells in slices increased substantially. Application of the Na^+/K^+ ATPase inhibitor ouabain decreased this K^+ rise, indicating that the K^+ accumulation was due, in part, to active uptake.

Active K^+ uptake has also been described in studies on cultured glial cells. In cultured mouse astrocytes, increased $[K^+]_o$ led to a substantial K^+ accumulation (measured by ^{42}K uptake), approximately half of which was ouabain-sensitive (Walz and Hinks, 1985). Similar findings have been reported for cultured oligodendrocytes (Kettenmann et al., 1987; Ballanyi and Kettenmann, 1990).

Activity-dependent increases in $[K^+]_o$ in the brain are often followed by a postactivity K^+ undershoot in which $[K^+]_o$ falls below prestimulus levels (Figure

47-2; Heinemann and Lux, 1975; Heinemann and Lux, 1977). This decrease can last for several minutes following intense neuronal activity. The $[K^+]_o$ undershoot is believed to be generated by active uptake of K^+ by neurons previously activated (Ballanyi et al., 1984), perhaps stimulated by excess internal Na^+ in these cells. This $[K^+]_o$ depletion may play an important role in $[K^+]_o$ regulation in that it provides a driving force for the restoration of K^+, temporarily stored in glial cells or transported by spatial buffering currents, back to the activated neurons (Dietzel et al., 1989).

Modulation of Pump Activity

The activity of the glial cell Na^+/K^+ ATPase increases following reactive gliosis. In rat cortex, pump activity is approximately twice as high in cobalt-induced epileptogenic tissue as it is in control tissue (Onozuka et al., 1987). Similarly, astrocytic pump activity increases ~40% in brain tissue from rats with experimentally induced hepatogenic encephalopathy (Albrecht et al., 1985). The increase in Na^+/K^+ ATPase activity will result in an enhancement of active uptake, and, perhaps to better $[K^+]_o$ regulation in damaged brain tissue.

PASSIVE POTASSIUM UPTAKE

Potassium Accumulation

A large component of K^+ accumulation in glial cells is ouabain-insensitive. This component is due to passive uptake and occurs by one of two mechanisms: (1) by coupled transport, via a $Na^+/K^+/2Cl^-$ or a K/Cl cotransporter, and (2) by K^+ influx accompanied by Cl^- influx through distinct channels and driven by Donnan forces (Boyle and Conway, 1941). Passive K^+ uptake accompanied by Cl^- influx results in an increase in internal osmolarity and to an influx of water into glial cells. Thus, passive uptake is, of necessity, coupled to glial cell swelling and to a decrease in the volume fraction of extracellular space. Indeed, neuronal activity and increased $[K^+]_o$ is often associated with decreases in extracellular volume (Dietzel et al., 1980; Ransom et al., 1985). It is important to note that decreased extracellular volume may be caused by neuronal as well as by glial cell swelling (Dietzel et al., 1989), although the extracellular volume changes seen in CNS white matter are primarily glial in origin (Ransom et al., 1985).

The *in situ* glial cell-olfactory slice experiment cited above (Ballanyi et al., 1987) provides evidence that passive K^+ uptake occurs *in vivo*. Potassium accumulation seen in these cells following electrical stimulation (Figure 47-4) was largely blocked by Ba^{2+} application, as was the stimulus evoked increase in $[Cl^-]_i$, suggesting that K^+ accumulation occurs, in part, by a passive influx of K^+ and Cl^- driven by Donnan forces. The observed 16 mM increase in intracellular $[K^+]$ was too large to be due solely to $K^+ + Cl^-$ uptake, however, suggesting that efflux of some other ion, perhaps Na^+, helped to maintain cellular osmotic balance. A K^+ cotransport mechanism appeared not to play a significant role in K^+ uptake.

Passive K^+ uptake has also been demonstrated in cultured glial cells, with both K^+ cotransport and K^+ flux through channels observed. In cultured astrocytes, a furosemide- and bumetanide-sensitive K^+ cotransporter led to K^+ accumulation following a rise in $[K^+]_0$ (Walz and Hinks, 1985; Walz, 1987). In at least some preparations, transport was dependent on both external Na^+ and Cl^-, suggesting that K^+ was taken up by a $Na^+/K^+/2Cl^-$ cotransporter (Kimelberg and Frangakis, 1985; Tas et al., 1987). Passive $K^+ + Cl^-$ influx through distinct channels was also observed in cultured astrocytes (Walz, 1987) and in cultured mouse oligodendrocytes (Ballanyi and Kettenmann, 1990).

Potassium cotransport into glial cells may be linked to active transport by a transmembrane Na^+ cycle (Walz and Hinks, 1986). Potassium influx via a $Na^+/K^+/2Cl^-$ cotransporter results in an increase in $[Na^+]_i$, which has the dual effect of stimulating the Na^+/K^+ ATPase and providing the excess internal Na^+ needed to actively pump additional K^+ into the cell. Transported Na^+ is recycled in this manner, and K^+ is accumulated within glial cells without disturbing internal Na^+ levels.

The relative contributions of K^+ cotransport and Donnan mechanisms responsible for passive K^+ accumulation in glial cells is unclear. Cotransport plays a minor role in at least one *in situ* preparation (Ballanyi et al., 1987) while its dominates in some astrocyte cultures (Walz, 1987). The issue is highlighted by the dramatic uptake differences seen in primary cultures of mouse and rat astrocytes. In a comparative study (Walz and Kimelberg, 1985), the cotransport inhibitor furosemide blocked K^+ uptake substantially in rat cells but had no effect on mouse cells. In contrast, the K^+ channel blocker Ba^{2+} had a much larger inhibitory effect in mouse cells than it did in rat cells. These differences in two closely related species could arise from a differential expression of K^+ channels and serve as a warning that cultured glial cells may be an inadequate model of K^+ uptake for glial cells *in vivo*.

Modulation of Potassium Uptake

Low Cl^- permeability may prove to be the limiting factor in glial cell K^+ accumulation driven by Donnan forces. In this respect, it is interesting to note that glial cell Cl^- permeability can be increased under certain conditions. Astrocyte Cl^- conductance increases as cells are depolarized (Bevan et al., 1985). Glial cells also possess large-conductance Cl^- channels that are normally inactive but open when the membrane is detached from a cell (in inside-out patches), suggesting that these channels are normally in an inactivated state (Gray et al., 1984; Barres et al., 1988). Channel activation may be triggered by an increase in neuronal activity (Barres et al., 1988). In addition, glial cells possess Cl^--permeable $GABA_A$ receptors (MacVicar et al., 1989; Malchow et al., 1989). Thus, neuronal activity may result in an increase in Cl^- permeability and to enhanced K^+ + Cl^- influx into glial cells.

Large glial cell depolarizations associated with spreading depression and hypoxia may also result in the activation of voltage-gated K^+ channels, such as delayed rectifier, A-type and Ca^{2+}-activated K^+ channels, which are not open near the normal cell resting potential. The resulting increase in glial cell K^+ permeability might lead to an increase in K^+ accumulation as well as to enhanced K^+ spatial buffering.

POTASSIUM SPATIAL BUFFERING

Theory

Excess K^+ released from active neurons can be buffered by its transfer to regions of neural tissue where $[K^+]_o$ is lower. This transfer can occur by diffusion of K^+ through extracellular space or by current flow through glial cells. The latter process is termed "K^+ spatial buffering" (Orkand et al., 1966). Astrocytes, due to their distribution within the central nervous system and their electrical coupling, are believed to be the glial cell principally involved in spatial buffering within the brain.

The K^+ spatial buffering process operates as follows: A local increase in $[K^+]_o$, generated by neuronal activity, results in an inbalance of K^+ equilibrium across glial cell membranes and to an influx of K^+ into glial cells. This K^+ influx depolarizes glial cells and drives out an equal amount of current from other cell regions. This current efflux will also be conducted by K^+ because glial cells are principally permeable to K^+. The net effect of this current flow is to transfer K^+ from regions where $[K^+]_o$ is higher to regions where $[K^+]_o$ is lower. The same amount of K^+ leaves the cells as enters them. Thus, to a first approximation, the spatial buffering mechanism does not result in an accumulation of K^+ within glial cells.

Spatial buffering currents are accompanied by a change in the osmotic balance in extracellular space and within glial cells (Dietzel et al., 1980). Although spatial buffering current is carried exclusively by K^+ across the glial cell membrane, it is carried largely by Na^+ and Cl^- in extracellular space and by Cl^- and organic anions, as well as by K^+, inside glial cells. As a result, in regions where $[K^+]_o$ is raised, the osmolarity decreases substantially in extracellular space and increases slightly within glial cells. (The change in osmolarity is proportional to the fraction of current carried by anions.) These osmotic shifts result in an influx of water into glial cells and to a shrinking of extracellular space (Dietzel et al., 1980).

Electrical Coupling

The distance over which K^+ is transported by the spatial buffering process is not limited by the size of a single astrocyte. Astrocytes are linked together by an extensive array of gap junctions which result in electrical coupling between cells (see Chapter 19). Thus, spatial buffering currents which enter one glial cell can flow through the glial syncytium and exit from a distant cell. In practice, spatial buffering through a glial syncytium is limited by the space constant of the syncytium. Current cannot be efficiently conducted over a long distance within a syncytium which has a short space constant.

The space constant of the astrocyte syncytium within the brain is difficult to assess because such basic cell properties as the specific membrane conductance, the distribution of membrane conductance, and the degree of electrical coupling between cells are not known. Nevertheless, estimates of the space constant of glial syncytia have been made. In the rat cerebellar cortex, a space constant of 200 μm was estimated, based on the transport of K^+ induced by an electric field (Gardner-Medwin, 1983a). Similar techniques yielded a shorter space constant of <60 μm for the frog optic tectum (Gardner-Medwin, 1985). A space constant of 104 μm was estimated for single processes (but not a syncytium) of acutely isolated type-1 rat optic nerve astrocytes (Barres et al., 1990). These space constant estimates suggest that the distance over which the K^+ spatial buffering process is effective is limited to hundreds of micrometers.

It should be noted that the transport of K^+ by spatial buffering can extend beyond the limits of sin-

gle cells, even if these cells are not electrically coupled. In the absence of electrical coupling, excess K^+ could be transported via spatial buffering to the distal extremes of a cell, where it would result in $[K^+]_o$ increases and the generation of spatial buffering currents in other cells with overlapping processes. The efficiency of such a spatial buffering process through "indirectly coupled" glial cells has not been determined.

Spatial Buffering in the Cortex

Several lines of evidence suggest that K^+ spatial buffering plays an important role in regulating activity-dependent K^+ variations within the brain. Studies in the rat cortex and cerebellum demonstrated that substantial K^+ transport occurs through current flow within cells. When a constant current was applied to the cortical surface, the amount of K^+ transported within the tissue was much larger than that predicted assuming that K^+ flux was confined solely to extracellular space (Gardner-Medwin, 1983b; Gardner-Medwin and Nicholson, 1983). The results indicated that five times as much K^+ was transported by current flow within cells as was transported through extracellular space. A large fraction of this cellular current was believed to be conducted through the glial syncytium. The results suggest that spatial buffering currents play an important role in regulating activity-dependent $[K^+]_o$ increases (Gardner-Medwin, 1983a).

Potassium spatial buffering currents have been shown to play an important role in clearing $[K^+]_o$ increases evoked by electrical stimulation in the cat cortex. Current source-density analysis of field potentials showed that current entered cells in the middle cortical layers, where evoked $[K^+]_o$ increases are largest, while currents left cells both above and below this region (Dietzel et al., 1989). These currents served to transfer K^+ away from the primary $[K^+]_o$ increase, removing 3 to 5 mM of K^+ from extracellular space during the 10 seconds of stimulation.

Evidence for K^+ spatial buffering in the cat cortex also comes from measurements of $[K^+]_o$ increases and shrinkage of extracellular space (Dietzel et al., 1980, 1982). During electrical stimulation, $[K^+]_o$ increases, although largest in the middle cortical layers, also occurred in more superficial and deeper cortical layers. Shrinkage of extracellular space, in contrast, was more sharply localized to the middle cortical layers. A potassium spatial buffer current flow, entering glial cells where $[K^+]_o$ increases are greatest, accounts nicely for these observations, as a reduction in extracellular space is predicted to occur in regions of K^+ influx into glial cells, but not in regions of K^+ efflux.

A study in the rat supraoptic nucleus (Coles and Poulain, 1991) also suggests that K^+ spatial buffering plays an important role in $[K^+]_o$ clearance. Antidromic activation of neurons in this preparation produced a $[K^+]_o$ increase only 7% of that predicted assuming no K^+ regulatory mechanisms. Evidence suggested that diffusion and net uptake of K^+ into neurons and glial cells played little role in K^+ regulation. Most of the excess K^+ appeared to be transported by a spatial buffer current to the subarachnoid space. (If K^+ currents were preferentially directed by glial cells to the subarachnoid space, this would constitute an example of K^+ siphoning.)

POTASSIUM SIPHONING

Theory

The spatial buffering mechanism, as originally proposed, presumes that K^+ conductance is distributed uniformly over the surface of glial cells. Influx of K^+ in regions where $[K^+]_o$ is raised is balanced by a K^+ efflux from all other glial cell regions. This current flow results in excess K^+ being transferred somewhat indiscriminately to all neural regions where $[K^+]_o$ is lower.

As reviewed in the following section, however, K^+ conductance in at least some glial cells is not distributed uniformly over the cell surface, but rather is localized preferentially to cell endfeet. As a result of this K^+ conductance localization, spatial buffering currents will be directed to specific regions of the nervous system. Instead of K^+ efflux occurring from all glial cells regions, efflux will be shunted preferentially from glial cell endfeet (Figure 47-5). This spatially directed variant of K^+ spatial buffering is termed "K^+ siphoning" (Newman et al., 1984) and results in, in at least some tissues, a more efficient regulation of $[K^+]_o$.

Within the brain, glial cell endfeet terminate at the pial surface, adjacent to the subarachnoid space, and at the surface of blood vessels. In the retina, the endfeet of Müller cells, the principal glial cells in this tissue, terminate at the inner limiting membrane, adjacent to the vitreous humor. Thus, K^+ siphoning results in the preferential transfer of K^+ to the subarachnoid space and, in the retina, to the vitreous humor. These fluid-filled spaces function as large reservoirs or sinks for the K^+. It is stressed that K^+ siphoning is simply a specialized form of K^+ spatial buffering in which K^+ currents are preferentially di-

FIG. 47-5. Regulation of $[K^+]_o$ by K^+ siphoning in the amphibian retina. Light-evoked neuronal activity generates $[K^+]_o$ increases in the inner plexiform layer (*IPL*) and the outer plexiform layer (*OPL*). These $[K^+]_o$ increases lead to K^+ influx into Müller cells (*M*) in the plexiform layers (*arrows*) and to K^+ efflux from the cell endfoot. The K^+ fluxes establish a radially oriented current within the retina (*solid lines*) which results in the transfer of K^+ from the plexiform layers to the vitreous humor. The current also generates a vitreous positive potential, the electroretinogram b-wave. [Modified from Newman (1985b), with permission.]

rected out of glial cells through high conductance regions.

Potassium siphoning also directs excess K^+ to the surface of blood vessels and results in a rapid $[K^+]_o$ increase at the blood vessel wall following neuronal activity (Paulson and Newman, 1987). The consequence of this $[K^+]_o$ rise is not known, although it has been implicated in the local regulation of blood flow within the brain (Paulson and Newman, 1987). [Brain vessels probably do not function as effective K^+ sinks as the blood-brain barrier is largely impermeable to K^+ and K^+ transport activity in vascular endothelial cells is relatively low (Goldstein, 1979).]

Localization of K^+ conductance to glial cell endfeet has the additional consequence of maintaining the cell membrane potential at a hyperpolarized value when $[K^+]_o$ is raised within the parenchyma. The glial cell membrane potential remains close to the K^+ equilibrium potential at the cell endfoot because a large fraction of the cell conductance resides in the endfoot. When K^+ is raised within nervous tissue, $[K^+]_o$ remains relatively low at the endfoot and the cell membrane potential is raised relatively little. This "clamping" of the cell membrane potential has the consequence of maintaining a large driving force for the influx of K^+ into glial cells and results in enhanced K^+ siphoning currents as well as greater passive K^+ accumulation.

Distribution of Potassium Channels in Glial Cells

Müller Cells. The distribution of K^+ conductance over the surface of glial cells has been best characterized in Müller cells, the principal glial cell of the vertebrate retina (see Chapters 4 and 56). In amphibian Müller cells, input resistance measurements indicate that ~90% of the total cell conductance is localized to the endfoot region (Newman, 1984, 1985a). This localization has been confirmed in voltage-clamp studies which demonstrate that the density of K^+ channels is far higher on the endfoot (38- to 95-fold) than in other cell regions (Brew et al., 1986; Newman, 1993).

Potassium channels are also localized in mammalian Müller cells, although their distribution is more complex. Conductance is high at the vitreal endfoot, as it is in amphibians. In species with vascularized retinas, K^+ conductance is also high in regions near the cell soma (where cell processes contact blood vessels), suggesting that Müller cell "endfeet" contacting blood vessels have high K^+ conductance (Newman, 1987).

Astrocytes. The endfeet of amphibian astrocytes also have high K^+ conductance (Figure 47-6). In freshly isolated salamander cells, specific membrane conductance was approximately tenfold greater at cell endfeet than in other cell regions (Newman, 1986).

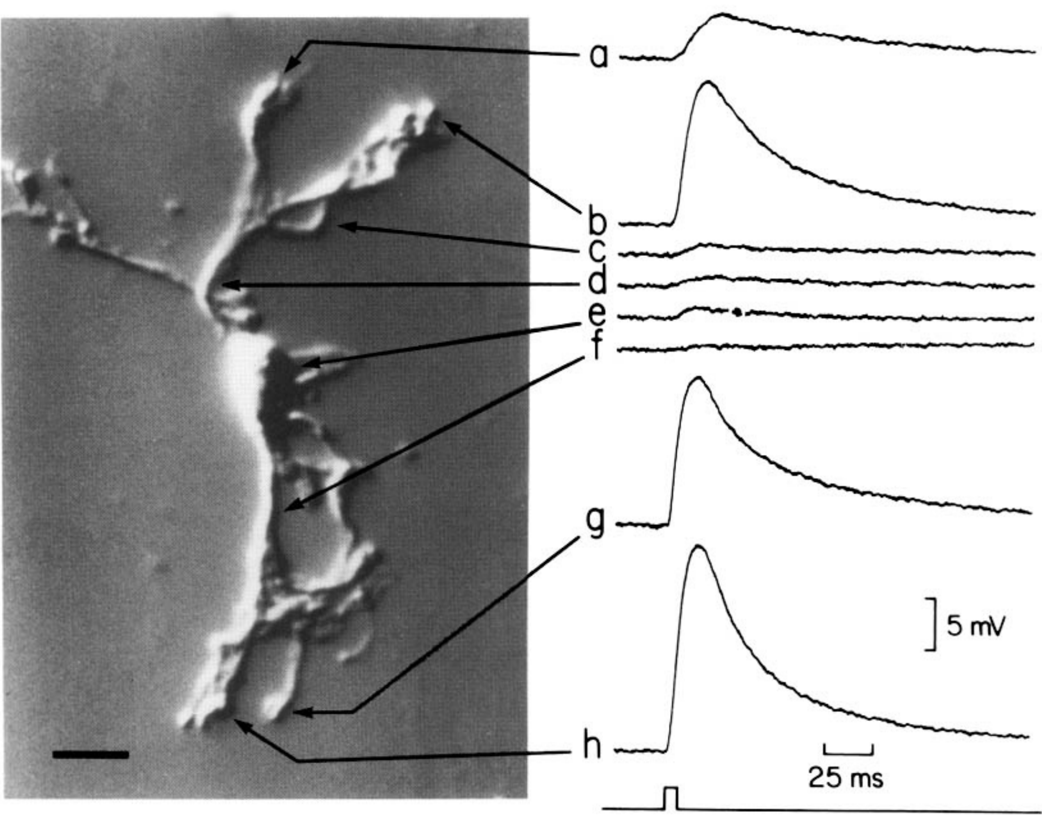

FIG. 47-6. Distribution of K^+ conductance in an amphibian astrocyte from the salamander optic nerve (freshly dissociated cell). Responses, recorded from the soma of the cell shown at left, are displayed at right. Responses were evoked by ejection of a high $[K^+]$ solution onto discrete regions of the cell (*arrows*). Much larger depolarizations were evoked when $[K^+]_o$ was raised at cell endfeet (*a, b, g, h*) than at cell processes (*c, d, f*) or the cell soma (*e*). Results indicate that local cell K^+ conductance is ~10-fold higher at the cell endfeet than in other cell regions. Similar results have been obtained from Müller cells of the amphibian retina. Scale bar = 20 μm. [From Newman (1986), with permission.]

The distribution of K^+ conductance in mammalian astrocytes has not yet been determined.

Potassium Channels

The type or types of K^+ channels which carry spatial buffer currents in glial cells determine, in part, the effectiveness of the K^+ buffering process. As reviewed in Chapter 11, glial cells possess several different types of voltage-gated K^+ channels. Only those channels which have a substantial open probability at the cell resting membrane potential will participate in the spatial buffering process. In mammalian astrocytes, it is not yet known which K^+ channel(s) constitute the resting K^+ conductance.

In amphibian Müller cells, in contrast, voltage-clamp studies have demonstrated that an inward rectifier K^+ channel is, for practical purposes, the only channel open at the normal resting potential (Brew et al., 1986; Newman, 1993). Channel density is low on most cell regions, but is high on the vitreal surface of the endfoot, where the density can exceed 100 active channels per μ^2. The conductance of this channel increases as the membrane potential is hyperpolarized past the K^+ equilibrium potential and as $[K^+]_o$ is raised. The channel is blocked by micromolar concentrations of Ba^{2+} (Newman, 1989).

The effect of the voltage- and K^+-dependent properties of Müller cell inward rectifying K^+ channels has been assessed in simulations of K^+ siphoning in the amphibian retina (Figure 47-7; Newman, 1993). Modeling results indicate that channel properties augment the clearance of K^+ due to K^+ siphoning. Given an instantaneous increase of K^+ from 2.5 to 3.5 mM in the inner plexiform layer, channel properties result in a 23% enhancement in the rate of K^+ clearance from the retina. This enhancement is increased to 137% for an initial K^+ increase to 12 mM.

Potassium Siphoning in the Retina

Potassium siphoning plays an important role in clearing light-evoked K^+ increases from the retina.

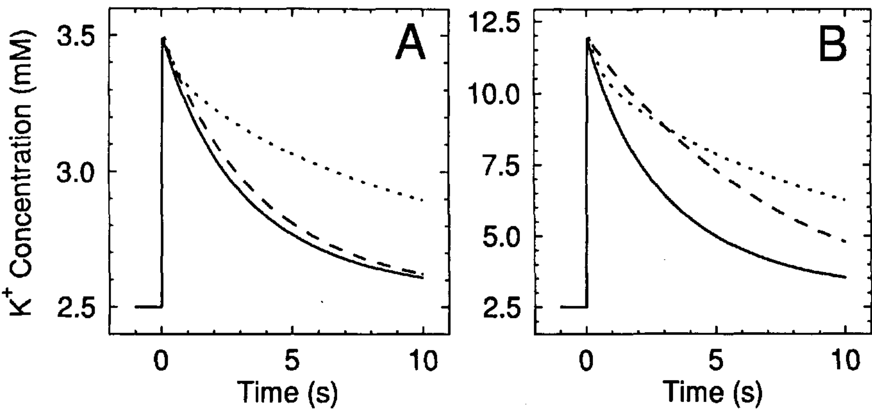

FIG. 47-7. Simulations of K^+ clearance from the amphibian retina. The time course of K^+ removal from the inner plexiform layer is shown following an instantaneous $[K^+]_o$ increase: (A) from 2.5 mM to 3.5 mM or (B) from 2.5 mM to 12 mM. The simulated increase was restricted to the inner plexiform layer. Potassium clearance was modeled for: *1*, K^+ siphoning with inward rectifying Müller cell K^+ channels (solid lines); *2*, K^+ siphoning with Ohmic Müller cell K^+ channels (*dashed lines*); *3*, K^+ diffusion through extracellular space (*dotted lines*). Potassium siphoning was more effective in clearing K^+ from the retina than was K^+ diffusion. Inward rectifying K^+ channels augmented the siphoning process, particularly when $[K^+]_o$ was raised to 12 mM. [From Newman (1993), with permission.]

When the retina is stimulated by light, a $[K^+]$ increase is observed in the vitreous humor. This increase is almost entirely abolished when Müller cell K^+ channels are blocked by Ba^{2+} (Karwoski et al., 1989). The Ba^{2+} blockade of Müller cell siphoning current not only abolishes the transfer of K^+ to the vitreous, it also results in an enlargement in light-evoked $[K^+]_o$ increases within the retina (Figure 47-8). In the toad retina, Ba^{2+} block of siphoning results in light-evoked $[K^+]_o$ increases which are more than double control levels (Oakley et al., 1992), while in the cat, Ba^{2+} block results in K^+ increases that are almost triple control levels (Frishman et al., 1992). In the cat, much of the K^+ is siphoned to the subretinal space (at the photoreceptor layer) rather than to the vitreous, because Müller cell K^+ conductance is largest at the distal end of cells in this species (Newman, 1987). In both the cat (Frishman et al., 1992) and toad (Oakley et al., 1992), this siphoning current helps to buffer the light-evoked $[K^+]_o$ decrease generated by the photoreceptors.

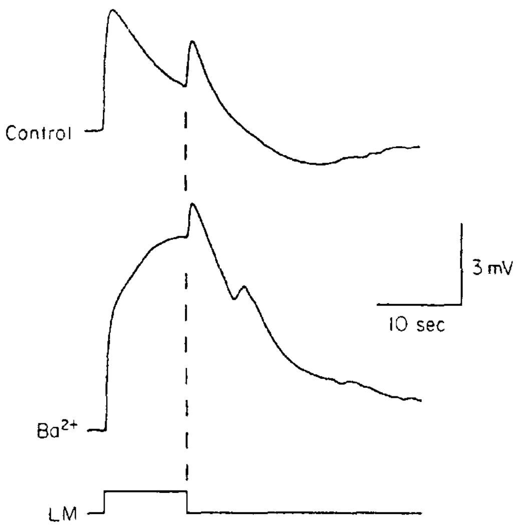

FIG. 47-8. Potassium siphoning in the toad retina (isolated retina preparation). Under control conditions, a 10-second light flash evoked a $[K^+]_o$ increase in the inner plexiform layer, which had both ON and OFF components. Addition of 200 μM Ba^{2+}, which blocked Müller cell K^+ channels, resulted in a substantial increase in the $[K^+]_o$ response. Experiments showed that the $[K^+]_o$ increase was due to the interruption of K^+ siphoning currents to both the vitreous humor and to the subretinal space. The 3 mV $[K^+]_o$ scale bar corresponds to ~0.51 mM. [Modified from Oakley et al. (1992), with permission.]

The effects of Ba^{2+} on K^+ regulation in the retina have also been modeled (Karwoski et al., 1989). Simulations predicted that in the amphibian retina, Ba^{2+} block of Müller cell channels should result in a severe reduction in the light-evoked $[K^+]_o$ increase in the vitreous humor and to an enhancement of the $[K^+]_o$ increase in the inner plexiform layer. The predicted changes matched the experimental results closely.

Theoretical Considerations

The K^+ siphoning process is critically dependent on the distribution of K^+ channels in glial cells. In amphibian Müller cells, for instance, high conductance at the cell endfoot (comprising 90% of the total cell conductance) ensures that most K^+ entering Müller cells from regions of raised $[K^+]_o$ will be directed out

the endfoot and into the vitreous humor. On the other hand, modeling studies indicate that a maximal amount of K^+ can be transferred away from the retina when only 50% of the cell K^+ conductance is localized to the endfoot (Brew and Attwell, 1985). Under these conditions, however, a greater percentage of the excess K^+ would be transferred to other retinal regions instead of the vitreous. Given that ~90% of total cell conductance is localized to the endfoot, it appears that the directed flow of K^+ current away from the retina is of greater importance than is the maximizing of K^+ transferred.

Effective K^+ siphoning presumes that K^+ current flow is not limited by the resistivity of the glial cytoplasm. This condition does not always hold. In the long slender Müller cells of the central portion of the rabbit retina, for instance, the estimated cell space constant is considerably shorter than the cell length, resulting in a substantial attenuation of siphoning currents (Eberhardt and Reichenbach, 1987).

Generation of Field Potentials: An Epi-Phenomenon of K^+ Spatial Buffering?

Electroretinogram. Light-evoked $[K^+]_o$ increases in the inner and outer plexiform layers of the retina establish a K^+ siphoning current within Müller cells directed from the retina to the vitreous humor. This intracellular current is balanced by a return current flow through extracellular space, directed from the vitreous to the distal retina (Figure 47-5). This current generates a vitreal positive potential across the retina which is believed to be the origin of the b-wave of the electroretinogram (ERG) (Newman, 1980). Similarly, other light-evoked $[K^+]_o$ variations in the retina are thought to evoke K^+ siphoning currents in Müller cells, leading to the generation of other ERG components, including the slow PIII potential (Witkovsky et al., 1975), the M-wave (Karwoski and Proenza, 1977; Sieving et al., 1986a), and the scotopic threshold response (Sieving et al., 1986b). Thus, the generation of these retinal field potentials may be thought of as epi-phenomena arising from the regulation of $[K^+]_o$ by Müller cell K^+ siphoning.

Electroencephalogram. Components of the electroencephalogram (EEG) may also be generated by K^+ siphoning or K^+ spatial buffering currents (Cohen, 1970). Fast components of the EEG occur more rapidly than observed activity-dependent variations in $[K^+]_o$ within the brain. Thus, these components must be generated directly by neurons. Slow EEG components, on the other hand, are sometimes correlated with variations in glial cell membrane potential and $[K^+]_o$ and could arise from current flow through astrocytes (Castellucci and Goldring, 1970; Somjen, 1970; Heinemann et al., 1979; see Chapter 20).

RELATIVE EFFECTIVENESS OF K^+ CLEARANCE MECHANISMS

Glial Clearance Mechanisms Operate Simultaneously

The K^+ regulatory mechanisms outlined above operate simultaneously to clear $[K^+]_o$ increases from extracellular space. It is important to note, however, that the mechanisms do not act independently and that operation of one mechanism may influence the operation of others.

There is a tradeoff between K^+ transfer and K^+ accumulation processes. Both K^+ spatial buffering and siphoning mechanisms depend on the selective permeability of glial cells to K^+. These mechanisms become less efficient as cell permeability to other ions, such as Cl^-, is increased. For cells with a large Cl^- permeability, much of the inward K^+ spatial buffering current generated by a $[K^+]_o$ increase will be balanced by a local influx of Cl^-. Thus, less K^+ will be transported to a distant site by K^+ efflux from other cell regions.

Spatial buffer current can also affect the efficiency of passive uptake mechanisms. Spatial buffer currents within glial cells are carried, in part, by anions as well as by K^+. Thus, both K^+ and Cl^- accumulate within glial cells in regions of K^+ influx (Dietzel et al., 1980). The increases in $[K^+]_i$ and $[Cl^-]_i$, in turn, reduce the magnitude of K^+ and Cl^- influx due to cotransport and Donnan mechanisms.

One of the most important questions in the field of K^+ regulation concerns the relative contributions of the different regulatory mechanisms. We are still a long way from answering this question definitively. As discussed in the following sections, however, theoretical as well as experimental studies have provided some general rules that indicate the relative importance of different regulatory mechanisms under specific conditions.

Temporal Characteristics

The temporal characteristics of activity-dependent $[K^+]_o$ variations play an important role in determining which mechanisms are effective in clearing K^+ from extracellular space. Active uptake of K^+ into neurons occurs rather slowly, having a time constant of tens of seconds (Gardner-Medwin, 1983a). Thus, active neuronal uptake is relatively ineffective in buf-

fering $[K^+]_o$ variations. Passive K^+ uptake will be effective in clearing brief $[K^+]_o$ increases, but will be less effective in clearing more prolonged increases as the capacity of glial cells (and neurons) to accumulate K^+ becomes saturated. Diffusion and spatial buffering mechanisms, in contrast, retain their ability to transfer K^+ to a distant site, even when a $[K^+]_o$ increase is prolonged (Gardner-Medwin, 1986).

Spatial Characteristics

The spatial characteristics of $[K^+]_o$ variations also play an important role in determining which $[K^+]_o$ clearance mechanisms dominate. Both active and passive uptake processes operate independently of the spatial extent of a $[K^+]_o$ increase. Uptake rates will be the same whether the size of a $[K^+]_o$ increase is large or small. Diffusion and K^+ spatial buffering, in contrast, are critically dependent on the spatial extent of an increase. For restricted $[K^+]_o$ increases (less than a few hundred micrometers), diffusion is more effective than is spatial buffering in dispersing K^+ (Gardner-Medwin, 1986). As the size of a $[K^+]_o$ increase grows, spatial buffering begins to dominate. In the rat cortex, the crossover point, when spatial buffering and diffusion are equally effective, has been estimated to occur for a sinusoidally modulated $[K^+]_o$ increase with a wavelength of ~700 μm (Gardner-Medwin, 1986). As a $[K^+]_o$ increase grows still larger, spatial buffering will be limited by the space constant of the glial syncytium. In the extreme case, when $[K^+]_o$ is raised uniformly throughout a tissue, both diffusion and spatial buffering will be completely ineffective in reducing the $[K^+]_o$ increase.

The K^+ siphoning process provides an exception to this rule. Even when $[K^+]_o$ is increased uniformly within the brain parenchyma, $[K^+]$ in the subarachnoid space at the pial surface of the brain, will remain relatively low. Thus, astrocyte endfeet at the pial surface will experience a $[K^+]$ that is lower than that within the brain and a K^+ siphoning current will be generated. This current will transfer K^+ from the brain to the cerebral spinal fluid in the subarachnoid space.

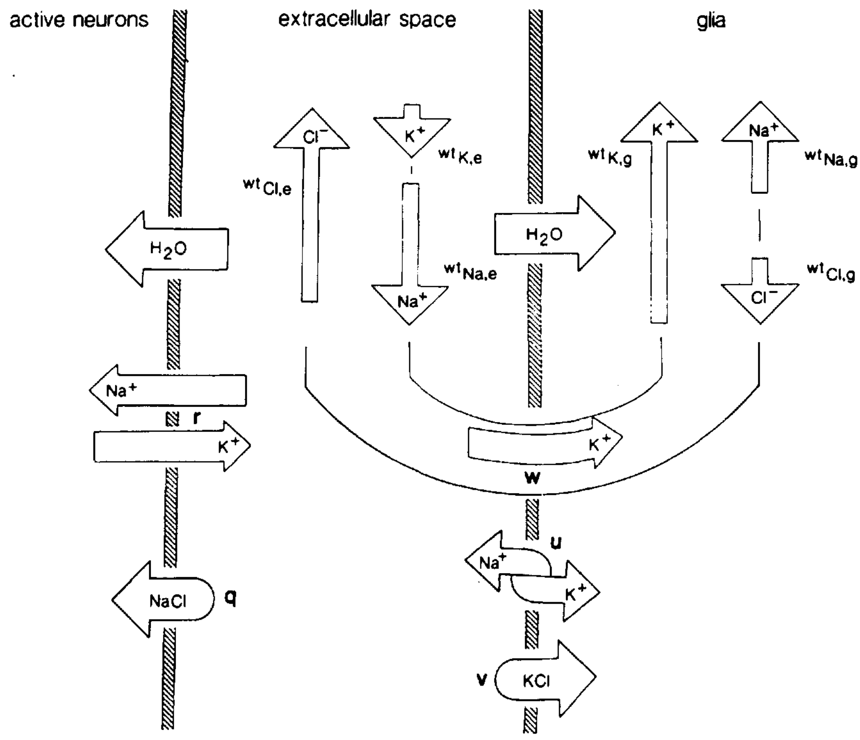

FIG. 47-9. Model of K^+ regulation in the cat cerebral cortex. The diagram indicates ion fluxes across the membrane of an active neuron (*left*), across the membrane and through a glial cell (*right*), and through extracellular space (*center*). In the model, neuronal activation leads to an influx of Na^+ and an efflux of K^+ from the neuron (*r*), which results in an increase in $[K^+]_o$. The $[K^+]_o$ increase, in turn, leads to passive uptake of KCl (*v*) and to active K^+ uptake (*u*) into the glial cell. A K^+ spatial buffer current is generated and is carried by K^+ across the glial cell membrane (*w*) and by Na^+, K^+, and Cl^- in extracellular space and within the glial cell. The ion fluxes result in a drop in osmotic pressure in extracellular space and in a rise of osmotic pressure in the neuron and glial cell, driving water into both cells. Calculations give an estimate of the relative contributions of glial regulatory mechanisms to the removal of K^+ from extracellular space: spatial buffering, 45%; active uptake, 39%; passive uptake, 16%. [From Dietzel et al. (1989), with permission.]

Potassium siphoning is most effective when a $[K^+]_0$ increase occurs near a large fluid body. In the retina, this condition is satisfied as all retinal regions lie within 250 μm of the vitreous humor (but see Eberhardt and Reichenbach, 1987). In the brain, K^+ siphoning will be effective for $[K^+]_o$ increases which occur near the cortical surface (perhaps 200 to 1000 μm beneath the surface, depending on the space constant of the glial syncytium). For deeper neural regions, other clearance mechanisms will dominate.

Models of K^+ Regulation

Mammalian Cortex. A comprehensive model of K^+ regulation in the cat cortex has been used to estimate the relative contributions of different regulatory mechanisms (Dietzel et al., 1989) (Figure 47-9). The model analyzes K^+ uptake during a 10-second period of stimulation by incorporating experimentally measured variations in intracellular and extracellular $[K^+]$, $[Na^+]$, and $[Cl^-]$ as well as changes in the extracellular volume fraction. Results indicate that during the stimulation period, the equivalent of 3 to 5 mM K^+ is removed from extracellular space by spatial buffering, 3.4 mM by action of a glial Na^+/K^+ ATPase, and 1.4 mM by passive K^+ uptake into glial cells. These estimates are, of necessity, imprecise as all of the parameters affecting K^+ regulation have not been determined in a single preparation.

Amphibian Retina. Potassium clearance has also been analyzed, both experimentally and analytically, using the amphibian retina preparation. As noted above, K^+ siphoning in the retina is selectively blocked by application of micromolar Ba^{2+}. With siphoning blocked, light-evoked $[K^+]_o$ increases within the retina grow larger while the $[K^+]$ increase in the vitreous humor is almost completely abolished. Simulations demonstrate that the small remaining increase in the vitreous (8 to 11% of control) is due to the transfer of K^+ by diffusion through extracellular space (Karwoski et al., 1989). These results demonstrate that K^+ siphoning plays a much more important role in clearing K^+ from the retina than does diffusion.

CONCLUSION

Glial cells possess a number of physiological mechanisms which contribute to K^+ regulation in the central nervous system. These processes, which include active and passive accumulation of K^+ and K^+ transfer by spatial buffer currents, play a dominant role in K^+ homeostasis within the nervous system. These processes have been characterized in both *in situ* and *in vitro* preparations. The relative contribution of each of these processes remains unknown, although general principals regarding their efficacy have been established. One of the challenges for future research is to determine the role that each of these K^+ regulatory mechanisms play in different tissues and for different levels of neuronal activity.

48 The role of glia in the inactivation of neurotransmitters

DAVID L. MARTIN

In 1907 Ernesto Lugaro suggested that glial cells might be involved in the inactivation of substances released by neurons, a speculation of remarkable foresight given the primitive knowledge of glial cells and communication between neurons at that time. In the years preceding Lugaro's article, the long-standing controversy between the neuronal and reticular theories of connectivity in the nervous system was being resolved in favor of the neuron theory (Ramón y Cajal, 1989), and the need to explain the propagation of nerve impulses between the separate neurons had become an important problem. According to Bacq (1975), most physiologists thought that the impulse was transmitted from one neuron to another by electrical currents. Although some thought the impulse could be transmitted chemically, there was no evidence that neurons actually secreted active substances until Loewi reported his discovery of *Vagusstoff* in 1921, 14 years after Lugaro's article. The electrical theory of synaptic transmission did not die easily. Despite the accumulating evidence for chemical synaptic transmission over the succeeding years, some physiologists continued to support the electrical mechanism, and it was not until J. C. Eccles converted to the chemical side in 1945 that serious opposition to chemical synaptic transmission ended (Bacq, 1975).

In 1950 George Koelle reported that nonspecific cholinesterase was localized in the nuclei of glial cells in autonomic ganglia, thus providing evidence that glia have the *capacity* to degrade a neurotransmitter. In discussing his findings, Koelle cited the views of de Castro, who regarded synapses as composed of three elements: the pre- and postsynaptic neural elements and the glia in which the terminals are imbedded. Koelle also thought that nonspecific cholinesterase in glia might have two functions—a transmission-terminating capacity and a protective capacity to prevent transmitter overflow from one synapse from inappropriately activating another synapse. Koelle subsequently refined his histochemical technique and determined that the nuclear location of nonspecific cholinesterase was artifactual, but that the glial location was genuine (Koelle, 1951, 1954). He also established that glia in the central nervous system possess nonspecific cholinesterase, but he was unwilling to extend his ideas about the functions of glia to the central nervous system, saying that "the occurrence of nonspecific ChE in nonnervous cells of the rat brain militates against the likelihood of its having an important role in central transmission" (Koelle, 1954). This cautious outlook stands in contrast to his previous, more expansive ideas about the relationship of glia to synaptic function in autonomic ganglia, where he seemingly felt that the relationship of the glial cholinesterase to cholinergic synapses was more clearly defined.

Because acetylcholine and the biogenic amines were the only serious transmitter candidates at that time, evidence that glia have the capability to inactivate other transmitters was not developed until later. In 1970 Hökfelt and Ljungdahl studied the uptake of [^{3}H]GABA by autoradiography. Although they clearly considered various types of glia as potentially responsible for some of the uptake, the resolution of their method was insufficient to firmly establish the cellular elements responsible. Henn and Hamberger (1971) compared the uptake of γ-aminobutyric acid (GABA), norepinephrine, dopamine, and serotonin by a cell fraction enriched in glial cells with that of a cell fraction enriched in neuronal perikarya, and argued that glia are capable of removing transmitters that overflow from the synaptic cleft. This work was part of a burgeoning interest in GABAergic function and was followed rapidly by a substantial number of studies on the abilities of glia to take up and metabolize transmitters (reviewed by Iversen and Kelly, 1975).

As we discuss in this chapter, glial cells, and astrocytes in particular, envelop synapses in a manner that would enable them to intercept transmitter molecules that overflow from the synaptic cleft, and they are equipped with the transport systems and enzymes that are necessary to degrade most known neurotransmitters. Thus the idea that astrocytes are appropriately placed and equipped to inactivate and

degrade transmitters is supported by good evidence. What is missing is a firm estimate of the quantitative importance of the inactivation of transmitters by astrocytes *in vivo* and *direct* evidence that astrocytes might have any regulatory effects on extracellular levels of synaptic transmitters.

THE MICROSCOPIC ANATOMY OF ASTROCYTES LENDS ITSELF TO THE INACTIVATION OF TRANSMITTERS

The structure of a central nervous system synapse and the location of the surrounding astrocyte is illustrated in Figure 48-1, an electron micrograph of a nerve ending in the suprachiasmatic nucleus (van den Pol et al., 1992). As indicated by the large vertical arrows, astrocytic processes closely surround the synaptic terminal. Vesicular release of the synaptic transmitter, glutamate in this case, is thought to occur at a specific release zone located at the synaptic thickening where the transmitter can immediately interact with its receptor. The mechanisms that inactivate transmitters differ among the various transmitter compounds but include degradation by extracellular enzymes, recapture by the neuron via specific transport systems, diffusion from the synaptic cleft, and inactivation by astrocytes. To reach the astrocyte, however, a transmitter molecule must not only escape from the cleft (in the region of the synaptic thickening) but must also escape from reuptake or enzymatic degradation as it diffuses through the interneuronal space surrounding the cleft. Thus, the amount of transmitter that reaches the astrocyte depends on the efficiency of the neuron's inactivating mechanisms.

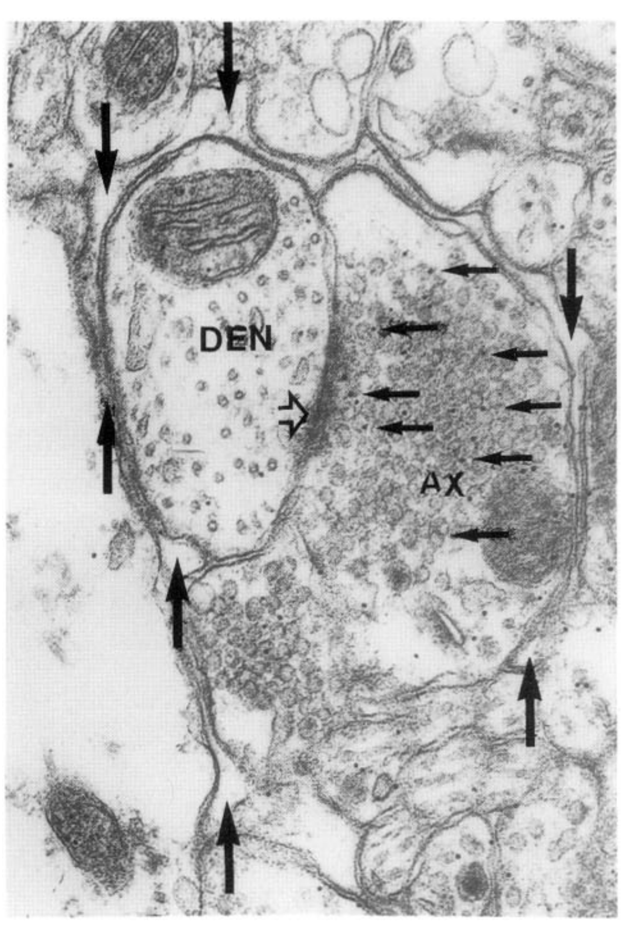

FIG. 48-1. Astrocytic processes surround a glutamatergic terminal in the suprachiasmatic nucleus of the rat and insulate it from the surrounding neuropil. The glutamatergic terminal (*AX*) is immunochemically labeled with colloidal gold particles (*small horizontal arrows*). It synapses (*open arrow*) with a dendrite (*DEN*). Astrocytic processes are indicated by *large vertical arrows*. [From van den Pol et al. (1992), with permission.]

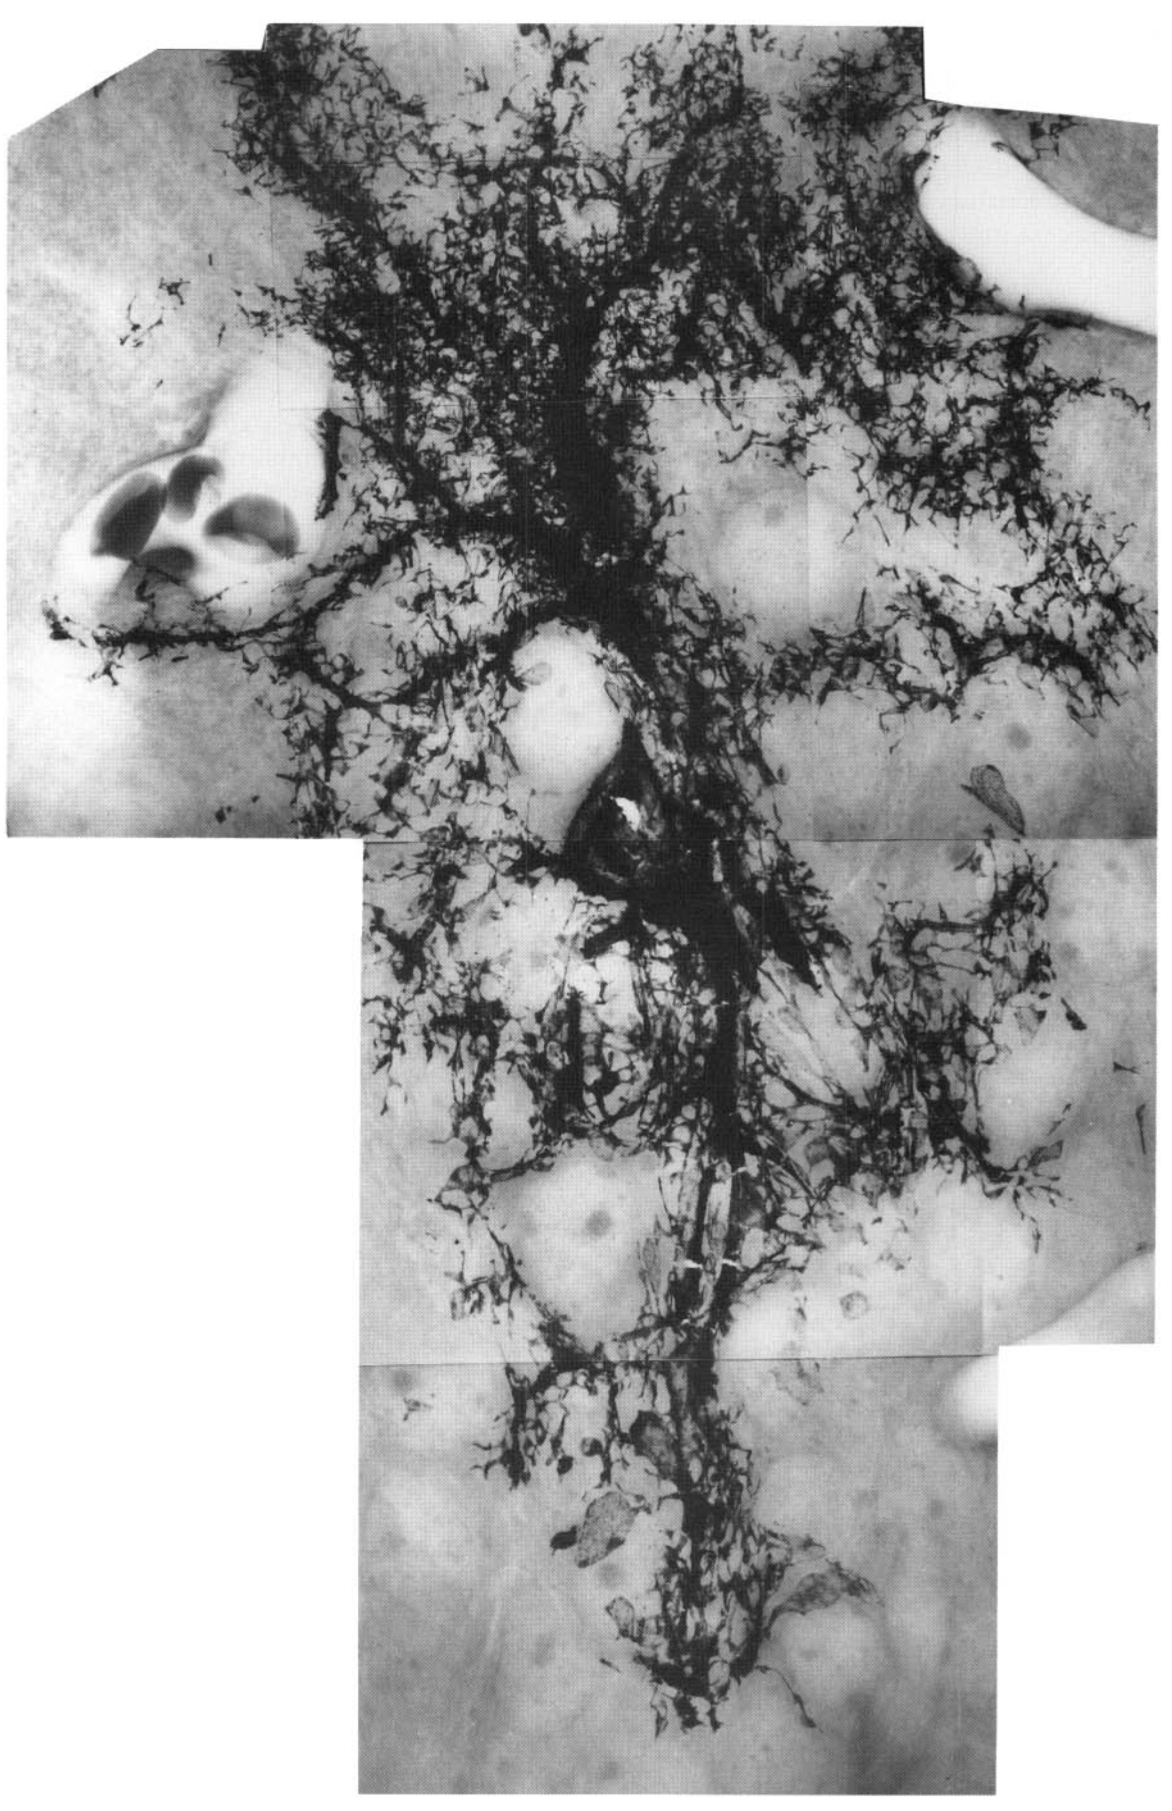
Although astrocytic cell bodies appear small in diameter when visualized with ordinary histochemical stains, astrocytes themselves are large in the sense that they have many exceedingly fine processes that penetrate a large volume of tissue and come into contact with many neurons at many locations, including both cell bodies and dendrites. Among the most dramatic demonstrations of these facts are the elegant images made by Kosaka and Hama (1986). Such images (Figures 48-2 and 48-3) clearly show the astrocyte's many fine veillike and sheetlike processes and also show that each astrocyte surrounds many neurons. Since each central nervous system neuron participates in many types of synaptic contacts, each astrocyte is probably equipped to deal with numerous transmitters. At present the number of different transmitters that an astrocyte can inactivate is not known; to my knowledge, there have been no studies of the colocalization of inactivating systems for different transmitters in astrocytes. As is discussed below, inactivating enzymes, such as glutamine synthetase, are present in perisynaptic astrocytic processes. However, the possibility that an astrocytic process is specialized to deal with the specific type of synapse that it surrounds remains a difficult problem.

GLIA POSSESS INACTIVATION SYSTEMS FOR MANY TRANSMITTERS

Table 48-1 provides a list of inactivating systems for neurotransmitters that are known to be present in glial cells. Some neurotransmitters and neuroactive compounds, particularly acetylcholine, adenosine triphosphate (ATP), and peptides, are degraded by ectoenzymes that are present on the external surface



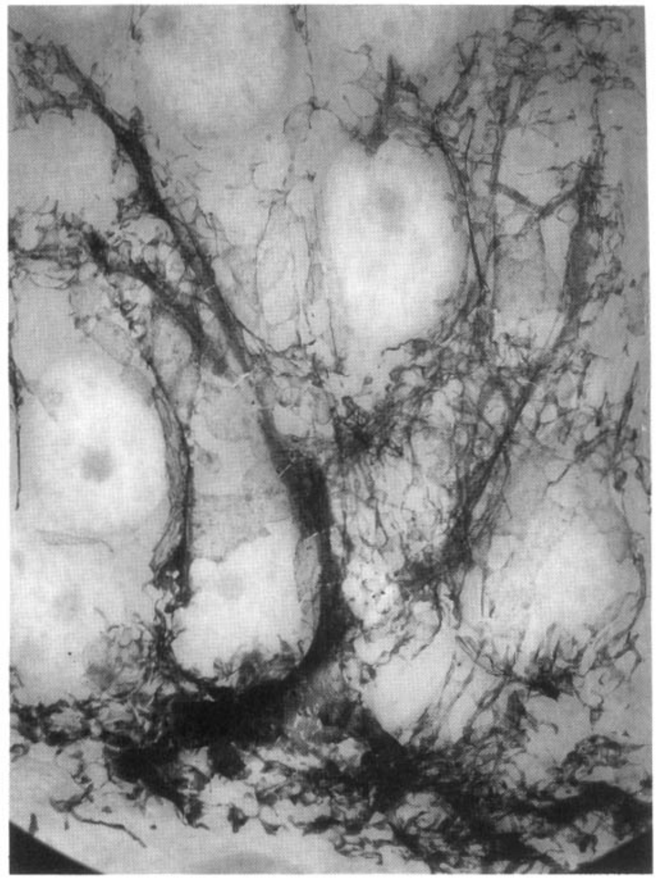
of cells. Other compounds are inactivated by transport systems that remove them from the extracellular space. In such cases, however, uptake is merely the first step of inactivation, as the compounds must be metabolized internally to complete the inactivation process.

Acetylcholine

Evidence that astrocytes contain cholinesterase was presented in the introduction to this chapter. Although glial cholinesterase is the so-called nonspecific type, it is able to degrade acetylcholine very well. In the central nervous system, specific acetylcholinesterase is found only in cholinergic neurons and, in fact, is used as a histochemical marker for those cells.

Excitatory Amino Acids

Astrocytes are thought to play a major role in the inactivation and metabolism of the excitatory amino acid glutamate; they can take up glutamate that escapes from neuronal reuptake systems and metabolize it in the tricarboxylic acid (TCA) cycle or convert it to glutamine. Glutamine produced by



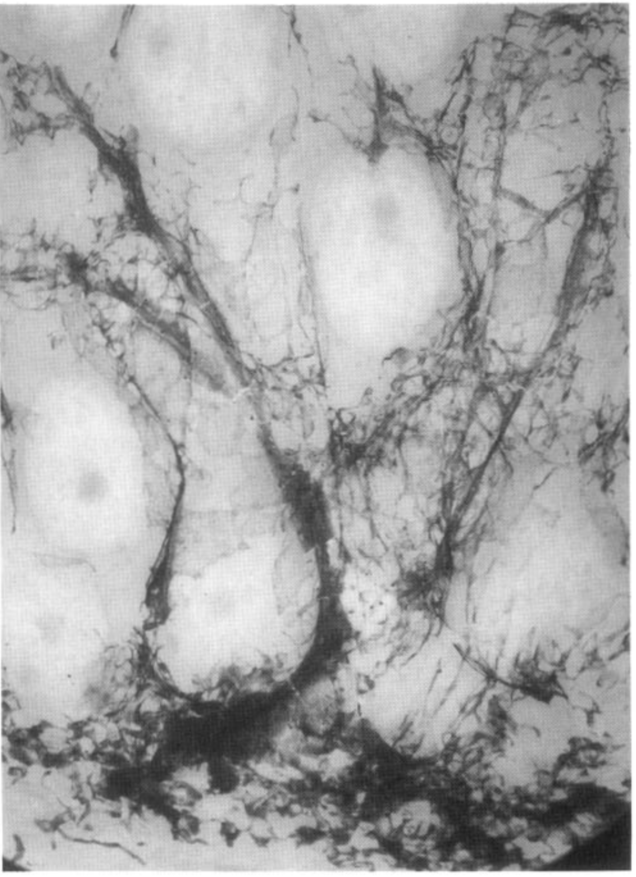


FIG. 48-3. Stereo pair of high-voltage electron micrographs of part of an astrocyte in the granule cell layer of the dentate gyrus. The astrocyte's soma is at the bottom, just left of center. Notice the numerous veillike and leafletlike processes. This astrocyte contacts several unimpregnated neurons in this plane, which can be recognized by the faint images of their nuclei and nucleoli. [Image is from Kosaka and Hama (1986), with permission. Original prints were kindly provided by the authors.]

FIG. 48-2. Photomontage of high-voltage electron micrographs of a Golgi-impregnated astrocyte at the border of the granule cell layer and the molecular layer of the dentate gyrus. 5-μm thick section. Astrocytic processes also extend above and below the plane of this image. The astrocyte's soma is in the center. Note the many fine, sheetlike processes which contact several neurons in this image. Faint images of the nuclei and nucleoli of unimpregnated neurons are evident in the unstained spaces surrounded by the astrocytic processes. A blood vessel with four erythrocytes is at upper left. Scale bar = 5 μm. [Image is from Kosaka and Hama (1986) with permission. Original prints were kindly provided by the authors.]

TABLE 48–1. *Transmitter Inactivating Systems Present in Glial Cells*

Transmitter	Transport systems	Enzymes
Acetylcholine	None	Nonspecific cholinesterase (Koelle, 1950; Koelle, 1954)
Adenosine	Present (Hertz, 1978; Matz and Hertz, 1990)	Adenosine deaminase; adenosine kinase (Matz and Hertz, 1989; Matz and Hertz, 1990)
ATP	None known	EctoATPase (Trams and Lauter, 1978)
Aspartate	Present[a]	Glutamic oxaloacetic transaminase (Schousboe et al., 1977; Schousboe and Hertz, 1984)
Dopamine	Present (Pelton et al., 1981; Kimelberg and Katz, 1986)	Monoamine oxidase (Levitt et al., 1982; Yu and Hertz, 1982; Hansson, 1984; Westlund et al., 1985); catechol-O-methyl transferase (Kaplan et al., 1979; Yu and Hertz, 1982; Hansson, 1984); phenol sulfotransferase (Yu and Walz, 1985)
GABA	Present[a]	GABA transaminase (Schousboe et al., 1977); succinic semialdehyde dehydrogenase
Glutamate	Present[a]	Glutamine synthetase (Martinez-Hernandez et al., 1977; Juurlink, 1982); glutamate dehydrogenase (Aoki et al., 1987; Madl et al., 1988); various transaminases
Glycine	Present[a]	Glycine cleavage system (Sato et al., 1991)
Histamine	Present (Rafalowska et al., 1987; Huszti et al., 1990)	Histamine-*N*-methyltransferase (Rafalowska et al., 1987; Huszti et al., 1990)
N-Acetylaspartyl glutamate (NAAG)	Transporter present for *N*-acetylaspartate and NAAG (O, Saab, personal communication)	
Norepinephrine	Present (Pelton et al., 1981; Kimelberg and Pelton, 1983)	See dopamine
Serotonin	Present (Ritchie et al., 1981; Liesi et al., 1981; Kimelberg and Katz, 1985; Kimelberg and Katz, 1986)	See dopamine

[a]Described by Schousboe in Chapter 15, this volume.

astrocytes is released into the extracellular space, and can be taken up by neurons where it serves as a precursor of glutamate synthesis (Balazs et al., 1970; Berl and Clarke, 1983). This glutamate-glutamine cycle has been studied extensively, and there is ample evidence that glial cells are capable of their part of the cycle (Schousboe, 1981; Waniewski and Martin, 1986; Erecińska and Silver, 1990). The glutamate-inactivating ability of astrocytes also is thought to be important in limiting the excitotoxic effects of glutamate on neurons. The resistance of astrocytes to glutamate-induced cell death undoubtedly helps them to play a protective role. Cultured oligodendrocytes, in contrast, appear to be as vulnerable to glutamate-induced cell death as cultured neurons (Oka et al., 1993). It is interesting that glutamate does not appear to damage cultured oligodendrocytes by a receptor-mediated mechanism but makes the cells vulnerable to free-radical attack by depleting them of cystine and lowering their glutathione content.

Astrocytes possess multiple uptake systems for glutamate (for detailed descriptions see Chapter 15, this volume; Erecińska and Silver, 1990; Flott and Seifert, 1991). One of the transport systems for glutamate is Na^+-dependent and capable of active transport, and a second is Cl^--dependent. Ca^{2+} also stimulates uptake (Flott and Seifert, 1991). Cl^- dependent uptake appears to account for a small fraction of total uptake in primary cultures of astrocytes (Flott and Seifert, 1991), but it is a more important contributor in glioma cells (Waniewski and Martin, 1984). The K_m for Na^+-dependent glutamate transport by cultured astrocytes is comparable to that of neurons, and the V_{max} is somewhat greater in astrocytes than in neurons, indicating that the astrocytes have ample transport capacity to take up glutamate that overflows from the synapse and to participate

in the glutamate-glutamine cycle (Drejer et al., 1982; Schousboe and Hertz, 1984). Because of the complex structural relationship of the synapse and the surrounding astrocytes (see Figure 48-1), the neuronal transport systems are exposed sooner to higher concentrations of synaptically released glutamate. Thus, the higher V_{max} in astrocytes does not indicate that astrocytes take up most of the glutamate released at the synapse.

A Na^+-K^+-coupled glutamate transporter that is located in glial cells was purified recently from rat brain (Danbolt et al., 1992), and glutamate transporters also have been cloned (Pines et al., 1992; Kanai and Hediger, 1992; Storck et al., 1992). Two of these transporters appear to be expressed by astrocytes but differ in sequence (Pines et al., 1992; Storck et al., 1992), indicating that astrocytes possess at least two structurally distinct glutamate transporters. In immunocytochemical studies, the fine processes of astrocytes were particularly strongly stained by antibodies against a glutamate transporter (Danbolt et al., 1992).

Glutamine synthetase is found in both astrocytes and oligodendrocytes but does not appear to be present in neurons in significant amounts (Martinez-Hernandez et al., 1977; Cammer, 1990). Juurlink and Hertz (1991) found that the specific activity of glutamine synthetase was sevenfold higher in cultures of type-2 astrocytes than in cultures of type-1 astrocytes, but the significance of the higher levels in cultured type-2 astrocytes is unclear. Immunocytochemical studies clearly show that glutamine synthetase is present in glial processes closely surrounding glutamatergic synapses (Derouiche and Frotscher, 1991). Glutamine and glutamine synthetase are not associated solely with glutamate and glutamatergic transmission, as glutamine is a major precursor of GABA synthesis (Erecińska and Silver, 1990, Battaglioli and Martin, 1991, Martin and Rimvall, 1993).

Immunocytochemical studies have shown that astroglia *in vivo* exhibit an intense but heterogeneous labeling for glutamate dehydrogenase (GDH), a mitochondrial enzyme that can convert glutamate to the TCA cycle intermediate α-ketoglutarate (Aoki et al., 1987; see Chapter 33, this volume). In contrast, neuronal labeling was uniform but of lower intensity. Intense astrocytic labeling for GDH appears to be associated with two factors. The first is glutamatergic transmission, as high levels of astrocytic GDH are found in regions that have large numbers of glutamatergic terminals. The second is a high level of neuronal activity, as a high level of GDH immunoreactivity in astrocytes is found in regions that are thought to have fewer glutamatergic terminals but stain strongly for cytochrome oxidase, another mitochondrial enzyme that is thought to be associated with high levels of neuronal activity.

Astrocytes also possess other enzymes of glutamate metabolism, including glutamic-oxaloacetic transaminase (GOT, aspartate aminotransferase) and phosphate-activated glutaminase (Schousboe et al., 1977; Schousboe and Hertz, 1984).

The proportion of transmitter glutamate that passes through astrocytes and returns to neurons via the glutamate-glutamine cycle is unclear because (1) the fraction of transmitter glutamate that is recaptured by neurons and (2) the fraction of glutamate that astrocytes convert to glutamine and return to neurons are unknown. Cultured astrocytes convert a major fraction of exogenous glutamate to glutamine and release it to the medium, while some glutamate carbon clearly enters the TCA cycle (Waniewski and Martin, 1986; Farinelli and Nicklas, 1992). The relative amounts of glutamate that are converted to glutamine and enter the TCA cycle differ among studies. Waniewski and Martin (1986) and Farinelli and Nicklas (1992) found that much more glutamate was converted to glutamine than entered the TCA cycle, whereas Sonnewald et al. (1993) reported that about 30% of labeled glutamate was converted to glutamine and that 70% entered the TCA cycle. It is important to note that there are many differences among these experiments, including the sources of astrocytes, concentrations of glutamate, and other incubation conditions. The exact partitioning of the metabolism of glutamate among the various pathways in cultured astroglial cells undoubtedly depends on the availability of other metabolites and precursors, such as ammonia (Waniewski, 1992), thus making extrapolation from *in vitro* systems to intact tissue tenuous at best.

The route by which glutamate enters the TCA cycle also appears to differ among experiments. Yu et al. (1982) reported that glutamate dehydrogenase appears to be responsible for producing most of the α-ketoglutarate that enters the TCA cycle, since the production of $^{14}CO_2$ from [1-^{14}C]glutamate was almost unaffected when GOT, and presumably other transaminases, were completely inhibited with aminooxyacetate. In contrast, Farinelli and Nicklas (1992) concluded that glutamate enters the TCA cycle mainly through transaminases, as the decarboxylation of [1-^{14}C]glutamate was inhibited by 70 to 90% when GOT was inhibited with aminooxyacetate.

The glutamate transporter also takes up L- and D-aspartate (Schousboe et al., 1977; Drejer et al., 1982; Barbour et al., 1991; Flott and Seifert, 1991). L-Aspartate appears to be taken up by astrocytes via the Na^+-dependent transport system at about half the rate of L-glutamate, but does not appear to be

transported at significant rates by the Cl^- or Ca^{2+}-dependent systems (Flott and Seifert, 1991). In contrast to glutamate, which can be metabolized by many enzymes, aspartate is principally converted to oxaloacetate by GOT, and thus the carbon skeleton enters the TCA cycle.

Gamma-Aminobutyric Acid

High-affinity GABA transport has been demonstrated in a variety of kinds of glia in several tissues, including glia-enriched cell fractions (Henn and Hamberger, 1971), cultured astrocytes from brain (Schousboe et al., 1977), satellite glia and Schwann cells in the superior cervical ganglion, satellite glia in dorsal root ganglion, pinealocytes, and gliocytes of the pituitary (for review see Iversen and Kelly, 1975). Although the ability of glia to transport GABA is commonly assumed to be related to GABAergic transmission, the function of a GABA transport system in the dorsal root ganglion is unclear, as these ganglia have no synapses.

Several distinct transport systems for GABA are present in brain. Glia contain both high- and low-affinity transport systems for GABA, but much of the low-affinity uptake is attributable to the high-affinity transport system for taurine (Martin and Shain, 1979). Inhibition studies indicate that the substrate specificities of the high-affinity transport systems differ among glia and neurons. In particular, glial transport is much more strongly inhibited by β-alanine than is neuronal transport, while neuronal transport is more strongly inhibited by 2,4-diaminobutyric acid (DABA) and *cis*-1,3-aminocyclohexane carboxylic acid (ACHC). There are exceptions to this rule, however, as in the rat retina where GABA uptake by Müller cells is more strongly inhibited by 2,4-diaminobutyric acid than by β-alanine (Iversen and Kelly, 1975). In addition, cultured type-2 astrocytes, which exhibit intense GABA uptake, appear to express the neuronal type of GABA transporter, as their GABA uptake system is strongly inhibited by ACHC but not by β-alanine (Wilkin et al., 1983; Johnstone et al., 1986). The presence of a GABA transporter in astrocytes also has been demonstrated by immunocytochemistry with an antibody raised against a GABA transporter isolated from rat brain (Radian et al., 1990). Both glial cells and neurons are stained, and the relative intensity of the glial and neuronal staining varies among brain regions. It is notable that the transporter was found in glial processes but not cell bodies. Multiple molecular forms of the GABA transporter have been cloned from brain recently (Guastella et al., 1990; Borden et al., 1992). The availability of molecular biological tools will doubtless greatly clarify which GABA transport systems are expressed in glia and where the glial transporters are located relative to GABAergic neurons.

High-affinity GABA transport activity in primary cultures of astrocytes from brain is quite variable, but, in general, astrocytes take up GABA less rapidly than glutamate. Some astrocyte cultures have little or no GABA transport capacity, even though they strongly express other astrocytic markers such as GFAP and glutamine synthetase (Levi et al., 1986; R. A. Waniewski, personal communication). One factor that may contribute to this variability is the cellular composition of the cultures. Cultured type-2 astrocytes exhibit markedly stronger uptake of GABA than do type-1 astrocytes (Levi et al., 1986; Johnstone et al., 1986), and the proportion of the two cell types in the cultures depends on culture conditions and the age of the cultures. A second factor may be the presence or absence of regulatory agents, as GABA transport activity responds to neuronally released factors. The ability of astrocytes to take up GABA is increased by prior exposure to β-adrenergic agonists (Hansson and Ronnback, 1991), and a protein released from cerebellar granule cells (Nissen et al., 1992).

Astrocytes in primary culture also take up GABA more slowly than do cultures of cortical neurons, which are mostly GABAergic (Schousboe and Hertz, 1984). This observation contrasts with glutamate uptake which is more rapid in astrocytes than in neurons, and has led to the idea that inactivation of GABA by astrocytes is quantitatively less important than inactivation of glutamate. This suggestion may be premature, however, as it is difficult to extrapolate from cultures to the *in vivo* situation, and the expression of GABA transporters by cultured astrocytes may be regulated by neuronal factors, as noted above.

Under most circumstances glia contain very little GABA and rapidly metabolize labeled exogenous GABA. GABA is degraded in two steps. First, GABA transaminase converts the carbon skeleton of GABA to succinic semialdehyde, which is then converted to the TCA cycle intermediate succinate by succinic semialdehyde dehydrogenase. When $[^3H]$GABA is used as a transport substrate, the label accompanies the carbon skeleton until it enters the TCA cycle when half of the label is lost as ^3H_2O in the first passage of the carbon skeleton through the cycle. Because glia contain little endogenous GABA there is little isotopic dilution when labeled GABA enters the cell, and much of the label is rapidly lost. As a result, GABA uptake by glia is usually enhanced sub-

stantially when GABA transaminase is inhibited (Schon and Kelly, 1974; Iversen and Kelly, 1975). In immunocytochemical studies, GABA-like immunoreactivity is rarely observed in glia unless the animal or tissue is pretreated with a GABA-transaminase inhibitor (Storm-Mathisen and Ottersen, 1986; Palmi et al., 1991). It is notable, however, that O-2A progenitors and oligodendrocytes in rat optic nerve contain GABA (Barres et al., 1990), and that GABA has been found in astrocytes in brainstem (Blomqvist and Broman, 1988).

Monoamines

In addition to studying GABA uptake, Henn and Hamberger (1971) also reported that glia-enriched cell fractions take up the monoamines norepinephrine, dopamine, and serotonin, albeit much less well than GABA. Uptake of all three monoamines was subsequently demonstrated with astrocytes in primary culture. Norepinephrine and serotonin uptake by cultured astrocytes appear to be very similar to uptake by neurons, as each is highly Na^+-dependent and inhibited by appropriate drugs with appropriately low IC_{50}'s (Ritchie et al., 1981; Tardy et al., 1982; Kimelberg and Pelton, 1983; Kimelberg and Katz, 1985, 1986). Cultured astrocytes also take up dopamine, but, in this case, Na^+ dependency was only observed with astrocytes cultured from hippocampus, and even then Na^+-independent uptake accounted for 70% of total uptake (Kimelberg and Katz, 1986). Astrocytes cultured from corpus striatum and cerebral cortex also took up dopamine, but the uptake was Na^+-independent.

Monoamine uptake by cultured astrocytes is extremely low in comparison to glutamate uptake. The rate of serotonin uptake, for example, is <0.1% of the rate of glutamate uptake, and the other monoamines are accumulated at slightly slower but similar rates (Kimelberg and Katz, 1986). Autoradiographic experiments have demonstrated that most of the astrocytes in the cultures take up [^{3}H]serotonin (Kimelberg and Katz, 1985; Katz and Kimelberg, 1985; Amundson et al., 1992), indicating that uptake is not due to a small population of highly active serotonin-accumulating astrocytes. Thus, the contrast in the rates of serotonin and glutamate uptake appears to be due to differences in the expression of the transporters rather than differences in the number of astrocytes that take up the transmitters.

The rate of astrocytic serotonin uptake is about an order of magnitude slower than that of brain slices (Katz and Kimelberg, 1985). Similarly, the rate of astrocytic dopamine uptake is about two orders of magnitude slower than synaptosomal uptake, and astrocytic norepinephrine uptake is one-third of synaptosomal uptake. (Pelton et al., 1981). Although such comparisons seem to imply that the astrocytic uptake of monoamines is of minor importance, the low transport capacity of cultured astrocytes may not reflect the actual transport capacity of the cells *in situ* but may be a result of growing the cells in highly purified cultures. Furthermore, local rates of uptake by astrocytes *in situ* could be considerably greater if the transport systems are localized in processes, as the GABA and glutamate transporters appear to be (see above).

The metabolism of monoamines is complex and leads to a variety of oxidized, deaminated, methylated, and sulfated products. Two of the principal enzymes of monoamine degradation, monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT), have been shown to be present in glia *in situ* by immunocytochemistry (Kaplan et al., 1979; Levitt et al., 1982; Westlund et al., 1985), and also are present in cultured astrocytes (Hansson, 1984). Cultured astrocytes also contain the enzyme responsible for sulfate conjugation (Yu and Walz, 1985). In keeping with these observations, cultured astrocytes convert norepinephrine to methoxyhydroxyphenylglycol and convert dopamine to dihydroxyphenylacetic acid and homovanillic acid, the expected products (Pelton et al., 1981). The metabolism of the monoamines is sufficiently rapid that the uptake of [^{3}H]norepinephrine and [^{3}H]dopamine is enhanced substantially by inhibitors of MAO and COMT, indicating that the cells rapidly degrade the transmitters and release the metabolites to the medium. This apparent increase in uptake resembles the apparent stimulation of GABA uptake by inhibitors of GABA-transaminase (see above). In both cases, the glia contain virtually no endogenous transmitter, so there is no isotopic dilution of the newly transported transmitter, and the labeled compounds are rapidly degraded.

Adenosine and Adenosine Triphosphate

Cultured astrocytes actively transport and metabolize adenosine (Hertz, 1978; Matz and Hertz, 1989, 1990). The K_m for adenosine uptake by astrocytes (3.4 μM) reportedly is lower than that for brain slices (19 μM), while the V_{max} is about twice that for brain slices. Astrocytes appear to metabolize adenosine by two pathways. In the first pathway, adenosine is converted to adenosine monophosphate (AMP) by adenosine kinase and thus enters the adenine nucleotide pool. In the second pathway, aden-

osine is degraded to inosine by adenosine deaminase. Much of the inosine rapidly appears in the culture medium of astrocytes, a finding that led Matz and Hertz (1989) to suggest that astrocytes possess an ectoenzyme that deaminates adenosine. This point does not appear to have been pursued further.

Adenosine uptake also serves as the final extracellular step for the inactivation of ATP. The initial steps are carried out by ectoenzymes that convert ATP to adenosine diphosphate (ADP) and AMP, and ultimately to adenosine. Although an ectoATPase has been found in cultures of mouse brain glia (Trams and Lauter, 1978) there appear to be no reports that other ectoenzymes of the pathway, such as ATP:AMP phosphotransferase, are present in glial membranes.

Histamine

Relatively little is known about the inactivation of transmitter histamine in brain (Hough, 1988; Schwartz et al., 1991). The major metabolic route of histamine inactivation is thought to be methylation by histamine-*N*-methyltransferase, as brain appears to contain little or no diamine oxidase (Schwartz et al., 1991). A high-affinity but low-capacity transport system for histamine has been found in an astroglia-enriched cell fraction (Rafalowska et al., 1987) and in cultured glia from chick cerebral hemispheres (Huszti et al., 1990). Each of these preparations also contained histamine-*N*-methyltransferase, and the chick glia were able to metabolically degrade histamine to N^{τ}-methylhistamine and N^{τ}-methylimidazoleacetic acid. Histamine uptake by chick glia is inhibited by 2-methylhistamine and 4-methylhistamine, an effect that was attributed to inhibition of histamine-*N*-methyltransferase. This result and interpretation contrast with the results of numerous studies showing that the uptake of GABA and the monoamines is increased when the degradation of these compounds is inhibited. It is notable that the 2- and 4-*N*-methylhistamine compounds are agonists at the H1 and H2 receptors, respectively.

N-Acetylaspartylglutamate

There has been considerable interest in the possibility that *N*-acetylaspartylglutamate (NAAG) is a transmitter in brain, but conclusive evidence supporting this possibility has been elusive. A peptidase that hydrolyzes NAAG to *N*-acetylaspartate and glutamate (NAALADase) has been identified and characterized (Slusher et al., 1992). NAALADase immunoreactivity is enriched in structures that contain NAAG, but has not yet been associated with glia (Slusher et al., 1992). Since NAALADase is an ectoenzyme, it was initially thought that it served to inactivate NAAG, but an alternative possibility has been suggested—namely, that NAAG is a glutamate precursor and that NAALADase generates free glutamate from newly released NAAG in the extracellular space (Meyerhoff et al., 1989). A transporter for *N*-acetylaspartate is present in cultured cerebellar astrocytes from rat brain but not in cerebellar granule cells (O. Saab, personal communication). This transporter appears to be specific for *N*-acetylated acidic amino acids and dipeptides (e.g., NAAG) and is distinct from that for glutamate. Although our understanding of the function of NAAG and *N*-acetylaspartate is still rudimentary, astrocytes are clearly involved.

THE ABILITY OF ASTROCYTES TO TAKE UP TRANSMITTERS IS DETERMINED BY THE KINETICS AND ENERGETICS OF TRANSPORT SYSTEMS

The rate of net transport is governed solely by the kinetic properties of a transport system when it is far from equilibrium, but as a transport reaction approaches equilibrium the rate of net transport decreases and the rate of exchange increases until, finally, equilibrium is reached and net transport stops. Most transport systems for neurotransmitters obtain the energy required to move the substrate from the cotransport of ions such as Na^+, K^+, and Cl^- (see Chapters 15 and 54, this volume; Martin, 1992). The glutamate transport system in retinal Müller cells, for example, is thought to involve the inward cotransport of two Na^+ and the outward transport of one K^+ and one OH^- or HCO_3^- per glutamate moved into the cell (Bouvier et al., 1992).

$$Glu_o^- + 2Na_o^+ + K_i^+ + OH_i^- \rightleftharpoons Glu_i^- + 2Na_i^+ + K_o^+ + OH_o^-$$

Because the ions are cotransported, these systems are often electrogenic, that is, the transport reaction involves the net movement of electrical charge across the membrane. As a result, the total energy available to drive transport can depend on the membrane potential as well as on the stoichiometry of the cotransport reaction (Martin, 1992).

A transport reaction can reach equilibrium because it generates a large transmembrane gradient of neurotransmitter or because changes in the ion gradients or membrane potential reduce the driving force available to drive transmitter uptake. For example, glutamate transport by Müller cells is highly

sensitive to $[K^+]_o$, and when $[K^+]_o$ is increased the driving force becomes too small to support the existing glutamate gradient and the system runs in reverse, thus transporting glutamate from inside to outside the cell (Szatkowski et al., 1990). A similar reversal of transport has been demonstrated for GABA (Chapter 54, this volume). Given this mechanism it seems possible that under conditions of high neuronal activity when $[K^+]_o$ is elevated the ability of astrocytes to take up and inactivate glutamate might be diminished. It is not known at present whether physiological changes in ion gradients and membrane potential actually do affect the ability of astrocytes to take up transmitters *in vivo*. The possibility that changes in ion gradients will affect the uptake of particular transmitters *in vivo* will depend on the stoichiometry of the transport reaction and the extent to which astrocytes maintain or develop a substantial internal concentration of transmitter. Because astrocytes normally contain extremely low levels of GABA and monoamines, their transport systems do not have to move these compounds up a large gradient, and their ability to take up these compounds might not be greatly affected by changes in ion gradients. In contrast, astrocytes do maintain appreciable concentrations of glutamate and aspartate, so the uptake of these compounds may be more significantly affected by membrane potential and ion gradients.

IS THE ABILITY OF ASTROCYTES TO INACTIVATE TRANSMITTERS PHYSIOLOGICALLY SIGNIFICANT?

The anatomical organization of astrocytes and their capacity to take up and metabolize synaptic transmitters has led to the suggestion of at least four specific functions for astrocytes in synaptic transmission (Koelle, 1950; Henn and Hamberger, 1971; Schousboe and Hertz, 1984). First, an astrocyte could help to terminate synaptic transmission at the individual synapses that it envelops. Second, an astrocyte might protect the synapses that it envelops against inappropriate activation by excess transmitter released elsewhere during either physiological or pathological events. Third, astrocytes could take up and metabolize transmitters and then return transmitter precursors to neurons, as in the glutamate-glutamine cycle, and finally, astrocytes might help to regulate synaptic transmission. In the last case, the term "regulate" has not been precisely defined, but seems to contain the idea that astrocytes do not merely intercept and degrade excess transmitter, but actually have an active function in determining the outcome of synaptic events. These ideas are not mutually exclusive, and most of the available evidence can be used to support more than one of them.

Several lines of evidence indicate that the ability of glia to inactivate synaptic transmitters is physiologically significant. First, the ability of astrocytes to take up and metabolize transmitters is not an artifact of tissue culture, but is characteristic of glial cells *in situ*. Uptake by glia *in situ* has been demonstrated by autoradiography and immunocytochemistry for GABA, glutamate, and serotonin (Iversen and Kelly, 1975; Garthwaite and Garthwaite, 1985; Kimelberg, 1986; Storm-Mathisen et al., 1986; Palmi et al., 1991; Anderson et al., 1992). As noted above, glia *in situ* also contain enzymes that degrade acetylcholine, GABA, glutamate, the catecholamines, and serotonin. The observation that metabolic inhibitors enhance the accumulation of radioactively labeled GABA, glutamate, and monoamines indicates that these cells do, in fact, metabolize the transmitters that they accumulate. The relationship of the uptake process to synaptic function is supported by studies of the regional differences in transport properties. Drejer et al. (1982) and Amundson et al., (1992) found that astrocytes cultured from brain regions with a high density of glutamatergic terminals (e.g., neostriatum) had a greater capacity to take up glutamate than did astrocytes from regions with fewer glutamatergic terminals. Similarly, the uptakes of serotonin and the catecholamines differ significantly among astrocytes cultured from different brain regions, although the regional correspondence between serotonin uptake and serotonin fibers was poorer than the correspondence of glutamate uptake with glutamatergic endings (Kimelberg and Katz, 1986; Amundson et al., 1992).

The ability of astrocytes to take up *endogenous* GABA and glutamate is strongly supported by immunocytochemical studies of the distribution of GABA and glutamate during pharmacological and physiological experiments. Inhibition of GABA-transaminase with aminooxyacetic acid or γ-vinylGABA leads to a substantial increase in GABA-like immunoreactivity in glial cells (Storm-Mathisen et al., 1986; Neal et al., 1989; Palmi et al., 1991). Quantitative immunocytochemical studies of the distribution of glutamate and glutamine indicates that the ratio of glutamate to glutamine is greatest in putative excitatory endings and lowest in glial cells (Ottersen et al., 1992). Following ischemia, glutamatelike immunoreactivity rises significantly in hippocampal astrocytes, especially in the mitochondria, while glutamine and taurine remain unchanged or fall somewhat (Torp et al., 1991). In pyramidal cells all three amino acids decrease during ischemia. Because glutamine synthesis requires ATP, the astrocytes would not be able

to convert accumulated glutamate to glutamine during ischemia, and thus astrocytic levels of glutamate would be expected to rise as the transport system accumulates extracellular glutamate. Thus the increased level of glutamate in the astrocytes appears to involve a redistribution of glutamate from the neurons to the astrocytes. Some of the increase in glutamate levels might result from the action of phosphate-activated glutaminase, a mitochondrial enzyme that also is present in glia. Finally, prolonged depolarization of hippocampal slices with high-K^+ medium also reduces the glutamate- and aspartatelike immunoreactivity in hippocampal neurons, while glutamate-, aspartate-, and GABA-like immunoreactivity simultaneously increase in astrocytes (Storm-Mathisen et al., 1986).

A few studies have provided evidence that transmitter-inactivating systems in astrocytes influence neuronal function. In an early study, Desmedt and LaGrutta (1957) compared the effects of selective inhibitors of specific and nonspecific cholinesterase on arousal in the cat's brain and concluded that pharmacological arousal results from inhibition of nonspecific cholinesterase, not the specific cholinesterase. Although they recognized that the nonspecific cholinesterase is a glial enzyme, they did not discuss the implications of their findings for glial function. Bowery et al. (1976) provided evidence that the GABA transport system in the satellite glia of the superior cervical ganglion can influence neuronal activity. During studies of the depolarization of ganglion neurons by β-alanine and GABA, they discovered that the effects of β-alanine were enhanced after the satellite glia were preloaded with GABA. They attributed this effect to elevated extracellular GABA resulting from the inhibitory effect of β-alanine on the reuptake of GABA by the glial transport system. That is, because β-alanine inhibited the uptake of effluent GABA into the glia, extracellular GABA levels rose and the neurons were depolarized. Although the ganglion glia contain little or no GABA *in vivo* and the physiologic function of this mechanism is unknown, these data do indicate that the GABA transport system in the ganglion glia is close enough to the neuron and is active enough to influence neuronal activity. The physiological importance of the glial GABA transport system also is supported by the observation that THPO (4,5,6,7-tetrahydroisoxazolo [4,5c]pyridin-3-ol) and THAO (5,6,7,8-tetrahydro-4H-isoxazolo [4,5c]azepin-3-ol), two relatively specific (but weak) inhibitors of the glial GABA transport system, have anticonvulsant activity (Schousboe et al., 1991).

Thus the current evidence indicates that inactivation of transmitters by astrocytes is physiologically significant in the sense that it does occur, but its exact relationship to synaptic transmission and its quantitative importance is not clear at all. Although the quantitative aspects of the problem are poorly understood, they are not unimportant, as the astrocyte's role would likely be considered minor if it only inactivated a few percent of the transmitter released at a synapse but highly significant if it inactivated, say, half. The exact function and quantitative importance of astrocytic inactivation undoubtedly differs among transmitters and neuronal circuits. It is widely accepted that the glutamate-glutamine cycle is quantitatively important in glutamatergic synaptic transmission (Schousboe and Hertz, 1984), although the exact proportion of glutamate handled by the pathway is unknown. Astrocytically produced glutamine is also a quantitatively important precursor of transmitter GABA (Martin and Rimvall, 1993), but this fact does not imply that astrocytes take up and degrade a large fraction of transmitter GABA in a GABA-glutamine cycle, as astrocytes cannot directly convert GABA to glutamine, and as noted above, GABA uptake by astrocytes is variable and somewhat slower than uptake by cortical neurons. Similarly, astrocytes take up monoamines relatively slowly, an observation that seems to suggest that astrocytes do not play an important role in the inactivation of monoamines. However, such observations may be misleading, as the transport systems may be strategically placed on the surfaces of astrocytes in order to effectively handle the overflow of a particular synaptic transmitter. Studies of transmitter inactivation by glia appear to be entering a new phase, as the genes for some of the transporters have been cloned and new, specific antisera to some of the transporters have been prepared. The advent of these new tools will greatly enhance our ability to investigate this fundamental aspect of glial function.

I thank Dr. Eleonora Aronica for translating and discussing the article by Lugaro. I thank Dr. A. N. van den Pol for permission to use Figure 48-1, and Dr. T. Kosaka and K. Hama for generously providing Figures 48-2 and 48-3.

49 Radial glial cells: scaffolding for brain construction

PASKO RAKIC

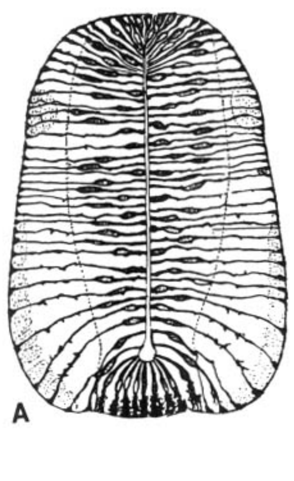
Among the nonneuronal cells that can be encountered in the mammalian brain, none are larger or more fascinating than radial glial cells. Although in most brain regions they are present only transiently, during a short developmental period they play a crucial role in the construction of the nervous system, first, by providing scaffolding for migrating neurons and, second, by participating in the formation of diverse glial cell lineages. The radial glial cell is a maverick among brain cellular elements in that it initially assumes one phenotype and subserves distinct developmental functions and then, after reentering mitotic cycles, it transforms into a morphologically and functionally different phenotype. The diversity of functions and morphogenetic transformations that have been observed in various vertebrate species suggests that this glial cell class may have played a special facilitatory role in the evolution of the central nervous system. This chapter is concerned with radial glial cells and their role in the developing mammalian brain, with particular emphasis on the primate telencephalon that was the focus of research in my laboratory.

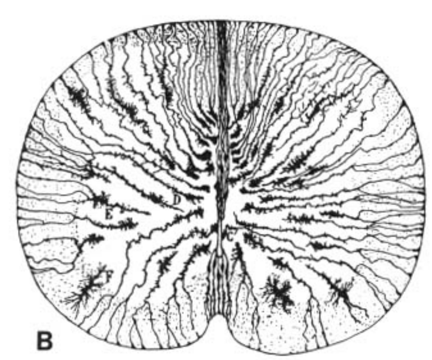
A LITTLE HISTORY

As the name implies, radial glial cells are a specialized nonneuronal cell class belonging to the astroglial cell lineage. They are a morphologically, biochemically, and functionally distinct cell class characterized by an elongated fiber of an even caliber that, initially during development, radially spans the entire cerebral wall from the ventricular to the pial surface. In most mammals, with some notable exceptions, the majority of radial glial cells disappear during late stages of ontogenetic development.

Radial glial cells impregnate remarkably well with most variants of the Golgi silver method and were described in the fetal human brain before the turn of the century (Ramón y Cajal, 1890; Lenhossék, 1895; Retzius 1993; Golgi, 1985). However, distinguishing between immature neuronal and glial cells in the developing nervous system is rather difficult. Ramón y Cajal had a hard time making up his mind as to the nature of "fetal radial cells," but eventually corrected his own initial misperceptions (Ramón y Cajal, 1890, 1909). In his study of the development of the chick embryo, he first thought that the "neuroepithelial" cells that span the entire width of the neural tube (Figure 49-1A) were exclusively neuroblasts, which subsequently would form the ventral and dorsal horns of the spinal cord. Later, however, he recognized the presence of additional "transitional" cells (also described by Lenhossék, 1895), which he designated as precursors of protoplasmic and fibrous astrocytes in the spinal cord (Figure 49-1B), mesencephalon (Figure 49-1C), and telencephalon (Figure 49-1D). Soon after the introduction of the Golgi method, numerous other investigators described elongated "fetal glia" under a variety of terms such as "epithelial cells" (Golgi, 1885; Ramón y Cajal, 1909), "radial cells" (Magini, 1888), "fetal ependymal cells" (Retzius, 1893, 1894), and "spongioblasts" (Lenhossék, 1895; Kölliker, 1896). More recent terms, such as "tanycytes" and "faserglia," have added to the confusion in the literature (see discussion in Schmechel and Rakic, 1979a). To avoid connotations beyond a morphological description, I adopted the term *radial glia* (Rakic, 1971a, 1972). This designation is now generally accepted and will be used throughout this chapter.

The difficulties in identifying immature cells with classical methods, their obscure function, and their transient presence, may be why radial glial cells were neglected soon after discovery. This cell type is rarely mentioned in textbooks of neuroanatomy or neurophysiology published in the first half of this century. However, the introduction of electron microscopy, which revealed the possible role of radial glia in neuronal migration (Rakic, 1971a, 1971b) reawakened the interest of researchers in these cells. More recently, application of immunocytochemistry and the development of *in vitro* systems have permitted the molecular characterization of radial glial cells and provided additional insights into their role





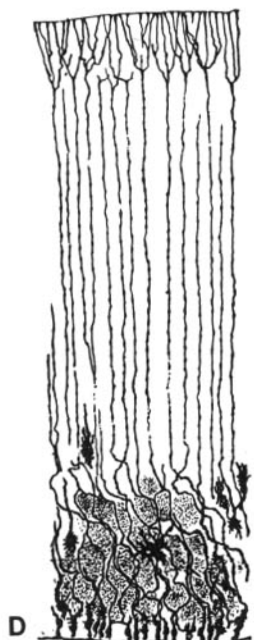


FIG. 49-1. (**A**) Primordial epithelium, including spongioblast (radial glial) cells of the spinal cord of the chick embryonic day 3 of incubation when, according to Ramón y Cajal (1909, Vol. 1, p. 662), they become stainable by the Golgi method. (**B**) Epithelial (radial glial) and displaced astroglial precursors and more mature astrocytes, stained by the Golgi method, in the spinal cord of the newborn mouse. This drawing shows explicitly different phases of morphogenetic transformation of glial cell line. (Ramón y Cajal, 1909, Vol. 1, p. 240). (**C**) Epithelial (radial glial) and (**D**) neuroglial cells of the cerebral cortex in neonatal rabbit stained with the Golgi method. [Adapted from Ramón y Cajal, 1909, Vol. 2, p. 859.]

during development (for review see Cameron and Rakic, 1991; Misson, 1991).

ORIGIN AND PHENOTYPE

Radial glial cells of the mammalian telencephalon, as in most other brain structures, have a distinct bipolar shape. Their spindle-shaped soma-containing nucleus is initially situated near the lumen of the cerebral vesicle with an inner endfoot anchored at the ventricular surface. From the other pole of the soma emanates an elongated fiber that ultimately terminates with a conical endfoot at the pial surface. During early embryonic development, these glial cells are an integral part of the columnar germinal epithelium with outwardly directed processes that stretch across the full thickness of the neural wall (Sidman and Rakic, 1973). As the cerebral wall becomes wider and more complex in configuration, radial fibers further elongate and curve, retaining an attachment to both the ventricular and pial surfaces. In the large human fetal brain, the length of a radial glial fiber may attain 15 to 20 mm, which makes them the largest and longest glial cells recorded (Rakic, 1984). Although the elongated shafts of radial glial fibers initially have smooth surfaces, during the midgestational period they develop numerous lamellate expansions that protrude laterally from the segment passing through the intermediate zone (Rakic, 1972; Schmechel and Rakic, 1979a).

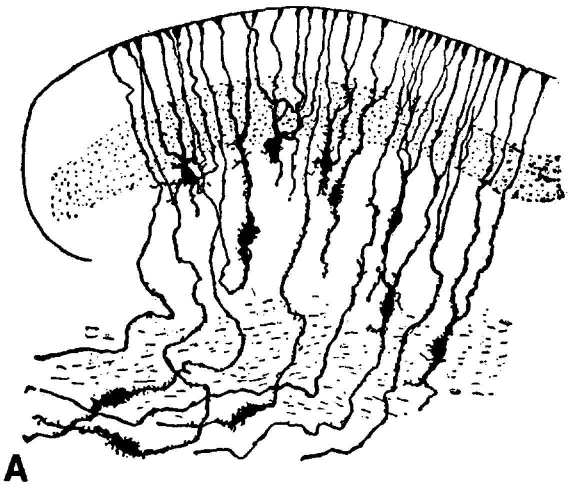
Golgi, electron microscopic, and immumocytochemical studies helped to determine the main cytological characteristics of radial glial cells in the mammalian telencephalon, which in essence are as follows (see Chapter 4, this volume):

1. An endfoot situated at the ventricular surface and connected with the adjacent cells by tight junctions
2. An ovoid nucleus with homogeneously dispersed chromatin

3. A spindle-shaped soma situated within the proliferative, ventricular, or subventricular zones
4. An elongated, radially oriented fiber that contains attenuated mitochondria, sheaves of 24-nm microtubules, an electronlucent cytoplasmic matrix, and, at later stages, an abundance of 9-nm intermediate filaments
5. An immunoreactivity to astroglial cell-specific markers, such as glial fibrillary acidic protein (GFAP) and to several other radial glia-specific antibodies (see below)
6. A terminal endfoot at the pial surface rich in glycogen granules (these endfeet form a continuous sheet at the outer cerebral surface, the so-called limiting membrane, which is coated externally by a basal lamina rich in collagen and laminin)

There are several morphological variations of the basic radial glial cell phenotype. For example, as suggested by Ramón y Cajal (1909), Bergmann glial cells of the mammalian cerebellum can be considered modified radial glial cells. The transitional forms of Bergmann glial cells as they evolve from the primitive radial glial cells during embryonic development are illustrated in Figure 49-2A. In primates, transformation from the radial glial phenotype into Bergmann phenotype occurs between 90 and 120 embryonic days (Rakic, 1975) and proceeds a major wave of granule cell migration from the external granular layer across the molecular layer. A similar morphogenetic transformation seems to occur during the course of vertebrate evolution. Thus, in adult amphibian and reptilian cerebellum, Bergmann glial cells retain contact with both ventricular and pial surfaces and have the general spindle-shaped morphology characteristic of the transient telencephalic radial glial cell (Figure 49-2B).

Both Golgi and immunocytochemical analyses of the primate telencephalon, using various glial cell-specific antibodies, show that radial glial cells are probably the earliest class of nonneuronal cells to appear in all major regions of the developing mammalian brain (Rakic, 1972; Levitt et al., 1981, 1983). For example, glial fibrillary acidic protein (GFAP)-positive radial glial cells were detected in the fetal brain of humans and nonhuman primates during the first quarter of gestation (Levitt al., 1983; Choi, 1986). However, it is possible that this nonneuronal cell line is established during even earlier developmental stages, since commitment to the glial cell lineage does not necessarily begin with the expression of GFAP (Cameron and Rakic, 1991). Initial discovery of a separate population of GFAP-positive dividing cells in the germinal ventricular zone (Levitt et al., 1993) indicated that astrocytic



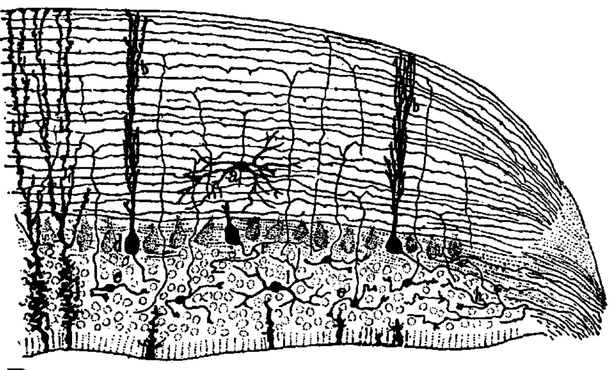


FIG. 49-2. (A) Sagittal section of the cerebellum of the newborn mouse stained with the Golgi method illustrates the transformation of epithelial (radial glial) cells into Bergmann glial cells (Ramón y Cajal, 1911, Vol. 2, p. 105). (B) Frontal (coronal) section of the adult reptilian cerebellum stained with the Golgi method shows that in many submammalian species the cerebellum does not contain Bergmann glial cells but rather radial glial cells, which remain present throughout life. [Adapted from Ramón y Cajal, 1909, Vol. 2, p. 77.]

glial cell lines diverge within the population of dividing precursor cells (Figure 49-3A). Most of the cells committed to the glial line retain their capacity to divide in the fetus (Schmechel and Rakic, 1979b) and infancy (Misson, 1991).

The developmental history of a radial glial cell line in the mammalian cerebrum has been clarified using a combination of methods, including sets of new mono- and polyclonal antibodies (for review see Cameron and Rakic, 1991). The presently available data indicate that progenitorlike or primary radial glial cells, which in nonprimates do not express the GFAP, are the earliest of the telencephalic glial cell sublineages to be identified by morphological and immunological criteria. This system of radial glial

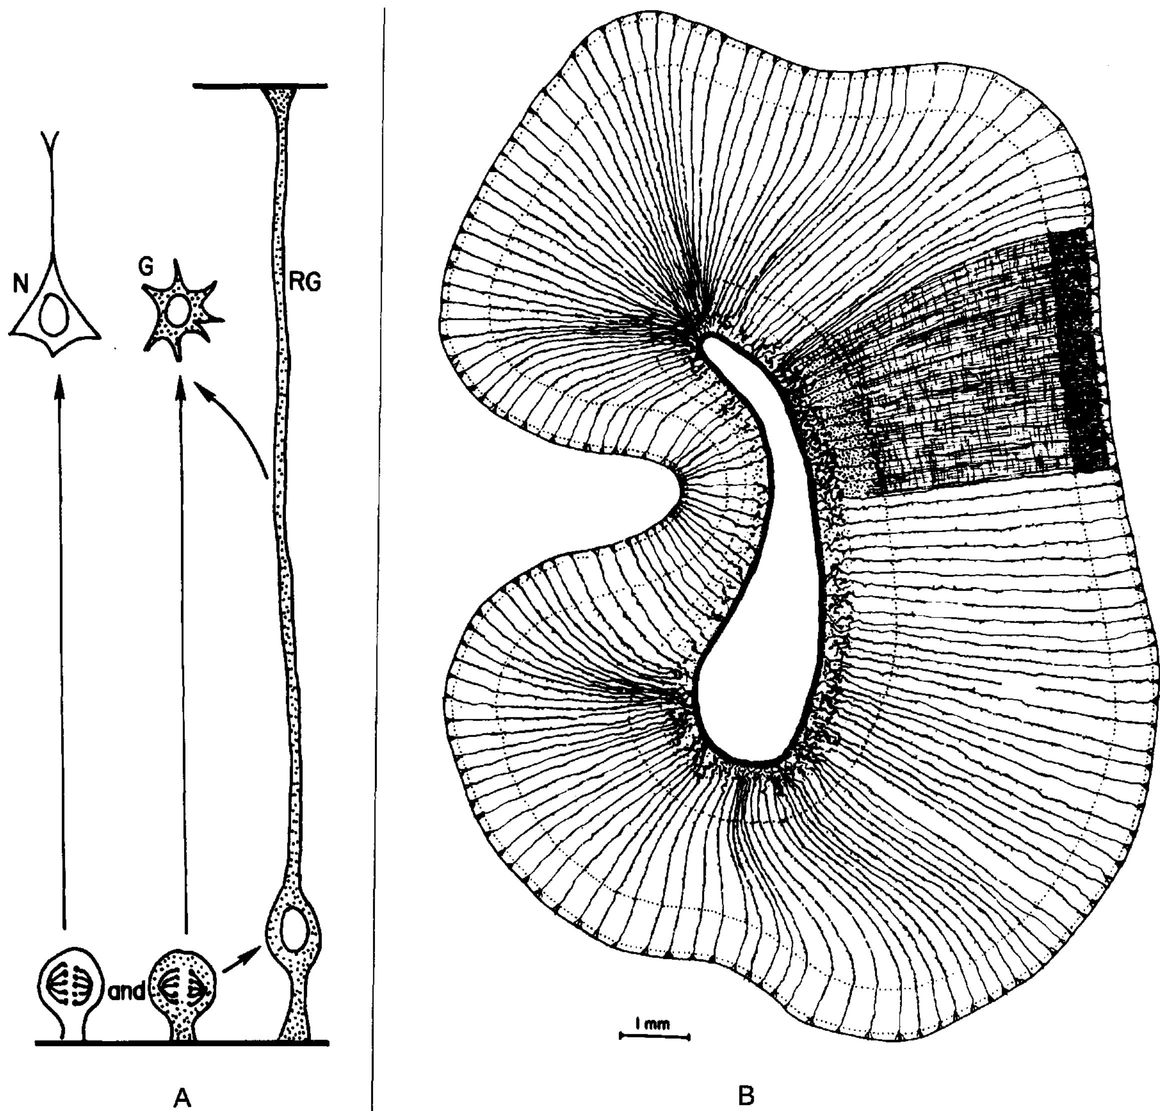

FIG. 49-3. (A) Dual cell line origin and concept of morphogenetic transformation of radial glial cells into astrocytes in the fetal monkey cerebrum based on Golgi, electron microscopic, and immunocytochemical analyses. GFAP-negative and GFAP-positive (*stippled*) dividing cells coexist throughout the period of neurogenesis. The GFAP-positive cells initially produce radial glial cells (*RG*); later, either directly or indirectly (*arrows*), they generate astrocytes (*G*) and various specialized astrocyticlike cells. Neurons (*N*) or perhaps also some nonneuronal cells originate from GFAP-negative precursors. [From Rakic (1981), with permission.] (B) Camera lucida drawing of a coronal section of a Golgi-impregnated occipital cerebral lobe in a 97-day-old monkey fetus. The incipient calcarine fissure is at the left. The radial glial cell somas are situated close to the cerebral ventricle and their elongated fibers extend to the 3 to 5 mm distant pial surfaces where they divide into several branches, each terminating with an endfoot. [Adapted from Rakic (1972), with permission.]

cells appears to be assembled in the telencephalon prior to the earliest migratory wave of postmitotic neurons in all species examined (Levitt et al., 1981, 1983; Rickmann et al., 1987; Gadisseux et al., 1989; Gressens et al., 1993). The original concept of two separate precursor cell lines and two alternative morphogenetic pathways for production of astrocytes in the primate is illustrated schematically in Figure 49-3A. Use of the retrovirus gene transfer method to label progeny of cells confirms the existence of separate glial cell lines in the developing mammalian telencephalon (Luskin et al., 1988). The emergence of the radial glial cell lineage and its differentiation from primitive neuroepithelial cells committed to neuronal cell precursors is also indicated by the expression of the radial glial cell-specific antigens RC1 and RC2 and the absence of immunoreaction with neurofilament (Frederiksen and McKay, 1988; Misson et al., 1988a, 1988b; Culican et al., 1990; Edwards et al., 1990). Although these two cell populations continue to coexist during the entire period of corticogenesis, their proportion changes in

harmony with the appearance of increasing increments of neuronal and astroglial cells (Levitt et al., 1983). At present, it is unclear whether the glial-specific RC1 and RC2 antigens are expressed in the multipotential glial progenitor cell as well as primary radial glial cells (Cameron and Rakic, 1991). This uncertainty is reflected in the cell lineage diagram (Figure 49-4).

Glial fibrillary acidic protein is present in the cytoplasm of glial cells in all vertebrate species, exclusive of cyclostomes, and provides a definitive marker of the astrocytic cell phenotype, including radial glial cells (Onteniente et al., 1983; Dahl et al., 1985; Bignami, 1991). The intermediate filament vimentin is also a very useful marker for the identification of radial glial cells, since the adjacent neuroepithelial cells are vimentin-negative. The phenotype of the primary radial glial cell in rodents is characterized by immunoreactivity to RC1, RC2, vimentin, Rat 401, and Ran-2. However, antigenic properties are changed during the emergence of a secondary phenotype as revealed by a substitution in the intermediate filament protein composition: vimentin to GFAP (Bovoienta et al., 1984; Pixley and De Vellis, 1984; Rickmann et al., 1987; Hutchins and Casagrande, 1989; Voigt, 1989). Similar studies of biochemical composition have not been carried out in primates.

FUNCTION AND PATHOLOGY

The striking geometrical regularity of radial glial cells in the developing central nervous system suggested that these cells may serve as a scaffolding for fragile embryonic neural tissue (Ramón y Cajal, 1909). The relationship between radial glial cells and migrating neurons was suggestive in classical light microscopic preparation (Figure 49-5) (Rakic, 1972). However, only resolution obtainable by a transmission electron microscope could reveal the close apposition between postmitotic migrating neurons and radial glial cells (Rakic, 1971a, 1972). This relationship is particularly explicit in developing cerebellar cortex between Bergmann glial fibers and granule cells (Figure 49-6) (Rakic, 1971). Several lines of evidence from both *in vivo* and *in vitro* analyses confirmed that contact interaction between the surface of radial fibers and migrating neurons plays a crucial role in the selection of the migratory pathway as well as in generating signals for displacement and stopping the movement of neurons (Caviness and Rakic, 1978; Gadisseux and Evrard, 1985; Rakic, 1988b; Edvards et al., 1990; Hatten, 1990; Misson, 1991; Komuro and Rakic, 1993). In terms of orientation and directionality of cell movement, migration can be classified into radial (proceeding from the ventricular to the pial surface) and tangential (running parallel to the brain surface). With regard to pathway selection, migrating neurons fall into three major categories: (1) gliophilic cells, which follow elongated glial fibers and bypass neurons that may be lying within their trajectory; (2) neurophilic cells, which follow neuronal, particularly axonal, surfaces and bypass glial shafts; and (3) biphilic cells, which display temporal or regional affinities toward either glial or neuronal surfaces (Rakic, 1985, 1990).

The gliophilic migration is particularly prominent during formation of the neocortex (Rakic, 1972) but occurs also in the developing hippocampus (Nowakowski and Rakic, 1978; Eckenhoff and Rakic, 1984). In each case electron microscopic analysis of closely spaced serial sections showed that with some notable exceptions (Rakic et al., 1974; Nowakowski and Rakic, 1978), typical migrating neurons in the primate cerebral wall adhere intimately and continuously to the neighboring glial fibers (Figure 49-7). In spite of clearly defined columns of migrating neurons aligned with radial glial cells, some postmitotic cells in the cerebral wall do not respect radial constraints (e.g., Tan and Breen, 1993). Although their identity is not clear, it appears that at least some of the tangentially migrating cells belong to a separate subclass, as observed in mouse telencephalon (Luskin et al., 1992) or in avian optic tectum (Gray and Sanes, 1991; Martinez et al., 1992). Many of the tangentially moving cells within the cerebral wall do not ever enter the neocortex (DeDiego et al., 1994). These findings suggest that some postmitotic cells may be neurophilic and are actually prespecified to move perpendicularly to the glial scaffolding along axonal pathways to subcortical structures. In spite of these exceptions, a majority of postmitotic cells in the mammalian cerebral wall become gliophilic and remain closely associated with adjacent glial cells while migrating to the cortical plate. This relationship is particularly prominent in primates, where migratory pathways are much longer and both radial and laminar organization is more pronounced than in subprimate species (Sidman and Rakic, 1973). See also Figures 49-3B and 49-7.

The affinity between gliophilic neuronal and radial glial fiber surfaces was implied by the failure of migration cells to follow any of a myriad of differently oriented cellular processes that they encounter during the journey to the cortex (Rakic, 1972). The leading process of migrating neurons morphologically polarized and contoured to dimensions of the radial glial fibers was suggestive of differential cell

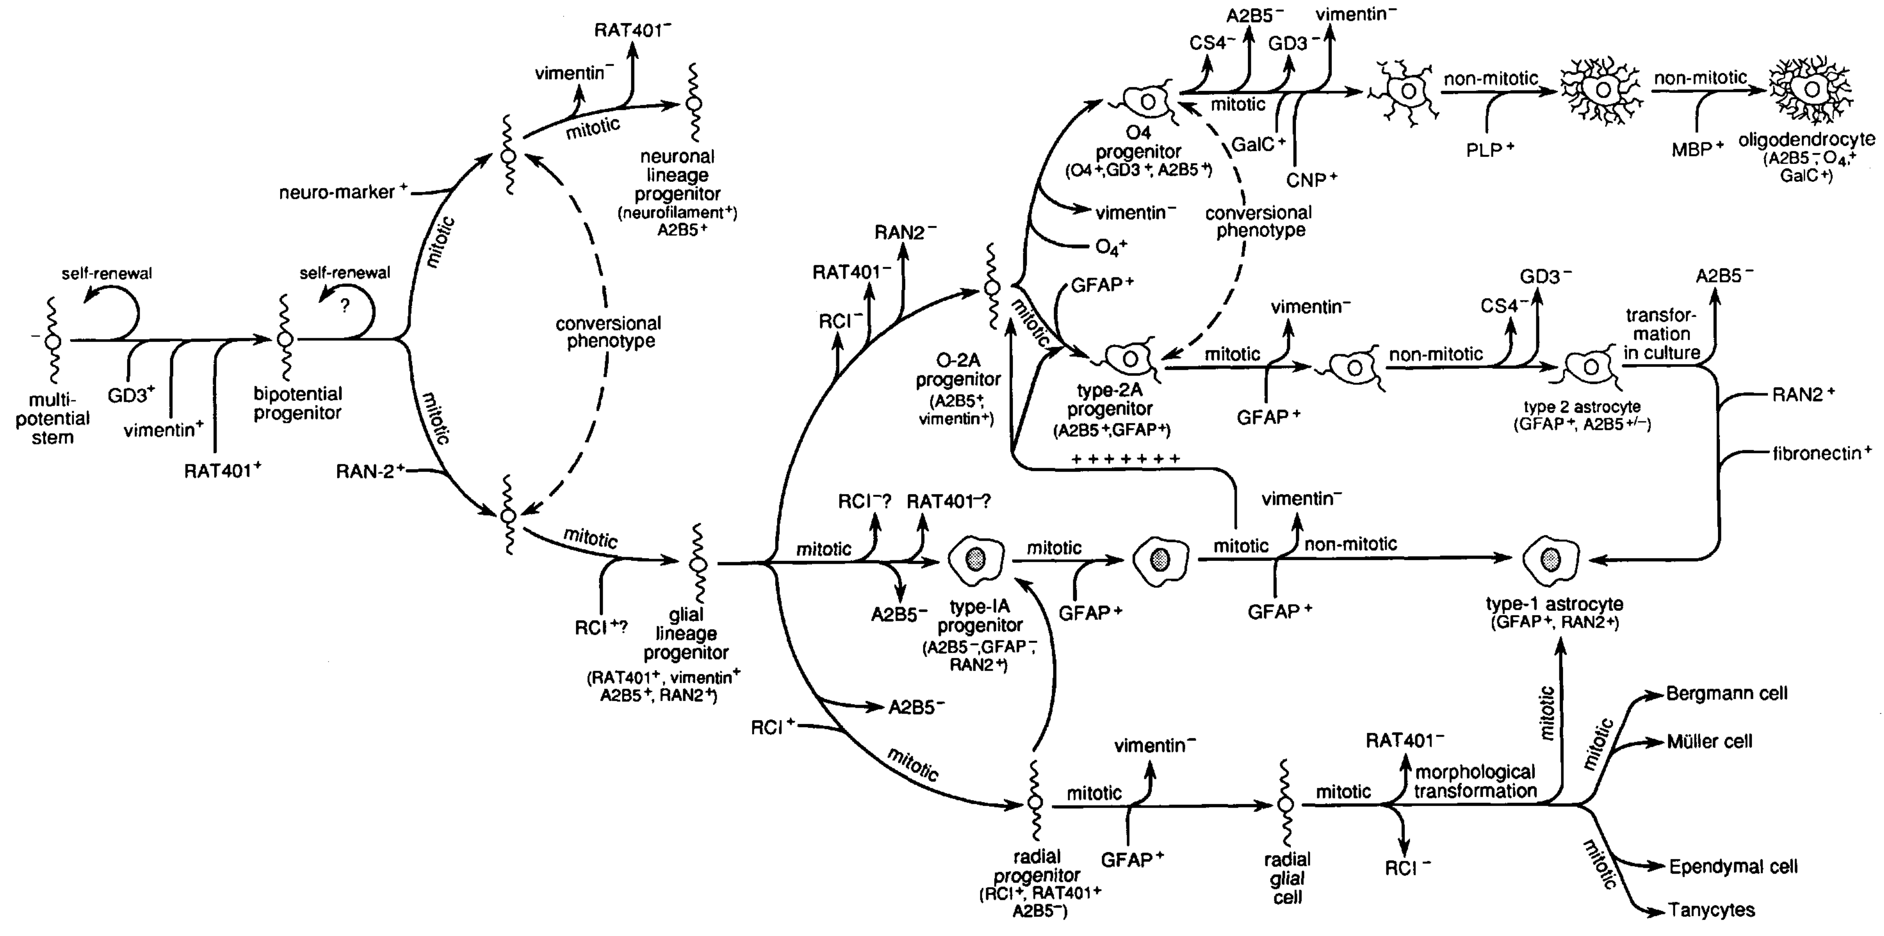

FIG. 49-4. Possible glial cell lineages that occur during the development of the cerebral cortex. In the past two decades we have witnessed introduction of a large number of molecular markers specific for various subtypes of glial cells. The acquisition or loss of antigenic components that accompany the progressive maturation of individual cell types are indicated by arrows with (+) or (−) signs. [Adapted from Cameron and Rakic (1991), with permission.]

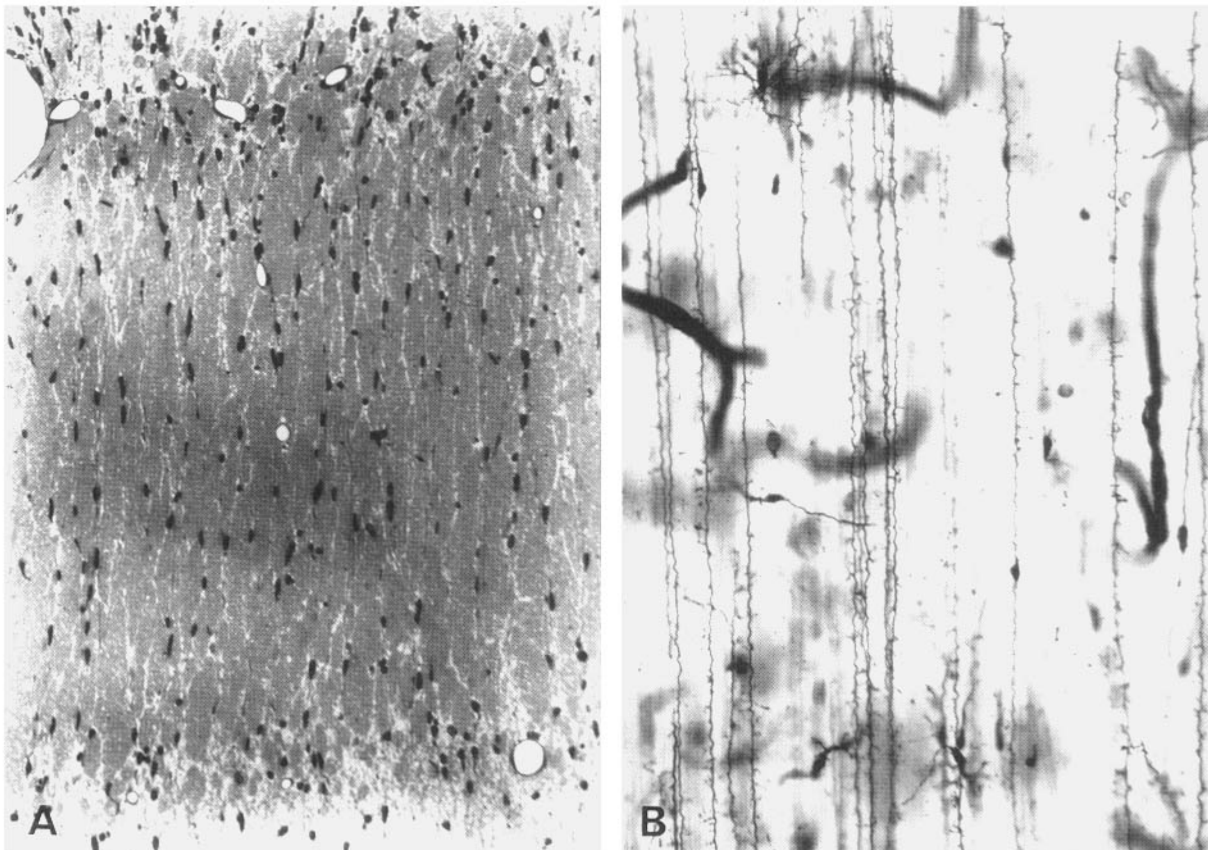

FIG. 49-5. (A) Photomicrograph of the toluidine blue stained section across the intermediate zone in the monkey cerebral wall at midgestation. Note cohorts of migrating neurons deployed in the separate streams running from the proliferative ventricular zone situated 1000 μm below to the cortical plate 2000 μm above. (B) Golgi impregnated section at the corresponding level of the fetal cerebral wall exposes elongated shafts of radial glial fibers and an occasional bipolar migratory neuron. [Adapted from Rakic (1990), with permission.]

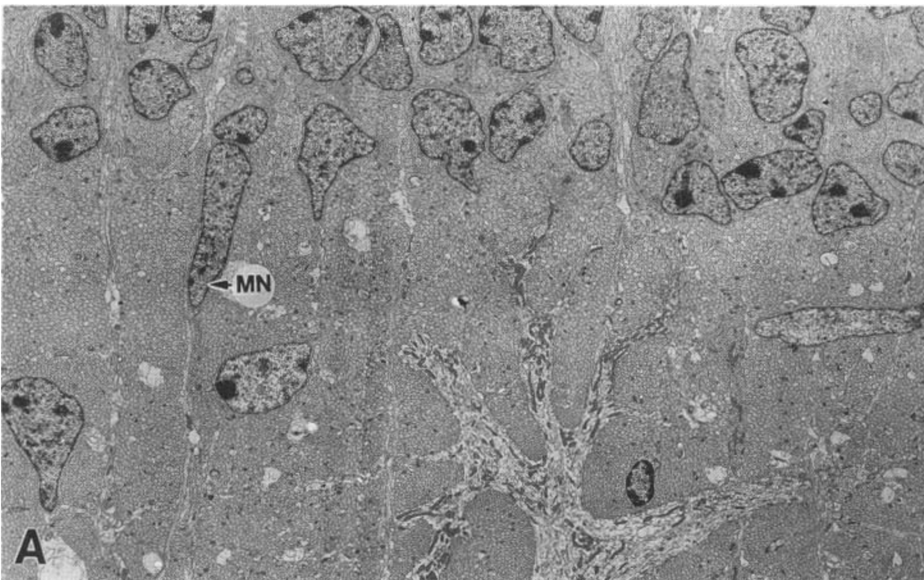
adhesion (Figure 49-7). Thus, fetal radial glial fibers provide transient scaffolding and impose radial constraints by providing guidelines that facilitate neuronal migration in the expanding cerebral wall.

Cerebellar granule cells can be classified as the biphilic category of migrating cells because their single descending process containing soma follows exclusively Bergmann glial fibers while their two horizontal neurites grow along parallel axonal fibers belonging to previously generated granule cells (Rakic, 1985). Shortly after its final cell division in the external granular layer, a newly generated granule cell takes a position in the deep part of the external granular, contacting a Bergmann glial fiber (cell 1 in Figure 49-8). It then transiently assumes a bipolar shape (cell 2) by emitting two horizontal cytoplasmic processes that run in the longitudinal plane of the cerebellar folium, at right angles to the growing Purkinje dendritic trees (Ramón y Cajal, 1909). These horizontal processes extend exclusively along the surface of parallel (axonal) fibers (Rakic, 1971b). Next, the granule cell becomes tripolar by forming a third, vertical cytoplasmic process, which elongates in close apposition to the shaft of Bergmann glial cells (cell 3). When the descending process reaches the appropriate length, the nuclear part of the granule cell becomes translocated within its volume. As a result, the entire soma passes across the complex and synaptically interconnected molecular layer. Several granule cells in succession follow the same Bergmann glial guide, as described for the developing cerebral cortex (Rakic, 1971b).

A change in position and shape of the cerebellar granule cells provides an example of the significance that cooperation between neuronal and glial cells has for the development of complex cellular and synaptic organization of a given brain structure. The migration is an essential prerequisite for forming granule cell shape: the horizontal and vertical segments of the cell trailing behind the nuclear region of the granule cell become the parallel fiber and vertical shaft, respectively. When the granule cell body



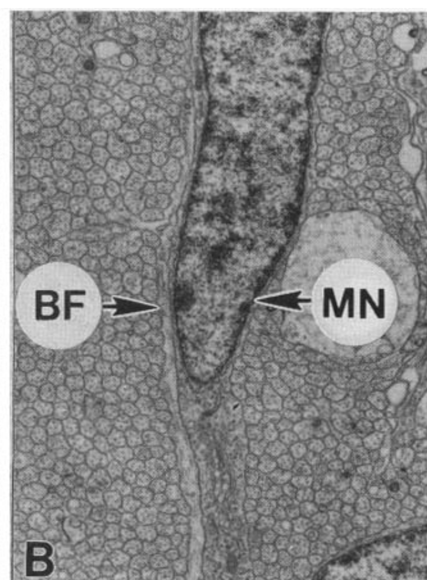


FIG. 49-6. (**A**) Low-power electron micrograph of the 135-day-old monkey fetus showing bipolar migrating neuron (*MN*) descending from the external granular layer situated at the top of this field, to the internal granule layer situated below. (**B**) An enlargement of the migrating neurons (*MN*) to show that its leading process is closely aligned with an electronlucent shaft of the Bergmann glial fiber (*BF*) as the cell penetrates the densely packed and already synaptically interconnected neuropil of the molecular layer. The migrating neurons move selectively along the surface of the glial fiber, although it simultaneously contacts a myriad of axons and other cell processes.

reaches Bergmann cell soma at the level of the Purkinje cell layer, it leaves its glial guide and takes up its permanent position in the internal granule layer (Figure 49-8 cells 5, 6, and 7). It then emits 3 to 5 short dendrites that contact the mossy fibers that originate in the brainstem. The position in the molecular layer where granule cells differentiate from round into bipolar form determines the depth of the prospective parallel fibers, so that early generated parallel fibers remain near the Purkinje cells, while those situated closest to the pial surface form the last, as evidenced by examining the position of parallel fibers belonging to cells 2, 3, 6, and 7 in Figure 49-6.

Selective displacement of migrating neurons along the glial surface can be explained by the differential adhesion mediated by several classes of recognition and/or adhesion molecules (Edelman, 1980; Rakic, 1981, 1985; Hatten, 1990; Rakic et al., 1994). So far, most of the identified molecules are present on the neuronal, or on both neuronal and glial, cell surface (e.g., Edmonson et al., 1984; Edelman and Crossin, 1991; Fishel and Hatten, 1991). Only recently two new membrane proteins, that may be involved in neuronal migration, were found transiently on the surface of the radial glial cells (Cameron and Rakic, 1994). These polypeptides are strategically localized in a form of well-defined junctions between the soma of migrating neurons and radial glial fibers. One important feature of potential recognition molecules is that their expression should be transiently present on the glial surface. These polypeptides are indeed expressed in the telencephalon and cerebellum only during the period of neuronal cell migration (Cameron and Rakic, 1994). In the cerebellum, where Bergmann glial cells persist in the adult, several other of its cytoplasmic and surface properties also change from the embryonic to adult form. However, a recent study shows that adult Bergmann glial can be induced to reexpress at least some of these immature components, including nestin, an intermediate filament normally present only during the active phase of neuronal migration (Sotelo et al., 1994). Such reexpression allows Bergmann fibers in the adult cerebellum to serve as conduits for implanted neuroblasts.

Recognition of, and attachment to, the appropriate substrate surface is not a sufficient condition to translocate a cell nucleus and the adjacent cytoplasm across densely packed neural tissue. Recent studies indicate that glial cells, though lacking the high excitability of neurons, are intimately associated with neurons through an exchange of signals regulated by the same species of ion channels (Barres, 1991). During development, the motility of migrating neurons seems to depend critically on Ca^{2+}-mediated assembling of cytoskeletal proteins regulated by a combination of several specific ion channels (Komuro and

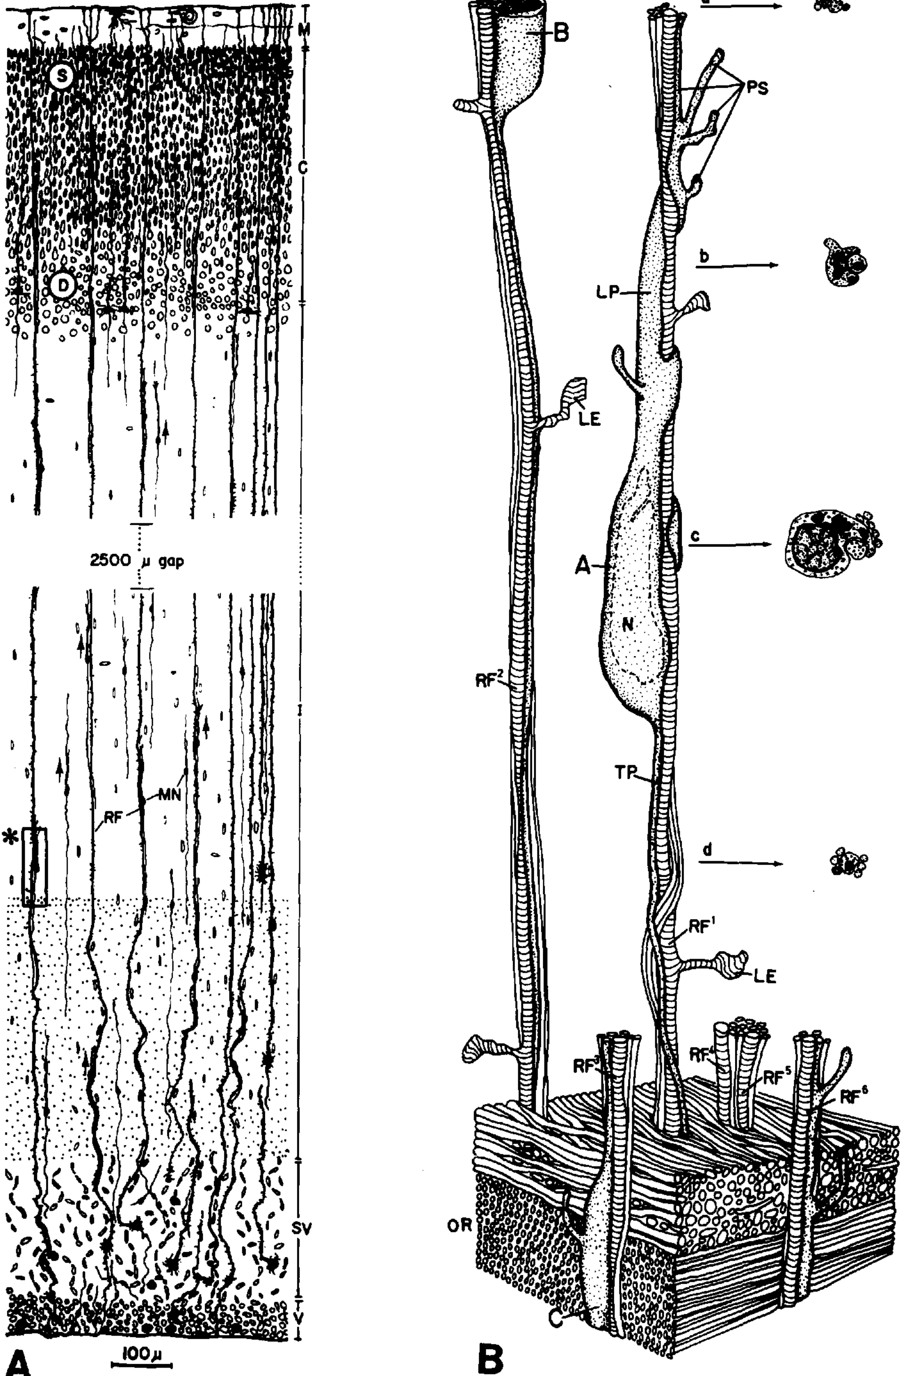

FIG. 49-7. (A) Camera lucida drawing of the occipital lobe of cerebral wall of the monkey fetus at midgestation. Composite illustration is derived from Golgi section (*black profiles of cell images*) and from adjacent section counterstained with toluidine blue (*outline profile of cell nuclei*). The middle 2500 μm of the intermediate zone, similar in structure to the sectors drawn, is omitted. The rectangle marked with an *asterisk* shows the approximate position of the three-dimensional reconstruction in Figure 49-7B. *C*, cortical plate; *I*, intermediate zone; *M*, molecular layer; *MN*, migrating neuron; *RF*, radial fiber; *SV*, subventricular zone; *V*, ventricular zone. (B) Three-dimensional reconstruction of migrating neurons, based on electron micrographs of semiserial sections of the occipital lobe of the monkey fetus. The reconstruction was made at the level of the intermediate zone indicated by the rectangle in Figure A. The subventricular zone lies some distance below the reconstructed area, whereas the cortex is more than 1000 μm above it. The lower portion of the diagram contains uniform, parallel fibers of the optic radiation (*OR*) and the remainder is occupied by more irregularly disposed fiber systems; the border between the two systems is easily recognized. Except at the lower portion of the figure, most of these fibers are deleted from the diagram to expose the radial fibers (*striped vertical shafts* RF_{1-6}) and their relations to the migrating cells A, B, and C, and to other vertical processes. The soma of migrating cell A, with its nucleus (*N*) and voluminous leading process (*LP*), is situated within the reconstructed space, except for the terminal part of the attenuated trailing process and the tip of the vertical ascending pseudopodium. Cross sections of *cell A* in relation to the several vertical fibers in the fascicle are drawn at levels *a–d* at the right side of the figure. The perikaryon of *cell B* is cut off at the top of the reconstructed space, whereas the leading process of *cell C* is shown just penetrating between fibers of the optic radiation (*OR*) on its way across the intermediate zone. *LE*, lamellate expansions; PS, pseudopodia. [Adapted from Rakic (1972), with permission.]

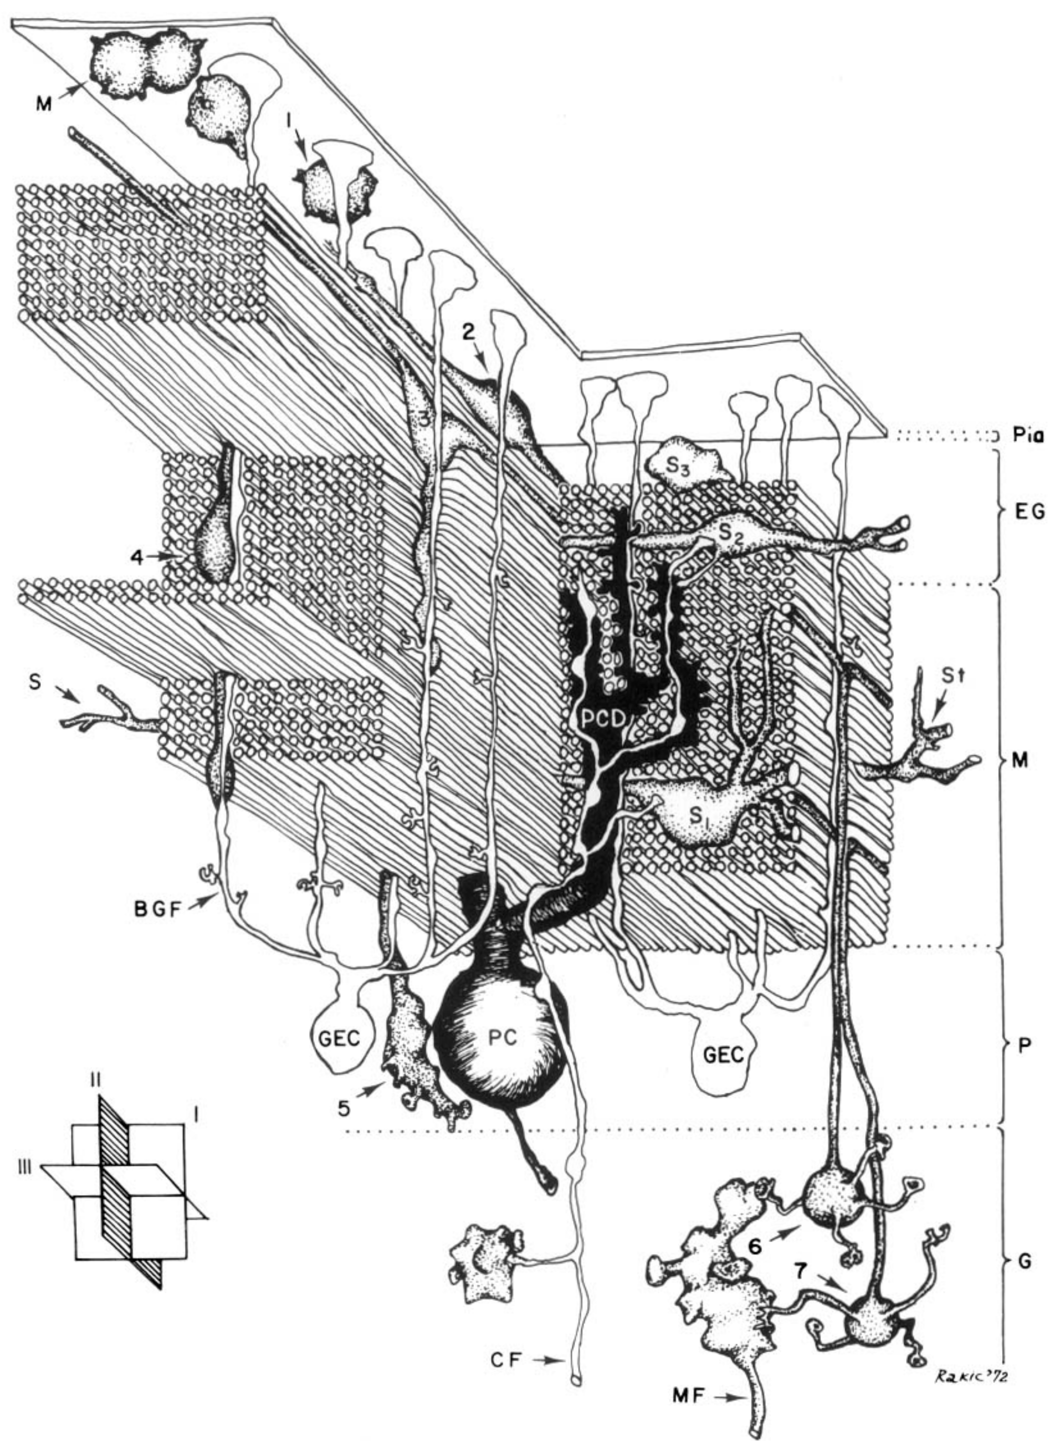

FIG. 49-8. Four-dimensional (time and space) reconstruction of the developing cerebellar cortex in the rhesus monkey. The geometric figure in the lower left corner indicates the orientation of the planes: *I*, transverse to the folium (sagittal); *II*, longitudinal to the folium; *III*, parallel to the pila surface. On the main figure, the thicknesses of the layers are drawn in their approximately true proportions for the 138-day-old monkey fetus, but the diameters of the cellular elements, particularly the parallel fibers, are exaggerated to make the reconstruction more explicit. A description of the temporal and spatial transformations of the postmitotic granule cells (*designated with numerals 1 through 7*) and stellate cells (*S*), as well as other details, are given in Rakic (1971b, 1973); *BGF*, Bergmann glial fiber; *CF*, climbing fiber; *D*, dividing external granule cell; *EG*, external granule layer; *GEC*, Golgi epithelial cell (Bergmann glia); *G*, granular layer; *M*, molecular layer; *MF*, mossy fibers; *P*, Purkinje layer; *PC*, Purkinje cell; *PCD*, Purkinje cell dendrite; *PF*, parallel fiber; S_{1-4}, stellate cells; *ST*, stellate cell dendrite. [Adapted from Rakic (1971b), with permission.]

Rakic, 1995; Rakic and Komuro, 1995). We found that blockade of N-type Ca^{2+} channels in cerebellar slices by using ω-conotoxin slows the rate of granule cell migration, although inhibitors of Cl^- and K^+ channels have no effect on the rate of granule cell migration (Komuro and Rakic, 1992). Likewise, application of *N*-methyl-D-aspartate (NMDA) receptor antagonists curtails cell migration, presumably by decreasing Ca^{2+} influx (Komuro and Rakic, 1993). The NMDA receptors may be activated by extracellular glutamate released mainly from ambient parallel fibers belonging to previously formed granule cells. However, neighboring glial cells may be involved in the regulation of glutamate. Indeed, inhibition of glutamate sequestration by the surrounding astroglia elevates endogenous extracellular glutamate and accelerates the granule cell migration rate (Komuro and Rakic, 1993). The molecular mechanisms of neuronal migration that involve participation of radial glial cells are among an active and promising area of research (e.g., see Rakic et al., 1994) and are not reviewed in detail here.

In addition to serving as a guide for migrating neurons and possibly for axonal growth cones (e.g., Silver et al., 1982; Norris and Kalil, 1991), the large surface of elongated glial fibers also may be involved in the signaling of information between proliferative zones and their distant terminations. Molecules, nutrients, and oxygen may be supplied by radial glial cells to the surrounding cells during embryonic stages when vascularization of the cerebral wall is absent or underdeveloped (Schmechel and Rakic, 1979a). The elongated fiber of radial glial cells may be involved in the transport process (Oksche, 1968) and would potentially enable them to communicate information from the developing cortical plate to centers of cell proliferation (Stensaas and Gilson, 1972). The possibility that such information is carried by molecules within the cytoplasm of radial fibers is supported by the demonstration of vigorous retrograde transport from endfeet to radial glial cell bodies (Ivy and Killacky, 1978). Modulation of glial cell behavior by the interaction of their distant processes has also been suggested to occur in newt optic tectum where deafferentiation of the molecular layer by enucleation of eyes resulted in a delayed increase in the mitotic activity of radial glial cells situated near the ventricular surface (Gaze and Watson, 1968). There is some evidence that the glial-limiting membrane formed by terminal attachments at the pial and vascular sheeting provides a modified blood-brain barrier and a cerebrospinal fluid brain barrier during embryonic stages (Oksche, 1968). Finally, the transient population of radial glial cells might also involve regulation of the voluminous extracellular fluid in loosely packed embryonic nervous tissue, a role postulated for astrocytes in adults (see Chapters 31, 47, and 48, this volume).

Disorders that are attributable to the damage of the transient glial scaffolding and indirectly to faulty neuronal migration range from gross malformations such as lisencephalia and polymicrogyria to the subtle heterotopia observed in the cerebrum of patients with developmental dyslexia and epilepsy. Because of multiple functions that involve interaction with the neighboring cells, and the transiency of radial glial cells, their involvement in the pathology is rather obscure, complex, and diverse. Usually, neuropathologists see the consequences long after the pathological reaction has been completed. Nevertheless, it is well recognized that the process of migration is highly sensitive to various physiological (e.g., ionizing radiation, heat), chemical (e.g., various drugs, carbon monoxide poisoning, excessive use of alcohol), and biological agents (some neurotropic viruses) as well as genetic mutations (e.g., Rakic and Sidman, 1973; Nowakowski, 1984; Caviness and Williams, 1985; Schull et al., 1986; Barth, 1987; Sherman et al., 1987; Caviness and Rakic, 1988). We only have begun to understand the role of radial glial cells in these defects. One scenario is that some of these agents interfere with neuron-glia interaction and indirectly impair neuronal pathfinding or cell motility. In many conditions, disruptive agents interrupt the radial glial fibers with little injury to neurons, which are, nevertheless, unable to move normally. For example, chronic exposure to alcohol may damage the radial glial cell membrane and interfere with the normal production and migration of neurons (Miller, 1986), and thus cause defects associated with fetal alcohol syndrome. Likewise, alcohol may affect the function of the NMDA receptor channel that regulates the rate of neuronal migration by controlling the influx of calcium ions (Komuro and Rakic, 1993). Malnutrition due to a low protein diet also affects development of glial scaffolding that may result in defects of neuronal migration. In spite of the relatively well-described pathological phenomena associated with defective neuronal migration, we are still ignorant about the cellular and molecular mechanisms underlying any of these processes.

DISSOLUTION AND EVOLUTION

In many submammalian species, radial glial cells persist throughout the life span (e.g., Ramón y Cajal, 1909; King, 1966). However, in primate telencephalon radial glial cells disappear, for the most part, at the end of neuronal cell migration to the cortex

(Rakic, 1972; Schmechel and Rakic, 1979a, 1979b). Analyses of transitional forms of radial glial cells in Golgi-stained and GFAP-immunolabeled sections prepared from cerebral cortex implied that radial glial cells were transformed into fibrillary astrocytes and/or protoplasmic astrocytes (Rakic, 1975, 1984; Choi and Lapham, 1978; Schmechel and Rakic, 1979a; Levitt and Rakic, 1980; Rickmann et al., 1987). The time table of the disappearance of radial glial cells in the primate neocortex, hippocampus, and cerebellum correlates with the initial appearance of astrocytes in these cortical regions (Rakic, 1971; Schmechel and Rakic, 1979a; Eckenhoff and Rakic, 1984).

A sequence of the morphogenetic transformations that lead to the formation of astrocytic cells in the adult neocortex, cerebellar cortex, and hippocampus are illustrated in Figure 49-8. Initially, the only glial cell elements present in all three regions are radial glial cells (Figure 49-8A–C). However, in the large primate telencephalon radial glial cell fibers attain enormous lengths, reaching several centimeters in the midterm human fetus (Rakic, 1984). In the macaque monkey, transitional forms between radial glial cells and astrocytes are first observed in the middle of the gestational period (Schmechel and Rakic, 1979b; Levitt and Rakic, 1980) a time period when the somata of some radial glial cells detach from the ventricular surface and become displaced to the intermediate zone (Figure 49-8). Subsequently, the cell forms of some radial glial cells may move to various depths of the cerebral wall and acquire typical, bushy astrocytelike appendages. Recently, the morphological transformation of radial glial cells into mature astrocytic cell classes has been confirmed following the uptake of fluorescent dyes by embryonic radial glial cells *in vivo* (Voigt, 1989).

The cellular or the molecular events that underlie the observed morphological transformation of radial glial cells are not known. In primary cultures of astrocytes, neuronal cells have been shown to exert an inhibitory effect on glial cell proliferation and, additionally, appear to regulate changes in astroglial cell shape from epitheliallike to radial or stellate (Sobue and Pleasure, 1984; Hatten, 1985, 1987; Ard and Bunge, 1988; Gasser and Hatten, 1990; Culican et al., 1990). Interestingly, in rhesus monkey a cessation in the mitotic activity of many radial glial cells accompanies the entire period of neuronal cell migration, which in this species approaches 2 months (Schmechel and Rakic, 1979b). Subsequent to the completion of neuronal cell migration, radial glial cells reenter the mitotic cycle, and many simultaneously undergo a transformation into astrocytes.

The morphological transformation of GFAP-positive radial glial cells into classical astrocytic cell forms, as well as alternative radial cell forms, appears to coincide with the loss of RC1, RC2, and Rat-401 antigens, which are not expressed in the adulthood (Hockfield and McKay, 1985; Misson et al., 1988a, 1988b; Edwards et al., 1990). A correlative analysis of antigenic and morphologic transformation *in vivo* (Caviness et al., 1989; Misson, 1991), *in vitro* (Culican et al., 1990) demonstrates that the morphological transformation of radial glial cells occurs concomitantly with a gradual acquisition of GFAP immunoreactivity and with a corresponding loss of RC1 immunoreactivity.

Many diverse mature forms of astrocytes, such as ependymoicytes, tanycytes, Bergmann glial cells, and Müller cells share basic morphological, immunological, and biochemical features with telencephalic radial glial cells (e.g., Bartlett et al., 1980; Edwards et al., 1990; Robinson and Dreher, 1990; for review see Fedoroff and Vernadakis, 1986 and Chapter 4). Therefore, these cells may be considered morphologically and biochemically divergent forms of embryonic radial glial cells that continue to be maintained in the adult mammalian brain. In the telencephalon, radial glial cells produce basically type-1 astrocytes. As suggested recently, a continued cell association with a selective microenvironment may allow for the maintenance of a modified radial glial cell form in the adult (Reichenbach, 1989). Based on the available data, it appears that both cell-cell interactions and cell lineages are likely to determine the fate of radial glial cells and their quantitative contribution to the astrocyte populations. Thus, the primordial fetal radial glial cell may be considered as a precursor that gives origin directly or indirectly to all major classes of astrocytes in the mammalian telencephalon (Rakic, 1984; Cameron and Rakic, 1991). While, during their short existence, radial glial cells contribute actively to brain construction, their progeny remain involved in brain functioning in health and disease during the entire life span.

As mammalian evolution proceeds from a smaller to a larger brain with an ever expanding surface of cerebral cortex, the radial glial cells increase in their number, their length, and the duration of their existence in individual embryonic development. Although the size of postmitotic cells does not increase appreciably from smaller to larger mammals, the journey that migrating neurons have to negotiate increases by an order of magnitude. In higher primates, including human, radial glial scaffolding is becoming more prominent than in any subprimate species (e.g., Figures 49-5 and 49-9). Based on a comparative embryological analysis of telencephalic development, we proposed the radial unit hypothesis

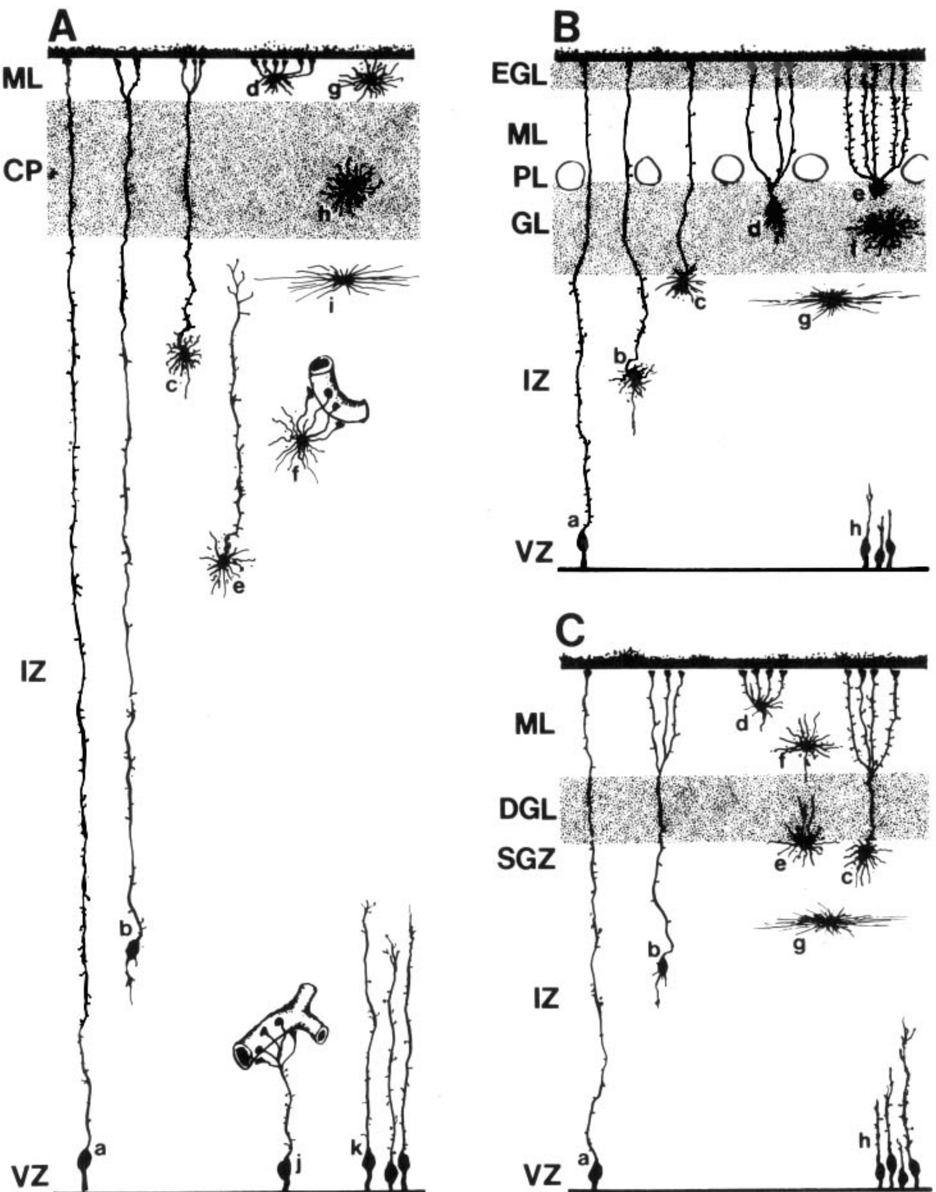

FIG. 49-9. Morphogenetic transformation of fetal radial glial cells into various astrocytic forms in the (**A**) cerebral hemisphere; (**B**) cerebellar hemisphere; (**C**) dentate gyrus of the hippocampus. *CP,* cerebral cortical plate; *EGL,* external granule layer; *GL,* granular layer (internal) of the cerebellum; *DGL,* dentate gyrus-granular layer of the hippocampal region; *IZ,* intermediate zone; *ML,* molecular layer; *PL,* Purkinje cell layer; *SGZ,* subgranular zone of the dentate gyrus; *VZ,* ventricular zone. Further explanation and designation of various transitional cell forms (*a–k*) is provided in the text. [From Rakic (1984), with permission.]

of cortical evolution (Rakic, 1990). According to this hypothesis, the mitotically active zone, situated at the surface of the cerebral ventricle, is depicted as a two-dimensional mosaic of proliferative units which constitute the rough protomap of the prospective species-specific cytoarchitectonic areas (Rakic, 1988b). Each radial unit consists of several clones that produce a cohort of neurons sharing a common site of origin in the ventricular zone, a common migratory pathway along the radial glial fascicle, across the intermediate and subplate zones, as well as the final columnar deployment (ontogenetic column) in the cortical plate (Figure 49-10). We postulated that the size of the cortical mantle, including the basic species-specific pattern of the cytoarchitectonic area, depends on the number of contributing radial units, while the thickness of the cortex depends on the magnitude of cell production within each unit. Although the initial number of units in a given species are likely to be set up early in embryogenesis by regulatory genes, the organization and final size of each cytoarchitectonic area is established

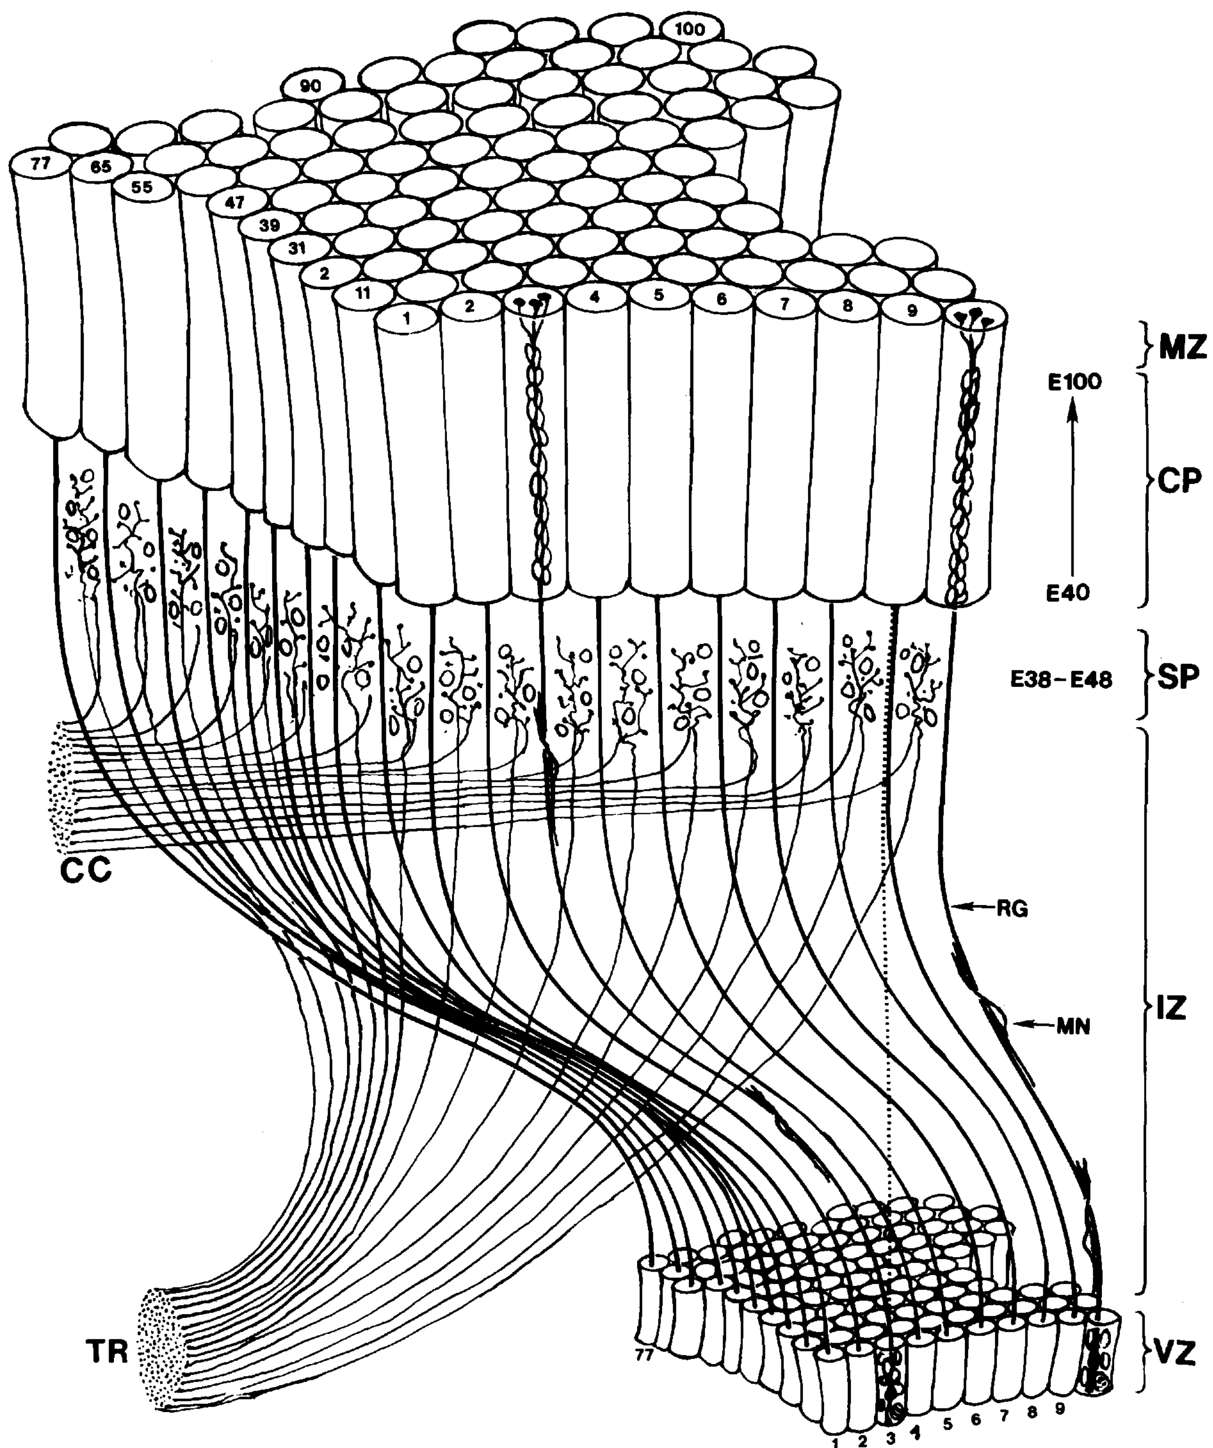

FIG. 49-10. The relationship between a small patch of the proliferative, ventricular zone (*VZ*) and its corresponding area within the cortical plate (*CP*) in the developing primate cerebrum. Although the cerebral surface in monkey expands during prenatal development, resulting in a shift between the *VZ* and *CP*, ontogenetic columns (*outlined by cylinders*) remain attached to the corresponding proliferative units by the grid of radial glial fibers. Cortical neurons produced by a given proliferative unit between embryonic (*E*) age 40 and E100 migrate in succession along common radial glial guides (*RG*) and form a single ontogenetic column. Each migrating neuron traverses the intermediate (*IZ*) and subplate (*SP*) zones, which contain "waiting" afferents originated in the thalamic radiation (*TR*) and other cortical areas in the same or other hemisphere (*CC*). After entering the cortical plate, each wave of migrating neurons bypasses the population of previously generated neurons and assumes a position at the interphase between the *CP* and marginal zone (*MZ*). As a result of this process, proliferative units 1–100 give rise to ontogenetic columns 1–100 that are arranged in the same relative position to each other. The glial scaffolding prevents a mismatch between proliferative unit 3 and ontogenetic column 9 (*dashed line*). Thus, the specifications of topography and/or modality depend on the spatial distribution of proliferative units, while the radial (*vertical*) position of neurons within each unit depends on its time of origin. [From Rakic (1988b), with permission.]

through interactions with appropriate afferents (Rakic, 1988b; Rakic et al., 1991). The enlargement of existing, or introduction of new, cytoarchitectonic areas in evolution could initially occur through a heterochronic process that includes a modification of the rate and cessation of cell proliferation during the phase of radial unit formation. We suggest that the new set of radial units interacts with afferent systems, creating an opportunity for the formation of novel input/target/output relationships, which, if heritable, may be subject to natural selection. Recent experiments on the embryonic brains of extant species, including induction of a novel cortical area by experimental manipulation of the developing thalamocortical input, support this hypothesis (Rakic et al., 1991). Thus, evolution of the neocortex may be intimately related to the evolution of radial glial scaffolding.

50 Formation of the blood-brain barrier

HARTWIG WOLBURG AND WERNER RISAU

The blood-brain barrier represents the interface between the blood that supplies nutrients to the brain, and the brain that requires homeostasis of its environment to function properly. The concept of the blood-brain barrier developed over the last hundred years after Paul Ehrlich and his pupil Edwin E. Goldman injected dyes into the vascular system and the cerebrospinal fluid and observed staining of the whole organism except the brain or of the brain only and not the vascular system and the peripheral organs, respectively. The term "blood-brain barrier" was introduced by Lewandowski (1900) after Biedl and Kraus (1898) and he himself had performed experiments using neurotoxic agents that affected the brain only when injected directly into the brain and not when injected into a vein.

The barrier separates plasma from brain interstitial fluid. It includes the vascular-glial complex within brain tissue (endothelial blood-brain barrier) on the one side, and the choroid plexus epithelium, the tanycytes in the circumventricular organs, and the arachnoid barrier (blood-cerebrospinal fluid barrier) on the other (Figure 50-1). The circumventricular organs include the hypothalamic median eminence, the pituitary, choroid plexus, pineal gland, subfornical organ, subcommissural organ, organum vasculosum lamina terminalis, and the area postrema (Leonhardt, 1980). The direct exposure of neurons in these areas to the blood milieu is of fundamental importance. The choroid plexus, for example, is responsible for the formation of the cerebrospinal fluid and is in contact with bloodborne substances that penetrate through fenestrated capillaries. Since the cerebrospinal fluid itself has free access to the neurons through the ependymal cell layer (at least in higher vertebrates), a barrier is necessary to avoid the exchange of substances between blood and neuropil via the brain ventricle. This barrier is localized in the choroid plexus epithelium and called the blood-cerebrospinal fluid barrier. Correspondingly, the other circumventricular organs also require this type of barrier. For example, the median eminence contains neurons synthetizing glandotrope hormone-releasing factors, which freely enter the blood and are destined to activate hormone-producing cells in the distant adenohypophysis. This tolopogy is also the basis of important feedback control of neuronal activity within the neuroendocrine organs by "sensing" hormones and other messengers in the blood. The blood-cerebrospinal fluid barrier is formed here by specialized ependymal cells called tanycytes. Another barrier that protects the brain from the blood is at the border between the outer cerebrospinal fluid compartment and the leaky blood vessels of the dura mater. This barrier is formed by the neurothelium, which consists of flat cells of the arachnoid layer facing the dura mater. The main characteristic of all three subtypes of the plasma-brain interstitial fluid barrier (endothelium, tanycytes/choroid plexus epithelium, and neurothelium) is the extensive elaborate network of complex tight junctions (Nabeshima et al., 1975; van Deurs and Koehler, 1979; Nagy et al., 1984; Mollgard and Saunders, 1986).

The site of the blood-brain barrier was identified by Reese and Karnovsky (1967) and Brightman and Reese (1969) as the vascular endothelial cells. This applies to all vertebrates except elasmobranch fishes, which have a glial blood-brain barrier (Cserr and Bundgaard, 1984) as do many invertebrates (Abbott, 1991; Lane, 1991). Generally, all blood vessels of the organism are lined by endothelial cells; abluminally they are associated with pericytes and/or smooth muscle cells. In peripheral organs, blood vessels allow more or less free access of bloodborne substances to the subendothelial space; access is provided by endothelial junctions, fenestrations, or discontinuities in the capillary walls, whose endothelial cells additionally are rich in pinocytotic vesicles. The tight junctions of brain endothelial cells alone form the structural basis of the barrier. A further prerequisite of impermeability is a low pinocytotic activity across the barrier cells (Peters et al., 1991), although a unidirectional transcytosis of proteins from blood to brain was recently described (Villegas and Broadwell, 1993).

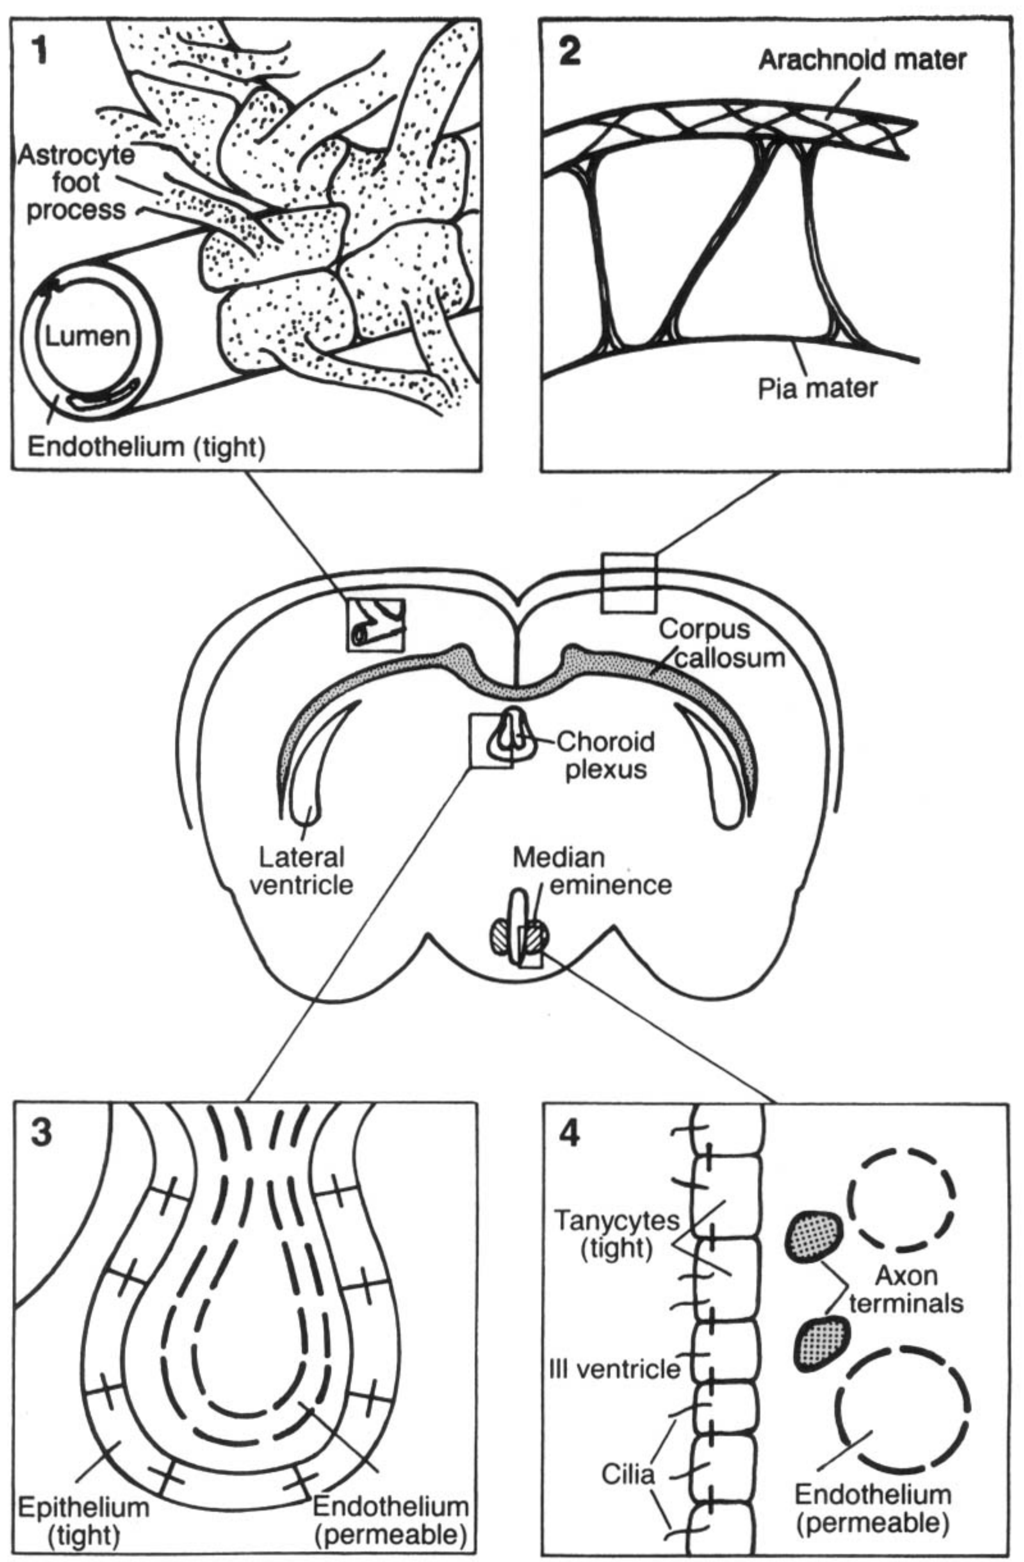

FIG. 50-1. Barriers and compartments in the brain. **Center:** Frontal section of a rat brain in the region of the median eminence. **Inset 1:** Endothelial blood-brain barrier. **Insets 2–4:** Blood-cerebrospinal fluid barrier—*inset 2:* the meningeal barrier at the surface of the brain; *inset 3:* the choroid plexus, which produces the cerebrospinal fluid out of bloodborne substances penetrating through fenestrated endothelia; *inset 4:* the blood-cerebrospinal fluid barrier in circumventricular organs such as the median eminence where tight junction-connected tanycytes avoid the exchange of substances between the ventricle and the neuropil. [From Risau and Wolburg (1990), with permission.]

DIFFERENTIATED PROPERTIES OF VERTEBRATE BRAIN ENDOTHELIAL CELLS

The fact that tight junctions occlude the intercellular cleft between endothelial cells and pinocytotic activity is reduced in the endothelium demands the existence of specific carrier systems for the transport of essential substrates of energy and amino acid metabolism to the brain. Hydrophilic substances such as proteins, amino acids, carbohydrates, and ions are normally not able to diffuse through endothelial membranes. Their transport is dependent on the availability of special transport systems or receptors. In fact, several specific carrier systems in brain endothelial cells were identified that allow the regulated exchange of substances between blood and brain. As a carrier of outstanding importance for the energetic supply of the brain, the glucose transporter was found to be inserted in high concentration in both the luminal and the abluminal membrane of brain capillary endothelial cell (for review see Dermietzel and Krause, 1991). This erythrocyte-type, insulin-independent, glucose transporter (GluT-1) is slightly asymmetrically expressed in the endothelium, in that more transporters appear to be inserted in the abluminal than in the luminal membrane (Farrell and Pardridge, 1991).

Other transporters found in the brain capillary endothelium are specific for amino acids (reviewed in Dermietzel and Krause, 1991) (Figure 50-2). The L-system is responsible for the transport of large neutral amino acids such as leucine, isoleucine, phenylalanine, dihydroxyphenylalanine (DOPA), valine, and tryptophan and is localized in both luminal and abluminal membranes of endothelial cells (Betz and Goldstein, 1978). Dopamine can penetrate the endothelium only through the abluminal membrane. Therefore, patients with Parkinson's disease who have serious dopamine deficits in the brain, cannot be treated by dopamine administration; however, treatment with L-DOPA is of limited efficiency as well as it enters the endothelium via the L-system and is converted into dopamine and DOPAC by the endothelial enzymes DOPA-decarboxylase and monoamine oxidase, respectively ("metabolic" blood-brain barrier; Goldstein and Betz, 1986). The so-called A-system, which is restricted to the abluminal membrane of endothelial cells selects small neutral amino acids such as glycine, alanine, and γ-aminobutyric acid (GABA) and cotransports Na^+-ions into the endothelial cytoplasm. In the luminal membrane, Na^+-influx and a Na^+/Cl^--cotransporter has been demonstrated (Betz, 1983). Na^+ would activate the abluminal Na^+-K^+-ATPase which in turn increases the uptake of K^+ from the brain interstitium into the blood through luminal K^+-channels. This could be facilitated by the activation of abluminal stretch-activated inward-rectifying Na^+/Ca^{2+}-channels (Popp et al., 1992) (Figure 50-2).

Another system possibly involved in the amino acid transfer from blood to brain and vice versa may be gamma-glutamyl transpeptidase (GGT). This enzyme catalyzes the transfer of gamma-glutamyl residue of glutathione to amino acids (Orlowski and Meister, 1970). Commonly, it was held to be a specific marker of brain capillary endothelium. However, new results have shown that this transpeptidase activity is associated with pericytes rather than with endothelial cells (Frey et al., 1991; Risau et al., 1992). Moreover, the finding that GGT is also present in permeable blood vessels speaks against the suggestion that this enzyme might be a reliable marker of blood-brain barrier (Risau, 1991). The role of GGT and other peptidases at the blood-brain barrier was comprehensively discussed recently by Brownlees and Williams (1993).

The impermeability of the paracellular pathway in brain endothelium requires—besides the facilitated diffusion of sugars and amino acids by appropriate transporters—mechanisms specific for the uptake of proteins such as transferrin, immunoglobulins, insulin, and other peptides and hormones (for reviews see Dermietzel and Krause, 1991). Evidence for the presence of coated pits (Broadwell, 1989), adsorptive transcytosis of proteins (Villegas and Broadwell, 1993), and receptors for transferrin, insulin, and low-density lipoprotein (LDL) (Jefferies et al., 1984; Duffy and Pardridge, 1987; Méresse et al., 1989a) in blood-brain barrier endothelium has been presented (see Figure 50-2). Receptor-mediated endocytosis of transferrin at the blood-brain barrier has been conclusively demonstrated by Roberts et al. (1993). However, the mechanism by which iron dissociates from the transferrin within the endothelium and is released from the abluminal pole of the vascular wall into the brain is unknown so far. Transferrin including its mRNA is present at least in oligodendrocytes, but there is no information available on the balance between intrinsic brain transferrin and transferrin derived from the blood (for further discussion see Roberts et al., 1993).

All transport systems described so far concerned hydrophilic compounds, which require special mechanisms of facilitated diffusion or specialized transport mechanisms. Unrestricted diffusion through the blood-brain barrier is, in principle, possible for substances that can cross biological membranes by virtue of their lipophilic properties. For these substances, control mechanisms might also exist that actively export them as soon as they have entered the brain en-

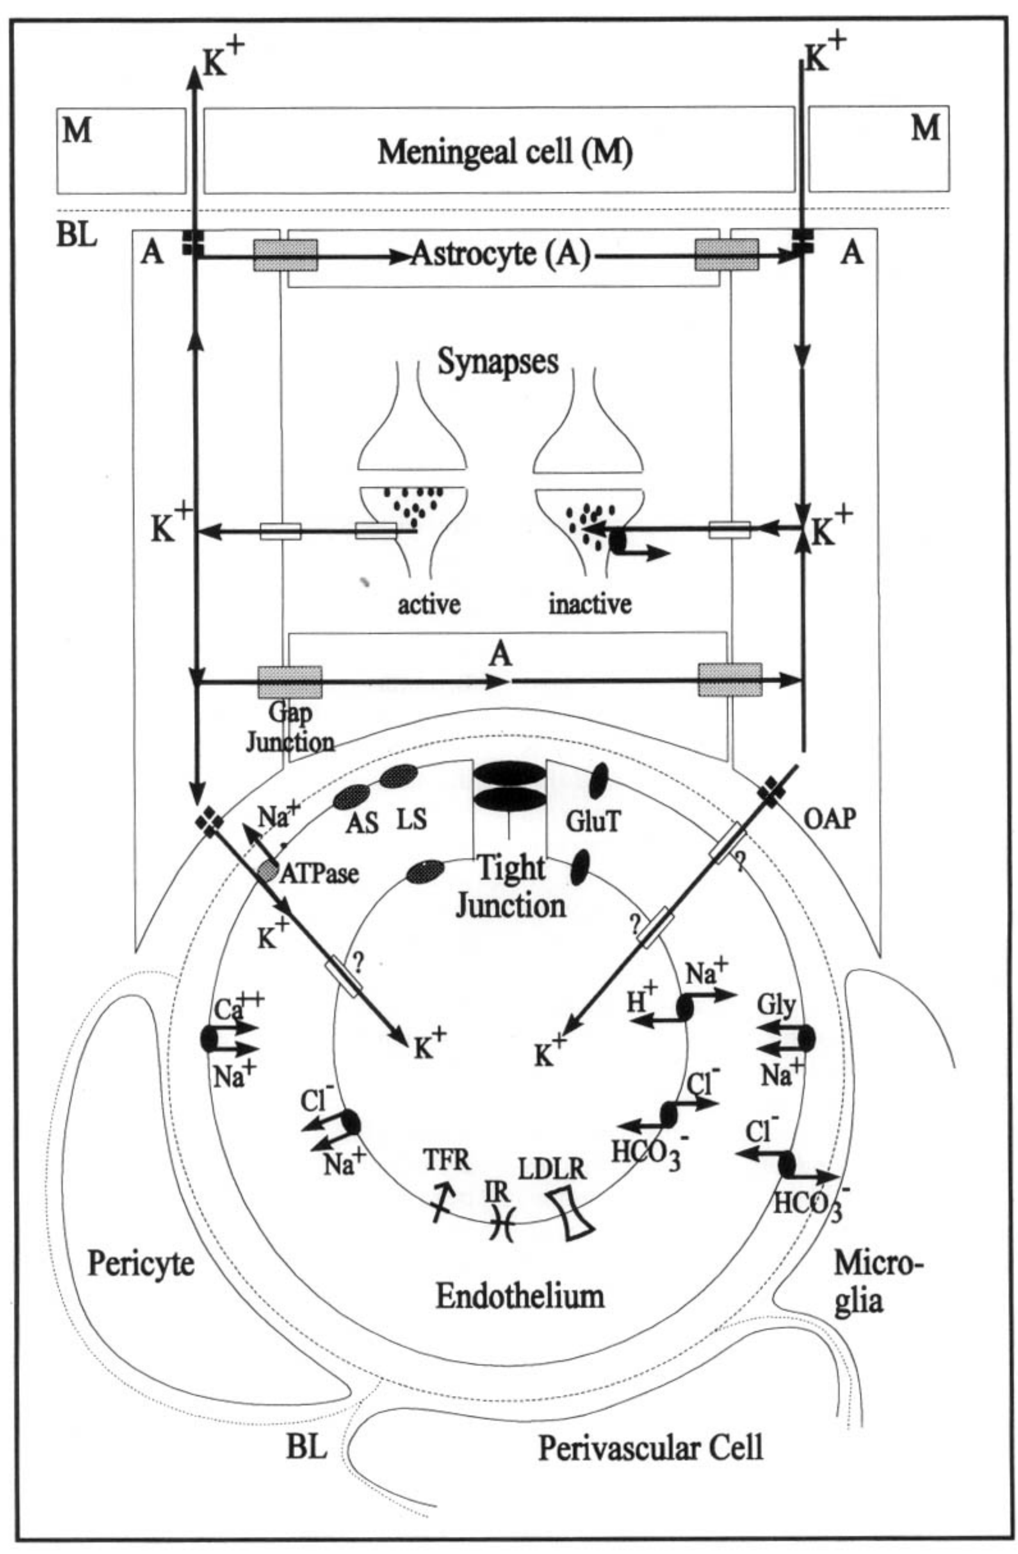

FIG. 50-2. Schematic and hypothetical representation of some intercellular (glioneuronal and gliovascular) communications in the central nervous system. The upper part of the figure shows the astrocytic syncytium, which is involved in K^+ homeostasis. Astrocytic endfeet, together with other cell types or their processes (microglial cells, perivascular cells, and pericytes) contact the perivascular basal lamina. In the endothelium, some of the known transporters, channels, and receptors are schematically illustrated. *AS*, A-system of amino acid transport (alanine preferring); *BL*, basal lamina; *GluT*, glucose transporter; *IR*, insulin receptor; *LDLR* low density lipoprotein receptor; *LS*, L-system of the amino acid transport (leucine preferring); *OAP*, orthogonal arrays of particles; *TFR*, transferrin receptor. [Modified from Risau and Wolburg (1990) and Risau (1991), with permission.]

dothelium. For example, the P-glycoprotein is a transmembrane glycoprotein that actively extrudes nonpolar molecules out of endothelial cells. It confers insensitivity for drugs for tumor chemotherapy (multidrug resistance) to cells that express this transporter, and has been shown recently to be expressed in blood-brain barrier endothelium (Cordon-Cardo et al., 1989). For example, vincristine applied to the vasculature was shown to be concentrated in the cerebrospinal fluid at a considerably lower level as compared to simultaneous plasma levels demonstrating a restricted entry through the blood-brain barrier endothelium (Jackson et al., 1981).

Several proteins have been localized to brain capillaries *in vivo* [e.g., alkaline phosphatase (Leduc and Wislocki, 1952), butyryl-cholinesterase (Joo and Csillik, 1966)]. By analogy to other cell types that express these proteins, they have been implicated in transport or metabolic processes at the blood-brain barrier. However, direct evidence for such a role is lacking. Recently, cytokines such as tumor necrosis factor were found to influence the blood-brain barrier permeability; however, the mechanism of how these mediators might operate in the brain endothelial cells is still a matter of speculation (Megyeri et al., 1992). Also, nitric oxide (NO) as an activator of the guanylate cyclase may play a role in the gliovascular interrelationship (Murphy et al., 1993). In the peripheral circulation, NO has been characterized as a potent relaxing factor. In brain microvessel endothelial cells the cytokine-inducable NO synthase has been detected by Durieu-Trautmann et al. (1993). Astrocytes as well as microglial cells are thought to be target cells of neuronal and endothelial NO; in addition, astrocytes and microglial cells have been shown to display NO synthase activity (for review see Murphy et al., 1993). Direct functional implications of the NO system for the regulation of the blood-brain barrier are not known so far. Furthermore, proteins have been identified in brain capillaries using monoclonal antibodies (Michalak et al., 1986; Risau et al., 1986b; Sternberger and Sternberger, 1987). Some of these proteins may be blood-brain barrier-specific in that sense that they are present at a much reduced or undetected level in permeable capillaries of the body. Some proteins present in other endothelial cells seem to be absent from brain endothelium. For example, the acetylated low-density lipoprotein (acLDL) receptor (Gaffney et al., 1985), thrombomodulin (Ishii et al., 1986), and the OX43 (Robinson et al., 1986) antigen seem to be downregulated in brain endothelial cells.

The HT7 protein is a cell surface immunoglobulinlike glycoprotein and a marker for blood-brain barrier endothelium (Risau et al., 1986a, 1986b; Albrecht et al., 1990; Seulberger et al., 1990). It is expressed on the surface of chick brain endothelial cells *in vivo* and *in vitro*. Recently, the OX-47 (Fossum et al., 1991) and gp42 (Altruda et al., 1989) proteins have been identified as homologous proteins in rat and mouse, respectively. We found that the OX-47 protein was present in rat brain endothelial cells throughout the culture period in primary and passaged cells suggesting that this protein is not downregulated *in vitro* (Risau, 1991). This is consistent with our results using HT7 antibodies in the chick (HT7 is a species-specific antibody). There is compelling evidence that the expression of this protein is modulated *in situ* and *in vitro* (Lobrinus et al., 1992). It is present in erythroblasts but not erythrocytes and it is induced in endothelial cells that invaded a brain transplant (Risau et al., 1986a). In addition, the 1W5 protein or neurothelin (Schlosshauer and Herzog, 1990), which is identical to the HT7 protein (Seulberger et al., 1992) is induced in neurons *in vitro*, and the OX-47 protein is expressed by activated but not resting T lymphocytes (Fossum et al., 1991). These results raise the possibility that if downregulation of this protein occurs by brain endothelial cells during the time in culture this may be masked by its simultaneous induction by the culture conditions. Thus, at this point it is impossible to distinguish between maintenance of protein expression due to maintenance of differentiated characteristics of brain endothelial cells and induction due to culture conditions. Studies are in progress to address this issue.

MORPHOLOGICAL PROPERTIES OF VERTEBRATE BRAIN MICROVESSELS AND ASSOCIATED CELLS

The morphology of brain microcirculation is well known and amply described (e.g., Wolff, 1963, 1987; Reese and Karnovsky, 1967; Brightman and Reese, 1969; Bär, 1980; Bradbury, 1984; Cserr and Bundgaard, 1984; Nagy et al., 1984; Coomber and Stewart, 1985; Mollgard and Saunders, 1986; Lane, 1991; Peters et al., 1991). In contrast to blood vessels outside the central nervous system, the brain capillaries show endothelia that are seamless or connected by complex tight junctions (Figures 50-3, 50-4, and 50-5). These tight junctions display impermeability of electron dense tracers such as horseradish peroxidase (MW 40,000), microperoxidase (MW 800), lanthanum hydroxide or thorium dioxide. Vessels in the circumventricular organs contain fenestrated endothelial cells and are leaky for these tracers (Dermietzel and Leibstein, 1978; Peters et al., 1991). Additionally, the perivascular space

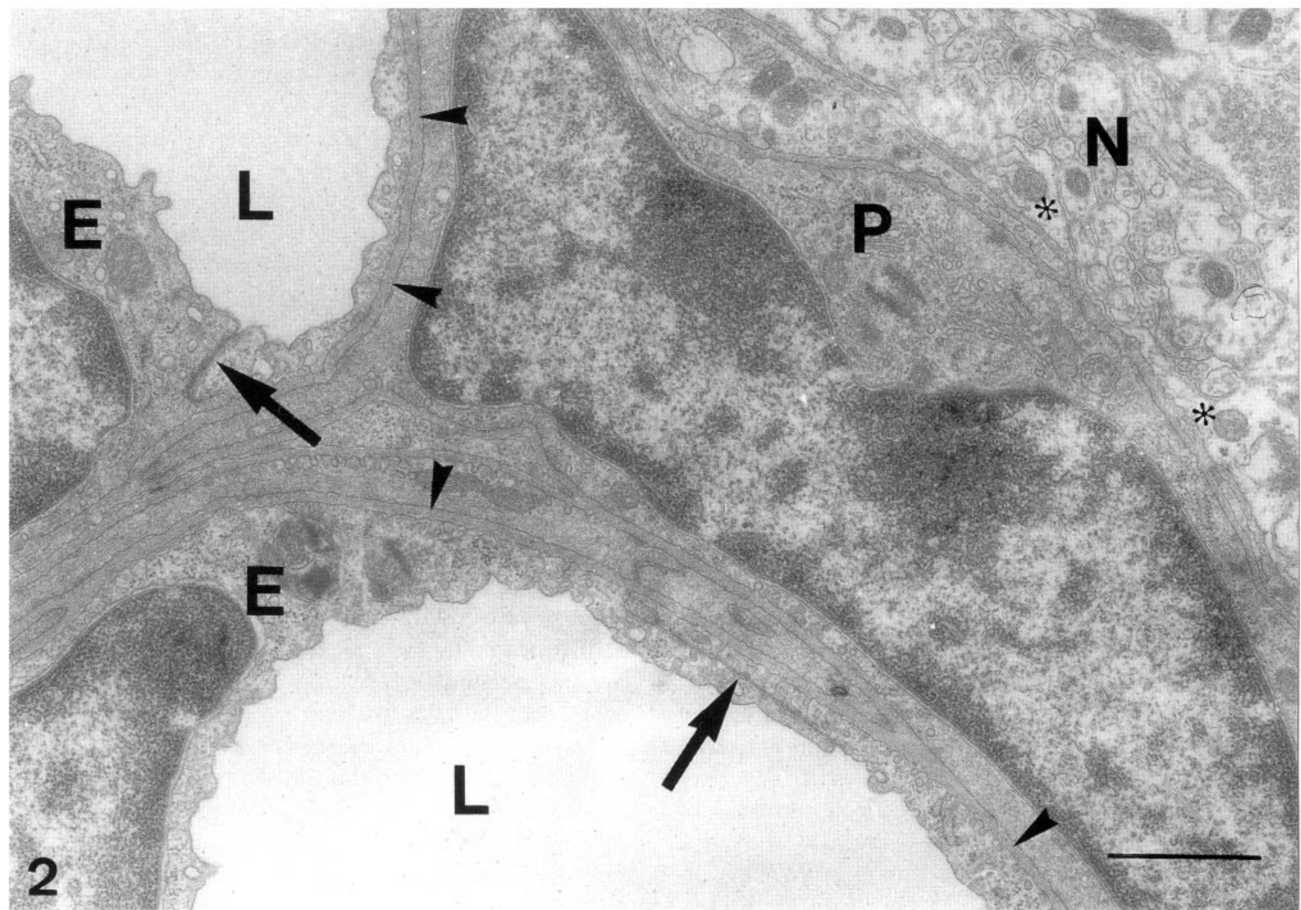

FIG. 50-3. Ultrathin section through small arterioles in the mouse cerebral cortex. *L,* vessel lumen; *E,* endothelial cell; *P,* pericyte or smooth muscle cell; *N,* neuropil. *Arrows,* endothelial tight junctions; *arrowheads* the thick basal laminae; *asterisks,* astrocytic endfeet. Bar = 1 μm.

around leaky vessels is large and filled with extracellular matrix (Dermietzel and Krause, 1991). In these vessels, the basal lamina is split into a subendothelial one and an astroglial one. During development of blood-brain barrier vessels, the perivascular space becomes smaller and smaller (Caley and Maxwell, 1970). The perivascular space of tight brain capillaries is very narrow and occupied by a common basal lamina that covers both the basal membranes of endothelial cells and the perivascular astroglial endfeet. In cerebral arterioles, pericytes, perivascular cells, and smooth muscle cells are completely surrounded by their own basal lamina (Graeber et al., 1992). Smooth muscle cells and pericytes are hardly distinguishable by ultrastructural criteria (Figure 50-3). Perivascular microglial cells are covered by a basal lamina only where they contact the endothelium (Lassmann et al., 1991). The astrocytes regularly ensheathe the blood vessels (Wolff, 1963; Brightman and Reese, 1969; Goldstein and Betz, 1986; Peters et al., 1991). Each astrocyte projects only one main process to a given capillary, otherwise giving rise to en passent contacts with the capillary wall (Wolff, 1987). Astroglial gap junctions are preferentially found between perivascular endfeet or processes.

In the freeze-fracture replica of astroglial endfoot membrane contacting the subendothelial basal lamina, orthogonal arrays or assemblies of particles (OAP) are visible (Landis and Reese, 1981) (Figure 50-5). These particles whose subunits measure 6 to 7 nm in diameter are believed to be transmembrane proteins (Landis and Reese, 1989) and develop perinatally in astroglial membranes (Anders and Brightman, 1979; Landis and Reese, 1981). They form clusters of 4 to more than 30 subunits covering each about 1000 nm^2 and about 50% of the endfoot membrane area. However, in areas where the endfoot looses contact with the basal lamina by deflection of the membrane towards the neuropil, the OAP density drops to 40 to $50/\mu^2$, corresponding to 4 to 5% of the membrane area in the neuropil. The OAP

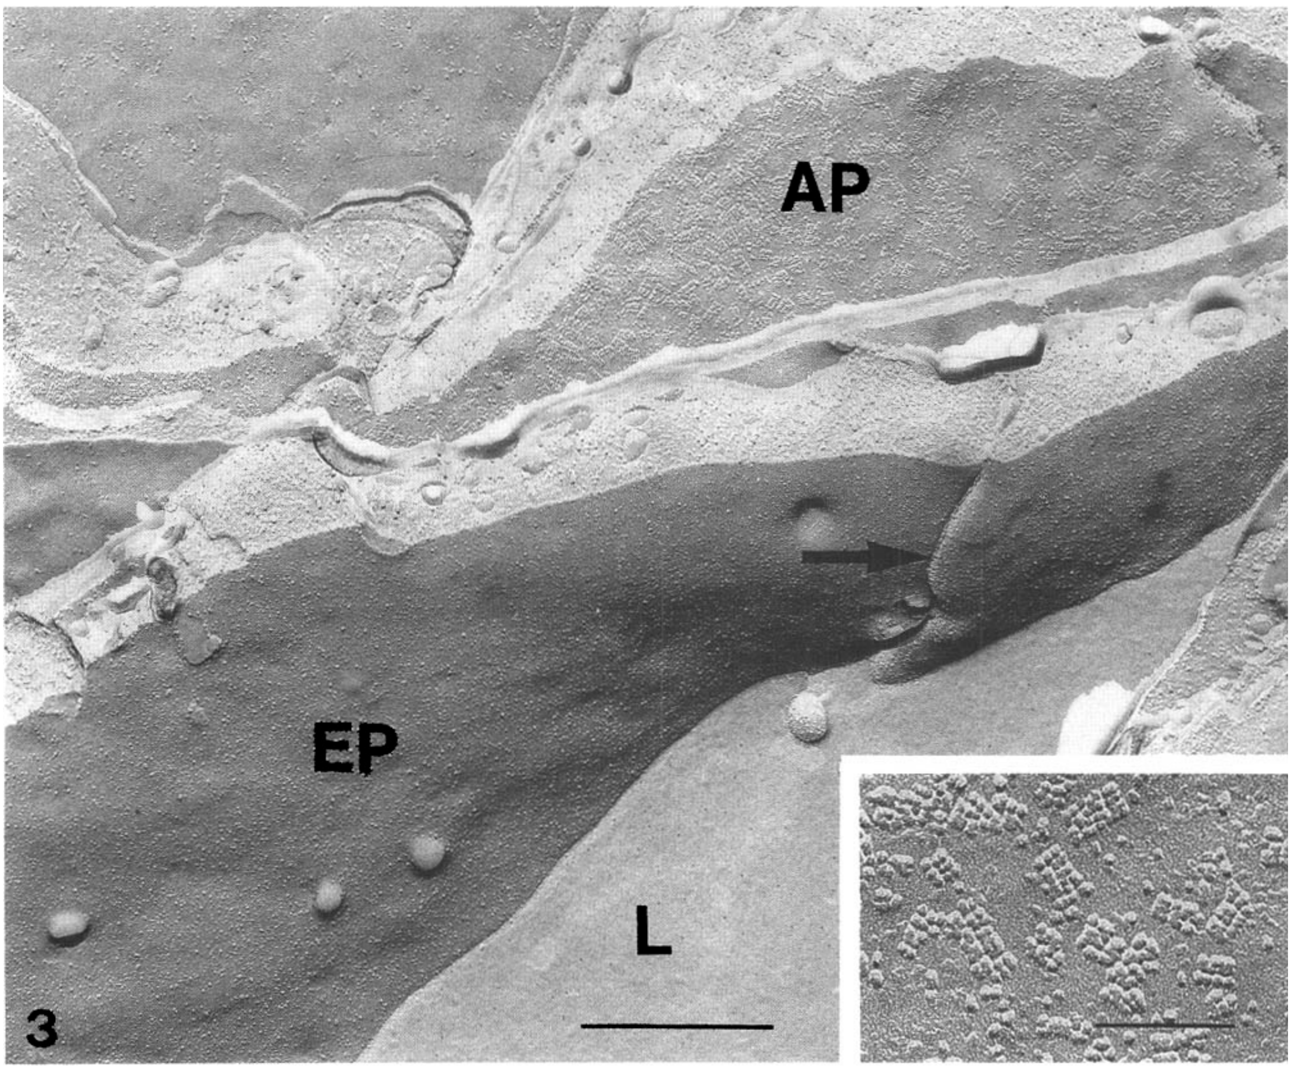

FIG. 50-4. Freeze-fracture replica of a capillary in the rat optic nerve. *L*, vessel lumen; *EP*, protoplasmic fracture face (P-face) of the luminal membrane of the endothelial cell; *AP*, P-face of an astrocytic endfoot with orthogonal arrays of particles (*higher magnification in the insert*); *arrow*, an endothelial tight junction (*membrane plane not exposed*). appear to be of vital significance for the working central nervous system as was suggested by (1) the absence of OAP in Müller cells *in vitro* in chicken retinae where morphogenesis took place, but physiological activity was not demonstrable (Wolburg et al., 1991), and (2) by the formation of OAP in Müller cells being dependent on retina maturation in chicken and pigeon (Bolz and Wolburg, 1992). These data suggest that neuronal activity as well as the contact with the basal lamina seem to be synergistically required to produce an OAP-related glial polarity (for further discussion see also Wolburg and Bäuerle, 1993). On the other hand, the formation of blood-brain barrier begins early in development [E13 in chicken (Wakai and Hirokawa, 1978), E14 in mouse (Risau et al., 1986a), for example] suggesting that neuronal migration and synaptogenesis requires a strict control of the microenvironment as well (Mollgard and Saunders, 1986). However, the definitive formation and maturation of the blood-brain barrier takes time up to postnatal age (Stewart and Hayakawa, 1987; Risau and Wolburg, 1990). In the differentiated brain, neuronal activity leads to extracellular increase in [K^+], which can be balanced better in more advanced stages of brain development (Connors et al., 1982) (see Figure 50-2). Presumably, the capability of the brain to stabilize extracellular ion concentrations is coupled to maturation of glia (Laming, 1988), including the polar distribution of OAP in astrocytic membranes. Astrocytes are believed to be the main site of spatial buffering due to their polarized conductance for K^+ ions. Thus, glial

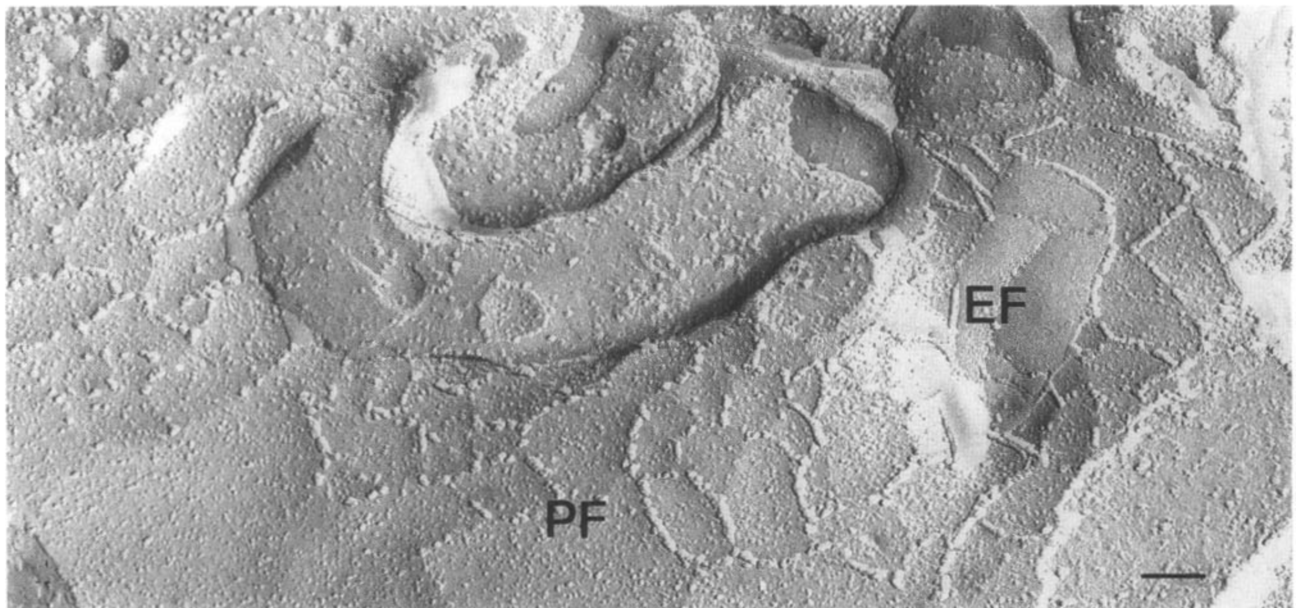

FIG. 50-5. Freeze-fracture replica of a capillary fragment freshly isolated from bovine brain. Tight junctions are associated with the P-face (*PF*); at the E-face (*EF*) grooves are sparsely occupied by single particles. Bar = 0.1 μm.

endfeet will shift K^+ from sites of high neuronal activity to perivascular sites where the K^+ concentration is maximal. The presumably high subendothelial K^+ concentration may be taken up by the abluminal Na^+/K^+-ATPase of the endothelium and released into the blood through luminal K^+-channels which are activated by intracellular Ca^{2+} (Popp et al., 1992) (Figure 50-2).

The lamina cribrosa of the optic nerve is a site where the blood-brain barrier is leaky (Tso et al., 1975; Flage, 1977). This fact was discussed regarding possible influences of plasma substances getting free access through leaky choroid vessels onto the marginal glial endfeet modulating certain properties of astrocytes within this region (Perry and Lund, 1990; Wolburg and Bäuerle, 1993). In most mammals, except of the rabbit, the lamina cribrosa is unmyelinated, giving rise to the hypothesis that it may be a barrier for migration of oligodendrocytes into the retina (ffrench-Constant et al., 1988). Interestingly, in the optic nerve of a myelin-deficient rat mutant (Rohlmann et al., 1992) as well as in the lamina cribrosa of the otherwise myelinated rat (Wolburg and Bäuerle, 1993) the density of OAP in astroglial endfeet is reduced. It seems therefore that where axons are nonmyelinated (including some of the circumventricular organs and the olfactory system) the blood-brain barrier is leaky (Perry and Lund, 1990) and astrocytes are altered (see also Dermietzel and Leibstein, 1978). Conversely, endothelial cells in culture are able to influence the OAP density in cocultured astroglial cells inducing tightly packed OAP (Tao-Cheng et al., 1990). Although the causal relationships between astrocytes, oligodendrocytes, and endothelial cells are far from being understood, the observations suggest that a high density of OAP in perivascular astrocytic endfeet belong to the set of characteristics associated—in higher vertebrates—specifically with the establishment of a functional blood-brain barrier.

ENDOTHELIAL TIGHT JUNCTIONS

Tight junctions are contact zones between epithelial cells that restrict or prevent the paracellular pathway ("gate" function as attributed by Mandel et al., 1993; for review see Madara and Pappenheimer, 1987). They form networks of strands in both partner cell membranes, which are believed to occlude the intercellular cleft. A close correlation between the complexity of these strands and the transepithelial electrical resistance has been demonstrated (Claude and Goodenough, 1973; Claude, 1978). They also contribute to the polarity of epithelia in that apical membranes differ from basolateral membranes in terms of lipid composition ("fence" function as attributed by Mandel et al., 1993). Many models were proposed to describe the molecular fine structure of tight junctions (for recent review see, for example, Lane et al., 1992); nevertheless, their biochemical identity is unknown as yet. Only associated

proteins such as the ZO-1 protein and cingulin were described (Stevenson et al., 1986; Citi et al., 1988). ZO-1 is a monoclonal antibody against a 225 kD protein associated with the cytoplasmic portion of tight junctions. The protein is present in brain capillaries *in vivo* (Watson et al., 1991) and in cultured endothelial cells (Rubin et al., 1991). Stevenson et al. (1988) have shown that the amount of ZO-1 protein did not correlate with junctional complexity and electrical resistance in MDCK cells. They suggested that the phosphorylation state of this protein might be important for the determination of the "tightness" of junctions. Thus, the regulation of protein phosphorylation in brain endothelial cells may be of major importance for the regulation of blood-brain barrier properties. These observations are consistent with results on brain endothelial cells (Risau, 1991), suggesting that the mere presence of the ZO-1 protein defined by the monoclonal antibodies is not diagnostic for blood-brain barrier properties of endothelial cells.

The electrical resistance of brain microvessels is established during development at a later stage than the impermeability for electron-dense tracers (for review see Rubin, 1991). Butt et al. (1990) reported impermeability for lanthanum in pial vessels of rat embryos, but an electrical resistance of only 300 ohm cm^2. Subsequently, the resistance increased up to greater than 1000 ohm cm^2. Provided that this is also valid for intracerebral microvessels (see Crone and Olesen, 1982) it could be suggested that a fully differentiated gliovascular system might be a prerequisite for the final maturation and maintenance of the blood-brain barrier. Detailed studies on the correlation between electrical resistance and tight junction structure in blood-brain barrier endothelial cells *in vivo* do not exist as yet. Instead, some related work has been performed in epithelial cells. Stevenson et al. (1988) have described low and high resistance MDCK cell tight junctions to be structurally identical. However, their pictures reveal that in low resistance MDCK cells more tight junction particles are associated with the E-face than in high resistance MDCK cells. In most epithelial tight junctions, such as in liver, intestine, kidney, or the retinal pigment epithelium, the tight junction strands are associated with the P-face; at the E-face, particle-free grooves predominate. Few E-face associated particles correspond with sites of interruptions of P-face associated strands as was shown in complementary freeze-fracture replicas (Noske and Hirsch, 1986; Mandel et al., 1993). In the vascular system, the tight junctions vary not only in terms of complexity of the strand network but also in terms of their association with the two membrane leaflets when regarding different segments of the vasculature. For example, venous as well as arterial endothelium show a poorly anastomosed network, with largely discontinuous strands associated with the E-face. At the P-face only particle-free ridges are seen (Simionescu et al., 1976; Mühleisen et al., 1989). Brain endothelial tight junctions are strongly anastomosed and associated with the P-face (Nagy et al., 1984; Shivers et al., 1984), although not so pronounced as in epithelia (Figure 50-5); for direct comparison of the tight junction structure in leaky endothelium and in tight pigment epithelium see Kniesel and Wolburg, 1993). Zampighi et al. (1991) and Mandel et al. (1993) have shown that the association of the tight junctions with one or the other leaflet of the membrane correlates with the permeability of the epithelial monolayer. Energy depletion results in both abolishing the "gate" function (increase of permeability) and inversion of the fracture pattern (increase of the number of E-face associated TJ-particles).

ASTROCYTES INDUCE THE BLOOD-BRAIN BARRIER *IN VIVO*

An important question is whether the blood-brain barrier properties of the endothelial cells are predetermined during early development of the vascular system or are induced after invading the brain environment. Several studies are in favour of the latter possibility. When transplanted into ectopic sites of host embryos of a different species, embryonic brain tissue has been shown to induce both angiogenesis in the host and blood-brain barrier characteristics in the invaded blood vessels. Conversely, when peripheral tissue was transplanted into the brain the invading capillaries lost their blood-brain barrier properties (Stewart and Wiley, 1981; Risau et al., 1986a). From these studies it was concluded that it is the brain microenvironment that determines the blood-brain barrier characteristics such as tight junctions of high complexity, high electrical resistance, and low permeability for lipid-insoluble substances. The early suggestion that astrocytes might play a role in this induction mechanism was substantiated by experiments performed by Janzer and Raff (1987). They provided direct evidence that astrocytes transplanted into the rat anterior eye chamber were capable of inducing a permeability barrier for dyes administered to the vascular system.

BLOOD-BRAIN BARRIER *IN VITRO*

The blood-brain barrier is a complex structure comprised of different cell types. In order to study in

more detail the role of single components of the blood-brain barrier, many efforts have been made to establish an *in vitro* blood-brain barrier system (Goldstein et al., 1984; Abbott et al., 1992; for review of the literature see Rubin, 1991; Joo, 1993). Pure endothelial cells have been isolated and examined as to whether or not the blood-brain barrier is maintained. Several lines of evidence suggest that cultured brain endothelial cells rapidly loose blood-brain barrier characteristics therefore not providing a suitable model of blood-brain barrier studies *in vitro*. On the other hand, many reports in recent years support the early suggestion that cocultured astrocytes or glioma cells may be able to reinduce blood-brain barrier properties in cultured endothelial cells. These properties included the activity of γ-glutamyl transpeptidase (De Bault and Cancilla 1980; De Bault, 1981; Maxwell et al., 1987; Dehouck et al., 1990; Tontsch and Bauer, 1991), the transport of neutral amino acids (Cancilla and De Bault, 1983), the polarity and activity of Na^+-K^+-ATPase (Beck et al., 1986; Tontsch and Bauer, 1991), the glucose uptake (Maxwell et al., 1989), and the expression of the HT7 protein (Lobrinus et al., 1992).

Of special interest is the question whether also the high electrical resistance and the complex tight junctions are among the properties of endothelial cells which can be reinduced and maintained in culture by astrocytes or other cells and factors. Indeed, Arthur et al. (1987) and Shivers et al. (1988) provided evidence for an astrocyte-mediated induction of tight junctions in cell culture which was also seen using astrocyte conditioned medium. Tao-Cheng et al. (1987) and Tao-Cheng and Brightman (1988) were also able to induce tight junctions in endothelial cells by astroglial cells *in vitro*, but their studies suggested that cell contact is required and that released factors are not sufficient. Neuhaus et al. (1991) have shown in a transfilter coculture system with bovine brain endothelial cells and rat astroglial cells cocultured separately on both sides of a cellagen filter which did not allow the direct contact of cell processes that complex tight junctions can be reinduced by astrocytes. Rubin et al. (1991) have shown that astrocyte-conditioned medium as well as increased cAMP levels enhanced both anti-ZO-1 immunoreactivity and the transendothelial electrical resistance in cultured bovine brain endothelial cells. Since ZO-1-immunoreactivity cannot be considered as a reliable marker of tight junction complexity, and since the absolute values of electrical resistance observed in endothelial cells are essentially lower than those measured in intact blood-brain barrier vessels (Butt et al., 1990; Crone and Olesen, 1982; Rutten et al., 1987), it may be concluded that culture conditions are hitherto not sufficient to mimick blood-brain barrier properties completely. It is of considerable interest that all published freeze-fracture replicas of cultured endothelial cells (Goldstein et al., 1984; Shivers et al., 1985, 1988; Arthur et al., 1987; Tao-Cheng et al., 1987; Méresse et al., 1989b) reveal tight junctions predominantly associated with the E-face (Figure 50-6). In contrast, high resistance MDCK cells or pigment epithelial

FIG. 50-6. Freeze-fracture replica of cultured bovine brain endothelial cells. The tight junctions are predominantly associated with the E-face (*EF*). *Arrows* mark ridges at the P-face (*PF*), which possess essentially fewer particles than that of freshly isolated endothelial cells (Figure 50-4). Bar = 0.1 μm.

cells do not loose the P-face association of tight junction particles *in vitro,* unless they suffer from energy depletion (Mandel et al., 1993). It appears that endothelial differ from epithelial tight junctions in that they require a constant impulse to maintain their tight junction integrity which may be lost due to a decay of tight junction-cytoskeleton connections (for further literature see Hageman and Kelly, 1985; Lane et al., 1992). This hypothesis would explain (1) the fact that blood-brain barrier endothelial cell tight junctions *in vivo* differ from those *in vitro* by the switch of the tight junction strands from the P- to the E-face, (2) the lower electrical resistance in cultured endothelial cells in comparison to intact blood-brain barrier capillaries, and (3) the sensitivity of brain capillaries against pathological disorders such as tumors, Alzheimer's disease, multiple sclerosis, and AIDS-associated syndromes. Apparently, brain endothelial cells need constant input from the brain microenvironment to maintain a functional blood-brain barrier. The most important goal in future research is the molecular identification of these factors.

We thank Andreas Reichenbach (University Leipzig, Germany) for discussions concerning Figure 50-2 and Uwe Kniesel for preparing Figure 50-2. Our research is supported by the Deutsche Forschungsgemeinschaft and the Max Planck-Gesellschaft.

51 Schwann cell functions in saltatory conduction

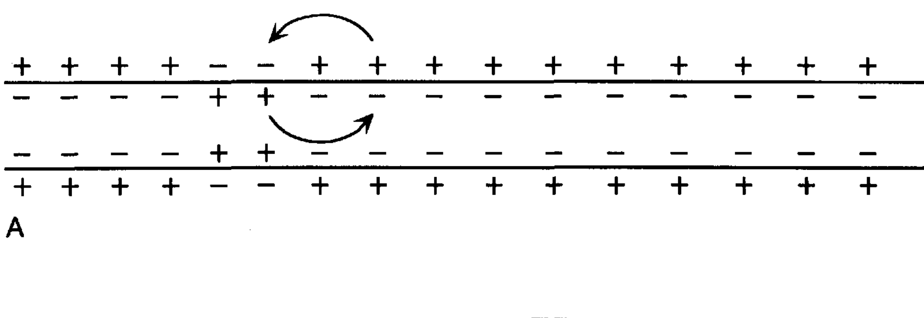
S. Y. CHIU

Schwann cells provide the myelin sheath for large axons of the peripheral nervous system, insulating regions of axons called the internode that are typically 1000 to 2000 μm long in large fibers. The axon is exposed between successive internodes at tiny gaps, each about 0.5 to 1.0 μm wide, called nodes of Ranvier. In the early 1950s, Stampfli, Huxley, and Tasaki provided the crucial piece of evidence that the node of Ranvier is the site of nerve excitation, with each node generating a high density of inward sodium current that helps excite consecutive nodes, leading to a mode of conduction termed saltatory conduction. The purpose of this chapter is twofold. First, it describes the classical role of Schwann cells in insulation and how they allow fibers to conduct with speed and efficiency. The treatment will be brief because this classical function of Schwann cell has been extensively reviewed (Hodgkin, 1964; Hille, 1977; Waxman, 1980). Second, it deals extensively with novel but somewhat more speculative roles of Schwann cells in relation to axonal functions based on recent discoveries that these cells express voltage-sensitive ion channels.

CLASSICAL ROLE OF SCHWANN CELLS IN NERVE CONDUCTION

Figure 51-1 summarizes the classical role of Schwann cells as providers of myelin and the two major advantages myelinated fibers have over nonmyelinated fibers of comparable size: faster conduction and lower energy expenditure. How myelination increases conduction velocity is best examined by first considering the mode of conduction of a nonmyelinated fiber (Figure 51-1A). Excitation is initiated at a small membrane area by membrane depolarization. This passive membrane depolarization leads to an activation of sodium channels, causing a regenerative influx of positive charges. This generates a local current that flows to depolarize the neighboring quiescent patch and triggers, in turn, a wave of sodium channel excitation that propels an undiminished wave of depolarization along the fiber at a constant velocity. In the case of nonmyelinated axons, the conduction is more or less continuous as the impulse propagates along excitable membrane patches that are immediately adjacent to each other. Myelination achieves faster conduction by using the myelin sheath to increase the spatial separation of the excitable patches—the nodes of Ranvier. Figure 51-1B shows that, for the same fiber diameter, covering parts of the axon with a myelin sheath forces the excitation current to effectively jump from one node to the next, with very little current lost in the internode because the myelin sheath has a very high membrane resistance and a small electrical capacity.

The geometry of the myelinated fiber is optimized for conduction. Thus, both the myelin thickness and the internodal length bear a relationship to the fiber diameter in such a way as to maximize the conduction velocity at a given fiber diameter (Rushton, 1951; Waxman, 1980). This type of dimensional analysis was pioneered by Rushton (1951), and the most insightful point made concerns the myelin thickness. Rushton argued that, for a given external fiber diameter, the myelin sheath can be neither too thick nor too thin. This can be readily seen from Figure 51-1. At a given outside fiber diameter, thickening the sheath to reduce the current loss across the internode does so at the expense of squeezing the core diameter of the axon, which tends to increase the core resistance and hence impedes the flow of axial current. There is thus an optimal myelin thickness, at a given outside diameter, that optimizes conduction. This myelin thickness is deduced to be 0.3 to 0.4 of the fiber diameter (Rushton, 1952; Waxman and Bennett, 1972), a prediction that is in remarkable agreement with experimental observations. An interesting price that myelination pays is that when compared to a nonmyelinated fiber of the same external diameter, the axon core diameter is always smaller because of the space taken up the myelin sheath (Figure 51-1). Thus, while large myelinated fibers always conduct faster than nonmyelinated fibers, in a very small myelinated fiber, the



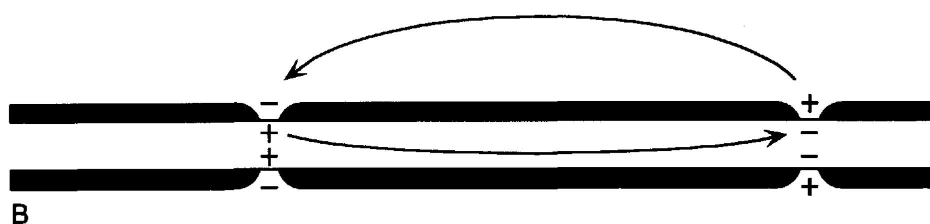


FIG. 51-1. (A) A nonmyelinated fiber and (B) a myelinated fiber illustrating the difference between continuous conduction and saltatory conduction. The two types of fibers are drawn with the same external fiber diameter.

core resistance can become so high that it actually conducts slower than a nonmyelinated fiber of the same fiber diameter. Waxman and Bennett (1972) deduced that it is only above a fiber diameter of 0.2 μm that conduction velocity is increased by myelination. This may explain why in the central nervous system, fibers less than 0.2 μm in fiber are rarely myelinated (Waxman and Bennett, 1972). Interestingly, myelinated fibers less than 1.0 μm in diameter are rare in the peripheral nervous system. This has been attributed by Ritchie (1982), not to a breakdown of Rushton's theory on the relation between myelin thickness and conduction, but rather to the fact that Schwann cells have a minimum size that puts a lower limit on the internodal length in small fibers. When myelinated fibers fall below 1 μm in diameter, the internodal length, which normally should be reduced linearly with diameter to achieve optimal conduction (Rushton, 1951), becomes fixed at the lower limit of the longitudinal length of a Schwann cell. This results in a deviation of the conduction velocity from the optimal value because the internodal length becomes inappropriately too long. Apparently, in the central nervous system in which axons are myelinated by oligodendrocytes, such size limitations on the internodal length do not exist because a single oligodendrocyte myelinates many axons with its fine processes.

Another important consequence of the insulation provided by the myelin sheath is that the metabolic costs of conduction are greatly reduced. The main metabolic cost is incurred not during conduction, which involves ions flowing passively down their ionic gradients, but during the recovery when excess sodium ions gained inside have to be pumped back out against their gradient. The larger the membrane area involved in excitation, the larger the amount of excess ions needs to be pumped out. By restricting excitation along myelinated fibers to tiny nodes of Ranvier, much less pumping of ions is required during the recovery than in nonmyelinated fibers. These two advantages of myelination, speed and efficiency, are best summarized by the following example (Hodgkin, 1964; Hille, 1977). A myelinated frog fiber, with a fiber diameter of 14 μm, has a conduction velocity of ~30 m/s at 24°C. To achieve a similar conduction velocity in a nonmyelinated squid axon, a much larger diameter of 500 μm is required. Conduction in the myelinated fiber involves 5 nodes of Ranvier per centimeter length of fiber, and, based on voltage-clamp data on single myelinated nerves and flux measurements, the myelinated fiber gains 1.3×10^{-16} mol sodium/cm length of fiber for each impulse. In comparison, each impulse in the 500 μm squid axon gains 5×10^{-13} mol sodium/cm. Thus, the metabolic energy needed to pump out the excess sodium ions following excitation is 4000 times larger in a nonmyelinated fiber than a myelinated fiber of comparable conduction velocity.

It is clear that Schwann cells are clearly designed to maximize the conduction velocity of myelinated fibers, as the dimensional analysis clearly indicate. What role is left for Schwann cells to play in saltatory conduction besides insulation? There are many other aspects of myelinated fibers, like the metabolic interactions between Schwann cells and axons, the refractory period, or the ability of the nerve to conduct trains of impulses, which also have important functional consequences on the performance of the system as a whole. Schwann cells do not simply leave the node as a hollow gap in the myelin, but decorate it with a system of intriguing membrane

specialization consisting of gap substance, microvilli, and a dense packaging of mitochondria. William and Landon (1963) first introduced the term "paranodal apparatus" to collectively describe these Schwann cell specialization at the node of Ranvier, and suggest that the paranodal apparatus "could provide a source of energy-rich compounds to fuel ion translocation mechanisms at the nodal axolemma, or play a role in controlling the ionic milieu within the nodal gap (Landon, 1981)." The recent discovery of voltage-sensitive ion channels on the Schwann cell membrane has further strengthened the view that these ensheathing cells can no longer be relegated to a backseat role of passive insulation. Indeed, dynamic ionic interactions between Schwann cells and axons are clearly possible.

Having reviewed the classical, insulation role of Schwann cells, we now turn to the main focus of this chapter, which is on potential new roles of Schwann cells in modulating nerve excitability through the use of voltage-sensitive ion channels expressed on the Schwann cell membrane. We shall only be concerned with Schwann cell-axon interaction in the fast time scale of saltatory conduction. Thus, other intriguing roles for Schwann cell ion channels that have long-term effects on myelinated fibers will not be examined. These include regulation of Schwann cell proliferation by potassium channels during myelin formation and nerve injuries (Konishi, 1989; Wilson and Chiu, 1989; Chiu, 1991), developmental regulation of Schwann cell cytoplasmic volume by potassium channels (Konishi, 1991), and the possible transfer of sodium channels to axons to support channel turnover (Gray and Ritchie, 1985; see Chapter 12, this volume).

How might Schwann cell ion channels affect excitability of myelinated nerves? We believe the key lies in whether ion channels on a Schwann cell are segregated to regions immediately adjacent to the axonal membrane. We will first survey the evidence for channel segregation on Schwann cells. Then we will examine how two types of Schwann cell channels, namely, voltage-sensitive sodium and potassium channels, might be functionally important in modulating nerve excitability.

ARE ION CHANNELS SEGREGATED ON MYELINATING SCHWANN CELLS?

When a Schwann cell elaborates myelin, it greatly increases its own membrane area, and spirals its membrane many times around an axon. Are ion channels expressed uniformly all over the Schwann cell membrane, or segregated to certain regions? An optimal interaction with axons might require relocating channels on Schwann cells to the axon's proximity. The Schwann cell membranes in immediate apposition to the axon consist of the innermost turn of the Schwann cell, as well as the paranodal membranes at a node of Ranvier. Results from patch-clamp analysis of ion channels have pointed towards channel segregation.

Potassium Channels

First hints that potassium channels might be segregated came from patch-clamp studies in which the channel density at the cell body was compared between nonmyelinating and myelinating Schwann cells of adult mammals, and in the myelinating type during early stages of myelin formation. Results from two laboratories have yielded similar results: potassium channels disappear from the cell body during the process of myelin elaboration (Chiu, 1987, Konishi, 1990a, 1990b; Wilson and Chiu, 1990a). Figure 51-2 (top) shows the two types of voltage-sensitive potassium channels recorded from the cell body of Schwann cells at early stages of myelin formation. One is a delayed rectifier, which activates around −40 mV (Konishi, 1990b; Wilson and Chiu, 1990a). The other is an inward rectifier, which is activated by membrane hyperpolarization and passes inward currents better than outward. As myelin is formed, both channels disappear from the cell body (Figure 51-2, bottom two panels).

One explanation for the disappearance of potassium channels from the cell body is that they are relocated to distal myelin processes or inner membrane turns of the Schwann cell (Figure 51-3). Two experimental approaches have been used to test this theory. Konishi (1991) reasoned that these channels should be revealed in whole-cell patch-clamp if the myelin was loosened. By cleverly inducing volume changes, using the water influx that accompanied the activation of the inward rectifiers, Konishi (1991) did find an increase in the size of potassium currents, which was interpreted as arising from channels located in the adaxonal Schwann cell membrane. Wilson and Chiu (1990b) took a more direct approach by placing a patch pipette at the paranodal region. The paranode was first widened with enzymes to make room for the pipette, and upon detecting channels with the pipette, Wilson and Chiu (1990b) proved, through the use of lucifer yellow staining, that the channels originated from Schwann cell membranes rather than from the adjacent, ion channel-enriched nodal membranes. Thus, at a time when potassium channels have all but disappeared from the cell body in adult myelinating cells, these

FIG. 51-2. FIG. 51-3. A model for channel segregation in myelinating Schwann cells. (Modified from Chiu (1991) with permission). (**A**) Channels are uniformly distributed in the premyelin state, (**B**) but become relocated to the inner membrane turns, (**C**) or the paranodal processes during myelin formation.

channels (both the delayed rectifiers and inward rectifiers) can be recorded at the paranode. Potassium channels therefore appear to be segregated in mature myelinated Schwann cells. It is important to note that other potassium channel types may be present, and channel segregation of this sort may not apply to all channels. Further, the mechanisms for achieving channel segregation are unclear; they could include dynamic relocation of channels from the soma to the processes (as suggested by the model in Figure 51-3), or a selective downregulation of the number of functional channels at the soma.

Recently, mRNAs for certain types of shaker potassium genes, which encode potassium channels of the delayed rectifying type, have been found to be expressed in rat sciatic nerves (Chiu et al., 1994). Since Schwann cells (presumably the myelinating type) are the major cells in sciatic nerves, the mRNAs are likely to come from myelinating cells. Interestingly, during the first 2 weeks of postnatal development, mRNA levels go up when somal channels are disappearing (Chiu et al., 1994) suggesting channels are synthesized but segregated to extrasomal regions. Recently, antibodies generated against a certain type of delayed rectifying potassium channel (Shaker Kv1.5) were used to directly con-

firm the paranodal localization of potassium channels in Schwann cells of rat myelinated nerves in immunohistochemical studies (Mi et al., 1995).

Sodium Channels

Saxitoxin binding studies have suggested the presence of sodium channels in Schwann cells of rabbit sciatic nerves (Ritchie and Rang, 1983). Patch-clamp studies on freshly isolated Schwann cells from rabbits have revealed voltage-sensitive sodium channels on the cell body of nonmyelinating cells, but not in the myelinating cells (Chiu, 1987, 1993). Hence, like potassium channels, sodium channels also might be segregated to myelin processes during myelin formation. However, immunohistochemical studies with a polyclonal antibody against sodium channels (7437 antisera) shows that antibody staining is present in the cell body cytoplasm, in the cell body plasma membrane, and in the paranodal Schwann cell processes (Ritchie et al., 1990). In another study using an antibody against a conserved region of all known sodium channel genes, Ferguson et al. (1992) have observed that in mouse sciatic nerves, patchy staining is present only in the paranodal regions of Schwann cells. Paranodal patch-clamp studies failed to reveal sodium channels (Wilson and Chiu, 1990b) but this failure might be related to a small sample size. Taken collectively, these various studies suggest that sodium channels are expressed in paranodal regions of Schwann cells, but whether these channels are segregated during myelin formation is still unresolved.

POTASSIUM CHANNELS

Schwann cell potassium channels can modulate excitability of myelinated fibers by regulating the potassium ion concentration in the periaxonal space between the myelin sheath and the axon. Interestingly, a need for potassium homeostasis arises because a mature myelin sheath, though conferring enough insulation for saltatory conduction, nevertheless is leaky to the extent of allowing some degree of activation of axonal channels under the sheath (Chiu, 1991).

How Tight is the Myelin Insulation?

Even though in our earlier review of saltatory conduction the myelin sheath is depicted as a perfect insulator (Figure 51-1), tracer studies have revealed that the periaxonal space between the myelin sheath and the internodal axon can communicate with the extracellular space, either via the Schmidt-Lanterman incisures or the paranodal junction (Hall and Williams, 1971; Mackenzie et al., 1984). Recent electrophysiological studies with single electrodes have demonstrated that during the passage of an action potential, a part of the action currents that flows into the internode takes a short cut in completing the circuit by flowing along the periaxonal space instead of transversing the thick myelin sheath (Barrett and Barrett, 1982). This is not enough to short out saltatory conduction, but clearly allows activation of axonal channels in the internode (see below). Indeed, even the transverse membrane resistance of the myelin sheath is finite to a degree to draw enough current to depolarize the node (Chiu and Ritchie, 1984). There is now mounting evidence that the internodal axolemma produces the resting potential crucial for stabilizing the myelinated nerves (Barrett and Barrett, 1982; Chiu and Ritchie, 1984).

Axonal Ion Channels Under the Myelin Sheath

The portion of a mammalian axon covered by myelin is populated with a rich repertoire of voltage-sensitive ion channels (Black et al., 1990), allowing a dynamic trafficking of ions in the periaxonal space. Fast activating potassium channels are expressed at a high density at the paranodal region and at a low density in both the nodal and internodal axolemma (Brismar, 1980; Chiu and Ritchie, 1980; Grissmer, 1986; Roper and Schwarz, 1989). Slow potassium channels are concentrated at the nodal axolemma and are expressed at a lower density elsewhere (Roper and Schwarz, 1989). Sodium channels have the highest density at the node, and in the internodal region the density drops to about 1/30 of the nodal density (Ritchie and Rogart, 1977; Chiu and Schwarz, 1987; Shrager, 1987).

Evidence that internodal and paranodal ion channels are activated during nerve activity is as follows. Bath application of potassium channel blockers has been shown to induce repetitive activities in myelinated nerves, an observation that has been interpreted as resulting from a removal of the stabilizing effects of paranodal potassium channels (Bowe et al., 1985). Recently, more direct evidence has come from studies in which a single internode is first impaled with a fine electrode to detect a resting potential, then the electrode tip is retracted slightly so that a resting potential is no longer detected. It is argued that the tip has backed into a space between the myelin sheath and the internodal axolemma, namely, a periinternodal space just outside the internodal axon

but completely under the myelin (David et al., 1992). This recording configuration allows a direct monitoring of the conductance of the internodal axolemma during normal nerve excitation, and has provided the strongest piece of evidence that potassium channels in the myelin covered portion of the axon are activated during saltatory nerve conduction.

Activation of Axonal Channels Under the Myelin Sheath Can Lead to Significant Potassium Accumulation

The stage is now set for a reasonable estimate of the magnitude of potassium accumulation in the periaxonal space of myelinated nerves (Chiu, 1991). Accumulation is likely to be nonuniform, since both the axonal channel density and width of the periaxonal space are heterogeneous. The periaxonal space is 20 nm along the entire internode proper and narrows to 3 nm along the myelin attachment junction at the paranode. The nodal gap is packed with a system of microvilli that occupies ~80 to 90% of the extracellular space (Berthold and Rydmark, 1983a). Ionic flux is very high at the node due to a high channel density, but a minute internodal flux could also cause significant accumulation because of the smallness of the periaxonal space, particularly at the paranodal junction (see Chapters 26 and 47, this volume). Variations in the series resistance of the periaxonal space can influence the degree of channel activation, hence the degree of potassium accumulation. Taking most of these factors into account, and using voltage-clamp data on channel densities, a computer simulation of potassium accumulation at the node-paranodal region for a large myelinated axon is made (Figure 51-4). The nodal gap is assumed to be 1 μm long and the paranodal segment is 4 μm long. Figure 51-4 shows axonal sodium and potassium currents in the nodal (Figure 51-4A) and the paranodal (Figure 51-4B) segment for a single nonpropagating action potential. Use-dependent accumulation of potassium is shown for the nodal gap (Figure 51-4C) and for the paranodal periaxonal space (Figure 51-4D), with the assumption that potassium clearance occurs only by diffusion. Even though the periaxonal series resistance prevents the paranodal channels from activating to the same extent as the nodal channels, the smallness of the periaxonal space in the paranodal junction, coupled with a relatively long time for diffusion clearance and a high density of delayed rectifying potassium channels at the paranodal axon, results in a use-dependent potassium accumulation that is much higher in the myelin attachment segment than in the nodal gap.

Even though there are theoretical reasons to believe that there is a high accumulation of potassium in the restricted space between the myelin sheath and the axon, this sort of potassium accumulation in myelinated nerves is difficult to verify experimentally. Conventional observations about potassium accumulation in the peripheral nerves, made by placing an ion-sensitive electrode in the extracellular space of rat sciatic nerves, have failed to indicate any significant increases in the extracellular potassium concentration during and following activity (Hoppe et al., 1991). For example, in adult rat sciatic nerves, stimulation could induce increases in extracellular potassium concentration of only several mM at 22°C, and at 37°C this increase rarely exceeds 1 mM (Hoppe et al., 1991). This is in contrast to nerves in the central nervous system where activity induces a much larger elevation in extracellular potassium (Connors et al., 1982). However, as discussed by Hoppe et al. (1991), conventional measurements of extracellular potassium accumulation with ion-sensitive electrodes may underestimate the true accumulation in specialized restricted spaces of myelinated nerves, like those underneath the myelin sheath or at the paranodal junction. Indeed, optical studies on myelinated nerves from the central nervous system, using voltage-sensitive dyes, have suggested that axonal discharge causes a differential accumulation of potassium in a highly restricted space at the paranode (Lev-Ram and Grinvald, 1986).

Do Schwann Cells Play a Role in Potassium Clearance?

The theoretical calculations of Figure 51-4 show that if diffusion is the only clearance mechanism, the extracellular potassium concentration might reach ~10 mM in the narrow ring of paranodal membrane flanking the node following high-frequency nerve transmission. This paranodal accumulation, if not dealt with, will depolarize the node and compromise conduction. In view of the classic role of glia in potassium buffering (Orkand et al., 1966), it is natural to examine how Schwann cells, particularly through the use of potassium channels, may regulate the ionic environment at the paranodal junction. A reasonable scheme is as follows. The inwardly rectifying potassium channels at the paranodal membranes of Schwann cells, by virtue of being maximally activated at the resting potential, might siphon the potassium at the paranodal junction into Schwann cells (Konishi, 1990b; Wilson and Chiu, 1990b). Activation of delayed rectifying potassium channels at a distal site may provide an exit for the incoming po-

(**A, B**) Ionic currents during a single nonpropagating action potential in the nodal region (*A*) and in the paranodal region (*B*). (**C, D**) Use-dependent accumulation of potassium in the nodal gap (C) and in the periaxonal space between the paranodal axon and paranodal myelin (*D*). Details of computation can be found in Chiu (1991). [From Chiu (1991), with permission.]

tassium ions, allowing for some sort of spatial buffering. The paranodal membrane of Schwann cells apparently is well designed to act as a potassium sink; the Schwann cell:axolemma membrane area at the node-paranodal region is about 10:1, as compared to 1:1 elsewhere along the fiber (Berthold and Rydmark, 1983b).

There is indeed some circumstantial evidence for this scheme. Wurtz and Ellisman (1986) have observed myelin vacuolization and myelin splitting at the paranode during high-frequency stimulation, which might indicate potassium fluxes across the Schwann cell paranodal pockets (Figure 51-6B). A specialization of glial and axon particles at the paranodal junction has been observed, and some of the particles might correspond to potassium channels in-

volved in ionic exchanges (Clayton and Ellisman, 1980). Konishi (1991) observed a swelling of the paranode when Schwann cell inward rectifiers were activated under voltage-clamp, presumably reflecting potassium and water influx. Interestingly, this swelling persists in the absence of external chloride, suggesting that there is little or no chloride movement into Schwann cells for potassium to accumulate at the site of entry. This is an important observation, since it suggests that once potassium ions are siphoned into the Schwann cell at the paranode, they are shunted elsewhere (e.g., exit via delayed rectifiers) rather than accumulated locally. The role of Schwann cells in potassium buffering may be particularly important in neonatal nerves when the myelin sheath is thin and loose and hence activity-dependent potassium accumulation is likely to be more pronounced (Connors et al., 1982). Konishi (1990b, 1991) has suggested that inward rectifiers may be localized to the innermost turn (adaxonal) of the Schwann cell to siphon potassium accumulated along the entire periaxonal space of an immature internode.

One experimental approach to test these proposed roles of Schwann cell potassium channels in potassium buffering involves applying agents to block potassium channels. In the studies of Baker et al. (1987) on rat spinal root myelinated nerves, bath application of 3 to 5 mM Cs^+, a blocker of inward rectifiers, did not impair the firing frequency of the nerves during tetanus, but did lead to a change in the threshold for excitation. In the studies of Hoppe et al. (1991) on rat sciatic nerves, bath application of Ba^{2+}, another potassium channel blocker, did not significantly change the amplitude of stimulated increases in extracellular potassium or the rate of potassium removal. In contrast, Ba^{2+} application led to an increase in activity-dependent potassium accumulation in the central nervous system, suggesting a role for uptake through potassium channels in potassium clearance (Ballanyi et al., 1987). All in all, testing the role of Schwann cell channels in potassium clearance by bath application of potassium channel blockers has two problems. First, since bath application of channel blockers affects both axonal and glial channels, it is unclear how to attribute changes in nerve excitability to a block of glial channels alone. Second, restricted diffusion may prevent bath applied agents to reach and block glial channels expressed in various restricted spaces of a myelinated fiber like the region underneath the myelin sheath. Until a better means becomes available of completely inhibiting Schwann cell potassium channels and does so selectively by not interfering with axonal channels, it would be difficult to assess experimentally the role of Schwann cell channels in modifying nerve excitability. In this respect, a future approach of selectively altering the expression of potassium channels in Schwann cells by transgenic technologies may be particularly useful in elucidating some of the proposed roles for Schwann cells discussed in this chapter.

SODIUM CHANNELS

It has been suggested that sodium channels at Schwann cells or glial processes can create a local depolarization (Gautron et al., 1992) or even trigger a local excitation (Black et al., 1989) that activates a cascade of events important for nodal function. As will be discussed below, the paranodal membranes of Schwann cell, because they are differentiated into various fine compartments with extremely high input resistance, can allow the opening of even a single sodium channel to produce a sizable depolarization. Furthermore, minute Schwann cell pockets or microvilli containing very small volumes of cytoplasm are present at the paranode, and these membrane compartments can function as transduction units to translate brief sodium channel activities into large fluctuations in the concentration of sodium, an important signaling molecule. We will consider these roles of Schwann cell sodium channels by computing the input resistance and sodium loading in various compartments of the paranode.

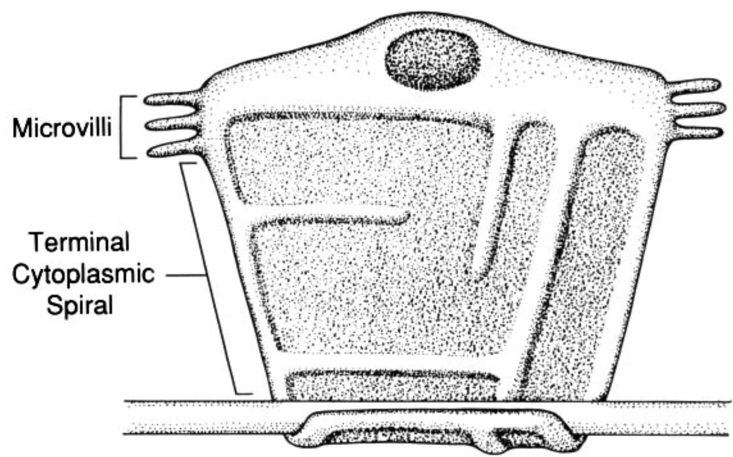
What is the Sodium Channel Density in Schwann Cells In Vivo?

We first need a reasonable value for the sodium channel density for Schwann cells *in vivo*. In freshly isolated Schwann cells from rabbit sciatic nerves, single-channel recordings from the cell body of nonmyelinating Schwann cells have revealed an average of about 2 to 3 overlapping channel openings per excised outside-out patch of area ~2 to 3 μm^2 (Chiu, 1993). This gives a lower limit of ~1 Na channel/μm^2 *in vivo,* at least at the cell body of nonmyelinating Schwann cells. For the case of the myelinating Schwann cells, functional Na channels cannot be detected at the cell body (Chiu, 1987, 1993), but the paranodal regions are strongly stained with antibodies against sodium channels (Ritchie et al., 1990; Ferguson et al., 1992). In the following calculations, we will assume a low sodium channel density of 1/μm^2 for the Schwann membranes at the paranode.

Single Sodium Channel Openings Can Lead to Significant Changes in Membrane Potential and Sodium Concentration in Various Paranodal Compartments of Schwann Cells

In a fully differentiated myelinating Schwann cell, the two paranodal compartments of particular interest are the terminal cytoplasmic spiral and the microvilli (Figures 51-5 and 51-6). Calculations are made of membrane depolarization and sodium loading in these regions by assuming a low sodium channel density of $1/\mu m^2$. To calculate the current generated by a single sodium channel, we assume a single-channel conductance of 20 pS (Shrager et al., 1985; Howe and Ritchie, 1990; Chiu, 1993) and an inward driving force of 100 mV when the channel is activated near the resting potential. Thus, each channel generates 2 pA a piece. Calculations are done for a large myelinated fiber with a fiber diameter of 17.5 μm and associated morphometric data taken from a review chapter by Thomas et al. (Table 1, 1993; the original data was that of Berthold and Rydmark, 1983a).

Terminal Cytoplasmic Spiral. Upon forming compact myelin, the Schwann cell cytoplasm is squeezed and redirected to form thin cytoplasmic tunnels. The terminal cytoplasmic spiral refers to a spiral of cytoplasm at the myelin attachment zone near the node of Ranvier, and is best illustrated by unrolling the myelin sheath from the axon (Fig. 5, top). The terminal cytoplasmic spiral is ~2530 μm long with a circular cross-sectional diameter of ~0.1 μm. When rolled back onto a single axon, this spiral makes 140 turns and comes into close contact over a ~4 μm length of paranodal myelin attachment zone. The cytoplasmic pockets seen hanging over the paranodal myelin attachment zone in fact come from the same cytoplasmic spiral (Figure 51-6B). Because this terminal cytoplasmic spiral is formed by myelin compaction, it is more or less electrically isolated from the rest of the cell, and thus can be treated as an



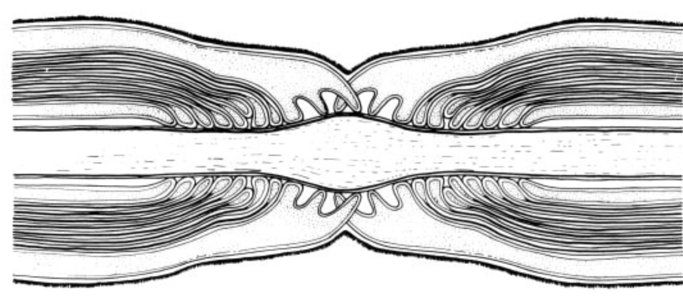


FIG. 51-5. A schematic drawing of the unrolling of a mature myelin sheath from an axon. **Top:** the unrolled sheath, showing the transverse and the longitudinal Schmidt-Lanterman incisures. Note the microvilli and the terminal cytoplasmic spiral. **Bottom:** when rolled back around the axon, the terminal cytoplasmic spiral runs around the paranodal attachment segment many times, creating Schwann cell pockets overhanging the paranodal axon.

(1991), with permission.]

infinite cable 0.1 μm in diameter using appropriate cable equations (Jack et al., 1975). Hille (1970) has pointed out that in small axons, the input resistance is so large that opening of a single sodium channel can lead to a large depolarization.

Table 51-1 shows a calculation of the input resistance of the terminal cytoplasmic spiral by assuming two values for the resting membrane resistivity for Schwann cells. One value (24,700 Ωcm^2) is calculated from the whole-cell clamp data of Howe and Ritchie (1990) on cultured mammalian Schwann cells, while the other value (1000 Ωcm^2) is typical for most biological membranes, and has been suggested to apply also to squid Schwann cells (Villegas, 1972). The calculated input resistance of the terminal cytoplasmic spiral, R_{input}, is extremely large, being 1.7×10^{10} Ω or 3.4×10^9 Ω for a 0.1 μm diameter spiral. As the spiral diameter is shrunk to 0.05 μm (see Figure 51-6B), the input resistance increases by 2 to 3 fold.

Table 51-1 shows the calculated local depolarization produced by one sodium channel that opens for a brief 1 ms. For the 0.1 μm spiral it is 6 to 7 mV per channel per millisecond, and for the 0.05 μm spiral it is 18 to 21 mV per channel per millisecond. Since inward rectifiers in Schwann cells are downregulated following axonal deprivation (Konishi, 1992), we believe that the membrane resistivity of 24,700 $\Omega\ cm^2$, which is taken from cultured cells, may be too high for *in vivo* Schwann cells. Hence in the following discussion, we will use parameters based on a membrane resistivity of 1,000 Ωcm^2.

Could depolarizations from individual sodium channels sum when several channels are opening simultaneously? This depends on the spacing of sodium channels along the spiral relative to the space constant of the terminal cytoplasmic spiral. Table 51-1 shows the calculated spacing between sodium channels, assuming a low density of $1/\mu m^2$, as well as the space constant of the terminal cytoplasmic spiral. The values in Table 51-1 allow a calculation of the size of the depolarization when multiple channels are open. A reasonable scenario is the activation of one turn's worth of sodium channels around the paranodal axon. For the terminal cytoplasmic spiral with an input resistance of 3.4×10^9 Ω, a space constant of 32 μm, and a spacing of 3.2 μm between sodium channels, one turn of the spiral around the paranodal axon (circumference ~15 μm) will have ~5 Na channels. If these five Na channels are to open simultaneously for 1 ms, each creating a local depolarization of 6 mV, the peak depolarization can be calculated by superimposition, and will equal $6 + 2*6*\exp[-3.2/32] + 2*6*\exp[-2*3.2/32] = 25$ mV, if a change in driving force upon depolarization is ignored.

The fact that a few sodium channels can depolarize the spiral by ~25 mV, the threshold of firing in most axons, raises the possibility of regenerative responses in the paranodal spiral. It should be noted that small neonatal optic nerve axons with a diameter of 0.2 μm can conduct action potentials with a sodium channel density as low as $2/\mu m^2$ (Waxman et al., 1989), and it has been suggested that a high input resistance is one reason for making conduction possible by allowing a few sodium channels to produce a large depolarization. Even before the demonstration of sodium channels in the paranodal regions of Schwann cells (Ritchie et al., 1990), Ellisman et al. (1980), based on the observed richness of sodium and calcium ions in the paranodal Schwann cell pockets, have already postulated the possibility that the terminal cytoplasmic spiral might be involved in excitation. The use-dependent changes in the structures of paranodal myelin loops may reflect some sort of propagating responses in the terminal spiral (Wurtz and Ellisman, 1986).

Now consider changes in sodium concentration in the terminal spiral. Activating one turn of the cytoplasmic spiral (flicking open 5 channels for 1 ms, each generating ~2 pA a piece) would generate a net influx of $\sim 6 \times 10^4$ Na ions. The volume of one turn of the spiral, 15 μm long and 0.1 μm in diameter, is $\sim 0.1\ \mu m^3$. The intracellular sodium concentration thus increases by ~1 mM. Further, the volume of the immediate extracellular space surrounding one turn of the spiral, with a 200 A space between the pockets, is approximately equal to the intracellular volume. This means that the extracellular sodium concentration should also drop by an equal amount. In total, activating only 5 sodium channels along one turn of the spiral (15 μm long) can alter the transmembrane sodium gradient by ~2 mM or 1 to 2% of the normal gradient. Thus, repetitive paranodal activities could easily lead to significant changes in spiral sodium. A dynamic redistribution of cation binding sites (thought to be reservoirs for sodium ions) between the node and the paranode has been observed during electrical stimulation (Zagoren and Arezzo, 1982).

Paranodal Schwann Cell Microvilli. There are about 800 Schwann cell microvilli in the nodal gap of a large fiber. Each microvillus is 0.084 μm in diameter and 1 μm long. A cross-sectional view at the node (Figure 51-6A) shows that the microvilli radiate toward the axolemma surface. The total membrane resistance of one villus is very high, probably on the

TABLE 51–1. *Input Resistance of the Terminal Cytoplasmic Spiral*

D (μm)	R_m (Ωcm^2)	l (μm)	t_m (ms)	R_{input} (Ω)	Depolarization by one Na channel opening for 1 ms (mV)	Spacing Na channel (μm)
0.10	24,700	158	25.0	1.7×10^{10}	7.0	3.2
	1,000	32	1.0	3.4×10^{9}	6.0	3.2
0.05	24,700	122	25.0	5.2×10^{10}	21.0	6.4
	1,000	25	1.0	1.0×10^{10}	18.0	6.4

D: diameter of the terminal cytoplasmic spiral (see Figure 51-5). The value of 0.1 μm is taken from Thomas et al. (1993, Table 1). The value of 0.1 μm is the normal value. Calculations also have been done for $D = 0.05$ μm to show the effects of a smaller spiral on the different parameters.

R_m: The assumed specific membrane resistance (Ωcm^2) for the Schwann cell membrane. The value of 24,700 Ωcm^2 is calculated from whole-cell patch clamp data on cultured mammalian Schwann cells (Howe and Ritchie, 1990). From table 1 of Howe and Ritchie (1990), the input resistance is 1.54 GΩ and somal capacity is 16.5 pF for myelinating Schwann cells cultured from adult rabbit sciatic nerves. Assuming a value of 1 μF/cm^2, this gives 24,700 Ωcm^2. The value of 1000 Ωcm^2 is taken from data on Schwann cells of the squid giant axon (Villegas, 1972).

l: Space constant of the terminal cytoplasmic spiral. The cytoplasmic spiral is approximated to be an infinite cable (Jack et al., 1975).

$$l = \left(\frac{r_m}{(r_a + r_0)}\right)^{1/2}$$

$$r_m = \frac{R_m}{\pi D},$$

$$r_a = \frac{R_a}{\pi (D/2)^2},$$

$$r_0 = \frac{R_0}{\pi D W},$$

where r_m is the membrane resistance per unit length, r_a is the intracellular resistance per unit length, and r_0 is the extracellular resistance per unit length. The specific membrane resistivity, R_m, is either 24,700 Ωcm^2 or 1000 Ωcm^2. The specific resistivity for the intracellular pathway, R_a, is assumed to be 166 Ωcm (Neumcke and Stampfli, 1982). This value is from rat sciatic nerves, and is higher than the typical frog value of 110 Ωcm; the mammalian value is considered more appropriate here. The specific resistivity for the extracellular pathway, R_0, is assumed to be 65 Ωcm (Barrett and Barrett, 1982). The extracellular resistance is calculated only for the immediate extracellular space surrounding one cytoplasmic pocket (see Figure 51–6B). This space, W, is taken to be 200 A. This value is obtained by surveying published micrographs from various laboratories [~240 A from Fig. 2 of Ellisman et al. (1987); ~260 A from Fig. 3–17 of Thomas and Ochoa (1984), ~200 A from Fig. 2 of Raine (1982); ~180 A from Fig. 6–15 of Peters et al. (1991)]. Note that immediately facing the axon, the space between the cytoplasmic spiral and the axon can narrow to ~3 to 5 nm.

t_m: membrane time constant, being equal to $R_m \times C_m$, where $C_m = 1$ μF/cm^2.

R_{input}: The calculated input resistance of the terminal cytoplasmic spiral. Note the input resistance is calculated for the case of the spiral wrapped around the paranodal region, and the calculation has taken into account the resistance in the extracellular space between adjacent turns.

$$R_{input} = \frac{(r_m\, r_a)^{1/2}}{2}$$

Depolarization per Na channel per millisecond: This column gives the local depolarization produced by one sodium channel opening for 1 ms generating 2 pA of inward current near the resting potential (see text). The voltage response is that of an infinite cable in response to a point application of a current step 2 pA in amplitude and 1 ms in duration. We estimate this voltage response from Fig. 3.3 of Jack et al. (1975) which gives the time course of the voltage change in an infinite cable subjected to a step current of infinite duration. The steady-state voltage is 2 pA $\times$ R_{input}. For case where the membrane time constant is 1 ms, the voltage at 1 ms is exactly 84% of the steady value. For the case where the membrane time constant is 25 ms, the voltage at 1 ms is ~20% of the steady value.

Spacing between Na channels: this spacing along the cytoplasmic spiral is calculated based on a density of 1 channel/μm^2.

order of ~10^{11} Ω. The intracellular resistance along the length of one microvillus is ~10^8 Ω, and connects the cytoplasm of each villus to the rest of the Schwann cell proper whose uncompacted membrane area is several orders of magnitude larger than the villus area. This suggests that the effective input resistance of one villus is approximately equal to 10^{11} Ω and 10^8 Ω in parallel, which is thus namely ~10^8 Ω. A complete equivalent circuit analysis of the microvilli is needed to substantiate this statement. Nevertheless, this suggests that the input resistance of a villus is at least one order of magnitude smaller than that of the cytoplasm spiral (10^9–10^{10} Ω, Table 51-1), suggesting a much smaller depolarization per sodium channel. However, given the intense sodium channel staining of the microvilli (Ritchie et al., 1990), a large depolarization is still possible with a high sodium channel density.

As for sodium loading in the microvilli, with each villus having a volume of ~0.005 μm^3, the opening of one sodium channel for 1 ms will increase intracellular sodium by ~4 mM. This increase is likely to be very transient, since sodium ions will diffuse immediately, along a short distance of ~1 μm, from the villus to the Schwann cell proper which acts like a large sink. Nevertheless, a repetitive activation of microvilli is likely to lead to large transient increases in intracellular sodium.

What Might Activate Sodium Channels in Schwann Cell Paranodes? Any substances released by the axon that can depolarize the Schwann membrane may result in sodium channel activation. A prime candidate is potassium ions released at the node-paranode regions during repetitive activity. Interestingly, computer simulations (Figure 51-4) suggest that activity-dependent potassium accumulation is higher in the paranodal periaxonal space than in the nodal gap, suggesting that the terminal cytoplasmic spiral (Figure 51-6B), rather than the microvilli (Figure 6A), will be differentially activated by potassium. Another candidate is a diffusable neuroactive substance (other than potassium) released by axons. For example, adenosine (Maire et al. 1984) and glutamate (Weinreich and Hammerschlag, 1975) are known to be released from frog and mammalian fiber tracts during repetitive nerve stimulation. Mammalian Schwann cells in culture express various neuroligand receptors (Lyons et al., 1992; Yoder et al., 1992), some of which could mediate membrane depolarization. In squid, axonal stimulation leads to complex changes in the membrane potential of Schwann cells via activation of glutamate and acetylcholine receptors (Evans et al., 1991).

Possible Physiological Roles of Activation of Schwann Cell Sodium Channels. First, sodium channels can be used to amplify voltage. The high input resistance of the terminal spiral permits the generation of large membrane depolarizations with a low sodium channel density. For instance, an initial potassium-mediated depolarization of the terminal spiral can be amplified significantly by recruiting just a handful of sodium channels around one spiral turn. Even larger depolarizations can be achieved by activating more spiral turns (e.g., using Table 51-1, it can be calculated that a 100-mV depolarization can be achieved by activating ~5 to ~35 channels, corresponding to ~2 to ~9 spiral turns, depending on the spiral diameter. The depolarization is an underestimate since a reduction in driving force is ignored when the membrane is depolarized). Any shrinkage of the spiral will increase the input resistance and augment this voltage amplification. For example, a 50% reduction of the spiral diameter from 0.1 μm to 0.05 μm (some pockets in Figure 6B have diameters of ~0.05 μm) will increase the depolarization per sodium channel by 300% (Table 51-1). Voltage amplification based on high input resistance allows the efficient use of a small number of sodium channels to generate large membrane depolarizations to drive or modulate certain membrane processes, like the delayed rectifying potassium channels (whose activation can provide an exit for potassium ions siphoned in through the inward rectifiers) or electrogenic carriers.

Second, use-dependent alterations of sodium gradients across Schwann cell membranes could modulate the net flux of substances through transporters whose operation is coupled to sodium ions. Transporters of amino acids are of particular interest. For example, the transporter for glutamate is coupled to sodium and potassium (Nicholls and Attwell, 1990), is electrogenic, and normally transports glutamate into cells. Under conditions of elevated internal sodium, elevated external potassium, and large membrane depolarizations, glutamate can be released by reversal of the uptake carrier. Other sodium-coupled carriers include those which transport adenosine across cell membranes. Schwann cells might modulate nodal excitability by releasing substances triggered partly by a change in sodium gradient. It should be pointed out that axons do appear to have receptors. The nodal membrane is richly stained with alpha-bungarotoxin (Freedman and Lenz, 1980), and could be the target for acetylcholine released from Schwann cells (Evans et al., 1991). Adenosine receptors have been suggested to be present on axons of myelinated nerves whose activation

may modulate sodium channels via cAMP dependent phosphorylation (Ribeiro and Sebastiao, 1987).

Besides amino acid transporters, two other carriers are worth mentioning. One is the Na/K ATPase, found to be located on the Schwann cell microvilli (Ariyasu et al., 1985). Use-dependent loading of sodium in the microvilli through sodium channels could be used to regulate the activity of this enzyme (Black et al., 1989; Gautron et al., 1992). Activation of the Na/K ATPase may assist potassium buffering by transporting potassium into the microvilli. Another carrier is the Na/Ca exchanger. This exchanger can be driven to deliver a net influx of calcium into the microvilli or the cytoplasmic spiral given the right sodium loading and large depolarizations. Confocal imaging analysis has shown that axonal activation leads to a calcium elevation in the paranodal Schwann cell cytoplasm, but this calcium change is suggested to be linked to a ryanodine receptor (Lev-Ram et al., 1992). It is interesting that Ca-ATPase is located primarily in the paranodal loops, suggesting a requirement for calcium homeostasis in this region (Mata et al., 1988). Intracellular calcium elevation in the paranodal apparatus may trigger calcium-dependent release of substances from Schwann cells, or have metabolic consequences like modulation of the glycogenloytic pathway (Ververken et al., 1982).

SUMMARY

Schwann cells of peripheral axons not only provide the insulation needed for saltatory conduction, but, as we have argued in this chapter, also can actively modulate nerve excitability through the use of voltage-sensitive channels expressed in the immediate vicinity of the axons. Potassium channels expressed at the paranodal region of Schwann cells could have a critical role in saltatory conduction by regulating the potassium concentration in the space between the myelin and the axon. A reasonable buffering scheme is one in which potassium is siphoned in through inward rectifiers, and exits distally through delayed rectifiers. We have also argued that the Schwann cell membranes at the paranode, because of their differentiation into regions of high input resistance and small cytoplasmic volumes, should, in principle, allow robust voltage and sodium signaling to occur with an extremely low density of sodium channels. Thus, a low density of voltage-sensitive channels on Schwann cells need not preclude these channels from exerting profound physiological effects on the cells. Sodium channel mediated signaling could drive various sodium-coupled, electrogenic membrane carriers that might affect nodal excitability through ligand release or modulation of the ionic environment. It is likely that an elucidation of these new roles for Schwann cells in saltatory conduction may require new techniques, like the use of transgenic animals in which the expression of Schwann cell channels can be selectively altered.

We wish to thank Carol Dizack and Terry Stewart for help in illustration and photography. This work was supported in part by grants NS-23375 from the U.S.P.H.S., RG-1839 from the U.S. National Multiple Sclerosis Society, and a Pew Scholar award in the Biomedical Sciences to S. Y. Chiu.

52 Glial cells and the supply of substrates of energy metabolism to neurons

JONATHAN A. COLES

Golgi, in 1886, and many others since then, have drawn attention to the fact that, since astrocytes are interposed between the pericapillary space and the neuronal membranes, and their endfeet envelop the capillaries, they may be part of the route by which metabolic substrates reach the neurons (see Chapter 32). This chapter limits itself to substrates of energy metabolism; in other words, how the glucose that passes out of capillaries ends up as carbon fuel in the neurons. Four possibilities that will be considered are illustrated in Figure 52-1. First, the astrocytes may play no role: the glucose simply diffuses round them (Figure 52-1A). Second, glucose may pass through astrocytes rather than through extracellular space on its way to the neurons (Figure 52-1B). Third, glucose may enter the astrocytes at their endfeet and be transformed into a different substance which is transferred to the neurons (Figure 52-1C). Fourth, glucose may enter astrocytes and be transformed into glycogen, which is broken down to supply substrate to the neurons when demand exceeds supply (Figure 52-1D). These possibilities are not mutually exclusive, and in mammals there is some evidence for the three processes A, C, and D; process B cannot be excluded (processes are indicated in Figure 52-1).

Much useful work on the subject has been done on invertebrates, some of it involving cells not originally called glial cells. The term *glial cells* is therefore used here to mean those cells with membranes close to neurons that appear to play no direct role in electrical signaling but may supply nutrients.

NO ANATOMICAL NEED FOR SUBSTRATES TO PASS THROUGH GLIAL CELLS THAT ENVELOP NEURONS

In the leech ganglion, solutes from the blood can reach the neurons by diffusing through extracellular clefts (Nicholls and Kuffler, 1964) (Figure 52-2A), but in most higher animals a blood-brain barrier is formed by junctions between a layer of cells of another type, through which substrates must pass. These barrier cells have different origins in different classes. In higher vertebrates they are the capillary endothelial cells (see Chapter 50) (Figure 52-2D). In insects, elasmobranchs and cephalopods the cells that form the blood-brain barrier are of glial origin (see Chapter 6) (Figure 52-2B, C); but, although substrates probably must pass through them, these barrier glial cells will not be considered here. We are concerned with glial cells, such as the astrocytes in vertebrates, or outer pigment cells in the bee retina, whose processes reach out to envelop neurons. These cells appear not to constitute a barrier to extracellular diffusion. Brightman and Reese (1969) concluded from electron microscope studies that molecules as large as ferritin can diffuse through the extracellular clefts between the pericapillary endfeet of mammalian astrocytes. In bee retina, where each cluster of sensory neurons is completely surrounded by a cylinder of glial cells, tetrodotoxin can pass rapidly through the glial cylinder to reach the neurons (Coles and Schneider-Picard, 1989a); it is probable that this substance diffuses through the extracellular clefts between glial cells rather than crossing glial cell membranes. Hence, as Kuffler and Nicholls (1966) concluded, there is no apparent *anatomical* necessity for metabolic substrates to be delivered to neurons by the adjacent glial cells.

UPTAKE OF GLUCOSE INTO NEURONS AND GLIAL CELLS

If substrates of energy metabolism are supplied to the neurons by glial cells, then the glial cells must first take up these substrates (or their precursors) in quantities sufficient for their own needs and those of the neurons as well. It is therefore of great interest to compare the uptake of substrates by glial cells and by neurons. In mammals over 95% of the substrate for brain work crosses the blood-brain barrier as glucose, so this is essentially a question of glucose uptake (see Lund-Andersen, 1979). Glucose may not be the main substrate in all species: in cockroach

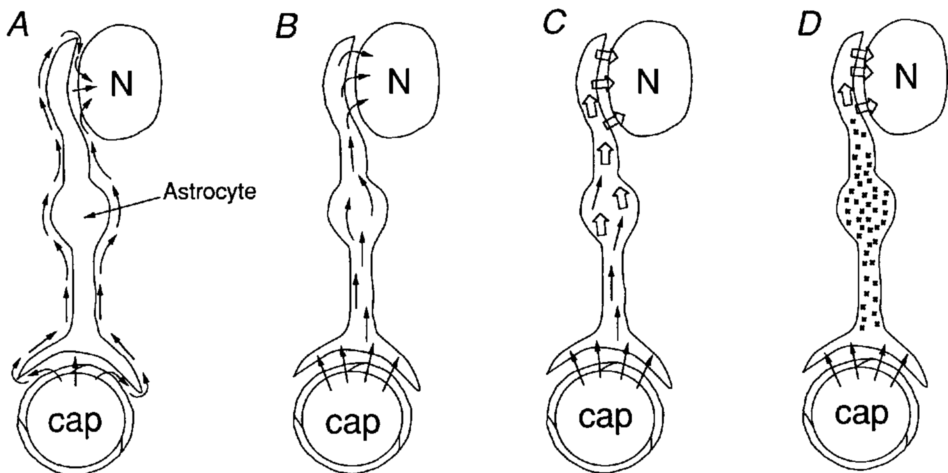

FIG. 52-1. Four hypothetical ways by which glucose leaving a capillary (*cap*) might end up as carbon fuel in a neuron (N). (A) Diffusion through extracellular clefts. (B) Movement of glucose through an astrocyte. (C) Glucose enters an astrocyte and is converted to another substance which is supplied to the neuron. (D) Glucose is used to make glycogen in the astrocyte; glycogen is broken down to provide a substrate for the neuron. *Thin arrows,* glucose; *fat arrows,* another substance, possibly alanine or lactate; *small crosses,* glycogen. Present experimental evidence does not clearly exclude any of the schemes.

(*Periplaneta americana*) where the hemolymph contains a high concentration of trehalose, a dimer of glucose, this appears to be the major substrate, even though glucose crosses the blood-brain barrier more readily (Treherne, 1960). However, most experimental studies on the uptake of carbohydrate have been devoted to glucose.

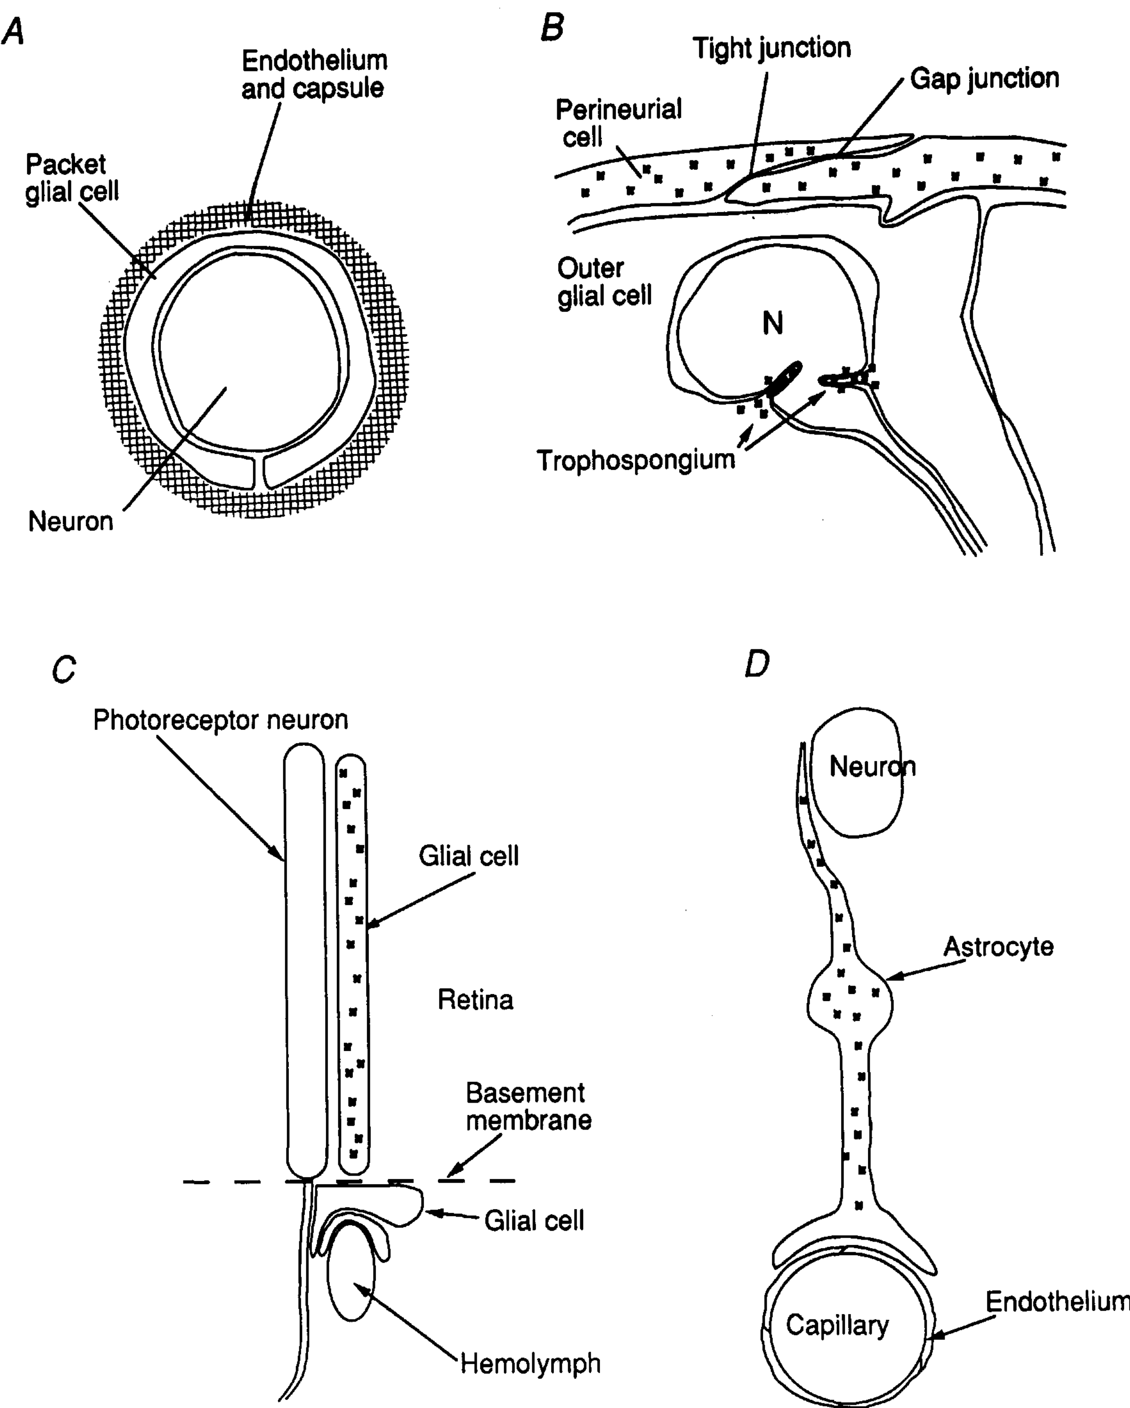
The question of which cells take up glucose that has been supplied by the blood is not easily resolved experimentally. Uptake studies can conveniently be performed on cells in culture, but the results may be misleading. Cells that were unable to take up the essential substrates provided in the culture medium would not survive, and would be automatically excluded from the study. Expression of many genes is known to be stimulated by the serum that is routinely included in culture media (e.g., Barres et al., 1989), and expression of the gene for the rat brain glucose transporter in neuronal cultures is stimulated by such factors as insulin and insulinlike growth factor-1 (Werner et al., 1989). Cell cultures are nearly always derived from fetal or neonatal tissue in which glia-neuron interactions are not fully developed (e.g., Ransom et al., 1985), and the neurons may obtain their metabolites differently from neurons in mature tissue. It is therefore preferable to look at glial cells and neurons either *in situ* or immediately after isolation. The first study of the iden-

FIG. 52-2. Simplified schemes of the routes from blood to neuron in four tissues. *Small crosses* indicate glycogen. (A) Leech neuron. Diagram based on that of Kuffler and Nicholls (1966) to illustrate the presence of diffusion pathways from the blood through clefts in the packet glial cells to the neurons in ganglia of leech ventral nerve cord. The full anatomy of the ganglion is given by Coggeshall and Fawcett (1964), Schlue et al. (1980), and Schlue and Deitmer (1980). Glycogen distribution, which is variable, is *not shown:* see the sections *In Leech Ganglion both Neurons and Glial Cells form Glycogen from Glucose* and *Invertebrate Ganglia.* (B) Insect ventral nerve cord. Having passed the blood-brain barrier formed by a layer of perineurial cells round the ganglion, substances must pass between or through the outer glial cells which surround the neuronal cell bodies (*N*); the inner glial cells are beyond the bottom of the figure. Based on Wigglesworth (1960) and Treherne and Scholfield (1981) for the ventral ganglia of cockroach (*Periplaneta americana*). (C) Bee retina. The retinas of the compound eyes of insects contain only one class of neuron, the photoreceptors. The retina of the drone is particularly large and simple. The elongated cell bodies of the photoreceptors extend for about 500 μm from the dioptric apparatus associated with each corneal facet to the basement membrane that forms the proximal boundary of the retina. Situated between the photoreceptors and lying parallel to them over their length are the glial cells known as "outer pigment cells." The basal membrane has the appearance of collagen. It is penetrated by the axons of the photoreceptors and by tracheoles. No blood vessels penetrate the retina; hemolymph channels run close to the proximal face of the basal membrane and are each surrounded by another class of cell called "pigmented glial cell" by Shaw (1978). The blood-retina barrier is at this level. Figure based on Perrelet (1970), Shaw (1978), and unpublished observations. (D) Vertebrate brain. The blood-brain barrier is situated at the capillary endothelium (Reese and Karnovsky, 1967). Astrocytes, radial glia and tanycytes have endfeet apposed to the capillaries (Chapters 1 and 4, this volume), but substances can diffuse freely through the extracellular clefts between the endfeet.

tity of the cells that took up glucose was made in the leech ganglion.

In Leech Ganglion Both Neurons and Glial Cells Form Glycogen from Glucose

Wolfe and Nicholls (1967) incubated leech ganglia in glucose-6-^{3}H for 10 minutes, washed them in inactive glucose for a further 10 minutes, and found that 17% of the radioactivity was in glycogen. They studied the cellular distribution of the newly formed glycogen by autoradiography. The perikarya of the neurons were densely marked, much more so than the cytoplasm of the surrounding packet glial cells; the neuropil glial cells were heavily marked. A freshly isolated neuron also took up glucose and formed glycogen. These results suggest that both neurons and glial cells took up glucose from the extracellular fluid. Using a technique



that is basically similar, but supplying the glucose analogue 2-deoxy-D-glucose rather than glucose itself, Pentreath and Kai-Kai (1982) found that radioactive glycogen was predominantly, but not exclusively, in the packet glial cells. It is difficult to reconcile these results. The species were similar but not identical (*Hirudo medicinalis* and *Haemopis sanguisuga*), and this could conceivably account for the difference. Alternative possibilities are that somehow the biochemical pathways allow glucose, but not deoxyglucose, to form glycogen in the neurons, or that the animals had been fed differently.

Glucose Uptake in Other Species

Cellular Localization of Glucose Uptake by 2-Deoxyglucose. 2-Deoxy-D-glucose (DG) is transported into cells by glucose transporters and converted mainly to deoxyglucose-6-phosphate (DG6P), with up to 20% appearing in other deoxyglucose phosphates (Dienel and Cruz, 1993). Further reactions are almost completely blocked, although a small amount can be incorporated into glycogen (1 to 10% with typical labeling protocols) (Pentreath et al., 1982). Injection of [^{14}C]DG into the bloodstream is followed by accumulation of [^{14}C]DG phosphates in the cells that took up glucose and the regions of brain that took up most glucose can be found by autoradiography of tissue sections (Sokaloff et al., 1977). The method, as normally used, lacks the spatial resolution necessary for identifying the cells that contain the marker substance. Resolution at a cellular level has been achieved in a few tissues by exposing them to a high concentration of [^{3}H]DG rather than [^{14}C]DG, or by using enzymatic analyses, as now described.

In Insect Retina, Glucose Is Selectively Taken Up by the Glial Cells. In the retina of the drone honeybee, the regularity of the arrangement of the neurons (photoreceptors) and the principal glial cells ("outer pigment cells") allows them to be distinguished in autoradiographs of cross sections. Tsacopoulos et al. (1988) incubated slices of retina in medium containing [^{3}H]DG for 60 minutes, washed for 30 minutes, then froze, lyophilized, and embedded the retina. The labeling was intense in the glial cells and undetectable in the neurons, even though these neurons consume far more energy than the glial cells do and have only limited reserves of carbohydrate (Tsacopoulos et al., 1983) (see the section Drone Retina). Earlier results by Buchner et al. (1984) on *Drosophila* that were fed [^{3}H]DG suggested that the same was true in this species.

In this key experiment, the photoreceptors must have been taking up some substrate of energy metabolism, but they did not take up glucose from the incubation medium. Since no other exogenous substrates were supplied, they were presumably receiving a substrate from the glial cells, and this substrate was not glucose. (Figure 52-1C).

Vertebrate Retina. The experimental accessibility and well-defined cell types made the retina the piece of vertebrate nervous tissue most promising for the identification of the cells that take up glucose. Basinger et al. (1979) incubated pieces of goldfish retina with 2 mM glucose and [^{3}H]DG, fixed them with glutaraldehyde, and embedded them. In dark-adapted retinas most of the photoreceptor neurons were labeled, and the labeling was less in light-stimulated retinas; this correlates with the way membrane currents in vertebrate photoreceptors are reduced by light. Labeling was also found in bipolar cells and horizontal cells (both neurons) of types that were likely to have been depolarized by the light stimulation. Witkovsky and Yang (1982) in isolated frog retina and Sperling et al. (1982) in monkey found densest labeling in the photoreceptors. In all these experiments the DG was supplied from a bath, and not by way of the blood vessels, so it is conceivable that the supply pathways differed from those *in vivo*. This objection was overcome by Morjaria and Voaden (1982), who injected [^{3}H]DG into the bloodstream of rats and, although unable to do autoradiography, separated the photoreceptors from the rest of the retina before measuring the radioactivity. They found that in retinas of dark-adapted rats nearly half the total radioactivity was in the photoreceptors. The photoreceptors of light-adapted rats were less labeled. This result is strongly in favor of direct uptake by neurons, although it cannot be excluded that DG passes into and then out of the retinal astrocytes without being phosphorylated and trapped (Figure 52-1B).

In contrast to these results favoring neuronal uptake, Poitry-Yamate and Tsacopoulos (1991), who dissected retinas of guinea pig under dim white light, and exposed them to [^{3}H]DG in the dark, found, in autoradiographs of frozen-dried and embedded sections, that the labeling was concentrated on the Müller glial cells, with no detectable labeling of photoreceptors or ganglion cells. In subsequent experiments, Poitry-Yamate and Tsacopoulos (1992) demonstrated the uptake of glucose into freshly isolated Müller cells and its conversion to glucose-6-P.

Mammalian Brain. Akabayashi and Kato (1992, 1993) used a variant of the usual DG method. They injected rats with nonradioactive DG, froze them,

dissected out single cells, and measured the cellular content of DG and DG6P by an enzymatic method. Although they did not report values for glial cells *per se,* they found that neuronal cell bodies from the dorsal horn had higher uptakes than did adjacent neuropile, which presumably included glial cell processes.

Conclusions Concerning the Cellular Localization of Glucose Uptake

In bee and fly retinas, glucose is taken up almost exclusively into glial cells. In vertebrate tissues the majority of papers report uptake predominantly into neurons, the glucose marker being supplied via the capillaries in the case of the work by Morjaria and Voaden (1982) and by Akabayashi and Kato (1992, 1993). In contrast, the work of Poitry-Yamate and Tsacopoulos (1991, 1992) favors glial uptake. A consistent pattern in the published work is that, with the exception of Wolfe and Nicholls (1967), all authors appear to have found results that fitted their expectations.

BRAIN GLUCOSE TRANSPORTERS

Knowledge of the cellular localisation and properties of glucose transporters in the brain would provide important information about the delivery of substrates to neurons. There is, general agreement that movement of glucose across the membranes of isolated brain cells, like that across the blood-brain barrier (Crone, 1965), is mainly by facilitated transport, that is, it is not coupled to some source of energy other than its concentration gradient (see Bachelard, 1975). Recently, there has been a rapid increase in knowledge about glucose transporters in the brain. The technique has been to screen brain cDNA libraries to find genes similar to those expressing previously known glucose transporters (for reviews see Silverman, 1991; Baldwin, 1993). The two principal glucose transporters found in this way in rat brain are:

1. The erythroid/brain glucose transporter, designated GLUT1. It is expressed in high levels in brain microvessels (Kasanicki et al., 1987) and has been reported in both neurons and glial cells in culture (Werner et al., 1989; Sadiq et al., 1990).
2. The transporter GLUT3, also sometimes known as the brain glucose transporter, is abundant in adult brain (Nagamatsu et al., 1992). As in the case of GLUT1, there are reports of GLUT3 both on neurons (Gerhart et al., 1992) and on cultured glial cells (Sadiq et al., 1990).

In addition, there are reports of the presence of other transporters, GLUT5 and GLUT7 (Simpson et al., 1994), and GLUT4 (Rayner et al., 1994).

At present, there appear to be no reports of a high density of glucose transporters on the astrocyte endfoot (Simpson et al., 1994).

THE METABOLIC FATE OF GLUCOSE

Most studies of uptake of deoxyglucose in the vertebrate nervous system have been interpreted as showing that glucose is taken up directly by neurons (see the section *Conclusions Concerning the Cellular Localization of Glucose Uptake*). If this were so it might be expected that most glucose would be rapidly oxidized to CO_2 and water. As we will see, this is not the case.

Drone Retina

The elucidation of the cellular localization of the biochemical pathways of energy metabolism has proceeded further in drone retina than in any other preparation and resulted in a clear and testable scheme (Tsacopoulos et al., 1994) (Figure 52-3). The preparation has several advantages, which are reviewed in Coles (1989). The only neurons are the photoreceptors, which contain almost all the mitochondria. They are dependent on aerobic metabolism (Dimitracos and Tsacopoulos, 1985), and their

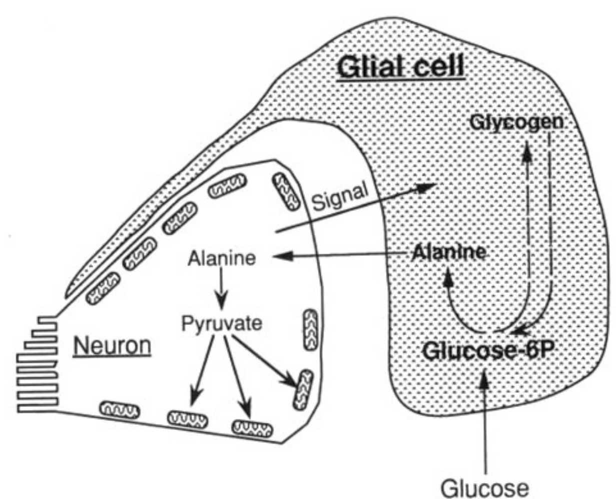


FIG. 52-3. Scheme of major steps in the supply of substrate of energy metabolism to photoreceptor neurons of the drone retina as proposed in Tsacopoulos et al. (1994). The signal from the neurons to the glial cells has not been identified.

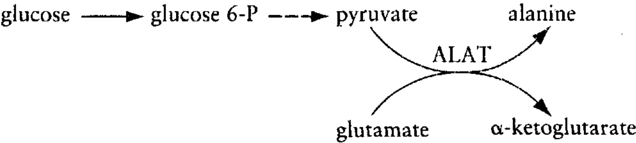
oxygen consumption can be increased by light stimulation. As stated in the section about the selective uptake in insect retina, exogenous glucose is taken up selectively by the glial cells so the cellular localization of at least the first reactions in the metabolism of glucose is known. The results, which are summarized here, provide a paradigm to be borne in mind in interpreting results from other species.

The Central Role of Alanine. Glucose is taken up selectively by the glial cells and converted to glucose-6-P (Tsacopoulos et al., 1988). Since glucose-6-P cannot cross the cell membranes, the next reaction must also be in the glial cells. After incubation of a retinal slice for 60 minutes in the presence of glucose whose carbons were uniformly labeled with $^{14}C([U\text{-}^{14}C])$, about half the radioactivity in tissue homogenates appeared in alanine (Tsacopoulos et al., 1994). Other labeled metabolites, in order of decreasing label, were: trehalose, glucose-6-P, glucose-1-P, α-ketoglutarate, glutamate, and a small amount of aspartate. Other amino acids, even those present in high concentrations in the retina, such as taurine and proline, were not detectably labeled, nor was any labeled lactate detected.

Biosynthesis of Alanine in Drone Retina. Tsacopoulos et al. (1994) propose that alanine is formed from glucose by the pathway, ubiquitous in eukaryotes, leading to amination of pyruvate by alanine transaminase (ALAT):



As mentioned above, α-ketoglutarate and glutamate are, after alanine, the two metabolites resulting from multiple reactions that are most heavily labeled after incubation in $[U\text{-}^{14}C]$glucose. The intermediates between glucose-6-P and pyruvate are unlikely to cross cell membranes so the pyruvate is probably formed in the glial cells. Arguments suggesting that the alanine is also formed in the glial cells are (1) that the necessary enzyme, ALAT, is present in freshly isolated glial cells (Veuthey et al., 1994); (2) that if pyruvate, an optimal substrate for mitochondrial respiration, reached the photoreceptors, it would make no apparent sense for it to be transformed into alanine there. Hence, since alanine *is* produced in the tissue, this probably occurs in the glial cells.

The Fate of the Alanine. If alanine were to be a substrate for the photoreceptors it would need to be reconverted to pyruvate for entry into the Krebs' cycle. The necessary enzyme, ALAT, is present in the photoreceptors as well as in the glial cells (Veuthey et al., 1994). Other compounds, notably proline, are involved in the energy metabolism, but the precise pathways have yet to be worked out. Addition of alanine or proline to the superfusate had no detectable effects on the electrophysiology or O_2 consumption in *slices* (nor did glucose, lactate, pyruvate, or trehalose) (Tsacopoulos et al., 1987). Hence, if any of these is an *in vivo* substrate, it must normally be supplied in adequate amounts by the glia.

Other Invertebrates

Treherne (1960) found that glucose injected into the hemolymph of cockroach is almost all converted to the disaccharide trehalose within 30 minutes. Three hours after an injection of $[U\text{-}^{14}C]$glucose into the hemolymph, the radioactive metabolites in the ventral cord were, in order of decreasing quantity, glutamate, glutamine, glycogen, aspartate, and alanine. Note that the incubation time was three times longer than that used by Tsacopoulos et al. (1994).

In the optic and vertical lobes of octopus brain, Cory and Rose (1969) found that after 2 hours incubation in $[U\text{-}^{14}C]$glucose, the amino acids with the highest specific activities were glutamine and alanine.

The Metabolism of Glucose to Amino Acids in Mammalian Brain

Within 20 minutes of injection of $[U\text{-}^{14}C]$glucose into cat or rat, about 70% of the radioactivity in the brain is in amino acids (Vrba, 1962; Gaitonde et al., 1965). At short times (5 and 15 minutes, in mouse) alanine has the highest specific activity (Shimada et al., 1973). The mean free alanine concentration in mouse brain (calculated from Shimada et al., 1973) is 0.75 mmol/L of cell water, but there are marked regional variations. This is low compared to the concentrations of some other amino acids, such as glutamate + glutamine (21.5 mmol/L of cell water). Hence alanine is both synthesized and metabolized rapidly.

When $[^{15}N]$glutamate is added to the medium bathing astrocytes cultured from rat forebrain, alanine is the most heavily labeled metabolite (Yudkoff et al., 1986). This implies the amination of pyruvate in glial cells, as in drone retinal glial cells.

It should be noted that heavy labeling of a compound does not necessarily mean that it is an intermediate in a pathway. Exchange of label could occur

if forward and backward reactions ran with equal velocities without any net flow of atoms (see Siesjö, 1978, p. 103). However, this appears not to be the case for alanine as Yudkoff et al. (1986) have shown that, whereas there was a net uptake of most amino acids by cultured astrocytes, there was a net release of alanine, which implies that there was a net synthesis.

Differences Between Species

Compared to drone retina, the compartmentation of energy metabolism between neurons and glial cells in mammalian brain is less marked, since mitochondria are quite numerous in astrocytes as well as neurons. Although lactate appears to play little role in the metabolism of drone retina it is clearly more important in mammalian brain, and if substrate transfer from glial cells to neurons exists, then lactate may be a major participant (see also the section *Brain Slices* below and Chapters 13 and 32).

EXOGENOUS SUBSTRATES THAT WILL SUPPORT NEURONAL ENERGY METABOLISM

Invertebrates

Leech Ganglion. Freshly isolated leech neurons will survive for hours with glucose as the metabolic substrate (Wolfe and Nicholls, 1967).

Bee Retina. It has been shown that drone photoreceptors take up little, if any, glucose (see the section *In Insect Retina, Glucose Is Selectively Taken Up by the Glial Cells*). Experiments have begun only recently on photoreceptors isolated from their glial cells (Tsacopoulos et al., 1994) and their substrate requirements are not yet defined.

Mammals and Birds

Brain Slices. Schurr et al. (1988) found that synaptic transmission in brain slices failed rapidly when the superfusate contained only 2 mM glucose but was maintained when the glucose was replaced by 2 mM lactate. The synaptic failure may have been due to the inhibitory action of increased extracellular adenosine, due, in turn, to decreased ATP (Fowler, 1993). It has long been known that the brain (of dog) takes up lactate from blood *in vivo* (Himwich and Nahum, 1929).

Cultured Cells. Facci et al. (1985) found that pyruvate, or α-ketoglutarate or oxaloacetate were essential for the survival of chick neurons. These compounds can be involved in the entry of amino acids into the Krebs cycle. In this system, pyruvate was released by astrocytes (Selak et al., 1985).

RELEASE AND UPTAKE OF ALANINE AND LACTATE

If substrates are transferred between cells via the extracellular space, they should be both released from and taken up by tissue.

Bee Retina

After drone retinal slices have been incubated in [$U^{14}C$]glucose, the principal metabolites that appear in the bath are, in order of decreasing quantity of radioactivity: alanine, glutamate, trehalose (Tsacopoulos et al., 1994). Alanine is also taken up by slices. Incubation in ^{14}C-alanine leads to the appearance of $^{14}CO_2$, which can only be formed, in any quantity, in the mitochondria of the photoreceptors, so part, at least, of the uptake is likely to be into the photoreceptors. The concentration of alanine in the interstitial fluid is 31 mmol/L (Cardinaud et al., 1994). This is higher than the mean concentration in the tissue of 14 mmol/L tissue water, so alanine would enter the photoreceptors down a concentration gradient.

Mammals: Alanine and Lactate

Isolated sympathetic ganglia release and take up alanine and lactate, both of which are formed from glucose (Larrabee, 1992). Astrocytes in primary culture release little glucose, but do synthesize lactate and release it (Walz and Mukerji, 1988) in greater amounts than alanine (Dringen, 1992; see also Yudkoff et al., 1986). It is perhaps pertinent that lactate is an effective substrate for brain slices (see the section *Brain Slices*). Changes in extracellular lactate concentration do not simply reflect changes in anaerobic carbohydrate metabolism. Local stimulation of brain tissue causes an increase in local blood flow that exceeds the local increase in oxygen uptake and PO_2 actually increases (Fox et al., 1988; this was also observed by Penfield, 1971). Despite increased availability of oxygen, extracellular lactate concentration also increases (Fellows et al., 1993).

The metabolism of mammalian neuroglial cells is described in detail in Chapter 32.

GLYCOGEN STORES

The conversion of glucose to glycogen allows a large quantity of carbohydrate to be stored in a cell with-

out a harmful increase in osmolarity. The questions that concern us here are whether glycogen is predominantly located in the glial cells, whether it is broken down in response to neuronal needs, and whether a product of the breakdown is transferred to the neurons (see also Chapter 33).

Invertebrate Ganglia

In several species, neuronal perikarya often have invaginations filled by glial fingers, called *Saftkanälchen* by Holmgren (1900). Wigglesworth (1960) showed by histochemistry and light microscopy that in the ganglia of the ventral nerve cord of cockroach, *Periplaneta,* these glial fingers (forming a "trophospongium") were associated with glycogen, but could not tell if the glycogen was in the glial cells or the neurons. The perineurial cells surrounding the ganglion contained much glycogen but there was little in most of the cytoplasm of the outer and inner glial cells that confront the neurons (Figure 52-2B). He also reported that after 3 to 4 weeks of starvation the ganglia had lost almost all their glycogen, but subsequent electron microscopic studies failed to confirm the mobilization of glial glycogen (N. J. Lane, personal communication). In ganglia of the snail, *Planorbis,* and the horse leech, *Haemopis,* glycogen is present in both neurons and glial cells but is generally more concentrated in the latter (Kai-Kai and Pentreath, 1981; Pentreath et al., 1984). In *Haemopis* the glycogen associated with the trophospongium is in the glial fingers, so this is probably also true in *Periplaneta.* Fischer (1968) reported that forcing *Haemopis* to swim to exhaustion caused depletion of glycogen in the glia but not the neurons. However, V. W. Pentreath (personal communication), when he attempted to confirm this, found a quite different result: the glycogen *increased* in the glial cells (and also in the neurons). Hence in these preparations there is no confirmed demonstration of degradation of glial glycogen in response to neuronal need.

Drone Retina: Evidence for Transfer of Substrates of Energy Metabolism from Glial Cell Stores to Neurons

An exceptionally marked compartmentation of energy metabolism in the drone retina between the neurons (photoreceptors) and the glial cells (outer pigment cells) is apparent from the fact that virtually all the mitochondria are in the neurons, while the glial cells are packed with glycogen granules (Perrelet, 1970; Dimitracos and Tsacopoulos, 1985). Since photoreceptor metabolism appears to be obligatorily aerobic, it is possible to calculate the substrate requirements of the photoreceptors from measurements of their oxygen consumption. A retinal slice superfused with a Ringer solution containing no metabolic substrate will function for several hours even when oxygen consumption is increased up to threefold above resting level by light stimulation (Tsacopoulos et al., 1981, 1994; Tsacopoulos and Poitry, 1983). During this time there is a decrease in tissue glycogen content. Within the experimental scatter of the first measurements (Tsacopoulos et al., 1987) this decrease was sufficient to supply the carbon substrate requirements of the mitochondria in the neurons. Recent measurements on larger numbers of retinas show that the decrease in glycogen alone is not sufficient, but also show that there is a decrease in the tissue content of trehalose and proline (Tsacopoulos et al., 1994). Nevertheless, taken together with other results these measurements constitute a convincing demonstration of neurons being supplied with part of the substrates for their energy metabolism from glial glycogen. However, it appears that only a small part of the glycogen stored in the retinal glial cells can usefully be supplied to the neurons. Drones, which live most of their lives in the dark hive, well fed by workers, use their vision only for the short periods, not longer than 40 minutes, when they fly out of the hive (Witherell, 1971). From the figures in Tsacopoulos et al. (1987), stimulation of the photoreceptors for this time would not consume more than about 10% of the retinal glycogen store.

Vertebrates

In vertebrate brain, glycogen is markedly more concentrated in astrocytes than in neurons (Oksche, 1961; Cataldo and Broadwell, 1986). In keeping with this, an antibody against glycogen phosphorylase isozyme B very selectively stained astrocytes and ependymal cells (Pfeiffer et al., 1990; Chapter 33, this volume). Is this glycogen used to provide substrate for neurons? Watanabe and Passonneau (1973) state that "The content of glycogen in the brain remains remarkably constant under a wide variety of conditions, including starvation. . . ." I have not found supporting data in the literature, probably because negative results were not published. Lowry et al. (1964) did show that brain glycogen is depleted within about 10 minutes during ischemia, but "the order of depletion of the compounds of the energy reserve was P-creatine, glucose, ATP, and glycogen, with the rates for the last two being nearly equal." That is, only when energy metabolism was so per-

turbed that [ATP] had begun to fall were the glycogen reserves drawn upon.

In contrast, glycogenolysis can be readily induced by a variety of transmitter substances (see the section *Neural Control of Glial Metabolism* below), although it is not known if products of glycogenolysis are transferred to neurons *in vivo*. However, in mixed cultures of astrocytes and neurons, Swanson and Choi (1993) found that after astrocyte glycogen content had been increased by insulin stimulation the neurons survived longer periods without exogenous glucose.

Conclusion: The Primary Function of Glial Glycogen Is Not to Serve as an Energy Store

Attempts in cockroach, leech, and mammals to induce glycogenolysis in glial cells by starving the animal have not produced confirmed, positive results. In slices of drone retina, neuronal activity does induce glycogen breakdown in the glial cells, but the quantity of glycogen available appears to far exceed any natural requirement by the retinal neurons. See Swanson (1992) for a different view.

NEURAL CONTROL OF GLIAL METABOLISM

There is evidence, in a range of species, that neuronal activity can modify glial metabolism (see also Chapter 32). Since it is the neurons that are active and have obviously increased metabolic needs, this control of glial metabolism, in ways that are not yet understood, may relate to the supply of substrates from the glia. In their classic work on leech ganglion and *Necturus* optic nerve, Kuffler and coworkers found little that affected glial cells apart from changes in extracellular [K^+]. Since K^+ is released into the extracellular space by electrically active neurons, it was an obvious candidate as a signal from neurons to glia (Kuffler and Nicholls, 1966), and the idea that raised extracellular [K^+] modifies glial metabolism has been investigated a number of times.

Invertebrates

Leech and Snail Ganglia. Pentreath and Kai-Kai (1982) found that nerve stimulation increased the uptake of 2DG into ganglia and its incorporation into glycogen, mainly in the glial cells. A similarly increased uptake was observed when the ganglia were incubated in a physiological saline solution in which [K^+] had been increased from its normal value of 4 mM to about 8 mM. Higher [K^+] caused less uptake. Nerve stimulation has been calculated to cause increases in extracellular [K^+] of about 4 mM in leech ganglion (Baylor and Nicholls, 1969). In this preparation K^+ appears to be a strong candidate for a signal, but at least nine neurotransmitters either increase or decrease the quantity of glycogen and multiple controls are therefore more likely (Pennington and Pentreath, 1987).

Drone Retina. Activation of metabolism in the photoreceptors by light stimulation increases the rate of incorporation of glycosyl groups into the glial glycogen both *in vivo* (Evêquoz et al., 1983) and in superfused slices (Evêquoz and Tsacopoulos, 1991). In slices incubated in the presence of 2-deoxyglucose, stimulation of the photoreceptors also increases the rate of formation of 2DG-6P (Brazitikos and Tsacopoulos, 1991). Raised extracellular [K^+], in contrast, appears to have little effect on glial metabolism. Evêquoz and Tsacopoulos (1991) bathed retinal slices in medium containing radioactive glucose and measured incorporation into glycogen. Like Pentreath and Kai-Kai (1982) for the leech, they doubled bath [K^+] but found that in drone retina this produced no significant increase in glycogen radioactivity. Another argument against an increase in extracellular [K^+] as a signal, at least under physiological conditions, is that during the rather uniform light stimulation that the drone retina is likely to experience when flying, extracellular [K^+] appears to rise little, if at all, beyond the value in the dark (Coles and Schneider-Picard, 1989b; Vallet and Coles, 1993). Nevertheless, during continuous stimulation with no increase in extracellular [K^+], there is an ionic response in the glial cells, indicating the presence of a signal, as yet unidentified (Coles and Schneider-Picard, 1989b).

Vertebrates

Raised extracellular [K^+] stimulates glucose uptake in *Necturus* optic nerve (Salem et al., 1975). In mouse cerebral cortical slices [K^+] promotes glycogen hydrolysis that depends on voltage-dependent Ca^{2+} channels (Hof et al., 1988). In addition to this mechanism, astrocytes (like leach glial cells) have receptors for a range of biological substances, including norepinephrine, serotonin, histamine, vasoactive intestinal peptide, and adenosine, all of which can decrease astrocyte glycogen stores, and may be involved in neural control (for references see Chapter 32, this volume; Cambray-Deakin et al., 1988; and Magistretti et al., 1993). In contrast, insulin causes increased formation of glycogen (Dringen and Hamprecht, 1992).

MAIN CONCLUSIONS

1. *There is no evidence in any preparation that glial cells release glucose to supply adjacent neurons.* (In those orders where glial cells form the blood-brain barrier these barrier glial cells may release glucose into the extracellular space of the nervous system, but the neurons are surrounded by other types of glial cell. Further, it is conceivable that if there were gradients of extracellular glucose concentration, then glucose might enter say one end of an astrocyte and leave at the other end; this would have some analogies with spatial buffering of K^+ [Chapter 47], but would be far less efficient because membrane potential would not contribute.)
2. Leech neurons take up glucose that is supplied by the blood to the extracellular spaces. There is evidence that this is also true in mammalian brain, spinal cord, and retina, although in the last case conflicting results have been published. In contrast, in bee retina glucose is obligatorily taken up only by glial cells which supply a different substrate, probably alanine, to the neurons (Figure 52-3). In vertebrate brain, glucose does not need to arrive through the capillaries, since superfused slices with no blood supply can function. *Some features of the metabolism of the mammalian brain might be more readily interpreted if substrates of energy metabolism were normally transferred from glial cells to neurons. Candidate substrates include lactate and alanine.*
3. In none of the preparations studied (ganglia of leech and cockroach, bee retina, mammalian brain) is there confirmed evidence that glycogen in glial stores is degraded *in vivo* to provide metabolic substrate for neurons.

I thank Q. Pittman, M. Tsacopoulos, and P. Voisin for helpful discussion.

53 Glial cells and activity-dependent central nervous system plasticity

CHRISTIAN M. MÜLLER

PLASTICITY IN THE CENTRAL NERVOUS SYSTEM

Plasticity in the central nervous system has been defined in many different ways. In principle, every change in the physiological properties or morphological appearance of elements in the brain can be subsumed under central nervous system plasticity. This may include developmental sequences, adaptive changes, or responses to central nervous damage. In this chapter the definition will be restricted to two major points. First, it deals only with plasticity relevant to changes in neuronal network properties—areal patterning, axonal circuitry, and functional transmission. This restriction excludes some experimental data summarized in other chapters of this book, for example, development and modifications of the blood-brain-barrier or control of cell lineage (e.g., Chapters 8 and 50). Second, it excludes those plastic changes that reflect genomically controlled developmental sequences, for example, growth or differentiation processes intrinsic to brain constituents. It also excludes the issue of functional regeneration after brain damage and refers instead to other chapters of this book. This chapter focuses on experience-dependent changes in neuronal properties related to development or to learning and memory. Experience- or activity-dependent adaptive changes will be defined as those changes in circuitry, morphology, or synaptic transmission of neurons which occur due to neuronal activity and result in long-lasting functional changes of the neuronal network.

Developmental plasticity and putative mechanisms of learning and memory appear to share a number of features (and possibly also mechanisms). They are therefore dealt with in a more or less parallel and comparative fashion.

A number of processes or phenomena related to the issues under consideration here are discussed in other chapters. Thus, I will restrict the description of such phenomena to the minimum essential for understanding of the models and hypotheses presented. In order to keep this overview brief, only selected examples will be used to support proposed mechanisms of glial involvement in plastic changes. A more detailed summary of experimental data can be found in Müller (1992a).

Developmental Plasticity

One of the most obvious activity-dependent plastic changes in the central nervous system occurs during the development of ordered projections. This includes the elaboration of both long-range projections and local circuitry. This developmental process can be separated into two successive phases: first an activity-independent phase leading to the elaboration of a fairly inaccurate set of neuronal connections, and then a phase of activity-dependent refinement. The first process seems to occur under genomic instruction and relates to neuronal migration, axonal pathfinding, and synaptogenesis (Dodd et al., 1988). The role of glial cells, especially astrocytes, in these processes is described in other chapters of this book (e.g., Chapters 27 and 28). The necessity for complementing this genomically structured patterning of neuronal circuitries by an activity-dependent process becomes clear when comparing the number of synaptic connections (about 10^{12}) to the overall information in the genome and considering the unpredictability and complexity of epigenetic influences on the functioning of the brain. Examples of the latter are the exact positioning of the eyes or corneal curvature, both being critical variables in the correct computation of stereoscopic depth by the central visual pathway. A more general epigenetic factor important for certain human brain structures is the country or area of birth—it is easy to see that this is of considerable importance for language-processing and language-producing structures.

The basic framework for the refinement of neuronal connections appears to follow two general rules:

1. From the preformed connections, the only ones that are stabilized are those that reveal functional effectiveness, as determined by the success in acti-

vating postsynaptic targets. This paradigm is extended by the feature that effective pathways can furthermore increase their local number of transmission sites (synapses) or efficacy (transmitter release or postsynaptic effects). The original hypothesis for this phenomenon has been formulated by Donald Hebb (1949) and was later extended by Gunther Stent (1973).

2. In the vicinity of transmission sites that follow the above-mentioned rule, synaptic sites that do not reveal effective transmission are downregulated (functional depression) or even eliminated (competitive plasticity).

Very often these two mechanisms are restricted to circumscribed periods during development, the so-called "sensitive" or "critical" periods. The temporal onset and the time course of these periods differs from species to species and between different structures. Comparative studies are therefore helpful to assess possible underlying mechanisms. The two mechanisms, that is, stabilization/proliferation of effective and destabilization/elimination of ineffective afferents, are sufficient to explain a number of activity-dependent refinements of neuronal connections. Two examples from the development of the visual system will clarify this point.

With respect to the activity-dependent stabilization of connections, the organization of retinal afferents to their target structures may serve as an example. Retinal afferents to postsynaptic structures are retinotopically organized, that is, neighborhood relations of cells in the retina coding for a given spot in the environment in the central nervous system are maintained in the pattern of synaptic connections in the target regions. This selective organization is gradually developed and refined. Once the afferent fibers have grown into the target and have elaborated a crude topography, visual experience will help to stabilize effective connections and eliminate inappropriately located synapses. This is mediated by the fact that afferents from neurons that terminate in regions where the majority of their "retinal neighbors" make synapses have a high chance to act in concert with their neighbors and activate postsynaptic cells. As these afferents have the opportunity to proliferate they will tend to increase their efficacy and/or synapse number at one given location in the retinotopic organization and thereby increase the chance for further stabilization and increase in efficacy. The activity-dependence of such a process can be shown by deprivation experiments or by suppressing neuronal activity with transmitter receptor antagonists or substances blocking action potentials, for example, tetrodotoxin or glutamate receptor antagonists (Schmidt, 1985). Under these circumstances no refinement of the physiological response specificity occurs.

The second paradigm, the elimination of a given "ineffective" set of afferents when it competes with "effective" afferents, can be clarified by summarizing the effects of monocular deprivation on the thalamocortical projections in the mammalian visual system. Afferents from either eye can convey information from an identical location in the visual environment, that is, are activated by stimuli in the same receptive field. Therefore these afferents compete for the same location in the retinotopic organization in the visual cortex. This normal competition, which usually leads to the spatial segregation of territories innervated by one or the other eye (for review see Müller, 1992a), can be driven into an extreme by depriving one eye from normal vision. Under these conditions the active set of afferents can stabilize and proliferate, while the other is eliminated on the long run because it can never participate in local postsynaptic activation. Again, this process can be shown to rely on neuronal activity as it can be prevented by appropriate pharmacological intervention (e.g., Harris and Stryker, 1986). This paradigm can be used for both the elaboration of local topographies and very global forms of organization, for example, the modality coded in a given sensory structure (auditory information in auditory cortex, visual information in visual cortex, etc.). Possible mechanisms of synapse stabilization and synapse elimination being the very basis for the elaboration of topographical connections will be summarized later.

In summary, developmental plasticity is usually refined to "critical periods" and is based on an activity-dependent selection from a set of exuberant, but imprecisely targeted, afferents by means of stabilization/proliferation and destabilization/elimination. These processes are the basis for the determination of areal boundaries, topographically organized long-range connections, and specific intrinsic connectivities.

Activity-Dependent Plasticity in the Mature System

Activity-dependent plasticity in the mature central nervous system is viewed as an equivalent to the behaviorally defined phenomena of learning and memory. Although the basic mechanisms may often be similar to those underlying developmental plasticity they usually lack a defined "critical period" and are generally believed to rely on changes in synaptic strength (efficacy) rather than resulting from a morphological change in the number/location of synapses. However,

both statements are far from exclusive. For example, it is sometimes hard to decide precisely whether a change in synaptic efficacy is due to a change in the number of transmission sites or due to some change in metabolic processes underlying synaptic strength. This will be clearer when considering hippocampal long-term potentiation as an example for activity-dependent plasticity of a mature system. With respect to the presence of "critical periods," it has to be noticed that efficacy changes may be more dramatic in immature systems than in mature systems (Harris and Teyler, 1984). It may therefore be considered that plasticity in the mature system results from the fact that the critical period for such phenomena is very long (sometimes lifelong).

Hippocampal long-term potentiation is probably the best studied form of activity-dependent plasticity in the mature system and is defined as a long-lasting increase in the efficacy of an afferent pathway to activate a postsynaptic target due to a brief, highly efficient stimulus (for review see Teyler and DiScenna, 1987). Originally this phenomenon was investigated by monitoring the (postsynaptic) field potential elicited by electric stimulation of an afferent pathway. This postsynaptic response is quite constant when the afferent pathway is stimulated at low frequency, for example, every 5 to 10 seconds. One burst of high-frequency stimulation to this pathway—tetanic stimulation with a frequency of 100 Hz for 1 second—results in a long-lasting increase in the efficacy of the afferent pathway to induce a postsynaptic field potential. The increase in the postsynaptic response can either result from the formation of more synaptic sites, or from an increased efficacy in existing synapses. The latter is currently assumed. This conclusion is mainly based on the observation that miniature excitatory postsynaptic currents, which originate from activation of a single synapse, are enhanced following long-term potentiation (Bekkers and Stevens, 1990; Malinow and Tsien, 1990). On the other hand, it has been shown that also the number of synapses is increased following the induction of long-term potentiation (Lee et al., 1980; Chang et al., 1984). It can therefore be assumed that both mechanisms may contribute to the manifestation/maintenance of long-term potentiation, new formation of synapses (similar to the paradigm described for developmental plasticity above) and an increase in synaptic efficacy due to "metabolic" changes. The latter can originate from an increase in transmitter release, a reduced transmitter metabolism/reuptake, an increased receptor sensitivity/availability, or an increase in the efficacy of receptor activation (e.g., increases of ion channel conductance). The analysis of the mechanisms underlying all these possibilities not only includes the final mechanisms proper, but also the intermediate "trigger steps." In the following sections I summarize several ways of how glial cells can contribute to such trigger steps and the proposed possibilities for manifestation of long-term potentiation and its maintenance.

Regeneration

Regeneration can be defined as the recapitulation of developmental processes in the mature system to compensate for central nervous injury. As this issue is discussed in further detail separately in Chapters 27 and 57, I will confine myself to those issues that may be relevant for the understanding of processes underlying normal development and activity-dependent plasticity. As will be outlined later, the widespread failure of regeneration in the mature mammalian central nervous system may shed some light on possible mechanisms underlying critical periods for developmental plasticity. Conversely, mechanisms underlying successful regeneration in certain brain structures or at certain developmental stages may help to understand possible mechanisms of synapse formation in activity-dependent increases of synaptic transmission.

Summary

In the last sections the basic features of activity-dependent plasticity have been outlined. Plasticity in the central nervous system was defined as a change in functional properties of synaptic connections being based on a morphological change (number and location of synaptic contacts) or "metabolic" changes (efficacy of synaptic transmission). Possible underlying mechanisms are summarized in Figure 53-1. With respect to developmental plasticity a crucial feature is the limitation of adaptive changes to restricted critical periods. Plasticity in the mature brain may be based on similar mechanisms but may persist because of a very long critical period. Limitations in the presence or persistence of plasticity over development may be similar to mechanisms that lead to limitations in regeneration. In the following sections I elucidate possible mechanisms of how glial cells can contribute to or even mediate changes in neuronal transmission which result from "experience."

GLIAL CELLS AND DEVELOPMENTAL PLASTICITY

Axon Growth and Areal Boundaries

One basic feature of brain architecture is the presence of functional subunits that are interconnected

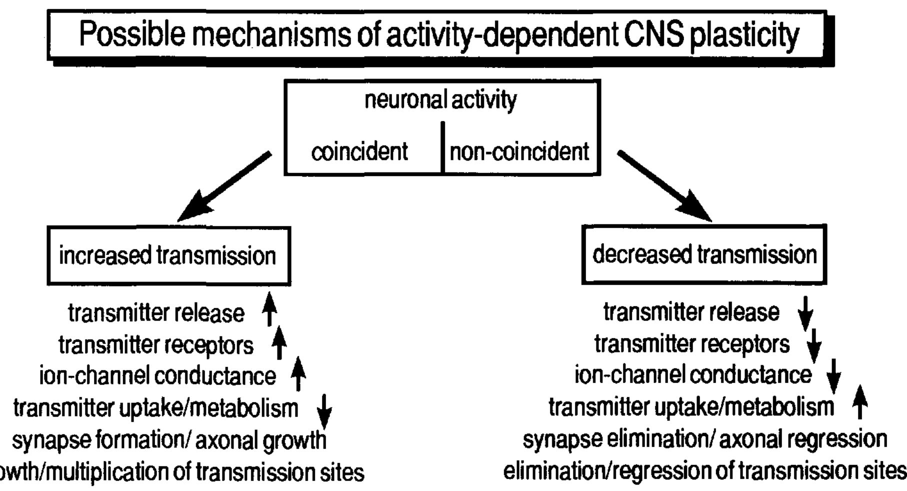

FIG. 53-1. Summary of possible mechanisms underlying activity-dependent plasticity of neuronal transmission. Depending on the correlation of pre- and postsynaptic activity synaptic efficacy can be either enhanced (coincident activity) or reduced (non-coincident activity). Note that the efficacy changes can be mediated by "metabolic" or "morphological" changes. See text for further information.

by specific projections. Neuronal activity has been shown to play an important role in the elaboration of the brains functional architecture. One example for the influence of neuronal activity in the elaboration of functional subunits comes from deprivation experiments. If one sensory modality is impaired, by sensory deprivation or removal of the sensory organs, the according representations are (or remain) functionally innervated by afferents from other modalities (Sur et al., 1990). This phenomenon is based on the principles of axon guidance and activity-dependent refinement of projections. In early development, axons are guided to their future target regions by environmental cues (Dodd et al., 1988). Three possibilities are currently discussed: (1) extracellular guidance molecules, which "mark" selective axon trajectories, (2) spatiotemporal limitations in the accessibility of target structures for innervation, and (3) diffusible molecular "attractors" for selective axonal populations.

To date it is unclear which (or which combination) of these mechanisms underlies axonal targeting. However, recent studies on the retinotectal system of the frog (Gooday, 1990) support the notion that glial cells may be an important component of such mechanisms. When growing axons, *in vitro*, have the opportunity to select between a glial monolayer cultured from tissue of their normal pathway *in situ* and one cultured from a neighboring region (which they do not cross in normal development), they select the former. This finding may indicate that astrocytes carry the information for axonal growth direction. Extracellular membrane proteins or soluble factors originating from glial cells may serve as the guidance molecules. Another guidance cue for outgrowing axons appears to originate from oligodendroglial cells, which express a neurite growth inhibitor. Myelinating oligodendrocytes have been shown to surround growth-permissive "tunnels" for late-growing fiber tracts, thereby contributing to their growth direction (Schwab and Schnell, 1991). As mentioned before, such guidance cues are not sufficient for the elaboration of precise projection patterns. In a following section I address the question of mechanisms for such refinement.

A second phenomenon in early development is the elaboration of area-specific neuronal morphologies and the crystallization of separate structures. The latter can be either areal or intraareal substructures. For both phenomena glial cells seem to be of considerable importance. With respect to neuronal morphology, it has been shown *in vitro* that dopaminergic cells of the mesencephalon elaborate their characteristic morphology only when cultured on a layer of astrocytes or in the presence of media conditioned by astrocytes from the appropriate central nervous system structure (Denis-Donini et al., 1984; Lieth et al., 1989; Rousselet et al., 1990). This effect can not be achieved when using striatal astrocytes. It can therefore be concluded that the glial environment plays an important role in the elaboration of local neuronal specificities. The underlying molecular mechanisms for the glia-neuronal interaction and the characteristics of the obvious regional heterogeneity of glial cells are not understood.

A similar importance of astroglial cells has been shown for the establishment of intraareal structures. A well-studied system is the somatosensory cortex of rodents. This structure is characterized by a highly specific architecture, the so-called "barrels." Barrels are circular arrangements of neuronal somata surrounding a central area containing the den-

drites and receiving the afferent fibers. Each barrel structure receives information of one specific whisker on the rodent's snout (Woolsey and van der Loos, 1970). The formation of barrels depends on the afferent input, and transplantation studies have suggested that the capacity for barrel formation is not confined to future somatosensory cortex (Schlaggar and O'Leary, 1991). One possible mechanism of barrel formation can be deduced from the developmental sequence. Following the ingrowth of afferent fibers, astrocytes initially form the future barrel boundaries. This can be shown by the rapid expression of cytoskeletal proteins at these locations and the expression of specific glycoproteins (Cooper and Steindler, 1986a,b). Only subsequently neuronal somata migrate to or aggregate at these boundaries. Experimental data from another, similar structure support the notion that astrocytes are essential for the formation of barrellike structures. In the developing olfactory system of an insect a very similar sequence of the crystallization of morphological substructures occurs (Tolbert and Orland, 1989). Again, afferent fibers grow into the target, induce glial cells to aggregate at future glomerular structures, which then serve as boundaries for migration of neuronal somata. It can be shown that the glial reaction is an essential step in the formation of glomeruli, as these do not form when the number of glial cells is significantly reduced by glial specific toxins or early irradiation (Tolbert and Orland, 1989).

The data summarized above indicate that glial cells, especially astrocytes, play an important role in the elaboration of areal subdivisions triggered by afferent input and the establishment of axonal connectivities. The underlying mechanisms of neuroglial and glia-neuronal information transfer are not yet understood. The latter seems to be mediated by membrane-bound or soluble glial proteins.

Refinement of Projection Patterns

As summarized in the introduction, mature central nervous circuitries elaborate from a crude projection pattern by the elimination of aberrant and stabilization/proliferation of accurate connectivities. Several observations point to an involvement of glial cells in according mechanisms. Synapse elimination can be mediated by at least three different mechanisms: (1) retraction of synaptic structures/axons, (2) active separation of synaptic boutons from postsynaptic structures and subsequent phagocytosis or degeneration, and (3) destabilization and lysis by environmental enzymes. Glial cells can contribute to the latter two mechanisms. From electron microscopic analyses of the developing spinal cord a sequence of events has been described that corresponds to the second putative mechanism. It could be shown that during early postnatal development of the cat boutons on spinal motoneurons are successively ensheathed by astroglial processes and separated from their postsynaptic target (Conradi et al., 1975). Concomitantly, axonal material was found engulfed in astrocytes. This paradigm would be in line with an involvement of astrocytes in developmentally regulated synapse elimination. Further support for such a causal relation comes from *in vitro* studies. Cultures from cerebellar tissue undergo two phases when cultured for prolonged time periods—an initial exuberant synaptogenesis followed by a period of reduction of synaptic density. When glial cells are eliminated from the cultures the second phase fails to take place (Meshul et al., 1987; Seil et al., 1988). However, substitution of glia by addition of optic nerve astrocytes reinduces the process. Electron microscopic observations have revealed a mechanism similar to the one described in the developing spinal cord. Also in cultured neuromuscular junctions synapse elimination takes only place in the presence of cocultured glial cells (Chapron and Koenig, 1989).

These data point to an important and essential role of astrocytes in activity-dependent synapse elimination. Studies on the developing mammalian visual cortex suggest that only immature astrocytes may mediate synaptic plasticity. The development of astrocytes in the cat visual cortex reveals a close temporal correlation with the critical period for cortical malleability (Müller, 1990, 1992b). Furthermore, transplantation of cultured, immature astrocytes to the mature visual cortex reinduces cortical plasticity restricted to the sites of transplantation (Müller and Best, 1989). Conversely, gliotoxic substances infused into the kitten visual cortex suppress cortical plasticity (Imamura and Mataga, 1993). The exact mechanisms underlying these findings are yet not fully understood, but it is suggested that the effect may correspond to an astroglia-mediated synapse elimination (Müller, 1992a). This may result from active synaptic displacement/phagocytosis, as proposed in the spinal cord and cerebellar cultures. A first step in the activity-dependent synapse elimination by glial cells may be the growth of astroglial processes following neuronal activation (Wenzel et al., 1991). This process may also be mediated by synaptic destabilization/degradation by secreted glial enzymes. *In vitro* studies have shown that astrocytes secrete significant amounts of proteases at time periods corresponding to the height of the crit-

ical period for cortical malleability (Kalderon et al., 1990).

A second glial population presumed to participate in synaptic and axonal remodeling are microglial cells. Transient macrophages, present in the cortical white matter have been shown to be involved in the phagocytosis of exuberant interhemispheric projections in the cat cortex (Innocenti et al., 1983). Recent data from our laboratory show that a similar phenomenon can also be observed at thalamocortical interconnectivities (Müller, in preparation). Up to now there is no evidence for a similar involvement of microglial cells/macrophages in synaptic remodelling of the developing cortex. However, following central nervous damage activated microglial cells have been shown to displace synapses from postsynaptic structures (Blinzinger and Kreutzberg, 1968). This may be indicative for differences in the mechanisms of "physiological" and "pathological" plastic events. From the summarized experiments it can be deduced that glial cells play an important role in the elimination of axons and synapses during development and following central nervous damage. Astrocytes seem to play the dominant role in synapse elimination during development, while microglia is involved in axon elimination during development and synapse displacement following central nervous injury. The mechanism of neuroglial information transfer triggering such events is yet unclear. The presence of such an information transfer is suggested by data from the hippocampal formation and the mammalian cortex, showing that astroglial morphologies and neuronal ensheathement by astrocytes is influenced by neuronal activity (Sirevaag et al., 1991; Wenzel et al., 1991). The signaling pathway may include cations released from active neurons, by neurotransmitters acting on glial receptors, or diffusible second messengers released from active neurons (Müller, 1992). The latter may include novel signaling mechanisms like nitric oxide, which have been shown to target glial biochemical signaling cascades (Agulló et al., 1992). A direct effect of the excitatory neurotransmitter glutamate on filopodia formation in astrocytes has recently been shown (Cornell-Bell et al., 1990) and may represent a first step in the separation of synapses from postsynaptic structures.

Besides their role in synapse elimination glial cells may also be involved in mechanisms of activity-dependent synapse formation. This can be mediated by a release of neurotrophic substances from glial cells or growth-promoting matrix molecules. There is abundant information about the capacity of glial cells to release neurotrophins. A detailed summary of such phenomena and mechanisms can be found in separate chapters of this book (e.g., Chapters 29 and 30).

CHANGES IN SYNAPTIC EFFICACY MAY INCLUDE GLIAL CELLS

Synapse Formation

As summarized above, changes of synaptic efficacy are thought to underlie learning and memory formation. Efficacy changes may originate from multiple mechanisms, some of which can involve glial cells. Efficacy changes due to the formation of additional synapses can be mediated by the mechanisms described for developmental plasticity, that is, the release of neurotrophic factors. Interestingly, growth factors have been shown to support or even induce long-term potentiation in the hippocampus (Terlau et al., 1990a, 1990b). Furthermore, tetanic stimulation has been reported to induce the release of neurotrophins and long-term potentiation-inducing agents (Sastry et al., 1988b; Xie et al., 1991). A more global effect mediated by the release of neurotrophins may explain the finding that long-term potentiation is not restricted to coincidently active pre- and postsynaptic structures, but is also expressed by activated afferent structures in the vicinity (Bonhoeffer et al., 1989).

Influences on Neuronal Excitability

Glial cells can also participate in efficacy changes due to metabolic changes in synaptic transmission. One possibility is an activity-dependent reduction of transmitter uptake by glial cells, which increases the availability of transmitter in the synaptic cleft. Arachidonic acid, which has been proposed as a signaling mechanism from activated neurons to the site of long-term potentiation manifestation (Williams et al., 1989) leads to a prolonged reduction of glutamate uptake into astroglial cells (Barbour et al., 1989). Another possibility for a glial role in activity-dependent efficacy changes is the release of substances by glial cells that affect the postsynaptic sensitivity to transmitters. Astroglia-conditioned media have been shown to increase responses of hippocampal neurons to NMDA-receptor agonists (Forsythe et al., 1988). Glycine, which has been shown to be released from glial cells (Zafra et al., 1990), may be a potential candidate for such an effect. Furthermore, astroglial cells may even release receptor agonists, which may change the excitability of nearby neurons. Homocysteic acid, an endogenous NMDA-receptor agonist, has recently been localized to central nervous astrocytes (Cuénod et al., 1990). Another mechanism for

the modulation of neuronal excitability by glial cells is the change of the extracellular pH (Ransom, 1992). A final possibility is a long-lasting change in the ionic milieu surrounding neurons which may change neuronal excitability.

Direct evidence for a glial participation in synaptic efficacy changes is as yet sparse. One experimental approach used concomitant glial depolarization by intracellular current injection paired with weak- and low-frequency afferent stimulation (Sastry et al., 1988a). It was reported that coincident afferent stimulation and glial depolarization induced long-term potentiation of surrounding hippocampal neurons. The failure to repeat this finding (Konietzko and Müller, unpublished observations) suggests to me that glial depolarization may not be sufficient to induce long-term potentiation in the hippocampus. However, it may be a necessary prerequisite, as blockade of astroglial depolarization by potassium channel blockers prevents long-term potentiation induction (Bonhoeffer and Müller, 1991). It can be hypothesized that glial transmitter receptors have to be activated coincidently with depolarizing signals from postsynaptic structures. Recent data from organotypic hippocampal cultures have shown that stimulation of afferent pathways induces an elevation of the intracellular calcium concentration in astrocytes (Dani et al., 1992). This signaling pathway may furthermore be important for activating possible mechanisms of glial cells that influence neuronal transmission. Recent data have shown that propagating calcium waves in astrocytes can trigger neuronal activity (Needergaard, 1994). Future investigations have to address this issue more specifically.

In summary, a hypothesis of long-term potentiation involving glial cells appears to be attractive, but is speculative. However, the presence of pathways for neuroglial signaling and the multiple possibilities for glial cells to influence neuronal synaptic transmission validate and call for additional studies on this possibility.

POSSIBLE RELATIONSHIP OF MECHANISMS CONTROLLING SUCCESSFUL REGENERATION AND DEVELOPMENTAL PLASTICITY

As detailed summaries on the role of glial cells in the control of successful regeneration can be found in other chapters of this book, I will restrict myself to summarizing the most important findings that can be related to developmental plasticity of neuronal circuitries. Regeneration relies both on the presence of growth-permissive factors in the extracellular environment, as well as on the absence of growth-inhibiting molecules. As detailed elsewhere (e.g., Chapter 57), both conditions rely to a great extent on glial-derived substances. It may be argued that critical periods for developmental plasticity share mechanisms with the control of regeneration, for example, an involvement of glial cells. Support for this hypothesis comes from correlative studies showing that myelination often corresponds to the time of termination of critical periods (Müller, 1992a). During myelination oligodendrocytes have been shown to express neurite growth inhibitors (Caroni et al., 1988; Schwab et al., 1988). Interestingly, it has been reported recently that neuronal activity considerably influences the oligodendroglial cell lineage (Barres and Raff, 1993). It can therefore be assumed that interactions between neurons and oligodendroglial cells determine the time course and the amount of myelination. This may be of considerable importance in explaining the prolongation of critical periods due to sensory deprivation and/or regional differences in the time course of myelination (Müller, 1990). Recent data from our laboratory have shown a correlation of the critical period for visual cortical plasticity and the occurrence of myelin-associated neurite growth inhibitors (Müller et al., 1993). Conversely, glial-derived matrix proteins, which support neurite growth, are predominantly or even exclusively expressed during critical periods. *In vitro* studies have shown that the growth permissiveness of visual cortical tissue reveals a gradual decrease with the time course of the critical period (Müller and Schoop, 1992). Further support for a causal relation of the ability of central nervous structures to perform regeneration and activity-dependent plasticity comes from studies in the olfactory system. These structures reveal a lifelong capacity to regenerate and also reveal a high degree of activity-dependent plasticity (Haberly et al., 1989; Doucette, 1990).

From the forementioned data it follows that glial cells may play an important role in the control of plasticity in the mammalian brain. Especially oligodendrocytes seem to be involved in the restriction of plastic changes in central nervous circuitries to early postnatal periods. Plasticity in structures that have passed the critical period may be reinduced using experimental manipulations which reinduce successful regeneration, namely, an inactivation of oligodendroglial neurite growth inhibitors (Schnell and Schwab, 1990).

In summary, regeneration may underlie similar constraints than critical period plasticity, namely developmental changes of the growth-permissiveness of the tissue. Glial cells may be viewed as the instructor defining temporal and spatial limits of developmental plasticity and regeneration. The mechanisms

SUMMARY

Activity-dependent plasticity plays an important role in the structuring of the central nervous system and allows adaptive changes to occur during development and in the mature system. Two basic mechanisms may explain most if not all plasticity phenomena: (1) morphological changes of the circuitry, that is, synapse formation and synapse elimination, and (2) "metabolic" changes affecting synaptic efficacy, e.g., changes in transmitter availability or neuronal sensitivity to transmitter substances. As shown in the present overview glial cells can easily be implemented in mechanisms underlying such phenomena. Possible mechanisms are summarized in Figure 53-2. Furthermore, several experimental data appear to be more logical when implementing a more global mechanisms of plasticity control than those assumed to act selectively at the synaptic level. As research on a possible role of glial cells in activity-dependent plasticity is a rather recent discipline it is impossible to offer a conclusive view or a fully proven hypothesis. However, the accumulating information on glial cells and their capacity to influence neuronal properties warrants inclusion of this cell population in experimental approaches to and theories of complex brain functions.

I thank Michaela Schweizer for helpful criticism and comments. This work was supported by the Bundesministerium f. Forschung und Technologie (0316902A).

54 Release of neuroactive amino acids from glia

GIULIO LEVI AND VITTORIO GALLO

ASTROCYTES AS RESPONSIVE ELEMENTS IN NEUROTRANSMISSION

During development and in the adult brain, astroglial cells are anatomically situated in close contact to neurons. Astrocytes not only influence information processing between neurons, but are themselves responsive elements in the central nervous system network. In fact, they express voltage- and ligand-gated channels (Barres et al., 1990a; von Blankenfeld and Kettenmann, 1991), as well as receptors coupled to other intracellular second-messenger systems (Murphy and Pearce, 1987; Jensen and Chiu, 1991). These functional properties suggest that astrocytes are a target for signals originating from neuronal activity.

Neurons and astrocytes appear to be part of a loop in which astroglial cells respond to chemical signals from neurons by sending back other messages in the form of neuroactive and neurotrophic substances, which include not only classical neurotransmitters and neuromodulators but also growth factors, cytokines, and prostanoids (for reviews see Merrill, 1991 and Martin, 1992). Most of the experimental studies that revealed such astrocyte features were performed with cultured cells, which may not exhibit the properties of mature, postmitotic astrocytes *in situ*. It is not clear to what extent the properties of astrocytes in the living brain are superimposable on those observed *in vitro*.

It has been long known that astrocytic uptake of neurotransmitters (amino acids and biogenic amines) released from nerve terminals is one of the inactivation mechanisms operating in synaptic transmission (Hösli et al., 1986; Kimelberg, 1986). Due to the absence of storage vesicles, the neurotransmitters taken up by astrocytes are generally rapidly catabolized and are therefore unlikely to be utilized again as chemical signals, as it is believed to be the case for nerve endings. Some transmitter amino acids (glutamate, aspartate, glycine, taurine), however, are present at fairly high concentrations in astrocytes (see Levi and Patrizio, 1992), which have the enzymatic machinery for their synthesis (Hertz, 1982; Huxtable, 1989). Another transmitter amino acid, γ-aminobutyric acid (GABA), appears to be present at minimal levels, but can be synthesized through the putrescine pathway (Barres et al., 1990b; Laschet et al., 1992). In view of the above considerations, it is interesting that recent evidence indicates that certain physiological and physiopathological stimuli can induce release of neuroactive amino acids from astrocytes.

In this chapter, we describe the different types of stimuli that can cause amino acid release, the possible mechanisms of release and alterations of release occurring in conditions mimicking some pathological states of the central nervous system. We will also briefly analyze the behavior of different subpopulations of astrocytes and, therefore, the possibility that these cells are functionally heterogeneous, as suggested also by many other studies (e.g., Shinoda et al., 1989; Usowicz et al., 1989; Wilkin et al., 1990; McCarthy and Salm, 1991; Amundson et al., 1992; Batter et al., 1992; Ito et al., 1992). Finally, we mention some recent studies of the release of glutamate from microglia, a glial cell type that is currently the object of intensive investigation because of its likely involvement in many neuropathological processes. The synthesis and release of neuroactive substances from astrocytes have been reviewed by Martin (1992). The term "release" is used here to mean "exit" from intracellular pools into the extracellular space, independently of the mechanism.

EXPERIMENTAL MODELS USED TO STUDY RELEASE FROM GLIAL CELLS

Because of the intrinsic heterogeneity of nervous tissue, most studies have utilized cell cultures enriched in astrocytes and other glial cell types to analyze the biological properties of these cells independently of other cellular partners present *in vivo*. In particular, the study of the release of neuroactive compounds from astrocytes *in situ* is hampered by the difficulty

of determining the cellular origin of the released material (e.g., astrocytic vs neuronal). An attempt to cope with this difficulty has been made by Paulsen and Fonnum (1989), who used an *in vivo* microdialysis technique to study the release of glutamate and GABA from the rat neostriatum previously treated with the gliotoxin fluorocitrate or with methionine sulfoximine, an inhibitor of the glial enzyme glutamine synthetase. The information provided by this technique, however, is related more to the role of glial cells as a source of transmitter amino acids for neurons than to the process of release from glial cells.

Astrocytes obtained from different brain regions of neonatal animals readily grow in primary culture and can be easily maintained *in vitro* for several days or weeks under conditions that prevent the survival and growth of neurons (Levison and McCarthy, 1991). Often, however, it is necessary to manipulate the cultures to minimize the contamination by oligodendrocytes, their progenitors, and/or microglial cells (McCarthy and DeVellis, 1980; Giulian and Baker, 1986). The purity of the cultures is usually assessed by immunocytochemical staining with antibodies raised against a panel of cell-specific antigens and, in particular, staining for glial fibrillary acidic protein (GFAP), a cellular marker for differentiated astrocytes (Bignami et al., 1972). Primary or secondary cultures are widely used to study the biochemical and physiological properties of a relative pure cell population of astrocytes generally obtained from a single brain area. It has to be noted, however, that studies performed with astrocytes obtained from different parts of the brain have revealed the existence of regional functional heterogeneity, possibly related to the functional specialization of anatomically related neurons (Drejer et al., 1982; Wilkin et al., 1990; Ransom, 1991; Amundson et al., 1992; Batter et al., 1992).

Some experimental studies have dealt with the question of whether astrocyte subtypes differ in their physiological properties (Lerea and McCarthy, 1989; Usowicz et al., 1989; Ito et al., 1992), including stimulus-coupled release of neuroactive substances (Gallo et al., 1989a; Levi and Patrizio, 1992). For this purpose, primary glial cultures have been further manipulated in order to obtain systems enriched in type-2 or in type-1 astrocytes (Aloisi et al., 1988).

Glial cell lines have also been frequently used to study astrocyte physiology and, in particular, release of neuroactive amino acids. For example, the transformed astroglial cell line LRM55 has been extensively used by Martin and coworkers to study taurine release and its mechanisms (Madelian et al., 1985; see below). LRM55 cells express GFAP and exhibit an astrocytic phenotype, including HCO_3^+/Cl^- exchange, glutamine synthesis, morphological changes induced by increasing intracellular cAMP levels and receptor-induced taurine release (Madelian et al., 1985; Martin et al., 1990).

RECEPTOR-INDUCED RELEASE OF NEUROACTIVE AMINO ACIDS FROM ASTROCYTES

Vertebrate glial cells and, in particular, astrocytes express a variety of neurotransmitter receptors, either coupled to membrane ionic channels, or to various intracellular second messenger systems (Murphy and Pearce, 1987; Barres et al., 1990a; Jensen and Chiu, 1991; von Blankenfeld and Kettenmann, 1991). Astrocytic neurotransmitter receptors have been well characterized in their pharmacology and functional properties (Kimelberg, 1988), which appear to be similar in culture and *in situ* (Kimelberg, 1988; Walz and MacVicar, 1988; Clark and Mobbs, 1992). The activation of some receptor types with the proper ligands causes release of various neuroactive compounds from astrocytes (Martin, 1992). The most detailed studies concern the receptor-stimulated release of amino acids (Drejer et al., 1982; Madelian et al., 1985, 1988; Gallo et al., 1989a and 1991; Levi and Patrizio, 1992).

Receptor-Induced Release of Taurine

Martin and coworkers have found that [^{3}H]taurine is released from the cell line LRM55 and from primary cortical astrocytes upon activation of β-adrenergic receptors (Madelian et al., 1985). In LRM55 cells the K_m and the B_{max} for the binding of the β-adrenergic agonist iodohydroxybenzylpindolol were of the same order of magnitude as those found in C6 glioma cells or in primary astrocytes (Madelian et al., 1985). Receptor agonists increased cAMP formation and caused [^{3}H]taurine release with a similar pharmacology. The β-adrenergic agonist isoproterenol was more effective than epinephrine and norepinephrine, and comparable EC_{50} values could be obtained from the dose-response curves of the three agonists on cAMP formation and [^{3}H]taurine release. The antagonists alprenolol and propranolol inhibited the agonist-induced cAMP increase and taurine release in the same concentration range and with similar IC_{50} values (Madelian et al., 1985). The link between cAMP and release of the amino acid was further suggested by the similarity of the time course of the effects on cAMP and taurine release and by the stimulation of [^{3}H]taurine release by the

cAMP analogue dibutyryl-cAMP (Madelian et al., 1985).

The release of [^{3}H]taurine triggered by β-adrenergic receptor activation was not affected by increasing or decreasing the intracellular Ca^{2+} concentration, nor by release of calcium from internal stores (Shain et al., 1989).

Waniewski et al. (1991) investigated whether taurine could be stored in different subcellular compartments and released from distinct pools. The findings in LRM55 glial cells were consistent with the idea that exogenous taurine mixes homogeneously with endogenous taurine and that both endogenous and radioactive taurine are released by isoproterenol from a single intracellular pool. Because the release of five other amino acids (aspartate, glutamate, glutamine, glycine, and alanine) was not affected by isoproterenol, the authors concluded that taurine release is not due to a nonselective loss of cytosolic components and suggested that it may be mediated by the membrane transport system. Other evidence, however, argues against this interpretation (see Martin, 1992, p. 89) and leaves the problem of the mechanism of isoproterenol-evoked taurine efflux unsolved.

Taurine can be released from glial cells also upon activation of different types of receptors (adenosine, serotonin, glutamate, and k-opiate receptors). Madelian et al. (1988) demonstrated that adenosine can increase cAMP accumulation and [^{3}H]taurine release in LRM55 cells, and a pharmacological characterization of the effects observed indicated the involvement of the A_2 subtype of adenosine receptors. Although the adenosine EC_{50} value for taurine release was much lower (1.6×10^{-6} M) than that for cAMP accumulation (5×10^5 M), the analysis of the dose response curve led the authors to suggest that taurine release may be triggered by relatively small increases of cAMP levels. A direct demonstration of the linkage between cAMP elevation and adenosine-induced taurine release is, however, lacking.

Agonists for other receptors were studied in less detail. For example, serotonin and the k-opiate receptor agonist U50-488 were shown to stimulate astroglial taurine release through a cAMP-independent mechanism, but the second messenger possibly associated with this effect is not known (Martin et al., 1988). Interestingly, both serotonin and U50-488 could, at appropriate concentrations, synergize with isoproterenol with respect to taurine release, while either inhibiting (serotonin) or leaving unchanged (U50-488) the cAMP response to isoproterenol. Thus, it seems that more than one intracellular second messenger can be involved in the regulation of taurine release from astrocytes (Martin et al., 1988).

The case of glutamate receptor activation illustrates yet another aspect of evoked taurine release. Ionotropic glutamate receptors of the kainate-AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) subtype are expressed mainly in the type-2 subpopulation of astrocytes (Usowicz et al., 1989; Jensen and Chiu, 1991; Wyllie et al., 1991), while type-1 astrocytes express mainly metabotropic glutamate receptors linked to phosphoinositide turnover (Pearce et al., 1986; de Barry et al., 1991; Jensen and Chiu, 1991). Exposure of type-2 astrocytes to micromolar concentrations of kainate or quisqualate stimulated the release of endogenous taurine (and of other amino acids, see below), while type-1 astrocytes were insensitive to these glutamate agonists (Levi and Patrizio, 1992). The releasing action of kainate and quisqualate was antagonized by 6-cyano-2,3-dihydroxy-7-nitro-quinoxaline (CNQX), a non-*N*-methyl-D-aspartic (NMDA) receptor antagonist inactive on metabotropic receptors. These observations suggest that taurine release was related to the depolarizing action of kainate and quisqualate, which was presumably more pronounced in type-2 astrocytes, due to the much greater expression of the corresponding ionotropic receptors in these cells.

In conclusion (see Figure 54-1, left panel), taurine can be released from astroglial cells upon activation of several types of neurotransmitter and neuropeptide receptors. In some cases the evoked release seems to be associated to an increase of intracellular cAMP concentration, or to other as yet unidentified second messengers, while in other cases release is probably caused by the depolarization consequent to the activation of ionotropic receptors. At least in the latter cases, it is likely that taurine efflux occurs through the Na^+-dependent membrane transport system, whose operation in an outward direction would be facilitated by the increased intracellular Na^+ concentration (see below, for a more detailed discussion).

The activation of glial receptors coupled to taurine release might indirectly cause inhibition of neuronal activity, but *in vivo* evidence to support this hypothesis is lacking.

Receptor-Induced Release of [^{3}H]γ-Aminobutyric Acid

Differently from neurons, glial cells express the non-NMDA subtypes of glutamate receptors, but not NMDA-activated channels (Sontheimer et al., 1988; Gallo et al., 1989a; Usowicz et al., 1989; Berger et al., 1992; Clark and Mobbs, 1992). We first demonstrated that activation of non-NMDA receptors

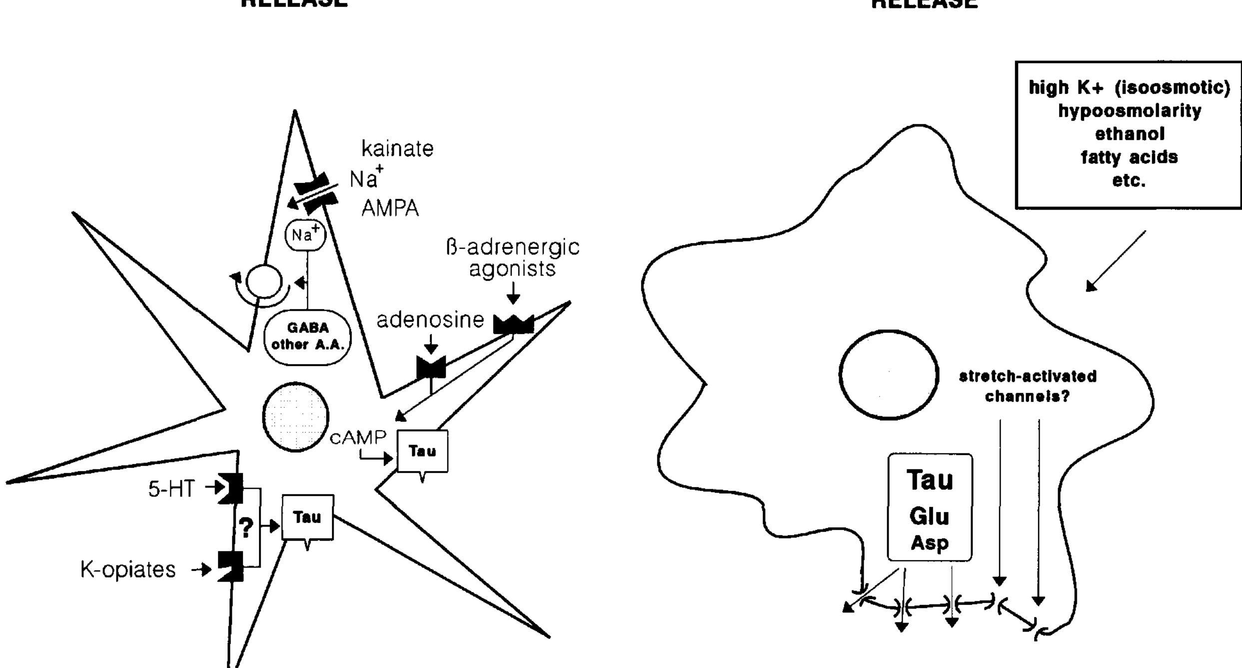

FIG. 54-1. Schematic view of the release of neuroactive amino acids from astrocytes consequent to receptor activation or swelling. See text for details.

by micromolar concentrations of kainate, AMPA and quisqualate stimulated [^{3}H]GABA release from type-2 astrocytes, whereas NMDA was totally ineffective (Gallo et al., 1989a, 1991). The releasing effects of the non-NMDA receptor agonists were inhibited by the antagonists kynurenic acid and CNQX (Gallo et al., 1989a, 1991). In particular, the IC_{50} values for CNQX inhibition of kainate- and quisqualate-stimulated release were in the low micromolar range, similar to those described for neurons (Gallo et al., 1991).

Non-NMDA receptor agonists did not stimulate [^{3}H]GABA release from astrocyte cultures highly enriched in type-1 astrocytes (Gallo et al., 1989a). This was not due to the limited ability of type-1 astrocytes to accumulate [^{3}H]GABA, as compared to type-2 astrocytes (Levi et al., 1983; Johnstone et al., 1986), since the same phenomenon was observed with preaccumulated [^{3}H]D-aspartate (Gallo et al., 1989a), which is avidly taken up by both types of astrocytes (Levi et al., 1983). A more likely explanation (see also below) is that the density of ionotropic non-NMDA receptors in type-1 astrocytes is much lower than in type-2 astrocytes.

Electrophysiological experiments (Usowicz et al., 1989; Wyllie et al., 1991) and fluorescence image analysis of intracellular Ca^{2+} (Jensen and Chiu, 1991) confirmed that glutamate-gated channels of the non-NMDA type are mainly expressed by type-2 astrocytes. In whole-cell patch-clamp recordings, glutamate, kainate, and quisqualate generated large depolarizing currents in type-2 astrocytes. In outside-out patches, single-channel currents induced by glutamate and its agonists displayed five distinct subconductance states identical to those previously identified in cultured central neurons (Cull-Candy and Usowicz, 1989; Usowicz et al., 1989). NMDA did not elicit any response in cerebellar astrocytes.

In the [^{3}H]GABA release experiments, evidence was obtained that glutamate agonists were acting at common receptors with different affinities. In fact, AMPA and quisqualate, applied together with kainate at concentrations around or above their EC_{50}, antagonized the stimulatory effect of kainate on [^{3}H]GABA release. On the other hand, the releasing action of kainate was potentiated by concentrations of quisqualate in the low micromolar range, particularly when the concentration of kainate was at the borderline of effectiveness (Gallo et al., 1989a, 1991). Also in this respect, the behavior of astroglial non-NMDA receptors was similar to that previously described for neurons (Gallo et al., 1989b).

We also addressed the question of the mechanism by which GABA is released in response to glutamate receptor-mediated depolarization. Based on the hypothesis that glutamate receptor-stimulated release

of [^{3}H]GABA could occur through the membrane transport system for GABA, cerebellar astrocyte cultures were preloaded with [^{3}H]GABA and then exposed to the potent GABA uptake inhibitor nipecotic acid for different periods of time, prior to stimulation with kainate. Five minutes of preincubation with nipecotic acid inhibited kainate-stimulated [^{3}H]GABA release by about 50%, whereas exposure to the transport inhibitor for 25 minutes reduced the releasing effect of kainate by 80% (Gallo et al., 1991). Nipecotic acid by itself did not modify [^{3}H]GABA release. In a parallel set of experiments, we also observed that [^{3}H]nipecotic acid was accumulated by type-2 astrocytes and that it could be released by kainate and quisqualate from the same cells (Gallo et al., 1991).

Additional evidence for the involvement of the membrane transport system in [^{3}H]GABA release from astrocytes was provided by experiments in which membrane transport was inhibited by manipulating the ionic composition of the extracellular medium. When the NaCl present in the medium was replaced by LiCl, [^{3}H]GABA uptake into type-2 astrocytes (a strictly Na^+-dependent process) was inhibited (Gallo et al., 1991), but the application of kainate still generated a large non-desensitizing current similar in size and noise level to that produced by kainate in the presence of Na^+ (Wyllie et al., 1991). This is consistent with the fact that Li^+ ions can permeate glutamate-gated channels similarly to Na^+ (Wyllie et al., 1991). Kainate-induced [^{3}H]GABA release was inhibited by about 40% in a medium containing 50% LiCl, and by more than 90% in the medium in which NaCl was totally replaced by LiCl (Gallo et al., 1991). These findings suggest that activation of non-NMDA receptors on type-2 cerebellar astrocytes causes a large influx of Na^+ (or Li^+) ions and that the increased intracellular Na^+ enhances [^{3}H]GABA release by facilitating the operation of the GABA carrier in an outward direction (see Figure 54-1, left panel). However, increased intracellular Li^+ does not support GABA outward transport. Indirectly, these observations also indicate that depolarization *per se* is not sufficient to elicit GABA release from astrocytes. A similar carrier-mediated release mechanism has been described for GABA in retinal horizontal cells (Schwartz, 1987) and for glutamate in retinal Müller cells (Szatkowski et al., 1990). All these findings support the idea that nonvesicular release of amino acids from glia can occur through their membrane carrier, and confirm the old observation that amino acid efflux from neural cells can be mediated by the membrane transport system (Levi et al., 1966).

Interestingly, also in oligodendrocyte/type-2 astrocyte (O-2A) progenitors, that take up [^{3}H]GABA and release it in response to glutamate receptor agonists, the releasing effect of kainate was strongly inhibited when Na^+ was replaced by Li^+ (Gallo et al., 1991).

What could be the functional significance of the [^{3}H]GABA release studies described in this paragraph? Is glutamate likely to stimulate GABA release from astrocytes *in vivo?* The *in vivo* concentration of GABA in astrocytes is probably very low, since these cells show only limited ability to synthesize the amino acid [GABA synthesis from putrescine has been reported to occur *in vitro* preferentially in type-2 astrocytes (Barres et al., 1990b), but also in a cell population presumably enriched in type-1 astrocytes (Laschet et al., 1992)] and the GABA taken up from the extracellular fluid is likely to be rapidly catabolized. Although it cannot be excluded that the activation of glutamate receptors stimulates the release of newly taken up GABA or of endogenously synthesized GABA from type-2 astrocytes, the most cautious way to look at the results reported in this section is to consider the behavior of preaccumulated [^{3}H]GABA as an index of the behavior of other endogenous amino acids (see following section).

Another aspect of the problem of the functional significance of the results described in this paragraph is the expression of ionotropic non-NMDA receptors by astrocytes *in vivo*. As already mentioned, in culture such receptors are present mainly in type-2 astrocytes and O-2A progenitors (see Barres et al., 1990b), although their expression in type-1 astrocytes was noted to increase with culturing time (Wyllie et al., 1991). Glutamate-activated currents were described also in glial cells *in situ*, using the patch-clamp technique in brain slices (Walz and MacVicar, 1988; Berger et al., 1992; Clark and Mobbs, 1992). In the living brain the identification of type-2 astrocytes is still elusive and the exact glial localization of non-NMDA receptors remains to be established.

Receptor-Induced Release of Endogenous Amino Acids

The studies reported above are compatible with the idea that release of neuroactive compounds from astrocytes and their progenitors can be regulated by fluctuations in the extracellular concentration of glutamate. Indeed, endogenous amino acids can be released from cultured astrocytes upon non-NMDA receptor activation. Using secondary cultures of rat neonatal cortex highly enriched in type-1 or type-2 astrocytes, it was found that the endogenous level of most amino acids was substantially higher in type-1

than in type-2 astrocytes. Yet the basal release of only two of these amino acids, glutamine and taurine, was higher in type-1 astrocytes (Levi and Patrizio, 1992). Cultured type-2 astrocytes released several but not all endogenous amino acids in response to kainate or quisqualate. Glutamate release was doubled over baseline and a significant increase in the release of aspartate, glycine, taurine, and alanine was also observed (Levi and Patrizio, 1992). Serine and glutamine were also released by kainate and quisqualate, respectively. The releasing action of the two agonists was reversed by the non-NMDA receptor antagonist CNQX, indicating that release occurred as a consequence of receptor activation. In type-1 astrocyte cultures, neither kainate nor quisqualate modified endogenous amino acid release (Levi and Patrizio, 1992). In the experimental conditions tested (10 minutes exposure to micromolar concentrations of agonists), neither kainate nor quisqualate caused any appreciable increase in cell volume, indicating that the evoked release of amino acids was not related to cell swelling (see below). It is instead likely that the enhanced release of the various endogenous amino acids occurred through a mechanism similar to that described for [^{3}H]GABA in the previous paragraph, namely Na^+-dependent, carrier mediated outward transport.

In rat hippocampal cultures containing mostly type-1 astrocytes, Lehmann and Hansson (1988) found that kainate (100 μM) enhanced glutamine and taurine release by 34 and 85% over baseline, respectively. At a higher dose (1 mM), kainate enhanced the release of all the amino acids measured, glutamate and aspartate being by far the most affected. The effect of kainate was strongly attenuated by the receptor antagonist kynurenic acid, although at millimolar concentrations. Several mechanisms, including cell swelling (see below), could be responsible for the releasing effect of millimolar concentrations of kainate observed in hippocampal astrocytes. However, the possibility of regional differences in excitatory amino acid receptor expression in type-1 astrocytes should also be considered, in view of the regional specialization of astrocytes observed in numerous studies (Drejer et al., 1982; Walz and MacVicar, 1988; Lerea and McCarthy, 1989; Shinoda et al., 1989; Spruce et al., 1990; Wilkin et al., 1990; Amundson et al., 1992; Batter et al., 1992).

DEPOLARIZATION-INDUCED AND SWELLING-INDUCED RELEASE OF AMINO ACIDS FROM ASTROCYTES

Several authors have reported that depolarization of cultured astrocytes with high K^+ stimulates the release of a restricted group of amino acids, namely, taurine (Philibert et al., 1988; Pasantes-Morales and Schousboe, 1989; Martin et al., 1990), glutamate and aspartate (Martin et al., 1990; Levi and Patrizio, 1992), and histidine (Albrecht and Rafalowska, 1987). There is, however, no consensus as to the mechanism by which these amino acids are released, and it is possible that the mechanism of release is not identical for all amino acids and for all glial preparations used. High K^+ is known to cause astroglial swelling when K^+ replaces Na^+ isoosmotically, and hypoosmotic swelling is associated to release of the same group of amino acids (Martin et al., 1990; Pasantes-Morales et al., 1990). On the other hand, exposure of astrocytes to high K^+ in hypertonic conditions depolarized the cell membrane (Walz, 1987), but induced neither swelling nor amino acid release (Martin et al., 1990), suggesting that depolarization is not sufficient to evoke release. At least in the case of taurine, the K^+-induced release has been attributed to the increased tension of the cell membrane due to the augmented cell volume rather than to increased outward transport (for review see Martin, 1992). Increased membrane tension could open stretch-activated ion channels (Kimelberg et al., 1990; Martin et al., 1990) linked to the cell cytoskeleton (Sachs, 1987) and taurine may diffuse through these channels (Figure 54-1, right panel). Indeed, Sanchez-Olea et al. (1991) have shown that in swollen astrocytes taurine fluxes are mediated by passive diffusion.

In the case of glutamate (and possibly aspartate), the astroglial transport system is highly sensitive to extracellular K^+, and elevated extracellular K^+ should facilitate outward transport when the ratio between intra- and extracellular glutamate is high (Martin 1992). In keeping with this expectation, Szatkowski et al. (1990) have elegantly demonstrated, by electrophysiological recordings in salamander retinal Müller cells, that glutamate is released through its membrane carrier upon depolarization. Glutamate transport is electrogenic, therefore glutamate movements across the membrane could be monitored by whole-cell patch-clamp recording of the current associated with activation of the membrane carrier. Elevated extracellular K^+ generated an outward current when Müller cells were patched with pipettes containing both cotransport substrates Na^+ and glutamate (Szatkowski et al., 1990). These experiments, however, do not rule out the possibility that in mammalian astrocytes a component of the K^+-induced glutamate release occurs by mechanisms similar to those hypothesized for taurine.

In contrast to the neuronal release of neurotransmitters, no clear evidence for a direct involvement of

Ca^{2+} in the depolarization-induced and swelling-induced release of amino acids from astrocytes has been provided. The K^+-induced release of taurine was reported to be enhanced (Holopainen et al., 1985) or inhibited (Philibert et al., 1988; Tigges et al., 1990) in Ca^{2+}-free medium containing 1 mM EGTA. Such a medium, however, caused a substantial increase in the spontaneous release of [^{3}H]taurine and [^{3}H]D-aspartate (Holopainen et al., 1985; Philibert et al., 1988; Martin et al., 1989; Holopainen and Kontro, 1990), which makes the results of K^+-evoked release difficult to interpret. Other observations agree in showing that hypotonic, high K^+-, or ethanol-induced amino acid release from astrocytes, believed to be due to swelling, are not Ca^{2+}-dependent (Martin et al., 1989, 1990; Kimelberg et al., 1990, 1993). It is pertinent to recall that exposure of astrocytes to hypotonic media causes a depolarization of the cell membrane proportional to the hypoosmolarity of the incubation medium (Kimelberg and O'Connor, 1988). The fact that Ca^{2+} ionophores are unable to stimulate taurine release from astrocytes (Shain et al., 1989) suggests that an increased intracellular Ca^{2+} level is not sufficient to elicit the release of this amino acid.

Astrocytes have been reported to express voltage-dependent Na^+ channels (Bowman et al., 1984; Barres et al., 1990a). In particular, type-2 astrocytes express the neuronal type of Na^+ channels (Barres et al., 1990b). It may be therefore surprising that veratridine (which depolarizes the cell membrane by locking Na^+ channels in an open position) was unable to elicit release of endogenous amino acids from either type-1 or type-2 astrocytes (Gallo et al., 1982; Levi and Patrizio, 1992). Although depolarization by itself is not expected to evoke amino acid release (see above), the increased intracellular Na^+ level, which should follow the exposure to the alkaloid, would be expected to facilitate outward amino acid transport, similar to that observed in the case of kainate-induced amino acid release (see the section *Receptor-Induced Release of [^{3}H]γ-Aminobutyric Acid*). It is possible that the density of Na^+-channels in the astroglial preparations used was not high enough to warrant a sufficient entry of Na^+ into the cells. At variance with the results summarized above, Holopainen and Kontro (1990) reported that veratridine (0.1 mM) caused a modest, but statistically significant enhancement in the release of preloaded [^{3}H]D-aspartate from cultured cerebellar astrocytes (presumably type-1).

In vivo, astroglial membranes are not believed to be depolarized by the propagation of action potentials. However, in extreme conditions such as epilepsy or spreading depression they could be depolarized by excess extracellular K^+. In view of the *in vitro* observations reported in this paragraph, high extracellular K^+ could elicit the release of some neuroactive amino acids either directly or by inducing astroglial swelling, and this might have functional consequences on neighboring neurons.

GLUTAMATE RELEASE FROM MICROGLIA

Microglial cells are generally believed to play an important role in brain inflammatory, autoimmune, and, possibly, neurodegenerative processes. It has also been suggested that microglia infected with the human immunodeficiency virus (HIV) or exposed to HIV products, such as the coat protein gp120, may produce neurotoxic substances (glutamate, quinolinic acid, or others) responsible for excitotoxic neuron death (Giulian et al., 1990; Gehrman et al., 1992; Lipton, 1992). In a recent study (Piani et al., 1991), it has been reported that microglial cells obtained from neonatal mice produce massive amounts of glutamate, when cultured in an apparently resting state, in a serum-free medium in the presence of 2-mM glutamine. The supernatant of such cultures, collected over a 6-hour period, contained 130 μM glutamate and was highly toxic for cultured cerebellar interneurons, such toxicity being prevented by NMDA receptor antagonists. When microglial cells were activated by exposing them to lipopolysaccharide (LPS) or interferon-γ only a modest increase in neurotoxicity of supernatants was observed (glutamate level, however, was not measured in these conditions). The release of glutamate from microglia is unlikely to be modulated or enhanced by the activation of ionotropic neurotransmitter receptors, which seem to be absent on microglial membranes (Kettenmann et al., 1990).

Although the above observations generated a lot of interest, in view of the possible identification of a microglia-produced neurotoxin, they should be interpreted with caution. Indeed, a massive production of glutamate by resting microglial cells would be hard to reconcile with normal brain function, considering the abundance of these cells in the brain (Lawson et al., 1990). Moreover, there seem to be substantial species difference in the ability of microglia to produce and secrete glutamate, and the magnitude of glutamate release (as evaluated by glutamate accumulation in the culture medium) varies in function of the experimental conditions adopted. In recently published experiments (Patrizio and Levi, 1994) we found that rat and mouse microglia subcultures grown in a serum-free, glutamine-free defined medium, released only minimal amounts of

glutamate over a 6-hour incubation period. In the presence of a physiological concentration of glutamine (0.5 mM), glutamate release was substantially increased. Moreover, mouse microglia was found to contain and release more glutamate than rat microglia. Since glutamate reuptake was virtually absent in microglia, glutamate accumulation in the culture medium increased with time and with cell density. For example, when 10^6 mouse microglial cells were cultured in 0.4 ml of medium in 2-cm^2 wells, the concentration of glutamate in the medium rose to about 60 μM in 6 hours, a value approaching that reported by Piani et al. (1991). A variety of microglia-activating or depolarizing agents, used to simulate pathophysiological conditions [lipopolysaccharide (10 to 100 ng/ml), HIV coat protein gp120 (0.1 to 10 nM), high K^+ (35 mM), or ATP (150 μM)], did not alter rat or mouse microglial glutamate release when the cells were cultured in serum-free medium. However, in the presence of 1% fetal calf serum [which contains protein factors necessary for binding of lipopolysaccharide to its receptor CD14 (Wright et al., 1990)], 100 ng/ml of lipopolysaccharide caused a 2- to 3-fold increase in the accumulation of glutamate in the medium in a 6-hour period. In conclusion, it can be hypothesized that microglia-derived glutamate might contribute to microglial neurotoxicity in those pathological conditions in which intense local recruitment of activated microglial cells takes place. This hypothesis, however, is not supported by *ex vivo* findings showing that the major neurotoxic product of activated microglia obtained from brains subjected to trauma or ischemia can not be identified with glutamate nor other glutamate agonists (Giulian et al., 1993). In conclusion, the issue of glutamate as a putative microglial neurotoxin should be subject to further examination, also in view of the fact that experimental data on human microglia are so far lacking.

PATHOPHYSIOLOGY OF AMINO ACID RELEASE FROM ASTROCYTES

As briefly mentioned in previous sections of this chapter, and amply discussed in recent reviews (Kimelberg et al., 1992; Martin, 1992), astrocyte swelling leads to an enhanced release of some neuroactive amino acids (taurine, glutamate, aspartate). Astrocyte swelling can be induced *in vitro* in a variety of conditions, such as hypoosmotic media, high K^+, high glutamate, ethanol, free fatty acids, lactoacidosis, and acid-base changes, and is known to occur *in vivo* in several pathological states, especially ischemia, trauma, hepatic encephalopathy, status epilepticus, experimental allergic encephalopathy, hypoxia, and brain surgery (for reviews see Kempski et al., 1992; Kimelberg, 1992; Kimelberg et al., 1992). It seems therefore legitimate to suggest that astrocyte swelling can determine an imbalance of extracellular neuroactive amino acids in the brain, which may have important functional consequences.

In other pathophysiological experimental models, the release of some amino acid seems to be affected quite specifically. For example, the neurotoxin aluminum, which has been implicated in the pathogenesis of several neurological diseases, has been reported to enhance the release of [^{3}H]taurine, but not that of [^{3}H]GABA, from cultured rat cortical astrocytes (Albrecht and Noremberg, 1991), while the release of [^{3}H]GABA appeared to be specifically enhanced by high K^+ in bulk-isolated astrocytes obtained from rats with experimental hepatogenic encephalopathy (Albrecht and Rafalowska, 1987). In both these studies, cell swelling was not measured, and only two amino acids were analyzed.

One important and still largely unsolved problem is the involvement of astrocytes in the pathogenesis of brain damage following an ischemic insult. In particular, we are referring to the possible role of astrocytes in the establishment of the high extracellular levels of glutamate that have been reported in the ischemic brain (e.g., Benveniste et al., 1984; Hagberg et al., 1985; Globus et al., 1988; Andiné et al., 1991; Katayama et al., 1991) and have been proposed to be responsible for the generation of ischemic neuronal damage (reviewed by Meldrum, 1989; however, see Globus et al., 1992 for some observations in apparent contrast with the generally held views).

It is difficult to study *in vivo* the cellular origin of the glutamate release induced by ischemia, and this problem has been approached *in vitro* using primary neuronal and astroglial cultures, with conflicting conclusions. Drejer et al. (1985) found that the high K^+-induced release of preloaded [^{3}H]D-aspartate was increased when cerebellar glutamatergic interneurons were exposed to "ischemic" conditions (anoxia + hypoglycemia), but was unaffected when astrocytes were subjected to the same treatment. More recently, Ogata et al. (1992) found that the "spontaneous" release of endogenous glutamate and aspartate was considerably enhanced in astrocyte cultures exposed to a similar "ischemic" condition, whereas the release from neurons was hardly affected. Cell swelling was not measured in either study. Although the two groups reached opposite conclusions, suggesting a major role of neurons (Drejer et al., 1985) or of astrocytes (Ogata et al., 1992), respectively, in the accumulation of extracellular glutamate during ischemia, the two sets of data

are not mutually exclusive. In fact, both the depolarization-induced release from neurons and the spontaneous release from astrocytes could contribute to the establishment of high extracellular glutamate levels. It is obviously difficult to suggest which of the two processes prevails *in vivo*. Since in the living brain extracellular K^+ has been found to be elevated under ischemia (Astrup et al., 1977; Hansen et al., 1980) it is possible that such elevation causes astrocyte swelling, which would lead to an enhancement of glutamate release from these cells, and neuronal depolarization, which would lead to synaptic release of glutamate, if the depolarized neurons are glutamatergic (see Figure 54-2).

CONCLUSIONS

Release of neuroactive amino acids from astrocytes can be induced by "physiological" stimuli, such as neurotransmitters acting at specific recognition sites on the astroglial membrane at "physiological" concentrations, as well as by "pathophysiological" stimuli, such as excess of K^+, excess of glutamate, neurotoxins, altered pH, and so on. Many stimuli of the latter type are secondary to different kinds of brain injury, and stimulate amino acid release through the induction of swelling.

The consequences of neuroactive amino acid release *in vivo* are, at present, only matter of speculation. For example, our knowledge on the existence of regional differences in the expression of neurotransmitter receptors is so far limited (Wilkin et al., 1990), and it is not known whether the release profile or the ability to undergo swelling is identical in astrocytes from different brain areas.

In very general terms, it can be suggested that in physiological conditions the release of neuroactive amino acids from astrocytes induced by the activation of various types of receptors or by small changes in the level of extracellular K^+, consequent to neuronal firing, may represent a further mechanism for finely tuning neuronal activity. It is conceivable that in pathological conditions such a mechanism will be disrupted, and that the establishment of vicious circles will cause self-potentiation of the pathological process. For example, the accumulation of extracellular glutamate and K^+ following an ischemic insult could induce astrocyte swelling with further glutamate and K^+ efflux and consequent potentiation of swelling and excitotoxicity (Figure 54-2).

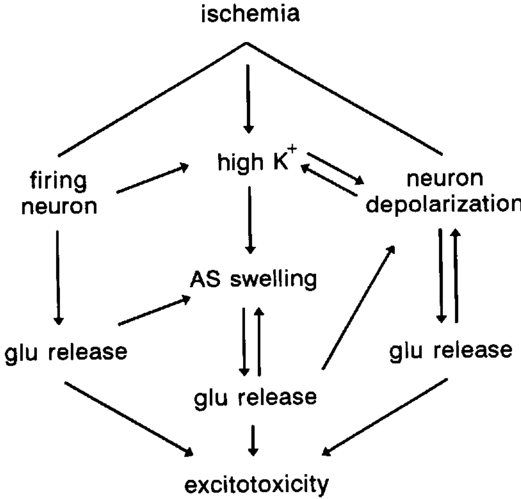

FIG. 54-2. Hypothetical vicious circles in ischemia-related glutamate neurotoxicity. Ischemia may increase glutamate (*glu*) release from firing neurons and cause neuron depolarization, and hence glu release, due to the rise in extracellular K^+. Extracellular K^+ could also cause astrocyte (*AS*) swelling and glutamate loss from these cells. The excess of extracellular glu could potentiate astrocyte swelling and neuron depolarization. The accumulation of extracellular glu resulting from these processes could be neurotoxic.

XI Role of Glia in Injury and Regeneration

This page intentionally left blank

55 Glial cells and regeneration in the peripheral nervous system

S. A. GILMORE AND T. J. SIMS

In the mid-nineteenth century August Waller carried out a series of investigations which documented that the "elementary" or "primitive" fibers (today designated axons) of a nerve underwent degenerative changes when removed from continuity with the brain or spinal cord. Section of the glossopharyngeal nerve in the frog revealed alterations distal to the site of division as early as the third day postlesion. The substance of these elementary fibers was noted initially to be separated into particles of various sizes, and by the twentieth day these particles were reduced to a granular state. These particles and granules were noted to be contained in what was called a "tubular membrane." Waller (1850) emphasized that such alterations were not unique to the glossopharyngeal nerve but occurred also following section of the hypoglossal nerve and the sciatic nerve. Thus, these early studies established clearly two basic principles of peripheral nerve morphology. First, that continuity of the nerve fibers or axons with a trophic center is necessary for survival. Second, that despite the degenerative changes in the axons, an element of the peripheral nerve associated with these degenerating axons and designated as the "tubular membrane" maintained its integrity. Another key early observation regarding peripheral nerves was that regenerating nerves grew toward distal stumps even when these stumps were misplaced (Ramón y Cajal, 1928). This nonrandom, directed growth was referred to as chemotropism or neurotropism by Ramón y Cajal, who suggested that substances diffused from the distal segment and attracted or directed the regenerating axons. The persistence of Schwann cells and their arrangement into organized "bands" distal to a site of nerve injury was described by von Büngner (1891), and it was these cells which Ramón y Cajal implicated in the production of these tropic substances. In the ensuing years, investigators have documented the potentials for axonal regrowth and defined the roles of other constituents of peripheral nerves, for example, endoneurial tubes, basal laminae, macrophages, and vasculature, in both degenerative and regenerative events in injured peripheral nerves (for reviews see Hall, 1989; Uzman et al., 1989; Fawcett and Keynes, 1990). This chapter focuses on the multifaceted roles of Schwann cells in these events.

SCHWANN CELL PROLIFERATION

During the course of normal growth and development, Schwann cells proliferate to accommodate elongation of growing neurites. Once a state of maturity is attained, proliferation ceases and the population is quiescent (Terry et al., 1974; Brown and Asbury, 1981). This state of quiescence undergoes a rapid transition when a nerve is injured, and within 2 to 3 days Schwann cells in the segment of nerve distal to an injury site revert to a proliferative state (Bradley and Asbury, 1970; Pellegrino et al., 1986). This proliferative state persists until axonal regrowth and myelination or ensheathement are complete.

Mitogens responsible for Schwann cell proliferation are not well understood (Eccleston, 1992). A number of conditions or agents have been demonstrated to be mitogens in the *in vitro* situation, but it is not clear that these play a functional role *in vivo*. Included among these are axonal contact, extracellular matrix, cyclic AMP analogues, and certain peptide growth factors. Of these, loss of axonal contact due to retraction of myelin was considered early (Causey and Palmer, 1953) and remained under investigation in recent years (Crang and Blakemore, 1986). In fact, the maintenance of Schwann cell-axonal association or contact has long been considered to be a major factor in inhibition of significant proliferative activities in the proximal portion of the injured nerve (Ingebrigtsen, 1916; Abercrombie and Johnson, 1942).

Axolemmal preparations and myelin membrane preparations individually exert mitogenic effects on Schwann cells *in vitro*, and the molecules responsible are thought to be membrane-bound polypeptides (Salzer and Bunge, 1980; Salzer et al., 1980). It is

likely that these stimuli come into play in quite different situations *in vivo*, and that different mechanisms are involved. For example, the axolemma exerts its effects directly on the Schwann cell surface and is functional during normal development and in regrowing or regenerative phases. An interesting consideration regarding the axolemmal influence relates to axoplasmic transport. One of the primary functions of fast anterograde axoplasmic transport is the delivery of material for insertion into the axolemma. If fast anterograde axoplasmic transport along a nerve is blocked by focal chilling prior to transection, the premitotic activity of Schwann cells is accelerated (Oaklander and Spencer, 1988). This observation suggests that the proliferation induced in Schwann cells in a segment of nerve in which fast anterograde transport mechanisms are no longer intact may be associated with depletion of a signal normally brought to the membrane by fast transport.

The myelin-derived stimulus as a Schwann cell mitogen, on the other hand, comes into play during Wallerian degeneration. Further, since this stimulus comes into play during a time when myelin is degenerating, the mitogenicity of myelin is considered by some to be dependent upon the presence of macrophages. Under usual circumstances, macrophages enter nerves at the site of injury and become involved with removal of myelin (Beuche and Friede, 1984; Perry et al., 1987; Stoll et al., 1989, and others) along with the Schwann cells (Berner et al., 1973; Nathaniel and Pease, 1963). *In vivo* evidence, on the one hand, indicates that Schwann cells fail to proliferate when a nerve is isolated from macrophages (Beuche and Friede, 1984). Other studies, on the contrary, demonstrate Schwann cell proliferation in explanted segments of nerve lacking macrophages (Crang and Blakemore, 1986). Inability to recruit macrophages into the injured nerve site retards clearance of degenerating myelin but does not preclude nerve regeneration (Lunn et al., 1989). Thus, although the role of macrophages in myelin-derived mitogenicity remains unsettled, it is generally agreed that myelin can serve as a mitogen and that the myelin-derived stimulus requires lysosomal processing by one or more cell types.

The use of myelin-enriched preparations to study Schwann cell proliferation *in vitro* raised the question of whether only those Schwann cells that previously formed myelin are capable of responding to a myelin-derived stimulus. Exposure of Schwann cells to such fractions resulted in proliferation of a portion of the cultured Schwann cells, and continued exposure of the daughter cells to the fraction resulted, in turn, in their proliferation (Yoshino et al., 1987). Evidence from that study, as well as from an earlier study by Salzer and Bunge (1980), suggests that the population of cultured Schwann cells that recognizes the myelin-enriched fraction is the population that previously formed a myelin sheath.

It is not clear if this mechanism exists *in vivo*, but several interesting observations on "myelinated" versus "unmyelinated" nerves merit comment. Schwann cell proliferation is much more robust in myelinated nerves than in unmyelinated nerves. For example, in a myelinated nerve, such as the sciatic nerve, a peak labeling index of 15.5% was noted autoradiographically on the third day following injury (Bradley and Asbury, 1970). A peak labeling index of only 2.5%, however, was noted following injury to the unmyelinated cervical sympathetic trunk (Romine et al., 1976). It has been posited that the increased cell proliferation noted in "myelinated" nerves may be related to the need to fill the space created by the loss of larger axons and their associated myelin coverings or to the participation of Schwann cells in removal of degenerating myelin (Joseph, 1950; Abercrombie and Santler, 1957; Abercrombie et al., 1959; Masurovsky and Bunge, 1971). The enhanced proliferation of Schwann cells in myelinated vs. unmyelinated nerves is considered to play a role in directing regenerating previously unmyelinated axons into the terrain of regenerating myelinating axons, as demonstrated along portions of the vagus nerves (Evans and Murray, 1954; King and Thomas, 1971). Such redirection remains unexplained.

ALTERATIONS IN PHENOTYPIC EXPRESSION

Schwann cells manifest a number of alterations on their cell surfaces and within their cytoplasm in the degenerating/regenerating situation. Intracellularly, intermediate filament protein expression changes, as would be anticipated considering the alterations in cell shape concurrent with Schwann cell activities during proliferative and reparative phases. Two intermediate filament proteins, vimentin and glial fibrillary acidic protein (GFAP), are normally expressed in myelinating and nonmyelinating Schwann cells, respectively. Upon loss of axonal contact, vimentin expression increases in the distal segment and becomes predominant there, while GFAP diminishes. This reverses with axonal regrowth and reestablishment of Schwann cell-axonal contact.

Trophic factor expression also undergoes significant fluctuation, which appears to reflect the status of Schwann cell-axonal contact. The repertoire of these, most of which have been elucidated during

recent years, supports the earlier idea of Ramón y Cajal (1928) that the presence of growth or trophic factors in peripheral nerve plays an important role in regeneration in the peripheral nervous system. The technical capabilities available in the last decade have made it possible to identify some of these factors and to characterize their roles. One of the growth factors associated with peripheral nerve regeneration is nerve growth factor (NGF), a target-derived substance critical to survival of primary sensory neurons, sympathetic ganglion neurons and certain cholinergic neurons of the central nervous system (CNS). The demonstrated capability of the sciatic nerve to release NGF continuously in a culture situation, where it lacked its target organ as a source for this substance, indicated that NGF was synthesized locally in the nerve (Richardson and Ebendal, 1982). This, then, raised the question of whether this phenomenon occurred *in vivo*. To answer this question Heumann and colleagues (1987) examined the levels of NGF and its messenger RNA ($mRNA^{NGF}$) in both intact and transected sciatic nerves of adult rats. They found that levels of NGF in the intact nerve were comparable to those in target tissue of NGF-responsive neurons. The level of $mRNA^{NGF}$ in intact nerve, however, was very low, in contrast to the high level in target tissues, suggesting very little local synthesis in the intact nerve. Following transection, increases of up to 15-fold in $mRNA^{NGF}$ occurred throughout the distal segment, and this increased message level was accompanied by local synthesis of NGF. The proximal segment of the injured nerve manifested changes in NGF synthesis only in its most distal portions, that is, adjacent to the transection site. *In situ* hybridization using a probe to localize the $mRNA^{NGF}$ confirmed its presence along the length of the distal segment and its restriction to the distal end of the proximal segment where neurite outgrowth is to occur. Thus, in response to injury the nerve is capable of synthesizing NGF.

The initial step in the sequence of events by which NGF normally exerts its effects on neurons involves the binding of NGF to specific receptors on the cell surface. The cell surfaces on which these receptors normally occur are surfaces of NGF-responsive neurons. An interesting and important exception to this is the presence of the class II receptors on surfaces of Schwann cells distal to an injury site but not in the intact nerve (Taniuchi et al., 1986, 1988). Immunocytochemical demonstration of the NGF receptor revealed its presence on *all* Schwann cells distal to an injury site and not a localization to Schwann cells associated only with appropriate sensory or autonomic axons. At the ultrastructural level these receptors were localized to the plasmalemma of the Schwann cells. Temporal analysis revealed that the presence of the class II NGF receptors on the Schwann cells was inversely related to axonal contact, that is, that the NGF receptors disappeared from the Schwann cell surface upon reestablishment of axonal contact. Taniuchi and colleagues proposed that these receptors bind the NGF produced by the Schwann cells to their surfaces where it, in turn, can exert both trophic (substrate) and tropic (chemotactic) influences upon the elongating neurites of sensory and sympathetic neurons. Thus, the Schwann cell acts as a temporary source of NGF for the regenerating axon.

The presence of the class II NGF receptors on *all* Schwann cells distal to the site of injury was unanticipated since not all axons in peripheral nerves (cranial or spinal) are NGF-responsive. Injury to a ventral spinal nerve root or to the vagus nerve in the neck, neither of which contains NGF-responsive axons, results also in the appearance of NGF-receptors on Schwann cells distal to the injury. The significance of this is not yet clear.

Another Schwann cell-derived factor upregulated in injured peripheral nerve is glial maturation factor β (GMFβ) (Bosch et al., 1989). Endogenous GMFβ can be demonstrated normally in astroblasts and Schwann cells. Injury (transection or crush) to the sciatic nerve reveals a pattern of expression of GMFβ, which parallels that described for the NGF receptor. In general, GMFβ expression is induced by loss of normal axonal-Schwann cell contact and is repressed by reestablishment of this contact.

The presence of increased trophic factors and/or their receptors in portions of peripheral nerve distal to an injury site is in keeping with the long-standing view of peripheral nerve as a source of trophic substances (Ramón y Cajal, 1928). Within this framework, however, the observation of a decrease in ciliary neurotrophic factor (CNTF) distal to a site of injury (Friedman et al., 1992; Rabinovsky et al., 1992) may appear to be paradoxical. Normal, mature peripheral nerve contains high concentrations of CNTF protein and its mRNA, and Schwann cells are considered as a source of this factor (Rende et al., 1992). Following crush or transection of the sciatic nerve, decreases were found in production of CNTF, in its mRNA level, and in immunoreactivity. Friedman and colleagues (1992) extended their studies of CNTF expression through the regenerative phases and found a reexpression of CNTF protein and its mRNA concurrent with axonal regeneration and myelination, as evidenced in expression of both CNTF and myelin genes. Thus, CNTF appears to be dependent upon the integrity of Schwann cell-axonal

interactions. Obviously, much remains to be elucidated regarding the types and functions of trophic factors produced by Schwann cells.

EXTRACELLULAR MATRIX/BASAL LAMINA

Schwann cells modify their environment by synthesizing and secreting extracellular matrix (ECM) components. These components and other molecules are organized into basal laminae, which surround the mature Schwann cell-axon units (Figure 55-1). Components of ECM can be considered in four categories: collagens; noncollagenous glycoproteins; glycosaminoglycans and proteoglycans. One of the major collagens of the basal laminae of Schwann cells is the type IV collagen which serves as a scaffolding for attachment of other components, *e.g.* fibronectin and laminin. The latter are noncollagenous glycoproteins which mediate interactions between ECM and other cells, and laminin, a component of all basement membranes, is synthesized by Schwann cells. Of the glycosaminoglycans, heparan sulfate proteoglycan is present in the Schwann cell basement membrane.

The formation of the basal lamina is dependent upon interactions between neurites and Schwann cells, and does not require the presence of fibroblasts. This persistence of the basal laminae, however, is independent of the presence of an axon. Intact ECM and its components (laminin and fibronectin) play important roles in neurite elongation during normal development and regeneration (Carbonneto, 1984). Following injury to peripheral nerve or its roots (Figure 55-2), the basal laminae persist as channels within which axons and their myelin degenerate and where Schwann cells proliferate, organize themselves as bands of Bünger and interact with growing neurites. Clearly, the presence of an intact basal lamina appears to be a prerequisite for regeneration in the peripheral nervous system. Components of the ECM in the peripheral nervous system, for example, laminin and certain collagens, are produced by Schwann cells (Bunge and Bunge, 1983; Cornbrooks et al., 1983). Whereas Schwann cell-axonal contact is essential for production of some components of the ECM, for example, laminin (Bunge and Bunge, 1983; Cornbrooks et al., 1983), other components are produced independently of this contact.

A number of roles have been suggested for the components of the ECM. One possible role is that of recruitment and binding of trophic factors so that they can be accessible to the tips of elongating axons. Another important role is that of providing an adhesive substrate upon which the growth cone of the axon can advance. For example, if the filopodia of a growth cone can attach to the substrate, it can then pull the growth cone along with it. If no adhesion occurs, these filopodia may again be incorporated into the growth cone and the latter fails to advance.

Each axon-Schwann cell unit, whether it represents a single "myelinated" axon or a group of ensheathed "unmyelinated" axons, is surrounded by a tube of basal lamina. A nerve, its roots or its branches are filled by these ECM tubes. Once the basal lamina scaffold is formed, it appears that its surfaces—outer (related to mesenchymal elements) vs inner (originally related to plasma membrane of Schwann cell)—are quite different. This consideration arises from observations made when using nerve grafts devoid of Schwann cells. When a segment of sciatic nerve was excised, repeatedly frozen to kill the Schwann cells, and then grafted back into the original site, the regenerating axons were noted to extend along the inner surface but not the outer surface of the basal lamina (Ide et al., 1983). The data derived from that study suggest that living Schwann cells are not as critical for nerve regeneration as is the presence of a basal lamina and that the inner surface of the basal lamina possesses properties that guide and signal neurite elongation. It is well documented that certain components of ECM have specific positions or arrangements (Bunge and Bunge, 1983); thus, it is not unreasonable to speculate that differences in distribution and types of substances on the inner vs. the outer surfaces of the basal lamina may serve to attract or to deter axonal elongation.

Laminin is a major constituent of all basal laminae and its presence in basal lamina of Schwann cells and muscle cells is considered to play a major role in guidance of regenerating neurites (Bignami et al., 1984; Keynes et al., 1984; Madison et al., 1988). Using antibodies against two major components of the Schwann cell basal lamina, laminin and heparan sulfate proteoglycan, it was possible to demonstrate immunohistochemically the persistence and alignment of these ECM molecules in the basal lamina of the distal stumps as long as 28 days following sciatic axotomy. This demonstration of the maintenance of the biochemical integrity is important, since the basal lamina channels act to align the Schwann cells mechanically and also since laminin in association with heparan sulfate proteoglycan promotes neurite elongation (Chiu et al., 1986; Sandrock and Matthew, 1987).

In contrast to the peripheral nervous system, the extracellular matrix of the central nervous system is

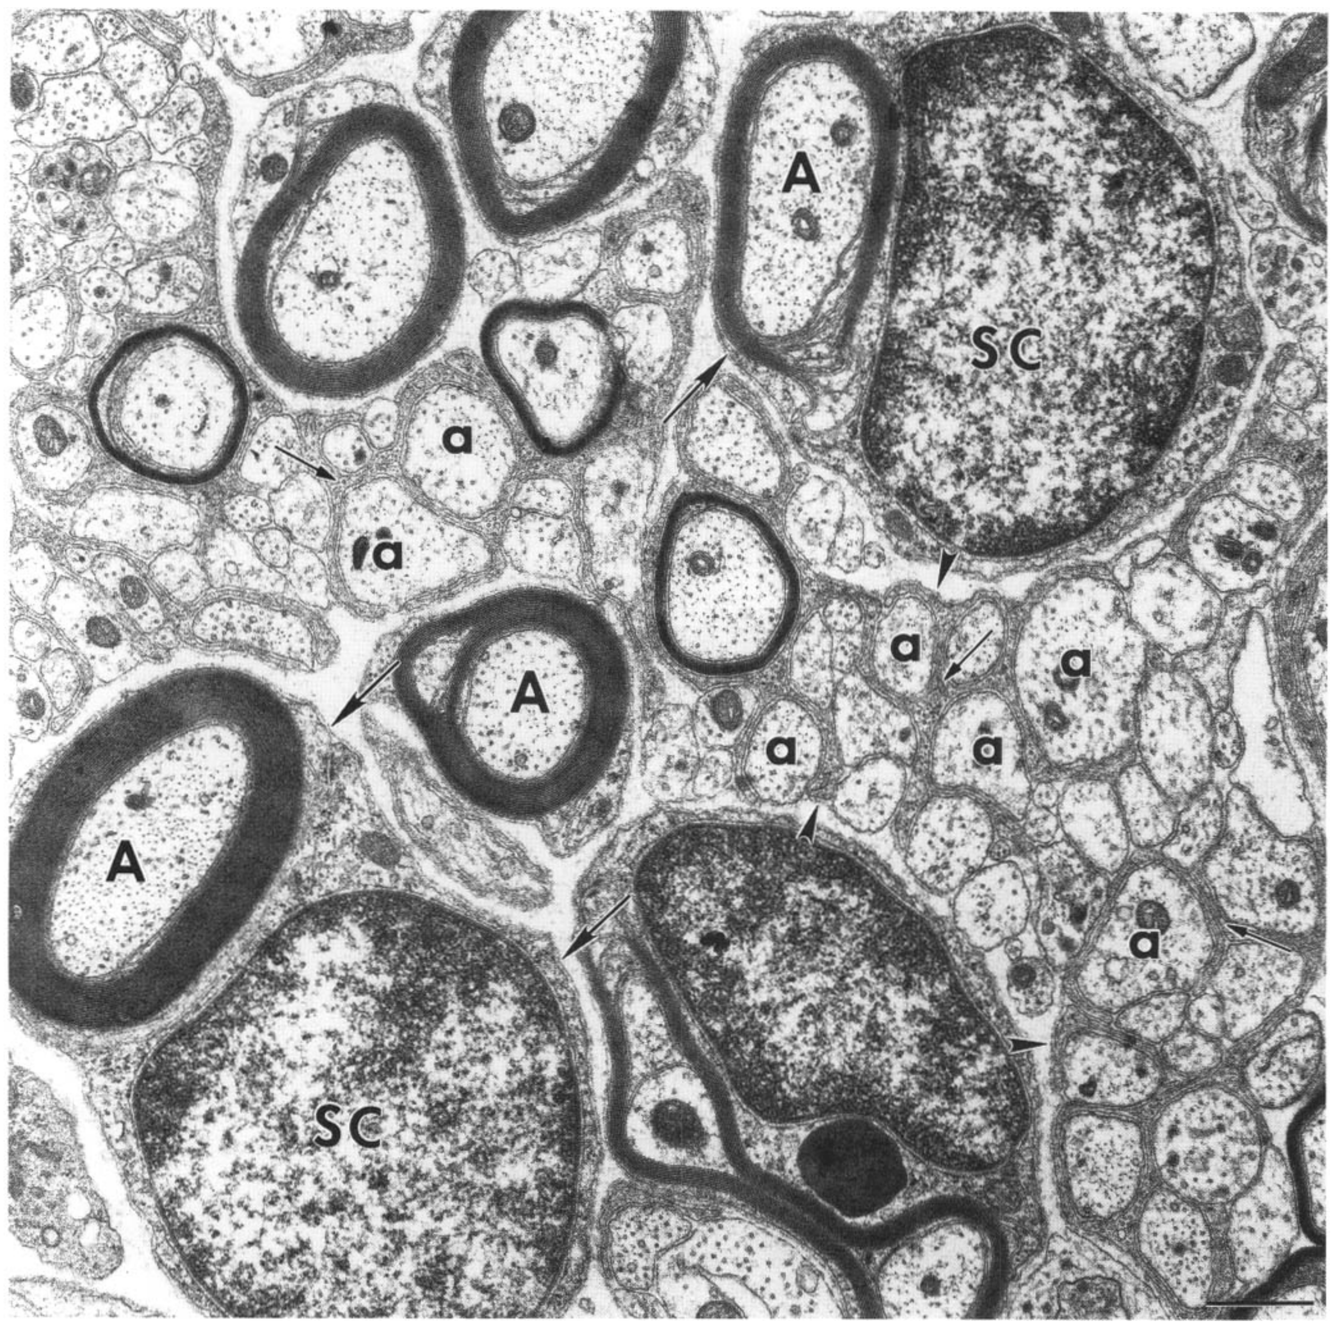

FIG. 55-1. An electron micrograph depicting associations between Schwann cells (*SC*) and axons within a dorsal rootlet of the lumbar spinal cord from a 10-day-old rat. Schwann cell differentiation is fairly advanced by this age, and individual axons exceeding 1.5 μm in diameter (*A*) are generally myelinated by a single Schwann cell, which is covered, in turn, by a basal lamina (*large arrows*). Axons of less than 1.5 μm in diameter (*a*) are generally grouped into bundles by ensheathing Schwann cell processes (*small arrows*). These bundles, in turn, are covered by a thin basal lamina (*arrowheads*). Scale bar = 1.5 μm.

amorphous and virtually lacks collagen and fibrous proteins. This absence of structure within the ECM of the CNS or of proteins responsible for the structured organization of the ECM are thought to contribute to the abortive or limited regenerative capabilities of neurites in the CNS. For example, CNS neurons can respond to laminin as do those of the peripheral nervous system (Liesi, 1985a). The CNS glia, however, do not form laminin continuously as do Schwann cells. It is the continuous expression of laminin that is considered to be critical to growth or elongation of neurites (Liesi, 1985b).

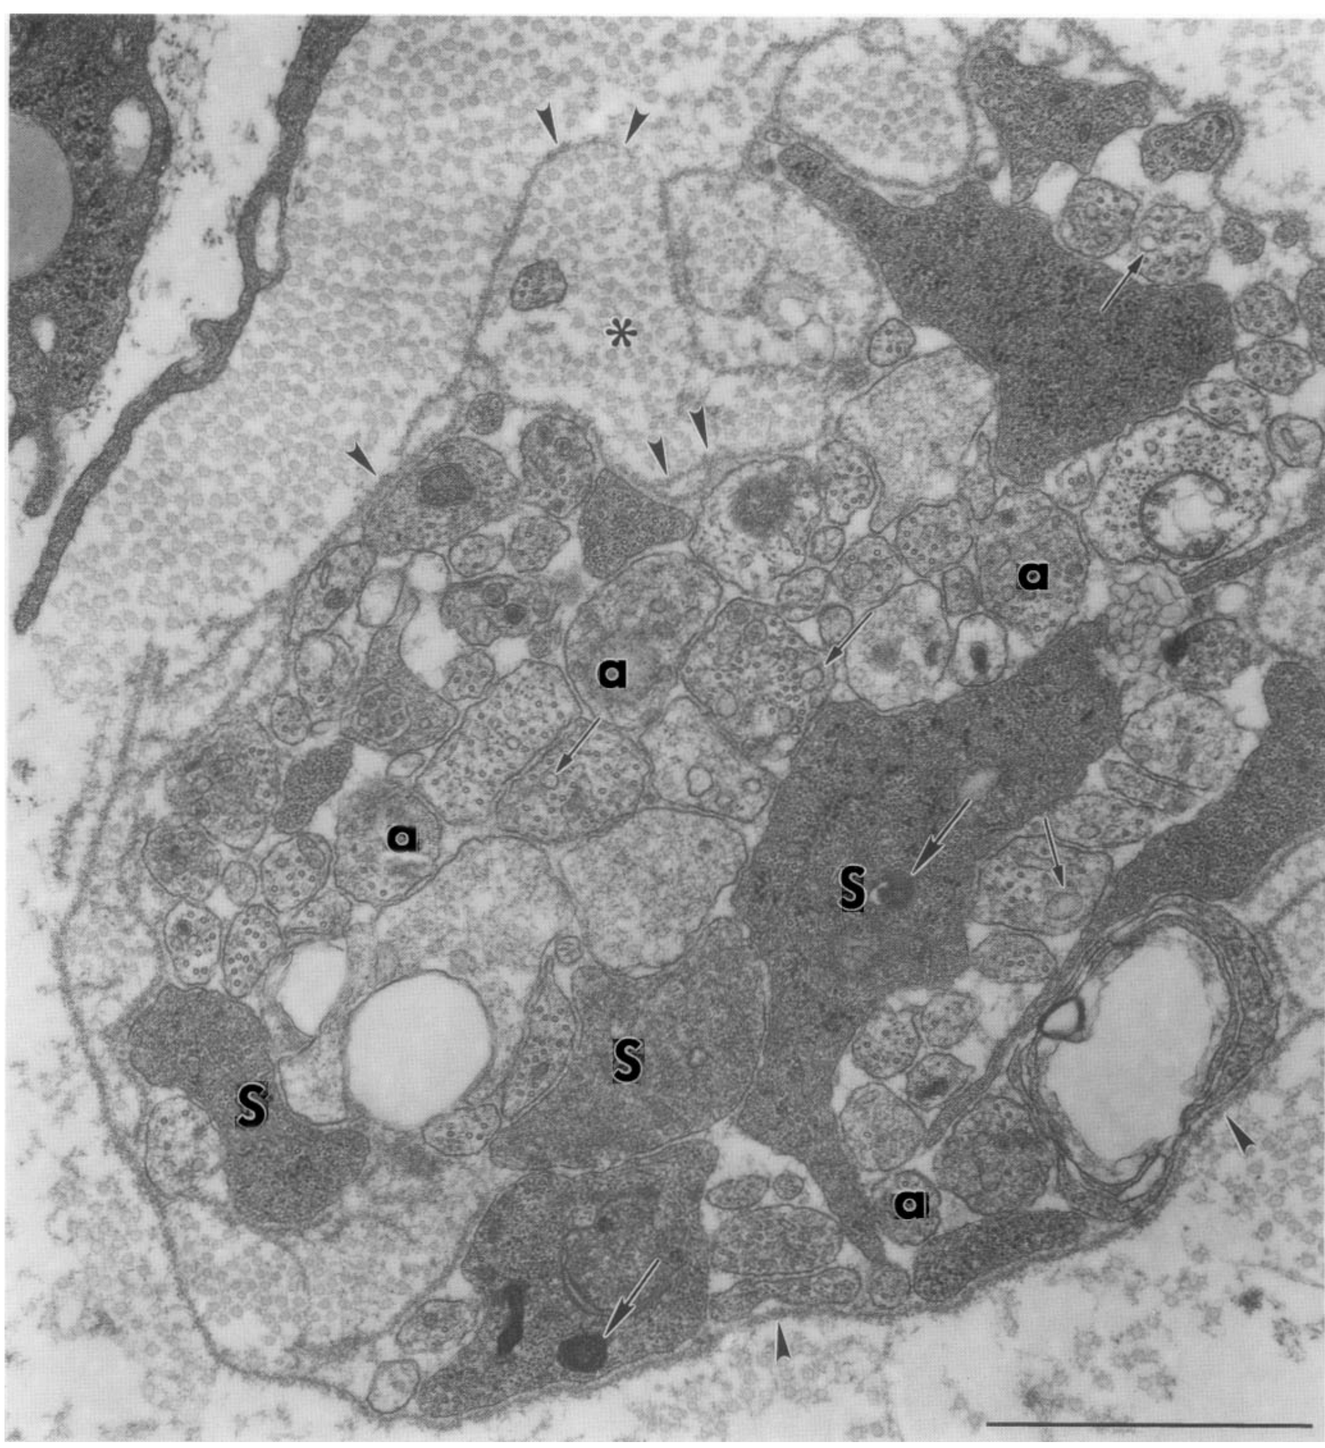

FIG. 55-2. An electron micrograph depicting regenerating axons 5 days following a crush lesion to the sciatic nerve in an adult rat. This sample was taken approximately 3 mm distal to the site of the lesion. Regenerating axons range between 0.08 μm and 2.0 μm in diameter at this time and distance from the lesion; the majority of the regenerating axons in this figure range between 0.1 μm and 1.0 μm in diameter. Regenerating axons (*a*) and Schwann cell processes (*S*) are organized into bundles surrounded, in turn, by a basal lamina (*arrowheads*). Schwann cell processes have a dense cytoplasm and often contain lysosomes (*large arrows*). These regenerating axons often contain microtubules and large pleomorphic vesicles (*small arrows*) reminiscent of growth cone vesicles observed in the developing nervous system. In some areas the basal lamina associated with the bundle forms loops (*double arrowheads*) that incorporate collagen fibers (*). Scale bar = 2.0 μm.

CELL ADHESION

Schwann cells have not only a tropic or attracting influence on elongating neurites, but also play a role in providing appropriate substrates to promote their extension. The laminin-heparan sulfate proteoglycan complex of the basal lamina normally supports growth of neurites, and this function can be inhibited or abolished by the presence of antibodies to this complex (Sandrock and Matthew, 1987). The growth-promoting role of Schwann cells is not solely dependent on basal lamina production, however, and *in vitro* studies have demonstrated that Schwann cells which develop little or no basal lamina in serum-free medium retain their growth-promoting properties (Ard et al., 1987).

The growth-promoting roles of Schwann cells appear to be due, in part, to cell adhesion molecules (CAMs) located on their surfaces. The neural cell adhesion molecule, L1, a surface molecule on postmitotic neurons in the CNS is present also on nonmyelinating Schwann cells in the sciatic nerve of both developing and adult mice (Faissner et al., 1984). Another CAM, the neural cell adhesion molecule (N-CAM), which plays a major role in binding apposing neuronal surfaces, is present also on nonmyelinating Schwann cells (Noble et al., 1985). The binding of neurons to glia is accomplished by a neuron-glia CAM (Ng-CAM), the expression of which is related to migration of neurons along glia and to neurite outgrowth and fasciculation (Thiery et al., 1985). Injury to the sciatic nerve in adult chickens and mice resulted in increased expression of both N-CAM and Ng-CAM in Schwann cells (Daniloff et al., 1986). The timing of their expression postinjury is such as to suggest that these adhesion molecules may be involved in formation of the bands of Bünger and in providing a substrate for neurite elongation. There was a return of these CAMs to normal levels at the time of remyelination. In a study of normal development and injury, the expression of two CAMs, N-CAM, which has been immunolocalized electronmicroscopically to both growth cones and Schwann cells (Martini and Schachner, 1988), and L1 was followed in the mouse (Nieke and Schachner, 1985). During the late embryonic period when most Schwann cells were proliferating, most of these cells expressed both L1 and N-CAM. As myelination progressed through the early postnatal period and into adulthood, expression was reduced and was confined to nonmyelinating Schwann cells. Transection of the sciatic nerve induced a rapid reexpression of both CAMs distal to the injury site, and more than a year was required for the level of the L1 CAM to return to normal.

Although the role of the reexpression of CAMs is not completely understood, they are considered to play important roles in outgrowth of the regenerating axons. Antibodies against N-CAM will inhibit the process of remyelination in regenerating nerves (Rieger et al., 1988). Antibodies against other CAMs, L1/Ng-CAM, N-cadherin, and integrins, applied together but not individually will inhibit growth of axons on Schwann cells *in vitro* (Bixby et al., 1988; Seilheimer and Schachner, 1988). Much remains to be elucidated regarding the roles of CAMs in regeneration *in situ*.

Another protein that may be involved in neurite outgrowth is the S-100 protein, a cytoplasmic protein of both Schwann cells and astrocytes, as well as certain axons. Its level of immunoreactivity is altered in the injured sciatic nerve (Kato and Satoh, 1983; Neuberger and Cornbrooks, 1989; Spreca et al., 1989), undergoing an initial decrease and a later increase. Evidence suggests that the increase in S-100 immunoreactivity in Schwann cells occurs as they become associated with regenerating axons. The role of this protein is not clear, but it is possible that it may be secreted as an extracellular protein and be involved in axonal elongation. Neurite extension properties have been attributed to the disulfide form of S-100β homodimer (Kligman and Marshak, 1985) and Van Eldick and coworkers (1988) suggest that S-100 secreted by CNS glia functions in a paracrine fashion to affect neurite outgrowth. A similar function may be carried out by the Schwann cells of the peripheral nervous system as suggested by Hall (1989).

MYELINATING VERSUS NONMYELINATING SCHWANN CELLS

Assuming that regenerating neurites are successful in traversing an injury site and in entering the distal segment, an important event that remains for reestablishment of structure and function is ensheathement or myelination of these neurites. This raises a basic question: Are there two distinct populations of Schwann cells—myelinating vs nonmyelinating or ensheathing? Or is there a single population capable of expression of either phenotype depending upon appropriate axonal signals? As early as the mid-1900s, cross-anastomosis experiments between myelinated and unmyelinated nerves provided evidence that the axon instructs the Schwann cell as to its need to be myelinated (Simpson and Young, 1945). Those experiments involved anastomoses between a predominantly myelinated thoracic spinal nerve and a predominantly unmyelinated nerve such as ante-

rior mesenteric or splanchnic nerves. Following approximation of the cut ends of these different nerves, axons growing out from the central "myelinated" segment of the thoracic spinal nerve continued to be myelinated in the terrain of the originally "unmyelinated" nerve, for example, the anterior mesenteric nerve, and vice versa. Thus, the parent axon directed the status of myelination. Although these experiments and other earlier studies established that the axon determined its status with regard to myelin formation, they did not provide definitive answers as to whether the distal segments into which the axons regenerated became populated by Schwann cells derived from the proximal segment. In other words, did Schwann cells migrate from the proximal segment into the distal segment? Experiments designed to focus on this question were carried out by Weinberg and Spencer (1976) and Aguayo and colleagues (Aguayo et al., 1976a, 1976b) in the mid-1970s. Their studies employed the cross-anastomosis method, utilizing a predominantly myelinated and a predominantly unmyelinated nerve as in the earlier studies, as well as nerve transplantation techniques. The techniques of tritiated thymidine autoradiography and electron microscopy were employed in these more recent investigations, and the combinations of these methods permitted the determination that significant migrations did not occur and that Schwann cells that previously were of the nonmyelinating or ensheathing type were capable of myelinating under appropriate axonal stimuli. Further, it was postulated that the Schwann cells that undergo division as a result of nerve injury possess a multipotentiality similar to that expressed during normal development. Certainly, the appearance of a number of other characteristics of developing Schwann cells, for example, cell adhesion molecules and surface receptors on Schwann cells at or distal to an injury site, as discussed above, would support this idea. Finally, it should be noted that axons control not only the behavior of Schwann cells with regard to myelin formation but also their survival. Denervated Schwann cells do not persist if the regenerating neurites are prevented from entering the distal segment of an injured nerve (Weinberg and Spencer, 1978).

The differentiation of Schwann cells subsequent to the signaling to be myelinated or to be ensheathed involves a number of changes within the cytoplasm. Since Schwann cell differentiation and maturation involves marked alterations in cellular shape, then alterations in intermediate filament proteins such as vimentin or GFAP are not surprising. Loss of axonal contact due to nerve injury elicits a vimentin-positive, GFAP-negative pattern in Schwann cells distal to the injury site, a pattern noted normally in early development. As Schwann cell differentiation occurs, subsequent to contact with the regenerating neurites, GFAP expression increases (ensheathing or nonmyelinating Schwann cells) and vimentin expression decreases (myelinating Schwann cells) (Neuberger and Cornbrooks, 1989), thereby reestablishing the pattern noted in normal mature nerve.

POTENTIAL ENHANCEMENT OF REGENERATION IN THE CENTRAL NERVOUS SYSTEM

The capacity of the peripheral nervous system to support axonal regeneration serves as the basis for attempts to enhance regeneration in the CNS through use of grafts or transplants of peripheral nerve or Schwann cells. This possibility was suggested early in this century by Ramón y Cajal and the earliest reports of such attempts appear to be those of Tello (1911a, 1911b). Definitive studies, however, depended upon development of such technical capabilities as tracing methods to determine sources of axons observed within a graft and culturing methods to provide sufficient numbers of Schwann cells for transplantation. Recent studies have shown that, when a peripheral nerve graft is placed within the territory of injured CNS axons, the graft can provide a favorable substrate for elongation of CNS axons and can serve as a "bridge" to allow these axons to extend from one region of the CNS to another (for review see Aguayo, 1985; Bray et al., 1987).

The use of peripheral nerve grafts in the CNS has revealed an interesting difference with regard to ability to support CNS axonal growth. To compare the capability of basal lamina tubes alone, in contrast to basal lamina tubes containing viable Schwann cells, to support growth of CNS axons, Smith and Stevenson (1988) implanted these structures into the diencephalon of adult hamsters. The grafts of basal lamina tubes only in which the Schwann cells were destroyed by freezing did not support axonal regrowth as did the graft containing both basal lamina and Schwann cells. This observation stands in contrast to peripheral nerve axons, which were capable of elongating into grafts of basal lamina tubes devoid of Schwann cells (Ide et al., 1983). Whether this reflects a difference between types of neurons remains to be answered.

Purified Schwann cell cultures and the collagen substrata on which they were grown have been grafted into brain (Kromer and Cornbrooks, 1985) or lesioned spinal cord (Paino and Bunge, 1991) in attempts to enhance axonal regeneration. In both sit-

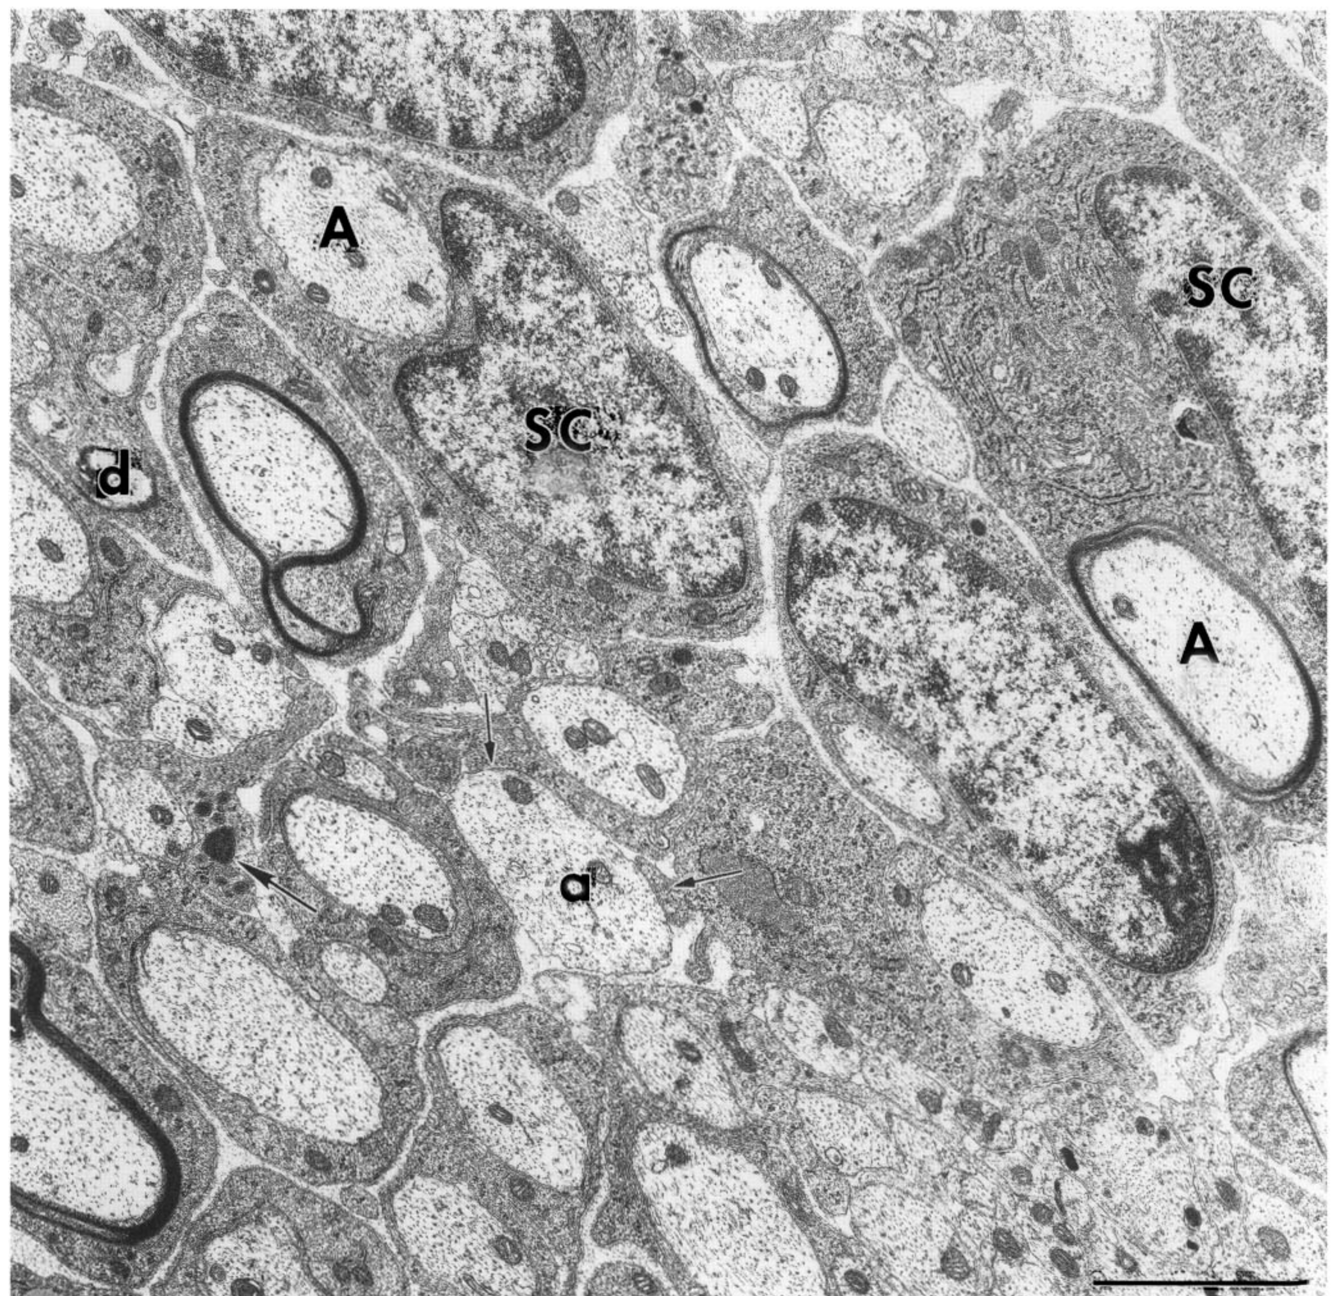

FIG. 55-3. An electron micrograph depicting Schwann cell-myelinated axons in the dorsal funiculus 7 days following injection of cultured Schwann cells into an irradiated portion of the lumbar spinal cord in a 16-day-old-rat. The injected Schwann cells were purified from primary cultures of newborn rat sciatic nerve. Single axons (*A*) with associated Schwann cells (*SC*) are in an early stage of myelination at this time. Some axons of medium diameter (>1.5 μm) are contacted but are not entirely surrounded by Schwann cell processes (*small arrows*). Some degenerative myelin products (*d*), as well as a few lysosomes (*large arrow*), are present in the cytoplasm of the Schwann cells; otherwise, the region occupied by the injected Schwann cells is remarkably free of pathological responses. Scale bar = 2.0 μm.

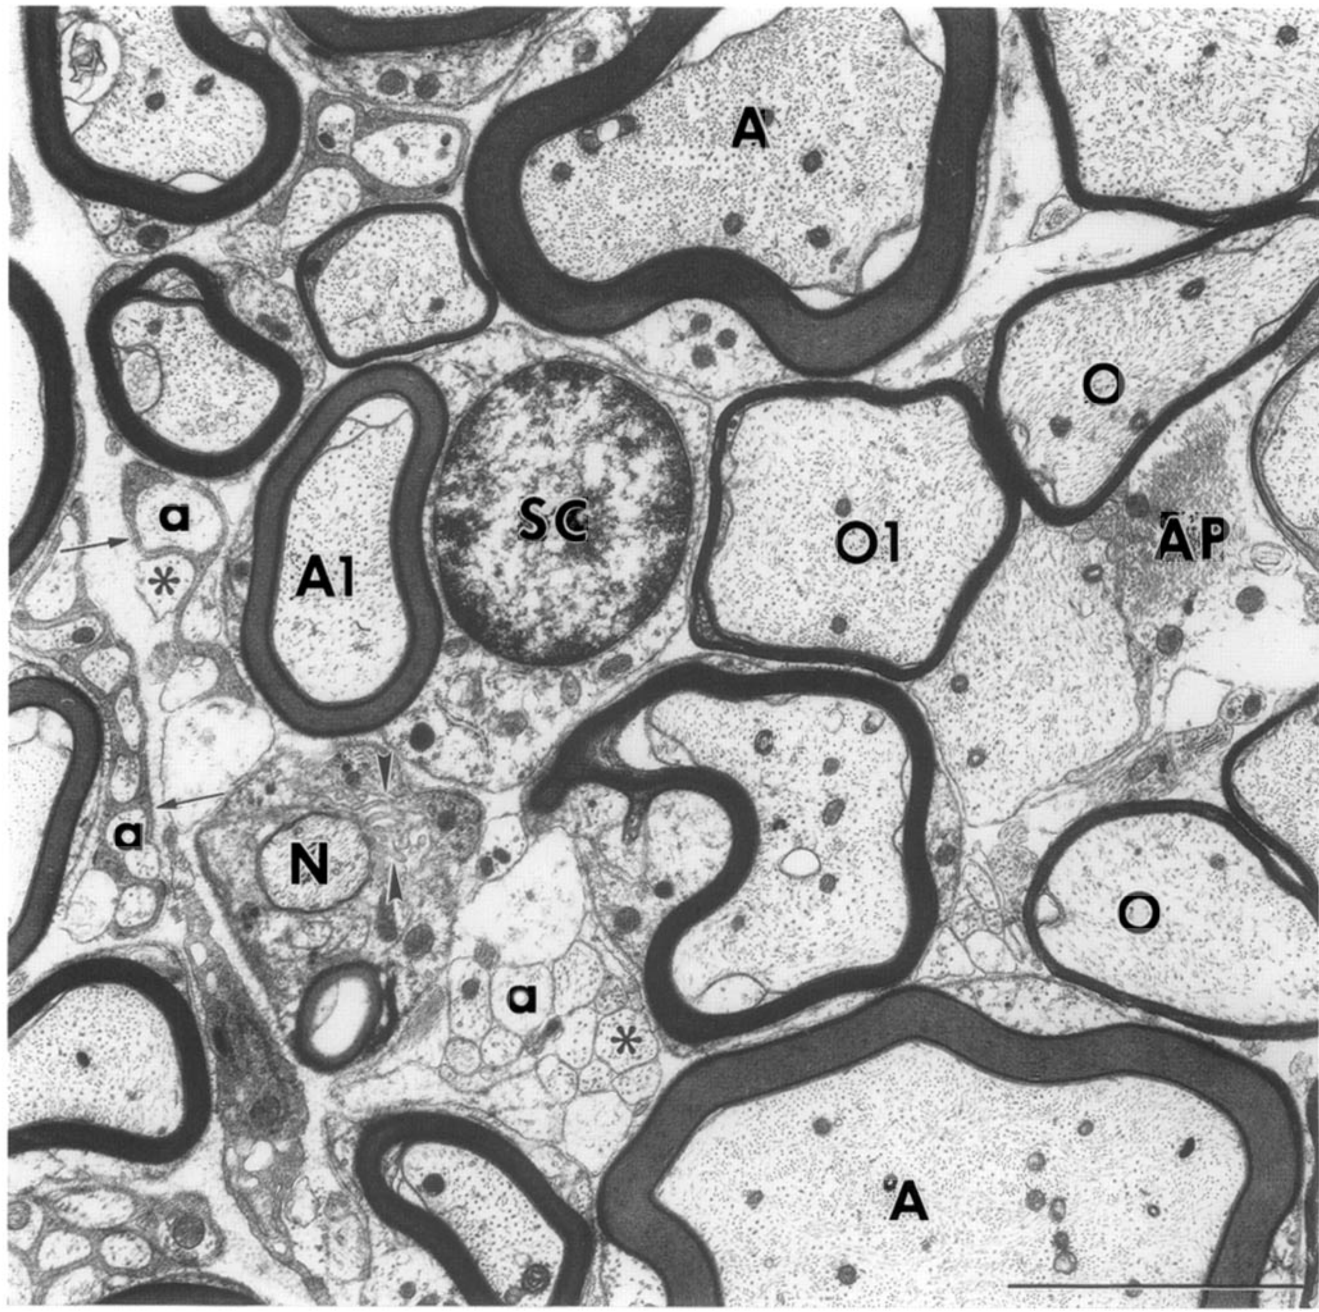

FIG. 55-4. An electron micrograph depicting Schwann cell-myelinated axons in the dorsal funiculus of a rat lumbar spinal cord 90 days following irradiation. As in the peripheral nervous system, intraspinal Schwann cells (*SC*) form sheaths of compact myelin on single axons of large diameter (*A*). Schwann cell-myelinated axons (*A*) are distinguished from oligodendrocyte-myelinated axons (*O*) by the greater thickness of their myelin sheaths on axons of similar diameter; compare axon, *A1*, having a much thicker myelin sheath derived from a Schwann cell with the adjacent axon, *O1*, surrounded by an oligodendrocyte-derived myelin sheath. Small diameter axons (*a*) remain unmyelinated (*) or surrounded by Schwann cell processes (*arrows*). Intraspinal Schwann cell processes (*arrowheads*) contact the nodal region of axons (*N*) in a manner similar to that observed in the peripheral nervous system. Although fewer in frequency than in the normal 90-day-old spinal cord, astrocyte processes (*AP*) are present in these regions of mixed myelin types. Scale bar = 4.0 μm.

uations regenerating axons, ensheathed or myelinated by the Schwann cells, were observed in the graft. Collagen grafts lacking Schwann cells failed to support axonal growth in the lesioned thoracic spinal cord.

Cultured Schwann cells lacking substrates also have been transplanted into the CNS in attempts to repair myelin deficits or enhance axonal elongation through lesion sites (Baron-Van Evercooren et al., 1992; Blakemore and Crang, 1985; Duncan et al., 1981; Martin et al., 1991) (Figure 55-3). Data derived from each of these investigations and from our laboratories (Gilmore and Sims, 1993) indicate that the transplanted Schwann cells support axonal elongation and/or ensheathe or myelinate axons. The types and origins of the axons with which these transplanted Schwann cells establish ensheathing or myelinating relationships is not always clear. Nonetheless, they provide clear evidence that Schwann cells, even those from immortalized lines (Baron-Van Evercooren et al., 1992), survive and form myelin following transplantation into the CNS.

In the foregoing experiments the physical integrity of the CNS was breached or disrupted to allow for

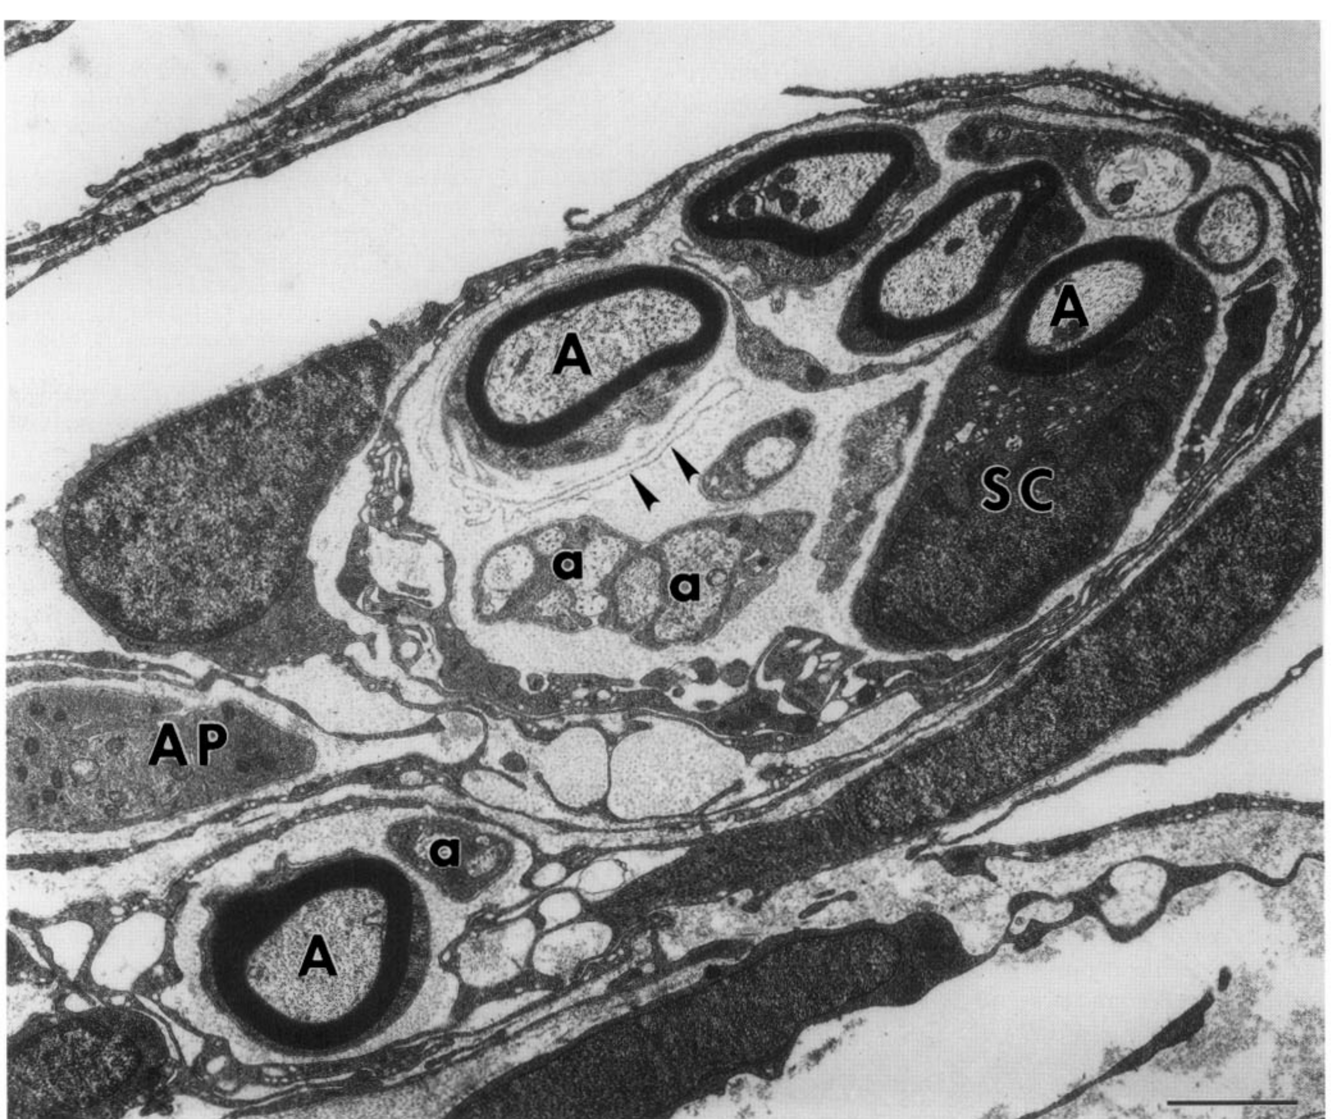

FIG. 55-5. An electron micrograph of regrowing dorsal root axons near the transition zone between central nervous system and peripheral nervous system, from an irradiated rat in which the dorsal root was lesioned 60 days earlier. Regrowing axons are associated with Schwann cells (*SC*) that form compact myelin on larger axons (*A*) or ensheathe axons of smaller diameter (*a*). An empty basal lamina tube remains within the fascicle (*arrowheads*). A small group of astrocyte processes (*AP*) is present, but these are markedly fewer than observed in a nonirradiated, root-lesioned rat in which this region consists principally of reactive astrocyte processes. Scale bar = 2.0 μm.

the placement of the cells, grafts or transplants. This physical disruption activates a series of responses in the astrocyte population and in the microvasculature, which, in turn, complicates evaluation of the behavior and potentials of Schwann cells within the CNS environment. A model in which Schwann cells can be induced to develop within the confines of the CNS in a predictable, reproducible fashion, has been developed by Gilmore and colleagues (Gilmore and Duncan, 1968; Gilmore and Sims, 1986). This model involves depletion of the glial population in the spinal cord of the immature rat by exposure to ionizing radiation. Subsequently, Schwann cells develop within the spinal cord, particularly in the dorsal funiculi, where they are capable of proliferating (Gilmore, 1971; Gilmore et al., 1982; Gilmore and Sims, 1986) and of myelinating or ensheathing axons (Gilmore and Duncan, 1968; Gilmore et al., 1982; Gilmore and Sims, 1986; Sims and Gilmore, 1989) (Figure 55-4), which under normal circumstances would be myelinated by oligodendrocytes. Given the predictability of this induction, the model has proven useful in evaluating many aspects of Schwann cell behavior in the CNS environment, including axolemmal/Schwann cell interactions (Black et al., 1986; Sims and Gilmore, 1989). Additionally, recent investigations by the authors (Sims and Gilmore, 1994) demonstrate that the presence of the radiation-induced Schwann cells in the dorsal root entry zone facilitates regrowth of lesioned dorsal root axons from the peripheral nervous system terrain of the dorsal root into the CNS terrain of the spinal cord (Figure 55-5).

Taken together, one important implication of the studies cited above based on paradigms ranging from grafting of segments of whole nerve to transplanting of cultured Schwann cells to other means, for example, radiation, of induction of Schwann cells within the CNS is that Schwann cells within the CNS environment possess many of the characteristics of Schwann cells in their normal peripheral nervous system domain. Their ability to sustain regrowth of injured axons and redirect them into their usual sites of distribution in some areas of the CNS provides fertile ground for further examination of Schwann cell capacities and interactions within the CNS milieu.

56 Gliosis

AMICO BIGNAMI AND DORIS DAHL

Bundles of 10-nm (intermediate) filaments in the astrocyte cytoplasm are the electron microscopic equivalent of glial fibers at the light microscopic level. Accumulation of glial fibers is the histological landmark of the astrocyte response to injury, appropriately named fibrous gliosis (Figure 56-1). These fibers fill up the space resulting from the loss of myelin and neurons.

Glial fibers first led to the discovery of neuroglia as a substance that appeared to be brain-specific and thus different from connective tissue but still distinct from nerve. In 1846, Rudolph Virchow, a German pathologist, identified under the ependymal lining of the lateral ventricles, "a structureless membrane, which often appeared to be formed by very fine and pale fibrils lying parallel to each other in a rather regular pattern" (Weigert, 1895). For several years Virchow thought he could dissect this membrane with a scalpel, but he later came to the conclusion that it extended without boundaries through the substance of the brain, forming a sort of connective tissue holding nerve together (hence the name neuroglia, which means nerve glue). Virchow was also the first to describe a pathological overgrowth of the substance he had discovered in the spinal cord of a patient with tabes, a form of neurosyphilis resulting in the degeneration of the dorsal columns. After hardening with chromic acid, a fine mesh of fibers had become apparent. Under these conditions, normal spinal cord tissue has a fine granular appearance probably due to the presence of birefringent myelin sheaths. In view of the techniques available to Virchow, one may understand Deiter's statement that the discovery of neuroglia appeared to be the result of divination rather than demonstrable facts (Weigert, 1895).

The next major step was the development by Weigert of a method allowing the selective staining of glial fibers (Weigert, 1895). The selectivity of the method for neuroglial fibers led Weigert to believe that they were made of a specific substance. This was an important factor for initiating studies aimed at demonstrating the specificity of the protein forming the glial fibers, that is, glial fibrillary acidic protein (GFAP). Furthermore, Weigert's illustrations provided the reference for assessing the specificity of GFAP antibodies (Bignami and Dahl, 1974a).

Excellent reviews of gliosis have been published (Reier et al., 1983; Lindsay, 1986; Reier, 1986; Malhotra et al., 1990; Hatten et al., 1991). Our main claim to originality in this chapter is that we do not view recent developments from the perspective of conventional neuropathology. The factors that trigger the astrocyte response to injury as well as the role of the reactive astrocyte in inflammation will not be discussed here (see Chapters 44, 45, and 46 in this volume).

PRIMARY AND SECONDARY GLIOSIS

Gliosis occurring in several neuropathological conditions, particularly gliosis associated with epilepsy (Ammon horn sclerosis) was believed in the past to result from a primary disease of the glia and thus to be kept distinct from gliosis resulting from destruction of nerve tissue, that is, secondary gliosis (Obersteiner, 1912). It is now believed that gliosis is almost invariably a secondary phenomenon, although not necessarily the result of neuronal degeneration. It is also believed that the glial scar may play a role in pathological events, such as the absence of functional regeneration in the central nervous system and epileptogenesis. Since the role of glia in regeneration is covered in Chapters 57 and 60, we confine our discussion to epileptogenesis.

Uptake of potassium and neurotransmitters are important glial functions (see Chapters 47 and 48). It is thus conceivable that impairment of these functions in a glial scar may result in the formation of an epileptic focus. In fact, an impairment of potassium homeostasis was proposed as a factor in the development of posttraumatic focal epilepsy (Pollen and Trachtenberg, 1970). However, no differences were observed between normal and gliotic cortex in the diffusion coefficient for potassium (Pedley et al., 1976; Dietzel and Heinemann, 1986). Furthermore, experimental elevation of the potassium concentration in damaged cerebral cortex did not result in seizures.

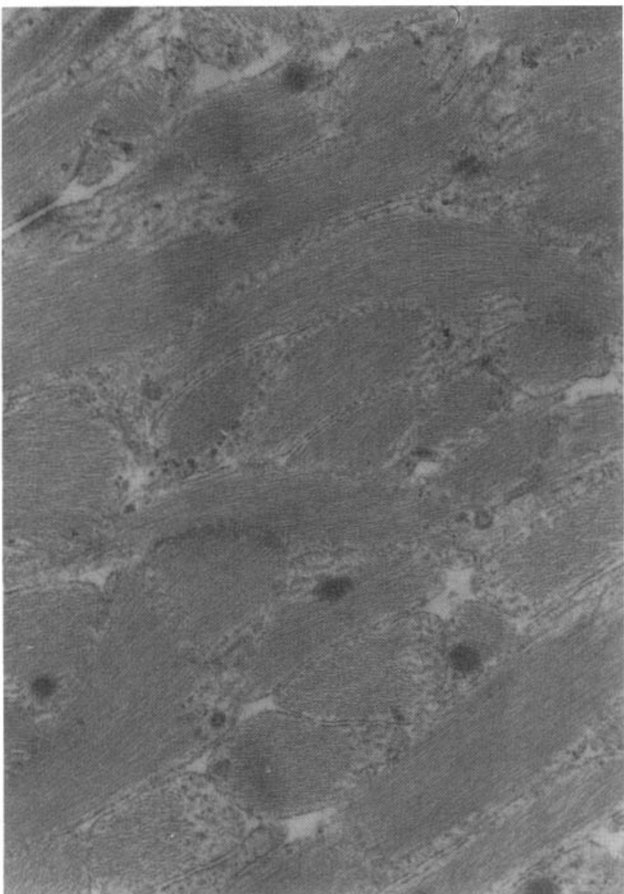

FIG. 56-1. Electron micrograph of the severely gliosed hypothalamus in a sheep with natural scrapie, a slow viral infection. Astrocyte processes are packed with intermediate filaments. The bundles of filaments appear as glial fibers by light microscopy. Gliosis is a prominent finding in slow virus infections. Antibodies raised to scrapie-infected brain selectively stained astrocytes by indirect immunofluorescence, thus suggesting that the agent was localized in these cells. However, the activity could be adsorbed by normal brain extracts (Gajdusek, personal communication). Compared to other brain proteins, glial fibrillary acidic protein (GFAP) is a good antigen and inoculation with human brain extracts may result in the production of GFAP antibodies. [From Dahl and Bignami (1973a), with permission.]

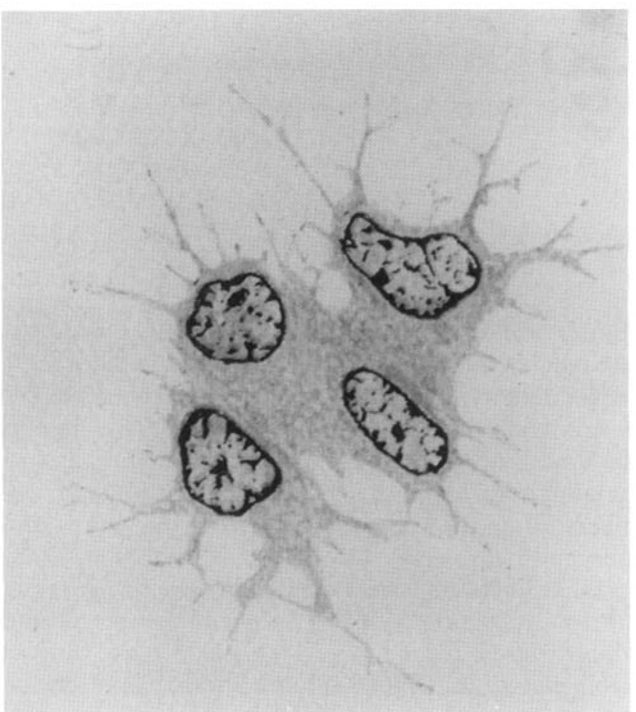

FIG. 56-2. *Gliarasen.* Figures like this first suggested that astrocytes are capable of dividing. In our experience, *Gliarasen* are numerous in subacute measles encephalitis where they may represent the end result of neuronal destruction (see Chapter 59 in this volume for the astrocyte response to selective neuronal necrosis). Nissl preparation. [From Spielmeyer (1922).]

A recent study of astrocyte cultures derived from epileptic foci suggests that neuronal excitability could result from abnormalities in the handling of glutamate (Magge et al., 1992). In these cultures, glutamate synthesis and uptake were markedly enhanced compared to cultures derived from normal brain.

A possible exception to the general rule that gliosis is a secondary phenomenon is represented by Huntington's disease. Lesions comparable to those observed in Huntington's disease, that is, loss of small neurons in the neostriatum and gliosis, can be experimentally produced by the nigrostriatal injection of several exogenous amino acids such as kainic acid (Coyle and Schwarcz, 1976). Quinolinic acid, an endogenous metabolite of tryptophan, produces similar changes, thus suggesting that it could play a role in the pathogenesis of Huntington's disease (Björklund et al., 1986). The marked increase of the anabolic enzyme for quinolinic acid in both experimental excitotoxic lesions and in Huntington's disease suggests that astrocytes are primarily involved in quinoline production, since they are the main cell population in these conditions and that they could possibly be responsible for neuronal damage.

HISTOPATHOLOGY

Protoplasmic Gliosis

Protoplasmic gliosis is not associated with the formation of glial fibers and is the characteristic finding of hepatic encephalopathy; this is covered in Chapter 63. Two other lesions traditionally considered as examples of protoplasmic gliosis are the *Gliarasen* (Figure 56-2) and neuronal satellitosis (Figure 56-3). Both lesions characteristically occur in the cerebral cortex and in-

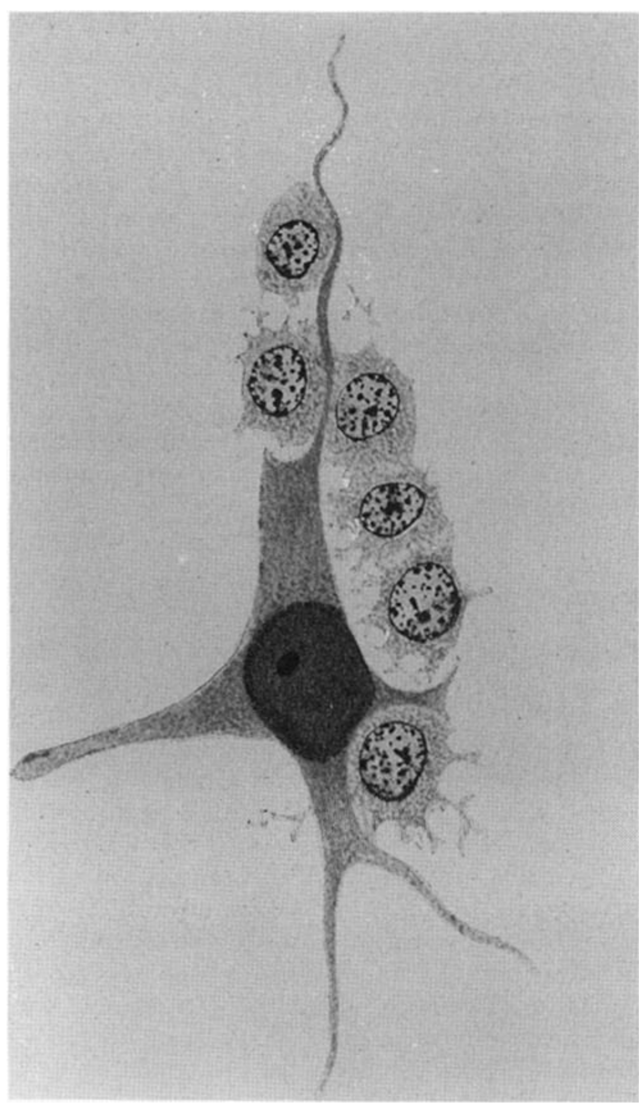

FIG. 56-3. Neuronal satellitosis. [From Spielmeyer (1922).] See Chapter 59 in this volume for the astrocyte reaction to neuronal damage *not* resulting in cell necrosis.

dicate neuronal damage. It should be noted that the absence of glial fibers was assessed by the method of Weigert and its modifications, and it is thus possible that astrocytes forming the lesions are, in fact, GFAP-positive, since GFAP immunohistochemistry is a more sensitive procedure. Conversely, the absence of GFAP in the astrocytes showing the characteristic changes of hepatic encephalopathy (Alzheimer's type II astrocytes) has been confirmed by immunohistochemistry (see Chapter 63).

Cell Division

The *Gliarasen,* pairs or quartets of astrocyte nuclei surrounded by thick protoplasmic processes (Figure 56-2), originally suggested that reactive astrocytes are capable of true hyperplasia, that is, cell division. Since mitotic figures are difficult to see in autopsy material, probably because most of them reach completion in the time interval between death and fixation, it was mistakenly believed that astrocyte division was amitotic.

Definite proof that division of reactive astrocytes actually occurs was difficult to obtain because [^{3}H]thymidine autoradiographic products were bleached by the method traditionally employed to stain astrocyte perikarya, that is, Ramón y Cajal's gold sublimate. Thus, it was difficult to ascertain the identity of the cells incorporating [^{3}H]thymidine in a brain wound, whether macrophages, fibroblasts, or astrocytes (Lindsay, 1986). Ultrastructural studies of pulse-labeled cells also did not provide an unequivocal answer, since macrophages, like astrocytes, may contain intermediate filaments. The question was conclusively answered in the affirmative by combining GFAP immunohistochemistry with tritiated thymidine autoradiography (Latov et al., 1979; Miyake et al., 1988; Janeczko, 1989). Incorporation of tritiated thymidine by reactive astrocytes is an early phenomenon, occurring as soon as 2 hours after injury and thus preceding GFAP expression (Janeczko, 1989). It should be noted, however, that upregulation of GFAP and fibrillogenesis are the main factors in the formation of the glial scar. Astrocyte proliferation is a relatively limited phenomenon mainly confined at the site of injury (Miyake et al., 1992).

Astrocyte division mainly occurs in brain injury associated with disruption of the blood-brain barrier. The number of astrocytes remained practically constant in rat optic nerve undergoing Wallerian degeneration (Skoff and Vaughn, 1971). Also, [^{3}H]thymidine labeling of GFAP-positive cells was not observed in spinal cord following rhizotomy, notwithstanding the presence of severe gliosis along the pathway of the degenerating dorsal root axons (Murray et al., 1990).

Isomorphic and Anisomorphic Fibrous Gliosis

Glial fibers are condensed but basically maintain their normal orientation (isomorphic gliosis, Figures 56-4 and 56-5); alternatively, glial architectonics is severely disrupted (anisomorphic gliosis, Figure 56-6). Isomorphic gliosis is typically observed in cases of selective damage to neurons and their processes. Conversely, severe tissue damage usually, but not invariably, associated with disruption of the blood-brain barrier, results in anisomorphic gliosis. Isomor-

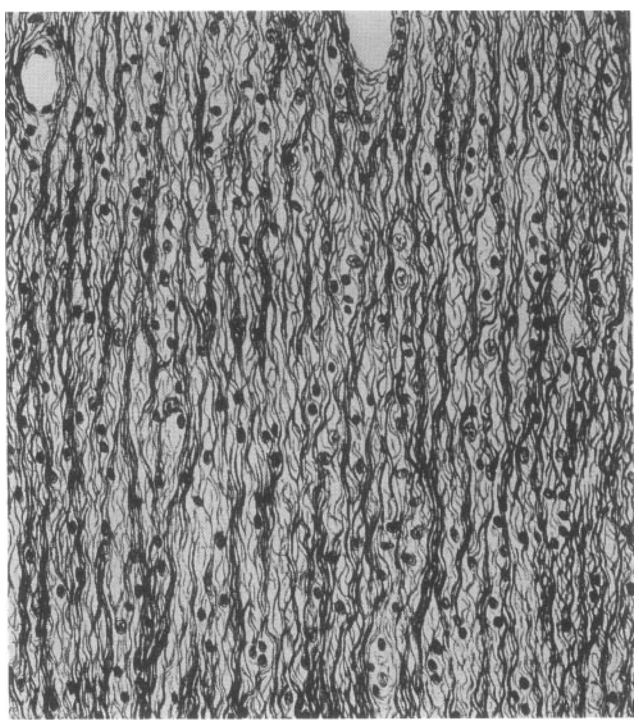

FIG. 56-4. Isomorphic gliosis of a degenerated spinal cord fiber tract. Weigert's staining for glial fibers. Note that fibrous astrocytes maintain their normal longitudinal orientation in the degenerated tract (compare with Figure 56-6). [From Spielmeyer (1922), with permission.]

phic and anisomorphic gliosis are easily distinguished in regions of the brain where glial fibers are regularly oriented, e.g., in myelinated tracts (Figure 56-4) and in the cerebellar cortex (Figure 56-5). Conversely, the distinction is not easy where glial fibers normally run an irregular course (Figure 56-7).

In isomorphic gliosis, the morphological findings do not provide incontrovertible evidence as to a real increase of glial fibers, since they could suggest a simple condensation of the glial framework as a result of the loss of nerve. The study of Kost-Mikucki and Oblinger (1991) is thus important in this respect because it shows significant increase of GFAP mRNA in pyramidal tracts undergoing Wallerian degeneration, a condition typically associated with isomorphic gliosis.

An interesting question is whether the dense glial scar characteristic of anisomorphic gliosis is the product of astrocytes originally located at the site of injury. A possibility to be considered is that astrocytes migrating from peripheral areas also participate in the process. In fact, the studies of Janeczko (1989) seem to point in this direction in that [^{3}H]thymidine labeled astrocytes, at first scattered over a relatively wide area, later became concentrated around the lesion. Astrocytes derived from primary cultures or from fetal central nervous system tissue are capable of extensive migration when transplanted to mature brain (see Zhou et al., 1990, for references), up to 5 cm in the spinal cord according to one report (Goldberg and Bernstein, 1988). Experiments with peripheral ganglia implants suggest that reactive astrocytes are also capable of migration (Rosenstein and Brightman, 1981; Dahl et al., 1991). Astrocytes were able to invade the grafted ganglia as evidenced by a positive reaction to GFAP antibodies only reacting with the "central" form of GFAP (Jessen et al., 1984) (Figure 56-8). Another point of interest was that reactive astrocytes did not appear to affect sensory neurons in DRG implants (Figure 56-9).

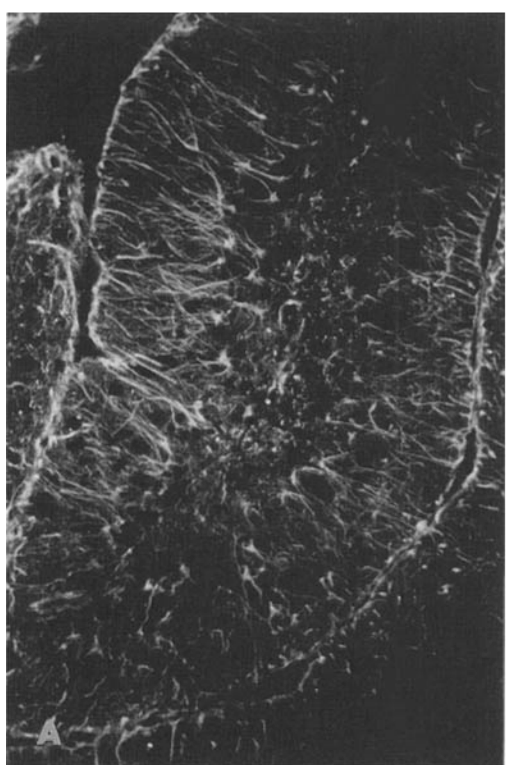
Gemistocytic Astrocytes

Large astrocytes with homogeneous cytoplasm (Figure 56-10) were called *Gemästate* (fattened) by Nissl and they are often referred to as gemistocytic astrocytes in the English literature. These cells are particularly numerous in regions undergoing severe fibrous gliosis and they were thus traditionally considered as the fiber-forming cells. Brain cytoskeletal proteins, including GFAP, are synthesized by free polysomes (Strocchi et al., 1982). Gemistocytic astrocytes share common features with neurons undergoing central chromatolysis, a basic reaction to axonal transection. Nissl granules consisting of parallel cisterns of rough endoplasmic reticulum are replaced by free ribosomes under this condition.

Formation of Accessory Glial Limiting Membranes

Astrocytes form the boundary between central nervous system and non-central nervous system tissues in both normal and pathological conditions. In normal brain, a continuous lining of astrocyte processes covered by a basal lamina is interposed between brain and meninges (external glial membrane) and between brain and blood vessels (perivascular glial membrane).

As to the formation of glial membranes in pathological conditions, a brain infarct can be considered as an example. Starting a few days after ischemic necrosis, reactive astrocytes surround the infarct with a thick mesh of fibrils, thus demarcating the necrotic tissue from viable brain and probably preventing the spread of edema. After a period of time that may vary from weeks to months depending on the size of the infarct, the glial scar covered by a basal lamina forms the new surface of the brain. The



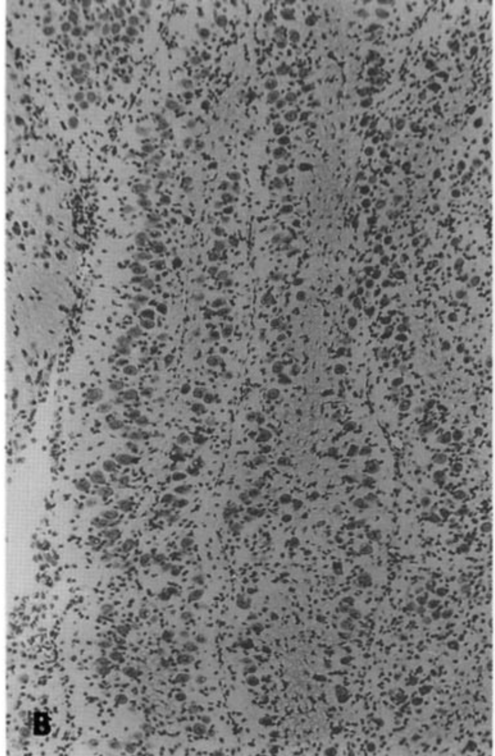


FIG. 56-5. (A) Isomorphic gliosis of cerebellum in 1-month-old homozygous weaver, a mouse mutation leading to the loss of the granule cell layer. (B) Note that the glial fibers maintain the general orientation of Bergmann glia in the atrophic cerebellum. Figure A: immunofluorescence with GFAP antiserum; B: toluidine blue stain. [From Bignami and Dahl (1974c), with permission.]

cyst resulting from the absorption by bloodborne macrophages of the necrotic tissue is now part of the subarachnoid space (Figure 56-11). If the infarct is deep in the brain, in cerebral white matter or in basal ganglia, the cyst is part of the perivascular space (Figure 56-12). Indirect evidence suggests that astrocytes may participate in the formation of the basal lamina. Astrocytes in primary culture synthesize variant forms of two basal membrane proteins, that is, laminin and fibronectin (Liesi et al., 1983; Price and Hynes, 1985; Liesi and Risteli, 1989). Astrocytes in culture also produce chondroitin sulfate proteoglycan (Gallo and Bertolotto, 1990) but it is still not known whether this proteoglycan is the heparan sulfate proteoglycan of basal laminae. According to a recent paper, post-translational modification of this proteoglycan may include substitution with chondroitin sulfate side chains (Murdoch et al., 1992).

Glycogen

In normal brain, glycogen is predominantly stored in astrocytes. Binding of norepinephrine and vasoactive intestinal peptide (VIP) to their receptors stimulates glycogenolysis, and this is also true for several substances released by neurons during depolarization such as adenosine and potassium. This suggests that astrocytes may help neurons with their energy requirements during periods of activity (Magistretti et al., 1986; Chapter 52, this volume).

Glycogen accumulation after an initial decrease is a distinctive feature of astrocytes responding to injury (for review see Haymaker et al., 1970). The process leading to glycogen accumulation is still unknown. An induction of glycogen synthesis resulting in a marked increase of glycogen concentration has been observed after VIP- and norepinephrine-induced glycogenolysis in primary astrocyte cultures (Sorg and Magistretti, 1992).

UPREGULATION OF GFAP EXPRESSION: A SENSITIVE INDICATOR OF BRAIN INJURY

GFAP is the subunit of glial-specific intermediate filaments and it is thus not surprising that GFAP expression is enhanced in reactive astrocytes. As noted above, accumulation of glial filaments is the characteristic finding of fibrous gliosis.

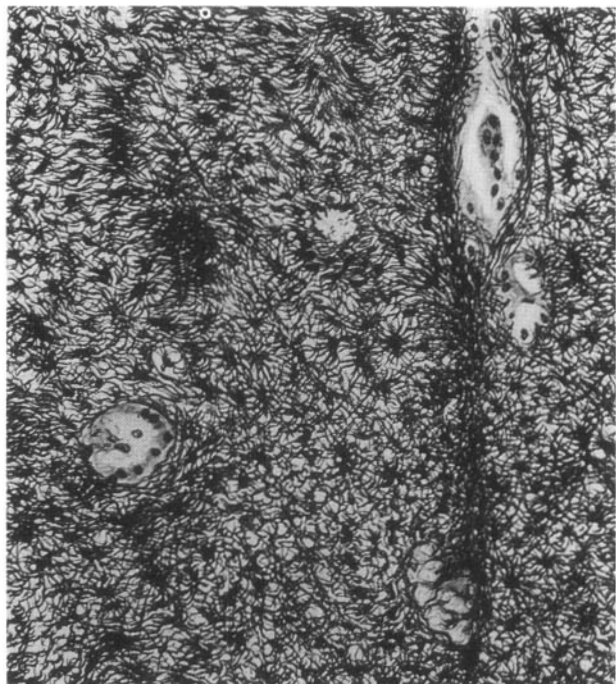

FIG. 56-6. Anisomorphic gliosis in an old multiple sclerosis plaque. Weigert's stain for glial fibers. [From Spielmeyer (1922), with permission.] Astrocytes from a dense mesh of fibers with no discernible pattern (compare with Figure 56-4).

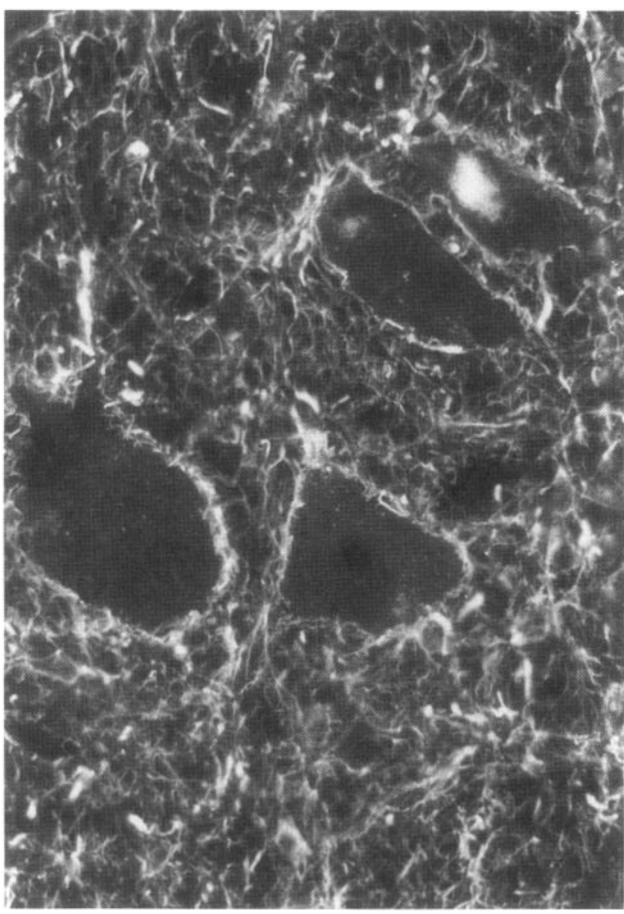

FIG. 56-7. Normal dog spinal cord gray matter stained with GFAP antiserum. Glial fibers form a delicate mesh with no recognizable orientation. The distinction between isomorphic and anisomorphic gliosis is practically impossible in such a location.

The factors that induce GFAP expression in development are probably different from those that operate in reactive astrocytes (Sarthy et al., 1991). Protoplasmic astrocytes in rat cerebral isocortex are GFAP-negative, but they convert into cells that stain brightly with GFAP antibodies 2 days after injury (Figure 56-13), mRNA for GFAP becoming maximal at 4 to 5 days (Cancilla et al., 1992). The same is true for Müller glia in the rat retina (Figure 56-14). The question may be raised as to whether GFAP is produced *ex novo* under these conditions or whether its production is upregulated, basal levels being too low for detection. We note that in the case of Müller glia, the negative immunohistological findings have been confirmed by *in situ* hybridization studies of GFAP mRNA expression, and it has also been shown that the GFAP gene is transcriptionally activated in Müller cells of mice with retinal degeneration (Sarthy et al., 1991). In mice as in rat, Müller glia convert into GFAP-positive cells in retinal detachment and degeneration (Dräger and Edwards, 1983; Shaw and Weber, 1983; Eisenfeld et al., 1984; Erickson et al., 1987). Interestingly, Müller cells in chick retina, which are normally GFAP-positive do not accumulate GFAP in response to degeneration (Semple-Rowland, 1991).

Since GFAP is the subunit of the filaments forming the glial fiber, increased immunohistological staining for GFAP is the equivalent of fibrous gliosis. However, GFAP immunohistology is much more sensitive than the traditional staining procedures for glial fibers, and it has been used to study astrocyte reactions to injury that would have been difficult to detect otherwise. In fact, this astrocyte response is often easier to demonstrate than the underlying brain damage. An important point raised by these studies is that gliosis is not necessarily a permanent phenomenon, as originally believed when it could only be demonstrated in areas of severe tissue injury. Transient gliosis, that is, increased GFAP immunostaining followed by return to normal levels, has been observed after excitotoxin lesions (Björklund et al., 1986), deafferentation (Gage et al., 1988; Anders and Johnson, 1990), transganglionic degeneration (Hajós et al., 1990), spreading depression (Kraig et al., 1991), chronic hypoxia (Zimmer et al., 1991)

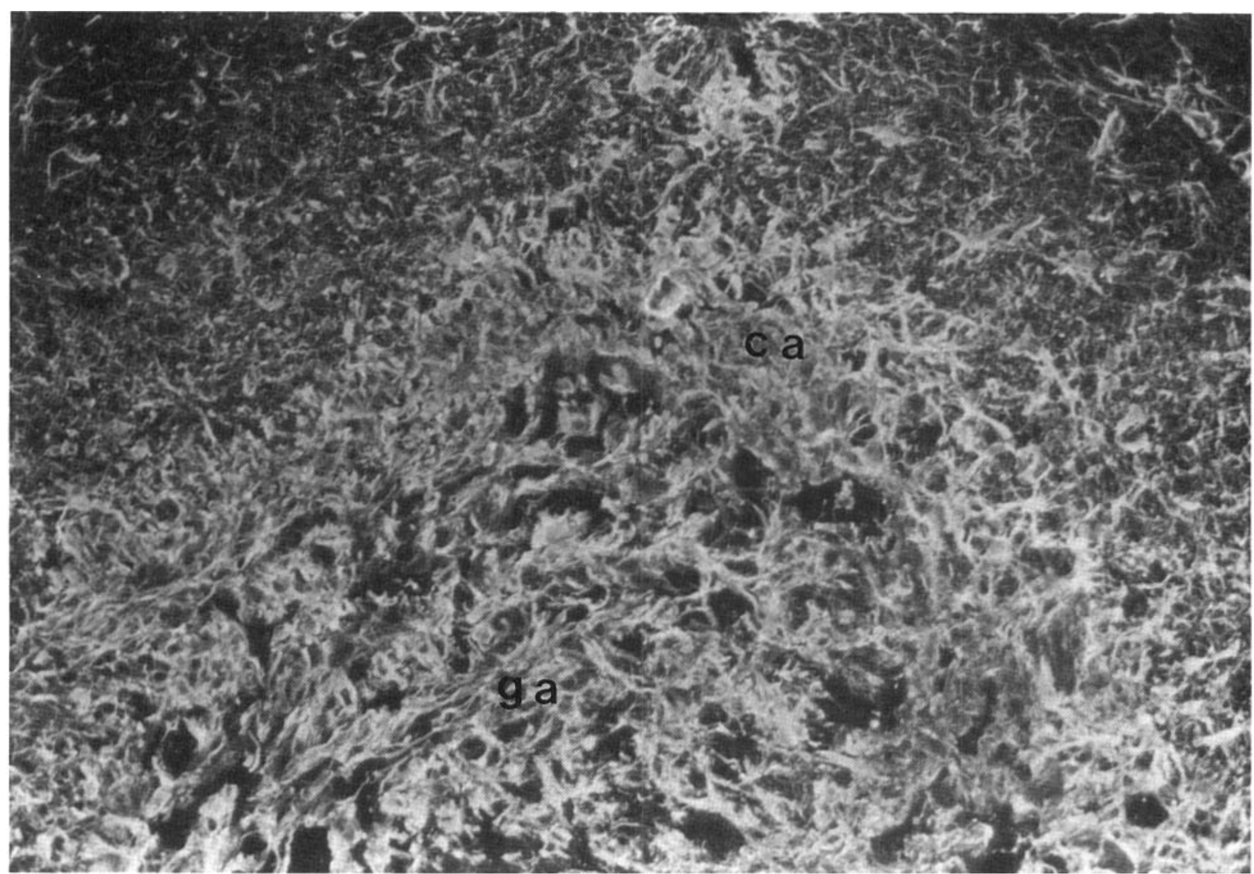

FIG. 56-8. Dorsal root ganglion grafted in rat cerebral hemisphere 1 month after operation and stained with a GFAP monoclonal antibody not reacting with the peripheral form of GFAP. The ganglion (*ga*) is surrounded by a dense glial capsule (*ca*). [From Dahl et al. (1991), with permission.]

and cortical devascularization except for the area surrounding the devascularized area (Herrera and Cuello, 1992).

Axonal Reaction

Gliosis that follows the reaction of the nerve cell to a lesion of its axons is not covered here because it is better discussed in association with the microglial changes (see Chapter 59). We only note that when the axonal reaction results in cell death, severe gliosis may occur which is readily detectable by traditional staining methods for glial fibers, for example, the severe gliosis of the thalamic nuclei relaying to the frontal cortex in patients with prefrontal leucotomy.

Terminal Degeneration (Deafferentation)

Electron microscopic studies of the lateral geniculate body after eye removal in the squirrel monkey showed that astrocyte processes were greatly enlarged and contained many filaments. Furthermore, they were seen to enwrap dense degenerated terminals (Wong-Riley, 1971). With GFAP antibodies, an astrocyte reaction was first detected one day after deafferentation in rat superior colliculus. At 21 days, a dense network of GFAP-positive fibers had become apparent (Schmidt-Kastner et al., 1993).

The astrocyte response to denervation has been particularly well studied in the dentate gyrus of the hippocampus, and this is probably because of the remarkable sprouting and heterotypical innervation that results from the lesion (Rose et al., 1976; Gage et al., 1988; Tanaka et al., 1991). The dramatic increase of GFAP immunoreactivity, which in the case of perforant path lesions selectively involves the outer molecular layer of the dentate gyrus, suggests that reactive astrocytes secrete neurotrophic factors as a necessary requirement for the sprouting response (Gage et al., 1988). Surprisingly, the expression of GFAP mRNA after lesions of the entorhinal cortex was not confined to the denervated part of the dentate gyrus but also involved areas that do not

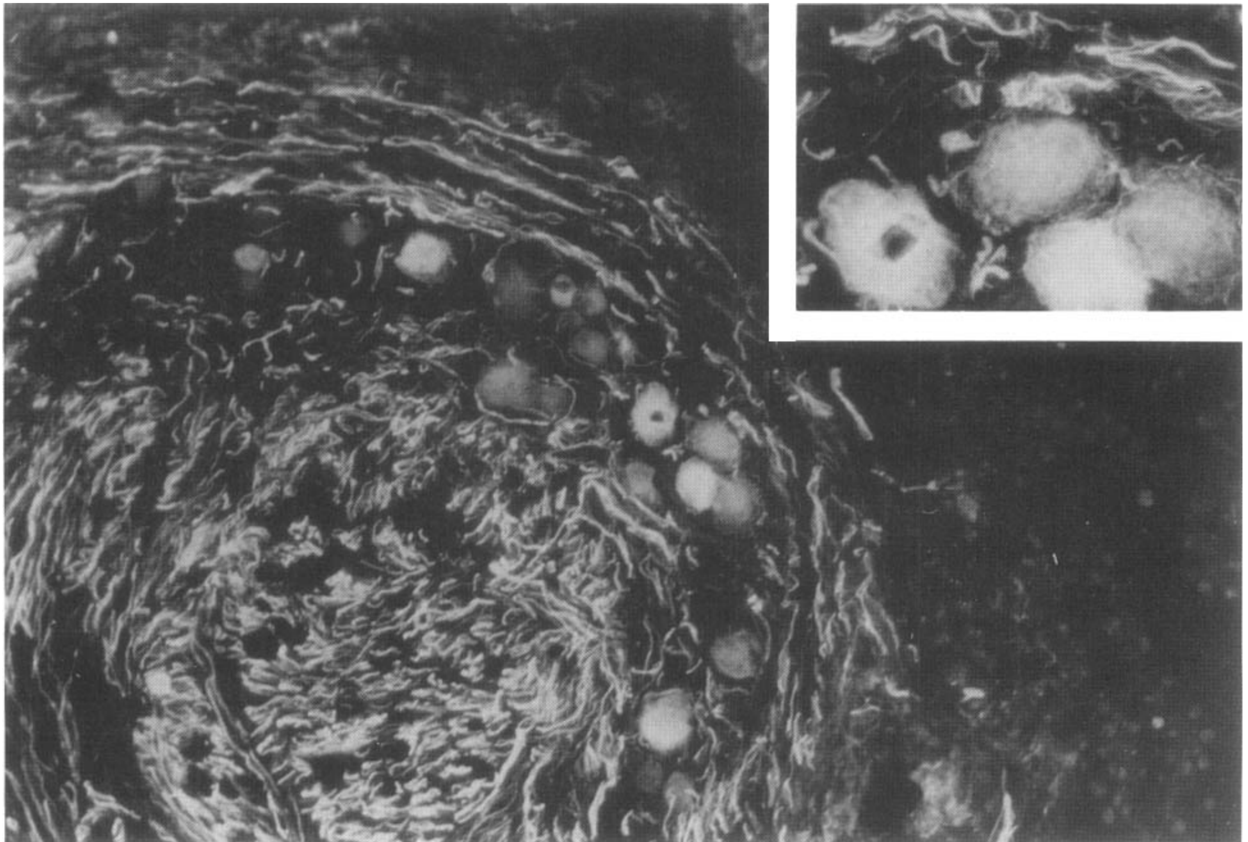

FIG. 56-9. Dorsal root ganglion (*DRG*) grafted in rat cerebral hemisphere 1 month after operation and stained by indirect immunofluorescence with a neurofilament monoclonal antibody. Note the normal appearance of DRG neurons. **Inset:** DRG neurons at higher magnification. [From Dahl et al. (1991), with permission.]

receive projections from the entorhinal cortex (Steward et al., 1990). Upregulation of GFAP mRNA levels was not dependent on induction of immediate early genes (Smith and Steward, 1992).

A vigorous astrocyte response to denervation was also observed in rat olfactory bulb (Anders and Johnson, 1990). The olfactory nerve is capable of functional regeneration after axotomy, thus suggesting that, as in the dentate gyrus of the hippocampus, reactive astrocytes are compatible with axonal growth.

Transganglional Degeneration

Sciatic nerve section or compression in the rat is followed by a marked increase of GFAP immunoreactivity occurring as early as 3 days after the lesion in the segmentally related ipsilateral dorsal horn (Hajós et al., 1990; Murray, 1990; Garrison et al., 1991). According to Hajós et al. (1990), the gliosis is due to degenerative changes of the central primary afferent terminals resulting from blockade of retrograde nerve growth factor transport in the injured nerve. In agreement with this hypothesis, gliosis markedly decreased as soon as the regenerating peripheral axons had reached their target.

"Functional" Damage

Increased GFAP immunoreactivity has been also reported in the apparent absence of structural damage, specifically in the hypoglossal nucleus after electrical stimulation of the hypoglossal nerve (Hall et al., 1989), in the hippocampus after repeated sessions of electroconvulsive shock (Orzi et al., 1990), in spreading depression induced by the application of potassium chloride to the cerebral cortex (Kraig et al., 1991) and in kindling, a permanent seizure disorder resulting from the daily application of electrical stimuli to susceptible parts of the brain (Khurgel et al., 1992). Electrically induced seizures in rat hippocampus also resulted in a rapid and dramatic increase in mRNA for GFAP (Steward et al., 1991).

Still little is known concerning the disruption of functional glial-neuronal interactions that may occur when astrocytes respond to injury. An example

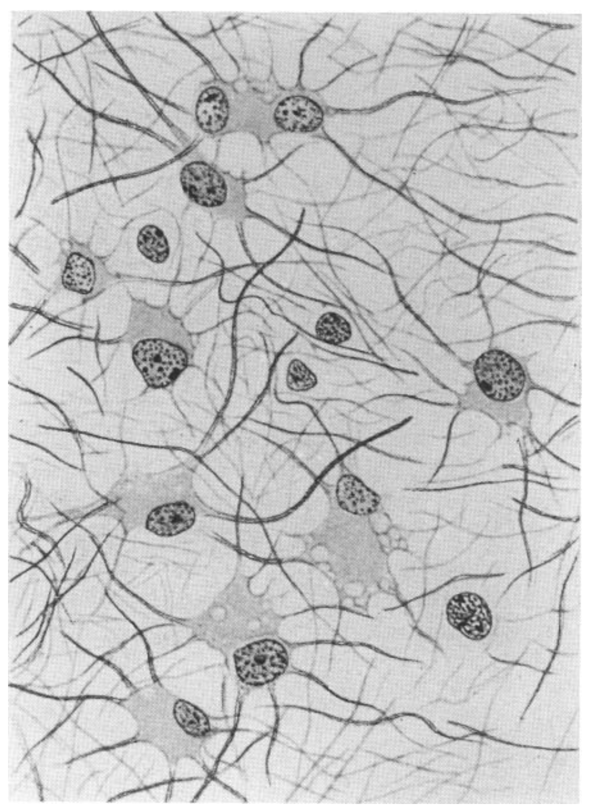

FIG. 56-10. Gemistocytic astrocytes in cerebral cortex. Weigert's stain for glial fibers. [From Spielmeyer (1922).]

would be the glutamate uptake system in reactive astrocytes. If uptake is enhanced, the neurons would get extra protection against the toxic effect of the excitatory neurotransmitter (see Chapter 48). Alternatively, the uptake system may be impaired, considering that the astrocyte machinery is switched to other tasks such as fibrillogenesis.

VIMENTIN IN REACTIVE ASTROCYTES

The protein composition of rat optic nerve in wallerian degeneration first suggested that vimentin accumulates in reactive astrocytes (Dahl et al., 1981a). The two main proteins in the gliosed nerves were GFAP and a 57 kD protein, which was identified as vimentin, the fibroblast-type intermediate filament protein (Figure 56-15). Furthermore, vimentin immunoreactivity was markedly increased compared to normal optic nerve (Figure 56-16).

Immature glia first express vimentin before they switch to astrocyte-specific GFAP (Dahl et al., 1981b), and the question may be asked whether the same is true for reactive astrocytes. This, in fact, does not appear to be the case, since in stabbed cerebral cortex vimentin is only expressed by astrocytes located in the vicinity of the mesenchymal scar while

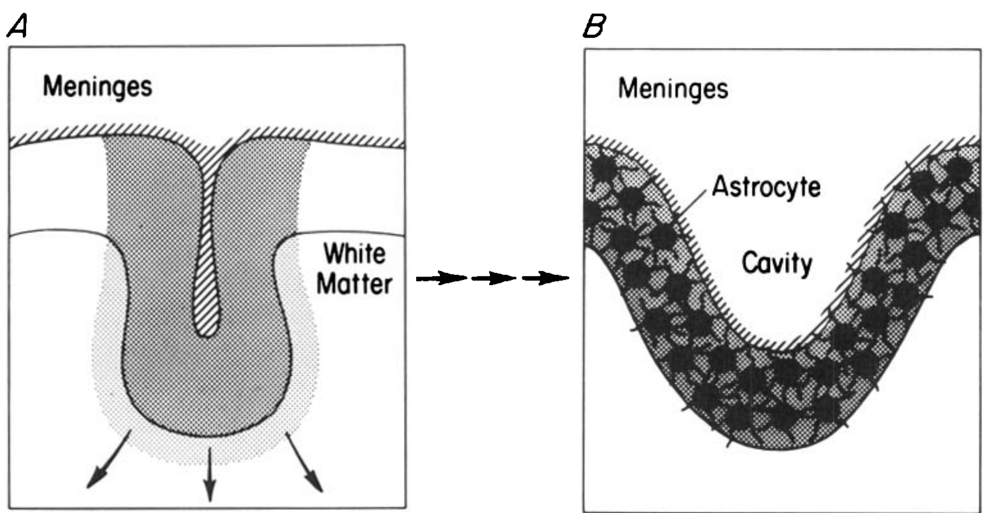

FIG. 56-11. **(A)** Cerebral infarct involving cortex and white matter. *Arrows* point to the spread of edema into the underlying white matter. **(B)** Final stage of the corticosubcortical infarct shown in Figure A. An astrocyte scar surrounds the cavity resulting from absorption of necrotic tissue by bloodborne macrophages. Note that the cavity is now part of the subarachnoid space and, as in normal cortex, the astrocytic scar is covered by a basal lamina (*dashed line*). [From Bignami (1991), with permission.]

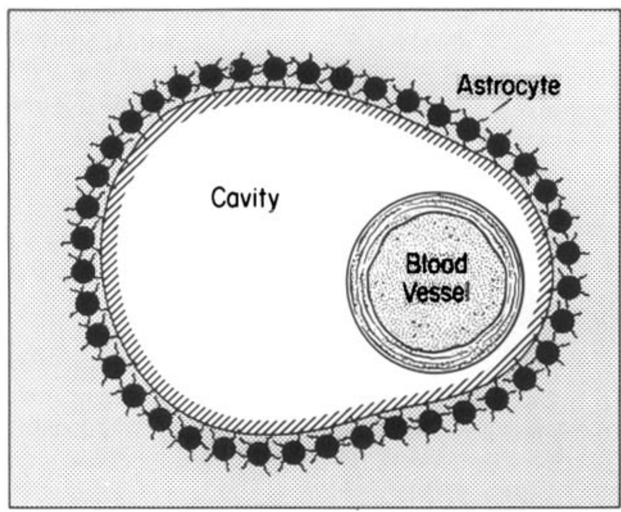

FIG. 56-12. If the infarct is deep inside the brain (e.g., in white matter or basal ganglia) the cavity resulting from reabsorption of the necrotic tissue is now part of the perivascular space. Such small cysts are often referred to as lacunar infarcts. The *dashed line* surrounding the cavity is the basal lamina.

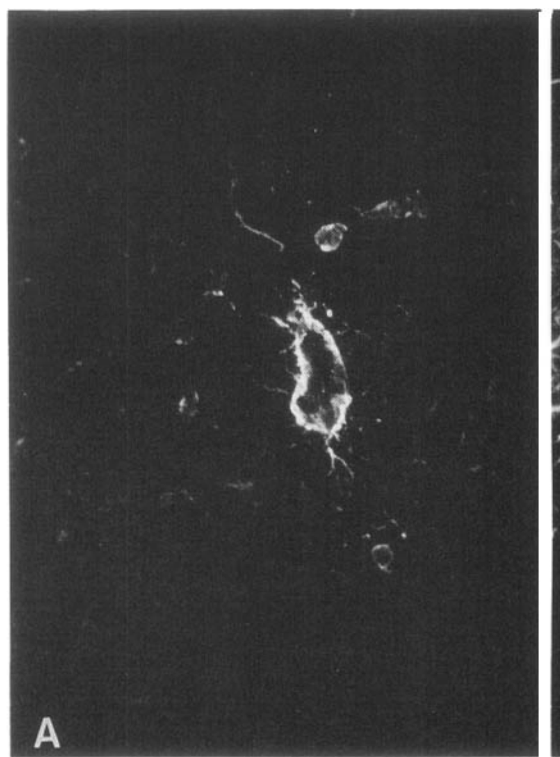
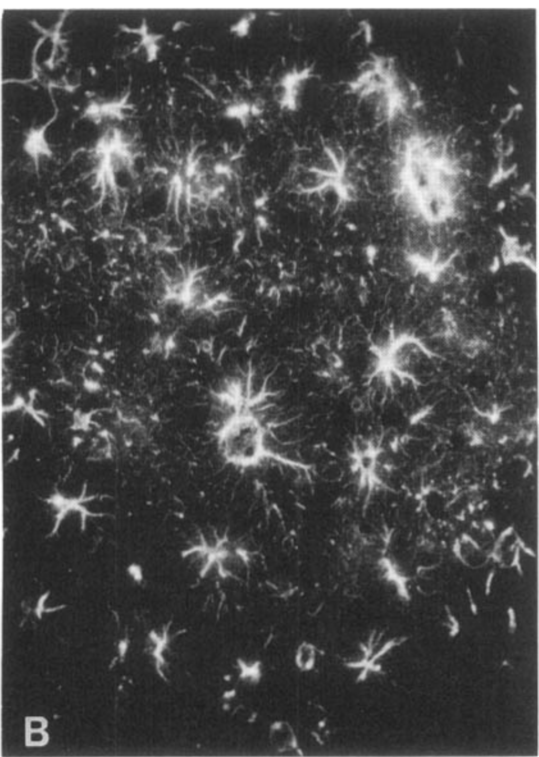
the astrocyte reaction as assessed by GFAP immunoreactivity extends far beyond (Pixley and deVellis, 1984; Schiffer et al., 1986; Mansour et al., 1990; Calvo et al., 1991). Conversely, white matter astrocytes which normally contain GFAP and, to a lesser extent, vimentin, accumulate both GFAP and vimentin (Mansour et al., 1990; Oblinger and Singh, 1993).

EXTRACELLULAR MATRIX

Compared to other tissues, surprisingly little is known about the composition of extracellular matrix in the brain. Perhaps the most important factor for the lack of research on this topic is the electron microscopic appearance of "well fixed" brain tissue. In these microphotographs brain extracellular space is markedly reduced from its physiological size, accounting for approximately 17 to 20% of the brain





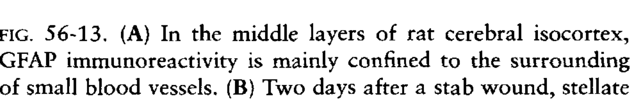


FIG. 56-13. (**A**) In the middle layers of rat cerebral isocortex, GFAP immunoreactivity is mainly confined to the surrounding of small blood vessels. (**B**) Two days after a stab wound, stellate astrocytes are readily apparent. [From Bignami and Dahl (1974b), with permission.]

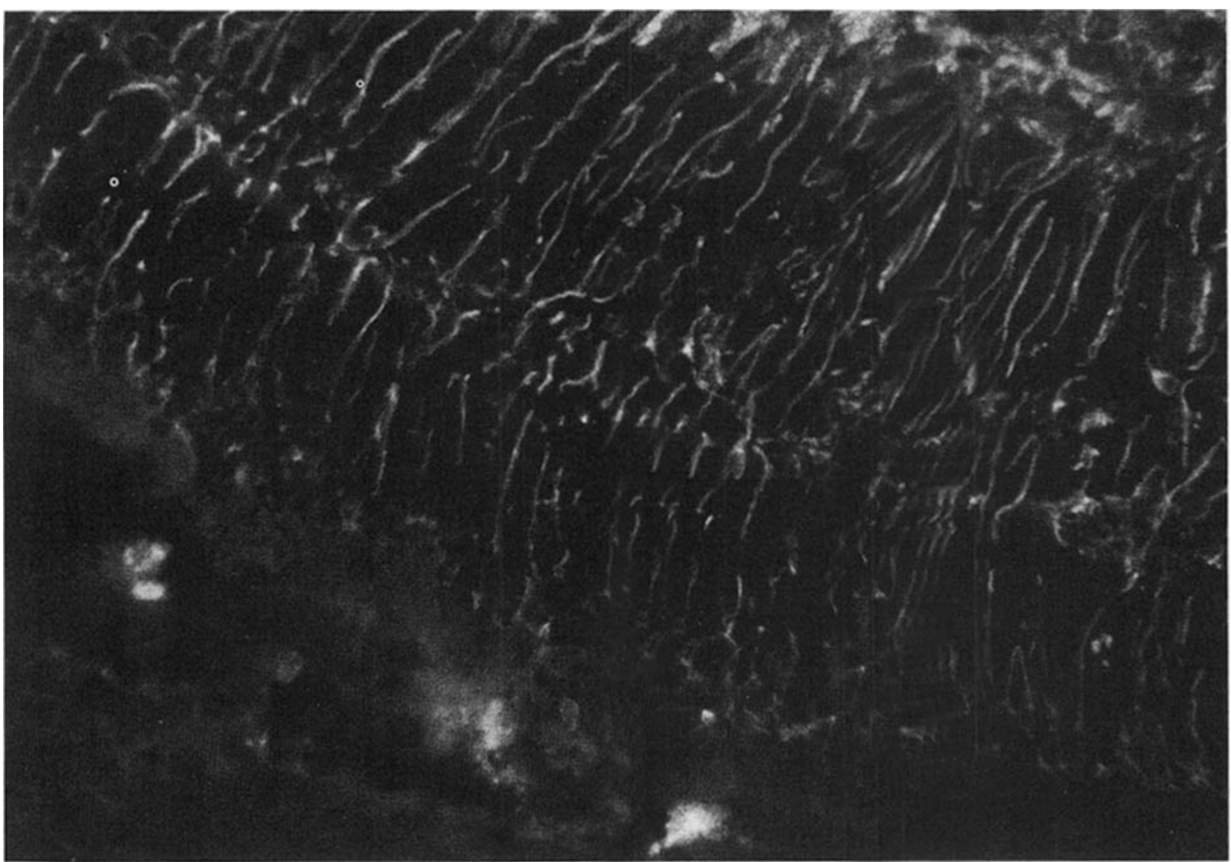

FIG. 56-14. Immunofluorescent staining with GFAP antiserum of the radial fibers of Müller in rat retina following optic nerve crush. [From Bignami and Dahl (1979), with permission.] In normal rat retina, GFAP immunoreactivity is confined to astrocytes in the ganglion cell and nerve fiber layers (see Chapter 43).

volume, to about 5%. Furthermore, this space appears empty. In accordance with light microscopic observations, it does not contain structures found extracellularly in other tissues, such as fibrils and basal membranes. Also, it is devoid of the electron dense material that one would expect if it contained proteins. It has now been shown that the apparent emptiness of brain interstitium is due to the fact that in brain, as in cartilage, hyaluronic acid (HA) plays a structural role in the formation of the extracellular matrix (for review see Bignami et al., 1993). The solubility of HA in aqueous fixatives is a well-known phenomenon. Furthermore, a 60 kD HA-binding protein is released intact from brain homogenates by hyaluronidase digestion, thus suggesting that it will also disappear from the sections if HA is dissolved (Asher et al., 1991). The protein was called glial HA-binding protein (GHAP) and this in view of the fact that its distribution is similar to that of GFAP at the light microscopic level. Amino acid sequence analysis indicates that GHAP derives from versican, a large chondroitin sulfate proteoglycan of precartilaginous mesenchyma either by limited proteolysis or alternative splicing. GHAP is mainly confined to white matter, while versican is found in both white matter and gray matter. In gray matter it forms characteristic perineuronal coats (the Golgi pericellular net) together with aggrecan, the chondrotin sulfate proteoglycan of mature cartilage.

HA and GHAP persist for long periods of time in white matter tracts and optic nerves undergoing Wallerian degeneration and isomorphic gliosis (Bignami et al., 1989) (Figure 56-17). The more pronounced staining of gliosed compared to normal optic nerve shown in Figure 56-17 could be due to the condensation of the extracellular matrix resulting from the loss of myelinated axons rather than increased synthesis. Conversely, we have not been able to detect GHAP and hyaluronic acid in dense anisomorphic white matter glial scars resulting from penetrating wounds and multiple sclerosis suggesting that glial processes in these scars are closely packed with little intercalated extracellular matrix (Dahl et al., 1989; Mansour et al., 1990, unpublished observations). If in cortical scars such loss of extracellular matrix also includes proteoglycans, it is tempting to

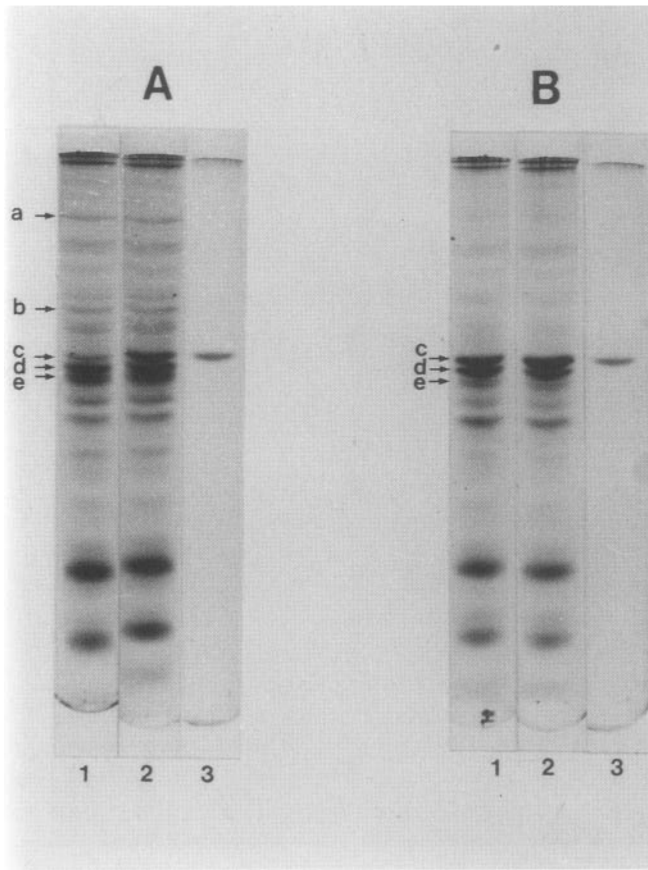

FIG. 56-15. Identification of vimentin in rat optic nerves, normal and degenerated, by SDS-PAGE. (A) Gel 1, normal optic nerve. Identified bands: *a*, 150,000 kD neurofilament protein; *b*, 70 kD-neurofilament protein; *c*, vimentin; *d*, GFAP; *e*, tubulinin. Gel 2, mixture of gel 1 with rat vimentin. Gel 3, rat vimentin. (B) Gel 1, optic nerve 3 weeks after enucleation. Identified bands as in Figure A. Gel 2, mixture of Gel 1 with vimentin. Gel 3, vimentin. Note in the degenerated nerves the disappearance of neurofilament proteins and the marked increase in vimentin. [From Dahl et al. (1981a), with permission.]

speculate that the phenomenon may contribute to the decrease in interstitial calcium that precedes seizures in epileptogenic foci and that would increase neuronal excitability (Dietzel and Heinemann, 1986). It is reasonable to assume that the negatively charged proteoglycans play a role in retaining divalent calcium (Ca^{2+}) in the neuronal microenvironment.

GLIOSIS IN IMMATURE BRAIN

The question of gliosis resulting from injury to immature brain, for example, before the onset of myelination, remains a matter for further investigation. In accordance with Berry et al. (1983), we found relatively little gliosis, as evidenced by GFAP immunohistochemistry, in rats stabbed at birth and sacrificed 2 days later (Bignami and Dahl, 1976). However, severe and diffuse gliosis was observed after 13 days or later, in accordance with Janeczko's (1988) finding of an extensive astrocyte proliferative response to injury in neonatal rat brain. Compared to adult rats, the distinctive features of stabbed newborn rats sacrificed 1 month after operation were the presence of white matter cavitation and the absence of a mesenchymal scar at the site of the stab. Similar results have been reported by Berry et al. (1983). Conversely, severe reactive gliosis as shown by GFAP immunoreactivity has been reported in various types of pre- and perinatal damage in the human brain by Roessmann and Gambetti (1986).

Differences have also been reported between adult and newborn rats in their astroglial response to spinal cord injury and dorsal root transection, gliosis in the spinal cord being much less intense in the newborn animals (Barrett et al., 1984; Murray et al., 1990).

While the extent and time course of gliosis following perinatal brain wounds remain a controversial issue, no differences have been shown between neonatal and mature astroglia in their response to Wallerian degeneration of rat optic nerve and hamster corticospinal tract, that is, isomorphic gliosis (Fulcrand and Privat, 1977; Trimmer and Wunderlich, 1990; Oblinger and Singh, 1993). In adult and newborn animals the end result was the formation of a dense glial scar occurring at a much earlier date in newborn animals. This probably in view of the fact that in Wallerian degeneration of adult central nervous system tracts the removal of myelin debris is a lengthy process (Bignami and Ralston, 1969).

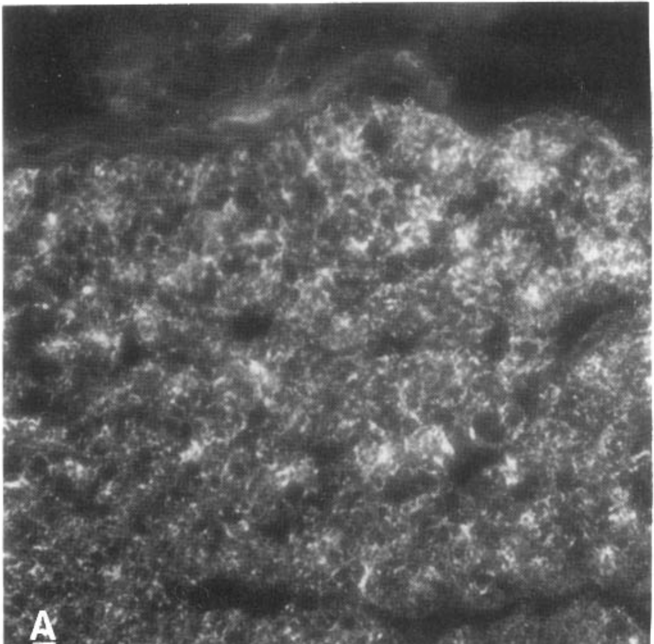
GLIOSIS IN SUBMAMMALIAN VERTEBRATES

Little is known about the astrocyte response to injury in submammalian vertebrates although perhaps it is an important topic, especially in view of the inherent capacity for regeneration of the central nervous system in fish and amphibia and of the putative role of gliosis in preventing regeneration of mammalian central nervous system tracts (Reier et al., 1983).

We have studied gliosis in goldfish spinal cord and we found that the regenerated spinal cord at the site of transection was almost completely devoid of GFAP immunoreactive material (Bignami et al., 1974). Conversely, gliosis was observed in the proximal and distal stumps of the transected spinal cord when their reunion was prevented.

Similar findings have been reported in goldfish op-

FIG. 56-16. (**A**) Staining of leptomeninges and glial septa in a transverse section of normal rat optic nerve. Immunofluorescence with vimentin antisera. (**B**) Intense staining of gliosed rat optic nerve 1 month after enucleation. Immunofluorescence with vimentin antisera. [From Dahl et al. (1981a), with permission.]



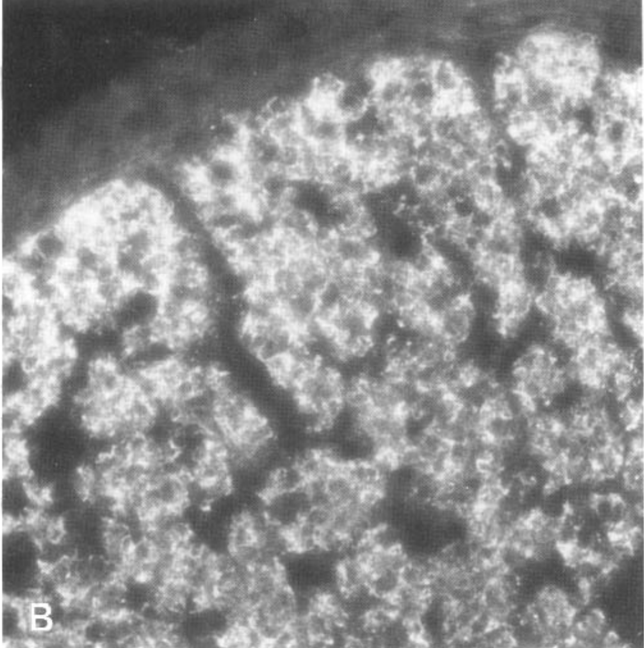


FIG. 56-17. Condensation of the extracellular matrix in rat optic nerve undergoing wallerian degeneration 55 days after crush. (**A**) Normal optic nerve is stained for hyaluronic acid (Bignami and Asher, 1992). (**B**) Degenerated optic nerve is stained with antibodies to the glial hyaluronate-binding protein.

tic nerve by Stafford et al. (1990). An interesting observation was that optic nerve astrocytes, which normally do not stain with GFAP antibodies (Dahl and Bignami, 1973b) and express keratin (Giordano et al., 1990) had become GFAP-positive after transection. More recently, it was shown that the GFAP-negative regenerated optic nerve filling the gap between proximal and distal stumps was populated by Schwann-like cells and thus bore a strong resemblance to peripheral nerve (Nona et al., 1992).

57 Oligodendrocyte inhibition of nerve fiber growth and regeneration in the mammalian central nervous system

MARTIN E. SCHWAB

In contrast to most organs of the body, which retain a life-long potential for renewal and plasticity, cell division does not occur in the adult central nervous system, and outgrowth of nerve fibers is extremely restricted. Many of the long-distance connections and fiber tracts are formed prenatally, and the postnatal differentiation of the nervous system includes a progressive restriction of fiber growth. In the adult, plastic changes in dendritic trees and axonal arborizations do occur and may in fact be much more common than previously assumed (Purves et al., 1986; Benowitz et al., 1988; Rossi et al., 1991, Woolf et al., 1992). However, the distances of growth are usually restricted to a few hundred microns, and rarely exceed 1 mm. Reactions to lesions of central fiber tracts in higher vertebrates parallel these developmental events: whereas fiber tracts can regenerate in very immature animals, this process is strongly restricted in later development and absent in most central nervous system fiber systems in the adult (Kalil and Reh, 1982; Bernstein and Stelzner, 1983; Shimizu et al., 1990; Hasan et al., 1991, Treherne et al., 1992). Although regenerative sprouting can occur, the length of these sprouts remains limited, and elongation beyond 1 mm does not occur.

In the search for an explanation of the limited fiber growth and regeneration potential of the adult central nervous system, the first hypothesis to be formulated and experimentally tested was that of an intrinsic inability of adult neurons to grow (for review see Ramón y Cajal, 1928). Since peripheral nerves (in particular following crush lesions, which are more conducive than transections) were well known for their successful growth of sensory and motor fibers over long distances, peripheral nerve grafts were placed into various areas of the central nervous system. These experiments allowed exposure of central neurons to a peripheral, regeneration-permissive tissue environment. The first successful experiments were published by F. Tello in 1911, and showed that nerve fibers from the rabbit neocortex invaded implants of peripheral nerves. Tello and later Ramón y Cajal (1928), therefore drew the conclusion that adult central nervous system neurons can regenerate their axons, but that the *tissue environment* is of crucial importance. They hypothesized that denervated Schwann cells produced trophic factors which attracted and sustained the regenerating axons. Interestingly, their results were reinterpreted by Le Gros Clark (1943) in light of the newly described peripheral innervation of cerebral blood vessels as fibers of peripheral neurons. He returned to the hypothesis that central nervous system neurons in their highly differentiated state would be unable to repeat early developmental processes. Probably due to its high plausibility, this hypothesis persisted until 1980, when A. Aguayo and his collaborators started an in-depth investigation of the role of peripheral nerve transplants as substrates for regenerating central nervous system axons. Their elegant, systematic studies showed that the old findings by Tello were correct and that probably the large majority of central nervous system nerve cells, including projection neurons as well as interneurons, are able to regenerate a lesioned axon in the environment of a peripheral nerve transplant (Richardson et al., 1980, 1984; David and Aguayo, 1981; Carter et al., 1989). Brainstem and spinal cord as well as retinal axons could be guided over distances of several centimeters by Schwann cells and their basement membranes. In recent studies this group showed that retinal axons guided to one of their main target areas, the superior colliculus, through a peripheral nerve graft established typical retinotectal arborizations in the correct layers with synapses closely resembling the normal retinotectal synapse type (Carter et al., 1989, 1991). Typical postsynaptic potentials could be recorded in the deep tectal layers upon light stimulation of the retina (Keirstead et al., 1989). In a related experiment where retinal axons were guided to the pretectal nuclei, a pupilloconstrictor reflex reappeared 6 to 8 weeks after transplantation

(Thanos, 1992). Thus, adult retinal ganglion cells not only possess the capability to regrow long axons, but they obviously retain the mechanisms necessary for target recognition and establishment of functional synapses. Interestingly, however, the fibers leaving the peripheral nerve graft invaded the central nervous system tissue only for a very limited distance of 0.6 mm at most (David and Aguayo, 1981; Carter, 1989; Thanos, 1992). Subsequent investigations of the cell biological mechanisms that could be responsible for this drastic difference between central and peripheral nervous tissue in their properties for neuronal regeneration led to a new concept, that of neurite growth inhibitors (Schwab and Thoenen, 1985; Schwab, 1990), and to the finding that oligodendrocytes are crucially involved in the expression of such molecules (Schwab and Caroni, 1988).

CENTRAL NERVOUS SYSTEM WHITE MATTER AS A CULTURE SUBSTRATE SHOWS NONPERMISSIVE PROPERTIES FOR NEURITE GROWTH

Schwann cells in peripheral nerve enhance the synthesis of neurotrophic factors as well as that of a number of growth-promoting cell adhesion and extracellular matrix molecules in response to denervation (Daniloff et al., 1986; Heumann et al., 1987; Martini and Schachner, 1988; Martini et al., 1990; Meyer et al., 1992). This finding strongly supported the original postulates by Tello (1911) and Ramón y Cajal (1928). However, the situation was much less clear with regard to the central nervous system. We therefore decided to directly test the role of neurotrophic factors *in vitro* by coculturing neurons with explants of adult rat sciatic nerves and optic nerves (central nervous system tissue) in the presence of saturating amounts of neurotrophic factors (Schwab and Thoenen, 1985; Caroni et al., 1988). The transplants were either viable or deprived of living cells by freezing. Interestingly, the results obtained closely corresponded to the *in vivo* situation: sympathetic, dorsal root ganglion, or retinal fibers grew into the sciatic nerve explants, but did not invade the optic nerves. We therefore concluded that neurotrophic factors (nerve growth factor or partially purified brain-derived neutrophic factor) were unable to provoke neurite ingrowth into central nervous system tissue. Instead, these results strongly suggested the presence of inhibitory components restricting neurite growth in central nervous system tissue. Since the same results were obtained with living or dead optic nerves, these components did not arise under the culture conditions but were probably constituents of the adult central nervous system.

Using frozen sections as a culture substrate for various types of neurons growing under neurite-promoting culture conditions Carbonetto et al. (1987) found a very similar result: peripheral nerve tissue was a favorable substrate, but optic nerves or spinal cord tissue did not support neurite growth. In subsequent experiments several groups confirmed this result and showed that in the central nervous system lack of cell adhesion and neurite growth was mainly associated with white matter (Crutcher, 1989; Savio and Schwab, 1989; Watanabe and Murakami, 1889; Khan et al., 1990; Sagot et al., 1991). (However, in comparison to peripheral nerves or artificial growth-promoting substrates, gray matter is not a good substrate either). Because peripheral nerves contain basement membranes around each axon/Schwann cell unit, which were shown to be preferred substrates for regenerating axons *in vivo* (Ide et al., 1983; Schwab and Thoenen, 1985), more detailled cellular and biochemical investigations on the localization of these hypothetical neurite growth inhibitory factors were needed.

IN VITRO INTERACTIONS OF NEURITES WITH GLIAL CELLS

Central nervous system glial cells were cultured at low cell density and characterized by a variety of marker antibodies. The addition of neurons to these cultures revealed large differences in the substrate properties of astrocytes and oligodendrocytes (Schwab and Caroni, 1988). Whereas neuronal cell bodies and, in particular, processes were frequently associated with astrocytes, oligodendrocytes, and the territory covered by their processes seemed to be strictly avoided. A number of recent studies have shown that astrocytes are a less homogeneous cell population than previously assumed, in particular also with regard to their expression of cell surface molecules and extracellular matrix constituents (Hatten et al., 1984; Smith et al., 1986; Grierson et al., 1989; Snow et al., 1990; McKeon et al., 1991). Whereas cultured astrocytes dissociated from embryonic or early postnatal central nervous system are generally excellent substrates for neurite growth, these favorable properties decline with progressive age (Smith et al., 1986, 1990; McKeon et al., 1991). Dense three-dimensional astrocyte networks *in vitro* are not penetrated by postnatal dorsal root ganglion neurites and may resemble the glial scars forming at central nervous system lesion sites (Fawcett et al., 1989a). As these cellular and molecular properties of astrocytes are discussed in other chapters of this book, we will restrict ourselves to oligodendrocytes.

Observations with dissociated cells showed the astonishing result that oligodendrocytes occupied neurite-free areas in dense neuritic networks in culture (Hatten et al., 1984; Schwab and Caroni, 1988; Fawcett et al., 1989b). Importantly, this phenomenon was restricted to differentiated oligodendrocytes ($GalC^+$). $A2B5^+$ precusor cells were often overgrown by neurites (Schwab and Caroni, 1988). Neurons responding by avoidance to oligodendrocytes were ganglion cells from dorsal root or sympathetic ganglia, retinal cells, neuroblastoma cells, and PC12 cells (Schwab and Caroni, 1988; B. Rubin and M. Schwab, unpublished results). Interestingly, neurites from goldfish retinal cells also responded to rat oligodendrocytes by growth arrest, and the oligodendrocyte effect extended also to nonneuronal cells like fibroblasts (Schwab and Caroni, 1988; Bastmeyer et al., 1991).

A detailed time-lapse study was conducted on the interaction between growth cones from rat dorsal root ganglia and oligodendrocytes derived from young postnatal rat optic nerves (Bandtlow et al., 1990). Interestingly, growth cone movement was completely arrested as soon as the tips of a few filopodia had contacted the oligodendrocyte processes. This contact led to retraction of lamellipodia and filopodia, collapse of the growth cone, and growth arrest over many hours. Astrocytes present in the same cultures were crossed at velocities similar to that on the laminin substrate.

All these observations led to the conclusion that oligodendrocytes are a good candidate for growth inhibitory effects in the adult central nervous system.

MEMBRANE PROTEINS OF CENTRAL NERVOUS SYSTEM MYELIN EXERT STRONG NEURITE GROWTH INHIBITORY EFFECTS

Central nervous system myelin was purified from adult rat spinal cord or brain by sucrose density gradient centrifugation, adsorbed to tissue culture dishes, and assayed for its substrate properties for dissociated dorsal root ganglion neurons, neuroblastoma cells, or 3T3 fibroblasts (Caroni and Schwab, 1988a) or adult rat retinal cells (Vanselow et al., 1990). Whereas survival of the cells was unaffected, all types of cells adhered poorly to the myelin substrate, and fiber outgrowth was severely inhibited. Fibroblasts remained round over several hours. Control substrates included peripheral nerve myelin and plasma membranes from liver. Both of these substrates promoted neurite outgrowth and rapid fibroblast spreading. Likewise, myelin of trout or goldfish spinal cord exhibited favorable substrate properties for neurite growth and cell spreading. The inhibitory substrate effect of central nervous system myelin was not extractable by organic solvents, that is, not associated with lipids. Trypsin treatment, in contrast, completely destroyed the inhibitory effect (Caroni and Schwab, 1988a). Removal of peripheral membrane proteins by treatment with high salt or pH 11 did not lead to solubilization of the activity. Rather, detergents like sodium dodecyl sulfate (SDS) or Chaps were required to solubilize the activity. Protein constituents with very similar properties were also found in bovine and human spinal cord myelin (C. Bandtlow and M. Schwab, unpublished observations). Separation of myelin proteins by SDS polyacrylamide gel electrophoresis (PAGE) followed by elution of the proteins, their reconstitution in artificial liposomes and subsequent bioassays on neurons and fibroblasts gave evidence for two main molecular weight fractions exhibiting inhibitory activity at 35 and 250 kD. Immunological data indicate molecular relationships between these two molecular weights (Caroni and Schwab, 1988b). Current work tries to fully purify these components and to obtain enough amino acid sequence information to be able to clone the corresponding cDNAs. Premilinary evidence from limited amino acid sequences points to novel proteins.

It will be of great interest to compare these oligodendrocyte proteins to other repulsive or inhibitory factors that have been characterized in particular in embryonic chicken brain (Raper and Kapfhammer, 1990), early embryonic chicken somite (Davies et al., 1990), and to the putative guidance molecule on posterior tectal membranes of E6–E12 chick embryos (Stahl et al., 1990). Whereas the cell types expressing these molecules are clearly not oligodendrocytes and their biological properties differ from the long-lasting paralyzing action of the myelin proteins, common motifs in the structure of these molecules might occur, and it is possible that more family members of neurite repulsing and neurite growth inhibitory molecules may be found.

Antibodies were raised against the SDS-PAGE purified 35 kD and 250 kD proteins, and monoclonal antibodies were selected for their ability to neutralize the inhibitory substrate action of central nervous system myelin (Caroni and Schwab, 1988b). Monoclonal antibodies (mAB IN-1 and IN-2) were found that strongly reduced the inhibitory action of living oligodendrocytes in the encounter with neurites (Bandtlow et al., 1990), as well as the effect of myelin substrates or myelin liposomes on neurite growth, fibroblast spreading, or growth cone collapse (Caroni and Schwab, 1988b; Bandtlow et al., 1993). When optic nerve explants were injected with

the antibody IN-1, large numbers of DRG neurites grew into the explants over many millimeters.

CELLULAR MECHANISMS OF GROWTH INHIBITION

The sequence of morphological events described above suggests a reorganization of the cytoskeleton with a long-lasting inactivation of the growth cone movement machinery. A similar event might happen in lamellipodia of fibroblasts. Very little information is available at present on these processes. The amount of purified inhibitory protein required to induce growth cone collapse is very low, suggesting specific interactions with putative neuronal membrane receptors. Calcium has recently been investigated as a possible constituent of the intracellular, postreceptor signal cascade. Indeed, fura-2 imaging showed an early, massive calcium increase in DRG growth cones upon contact with liposomes containing the purified 35 kD myelin protein (Bandtlow et al., 1993). Both calcium increase and subsequent growth cone collapse, were prevented by preincubation of the liposomes with mAB IN-1. Interestingly, calcium channels blockers had no effect on this calcium increase. In contrast, Dantrolene, a drug preventing the release of calcium from chaffein-sensitive intracellular stores, prevented growth cone collapse after treatment with 35 kD liposomes (Bandtlow et al., 1993). These results suggest that an intracellular calcium release is crucially involved in the collapse of rat DRG growth cones upon contact with myelin-associated inhibitory proteins. This finding is in line with the calcium homeostasis model predicting that very high intracellular calcium concentrations result in growth cone collapse and growth arrest (Kater and Mills, 1991).

Recent evidence from M. Fishman's laboratory indicated that pertussis toxin, which interferes with the action of certain G proteins, is able to block the effect of central nervous system myelin and purified 35 kD protein (Igarashi et al., 1993). On the other hand, Mastoparan, an activator of G_i/G_o proteins, leads to growth cone collapse, suggesting that G proteins are involved in this signal cascade.

OLIGODENDROCYTE INHIBITORY PROTEINS APPEAR SIMULTANEOUSLY WITH DIFFERENTIATED OLIGODENDROCYTES IN CENTRAL NERVOUS SYSTEM DEVELOPMENT

Inhibitory activity that can be neutralized by the mAB IN-1 was found in rat optic nerves and spinal cord from the time of birth on (Caroni and Schwab, 1989). This time point exactly corresponds to the appearance of $GalC^+$ oligodendrocytes in the optic nerve. Interestingly, however, compact myelin and its main constituents, proteolipid protein and myelin basic protein, are only formed about 1 week later in the optic nerve. The time of appearance of inhibitor proteins also correlates with the end of axon growth in the optic nerve (for references see Caroni and Schwab, 1989). These findings speak in favor of a neurite growth inhibitory function of oligodendrocytes *in vivo*. Immunohistochemical studies of various regions of the adult rat central nervous system showed that IN-1 antigenicity is localized to myelin in white matter, myelinated segments of axons in gray matter, and to oligodendrocytes (Rubin, et al., 1994).

OLIGODENDROCYTE-ASSOCIATED INHIBITORS CAN ACT AS BOUNDARY MOLECULES FOR LATE GROWING CENTRAL NERVOUS SYSTEM FIBERS

In a given central nervous system region, myelin formation is known to occur in a mosaiclike pattern with high tract and regional specificity. Thus, various fiber tracts or nuclear areas in the brainstem or in the spinal cord myelinate at precise time points within the first 2 postnatal weeks in the rat (Rozeik and von Keyserlingk, 1987; Schwab and Schnell, 1989). The period of myelination in the early myelinating tracts overlaps with the period of axon growth in late-developing fiber systems. The possibility, therefore, exists that oligodendrocyte-associated neurite growth inhibitory proteins serve as "no-go" signals in certain anatomical structures. This hypothesis was investigated in two systems, the corticospinal tract in the spinal cord (Schwab and Schnell, 1991), and the termination layers of the retinal fibers in the superior colliculus (Kapfhammer et al., 1992).

Corticospinal tract axons grow into the rat spinal cord at birth and complete their growth around postnatal day 10 (P10). Most of the fibers grow in the dorsal funiculus, adjacent to the ascending sensory fasciculus cuneatus and gracilis. These ascending tracts start myelination in the cervical spinal cord around day P1. It was interesting to see that a very sharp border exists between the corticospinal tract and the sensory tracts in the cervical and upper thoracic spinal cord, whereas this border was less precise in the lower half of the spinal cord (Schwab and Schnell, 1991). This pattern corresponded exactly to the presence of differentiated oligodendrocytes in the sensory tracts in the rostral half of the spinal cord and their absence in the caudal half of the spinal cord at the time of corticospinal tract fiber ingrowth. Two

experimental paradigms were used to further test the hypothesis of negative guidance by oligodendrocyte-associated inhibitory proteins: oligodendrocyte development was prevented by neonatal x-irradiation of the spinal cord, or, alternatively, mAB IN-1 was applied to newborn rats. In both cases, tracing of the corticospinal tract resulted in identical anatomical abnormalities: (1) the sharp border between corticospinal tract and ascending sensory tracts in the rostral spinal cord was absent, and (2) outgrowth of collaterals into the gray matter occurred prematurely. These results show that the development of tracts at different times can lead to anatomical separation by the expression of oligodendrocyte-associated inhibitory proteins. In addition, oligodendrocytes seem to be able to restrict or delay the outgrowth of collateral branches.

Destruction of the upper layers of the *superior colliculus of hamsters* at birth leads to an ingrowth of retinal axons into the contralateral optic tectum (So and Schneider, 1978). Interestingly, these fibers do *not* grow in a pattern appropriate for retinal axons; they completely avoid the optic fiber layer (stratum opticum) and only innervate the most superficial part of the stratum grisium superficiale. Since these axons reach the optic tectum about 5 days later than the normal retinal axons, they encounter differentiating oligodendrocytes in the stratum opticum (Jhaveri et al., 1992). The mAB IN-1 was therefore applied at the time of operation (Kapfhammer et al., 1992). This resulted in the restoration of a seemingly normal anatomical pattern; the recrossing retinal fibers now grew and terminated in both, the stratum opticum and the stratum grisium superficiale. As the superior colliculus is a cortical structure, these results show that the oligodendrocyte-associated IN-1 antigents can also be involved in closing down neurite growth in particular layers of cortical brain structures at given developmental times.

NEUTRALIZATION OF INHIBITORY PROTEINS *IN VIVO* ENHANCES REGENERATION OF TRANSECTED AXONS IN SPINAL CORD AND BRAIN

In the studies on *spinal cord* tract we again concentrated on the corticospinal tract due to its large number of fibers, its defined localization, and the ease with which this tract can be labeled with the sensitive anterograde tracer wheat germ agglutinin-horseradish peroxidase (WGA-HRP). Oligodendrocyte-associated inhibitory activity was compromised in two different ways: by deleting the dividing oligodendrocyte precursors by high-dose x-irradiation (Savio and Schwab, 1990), or, alternatively, by the application of mAB IN-1 (Schnell and Schwab, 1990, 1993). Complete bilateral transections of the dorsal two-thirds of the spinal cord were done in the thoracic region, and regeneration was studied at 2 to 12 weeks of survival. Animals were young (2 to 4 weeks) or fully adult (12 weeks) at the time of the lesion; regeneration of corticospinal tract axons has been shown to be completely absent at these ages in earlier studies (Bernstein and Stelzner, 1983). This finding was confirmed in all our controls, including rats with control antibodies (Figure 57-1). Interestingly, almost identical results were obtained with the two experimental paradigms: in the absence of oligodendrocytes and myelin, or in the presence of the

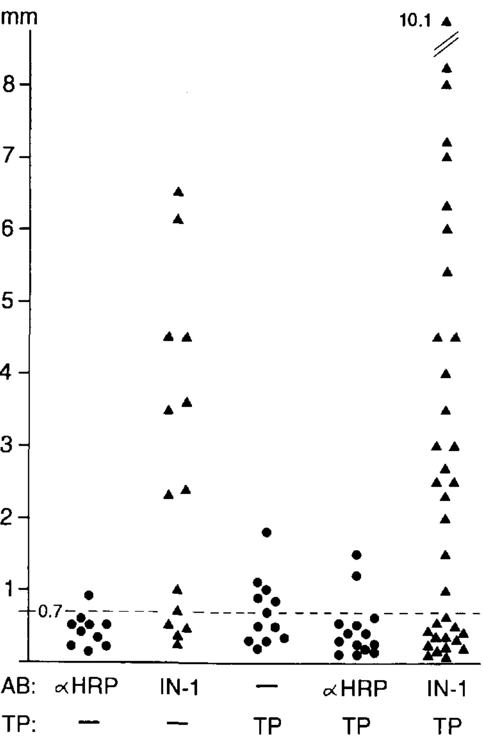

FIG. 57-1. Maximal distances of corticospinal tract (*CST*) elongation in presence or absence of an E14 spinal cord transplant (*TP*) and the antibody (*AB*) IN-1 directed against the oligodendrocyte-associated neurite growth inhibitors, or a control *AB* (anti-HRP). Each symbol represents the maximal regeneration distance of an individual rat. *Dashed line:* sprouting distance of 0.7 mm. Camera lucida drawings of two controls and two IN-1 animals are shown Figure 57-2A–D, and darkfield micrographs of regenerating fibers in Figure 57-3A–F. *Methods:* The dorsal half of the spinal cord was transected bilaterally at the lower thoracic level in 3- to 4-week-old rats. Some of the animals simultaneously received a transplant of embryonic day 14 (*E14*) spinal cord tissue at the lesion site. Control (anti-HRP) or IN-1 antibodies were applied as hybridoma tumors transplanted to the left parietal cortex. The corticospinal tract was traced by anterograde transport of WGA-HRP from the right sensory motor cortex 2 to 3 weeks after the lesion. [From Schnell and Schwab (1993), with permission.]

inhibitor-neutralizing antibody IN-1 a small percentage of corticospinal tract axons were found to elongate from the lesion site over several millimeters toward the caudal end of the spinal cord (Savio and Schwab, 1989; Schnell and Schwab, 1990, 1993). Great variations existed from animal to animal in the distance of regeneration (Figure 57-1). However, in most of the successfully regenerating animals distances of 4 to 6 mm were obtained (Figures 57-1, 57-2, and 57-3). The best cases showed regenerations which reached the lower lumbar and sacral spinal cord. The relatively small number of regenerating fibers could be due to several factors: in the antibody-treated animals, penetration of antibodies into the central nervous system tissue was quite variable and, at longer distances from the lesion site, very limited.

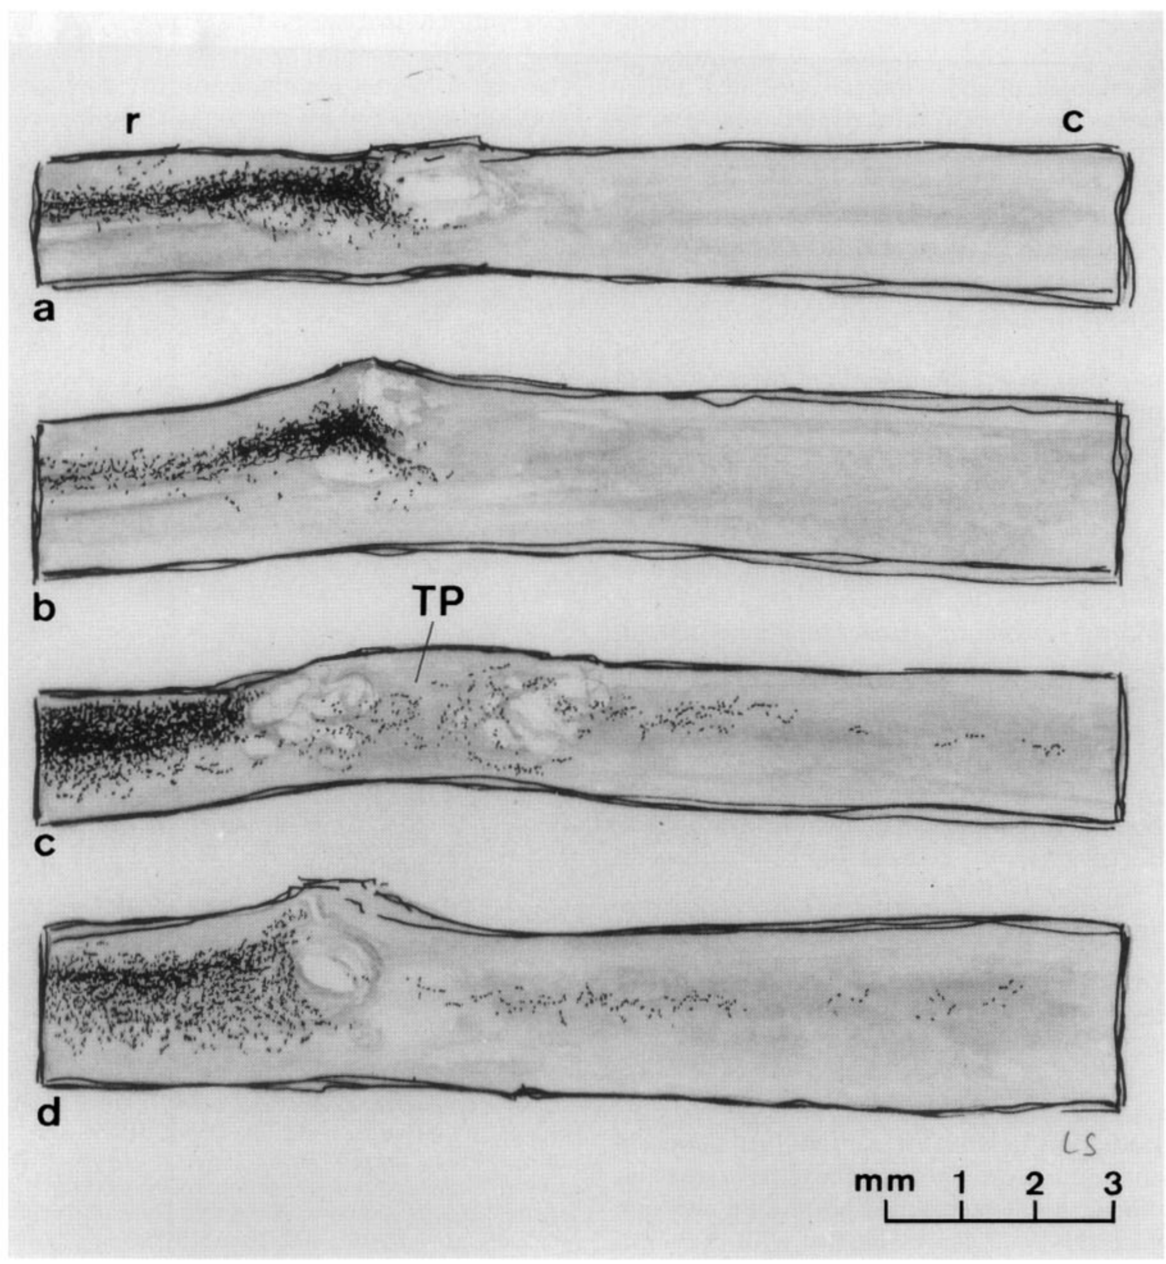

FIG. 57-2. Camera lucida drawings. (**A, B**) Consecutive, parasagittal sections of two control antibody (anti-HRP)-treated rats. (**C, D**) Two IN-1 antibody treated rats. All animals (except Figure B) possess embryonic days 14 to 16 spinal cord transplants (*TP*). Regenerative growth of corticospinal tract fibers over long distances is present exclusively in the IN-1-treated rats; 6 to 8 consecutive sections were compiled and projected on top of each other. Note the typical irregular course of the regenerated fibers. *r*, rostral; *c*, caudal; *m*, medial; *l*, lateral aspect of the spinal cord; *blank areas,* lesion caverns.

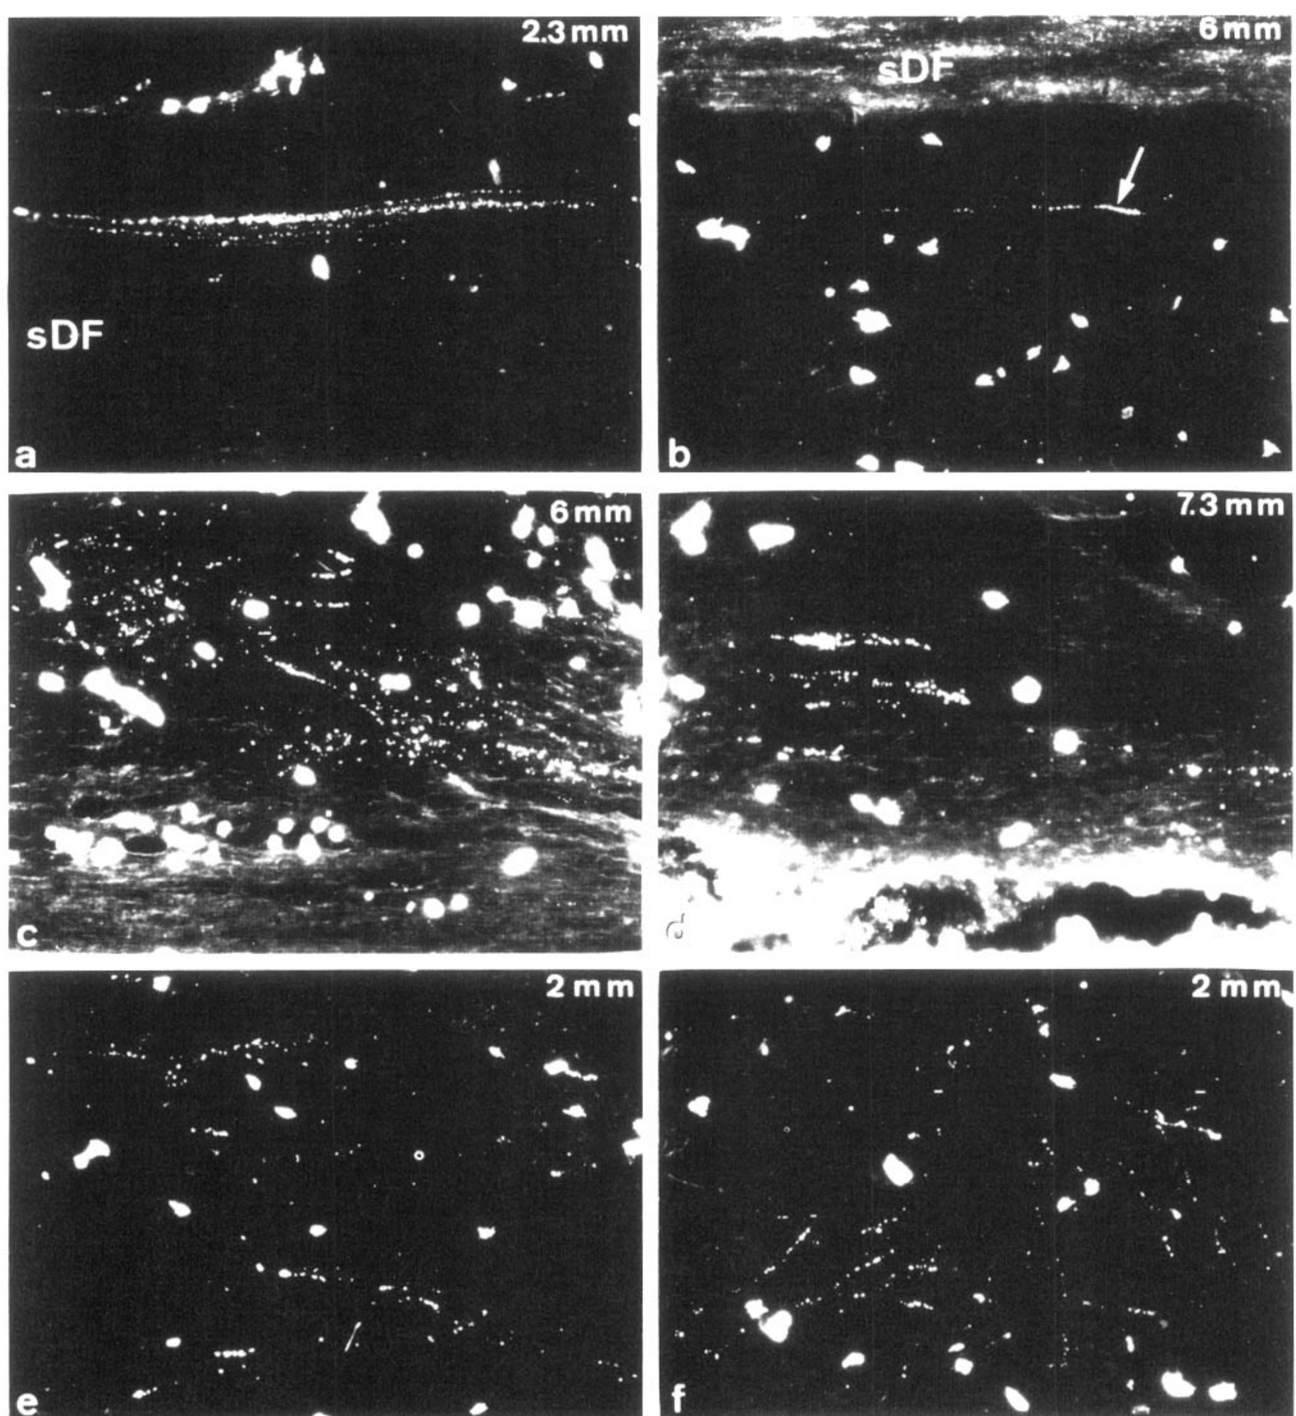

FIG. 57-3. High magnification darkfield micrographs of regenerating corticospinal tract fibers at 2 to 7.3 mm caudal of the lesion. (**A**) Fascicle of regenerating fibers in the sensory tracts of the dorsal funiculus (*sDF*). (**B**) Single axon with growth cone in the original corticospinal tract position ventral to the sensory tracts of the dorsal funiculus. (**C**) Fibers and fascicles in gray matter, (**D**) dorsolateral (*upper bundle*) and ventral funiculus of the same rat at 6 and 7.3 mm from the lesion. (**E, F**) Branching fibers in gray matter. Rats were lesioned at 3 to 5 weeks and survived for 2 to 4 additional weeks. ×120.

In addition, the lesion area itself was clearly an obstacle to regenerating fibers. Often, the majority of the regenerative sprouts were unable to cross the lesion area and failed to reach the caudal end of the lesion site (Figure 57-1). Almost all of the crossing fibers used intact spinal cord tissue (mostly ventral gray and white matter) as a bridge. Thus, it is not excluded or even probable that additional inhibitory factors occur at these lesion sites, which impair the crossing of this area by regenerating fibers. An additional factor is the regenerative sprouting itself, which, in the case of the corticospinal tract, is not very robust. Experiments with transplants of embryonic spinal cord tissue and recent experiments with trophic factors indicate that this sprouting response can be significantly enhanced (Schnell and Schwab, 1993; Schnell et al., 1993). Interestingly, however, the regenerative sprouts did not exceed distances of more than 0.7 to 1 mm unless the antibody IN-1 was present (Figures 57-1, 57-2, and 57-3).

Using IN-1 antibodies in *fimbria fornix* ablation lesions we could show that the reinnervation of the hippocampus by septal cholinergic axons is accelerated by this antibody (Cadelli and Schwab, 1991). At 2 to 5 weeks after the lesion and the implantation of a 2-mm-long extracellular matrix bridge, regenerated fibers could be found preferentially in their former target areas. These findings show that IN-1 antigens severely impair regeneration also in the hippocampus and in gray matter areas.

Preliminary results in rat *optic nerves* closely resemble results obtained in spinal cord. Deletion of oligodendrocytes by x-irradiation or application of the antibody IN-1 following an intracranial crush lesion led to regeneration of axons over a distance of several millimeters.

The paralellisms of the results of the two experimental paradigms studied, and the fact that a monoclonal antibody directed against 35/250 kD inhibitory proteins of oligodendrocytes had such a drastic effect under *in vivo* conditions strongly argue for a significant role of oligodendrocytes in restricting central nervous system regeneration. This hypothesis is supported by experiments in chick embryos, which showed that spinal cord tract regeneration stops exactly at the time of the appearance of oligodendrocytes and myelin (Shimizu et al., 1990; Hasan et al., 1991). Deletion of oligodendrocytes by immunocytolysis prolonged the regeneration-permissive period by several days (Keirstead et al., 1992). However, additional negative signals, in particular in lesion areas, as well as important roles for positive substrate molecules, trophic factors, and intrinsic neuronal determinants must be assumed and will form the basis for future investigations.

In conclusion, oligodendrocytes, in addition to their function as myelin-forming cells, also express potent neurite growth inhibitory proteins. These molecules are expressed at the time of myelination and throughout adult life. Their physiological functions may be to inhibit the access of late growing fibers to certain territories during development, and to restrict sprouting and plasticity in the adult. Following central nervous system lesions in rats, significant long distance elongation of fibers was obtained by the neutralization of these inhibitory proteins, or by the deletion of oligodendrocytes. This result suggest an important role of these myelin-associated neurite growth inhibitors in the context of central nervous system regeneration.

58 Transplantation of glial cells

W. F. BLAKEMORE, A. J. CRANG, AND R. J. M. FRANKLIN

Glial cell transplantation into the central nervous system offers an experimental approach to help unravel the complex interactions that occur between central nervous system glia, Schwann cells, and axons during repair and development. Although glial cell transplantation, in the form of peripheral nerve grafting was carried out by Santiago Ramón y Cajal and Francisco Tello early in this century, it was the development of glial cell culture techniques, and the consequent increase in our understanding of glial cell lineages, that added a new dimension to this experimental paradigm. Labeled glial cells can now be introduced into the developing nervous system to examine aspects of development and glial cell lineage, while transplantation of glial cells into lesion environments yields information about cell-cell interactions in repair, and opens up the possibility of influencing normal cell responses by transplantation. This chapter concentrates on the principles underlying glial cell transplantation and documents some of the results achieved over the last decade.

PRACTICAL CONSIDERATIONS THAT UNDERLIE GLIAL CELL TRANSPLANTATION

As the normal glial population of the central nervous system has an intrinsic replacement capacity, there are two major issues that must be addressed when carrying out and interpreting glial cell transplantation studies. First, one must be able to identify the transplanted cells, either directly in order to study migration and integration into normal tissue, or by using an experimental design that allows identification of the effect of transplantation in a pathological situation. Second, one must have sufficient information about the composition of the transplant to be able to relate the subsequent observed behavior of transplanted cells to the preparation introduced.

Identification of Transplanted Cells

Various strategies have been used to distinguish transplanted cells from host cells and nearly all impose limitations on the type of studies that can be undertaken. Transplanted cells can be labeled with vital dyes such as fast-blue (Rosenbluth et al., 1990; Hasegawa and Rosenbluth, 1991; Hatton et al., 1992) and bisbenzimide (Hoechst dyes 33258 and 33342) (Figure 58-1) (Baron-Van Evercooren et al., 1991; Gansmüller et al., 1991; Tourbah et al., 1991) or fluorochrome-conjugated lectins (Goldberg and Bernstein, 1987; Bernstein and Goldberg, 1989) for subsequent identification using fluorescence microscopy. These labels, like the use of tritiated thymidine, suffer the disadvantage of dilution by repeated division of cells. Thus, following transplantation of highly proliferative populations of cells the intensity of label signal within the progeny may fall below the threshold for detection. With vital dyes care must be taken to wash cells prior to transplantation in order to prevent direct labeling of host tissue by free label present within the transplant preparation. Phagocytic uptake of fluorescent microspheres (Emmett et al., 1988; Hatton et al., 1992) has also been used to label cells but suffers similar dilution problems as the vital dyes. An additional feature of this approach is that microspheres are preferentially taken up by astrocytes and microglia rather than oligodendrocyte lineage cells. This may be deemed an advantage or disadvantage, depending on whether a pan-marker or cell-specific marker is required. With many of the aforementioned labels the possibility exists that host cells may incorporate label liberated from transplanted cells as either a spontaneous process or as a consequence of cell death or damage. This, however, appears not to be a problem with tritiated thymidine where there is no evidence of uptake of thymidine from transplanted cells into host cells (Emmett et al., 1991).

If protocols require identification of transplanted cells and their progeny, there are few suitable markers available. One approach is to use species-specific markers, and these have been successfully used to identify and trace migration of astrocytes following xenografting (Jacque et al., 1986; Zhou et al., 1990). Another approach is to use genetic markers. Genetic markers can be inherent, such as the detection of repeat sequence on the Y chromosome by *in situ* hybridization following transplantation of male cells

FIG. 58-1. Vital stains can be employed to allow the distinction of transplanted cells from host tissue. Here transplanted cells labeled with the Hoechst dye 33342 can be easily detected following transplantation using long-wavelength UV fluorescence excitation of cryostat sections. ×100. [Micrograph kindly provided by M. Gumpel and A. Baron-Van Evercooren.]

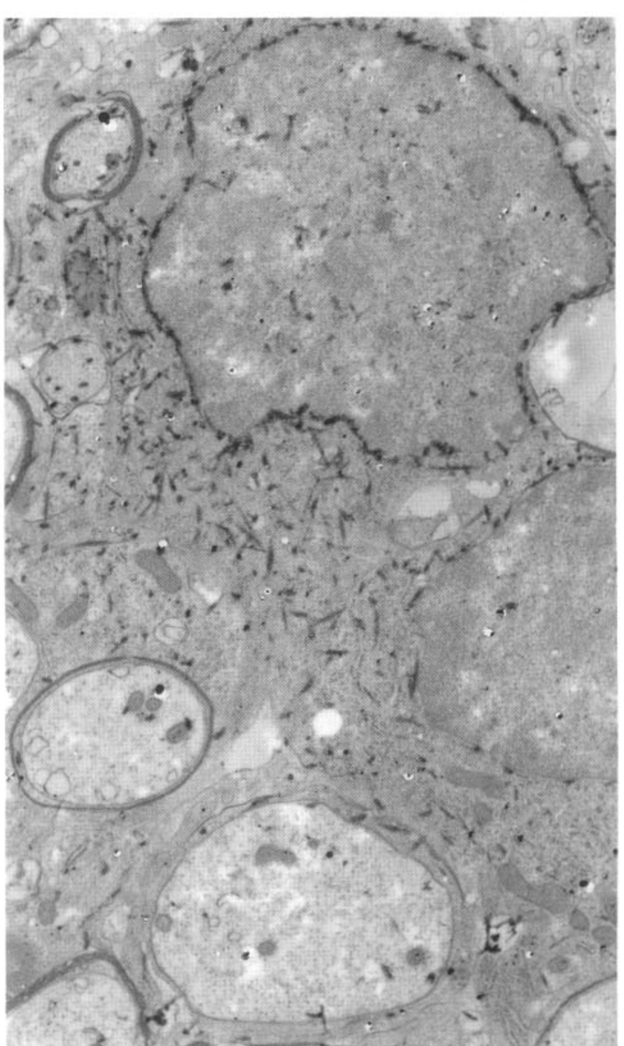

FIG. 58-2. The introduction of foreign genes into cells prior to transplantation in principle allows the identification of all the progeny of a transplanted cell preparation. In this micrograph, rat O-2A progenitor cells expressing *E. coli* β-galactosidase develop into oligodendrocytes following transplantation into an area of demyelination. The β-galactosidase reaction-product is visible as electron-dense spicules within the cytoplasm of the oligodendrocyte and in association with oligodendrocyte processes that have surrounded the demyelinated axons. Unstained section. ×13,000.

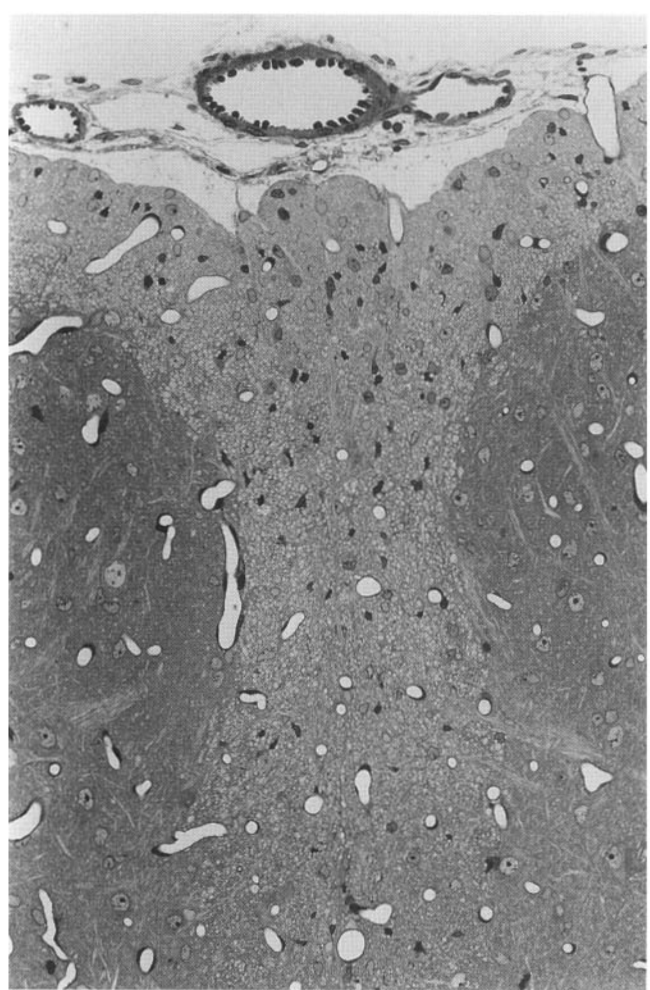
into female recipients (Harvey et al., 1992). At present, probes to rat cells are not available. Alternatively, they can be foreign genes present within transgenic animals or introduced into cultured cells by transfection. An example of transgenic-derived donor material is provided by the study of Huppes and coworkers (1992), who transplanted tissue from a transgenic mouse containing multiple copies of the bacteriophage lamda gene. The introduction of reporter genes into cultured cells has also been used successfully to identify transplanted cells (Figure 58-2.) (Langford and Owens, 1990; Groves et al., 1993). This technique has the disadvantage of requiring dividing cells for retroviral insertion and suffers from the problem that not all transfected cells express the gene product. The use of marker genes, such as *LacZ,* under cell-specific promotors, may ultimately provide excellent material for glial cell transplantation studies.

The problems associated with many of the cell-labeling techniques can be overcome by transplanting cells into situations where the simple presence of glial cells or myelin sheaths identifies them as being of transplant origin. In the case of oligodendrocytes, this is achieved by introducing normal cells into myelination-defective mutants, such as the myelin basic protein-deficient Shiverer mouse (Gumpel et al., 1983; Friedman et al., 1986; Kohsaka et al., 1986; Gumpel et al., 1989), or the various proteolipid protein mutants: the myelin-deficient rat (Duncan et al., 1988; Rosenbluth et al., 1990) (Figure 58-3), the Jimpy mouse (Lachapelle et al., 1991) and the shaking pup (Archer et al., 1992). All the proteolipid protein mutants show such severe hypomyelination that myelin formation observed following transplantation can be related to transplanted cells. Immunostaining for proteolipid protein can if necessary be used to distinguish host, proteolipid protein-deficient myelin from the proteolipid protein-positive myelin produced by transplanted cells (Duncan et al., 1988). Myelin basic protein-positive normal myelin



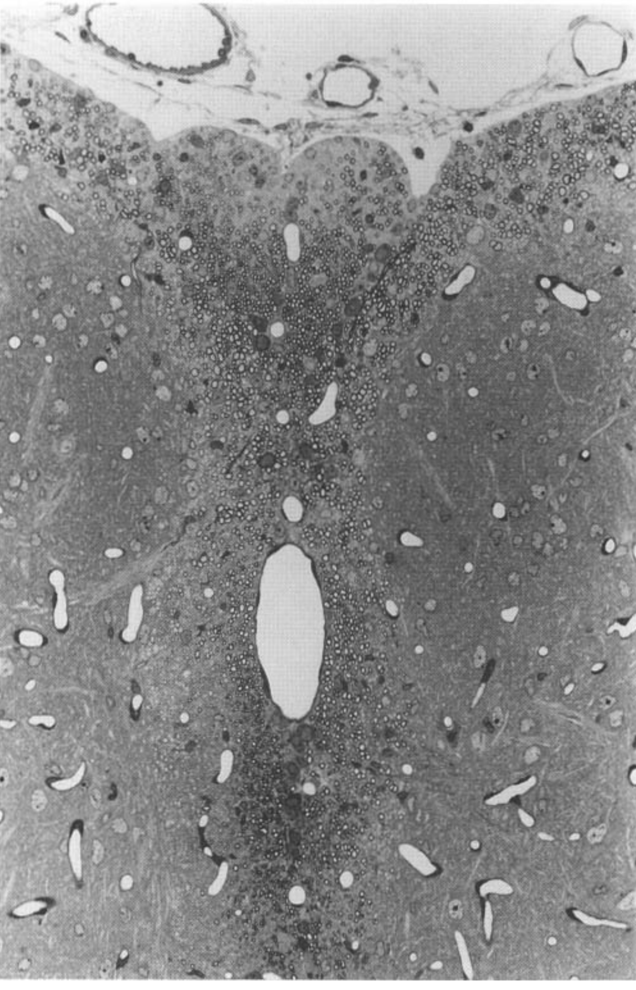


FIG. 58-3. Myelination mutant animals allow the identification of transplanted wild-type oligodendrocytes. (A) The spinal cord of the myelin-deficient rat contains no myelinated axons and so the myelinating potential of transplanted cell preparations can be related to the extent of myelination seen in transplanted animals. (B) At 12 days following the transplantation of a mixed glial cell culture prepared from neonatal normal rats, regions of oligodendrocyte myelination are found. ×220. [Micrographs kindly provided by I. Duncan and D. Archer.]

is easily recognized in the Shiverer mouse either by immunocytochemistry (Lachapelle et al., 1984), or by electron microscopy (Gansmüller et al., 1986) (Figure 58-4). Areas of the central nervous system that are not normally myelinated, such as the retina, also provide a situation where the presence of myelination following transplantation can be related to transplant-derived cells (Huang et al., 1991).

An alternative application of this strategy is to create glial-deficient lesions that have no inherent repair capacity (Blakemore, 1977; Blakemore and Patterson, 1978; Blakemore and Crang, 1988; Crang et al., 1992). This can be achieved by injecting gliotoxins such as ethidium bromide into tissue that has been exposed to 40 Gy of x-irradiation. Following the injection of ethidium bromide into white matter, both oligodendrocytes and astrocytes are intoxicated, and their subsequent death leaves demyelinated axons in a region devoid of central glial cells (Figure 58-5). Such lesions have clearly defined edges that allow areas of remyelination and repair to be easily identified. The essential nonrepairing nature of the lesion can be rigorously tested by showing that the injection of cell preparations shown to recruit cells in normal animals fails to recruit cells from the host when injected into x-irradiated lesions (Blakemore, 1992; Crang et al., 1992). Furthermore, there is a direct correlation between the nature of repair observed and the composition of the cells introduced into this environment. This nonrepairing, cell-free lesion therefore provides a suitable system in which to assess the ability of transplanted glial cells to associate with demyelinated axons and reconstruct central nervous system environments.

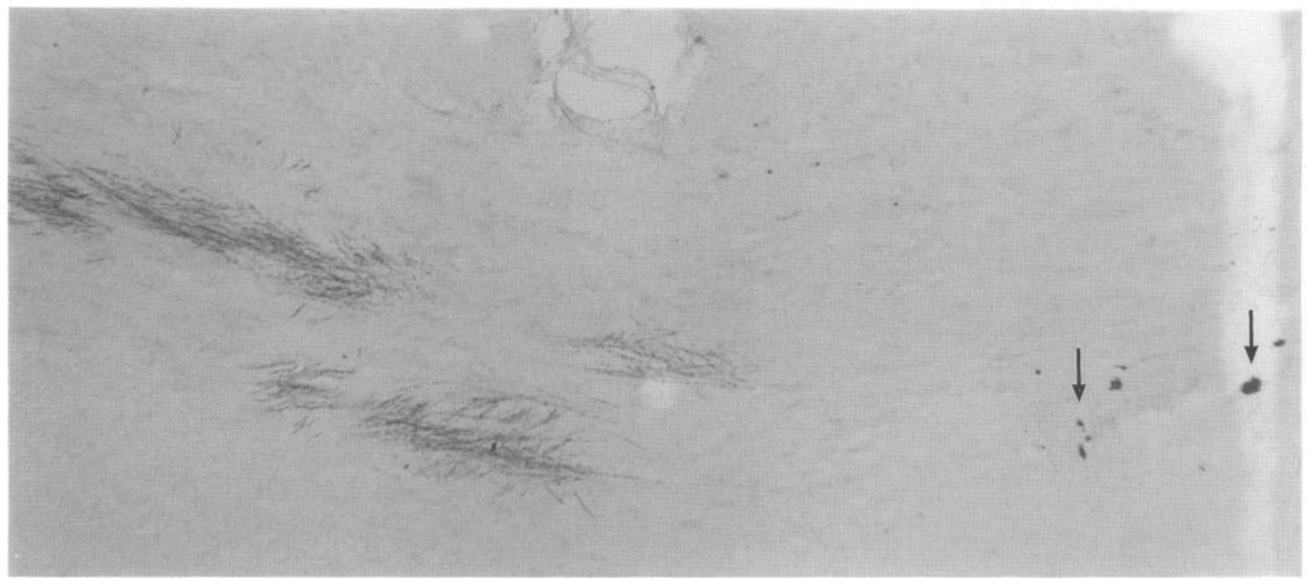

FIG. 58-4. Mice homozygous for the autosomal recessive mutation *shiverer* lack myelin basic protein (*MBP*). In this micrograph, MBP-containing myelin sheaths are detected 23 days after transplantation of a fragment of normal E15 central nervous system tissue into a newborn *shiverer* mouse brain. The two patches of myelination are present at some distance from the point of implantation marked by carbon (*arrows*). ×100. [Micrograph kindly provided by M. Gumpel and F. Lachapelle.]

In pathological situations in which normal glial responses are intact, transplanted cells require labels in order to be individually identified. However, the effects of transplantation can be demonstrated using simple morphological analysis. An example is provided by the ability to transplant glial cells to alter the repair of experimentally induced demyelinating lesions in the central nervous system. Following the injection of ethidium bromide into normal white matter of the spinal cord of the rat, the demyelinated axons are normally remyelinated mainly by Schwann cells (Graça and Blakemore, 1986). However, when mixed glial cell cultures are injected into the lesion, remyelination is mainly carried out by oligodendrocytes and this can be documented quantitatively using plots of Schwann cell versus oligodendrocyte remyelination (Blakemore and Crang, 1989, 1992) (Figure 58-6). Similarly, the ability of astrocyte transplantation to reduce the area of necrosis that follows spinal concussion can be documented by morphological and functional assessment of transplanted and nontransplanted groups of animals (J. Wrathall, personal communication).

Manipulating the Transplant Composition

Most of the early work involving transplantation into myelin mutants addressed relatively straightforward issues, such as whether axons could be myelinated by transplant-derived oligodendrocytes and the area over which this could be achieved. To some extent, the recipient environment provided by the myelin mutants imposes these limitations. For example, the Shiverer mutant is appropriate for studying the oligodendrocyte lineage rather than the astrocyte lineage. Moreover, the precise identification of the cell populations introduced was not a major concern, as both the environment into which the transplant was introduced and the markers used to identify the transplanted cells dictated the questions that could be addressed. Glial cell transplantation studies are now entering a new era in which more exacting questions are being asked. At present, this represents the most challenging area in the field. When tissue fragments are used as the source of transplanted cells it is only possible to analyze and comment on the cells that emerge from the tissue fragment. While this is largely controlled by the environment, a degree of control can be exercised by using fragments obtained from animals of different age (Gumpel et al., 1985; Friedman et al., 1986; Rosenbluth et al., 1990), or brain area (Jacque et al., 1991), or pathological tissue such as degenerated optic nerve (Ludwin, 1992).

When the transplanted tissue has been subjected to tissue culture before transplantation, it is possible not only to identify the cell types that will comprise the transplant but also to subject the cultures to a series of *in vitro* manipulations that will enrich the cell suspension for particular subsets of cell. These

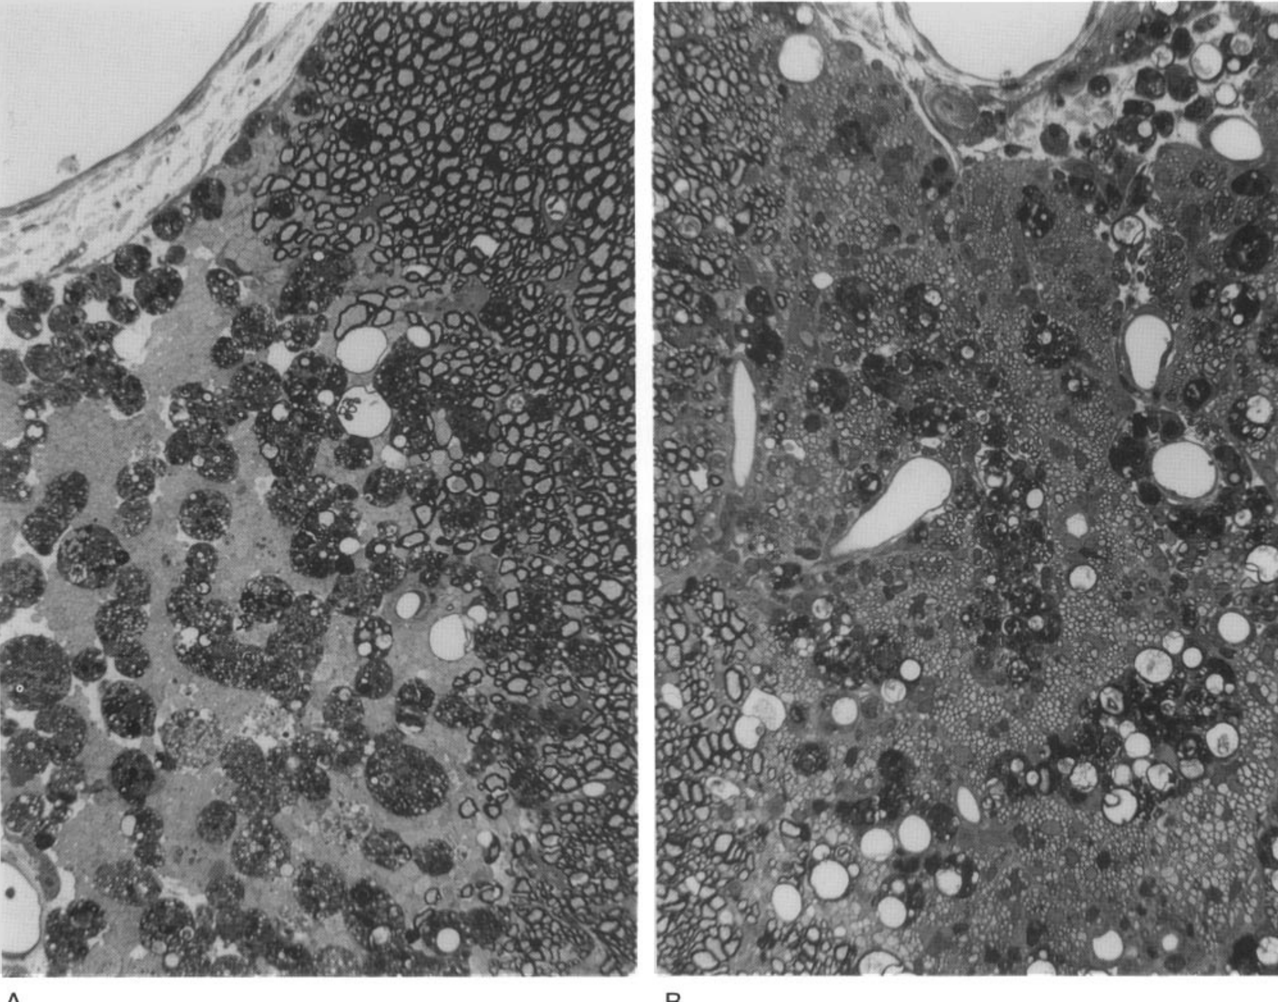

FIG. 58-5. The nonrepairing ethidium bromide white matter lesion provides a situation in which to assess the ability of transplanted glial cells to associate with demyelinated axons and reconstruct central nervous system environments. (**A**) Following the injection of ethidium bromide into an area of spinal cord exposed to 40 Gy of x-irradiation, demyelinated axons clump together in a glial cell-free environment and there is no evidence of remyelination. The lesion contains debris-filled macrophages and has a clearly defined edge. (**B**) Transplantation of cultures of syngeneic mixed glial cells into nonrepairing lesions results in the reconstruction of a normal central nervous system glial cell environment, most of the demyelinated axons being remyelinated by oligodendrocytes. ×340.

procedures include separation of heterotypic mixed glial bilayers (Blakemore and Crang, 1989), depletion by complement-mediated immunocytolysis (Franklin et al., 1991) or x-irradiation (Franklin et al., 1993a), and purification by cell sorting (Duncan et al., 1992) or panning (Warrington et al., 1993). A more recent approach is to obtain pure populations of cells of specific phenotypes by exposure to growth factors (Groves et al., 1993) or by the creation of cell lines of either central glia (Crang et al., 1992; Barnett et al., 1993; Trotter et al., 1993) or peripheral glia (Baron-Van Evercooren et al., 1992a, 1992b, Jung et al., 1994) (see below). The ability to determine the transplant composition with some precision provides the experimenter with the necessary control to address subtle questions about complex cellular interactions. However, the ability to accurately describe the content of a tissue culture derived transplant is limited not only by the range of antibodies available to identify cells in culture, but also by the ability to visualize very small numbers of antibody-labeled cells in high-density cultures. The possibility of unrecognized contaminants even within well characterized cell preparations must be taken into account when interpreting the effects of transplantation, since such cells can become, or give rise to, major populations in certain transplanted environments (Blakemore et al., 1987b; Crang and Blakemore, 1989; Franklin et al., 1992a, 1992b, 1993a).

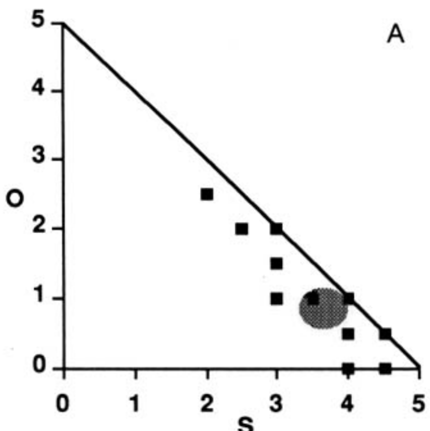

FIG. 58-6. The nature and extent of the repair of spinal cord white matter ethidium bromide lesions can be documented quantitatively by using plots of oligodendrocyte (*O*) versus Schwann cell (*S*) remyelination. The proportion of axons remyelinated by oligodendrocytes and Schwann cells, and the proportion of axons that remain demyelinated are estimated for 1-μm plastic sections cut from each lesion-containing block (see Blakemore and Crang, 1992). Thus, a section in which all the available axons are remyelinated by oligodendrocytes would have an oligodendrocyte remyelination score of 5, a Schwann cell remyelination score of 0, and a demyelinated axons score of 0. The mean oligodendrocyte and Schwann cell remyelination scores are indicated ±2 SEM and the shaded domains enclosed by these limits represent an average repair for the group of animals. Nonoverlapping repair domains in these representations therefore indicate significantly different results; the direction of their displacement from each other indicates which parameters contribute to the difference. (**A**) Following the injection of ethidium bromide into spinal cord white matter, the demyelinated axons are remyelinated mainly by Schwann cells. (**B**) When mixed glial cell cultures are injected into the demyelinating lesion, remyelination is mainly carried out by oligodendrocytes.

Migration Studies

Migration of glial cells following transplantation can not be followed directly, but it can be inferred by killing animals at different survival times and plotting the expanding distribution of suitably labeled cells (see above for constraints of cell labeling techniques). From these "snapshots" the rate and extent of migration of cells can be established. In order to obtain a true picture of the extent to and rate at which cells migrate, it is necessary to know the limits to which the cells are distributed by the physical process of transplantation alone. When cells are transplanted as a cell suspension, this may be highly variable and difficult to assess. Thus, the precise point of injection at which cells start to migrate cannot be easily established. For this reason the most reliable studies on cell migration have involved transplanting cells within tissue fragments (Lachapelle et al., 1984), or within aggregates (Emmett et al., 1991).

WHAT HAVE TRANSPLANTATION STUDIES TOLD US ABOUT THE BIOLOGY OF GLIAL CELLS?

Oligodendrocytes

Transplantation of cells of the oligodendrocyte lineage into neonatal recipients has been used to study migration of myelin-forming cells and to examine concepts about migration and differentiation that have emerged from *in vitro* studies on cell lineage and development. For technical reasons these studies have been carried out using the myelin mutants. The initial studies in the Shiverer model using fragments of central nervous system tissue, as the source of myelin-forming cells, showed that cells migrated long distances from the site of implantation before differentiating into myelin-sheath-forming oligodendrocytes (Gumpel et al., 1983; Lachapelle et al., 1984). Recent studies using Hoechst dye labeling and immunocytochemical identification of cells (Gansmüller et al., 1991), or immunopurification of the transplanted cells (Warrington et al., 1993), have demonstrated that oligodendrocyte precursor cells migrate and then divide at the site of terminal differentiation, with the more immature phenotypes giving rise to the largest areas of myelination. Transplantation of O1+ cells (Warrington et al., 1993), or of cells that persist in areas of gliosis following axon degeneration (Ludwin, 1992), result in only small areas of myelination, located close to the site of transplantation. A start has been made to examine the migration of cells toward areas of demyelination in adult animals. These studies indicate that cells migrate from fragments of transplanted tissue toward areas of demyelination (Gout et al., 1988;

Gumpel et al., 1989), in contrast to random migration if no lesion is present.

In the Shiverer mutant, the transplanted cells have to compete with host cells for axons as they migrate within a myelinating environment. In the myelin-deficient rat, there is little if any host myelination, and long-distance migration of cells has not so far been observed (Rosenbluth et al., 1990). It is thus an ideal model for determining the areas of tissue that can be populated by transplanted cells. Using this mutant it has been shown that the age of the transplanted cells or central nervous system fragment can be directly related to the extent of myelin sheath formation (Rosenbluth et al., 1990; Archer et al., 1993); little or very restricted myelin sheath formation is seen following transplantation of material from adult animals. This observation confirms earlier studies made using the Shiverer model (Gumpel et al., 1985; Friedman et al., 1986). However, in a recent study, extensive myelination was claimed following transplantation of FACS purification of O1+ cells obtained from adult animals (Duncan et al., 1992). It is likely that further studies will be needed before a full understanding of the myelinating potential of cells from the adult nervous system is accomplished.

The shaking pup deserves special mention, as this is the only large animal in which extensive myelination has been achieved following transplantation. Using these animals Duncan and Archer have shown that extensive migration (up to 3 cm) and myelination was present 11 weeks after transplantation of fetal tissue into the spinal cord of a 14-day-old pup (Archer et al., 1992; I. D. Duncan, personal communication). No evidence of rejection was observed.

A series of cross-species studies have been carried out, demonstrating that oligodendrocytes from one species will form myelin sheaths around axons of another species, that is, mouse (Crang and Blakemore, 1991), cat (unpublished observations), and dog (Archer et al., 1994) will myelinate rat axons; rat (Lubetzki et al., 1988), sheep (Ludwin and Suchet, 1993), and human (Gumpel et al., 1987) will myelinate mouse axons; and rat will myelinate cat axons (unpublished observations). Most of the xenografting experiments have been carried out in neonatal animals and in these circumstances no evidence of rejection has been reported. However, when mouse and cat cells are introduced into demyelinating lesions in adult rats, high levels of immunosuppression are needed to prevent rejection (Crang and Blakemore, 1991) (Figure 58-7), and transplanted xenogeneic cells are rapidly rejected on removal of immunosuppression (Blakemore, 1992).

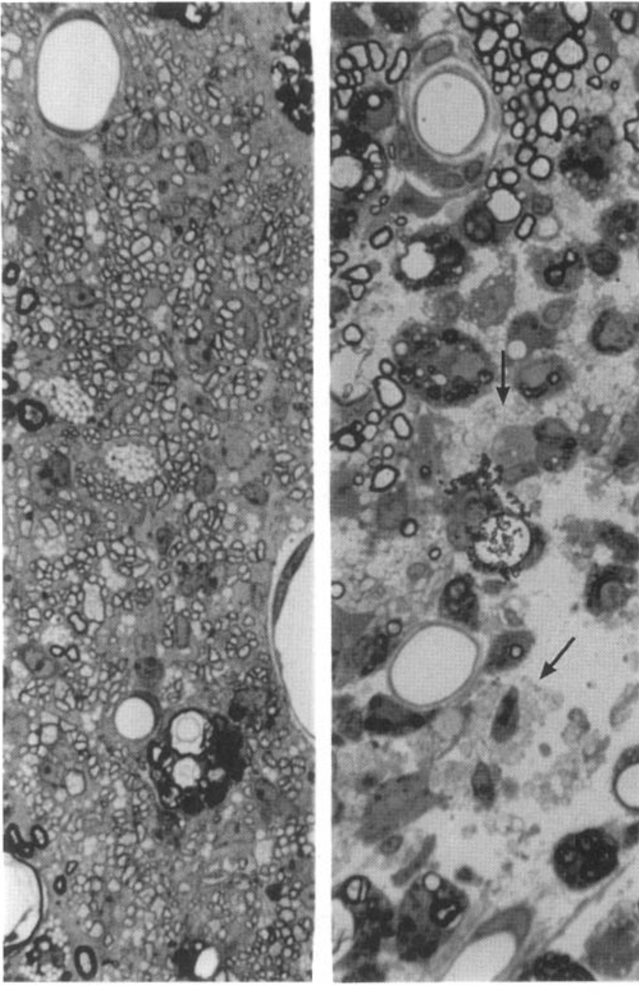

FIG. 58-7. When xenogeneic glial cells are transplanted into demyelinating lesions in adult rats, immunosuppression is required to prevent rejection. (**A**) Following transplantation of mouse mixed glial cell cultures into x-irradiated ethidium bromide lesions in rats, reconstruction of a central nervous system glial environment only occurs in immunosuppressed hosts. ×410. (**B**) In nonimmunosuppressed rats, lesions transplanted with mouse mixed glial cell cultures show no evidence of repair and demyelinated axons (*arrows*) exist in areas infiltrated by inflammatory cells. ×670.

Schwann Cell Transplantation

Schwann cells are not normal occupants of the glial environment of the central nervous system. However, they are able to myelinate demyelinated central nervous system axons in situations where there is concurrent loss of both astrocytes and oligodendrocytes. This situation essentially leaves demyelinated axons outside the central nervous system and arises in certain disease states, or can be created by the injection of various gliotoxic chemical into white matter tracts. Such lesions are normally repaired largely by Schwann cells. If this normal repair re-

action is inhibited by local high-dose x-irradiation, the axons can be remyelinated by transplanted Schwann cells, which can be either placed over (Blakemore, 1977, 1980, 1984), or into the area of demyelination (Harrison, 1980; Duncan et al., 1981; Blakemore and Crang, 1985; Baron-Van Evercooren et al., 1991). Their subsequent behavior, *vis-à-vis* the demyelinated axons, parallels their behavior with neurites from cultured dorsal root ganglia so elegantly explored by the Bunges (Bunge and Bunge, 1983). Thus, they migrate along blood vessels and along the pial collagen and they require contact with collagen in order to myelinate (Blakemore and Crang, 1985).

Astrocytes deny Schwann cells access to demyelinated axons. Thus, when Schwann cells are injected into astrocyte-containing areas of demyelination (Duncan et al., 1981) or myelination failure, such as exists in the myelin-deficient rat, the extent of myelination achieved is very restricted (Duncan et al., 1988). When injected into normal tissue initial migration is followed by the disappearance of transplanted cells (Blakemore et al., 1986; Baron-Van Evercooren et al., 1992a). Transplanted Schwann cells have recently been demonstrated to migrate through normal tissue toward areas of demyelination (Baron-Van Evercooren et al., 1992b). Areas of demyelination have been repaired by transplanted Schwann cell lines (Baron-Van Evercooren et al., 1992b; Jung et al., 1993), and cross-species remyelination by Schwann cells has also been reported, namely, mouse/rat (unpublished observations); rat/mouse (Duncan et al., 1981; Baron-Van Evercooren et al., 1991) cat/rat (unpublished observations); rat/cat (Blakemore et al., 1987a). Schwann cell lines have been used in various transplantation studies, and, although such cells are capable of myelinating demyelinated axons, the ability to do this for some cell lines appears to decrease with increasing passage number (Jung et al., 1994).

Astrocytes

Studies on transplanted astrocytes differ from those primarily concerned with the behavior of oligodendrocyte lineage cells in two respects. First, the accurate description of the donor material that has been a feature of recent oligodendrocyte studies has not been matched in astrocyte studies because of our incomplete understanding of astrocyte development and the diversity of mature astrocyte forms. Second, the unavailability of astrocyte-deficient recipients equivalent to the myelination mutants used in oligodendrocyte studies means that studies on the behavior of transplanted astrocytes have mainly been carried out using normal recipients. This has necessitated the use of a wide variety of labels including species-specific antibodies (Jacque et al., 1986; Zhou et al., 1990), tritiated thymidine (Lindsay and Raisman, 1984; Emmett et al., 1991), microspheres (Emmett et al., 1988; Hatton et al., 1992), and lectins (Goldberg and Bernstein, 1987). In spite of the limitations imposed by both the labels used (see above) and the environment into which they are introduced, an important issue to emerge from these studies is the tendency for astrocytes to migrate away from the point of transplantation. This migration can be extensive within both neonatal (Suard et al., 1989; Zhou et al., 1990; Jacque et al., 1992) and adult central nervous system (Goldberg and Bernstein, 1987; Emmett et al., 1991), although a recent report indicates that the extent of migration decreases with increasing age of recipient (Zhou and Lund, 1993). Migrating astrocytes appear to take a variety of pathways during migration, of which the perivascular space is the most widely reported (Lindsay and Raisman, 1984; Goldberg and Bernstein, 1987; Emmett et al., 1988, 1991; Smith and Miller, 1991), although other routes may be used, such as in association with the glia limitans or ventricular wall (Goldberg and Bernstein, 1987; Hatton et al., 1992) or within fiber bundles (Zhou et al., 1990; Hatton et al., 1992; Jacque et al., 1992). Our own studies indicate that transplanted astrocytes migrating within the subpial space are able to enter the underlying white matter across an intact glia limitans (Franklin et al., 1993c). Currently, there is no clear consensus whether it is only immature astrocytes that migrate (Ignacio et al., 1990; Smith and Miller, 1991; Franklin and Blakemore, 1993) or whether mature astrocytes are also able to migrate (Emmett et al., 1991).

The factors that govern astrocyte migration appear to relate to the environment into which astrocytes are transplanted, rather than being an intrinsic property of the transplanted cells (Zhou et al., 1990; Jacque et al., 1991; Hatton et al., 1992; Zhou and Lund, 1993). This tendency for local environmental cues to override intrinsic determinants of behavior is also observed in the morphologies adopted by transplanted astrocytes when they become integrated into the host environment. Thus, transplanted astrocytes of striatal origin that migrate into the cerebellum will assume the morphology of cerebellar astrocytes rather than striatal astrocytes (Jacque et al., 1991).

The behavior of astrocytes within central nervous system lesions has been addressed using the x-irradiated ethidium bromide lesion. When purified populations of astrocytes are transplanted into a glia-

free environment consisting of demyelinated axons, the astrocytes are able to form an integrated astrocytic environment where the demyelinated axons are separated from one another by astrocyte processes (Franklin et al., 1993a) (Figure 58-8). This ability to integrate within glia-free lesions is disturbed by the presence of large numbers of Schwann cells (Franklin et al., 1992a) or meningeal cells (Franklin et al., 1992b). In these situations the astrocytes tend to form small, dissociated clumps of cells that exclude axons (Franklin et al., 1992a, 1992b). The ability of Schwann cells to disrupt the integrative behavior of astrocytes appears to be considerably reduced by the presence of cells of the O-2A lineage (see below). In certain circumstances, the introduction of certain astrocyte preparations into areas of demyelination is followed by extensive axonal degeneration, while, with other preparations, it is not (unpublished observations). The reason for these paradoxical results is at present unknown, but it likely reflects the heterogeneity of astrocytes, which will be difficult to explore until a fuller understanding of astrocyte diversity is available.

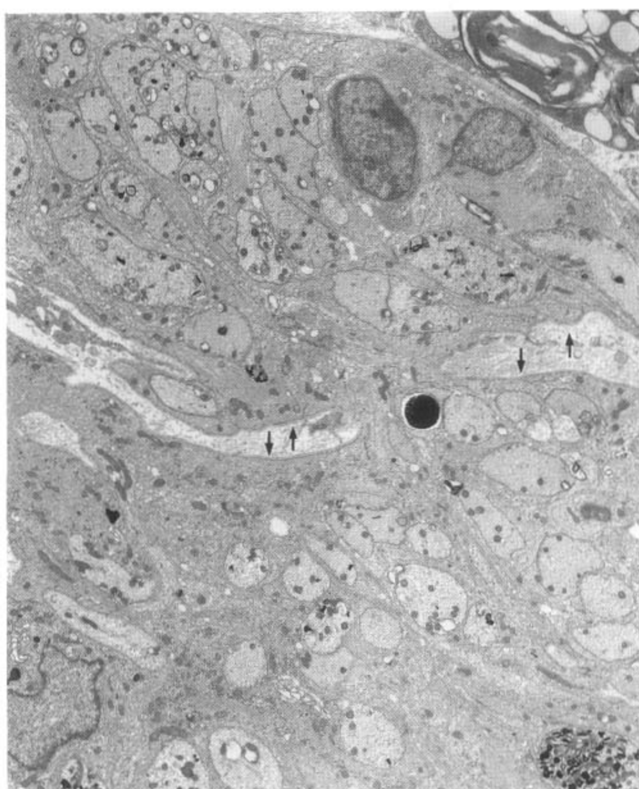

FIG. 58-8. The behavior of astrocytes within central nervous system lesions can be examined using the x-irradiated ethidium bromide lesion. Following transplantation of purified astrocyte cultures into demyelinating lesions, an integrated astrocytic environment around the demyelinated axons is formed with a border resembling a glia limitans (*arrows*). ×4000.

Transplantation of Progenitor Cells

Expansion of cells using growth factors or under the influence of conditionally acting oncogenes offers the prospect of obtaining large numbers of clonally derived cells for transplantation. The myelinating and repair potential of glial cell progenitors prepared using these techniques have been investigated in three studies. O-2A progenitors expanded *in vitro* by exposure to a combination of basic fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF) for 3 weeks are capable of generating oligodendrocytes that myelinate demyelinated axons following transplantation (Crang et al., 1992; Groves et al., 1993) (Figure 58-9). However, if such cells are maintained on growth factors for many months prior to transplantation not all the cells dif-

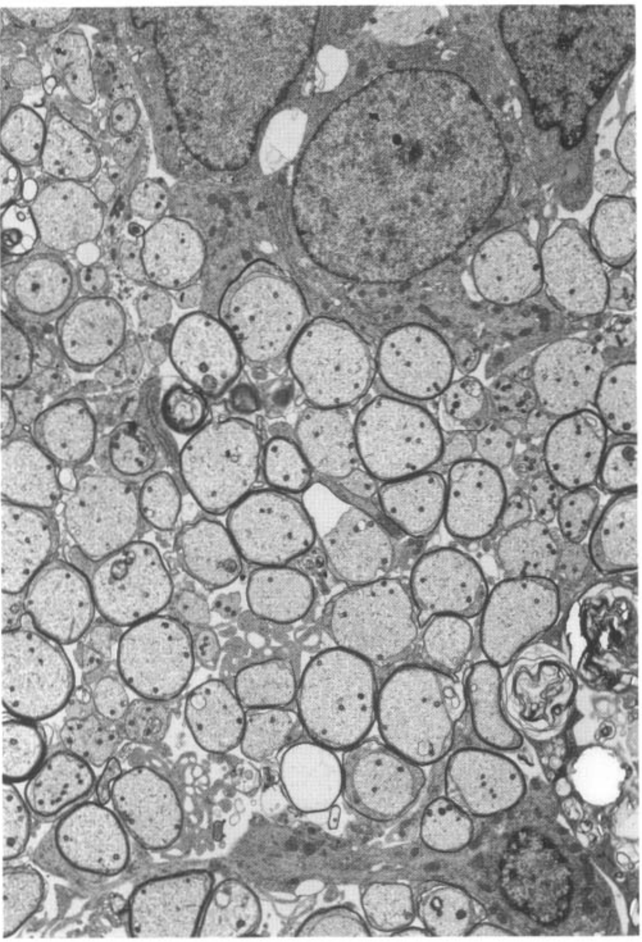

FIG. 58-9. The x-irradiated spinal cord ethidium bromide lesion provides a useful environment in which to examine the potential of glial progenitor cells to reconstruct a central nervous system glial environment. At 21 days following transplantation of O-2A progenitors expanded from optic nerve cultures by exposure to basic fibroblast growth factor and platelet-derived growth factor, extensive oligodendrocyte remyelination is found. ×4000.

ferentiate into oligodendrocytes on introduction into glial-free areas of demyelination (Groves et al., 1993). In this study the transplanted O-2A progenitors largely differentiated into oligodendrocytes. However, a different result was found following on transplantation of cloned progenitor cells produced using retroviral insertion of the temperature-sensitive SV40 large-T gene, since these cells gave rise to astrocytes as well as myelin-producing oligodendrocytes (Barnett et al., 1993; Trotter et al., 1993). These studies show that progenitor cells can be bipotential in pathological situations, a property that has not been demonstrated in normal development. An interesting difference was found between the two studies. In one study, the infection was made using mouse cells, and the resulting clonal cell lines contained both astrocytes (glial fibrillary acidic protein [GFAP+] cells) and progenitors on *in vitro* analysis prior to transplantation (Trotter et al., 1993), while in the other study the rat optic nerve-derived cell line was maintained in an undifferentiated state *in vitro* by continual exposure to PDGF and basic FGF (Barnett et al., 1993). On transplantation the mouse cell line gave rise to an integrated mixture of astrocytes and oligodendrocytes within the area of demyelination, while the rat cell lines gave areas that contained mainly one cell type or the other. In both cases not all cells differentiated and the ability of cells to differentiate into recognizable glial cells decreased with prolonged growth *in vitro*.

The Use of Glial Cell Transplantation to Study Cellular Interactions During Repair of Central Nervous System Demyelination

Demyelinated central nervous system axons can be remyelinated either by oligodendrocytes or Schwann cells. Which of these two types of repair occurs depends on the complex series of interactions between axons, cells of the oligodendrocyte and astrocyte lineages, and Schwann cells. Specific roles for these various cell types in determining the type of repair that follows demyelination have been revealed by creating situations where only certain cell types are present, or where the relative number of a particular cell type has been increased or decreased. This can be achieved by transplanting various glial cell cultures into x-irradiated and nonirradiated ethidium bromide lesions (Blakemore and Franklin, 1991).

The essential role of the astrocyte in creating environments where oligodendrocytes rather than Schwann cells can remyelinate central nervous system axons has been demonstrated using the nonirradiated ethidium bromide lesion. Following ethidium bromide injection into spinal cord white matter most of the axons are remyelinated by Schwann cells. *A priori*, one would predict that the balance of repair could be shifted toward oligodendrocyte remyelination by supplementing the number of oligodendrocytes by transplantation. However, when a central nervous system glial culture enriched for O-2A lineage cells is transplanted into the ethidium bromide lesion at the beginning of the repair process, the majority of axons are still remyelinated by host-derived Schwann cells (Blakemore and Crang, 1989). This observation indicates that when oligodendrocyte lineage cells are in direct competition with Schwann cells for demyelinated axons to remyelinate, then Schwann cell remyelination will prevail. The repair of the ethidium bromide lesion can, however, be changed in favor of oligodendrocyte remyelination by transplanting a mixed glial cell culture that contains a higher proportion of astrocytes (Blakemore and Crang, 1989). Moreover, the balance can also be shifted toward oligodendrocyte remyelination, albeit to a lesser degree, by transplantation of astrocytes alone (Franklin et al., 1991). These observations strongly support the concept that the presence of astrocytes favors oligodendrocyte remyelination, while their absence will favor Schwann cell remyelination. Astrocytes may also influence the "quality" of the myelin sheaths formed by oligodendrocytes (Franklin et al., 1993b).

The tendency for oligodendrocytes to be "outcompeted" by Schwann cell in the absence of astrocytes is only reversed when the former are present in sufficient numbers, and the Schwann cell contribution is limited. This situation can be created by using the x-irradiated ethidium bromide lesion, where, as has been discussed earlier, the host glial response is completely suppressed (Crang and Blakemore, 1989). In this situation, the cell types that interact with one another in the reconstruction of a glial environment are entirely governed by the composition of the transplant culture. When an oligodendrocyte lineage culture, depleted of astrocytes but containing the small contaminating population of Schwann cells invariably found in central nervous system cultures, is transplanted into an irradiated lesion most of the remyelination is by oligodendrocytes (Blakemore and Crang, 1989). This result also indicates that, while an astrocyte presence favors oligodendrocyte remyelination, it is not a necessity, a view that is supported by the ability of purified populations of O-2A progenitors to generate large numbers of myelinating oligodendrocytes in the absence of significant numbers of astrocytes (Groves et al., 1993). These studies indicate a dynamic balance between peripheral and central glia during the repair

of demyelinating lesions, where astrocytes are necessary to secure oligodendrocyte remyelination in the face of competition from Schwann cells.

This relationship between astrocytes and Schwann cells has been investigated in more depth by transplantation studies, revealing a further level of complexity. For it is now apparent that astrocytes are only able to restrict Schwann cell remyelination with the support of cells of the O-2A lineage. This conclusion was reached by the observation that, following transplantation of astrocyte cultures containing low numbers of Schwann cells and O-2A lineage cells into an x-irradiated lesion, extensive Schwann cell remyelination occurs (Crang and Blakemore, 1989; Franklin et al., 1992b). Thus, in spite of the presence of large numbers of astrocytes in the transplant, it is the small population of Schwann cells that expand to repair the lesion and not the small population of O-2A lineage cells. Indeed, in the absence of O-2A lineage cells, astrocytes may even enhance Schwann cell remyelination (Franklin et al., 1992b). The paradoxical behavior of astrocytes with regard to Schwann cell remyelination can be related to the arrangements adopted by transplanted astrocytes in the presence or absence of O-2A lineage cells. When O-2A lineage cells and astrocytes are present, together they combine to create large areas of reconstructed central nervous system white matter. In contrast, in the absence of O-2A lineage cells, astrocytes form dissociated clumps of cells from which many axons are excluded and hence are available for remyelination by Schwann cells (Franklin et al., 1992b, 1993b). These results suggest a role for O-2A lineage cells in influencing the ability of transplanted astrocytes to integrate within central nervous system lesions, an essential behavior if axons are not to be myelinated by Schwann cells. Thus by using the two types of ethidium bromide lesion and cultures of varying composition, it has been possible to demonstrate that the cell defined in tissue culture as the type-1 astrocyte is capable of excluding Schwann cell from the central nervous system (Blakemore and Crang, 1989). However, for this cell to fulfil this function in pathological situations, cells of the O-2A lineage are also required (Franklin et al., 1992a).

The recognition that O-2A lineage cells are essential for promoting astrocyte control of Schwann cell invasion into glial free lesions, together with the demonstration that mouse oligodendrocytes will myelinate rat axons (Crang and Blakemore, 1991) has formed the basis for the creation of a central nervous system environment, which resembles the chronically demyelinated central nervous system plaque of multiple sclerosis and provides a new model of immune-mediated demyelination (Blakemore, 1992). In this system, a chimeric cell suspension of isogeneic rat astrocytes and xenogeneic mouse O-2A lineage cells is transplanted into a demyelinating ethidium bromide lesion made in normal rat spinal cord, the survival of the mouse component of the transplant being controlled by immunosuppression. Thus, in immunosuppressed recipients, the mouse cells survive and remyelinate the demyelinated axons, and also assist in the establishment of the transplanted rat astrocytes, so that the lesion is remyelinated with central rather than peripheral myelin. If the immunosuppression is subsequently removed, the mouse cells are rejected and the axons are demyelinated for a second time. In contrast to the nontransplanted ethidium bromide lesion (Graça and Blakemore, 1986), the axons are remyelinated by oligodendrocytes. This is because a glial limitans exists, created by the transplanted rat astrocytes. Using this system it is possible to examine remyelination of an area of immune-mediated demyelination, which is self-limiting and not directed primarily against oligodendrocyte specific epitopes, as occurs in other models of allergic encephalomyelitis.

A modification of this system creates a further model. If at the same time as initiating rejection of the mouse cells by removing immunosuppression, the lesion area is exposed to 40 Gy of x-irradiation, the host-mediated remyelination that follows rejection of the mouse myelination can be suppressed. As a result, the demyelinated axons are left in an astrocyte environment which models the chronically demyelinated multiple sclerosis plaque (Blakemore and Crang, 1994).

CONCLUSION

Glial cell transplantation is a new and rapidly developing area of glial cell biology. It is becoming clear that the technique provides the investigator with a degree of experimental control over *in vivo* situations that has hitherto been available only for *in vitro* studies. This has enabled studies to be undertaken in developing or pathological central nervous system to validate concepts of glial cell behavior developed in tissue culture and to address fundamental questions about central nervous system regeneration. Already a clearer picture is emerging of the complex cell-cell interactions that occur in pathological situations in the central nervous system. The value of glial cell transplantation as an experimental procedure has also opened up the exciting prospect of using this technique to alter or augment

glial cell populations in clinical situations in order to stimulate or modify regeneration in the central nervous system.

59 Microglia in experimental neuropathology

JOCHEN GEHRMANN AND GEORG W. KREUTZBERG

Dedicated to Henry deF. Webster

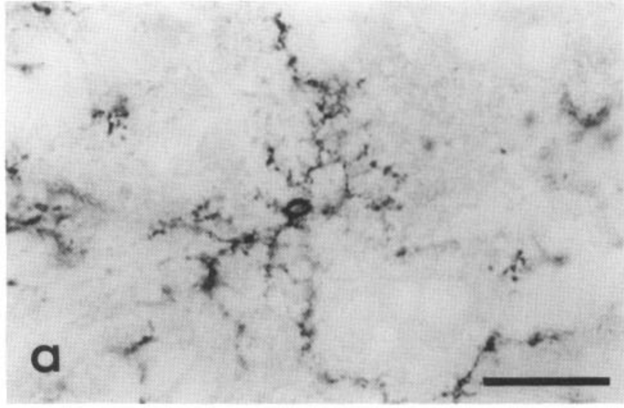
Microglia are ubiquitously distributed in nonoverlapping territories throughout the nervous system. These resident cells contribute up to 20% of the total glial cell population in the brain (Perry and Gordon, 1988; Lawson et al., 1990; Peters et al., 1991). Microglia can be best identified by means of silver impregnations, histochemical stainings (Kreutzberg and Barron, 1978), lectin stainings (Streit and Kreutzberg, 1987), and by several monoclonal antibodies that recognize antigens specific for cells of the monocyte/macrophage lineage (Dijkstra et al., 1985; Perry et al., 1985; Perry and Gordon, 1988; Gehrmann and Kreutzberg, 1991; Flaris et al., 1993). At the light microscopic level, all these stains show resting microglia to possess a characteristic ramified morphology with several crenellated processes. Their morphology appears to depend to some extent on their location (Perry et al., 1985; Streit et al., 1988; Gehrmann and Kreutzberg, 1991) (Figures 59-1A,B). At the ultrastructural level, resting microglia have a characteristic nucleus with a prominent heterochromatin but a rather scanty cytoplasm (for review see Peters et al., 1991 and Chapter 10) (Figure 59-1C).

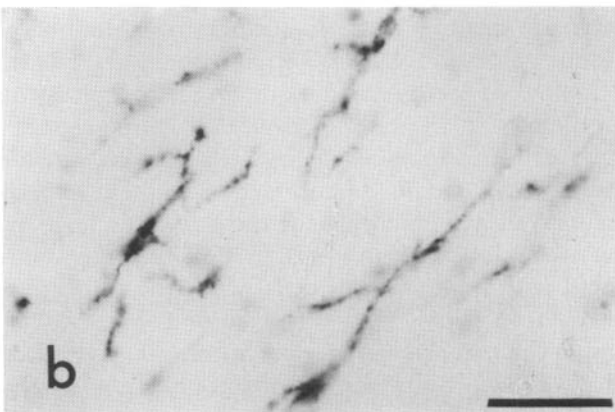
An important but still controversial issue of microglial biology concerns the cells' origin. In line with del Rio Hortega's initial postulate (Rio Hortega, 1919, 1932), the generally held view is that the resident microglia are of mesodermal origin, possibly derived from a bone marrow or embryonic precursor cell. These cells and/or lineage-related peripheral monocytes/macrophages invade the central nervous system at an early stage via the vasculature and eventually give rise to the typical process-bearing resident microglia (Ling and Wong, 1993). In contrast, a microglial progenitor cell has been thought to develop from nutrionally deprived astroglial cultures (Richardson et al., 1993), thus raising again the question of a neuroectodermal origin of microglia.

The close antigenic and lineal relationship of microglia to monocytes/macrophages, however, is further underlined by the fact that all monoclonal antibodies raised so far against microglia also cross-react with macrophages in peripheral tissues (Dijkstra et al., 1985; Perry et al., 1985; Gehrmann and Kreutzberg, 1991; Flaris et al., 1993). In this respect, it is interesting to note that microglia display a characteristic channel pattern distinct from peripheral monocytes/macrophages (Kettenmann et al., 1990).

Linked to the question of microglial origin is the problem of microglial turnover, that is, the replacement of intrinsic microglia by cells residing outside the brain. Based on bone marrow chimera experiments, resident microglia in the adult rat have an extremely low (i.e., lower than 1%) turnover compared with bone marrow cells, while the percentage of replaced cells is high in the leptomeninges (60%) and in the perivascular compartment (30%) (Hickey et al., 1992). In this respect, macrophages/microglia in a perivascular position are particularly important for brain immune surveillance at a site close to the blood-brain barrier. Two types of cells can be distinguished. First, are the perivascular cells, which are distinct from the smooth muscle-related lineage of pericytes. These perivascular cells express macrophage markers, are ultrastructurally enclosed within the basal lamina, can be induced to phagocytose and constitutively express major histocompatibility complex (MHC) class II antigens (Graeber et al., 1989, 1992). Second, are the perivascular microglia, which form a subpopulation of resident, parenchymal microglia. These perivascular microglia are found within the central nervous system parenchyma proper, but make direct contact with the tissue side of the adjoining basal lamina, thus forming part of the perivascular glia limitans similar to perivascular astrocytic endfeet (Gehrmann and Kreutzberg, 1991; Lassmann et al., 1991). In an immunopathological context, they rapidly express MHC class II antigens and furthermore have the capacity to phagocytose (Vass and Lassmann, 1990; Lassmann et al., 1991; Gehrmann et al., 1993a).

While the function of resting microglia is still largely unknown, it has become clear from observations in neuropathology that resting microglia rapidly undergo characteristic morphological





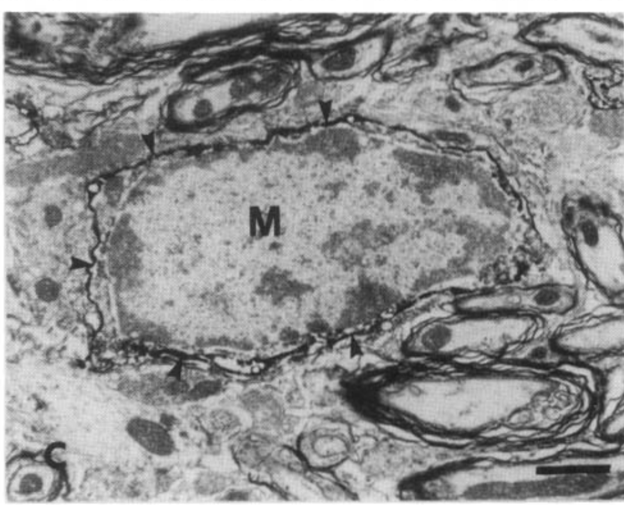


FIG. 59-1. Morphology of resting microglia in the rat. MUC 102 immunocytochemistry. While microglia (A) in the gray matter have a stellate morphology, (B) they display a bipolar morphology in the white matter. (C) At the electron microscopic level an immunostained microglia (*M*) (the *arrowheads* indicate the sites of the diaminobenzidine (DAB) reaction product) has a typical nucleus with a prominent heterochromatin and a rather scanty cytoplasm. Scale bar (Figures A and B) = 25 μm; Figure C = 1 μm.

changes in response to injury. It was Franz Nissl who first clearly recognized the capacity of intrinsic microglia to transform rapidly from a resting to an activated state in response to injury (Nissl, 1899; 1904). The terminology used to describe activated microglia has been confusing. These cells have been termed, for example, inflammation globules (*Entzündungskugeln*), foamy cells (*Schaumzellen*), granule cells (*Körnerzellen*), lattice cells (*Gitterzellen*), or rod cells (*Stäbchenzellen*). With the advent of monoclonal antibodies in recent years it has become possible to study more precisely the process of microglial activation. Microglial activation appears to follow a rather stereotypic pattern of cellular responses and occurs in a graded fashion. Activation becomes apparent mainly in the form of proliferation (in contrast to astrocytes which tend not to proliferate, but become hypertrophic) (Cammermeyer, 1965; Kreutzberg, 1968; Sjöstrand, 1965; Graeber et al., 1988), recruitment to the site of injury, morphological and immunophenotypical changes, as well as alterations in their functional properties, for example, the release of cytokines (Frei et al., 1987; Streit et al., 1988; Giulian et al., 1989; Gehrmann et al., 1992a, 1992d; Finsen et al., 1993; Flaris et al., 1993).

In terms of morphological changes, many transitional and intermediate morphologies of activated microglia occur, a fact which might have led to the confusing terminology of microglia in the past. In the first step of activation, microglia usually become hypertrophic with several stout processes but do not become phagocytic. If neuronal and/or terminal degeneration occur in the brain parenchyma, activated microglia further transform into phagocytic cells (Streit and Kreutzberg, 1988; Gehrmann et al., 1991a) and, under certain conditions morphologically resemble round, lipid-laden cells with a morphology similar to that of foamy macrophages (Brierley and Brown, 1982).

In this respect, the model of sublethal and lethal nerve injury has been particularly useful, since the blood-brain barrier remains unimpaired, allowing one to study exclusively the response of intrinsic microglia. All these studies underline the capacity of resident microglia to transform rapidly into intrinsic phagocytes of the brain, a process, which, due to its pronounced cytotoxic potential, seems to be under strict control *in vivo*. In addition to resting microglia, two types of activated microglia can be distinguished: an activated, but nonphagocytic microglia and an activated, phagocytic cell, which is equivalent to an intrinsic brain phagocyte. The most conspicuous immunophenotypical changes include the increased or even *de novo* expression of surface

molecules, some of which, such as MHC class I and II antigens, are normally found only on cells of the immune system. In line with their capacity to phagocytose and to release several immunomodulatory substances, these immunophenotypical properties indicate that microglia in fact form part of an intrinsic immune mechanism of the nervous system. Upon even remote lesions and/or pathological conditions lacking obvious neuropathological changes microglia appear to be rapidly activated as part of an early central nervous system immune defense system.

THE MICROGLIAL RESPONSE TO EXPERIMENTAL BRAIN INJURY

Peripheral Nerve Injury

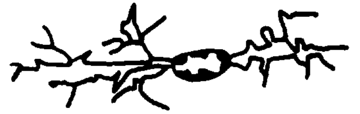
Peripheral nerve injury leads to well-defined retrograde and/or anterograde changes in the central nervous projection areas. Unlike most other experimental models, these remote nerve lesions (the brain itself is not touched) have the advantage of leaving the blood-brain barrier intact. Thus the reaction of intrinsic microglia can be studied in the complete absence of any infiltrating hematogenous macrophage. In particular, the facial nerve axotomy paradigm has proved to be suitable for studying the graded response of intrinsic microglia to injury. The facial nerve is cut unilaterally at its exit at the foramen stylomastoideum, and the remote microglial response is then studied in the facial nucleus of origin with the nonoperated side serving as an internal control. Following facial nerve axotomy a defined microglial reaction occurs (Figures 59-2 to 6). Within 3 to 4 days after the axotomy resident microglia, but not astrocytes, proliferate mainly around the injured facial motoneurons (Cammermeyer, 1965; Kreutzberg, 1966; Graeber et al., 1988a) (Figure 59-3). From 24 hours onward, several marker molecules, such as the CR3 complement receptor (Graeber et al., 1988b), are increased on hypertrophic, but still ramified, microglia. Activated microglia further express the intermediate filament protein, vimentin (Graeber et al., 1988c), the ectoenzyme 5′-nucleotidase (Kreutzberg and Barron, 1978; Schoen et al., 1992) (Figure 59-4), leukocyte function associated antigen-1 (Moneta et al., 1993), the CD4 antigen and MHC class I, and with some delay also class II molecules (Streit et al., 1989a, 1989b). Interestingly, the increased expression of MHC class II molecules appears to be under corticoid control, since treatment with dexamethasone downregulates its expression (Kiefer and Kreutzberg, 1992). Following facial nerve axotomy, activated microglia furthermore show an early de novo expression of the amyloid precursor protein (APP). Since APP immunoreactivity is found ultrastructurally within the endoplasmic reticulum of activated microglia, and since cultured microglia also synthesize APP mRNA, microglia appear to contribute to some extent to APP formation *in vivo* or even amyloidogenesis itself (Banati et al., 1993a). In addition, activated microglia show an increased expression of receptors for granulocyte-macrophage and macrophage colony-stimulating factors, both of which may regulate microglial proliferation (Raivich et al., 1991). Another cytokine, which is induced following facial nerve transection and most likely localized on activated microglia, is the transforming growth factor-beta 1 (TGFβ1) (Kiefer et al., 1992). From day 4 after axotomy onward activated microglia ensheath the soma of the injured facial motoneurons with their broadened cellular processes. As seen in semithin sections, one facial motoneuron is then usually covered by three to four microglia. Ultrastructurally, activated perineuronal microglia begin to displace afferent synaptic terminals from the motoneuron surface (Figure 59-6). This process, first described by Blinzinger and Kreutzberg (1968), is now generally referred to as synaptic stripping. It might lead to a synaptic deafferentation at somatic and stem dendritic sites, which in turn are important for the synaptic reorganization following neuronal injury.

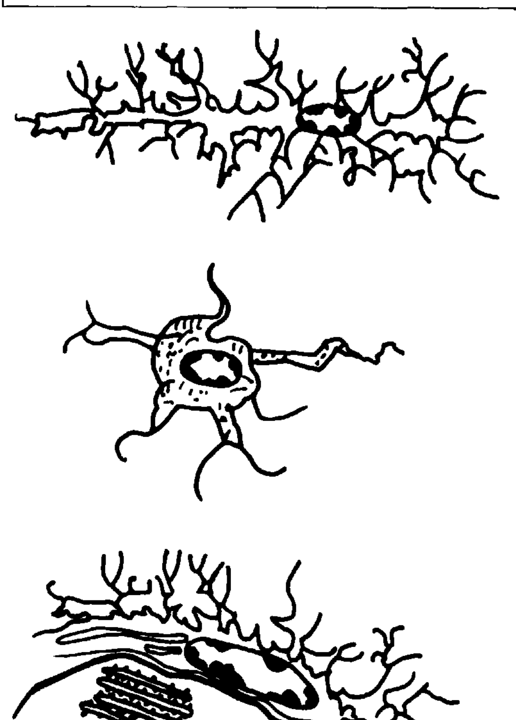
Under all these conditions, microglia become activated but do not become phagocytic. However, if facial motoneuron death is induced experimentally by the injection of toxic ricin into the facial nerve, microglia rapidly become phagocytic (Streit and Kreutzberg, 1988) (Figure 59-2). They transform into true brain macrophages, which eventually remove the neuronal debris. These experimental observations following sublethal (caused by facial nerve axotomy) and lethal (caused by ricin injection) motoneuron injury underline the fact that the microglial response to injury occurs in a graded fashion. First, microglia become activated, but not phagocytic, then, in a second step, if neuronal and/or terminal degeneration occur, they transform further into intrinsic phagocytes of the brain (Streit et al., 1988; Gehrmann et al., 1991a).

In contrast to facial nerve axotomy, which leads to a pure retrograde neuronal response, axotomy of the sciatic nerve induces a variety of neuronal and axonal reactions in different locations (Gehrmann et al., 1991b). While retrograde reactions occur in the ventral gray matter of the lumbar spinal cord and the corresponding dorsal root ganglia, transgan-

RESTING MICROGLIA

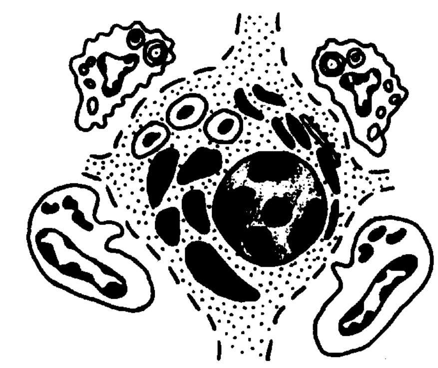
In their resting state microglia have a typical ramified morphology which is adapted to their microenvironment (i.e. in the white matter they have a bipolar morphology, and in the grey matter a stellate morphology). In addition microglia have a characteristic nuclear morphology with a prominent heterochromatin. They express several molecules constitutively (i.e. the CR3 complement receptor, the MUC 101 & 102 epitopes, LFA-1, α-D-Galactose containing glycoconjugates which are recognized by GSI-B_4) while other molecules are only expressed at low levels (CD4, vimentin, MHC class I and II molecules) or are absent from resting microglia (ED 1-3, Ki-M2R).





ACTIVATED, BUT NON-PHAGOCYTIC MICROGLIA

In response to sublethal neuronal injury (i.e. after facial nerve transection) resting microglia proliferate (for comparison see Fig. 3) and undergo characteristic morphological changes mainly by becoming hypertrophic. Proliferating microglia in a perineuronal position are found in direct apposition to the surface of the injured motoneuron whereby apparently detaching afferent synaptic terminals from the neuronal surface ("synaptic stripping"). These activated microglia, however, do not become phagocytic. In addition, they show a markedly increased expression of several marker molecules (CR3, MUC 101 & 102, GSI-B4, LFA-1, CD4, vimentin, MHC class I and II antigens and APP). They also appear to newly synthesize TGF-β1.



ACTIVATED, PHAGOCYTIC MICROGLIA

Neuronophagia: in response to lethal neuronal injury (i.e. after toxic Ricin injection into the facial nerve) microglia become activated and furthermore triggered to transform into phagocytic cells. The marker molecule expression is similar to that observed after sublethal injury with the exception that under certain conditions these cells aquire typical "macrophage" markers such as ED1.

FIG. 59-2. Graded response of microglia to neuronal injury. Resting microglia have either a bipolar or a stellate morphology and express several marker molecules (characteristic of cells of the monocyte/macrophage lineage) constitutively. Each cell is furthermore characterized by a typical nuclear morphology with a prominent heterochromatin. Following peripheral nerve transection, microglia change into an activated, but nonphagocytic state. They show an increased expression of several marker molecules and undergo characteristic morphological changes mainly by becoming hypertrophic. At the ultrastructural level activated microglia are found in a close perineuronal position detaching synaptic terminals from the neuronal surface. Under conditions of neuronal cell death, activated microglia further transform into phagocytic cells containing typical phagosomes. [Adapted from Streit et al. (1988), with permission.]

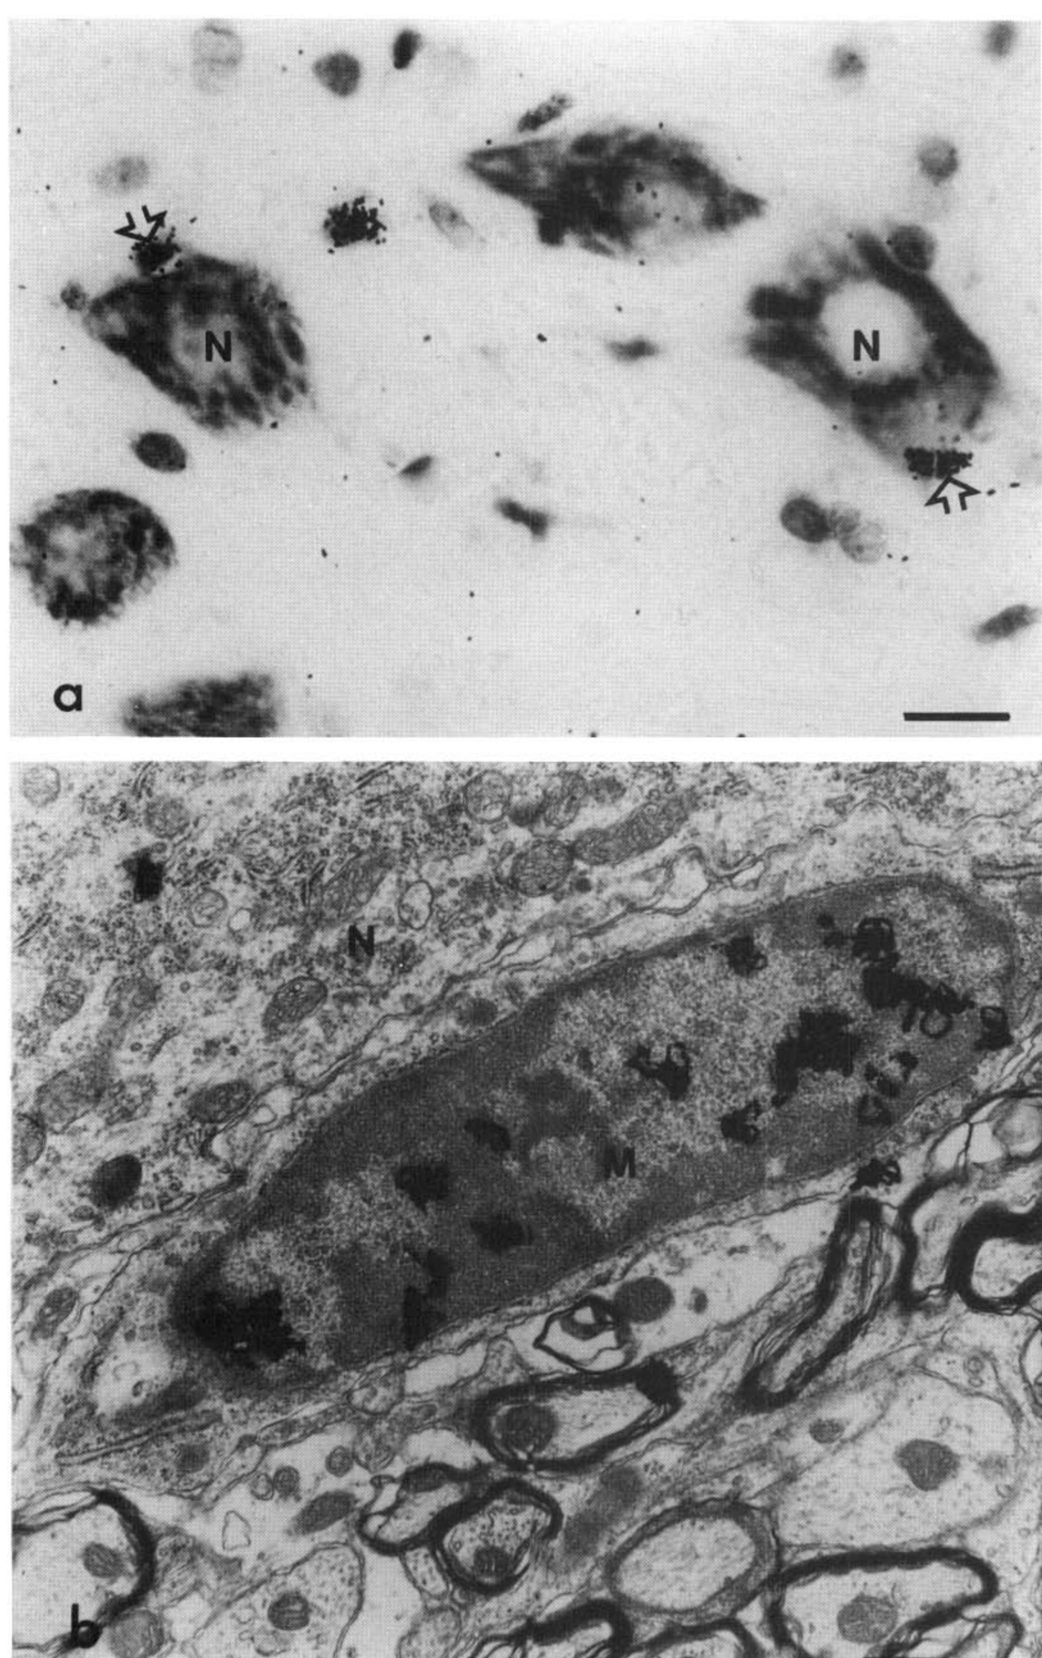


FIG. 59-3. Microglial proliferation in the rat facial nucleus 4 days after facial nerve transection. (3H)Thymidine autoradiography. (**A**) At the light microscopic level, several small glial cells are labeled. (**B**) Electron microscopy demonstrates that the silver grains are localized on the nucleus of a perineuronal microglia (*M*). Scale bars: Figure A = 25 μm, Figure B = 1 μm (Photographs by courtesy of Manuel B. Graeber.)

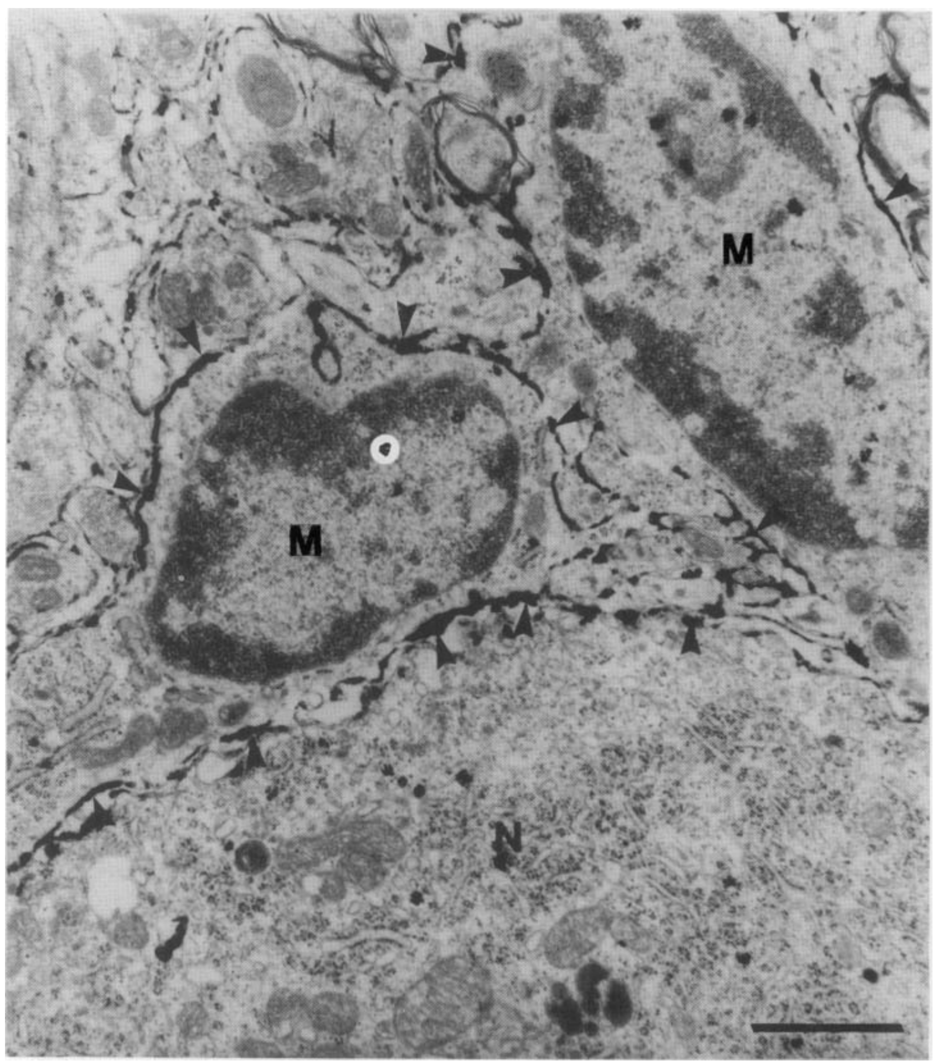

FIG. 59-4. 5′-Nucleotidase histochemistry in the rat facial nucleus 7 days after facial nerve transection. At the electron microscopic level the surface of two perineuronal microglia (*M*) is strongly labeled by 5′-nucleotidase reaction product (*arrowheads*). *N*, facial motoneuron. Scale bar = 1 μm.

glionic changes take place in the dorsal gray matter and the ipsilateral nucleus gracilis due to the degeneration of the central branches of the primary afferent sensory fibers and terminals. Microglial reaction and proliferation are observed from 24 hours after axotomy onward at all these locations (Gehrmann et al., 1991b), but the rapid and remote microglial response in the nucleus gracilis is especially intriguing (Gehrmann et al., 1991b). In this area, early molecular changes in axonal and synaptic terminals that precede the appearance of argyrophilic degeneration products seem to be sufficient to induce microglial proliferation and activation. This early reaction further supports the concept that resident microglia are central nervous system cells which respond to even subtle and remote pathological stimuli.

Wallerian Degeneration

Transection of the optic nerve, usually performed behind the globe 1.0 to 1.5 cm distant from the contralateral superior colliculus, leads to an anterograde Wallerian degeneration, which develops along the optic tract and in the contralateral superior colliculus. Apart from the directly injured optic nerve stump, there is no evidence for a gross impairment of blood-brain barrier function in these areas. Within the denervated optic nerve the rapid and gradually extending reaction of microglia/macro-

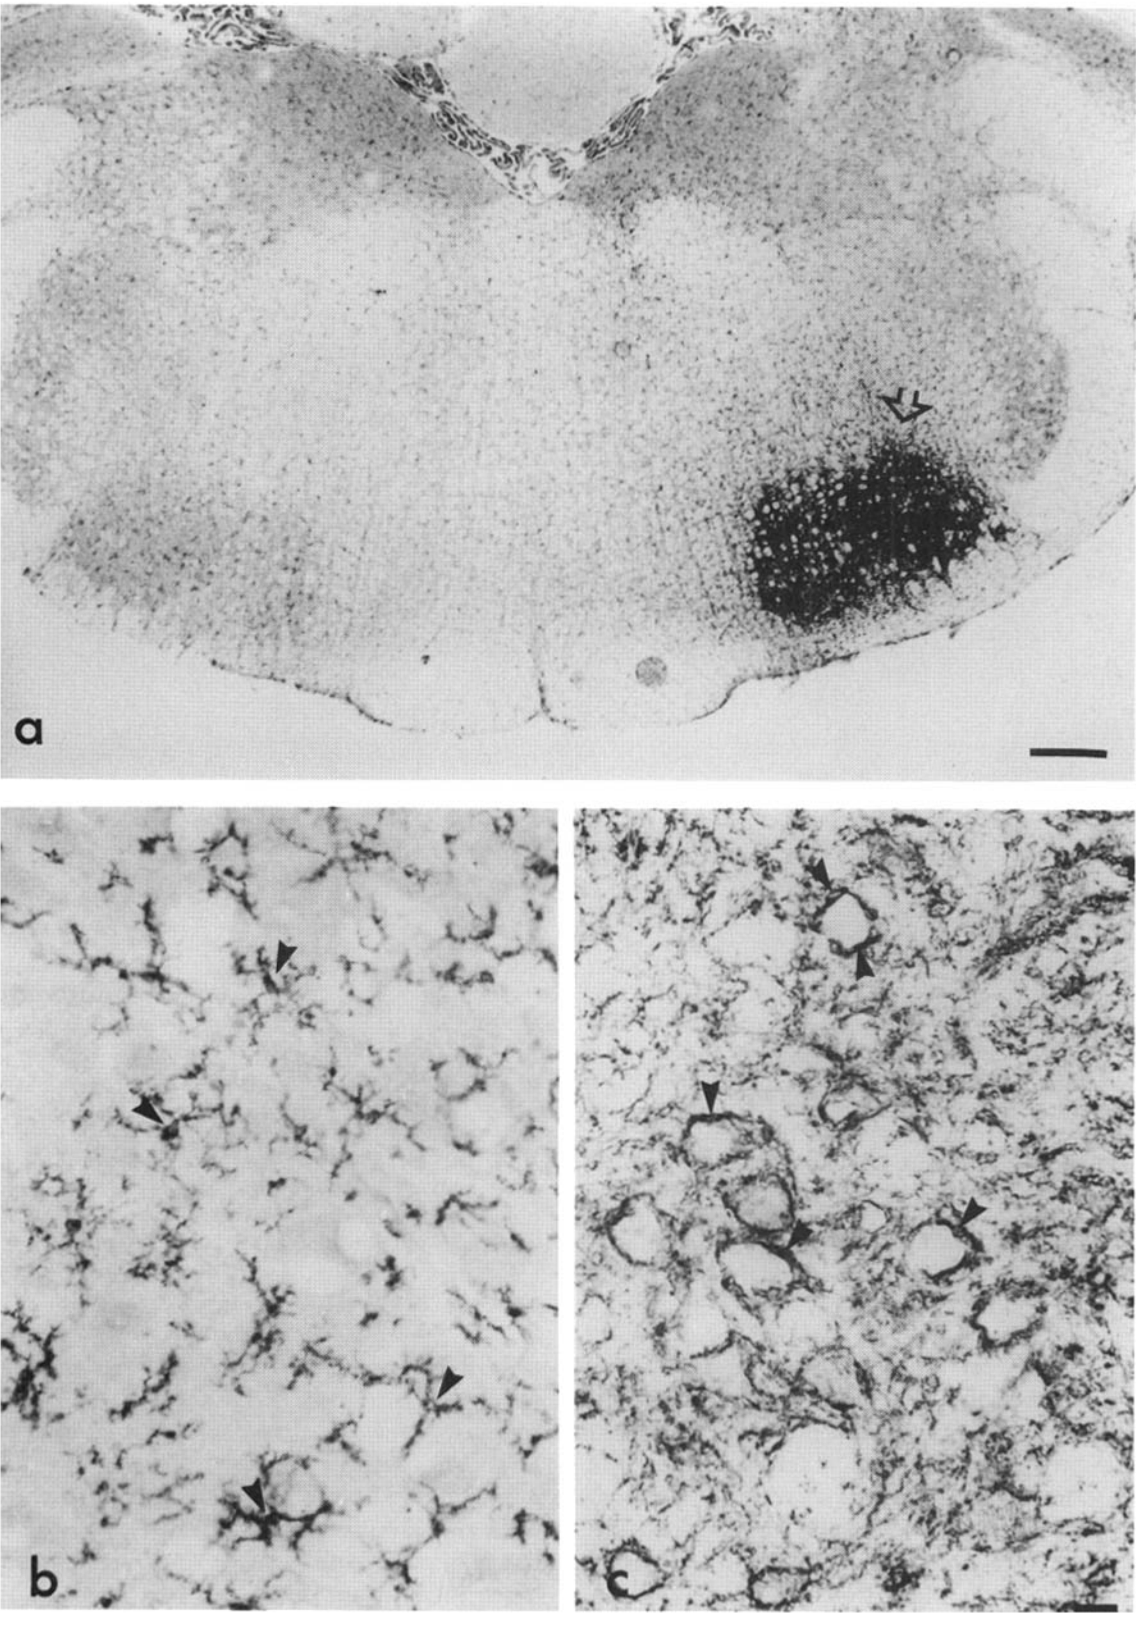

FIG. 59-5. Response of microglia to transection of the rat facial nerve. MUC 102 immunocytochemistry. (A) The overview of a rat brainstem shows that the microglial immunoreactivity is strongly increased on the facial nucleus (*arrow*) ipsilateral to the side of facial nerve transection after 5 days. Scale bar = 500 μm. [From Gehrmann and Kreutzberg (1991) with permission.] (B) In the intact control nucleus microglia have a ramified morphology characteristic of resting cells. (C) Five days after facial nerve transection the facial motoneurons are surrounded by strongly immunoreactive perineuronal microglia. Scale bar = 25 μm.

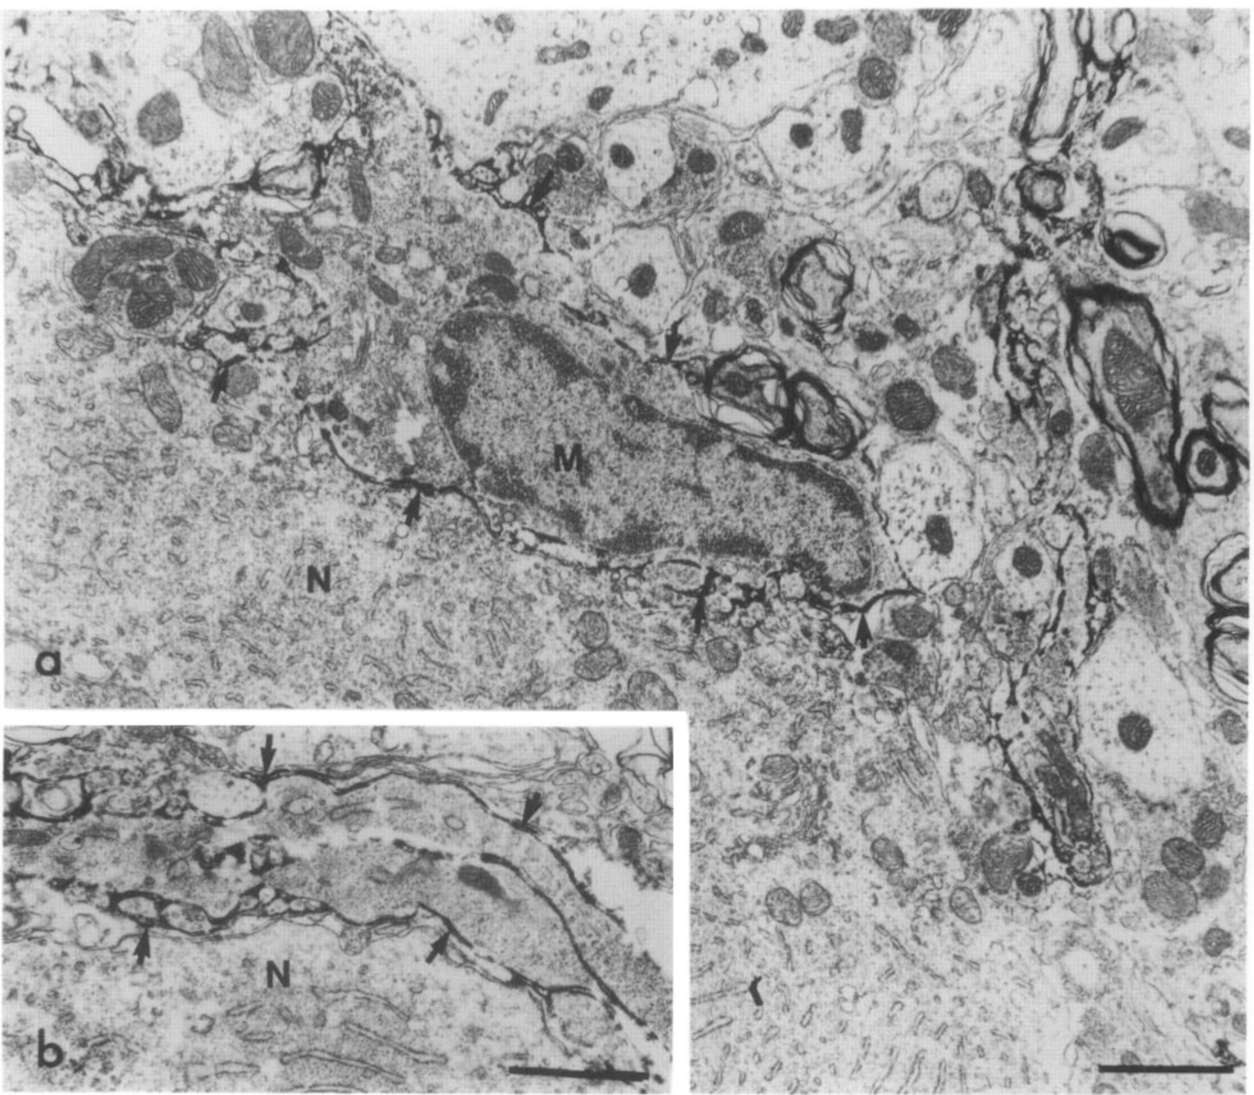

FIG. 59-6. Ultrastructure of a perineuronal microglia in the operated facial nucleus. (**A**) MUC 102 immunoelectron microscopy (*arrowheads* indicate the sites of the diaminobenzidine (DAB) reaction product). Five days after facial nerve transection, a perineuronal activated microglia (*M*) is situated in the close vicinity of an injured facial motoneuron (*N*). Higher magnification in Insert **B** shows stacks of microglial processes which make direct contact with the neuronal surface. Scale bars = 1 μm. [From Gehrmann and Kreutzberg (1991) with permission.]

phages is an early feature of Wallerian nerve degeneration (Konno et al., 1989; Rao and Lund, 1989). These cells usually have a morphology similar to that of foamy macrophages, which is compatible with the notion that they are involved in the removal of the slowly degenerating myelin sheath. In addition, macrophages obtained from transected optic nerves produce a favorable substrate for nerve regeneration *in vitro,* suggesting that the macrophage response (similar to the situation after peripheral nerve axotomy) might also enhance central nervous system repair mechanisms (David et al., 1990). In the superior colliculus, a spatially distinct reaction of microglia occurs. Whereas increased expression of the CR3 complement receptor, of the leukocyte common antigen and of MHC class I molecules is observed on activated microglia throughout the deafferented colliculus, *de novo* expression of CD4 and MHC class II molecules is restricted to the stratum opticum (Flaris et al., 1993). Both types of reactions reach a peak 7 days after optic nerve transection. Since the stratum opticum is the nerve cell layer to which the myelinated axons of the retinal ganglion cells project, this restricted expression of class II molecules support the assumption that myelin and/or myelin breakdown products could be instrumental in regulating class II expression on microglia (Smetanka et al., 1990).

Anterograde Degeneration in the Deafferented Dentate Gyrus

Lesion of the entorhinal cortex leads to the degeneration of its projection to the outer molecular layer of the dentate gyrus where the corresponding granule cells are depleted of their afferent input. Following a short period of lesion-induced axonal and terminal degeneration, reinnervation of the molecular layer takes place due to the sprouting of cholinergic fibers arising from the septal nuclei. Activated microglia, but not reactive astrocytes, appear as early as 24 hours postlesion in the deafferented dentate gyrus (Fagan and Gage, 1990; Gehrmann et al., 1991a). The microglial reaction peaks around day 3 postlesion and is no longer easily detected after 8 days. It is thus terminated before the onset of collateral sprouting events. Ultrastructurally, dark terminal degeneration is detectable within 24 hours postlesion (Gehrmann et al., 1991a). At the same time, activated microglia begin to phagocytose these degeneration products. Therefore, terminal degeneration most likely provides the stimulus for microglial proliferation, activation, and transformation into intrinsic phagocytes, which remove the degenerating material. Interestingly, the early and transient microglial reaction precedes the later and persisting astrocyte reaction. Although the involvement of cytokines and trophic factors is still controversial in this lesion paradigm, the sequential activation of microglia and astrocytes could have functional importance. Activated microglia might induce astrogliosis, while the ensuing astrocytic reaction might subsequently support regenerative sprouting events (Fagan and Gage, 1990).

Penetrating Brain Injury

The most commonly studied model of direct (penetrating) brain injury is the stab wound model in which a penetrating injury to the cortex is performed stereotactically to a depth of approximately 1 mm from the cortical surface. The ensuing cellular response is mainly limited to the site of the needle tract and the tissue directly surrounding the lesion. It resembles a wound healing reaction, and due to the obvious blood-brain barrier damage, involves both intrinsic microglia as well as hematogenous macrophages in addition to other infiltrating blood cells such as leukocytes, granulocytes, and monocytes (Giulian et al., 1989). Round hematogenous macrophages are mainly found within the lesion itself, whereas process-bearing, hypertrophic intrinsic microglia occur at the edge of the lesion. Both types of mononuclear phagocytes, intrinsic and extrinsic, are detectable in increased numbers within the first 10 hours postlesion. Their reactivities peak around day 2 and decline until 10 days postlesion (Giulian et al., 1989). At day 5 postlesion ramified hypertrophic microglia localized at the edge of the injury notably express MHC class II and the CD4 antigen while faintly expressing the ED1 marker (Flaris et al., 1993). In general, the microglial reaction following direct penetrating trauma to the rat brain is less pronounced than that observed, for example, in response to an inflammatory lesion. Interestingly, at day 2 (i.e., at the peak of mononuclear phagocytic activity) considerable amounts of IL-1 can be identified in the lesion area (Giulian et al., 1989). Since IL-1 appears to control astrogliosis (Giulian and Lachman, 1985; Giulian et al., 1986), it has been postulated from these results that IL-1 released by activated macrophages/microglia could be responsible for the sequential activation of astrocytes starting from day 5 onward. Other mediator substances which could be involved are interleukin-6 which has been measured by microchamber dialysis techniques (Woodroofe et al., 1991) and, also TGFβ1 which could be localized on macrophages/microglia at the edge of a stab wound by *in situ* hybridization (Lindholm et al., 1992).

Ischemia

Transient arrest of the cerebral blood circulation leads to neuronal cell death in selectively vulnerable brain regions, such as the dorsolateral striatum and the hippocampal CA1 and CA4 regions (Spielmeyer, 1925; Vogt, 1925; Scholz, 1953; Pulsinelli, 1982). Unlike neurons, glial cells survive such a transient ischemic injury. It is now well established that glial cells further respond to ischemia by becoming activated. The resulting neuropathological process has been defined as that of a selective neuronal necrosis. While astrocytic reactions, as indicated by increases in glial fibrillary acidic protein immunoreactivity, are well documented (Schmidt-Kastner et al., 1990; Petito et al., 1990), relatively little is known about the reactions of resident microglia except for some information pertaining to their role as phagocytes in hypoxia (Brierley and Brown, 1982).

Based on studies on transient forebrain ischemia induced by four-vessel occlusion, the microglial reaction has been examined more intensively (Morioka et al., 1991; Gehrmann et al., 1992a, 1992c; Finsen et al., 1993). Microglia appear to be activated as early as 20 minutes following the ischemic injury (Morioka et al., 1991). From day 1 onward, they proliferate and show an increased expression of sev-

eral surface molecules, most conspicuously MHC class I and II molecules. Although there is some discrepancy in the time course of the microglial reaction (most likely due to different time intervals of the ischemic injury). A pronounced microglial reaction occurs in the dorsolateral striatum and the hippocampal CA1 (with an accentuation of the stratum pyramidale and lacunosum moleculare) and CA4 (Figure 59-7). In the stratum pyramidale of the CA1 sector, microglia have been observed at the ultrastructural level to be phagocytosing degenerated material which resembles that of the foamy macrophages described in infarcts (Gehrmann et al., 1992c) (Figure 59-7). Immunoelectron microscopy indicates that perivascular microglia are also actively involved in the phagocytosis process and are rapidly inducible for MHC class II expression (Gehrmann et al., 1992c). Interestingly, resident microglia appear to make frequently contact with neighboring structures, such as the neuronal soma or dendrites (even while those are still intact) as if they were scanning their microenvironment for possible tissue damage (Gehrmann et al., 1992c). This again suggests that microglia function as a network of resident cells which can become rapidly activated in case of tissue damage.

In the stratum radiatum of the CA1 sector, activated microglia assume a typical rod cell morphology and are ultrastructurally observed to phagocytose the degenerating dendrites of the CA1 pyramidal neurons. In contrast, there is almost no microglial reaction in the hippocampal CA3 which is relatively spared by the ischemic injury in most models of ischemic injury.

In addition, a delayed microglial reaction can be observed in other locations with a less pronounced selective vulnerability such as the substantia nigra and the anterior parts of the thalamus (Gehrmann et al., 1992b). In white matter tracts hypoxia/ischemia leads to diffuse axonal swelling and injury (Hirano et al., 1967), which is accompanied by a markedly increased MHC class II expression on microglia (Gehrmann et al., 1992b). In ischemia, as well as in other models of experimental injury, the microglial reaction furthermore serves as an early and sensitive marker for the temporal and spatial distribution pattern of impending neuronal damage. In the neocortex, for example, activated microglia are either concentrated in layer 3 (probably reflecting the selective vulnerability of layer 3 neurons) or arranged in columns to the cortical surface. This arrangement in columns most likely reflects both anterograde and retrograde changes induced in cortical neurons by the simultaneous neuronal cell death in interconnected thalamic nuclei (Gehrmann et al., 1992b). In addition, activated microglia in ischemia have recently been shown to express newly the mRNA of TGFβ1 and IL-1 (Wießner et al., 1993).

What causes the rapid microglial reaction in ischemia? Manifest neuronal cell death is certainly a strong stimulus for the activation of microglia which become phagocytic and remove the tissue debris. Since full-blown neuronal cell death lags behind the early activation of microglia, manifest cell death does not appear to be the only candidate. In addition to early ultrastructural and biochemical neuronal changes, other factors such as release of exitotoxic amino acids, cytokines, and also increased ion fluxes could play a role. Since ischemia is associated with pronounced changes in extracellular potassium, and since microglia are sensitive to changes in potassium due to their unique potassium channel pattern (Kettenmann et al., 1990), we have postulated that potassium might be among the factors that trigger the activation of microglia in ischemia. Following cortical spreading depression, which leads to increased potassium fluxes across membranes, microglia become transiently activated throughout the cortex in the absence of neuropathic changes (Gehrmann et al., 1993b).

While it is clear that the microglia will respond to neuronal damage by becoming activated, it is still possible that the early microglial reaction further augments tissue damage due to the pronounced cytotoxic potential of this cell. Interestingly, treatment with drugs that supposedly interfere with macrophage reactions, such as chloroquine, improve the neurological status in animals with spinal cord ischemia (Giulian and Robertson, 1990). In addition, the microglial reaction is almost absent in rats treated with the *N*-methyl-D-aspartate (NMDA) antagonist MK-801 (Streit et al., 1992), although it has been argued that MK-801 acts primarily by rescuing neurons and thereby abolishes the most crucial stimulus for microglial activation. Obviously, the question of microglial cytotoxicity and other functions of this cell type in ischemia deserve further attention, since interference with the process of microglial activation could provide new clues to the treatment of neurological diseases such as stroke.

Experimental Autoimmune Encephalomyelitis

The nervous system has long been considered an immunologically privileged site. This view has been based on four main arguments: (1) lack of lymphatic drainage, (2) seclusion from the periphery by a tight blood-brain barrier, (3) impaired rejection of transplants, and (4) lack of intrinsic antigen-presenting

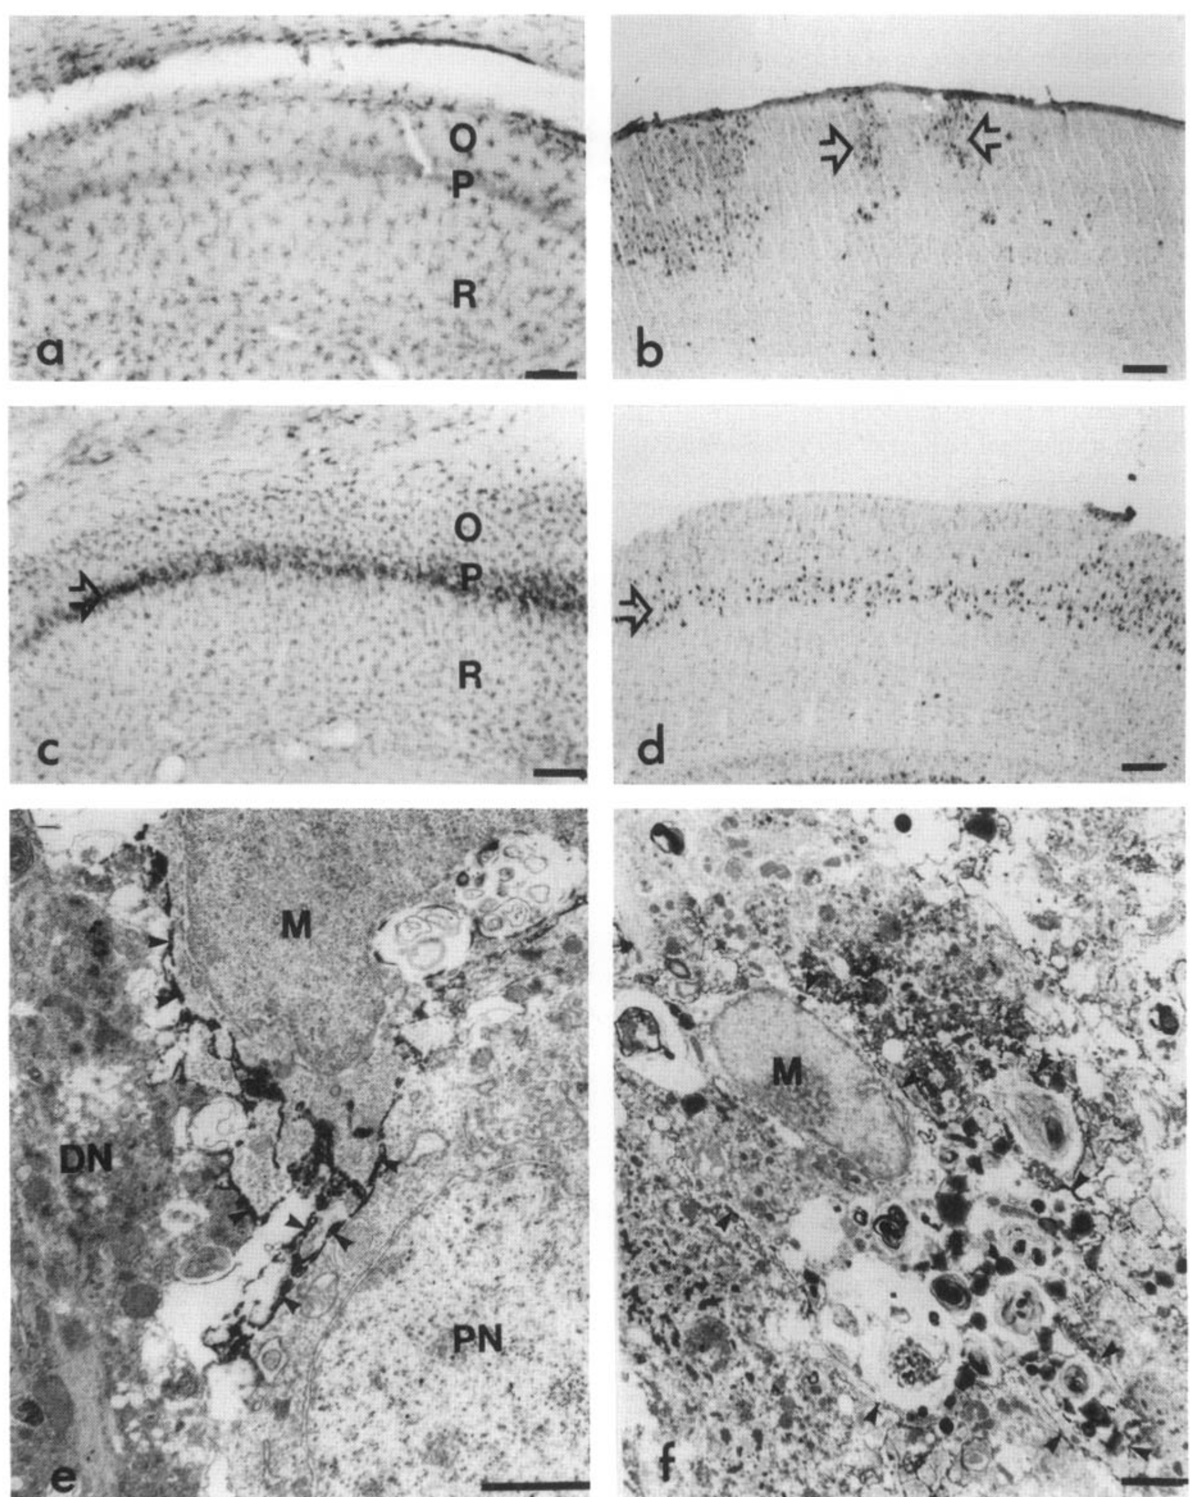

FIG. 59-7. Microglial response to global ischemia (induced by 30 minutes of a four-vessel occlusion) in the hippocampal CA1 sector. (**A,B,C,D**) Light microscopy. Three days after the ischemic injury (*C*) activated microglia are prominent throughout all layers of CA1, but particularly in the stratum pyramidale (*P*) O, str. oriens; *P*, str. pyramidale; *R*, str. radiatum. In the parietal cortex MHC class II immunoreactive microglia are arranged either in columns to the cortical surface (*B*) or are concentrated within layer 3 (*D*). (**E,F**) MUC 102 immunoelectron microscopy (The *arrowheads* indicate the sites of the diaminobenzidine (DAB) reaction product). (*E*) An immunoreactive microglia is interposed between two types of CA1 neurons (i.e., a pale type of neuron (*PN*), that may eventually survive, and a dark, degenerating neuron (*DN*). (*F*) Example of phagocytic microglia (with a morphology similar to that of a "foamy macrophage") which contains several phagocytosis products within its enlargened cytoplasm. Scale bars: Figures A–D = 25 μm; E and F = 1 μm. [Figures B and D from Gehrmann et al. (1992b), Figures E and F from Gehrmann et al. (1992c), with permission.]

cells (for review see Wekerle et al., 1986). Although these properties render the nervous system an immunologically distinct organ, the immune system obviously locates foreign antigens within the nervous system and subsequently induces immune reactions (e.g., inflammation) therein. One way by which immune surveillance is performed in the nervous system has been elucidated by Wekerle et al., (1986). Immunocompetent, activated T lymphocytes can enter the brain in an apparently random fashion subsequently patrolling the brain in search of their specific antigen (Hickey et al., 1991).

The histopathological hallmark of T cell-induced autoimmune diseases are perivascular lesions, consisting mainly of T lymphocytes, B lymphocytes, and macrophages. Within the inflammatory lesion many of the mononuclear cells are macrophages, predominantly ED1-positive, a few ED3-positive, but almost no involvement of ED2-positive cells (Flaris et al., 1992). As demonstrated first by Vass et al. (1986) and by Matsumoto et al. (1986), there is furthermore a generalized reaction of resident microglia within the parenchyma: Microglia proliferate, show an increased expression of several surface molecules, most conspicuously MHC class II antigens, and transform morphologically into either a rod-shaped or round, ameboid form. In the vicinity of the perivascular cuff, hypertrophic reactive astrocytes encase the primary core of the inflammatory lesion (consisting mainly of mononuclear cells) and are thus arranged in a way as if to prevent the interaction between infiltrating activated T lymphocytes and activated microglia (Matsumoto et al., 1992).

The functional role of this macrophage/microglial reaction is not yet fully understood. Both types of cells could initiate and maintain the immune reaction by virtue of their *in vitro* antigen-presenting capacity. In this respect, two types of resident central nervous system cells could be important. First, perivascular ED2-positive cells (Graeber et al., 1989), which have also been demonstrated in human brain (Graeber et al., 1992), could be involved. These cells express MHC class II molecules constitutively and can be triggered to phagocytose foreign material. Second, perivascular microglia, which are intraparenchymal cells but also form part of the glia limitans, could also be involved. (Gehrmann and Kreutzberg, 1991; Lassmann et al., 1991) (Figure 59-8). These cells can also be rapidly induced to phagocytose as well as to express MHC class II antigens. Immunoelectron microscopy has indeed shown an activation of these perivascular microglia in experimental autoimmune encephalomyelitis (EAE) (Gehrmann et al., 1993a).

In addition, macrophages/microglia could be involved in mediating tissue damage both by phagocytosis and the release of harmful mediators. In fact, depletion of macrophages prior to the onset of disease by injection of either silica or liposomes attenuates the disease (Huitingta et al., 1990). Bone marrow chimera experiments by Hickey et al. (1992) have demonstrated that the turnover of resident microglia is rather low in the adult central nervous system, whereas a high percentage of perivascular and meningeal cells is repopulated from the bone marrow. Interestingly, EAE can be equally well induced in bone-marrow chimeras as well as in sham controls (Lassmann et al., 1993). This indicates a more pronounced role of perivascular and meningeal macrophages in initiating central nervous system autoimmune disease than of resident microglia.

Brain Abscess

The brain responds to a bacterial infection by the formation of a typical bacterial abscess surrounded by a fibrous tissue capsule. A brain abscess can be experimentally induced by injection of *Staphylococcus aureus*-loaded agarose beads into the cortex (Flaris and Hickey, 1992). In the early phase of infection, there is a widespread infiltration of neutrophils, granulocytes, and monocytes/macrophages into the necrotic area surrounded by an edema. In the second phase of disease, usually referred to as chronic cerebritis (i.e., between 4 and 8 days postinoculation) ED1-, ED3-, but also strongly ED2-positive macrophages along with some lymphocytes infiltrate the edema zone around the necrotic core. This influx, particularly the appearance of ED2-positive cells, takes place just before collagen deposition and capsule formation occur from day 9 onward (Flaris et al., 1993). Activated microglia external to the capsule scar then start to appear along with a concomitant astroglial reaction. Since the immunological reactions in brain abscess are distinct from those observed in T cell-mediated EAE (the latter resembling a T cell-mediated reaction of the delayed type hypersensitivity type), this model might provide an interesting approach for studying microglial reactions to acute infections.

Experimental Autoimmune Neuritis

The peripheral nervous system counterpart of EAE is experimental autoimmune neuritis (EAN). Either sensitization of susceptible animals to peripheral nervous system tissue (Waksman and Adams, 1955) or the passive transfer of autoaggressive T line cells specific for the P2 or the P0 protein of the peripheral

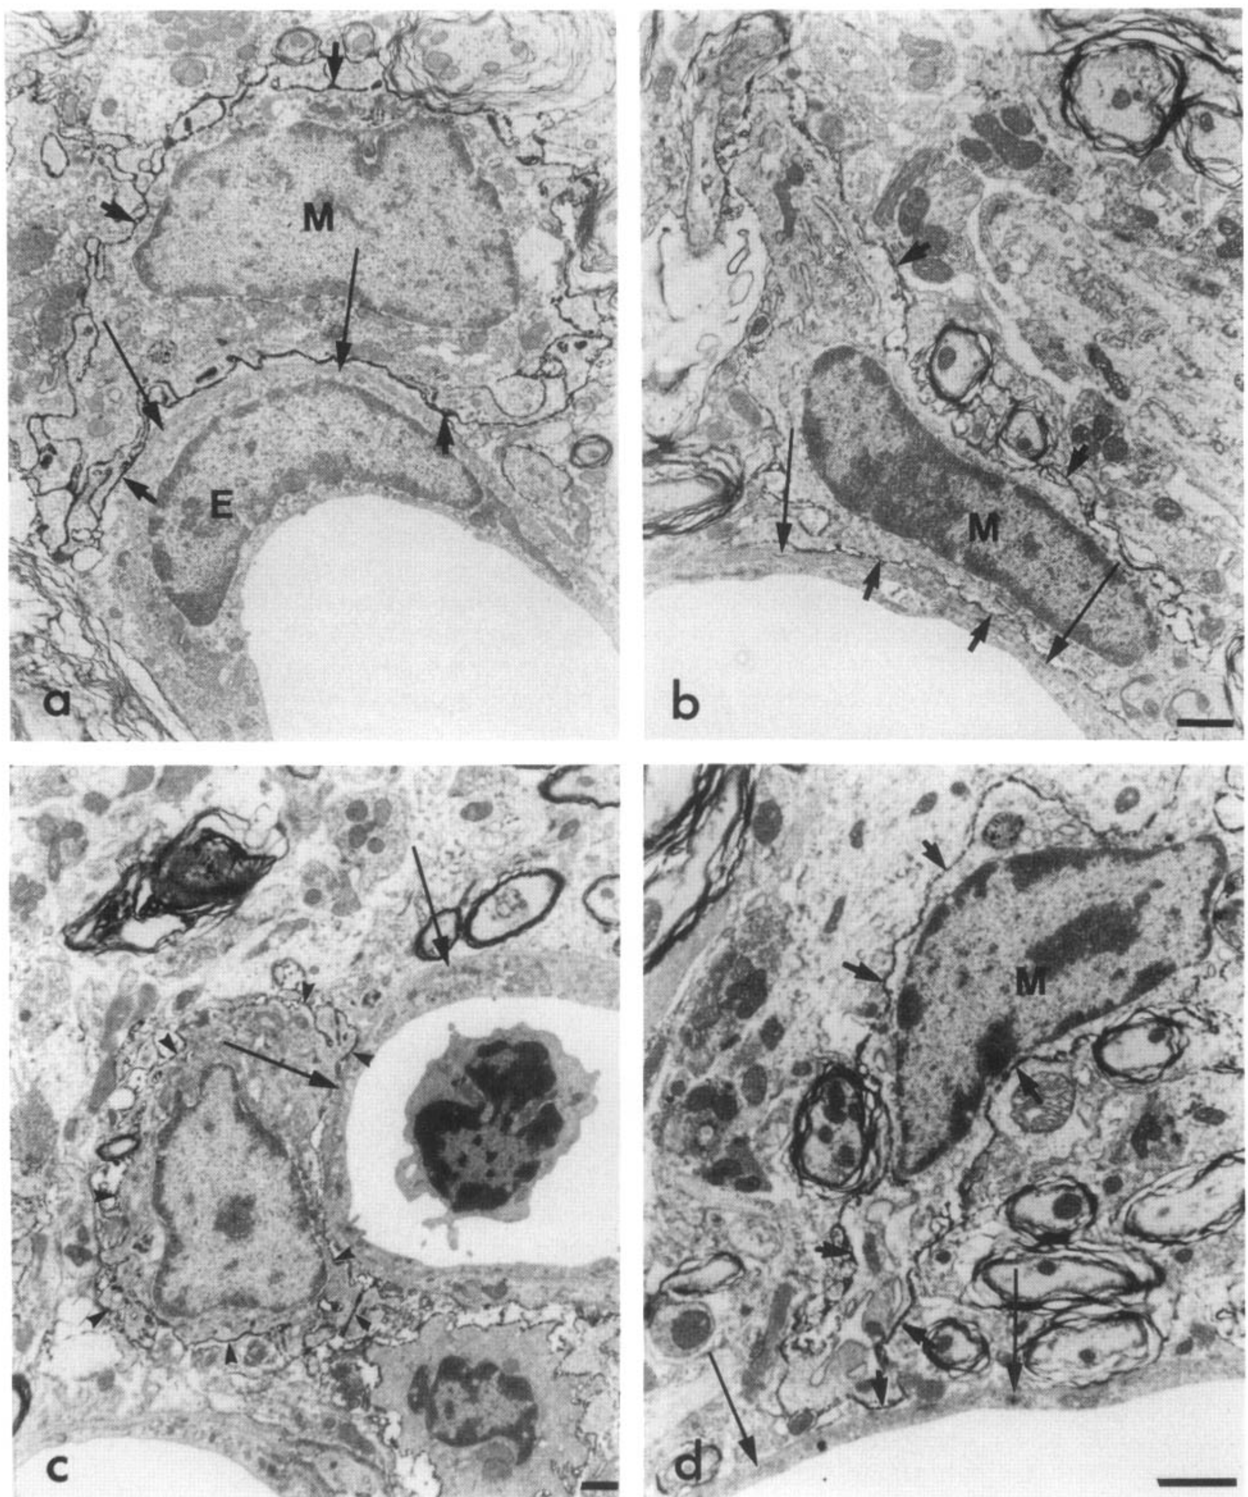

FIG. 59-8. Ultrastructure of perivascular microglia in experimental autoimmune encephalomyelitis (EAE) (*A* and *C*) and autoimmune neuritis (EAN) (*B* and *D;* 7 days after T cell transfer). (*A, B*): OX-6 immunoreactivity (indicating the presence of MHC class II molecules). (*C, D*) MUC 102 immunoreactivity. The arrowheads indicate the sites of the reaction product. (**A**) At an early stage of disease development in EAE (i.e., 4 days after T cell transfer), a perivascular microglia expresses high levels of MHC class II molecules on its surface (cf. Figure B). In addition, it extends several cellular processes which extend its surface area. (**B**) In contrast, in EAN a perivascular microglia expresses rather low levels of MHC class II molecules on its surface (cf. Figure A). (**C**) At the peak of clinical disease (i.e., after 7 days) numerous immunoreactive perivascular microglia and/or invading macrophages (due to impaired blood-brain barrier function) are found in the vicinity of blood vessels. (**D**) An immunostained perivascular microglia is directly incorporated within the perivascular glia limitans. Scale bars = 1 μm. [Figure A: from Gehrmann et al. (1993a), Figures B and D from Gehrmann et al. (1992d), with permission.]

nervous system myelin sheath leads to a pure peripheral nervous system autoimmune disease (Linington et al., 1984). Related to this autoimmune peripheral nervous system disease, a pronounced microglial reaction occurs within the spinal cord at sites that are topographically related to the main areas of peripheral nervous system inflammation (Gehrmann et al., 1992d, 1993a). This microglial response is most conspicuous in the ventral and dorsal gray matter of the lumbar, thoracic and cervical spinal cord. However, it is more pronounced in the lumbar and thoracic spinal cord than in the cervical spinal cord, since peripheral nervous system damage is more severe in the sciatic nerve and the lumbosacral fibers than in the brachial nerve and the cervical nerve roots. Interestingly, at least in the model of passive transfer EAN, this microglial reaction occurs very rapidly, preceding even to some extent the pathological changes in the peripheral nerve, such as inflammation and edema formation. Microglial activation in this process becomes apparent by proliferation, immunophenotypical changes, most conspicuously an increased expression of MHC class II molecules, morphological changes, and the release of cytokines such as TGFβ 1 (Kiefer et al., 1993). Similar to the situation after peripheral nerve transection, activated microglia are found to surround motoneurones in the ventral gray matter. Ultrastructurally, these perineuronal microglia are found to displace afferent synaptic terminals from the neuronal surface (Figure 59-9). In addition to the spinal cord, a microglial reaction also takes place in remote projection areas within the lower brainstem. These areas include the nucleus gracilis (the projection field of the lumbar primary afferent sensory fibres) and the nucleus cuneatus (the projection field of the cervical fibers). This microglial reaction is strictly confined to the terminal projection fields themselves and is not seen in the neighboring tissue. It is correlated to some extent with the presence of degenerating axonal and synaptic terminals, which are then gradually removed by phagocytic microglia. The rapid activation of microglia in EAN at sites remote from the primary peripheral nervous system lesion suggests that rapid remote signaling might occur in autoimmune inflammation.

Neurotoxin Lesions

Direct injection of neurotoxins into the brain results in neuronal injury and, furthermore, induces a vigorous inflammatory reaction. Unlike remote brain lesions, such as the facial nerve axotomy paradigm, these toxic lesions massively disrupt the blood-brain barrier, thus allowing the influx of hematogenous cells into the lesioned area. Intracerebral injection of kainate or ibotenate leads to a massive macrophage/microglial reaction at the site of injection while in sham-operated controls (given an intracerebral saline injection) only a reaction along the needle tract is found similar to that observed following a stab wound (Coffey et al., 1990; Andersson et al., 1991; Finsen et al., 1993). Within the lesioned area a high percentage of these reactive cells appears to be blood-derived based on three observations: (1) the blood-brain barrier is massively impaired; (2) the reactive cells share many morphological and immunophenotypical features with peripheral monocytes/macrophages and (3) systemic irradiation prior to the injury diminishes the response which is in line with the assumption that blood-derived monocytes are recruited in large numbers from the blood into the lesioned area (Coffey et al., 1990). Excitotoxic amino acids have been particularly implicated in the pathogenesis of neurological disorders. While commonly used excitotoxic amino acids such as kainate and ibotenate lead to rather nonselective forms of neuronal injury, injection of quinolinic acid into the rat striatum leads to a selective necrosis of GABAergic neurons. In addition to a strong macrophage/microglial reaction in the injured striatum itself, microglial activation occurs in a temporarilly and spatially organized pattern also in striatal projection areas such as the globus pallidus and the substantia nigra (Toepper et al., 1993). Moreover, a microglial response takes place in areas (e.g., the ventrolateral thalamus) that are only indirectly connected to the lesioned striatum. While anterograde degeneration of striatal projection neurons most likely causes the microglial reaction in first-order projection areas, other mechanisms, possibly neuronal hyperexcitation following removal of inhibitory striatal input, could be responsible for the microglial response in remote, only indirectly linked projection areas.

Experimental Gliomas

Microglia exhibit a pronounced cytotoxicity toward tumor cells *in vitro* (Frei et al., 1987). Macrophage/microglial reactions occur in and around human brain tumors as originally described by Penfield (1924). Implantation of rat glioma cell lines, such as the RG-2 glioma cell line, into the cerebrum offer an experimental approach to study the microglial response to brain tumors (Morioka et al., 1992). Depending to some extent on the number of injected cells and their growth kinetics, massive brain tumors

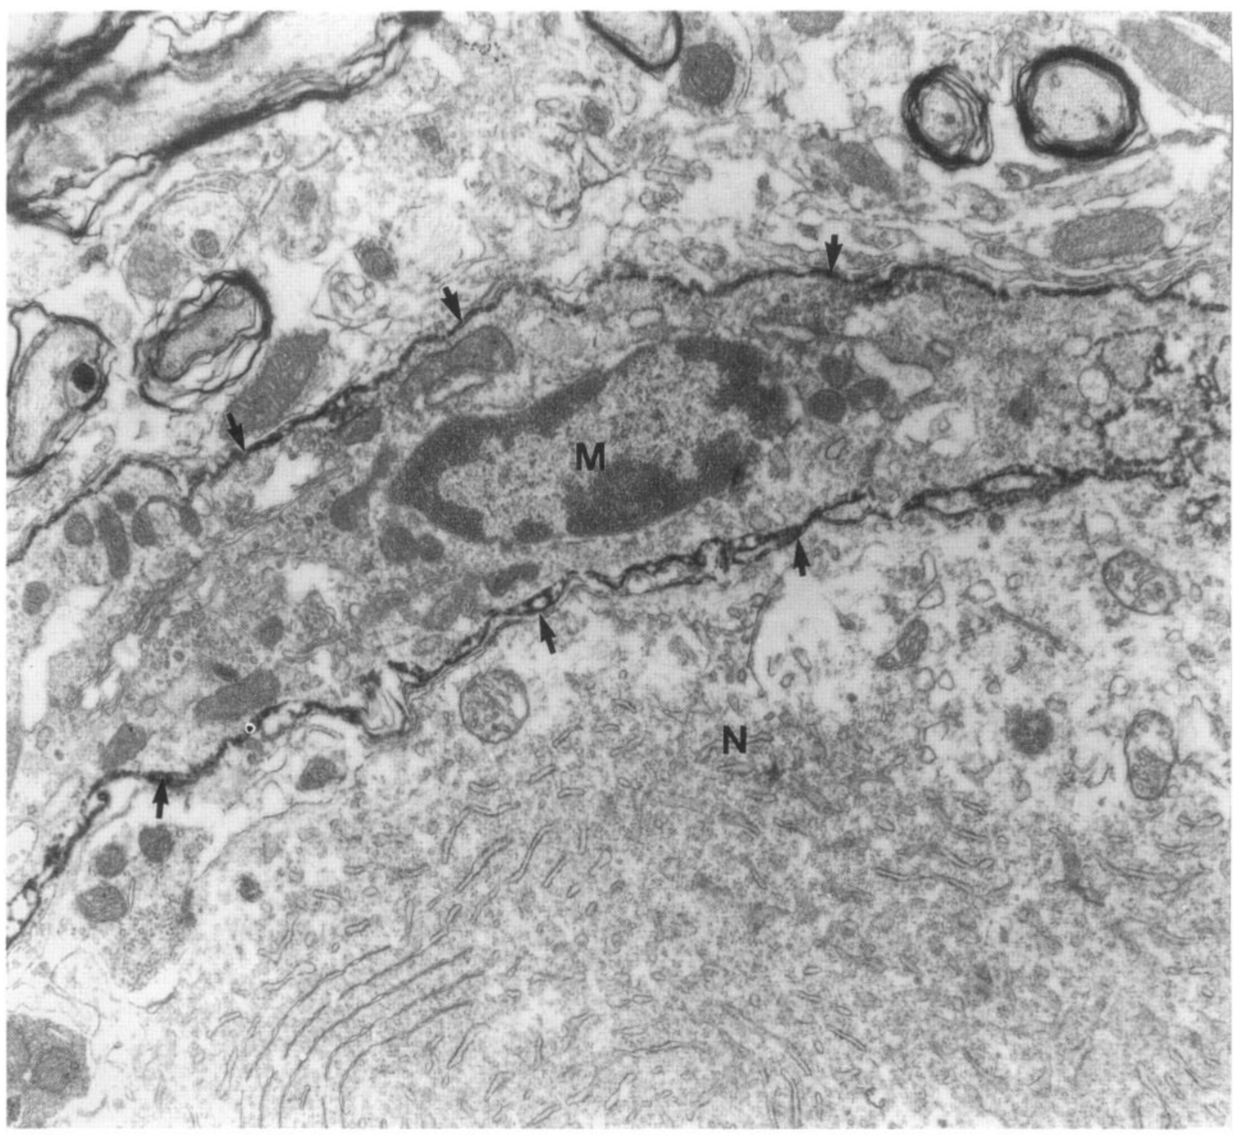

FIG. 59-9. Ultrastructure of a perineuronal microglia in experimental autoimmune neuritis. MUC 102 immunoelectron microscopy (*arrowheads* indicate the sites of the reaction product). Microglia is found in the ultimate vicinity of a motoneuron surface in the ventral gray matter of the lumbar spinal cord 7 days after T cell transfer. Scale bars = 1 μm. [From Gehrmann et al. (1992d), with permission.]

develop often with central necrosis and bleeding. The tumor mass is surrounded by a dense band of reactive cells, which sometimes extends into the contralateral hemisphere via the corpus callosum. From the center to the periphery of the tumor a gradient of reactive cells occurs. Within the center most cells morphologically and immunophenotypically resemble blood-derived macrophages, while toward the periphery the percentage of these cells diminishes in favor of intrinsic microglia-derived brain macrophages (Morioka et al., 1992). Although the tumor is thus heavily infiltrated by potentially cytotoxic cells, there is hardly any evidence for a pronounced *in vivo* tumor cytotoxicity of macrophages/microglia. Whether this occurs as a result of a suppressive activity of the tumor cells on microglia or as a result of impaired function of microglia, is one of the key questions in understanding their contribution to tumor immunology.

Transplantation

Interest in transplantation immunology has increased due to experimental clinical trials with intracerebral grafting of fetal human dopaminergic

brain tissue to patients with Parkinson's disease. Intracerebral rejection of xenogenic grafts is impaired in the brain compared to grafts placed at an extracerebral site, an observation that has supported the view of the brain as an immunologically privileged site (Medawar, 1948). Nevertheless, histoincompatible xenogenic central nervous system grafts are prone to undergo rejection (Finsen et al., 1991). In contrast, graft rejection is less pronounced and occurs with a delay in allogenic transplants. Due to their pronounced immunological properties, microglia seem to be particularly involved in graft rejection and phagocytosis. Studies on neural mouse xenografts into adult rat recipient brains have demonstrated that within 3 weeks following transplantation the graft gets infiltrated with leukocytes, T lymphocytes, and, most strikingly, macrophages. After 5 weeks only a heavily infiltrated residual graft remains (Finsen et al., 1991). Due to impaired blood-brain barrier function (as evidenced by massive leakage of serum proteins into the graft) the majority of the latter cells is probably blood-derived. In the host brain surrounding the graft resident microglia become activated, and exhibit strikingly increased MHC class I and class II antigen expression. In contrast, astrocytes express little class I immunoreactivity, and no class II. They rather respond by increased glial fibrillary acidic protein immunoreactivity (Finsen et al., 1991) and do not phagocytose except for terminals (Raisman and Field, 1990). Host macrophages and activated host as well as donor microglia might act as immunostimulatory cells on CD4-positive T-helper cells. These CD4-positive T cells are essential for the rejection of central nervous system grafts as shown by lymphocyte depletion studies. They most probably become stimulated by host and/or donor class II-positive macrophages/microglia. In contrast, the increased class I expression on donor glial cells (including microglia and astrocytes) makes these cells susceptible to cell lysis by host-derived CD8-positive T-cytotoxic cells. Interference with this crucial macrophage/microglial response might thus lead to improved graft survival in the brain.

Viral Infections

Microglia may respond to viral infections in two principal ways: they either become activated but not primarily infected, or they are the primary targets of a virus. The former mechanism takes place in the case of herpes simplex virus (HSV) infection, whereas a microglial viral tropism has been observed both experimentally and clinically in retroviral infections. Infection of rats with HSV type I by corneal scarification leads to a pronounced neuronal infection first via cranial nerves, mainly the trigeminal nerve (Weinstein et al., 1990). One week postinoculation (i.e., at the onset of severe clinical disease) the infection has spread to neurons throughout the brain, including the entire brainstem, thalamus, hypothalamus, cerebellum, and cortical layers 1 to 3. At the sites of infection the tissue is heavily infiltrated with granulocytes, T lymphocytes, and monocytes. In addition, microglia become activated as indicated mainly by dramatically increased MHC class I and II expression. While this microglial reaction is initially confined to the primary sites of infection, at the peak of infection (i.e., by days 8 to 10) activated microglia are detectable throughout the entire brain, including areas that are apparently free of obvious infection (Weinstein et al., 1990). In HSV-1 infection, a generalized microglial activation thus occurs, and activated class II-positive microglia may well serve to present viral antigen to CD4-positive T lymphocytes thereby augmenting the immune attack to the brain.

In contrast, murine retroviruses, such as the recombinant wild mouse ectotropic retrovirus (FrCasE), show a primary microglial tropism with both resident microglia and perivascular cells becoming heavily infected (Lynch et al., 1991). Interestingly, cytopathological changes occur in neurons adjacent to infected microglia rather than in areas with a primary neuronal infection. This observation points to the potentially cytotoxic capacity of infected microglia and show some similarities to observations in HIV encephalitis.

In HIV encephalitis, microglia/macrophages are the primary viral targets (for review see Budka, 1991). *In vitro,* microglia/macrophages rather than any other central nervous system cell type can be easily infected by the virus. *In situ,* a histopathological hallmark of HIV encephalitis is the presence of multinucleated giant cells, which contain large numbers of viral RNA copies per cell (Petito et al., 1986). These cells are thought to be microglia/macrophage-derived and most probably result from the local fusing capacity of HIV. Several pathways could exist for HIV infection within the central nervous system. Virus-infected monocytes/macrophages could enter the brain as "trojan horses" and subsequently spread the infection to resident microglia. The precise entry route of these infected cells is still unclear. However, perivascular cells could be particularly involved, since they are constantly repopulated at a high percentage (30%) by bone marrow cells in the adult central nervous system (Hickey et al., 1992). Bone marrow-derived cells, once infected, could thus enter the brain possibly via a natural homing mechanism.

Alternatively, microglia could become directly infected during the viremia phase. In view of their pronounced cytotoxic potential and the cytopathological changes seen in HIV encephalitis, virus-infected microglia could mediate neuronal injury in AIDS (for review see Lipton, 1992 and Chapter 44, this issue).

RESIDENT MACROPHAGES OF THE PERIPHERAL NERVOUS SYSTEM AND THEIR RESPONSE TO INJURY

Resident macrophages form a prominent, but little recognized component of the peripheral nervous system. They comprise between 1 and 4% of the total endoneurial cell population in the normal peripheral nerve (Oldfors, 1980). These resident peripheral nervous system macrophages have a ramified morphology with processes oriented parallel to the long axis of nerve fibers similar to that of resident microglia in the central nervous system white matter. They show immunophenotypically similarities to central nervous system microglia but also certain differences (Monaco et al., 1992).

Following peripheral nerve injury monocytes/macrophages participate in the phagocytosis of the myelin sheath for example during Wallerian degeneration (Monaco et al., 1992). The involvement of resident peripheral nervous system macrophages in Wallerian degeneration is still a matter of debate. Whereas studies in the C57BL/Ola mouse mutant by Perry et al. (1985) purport to show a major role of hematogenous macrophages (Lunn et al., 1989), there is evidence that resident macrophages could also be involved. *In vitro,* marked myelin phagocytosis occurs, for example, also in nerves without added monocytes (Hann-Bonnekoh et al., 1989), suggesting that resident peripheral nervous system macrophages can be a relevant source of mononuclear phagocytes under certain conditions. The presence of activated macrophages in the injured peripheral nerve is functionally important. Macrophages induce, for example, the synthesis of endoneurial nerve growth factor by secreting interleukin-1 (Lindholm et al., 1987) and could thus be instrumental for regulating peripheral nervous system regeneration.

In addition, activated macrophages, whether derived from the blood or resident in the peripheral nerve, play an important role during nerve inflammation such as in EAN. Macrophages, but not Schwann cells, express MHC class II antigens *in vivo* during EAN (Schmidt et al., 1991). Based on this in vivo demonstration, resident, MHC class II-positive macrophages could qualify as the main intrinsic antigen-presenting cells during EAN. In addition, activated macrophages could cause tissue damage in such immune-mediated peripheral nervous system disorders by elaborating an array of potentially harmful molecules (for review see: Hartung et al., 1992). In summary, the peripheral nervous system is provided with a population of resident macrophages that show certain morphological, functional and immunophenotypical similarities with central nervous system microglia.

FUNCTIONAL REPERTOIRE OF ACTIVATED MICROGLIA

In vivo, a characteristic property of microglia is their swift activation following injury to the brain and their capacity for site-directed phagocytosis. The potentially cytotoxic action of microglia could thus contribute to tissue damage and in turn interference with microglial cytotoxicity might ameleriote the extent of tissue insult. There are two principal ways by which activated microglia can act as cytotoxic cells. First, they can act as phagocytes which involves direct cell-to-cell contact. Second, they are capable of releasing several potentially cytotoxic substances. A summary of the main secretory products of microglia is given in Table 59-1. Cultured microglia release high amounts of hydrogen peroxide (Colton and Gilbert, 1987) leading to neuronal cell death in neuron-microglial cocultures (Thery et al., 1990). As evaluated by flow cytometry they are characterized by a high spontaneous respiratory burst activity, which is even higher than that of control peripheral macrophages, such as thioglycolate-elicited peritoneal macrophages (Banati et al., 1991). Other cytotoxic products of microglia are reactive nitrogen intermediates. Microglia produce high amounts of NO, particularly when stimulated with interferon-gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α). In addition, microglia release proteinases such as cathepsin B/L and the urokinase-type plasminogen activator (for review see Banati et al., 1993b). This proteolytic activity might also be

involved in tissue remodeling during repair as well as in the cleavage of certain precursor peptides.

Cytokines, such as interleukin-1 (IL-1) and TNF-α, also appear to play a role in microglial cytotoxicity. IL-1 inhibits rat oligodendrocytes *in vitro* (Merrill, 1992). TNF exerts a cytotoxic effect on myelin-forming cells *in vitro*. Interestingly, the lytic action of microglia upon oligodendrocytes can be inhibited by administration of TGF-β1 (Merrill and Zimmermann, 1992), a cytokine, which has in turn been localized in activated microglia themselves *in vivo*. Although there is broad evidence from *in vitro* experiments for a role of cytokines in microglial cytotoxicity, the cytokines relevant for the *in vivo* situation still remain to be identified.

Finally, microglia produce large amounts of glutamate and to some extent also aspartate *in vitro* (Piani et al., 1991). The release of excitatory amino acids points to a crucial role for microglia in NMDA receptor-mediated neuronal injury, which could be particularly important in ischemia.

Several lines of evidence support a key role of microglia during immunopathologies: (1) they are potentially phagocytic cells (Streit and Kreutzberg, 1988; Giulian et al., 1989; Gehrmann et al., 1991a), (2) related to this they have a pronounced cytotoxic potential (Colton and Gilbert, 1987; Thery et al., 1990; Banati et al., 1993b), (3) upon activation they rapidly upregulate the expression of several immunomolecules, such as MHC molecules, the CD4 antigen, and adhesion molecules (for review see Streit et al., 1988), (4) they can effectively present antigen in the molecular context of MHC class II expression to CD4-positive T lymphocytes (Frei et al., 1987; Matsumoto et al., 1992), (5) in the context of MHC class I expression they may become targets of cytotoxic CD8-positive T lymphocytes, and (6) they secrete as well as respond to several cytokines (Frei et al., 1987; Giulian and Ingeman, 1988; Merrill, 1992). *In vitro,* microglia are capable of presenting foreign antigen to CD4-positive T cells in the range of the antigen presenting capacity of professional antigen-presenting cells, such as thymocytes (Frei et al., 1987; Matsumoto et al., 1992). This antigen-presenting function is already maximal under basal, nonstimulated culture conditions and thus surpasses that of astrocytes, which usually have to be primed by IFN-γ to act as antigen-presenting cells (Matsumoto et al., 1992). In addition, rat microglia and, more conspicuously, human microglia show a considerable constitutive expression of MHC class II antigens *in vivo*. Interestingly, in the rat this occurs mainly at central nervous system locations such as lumbar spinal cord, which are primary targets for inflammation. In response to intrathecal application of proinflammatory cytokines, IFN-γ and TNF-α, microglia rather than any other cell type in the central nervous system show a dramatically increased MHC class II expression (Vass and Lassmann, 1990). All these properties make the microglia an important immuneffector cell in the brain.

POSSIBLE SIGNALS FOR MICROGLIAL PROLIFERATION AND ACTIVATION *IN VIVO*

While microglial proliferation and activation are common phenomena in the injured nervous system, little is known about how these processes are regulated *in vivo*. Cytokines appear to be involved in these mechanisms. Colony-stimulating factors (CSFs) are strong mitogens for microglia *in vitro* and furthermore influence their morphological and functional differentiation (Giulian and Ingleman, 1988; Hao et al., 1990, Suzumura et al., 1990). This group of factors consists of three main members: multi-CSF (also known as IL-3), granulocyte macrophage CSF (GM-CSF) and macrophage CSF (M-CSF) (also known in the mouse as CSF-1). While the role of multi-CSF or IL-3 is still debated *in vitro* and *in vivo,* GM-CSF and M-CSF clearly enhance microglial proliferation *in vitro*. These factors act through specific receptors on the microglial surface. The MCSF receptor is a single-chain tyrosine kinase related to the platelet-derived growth factor and the stem cell factor receptor (c-kit), whereas the GM-CSF receptor consists of a heterodimer belonging to the family of hematopoetic growth factor receptors. Following injury activated microglia upregulate within 24 hours the expression of both the M-CSF and the GM-CSF receptor (Raivich et al., 1991a). The *in vivo* sources of the respective ligands, M-CSF and GM-CSF, still remain open. Based on *in vitro* observations, activated microglia as well as reactive astrocytes may be potential sources for these microglial mitogens. An *in vivo* role of CSFs for microglial proliferation is supported by recent experiments by Fedoroff and colleagues and Raivich and colleagues in the opi mouse. Opi mice have a frameshift mutation in the M-CSF gene and, most likely due to the absence of M-CSF, facial nerve axotomy does not lead to microglial proliferation (Raivich et al., 1994).

Studies in experimental neuropathology show that the microglia rather than any other cell type in the brain responds to injury. Microglial activation may even precede pathological changes or occur in the absence of obvious neuropathic changes. Thus microglia appear to respond rapidly to even subtle changes in their microenvironment. Microglia dis-

play a unique potassium channel pattern *in vitro* (Kettenmann et al., 1990), which may make them more sensitive to changes in extracellular potassium than any other cell type in the brain. In view of this channel pattern of microglia, it has been postulated that microglia could be extremely susceptible to neuronal depolarization and associated changes in extracellular potassium. In the model of cortical spreading depression (CSD) recurrent cortical depolarizations can be elicited by the transient, extradural application of high potassium. A microglial reaction with an immunocytochemical peak 24 hours after the end of CSD occurs in the entire cortex ipsilateral to the side of CSD induction but not in deeper brain areas (Gehrmann et al., 1993b). This microglial reaction occurs in the absence of neuropathological damage except for the direct site of potassium application. Although CSD induces several metabolic changes other than increased potassium fluxes across membranes, for example, release of glutamate, hypoperfusion, increased glucose consumption, the microglial reaction after CSD provides further evidence that potassium might be involved in regulating microglial activation *in vivo*.

In addition, neurotransmitters may act as signaling substances on microglia. Most information on this topic comes from *in vitro* studies, mostly electrophysiological measurements. While classical neurotransmitters such as GABA or glutamate, which act on astrocytes or oligodendrocytes have no apparent effect on microglia, acetylcholine and purines might be involved. Carbachol, a muscarine acetylcholine agonist, leads to increased calcium fluxes in cultured microglia. Adenosine triphospate (ATP) a P2-purinoreceptor agonist changes the electrophysiological properties of microglia by promoting depolarization (Kettenmann et al., 1993). Since ATP can be released as a cotransmitter (e.g., with norepinephrine or acetylcholine) and is furthermore released by several other cell types during tissue injury, ATP could be involved in microglial activation.

CONCLUSIONS

In summary, microglia form a network of resident central nervous system immuneffector cells. Microglial activation occurs after injury or changes in the microenvironment, often either before or without detectible changes in other cell types. The mechanisms by which microglial activation and proliferation are regulated *in vivo*, however, still is obscure. More insight into how these processes are regulated *in vivo* might provide a better understanding of how immune reactions in the central nervous system could be manipulated.

60 Glial cells and axonal regeneration in the central nervous system

CLAUDIA A. O. STUERMER

Unlike neurons of amniotic vertebrates, such as mammals, birds, and reptiles, those in the central nervous system of fish and amphibians are capable of spontaneously regenerating their axons (for review see Gaze, 1970). In fish, this applies to several central nervous system fiber tracts and includes among others the visual pathway and descending tracts of the spinal cord (Bunt and Fill-Moebs, 1984; Wanner and Stuermer, 1992; Sharma et al., 1993). Yet with regard to axon-glial cell interactions, the retinal projection to the midbrain tectum—and hence regeneration of retinal ganglion cell axons through the optic nerve and tract up into the tectum—has been more closely analyzed than other central nervous system tracts of the fish. The axonal response to injury in the amphibian visual system has also been studied extensively; a substantial proportion of retinal ganglion cells (between 30 and 70%) in this system regenerate their axons (for review see Stelzner et al., 1986). However, since the contribution of amphibian central nervous system glia to the success or failure of axonal regeneration remains elusive, this chapter is predominantly concerned with the interplay of regenerating retinal ganglion cell axons and glial cells in the fish visual pathway.

Preceding chapters have discussed the reasons for the failure of axonal regeneration in the mammalian central nervous system, whose oligodendrocytes and myelin carry axon growth-inhibiting molecules on their surface (Caroni and Schwab, 1988a; Schwab and Caroni, 1988) and where astrocytes forming a so-called glial scar acquire nonpermissive properties (for review see Bovolenta et al., 1991). We have learned, however, that in the rat, a few central nervous system axons do regenerate successfully under certain circumstances. *In vivo*, some previously injured axons regrow when the oligodendrocyte-associated axon growth inhibitor is neutralized by specific antibodies (Schnell and Schwab, 1990), when oligodendrocytes are absent or sparse (Savio and Schwab, 1990; Berry et al., 1992) or when the optic nerve is surgically replaced by a peripheral nerve graft with living Schwann cells (Benfey and Aguayo, 1981; review: Bray et al., 1992). *In vitro*, segments from the adult rat retina will extend axons when removed from their normal optic nerve glia environment, as for instance, when the retinal segments are explanted onto a substrate consisting of Schwann cells or immature astrocytes (Bähr and Bunge, 1989, 1990). The number of rat retinal ganglion cells that do regenerate their axons *in vivo* or *in vitro* is, however, small and does not exceed more than 5% of the total number of retinal ganglion cells (Villégas-Pérez et al., 1988).

In contrast to the rat, retinal ganglion cell axonal regeneration in fish occurs spontaneously and does not require surgical aids, such as grafts, or the neutralization of possible inhibitors. Nor are there astrocytic glial scars in fish. Furthermore, in fish all or nearly all retinal ganglion cells, not just a fraction, are capable of regenerating their axons (Meyer et al., 1985). Finally, axonal regeneration in fish leads to the restoration of a retinotopic map in the visual target center, the optic tectum, and to recovery of normal vision and visuomotor behavior (for review see Gaze, 1970).

While recovery of function after optic nerve injury in fish has been known for several decades, studies on the particular role of the glial cells for the success of axonal regeneration were only recently undertaken. Thus far, the characteristics of glial cells that are partners to neurons in the central and peripheral nervous systems are far better analyzed in mammals than in fish. With the knowledge that Schwann cells of the mammalian peripheral nervous system allow and support axonal regeneration and that oligodendrocytes and central nervous system myelin inhibit axonal growth, two questions arose: Does the fish central nervous system contain typical oligodendrocytes? How does the myelin-forming glial cells of the fish central nervous system differ from those in the peripheral nervous system? (Jeserich and Rauen, 1990).

Before turning to the issue of glial cell contribution to axonal regeneration in the fish optic nerve,

the characteristics of myelin and myelin-forming cells of fish central and peripheral nervous systems are briefly summarized.

CENTRAL NERVOUS SYSTEM AND PERIPHERAL NERVOUS SYSTEM MYELIN AND MYELIN-FORMING CELLS IN TELEOSTS

Studies of the phylogeny of myelin proteins have detected similarities, but also some striking differences, in the myelin protein composition of fish and mammals (Waehneldt and Jeserich, 1984; Jeserich and Waehneldt, 1986a, 1986b, 1992). Fish peripheral nervous system and central nervous system myelin contains, as does myelin in mammals, substantial amounts of myelin basic protein (MBP). However, the unglycosylated hydrophobic proteolipid protein (PLP) of the mammalian central nervous system myelin appears to be absent from fish central nervous system myelin, or at least not expressed to such an extent as in mammals. Instead of PLP the fish central nervous system myelin exhibits two glycosylated, *hydrophobic proteins*, IP1 and IP2 with molecular weights of 23 kD and 27 kD, respectively, which are recognized by the antibody 6D2. These two proteins are not found in mammalian central nervous system myelin. Interestingly, the IP1 and IP2 proteins are recognized by antibodies against P0, the structural myelin protein of the mammalian peripheral nerve system. P0 is defined as a cell adhesion molecule of the immunglobulin superfamily (Sakamoto et al., 1987; Williams and Barcley, 1988) and appears to function in the peripheral nervous system as PLP does in the central nervous system. The N-terminal amino acid sequence of IP1 and IP2 has similarities to that of mammalian P0 (Schliess and Stoffel, 1991; Jeserich and Waehneldt, 1992), but further molecular characterizations of IP1 and IP2 have not been carried out.

6D2 immunoreactivity is also associated with fish peripheral nervous system nerves. Still, this does not imply that the fish central nervous system myelin-forming cells are identical to myelin-forming cells of the peripheral nervous system or that they perhaps even represent Schwann cells. Earlier electron microscopic examinations of axonal regeneration in the goldfish oculomotor nerve demonstrated clearly that peripheral nervous system axons are associated with and remyelinated by cells with typical characteristics of Schwann cells (Scherer and Easter, 1984). Myelin-forming cells in the fish peripheral nervous system show a one to one relationship with myelinated axonal segments, as is typical for Schwann cells of the mammalian peripheral nervous system (Scherer and Easter, 1984). Furthermore, their mammalian peripheral nervous system counterparts, like these fish Schwann cells, produce a basal lamina that is missing from oligodendrocytes of both fish and mammals. Moreover, recent data have demonstrated immunocytochemically the expression of nerve growth factor (NGF) receptors by fish peripheral nervous system-derived Schwann cells in culture (Bastmeyer and Stuermer, 1992). Much as in mammals, anti-NGF receptor immunoreactivity is not found on the central nervous system-derived glia cells of fish.

There is another protein in fish, the 36k protein, that is specific for fish central nervous system myelin and absent from the peripheral nervous system (Jeserich and Rauen, 1990), substantiating a clear distinction between central nervous system and peripheral nervous system myelin and myelin-forming cells in fish. The central nervous system/peripheral nervous system distinction was further supported by electron microscopic examinations. These electron microscopic studies have revealed a close structural similarity between myelin-forming cells in the fish central nervous system with mammalian oligodendrocytes, in that the cells extended myelinating processes to nerve fibers in their vicinity (Jeserich and Waehnelt, 1986b). This classifies them as oligodendrocytes.

It is clear for mammals and birds that Schwann cells and oligodendrocytes derive from different lineages. The former are neural crest derivatives and oligodendrocytes arise from central nervous system subventricular zones. Glial precursor cells giving rise to oligodendrocytes have been characterized by a ganglioside epitope defined by the antibody A2B5 (Raff et al., 1983).

Jeserich and Stratmann (1992) isolated central nervous system glial cells from the developing trout brain. In addition to glial fibrillary acidic protein (GFAP)-positive astrocytes, cells with multiple processes morphologically resembling oligodendrocytes also developed in these cultures (for review see Jeserich et al., 1990). The latter in fact differentiated from bipolar precursor cells, which exhibit the A2B5 epitope (Jeserich and Stratmann, 1992). Oligodendrocytes isolated from trout at various developmental stages express myelin proteins in a chronological sequence. At stage 28, IP2 and galactocerebroside (GalC) are present; at stage 30, 36k is expressed, and at stage 32, IP1. MBP was not detected in glial cells in culture but was found in parallel with IP2 in sections from the developing trout brain (Jeserich and Stratmann, 1992). With time in culture, however, trout oligodendrocytes cease to express GalC, 36k, and IP1, but continue to show IP2. When cultured as precursors, however, the A2B5-positive cells do

not differentiate beyond the level of IP2 expression, which signifies the initial step of oligodendroglial development *in vivo* (Jeserich and Stratmann, 1992).

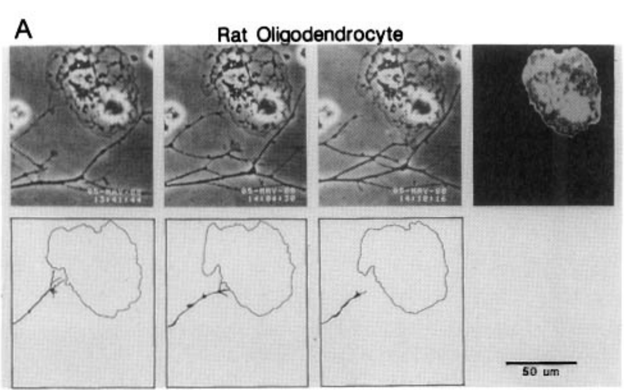
In summary, myelin in fish is formed by typical oligodendrocytes in the central nervous system and by Schwann cells in the peripheral nervous system. However, some of the major central nervous system myelin proteins of fish oligodendrocytes differ from those in mammals. Furthermore, fish oligodendrocytes *in vitro* do not retain or—when plated as precursors—do not spontaneously reach the differentiation stages that they exhibit *in vivo.*

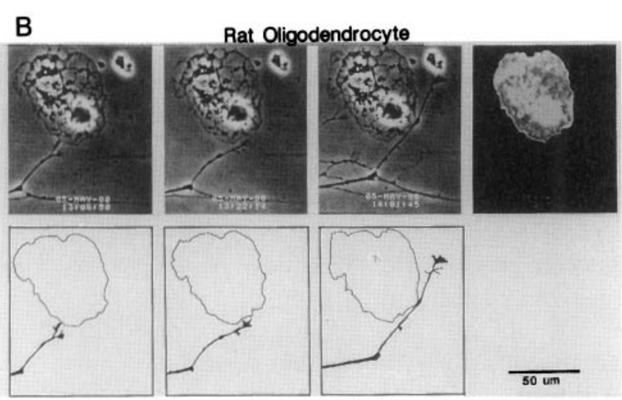
But do oligodendrocytes in the fish central nervous system, particularly in the optic nerve, possess similar growth-inhibiting molecules as mammalian oligodendrocytes? One could argue that successful axonal regeneration would still be possible in the presence of inhibitors if fish retinal axons were able to overcome the inhibitory properties of these glial cells by producing, for instance, substances such as proteases that would inactivate molecules or if fish axons lacked the sensitivity (receptors) for inhibitors. Alternatively, successful regeneration is perhaps to be expected if fish oligodendrocytes and central nervous system myelin do not express such inhibitory molecules.

RESPONSE OF FISH AXONS TO RAT AND FISH CENTRAL NERVOUS SYSTEM MYELIN AND OLIGODENDROCYTES

Whether fish retinal ganglion cell axons are sensitive to the mammalian central nervous system myelin/oligodendrocyte inhibitor was addressed in the first of a series of cross-species coculture assays.

The first assays examined the interaction of regenerating fish retinal axons with mammalian oligodendrocytes. Rat optic nerve oligodendrocytes were cocultured with fish retinal explants (Bastmeyer et al., 1991), and the contact of the growing fish axons with the mammalian glial cells was monitored with time-lapse videomicroscopy. When the fish axons touched the mammalian oligodendrocytes, the growth cones collapsed (Figure 60-1A) and pulled back, or the axons grew around the cells but did not cross them (Figure 60-1B). In the presence of the specific antibody IN1 which neutralizes the mammalian inhibitor (Caroni and Schwab, 1988b), however, the fish axons grew over the mammalian oligodendrocytes (Figure 60-2). These results indicated that regenerating fish retinal axons are indeed sensitive to the mammalian oligodendrocyte/myelin-associated inhibitory proteins. In fact, the fish axons reacted in a manner that was identical to the behavior





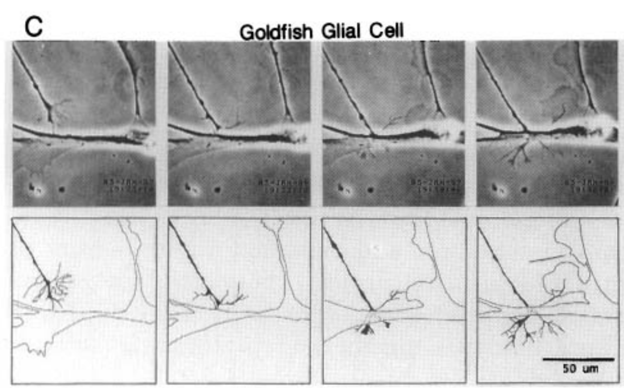


FIG. 60-1. Selected frames from time-lapse video sequences and camera lucida tracings showing (A,B) the encounter of goldfish retinal growth cones with mammalian oligodendrocytes, and (C) a goldfish optic nerve oligodendrocyte *in vitro*. The growth cones either collapse upon contact with a mammalian oligodendrocyte (Figure A) or grow around the cell (Figure B), but they cross fish oligodendrocytes freely (Figure C). The mammalian oligodendrocyte was labeled with the antibody GalC (fluorescence image at *right*).

FIG. 60-2. Contacts of goldfish retinal axons with a highly branched rat oligodendrocyte in the presence of MAB IN-1 observed with time-lapse videomicroscopy. (**A,B,C**) One axon grows over the oligodendrocyte (*arrows*) and crosses several of its processes. Another axon (*arrowheads*) grows along the cell perimeter. (**D**) The oligodendrocyte was identified with GalC (fluorescence image). Time in hours, minutes, and seconds is shown at the lower right of each frame. Scale bar, 20 μm for Figures A–D.

of mammalian axons upon encountering mammalian oligodendrocytes and central nervous system myelin (Fawcett et al., 1989; Bandtlow et al., 1990). The sensitivity of fish retinal ganglion cells to the mammalian inhibitor was confirmed by offering mammalian central nervous system myelin as a substrate for the growth of fish retinal axons. On mammalian central nervous system myelin, fish retinal ganglion cells failed to extend axons (Bastmeyer et al., 1991).

The next step was an evaluation of the reaction of growing axons to oligodendrocytes derived from the fish optic nerve and to fish central nervous system myelin. This required isolating these glial cells and identifying them in culture.

Glial cells were obtained from the regenerating fish optic nerve and tract either by dissociation or by explanting segments of the nerve from which glial cells emigrated. One type of cell morphologically resembled astrocytes and exhibited a high density of anti-GFAP-positive fibrils. These cells never expressed any myelin marker proteins. They divided in culture, but stuck together in typical clusters (Hoppe et al., 1991).

The other glial cell type was typically bipolar in appearance with membraneous veils over its entire surface and could be identified as belonging to the oligodendrocyte lineage. When optic nerves were dissociated and the isolated cells probed with antibodies, some of these cells showed anti-36k and -6D2 immunoreactivity within a few hours after plating. At later times in culture, these glial cells, as well as elongated ones emigrating from nerve explants, divided and, within a few weeks, formed a networklike carpet.

Unlike mammalian oligodendrocytes that differentiate in culture and acquire further markers, such as GalC immunoreactivity, fish optic nerve/tract-derived oligodendrocytes remain GalC-negative. Fish optic nerve/tract oligodendrocytes in early dividing cultures expressed GFAP fibrils, which extended into the elongated processes. However, staining with anti-GFAP was always weaker than with fish astrocytes, and was transient and coexistent with myelin markers IP2 and 04 immunoreactivity. With time in culture, oligodendrocytes lost GFAP and gained in addition to 04 increased 6D2 immunoreactivity (Bastmeyer et al., 1991). They did not show spontaneous 36k immunoreactivity, but acquired this myelin protein when they were cocultured with axons (Bastmeyer et al., 1994). Furthermore, in these cocultures with retinal axons, the optic nerve/tract oligodendrocytes began to enwrap axons, one cell associated with several axons, in a manner characteristic of the onset of myelination (Figure 60-3) (Bastmeyer et al., 1993). Thus, despite their otherwise unusual characteristics, the goldfish optic nerve/tract-derived glial cells are to be considered counterparts of mammalian oligodendrocytes.

When fish retinal growth cones encountered fish oligodendrocytes in a coculture, the axons readily crossed them (Figure 60-1C). This implies the absence of growth inhibitors. But would fish oligodendrocytes produce inhibitors upon further differentiation, as they do *in vivo* but not *in vitro*? If so, the

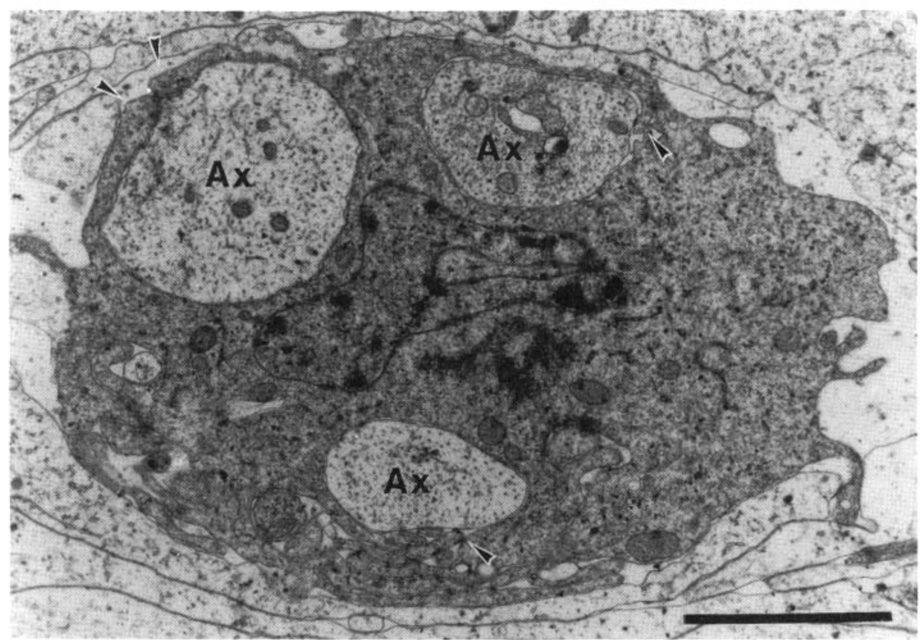

FIG. 60-3. Fish oligodendrocyte ensheathing rat retinal axons. This electron micrograph was taken from a 4-week-old coculture of fish glial cells and rat retinal axons. The dark cytoplasm and the idented nucleus identify the cell as an oligodendrocyte. The cell has totally surrounded the axons (*Ax*) and has formed vermicular processes (three of which are marked by *arrowheads*) around them. The axons are identified by their electronlucent cytoplasm, neurofilaments, microtubules and the absence of ribosomes. Scale bar: 2 μm.

inhibitory influence on axon growth should be found in the optic nerve myelin or central nervous system myelin of adult animals.

When fish retinal explants were grown on a substrate of fish central nervous system myelin, axons extended and were capable of elongating on the myelin substrate. A similar observation was made when rat axons were confronted with fish central nervous system myelin (Vanselow et al., 1990). Even for rat retinal axons, fish central nervous system myelin was a growth-permissive substrate. In the reverse experiment, with rat central nervous system myelin as substrate, outgrowth of axons from fish retinal explants and rat axons failed (Bastmeyer et al., 1991). These results are in accordance with earlier data, which already had indicated the absence of axon growth inhibitors from fish optic nerve myelin. Carbonetto and colleagues (1987) showed that rat dorsal root ganglia (DRG) would extend axons when offered thin cryostat sections of fish optic nerves as a substrate. These neurons, however, would not grow on sections of mammalian central nervous system nerves.

Taken together, the outcome of these experiments is consistent with the notion that fish oligodendrocytes and central nervous system myelin lack the axon growth-inhibiting proteins of mammals, and fish retinal axons, much like axons of higher vertebrates, are sensitive to inhibitors of mammalian central nervous system myelin and oligodendrocytes. In other words, one reason for the success of axonal regeneration in the fish optic nerve could be the absence of inhibitors and thus the growth-permissive properties of the fish oligodendrocytes and the fish central nervous system myelin.

To test whether this conclusion from *in vitro* studies would also apply to the *in vivo* situation, we attempted to identify the elements associated with the regenerating growth cones in the fish optic nerve (Strobel and Stuermer, 1994). The growth cones of the regenerating axons were labeled with horseradish peroxidase from the eye. From ultrathin serial sections, the growth cones and the elements with which they were in intimate contact were reconstructed. Regenerating growth cones were found in direct membrane to membrane association with myelin debris (Strobel and Stuermer, 1994), a situation that would not be encountered in the mammalian central nervous system. They also were in close contact with a type of an oligodendrocyte precursor or a microglial cell based on criteria derived from work on mammalian glial cells and data from fish studies (Dowding et al., 1991). Growth cones were also seen in contact with other cell types of the regenerating optic nerve, indicating that they may not have a strong preference for a specific type of cell. However, these observations support the idea that myelin/oligodendrocyte-associated inhibitory molecules which repel or negatively affect regrowing fish retinal axons may be absent from the goldfish optic nerve *in vivo*.

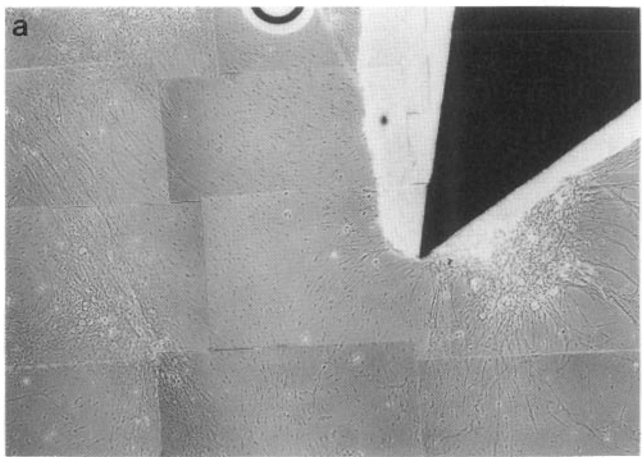
GROWTH OF FISH AND RAT AXONS ON FISH OLIGODENDROCYTES *IN VITRO*

Further experiments extended this conclusion: beyond their lack of inhibition influence, fish optic-

nerve-derived oligodendrocytes are—at least in their differentiation state observed *in vitro*—extremely growth supportive. Evidence fostering this view include, first, that the number of axons emerging from fish retinal explants on a substrate of fish oligodendrocytes was higher (Bastmeyer et al., 1993) than on any other substrate used so far (Vielmetter et al., 1990). Moreover, when retinal explants were placed on untreated plastic coverslips they failed to extend axons. In the presence of fish oligodendrocytes, however, a substantial number of axons emerged from the retinal explant, suggesting that these glial cells indeed promote axonal growth (Bastmeyer et al., 1993; for review see Stuermer et al., 1992). Furthermore, the retinal growth cones appeared to grow preferentially in close contact with the oligodendrocytes, rendering the impression that these glial cells carry surface-associated molecules recognized by the growth cones as favorable substrates for their elongation. Some axons also grew in areas where the oligodendrocytes had been but from which they had migrated away (Stuermer et al., 1992), giving the impression that the glial cells may leave some growth-promoting molecules on the coverslip.

These observations stimulated another cross-species experiment to address the following question. Since the inhibitory proteins of the mammalian oligodendrocytes negatively affected the fish retinal axons, would the growth-supportive properties on the surface of the fish oligodendrocytes exert a positive influence on injured rat retinal axons? Segments from the adult rat retina were explanted onto the network-like carpet of fish oligodendrocytes (Bastmeyer et al., 1993; for review see Stuermer et al., 1992). These cocultures necessitated conditions that were a compromise between the requirements of warm- and cold-blooded vertebrates. Thus, cultures were grown at a temperature of 28°C but without the additional O_2/CO_2 supply commonly used for rat neural tissue. Adult rat retina explants usually fail to regenerate axons under such conditions. Yet in the presence of the fish oligodendrocytes, a large number of axons emerged from the rat retinae (Figure 60-4) and reached lengths of up to 4 to 5 mm. These rat axons grew in close contact with the surfaces of the fish oligodendrocytes and avoided fish oligodendrocyte-free regions. Thus, fish oligodendrocytes *in vitro* apparently possess cell surface-associated molecules that stimulate axonal regeneration. These molecules not only promote axonal regeneration of fish retinae but also of adult rat retinae.

A candidate molecule that may contribute to the growth supportiveness of fish oligodendrocytes *in vitro* was identified by the goldfish-specific monoclonal antibody (MAb) E 587. E 587 is directed against a 200 kD glycoprotein (Vielmetter et al., 1991), related to the class of the L1 family of cell adhesion molecules (Rathjen et al., 1987; Lagenaur and Lemmon, 1989). While usually distributed evenly on the surface of the fish oligodendrocytes, this protein appears to cluster when processes of two cells overlap (Figure 60-5A–C) (Bastmeyer et al., 1993). The E 587 antigen is also found on regenerating fish retinal axons (Vielmetter et al., 1991), an



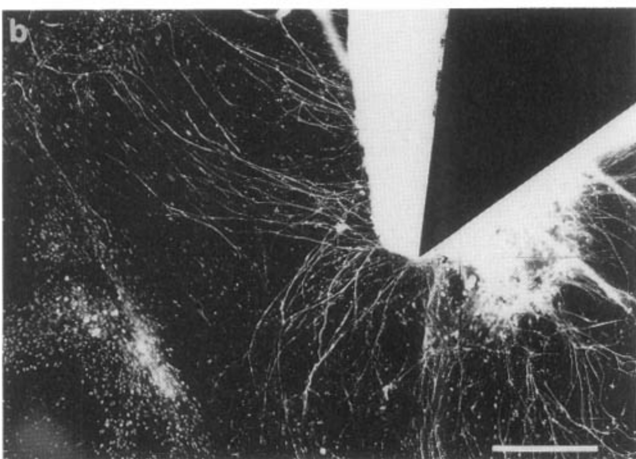


FIG. 60-4. A segment of the retina of an adult rat, explanted onto fish glial cells. Photomicrograph of the coculture, (**A**) in phase contrast, and (**B**) after staining the axons with the antineurofilament antibody SMI 31. (**A**) Rat retinal explant attached to a filter (*black triangle*). *Arrowheads* mark boundaries between purely oligodendrocyte territory and clusters of astrocytes, into which a few oligodendrocytes have penetrated. The *arrows* point to a cell free region. The cells at the lower right are glial cells which have emigrated from the rat retinal explant. (**B**) The rat retinal axons extend along the fish oligodendrocytes and can be seen to follow the elongated orientation of the oligodendrocytes. The rat axons rarely cross regions free of glial cells and only a few grow onto the fish astrocyte cluster. (Unspecific staining of the nuclei of the cells by SMI 31.) Scale bar for both figures, 500 μm.

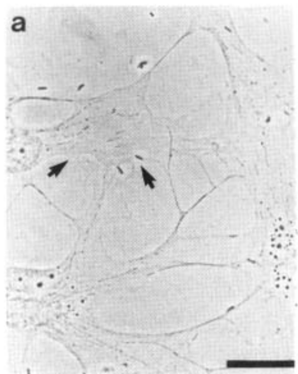

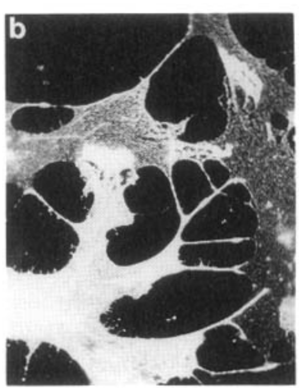

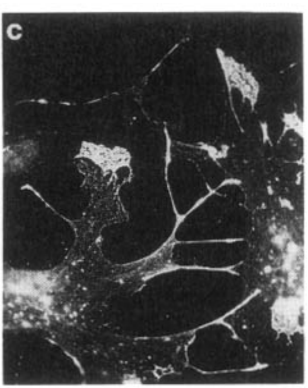

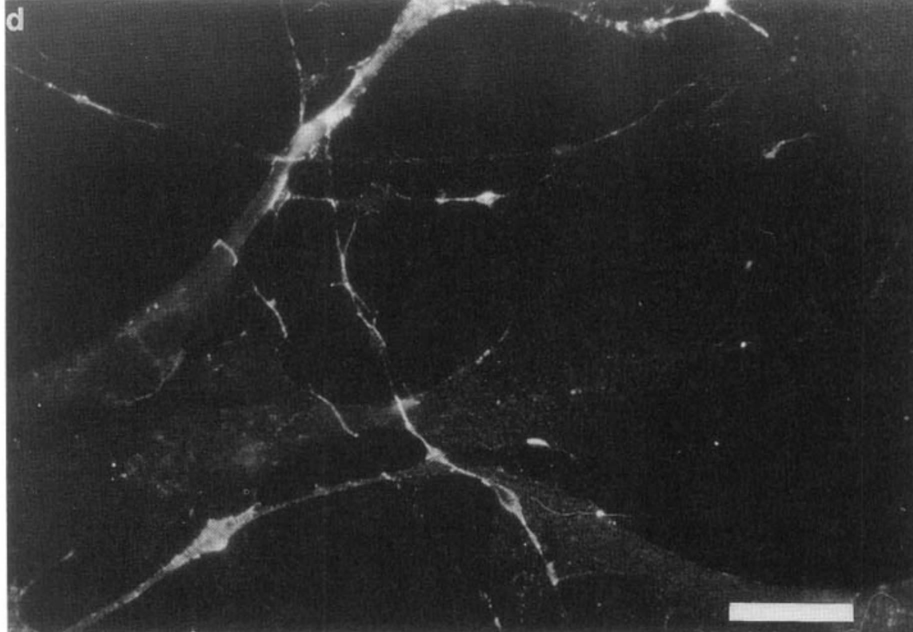

FIG. 60-5. Fish oligodendrocytes in culture. (**A**) Phase contrast. *Arrows* point to overlapping processes of oligodendrocytes. (**B**) Same area showing immunoreactivity to 04, which labels the entire glial cell surface. (C) Same area showing E 587 immunoreactivity, which is predominantly accumulated along areas of contact between two cells. (D) When fish retinal axons grow on the surface of fish oligodendrocytes, the E 587 antigen accumulates at contact sites between the axon and the cell. Where growing on the laminin-coated glass coverslip, the axons exhibit very little MAb E 587 immunoreactivity (*arrows*) but are brightly stained where they grow on the oligodendrocytes (*arrowhead*). Scale bar in Figure A applies to all figures: 20 μm.

interesting aspect that will be considered more closely below. When the regenerating axons grow along the surface of the oligodendrocytes, the area of contact between the axon and the cell again exhibits a striking contact-dependent accumulation of the antigen (Figure 60-5D) (Stuermer et al., 1992). This contact-dependent clustering implies involvement of this protein interaction of the axons and the glial cells. This has recently been confirmed in ongoing experiments using the E 587 antibody to interfere with function (Giordano et al., 1993); Bastmeyer, unpublished results). Whether E 587 antigen contributes to retinal axonal regeneration along oligodendrocytes *in vivo* awaits the outcome of further experiments.

RESPONSE OF THE FISH RETINAL GANGLION CELLS TO OPTIC NERVE SECTION: REEXPRESSION OF GROWTH-ASSOCIATED CELL SURFACE PROTEINS

To regenerate successfully, a neuron whose axon has been cut must reinduce the relevant intracellular mechanisms and synthesize the necessary proteins to support axonal growth. Moreover, the long-range

pathfinding functions that operate during development must be reactivated, as well as the conditions required for the reestablishment of the appropriate connections in the target. At the molecular level, these functions are only beginning to be elucidated. The success of retinal axon regeneration and the restoration of vision in fish implies that the fish ganglion cells and their targets possess the required features.

Earlier studies have demonstrated that fish retinal ganglion cells enlarge and increase their RNA and protein synthesis manifold after optic nerve transection (McQuarrie and Grafstein, 1981). Among the proteins whose quantities are elevated in response to injury, a few were identified, such as the growth-associated protein Gap 43 (for review see Skene, 1991), cytoskeletal proteins, and proteins needed for the addition of new membranes (Perry et al., 1985, 1987; Benowitz et al., 1991).

The extent of this injury-induced reexpression of growth-relevant proteins in the fish retina exceeds that of the rat retinal ganglion cells manifold. Gap 43, for instance, reappears on a limited number of rat ganglion cells and Gap 43-positive retinal ganglion cells correlate numerically with rat retinal ganglion cells, which, under favorable conditions, would regenerate an axon (Doster et al., 1991). However, Gap 43 reappears only on these rat retinal ganglion cells when the optic nerve is severed close to the eye. If a lengthy piece of optic nerve remains connected to the eye (as is the case if the optic nerve crush is made closer to the brain) the injured retinal ganglion cells fail to exhibit Gap 43 (Doster et al., 1991; Skene, 1991). Skene raised the interesting possibility that the presence of oligodendrocytes which express growth inhibitors may supress synthesis of growth-associated proteins such as Gap 43 via a retrograde signal along the axons (Skene, 1989, 1991). Cuts close to the eye and separation from the optic nerve oligodendrocytes releases this suppression and allows renewed protein synthesis—at least in a few "competent" neurons. This view is consistent with the immediate upregulation of protein synthesis in injured retinal ganglion cells of fish and the absence of growth inhibitors from fish optic nerve oligodendrocytes.

Along this line, several recently identified cell surface-associated proteins were found to be reexpressed during fish retinal ganglion cell axonal regeneration. Three of these molecules belong to the class of cell adhesion molecules (E 587 antigen being one of them) and may play a role in axonal pathfinding and target reinnervation (Wehner and Stuermer, 1989; Bastmeyer et al., 1990; Stuermer, 1991b; Vielmetter et al., 1991; Paschke et al., 1992). They were discovered using monoclonal antibodies (MAbs), and defined as growth-associated cell surface proteins, since the MAbs always and only stained axons that were in a state of growth. These included, for instance, all retinal axons in the goldfish embryos, and those newly added in the adult (Stuermer et al., 1992). More mature axons had lost their MAb immunoreactivity but all regenerating retinal axons in the retina, in the optic nerve and tract, and in the retinorecipient layers of the tectum reexpressed these proteins on their surfaces (Wehner and Stuermer, 1989; Bastmeyer et al., 1990; Vielmetter et al., 1991; Paschke et al., 1992). Thus, retinal ganglion cells in fish retain their ability to reexpress growth-associated cell surface proteins —thought to assist axonal pathfinding—throughout adulthood. Reexpression is induced when the axons are severed and then regenerate. Furthermore, the ganglion cells are capable of downregulating the expression of these proteins once appropriate connections with the target have been reformed.

The regulated reexpression of the growth-associated proteins by fish retinal ganglion cells conforms with Skene's hypothesis. Because inhibitors are absent from fish optic nerve oligodendrocytes and myelin there is no suppression of renewed protein synthesis. Indeed, the presence of growth-stimulating molecules on fish glial cells could function as a positive feedback signal for the fish retinal ganglion cells and thus enhance the reexpression of growth-associated proteins and the reextension of severed axons. Experiments for testing this hypothesis are underway and may determine whether such postulated feedback pathways from glial cells to neurons exist.

ASTROCYTES IN THE REGENERATING FISH RETINOTECTAL PATHWAY

A possible role of astrocytes in axonal regeneration in the fish optic nerve/tract and tectum has been proposed (Murray, 1976; Nona et al., 1989; Levine, 1991), but the axon-astrocyte interplay during axonal regeneration is not understood. One reason is that the common marker for astrocytes, GFAP, is not expressed by all presumed astrocytes in the fish visual pathway, nor is it expressed exclusively by astrocytes. Even oligodendrocytes from regenerating optic nerve/tract in early stages of their differentiation contain anti-GFAP positive fibrils (Bastmeyer et al., 1991) and may or may not transiently produce cytokeratins. Fish glial cells exhibit additional filament proteins (Jones et al., 1986; Maggs and Scholes, 1986), one of which has been identified as a cytokeratin (Giordano et al., 1989). It is not known whether cytokera-

tin(s) are contained solely in astrocytes or in both astrocytes and undifferentiated oligodendrocytes.

Moreover, the filament protein expression pattern in fish optic nerve/tract glial cells changes after optic nerve injury and changes again when the axons regenerate and grow toward the tectum (Maggs and Scholes, 1986; Levine, 1989; Levine, 1991; Stafford et al., 1990). As more of these fish glial filament proteins are being characterized on a molecular level, and new probes are being generated, the cell type (and its differentiation stage) that expresses these proteins will probably be determined in the near future.

In optic nerve/tract glial cultures such as those described above, both GFAP-positive astrocytes and oligodendrocytes proliferated, but the astrocytes formed small clusters interspersed among the network of oligodendrocytes (Bastmeyer et al., 1993). As discussed earlier, regenerating axons—whether from fish RGCs or rat RGCs—grew in intimate contact with the surface of the fish oligodendrocytes. Surprisingly, when the axons met the astrocyte clusters they grew around them rather than crossing them (Bastmeyer et al., 1993). Thus, fish axons, as well as those of the rat, preferred the surface of the fish oligodendrocytes over astrocytes for their growth. Whether this unexpected result is solely characteristic of these cultures or also applies to the *in vivo* situation remains to be clarified.

In this respect, it is interesting to note that upon optic nerve crush the crush zone of roughly 500 μm remains free of glia filament-expressing glial cells for weeks (Stafford et al., 1990; Levine, 1991). Elongated GFAP-positive cells on both edges of this zone are oriented parallel to the direction of growth of the axons. With time, similar cells populate the crush zone. Although the identity of these cells and their role in axonal regeneration remains elusive, their presence at least substantiates the earlier findings that there is no such structure as a glial scar in fish.

Hopkins et al. (1985) demonstrated a generally elevated level of laminin immunoreactivity in sections of the regenerating goldfish optic nerve. The identity of the cells that would produce this growth-promoting extracellular matrix molecule is not known. However, this together with the findings that fish central nervous system myelin and oligodendrocytes lack axon growth inhibitors and that fish oligodendrocytes at least in culture, carry an L1-like molecule on their surfaces, support the notion that severed retinal axons and newly formed growth cones in fish find a hospitable rather than hostile environment for their regenerative growth.

CONCLUSION

In contrast to mammals, central nervous system myelin and oligodendrocytes of the fish visual pathway perhaps do not carry axon growth-inhibiting proteins, but are growth-permissive instead. The absence of growth inhibitors is likely to be one of the reasons that fish retinal ganglion cells can so successfully regenerate their axons. In fact, fish oligodendrocytes of differentiation stages that they reach in culture express axon growth-promoting molecules and allow the regrowth along their surface of not only fish axons but also rat retinal ganglion cell axons. Whether fish oligodendrocytes exert a growth-stimulating effect on injured axons *in vivo*, however, needs to be further investigated.

It appears reasonable to assume that the reexpression of sets of growth-associated proteins by injured neurons are a necessary prerequisite for axonal regrowth. In fish, at least the upregulation of protein expression by all retinal ganglion cells always occurs in parallel with axonal regeneration. It will be interesting to learn whether and how the properties of the glial cells in the vicinity of the axons influence —positively or negatively—protein expression of the injured neurons.

61 Brain edema

HAROLD K. KIMELBERG

CELLULAR AND VASOGENIC EDEMA

It is well-recognized that brain edema is an important component of the pathophysiology of stroke and traumatic brain injury, as well as a number of other pathological states. Brain edema has been broadly classified into two major categories (Klatzo et al., 1984): vasogenic edema and cellular or cytotoxic edema. These are illustrated in the scheme shown in Figure 61-1. It should, however, be emphasized that the term *edema* is best restricted to conditions in which there is always a *gain* of water, with or without cell swelling. Such water has to come from outside the central nervous system crossing the endothelial cells of the blood-brain barrier, as shown in Figure 61-1. The blood-brain barrier allows water to pass, but excludes polar substances, unless there are specific carrier systems present (Davson, 1976; Goldstein and Betz, 1986). The general term for a gain of water by the brain from the blood is *vasogenic edema.* There is commonly an increased extracellular space, but cell swelling can also occur (Klatzo et al., 1984) (see Figures 61-4 and 61-6 and the section *Volume Measurements In Situ* below). However, cell swelling can also occur without a gain of water when there is simply a *shift* of water from the extra- to intracellular space. This can occur under nonpathological conditions, for example with intense neuronal activity (Van Harreveld and Schade 1962; Ransom et al., 1985). As shown later in Figure 61-4, pure cellular swelling may also be a first step in brain edema, which subsequently occurs during the reperfusion phase after ischemia (Hossman, 1971). Water gain will increase volume within the closed cranial cavity, leading to an increased intracranial pressure (ICP), which can be readily measured by pressure transducers. Increased intracranial pressure will also occur with increased intracranial blood volume, which is a serious problem in traumatic brain injury when the intracranial compliance $\Delta V/\Delta ICP$ (the ratio of a brain volume increase to the resulting pressure increase) is often low (Popp et al., 1995).

The proportion of extracellular and intracellular volume increases that occur in edema can be roughly determined by electron microscopy of tissue removed after surgery, which is rapidly fixed, or by perfusion-fixation of tissue *in situ* in animals (Van Harreveld, 1966; 1972; Bullock et al., 1991). Van Harreveld (1966) has pointed out that even perfusion-fixation can cause fixation-induced cell swelling due to cellular uptake of electrolytes, and he has shown that only rapid freeze substitution methods consistently gives reliable electron microscopy results.

An estimate of the size of the extracellular space has been made using electrical resistance (impedance) studies in experimental animals (Van Harreveld and Schade, 1962; Hossman, 1971; Hansen and Olsen, 1989) and it seems likely that such methodology can be applied clinically (Holder, 1992). The volume relations of the different intracranial compartments are as follows (Rapoport, 1979)

$$V_{Blood} + V_{CSF} + V_{Brain} = \text{constant} \quad (1)$$

$$V_{Brain} = V_E + V_I \quad (2)$$

where V_E = extracellular volume and V_I = intracellular volume. Relative changes in V_E and V_I can be measured with impedance methods utilizing equations originally derived by Maxwell, simplified to

$$\frac{1 - r_1/r}{2 + r_1/r} = \frac{\rho}{2} \quad (3)$$

where r_1 would represent the specific resistance of the extracellular space (V_E) and r the specific resistance of total brain ($V_E + V_I$); ρ = the fractional volume of the cells (Van Harreveld, 1966). This relation is based on the fact that the cells will essentially be nonconductors of current compared to the extracellular space. Alternating current is used to avoid polarization effects and neuronal excitation. At high frequencies, the capacitative component of the impedance will be much less than the resistive component. r_1 can reasonably be assumed to be the same as cerebrospinal fluid (50 Ωcm) and r can be measured. Values of 232 to 284 Ωcm have been measured for forebrain cortex (Van Harreveld, 1966). Substituting in equation 3 for a median value for r of 258, ρ = 0.73 giving an extracellular space

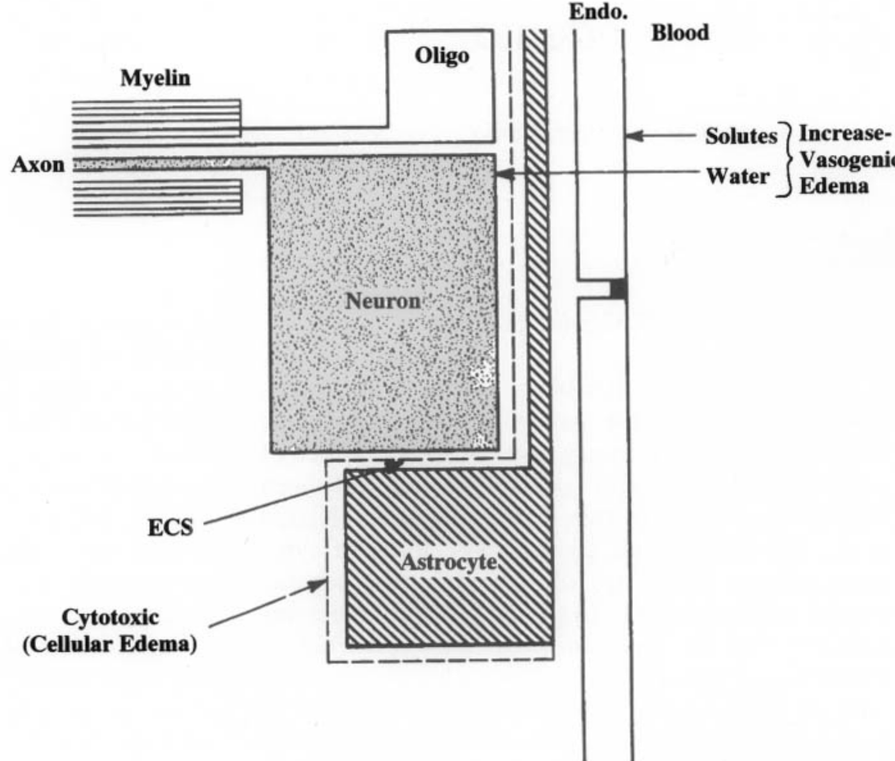

FIG. 61-1. Diagram of blood-brain barrier at the level of the brain capillary showing surrounding cells. Shown are the two different types of edema; vasogenic edema with net gain of solute and water due to loosening of the blood-brain barrier with entry of protein, salts and water. This is contrasted with cellular or cytotoxic edema principally involving intracellular swelling of astrocytes and dendrites (*not depicted*). See text for further discussion and contrast of cellular edema (gain of water) with cellular swelling (no gain of water) where cells, principally astrocytes, swell at the expense of the extracellular space. [From Kimelberg (1992), permission.]

of approximately 27%. Further refinements in techniques are needed to reduce errors, but in theory a dynamic readout of changes in the extracellular space as a function of stroke, epilepsy, and even neuronal activity are possible (Holder, 1992). It is also important that r_1 does not change due to alterations in its total electrolyte concentration. The principle of the lack of persistence of osmotic gradients for animal cells implies this will only occur if hypoosmolarity develops, and this can be measured if r_1 can be taken as the same as the specific resistance of the cerebrospinal fluid.

In vasogenic edema increased osmoles and water enter the brain generally due to breakdown of the blood-brain barrier. The blood-brain barrier is primarily due to intercellular occluding tight junctions between the endothelial cells lining the blood vessels and capillaries of the central nervous system of highly developed animals, and seems to be induced early on in development by factors, in part, produced by the surrounding astrocyte processes (Janzer and Raff, 1987; Neuhaus et al., 1991; Chan-Ling and Stone, 1992). The tight junctions exclude even small ions and only lipid-soluble substances are freely permeable (Davson, 1976; Goldstein and Betz, 1986; Abbott and Revest, 1991). Thus, very active transport systems are present for moving polar substances into and out of the brain. For example, the D-glucose transport system is present at a very high density, and there are a number of different amino acid carriers (Johansson, 1990). The existence of the blood-brain barrier means that a highly modified version of Starling's principle applies to the brain; excess water and solute are efficiently kept out, since any water entering the brain does so without solute and purely under hydrostatic pressure. The opposing osmotic force due to the retained ions and plasma proteins in the blood, then sets up an immediate opposing force driving the water back into the blood (Rapoport, 1979; Cserr and Patlak, 1991). With the breakdown of the blood-brain barrier, this control is lost, the barrier is breached and an ultrafiltrate of blood is driven by blood pressure into the brain. The blood cells are presumably retained by the residual permeability of the blood-brain barrier except in injury sufficient to lead to hemorrhage. Most of this ultrafiltrate fluid accumulates in the white matter due to the greater compliance of this region, that is, white matter will more easily accept the increased volume at a given pressure. This is likely due to the greater ease of separation of the parallel oriented white matter tracts (Rapoport, 1979).

The origin of cellular swelling is less clear and, as noted above, it has also been referred to as cytotoxic edema to distinguish it from vasogenic edema (Klatzo et al., 1984). It is very prominent in ischemia, hypoxia, and brain trauma, and under such conditions shows marked focal and dispersed swelling of the

soma and processes of astrocytes (Van Harreveld, 1972, 1982; Kimelberg and Ransom, 1986). Swelling of the astrocytic processes surrounding blood vessels and capillaries of the brain are very prominent in many pathological states (Table 61-1) and an illustration of perivascular astrocytic swelling after experimental traumatic brain injury is shown in Figure 61-2. Swelling of some neuronal elements, especially dendrites, is also seen, but swelling of the neuronal cell soma is more limited and swelling of oligodendroglia is generally absent (Van Harreveld, 1966; Van Harreveld and Fifkova, 1971). Reduction of the extracellular space is seen in ischemia as measured by an increase in brain impedance (Van Harreveld and Schade, 1962; Hossman, 1971; Van Harreveld, 1972; Hansen and Olsen 1989; and see above). Increased concentrations of membrane-impermeant molecules in the extracellular space are seen after irreversible ischemia, as measured by intracranial microdialysis, are also indicative of a decreased extracellular space (Katayama et al., 1992). However, in this model the decrease in extracellular space was transient occurring for only 2–3 minutes after ischemia. Also shown in this study is the rapid rise of $[K^+]_e$ (see Figure 61-3). However, actual concentrations in the extracellular space cannot be reliably obtained by microdialysis methods.

Figure 61-4 shows that in reversible cat brain ischemia cell swelling, assumed to occur because a decrease in the extracellular space was measured by an increased impedance (see Figure 61-4B), can precede actual edema formation as measured by a gain of brain water (Figure 61-4A). There was a rapid onset of cell swelling, but initially no net gain of brain water. However, large increases in $[K^+]_o$ would undoubtedly occur during this period (Hossmann et al., 1977; Katayama et al., 1992) (Figure 61-3), and this should activate astrocytic swelling as discussed below. However, since there is no gain of brain water during the ischemic period cell swelling could only be at the expense of a decreased extracellular space, measured by the impedance measurements. During the recirculation phase following the reversible ischemia a rapid increase in brain water occurs, presumably because water shifts from the now functioning vascular compartment to both the extracellular space and to the brain cells (see the first two paragraphs of this section). This gain of fluid could be due to a transient increased permeability of the blood-brain barrier or an increased osmolarity in the brain, such as increased breakdown of glycogen specifically localized in astrocytes (Kimelberg and Norenberg, 1994). Thus, based on the temporal relationships of Figure 61-4, the key events in setting the stage for edema formation (i.e., water gain) appear to have occurred early, during a phase of presumed pure cell swelling.

Clinically, astrocytic swelling has been described as a prominent and early feature associated with cerebral contusion in head-injured patients operated on for mass effects, as compared to brain tissue from patients operated on for epilepsy or gliomas. The tissue was removed and immediately immerse-fixed. As noted by Bullock et al. (1991): "Massive astrocytic swelling ("cytotoxic" edema) was seen 3 hours to 3 days after injury, maximal in perivascular foot processes, and compressing some of the underlying capillaries. The tight junctions were not disrupted. Neuronal damage was most marked three to 11 days after injury."

MECHANISMS OF CYTOTOXIC EDEMA

It remains obscure why astrocytic swelling occurs so frequently (Table 61-1). There have been numerous suggestions but little hard evidence due to the relatively limited work in this area and the difficulty of extrapolating work *in vitro* to properties *in vivo*. It is also undoubtedly a complex phenomenon *in vivo*, probably with several causes (Kimelberg, 1992). Early studies on astrocytic swelling had used brain slices as *in vitro* models (Bourke et al., 1983), but the relative contribution of neurons and glia to the overall swelling could not be distinguished in these studies although previous ultrastructural work had suggested a major contribution of astrocytes to the overall slice swelling. The most common current *in vitro* approach to studying pure astrocytic swelling

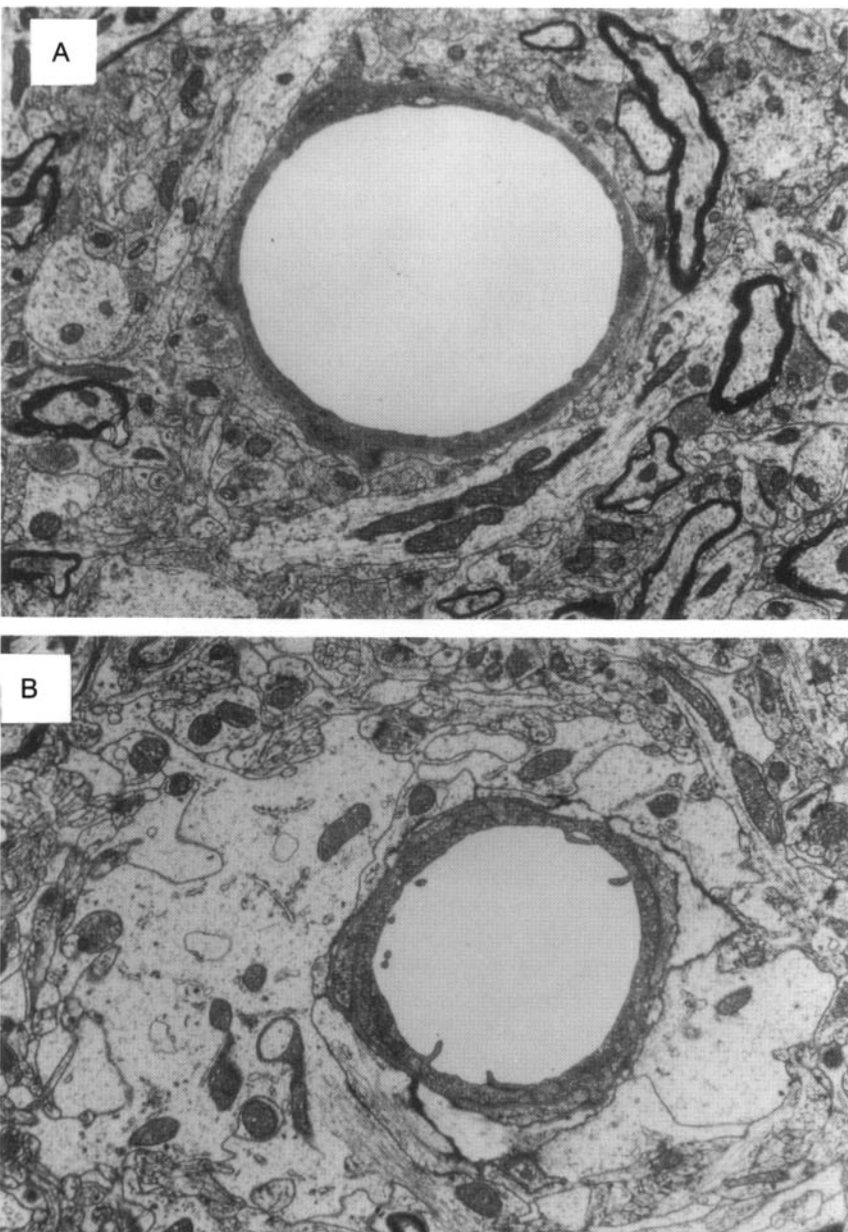

FIG. 61-2. (A) Electron micrographs of tissue from motor cortex of control, non-injured cats. (B) Electron micrograph of tissue from motor cortex of an experimental animal 40 minutes after closed head injury. Note swollen astrocytic profiles around capillary in bottom micrograph. [From Nelson et al. (1982), with permission.]

was first adopted in the early 1980s. It involved the use of primary monolayer cultures, that consist of 95% or more GFAP (+) astrocytes, prepared from neonatal rat brains. However, with such monolayer cultures there are problems in measuring cell volume in a dynamic and direct manner. In order to avoid the unknown changes in cell properties that could be caused by removing these anchorage-dependent monolayer cell cultures from the substratum on which they are growing radiolabeled intracellular space indicators have been used. Figure 61-5 shows such a study using [^{14}C]3-O-methyl-D-glucose, which is transported on the Na^+-independent, facilitatory diffusion glucose carrier present in these cells (also see below). It can be seen that in isotonic media the cells excluded [^{3}H] mannitol, used as an extracellular space marker, but when swollen by exposure to hypotonic media not only did the intracellular 3-O-methyl-D-glucose space increase, but [^{3}H]mannitol also appeared to enter the cell. Thus marked permeability changes appear to occur due to cell swelling that allow otherwise membrane-permeant molecules like mannitol to enter the cell.

Intracellular swelling can be due either to an uptake of osmoles such as Na^+, Cl^-, K^+ or glutamate (or some combination of these), from the extracellular to intracellular spaces with a shift of osmotically obligated water to the intracellular space

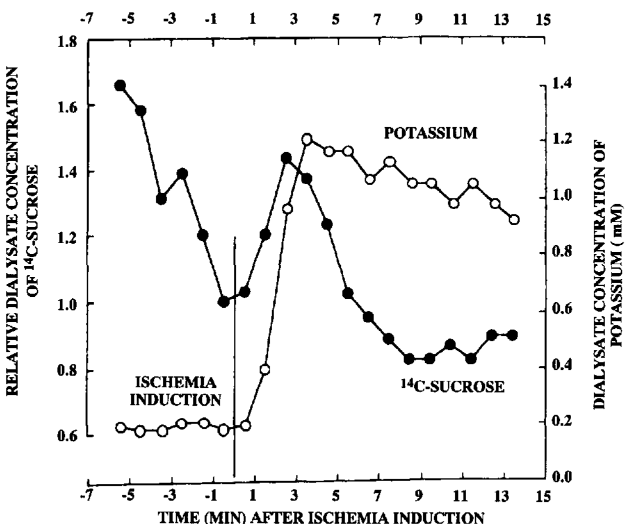

FIG. 61-3. Representative example of changes in extracellular K^+ (○) and ^{14}C-sucrose (•) measured from the same microdialysis probe after total irreversible cerebral ischemia in rats. [From Katayama et al. (1992), with permission.]

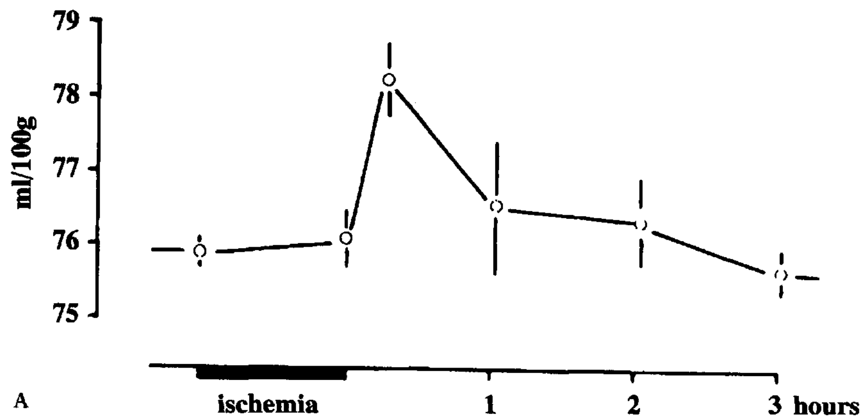
(Kimelberg, 1992), or generation of increased osmoles within the cell (so-called ideogenic osmoles). Figure 61-6 shows some of the major transport processes likely to be involved in cellular edema, superimposed on the model shown in Figure 61-1. In Figure 61-6, no. 1 shows influx of KCl due to Donnan forces driven by raised $[K^+]_o$ (Boyle and Conway, 1941; Barres et al., 1990a; Walz, 1992). Increased $[K^+]_o$ (>20 mM and up to 80 mM) is often seen in stroke and head injury (Kimelberg and Ransom, 1986; Siesjo, 1992; Nilsson et al., 1993). Direct measurements using ion specific electrodes in presumed glial cells (nonexcitable, large negative resting membrane potentials) in guinea-pig olfactory cortex have shown increased K^+_i and Cl_i^- activities with increased neuronal activity which was blocked by Ba^{2+} (Grafe and Ballanyi, 1987). Thus, this uptake is likely to be through K^+ channels, of which there are several types in astrocytes (Sonnhof, 1987; Barres et al., 1990a, 1990b). Cl^- channels will also be needed for KCl uptake. The Cl^- channels present in astrocytes are not usually open at normal resting membrane potentials, but a large conductance anion



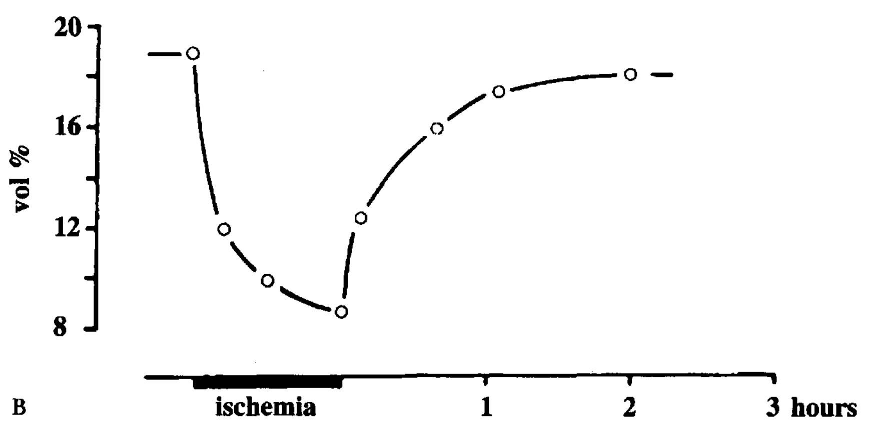


FIG. 61-4. Changes in (A) brain water and (B) extracellular space in cat brain during and after 1 hour of complete ischemia. Values are means ± SEM. Extracellular space was calculated from specific cortical impedance using the Maxwell equation (equation 3 in text). [From Hossman (1976), with permission.]

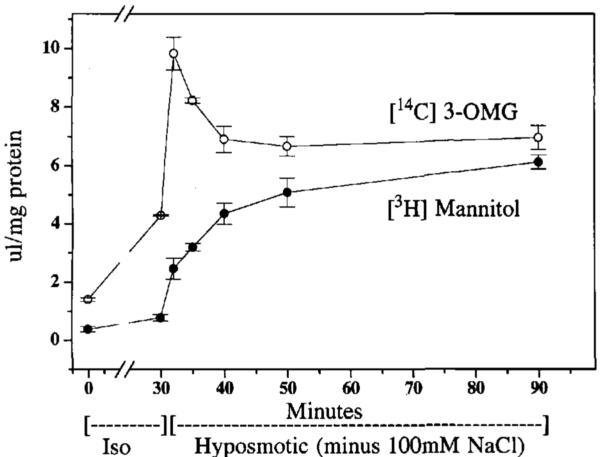

FIG. 61-5. Effect of exposing primary astrocyte cultures to hypotonic medium on the [^{14}C]3-OMG (○) and [^{3}H]mannitol (•) spaces. The first two values represent the zero time and the value after 30 minutes in isotonic medium, respectively. Thereafter, the cultures were exposed to hypotonic medium (100 mM NaCl removed) as indicated. Each point represents the mean ± SEM of four separate wells. [From Kimelberg et al. (1992), with permission.]

channel and the smaller conductance Cl^- channels so far seen in astrocytes are voltage-sensitive (Jalonen, 1993; Sonnhof, 1987).

Other mechanisms for astrocytic swelling that have been proposed are HCO_3^- and H^+ leaving the cell in exchange for Cl^- and Na^+, respectively on the appropriate exchangers (Figure 61-6, no. 2). Studies by Bourke et al. (1983) using brain slices and by Kimelberg et al. (1979) using primary astrocyte cultures, led to the suggestion that swelling may occur by simultaneous operation of Cl^-/HCO_3^- and Na^+/H^+ exchange transport, with H^+ and HCO_3^- cycling from the intra- to extracellular spaces via membrane-permeant CO_2. The HCO_3^- and H^+ ions can turn over many times by cycling into and out of the cell via membrane-permeant CO_2, with intracellular hydration to HCO_3^- and H^+ and extracellular dehydration back to CO_2 (Kimelberg et al., 1979; Kempski et al., 1990). The intracellular hydration of CO_2, and perhaps the extracellular too, is likely to be accelerated by carbonic anhydrase. Thus, there will be a net transfer of NaCl from the extra- to intracellular space. This NaCl is likely to be less effectively pumped out when the (Na^+,K^+) pump activity is reduced due to lowered intracellular ATP levels, and thus there will be intracellular swelling at the expense of the extracellular space. Swelling can also occur in ischemia because of the breakdown of macromolecular glycogen that is specifically localized in astrocytes (Kimelberg and Norenberg, 1994) to glucose, and finally to lactate, since there is a net generation of many moles of lactate from 1 mole of glycogen, which will lead to swelling of the intracellular compartment within which it is produced, if it is retained.

It has been shown that glutamate or kainic acid (KA) when injected into the central nervous system causes swelling of retinal Müller cells and astrocytes (Van Harreveld and Fifkova, 1971; Van Harreveld, 1982). These effects could operate through glutamate or kainic acid stimulating neurons and increasing production of the metabolic products CO_2 or H^+ leading to astrocytic swelling by the exchange processes described above, or glutamate or kainic acid could have a direct effect on astrocytes themselves. It is well established that astrocytes take up glutamate by a Na^+-dependent transport mechanism and such uptake could lead to swelling. However, [^{3}H]kainic acid is not taken up by primary astrocyte cultures (Kimelberg et al., 1989), and Sontheimer et al. (1988) showed that the depolarization of primary cortical astrocyte cultures by both L-glutamate and kainic acid is best described by the activation of an AMPA (aminohydroxymethylisoxazole propionic acid)/kainate ionotropic type of excitatory amino acid receptor. On this basis, swelling could be due to direct activation of astrocytic receptor channels leading to Na^+ entry. Cl^- would presumably enter on channels perhaps also activated by the AMPA/KA receptor or by membrane depolarization.

Fatty acids and free radicals can lead to swelling presumably because they can cause breakdown of the selective permeability of the membranes leading to nonselective ion influx. This influx should be principally of Na^+ and Cl^- because of the high extracellular concentrations of these ions. Because of the appearance of measurable free radicals and the protective effects of antioxidants, such as the 21 aminosteroids or "lazaroids" (Braughler and Hall, 1992), and superoxide dismutase (Kontos and Wei, 1986), free radicals are now considered to be an important component of damage during ischemia and trauma, and may be especially significant for long-term secondary effects. There are a number of free radical species which are oxygen-based, such as the superoxide anion $O_2\cdot^-$ (Kontos and Wei, 1986). These are produced because of incomplete reduction of oxygen by electron donors. Hydrogen peroxide (H_2O_2) can also be formed. The very short-lived hydroxyl free radical ($\cdot OH$) is formed from H_2O_2 in a reaction catalyzed by free iron. Such free iron can be liberated from the heme groups of hemoglobin or released from ferritin and transferrin after hemorrhage. These free radicals are deleterious due to their ability to form an oxidative cascade affecting the fatty acid side chains of membrane phospholipids, leading to peroxidatic

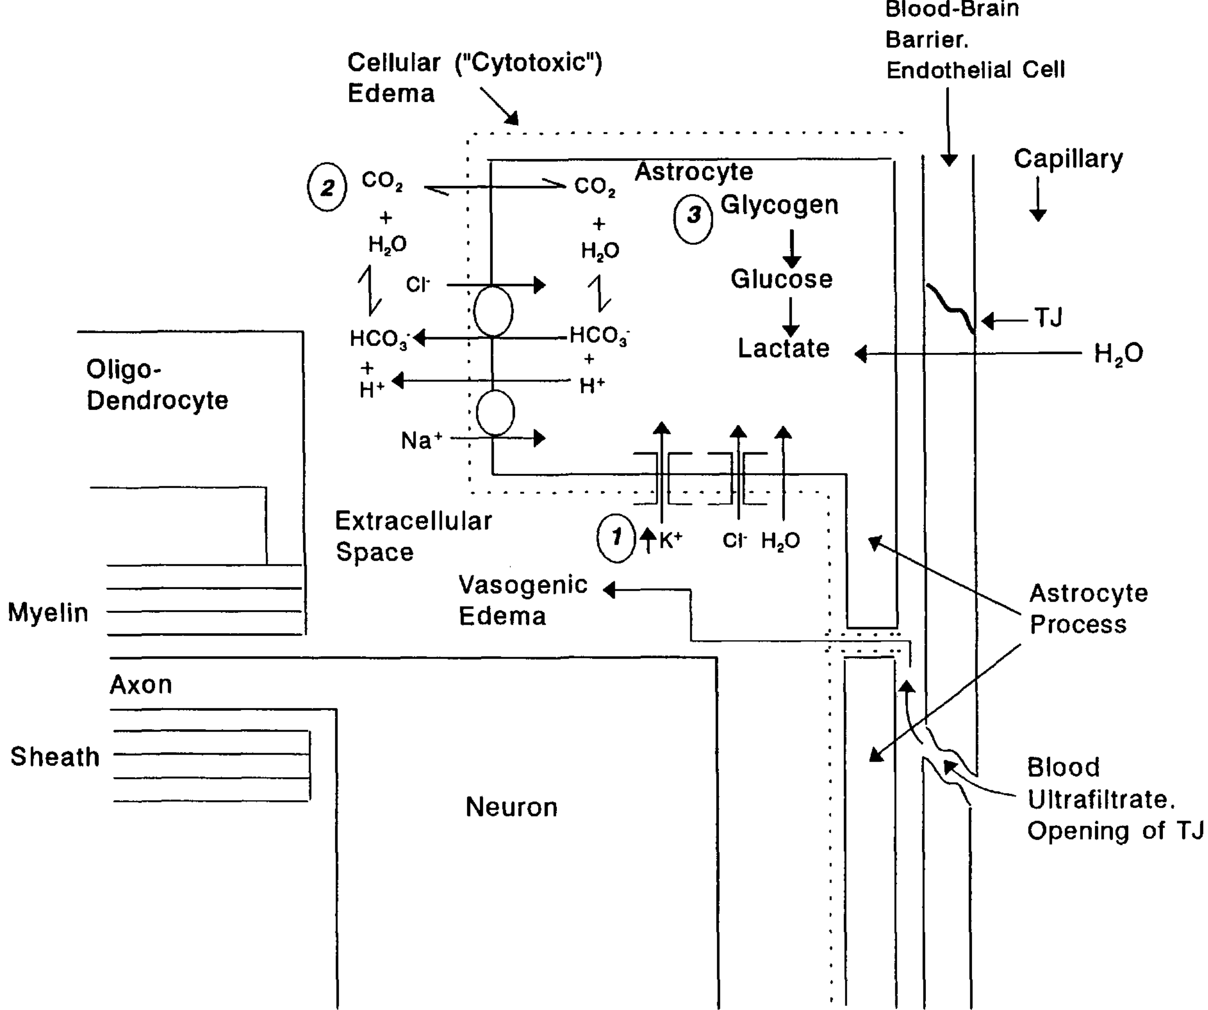

FIG. 61-6. Postulated mechanisms of cellular edema (also see text). For completeness vasogenic edema, due to "opening" of the tight junctions (*TJ*) between the endothelial cells with a blood ultrafiltrate moving into the brain driven by blood pressure, is also shown. Cellular or vasogenic edema can coexist but, in its purest form, cellular edema need not result in a gain of brain water because the cells can swell at the expense of the extracellular space. This can also occur under nonpathological intense neuronal activity and preferably should be referred to as "cellular swelling." Three postulated and numbered causes of astrocytic swelling are depicted in the diagram (see text for further details): 1, influx of K^+ and Cl^- driven by raised extracellular K^+ (Donnan swelling); 2, intracellular hydration of CO_2-producing H^+ and HCO_3^- and their exchange for extracellular Na^+ and Cl^-, respectively; 3, generation of osmoles within the cell, for example, by metabolism of the macromolecular glycogen in astrocytes to a number of moles of glucose and lactate. [From Popp et al. (1995), with permission.]

breakdown of the membrane phospholipids and the generation of further free radicals (Kontos, 1989). All these effects will break down the selective permeability of cell membranes leading to membrane depolarization and influx of Na^+ and Cl^- with water, and ultimately cell destruction. Free radicals can also directly affect proteins, such as glutamine synthetase (Halliwell and Gutteridge, 1985). Current debate centers on when and how these mechanisms might be involved in ischemia and trauma (Kontos, 1989). The effects of oxidation and free radicals on cells might be expected to be nonspecific and it is not clear why they would selectively produce swelling of astrocytes and dendrites. However, localized production of free radicals or increased susceptibility are a few of many possibilities. The free radicals might be expected to ultimately cause a breakdown of the blood-brain barrier, leading to vasogenic edema (Figure 61-6).

A number of transmitters or neuromodulators have been shown to produce HCO_3^--dependent swelling in brain slices (Bourke et al., 1983), and one of the most potent of these is adenosine (or the nonmetabolizable analogue 2-chloroadenosine). Adeno-

sine was found to lead to marked swelling of astrocytes as shown by electron microscopy after superfusion of adenosine over exposed cat cerebral cortex (Bourke et al., 1981). In brain slices *in vitro* adenosine may have direct effects on astroglial adenosine receptors or indirectly cause astrocytic swelling by activating neurons, while in intact animals adenosine also increases blood flow.

Increased $[Ca^{2+}]_i$ can be damaging to cells, and may also lead to swelling. Increased $[Ca^{2+}]_i$ will cause activation of Ca^{2+}-dependent proteases and phospholipases, leading to hydrolysis of proteins and membrane phospholipids, respectively. For example, phospholipase C breaks down membrane phospholipids into their constituent diacylglycerols and phosphoryl head groups. In pathological situations diacylglycerol can be further broken down by other phospholipases, namely A1 and A2, to liberate the two fatty acids bound to the glycerol backbone. The unsaturated fatty acids at position 2, such as arachidonic acid, are particularly pluripotential. The phospholipases, particularly the A forms, are very sensitive to Ca^{2+}. Free fatty acids lead to disruption of the lipid portion of the membrane by having a detergentlike effect, breaking apart the necessary hydrophobic packing needed to maintain the integrity of the lipid bilayer. This disruption will serve to short-circuit the normal impermeability of the lipid bilayer and thus the selective permeability of the cell membrane. These changes can also alter the lipid microenvironment of membrane proteins and consequently the activity of ion pumps and channels, also leading to dissipation of membrane gradients. Products of arachidonic acid, namely the leukotrienes and prostaglandins can also lead to activation of K^+, Cl^-, and Na^+ channels, which could lead either to cell swelling or shrinkage (Hoffmann and Kolb 1991).

Hepatic encephalopathy, as encountered in Reye's syndrome and other pathological states (see Table 61-1), has been shown to result in electron-lucent astrocytes, as seen by electron microscopy, indicating cell swelling. Such swelling could be related to metabolism of excess ammonia, formed in these disorders, by the glutamine synthetase that is present at high concentrations in astrocytes (Norenberg, 1981; Chapter 63, this volume). Another possibility is that increased ammonia enters the astrocyte across the blood-brain barrier to form ammonium ions intracellularly. Direct determinations *in vivo* with ion-specific pH microelectrodes have given a mean value for the intracellular pH of astrocytes of 7.04 with a range of 6.73 to 7.38 (Chesler and Kraig, 1989). This means that 99% of intracellular ammonia will be in the form of NH_4^+. An increase of NH_3, leading to a greater $[NH_4]_i$, would alkalinize the interior of the cell, leading to an increase in $[HCO_3^-]_i$, which could then exchange for $[Cl^-]_o$, resulting in an accumulation of NH_4Cl in the astrocyte. It is known that excess CO_2 exacerbates the effects of hepatic encephalopathy (Norenberg, 1981), and this could be a source of the increased intracellular H^+ and HCO_3^-.

Recently it has been reported that in the early stages of experimental allergic encephalitis (EAE) induced in rats by injection of purified guinea pig myelin, there is marked swelling of perivascular astrocytes associated with increased immunoreactivity for glial fibrillary acidic protein (GFAP) (see Table 61-1). This increased immunoreactivity occurs without an increase in total GFAP content, suggesting increased exposure of epitopes on GFAP, perhaps due to its depolymerization in swollen astrocytes (Eng et al., 1989).

Although it seems likely that astrocytes *in situ* mainly swell by mechanisms other than exposure to hypotonicity, significant hypoosmolarity is also seen clinically. Both hyponatremia, as well as hypernatremia, are encountered after traumatic brain injury (Popp et al., 1995), and hyponatremia due to inappropriate secretion of antidiuretic hormone is a common clinical problem. Swelling of primary astrocyte cultures or C6 glioma cells *in vitro* due to media made hypotonic by reduction of NaCl is followed by a characteristic regulatory volume decrease (RVD), and is associated with release of K^+, Cl^-, and amino acids (Kempski et al., 1983; Kimelberg and Frangakis, 1985; Olson et al., 1986; Pasantes-Morales and Schousboe, 1988; Kimelberg et al., 1990). Work *in vivo* has shown that astroglial swelling occurs and spontaneously resolves after experimental acceleration-deceleration closed-head injury (Barron et al., 1988). However, the time course of swelling and RVD *in vitro* after exposure to hypotonic media is faster than the onset of astroglial swelling and its resolution *in vivo*. This difference could be due to a balance of slowly developing swelling forces and normal RVD forces *in vivo*. However, this slower rate of swelling, is seen in primary astrocyte cultures using high extracellular K^+ or L-glutamate to swell the cells (O'Connor et al., 1993b). It is associated with a slower amino acid release (Kimelberg and Goderie, 1991) than the rapid initial release due to exposure to hypotonic media (O'Connor and Kimelberg 1993). This emphasizes the need for studying the kinetics of cell swelling to see how swelling *in vivo* compares to swelling *in vitro* due to different influences; in the next section experimental methods for measuring swelling are briefly discussed.

METHODS FOR MEASURING EDEMATOUS VOLUME CHANGES

Cell Monolayers In Vitro

A large amount of the work done on the mechanisms and consequences of cell swelling utilizes cell cultures for ease of analysis of volume changes in a homogeneous cell population. The use of cell cultures for *in vitro* studies on cell volume regulation has allowed researchers to focus on understanding mechanisms at the cellular level. Cell cultures can be classified according to a variety of criteria, including whether they are grown directly from tissue (primary cultures) or they are normal or transformed established cell lines. Primary cultures of normal neurons or glia are thought to be best for studying the properties of the normal central nervous system cell types.

Some cell types can be grown as suspension cultures, for example, lymphocytes, and such cells are very convenient for studies using the Coulter Counter or a light-scattering technique to measure cell volume. This Coulter counter technique has also been applied to C6 glioma cells (Kempski et al., 1983) and primary astrocyte cultures (Olson et al., 1986). Since these cultures grow as monolayers, the cells first have to be removed from culture dishes either by enzymatic treatment, usually with trypsin, by using a Ca^{2+} chelator or by mechanical scraping, to make a uniformly dispersed cell suspension. However, such detachment of substrate-attached cells will affect the shape and transport properties, including all aspects of passive, facilitated, and active permeability of cell membranes, introducing uncertainty with regard to the properties measured.

When cells are left in their normal attached state, intracellular volume has most frequently been measured using equilibration with [^{14}C−]3-O-methylglucose (3-OMG), as originally described for hepatocytes (Kletzien et al., 1975) and applied to primary astrocyte cultures by Kimelberg and Frangakis (1985) (see Figure 61-5). [^{14}C]urea has also been used in glial monolayer cultures (Martin and Shain, 1979). We have used both methods for primary astrocyte cultures, and, although both report regulatory volume decrease and regulatory volume increase response, such indirect radiolabeled tracer studies introduce methodological problems. One of the important drawbacks of this method is its inability to measure rapid changes in cell volume. This technique is limited to collecting data points at probably not less than 30-second intervals because one needs to completely remove the extracellular tracer by washing. Other problems concerning this technique are whether there is leakage of the tracer when the cell is swollen, what intracellular volume is actually being measured, that is, are the tracers excluded and/or concentrated in certain areas of the cell, does swelling and volume regulation cause the equilibrium rate of the tracer to change and are there impurities in the marker that would cause errors in the measurement of volume? It is also, of course, vital that the marker is nonmetabolizable as metabolism would cause serious errors in the volume measurement. For [^{14}C]3-OMG the cells must only have the equilibratory, phloretin-sensitive, Na^+-independent carrier, which has been shown to be the case in primary astrocyte cultures (Kimelberg and Frangakis, 1985), since 3-OMG is carried on the glucose carrier in a similar manner to glucose. However, in the presence of excess glucose any glucose gradient will cause an identical 3-OMG gradient to develop, which will affect the apparent intracellular 3-OMG space and therefore intracellular "volume."

As an alternative to the above methods an impedance method, similar to that used for *in vivo* measurements of extracellular space (see the section *Cellular and Vasogenic Edema*), has been developed for measuring dynamic changes in cell volume of primary astrocyte monolayer cultures (O'Connor et al., 1993b). In this method monolayer cell cultures are placed in a confined channel containing a salt solution and the impedance or electrical resistance of the small channel over the cells is measured using an applied AC field at 500 Hz, at which frequency the cell impedance is very high relative to the fluid impedance. If the volume of the cells increases, the volume of the solution within the channel available for resistive current conduction will decrease by the same amount. Figure 61-7 shows results using this method for three different effectors of cell colume changes, all added at 0 time. Exposure to hypotonic solutions shows the expected rapid initial swelling followed by a gradual regulatory volume decrease back to control volume. The slow rise in volume upon exposure to isosmotic medium containing increased K^+ (50 mM KCl replacing 50 mM NaCl), is consistent with a slow increase in volume due to KCl uptake. The slow rise response to 0.1 mM glutamate is also consistent with glutamate uptake. Thus this method allows measurements of volume changes in real time.

There are also a number of microscopic imaging methods, changes in fluorescence probe concentrations and laser and visible light scattering. These have been recently reviewed in detail elsewhere (MacKnight and Leader, 1989).

Volume Measurements In Situ

In order to correlate the findings in cultures or tissues *in vitro* with behavior of cells *in vivo* it is nec-

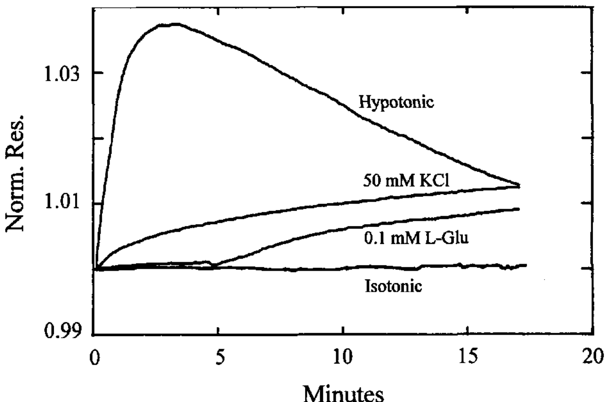

FIG. 61-7. Volume increases in primary astrocyte cultures, measured as increases in normalized resistance (y axis) using an impedance method. These were produced by exposure to hypoosmotic media (minus 100 mM mannitol), isoosmotic 50 mM KCl media (replaces equivalent NaCl) and 0.1 mM glutamate as indicated, all starting at $t = 0$. An isotonic control exposure is also shown (*bottom trace*). See text for further details. [From data in O'Connor et al. (1993b) with permission.]

essary, of course, to have methods for making such measurements. MacKnight and Leader (1989) have recently discussed such techniques in detail for epithelial cells. Ransom et al. (1985) used a membrane impermeant cation TMA^+ (trimethylammonium) injected into the extracellular space and measured its activity with potassium selective electrodes, which are far more sensitive to TMA^+ than K^+. As the nerve was stimulated extracellular TMA^+ activity rose, consistent with a decrease in the extracellular space. Also this decrease was proportional to changes in extracellular potassium, which causes swelling of glial cells. Developmental aspects of the study also indicated that it was likely to be the glial cells that were swelling. Ballanyi et al. (1990) have also used TMA^+, or choline, which behaves similarly, and recorded intracellularly from leech neuropil glial cells which had accumulated these compounds after bath application. It was shown that elevation of the extracellular potassium concentration caused a depolarization of the cell membrane potential as expected and a decrease in the intracellular choline signal, consistent with the neuropil leech glial cells having swollen.

As discussed in detail in the first section of this chapter, impedance methods were applied by Van Harreveld (1966) and Hossman (1971), to mammalian brain *in vivo*. These methods allow only measurements of the overall extracellular/intracellular changes. In these pioneering studies it was shown that conditions such as asphyxia or ischemia caused a marked increase in the measured impedance of the tissue consistent with cellular swelling and reduction of the extracellular space. An example of the impedance method applied to global cerebral ischemia in the cat was shown in Figure 61-4B. During complete ischemia there was an initial 50% decrease in extracellular space, presumably due to rapid onset of cell swelling, but no net gain of brain water (Hossman et al., 1977). During the ischemic phase, large increases in $[K^+]_o$, due to loss of K^+ from and gain of Na^+ by cells (see Figure 61-3) would undoubtedly have occurred (Hossman et al., 1985), and should activate astrocytic swelling. However, since there was no gain of brain water, this swelling could only be at the expense of a decreased extracellular space, consistent with reuptake of KCl, with the cells retaining the Na_i^+ already gained. Other factors such as an increase in intracellular osmolarity should also occur because of increased glycogenolysis and lactate production. During the "recirculation phase," a rapid increase in brain water occurred (Figure 61-4A), presumably because water shifts from the recirculating blood to both the extracellular space and brain cells. This fluid shift could be due not only to an increased osmolarity of the brain, but also a transient increased permeability of the blood-brain barrier. However, this was not shown. Since ischemia has been shown by electromicroscopy in many experiments to lead preferentially to astrocytic swelling (Jenkins et al., 1982; Garcia, 1984; Kimelberg and Ransom, 1986) it is quite possible that a major contribution to the decrease in the extracellular space seen in Figure 61-4B was astrocytic swelling. However, Van Harreveld and Fifkova (1971) also found, using rapid freeze substitution techniques with electron microscopy, that under the same conditions there was marked dendritic swelling. The relative contributions of glial and dendritic swelling to the decreased extracellular space seen in ischemia cannot be determined using the impedance methodology alone.

Note Added in Proof: Magnetic resonance imaging (MRI) especially a technique termed *Diffusion Weighted* (DW) MRI, is currently being used to measure movement of water from the extra- to intracellular space (Campagne et al., 1994).

CONSEQUENCES OF ASTROCYTIC EDEMA

Regulatory Volume Decrease and Release Phenomena

Primary astrocyte cultures, when swollen in hypotonic media, show RVD as do most cells, reestablishing their preswelling volume by losing ions (Kimelberg and Frangakis, 1985; O'Connor and

Kimelberg, 1993a). They also release amino acids such as [^{3}H]taurine, [^{3}H]D-aspartate and [^{3}H]L-glutamate, which these cells had previously accumulated, or the endogenous amino acids (Pasantes-Morales and Schousboe, 1988; Kimelberg et al., 1990; Pasantes-Morales et al., 1990). *In vivo*, significant hypoosmolarity is almost always due to lowered plasma Na^+ concentration as in hyponatremia, and this condition also leads to loss of taurine, aspartic and glutamic acids from the brain (Gullans and Verbalis, 1993). In Figure 61-8 we also show release of [^{3}H]D-aspartate from primary astrocyte cultures due to exposure to high K^+ media. This release has a slower onset time than hypotonic media-induced release, but is also inhibited by L-644,711 (see next paragraph).

Clinically hyponatremia, and also hypernatremia, are encountered as one of the systematic manifestations of traumatic brain injury (Popp et al., 1995). The finding of marked release of glutamate by swollen astrocytes leads to the interesting possibility that, when astrocytes swell *in vivo*, they release excitotoxic amino acids such as L-glutamate and L-aspartate. This in turn can cause neuronal injury due to excessive activation of NMDA and other glutamate receptors, as postulated in the excitotoxicity concept (Choi, 1988). Thus any drugs that are found to inhibit this release, as astrocytes are a potential source of L-glutamate released in pathological states (Farinelli and Nicklas, 1992), may be effective in alleviating secondary injury in stroke or trauma. This hypothesis is supported by the protective effects of the anion transport blocker L-644,711 in animal models of closed head injury and focal ischemia (Cragoe et al., 1986; Kimelberg et al., 1987; Kohut et al., 1992). *In vitro*, L-644,711 and other anion transport inhibitors including SITS, inhibit swelling-activated release of [^{3}H]taurine and [^{3}H]L-glutamate from swollen astrocytes (Kimelberg et al., 1990) (Figure 61-8). However, these anion transport inhibitors have not been investigated extensively in relation to other possible ways they can affect ischemic or other damage so that other reasons for the protective effects of L-644,711 are possible. Thus, L-644,711 has been shown to inhibit superoxide release from neutrophils (Bednar et al., 1992). However, L-644,711 does not act as a direct antioxidant of lipid peroxidation (Metsä-Ketelä, University of Tampere, unpublished observations).

How Is Astrocytic Swelling Transduced to Release Phenomena?

Role of Calcium. Because of the potential importance of astrocytic swelling to neuronal damage, mechanisms of volume regulation and the consequences of astrocytic swelling are now being studied more fully. Both extra- and intracellular Ca^{2+} have been shown to influence cellular volume regulation in a number of different cell types (McCarty and O'Neil, 1992). In some cells, removal of extracellular Ca^{2+} prevents osmolyte efflux and blocks volume recovery. In the case of primary astrocyte cultures, both extracellular and intracellular Ca^{2+} have also been found to be required for volume regulation as measured by the impedance method (O'Connor and Kimelberg, 1993a). Bender et al. (1992) have shown that, using radiolabeled 3-O-methyl-D-glucose to measure changes in cell volume, calmodulin antagonists completely inhibit RVD in primary astrocyte cultures.

Most vertebrate cells accomplish RVD from hyposomotic swelling principally through efflux of K^+ and Cl^- (McCarty and O'Neil, 1992). In some cells

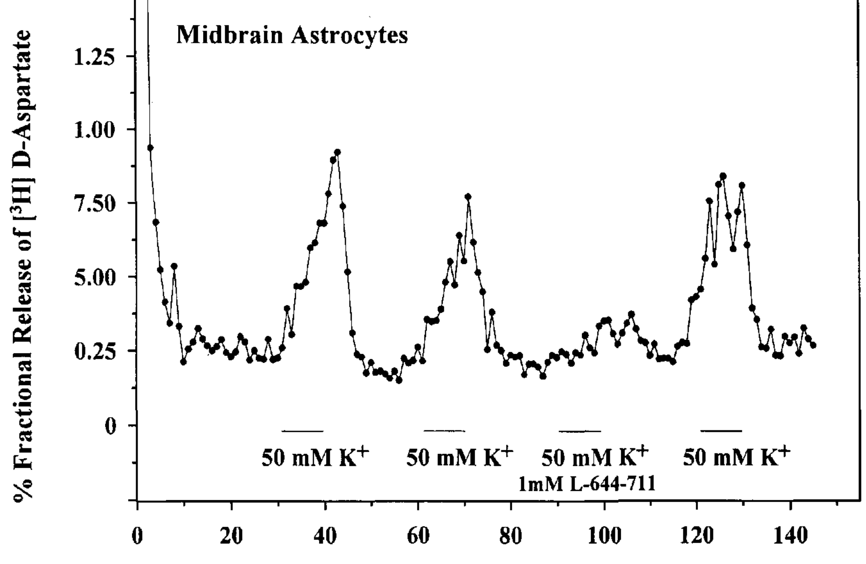

FIG. 61-8. Release of previously accumulated [^{3}H]D-aspartate from astrocytes prepared from the midbrain region of 1-day-old Sprague Dawley rats and grown for 4 weeks. Release was measured at 37°C, using a constant perfusion system, in which the control HEPES solution was changed, as indicated, to media containing 50 mM K^+ by isotonic replacement of Na^+ with K^+, plus and minus the anion transport inhibitor L-644,711. Results are expressed as a percentage of the radioactivity present at the beginning of each 1-minute collection period obtained by sequentially adding back the radioactivity released. [From Kimelberg and Goderie (1991), with permission.]

this is through separate K^+ and Cl^- channels (Hoffmann and Kolb, 1991), while in others the K^+ movement is totally Cl^--dependent and may be due to KCl cotransport (McCarty and O'Neil, 1992). A swelling-induced rise in Ca^{2+} often seems to stimulate K^+ movement through channels in RVD because both $[Ca^{2+}]_i$ rises and quinine and other compounds that inhibit Ca^{2+}-dependent K^+ channels, block or reduce cell volume recovery, for example, in Ehrlich ascites cells (Hoffmann and Kolb, 1991). However, recent data have shown that quinine can also inhibit anion channels (Roy and Malo, 1992). In primary astrocyte cultures Ca^{2+} seems to be required for swelling-induced K^+ and Cl^- efflux, and quinine also blocks RVD in these cells (O'Connor and Kimelberg, 1993a). Ca^{2+}-activated K^+ channels have been reported in astrocytes (Barres et al., 1990a; Tse et al., 1992) and in retinal Müller cells (Puro et al., 1989). One possible source of the increase in free Ca^{2+} could be increased Ca^{2+} influx into the cell through voltage-dependent Ca^{2+} channels or through swelling-activated nonspecific cation channels that are permeable to Ca^{2+}. An additional source is release from intracellular Ca^{2+} stores. Hypotonic media-induced swelling of astrocytes has been shown to cause a significant increased uptake of extracellular Ca^{2+} as measured with radiotracer $^{45}Ca^{2+}$ added extracellularly, and this uptake was partially blocked (60%) by the Ca^{2+} L-channel blocker nimodipine at 10^{-6}M. Increased $[Ca^{2+}]_i$ released from internal stores due to hypotonic swelling was also shown in the same study using fura-2 (O'Connor and Kimelberg, 1993a). This uptake into astrocytes upon swelling may be, in part, responsible for the marked decrease in extracellular Ca^{2+} seen in spreading depression, ischemia and trauma when astrocytes are also swollen (Hansen, 1985; Nilsson et al., 1993).

Other Second Messengers. In contrast to the amount of information on Ca^{2+} and volume regulation, there is a relative paucity of information regarding the involvement of other second messengers in cell volume regulation. Watson (1989) showed an increase in both intracellular calcium and cAMP subsequent to hypotonic media-induced swelling in mouse lymphoma cells. In a later study, however, he indicated that the cAMP increase did not appear to be involved in either the initial volume expansion or the extent of the subsequent regulatory volume decrease (Watson, 1990). Meijer and Hue (1991) have shown that the swelling of hepatocytes increases intracellular levels of inositol 1,4,5-triphosphate (IP_3), Ca^{2+} and cAMP. Haussinger and Lang (1991) have emphasized that cell swelling can accompany activation of second messengers by various hormones and may be a component of metabolic control in liver and other cells. There is clearly a need to study further the activation of IP_3 and cAMP, as well as Ca^{2+}, in astrocytes due to swelling, and the physiological consequences of such changes. Bender et al. (1993) have recently reported increased phosphatidylinositol hydrolysis in primary astrocyte cultures exposed to hypoosmotic media. This increased hydrolysis was blocked by a phospholipase C inhibitor, which also inhibited regulatory volume decrease.

Potassium and Anion Channels Activated in Astrocytes by Swelling

K^+ (measured with $^{86}Rb^+$) and $^{36}Cl^-$ efflux studies have shown swelling-induced release of K^+ and Cl^- from astrocytes *in vitro* (O'Connor and Kimelberg, 1993b). Swelling-activated membrane potential changes and whole-cell currents have also been reported in the same types of cultures (Kimelberg and O'Connor, 1988; Kimelberg and Kettenmann, 1990). These data strongly suggest that changes in channel activity occur during regulatory volume decrease in astrocytes *in vitro*. One of the first functions supporting the survival of single-cell organisms would have been the ability to regulate their cell volume in an environment of changing osmolarity, and also cell swelling due to Donnan forces because of impermeant intracellular macromolecules. Thus, swelling-induced channels may represent a well-conserved channel family. Mechanical stress, stretch, bending and shearing of the cell membrane are postulated direct signals for the activation of such channels. Patch-clamp techniques have given the possibility of mimicking these mechanical forces by applying pressure directly to the cell membrane and then recording changes in ion channel activity in the same patch. Such perturbations are found to activate channels, which were originally described in cultured muscle cells and termed stretch-activated ion channels or SACs (Guhary and Sachs, 1984). SACs have now been found in a wide variety of cell types ranging from bacteria to mammalian cells (Kullberg, 1987; Sackin, 1994).

The channels opened by the microelectrode pressure technique in animal cells are usually nonspecific cation channels and are permeant to divalent cations such as Ca^{2+}, as well as K^+ and Na^+ (Guhary and Sachs, 1984; Kullberg, 1987; Sackin, 1994). K^+ and nonspecific cation SACs, measured in the cell-attached mode with pressure applied through the cell-attached patch pipette, have been found at high densities in primary astrocyte cultures. In this comprehensive study both nonspecific cation and K^+-

selective channels sensitive to increased, or both increased and decreased pipette pressures were found (Bowman et al., 1992).

A number of recent studies have now shown anion currents and anion channels that are activated by swelling and/or pipette suction. One type is a large conductance anion channel of around 300 pS, which is seen in a number of cell types. Other anion channels of 7 pS and 20 to 30 pS conductances, respectively, have also been reported (Sackin, 1994). It is possible that some of these channels also carry amino acids, albeit with lower conductances (Roy and Malo, 1992). As noted in the section *Regulatory Volume Decrease and Release Phenomena* astrocytes *in vitro* release amino acids when swollen, and this may occur through such channels. In the limited extracellular space of the brain such release of glutamate and aspartate is potentially neurotoxic (Choi, 1988). However, while swelling-induced $^{36}Cl^-$ efflux in primary astrocyte cultures is Ca^{2+}-dependent, amino acid efflux appears to be Ca^{2+}-independent (O'Connor and Kimelberg, 1993). Thus we may need to postulate different channels for Cl^- and amino acids in astrocytes. Studies on astrocytes in the cell-attached mode have shown that hypotonic recording solutions, in the cell-attached mode, increases the occurrence of a high-conductance (250–300 pS), voltage-sensitive Cl^- channel in cultured astrocytes (Jalonen, 1993). This same channel is frequently seen in inside-out excised patches in cultured astrocytes (Gray and Ritchie, 1986; Sonnhof, 1987; Jalonen, 1993), and in acutely isolated GFAP (+) astrocytes (Jalonen et al., 1992). It is inhibited by the anion transport inhibitor L644,711 (Jalonen, 1993) which also inhibits swelling-induced efflux of amino acids from astrocytes (Kimelberg et al., 1990), supporting the possibility that glutamate and aspartate can also pass through this channel. Used *in vivo* L-644,711 reduces injury in animal models of both head injury and stroke (see next section). For the large anion channel studied in astrocytes, the delayed activation seen after excision of the patch suggests that this channel is normally always closed in the resting state and becomes activated when the cell swells (Jalonen, 1993).

POTENTIAL THERAPIES OF BRAIN EDEMA

Treatment of brain edema where there is a net gain of fluid is naturally directed at reducing the brain swelling. Immediate benefit can be achieved by lowering P_{CO_2} by hyperventilation; this reduces cerebral blood volume, with a consequent rapid reduction in intracranial pressure (Popp et al., 1995). Another common approach is the use of intravenous mannitol to make the blood hyperosmotic to withdraw water from the brain (Pollay, 1985). However, mannitol will only work in this way where the blood-brain barrier remains intact, and there often appears to be a delayed rebound phenomena due to mannitol entering the brain. *In vitro*, mannitol also enters swollen astrocytes (see Figure 61-4).

Other therapies are targeted to likely effectors or secondary consequences of edema. Such therapies include glutamate receptor antagonists, Ca^{2+} transport blockers and free radical scavengers of antioxidants (McIntosh, 1993). The way in which cell swelling can lead to some of these consequences has been discussed in previous sections. Therapeutic strategies have also been directed to inhibiting astrocytic swelling. In an experimental (cat) closed-head injury model, a significant decrease in mortality and improvement in the rate of neurological recovery was found with L-644,711 which also inhibited astrocytic swelling in this same model (Nelson et al., 1982; Kimelberg et al., 1987; Barron et al., 1988), presumably by blocking anion channels or other anion transport systems. The compound was given after the initial trauma, but before a secondary imposed hypoxic period. L-644,711 has also been found to be effective in a rabbit model of focal ischmia where it reduces the infarct size by up to 85% (Kohut et al., 1992) and has been reported to cause remarkable recovery from an otherwise lethal tyramine-induced model of Reye's syndrome in dogs, which shows brain edema (Faraj et al., 1988).

Mechanosensitive channels and mechanosensitive secondary messenger systems are attractive candidates for a link between the immediate mechanical forces set up by head injury and the harmful secondary events, including brain edema, which are thought to be highly significant in determining the outcome from a traumatic brain injury (TBI) that is not immediately fatal (Popp et al., 1995). The unique component of TBI are the short-lived and random forces acting on the brain due to the acceleration/deceleration forces experienced by brain tissue caused by the sudden blows sustained in TBI. This "commotio cerebri" sets up shear forces within the brain tissue, and also bruising due to impact of the brain on the internal surfaces of the skull. The shear forces are thought to be the cause of the diffuse axonal injury seen in TBI, where axons are disrupted at right angles to their longitudinal axes, but even these effects may be delayed and thus are likely to be secondary to the mechanical forces (Povlishock, 1985). Thus influx of Ca^{2+}, Na^+ (with Cl^-), on mechanosensitive channels leading to swelling and all the processes dependent on the adenyl cyclase and

phosphatidylinositol-linked second-messenger systems may be directly and rapidly activated by the forces encountered in TBI, acting at the cellular level. Influx of Ca^{2+} can then lead to transmitter release and K^+ leading, in part, to the astrocytic swelling and secondary edema occurring in TBI. Such swelling will be further exacerbated by ischemia and hypoxia, which are secondary events in TBI, but could also be a result of a primary activation of mechanosensitive events causing vasoconstriction due to influx of Ca^{2+} into arteriolar smooth muscle or release of vasoconstrictors. Although purely speculative, mechanosensitive channels and other mechanosensitive processes could be a link between mechanical trauma and subsequent metabolic changes and thus be useful targets for future therapies.

CONCLUSIONS

The characteristics of brain edema can range from a pure cell swelling with no observable gain of water, to a gain of water with increased intracranial pressure with or without cell swelling. Cell swelling, principally of astrocytes, probably occurs under normal conditions in a controlled fashion where it may be a concomitant of ion homeostatic processes in the astrocytes, and as such can occur during periods of intense neuronal activity where no pathology occurs (Ransom et al., 1985). However, in a pathological state there is also energy failure and such swelling can be of a sufficiently long duration to be pathological, for any of the reasons discussed in the preceding sections.

Studies related to cell swelling *in vitro* often involve studies on astrocytes, since these, as shown by electromicroscopy, are the major cells that appear swollen in pathological states such as trauma and ischemia. However, this should not be taken to exclude the contribution of other types of cells swelling in cellular edema, and indeed marked dendritic and some axonal swelling was observed in the early electron microscopic work of Van Harreveld (1966).

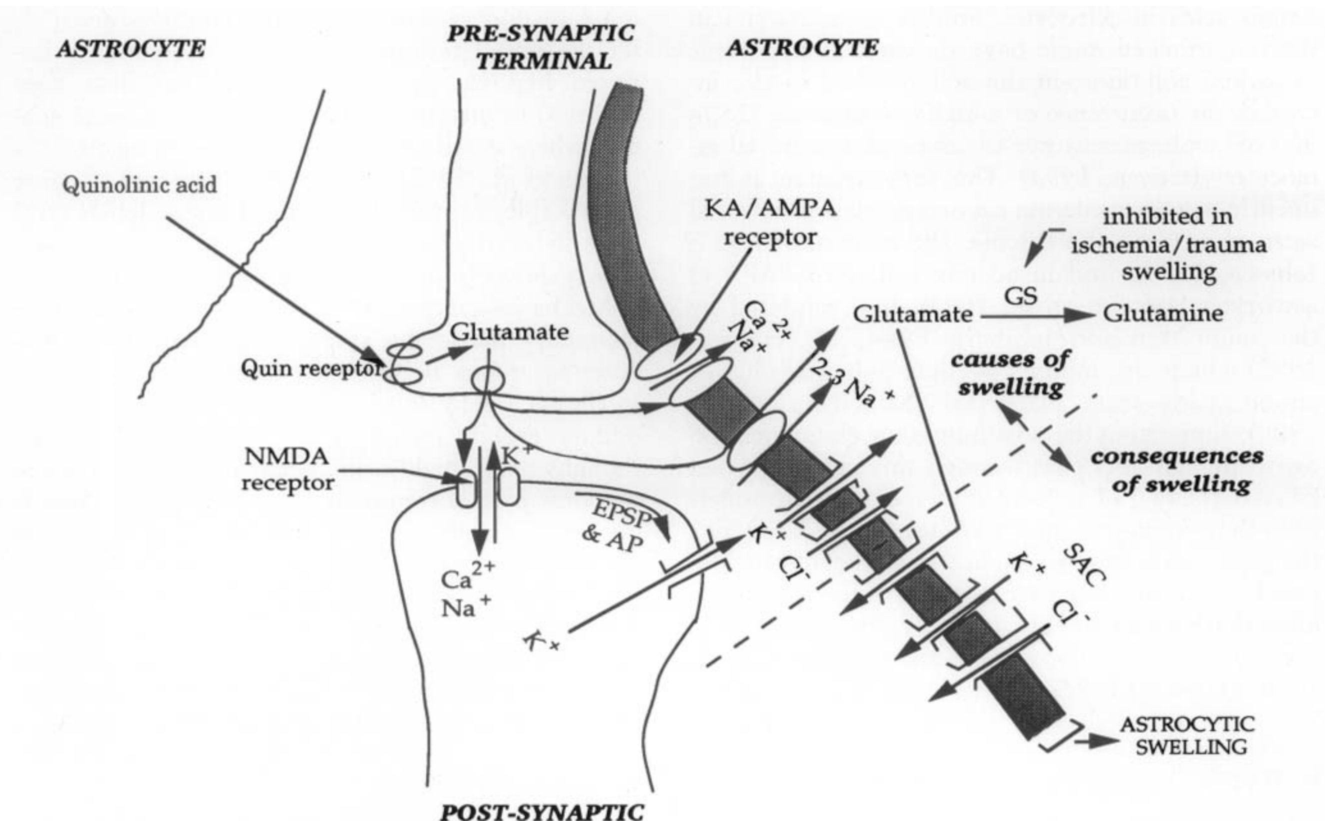

FIG. 61-9. Possible causes and effects of astrocytic swelling on glutamate and K^+ uptake and release by astrocytes. Causes of astrocytic swelling (*upper left of dotted line*) include activation of the astrocytic KA/AMPA receptor by glutamate leading to influx of Na^+ and Ca^{2+}, uptake of excess glutamate with Na^+ and uptake of KCl due to increased $[K^+]_o$ (Donnan uptake). On the *lower, right half of the dashed line* are shown possible consequences of astrocytic swelling. These include increased release of glutamate or KCl, thus short-circuiting these normally protective uptake mechanisms. In addition, the inhibition of glutamine synthetase (*GS*) reported to occur in ischemia which will lead to increased glutamate concentrations in astrocytes is also shown. *SAC*, stretch activated channels.

These other possible cell contributions have yet to be studied in detail. Studies *in vitro* have indicated that astrocytes can swell due to uptake of KCl or glutamate. When exposed to hypotonic solutions astrocytes swell rapidly and then regulate their volume back to normal, that is, they show regulatory volume decrease due to changes in their membrane permeabilities. These include increased permeability to Ca^{2+}, K^+, Na^+, and Cl^-. The release of K^+ and Cl^- occurring after swelling is a major component of regulatory volume decrease. Transport of these ions into and out of astrocytes can contribute to the changes in extracellular ion levels seen in pathological states *in vivo*, namely the marked falls in extracellular Ca^{2+} and Na^+ and increased K^+, seen in ischemia and spreading depression. The increased $[K^+]_o$ will, in turn, lead to cell swelling and thus to the decreased extracellular space measured *in vivo*. Possible deleterious consequences of cellular edema involving astrocytic swelling, include the release of neuroactive agents such as excitatory amino acids, changes in extracellular ion levels and a decreased extracellular space. Possible mechanisms for the swelling-activated release processes have been discussed in this chapter. All these effects are depicted in the speculative scheme shown in Figure 61-9. Successful future therapies for cellular edema occurring in cerebral ischemia and trauma are likely to be more fruitfully addressed when the mechanisms of swelling are better understood, and the benefits of such therapies will be better appreciated when the consequences of astrocytic and other cell swelling are more precisely defined.

During the writing of this chapter I was supported by NIH grants: NS 19492 and NS 23750, and NS 30303 from NINDS. Experimental work from my laboratory quoted in this chapter was supported by NS 23750 and NS 30303. I thank MacKenzie Stewart, Michael Grabowski, and Susan Goderie for invaluable help in preparing this chapter.

62 Epilepsy

UWE HEINEMANN, CLAUDIA EDER, AND ANTJE LAß

Epilepsy is a condition in the human or animal brain where—unrelated to an acute infection or metabolic disorder—seizures occur repetitively. A seizure is a momentary disturbance of neuronal function associated with motor behavioral abnormalities and disturbances of attention, cognition, and consciousness. Seizures are always caused by a strong synchronization of neuronal activity in a large population of central neurons. The seizures may or may not be associated with large increases in average firing rates (Ayala et al., 1973; Kostopoulos et al., 1983). Seizures with strongly increased firing rates account for the typical tonic and clonic contractions of body musculature, provided the underlying activity has recruited the motor system.

Attacks of hyperactivity are not restricted to epilepsy but occur also in neuralgia and causalgias. These are pain syndromes that seem to depend on repetitive firing in nerve fibers. These pain attacks are like convulsant seizures, sensitive to drugs that suppress repetitive firing (e.g., carbamazepine, phenytoin) (Macdonald et al., 1986). Focal or primarily generalized convulsant seizures are, in addition, sensitive to gamma-aminobutyric acid (GABA) mimetic drugs such as the benzodiazepines and the barbiturates (Macdonald et al., 1986).

Status epilepticus is a condition in which seizures recur frequently. In this sense, most acutely induced seizure models are conditions of a status epilepticus. The convulsant status epilepticus is a life-threatening condition due to development of brain edema (Dietzel et al., 1986), changes in blood pH and ionic alterations in the blood plasma, disturbances in circulation and respiratory control (drop of blood pressure), and hormonal regulation. Status epilepticus combined with hypoxia is a condition in which neuronal damage is easily provoked (Meldrum et al., 1993). The convulsant status epilepticus, if not blocked immediately, can become, after some time of ongoing activity, refractory to presently available anticonvulsant drugs, including the barbiturates and benzodiazepines as well as valproic acid.

Usually, seizures can be controlled by anticonvulsant and antiabsence drugs. However, between 10 and 20 percent of epileptic patients do not experience complete control of their seizure disorder by presently marketed drugs. Most drug-resistant seizures are generated in the temporal lobe. These seizures commence most frequently in the hippocampus, but sometimes also in the entorhinal cortex (Wilson et al., 1991). Temporal lobe epilepsy is associated with a reduction of nerve cell numbers in the hippocampal formation, including the entorhinal cortex, the hilus of the dentate gyrus, the cornu ammonis, and the subiculum. The tissue is characterized also by a proliferation of glial cells (hippocampal sclerosis) (Sloviter, 1983).

The processes that render the brain prone to the generation of seizures are often unknown. Disturbances in cell migration and maturation of neurons, induction of malformations such as microgyri, double cortex with a preserved subcortical plate, and survival of normally transient cells such as the horizontal cells in the neocortex and hippocampus, are among the developmental abnormalities involved in epileptogenesis (Wolf et al., 1993). Increased frequencies of surviving horizontal cells are also found in genetically determined epilepsies such as the absences (Meencke et al., 1984; Meencke, 1987). Lesion-induced alterations in the central nervous system often also underlie epileptogenesis. These include trauma, infection, and hypoxia- or ischemia-induced lesions, as well as to changes observed after some forms of status epilepticus (Kapur et al., 1989). Tumors are also often the cause of seizures. In a great number of epilepsies even a detailed morphological analysis does not reveal obvious causes of seizures (Wolf et al., 1993). These are therefore most likely dependent on functional alterations in nerve cells and glia.

Glial cells may well be involved both in epileptogenesis as well as in ictogenesis. Focal or global alterations in radial glia may be critical for migration and maturation disturbances (McConnell, 1991; O'Rourke et al., 1992; Roberts et al., 1993). Microglial activation causes neurodegenerative alterations with stripping of dendritic contacts (Gehrmann et al., 1991) and immunological reactions that may damage the neurons. They also could be involved in the formation of reactive astroglia. Factors released

from astroglia and microglia might affect the neuronal behavior and precipitate seizures, for example, due to blockade of potassium and activation of calcium currents (Plata-Salamán et al., 1992; Relton et al., 1992; Plata-Salamán et al., 1993). Alterations in oligodendroglia may be involved in the generation of action potentials in ectopic sites comparable to neuralgias. Disturbances in glial cell metabolism might affect the synthesis of the inhibitory neurotransmitter GABA. Glial changes in excitatory amino acid transport may be involved in the generation of seizures (Barbour et al., 1989; Flott et al., 1991; Piani et al., 1993). Changes in spatial potassium buffering as well as alterations in K^+ homeostasis may contribute to the generation and spread of seizures (Grisar, 1986; Yaari et al., 1986). Release of growth factors could affect sprouting, increase excitatory coupling, and thereby contribute to the formation of an epileptogenic zone.

Epilepsy as a condition for augmented readiness to generate seizures is often not stable. As a rule of thumb, 30% of epilepsies heal, 30% remain stable, and 30% become worse. This may involve the transition from nonconvulsant seizures, such as petit mal seizures, to convulsant primarily generalized or partial seizures with secondary generalization or the transition from drug-responsive to drug-resistant seizures. None of the presently available drugs prevents the progression from drug-sensitive to drug-resistant seizures nor the development of seizures following brain lesions. A reasonable percentage of these patients is treated with some success by surgery. This provides us with a good source of tissue in which alterations of neuronal and glial function, possibly leading to seizures or providing for an augmented readiness to generate seizures, can be studied.

MECHANISMS UNDERLYING SEIZURE GENERATION

Seizure generation (ictogenesis) and epileptogenesis are two different processes. Epileptogenesis is the process underlying a change in neuronal and glial cells, as well as in network properties, which facilitates the generation of seizures. Ictogenesis is the actual process of generation of relative short disturbances of neuronal function, in which many nerve cells are synchronously active. These states are often associated with neuronal "hyperactivity." Primarily generalized seizures are considered as different from focal and eventually secondarily generalized seizures. Primarily synchronized seizures are fits that display a simultaneous onset of seizure activity in electroencephalographic (EEG) recordings from both hemispheres. They can be of convulsant and nonconvulsant nature. Focal seizures commence in a circumscribed area and then eventually recruit more and more of the central nervous system into seizure activity.

A seizure is likely to occur when the balance between excitation and inhibition is disturbed. This balance is often intact between seizures. The balance between excitation and inhibition is organized on two levels: the synaptic and the cell intrinsic levels. On the synaptic level, either disturbance of GABA function or augmentation of glutaminergic function are essential. Thus a reduced production of GABA (Meldrum, 1989), diminished excitability of GABA-ergic cells (Bekenstein et al., 1993), diminished GABA release, alterations in postsynaptic receptors (Kamphuis et al., 1989; Kamphuis et al., 1991), disturbance of the intracellular chloride regulation (Lux et al., 1970; Loracher et al., 1974), and changes in the transmembrane K^+ concentration gradient (Rausche et al., 1989) are all conditions that promote the generation of seizures. Glial cells may contribute to this disturbance by augmented uptake or consumption of GABA. Experimentally, GABA antagonists, drugs that block GABA synthesis and drugs that interfere with the GABA-dependent chloride currents by depression of Cl^- extrusion from cells, are capable of inducing seizures (Lux et al., 1978; Heinemann et al., 1989).

Similarly, the main excitatory neurotransmitter glutamate may be released in excess. This would occur when action potential generation occurs at branching points and in or near presynaptic endings at ectopic sites (Gutnick et al., 1972). Moreover, the number of excitatory nerve cell terminals may be increased (Sutula et al., 1988), the number, affinity, or gating mechanisms of glutamate receptors may cause increased postsynaptic currents (Walther et al., 1986), and changes in the transfer from dendritic sites of information pick up to the nerve cell soma due to changes in passive and/or active dendritic properties would also augment synaptic excitatory coupling (Kuno et al., 1970). Obviously, reduced glutamate uptake will increase extracellular glutamate levels and thereby eventually affect synaptic excitatory transmission. Synaptic stripping by microglia, the generation of dendritic action potentials and changes in the extracellular resistance, and thereby in the dendritic transfer function, will all cause augmented excitatory synaptic coupling and contribute to epileptogenesis. Indeed the excitatory action of glutamate has been discovered by showing that glutamate and its agonists precipitate seizures (Curtis et al., 1970). Activation of NMDA receptors

by reduced extracellular Mg^{2+} also contributes to seizure generation (Walther et al., 1986).

The balance of synaptic excitation and inhibition has a counterpart on the intrinsic cell level. Excitatory currents such as Na^+, Ca^{2+}, and unspecific cation currents are controlled by repolarizing voltage and Ca^{2+}-dependent K^+ or Cl^- currents. Again, blockade of these inhibitory currents by 4AP and TEA, for example, will precipitate epileptiform activity (Baranyi et al., 1979; Schwartzkroin et al., 1980) as do agents that remove inactivation of Na^+ currents. Chloride currents depend strongly on the transmembrane Cl^- concentration gradient. Agents that block Cl^- extrusion from cells cause an increase in intracellular Cl^- concentration and weaken Cl^- influx when Cl^- currents are activated, augmenting the risk of seizures. Indeed hydrazines and ammonium are well known to block chloride extrusion and contribute to seizure generation (Lux et al., 1986). A change in the transmembrane K^+ concentration gradient by reducing K^+ outward currents contributes to seizure generation and can, in some cases, underlie ictogenesis (Konnerth et al., 1984; Traynelis et al., 1988). Also, blockade of Ca^{2+}-dependent K^+ currents can be involved in the generation of seizures (Hablitz, 1981).

Finally, changes in the expression of ionic channels may be important to increase epileptogenicity. Thus increased expression of currents involved in burst discharges, such as Ca^{2+} and persistent Na^+ currents, may increase the number of burster cells in the central nervous system. Such changes, as well as downregulation in K^+ currents, will also augment synaptic input to dendrites and affect the dendritic integration properties.

Changes in ion homeostasis due to neuronal activity and alterations in oligodendrocyte or astrocyte function will eventually also contribute to augmented epileptogenesis. Thus reductions in $[Ca^{2+}]_0$ and $[Mg^{2+}]_0$ augment glutamate currents, particularly those mediated by NMDA receptors (Köhr et al., 1988) and increase neuronal excitability (Mody et al., 1988). Increases in $[K^+]_0$ will shift the reversal potential of glutamate currents to more depolarized levels, with a subsequent increase in glutamate current amplitude (Heinemann et al., 1990).

Glial cells can affect the balance between excitation and inhibition in many ways. The synaptic content of GABA and glutamate depends on glial metabolic activity. Thus glial cells may be stimulated to create more energy-rich particles. This will eventually lead to a reduction in the glial—and subsequently also neuronal—GABA pool. On the other hand, augmented release of glutamine will help nerve cells in the production of glutamate and thus contribute to seizure generation.

Glial cells may play a role in ictogenesis not only by affecting the extracellular glutamate and GABA levels and the ionic homeostasis. Glial cell swelling will decrease the extracellular space size and eventually augment extracellular ionic changes and transmitter levels. Decreases in extracellular space size have recently been shown to contribute to seizure recruitment (Dudek et al., 1990).

Glial cells, moreover, play an important role in detoxification. It is not inconceivable that during seizures free radicals are produced. The detoxification of free radicals depends on intracellular glutathione levels (Murphy et al., 1989; Vornov et al., 1991). Alterations in glutathione levels present in glial and nerve cells will affect the detoxification. This in turn may have effects on neuronal excitability. Production of nitric oxide and carbon monoxide is also dependent in some brain regions on glial function (Boje et al., 1992; Lafon-Cazal et al., 1993; Liu et al., 1993; Ruppersberg et al., 1993; Sagara et al., 1993). Since these agents are thought to promote presynaptic glutamate release (Stevens, 1993) this would affect neuronal transmission. They often also activate enzyme systems, which in turn affect neuronal excitability.

Between seizures the central nervous system often works completely normal, indicating that many of the above changes are secondary to conditions that result from a more or less arbitrarily occurring disregulation. One factor possibly of importance is the release of stress-related hormones such as corticotropin-releasing hormone or gluco- and mineralocorticoids (Nomizu et al., 1989; Joels et al., 1990; Baram et al., 1991). Effects of sexual steroids on GABA receptors (Harrison et al., 1987; Turner et al., 1989; Chvátal et al., 1991) may also play a role in such disregulatory behavior. Sleep-related changes in the release of catecholamines may be of similar importance (Chauvel et al., 1986; Wada et al., 1993).

PRINCIPLES OF SEIZURE GENERATION

Seizures are generally classified with respect to generalization (primarily, secondarily), behavior characteristics (absence, petit mal, grand mal), type of motoric symptoms (drop attacks, Jacksonian march, etc) and with respect to site of origin (temporal, frontal, simple, complex, etc). An important classification may also be based on pharmacological responsiveness. Thus, petit mal seizures are sensitive to drugs that block T-type Ca^{2+} channels (Coulter et al., 1989), while grand mal seizures are sensitive to

drugs that augment GABAergic function or reduce repetitive firing by interference with sodium channels (Macdonald et al., 1986). It seems that most anticonvulsant and antiabsence drugs have more than one action, a reason why these agents in fact can be used in a broad group of disorders.

Seizures can be induced by all drugs that interfere with the balance between inhibitory and excitatory mechanisms. The symptoms of such drug-induced seizures depend on the route of application. Systematically applied convulsants lead to primarily generalized nonconvulsant or convulsant activity. Focal application causes local disturbances with locally induced hyperactivity. The symptoms evolving from a seizure relate not only to consciousness and motor symptoms but also may affect emotional and memory functions. They depend on the area of disturbance. Thus analysis of seizures and of their morphological, electrophysiological and psychological correlates promote an insight into brain function.

When convulsants are systemically applied, the locus minoris resistentiae for induction of seizures seems to be the thalamus. When the dose is low, absence-like seizures ensue. These exploit local rhythm generating mechanisms of the thalamus. Thalamocortical projection neurons express transient Ca^{2+} currents. These are activated by depolarization. These channels show a voltage-dependent inactivation and a sufficient hyperpolarization both with respect to amplitude and duration is required for removal of inactivation (Carbone et al., 1984). Depolarization of thalamic neurons to about −50 mV sets the condition for rhythm generation. Then an inhibitory potential triggers a low threshold Ca^{2+} spike due to removal of Ca^{2+} current activation. This in turn elicits a burst of 1 to 3 action potentials (Jahnsen et al., 1984), which reach the cortex and the nucleus reticularis thalami (NRT). Each cell in the NRT generates long-lasting inhibitory postsynaptic potentials (IPSPs) in a large group of thalamic projection neurons. These IPSPs remove again the inactivation of Ca^{2+} channels and upon termination of an IPSP a new low threshold Ca^{2+} spike is generated with subsequent generation of sodium-dependent action potentials. The projected activity into the cortex causes activation of cortical columns. Their lateral connections and the projections back into the thalamus help in synchronization. Under these conditions cortical neurons display large IPSPs (Kostopoulos et al., 1983). This is why some authors consider these seizures as inhibitory in nature.

If the thalamus is activated more strongly, primarily generalized convulsant seizures ensue. These are no longer only characterized by augmented inhibition and by an abnormal synchronization but by high-frequency discharges (Gutnick et al., 1975; Heinemann et al., 1979). It was assumed initially that this activity represents the recruitment of the thalamus from the neocortex into seizure activity. However, it was later shown that seizure-like events can also be induced in isolated thalamic nuclei (Heinemann et al., 1979). Interestingly, stimulation of afferent fibers in the lemniscus does not cause seizure-like events in the thalamus. This may be related to the fact that such stimulation does not cause major ionic changes in the thalamus. Thus neither slow DC field potentials nor larger ionic changes of $[K^+]_0$ can be caused by afferent stimulation (Gutnick et al., 1979). The reasons for this resistance are not quite clear. It may be speculated that the particular organization of glial cells ensheathing synaptic glomeruli plays an important part in this protective role. Differences in expression of K^+ channels and the fact that all afferent fibers to the thalamus are relatively fast-conducting and well-myelinated may be important too.

Focal convulsant application in the neocortex leads to local interictal and ictaform events with typical associated DC and ionic changes. The interictal discharges depend intracellularly on unitary depolarizations of the neuronal membrane paroxysmal depolarization shift [PDS] (Matsumoto et al., 1964). These events are usually initiated in layer 4 to 5 where pacemaker cells have been found (Gutnick et al., 1982). They recruit the deep and if inhibition is impaired also related superficial neurons into the abnormal activity. The PDS represents therefore usually giant EPSPs with components of non-NMDA and NMDA receptor-mediated components.

The generation of seizures depends on the rapid succession of interictal discharges sometimes driven by peripheral input. Positive feedback can also be provided by backfiring of secondarily recruited areas in the zone of interictal activity (Jones et al., 1990).

Seizurelike events are characterized by prolonged depolarizations of neuronal elements to about −30 mV and sustained slow shifts of the extracellular field potential and the EEG. These slow shifts are superimposed by high-frequency low-amplitude transients during the tonic phase and large-amplitude low-frequency during the clonic phase. Intracellularly the clonic afterdischarges are similar to PDS superimposed on a slowly repolarizing membrane potential transient. Tonic and clonic activity refer to the fact that in a freely behaving animal or in man such episodes are associated with tonic and clonic muscle contractions, provided such activity has recruited the motor cortex.

The tonic phase represents an episode of sustained neuronal depolarization, while PDS-like afterdis-

charges underlie the generation of clonic-like electrographic events. Both seizure-like events and interictal-like activity can be studied also in *in vitro* slice preparations. Initially, such preparations displayed only interictal-like discharges. Meanwhile, a number of *in vitro* seizure models exist with a comparable seizure phenomenology as that observed in man and in experimental animal models.

IONIC CHANGES DURING SEIZURES

Primarily generalized and focal convulsions are characterized by marked changes in the ionic environment. During interictal discharges in intact animals rises in $[K^+]_0$ by up to 2 mM have been observed. $[Ca^{2+}]_0$ may decrease by 0.1 to 0.3 mM. However, not all interictal discharges are that large. Thus we find in entorhinal cortex slices that only the interictal discharges immediately before a seizure are associated with such ionic alterations. The interictal discharges before are associated with much smaller ionic changes. Likewise in *in vitro* models of hippocampal epilepsy only small rises in $[K^+]_0$ by about 0.3 mM are seen during recurrent short discharges considered by many as models of interictal activity. This might suggest that there are two types of interictal discharges: one which is a precursor of convulsant activity and one which represents a state of activity preventing development of ictaform activity. Indeed, blocking of generation of short recurrent discharges in the hippocampus sometimes leads to generation of seizurelike events (Swartzwelder et al., 1987).

These seizure-like events are accompanied by rises in $[K^+]_0$ to about 10 mM in the neocortex and to about 12 mM in the hippocampus. $[Na^+]_0$ may decrease by about 15 mM, $[Ca^{2+}]_0$ by up to 0.6 mM in iatrogenically induced seizures and by more than 1 mM during photically induced seizures in the photosensitive baboon. $[Cl^-]_0$ may decrease by up to 10 mM or increase during a seizure. Seizures are further associated with decreases in $[Mg^{2+}]_0$ and by acidic pH shifts. Each seizure is associated with a decrease in ES size by up to 50 percent in cats and by about 20 percent in rats. These decreases in ES size are due to transmembrane ion fluxes. The difference in ES size changes might be related to differences in the average length constant of a glial syncytium. The glial syncytium in cat neocortex is assumed to have a longer length constant than that in rat neocortex (Gardner-Medwin, 1981).

The ionic changes can be shown to produce a number of effects that promote the generation of seizures. Rises in $[K^+]_0$ reduce often voltage, Ca^{2+}, and transmitter-activated outward currents including those activated by GABA via $GABA_B$ receptors (Rausche et al., 1989; Ficker et al., 1992). Rises in $[K^+]_0$ augment spontaneous transmitter release. Glutamate currents become more effective upon rises in $[K^+]_0$ due to a depolarizing shift of the reversal potential. Moderate increases in $[K^+]_0$ therefore promote excitatory synaptic transmission (Rausche et al., 1990). Decreases in extracellular Ca^{2+} augment neuronal excitability due to shifts in the steady-state activation behavior and reduced surface charge screening. Evoked synaptic transmission is also sensitive to reductions in $[Ca^{2+}]_0$. Synaptic inhibition tends to fail before excitatory synaptic transmission (Jones et al., 1987). In addition lowering of $[Ca^{2+}]_0$ has promoting effects on activation of NMDA receptors, a subclass of glutamate receptors, which may be important in some forms of epilepsy (Köhr et al., 1988). Decreases in extracellular space size are also important. Thus, it has been shown that lowering of $[Ca^{2+}]_0$ elicits seizure-like events in the CA1 field of the hippocampus (Haas et al., 1984). When the extracellular space is shrunken by appropriate measures, also other structures are capable to produce seizure-like events upon lowering of $[Ca^{2+}]_0$ (Dudek et al., 1990). Interestingly, seizure-like events produced by lowering extracellular Ca^{2+} persist when evoked synaptic transmission is blocked. Under this condition, seizure-like events can even spread. The mechanisms of seizure spread seem to depend on extracellular K^+ accumulation. Indeed, simultaneous measurements of rises in $[K^+]_0$ and local seizure onset show that rises in $[K^+]_0$ precede local seizure onset. Three arguments point to a role of potassium in precipitation of low Ca^{2+} seizures: When $[Ca^{2+}]_0$ is lowered in the presence of low potassium levels the point of seizure onset occurs later or not at all. When seizures are induced by local stimulation, seizures commence only when $[K^+]_0$ is increased to between 5 and 6 mM. Finally, local injection of K^+ induce seizure-like events only when $[K^+]_0$ is increased to levels near 5 mM. These findings suggest that seizure spread under conditions of blocked chemical synaptic transmission occurs due to potassium release from activated cells into its surround. Indeed, the rises in $[K^+]_0$ commence often long before seizures ensue and before local neuronal activity increases.

CONTRIBUTION OF SPATIAL K^+ BUFFERING TO K^+ REGULATION DURING SEIZURES AND GENERATION OF SLOW NEGATIVE FIELD POTENTIALS

It was quite early recognized that glial cells may serve a function in $[K^+]_0$ homeostasis (Kuffler et al.,

1966). During a single action potential, :$[K^+]_0$ increases by 0.01 to 0.02 mM (Heinemann et al., 1975). If cells fire with high discharge frequencies this would amount to a dramatic increase in $[K^+]_0$. For example, nerve cells fire during a seizure with frequencies up to 200/s for periods as long as a minute. Provided there were no K^+ regulation, this would amount to a K^+ accumulation of some 50 mM. Rises in $[K^+]_0$ during a seizure are limited to about 12 mM in the hippocampus and to about 1 mM in neocortical structures. Three mechanisms can contribute to the limitation of rises in $[K^+]_0$: Na-K-ATPase activation, KCl cotransport into glial cells and spatial redistribution of K^+ through glial cells from sites of maximal neuronal activation into the less active surround (Figure 62-1). In chronic epileptic tissue the glial sodium potassium ATPase seems to be altered (Grisar, 1984). For spatial K^+ buffering through glial cells three requirements are necessary:

1. K^+ elevations should not be homogeneous throughout all cortical layers. This is the case during seizure activity (Dietzel et al., 1980).
2. Glia cells must respond with a near Nernstian depolarization to elevations in $[K^+]_0$ (Lothman et al., 1975).
3. Glial cells must be spatially extended and/or electrically coupled.

Under these circumstances glial cells will locally be depolarized by K^+ accumulation. This depolarization will spread along the surface of glial cells and propagate electrotonically into neighboring cells through gap junctions. As a result the depolarization of the glial cell will be smaller than expected from the K^+ equilibrium potential and a driving force for K^+ uptake into glial cells will develop. At remote sites the glial cells will be depolarized more than expected from local K^+ accumulation and therefore K^+ will be released. Due to the uptake of K^+ into glia negative field potentials at the site of maximal K^+ accumulation will develop, while at sites of maximal K^+ accumulation a positive slow field potential will appear. The extracellular potential gradient leads to a current flow from remote sites into the active focus. This will be carried predominantly by the majority ions Na^+ and Cl^- according to the respective concentration and ion mobility. This results in a charge transfer with Na^+ ions moving to the site of

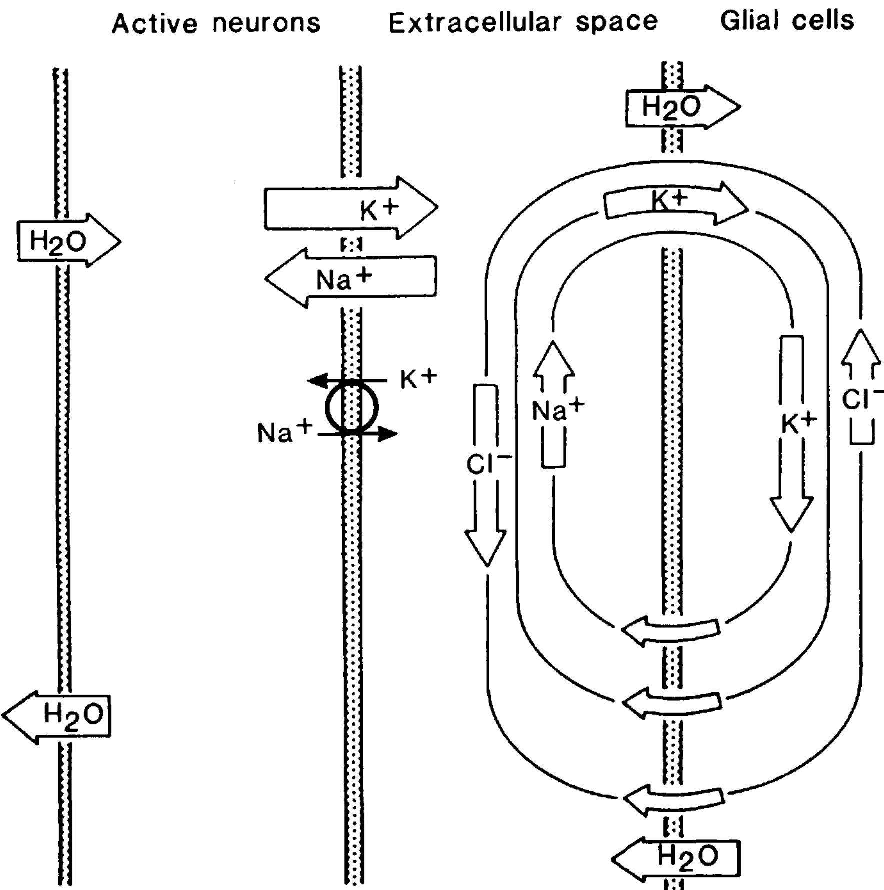

FIG. 62-1. Scheme of spatial K^+ buffering. *Open arrows* indicate concentration driven or current transport. The K^+ transport into glia creates a negative extracellular field potential, the K^+ release from glia creates a positive field potential. Due to current transport effects (current in biologic media is carried by cations and anions) the number of K ions taken up into glia is not fully substituted by Na ions. This results in osmotic imbalances leading to changes in the size of the extracellular space.

maximal K^+ accumulation and chloride ions moving away from such sites. As a result of this transport number effect not all K^+ ions moving into glia will be substituted by Na^+ ions and an osmolar imbalance develops, leading to water uptake into glia and shrinkage of the extracellular space (Figure 62-1).

A causal role for rises in $[K^+]_0$ in the generation of slow negative fp has been suggested by a number of observations:

1. Pharmacological treatments (barbiturates, phenytoin, etc), which reduced the changes in $[K^+]_0$, also reduced the amplitude of the slow negative fp's.
2. Experimental procedures which produced decreases in $[K^+]_0$ were associated with generation of positive fp (Heinemann et al., 1975).
3. Artificial increases of $[K^+]_0$ by iontophoresis, pressure application or superfusion always induced slow negative fp (Heinemann et al., 1984).
4. At sites where the negative fp were the largest, the changes in $[K^+]_0$ were also maximal that is, in the dorsal horn of the spinal cord (ten Bruggencate et al., 1974), the middle cortical layers of neocortex the stratum pyramidale of hippocampus (Benninger et al., 1980), the stratum granulare of the dentate gyrus, or the stratum moleculare in the cerebellum (Nicholson et al., 1978). As expected from the spatial buffer hypothesis slow fp's recorded at sites remote from those where the maximal increases in $[K^+]_0$ occurred were usually positive in polarity.

The extent by which glial cells contribute to the generation of slow fp is difficult to estimate because for many neuronal types long dendritic trees may be oriented in parallel to the K^+ concentration gradient in the tissue. This applies, for example, to the hippocampus and the neocortex. Prolonged depolarization of pyramidal cell somata may lead to a charge transfer into the passive dendrites with a current sink at the soma level and a current source at remote sites. We have recently therefore studied the relationship between the CSD density distribution of slow field potentials and changes in $[K^+]_0$ in rat hippocampal slices. We found that alvear stimulation resulted in two current sinks: one at the site of maximal K^+ accumulation and one in the stratum radiatum. Blockade of synaptic transmission by lowering $[Ca^{2+}]_0$ or by application of a cocktail of glutamate antagonists reduced the current sink in the stratum radiatum but left the current sink in the stratum pyramidale largely unchanged, that is, the layer where rises in $[K^+]_0$ were maximal. Conversely, when we reduced glial cell K^+ conductances by application of Ba^{2+} (Grafe et al., 1987) the current sink in the stratum pyramidale disappeared, while the current sink in stratum radiatum was still present (Figure 62-2). As predicted from the spatial K^+ buffer hypothesis glial membranes were in the stratum pyramidale slightly less depolarized than expected from the Nernst equation for the simultaneously measured rises in $[K^+]_0$ in this layer, while at remote sites the transmembrane glial potential was bigger than expected for a Nernstian depolarization of glial cells with the local measured rises in $[K^+]_0$ (Albrecht, Luxemburger-Weber, Leweke, and Heinemann, in preparation).

K^+ REDISTRIBUTION THROUGH GLIAL CELLS DURING EPILEPTIFORM ACTIVITY

A further analysis of the current source distribution was therefore made with respect to the question how much potassium could be shifted through the glial syncytium during seizures in cat neocortex and rat

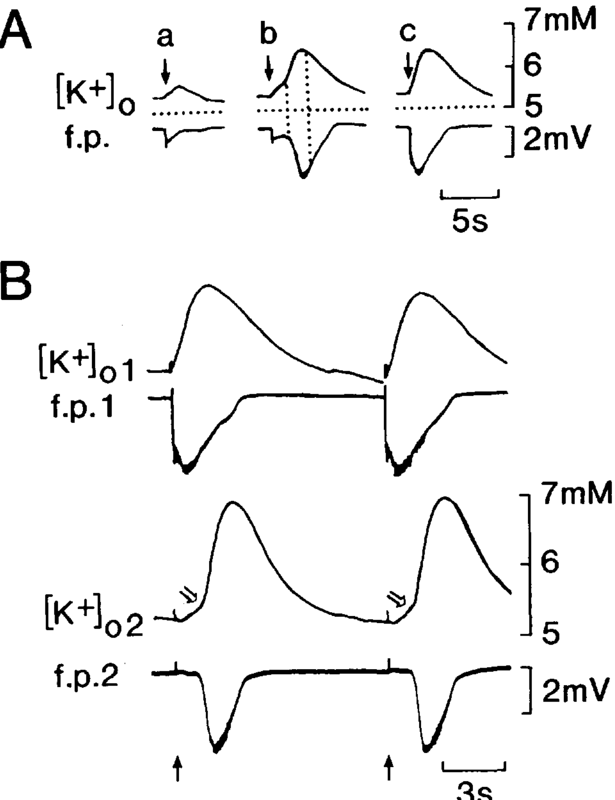

FIG. 62-2. Induction of low Ca^{2+} seizures depends critically on extracellular K^+. (A) Stimulus-induced discharges develop into spreading discharges only when critical K^+ concentration is surpassed. Recording in area CA1 with a K-sensitive microelectrode during nearby stimulation of SP. *a–c*: increasing stimulus intensities. (B) Simultaneous records of single stimulus-induced spreading epileptiform discharges in rat area CA1. Note that the discharge at recording position 2 commences considerably after the onset of the first discharge. The secondary response is preceded by a rise in extracellular $[K^+]_0$.

hippocampus. While in cat cortex this amounts to about a millimole per second, the value was considerably higher in the hippocampus.

To test the effectiveness of spatial K^+ buffering during low Ca^{2+}-induced epileptiform activity, we measured the changes in $[K^+]_0$ occurring during these seizures in the hippocampal area CA1 and the functionally uncoupled but neighboring dentate gyrus (Figure 62-3). As during stimulus-induced seizures, rises in $[K^+]_0$ were largest in the stratum pyramidale of area CA1 with a decline in amplitudes toward stratum radiatum. However, transient changes in $[K^+]_0$ could still be measured in the dentate gyrus (Albrecht et al., 1989). This suggests that spatial K^+ buffering is effective in redistributing $[K^+]_0$ in the three dimensions of space.

The interesting aspect of this type of activity is that it can still spread, although this type of activity persists under conditions where synaptic transmission is blocked. At sites that are secondarily recruited into seizures, the seizures are preceded by rises in $[K^+]_0$. It is possible that such rises are sufficient to trigger epileptiform activity. Indeed, artificial focal application of K^+ can trigger a spreading epileptiform event.

It seems that in addition to spatial buffering the generation of slow field potentials is also involved in the spread and induction of this type of activity. This is suggested by the finding that the field potential gradients are in the order of 40 mV/mm. Such gradients are experimentally sufficient to excite cells as has been shown for the dentate gyrus and the cerebellum (Jefferys, 1981; Hounsgaard et al., 1989). The field potential gradients can be reduced by superfusing the slices. This will short-circuit the field potential gradients along the dendritic trees of hippocampal pyramidal cells. It can be shown that such maneuvers block the low Ca^{2+}-induced epileptiform activity. Thus it appears that spatial K^+ buffering by redistribution of $[K^+]_0$ and by contribution to generation of slow field potentials contributes to the nonsynaptic spread of seizure activity. This contribution will, however, vary dependent on the spatial voltage gradients associated with K^+ buffering. These are in the order of 10 to 12 mV/mm in the thalamus and less than 10 mV/mm in the neocortex but may increase under conditions of brain edema.

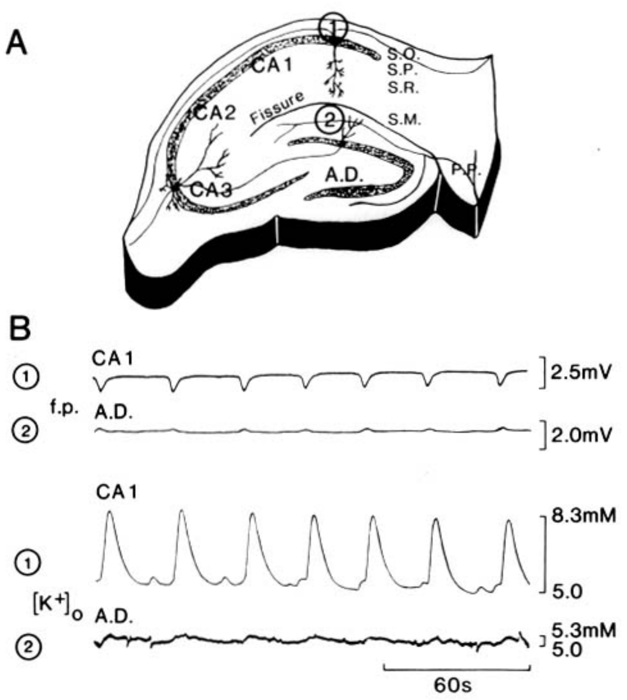

FIG. 62-3. Simultaneous record of seizure-like events in area CA1 and the dentate gyrus. The dentate gyrus does not actively participate in the SLEs. Yet each positive field potential in the dentate gyrus is associated with a small increase in $[K^+]_0$. Recording positions as in the inset.

SPATIAL K^+ BUFFERING IN CHRONIC EPILEPTIC TISSUE

That the gliosis often associated with an epileptogenic area contributes to seizure generation is suggested by the fact that surgical removal of such areas cures often the epileptic disorder. Indeed, the clinical observation of a shrunken hippocampus is taken as evidence for a seizure initiation site.

Since chronic epileptic foci are characterized by a considerable gliosis the question arises whether gliosis contributes to epileptogenesis by failure in K^+ regulation. This is very likely not the case. In glial tissue of this type K^+ accumulation is normal. The generation of slow field potential shifts by artificially increasing extracellular potassium still works. Also an indirect test for spatial K^+ buffering suggests that these cells are probably efficient in buffering extracellular K^+. This test is based on the transport number effect (Gardner-Medwin, 1980). If a DC current is applied through the cortex, ions move with the current according to mobility and concentration. Measurements of changes in $[K^+]_0$ show that the change in $[K^+]_0$ is much larger than expected from the transport number. This can be explained when it is assumed that some of the current moves through the relative low ohmic glial cells which express predominantly K^+ channels in their membrane. If such a test is applied to gliotic tissue the observed changes in $[K^+]_0$ are somewhat larger than in normal tissue suggesting that glial cells buffer potassium more ef-

fectively. This may very well facilitate the spread of epileptiform activity in such tissue.

The situation may, however, be different in chronic temporal lobe epilepsies with a sclerotic hippocampus. This is characterized by a profound gliosis. Recently, it has been reported in one model of chronic temporal lobe epilepsy produced by application of kainate that the reactive astrocytes are positive for markers of astrocytes type II (Represa et al., 1993). This marker indicates in tissue culture conditions and in the rat optic nerve astrocytes derived from a common precursor cell with oligodendrocytes. Whether the properties of such astrocytes differ with respect to K^+ regulation is unknown. One might also hypothesize that these cells have different properties for glutamate and GABA uptake and different capability for release of excitability modulating agents.

EPILEPTOGENESIS IN JUVENILE TISSUE

The readiness of a given area of the brain to generate seizure-like events varies with age. Thus it has been shown in *in vitro* preparations that seizure-like events are more readily generated in juvenile than in adult tissue. These seizure-like events are accompanied in the neocortex and hippocampus by abnormally large rises in $[K^+]_0$ (Hablitz et al., 1987; Hablitz et al., 1989). We have looked into the hippocampus to see whether this is related to any morphological alterations. It was found that GFAP-positive astrocytes are in the first week postnatally mostly restricted to the alveus and the molecular layer. The stratum radiatum has normal cells numbers for GFAP positive astrocytes at about 2 weeks after birth, while close to the stratum pyramidale it takes about 3 weeks to reach adult cell numbers (Nixdorf, Albrecht, and Heinemann, in preparation). However, in this age there is still abnormal K^+ accumulation, suggesting that glial cells are still unable to buffer extracellular potassium concentration. This might be related to a delayed maturation of glial cells in terms of expression of K^+ channels. Moreover, there is evidence that young astrocytes express glutamate and GABA receptors, with the possible result that the cells are depolarized by neurotransmitters (Blankenfeld et al., 1991; Steinhäuser et al., 1992). This would interfere with spatial K^+ buffering. When we tested for responses in gliotic tissue following exposure to kainate or in gliotic tissue near a scar focus we found however no effects of glutamate and GABA on extracellular ionic changes suggesting that spatial K^+ buffering is not hampered by such affects in gliotic tissue (Heinemann et al., 1984).

GLIAL CELLS AND pH REGULATION

Recently, there was considerable interest in the regulation of extracellular pH. It is now clear that glial cells contribute to changes in pH (see Chapter 14). Changes in pH in turn promote or reduce the probability of seizure generation. Thus alkalosis is proconvulsant by promoting activation of NMDA receptors and of voltage regulated ion channels. Acidosis in turn is considered to be anticonvulsant (Caspers et al., 1987). So far, nobody has looked at whether pH regulations is altered in chronic epileptic tissue. However, alterations in carbon anhydrase properties have been reported for gliotic tissue (Guillaume et al., 1991).

PROPERTIES OF GLIAL CELLS FROM DIFFERENT TYPES OF EPILEPTIC TISSUE

Surgery from epileptic patients has provided us with human material coming directly from such patients. It is possible even from poorly preserved specimens to cultivate glial cells. If intracellular Ca^{2+} is monitored in such cultures spontaneous and glutamate-induced oscillations are observed, which spread through the glial syncytium. The claim has been made that such Ca^{2+} waves differ in cultures coming from the surround of tumors and from epileptic tissue. However, convincing statistical material has not yet been presented.

STATUS EPILEPTICUS AND GLIAL CELLS

One of the biggest risks in terms of mortality for a patient who suffers from epilepsy is that he develops a convulsant status epilepticus. Usually a status epilepticus can be well controlled by immediate infusion of phenytoin or benzodiazepines. However, if the condition lasts for some time the risk is that the seizures become pharmacologically uncontrollable with presently available drugs. This condition can be mimicked in cortical slice preparations. If seizure-like events are induced by lowering extracellular Mg^{2+} and subsequent facilitated activation of NMDA receptors for glutamate seizure-like events develop in entorhinal cortex slices and in the neighboring subiculum as well as in the neocortical portions of the temporal lobe (Dreier et al., 1991) (Figure 62-4). These seizure-like events recur very frequently and thus mimic a status epilepticus. Initially these seizure-like events respond to classical anticonvulsants. However, after some time of exposure to low Mg^{2+}-containing artificial cerebrospinal fluid interictal discharges and clonic like after

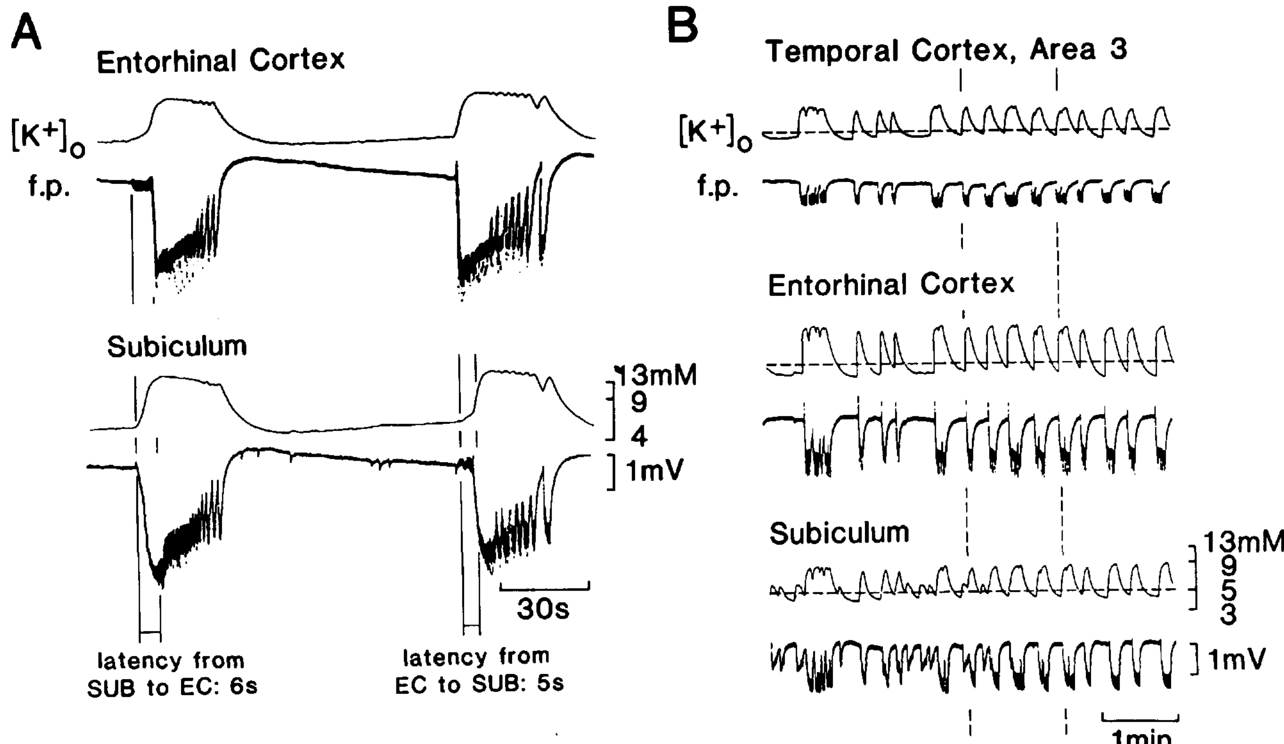

FIG. 62-4. Different patterns of epileptiform discharges in rat entorhinal cortex slices. SLEs were induced by lowering $[Mg^{2+}]_0$. (A) SLEs characterized by tonic- and cloniclike electrographic discharges. Note changing focus from the subiculum to the EC. Note that each structure, before being recruited into seizure activity, shows a rise in $[K^+]_0$. (B) Late epileptiform discharges in the entorhinal cortex slice with simultaneous activity in three different areas. This activity does not respond to clinically employed classical anticonvulsants, but responds to GABA and GABA uptake blockers.

discharges disappear. The frequency of discharges increases dramatically. These events are no longer controlled by presently marketed anticonvulsants (Heinemann et al., 1991). They also do not respond to AMPA-type receptor antagonists, although they are still sensitive to NMDA receptor antagonists. This condition can be induced immediately when GABA receptor antagonists are applied together with the low Mg^{2+} medium. This suggests that a failure in GABAergic neurotransmission is involved in the transition from the drug sensitive to the "drug-resistant" form of status epilepticus. Indeed, drugs that augment postsynaptic GABA actions, such as barbiturates and benzodiazepines, are ineffective in controlling these seizures. However, GABA, the $GABA_A$ receptor agonist muscimol and the $GABA_B$ receptor agonist baclofen can still block this activity. Thus changes in the efficacy of $GABA_A$ receptors to mediate inhibition are likely not responsible for the transition to drug-resistant status epilepticus-like activity. Since GABA uptake blockers are able to reverse and eventually block the difficult to treat status epilepticus it can be assumed that failure in GABA release is involved. This could be due to transfer of GABA from presynaptic endings into glia. Under the enormous metabolic demand during seizure activity some of this GABA may be burnt in the GABA shunt for production of ATP. It is likely that glial cells by removing synaptically released GABA play an important role in the transition from drug sensitive status epilepticus to a condition where presently marketed drugs fail to block this activity. The enormous cell swelling involving glial cells may in addition be a cofactor in the generation of this life-threatening condition.

CONCLUSIONS

Glial cells are abundant in the brain and often show distinct morphological alterations in an area of epileptogenesis. Thus brain injury often leads to gliosis in the surround of the scar. In this region nerve cells undergo regenerative and degenerative alterations, which are essential in generation of abnormal excitability. Similarly, supposed areas of epileptogenesis in the temporal lobe are characterised by reactive gliosis. These alterations of glial cell morphology include changes in GFAP positive processes and possibly also increases in numbers. Based on the assumption that glial cells are involved in potassium homeostasis it

was suggested that glial cell function in such areas is impaired. This disturbance of glial cell function was thought to render them incapable of maintaining normal potassium concentrations in the central nervous system. This in turn should lead to abnormal potassium accumulation with the result that seizures are generated. However, present evidence suggests that this is not the case. However, spatial K^+ buffering in normally functioning cells may well contribute to spread of epileptiform activity.

Since the development of modern glial research many more functions of glial cells have been elucidated. Thus it was shown that glial cells may be involved in transporting nutritional and other metabolic elements in and out of the brain across the blood-brain barrier. They serve many metabolic functions, and supply a major part of brain energy. In doing that, they use the GABA shunt for energy production; this may, during abnormal hyperactivity, very well lead to burning of GABA and thereby reduction of available GABA. Since GABA is the most important central inhibitory neurotransmitter, this would lead to a reduction of GABA levels and thereby aggravate seizures.

Astrocytes are involved in uptake of neurotransmitters from the extracellular space. Thus reduced glutamate or increased GABA uptake may well be involved in seizure generation.

More recently it was discovered that astrocytes release cytokines. These are hormones which have activating functions not only on the immune system, including microglia but also have effects on nerve cells, which may promote generation of hyperactivity.

Glial cells also express growth factors and release them. Following seizures, this expression is increased. Whether such growth factors contribute to epileptogenesis is not quite clear. However, the possibility must be investigated.

Although many of the more recently established glial functions may be involved in epileptogenesis as well as in generation, spread and termination of seizures such involvement was in many cases not rigidly tested. In other cases the multitude of mechanisms of seizure generation and seizure spread have not been considered.

Although glial cells show marked alterations during epileptogenesis we know surprisingly little about their role in epileptogenesis, seizure initiation, seizure spread, and seizure termination. There is scattered information here and there but this information is still sparse. There are well-defined epilepsy models in which these questions can be studied.

This research was supported by DFG grant He 1128/6-2, a grant from the BMFT and the SFB 194.

We are grateful for expert technical assistance to M. Bullmann and G. Heske for preparation of the manuscript, figures, and experiments. We thank R. Empson for reading early versions of this manuscript and for helpful discussions.

63 Hepatic encephalopathy

MICHAEL D. NORENBERG

Hepatic encephalopathy (HE) or hepatic coma represents the neurological consequence of liver failure or the shunting of blood away from the liver (portal-systemic shunt). HE is probably the best example of a clinical condition in which astrocytes play a key and perhaps dominant role in pathogenesis. It is also a disease that has provided important insights into ammonia and glutamate metabolism as well as contributions to the concept of glial-neuronal interactions. As will be discussed, ammonia is a prime candidate as the neurotoxin in HE, and the astrocyte is the cell where ammonia is primarily metabolized. Our working hypothesis has been that astrocytes are mainly affected by toxins in HE and that abnormal glial function disturbs the microenvironment leading to disordered neuronal activity.

CLINICAL FEATURES

Impaired neurological function is one of the most common events in terminal liver failure. HE is generally divided into acute and chronic forms. Acute HE (fulminant hepatic failure) results from diffuse massive liver necrosis, usually occurring in the absence of preexisting liver disease. It is seen following viral hepatitis, drug toxicity (acetaminophen, halothane, nonsteroidal antiinflammatory agents) and various hepatic poisons (mushroom/Amanita phalloides, volatile hydrocarbons). It presents with the rapid development of delirium, seizures, and coma, and has an extremely poor prognosis. The principal cause of death in fulminant hepatic failure is brain edema associated with increased intracranial pressure. The only currently effective treatment is liver transplantation.

Chronic HE, sometimes referred to as portal-systemic encephalopathy, is far more common, is seen with preexisting liver disease (usually cirrhosis), and is commonly precipitated by infection, gastrointestinal hemorrhage, excessive diuresis, electrolyte imbalance, high protein diet, constipation, and the use of sedatives and hypnotics. The clinical picture is characterized by altered mental state, change in personality, altered mood and behavior, diminished intellectual capacity, abnormal muscle tone with brisk deep-tendon reflexes, and often a Babinski response. A characteristic tremor (asterixis) is seen but is not diagnostic of HE. Seizures are relatively rare. Electroencephalographic (EEG) abnormalities are frequently found. The patients often display a disturbed diurnal rhythm with abnormal sleeping patterns. In late stages the patients hyperventilate, resulting in respiratory alkalosis. Ultimately, patients develop a disturbance in the level of consciousness ranging from confusion to stupor and coma. With adequate treatment, the patients usually recover, although irreversible syndromes are known (Norenberg, 1981).

PATHOLOGICAL CHANGES IN HUMANS AND EXPERIMENTAL ANIMALS

The main pathologic change in acute HE is brain edema. Grossly, the brain shows evidence of transtentorial and tonsillar herniation. Astroglial swelling dominates the microscopic picture in human (Kato et al., 1992) as well as in the majority of experimental animal studies (Norenberg, 1977; Traber et al., 1987; Swain et al., 1991) (Figure 63-1).

In chronic HE, edema is absent but astrocytic changes continue to be prominent. As originally reported by von Hosslin and Alzheimer (1912) and more definitively described by Adams and Foley (1953), gray matter astrocytes are the cells affected (protoplasmic astrocytosis, Alzheimer type II astrocytosis). The cells have enlarged, pale nuclei with peripheral margination of chromatin and often prominent nucleoli (Figure 63-2). In long-standing cases, intranuclear glycogen is found. The cells possess an increased amount of lipofuscin. Loss of glial fibrillary acidic protein (GFAP) is characteristic (Sobel et al., 1981). Whether there is a true astroglial proliferation is unclear (Norenberg, 1981). These glial changes correlate with blood ammonia level and clinical state (Adams and Foley, 1953; Norenberg, 1981; Martin et al., 1987). No significant or consistent neuronal morphological changes have

FIG. 63-1. Electron micrograph of a swollen astrocyte from an experimental model of acute HE. The cytoplasm is enlarged and electronlucent, with prominent membrane-bound vacuoles. Glycogen granules are scattered throughout the cytoplasm.

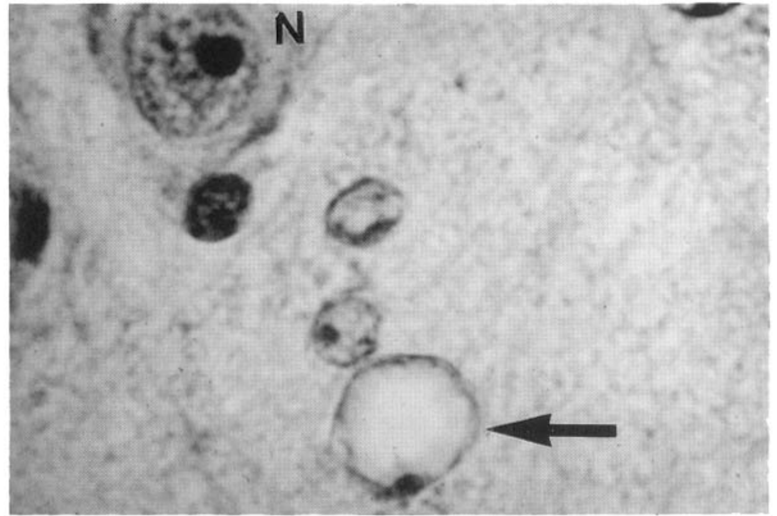

FIG. 63-2. Alzheimer type II astrocyte (*arrow*) showing nuclear enlargement and clearing, with the chromatin displaced to the periphery. Two adjacent relatively normal astrocytes are also present. A nearby neuron (*N*) is normal.

been identified (Adams and Foley, 1953; Norenberg, 1981; Martin et al., 1987).

Most experimental studies have shown great similarity regarding the astrocyte changes in HE. Initially, the cells show hypertrophy with increased number of mitochondria, smooth and rough endoplasmic reticulum, and an increase in cytoplasmic glycogen. As coma ensues, evidence of degeneration is observed characterized by increased cytoplasmic lucency (hydropic changes), the presence of cytoplasmic vacuoles and the occurrence of degenerated mitochondria. It was speculated that the early alterations were reactive ones, presumably due to hyperammonemia, whereas the later degenerative changes were a consequence of bioenergetic failure due to excessive glial involvement in ammonia detoxification. (For review see Norenberg, 1981).

PATHOGENETIC MECHANISMS

The pathogenetic mechanisms involved in HE are still unknown. Three views currently dominate: (1) the toxin/ammonia hypothesis and related disturbance in glutamate metabolism and neurotransmission, (2) abnormal GABAergic neurotransmission related to the presence of endogenous benzodiazepines or benzodiazepine-like compounds, and (3) the monoamine hypothesis. As developed in this article, these views are not necessarily mutually exclusive.

Ammonia

The role of toxins has dominated pathogenetic views for decades. This concept states that gut-derived nitrogenous products accumulate systemically because of failure by the diseased liver to clear these substances. A number of toxins have been incriminated; chief among these has been ammonia, whose actions have been extensively investigated. It is certainly the best known toxin, and remains to date the best candidate likely to play a key role in HE.

Evidence for the ammonia hypothesis is compelling. Arterial, cerebrospinal fluid, and brain levels usually correlate well with the clinical state (Conn and Lieberthal, 1978). Increased cerebrospinal fluid level of glutamine (a product of ammonia metabolism) is among the best indicator of encephalopathy (Hourani et al., 1971). Blood ammonia levels (usually venous) sometimes do not perfectly correlate with the clinical state. This lack of precise correlation has been the biggest drawback in unequivocally accepting the importance of ammonia. However, reasonable explanations have been provided that deal with these occasional discrepancies (Conn and Lieberthal, 1978).

Factors that lead to increased levels of blood or brain ammonia (administration of ammonium salts and resins, high protein diet, gastrointestinal bleeding, hypokalemia, constipation) all make HE worse. Indeed, procedures geared toward reducing blood ammonia levels form the basis for the treatment of HE. Further linking ammonia to HE are reports that patients with hereditary hyperammonemia have similar clinical and pathological findings as in HE. Lastly, experimental procedures that increase blood or brain ammonia, reproduce the same astrocytic changes present in HE.

Ammonia is derived mainly from the gut through the breakdown of nitrogenous substances by bacterial action. It is then carried to the liver where it is converted to urea. In disease states, where the liver is incapable of converting ammonia to urea, or in the presence of venous shunts resulting in portal blood bypassing the liver (portocaval shunts), ammonia reaches the brain where it is principally metabolized to glutamine, as the complete urea cycle is absent in brain (Sadasivudu and Hanumantharao, 1974). This action is carried out by glutamine synthetase, an ATP-consuming reaction, that is present mostly in astrocytes (Norenberg, 1983) (Figure 63-3). A reduction in brain glutamate and an increase in brain glutamine are important consequences of ammonia fixation. As discussed below, both of these effects of ammonia appear to play a major role in the pathogenesis of HE.

Glutamine released from astrocytes is taken up by nerve endings where it is converted to glutamate through the action of glutaminase (Bradford and Ward, 1976). Glutamate released from nerve endings is then picked up by astrocytes completing the so-called glutamate-glutamine cycle (Shank and Aprison, 1981). The key components of the cycle, namely, glutamate uptake, glutamine synthesis, and glutamine release have all been convincingly shown in astrocyte cultures (Waniewski and Martin, 1986; Farinelli and Nicklas, 1992).

Normally, glutamine synthetase works at maximal capacity (Cooper et al., 1985). Increases in GS activity are generally not found in hyperammonemia (Cooper et al., 1979). In fact, glutamine synthetase is decreased in portocaval-shunted rats (Butterworth et al., 1988a) and in human postmortem tissue (Lavoie et al., 1987a). Thus, the ability of the brain to fix ammonia in HE and other hyperammonemic states may be limited (Butterworth et al., 1988a). Work in cell culture fits with the above *in situ* observations in that no significant change is seen early on; however, with longer term treatment, glutamine

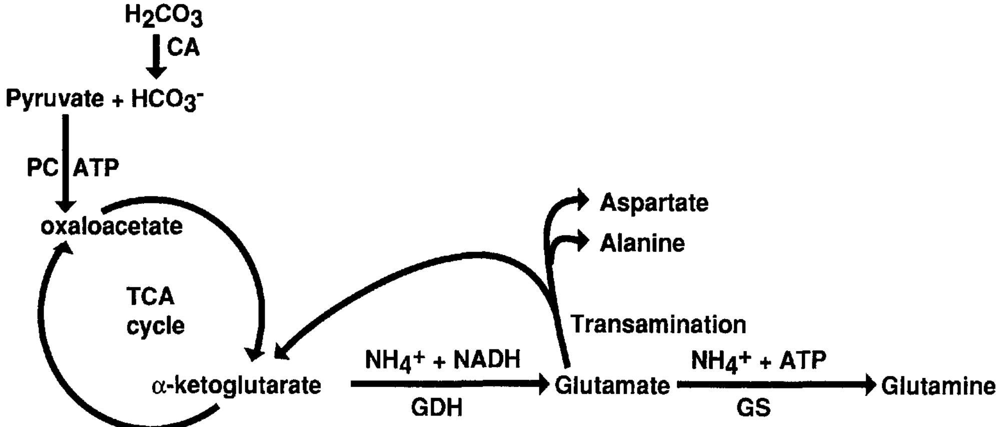

FIG. 63-3. Metabolic pathways of ammonia and glutamate metabolism. *CA*, carbonic anhydrase; *PC*, pyruvate carboxylase; *GDH*, glutamate dehydrogenase; *GS*, glutamine synthetase.

synthetase activity is significantly reduced (Norenberg et al., 1986). This may be indicative of an astroglial dysfunction, which may place the central nervous system at risk when challenged with prolonged high blood levels of ammonia.

Ammonia is clearly a neurotoxin (Cooper and Plum, 1987). High concentrations of ammonia result in seizures and death, while at lower concentrations, stupor, and coma predominate. The mechanisms of ammonia toxicity, however, are still not completely known.

The original view of energy failure proposed by the Bessmans (1955) remains highly controversial and, while having many detractors, cannot be totally dismissed (for review see Cooper and Plum, 1987). It would appear that acutely, there are no losses of high-energy metabolites (Hawkins et al., 1973); however, chronically, a component of energy failure is present. One possible mechanism is the inability of the malate-aspartate shuttle to generate reducing equivalents, secondary to an ammonia-induced fall in glutamate (Hindfelt et al., 1977).

Ammonia theoretically can alter the intracellular pH, an aspect that has been largely ignored in pathogenetic considerations. In most cells, ammonium chloride produces a transient rise in pH (Roos and Boron, 1981). The situation in brain is not clear. Portocaval-shunted rats show an increase in pH in astrocytes (Swain et al., 1991). However, nuclear magnetic resonance studies have generally shown no change in pH (Fitzpatrick et al., 1989) and one study even showed a fall in pH, presumably due to the generation of lactic acid (Brooks et al., 1989). Since pH can alter cell function (Häussinger, 1988), changes in intracellular pH may turn out to be one of the most important properties of ammonia.

Other effects of ammonia include inhibition of carbonic anhydrase and glutaminase, loss of vascular autoregulation, defective protein synthesis, enhanced carbon dioxide fixation, disinhibition of phosphofructokinase, fall in monoamine oxidase, and inhibition of Na^+,K^+-ATPase. Which of these changes may contribute to neurotoxicity and which are adaptive changes, is not clear. (For reviews and references see Norenberg, 1981; Cooper and Plum, 1987).

Ammonia may also interfere with glutamate-mediated excitatory neurotransmission. Brain glutamate levels in humans and in experimental animals are generally depressed (Hindfelt et al., 1977; Lavoie et al., 1987a; Dejong et al., 1992). Decrease in glutamate occurs in cultured astrocytes following ammonia treatment (Waniewski, 1992). The decrease in glutamate is largely due to glutamine formation during the process of ammonia detoxification.

Elevated levels of extracellular glutamate have also been described (Moroni et al., 1983; Therrien and Butterworth, 1991; Bosman et al., 1992). This elevation could be due to increased release of glutamate from neurons. At levels greater than 5 mM, ammonia stimulates glutamate release from synaptosomes (Erecinska et al., 1987). Other studies indicate that while basal levels of extracellular glutamate are not altered (Tossman et al., 1987), they increase following stimulation with high concentrations of K^+ (Tossman et al., 1987). Hippocampal slices from portocaval-shunted rats show increased glutamate release or "overflow" (Butterworth et al., 1991). The increase in extracellular glutamate could also be due to failure to take up glutamate. Ammonia inhibits synaptosomal glutamate uptake (Mena and Cotman, 1985) and work with astrocyte

cultures also indicate that ammoniated cells have a decreased capacity to take up glutamate from the medium (Norenberg et al., 1985). Sera and cerebrospinal fluid from patients with HE inhibit glutamate uptake in rat hippocampal slices (Schmidt et al., 1990). It appears that the increase in extracellular glutamate can come from increased neuronal release as well as decreased uptake.

Ammonia may also influence glutamatergic neurotransmission by downregulating glutamate receptors, possibly secondary to increased levels of extracellular glutamate (Peterson et al., 1990). Ammonia may also act directly on the postsynaptic aminohydroxymethylisoxazolepropionic acid (AMPA) receptor (Fan et al., 1990). However, the status of glutamate receptors remains unclear as increased binding to glutamate receptors in membrane preparations of galactosamine-treated animals were observed by Ferenci et al. (1984), while Zimmermann et al. (1989) did not observe such changes in rats treated with thioacetamide. Whether these discrepancies reflect species differences, model differences, or variations in the timing of the experiments, remains to be worked out.

Not as much work has been done with other proposed toxins, including short-chain fatty acids, mercaptans, phenol, endotoxin, and "middle molecules." Some of these may act synergistically with ammonia. (For review see Zieve, 1987).

Ammonia/Hepatic Encephalopathy and Brain Edema

The mechanisms involved in the production of HE-associated edema are controversial. Vasogenic, that is, the extracellular accumulation of fluid due to a disturbance of blood-brain barrier (BBB), and cytotoxic (intracellular accumulation of fluid) mechanisms have been proposed.

Support for the vasogenic origin of brain edema in HE comes from Livingstone et al. (1977), Horowitz et al. (1983), and Zaki et al. (1984). The models used, however, are associated with hypotension and hypoglycemia, both of which are known to induce vasogenic edema. The response to mannitol and ineffectiveness of glucocorticoids in the treatment of HE-associated edema do not support a vasogenic process. Lack of evidence of blood-brain barrier dysfunction in man and animal studies (Knudsen et al., 1988; Roy et al., 1988; Bassett et al., 1990) suggests that factors other than breakdown of the blood-brain barrier are involved in the production of edema.

Animal studies have emphasized astrocyte swelling as a major component of the edema associated with HE (Norenberg, 1977; Traber et al., 1987; Swain et al., 1991). The swelling correlates well with levels of ammonia (Swain et al., 1992). Benjamin et al. (1978) showed that ammonia causes swelling in tissue slices and Ganz et al. (1989) demonstrated that the swelling was mostly confined to astrocytes. Cell culture studies of ammonia-treated astrocytes also show cell swelling (Norenberg et al., 1991). Taken together, there is strong evidence to indicate that the main mechanism for brain edema in HE is cytotoxic, that the fluid is largely in astrocytes, and that ammonia is an important factor in the production of edema.

Gamma-Aminobutyric Acid/Benzodiazepines

A major working pathogenetic hypothesis in HE deals with the role of excessive GABAergic tone in HE. It was originally believed that there was increased blood GABA and increased GABA and benzodiazepines (BZD) receptors in brain (Schafer et al., 1983). Subsequent studies showed no changes in brain GABA levels in humans and experimental animals (Butterworth and Giguere, 1986; Butterworth et al., 1988a; Zimmermann et al., 1989). No changes in GABA receptors were found in experimental animals (Mans et al., 1992; Zimmerman et al., 1989). Furthermore, no changes in BZD receptors were found in thioacetamide-treated rats (Zimmermann et al., 1989), or in portacaval-shunted rats (Maddison et al., 1987). No change in GABA or BZD binding sites were noted in human postmortem tissue (Rossle et al., 1989).

Against these negative findings is the observation that flumazenil, a BZD receptor antagonist, is capable of reversing HE coma (Ferenci et al., 1989). Improvement with flumazenil has also been observed in thioacetamide-treated animals (Gammal et al., 1990). These findings prompted Mullen and colleagues (1988) to propose that elevated levels of BZD ligands might be responsible for HE. Indeed, compounds with agonist activity on the BZD receptor were found in humans and experimental animals with HE (Mullen et al., 1990). One of these ligands appears to be diazepam binding inhibitor (DBI), an endogenous polypeptide capable of displacing BZD binding from both central and peripheral BZD receptors (Costa and Guidotti, 1991), and which has negative allosteric effects on the binding of GABA to the $GABA_A$ receptor (Ferrarese et al., 1987). Increased levels of DBI were identified in cerebrospinal fluid of patients with HE (Rothstein et al., 1989). Basile found that brain extracts from experimental

animals and humans with fulminant hepatic failure inhibited binding with flumazenil and identified these compounds as 1,4-benzodiazepines (Basile et al., 1989; Basile et al., 1991).

However, there are problems with the BZD hypothesis. No response to flumazenil were observed in various experimental animals (Zieve et al., 1987; Gammal et al., 1990; Van Der Rijt et al., 1990) and the clinical response to flumazenil has not been impressive in larger populations of patients (Van Der Rijt et al., 1989; Pomier Layrargues et al., 1990). Recent reports, however, indicate that the use of partial inverse agonists of the BZD receptor (Ro 15-4513, Ro 15-3505) may be helpful (Bosman et al., 1991; Steindl et al., 1991). The issue of benzodiazepines is a hotly debated one, which nevertheless represents a major working hypothesis at the present time.

In linking the potential role of GABA and BZD to astrocytes, it may be recalled that astrocytes also possess BZD receptors, although they are of the peripheral-type which have been found in tissues outside the central nervous system. Within the central nervous system, most of the receptors are found on glial cells (McCarthy and Harden, 1981), and as in other tissues, appear to be present chiefly on mitochondria (Itzhak et al., 1993). The functions of this receptor are poorly understood.

An important aspect of the peripheral-type BZD receptor is its involvement in the intracellular transport and metabolism of cholesterol and the production of neurosteroids (Mukhin et al., 1989; Papadopoulos et al., 1991). DBI and DBI-derived peptides, by activating the peripheral receptor, can generate the production of neurosteroids. These steroids can positively modulate the $GABA_A$ receptor (Romeo et al., 1992). This process can be blocked by PK 11195, a specific blocker of the peripheral receptor. The production of neurosteroids in astrocytes through stimulation of the peripheral BZD receptor provides a potentially important link between astrocytes and the function of the neuronal $GABA_A$ receptor.

Upregulation of the peripheral-type BZD receptor have been observed in ammonia-treated astrocytes (Ducis et al., 1989), in portocaval-shunted rats (Giguere et al., 1992) and in human postmortem tissue from encephalopathic patients (Lavoie et al., 1990). As this receptor is largely mitochondrial, it may simply reflect the increased number of mitochondria found in astrocytes in experimental HE (Norenberg, 1977) and in ammonia-treated astrocyte cultures (Gregorios et al., 1985). Alternatively, through the generation of neurosteroids this receptor may contribute to alterations in GABAergic tone. See below for potential involvement of the peripheral receptor in cell swelling.

Monoamines

Studies into the pathogenesis of HE in the 1970s and early 1980s were dominated by the false neurotransmitter hypothesis (Fischer and Baldessarini, 1976). The concept proposed that gut-derived false neurotransmitters either replaced the "true" neurotransmitters or that these false neurotransmitters (octopamine, tyramine, phenylethylamine) resulted in a depletion of dopamine and norepinephrine and a rise in serotonin. This view was subsequently modified to include elevations in aromatic to branched-chain amino acid ratio in the blood of patients with HE (Fischer, 1984). This change in the ratio allows for greater amounts of aromatic amino acids (phenylalanine, tyrosine, and tryptophan) to enter the brain (James et al., 1978). As these amino acids are precursors for neurotransmitters, increased blood levels of aromatic amino acids were believed to result in abnormal levels of neurotransmitters. This concept was subsequently linked to ammonia by noting that the transport of aromatic amino acids across the blood-brain barrier was stimulated by exchange with brain glutamine (derived from ammonia). Abnormalities in the blood-brain barrier have also been proposed as a mechanism for increased central nervous system levels of tryptophan and its metabolites (Jessy et al., 1990).

However, increasing brain levels of octopamine or reducing norepinephrine did not result in coma (Zieve and Olsen, 1977); in fact, norepinephrine levels were found to be increased in thioacetamide-treated rats (Yurdaydin et al., 1989). Postmortem material did not disclose changes in norepinephrine, dopamine, or octopamine (Cuilleret et al., 1980). There is currently little support for the false neurotransmitter hypothesis.

Abnormalities in serotonin have long been suspected to play a role in HE. Increased levels of tryptophan and/or 5-hydroxyindolacidic acid (5-HIAA) in cerebrospinal fluid in humans and animals correlate very well with the level of encephalopathy (Ono et al., 1978). Increased serotonin turnover has been described in portocaval-shunted rats (Bengtsson et al., 1991) and increased levels of the serotonin metabolite 5-HIAA as well as tryptophan have been found in hyperammonemic mice with congenital ornithine transcarbamylase deficiency (Batshaw et al., 1988) and in urease-treated rats (Bachmann and Colombo, 1983). There are intriguing associations between serotonin and HE, and it is likely that it is involved in the pathogenesis of HE. It should be noted that tryptophan is a precursor of quinolinic acid, which has been implicated in HE (see below).

STUDIES IN CELL CULTURE

Mossakowski and coworkers (1970) were the first to demonstrate that treatment of astrocytes with ammonia, copper, and sera from humans and experimental animals with HE produced Alzheimer type II-like changes in culture. The metabolic pathways of ammonia in cultured astrocytes and its effects on glutamate metabolism and on bioenergetics have been studied in detail (Yudkoff et al., 1984; Hertz et al., 1987; Fitzpatrick et al., 1988).

Our work dealing with the morphologic effects of ammonia and its synergism with other toxins, the protective effect of carnitine and branched-chain amino acids, the effect of ammonia on various glial specific enzymes and neurotransmitter uptake, the role of cyclic AMP, changes in protein phosphorylation, and effects on the peripheral-type benzodiazepine receptor have been summarized in other articles (Norenberg et al., 1986; Norenberg, 1989).

Calcium

In view of the potential involvement of the peripheral benzodiazepine receptor in HE (see above) and since the peripheral benzodiazepine receptor may influence astroglial calcium homeostasis (Bender and Hertz, 1985), we examined the effect of ammonia on calcium flux (Neary et al., 1990). Three-day treatment with ammonia resulted in a 35% decrease in influx, and a decrease in calcium accumulation without a change in efflux. Preliminary findings using a calcium imaging system suggests that the free cytosolic calcium is also reduced. As calcium is important in the regulation of many cellular processes, such reduction in calcium may have profound effects on cell function. Consistent with a role of calcium in the effects of ammonia on astrocytes, are studies showing that increasing cellular calcium levels by treatment with extracellular ATP (Neary et al., 1989) results in the reversal of many of the ammonia effects, including morphology, cell swelling, and GFAP content (Neary and Norenberg, 1992; Norenberg et al., 1992).

Cytoskeletal Proteins

Loss of GFAP is one of the characteristic features of HE in humans (Sobel et al., 1981). We have observed that a 4-day treatment with 10 mM ammonium chloride decreased GFAP content in cultured astrocytes by 35% (Norenberg et al., 1990). The effect was dose-dependent and was less prominent in cells that had been maintained in dibutyryl cyclic AMP. An even more impressive finding was the almost total absence of GFAP mRNA after a 1-day treatment with ammonia (Norenberg et al., 1992). This loss of GFAP mRNA appears to be due to mRNA instability (Neary et al., 1993). These changes in GFAP and GFAP mRNA could be prevented by extracellular ATP (Neary and Norenberg, 1992). No change in vimentin mRNA was observed while a slight fall in actin was noted. The significance of changes in cytoskeletal proteins in ammonia-treated astrocytes is not clear, although as discussed below, these proteins may play a role in ammonia-induced cell swelling.

Astrocyte Swelling

Treatment of astrocytes with ammonia results in cell swelling (Norenberg et al., 1991). Using primary astrocyte cultures, we have initiated a number of studies aimed at understanding the cellular mechanisms underlying this process.

Calcium plays a major role in volume regulation (McCarty and O'Neil, 1992) and the involvement of calcium-dependent protein kinases in regulating astrocyte cell volume has been recently emphasized (Bender et al., 1992a, 1992b; Bender et al., 1993). We have shown that ammonia results in a decrease in calcium intracellular content (Neary et al., 1990) and that the addition of extracellular ATP, known to increase intracellular calcium levels (Neary et al., 1989), caused a significant reduction in swelling in ammonia-treated astrocytes (Neary and Norenberg, 1992).

Cyclic AMP diminishes the cytopathic effect of ammonia (Gregorios et al., 1986). This may be relevant to the issue of cell swelling as treatment of cultures with dibutyryl cyclic AMP have a smaller water content and volume regulate more efficiently (Bender et al., 1992b). The effect of cyclic AMP on volume regulation may be related to greater calcium currents (Barres et al., 1989).

Whether the abnormalities in the cytoskeleton contribute to cell swelling is highly speculative. Nevertheless, there is evidence that the cytoskeleton plays a role in ion transport (Solomon, 1989) and volume regulation (Cornet et al., 1993). Cyclic AMP-treated cells are more resistant to swelling and, interestingly, they have a greater amount of GFAP (Chiu and Goldman, 1985).

The benzodiazepine system may also contribute to swelling. An interaction between peripheral benzodiazepine ligands and diuretics have been described (Lukeman and Fanestil, 1987). We have examined the effect of peripheral benzodiazepine on ammonia-

induced astrocyte swelling (Norenberg and Bender, 1993). Treatment with the agonist Ro 5-4864 exacerbated the swelling whereas use of a peripheral antagonist, PK 11195, diminished the extent of swelling. How these benzodiazepine-induced changes are brought about is not known. Perhaps the involvement of the peripheral receptor in calcium homeostasis may be a factor (Bender and Hertz, 1985).

We have investigated the possible role of *myo*-inositol in astrocyte swelling as this compound is capable of acting as an osmolyte and has been implicated in the maintenance of intracellular osmolarity (Sherman, 1989). We have found that 3-day treatment of astrocytes with ammonium chloride (5 mM) decreased *myo*-inositol uptake by 50%. These findings are in keeping with a 50% reduction in *myo*-inositol content in patients with HE as determined by proton magnetic resonance spectroscopy (Kreis et al., 1992). Such a reduction in *myo*-inositol uptake may reflect an adaptive response to ammonia-induced swelling.

Methionine Sulfoximine

The concept that glutamine may be exerting a deleterious effect in HE is an important one. Based on the views of the Bessmans (1955) that ammonia may be deleterious through the process of ATP-consuming glutamine synthesis, Warren and Schenker (1964) described a protective effect of methionine sulfoximine (MSO) (an inhibitor of glutamine synthetase) against ammonia-induced seizures, despite the fact that MSO is a potent convulsant in its own right, albeit with a rather prolonged latent period (Proler and Kellaway, 1962). Gutierrez and Norenberg (1975) showed that MSO produced the identical changes seen in HE, namely, the Alzheimer type II change. In one regard that was not surprising, as MSO results in a striking elevation of blood and brain ammonia levels (Warren and Schenker, 1964). However, the so-called protective effect of MSO remained puzzling in that an agent that protected against ammonia, itself increased ammonia levels and produced the histological changes associated with ammonia.

There is currently a resurgence of interest in MSO and the possible detrimental effects of excessive glutamine levels following the publications by Brusilow and colleagues (Brusilow and Traystman, 1986; Takahashi et al., 1991). Hawkins and Jessy (1991) and Hawkins et al. (1993) have shown that the effects of ammonia on glucose utilization and neutral amino acid transport (tryptophan and leucine) can be reversed by MSO. Swain et al. (1992) showed a correlation between edema and brain glutamine levels.

In recent studies, our laboratory has examined the effect of MSO on ammonia-induced toxicity. MSO diminished the extent of ammonia-induced cytopathic changes, cell swelling, glycogen loss, and *myo*-inositol transport (Norenberg et al., 1993). It thus appears that even in an *in vitro* system, MSO has a protective effect. Whether all of these effects can be explained by an inhibition of glutamine synthetase remains to be determined. MSO results in a massive release of glutamine from astrocytes (Albrecht and Norenberg, 1990), increased glutamate uptake in brain slices (Rothstein and Tabakoff, 1985), increased brain glycogen content (Folbergrova et al., 1969; Gutierrez and Norenberg, 1977), and increased GFAP content *in vivo* (Yamamoto et al., 1989). Much is still to be learned about the mechanism of action of MSO.

Glycogen

Abnormalities in glycogen metabolism have been described in HE (Norenberg, 1981); early on, there seems to be a decrease in glycogen, whereas later, there appears to be an increment (Zamora et al., 1973). Such an effect on glycogen, a substance that is largely found in astrocytes (Ibrahim, 1975), could have a profound effect on energy metabolism in states of substrate deficiency. We have found that glycogen content in astrocyte cultures is reduced by ammonia in a dose-dependent manner (Dombro et al., 1993). The reduction in glycogen could be significantly diminished by treatment with MSO (Norenberg et al., 1993). Importantly, the ability of astrocytes to hydrolyze glycogen by beta-adrenergic stimulation was diminished. These findings indicate that ammonia interferes with glycogen metabolism and additionally may disrupt important interactions between astrocytes and neurons.

PATHOGENETIC INTEGRATION

The studies described above indicate that, while initially the astrocyte attempts to respond to the metabolic challenge posed by ammonia, serious effects occur that may impair the cell's ability to further respond to the toxic insult. The astrocyte is actively involved in ammonia fixation; this may or may not be harmful. With high ammonia doses the astrocyte may not be able to adequately remove sufficient ammonia; the "spillover" may have direct neuronal effects or lead to deleterious effects to astrocytes. Glutamine synthetase activity is ultimately diminished, leading not only to further increases in tissue ammonia, but to the potential toxic consequences of

elevated glutamate levels. The latter may not only have effects on neurons, but is also capable of causing astroglial swelling (Kimelberg and Ransom, 1986).

Abnormalities in glutamate homeostasis and glutamate neurotransmission induced by ammonia represents a common theme in many views regarding HE. Whether it is due to failure of glutamate uptake, disordered glutamate metabolism, or abnormal glutamate receptor function remains to be established. With regard to glutamate receptors, the defect could possibly reside in glial cells, which have both ionotropic and metabotropic types of receptors. Clearly, there is still much to be learned regarding the role of impaired astrocytic ammonia and glutamate metabolism in the pathogenesis of HE.

If there is excessive glutamate release or content in the extracellular space, one needs to consider the possibility of excitotoxicity as a pathogenetic mechanism (Moroni et al., 1983). In keeping with this view, are the protective effects of MK-801 and AP-5 (Marcaida et al., 1992), NMDA receptor antagonists, on acute ammonia toxicity.

The potential involvement of quinolinic acid in HE is pertinent. Quinolinic acid, a tryptophan metabolite, is an agonist of the NMDA receptor (Stone and Perkins, 1981) and increased brain levels were reported in portocaval-shunted rats (Moroni et al., 1986a) and in the cerebrospinal fluid of humans with liver failure (Moroni et al., 1986b). It should be noted that the enzymes involved in quinolinate metabolism appear to be largely located in astrocytes (Kohler et al., 1987; Okuno et al., 1987).

Glycine has allosteric effects on the NMDA receptor (Fagg and Baud, 1988). Cerebrospinal fluid and brain glycine increase following hepatectomy (Tossman et al., 1987; Bosman et al., 1992). Kohno et al. (1990) reported hyperglycinemia in cirrhosis, which correlated with HE. Yudkoff et al. (1986) have described a robust glycine uptake by astrocytes. Possible failure of astrocytes to take up glycine, could result in excitotoxic injury.

The GABA/benzodiazepine hypothesis also involves astrocytes. Ammonia-treated astrocytes have a diminished capacity for GABA uptake (Norenberg et al., 1986). The upregulation of the peripheral-type benzodiazepine receptor was commented upon above. Of considerable interest is the production of neurosteroids that may impact on the neuronal GABA receptor (Papadopoulos et al., 1992; Romeo et al., 1992).

While the present focus on HE has been centered on ammonia/glutamate and benzodiazepines, abnormalities in monoamines are still a factor to contend with. Here, too, astrocytes may be involved. Receptors for norepinephrine and serotonin exist on astrocytes (Murphy and Pearce, 1987). Adrenergic receptors may be involved in HE as it has been reported that HE can be precipitated with propranolol (Nieminen and et al., 1988), a beta-adrenergic blocker, although this issue is controversial (Cales et al., 1989). Monoamines can be actively taken up by astrocytes (Katz and Kimelberg, 1985). Contributing to possible derangements in this system is the reduction in isoproterenol-stimulated cyclic AMP levels (Liskowsky et al., 1986), abnormal protein phosphorylation (Neary et al., 1987), and inhibition of monoamine oxidase activity (Norenberg et al., 1988).

Related to the issue of monoamines is a disturbance in the function of the blood-brain barrier, leading to abnormal levels of amino acid precursors of neurotransmitters. As astrocytes appear to be involved in the regulation of endothelial function (Janzer and Raff, 1987), a disturbance in astrocytes could contribute here as well.

Figure 63-4 illustrates the relationship of various pathogenetic mechanisms in HE to astrocytes.

CONCLUSIONS

This review has focused on the role of astrocytes in the pathogenesis of HE. This is not to say that cells other than astrocytes are not involved. Ultimately there must be neuronal effects for clinical disease to express itself. However, the role of these other central nervous system components is less clear.

While the precise mechanism of HE is still not known and the existing views are controversial, it is clear that the astrocytes play a key role in this clinical disorder. We have attempted to advance the concept that hepatic encephalopathy represents a primary gliopathy, perhaps leading to an interference with glial-neuronal communication. Such an astro-

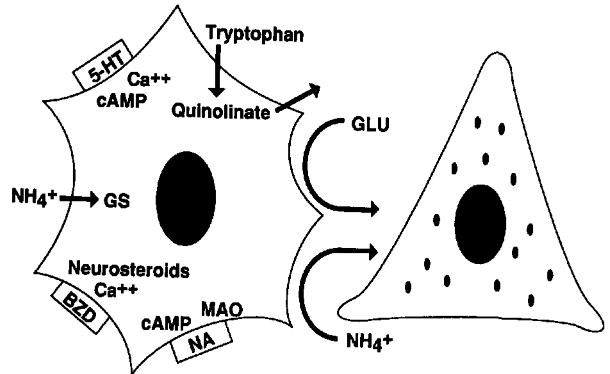

FIG. 63-4. Schematic diagram of various potential mechanisms involved in hyperammonemia and hepatic encephalopathy.

cyte injury could result in impaired neuronal and perhaps endothelial function.

Astrocyte swelling remains a major clinical problem whose pathogenesis is still poorly understood. Important new insights have evolved in recent years that promises to provide new leads into its cause and treatment. A better understanding of the role of calcium, cytoskeletal proteins, benzodiazepine receptors, and organic osmolytes should help in this regard.

The study of hepatic encephalopathy has provided a means for better understanding of the role of astrocytes in central nervous system function. This approach should continue to yield further insights into critical issues such as their involvement in neurotransmitter metabolism, detoxification, glial-neuronal interactions and other neurological disorders.

I am indebted to Drs. Luz-Oliva B. Norenberg, Jocelyn H. Bruce, Joseph T. Neary, and Alex S. Bender who contributed much to the ideas and work presented in this article. I wish to thank Drs. Jocelyn H. Bruce and Carol K. Petito for their critical reviews of this manuscript. Ms. Celeste A. Bowen assisted in the preparation of this manuscript. This work was supported by the Department of Veterans Affairs (Merit Review and GRECC) and NIH grants DK38153 and NS30291. Dr. Norenberg is a Medical Investigator of the Department of Veterans Affairs.

64 Glial response to brain ischemia

RICHARD P. KRAIG, CHRISTOPHER D. LASCOLA, AND ANTHONY CAGGIANO

Glial cells, once considered to be mere supportive cells that nurtured the more robust activities of adjacent neurons, are now recognized as potentially the most dynamic cells within brain. Each glial phenotype appears to possess its own unique medley of channels, transporters, receptors, and enzymes (Murphy, 1993). Each can release and respond to a variety of organic and inorganic ions, lipids, and peptides (Kimelberg, 1988). Even cells of the same phenotype may be functionally different because of unique environmental conditions. Little is known about how these glial phenotypes interact during normal or pathologic conditions.

One actively studied area of glial function is their response to brain injury, including that following ischemia. After an ischemic insult, astrocytes and microglia undergo characteristic morphological and physiological changes and upregulate many proteins (for review see Eddleston and Mucke, 1993). Although the mechanisms underlying these changes remain poorly defined, alterations are likely in early response genes, cytokines, cytoskeletal elements, adhesion molecules, and enzymes. Frequently, changes in these parameters can only be surmised, based on their known roles in other cells outside of the central nervous system.

This chapter is not an exhaustive review of all up- and downregulated glial molecules following ischemia, important as they may be. Instead, we attempt to relate many important physiological observations made primarily *in vivo*, but also *in vitro*, to current theories of ischemic brain injury. We will take a decidedly systems approach. No brain cell exists in isolation. Glial cells potentially interact with each other, with the vasculature, with bloodborne elements, and with products from still other organ systems. If maintenance of normal function requires interaction between cells and their environment, it follows that degeneration, and possibly the lack of regeneration from ischemic injury, also depend on such interactions.

ASTROCYTES MAY AGGRAVATE ISCHEMIC BRAIN INJURY

How astrocytes influence the development of the brain's response to ischemic injury may be one important example of interactive cellular behavior in brain. Depending on the nature of the ischemic insult, astrocytes may in one instance be responsible for the destruction of brain tissue associated with infarction, and in another may serve to protect neutral cells from ischemic challenge and milder perturbations, such as spreading depression. The spectrum of astrocytic responses might be directly related to their role in ion homeostasis, and in addition seems to depend on their unique energy capacities. Their handling of two ions in particular, H^+ and Ca^{2+}, seems most relevant to the development of the tissue's response to ischemic insult.

A global reduction in blood flow of minutes duration destroys selectively vulnerable neurons (for review see Graham, 1992). Yet when brain glucose content is elevated shortly before the onset of global ischemia, all brain cells can be destroyed with the development of pan necrosis (i.e., infarction) (for review see Plum, 1983). Since glucose is converted to lactic acid under such conditions (Krebs, 1975), many have assumed that excessive acidosis is a necessary concomitant for the development of brain infarction. Glycogen is preferentially found in astrocytes within adult brain. If glycogen is a source of glucose for astrocytes, Plum (1983) reasoned that astrocytes might accumulate both hydrogen ions and osmols during ischemia. The latter conceivably could result in astrocytic acidosis and swelling. Supporting evidence for this supposition came from histological studies that show marked swelling and ultimate disruption of astrocytic cell membranes within zones of infarction from hyperglycemic, global ischemia (for review see Plum, 1983). The mechanisms by which astrocytes swell from ischemia remain largely inferential (Kimelberg et al., 1992). Furthermore, the carbohydrate source for increased lactic acidosis is also unknown. However, evidence is available to suggest that astrocytes can become profoundly more acidotic than their surrounding milieu. The molecular mechanisms by which excessive acidosis might irreversibly injure astrocytes and, as a result, brain tissue are unknown. However, perhaps the most attractive hypotheses center on acid-

induced free radical injury (Pulsinelli et al., 1985; Siesjo et al., 1985).

Initially, indirect evidence was used to suggest that astrocytic intracellular pH (pH_i) can become 1 to 2 orders of magnitude more acidotic than the interstitial space and adjacent neurons (Kraig et al., 1985, 1986). Measurements of interstitial pH and tissue carbon dioxide tension (P_{CO_2}) were combined with gross estimates of intracellular volume distribution to suggest this preferential acidosis of astrocytes. Although these initial measurements have been the subject of dispute (Katsura et al., 1991, 1992), direct measurements of pH_i from presumed astrocytes are now available to resolve this controversy.

Intracellular, double-barrel, and pH-sensitive microelectrodes were used to determine the pH_i of astrocytes during terminal ischemia in rodents made hyperglycemic before the onset of terminal ischemia (Kraig and Chesler, 1990). Under these conditions two foci more acidic than interstitial space (6.17 to 6.20 pH) are found. The first is only occasionally seen at the onset of ischemia and reaches 3.82 to 4.89 pH, while the second is seen 5 to 46 minutes after the onset of ischemia and reaches 4.46 to 5.93 pH. A small direct current potential and massive increase in cell input resistance support the contention that these acidic foci are from intracellular space. Horseradish peroxidase injections via the reference barrels of selected pH-sensitive microelectrodes more obviously associate these extreme levels of acidosis with astrocytes. However, even the latter data must be regarded as preliminary, since astrocytic morphology changes so dramatically as the cells become extremely acidotic (Kraig and Chesler, 1990). Immunohistochemical characterization of dye-filled acidic foci, from work in progress, should confirm the identity of the acid foci as astrocytic.

Three principal events must occur for astrocytes to become more acidotic than their surrounding milieu during terminal ischemia, when all high-energy phosphates are depleted. First, continued acid accumulation must take place in these cells. Under anoxic conditions, protons are generated when adenosine triphosphate (ATP), made by anaerobic glycolysis, is hydrolyzed (Krebs, 1975). Brain glycolytic activity may be highest in astrocytes (Phelps, 1972; Passoneau and Crites, 1976). Furthermore, astrocytes are intimately involved in cellular and interstitial ion homeostasis, processes that are believed to require considerable ATP consumption (Walz, 1989). Thus, astrocytes may generate excessive acidity when they attempt to reestablish their ionic environments or that of the interstitial space (Hansen, 1985) after the onset of ischemia. The second requirement, that cellular membrane impermeability to ions remains intact, is discussed more extensively below. The third requirement for astrocytes to remain more acidotic than their outside environment is that more pH-related anions [e.g., lactate or bicarbonate (HCO_3^-)] remain outside these cells than are found within them (see Figure 64-1). Evidence already exists to support this notion of cation-anion distributions. For example, previous indirect measurements of pH and tissue P_{CO_2} show that more HCO_3^- is found in the interstitial space than in cells presumed to be astrocytes (Kraig et al., 1986). Furthermore, Walz and Mukerji (1988) have shown more lactate is found outside than within astrocytes in culture when these cells are made anoxic. However, experiments done in cultured systems need to be carefully evaluated when considered as evidence in support of observations made *in vivo*. Cells in culture are exposed to a relatively infinite external environment when compared to conditions *in vivo* (Hansen, 1985; Kraig et al., 1986; Smith et al., 1986). Indeed, such differences in experimental conditions may explain why the pH_i of astrocytes can rapidly equilibrate with the pH of the external milieu *in vitro* during various imposed pH perturbations (Mellergard et al., 1992), and yet remain an order of magnitude more acidic than the interstitial space *in vivo* during terminal ischemia (Kraig and Chesler, 1990).

The suggestion that at least one cell type, namely, astrocytes, can retain or increase their cell input resistance in the face of a loss of all high-energy phosphate stores goes against conventional logic of stroke pathophysiology. The usual assumption is that all brain cells lose the capacity to restrict ion movement across their plasma membranes with the loss of ATP stores. This belief probably arises from the following facts. First, ion gradients are largely determined by active processes (i.e., require ATP) (Erecinska and Silver, 1989). Second, high-energy phosphates are lost within a few minutes of the onset of global ischemia (Lowry et al., 1964). Third, large changes in interstitial ion concentrations that occur shortly after the onset of global ischemia suggest dissipation of these ion gradients (Hansen, 1985; Siesjo and Bengston, 1989). Fourth, ischemia causes the generalized release of neurotransmitters (Benveniste et al., 1984), which can increase membrane conductance to various ions. However, in spite of these strong implications, few direct measurements exist to confirm a total loss of membrane resistance during ischemia—indeed, evidence exists to the contrary.

Cell input resistance and plasma membrane resistivity are the best means by which to assess cell permeability to all ions. These passive electrical properties of cells are typically measured with intracellular

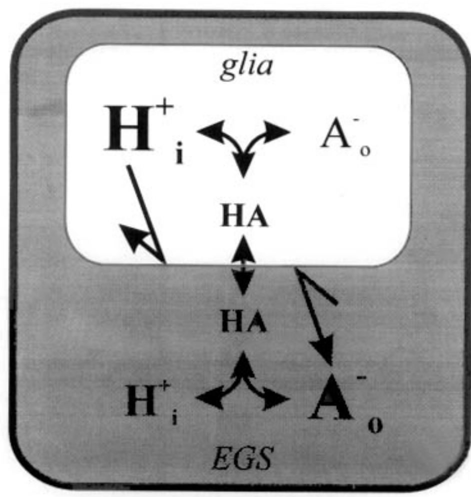

FIG. 64–1. Mechanism by which extreme astrocytic acidosis could be maintained during hyperglycemic and severe ischemia. The notion that a *trans*-membrane pH gradient could exist long after the loss of high-energy stores from brain ischemia is contrary to accepted general knowledge in stroke research. Most assume that membrane integrity is immediately lost with the loss of high-energy stores. Of course membranes will ultimately disintegrate from ischemia. However, data derived from cellular physiological techniques is now available to indicate that plasma membranes of astrocytes can remain intact for at least an hour after the onset of complete ischemia (see text for details). Direct measurements of presumed astrocytes during hyperglycemic and complete ischemia made with microelectrodes show that these cells remain more than an order of magnitude more acidotic than their surrounding milieu for up to an hour after the loss of high-energy phosphates from ischemia (Kraig and Chesler, 1990). The molecular mechanisms by which astrocytes accomplish this heretical feat remain undefined. Nonetheless, at least three essential phenomena must occur. First, astrocytic membranes must remain intact. Second, these cells must accumulate proton equivalents without absorbing bicarbonate from the interstitial space. Acidic inhibition of membrane transport systems for proton equivalents coupled to intact cell membranes and proton production within astrocytes would fulfill these requirements. Yet astrocytic membranes are still likely to remain permeable to nonionized organic acids (*HA*) such as lactic acid, so the concentration of HA would be expected to be equal within astrocytes and the extraglial space (*EGS*). Thus, a third requirement is needed for astrocytes to remain more acidic than the EGS. This requirement is simply that the EGS be a restricted compartment where the concentration of pH-related anions is greater than that found in astrocytes. If true, then the proton gradient across the astrocytic plasma membrane would simply be equal to the inverse of the *trans*-membrane anion ratio.

For example,

$$pH_i = pK_a + \log \frac{A_i^-}{HA_i} \quad (1)$$

and

$$pH_o = pK_a + \log \frac{A_o^-}{HA_o}, \quad (2)$$

where A_i^- and A_o^- are intracellular and interstitial conjugate bases, respectively (e.g., lactate or bicarbonate). If the ionization equilibrium constant (K_a) for a given acid is the same in the intracellular and interstitial space and that

$$[HA]_i = [HA]_o; \quad (3)$$

then by substituting Equations 1 and 2 into 3,

$$\frac{[H^+]_i}{[H^+]_o} = \frac{[A^-]_o}{[A^-]_o},$$

where H_i^- and H_o^+ are the intracellular and interstitial proton concentrations, respectively. [Modified from Kraig and Chesler (1990).]

or patch-clamp microelectrodes. Such measurements show that depolarization of neurons and glia are not associated with a total loss of cell input resistance. For example, neurons depolarized by exposure to hypoxia in brain slices show a dramatic reduction in cell input resistance (Fujiwara et al., 1987). However, they do not completely lose input resistance. In addition, neuronal input resistance only drops to about 40% of normal when these cells are depolarized by spreading depression (Czeh et al., 1992), a propagating phenomenon of susceptible brain tissue that has many metabolic and biophysical similarities to ischemia (Bures et al., 1974). Astrocytes lose even less of their normal input impedence during spreading depression. Most (Kraig, 1990) or all (Kraig, unpublished observations) of astrocytic input resistance is retained during spreading depression. The explanation for these observations must lie in studies of (1) ion channel, receptor, and transporter density as well as distribution in brain cells; (2) the combined effects of changes in intracellular and interstitial milieu on these membrane-based mechanisms for ion translocation; and (3) retained integrity of the plasma membrane lipid bilayer. Perhaps even more startling than preserved ion impermeability during depolarization is the realization that cell input resis-

tance of astrocytes can *rise* when ATP stores are exhausted. When cultured astrocytes are poisoned by blockade of aerobic and anaerobic glucose metabolism their membrane potential declines to near zero (Harold and Walz, 1992). However, under these conditions, the input resistance of these cells does not fall but instead rises by more than an order of magnitude!—precisely what is seen *in vivo* during hyperglycemic terminal ischemia (Kraig and Chesler, 1990).

How astrocytic input resistance could rise is unknown but can be attributed to changes in plasma membrane surface area, specific resistance of the cell membrane, and/or the degree of electrical coupling between adjacent glia cells. Acidosis can influence each of these variables. First, morphological evidence, obtained from horseradish peroxidase injections, suggests distal processes of astrocytes are lost when these cells become extremely acidotic (Kraig and Chesler, 1990). Loss of astrocytic endfoot processes (during global ischemia) was first recognized by Alzheimer in 1910 (Penfield, 1928). He noted that astrocytes can undergo a process he termed "clasmatodendrosis" (i.e., disintegration of branches), which results in these cells assuming an ameboid shape with a clear reduction in surface area. Since most of the potassium conductance of astrocytes may be in their endfoot processes (Newman, 1986), loss of these distal processes in ischemia would be expected to result in a rise in cell input resistance. Second, the specific membrane resistance of astrocytes may rise with acidosis, since conductance through potassium-sensitive channels decreases with a reduction of extracellular pH (Walz and Hinks, 1987). Indeed, ion channels show an increase in open probability with alkalinization and a pronounced decreased below pH 7 (Lang et al., 1988). Third, astrocytic coupling via gap junctions falls during hypercapnia (Conners et al., 1984) or exposure to lactic acid (Anders, 1988) and therefore, presumably during acidosis from ischemia.

Whether these astrocytic changes, namely, extreme acidity ($\approx$5.3 pH), increased input resistance, and loss of distal processes influence the evolution of infarction remains unknown. One must first note that these three fundamental changes in ischemic astrocytes have only been defined, thus far, during hyperglycemic and terminal ischemia. Reperfusion is needed for the development of infarction (Graham, 1992). Preliminary evidence (Kraig, unpublished observations) suggests that astrocytes also become more acidotic (e.g., $<$6 pH) than their external environment (6.2 pH) during severe global ischemia under hyperglycemia (e.g., blood glucose $\approx$400 mg/dl), conditions known to produce infarction (Pulsinelli et al., 1982b). Furthermore, when lactic acid is injected directly into brain for a period equal to that which can produce infarction from global ischemia (and hyperglycemia), a threshold pH of 5.3 must be surpassed to cause tissue necrosis (Kraig et al., 1987).

How astrocytic pH_i changes during focal ischemia is unknown. However, several lines of evidence suggest that astrocytic pH_i can be an order of magnitude higher in focal than global infarction, and yet in both instances, infarction can still develop from a common pH-related mechanism (Kraig, 1990). This suggestion follows from the following considerations of astrocytic HCO_3^-. First, during hyperglycemic and terminal ischemia, astrocytic pH_i reaches 5.3 (Kraig and Chesler, 1990), while tissue P_{CO_2} is approximately 400 torr (Kraig et al., 1986; Katsura et al., 1992). Assuming tissue P_{CO_2} is at least a minimum estimate of astrocytic CO_2, the HCO_3^- concentration of these cells can be calculated via the Henderson-Hasselbach equation to be approximately 2 mM (Kraig and Chesler, 1990). Bicarbonate is essential for the sequestration of iron within transferrin. Free iron in an excessively acidic environment (e.g., 2 mM HCO_3^-?) may catalyze the generation of free radicals with subsequent irreversible injury of membranes by lipid peroxidation (Pulsinelli et al., 1985; Siesjo et al., 1985). If the same injurious process proceeds within astrocytes during focal ischemia, the increased level of blood flow found there compared to global ischemia would mean tissue P_{CO_2} and (CO_2 within astrocytes) was lower than 389 torr, perhaps about 50 to 100 torr. This would mean astrocytic pH_i would be 5.9 to 6.2 if the critical level of HCO_3^- was also 2 mM.

It seems unlikely that all astrocytes uniformly will surpass some critical reduction in HCO_3^- during the development of infarction, since residual blood flows through ischemic zones in global (Pulsinelli et al., 1982a) and focal (Ginsberg, 1990) ischemia. Residual blood flow could allow continued glucose delivery to brain and escape of proton equivalents. Thus, it is likely that the pH_i of astrocytes will vary in space and time, depending on unique environmental conditions of individual cells. Support for this suggestion can be seen even in terminal ischemia, where no blood flows through ischemic brain, yet average pH_i is heterogeneously distributed throughout cortex (LaManna et al., 1992). With blood continuing to flow residually through ischemic tissue, such a pH_i heterogeneity might only be enhanced. This implies that if pH (or astrocytic pH_i) is a sole determinate of infarction, then infarction will proceed from separated microfoci that coalesce with time. Alternatively, pH may not be the sole determinant of infarction. Instead, other cellular changes might also

result in infarction or perhaps be responsible for the coalescence of acid-induced microinfarcts.

Another cellular change that either could be injurious or amplify the affect of changes in pH_i is alterations in intracellular calcium ($Ca^{2+}{}_i$). This possibility arises from observations that cultured astrocytes can be injured irreversibly by transient exposure to reduced levels of extracellular Ca^{2+} or reversibly by prolonged exposure to excitatory amino acids.

The "Ca^{2+} paradox," first described in heart, occurs after a transient period of reduced extracellular Ca^{2+}. When the Ca^{2+} concentration of the perfusate is returned to normal, myocardial Ca^{2+} rises from a large influx (Alto and Dhalla, 1979). Young believes the Ca^{2+} paradox may be important to the pathogenesis of ischemic and traumatic brain injury (Young, 1986, 1987). When neural cells (astrocytoma cells, spinal glia, and neuroblastoma cells) are exposed to a transient period of reduced extracellular Ca^{2+}, $Ca^{2+}{}_i$ rises only in glial cells after the incubation media is returned to one with a normal level of Ca^{2+} (Kim-Lee et al., 1992). Furthermore, phase contrast microscopy shows that only glia are irreversibly injured by this process. If such a process occurs *in vivo*, perhaps perineuronal astrocytes are selectively killed after ischemia, and their death then results in the loss of selectively vulnerable neurons (Kim-Lee et al., 1992).

Astrocytes may also be injured in a Ca^{2+}-dependent fashion following exposure to excitatory amino acids released during ischemia (Koyama et al., 1991). In culture, astrocytes swell and their nuclei become pale and watery after several hours incubation with L-glutamate, L-aspartate, or L-alpha-amino diacids such as L-homocysteic acid (Bridges et al., 1992). Although the swelling induced by L-alpha-amino diacids eventually leads to cell lysis, that produced by glutamate and aspartate appears ultimately reversible. The mechanisms underlying astrocytic swelling and recovery *in vitro* or *in vivo* remain only partially defined, and how Ca^{2+} might influence astrocytic volume regulation is even less clear. Moreover, the functional consequences of cell swelling, short- and long-term, both to the astrocyte and to the surrounding brain during ischemia are unclear. It is possible that astrocytic mechanisms for ion and neurotransmitter homeostasis become disrupted during swelling, producing the aberrations in interstitial K^+, pH and neurotransmitters that ultimately lead to cell death.

Of course other changes associated with disturbances in pH_i and $Ca^{2+}{}_i$ homeostasis described above may also contribute to effect injury of brain cells. Astrocytes, for example, have long been thought to be the principal regulators of interstitial K^+ homeostasis through K^+ uptake and spatial buffering (Barres, 1991). The excessively high interstitial K^+ concentrations seen in ischemia could potentially arise from changes in pH_i and $Ca^{2+}{}_i$ directly influencing the mechanisms underlying K^+ homeostasis. As discussed below, alkalotic shifts in astroglia during evoked neuronal activity or spreading depression are associated with a simultaneous rise in intracellular concentrations of HCO_3^- and K^+ (Kraig and Chesler, 1988). If HCO_3^- serves as a requisite anion for K^+ uptake, its depletion from acid production during ischemia would greatly impede astrocytic removal of K^+ from the interstitial space. In addition H^+ ions modulate the activity of various membrane channels (Kimelberg, 1988; Lang et al., 1988; Gifford et al., 1990; Tang et al., 1990; Vyklicky et al., 1990; Kaku et al., 1993) and transporters such as the Na/K ATPase (Breitwieser, 1987); acidosis might effectively shut these pathways for K^+ entry into astrocytes during ischemia. Finally, high astrocytic $Ca^{2+}{}_i$, such as can occur from exposure of these cells to excitatory amino acids (Finkbeiner, 1993) or activation of voltage-sensitive Ca^{2+} channels (Barres et al., 1989), could lead to the release of K^+ from astrocytes via Ca^{2+}-activated K^+ channels (MacVicar et al., 1991), if astrocytes were first depolarized past their equilibrium potential for K^+. In kainate-lesioned brain slices and in culture, astrocytes are known to release K^+ in response to kainate (MacVicar, 1988).

H^+ or Ca^{2+} ions alone are probably rarely the sole determinants of cell death from ischemia. Most parameters of cell vitality, when taken past some extreme, may become a factor critical to the destruction of cells. In this regard severe brain (and perhaps astrocytic) acidosis may be the most important factor involved in infarction from global ischemia under hyperglycemic conditions. However, as ischemic conditions become less absolute (i.e., as in focal ischemia) it is likely that other key variables will interact with pH changes to effect cell injury. It is plausible that pH changes may combine with other phenomena to protect cells from injury.

ASTROCYTES MAY AMELIORATE ISCHEMIC BRAIN INJURY

The notion that increased acidity in ischemic brain could enhance neuronal survival initially came from evidence that showed glutamate (e.g., *N*-methyl-D-aspartate) receptor-mediated whole-cell currents in neurons are reduced at acidic extracellular pH (Tang et al., 1990; Traynelis and Cull-Candy, 1990; Vyk-

licky et al., 1990). Furthermore, lowered extracellular pH reduces injury of neurons *in vitro* from glutamate exposure (Gifford et al., 1990; Tombaugh and Sapolsky, 1990; Kaku et al., 1993). However, in light of recent work from Siesjo's laboratory it is uncertain if these results are relevant to conditions *in vivo*. Katsura and coworkers (1994) show that acidosis from hypercapnia aggravates neuronal injury from global ischemia instead of reducing it. Taken together, these results suggest that acidity from ischemia (at least of the interstitial space) may under certain circumstances protect brain tissue from irreversible injury. Yet if such protection can occur from increased acidity *in vivo*, it is likely to do so from events that are more complex than a simple modulation of ionic conductances.

Given that astrocytes are intimately involved in both interstitial pH regulation (Walz, 1989) and brain glutamate homeostasis (Schousboe et al., 1993), these cells might enhance the survival of ischemic neurons. Evidence for this suggestion has been derived from experiments with cultured cells. For example, astrocytes increase the survival of cultured neurons to transient exposure to hypoxia (Yu et al., 1989) or anoxia (Vibulsreth et al., 1987). Furthermore, neuronal cultures are less susceptible to the excitotoxic effects of glutamate when astrocytes are also present (Rosenberg and Aizenman, 1989; Sugiyama et al., 1989). Whether or not this effect is solely due to alterations in glutamate homeostasis remains controversial (Vibulsreth et al., 1987). Elevated glucose levels can also protect astrocytes in culture from irreversible injury by anoxia (Kelleher et al., 1993). As mentioned previously, caution should be exercised when extrapolating these *in vitro* observations to those anticipated *in vivo* because of (1) the relatively infinite extracellular milieu of culture systems compared to the interstitial space *in vivo*; (2) the tendency to keep extracellular constituents at normal levels and only alter experimental variables *in vitro*, rather than change extracellular constituents to levels known to exist during ischemia (e.g., reduced levels of sodium, chloride, calcium, bicarbonate, and phosphate, and elevated levels of protons, carbon dioxide, and potassium) in parallel with changes of experimental variables; (3) the tendency to use primary culture systems *in vitro*, which preclude subtle (or as yet undefined) cell-cell interactions that would otherwise be present. With these caveats aside it should be said that if pH (and/or astrocytes) can be both harmful or helpful, it will be because of the way this physicochemical variable and cell type interact with other relevant variables and cell types. If true, this suggests that experiments designed to examine the cellular (and potentially, molecular) bases for ischemic brain injury should strive to study these phenomena in tissue-based structures with tools that have the capacity to make measurements at a cellular level.

REACTIVE GLIOSIS

Astrocytic Changes

If astrocytes are not destroyed along with other brain cells by ischemia (e.g., infarction) they are transformed into so-called reactive species (Graham, 1992). Reactive astrocytosis is defined as a hypertrophy and hyperplasia of these cells that is associated with increased glial fibrillary acidic protein (GFAP) (Graham, 1992). This classical denotation has been extended by Petito and coworkers (1990) who have shown that global ischemia can induce two variations of reactive astrocytosis. The first consists of hypertrophy, increased GFAP staining, and hyperplasia that persists for at least 5 weeks after ischemia. It is seen in zones where neurons are destroyed. The second consists of astrocytic hypertrophy and increased GFAP staining, which persists for about 2 weeks and is not associated with astrocytic hyperplasia. The latter is seen in neocortex where few neurons are destroyed.

How astrocytes are transformed into reactive species remains uncertain. Spreading depression (SD), a gross perturbation of brain, can be used to study the phenomenon of reactive astrocytosis. SD is defined as a propagating, transient loss of spontaneous and evoked neuronal activity that is associated with a large, negative direct current potential in interstitial space (Bures et al., 1974). It is known to occur *in vivo* as well as *in vitro* in brain slices (Snow et al., 1983) and, potentially, explant cultures (Dani et al., 1992) where normal brain cytoarchitecture largely remains intact (Gähwiler et al., 1992). SD has many metabolic and biophysical similarities to processes that occur during ischemia (Bures et al., 1974). Large changes of interstitial potassium, sodium, hydrogen, calcium, chloride (Nicholson and Kraig, 1981), HCO_3 and carbon dioxide (Kraig and Cooper, 1987), glutamate, and lactate (Krivanek, 1961; Mutch and Hansen, 1984; Scheller et al., 1992) as well as in arachidonic acid (Lauritzen et al., 1990) occur. Importantly, however, SD does not cause irreversible injury of brain cells (Nedergaard and Hansen, 1987) and does not open the blood-brain barrier (de-Araujo-Pinheiro and Martins-Ferreira, 1984).

SD causes changes in astrocytes that resemble the reactive astrocytosis described by Petito and col-

leagues in neocortex after global ischemia (Kraig et al., 1991). Recurrent SD induces a significant increase in GFAP staining and astrocytic hypertrophy that persists for 2 weeks before returning toward normal by 4 weeks. This increase in GFAP staining is associated with a parallel, significant increase in GFAP content that seems mostly due to cellular hypertrophy and not hyperplasia (Kraig et al., 1995).

Although the mechanisms by which astrocytes are transformed into reactive species following SD remain unknown, changes in the concentration of various ionic species must be considered as prime candidates. For example, a rise in pH_i is commonly associated with increased metabolic activity (Busa and Nucitelli, 1984). During SD, as the brain generates lactate (Krivanek, 1961; Mutch and Hansen, 1984; Scheller et al., 1992) and the interstitial pH principally swings more acid (Kraig et al., 1983; Mutch and Hansen, 1984), astrocytes become markedly more alkaline. Astrocytic pH_i is normally around 7.0. During SD it typically rises to 7.6 to 7.8 before returning to normal as the cells repolarize (Chesler and Kraig, 1987, 1989) (Figure 64-2). A depolarization-induced alkalinization occurs in a variety of cells and has recently been characterized in cultured astrocytes (Boyarsky et al., 1993). Others have argued that a rise in pH_i is not essential for the initiation of anabolic activities (Ganz et al., 1989). The latter view, however, is tempered by the suggestion that a rise in pH_i is necessary only in those cells whose resting pH_i is not already sufficiently alkaline (Whitfield, 1990). An alternative possibility to pH_i changes is that a rise in intracellular potassium initiates reactive astrocytosis (Kraig and Jaeger, 1990). The massive rise in pH_i described above is associated with an approximate 50 mM increase in HCO_3^- concentration (Kraig and Chesler, 1988) that is probably accompanied by a nearly equivalent rise in intracellular potassium (Kraig and Jaeger, 1990). 3T3 fibroblasts divide when their internal potassium rises above 100 mM, a change seen in astrocytes during SD (Lopez-Rivas et al., 1982). Glutamate, which also depolarizes astrocytes (Bowman and Kimelberg, 1984), may initiate reactive astrocytosis, perhaps because of a rise in $Ca^{2+}{}_i$ (Cornell-Bell et al., 1990; Glaum et al., 1990; Jensen and Chiu, 1990) and such a rise is a well-recognized trigger for increased vital processes within cells (Busa and Nucitelli, 1984; Whitfield, 1990). Astrocytic $Ca^{2+}{}_i$ is known to rise during SD (Kraig and Lascola, 1992, 1994) (Figure 64-3), and thus this rise may be stimulated through neurotransmitter receptors such as ionotropic and

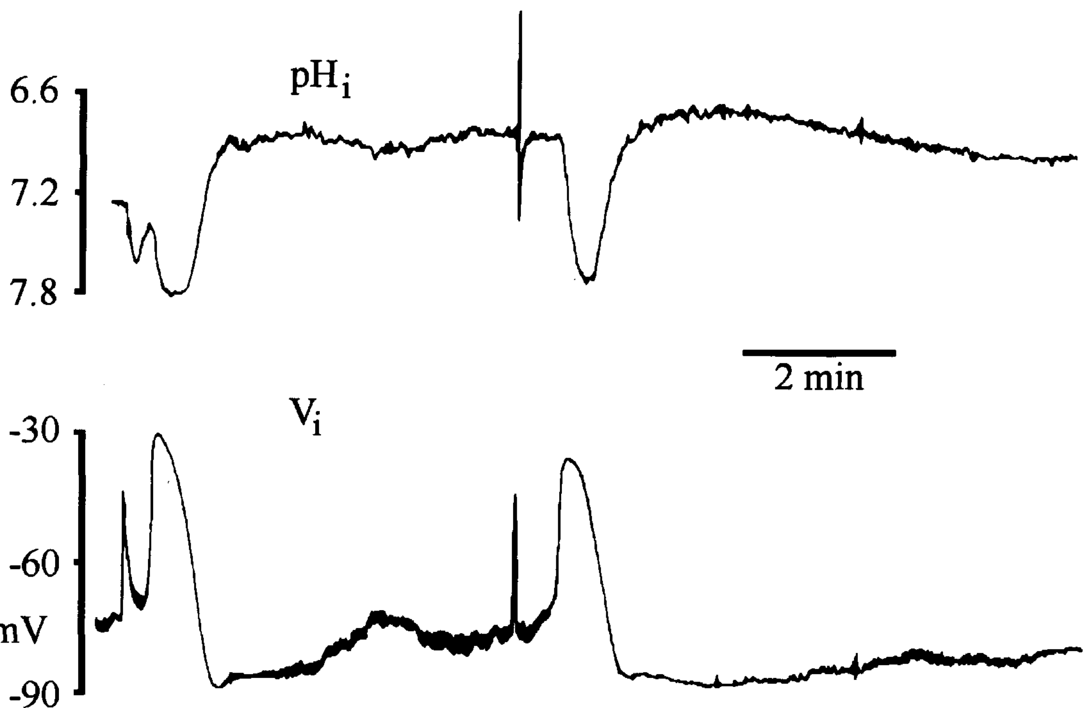

FIG. 64–2. Astrocytic pH_i responses to successive spreading depressions (SDs). Records show pH_i (*upper record*) and simultaneously measured membrane potential (V_i) (*lower record*) from a rat neocortical astrocyte measured *in vivo* with a double-barrel pH-sensitive ion-selective microelectrode. SD was induced by brief 100 Hz surface, bipolar electrical stimulation (*arrows*). Resting astrocytic pH_i is 7.0 and during SD can rise to as much as 7.6 to 7.8 before swinging slightly acid during repolarization and recovery from SD. (Modified from Chesler and Kraig (1989).]

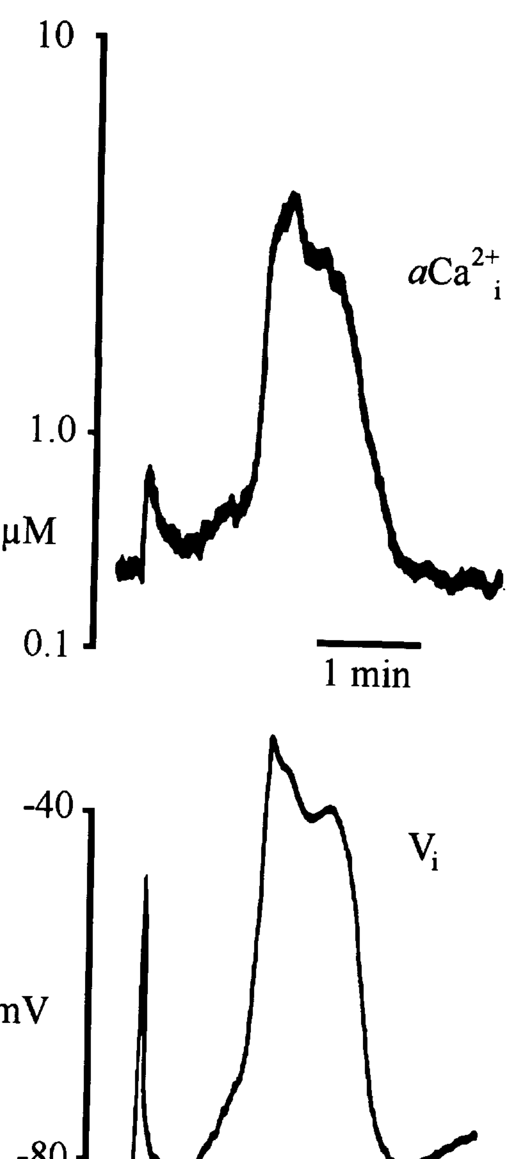

FIG. 64–3. Astrocytic $Ca^{2+}{}_i$ change during spreading depression. Astrocytic $[Ca^{2+}]_i$ was measured with a Ca^{2+}-sensitive and double-barrel microelectrode. A 100-Hz surface, bipolar electrical stimulus was used to elicit SD (*arrow*). Astrocytic $Ca^{2+}{}_i$ activity (*upper record*) rose from a baseline of about 200 nM to more than 3 μM during maximal depolarization as shown by simultaneous recording of membrane potential (*lower record*). Membrane potential was initially -82 mV before falling to -30 mV during SD. [Modified from Kraig and Lascola (1994).]

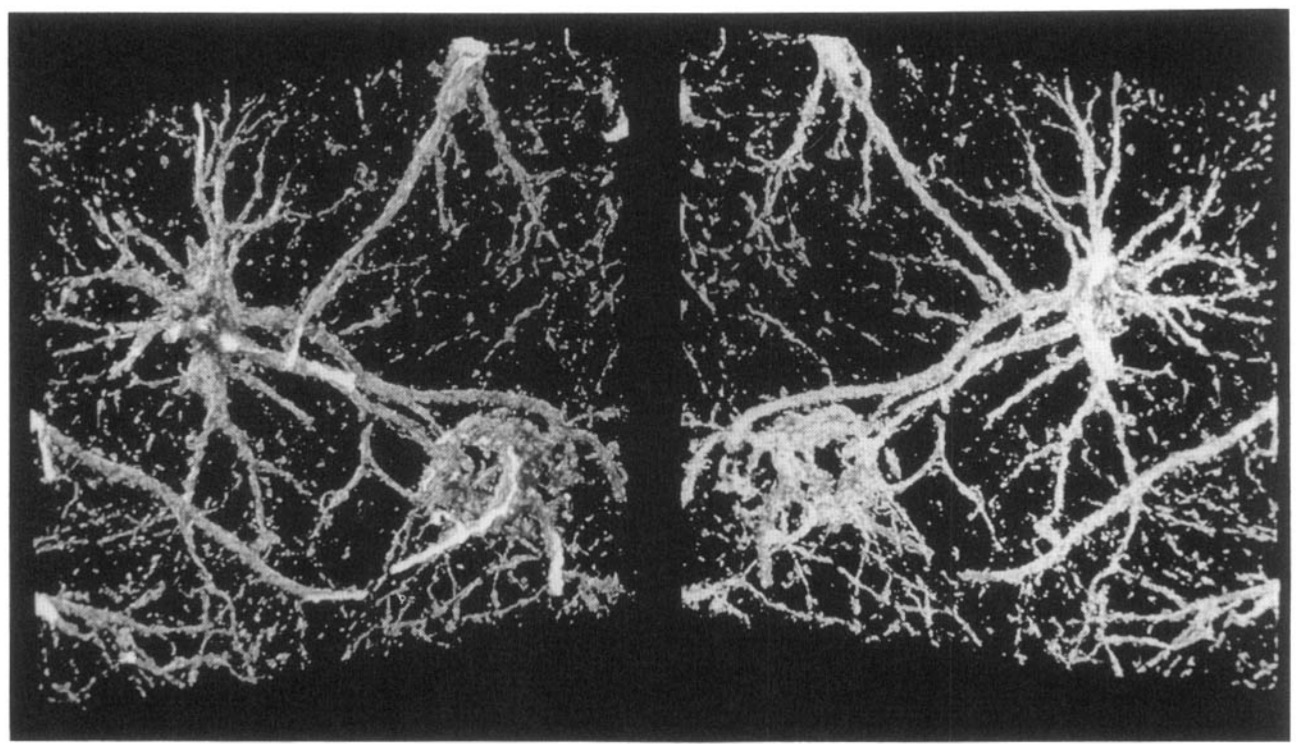
metabotropic glutamate channels believed to present on astrocytes.

It is possible that reactive astrocytosis is not triggered by any singular change in some variable but instead reflects the combined effects of various changes. An example of this possibility is the potential synergistic effect of changes in pH_i and $Ca^{2+}{}_i$. Busa and Nucitelli (1984) were the first to point out that a rise in pH_i might affect the degree to which a rise in $Ca^{2+}{}_i$ influences calcium-dependent processes. They reasoned that a rise in pH_i of 0.5 would have the same effect as a fivefold rise in $Ca^{2+}{}_i$. Astrocytic pH_i rises by more than 0.5 during SD and $Ca^{2+}{}_i$ rises by 1 or 2 orders of magnitude. Together these ionic changes may be powerful synergists for astrocytic activation.

Cultured astrocytes are often used to examine how astrocytes are transformed into reactive species (for review as Eddleston and Mucke, 1993). An important caveat with the use of cultured systems for studying this phenomenon ought to be mentioned. Astrocytes in culture never fully mature. They continue to express vimentin, for example, while only developing astrocytes or ones made reactive do so *in vivo* (DeVellis et al., 1986). Thus, cultured astrocytes may already be "reactive" in at least some aspects of their behavior. Nonetheless, isolated systems have distinct experimental advantages over whole-animal preparations. To explain the mechanisms by which ischemia transforms astrocytes into reactive species will, no doubt, require the association of studies done both *in vitro* and *in vivo*. It is our belief that the utility of such studies can be maximized when they are done in parallel so that analogies can easily be drawn between these two systems.

Microglial Changes

Not only ionic species but *cells* may interact to effect astrocytic changes. After ischemia, microglial cells respond by changing their morphology, dividing and increasing the expression of major histocompatibility complex (MHC) antigens (Finsen et al., 1993). Microglia secrete and are influenced by a host of cytokines and their activation may allow these cells to induce reactive changes in astrocytes (Benveniste, 1992). This has led some to wonder if an ischemia-induced increased permeability of the blood-brain barrier allows soluble cytokines from the vasculature to affect changes in microglia (Finsen et al., 1993). Alternatively, stimuli that activate microglia cells may come from within the brain. For example, Gehrmann and coworkers (1993) speculate that the unique pattern of potassium channels found on microglia *in vitro*, if present *in vivo*, would make these cells highly susceptible to depolarization by potassium released from neurons. They sought to test this possibility by determining if SD could activate microglia *in vivo*. They show that after 1 hour of recurrent SD, microglia are activated (e.g., increased OX-42, OX-18 (MHC-I) and OX-6 (MHC-II) immunohistochemical staining) (Gehrmann et al., 1993). (OX-42 is an antibody that recognizes the



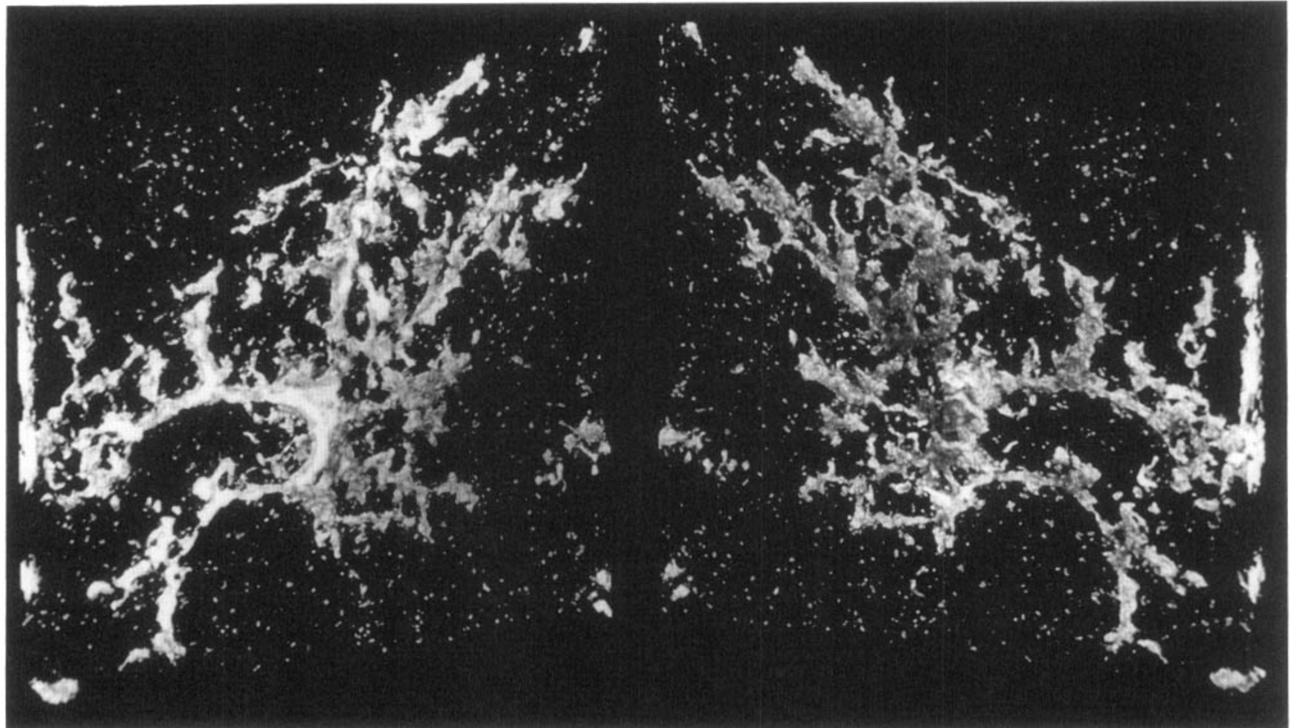


FIG. 64-4. Three-dimensional reconstructions of deconvolved glial images produced by computer-based digital confocal microscopy. Brightfield images of reactive astrocytes (*upper panel*) and normal microglia (*lower panel*) are shown. Astrocytes were stained with GFAP and microglia with OX-42. Both staining protocols used diaminobenzidine as the chromogen. Images were created with a 12-bit resolution cooled CCD camera (CH250; Photometrics, Inc.) through a red (660 nM) filter. Images were deconvolved and reconstructed using Microtome and Voxblast, respectively, two software packages available from Vaytek, Inc. Resultant images were false-colored, turned into photographic slides and finally into prints. Left: Front views. Right: Back views of the same cells. These images begin to illustrate the fine detail and three-dimensional aspects of brain cells that can be seen using digital confocal microscopy. (Kraig, Caggiano and Lascola, unpublished observations.)

complement receptor-3 surface adhesion molecule on microglia). The activation of microglia from SD is transient, reaching a peak at 24 hours after SD before returning to normal in approximately 3 days. Since these workers could elicit a microglial and not astrocytic activation after 1 hour of SD, they concluded that microglial activation might precede (and be more easily elicited?) than that of astrocytes. Indeed, Gehrmann and coworkers elicited an average of 8 SDs over an hour, while work from our laboratory has used a paradigm of 3 hours of SD (and an average of 21 SDs) to activate microglia (Caggiano and Kraig, 1993) and astrocytes (Kraig et al., 1991). Thus, the possibility that SD activates microglia earlier than it does astrocytes or even that SD can activate microglia preferentially remains an exciting possibility.

What causes the activation of microglia from ischemia remains unknown. Blood-brain barrier permeability is not increased during SD (de-Araujo-Pinheiro and Martins-Ferreira, 1984). Thus, if activation from SD proceeds by the same mechanisms that occur during activation from ischemia, disruption of the blood-brain barrier does not seem to be a necessary prerequisite. Not only do microenvironmental signals endogenous to brain (Gehrmann et al., 1993) need to be considered as potential stimuli for activation of microglia (and astrocytes) but also systemic signals. For example, systemic administration of tumor necrosis factor-α or interfon-γ lead to increased MHC-II expression on microglia without causing tissue injury (Vass and Lassmann, 1990; Lassmann et al., 1991). Furthermore, endocrine-immune interactions can modulate reactive gliosis. Systemic administration of steroids significantly reduces not only microglial but astrocytic gliosis from SD (Caggiano and Kraig, 1993). Clearly, the behavior of microglia and that of astrocytes seems destined to be defined as an intimate interaction between changes within and outside of brain.

SUMMARY AND CONCLUSIONS

Glial cells, like other living things, do not exist in isolation. Rather they interact with other brain cells, the vasculature and substances from other organ systems. The concept that interactions necessarily occur between glia and their environment is likely also to apply to how these cells respond to ischemic brain injury. The notion of interaction may be applied equally well to how ions, molecules, cells, and even tissues influence the behavior of these cells.

Given the high capacity of astrocytes (and microglial) to influence and be influenced by changes in their microenvironment, one must decide how best to study reactive gliosis. Animal preparations that include multiple cell types seem best suited for the examination of interactive cellular behavior. Whole-animal studies are indispensible for the definition of the magnitude and extent of changes that occur in experimental variables during and after ischemia. However, whole-animal studies are limited by a relative inability to manipulate experimental conditions compared to *in vitro* preparations. Improved access is provided by *in vitro* preparations but with the advantage of "complete control" of the external milieu, comes the responsibility for defining all aspects of this control. Brain slices are well suited for acute studies that examine plasma membrane-based issues of cellular interaction, while mixed and cocultures are well suited for more long-term studies. Reaggregate and slice culture systems may be the most advantageous tissue culture preparations, since a high degree of cytoarchitectural integrity is maintained in these systems. Techniques most useful for the assessment of reactive gliosis include those that emphasize the use of micropipettes and microscopy. The former include intra- and extracellular electrodes, patch-clamp pipettes and ion-selective microelectrodes, while the latter include video microscopy and quantitative voltage and ion-selective dyes as well as immunohistochemical imaging that can be coupled to a confocal microscope (Figure 64-4). These preparations and techniques are those that seem likely to maximize astrocytic (and microglial) abilities to interact with their external environment.

This work was supported by The National Institute of Neurological Disorders and Stroke grant (NS-19108), an Established Investigator Award from the American Heart Association, the University of Chicago Brain Research Foundation and the American Heart Association of Metropolitan Chicago (RPK). CDL was supported by HD-07009; AC was supported by T32GM-07281. We thank Mr. Pierce Park for his participation in producing the images for Figure 64-4.

65 Idiopathic and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced Parkinsonism

DONATO A. DI MONTE AND J. WILLIAM LANGSTON

The precise mechanisms of neuronal degeneration in human neurologic disorders remain mostly unknown. In the past few years, however, studies utilizing novel or refined experimental models have suggested that nerve cell death may be the result of a concerted sequence of metabolic, biochemical, and toxic events. Current knowledge also suggests that, although the final target of neurodegeneration may be a rather selective nerve cell population, other types of cells may play a role in degenerative processes. In recent years, glial elements have attracted increasing attention as possible participants in the pathogenesis of neuronal damage.

Parkinson's disease is one of the most common neurodegenerative disorders of aging; it results from the selective loss of dopaminergic neurons in the nigrostriatal pathway. It is an excellent example of how our knowledge about neurodegenerative processes has been enhanced and reshaped in the past few years thanks to the availability of new experimental tools. Ten years ago it was discovered that a simple pyridine derivative, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), was able to cause the selective destruction of nigrostriatal dopaminergic neurons (Burns et al., 1983; Langston et al., 1984a) and a syndrome in humans that was clinically indistinguishable from idiopathic parkinsonism (Langston et al., 1983). The MPTP model of parkinsonism has since provided a number of clues about the mechanisms that might lead to neurodegeneration in Parkinson's disease as well as other neurologic disorders. Of particular interest are the results from studies of MPTP-induced neurotoxicity which support the hypothesis that a multistep process leads to neuronal death; these studies have also suggested that an active role is played by astrocytes. In this chapter, the mechanisms of neuronal death in idiopathic and MPTP-induced parkinsonism will be discussed. Events that are likely to involve astrocytes are emphasized so that the reader can expect to obtain insight into the direction of future studies concerning the role of glial cells in neurodegenerative disorders.

PARKINSON'S DISEASE

Clinical and Pathological Features

Idiopathic Parkinson's disease is a progressive age-related neurodegenerative disorder. It is rarely observed before the age of 40 and its prevalence increases with advancing age (Kurland et al., 1973). Its clinical manifestations are essential for the diagnosis, due to the absence of measurable biological markers of the disease; indeed, the clinical diagnosis of Parkinson's disease can only be confirmed postmortem by pathologic examination of the brain. Cardinal features of Parkinson's disease include bradykinesia, resting tremor, rigidity and postural instability. Once the diagnosis is made, the clinical syndrome advances usually at a relatively slow rate, progressively impairing, however, the normal activity of the patient and his ability to care for himself.

Degeneration of the pigmented neurons in the pars compacta of the substantia nigra represents the cardinal neuropathologic feature of Parkinson's disease. Nerve cell loss is not equally severe throughout the substantia nigra and it is not confined within this region of the brain, however. The most severe cell loss is observed in the lateral and ventral cell groups of the substantia nigra (Gibb et al., 1990), and neuromelanin-containing noradrenergic neurons of the locus ceruleus are also affected by degenerative processes in nearly all typical cases of Parkinson's disease (Forno, 1982). Another hallmark of neuronal degeneration in Parkinson's disease is the presence of eosinophilic inclusions, called Lewy bodies, within the cytoplasm of nerve cells (Forno, 1982). The significance of Lewy bodies remains unknown, although they are thought to be indicative of an ongoing degenerative process. The most common ob-

servation concerning astrocytes in the parkinsonian brain is the presence of glial scars; they are usually localized in the areas most severely affected by neurodegeneration (*i.e.*, the lateral and ventral portions of the zona compacta of the substantia nigra) and are most likely the result of a secondary reaction to the nerve cell loss (Forno et al., 1992).

A large number of reactive microglia phagocytosing dopaminergic cells have been observed in the substantia nigra pars compacta of parkinsonian brains using immunohistochemical staining for HLA-DR (McGeer et al., 1988). HLA-DR is a human glycoprotein of the group II major histocompatibility (MHC) class; its major function is probably to present foreign antigen to T-helper lymphocytes. The precise role of HLA-DR-positive microglia in dopaminergic cell death remains to be clarified. However, the finding by McGeer and colleagues is consistent with the hypothesis that an ongoing neuropathological process underlies Parkinson's disease and is still active at the time of death of parkinsonian patients.

Neurochemistry

From the neurochemical point of view, Parkinson's disease is characterized by a severe depletion of dopamine in the nigrostriatal pathway. This depletion is the result of death of the dopaminergic neurons which are localized in the substantia nigra and project their axons to the striatum (Anden et al., 1984). Similar to the unequal distribution of neurodegeneration in the substantia nigra, a gradient of dopamine loss is observed in the striatum, with a greater depletion in the putamen than in the caudate; also, within the putamen, the posterior region is more affected than the anterior portion (Kish et al., 1988).

As already mentioned, the pathogenesis of neuronal death in Parkinson's disease is far from being understood. Among the numerous hypothesized mechanisms, the one that has received the most attention in the past decade is perhaps the oxidative stress hypothesis (Cohen, 1983). Oxidative stress is defined as a toxic condition in which the cellular oxidation/reduction (redox) balance is shifted toward oxidation. This may occur as a consequence of accumulation of oxygen free radicals (*e.g.*, the superoxide anion radical, O_2^-, or hydrogen peroxide, H_2O_2) due to an excessive production and/or decreased scavenging ability; oxygen radicals are very reactive chemical species able to oxidize DNA, membrane lipids, essential enzymes, and structural proteins, thus causing impaired cellular activity and eventually cell death.

It has been suggested that the brain in general may be particularly susceptible to free radical damage for reasons such as the high content in polyunsaturated fatty acid side chains of the membrane lipids and the relative poor activities of enzymatic defense mechanisms (*e.g.*, catalase, superoxide dismutase, and glutathione peroxidase). There are also reasons to hypothesize that, within the brain, the monoaminergic system may represent a preferential target for oxidative stress. Both the enzymatic and nonenzymatic oxidation of dopamine can generate H_2O_2:H_2O_2 is a product of dopamine conversion via monoamine oxidase (MAO) and could also be formed during dopamine autoxidation (Graham, 1978) (Figure 65–1). Under normal conditions, H_2O_2 is reduced enzymatically by catalase and glutathione peroxidase. However, if the rate of H_2O_2 production overwhelms these defense systems, H_2O_2 could be accumulated, resulting in the oxidation of essential cellular macromolecules. Furthermore, in the presence of transition metals such as iron and copper, H_2O_2 could generate even more reactive and deleterious oxygen species,

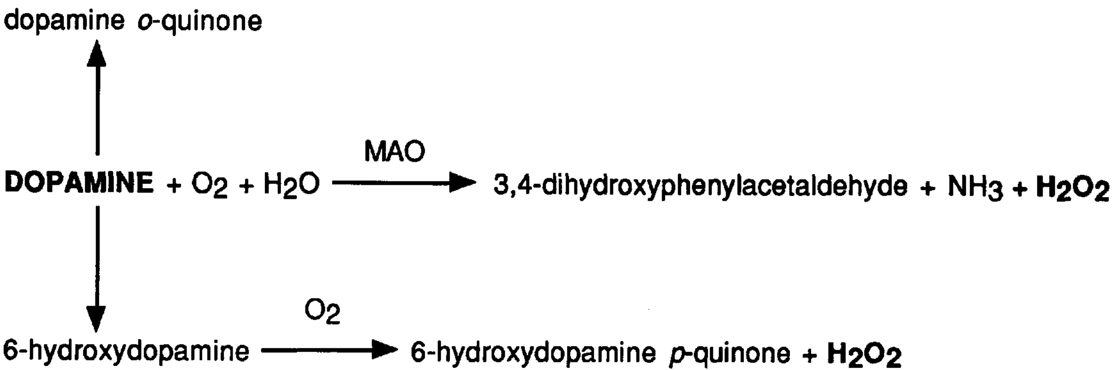

FIG. 65-1. Oxidative pathways of dopamine metabolism. Hydrogen peroxide (H_2O_2) could be formed during dopamine autoxidation and as a product of dopamine metabolism via monoamine oxidase.

such as the hydroxyl radical (Halliwell and Gutteridge, 1984). Interestingly, iron is unevenly distributed throughout the brain (Hill, 1988), and the relatively high content of iron in the substantia nigra may represent another mechanism for an increased susceptibility of nigrostriatal dopaminergic neurons to oxidative stress. The substantia nigra is also rich in neuromelanin, a product of catecholamine autoxidation (Graham, 1978). Neuromelanin can bind iron (Youdim et al., 1989), and reactions involving neuromelanin could represent additional sources for free radicals.

If dopamine metabolism and oxygen radical production play a role in the nigrostriatal nerve degeneration in Parkinson's disease, then it is conceivable that astrocytes may be involved in these processes. The relationships between glial cells, dopamine turnover, oxidative stress, and loss of dopaminergic activity in Parkinson's disease are schematized in Figure 65-2 and are discussed in the following section.

Role of Glial Cells in Dopamine Metabolism and Oxidative Stress

The action of dopamine as a neurotransmitter is terminated at least in part by its extraneuronal metabolism, and a key role in this metabolism is attributed to MAO-B, an enzyme localized within astrocytes (Levitt et al., 1982; Westlund et al., 1985). For these reasons, changes in glial MAO-B have been suggested to affect dopaminergic neurotransmission (Knoll, 1985) and may ultimately contribute to the main pharmacologic feature of Parkinson's disease, that is, the decline of nigrostriatal dopaminergic activity. Interestingly, significant changes in MAO-B do occur physiologically in the brain: higher MAO-B levels have been measured in older humans and older animals and have been thought to reflect an increasing proportion of glial cells in the aging brain (Robinson et al., 1971; Benedetti and Keane, 1980; Fowler et al., 1980; Irwin et al., 1992). As shown in Figure 65-2, increased glial MAO-B activity may lead to a higher rate of dopamine turnover and to an age-related decrease in dopaminergic signal transmission; these changes may predispose to parkinsonism, particularly if they eventually result in the damage of dopaminergic neurons. Thus, the involvement of astrocytes in dopamine metabolism not only may contribute to the loss of dopaminergic activity observed in Parkinson's disease, but it may also explain, at least in part, the role of aging as a risk factor for parkinsonism (Kurland *et al.*, 1973).

MAO-dependent dopamine metabolism may also represent a major source of oxidative stress by generating H_2O_2 (Figure 65-1). Experimental evidence supports this hypothesis. For example, enhanced dopamine turnover caused by reserpine or haloperidol has been shown to result in increased levels of oxidized glutathione (GSSG) in the mouse striatum (Spina and Cohen, 1989). H_2O_2 production via MAO is probably responsible for this effect since oxidative stress could be prevented by the MAO inhibitors clorgyline and deprenyl (Spina and Cohen 1989; Cohen and Spina 1989). This MAO-related pathway of oxidative damage has long been proposed to play an important role in neuronal cell death in Parkinson's disease (Cohen, 1983). The extraneuronal localization of MAO B (Levitt et al., 1982; Westlund et al., 1985) also suggests the involvement of glial cells in these processes: H_2O_2 could be generated by astrocytes and, because of its ability to cross cell membranes (Halliwell and Gutteridge, 1984), it might then attack its neuronal targets (Figures 65-2 and 65-3).

It is noteworthy that, while being a source for H_2O_2, glial cells may also exert a protective function against oxidative stress. This is because glutathione, a key molecule in the detoxification of H_2O_2, appears to be present in relatively high concentrations in astrocytes as compared to neuronal cells (Slivka et al., 1987; Raps et al., 1989). Reduced glutathione (GSH) is the source of electrons for the reduction of H_2O_2 catalyzed by glutathione peroxidase, and depletion of GSH levels has been associated with a greater vulnerability of cells to oxidative stress (Orrenius et al., 1985). It is potentially relevant, therefore, that decreased levels of glutathione have been reported in the brain and in the substantia nigra of parkinsonian patients as compared to control subjects (Perry et al., 1982; Riederer et al., 1989), leading to the speculation that Parkinson's disease may be a disorder due to nigral glutathione deficiency (Perry et al., 1982). This impairment of defense mechanisms against H_2O_2 accumulation may reflect a specific feature of glial cells in the parkinsonian brain. Furthermore, due to the possible involvement of astrocytes in both the generation and detoxification of H_2O_2, the presence of high GSH levels in these cells may protect them from oxidative injury; in contrast, lack of GSH in neuronal cells may predispose them to be damaged by the H_2O_2 formed in the process of dopamine turnover. This concept that H_2O_2 might cause different cytotoxic effects in astrocytes as compared to neurons due to the presence or lack, respectively, of glutathione is schematized in Figure 65-3.

The possibility that nigrostriatal dopaminergic neurons may be particularly vulnerable to oxygen radical production does not necessarily imply that

Aging

Glial proliferation

Increased MAO B activity

Metabolic activation of neurotoxicants

Increased rate of dopamine metabolism

Increased H_2O_2 production

Oxidative stress

Neuronal damage

Neuronal damage

Loss of dopaminergic activity

FIG. 65-2. Possible relationships between glial cells, monoamine oxidase, oxidative stress, and loss of dopaminergic activity in Parkinson's disease.

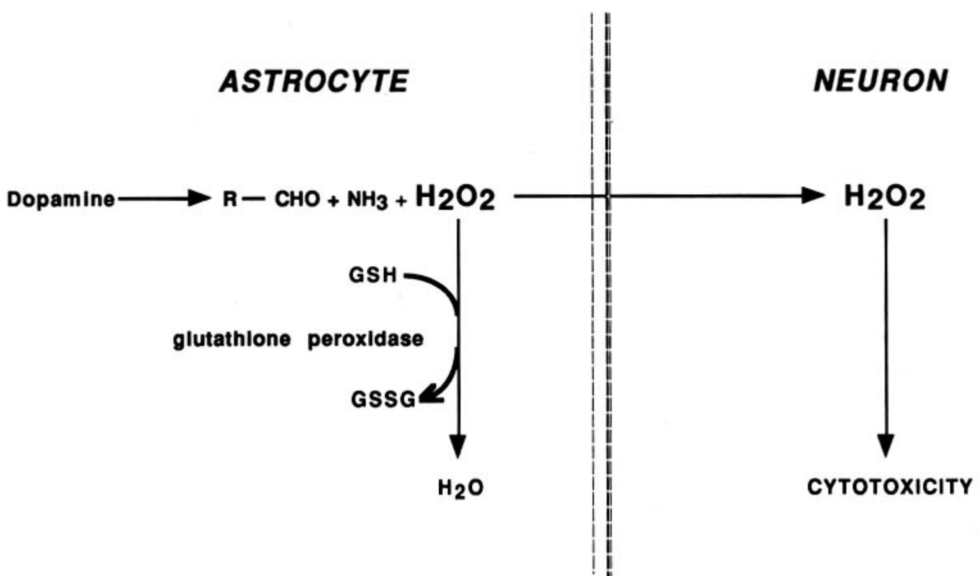

FIG. 65-3. Fate of the hydrogen peroxide (H_2O_2) generated in glial cells via monoamine H_2O_2 can be reduced to H_2O at the expense of glutathione (GSH) within astrocytes, or it may cross astrocyte and neuronal membranes. The lack of glutathione may make neurons more vulnerable to the cytotoxic effects of H_2O_2.

oxidative stress is the prominent cause of neurodegeneration in Parkinson's disease. Indeed, the free radical hypothesis for the pathogenesis of idiopathic parkinsonism remains quite controversial (Caine, 1992; Fahn and Cohen, 1992). More recently, toxic mechanisms other than oxidative stress have been suggested to play a role in nigrostriatal neurodegeneration. In particular, an impairment of mitochondrial energy production and/or the activation of excitatory amino acid receptors have been hypothesized. These novel pathogenetic hypotheses mostly stem from studies on MPTP neurotoxicity, and are discussed in greater detail in the next section.

MPTP-INDUCED PARKINSONISM

It is not surprising that the discovery of MPTP in 1982 immediately prompted great expectations among scientists working in the field of neurodegenerative disorders. Individuals who injected themselves with batches of "synthetic heroin" contaminated with MPTP developed a clinical syndrome virtually indistinguishable from severe idiopathic parkinsonism (Langston et al., 1983). It was therefore predicted that MPTP poisoning would become an excellent model for elucidating the process of neurodegeneration in human brain. The clinical similarities between MPTP-induced and idiopathic parkinsonism have since been further characterized (Tetrud et al., 1989). These similarities not only concern the major features of the disorder, but include more subtler signs, such as hypomimia, seborrhea, and micrographia. Moreover, MPTP patients responded to levodopa therapy and developed the typical side effects of this treatment, including end-of-dose "wearing off" and peak-dose dyskinesia. Positron emission tomography (PET) scanning has also revealed a reduction in striatal radioactivity in individuals exposed to MPTP as compared to age-matched controls (Caine et al., 1985).

The ability of MPTP to damage the nigrostriatal dopaminergic system as a primary target has been confirmed by both neurochemical measurements and neuropathologic studies in the monkey and rodent models. A severe and long-lasting depletion of striatal dopamine is consistently observed after systemic administration of MPTP to monkeys (Burns et al., 1983; Jenner et al., 1986; Irwin et al., 1990) or mice (Heikkila et al., 1984a; Melamed et al., 1985; Irwin et al., 1992). Whether or not MPTP is able to cause a regional pattern of dopamine loss in monkeys similar to that observed in Parkinson's disease remains controversial (Pifl et al., 1988), although a more pronounced dopamine depletion in the putamen than the caudate nucleus has been reported by Irwin et al., (1990).

From the pathologic point of view, the MPTP monkey model has revealed striking similarities as well as some differences with Parkinson's disease. The main similarities are (1) a marked destruction of neurons in the zona compacta of the substantia nigra (Burns et al., 1983; Langston et al., 1984a); (2) the occurrence of nerve cell loss in the locus ceruleus in the majority of MPTP-treated squirrel monkeys (Forno et al., 1986; Forno et al., 1993); (3) the presence of glial scars in the areas most severely affected by neurodegeneration (Forno et al., 1992), and (4) a more extensive loss of [^{3}H]mazindol binding in the putamen as compared to the caudate nucleus (Moratalla et al., 1992). The most relevant neuropathologic difference is the absence of typical Lewy bodies in animals exposed to MPTP. Abnormal nerve cells with inclusion bodies have been described in MPTP-treated squirrel monkeys (Forno et al., 1986; Forno et al., 1993); these inclusions are not a consistent finding, however, and do not display the morphological and immunocytochemical features of Lewy bodies.

Mechanisms of MPTP Neurotoxicity

Shortly after its discovery, MPTP was found to be converted by MAO-B into its fully oxidized 1-methyl-4-phenylpyridinium (MPP^+) metabolite (Chiba et al., 1984). MPP^+ represents the ultimate mediator of MPTP neurotoxicity, since (1) the damaging effects of MPTP exposure can be prevented by MAO-B inhibitors (Heikkila et al., 1984b; Langston et al., 1984c; Cohen et al., 1985), and (2) MPP^+ itself induces toxic effects similar to those seen after MPTP treatment (Langston et al., 1984b; Markey et al., 1984; Bradbury et al., 1986; Wu et al., 1992). The critical role played by MPP^+ in MPTP toxicity may also explain, at least in part, the selective action of MPTP toward the nigrostriatal dopaminergic system: MPP^+ has been shown to be actively taken up by dopaminergic neurons (Javitch et al., 1985) and it could be selectively accumulated within neurons of the substantia nigra also due to its binding to neuromelanin (D'Amato et al., 1986).

The biochemical mechanisms of cell death caused by MPP^+ have been the subject of some controversy. It was initially thought that MPP^+-induced cytotoxicity may result from free radical generation and consequent oxidative stress (Kopin et al., 1986). This hypothesis was suggested by the similarity of the chemical structure of MPP^+ with that of the herbicide paraquat, a known oxygen radical-generating

compound (Di Monte and Smith, 1988). Also, the possible involvement of oxidative stress in MPTP/MPP^+ toxicity appeared particularly attractive due to the suggested role of oxygen radicals in the pathogenesis of idiopathic parkinsonism as well. Subsequent studies have revealed significant differences in the mechanisms of cytotoxicity of MPP^+ and paraquat (Di Monte and Smith, 1988), however, and convincing evidence for a critical contribution of oxidative stress to MPTP/MPP^+ toxicity is still lacking.

It is now widely accepted that MPP^+-induced cell death may be a consequence of its ability to impair energy production by mitochondria. MPP^+ can be accumulated into the mitochondrial matrix, probably via the mitochondrial transmembrane potential (Ramsay and Singer, 1986; Sayre, 1989), and then it is capable of blocking the electron flow of the respiratory chain at the level of complex I (Nicklas et al., 1985). It is possible that an increased rate of oxygen radical generation may result from the interaction of MPP^+ with mitochondrial respiration and may contribute to the damaging effects of MPP^+ within these organelles (Cleeter et al., 1992). However, it is also quite evident that the major consequence of the action of MPP^+ as a mitochondrial poison is a failure of the cell to generate sufficient energy to support its function. Indeed, MPP^+ cytotoxicity has been directly linked to ATP depletion in a variety of *in vitro* systems (Di Monte et al., 1986; Denton and Howard, 1987; Wu et al., 1992), and more recently, MPP^+-induced ATP loss has been demonstrated to occur in the mouse brain after systemic administration of MPTP (Chan et al., 1993b).

The ability of MPP^+ to impair mitochondrial energy production may also help to elucidate recent findings suggesting a role of excitatory amino acid receptor activation in MPTP neurotoxicity (Turski et al., 1991; Zuddas et al., 1992). Adenosine triphosphate (ATP) depletion caused by MPP^+ could activate *N*-methyl-D-aspartate (NMDA) receptors by increasing the release and/or decreasing the reuptake of excitatory amino acids (Nicholls and Attwell, 1990). Furthermore, the membrane depolarization resulting from ATP depletion could relieve the voltage-dependent Mg^{2+} block of NMDA receptors, thus increasing their sensitivity to excitatory amino acids (Henneberry et al., 1989; Zeevalk et al., 1991). The role of excitatory amino acids in MPTP-induced neurodegeneration remains controversial (Sonsalla et al., 1989; Kupsch et al., 1992; Storey et al., 1992; Chan et al., 1993a) and certainly requires further clarification. However, it is noteworthy that the relationship between a failure of energy production and excitatory amino acid receptor activation has been hypothesized to underlie neuronal damage in human neurodegenerative disorders (Beal, 1992). Thus, studies with the MPTP model may once more contribute to enhance our understanding of the processes of cell degeneration in neurologic diseases.

Role of Glial Cells in MPTP Biodisposition

As mentioned earlier, MPTP is not toxic itself but needs to undergo a two-step process of metabolic activation in order to damage tissues. First, MPTP is converted to the 1-methyl-4-phenyl-2,3-dihydropyridinium ($MPDP^+$) intermediate, and then $MPDP^+$ is further oxidized to the toxic metabolite MPP^+. The conversion of MPTP to $MPDP^+$ is catalyzed by MAO-B (Chiba et al., 1984), whereas no enzymatic activities and/or catalytic factors have been identified to date to be responsible for the subsequent formation of MPP^+. The role of MAO-B in the initial oxidation of MPTP to $MPDP^+$ points to astrocytes as a primary locus for MPTP metabolism. This reaction could also take place within MAO-B containing serotonergic neurons (Levitt et al., 1982; Westlund et al., 1985). The contribution of these neuronal cells to MPP^+ formation is unlikely to be significant, however, since studies in mice have indicated that lesions of serotonergic neurons do not attenuate MPTP neurotoxicity (Melamed et al., 1986; Brooks et al., 1989).

The ability of glial cells to bioactivate MPTP has been demonstrated by *in vitro* metabolic studies with primary astrocyte cultures. Astrocytes in culture have been shown to generate MPP^+ from MPTP (Ransom et al., 1987; Schinelli et al., 1988) via a MAO-dependent pathway (Ransom et al., 1987; Marini et al., 1989). Subsequent studies have revealed that, in addition to MPP^+, two other metabolites can be measured in astrocyte cultures exposed to MPTP, namely, $MPDP^+$ and MPTP *N*-oxide (Di Monte et al., 1991). Production of $MPDP^+$ is blocked by MAO inhibitors (Di Monte et al., 1991); since this inhibition prevented MPP^+ formation as well, data are consistent with the role of $MPDP^+$ as an intermediate metabolite in the bioactivation of MPTP. MPP^+ could also be generated after direct addition of $MPDP^+$ to astrocyte cultures (Wu et al., 1992); this reaction was unaffected by MAO inhibitors, however, indicating that MAO is involved only in the first step of MPTP oxidation to MPP^+. In fact, since the rate of oxidation of $MPDP^+$ to MPP^+ was found to be similar in the presence or absence of cells, a nonenzymatic mechanism of conversion appears to be quite likely (Wu et al., 1992).

The ability of astrocytes *in vitro* to generate MPTP *N*-oxide has been further characterized by studies

showing that this metabolite is probably the product of MPTP conversion via the flavin-containing monooxygenase (Di Monte et al., 1991). The role of this metabolic pathway in MPTP metabolism *in vivo* remains to be elucidated. It is noteworthy, however, that, at least *in vitro*, flavin-containing monooxygenase activity can oxidize MPTP without generating the toxic MPP^+ metabolite; this suggests that metabolic processes within astrocytes may be involved in both bioactivation and detoxification of MPTP.

If glial cells play an essential role in the conversion of MPTP to MPP^+, the mechanism by which this toxic metabolite reaches the extracellular space and thus becomes available for accumulation into dopaminergic neurons needs to be elucidated. Any proposed mechanism should take into consideration the fact that MPP^+ would not be expected to cross cell membranes easily due to its charged chemical structure. It is possible that leakage of MPP^+ into the extracellular compartment may be a consequence of damage to the very same glial cells which generate this toxic metabolite. This relatively simple explanation is supported by histopathological evidence *in vivo* showing acute damage of astrocytes after systemic administration of MPTP to mice (Adams et al., 1989). The ability of both MPTP and MPP^+ to damage glial membranes is further indicated by results with primary astrocyte cultures in which increasing levels of lactate dehydrogenase (a cytosolic enzyme) were measured extracellularly after treatment with either of the two compounds (Di Monte et al., 1992b; Wu et al., 1992).

In vitro studies have revealed that, in the presence of MPTP, significant levels of MPP^+ can be accumulated in the extracellular space well before any apparent damage to astrocyte membranes (Di Monte et al., 1991; Di Monte et al., 1992b). Thus, mechanism(s) other than cytotoxicity are likely to contribute to the biodisposition of MPP^+. Abundant evidence now suggests that MPP^+ itself can cross cell membranes. Indeed, recent studies have revealed that (1) the positive charge of MPP^+ is delocalized throughout the pyridinium ring, resulting in a certain degree of lipid and membrane solubility (Reinhard et al., 1990), (2) MPP^+ can be measured intracellularly after its addition to astrocyte cultures (Wu et al., 1992), and (3) when astrocytes are pretreated with MPTP and then washed and incubated in MPTP-free fresh medium, intracellular levels of MPP^+ rapidly decline while extracellular MPP^+ concentrations rise in a stoichiometric manner (Di Monte et al., 1992c).

A third mechanism that could account for the presence of MPP^+ in the extracellular compartment may involve the ability of $MPDP^+$ to cross cell membranes (Di Monte et al., 1992c). $MPDP^+$ could be generated intracellularly from MPTP by MAO and it could cross astrocyte membranes, possibly in the form of the lipophilic free base 1,2-MPDP. Then, MPP^+ may be formed directly outside the cells via autoxidation of $MPDP^+$ (Figure 65-4). A rapid extracellular conversion of the unstable $MPDP^+$ metabolite is suggested by findings showing that $MPDP^+$ levels in the medium remain relatively low and constant throughout the incubation of astrocyte cultures in the presence of MPTP (Di Monte et al., 1991).

Taken together, experimental data are compatible with a primary role of glial cells in MPTP biodisposition, having characterized the process of metabolic activation of MPTP to MPP^+ as well as the mechanisms of MPP^+ "delivery" into the extracellular compartment. It is noteworthy that MPP^+ may become available for neuronal uptake without damaging necessarily glial cells. This possibility may explain why astrocytes are not a more obvious target for MPTP toxicity *in vivo* (Forno et al., 1992). It also underlines the role of mechanisms for "trapping" MPP^+ within neurons (*e.g.*, the continuous reuptake of MPP^+ and/or its binding to neuromelanin) in the selective action of MPTP (Figure 65-4).

Role of Glial Cells in MPTP-Induced Neurotoxicity

Once MPP^+ is accumulated into dopaminergic neurons, the subsequent series of biochemical/toxic events is likely to involve inhibition of mitochondrial respiration and consequent failure of energy supplies. Could glial cells play a role also in this final stage of MPTP neurotoxicity? The answer to this question necessarily involves speculative mechanisms, since our knowledge of MPP^+ action *in vivo* remains quite scarce and the role of astrocytes in brain energy metabolism has just started to be explored in detail. Glial cells have long been proposed to act as an energy source for neurons, however (Kuffler et al., 1984). One mechanism that might account for this function is their ability to accumulate energy substrates in the form of glycogen (Guth and Watson, 1968; Cataldo and Broadwell, 1986); in conditions of increased neuronal activity, glycogenolysis may be activated in astrocytes in order to sustain energy demand (Magistretti et al., 1986). Thus, it can be hypothesized that glial cells may provide metabolic support to counteract MPTP-induced failure of energy supplies. This metabolic support may only be partial and/or temporary, however, and therefore it may not prevent irreversible damage of neurons exposed to high levels of MPP^+ for a longer period of time.

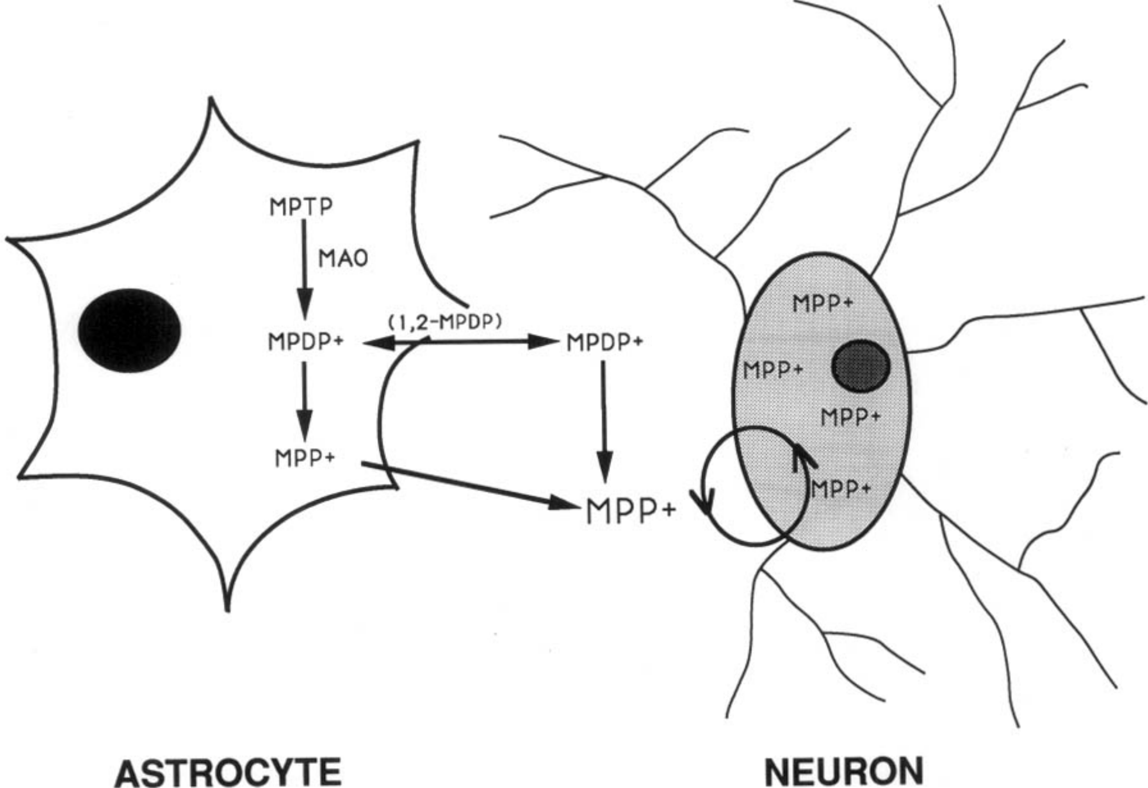

FIG. 65-4. Generation and disposition of MPP^+ as a consequence of MPTP metabolism in astrocytes. The ability of dopaminergic neurons to take up and retain MPP^+ is likely to play a role in their selective susceptibility to MPTP/MPP^+ neurotoxicity.

As a consequence of impaired energy production, MPTP/MPP^+ action may involve excitatory amino acid receptor activation, suggesting another possible role for glial cells in MPTP-induced neurotoxicity. Glial cells are able to accumulate glutamate via a high-affinity uptake system (Hertz, 1979) and to convert glutamate to glutamine by glutamine synthetase (Martinez-Hernandez et al., 1977). Therefore, if neuronal damage is related to an increased release of excitatory amino acids and/or an increased sensitivity of NMDA receptors to excitatory amino acids, expression of MPP^+ neurotoxicity may depend on the ability of astrocytes to modify the extracellular concentrations of glutamate. Interestingly, this function of glial cells may conceivably result either in a protective or a damaging role. Astrocytes may protect against MPP^+-induced excitotoxic injury by scavenging glutamate from the extracellular space, thereby reducing the exposure of NMDA receptors to this excitatory amino acid. However, active uptake of glutamate by glial cells requires ATP and therefore may become less efficient after MPP^+ exposure; such a mechanism would contribute to increase the extracellular levels of excitatory amino acids and could possibly enhance excitotoxicity. Another mechanism by which astrocytes may exacerbate excitotoxic neuronal damage caused by MPTP/MPP^+ is suggested by the finding that injured glial cells may themselves release excitatory amino acids such as glutamate, aspartate, and taurine (Kimelberg et al., 1990). Studies in the past few years have already focused on the role of excitatory amino acids and glial cells in the hypoxia/ischemia model of neuronal injury (Choi, 1988; Yu et al., 1992); information acquired from these studies may provide directions for future work on the possible involvement of astrocytes and excitatory amino acids in MPTP-induced "chemical hypoxia."

CONCLUSIONS

The role of glial cells in idiopathic and MPTP-induced parkinsonism has been discussed separately in the previous sections of this review. It is important to underline, however, that, besides the clinical and neuropathologic similarities, idiopathic and MPTP-induced parkinsonism share a number of relevant features. Furthermore, the MPTP model has provided valuable clues on mechanisms of neuronal injury that have just started to be investigated in the idiopathic disorder. Some of these common features

and mechanisms point to astrocytes as possible active participants in the process of neurodegeneration and therefore will be summarized next.

MAO Activity

The involvement of MAO in the pathogenesis of neurodegeneration appears to be a recurrent theme in both idiopathic and MPTP-induced parkinsonism. This is because of (1) the important function of MAO in dopamine metabolism, (2) the generation of H_2O_2 as a product of MAO catalytic activity, and (3) the ability of MAO to bioactivate neurotoxicants such as MPTP. For all these reasons, in 1986 and 1987, two separate clinical trials were initiated in order to test the effects of chronic administration of the MAO-B inhibitor deprenyl on the course of Parkinson's disease. Results of both these studies have indicated that deprenyl treatment delays the need for levodopa therapy in patients with early Parkinson's disease (Tetrud and Langston, 1989; Parkinson Study Group, 1989), adding strong support to the view that MAO activity may be a "risk factor" for the degeneration of dopaminergic neurons.

The function of glial cells in both MAO-dependent dopamine metabolism and MPTP biotransformation probably represents the strongest evidence in favor of their involvement in the pathogenesis of human parkinsonism. A number of questions remain to be explored, however, on the activity of glial MAO in relation to dopaminergic neurodegeneration. For example, regional differences in glial MAO-B expression need to be investigated as a possible reason for selective neuronal damage. Also, the function of astrocytes as a source of H_2O_2 as well as in defense against H_2O_2 accumulation should be further characterized. Finally, the possibility that metabolic pathway(s) other than the MAO-dependent one may contribute to the conversion of MPTP to MPP^+ in glial cells requires attention. This possibility is suggested by studies both *in vivo* and *in vitro* showing that MPP^+ generation cannot be completely blocked by MAO inhibitors (Langston et al., 1984c; Markey et al., 1984; Di Monte et al., 1991).

Aging

Another important feature shared by idiopathic parkinsonism and MPTP neurotoxicity is an increased susceptibility with age. Aging has long been acknowledged as the only unequivocal risk factor for Parkinson's disease (Kurland et al., 1973) and, interestingly, the sensitivity to MPTP-induced dopamine depletion and damage to dopaminergic neurons has been shown to be enhanced in older animals (Jarvis and Wagner, 1985; Gupta et al., 1986; Irwin et al., 1992). These age-related effects of MPTP have been correlated with changes in brain levels of MAO-B (Irwin et al., 1992). Since an increased expression of MAO-B activity has also been measured in the aging human brain (Robinson et al., 1971; Fowler et al., 1980), it is conceivable that MAO-B changes may play a prominent role in making the aged brain more vulnerable to nigrostriatal degeneration. Other mechanisms might contribute to this effect, however. For example, recent work in our laboratory has revealed that mitochondrial energy production declines with age in the monkey striatum (Di Monte et al., 1993). These results are particularly intriguing given the likely involvement of mitochondrial poisoning in MPTP action and the possible occurrence of mitochondrial complex I deficiency in Parkinson's disease as well (see next section on mechanisms of neurodegeneration).

As noted earlier, the age-related increase in MAO-B activity has been attributed to a greater proportion of MAO-B-containing astrocytes in the older brain (Benedetti and Keane, 1980; Fowler et al., 1980; Irwin et al., 1992), suggesting that aging processes related to glial cells may ultimately contribute to the pathogenesis of parkinsonism. This possibility reveals another area for relevant future investigations. Do age-dependent changes in astrocyte functions and characteristics incrase the risk for neuronal damage? Such changes might include a decline in energy production which, in turn, may affect the ability of astrocytes to sustain neuronal energy demand in conditions of "metabolic stress."

Mechanisms of Neurodegeneration

The final events leading to irreversible neuronal damage in human parkinsonism are quite controversial and remain essentially unknown. The oxidative stress hypothesis, while based on a number of valid considerations and indirect evidence, is apparently inconsistent with our knowledge about the mechanism of action of MPTP. In the MPTP model, the ability of MPP^+ to inhibit mitochondrial respiration is more likely to be the primary event leading to neuronal damage, and findings of recent studies in humans have raised the possibility that a similar mechanism may play a role in Parkinson's disease as well. Indeed, a decrease in mitochondrial respiratory chain enzyme activities has been measured in different tissues of parkinsonian as compared to control subjects (Bindoff et al., 1989; Parker et al., 1989; Schapira et al., 1990). In the brain, this decrease ap-

pears to be selective both for the substantia nigra and for mitochondrial complex I (Schapira et al., 1990).

The controversy over the mechanism of neurodegeneration in human parkinsonism may only be apparent, however, and could certainly be reconciled. There is little doubt that links exist between oxygen radical production and mitochondrial damage: mitochondria are primary targets for oxidative stress and, vice versa, oxygen radicals may be generated as a consequence of impaired mitochondrial activity (Di Monte et al., 1992a). Furthermore, as already mentioned, other damaging events, such as the activation of excitatory amino acid receptors, may be triggered by mitochondrial damage and/or oxidative stress. Thus, different toxic mechanisms may be set in motion by the initial biochemical change and may all contribute to neurodegeneration. Even more importantly, the process of neuronal damage may ultimately be affected by agents acting against oxidative stress as well as by compounds able to supplement cellular energy supplies or attenuate excitotoxicity.

It is noteworthy that glial cells may play a role in all of these toxic mechanisms. They could contribute to H_2O_2 production (via the MAO-dependent dopamine and MPTP metabolism) while representing a primary locus for H_2O_2 scavenging by glutathione peroxidase; they may provide energy support for neurons in conditions of metabolic stress, and protect against NMDA receptor activation by the active uptake of glutamate. Additional studies on astrocyte function in these processes may not only contribute to our understanding of the pathogenesis of parkinsonism, but it even seems possible that such studies will help us to unravel the biochemical and toxic basis of other neurodegenerative diseases as well.

We wish to thank I. Irwin and Drs. P. Chan, L. E. Delanney, and M. S. Sandy for their comments on the manuscript. We gratefully acknowledge David Rosner for his help in the preparation of this manuscript. This work was supported by The Parkinson's Institute.

66 Inherited disorders of myelination of the central nervous system

IAN D DUNCAN

The elaboration of the myelin sheath by the oligodendrocyte and Schwann cell in the central and peripheral nervous systems is one of the most remarkable and fascinating aspects of neural development. In the central nervous system the oligodendrocyte, which has a small cell soma, supports as many as 50 flattened expansions of spirally wrapped, tightly compacted myelin membrane via slender cytoplasmic "arms" (Morell and Norton, 1980; Wood and Bunge, 1984). In marked contrast, myelination in the peripheral nervous system is accomplished by Schwann cells, which generate only one myelin segment. During myelination, oligodendrocyte and Schwann cells produce vast quantities of plasma membrane and insert into the lipid matrix the myelin-specific polypeptides that participate in the initial organization and subsequent maintenance of the myelin sheath. In order to initiate the myelination proce^s, myelinating cells must induce and express the genes encoding the myelin proteins at high levels, and must orchestrate the insertion of these polypeptides into the rapidly expanding regions of the plasma membrane that will comprise the "myelin domains" of the cell surface. The critical requirement for myelination of the nervous system to proceed according to schedule and to be maintained is demonstrated in inherited and acquired diseases where myelin does not develop normally or is lost as a result of demyelinating process. In both instances, the lack of insulation of axons leads to disruption of neurological function with debilitating and often fatal consequences.

Our understanding of myelination and the myelin sheath has been greatly advanced in the last decade, following the application of molecular biological techniques to study this developmental process. In particular, the cloning of the major myelin genes of the peripheral nervous system and central nervous system have provided the tools with which to begin to explore the patterns of expression of the myelin genes and their developmental regulation (Sutcliffe, 1987; Campagnoni and Macklin, 1988; Lemke, 1988).

While much information on myelination has been derived from the use of such molecular techniques in the study of the normal nervous system, mutant animals in which this process is disrupted have provided alternative approaches to study myelination (Baumann, 1980; Duncan et al., 1990). These animals, collectively known as the myelin mutants, have been crucial to understanding the function of individual myelin proteins, both in the structure of the myelin sheath and in the myelination process, particularly in the central nervous system. However, the correlation between the genotype and resultant phenotype of the myelin mutants is often not straightforward; in the X-linked mutants, for instance, the relationship between described mutations and abnormal oligodendrocyte development and early oligodendrocyte death are not yet explained (Duncan, 1990; Hudson and Nadon, 1992; Skoff and Knapp, 1992). Findings such as these have provided many new opportunities to study the role(s) of individual myelin proteins in the division, maturation, and survival of the myelinating cell. It is likely that these issues will only be resolved by the combination of molecular and cellular techniques.

The myelin mutants can be divided according to their mode of inheritance into two major categories, the X-linked mutants and those that are inherited as autosomal recessive traits. The X-linked mutants form the largest and most homogeneous group as their genetic defects are linked to a single chromosome and in the majority a mutation in the proteolipid protein gene has been identified (Hudson and Nadon, 1992). In contrast to the great advances made in recent studies of the X-linked mutants, less is known about the molecular defects in those of autosomal origin. This chapter presents the X-linked mutants as a group and describes the known features of the autosomal recessive myelin mutants, particularly the effects of these mutations on neuroglia. The molecular genetics of these mutations are discussed in Chapters 38 and 39.

THE X-LINKED MYELIN MUTANTS

The X-linked myelin mutants have been discovered in a wide range of species, including man (Pelizaeus-

Merzbacher disease) (Hudson and Nadon, 1992), dog (shaking pup [*sh pup*]) (Griffiths et al., 1981), pig (type A III hypomyelinogenesis congenita) (Blakemore et al., 1974), rat (myelin-deficient [*md*]) (Dentinger et al. 1982; Jackson and Duncan, 1988), rabbit (paralytic tremor [*pt*]) (Taraszewska, 1988), mouse (jimpy [*jp*]) and its alleles, myelin synthesis deficiency (jp^{msd}) (Skoff and Knapp, 1992) and rumpshaker (jp^{rsh}) (Griffiths et al., 1990). In addition to this list, a new proteolipid protein (PLP) mouse mutant called jp^{4J} has very recently been reported (Billings-Gagliardi et al., 1994). This new mutant has a shorter life-span than *jp* and appears to have a more marked deficiency of myelin and oligodendrocytes.

The severity of the myelin defects leads to the majority of these mutations being lethal, but the *sh pup*, *pt* rabbit, and jp^{rsh} mouse are able to live for extended periods of time and are fertile. In general, the longer life span of these mutants relates to the greater amount of myelin in the central nervous system. Thus, the *md* rat and *jp* mouse, which have the least myelin die earlier than jp^{rsh} and the *sh pup*, which have considerably more. While the correlation between lack of myelin and the early demise of the affected mutant holds true overall, a longer-lived "strain" of the *md* rat has arisen, which lives for up to three times as long as the original "strain" of *md* rat, although it has no more myelin (Duncan et al., 1995).

The major phenotypic abnormalities seen in the X-linked mutants are in (1) the amount of myelin, (2) myelin structure, (3) oligodendrocyte number and cytoplasmic abnormalities, and (4) astrocytic responses. Each of these is presented in the following sections and differences between mutants discussed. A summary of these changes is presented in Table 66-1.

Amount of Myelin

There are great variations in the severity of the myelin defects seen in the central nervous system of the X-linked mutants, ranging from little to no myelin in the *md* rat, to considerable amounts of myelin in jp^{rsh}. Figure 66-1 demonstrates this range of myelin deficiencies. In the most severely affected mutants, the later myelinating parts of the central nervous system, such as the brain and optic nerves have consistently less myelin than the spinal cord. This is not surprising, as both the *md* rat and *jp* mouse die at 23 to 25 days of age, at a time when myelination, in the normal animal, of more rostral areas such as the corpus callosum would still be occurring. In the most severely affected mutants, such as *jp* and the *md* rat, dysmyelination is the predominant abnormality with the majority of axons being unensheathed and those that are myelinated, having a poorly compacted myelin sheath (Figure 66-2). In

TABLE 66-1. *Summary of the Phenotypic Abnormalities in the X-Linked Myelin Mutants*

Phenotype	jp	jp^{msd}	jp^{rsh}	md rat	shaking pup	PMD

the less severely affected mutants such as jp^{rsh}, hypomyelination is the predominant abnormality with most axons being myelinated but with inappropriately thin myelin sheaths (Figure 66-1).

Microscopic examination of the spinal cord of *jp* and the *md* rat shows that myelinated fibers are mainly seen in the ventral and lateral columns, often in a clumped pattern or less commonly as scattered fibers. In *jp* it has been estimated that the amount of myelin in the spinal cord is 1.6% of controls (Duncan and Hammang, 1989) but jp^{msd} has approximately twice the amount of myelin as *jp* (Billings-Gagliardi and Adcock, 1980). In the *sh pup*, qualitative comparisons suggest that more myelinated fibers are seen than in *jp* and the *md* rat, but as in the murine mutants, there can be marked animal-to-animal variation. Shaking pups have lived up to 23 months of age, and, while more central nervous system myelin may be seen in the older animals, there is persistent hypomyelination and lack

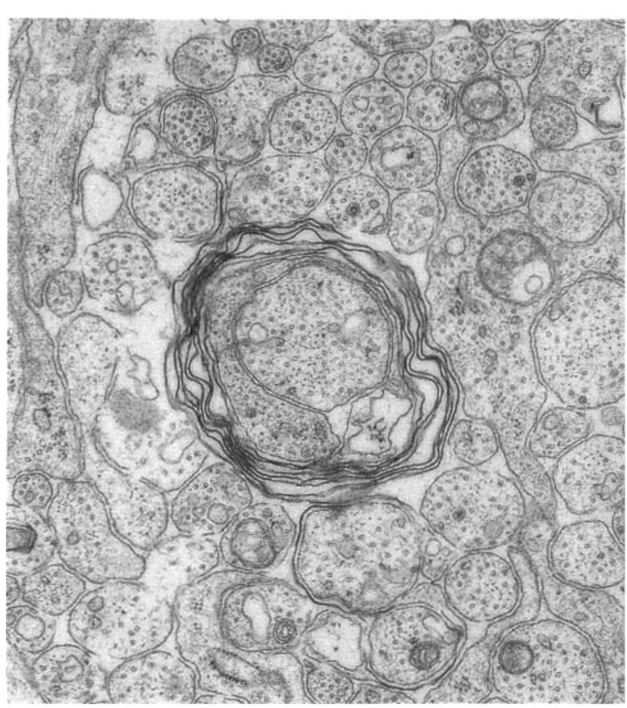

FIG. 66-2. Electron micrograph of a typical poorly compacted myelin sheath surrounded by many unensheathed axons from an *md* rat. These abnormalities are the hallmarks of dysmyelination. ×27,600. [From Duncan (1990), with permission.]

of ensheathement of many axons. The relationship between myelin sheath thickness and axonal diameter is often abnormal in the *sh pup*, with smaller axons frequently having thicker myelin sheaths than larger axons (Duncan and Griffiths, 1983). However, these smaller axons may also have shorter internodes, suggesting that mutant oligodendrocytes are restricted in the amount of membrane they can produce.

In jp^{rsh} there is much more myelin than in the other X-linked murine mutants (Griffiths et al., 1990). However, quantitative studies of myelin in the spinal cord and optic nerve have shown differences in development of the defect in these areas (Fanarraga et al., 1992). In the spinal cord, there is a progressive increase in the number of axons that are myelinated, and by 90 days most have a myelin sheath, although the larger diameter axons remain hypomyelinated. In the optic nerve, myelination commences normally and sheaths are appropriately thick, but many axons, even in 1-year-old mice, remain nonmyelinated. The reasons for these differences are not known, but it may relate to the fact that there are fewer oligodendrocytes in the optic nerve than normal in jp^{rsh}, whereas the converse is true in the spinal cord (Fanarraga et al., 1992). It may also relate to the apparent differences in the normal central nervous system between the numbers of axons myelinated by oligodendrocytes in the spinal cord compared to the brain (Remahl and Hildebrand, 1990) or to the presence of larger axons in the spinal cord. This difference between the myelin deficit in jp^{rsh} spinal cord and optic nerve remains to be resolved.

The *pt* rabbit has similar amounts of myelin to jp^{rsh}, with the main abnormalities in this mutant being a delay in myelination (Taraszewska, 1988). There is persistent hypomyelination and many small axons remain nonmyelinated. In Pelizaeus-Merzbacher disease in man, a detailed, high-resolution analysis of the amount of myelin has been impossible because of the lack of tissue for plastic embedding. In addition, there are numerous variants of Pelzaeus-Merzbacher disease with different genetic backgrounds (Hudson and Nadon, 1992), which complicates the picture. In certain forms of the disease, no myelin is seen grossly or in paraffin-embedded sections, but in others, the presumptive white-matter tracts have a patchy or "tigroid" appearance. Immunocytochemical labeling with antibodies to myelin proteins suggests that such patches are islands of myelin (Koeppen et al., 1987).

Myelin Structure and Composition

Just as with myelin volume, there is a marked variation in the structure of the myelin sheaths seen in the X-linked mutants. In the dysmyelinating mutants, there is only rare evidence of compact myelin, with most ensheathed axons being surrounded by uncompacted whorls of membrane (Figure 66-2). In both *jp* and its allele, jp^{msd} and the *md* rat, however, there are occasional fibers with well-compacted myelin sheaths, which have up to 20 myelin lamellae (Figure 66-3). On detailed examination of these sheaths, however, the intraperiod line is abnormally compacted and it is difficult to distinguish the major dense and putative intraperiod lines (Duncan et al., 1987b; Duncan and Hammang, 1989; Hudson and Nadon, 1992). However, in *jp*, jp^{msd}, and *md*, occasional stretches of the intraperiod line appear to have a normal structure. In *jp*, it has been suggested that well-compacted sheaths are usually seen in younger mice; in older *jp* mice, most myelin is poorly compacted (Nagara and Suzuki, 1982), which suggests that the sheaths are unstable.

In the mutants where hypomyelination is the predominant abnormality, myelin compaction is usually more normal, although many fibers have some loosening of compaction (Figure 66-2). In the *sh pup*, there is no evidence of an abnormality in the intra-

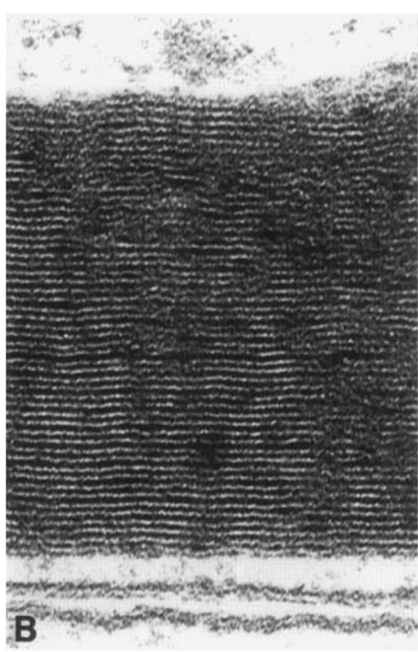

FIG. 66-3. Electron micrographs showing myelin sheaths from an (A) normal rat and (B) myelin-deficient rat spinal cord at 23 days of age. In the normal rat, a double intraperiod line is present, whereas in the *md* rat myelin there is a complete compaction of the intraperiod line, which cannot be distinguished from the major dense line. ×250,000. [Modified from Duncan et al. (1987b), with permission.]

period line, but in jp^{rsh} some sheaths show an abnormal compaction, whereas others do not (Griffiths et al., 1990).

Nodes of Ranvier in these mutants vary in their degrees of normality. In the *sh pup*, many heminodes are seen and the paranodal loops showed a number of abnormalities (Griffiths and Duncan, 1981). Frequent astrocytic interdigitations are seen at heminodes and this will be discussed later. Abnormalities in the paranodal axoglial junction have also been described in the *md* rat (Rosenbluth, 1987) as well as aberrant astrocytic invasion.

The protein composition of the myelin found in the X-linked mutants has been extensively investigated, particularly with regard to the presence or absence of proteolipid protein (PLP), as a severe reduction in PLP could relate directly to the lack of myelin. Biochemical data have shown that PLP is almost absent in the severely affected mutants (*jp* and the *md* rat) and that other myelin proteins, including myelin basic protein (MBP), are dramatically reduced (Quarles, 1990). Immunolabeling of myelin in *jp* and *md* with antibodies to PLP and MBP shows that the myelin present is PLP-negative but MBP-positive (Duncan et al., 1987b; Duncan and Hammang, 1989). The lack of PLP has been suggested to result in the abnormal compaction of the intraperiod line (Figure 66-3). Those mutants with more myelin present a more complex picture however. In the *sh pup*, myelin is PLP- and MBP-positive, but there appears to be less PLP than in wild-type myelin, (Yanagisawa et al. 1987) suggesting a delay or deficiency in incorporation of PLP into the myelin membrane. In jp^{rsh}, labeling with antibodies against only PLP or PLP/DM20 reveal different results. Staining of white matter in jp^{rsh} with an anti-PLP-specific antibody is markedly reduced compared with wild type (Griffiths et al., 1990). However, modest staining of myelin in jp^{rsh} is seen with the antibody recognizing PLP and DM20, which increases with age (Fanarraga et al., 1992). The key role that DM20 may play in jp^{rsh} and in the other X-linked mutants will be discussed further below.

In Pelizaeus-Merzbacher disease in man, immunolabeling of the scattered myelin present in the brain with antisera to MBP, myelin-associated protein (MAG), and cyclic nucleotidephosphodiesterase (CNP) is positive, but PLP-negative (Koeppen et al., 1987).

Oligodendrocytes - Lineage and Cytoplasmic Alterations

Much of the earlier work on *jp* and the other X-linked mutants centered around the description and estimates of the number of glia, in particular the oligodendrocytes. There is general agreement in the literature that there is a reduction in the number of mature oligodendrocytes in the X-linked mutants, with the exception of jp^{rsh} (Skoff and Knapp, 1992). However, there appears to be a significant population of cells, at least in *jp*, which label with galactocerebroside antibody, an early marker of the mature oligodendrocyte. Quantitative labeling of oligodendrocytes in the 15-day-old *jp* cerebellum la-

beled with a galactocerebroside antibody showed no statistical difference from controls in the number of positive cells. (Ghandour and Skoff, 1988). An increase in oligodendrocyte cell death between 15 and 25 days of age, the time at which *jp* usually dies, may account for the apparent paucity in oligodendrocytes as described by others. Ultrastructural studies of the *jp* central nervous system, and many of the other mutants have described many cells with features of immature oligodendrocytes (Figure 66-4), and there is a general inference that mutations in the PLP gene result in an abnormality of oligodendrocyte development (Nadon et al., 1990; Skoff and Knapp, 1992). In the *md* rat, there is also a reduction in the number of oligodendrocytes (Dentinger et al. 1985; Jackson and Duncan, 1988), and in the *sh pup*, quantitation of oligodendrocytes in the spinal cord also shows a reduction, although many of the oligodendrocytes appear mature (Duncan and Griffiths, 1983). The exception to this rule of oligodendrocyte reduction in the X-linked mutants is *jp^rsh^*, which has more oligodendrocytes than normal in the spinal cord, although slightly less in the optic nerve (Fanarraga et al., 1992).

While many oligodendrocytes appear immature in the X-linked mutants, others show cytoplasmic and nuclear changes, most of which are nonspecific signs of early cell death, but certain abnormalities are unique and could provide clues to the biochemical nature of the defect. The earlier literature, especially on *jp*, concentrated on the nonspecific ultrastructural changes in oligodendrocytes with cytoplasmic accumulation of lipids and membranous tubules (Skoff and Knapp, 1992). The *md* rat and *sh pup*, however, share a unique oligodendrocyte abnormality of rough endoplasmic reticulum (RER) (Dentinger et al. 1985; Duncan and Griffiths, 1983), which is distended and contains a floccular/proteinaceous material (Figure 66-5). The initial swelling of the RER is usually associated with accumulation of an electron dense substance in the cisterns (Figure 66-5A), but as the swellings enlarge, the stored material becomes

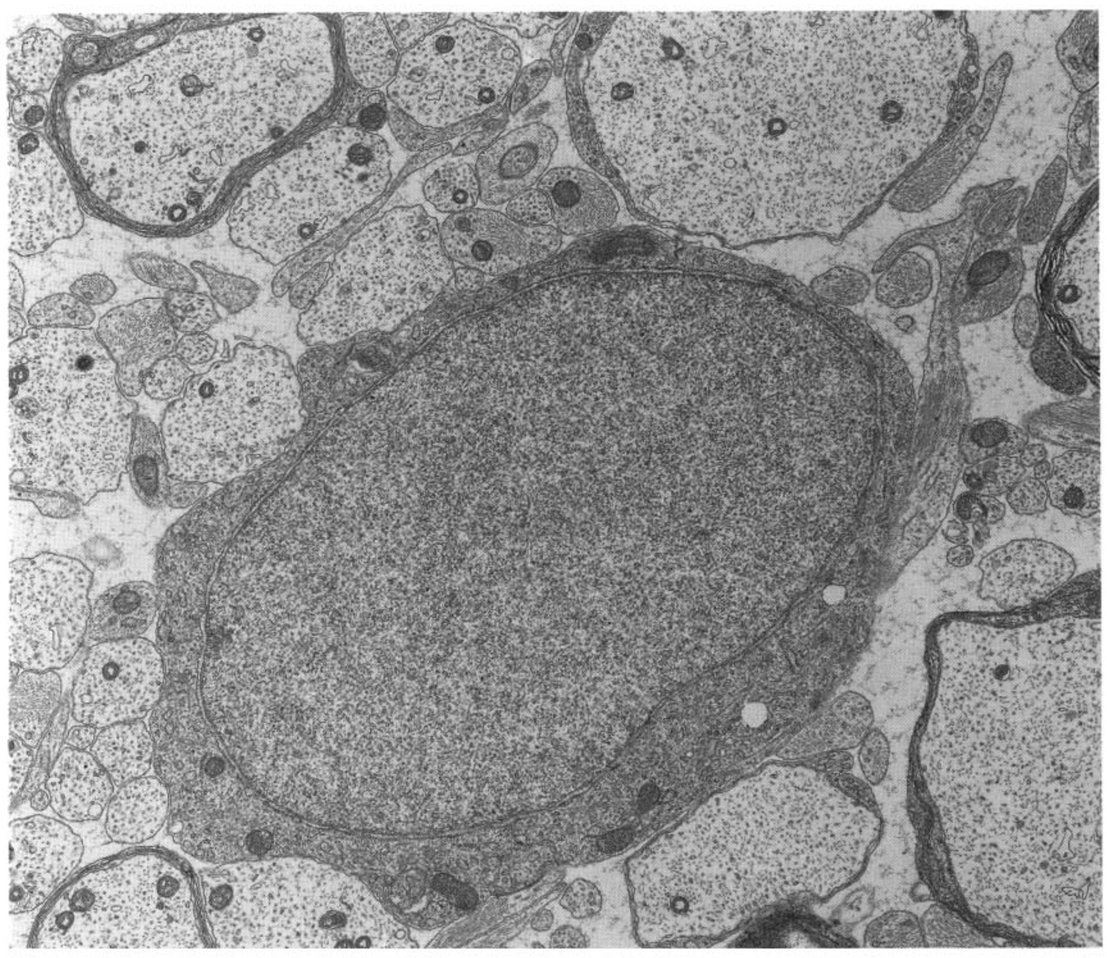

FIG. 66-4. Electron micrograph showing an immature oligodendrocyte in the spinal cord of a 4-week-old shaking pup, which is in contact with a number of nonmyelinated axons. ×11,200.

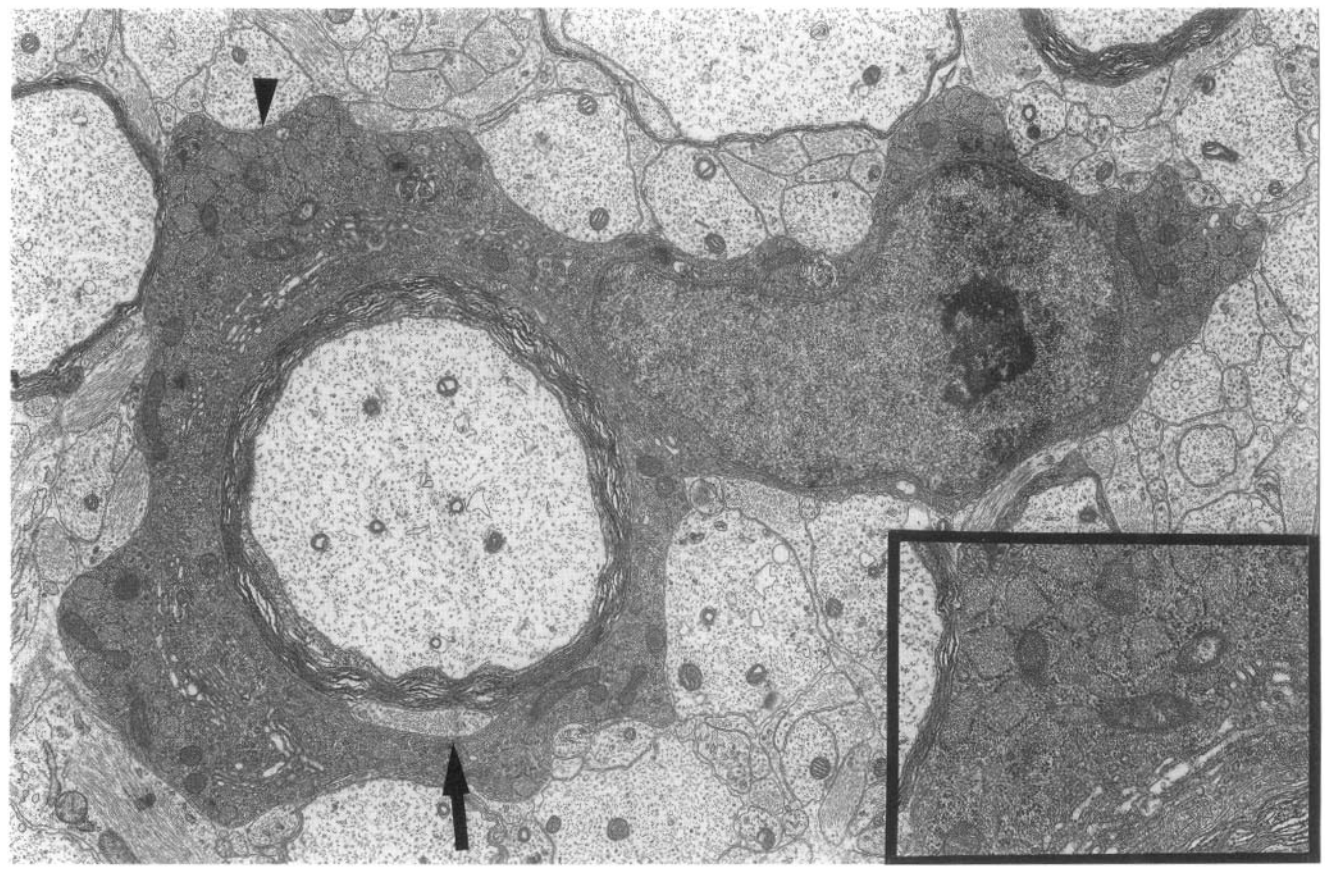

FIG. 66-5. Electron micrographs from the spinal cord of a 4-week-old shaking pup demonstrating distension of the rough endoplasmic reticulum (RER) in oligodendrocytes. **(A)** In this cell the myelin sheath is surrounded by copious cytoplasm with prominent Golgi apparatus and RER (*arrowhead*), which is seen in more detail in the *inset*. An aberrant astrocyte process (*arrow*) is present between the myelin sheath and oligodendrocyte cytoplasm. *Inset*: The RER contains a dark, electron-dense material. ×10,000; **Inset** ×18,500. **(B)** In this oligodendrocyte, swelling of the RER, which contains floccular material, is more marked than the cell in Figure A. This cell may also be myelinating the axon seen in the inset, which has 3 to 4 layers of uncompacted myelin. Many adjacent large diameter axons are unensheathed. ×7150; *Inset*: ×13,400. (*Figure continued.*)

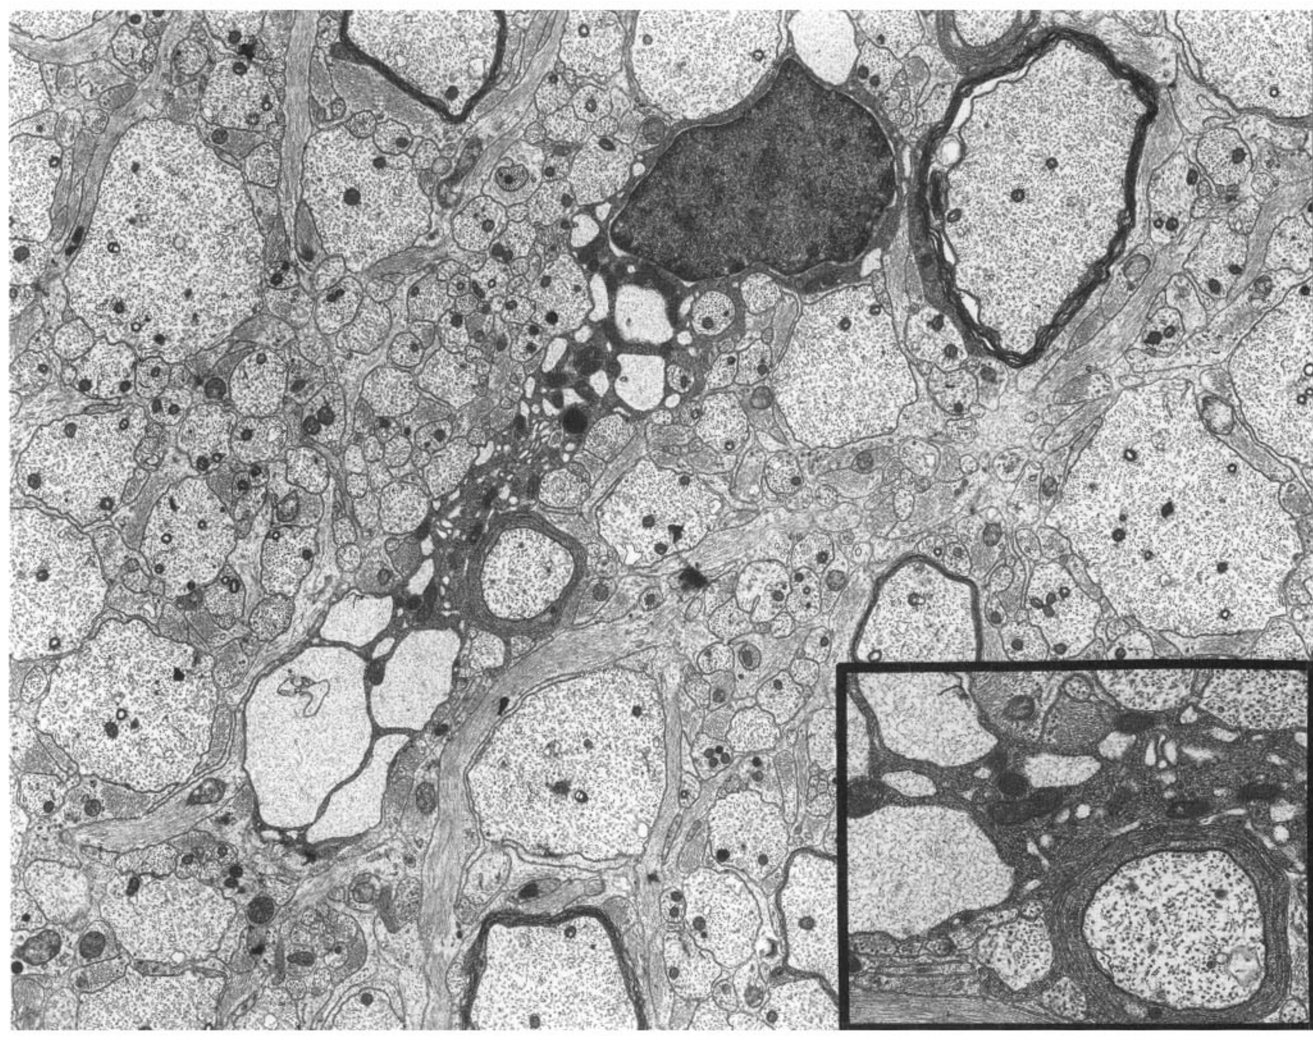
more floccular and there is distention of the perinuclear envelope (Figure 66-5B). A single report of RER swellings in oligodendrocytes in a patient with Pelizaeus-Merzbacher disease (Adachi et al., 1990) suggests this should be more carefully looked at in the future. Several other mutants have been described to have mild RER distension in oligodendrocytes, but this is modest compared to that seen in the *md* rat and *sh pup*. This swelling presumably indicates a failure or slowing of transport of proteins from the RER to the Golgi, perhaps as a result of abnormal folding of the mutant protein. In two of the mutants (*sh pup* and *md* rat) an insertion of a proline into the PLP molecule could result in this transport defect. A similar transport defect may be present in *jp*, where PLP has been demonstrated to be blocked in the Golgi (Rousell et al., 1987), and although the RER does not swell, it is possible that the abnormal protein is rapidly degraded. As of yet, it has not been possible to demonstrate specific accumulation of PLP in the distended RER of the *md* rat or *sh pup*.

More advanced changes in oligodendrocytes, leading to cell death, are common in certain mutants, especially *jp* and the *md* rat. In Figure 66-6, the range of changes found in the *md* rat oligodendrocyte from the massive distention of RER, to margination of nuclear chromatin and finally to pyknosis are seen. The significance of oligodendrocyte death in *sh pup* has not been defined, and it does not appear to be significant in jp^{rsh}. Whether some of this cell death is a result of an increase in programmed cell death (apoptosis) (Barres et al., 1992) or necrosis, remains to be decided.

Proliferation of oligodendrocytes is abnormal in both *jp* (Skoff, 1982; Privat et al., 1982) and the *md* rat (Jackson and Duncan, 1988), but in *jp* there is also evidence of a cell cycle defect as shown by quantitative comparison of cell division and tritiated thy-



B

FIG. 66-5. (*Continued*)

midine labeling (Knapp and Skoff, 1987). Despite an increase in the labeling index in *jp*, there are fewer mitotic cells, and this discrepancy remains to be explained. In contrast, in the spinal cord of jp^{rsh} there is an increase in the number of thymidine-labeled cells compared to controls and a clear increase in glia (M. Fanarraga, personal communication). Although not quantitated, abnormal cell proliferation has also been seen in the *sh pup* (Figure 66-7).

The correlation between oligodendrocyte division, development, function and early cell death, remain as perplexing topics in the X-linked mutants. Careful interpretation of the known facts along with new data may provide important clues, such as the recent finding of early expression of DM-20 mRNA in the 10-day mouse embryo, well before PLP is detectable (Timsit et al., 1992), suggesting that DM-20 may be crucial to the development and survival of the oligodendrocyte. In the *md* rat and *sh pup*, it appears that oligodendrocytes with distension of the RER can ensheathe and myelinate axons, and so a PLP mutation does not totally prevent these oligodendrocyte functions. In jp^{rsh}, it is postulated that the mutation uncouples the defects of hypomyelination and failure of oligodendrocyte development and cell death, which are seen in the other X-linked mutants (Schneider et al., 1992).

Axonal Changes

Axons in many of the X-linked mutants have been found to be abnormal with accumulation of axonal organelles frequently leading to giant axonal spheroids (Barron, 1987) (Figure 66-8). This usually occurs after the myelin defect has become apparent and it is general opinion that these changes are all secondary to the myelin defect as they can also be

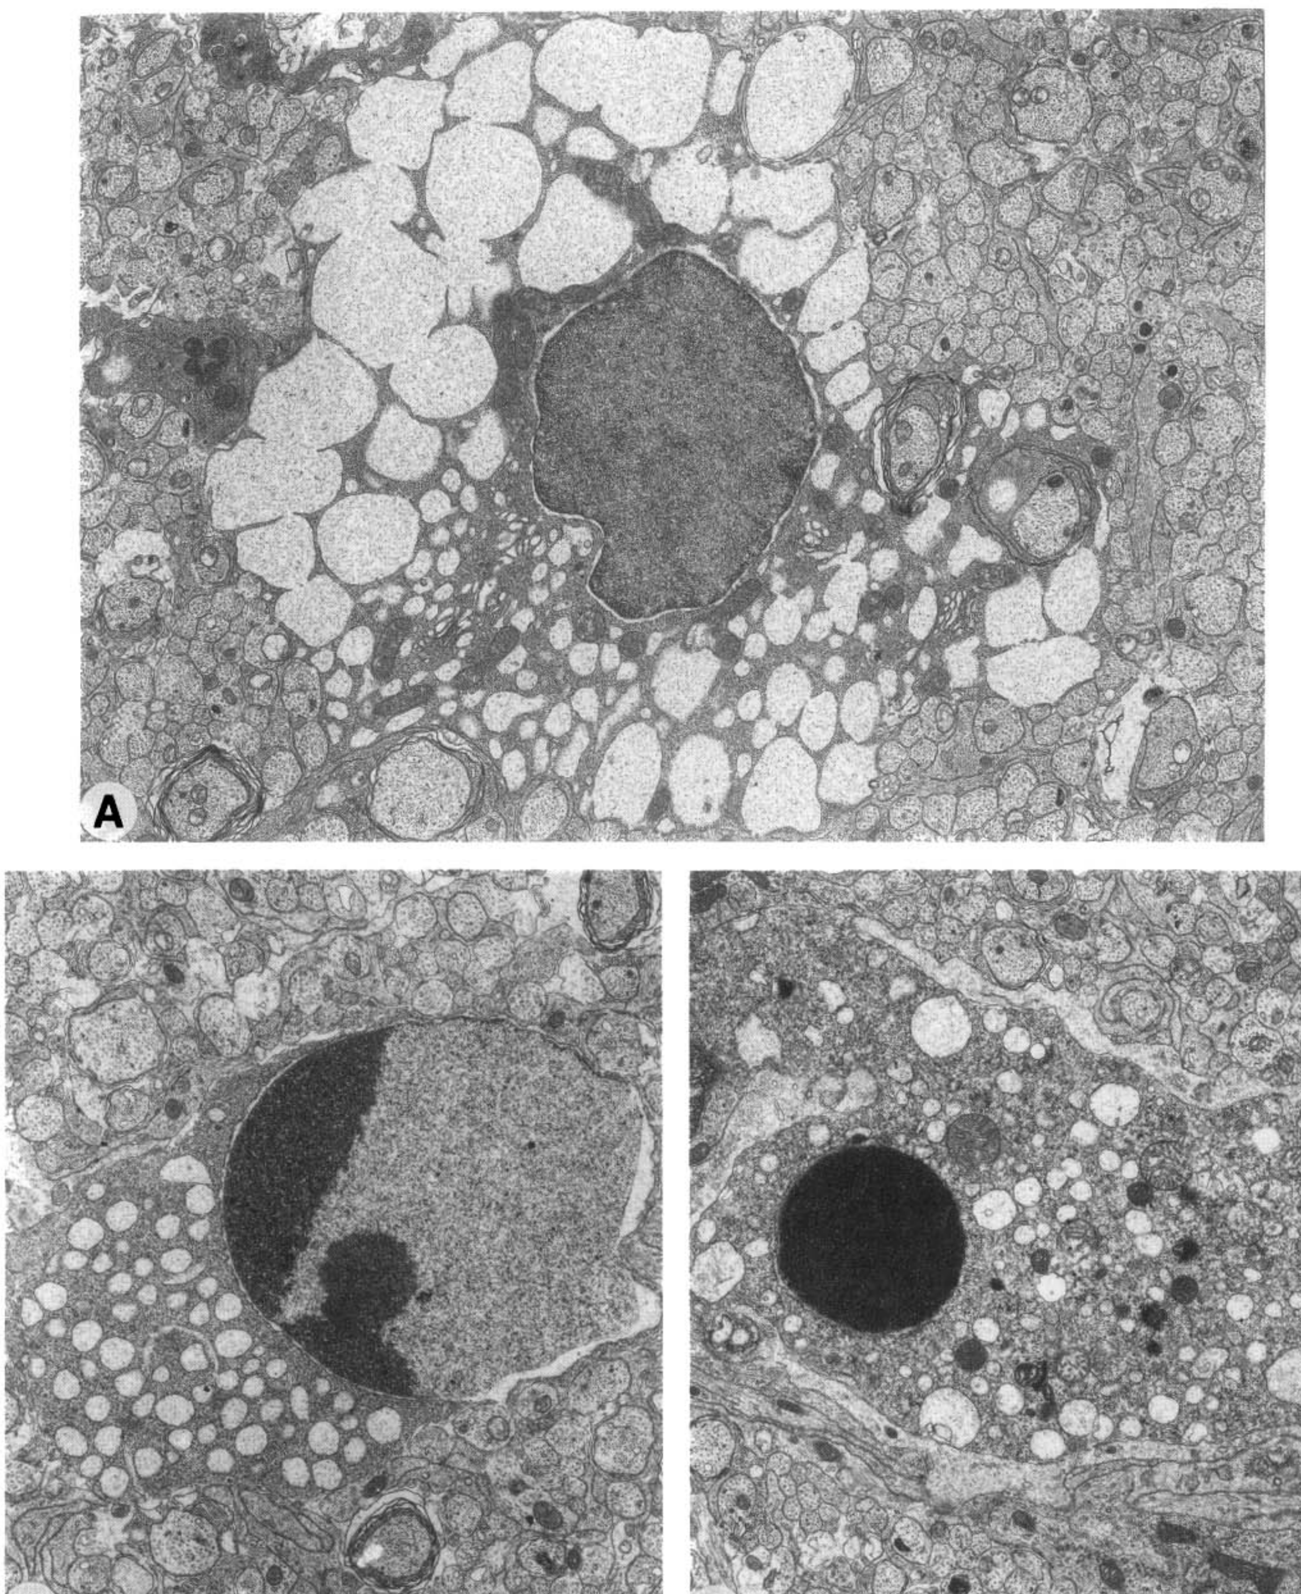


FIG. 66-6. Electron micrographs from the optic nerve of an *md* rat showing the range of oligodendrocyte changes from massive distension of rough endoplasmic reticulum (RER) to cell death. (**A**) The distended RER occupies most of the cytoplasm but the nucleus of the cell is normal. ×9800. (**B**) Early evidence of cell death, where the nucleus has margination of chromatin and the cytoplasm contains distended RER. ×9700. FIG. 66-7. Sections from the optic nerve of (**A**) a 21-day-old normal dog optic nerve and (**B**) an 18-day-old shaking pup. Each dog was pulse labeled prior to sacrifice with triated thymidine. In the normal optic nerve most axons are myelinated and only one labeled cell (*arrow*) is seen. In contrast, in the shaking pup optic nerve, few axons are myelinated and many heavily labeled cells are seen. These cells have the light microscopic appearance of oligodendrocytes. Toluidine blue; ×1100. [From Duncan (1987). *J. Vet. Intern. Med.*, 1:10–23, with permission.]

seen in certain autosomal recessive mutants (*qk* and *shi*). The significance of an increase in proteolysis in retinal ganglion axons of *jp* and jp^{msd} (Nixon, 1982) remains to be resolved. Further information on axons in the X-linked mutants has come from freeze-fracture studies; in the *md* rat patches of E-face particles in the *md* rat adjacent to astrocyte processes have been reported (Waxman et al., 1990). These patches may represent voltage-sensitive sodium channels, involved in conduction of impulses which

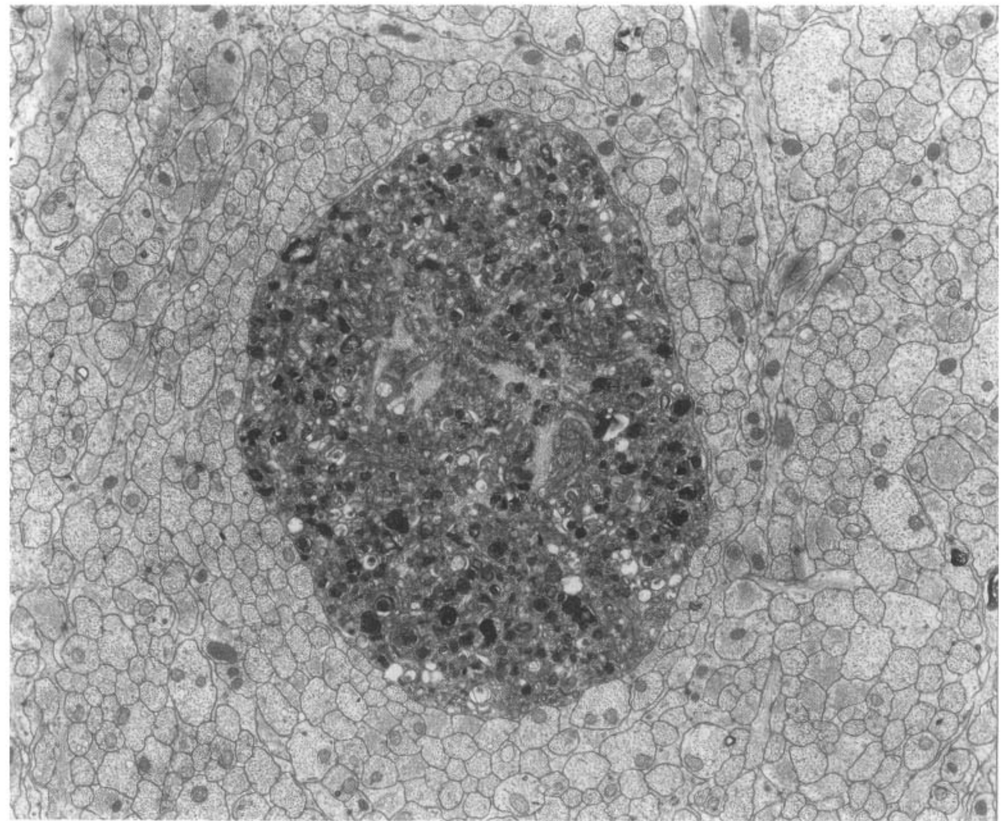

FIG. 66-8. Electron micrograph from the corticospinal tract of an 18-day-old *md* rat. A huge spheroid containing a variety of effete organelles is present. ×8300.

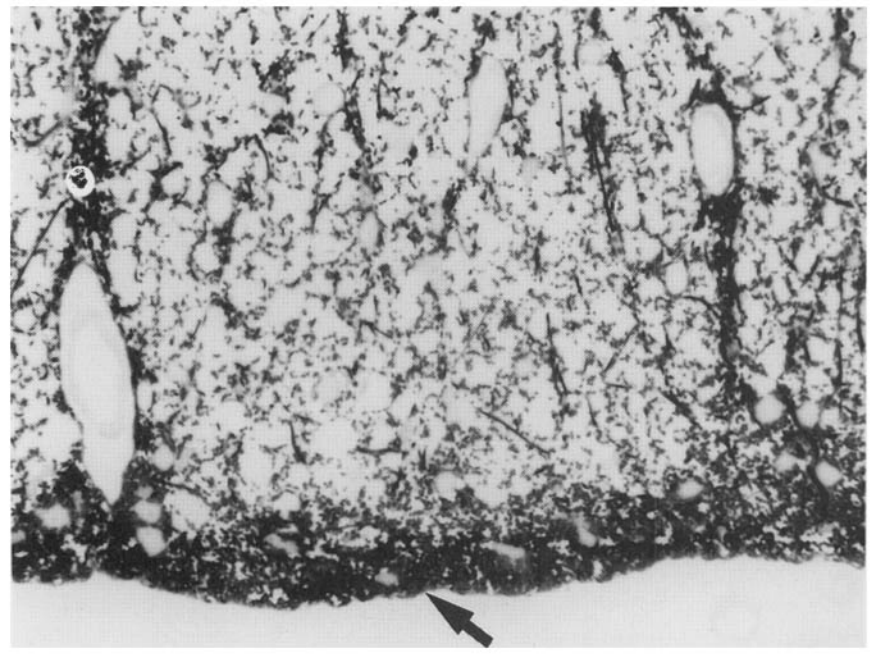
have been shown to occur normally in the *md* rat spinal cord axons (Utzschneider et al., 1992).

Glial cell transplant studies have provided further proof that axons in the md rat, *jp* mouse and *sh pup* can be myelinated, and hence confirming the primary oligodendrocyte defect in these mutants. In addition, quantitative data in the *sh pup* (Duncan et al., 1983) and *md* rat (Dentinger et al., 1985) shows that there are no significant differences in axonal size from controls.

Astrocytes and Microglia

Changes in morphology of astrocytes is a common feature in the X-linked mutants (Baumann et al., 1986). The predominant abnormality is an astrocytic hypertrophy, with an increase in the number of astrocytic processes and glial filaments as seen on electron microscopy and by glial fibrillary acidic protein (GFAP) immunolabeling (Figure 66-9). A more severe gliosis is seen in the mutants with least myelin, that is, in *jp* and *md*, and is least in jp^{rsh}. It has been suggested that this does not relate entirely to myelin loss or absence, as gliosis is seen in spinal cord gray matter of *jp*, and in the central nervous system of the female heterozygotes (Skoff and Knapp, 1992). Freeze-fracture analysis of reactive astrocytes in *md* shows an abnormal development of orthogonal arrays of particles in parenchymal and endfoot processes which may affect normal glial-axonal interactions (Rohlmann et al., 1992).

A prominent astrocytic abnormality in *jp*, *md*, and the *sh pup* is the presence of astrocyte processes between the axon and the myelin sheath (Griffiths and Duncan, 1981; Dentinger et al., 1982; Omlin and Anders, 1983) (Figure 66-10). It is not certain whether this represents aberrant, late oligodendrocyte ensheathement of these astrocytic processes, which frequently abut axons, or the invasion of periaxonal abnormal spaces along the myelin sheath, such as at paranodes (Rosenbluth, 1987). In addition to these structural abnormalities, cultured *jp* astrocytes have been shown to have an abnormal response to high levels of K^+ stimulation and a higher pH than normal astrocytes (Skoff and Knapp, 1992). Whether these alterations in their physiology could result in changes in their putative role in ion



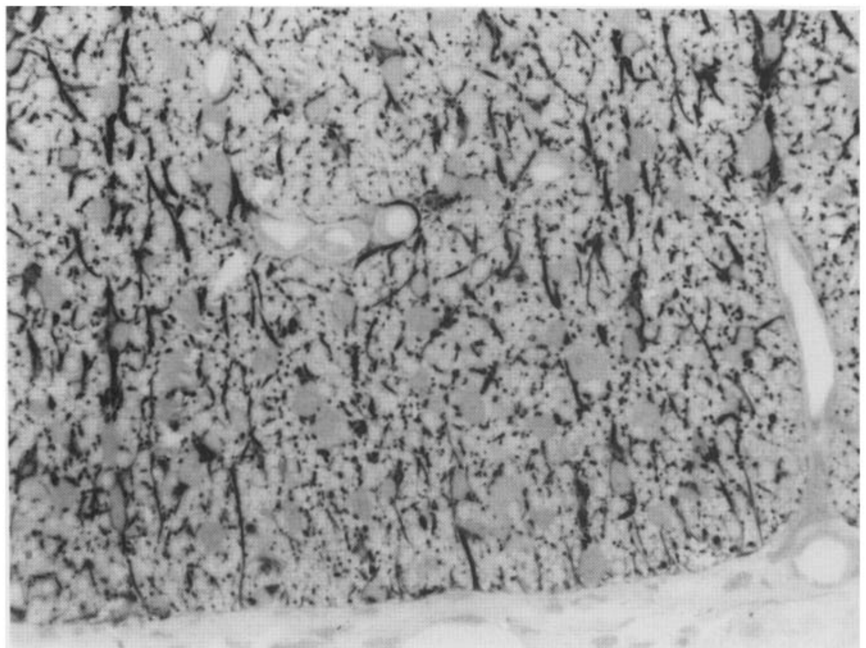


FIG. 66-9. The ventral spinal cord from (**A**) a 13-week-old shaking pup, and (**B**) a normal age-matched control, immunolabeled for glial fibrillary acidic protein (GFAP). In the mutant (Figure A), there is an increase in GFAP activity, both in the subpial area (*arrow*) and in the neuropil. ×500. [From Duncan (1987). *J. Vet. Intern. Med.*, *1*:10–23, with permission.]

exchange or growth factor secretion (e.g., platelet-derived growth factor), remains unknown.

Microglia are numerous in the white matter of both *jp* (Skoff and Knapp, 1992) and the *md* rat (Dentinger et al., 1985; Jackson and Duncan, 1988), especially at the time of maximum oligodendrocyte death in these two mutants. Immunolabeling of microglia in the *md* rat at 20 days of age and in the "aged" strain of *md* (Duncan et al., 1995) at 70 days shows a significant decrease in the older rat (Duncan and Li, unpublished data) corresponding to the reduced oligodendrocyte cell death at older ages.

HETEROZYGOTES

The female heterozygote carriers of the X-linked myelin mutants have the potential to demonstrate myelin mosaicism in the central nervous system as a result of the process of random X-linked inactivation

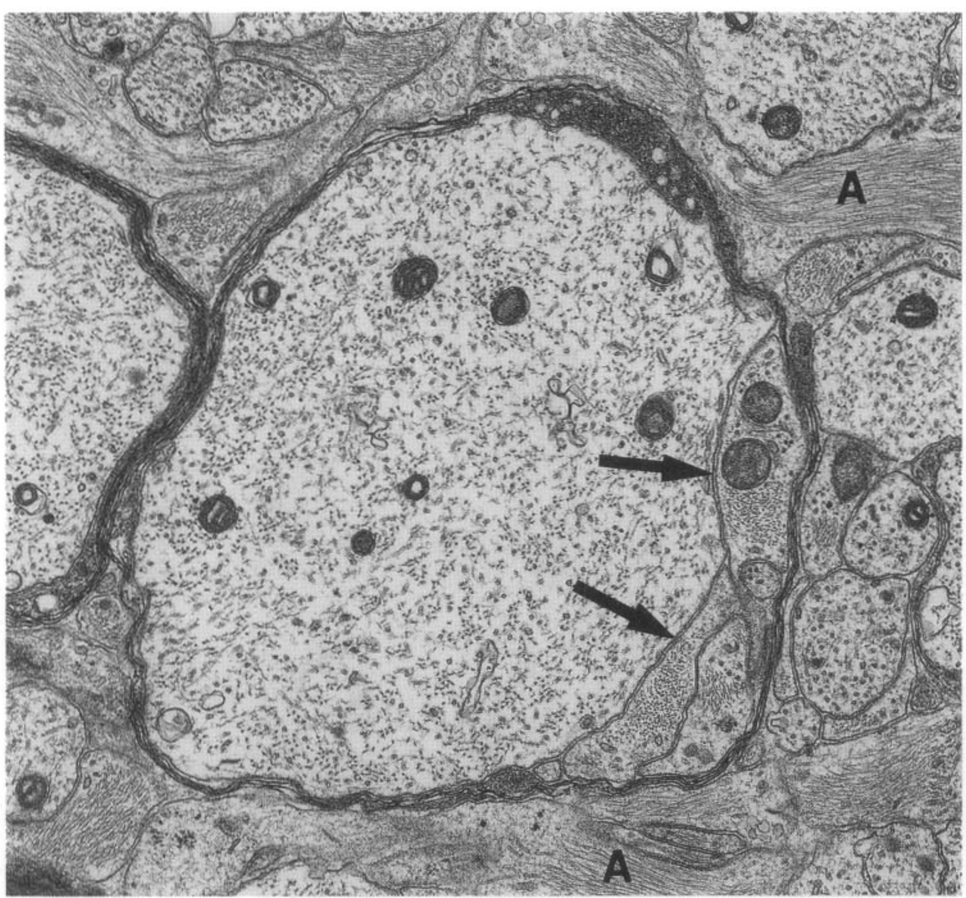

FIG. 66-10. Electron micrograph from the spinal cord of a 4-week-old shaking pup. A large diameter axon which has (2 to 3) lamellae has three astrocyte processes (*arrows*) interdigitated between the axon and the thin myelin sheath. Astrocyte processes (*A*), packed with glial filaments are obvious in the neuropil. ×17,900.

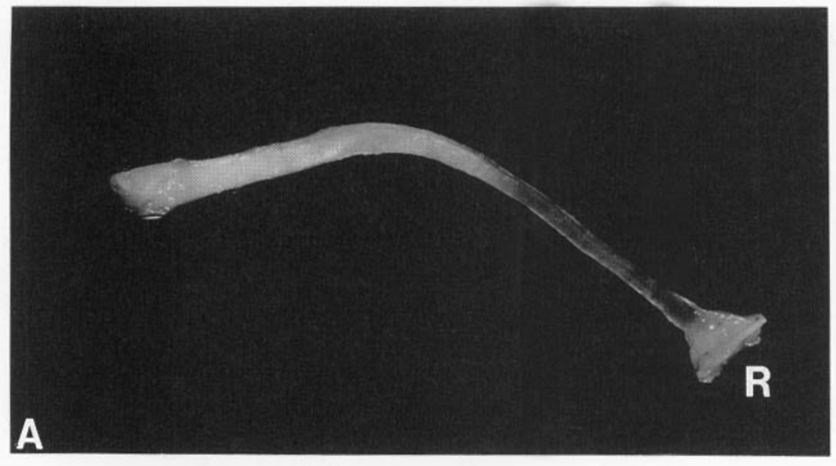
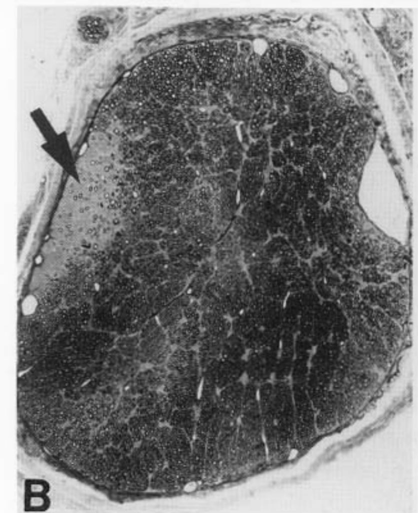
(Lyon, 1972). Such mosaicism was first described in the optic nerve of the *jp* mouse heterozygote (Skoff and Montgomery, 1981), and has since been described in the same structure in the *md* rat and *sh pup* (Duncan et al., 1987a). In the *md* rat, a detailed study of the optic nerves has shown that certain nerves show a gross deficiency in myelination, (Figure 66-11), which is the result of either absence of myelin, or a mosaic pattern consisting of adjacent patches of myelination and nonmyelination (Figure 66-11) (Duncan et al., 1993). A semiquantitative analysis of the distribution of the myelin defect in young and old *md* heterozygotes, has shown that the retinal end of the nerve is more severely affected (Duncan et al., 1993), providing further indirect evidence supporting the theory of longitudinal migration of the oligodendrocyte progenitor in the optic nerve (Small et al., 1987) as opposed to its radial spread. In *jp*, *md*, and the *sh pup*, mosaicism is more marked in the optic nerve than in any other areas of the central nervous system. Patches of nonmyelination or hypomyelination in the spinal cord have only been seen in the *sh pup* and *md* rat (Duncan, unpublished). In *jp* a more diffuse hypomyelination is present in the spinal cord (Bartlett and Skoff, 1986) and anterior commissure (Rosenfeld and Friedrich, 1984), which compensate with time (Bartlett and Skoff, 1986; Rosenfeld and Friedrich, 1986). Differences in cell death and proliferation in *jp* heterozygotes from affected males have been summarized by Skoff (Skoff and Knapp, 1992). The apparent predilection for mosaicism in the optic nerve therefore suggests that it has a different pattern of oligodendrocyte progenitor migration and population from the remainder of the central nervous system, or there is a limit in the ability to recruit normal cells into the optic nerve for repair purposes.

The findings in jp^{rsh} differ from the observations described above (Fanarraga et al., 1991). Optic nerves of female carriers show no amyelinated patches or hypomyelination, and in the spinal cord, only scattered hypomyelination is seen. Occasional





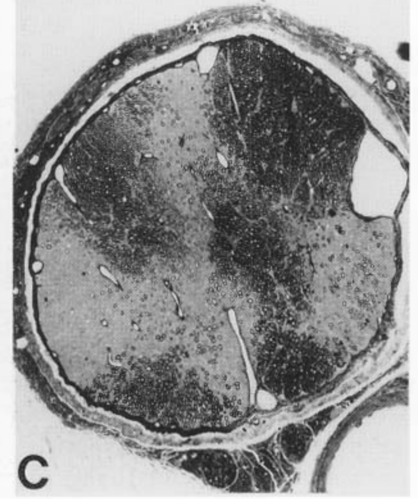


FIG. 66-11. (A) The whole optic nerve from a 14-month-old *md* rat heterozygote. The retinal end (*R*) of the nerve is transparent indicating a total absence of myelin in contrast to the chiasmal end of the nerve. (B and C) Sections from different areas of the same optic of 6-month-old known heterozygote. In the section nearer to the chiasm (Figure B), only a small patch of nonmyelination (*arrow*) is seen. Closer to the retina (Figure C), an obvious mosaic pattern of myelin and nonmyelination can be seen. The myelinated areas have well circumscribed boundaries. Toluidine blue; Figure A: ×7; Figures B and C: ×187. [Modified from Duncan et al. (1993) with permission.]

myelinated fibers which are MBP-positive and PLP-negative as determined by immunolabeling are seen in the spinal cord (Fanarraga et al., 1991).

Affected female rats born to known *md* heterozygotes have been found in three *md* rat colonies (Rosenbluth et al., 1990; Koeppen et al., 1992; Duncan, unpublished data). These female rats have an identical phenotype to the hemizygote males and examination of their karyotype has shown that they have X-monosomy.

AUTOSOMAL RECESSIVE MYELIN MUTANTS

This group of mutants is more heterogeneous and fewer in number than the X-linked mutants. Four of these, the shiverer (*shi*) mouse and its allele shi^{mld}, the quaking (*qk*) mouse, and the *taiep* rat are described together and mention made of other less well characterized mutants of autosomal recessive nature, where hypomyelination is seen. A summary of the abnormalities in these mutants is outlined in Table 66-2.

Amount of Myelin and Myelin Structure

The myelin deficit seen in all of these mutants is not as marked as seen in the most severely affected X-linked mutants. Comparison of quantitative data on the amount of myelin in *shi* (Billings-Gagliardi et al., 1986) and *qk* (Nagara and Suzuki, 1981) suggests that there is considerably less myelin in the central nervous system of *shi*, although the quantitative methods were different in each study. However, it has been estimated that *shi* optic nerve has about 20% of controls (Billings-Gagliardi et al., 1986), whereas *qk* optic nerve has 60% (Friedrich, 1974). In *qk*, the myelin defect is most marked in the initial stages of myelination and there is a steady increase in myelin with time (Nagara and Suzuki, 1981). A notable difference between *shi* and shi^{mld} has been reported. The latter lives for slightly longer than *shi* and this has been associated with an increasing amount of myelin, with the presence of MBP in older shi^{mld} mice (Matthieu et al., 1986). Subtle differences in the amount of myelin and its ultrastructure, and indeed in the survival time of shi^{mld} mice derived

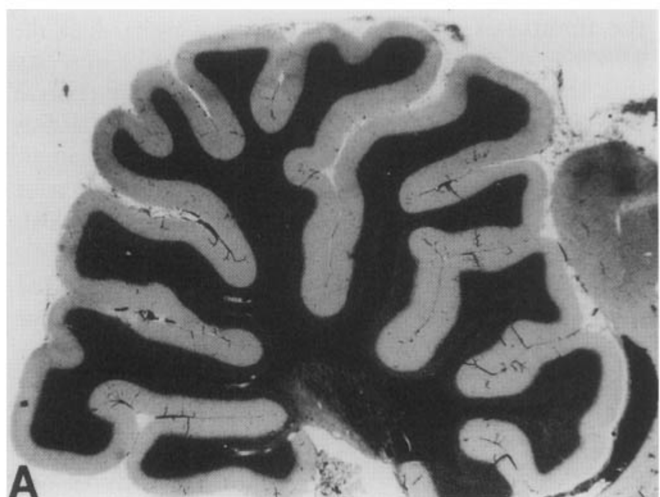
TABLE 66-2. *Summary of the Phenotypic Abnormalities in the Autosomal Recessive Central Nervous System Myelin Mutants*

Phenotype	shi	shi^{mld}	qk	taiep
Amount of myelin	+	++ but ↑ with time	++ Hypomyelination ↑ with time	+++ Hypomyelination but then progressive demyelination
Myelin structure	neg MDL	pos/neg MDL	Abnormal radial component	Normal
Myelin immunolabeling	MBP-neg	MBP-neg (with time some myelin MBP-pos)	NAD	MBP and PLP-pos
Oligo number	↑	?	↑	?↑
Oligo structure	Initially ↑ vacuoles	Initially ↑ organelles ↑ microprocesses	↑ Membranous profiles in young mice	Progressive microtubular increase
Oligo proliferation	NE	NE	NE	?
Cell death	NAD	NAD	NAD	NAD
Gliosis	NAD	NAD	+	?
Microglia	NAD	NAD	NAD	NAD

MDL, major dense line; MBP, myelin basic protein; PLP, proteolipid protein; Oligo, oligodendrocyte; NAD, no abnormality detected; NE, not examined; +, severe reduction in myelin; ++++, normal.

from different backgrounds, have been identified, and this should be kept in mind when comparisons are made (Shen et al., 1985). In the *taiep* rat, myelination appears to commence normally, although myelin sheaths may be thin, but the major abnormality appears later in life with the progressive loss of myelin from more rostral structures such as the corpus callosum, cerebellum, and optic nerves (Duncan et al., 1992) (Figure 66-12). In the spinal cord of older *taiep* rats is a diffuse loss of myelin in the lateral and ventral white matter. However, the most striking deficit is in the fasciculus gracilis and corticospinal tracts, where by 12 months of age, few axons are myelinated (Figure 66-13).

In all three mutants the myelin sheaths axons are thin, although in *taiep*, many axons have a normal myelin sheath. In both *shi* and *qk*, the myelin formed is often poorly compacted and in *shi* the myelin formed lacks a major dense line. In *shi^{mld}* however, the increase in myelin is associated with the presence of a major dense line in thicker myelin sheaths, a result of the later deposition of MBP in *shi^{mld}* myelin



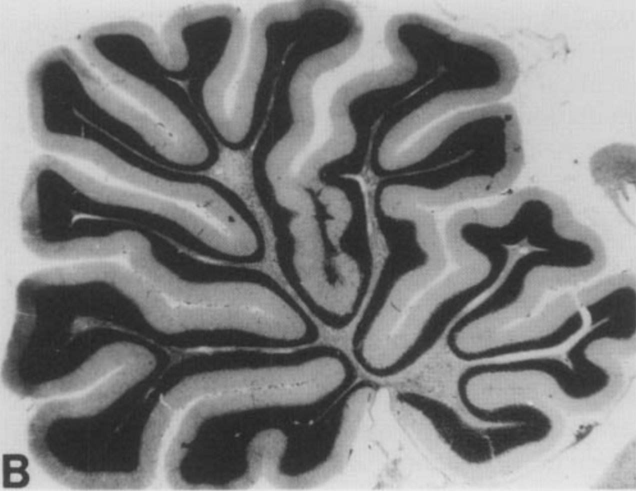


FIG. 66-12. The cerebellum from (A) a 12-month-old normal and (B) *taiep* mutant rat. A lack of myelin can be noted in the cerebellar white matter and brainstem of the *taiep* rat. Heidenhain stained; ×20.

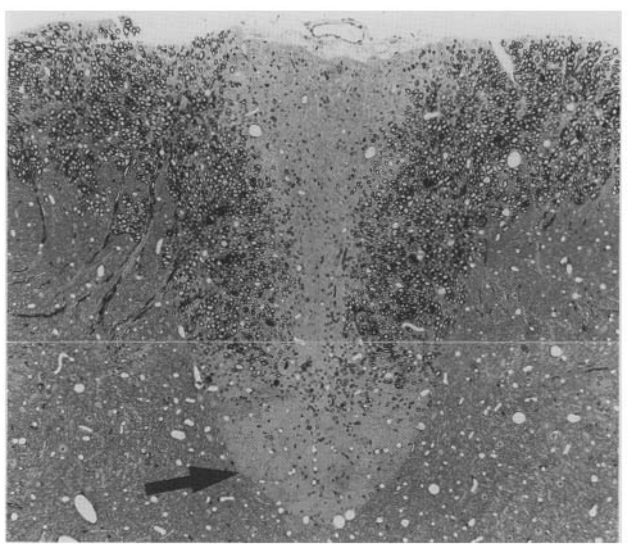

FIG. 66-13. The dorsal columns from a 12-month-old *taiep* rat. The fasciculus gracilis and the corticospinal tract (*arrow*) have almost no myelin present, compared to the adjacent fibers of the fasciculus cuneatus. Toluidine blue; ×160. [Modified from Duncan et al. (1992), with permission.]

(Mikoshiba et al., 1992). As the *qk* mouse ages, myelin sheaths become thicker, and there is much less evidence of aberrant myelin formation as is seen in young *qk* mice, suggesting that *qk* mice oligodendrocyte are eventually capable of forming normal compact myelin (Nagara and Suzuki, 1981). *Taiep* myelin in contrast, appears to have a normal ultrastructural appearance (Duncan et al., 1992).

The peripheral nervous system of *shi* and *qk* have also been examined in detail. In *shi*, despite the total lack of MBP, the structure of myelin in the peripheral nervous system is almost normal, with no hypomyelination and a normal intraperiod line. In *qk*, earlier work had suggested that hypomyelination was seen in the peripheral nervous system (Samorajski et al., 1970), but a morphometric study of myelin sheath thickness and internode length has shown that *qk* internodes are very short and that the myelin sheaths have an appropriate diameter (Beuche and Friede, 1985). Initial analysis of the *taiep* peripheral nervous system indicates that myelination is normal.

Oligodendrocyte Number and Abnormalities

Unlike the X-linked mutants which overall have a reduction in the number of mature oligodendrocytes (with the exception of jp^{rsh}), *shi*, *qk*, and *taiep* have all been reported to have more oligodendrocytes than normal (Friedrich, 1975; Nagara and Suzuki, 1981; Duncan et al., 1992). This has been most critically evaluated in *qk* (Friedrich, 1975; Nagara and Suzuki, 1981), where a two- to fourfold increase has been reported in the optic nerve and in the spinal cord (Friedrich, 1975). In *taiep*, there appears to be a generalized increase in oligodendrocytes throughout the central nervous system, but this has to be confirmed by detailed morphometry. Quantitation of oligodendrocyte number can be inaccurate because of the differences in the area of the white matter between mutant and wild type (Friedrich, 1975). In addition, the identification of either mature or immature oligodendrocyte is difficult at the light and electron microscopic levels, and immunolabeling may be required. If an increase in oligodendrocyte numbers is proven in these mutants (already shown in *qk*), this may provide an opportunity to study the mechanisms behind this, that is, whether this results from increased cell division or survival, with fewer oligodendrocyte progenitors undergoing programmed cell death (Barres et al., 1992). If the increase is due to abnormal cell division, it should be determined whether this results from persistent nonmyelination.

In none of these mutants has an increased oligodendrocyte cell death been reported, but cytoplasmic changes in the oligodendrocytes in each have been documented. In *shi*, between 2 and 4 weeks of age, oligodendrocytes have prominent vacuoles and vesicles, but these changes are not seen in mature mice (Inoue et al., 1983). Similar abnormalities have been reported in shi^{mld} (Matthieu et al., 1986). A prominent ultrastructural abnormality seen in *shi* is the collection of oligodendrocyte microprocesses (Shen and Billings-Gagliardi, 1985). This has also been reported in the *taiep* rat (Duncan et al., 1992) and may reflect abnormalities of the oligodendrocyte cytoskeleton. In neonatal *qk*, there is a prominent dilatation of smooth endoplasmic reticulum and vesicle proliferation, but these changes are not seen in older *qk* mice (Nagara and Suzuki, 1981).

The *taiep* rat has the most unique oligodendrocyte cytoplasmic abnormality, with marked accumulation of microtubules throughout the oligodendrocyte cytoplasm (Duncan et al., 1992). The microtubules frequently become associated with smooth endoplasmic reticulum (Figure 66-14). The first signs of microtubule accumulation is seen at about 1 month of age and progresses with age. In the older rats, evidence on myelin breakdown is seen on electron microscopy (Figure 66-14). This mutant provides a model in which to define the critical role of the microtubular network in myelination and myelin maintenance. If a progressive accumulation of microtubules is the primary defect in *taiep*, the myelin defect may result from a disturbed and later deranged transport of myelin proteins within the oligodendrocyte.

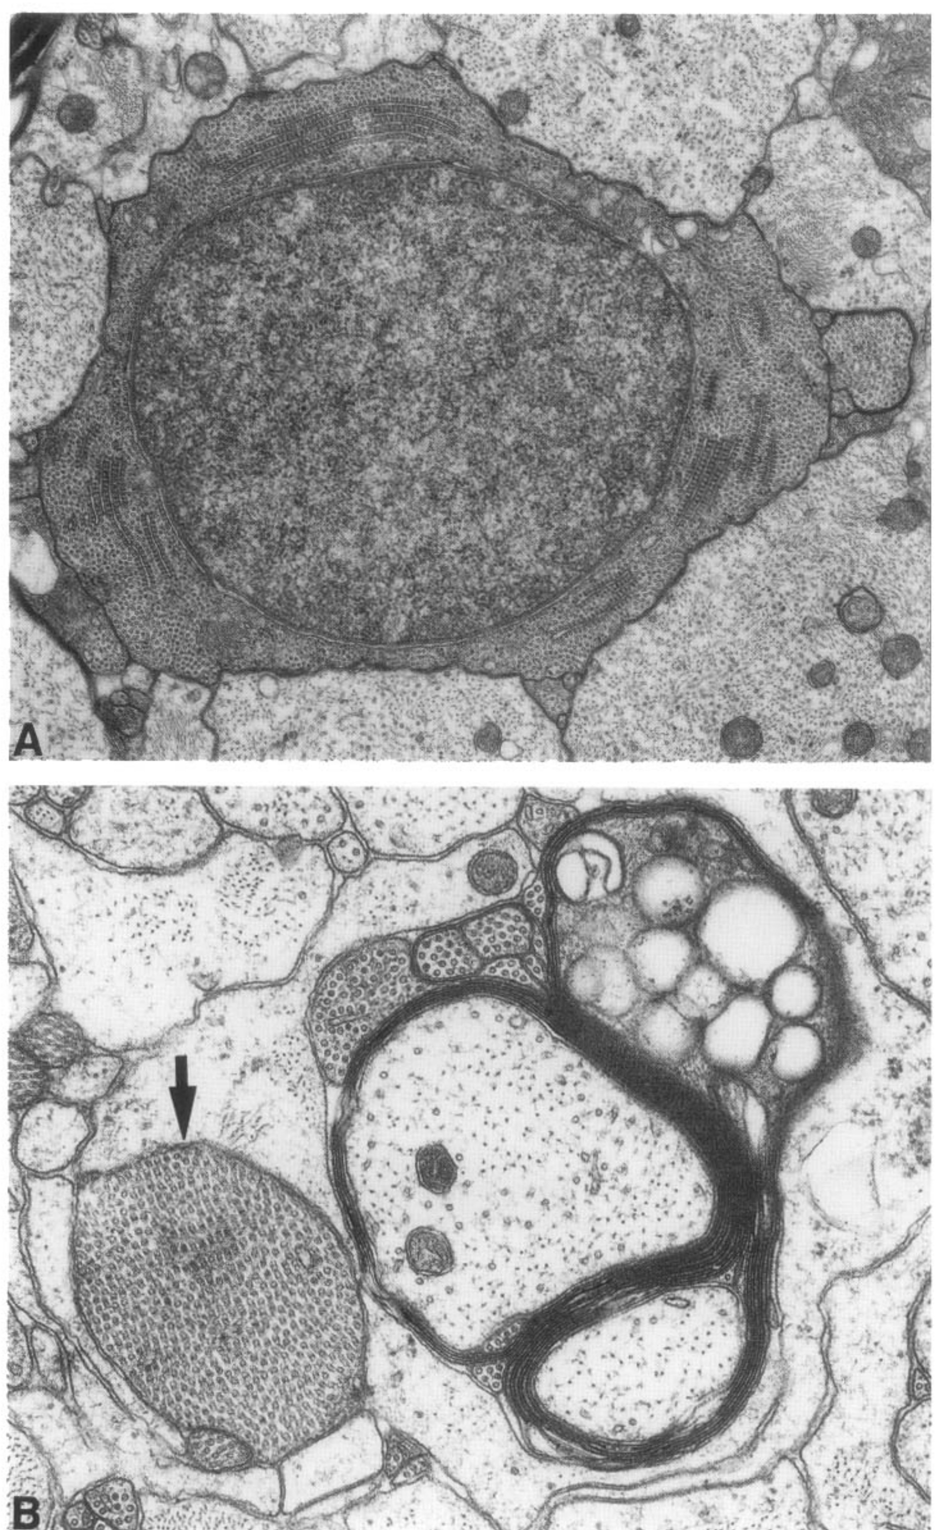

FIG. 66-14. Electron micrographs from a 9-month-old *taiep* rat. (**A**) The oligodendrocyte has an increased number of microtubules, some of which run in parallel arrays along smooth cisternae. (**B**) The myelinated fiber present has an aberrant myelin sheath, which is starting to break down, and has a duplicated outer mesaxon. An adjacent oligodendrocyte process (*arrow*) is packed with microtubules. Figure A: ×18,700; Figure B: ×40,500. [Modified from Duncan et al. (1992), with permission.]

Other Glial and Axonal Changes

In general, an astrocytic response to the primary glial abnormality is not a marked feature in these mutants. In fact, there is only a mild gliosis in *qk* and no evidence of this has been emphasized in *shi*. The *taiep* rat shows moderate ultrastructural evidence of gliosis but immunocytochemistry for GFAP has yet to be performed. Quantitation of GFAP by Western blot analysis may be the most accurate way to determine the astrocytic response in these mutants (Norton et al., 1992).

Unlike the X-linked mutants there is no evidence of a microglial proliferation. Likewise, there are few significant changes in axons with only occasional axonal spheroids reported in the *qk* cerebellum and a moderate number in the *taiep* central nervous system. However, more extensive vacuolar degeneration of nerve roots, similar to that seen in the aging peripheral nervous system has also been described in *qk* (Suzuki and Nagara, 1982). The possibility of abnormal interactions between axon and oligodendrocytes in these mutants has been suggested in a report of sodium channel density in the *shi* mouse (Noebels et al., 1991). In the *shi* brain, there is a marked excess of sodium channels, suggesting a failure of downregulation of sodium channel density in *shi* axolemma as a result of an abnormal cell-cell interaction (Noebels et al., 1991).

OTHER AUTOSOMAL RECESSIVE MUTANTS

A number of other less well-known myelin mutants have been reported, which cannot be discussed in detail here, but which are summarized for completeness. Two murine mutants have been described, the Syrian mutant hamster (Nunoya et al., 1985; Kunishita et al., 1986) and the zitter rat (Kondo et al., 1991; Kondo et al., 1992), which show mild hypomyelination. The hamster shows a delay in myelination of the central nervous system, but with all myelin proteins being present in the myelin formed (Kunishita et al., 1986). The zitter rat shows more pronounced hypomyelination in the spinal cord than the hamster, which persists to 37 weeks of age. Accumulation of abnormal membranous structures and a distension of the RER, perinuclear cisternae, and Golgi in oligodendrocytes are the most prominent feature of this mutant, and may indicate a defect in membrane biosynthesis. All the major myelin proteins are present in zitter myelin. A very recent report of a severe myelin deficiency in a strain of Long Evans rats appears to offer new opportunities to explore the myelination process (Delaney and Kwiecien, personal communication). This rat has no myelin in the central nervous system as seen on light microscopy, yet lives to 3 to 5 months of age. Preliminary ultrastructural studies suggest premature oligodendrocyte death and abnormal oligodendrocyte development (Duncan, unpublished data).

In the dog, two breeds have been found to have an inherited defect which results in a delay in myelination of the peripheral lateral and ventral white matter of the spinal cord (Vandevelde et al., 1978; Kornegay et al., 1987). This may result from a delay or failure of migration of oligodendrocyte progenitors to these sites (Duncan, unpublished information). Finally, dysmyelination has been reported in the central nervous system in certain storage disorders, including caprine β-mannosidosis (Lovell and Boyer, 187) and canine GM1 gangliosidosis (Kaye et al., 1992).

CONCLUSION

New mutants with defects in other myelin proteins, such as MAG or CNP, are eagerly sought, as is the final definition of the *qk* mutation. As with P_0 in the peripheral nervous system (Giese et al., 1992) gene knockout strategies, ablating expression of MAG and CNP, may confirm their postulated roles in myelination. Indeed new mutants may lead to the finding of undescribed central nervous system proteins such as was the case of peripheral myelin protein-22 in the peripheral nervous system and the *trembler* mutant (Suter et al., 1992). Despite the many recent advances, a complete understanding of the myelination process is still elusive, and myelin mutants will continue to play a pivotal role.

I am grateful to Dr. I. R. Griffiths for his comments on this review. The work quoted from my laboratory has been supported by NIH, NS23124, and the Elizabeth Elser Doolittle Trust.

67 Viral infections of neuroglial cells

BY MONIQUE DUBOIS-DALCQ

Viruses that spread and replicate in the nervous system are often called neurotropic because they can make their way to nervous tissue where they find specific cellular receptors for binding and entry and a milieu favorable to their replication. In this chapter I will describe how certain viruses infect neuroglial cells—oligodendrocytes, astrocytes, microglia and ependyma in the central nervous system and Schwann cells in the peripheral nervous system—and how these infections cause experimental and human neurological diseases. Viruses can indeed affect neuroglial cell survival and functions, leading to neuropathological changes such as demyelination, chronic inflammation, and even neurodegeneration. First, I discuss common properties and mechanisms underlying viral diseases of neuroglial cells. Then I review selected examples of such viral diseases and how their molecular pathogenesis is currently being studied.

Are Neuroglial Cells Susceptible to Many Different Viruses and Is Infection of Neuroglial Cells Selective?

Both DNA and RNA viruses, including retroviruses, can infect neuroglia in animal and man. The names, families, and main structural properties of these viruses are summarized in Table 67-1, which may serve as a guide to the abbreviations of virus names used throughout this chapter. Several of these viruses can also replicate in neurons, but lentivirus and human polyoma virus expression appears to be truly restricted to neuroglia. A few important viruses that are pathogenic in humans show a tropism selective for neurons, such as rabies virus, which replicates in many central nervous system neurons; the human poliovirus, which selectively infects spinal cord motoneurons; and latent forms of herpes simplex virus types 1 and 2 (HSV-1 and -2), which reside in sensory ganglia neurons (for reviews see Johnson, 1982; Kristensson and Norrby, 1986; Fields et al., 1990).

How Do Neurotropic Viruses Spread to the Brain?

First, a virus can spread directly to a neural site such as the olfactory epithelium (coronaviruses; it is not clear that this route is ever used in natural infections) (Lavi et al., 1988), the sensory nerve terminals in the skin or mucosa (HSVs), or the neuromuscular junction (rabies, polio?) (Ren and Racaniello, 1992). Viruses can also disseminate from the blood to the brain by passing through the fenestrated endothelium of the choroid plexuses to the cerebrospinal fluid or by traversing and/or replicating in brain endothelial cells (mouse retrovirus, Cas BrE, see below). Finally, viruses can bypass the tight junctions between brain endothelial cells, crossing the blood-brain barrier inside blood mononuclear cells (T cells, B cells, or monocyte-macrophages), a situation frequently seen with viruses that infect both the immune and the nervous systems (lentiviruses, HTLV-1, measles virus, JC virus).

Have Receptors for Neurotropic Viruses Been Characterized?

The human poliovirus receptor has been characterized both functionally and structurally; it is a member of the immunoglobulin superfamily (Mendelsohn et al., 1989). Mice that do not express the poliovirus receptor and are normally not susceptible to infection with human poliovirus can be made susceptible by transferring the poliovirus receptor gene to the mouse germline (Ren and Raccaniello, 1990). When transgenic mice expressing this receptor in several organs including the nervous system were infected with human poliovirus, virus replicated only in the brain, spinal cord, and muscle, indicating that viral tropism is governed not only by expression of the poliovirus receptor gene but also by host cell factors (Ren and Racaniello, 1992). It is not known yet whether the receptor for the mouse picorna viruses that cause a demyelinating disease (see the section *Infections With Theiler's Murine Encephalomyelitis Virus* below) is related to the poliovirus receptor.

Although much progress has been made recently in the characterization of other viral receptors, their role in infections of the nervous system is not yet clearly established. In addition, viruses may be able to use alternate receptors for their entry or may need

TABLE 67-1. *Viruses Infecting Neuroglial Cells*

Virus Families	Structural Properties of the Viruses	Specific Virus Names	Cell Type Infected	Mode of Propagation	Receptor Known?
I RNA viruses					
Picornaviridae	Nonenveloped icosahedral symmetry	Poliovirus	Anterior horn neurons and some brain nuclei	Intestinal tract → blood → brain to muscle?	Poliovirus receptor (humans)
	28–30 nm 1SS RNA ~8 kb	Theiler murine encephalitis virus (TMEV)	Neurons first; astrocytes and oligodendrocyte later		?
Togaviridae	Enveloped, with fine peplomers 60–70 nm 1SS RNA ~12 kb	Pestivirus Border disease in sheep	Oligodendrocytes *in vivo* and *in vitro*; astrocytes and neurons also *in vitro*	*In utero*	?
Coronaviridae	Enveloped, with club-shaped spikes Helical nucleocapsid	Corona virus A59 in mice,		Intestinal tract, blood, olfactory neurons, endothelial cells?	Carcinogenic embryonic antigen (CEA) variants; accessory molecule?
	80–160 nm (mouse:90) 1SS RNA, 16 to 31 kb	JHM in rats and mice			
		229E in humans		Respiratory tract	Aminopeptidase
Paramyxoviridae	Enveloped, large peplomers, Helical nucleocapsid, Pleomorphic, 150–300 nm	Measles virus (MV) (subacute sclerosing panencephalitis) (SSPE)	Neurons, astrocytes, and oligodendrocytes	Blood brain, in lymphocytes and monocytes-macrophages?	Neuraminic (sialic acid)
	1 negative sense SS RNA, 16–20 kb	Canine distemper virus (CDV)	Astrocytes and oligodendrocytes		
II DNA viruses					
Papovaviridae: Polyomaviruses	Nonenveloped icosahedral symmetry, 45 nm, circular dsDNA, 5 kb	JC virus (JCV, human) (progressive Multifocal leukoencephalopathy)	Oligodendrocytes and astrocytes	Bone marrow → circulating white cells → brain; from genitourinary tract?	?
		Simian virus 40			? Class I molecules
Herpesviridae	Enveloped, spikes, icosahedral nucleocapsid, ~150 to 200 nm 1ds DNA 120–200 kb	Herpes Simplex Virus type 1 and 2 (HSV-1 and 2)	Latency in sensory neurons; Schwann cells, astrocytes, and oligodendrocytes	Skin and genital mucosa → sensory nerves and ganglia. Trigeminal and olfactory tracts → CNS	Heparin sulfate proteoglycan; accessory molecule?
		Varicella zoster (VZV)	Latency in sensory neurons; Schwann cells	Skin and mucosa → sensory nerves and ganglia	
		Cytomegalovirus (CMV)	Ependymal cells, other neuroglial cells?	Congenital infection; blood → brain, in monocytes.	
III Retroviruses					
Type C oncoviruses	Enveloped, spikes; icosahedral/helical nucleocapsid 80 to 130 nm	CasBrE ecotropic retrovirus (Lake Casitas wild mouse)	Cerebellar neurons; microglia; endothelial cells	Blood viremia → brain	?

(*Table continued on next page*)

TABLE 67-1. *(Continued)*

Virus Families	Structural Properties of the Viruses	Specific Virus Names	Cell Type Infected	Mode of Propagation	Receptor Known?
Lentiviruses	2 SS −9 kb RNAs Reverse-transcription → integration of	Visna virus (sheep)	Choroid plexuses, macrophages and oligodendrocytes??	Blood → brain, in T cells and monocytes-macrophages?	50K protein?
	proviral DNA → RNA transcripts	Human and simian immunodeficiency viruses (HIV-1, SIVS)	Microglia; immature fetal astrocytes; Oligodendrocytes??	Blood → brain, in T cells and monocytes-macrophages?	CD4 galactocerebroside?
Oncovirinae		Human T cell leukemia virus (HTLV-1)	Macrophages, microglia? T cells?		?

Compiled from information in *Fields Virology* (1990), Dubois-Dalcq et al. (1984) and references quoted in the text. It should be noted that this is not an exhaustive list of all viruses that infect neuroglial cells but rather a series of selective and well-known examples of such infections.

accessory molecules only found in certain cell types. In enveloped viruses, it is always a major viral glycoprotein extracellular domain that contains the specific recognition sites for cellular receptors. The receptor for mouse hepatitis virus (MHVR1) is recognized by the S protein of these coronaviruses and is a member of the carcinoembryonic antigen (CEA) family of glycoproteins, which are also part of the immunoglobulin superfamily (Williams et al., 1991). Although several strains of MHV specifically infect neuroglial cells (see below), one type of transcripts for MHVR1 present in liver and gut—mmCGM1—is not significantly expressed in the brain of susceptible mice. However, a splice variant—mmCGM2—is found in the central nervous system, suggesting that MHV may utilize different CEA molecules in the liver and in the brain (Yokomori and Lai, 1992a). In addition, mouse coronaviruses may require a second factor for their entry in specific host cells (Yokomori and Lai, 1992b). Surprisingly, a different molecule, human aminopeptidase N is the receptor for human coronavirus 229E, a virus which is related to the mouse MHV (Yeager et al., 1992). This cell surface glycoprotein, found in a synaptic fraction, is thought to help break down neurotransmitters in the brain and could allow human coronaviruses to enter cells in the nervous system (see below) (Murray et al., 1992; Stewart et al., 1992). Most recently, the membrane cofactor protein CD46 has been identified as a functional receptor for measles virus (Dorig et al., 1993). This protein is widely distributed on human cells and is a member of the regulators of complement activation gene cluster on chromosome 1.

HSV-1 can use as receptors heparan sulfate moieties of cell surface proteoglycans which are widely distributed on animal cells (Sieh et al., 1992). However, viral entry can still occur—although at low efficiency—in a mouse L cell mutant defective in the synthesis of these glycans (Gruenheid et al., 1993). Finally, HIV-1 uses the CD4 molecule, which functions in the recognition process between T cells and antigen presenting cells, to enter not only T cells and monocyte-macrophages but also microglial cells (Jordan et al., 1991). In some cells, an additional molecule may interact with a region of the HIV-1 surface glycoprotein (gp120) toward the amino terminus from the CD4 binding site called the V3 loop and involved in virus tropism (see below). Interestingly, galactocerebroside, a glycolipid highly expressed on oligodendrocytes, can serve as an alternate receptor for HIV-1 in central nervous system cell lines (Harouse et al., 1991). Thus, viruses use cell type-specific surface molecules, some of them with important functions, for their binding and entry.

Is There a Particular Time at Which Viral Infections of Neuroglia are Occurring?

With viruses that show tropism for both neurons and glia, virus expression tends to be confined to neuroglia when the organism becomes immunocompetent and the nervous system cells is differentiated. For instance, the JHM strain of mouse coronaviruses will cause acute lethal encephalitis in newborn rats and mice while it induces a demyelinating disease in older animals (see below) (Weiner et al., 1973; Sorensen et al., 1980). In addition, viral persistence is more likely to occur in the nervous system in the face of a more mature immune and nervous systems as observed in measles virus infection of rodents (reviewed in Dubois-Dalcq, 1979). On the other hand,

intrauterine infection may affect a specific neuroglial cell at a critical stage of development, hampering its differentiation. Such mechanisms may be at play in the hypomyelination observed in lambs affected with border disease, an infection caused by a sheep pestivirus (Potts et al., 1985). However, all types of central nervous system cells are susceptible to this virus *in vitro* (Elder et al., 1987). Infection of ependymal cells *in utero* is particularly frequent in congenital infections with RNA viruses, often resulting in hydrocephaly in animals (reviewed in Coyle, 1991). In humans, cytomegalovirus can infect ependymal cells *in utero* in the first half of pregnancy. Individual viral proteins may also have a detrimental effect on neuroglial cell development as suggested by experiments with transgenic mice, which express the early region and T antigen of the JC papovavirus in oligodendrocytes and develop dysmyelination (Small et al., 1986). However, it is not known whether viral proteins may act in this way in the course of natural infection.

What Factors Influence the Outcome of Viral Infections of Neuroglial Cells?

Viruses may cause cytopathic effects such as cell fusion (in microglia or astrocytes) or lysis (in oligodendrocytes) which can be followed by gliosis, formation of microglial nodules and/or demyelination. Of great influence on the outcome of these viral infections is the way the immune system acts within the central nervous system as discussed in Chapters 44, 45, and 46. Antibodies as well as interferon-regulated antiviral genes are important in limiting viral spread (Arnheiter et al., 1990). However, viral infections of neuroglia can only be efficiently cleared by cytotoxic T cells. As activated T cells are able to migrate in and out of the central nervous system (Hickey et al., 1989), cytotoxic *T* cells sensitized to viral antigens present in the central nervous system will interact with antigen-presenting cells such as microglial cells, which can express class I and II molecules (reviewed in Sedgwick and Dorries, 1991). When clearing of viral infection is complete, neuroglial cells are able to regenerate and remyelinate as seen in rats and mice. Depending on the genetic makeup of the MHC complex, the host susceptibility to viral infection and the establishment of viral persistence in the nervous system will vary (Brahic et al., 1991). If viral infection is prolonged, T cells may become sensitized to host antigens such as myelin proteins (myelin basic protein [MBP], proteolipid protein [PLP]), leading to autoimmune demyelination. Sensitization to MBP has been demonstrated in rats infected with JHM coronavirus (Watanabe et al., 1983) or with measles virus (Liebert et al., 1987). Besides, measles virus infection of the central nervous system enhances its susceptibility to autoimmune T cell aggression (Liebert et al., 1990).

Another possibility is that molecular mimicry between viral proteins and host nervous system proteins may allow autoimmunity to develop after removal of the initial immunogen ("hit and run" event; reviewed in Oldstone et al., 1987). For instance, a measles viral peptide corresponding to a sequence in this virus phosphoprotein is homologous to a 8-10 amino acid encephalitogenic site of rabbit MBP and can induce inflammatory cells accumulation around the vessels in the central nervous system. Such molecular mimicry and "hit and run" events may explain why cerebrospinal fluid lymphocytes proliferate in response to both viral and host antigens in acute postinfectious encephalomyelitis in which virus can rarely be isolated from the brain (Oldstone, 1987). Finally, virus infection microglia and macrophages may indirectly affect other nervous system cell types (Giulian et al., 1990) by triggering astrocytes to synthesize neurotoxic cytokines as suggested by *in vitro* experiments with HIV-1 (Genis et al., 1992). Besides viral proteins small metabolites released by activated microglia may damage neurons and/or oligodendrocytes or alter their specialized functions (see below).

Are There Viral Molecular Determinants That Control Tropism for a Particular Nervous System Cell Type, Neurovirulence, and Viral Persistence?

A striking example of control of tropism by viral determinants is the case of mouse reoviruses in which the type 1 specifically infects ependymal cells and causes hydrocephalus, while the type 3 only infects neurons and causes acute meningoencephalitis. As reoviruses have a multiple segmented genome, infection with viruses containing reassorted segments showed that the viral S1 gene encoding the viral outer capsid sigma 1 determines this cell tropism (for review see Tyler and Fields, 1990). Determinants of viral persistence have been studied in mouse picornaviruses and demyelinating diseases are often associated with reduced virulence and cytopathogenicity of the virus (see below). Moreover, when the virus resides in the brain for prolonged periods of time, it may evolve and undergo repeated mutations and/or deletions, resulting in the emergence of "brain-specific variants" with defects favoring persistence inside the infected cells in a form invisible to the immune system (lentiviruses, measles virus, JC

virus). Thus the viral genetic makeup and the evolutionary changes of neurotropic viruses in the brain are important determinants of disease pathogenesis.

I will now describe specific examples of viral infections of glia in animals and men. I have grouped the infections of astrocytes and oligodendrocytes together because viruses rarely infect only myelin-forming cells. Microglial infections will be dealt with in a separate section.

VIRAL INFECTIONS OF OLIGODENDROCYTES AND ASTROCYTES

Infections with Theiler Murine Encephalomyelitis Virus

The nonvirulent DA strain of the Theiler murine encephalomyelitis virus (TMEV); a picornavirus, causes a biphasic disease of the central nervous system in SJL/J mice inoculated intracerebrally at 4 to 5 weeks of age. In this TMEV model, infection of neurons appears to be a prerequisite of the infection of neuroglia. An initial phase of encephalitis and infection of the spinal cord recedes and is followed by a persistent infection of neuroglial cells and demyelination (Patick et al., 1990a) (Figure 67-1A). Scattered neuroglial cells expressing both viral RNA and proteins are found in animals persistently infected with TMEV (Figure 67-1B). Although oligodendrocytes are most frequently infected, astrocytes and microglia can also express viral RNA (Aubert et al., 1987). Deletion analysis indicates that determinants of persistence and demyelination are located between the C-terminal end of the VP3 capsid protein and the N-terminal extremity of protein 2A, as the VP1 gene can attenuate the highly virulent GD VII strain when chimeric viruses are constructed (Tangy et al., 1991, 1993). Other studies with intratypic recombinant viruses indicate that multiple gene segments influence the number and extent of demyelinating lesions (Rodriguez and Roos, 1992).

The susceptibility to this mouse virus-induced demyelinating disease is genetically determined (Patick et al., 1990b). Congenic mice with different MHC haplotypes indeed show either no lesions or different degrees of demyelination after inoculation with the DA strain. Resistance appears determined by efficient presentation of viral antigen to the immune system, resulting in local clearing of the virus and prevention of demyelination. Two different loci determine the persistence of the virus and demyelination: the H2D region of the MHC complex and another locus outside of this complex (Bureau et al., 1992). Thus it is likely that CD8+ cytotoxic T cells play a major role in the outcome of this central nervous system viral infection. To test this hypothesis, DA virus was inoculated intracerebrally into beta$_2$ microglobulin knockout mice, which fail to express class 1 MHC molecules, and therefore lack CD8+cells (Fiette et al., 1993). Although these beta$_2$ microglobulin-deficient mice were of a strain normally resistant to TMEV infection, they failed to clear virus and went on to develop demyelination. Thus CD8+ cells are required to clear the virus but do not appear to mediate demyelination, raising the possibility that viral persistence in oligodendrocytes may alter the expression of myelin genes.

Interestingly, certain treatments of DA-infected animals can decrease the extent of demyelination and can even enhance repair (Patick et al., 1991). For instance, intraperitoneal injection of tumor necrosis factor-alpha considerably decreased the degree of demyelination observed after intracerebral inoculation of the DA strain in SJL/J mice, even though virus expression is not affected (Paya et al., 1990). Furthermore, intraperitoneal injection of immunoglobulins from mice immunized against spinal cord homogenate caused enhanced remyelination in these infected mice (Rodriguez et al., 1991) (Figure 67-1C).

Infection with Mouse Coronaviruses

Certain strains of MHV replicate in the central nervous system; the JHM strain is particularly neurotropic for both rats and mice (Weiner et al., 1973; Sorensen et al., 1980). When inoculated intracerebrally at 3 to 4 weeks of age, the MHV-A59 strain replicated in some strains of mice (such as C57 BL/6 and BALB/c; SJL/J are resistant), causing a paralytic disease with demyelination at 2 to 4 weeks (Godfraind et al., 1989. Jordan et al., 1989). MHV-A59 can trigger a rigorous immune response which cleared the virus from the demyelinating lesions, allowing the nervous tissue to react to injury and repair myelin. Remyelination started around 4 weeks and continued for the following 8 to 12 weeks. *In situ* hybridization studies of myelin gene expression in the first week after viral infection showed a rapid loss of myelin gene transcripts concomitant with active viral replication in oligodendrocytes before demyelination was observed (Jordan et al., 1989). At 3 weeks, however, new myelin gene transcripts were already detected in the lesions, that is, before remyelination started (Jordan et al., 1990). The first transcripts to be detected were the early developmental forms of MBP mRNAs which were increased up to 17 times over control. It thus appears that

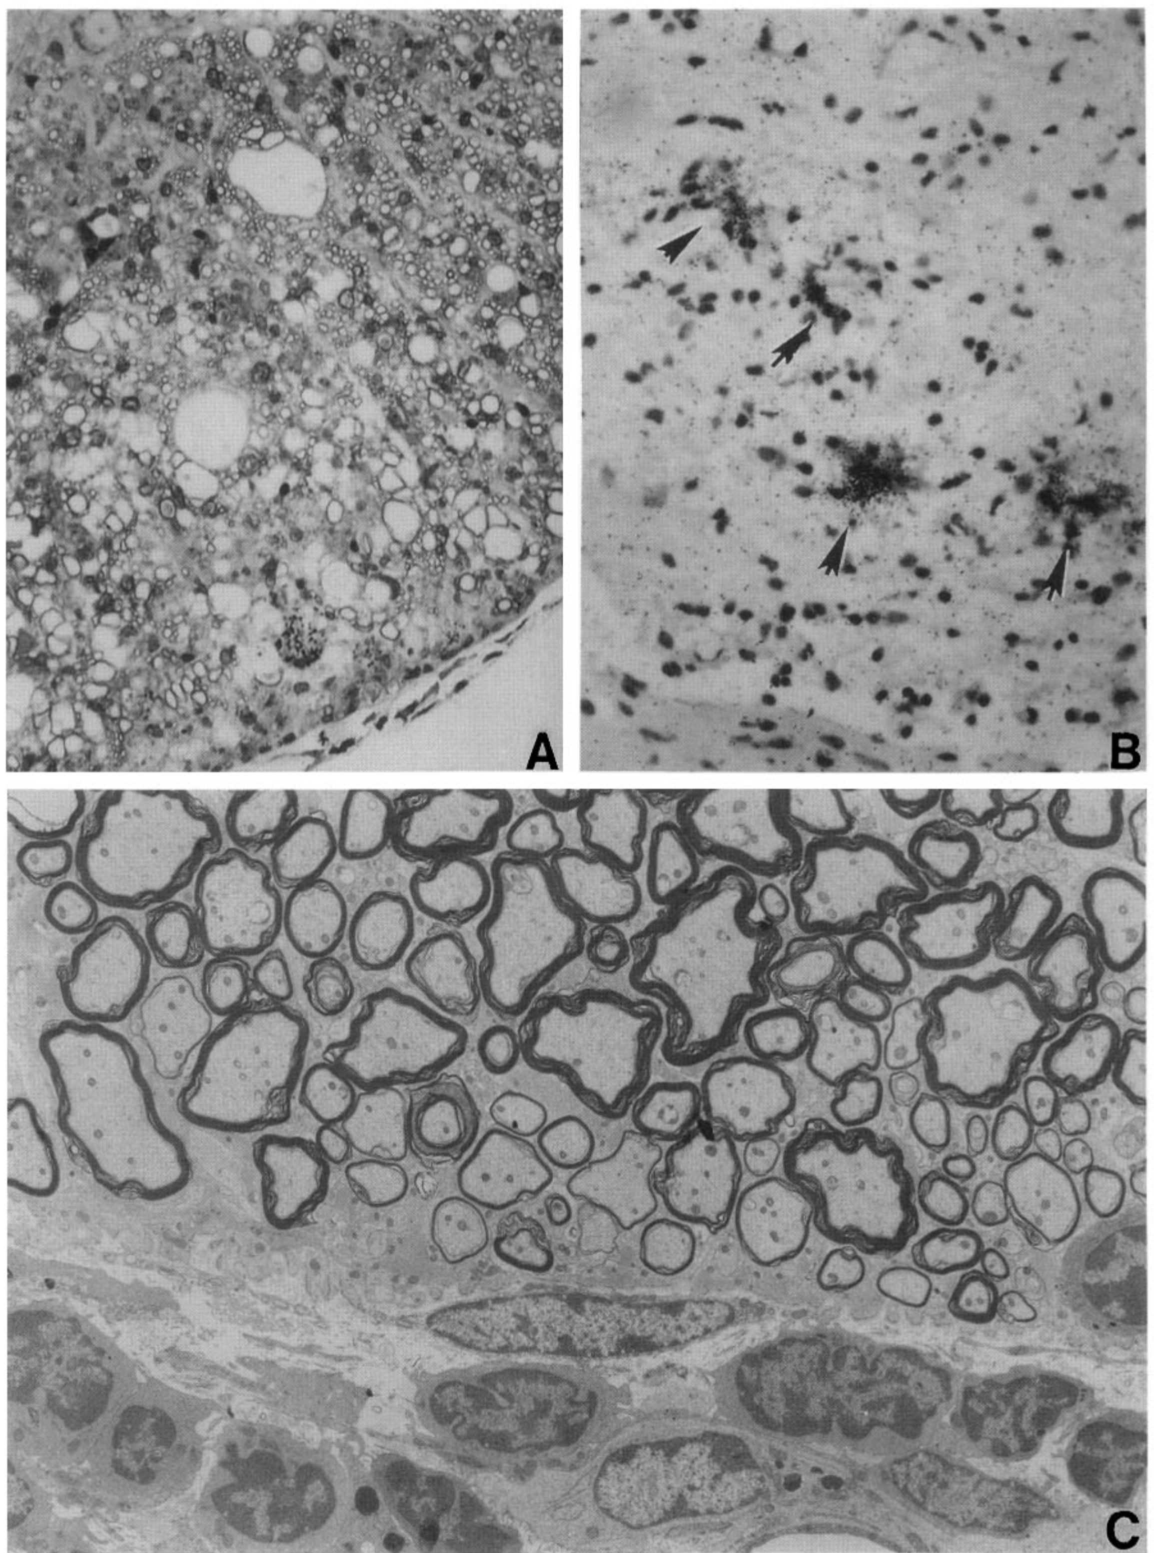

FIG. 67-1. Biological features of the demyelinating disease caused by the DA strain of TMEV in SJL/J mice. (**A**) Cross section through the spinal cord of mice infected for 45 days reveals extensive inflammation and prominent myelin destruction with preservation of the axons (glycol methacrylate embedding and erichrom/cresyl violet staining). (**B**) Combined immunocytochemistry and *in situ* hybridization for TMEV-specific RNA and protein reveals scattered positive cells in the spinal cord white matter of infected mice. (**C**) Mice infected for several months with TMEV were treated with spinal cord homogenate antiserum for a month: multiple remyelinated axons in the vicinity of an intense inflammatory response surrounding a capillary are seen in this electron micrograph (uranyl acetate and lead citrate; ×4900). [All micrographs are courtesy of Dr. C. Rodriguez with permission of the Society for General Microbiology. Figure A: Patick et al. (1990) and of the U.S. and Canadian Academy of Pathology; Figure C: Rodriguez et al. (1991).]

regenerating oligodendrocytes can reset their myelination program after viral infection has been cleared.

Oligodendrocyte precursors were found to proliferate throughout the spinal cord of A-59 infected mice already at 1 week postinoculation and up to 4 weeks (reviewed in Dubois-Dalcq and Armstrong, 1990). When cultured rat oligodendrocytes at different stages of development were inoculated with the JHM strain, few cells of the oligodendrocyte lineage became infected if they were maintained at a precursor stage by the addition of mitogens (Pasick and Dales, 1991). Thus progenitor cells are less susceptible to viral infection and may quickly respond to mitogenic signals in the lesion during the early phase of the disease (Godfraind et al., 1989). This may favor the birth of new oligodendrocytes with rapid remyelination and recovery in these rodents.

It is possible that human coronaviruses such as the 229E strain (which causes pulmonary infections) may occasionally invade the central nervous system as suggested by a recent reverse transcriptase-polymerase chain reaction analysis of RNA extracted from multiple sclerosis brain. Specific 229E sequences were detected in 4 of 11 patients but in none of 11 controls, including patients with other neurological diseases (Stewart et al., 1992). An other study has identified coronavirus mRNA by *in situ* hybridization in 12 of 22 multiple sclerosis brains (Murray et al., 1992).

Infections with Mouse Retroviruses Containing the Bacterial Galactosidase Enzyme Gene LacZ

Mouse retroviruses expressing the LacZ gene (Sanes et al., 1989) have been used to follow the fate of dividing neuroglial cell precursors in the developing brain. The BAG virus infected one precursor cell which migrated into the white matter, divided, and differentiated into myelinating oligodendrocytes. Four weeks after injection of the virus in the newborn rat subventricular zone, the white matter contained oligodendrocytes expressing LacZ in their entire cytoplasm and myelin internodes (Figure 67-2).

Infections with Paramyxoviruses

On rare occasions, measles virus can invade the central nervous system and persist in the human brain, causing two lethal diseases known as subacute sclerosing panencephalitis (SSPE), occurring 5 to 10 years after the initial measles virus infection and measles inclusion body encephalitis (MIBE) in immunocompromised hosts (for review see Schneider-Schaulies and Liebert, 1991). The virus can infect both neurons and neuroglial cells, including oligodendrocytes, where characteristic type A Cowdry inclusions made of viral nucleocapsids can be seen in the nucleus (for review see Dubois-Dalcq, 1979). Although this RNA virus replicates in the cytoplasm, uncoated measles virus nucleocapsids can indeed migrate to and accumulate in the nucleus. Experimental models of measles virus persistence in the central nervous system have been reviewed (Rammohan et al., 1983). In humans, it is not clear how and when the virus enters the central nervous system and why it stays silent for so long, causing SSPE only in rare cases. Measles virus strains persisting in the brain of SSPE patients were found to be defective as mutations accumulated in all viral genes, particularly the hemagglutinin (HA) and M genes (for review see Billeter and Cattaneo, 1991). For instance, 20 A to G mutations were found in the HA gene of an SSPE virus with strongly reduced hemadsorption, and 50% of the C residues were changed to U in the M gene of a patient with MIBE (Cattaneo et al., 1989; for review see Schneider-Schaulies and Liebert, 1991). This biased hypermutation is probably due to the action of a double-stranded RNA/unwinding/modifying enzyme acting on double-stranded regions between plus and minus measles virus RNA strands, which may form through faulty viral transcription or replication (ibidem). The M protein of a neurovirulent SSPE strain—which differed from its progenitor measles virus by 15 amino acid substitutions—failed to associate with the nucleocapsid and stayed diffuse in the cytosol instead of associating with the plasma membrane, a step necessary for viral budding (Hirano et al., 1992).

There are several other factors that play a role in measles virus persistence in the central nervous system (for review see Schneider-Schaulies and Liebert, 1991). Central nervous system cells can downregulate measles virus transcription more than other cell types. Consequently, little viral envelope genes are expressed and infected cells escape immune recognition, allowing the infection to perpetuate in the face of a strong immune response. Specific cytotoxic T cells recognizing the measles virus nucleocapsid protein could, however, clear the infection if antigens were presented in the context of class 1 molecules, but these are usually not expressed by neurons and oligodendrocytes in which the virus resides. Thus, in SSPE, the infection persists unabated.

Canine distemper virus (CDV), closely related to measles virus, causes a demyelinating disease in dogs known as Carre disease. Both astrocytes and macrophages in spinal cord lesions have been shown to contain viral inclusions made of nucleocapsids (for

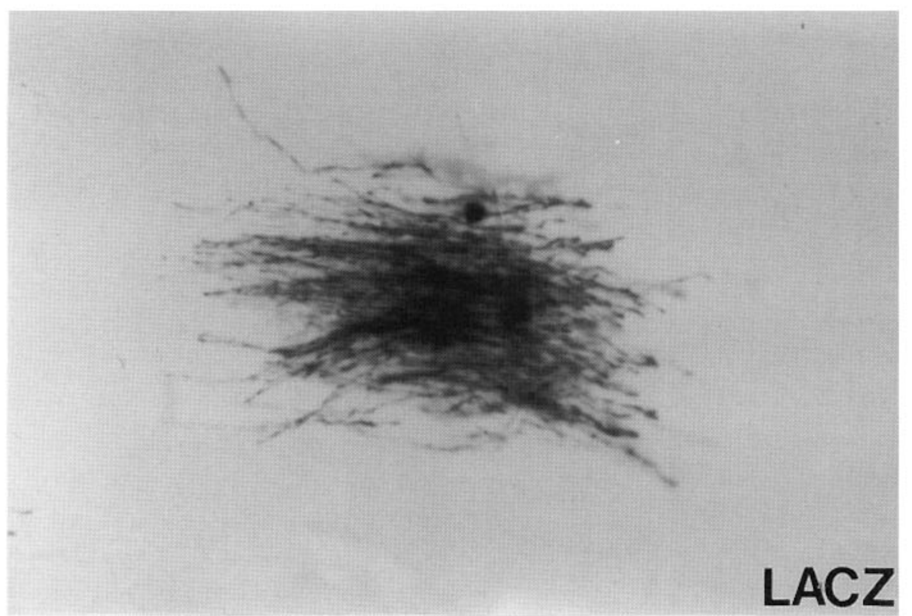

FIG. 67-2. Four oligodendrocytes and their numerous myelin sheaths all highly express the *E. coli* LacZ gene 4 weeks after injection in the subventricular zone of a recombinant retrovirus containing this gene (BAG retrovirus). The virus infected one precursor cell that migrated into the white matter, divided and differentiated into myelinating oligodendrocytes. The blue reaction product of the enzyme—XGal is diffuse throughout the cell body and processes, including the myelin internodes. [Micrograph courtesy of S. W. Levison and J. E. Goldman at Columbia Medical school, New York.]

review see Dubois-Dalcq et al., 1979). Antimyelin antibodies have been found as well as images of stripping of myelin by mononucleated cells, suggesting an autoimmune component to this chronic viral demyelinating disease.

Infections with Human JC Polyomavirus

JCV specifically infects human oligodendrocytes in immunocompromised hosts, causing a disease called progressive multifocal leukoencephalopathy (PMI). The virus accumulates in the nucleus of oligodendrocytes (Figure 67-3A, B) and causes lysis, leading to the formation of small foci of demyelination which then fuse and form extensive lesions (for review see Major et al., 1992). In contrast, astrocytes —often enlarged and called "bizarre"—also harbor viral DNA but rarely harbor virions or show lysis *in vivo*. Cultured astrocytes, however, can support JCV replication and assembly of virus. *In vitro*, the virus grows best in human fetal neuroglial cells and astrocytes as well as Schwann cells, but not in neurons. When inoculated in hamsters and owl monkeys, JCV caused astrocytomas and medulloblastomas where the JC T antigen was sometimes detected prior to tumor formation (Ressetar et al., 1990). There is, however, no known association between human glioblastomas and JC virus expression.

JCV is a very ubiquitous virus; 65% of adolescents and 92% of adults in urban areas have JCV antibodies (reviewed in Major et al., 1992). The incidence of PML has increased with the occurrence of the AIDS epidemic (close to 4% of AIDS cases develop this disease). Virus DNA was detected in B cells in the bone marrow and in brain lesions (Hough et al., 1988). JCV genome has been detected by PCR in circulating white cells of PML patients and of HIV-1 positive patients without clinical symptoms of PML (Tornatore et al., 1992). However, JCV genomic sequences were not found in control and multiple sclerosis brains (Buckle et al., 1992), throwing doubt on the suggestion that JCV DNA may reside in non-PML affected brains (White et al., 1992). Thus, in some cases, this ubiquitous virus may spread to the brain and persists at this site without causing a demyelinating disease unless the immune system becomes compromised. Studies of the molecular makeup of JCV isolated from different patients and organs suggest the existence of an *archetype virus*—in kidney and urine of transplanted patients and pregnant women—and a *brain form*, which shows duplications and/or deletions in the noncoding regulatory region (discussed in Major et al., 1992; White et al., 1992).

Why does JCV infect specifically oligodendrocytes and astrocytes in the central nervous system? Class 1 MHC proteins are an essential component of the receptor for simian virus 40, which is closely related to JCV (Breau et al., 1992). The possibility must be considered that class 1 molecules, which are highly expressed in astrocytes and oligodendrocytes in PML lesions (Achim and Wiley, 1992), may serve as the JCV receptor. Moreover, host cell factors clearly play an important role in the restricted expression of JCV. In human fetal neuroglial cells, two proteins bind specifically to the 98 bp repeats present in the regulatory region of the MAD-1 strain of JCV, a prototype brain isolate (reviewed in Major et al., 1992).

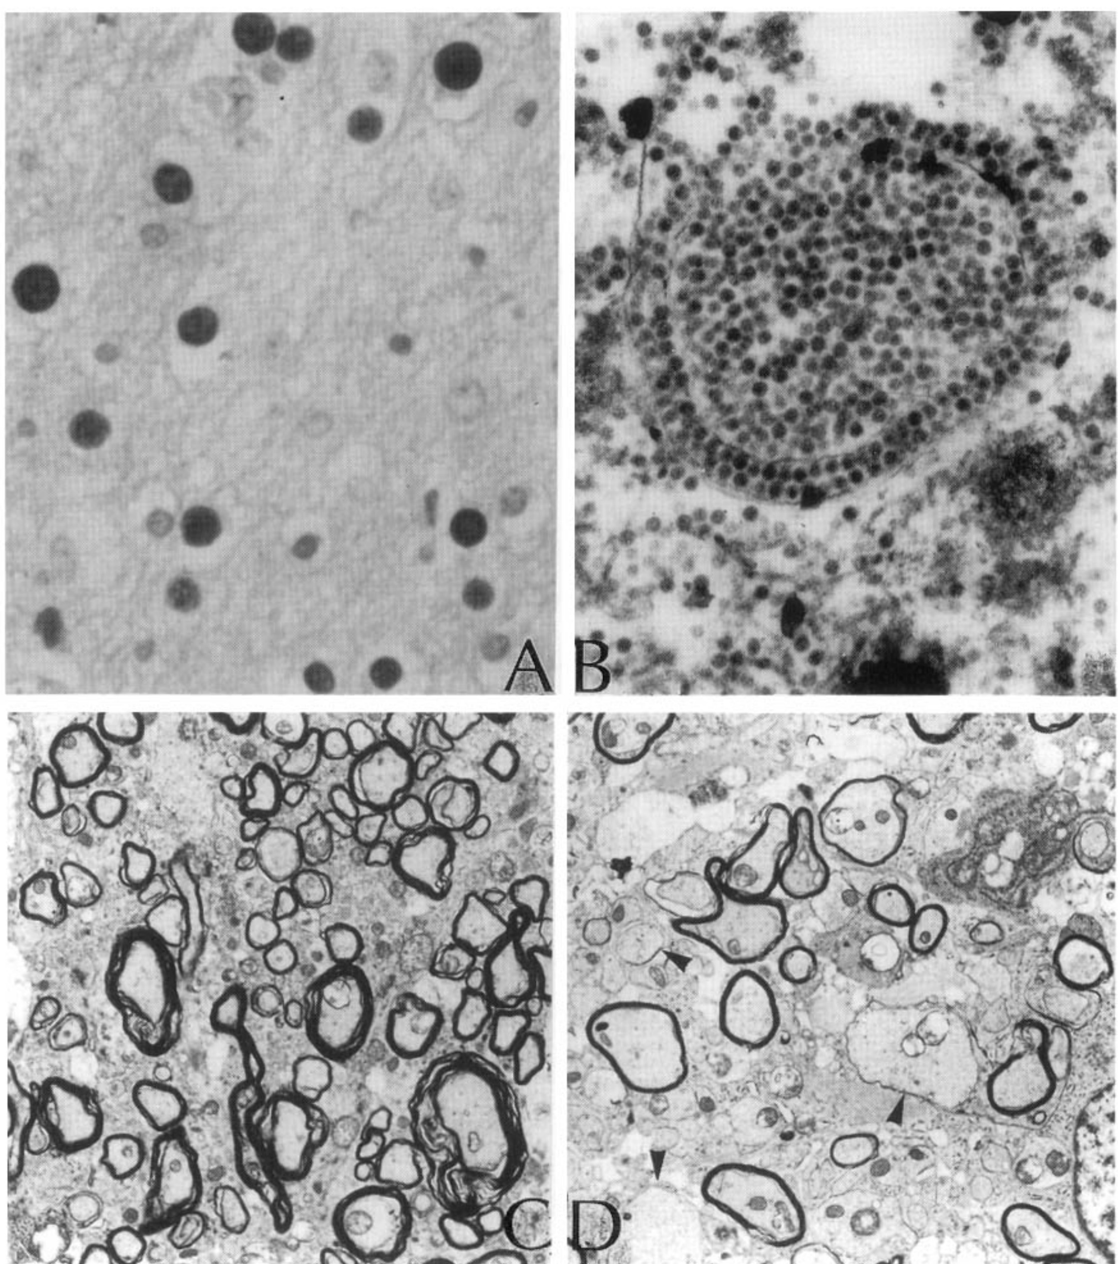

FIG. 67-3. JC virus infection and expression alters oligodendrocytes in the human disease PML and in *transgenic mice*. (*A*) JCV viral DNA was detected with a biotin-labeled DNA probe and immunoperoxidase histochemistry in the nuclei of most oligodendrocytes in a PML lesion. (B) Electron micrograph of the nucleus of an infected oligodendrocyte filled with papovavirions. (C and D) show the spinal cord of a control (*C*) and a transgenic mouse (*D*) expressing the SV40 large T antigen under the control of the JC promoter. The JC promoter drives the expression of the SV40 T antigen in oligodendrocytes and results in central nervous system hypomyelination (*D*). Figures A and B: courtesy of Major et al. (1992); and Berger et al. (1992). Figures C and D: courtesy of Feigenbaum et al. (1992), with permission of the American Society for Microbiology.]

Studies in transgenic mice have shown expression of the JCV early region and T antigen in oligodendrocytes *in vivo* (Small et al., 1986). The JCT antigen blocked expression of myelin proteins by oligodendrocytes, although some myelin gene transcripts were detected (Trapp et al., 1987). Tissue and cell specificity of the JC promoter was demonstrated in transgenic mice by exchanging the SV40 and JC regulatory regions to produce chimeric constructs designated JC (SV40) and SV40 (JC) (Feigenbaum et al.,

1992). The JC (SV40) constructs produced dysmyelination in transgenic mice (Figure 67-3C, D); in addition, choroid plexus tumors arose in these mice as they did in the SV40 (SV40) transgenics. In contrast, the SV40 (JC) caused choroid plexus tumors but no dysmyelination. The JC regulatory regions therefore play a crucial role in directing expression of T antigen in oligodendrocytes, resulting in myelin alteration.

Infections with Herpes Viruses in Human and Animal Models

HSV type 1 and type 2 are well known for causing latent infections of sensory ganglia, but they can also induce central nervous system demyelination in rodents. Mice inoculated with HSV-1 in the cornea developed infection in the trigeminal nerve at the root entry where astrocytes and oligodendrocytes produced virions and central nervous system demyelination was observed (Townsend et al., 1981). Intracerebral inoculation with HSV-2 is often lethal for mice, but the surviving animals developed demyelination in spinal cord and optic nerve (Martin, 1982). Viral antigen was found in axonal tracts showing demyelination, suggesting that virus could spread from the axon to several myelin internodes and their respective oligodendrocytes (for review see Martin et al., 1988) (Figure 67-5). It was therefore proposed that HSV-2 may have a demyelinating potential in humans when reactivated, but convincing evidence for this is still lacking.

Herpes viruses can notably infect many nervous system cells *in vitro*, among them Schwann cells. Varicella zoster virus (VZV) is no exception to this rule as it can infect cultured fetal human fetal Schwann cells and astrocytes (Assouline et al., 1990). After an initial disseminated infection in childhood, VZV becomes latent in DRG and may get reactivated years later, producing shingles. The possibility that the virus spreads not only in neurons but also in Schwann cells during the latency period has been raised. Another important pathogen in humans, cytomegalovirus, infects white cells and cells of the monocyte-macrophage lineage, which can invade the peripheral nervous system roots and dorsal root ganglia, as seen in patients with AIDS (Behar et al., 1987). The virus can also invade the brain where it infects the ependyma lining the ventricles and forms characteristic "cytomegalic cells," which contain viral inclusions and are most likely cells of the monocyte-macrophage lineage. In AIDS patients, cells containing both cytomegalovirus and HIV-1 proteins have been detected in ventriculoencephalitis cases (Fiala et al., 1992).

VIRAL INFECTIONS OF MICROGLIA AND BRAIN MACROPHAGES

Microglia and brain macrophage infections are mostly caused by retroviruses that show dual tropism for certain white blood cells and the central nervous system. (See Chapter 44 for details on the normal functions of microglia.)

Infections with Neurovirulent Mouse Ecotropic Retrovirus CasBrE

The Lake Casitas wild-mouse population has a high incidence of infectious murine leukemia virus infection, and these wild mice can develop two different diseases, a pre-B cell lymphoma (18%) and a hindlimb paralysis (12%) (for review see Portis, 1990). As determinants of neurovirulence reside in the *Env* gene, a chimeric virus was constructed with *Env* gene inserted into Friend MuLV (FrCase) (Lynch et al., 1991). This highly neurotropic virus caused neuronal spongiform degeneration, as seen in the wild-mouse disease, with postsynaptic vacuolation in the absence of gliosis (Lynch et al., 1991). However, viral RNA and proteins were not detected in these altered neurons but were present in microglial cells, which produced viral particles (Figure 67-4 A, B, C). Viral replication could also occur in endothelial cells and pericytes throughout the central nervous system. In contrast to the spinal cord neurons, granular neurons of the cerebellum were supporting viral replication without any signs of cytopathology. These observations suggest that the neurodegenerative disease is an indirect consequence of viral infection, as may also be the case with other retroviral infections of the nervous system (see below).

Infection with Lentiviruses (Visna, HIV-1, SIV)

Visna Virus Infection of Sheep. Natural visna virus infection of the sheep has long been proposed as model for human demyelinating diseases (for review see Nathanson et al., 1985; Zink et al., 1991). Both visna virus and HIV-1 are related members of the family of lentiviruses and can infect the brain. HIV-1 infects both T cells and macrophages, resulting in immunodeficiency, while visna virus infects primarily differentiated macrophages. Visna virus is probably transported to the brain in infected monocytes, and viral replication is triggered when the infected cells differentiate into macrophages. Infected sheep usually show repeated episodes of central nervous system inflammation and demyelination, followed by myelin repair, with numerous CD8 cytotoxic/suppressor T cells present in the perivascular cuffs. Double-labeling for macrophage markers and viral mRNA have con-

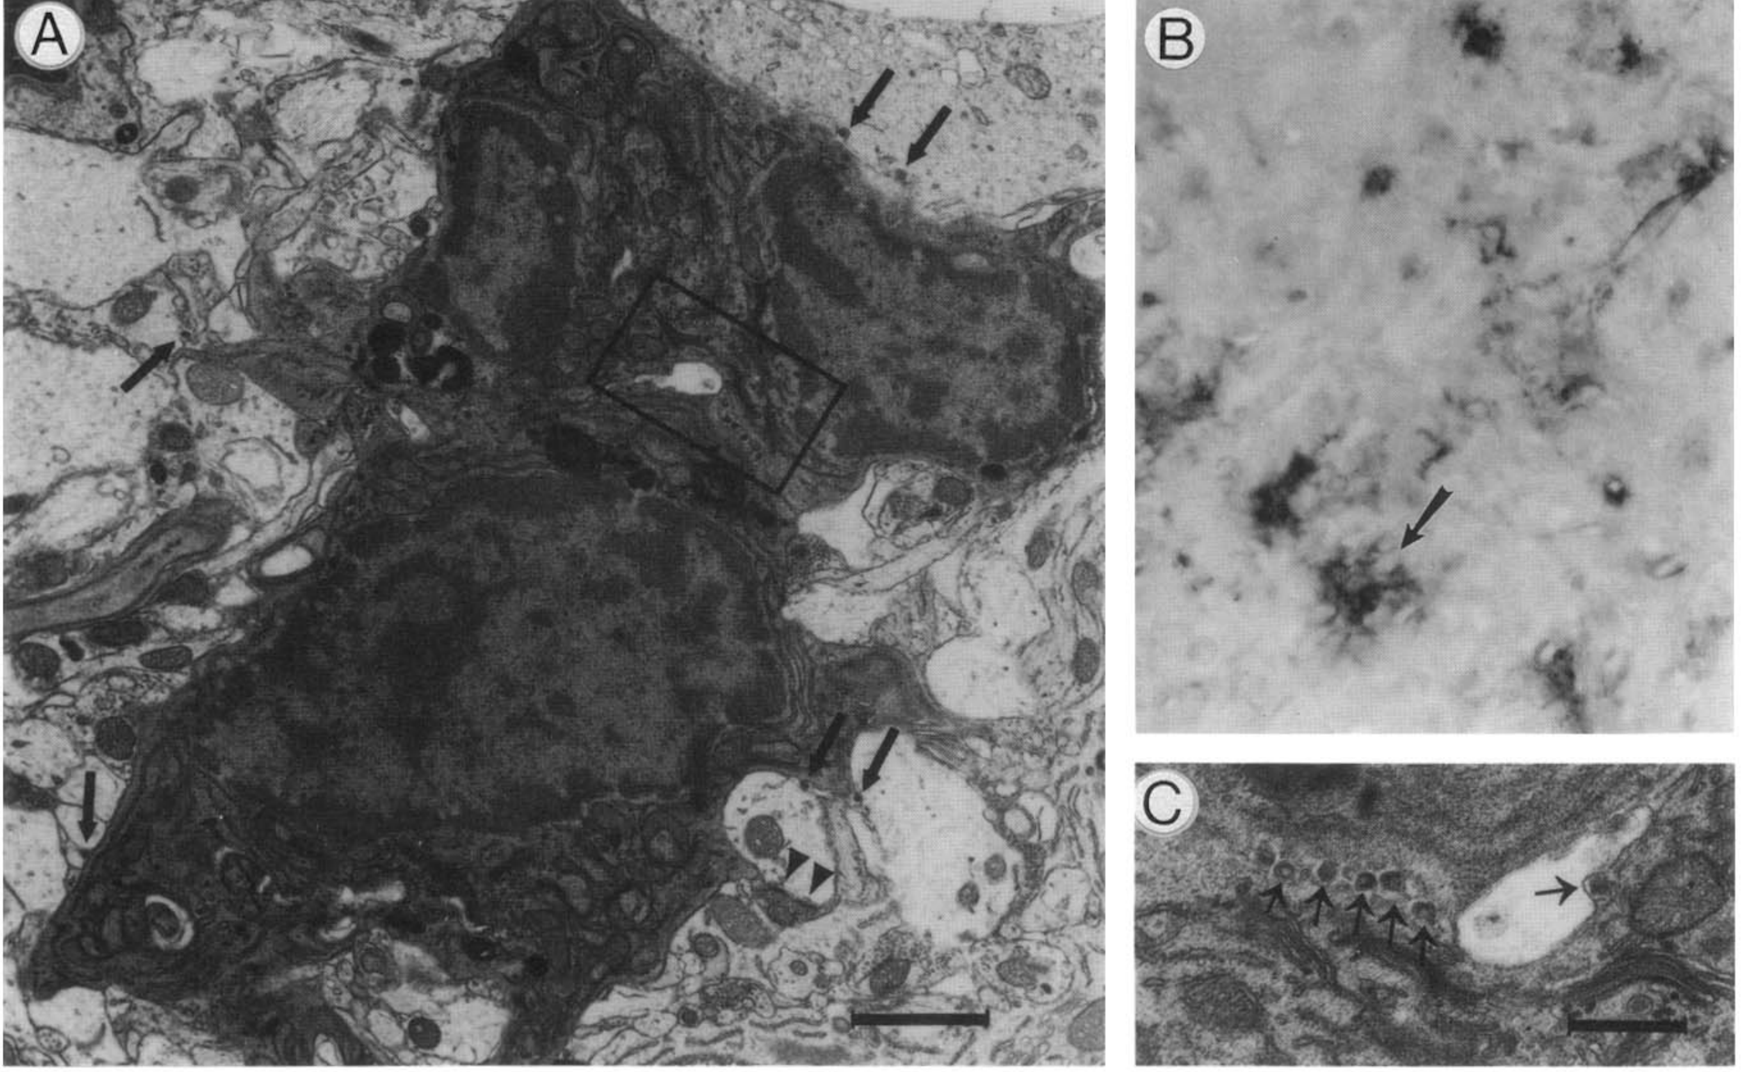

FIG. 67-4. Infection of microglial cells in mice infected with a highly neurovirulent recombinant form of the wild mouse ecotropic retrovirus (FrCasE). (**A**) Electron micrograph of an infected microglial cell in the lateral vestibular nucleus 17 days postinoculation. Note the dark cytoplasm, lipofuscin granules, and ropelike endoplasmic reticulum typical of ramified microglia. Budding viruses are seen between microglia and the adjacent surrounding vacuoles in the box enlarged in **C**. (**B**) Env protein staining in scattered ramified microglial cells (*arrows*) as well around the vessels. Bar = 1 μm. [Courtesy of Lynch et al. (1991), with permission of the Cell Press.]

firmed that macrophages and/or microglia are the predominant host cells for viral replication in the brain (Zink et al., 1991). Moreover, these infected cells, when activated by cytokines such as gamma-interferon, produce more virus and express MHC class 2 antigens. In addition, some other neuroglial cells may be latently infected, harboring proviral DNA detectable in infected tissues by highly sensitive methods such as *in situ* polymerase chain reaction amplification (Staskus et al., 1991).

Infections with HIV-1 and Related Simian Viruses. HIV-1 causes the AIDS-associated psychomotor complex in a substantial proportion of patients, who develop either neuropathy, encephalitis, leukoencephalopathy, myelopathy, or diffuse gray matter poliodystrophy (Budka et al., 1991). The neuropathological lesions range from gliosis to demyelination, and sometimes neuronal loss (for review see Dubois-Dalcq et al., 1990; Spencer and Price, 1992). SIV also causes a very similar meningoencephalitis (Desrosiers et al., 1991). There is overwhelming evidence that the major target of HIV-1 infection in the brain are cells of the monocyte-macrophage lineage, including microglia. Scattered microglial cells often express viral protein *in vivo* (Dickson et al., 1993) (Figure 69-5) and *in vitro* where cultured human microglia produce virions from their cell surface (Figure 67-6 C). HIV-1 strains with tropism for monocyte-macrophage (including the brain isolate JrFL) replicated well in primary human brain cultures, while none of the T cell adapted isolates grew in these cultures (Watkins et al., 1990). HIV-1 caused a progressive clustering and fusion of infected microglial cells (Figures 67-6A and B) mimicking the two pathological hallmarks of HIV-1 infection in the central nervous system: microglial nodules and multinucleated giant cells. Differentiated cells of neuroectodermal origin could not be infected by either a lymphotropic virus (LAV or LAI) or the monocyte/macrophage tropic strain JrFL (Sharpless et al., 1992b). Neither primary astrocytes from adult human brain nor differentiated neuronal cells (HCN-1) allowed the virus to go through cycles of reverse transcription and replication. Similarly, human oligodendrocytes did not get productively infected by these viral strains and developed a normal phenotype in the presence of ongoing infection of microglial cells. Thus, HIV-1 entry and/or expression in differentiated central nervous system cells appears to be a rare event or inefficient process. The situation may be different in the less mature brain as rare astrocytes were found to express HIV-1 in some cases of pediatric AIDS (Tornatore et al., 1994).

It appears that the neuropathological alterations in AIDS may be indirectly caused by viral and/or excitotoxic factors or cytokines released by infected microglia and macrophages in the brain (for review see Dubois-Dalcq et al., 1991). Moreover, specific interaction between infected monocytes/macrophages and astrocytes may trigger the production of neuronotoxic factors such as tumor necrosis factor-alpha, interleukin 1-beta, and arachidonic acid metabolites (Genis et al., 1992; Tyor et al., 1992; Dickson et al., 1993). It is interesting that the HIV-1 viral glycoprotein gp41 shares a common epitope with an astrocyte protein and that antiastrocyte antibodies recognizing this epitope are found in the cerebrospinal fluid of

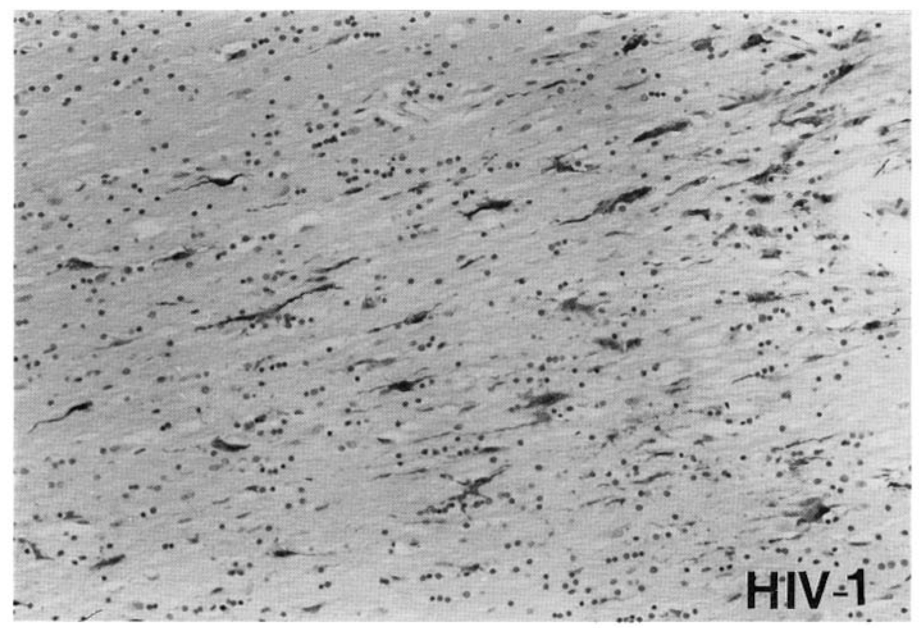

FIG. 67-5. Microglial cell infection in the AIDS encephalitis as demonstrated by immunostaining for gp 41 viral glycoprotein in the internal capsule of an AIDS patient. (Adjacent section stained with hematoxylin and eosin showed no obvious pathology.) [Courtesy of D. W. Dickson at Albert Einstein College of Medicine, New York.]

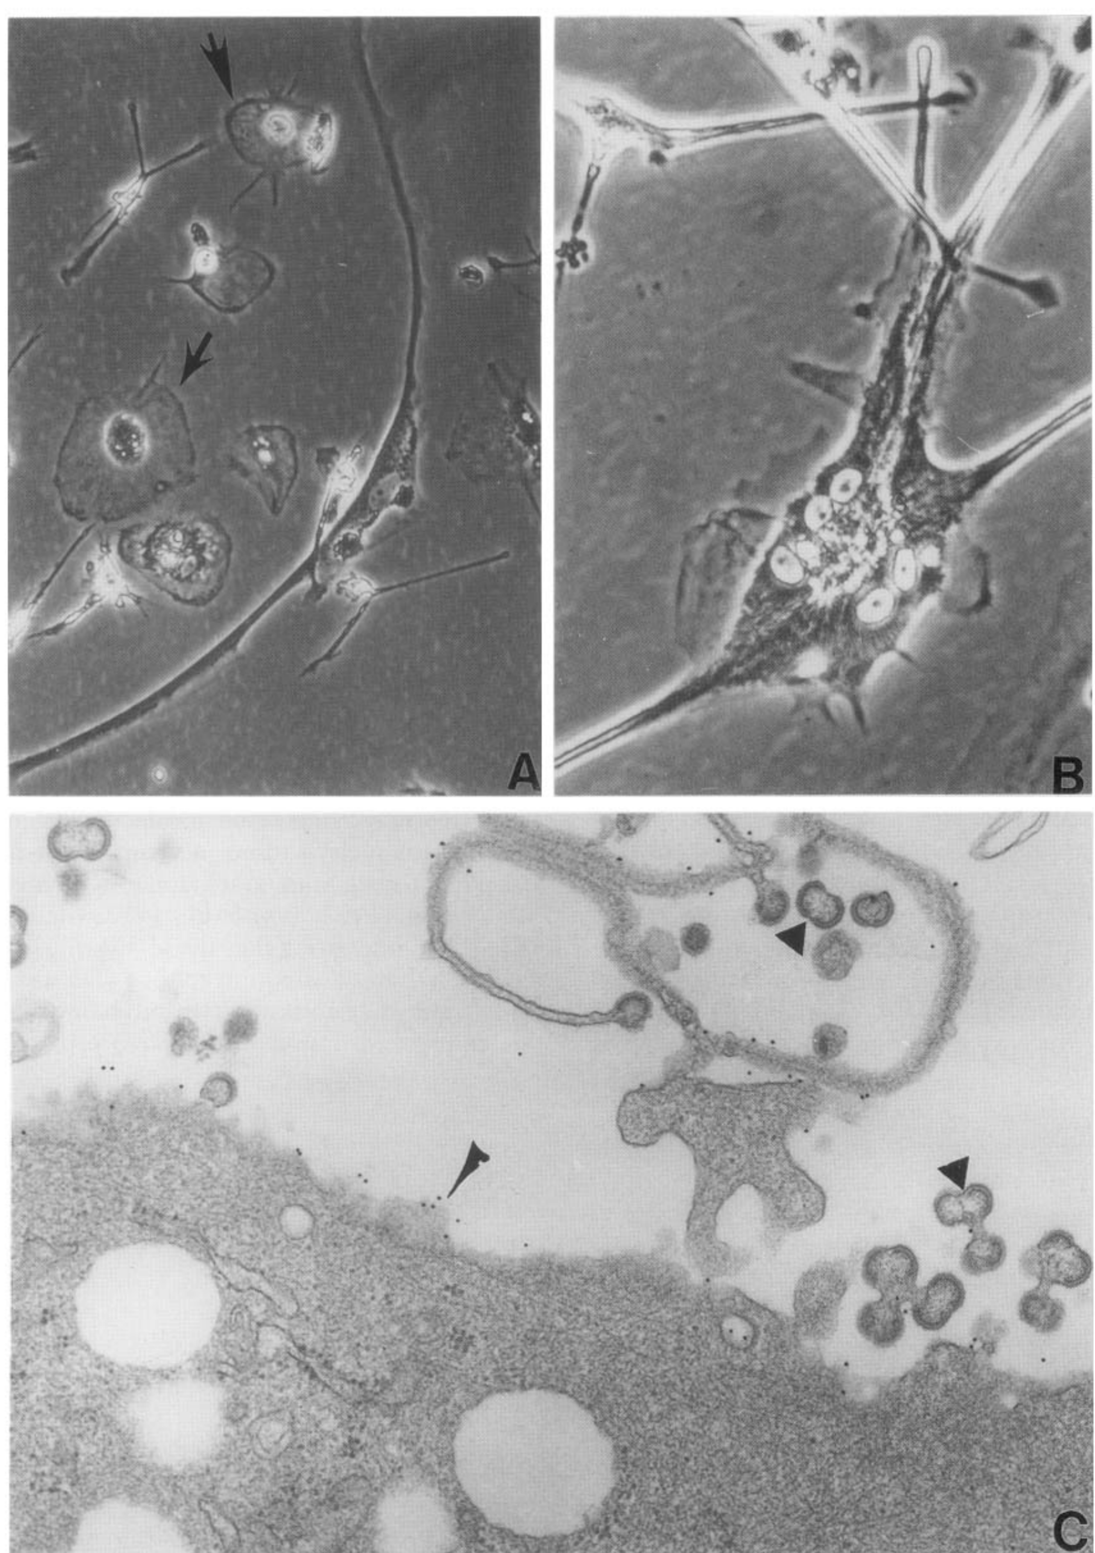

FIG. 67-6. Infection of cultured human microglia with HIV-1 strain AD-87 or ADA (Watkins et al., 1990; Genis et al., 1992). (**A**) Uninfected cultures contain ameboid (*arrows*) and elongated microglial cells, (**B**) At 12 days postinoculation with the virus giant multinucleated cells are prominent. When such cells are labeled in the cold with immunogold for the Leu M5 antigen characteristic of cells of the monocyte-macrophage, typical HIV-1 lentiviral particles are seen budding from the membrane of cells bearing gold particles. ×51,000.

AIDS patients with neurological complications (Yamada et al., 1991) (see discussion above on molecular mimicry).

The HIV-1 promoter—called the long terminal repeats or LTR—can direct the expression of the LacZ gene in transgenic mice (Corboy et al., 1992). Mice generated with central nervous system-derived LTRs (from the JrFL and JrCSF strains derived from the same patient) directed expression of LacZ to the nervous system, particularly in neurons, but also in some microglial cells and astrocytes. As HIV-1 LTRs can drive gene expression in a variety of transfected cell types *in vitro*, these transgenics observations may reflect the lack of host cell constrains on expression of the HIV-1 genome, except in situations where specific LTR mutations occur. The lack of evidence of infection of neurons by HIV-1 in the natural disease suggests that the restricted expression of HIV-1 in the brain of infected patients may be mostly due to constraints on viral entry rather than cell-specific intracellular factors.

Does the CD4 receptor mediate HIV-1 entry in the central nervous system, and are there specific molecular determinants in the virus that control tropism for central nervous system-derived microglial cells? Using RT/PCR on enriched microglial cells populations, CD4 transcripts were detected in populations enriched in microglia (Jordan et al., 1991). Viral infections of human brain cultures with monocyte/macrophage tropic strains can be prevented by preincubation with antibodies recognizing the CD4 binding site for the gp 120 envelope protein of HIV-1. To determine whether the *Env* gene of HIV-1 plays a role in microglial cell tropism, chimeric viruses were tested, which contained either the entire *Env* gene or portions of this gene from the JrFL neurotropic strain inserted into a lymphotropic strain genome (Sharpless et al., 1992a). These experiments showed that a region of the gp120 glycoprotein encompassing the V3 immunodominant loop was essential for efficient entry in microglia and that the same molecular determinants controlled microglial cell tropism and monocyte/macrophage tropism. Interestingly, an antipeptide antibody specific for the V3 loop of JrFL brain isolate could block viral entry in human brain microglia. Therefore, both the CD4 receptor and the V3 loop are potential targets for therapeutic strategies aiming at blocking HIV-1 spreading to the brain.

Infections with Human T Cell Leukemia Virus (Oncovirinae)

HTLV-1-associated myelopathy or tropical spastic paraparesis (HAM/TSP) is a chronic neurological illness occurring in clusters in various parts of the world (Japan and the Caribbean Islands; some areas of Africa, South America, and Indonesia), and the virus spreads by heterosexual contacts and/or transfusion (for review see Gessain and Gout, 1992). The neuropathology consists of chronic meningomyelitis with perivascular cuffing made mostly of CD8+ cells, demyelination with axonal loss, and discrete gliosis. It is unclear why the same virus can cause paralysis in some patients and acute T cell leukemia in others. TSP patients have elevated HTLV-1 antibodies and viral-specific cytotoxic T cells. Circulating white cells contain many enlarged activated T cells—some are called "flower cells"—expressing MHC class 1, showing increased proliferation *in vitro* and often carrying the viral genome (50% CD4 cells) and proteins. (These cells are not monoclonal or transformed as in acute T cell leukemia.) Cytotoxic T cells, recognizing the regulatory Tax protein, have been found in the cerebrospinal fluid and may target nervous system cells expressing the virus. Which cell type is infected in the central nervous system of TSP patients is unclear, but the virus can infect cultured monocyte/macrophages (Koralnik et al., 1992) and microglial cells with increased expression of interleukin-6 and tumor necrosis factor-alpha by these HTLV-1 infected cells (Hoffman et al., 1992). In inoculations of primary human brain cultures with two different strains of HTLV-1, (one from an acute T cell leukemia patient and the other from a TSP case), a slow protracted infection with positive detection of the viral genome in the cultured brain cells was observed (I. Koralnik et al., unpublished observations). To determine whether the virus is latent or persistent in the central nervous system tissues of TSP patients and in which cell it resides, *in situ* PCR is now being used to detect single proviral DNA copies or a small number of RNA copies coding for specific viral genes. Another possibility is that, in TSP patients, infected T cells which have migrated to the spinal cord and/or brain are the only infected cells in the central nervous system and that these cells may recognize a central nervous system specific antigen, leading to autoimmune demyelination and axonal damage.

Intriguing is the observation that the expression of the HTLV-1 Tax gene under its own LTR in transgenic mice causes peripheral nerve tumors reminiscent of schwannomas (Nerenberg et al., 1987). This animal model is reminiscent of Von Recklinghausen's disease, but there is no evidence of involvement of HTLV-1 in this human affection. This raises the question of the relevance of such transgenic models to the pathogenesis of viral diseases. In transgenics, the viral genes are inserted in every cell of the body,

and viral gene expression can start early in development. In contrast, viruses come at a precise time in life and invade their host as intact infectious organisms, requiring stringent conditions for their entry, spreading, and replication, triggering a complex series of reactions of the immune system and nervous tissues. All these events then result in a particular viral-induced nervous system disease of which the molecular pathogenesis has to be studied with full awareness of the natural history of the disease. Nevertheless, transgenics may be useful models, particularly to study genes coding for proteins influencing the spreading and outcome of viral infection, such as viral receptors (Ren and Raccaniello, 1992) and antiviral intracellular factors (Arnheiter et al., 1990).

I thank all my colleagues who contributed data and micrographs to this chapter: Drs. Moses Rodriguez, Steve Levinson and James Goldman, Gene Major, Lionel Feigenbaum and Gilbert Jay, Dennis Dickson and Peter Kelly. Drs. Heinz Arnheiter and Eric Verdin critically reviewed the manuscript. I also thank Pauline Ballew and Claire Gibson for help with editing and bibliography as well as Ray Rusten for skillful photographic work.

68 Alzheimer's disease

RICHARD B. BANATI AND KONRAD BEYREUTHER

ALZHEIMER'S DISEASE: A CONTROVERSY FROM THE BEGINNING

The story of the Alzheimer's disease syndrome is a history of discovery and rediscovery. An animated discussion about its true nature started with its first description and has centered around one fundamental question ever since: What distinguishes Alzheimer's disease from normally occurring processes of aging? Based on Alzheimer's histopathological description, this chapter is largely descriptive. It is confined to the discussion of some fundamental glial reactions that accompany neuronal reactions and might thus be helpful in understanding the cellular pathophysiology of Alzheimer's disease (for review of the molecular biology of Alzheimer's disease see St. George-Hyslop, 1989; Beyreuther and Masters, 1991).

In 1906, Alois Alzheimer published a report of a peculiar disease of the cerebral cortex ("Über eine eigenartige Erkrankung der Hirnrinde"; A. Alzheimer, 1906). In the course of 4½ years, a 51-year-old woman became increasingly helpless, with severe signs of cognitive dysfunction, including defects in memory, attention, and planning, followed by failure of language, visuospatial functions, and a deterioration of general intelligence. Despite the resulting dementia syndrome, the patient's personality initially remained comparatively well preserved. Upon neuropathological examination the brain showed generalized atrophy with no further macroscopical changes. Using the silver-staining technique of his colleague M. Bielschowsky, Alzheimer found peculiar *neurofibrillary tangles* in areas where neurons had obviously been lost. In addition, the brain contained numerous small *miliare Herde* (miliary foci), later called *senile plaques* (Simchowicz, 1910). They were composed of an unusual and strongly birefringent material, namely, amyloid. These lesions were surrounded by fibrous glial cells (astrocytes) and a large number of cells loaded with lipids (microglia/macrophages) (Figure 68-1).

The first case of Alzheimer's disease ever to be described was sent from Frankfurt to A. Alzheimer, who was then assistant at the Psychiatric University Clinic in Munich. In 1911, after the diagnosis of the disease had been established, Alzheimer described a case of this disease in the 56-year-old day-laborer Johann F. The following is an excerpt from his detailed description, including most of the neuropathological features we know today (Alzheimer, 1911).

[General Appearance of a Brain with Presenile Dementia and Distribution of the Plaques]*

The microscopical investigation showed the cortex to be filled with . . . plaques to various degrees. The number of plaques generally corresponded with the macroscopically visible atrophy. In the frontal cortex they were found frequently, in the central gyri occassionally, in the parietal and partly in the temporal lobes in enormous masses, and in the occipital lobes, again, less frequently. No considerable differences existed between left and right. They were also frequent in the striatum, the nucleus lentiformis, and the thalamus. In the cerebellum they accumulated in individual lobuli, whereas in wide areas they were missing completely. Also in the grey matter of the pons, in different nuclei of the medulla oblongata, they were occassionally detectable. In the spinal cord, I saw only a single small plaque in the dorsal horn of a thoracic section.

Amongst the plaques of the cortex were quite a number of such extraordinary size as I have never seen them before, not even in the cornu ammonis of the senile dementia. They often reached through several layers. Some of them obviously resulted from fusion of smaller ones, because they harboured several central inclusions; others, however, showed a particularly large central body with an extremely wide "Hof" [halo of surrounding tissue]. Almost regularly, one could observe at the height of a lobe fewer plaques than at its sides and particularly at the base of a lobe. Also, in regions where they appeared particularly numerous, the plaques lay rarely in the first layer of the cortex, but rather started where the glial reticulum of the transition zone into the first small cellular layer fairly suddenly becomes denser. Occassionally, some very small plaques lay close to the border [of the transition zone]. They accumulated most prominently in the second and third layer; in the deeper

cortex they became rarer, but in the white matter they were still numerous.

[Description of the Plaques and the Amyloid Deposits]

... Looking into a section of a particularly severely affected area fixed by Weigert's glial impregnation and stained with my modification of Mann's stain, we realize at low magnification dark spots of roundish, egg-shaped, often irregular form and different size, in extraordinary numbers. ... In the center of a great many foci, a large central body can be seen. It stands out due to its intensive blue staining. In smaller plaques, it [the central body] usually appears round, but at higher magnification not quite regularly delineated: in larger plaques its shape is more irregular; often one cannot see sharp borders, but some ragged protrusions disappearing in the surrounding, or it seems as if the central core disseminates into delicate, radially arranged spines. Otherwise, the core of the plaque appears homogeneous; cellular remnants cannot be seen.

... This core of the plaque in the cortex is regularly surrounded by a "Hof" [halo], which is brighter than the core but darker than the neighbouring tissue and usually several times bigger than the diameter of the core. Unlike the core, it [the "Hof"] is of a very complicated structure. First, we see slightly or more darkly stained, apparently homogeneous lumpy formations of very different size: from all their appearance, they are amorphous masses deposited here. Further, in the halo cellular elements can be detected, which, beyond doubt, have to be interpreted as glial cells. At one time large, at another time small, they sometimes show apart from their nucleus only little, slightly stained [Alzheimer used a modified Weigert's and Mann's staining procedure] [cyto-] plasm; again, at other times they are filled with greenish-yellowish substance with their nucleus displaced to the periphery, like we see this in "Körnchenzellen" ["granular cells", a term usually taken to describe activated microglia/brain macrophages] of any origin. Less frequently one sees forms of glial cells, which due to their small nucleus and evenly stained lobulated cell body one would like to count as ameboid [glia]. The proper fiber-forming glial cells do usually not lie within the halo of a plaque. However, in contrast to ordinary cases of senile dementia, we observe many more fiber-forming glial cells [astrocytes] which lie in the immediate vicinity of the plaque and send fibres into the halo but do not reach the core. They extend between the lumpy formations mentioned above. In rare cases, one observes how a fiber-forming glial cell ... sends into the halo an additional protoplasmic protrusion with a thick plump ending filled with green-coloured lipoid granules. Also "Stäbchenzellen" -like elements ["rod-cells", a term often used for microglia], obviously of glial origin, sometimes are lying in the halo; near both poles of the core is a satchel filled with greenish granules.

...

While in the cortex we hardly ever find in the core of a plaque without a halo, we come across many such halos without a core. ... However, in the cortex we find small and often irregularly shaped darker spots without clear inclusions so frequently that I must think that the just described fully differentiated plaques are preceded by a stage in which "[sich das] Gewebe verdichtet" [the tissue condenses]. ...

A particularly close relationship of the foci with the [blood] vessels cannot be observed .... it rather looks as if they [the foci] push aside the capillaries ...

Apart from the already mentioned pathological glial cell forms in the vicinity of the plaque, we generally see in the tissue, other than small, dark glial nuclei with little differentiated chromatin and very little [cyto-] plasm, accumulations of glial cells with a larger often oval nucleus and star-shaped cell bodies often covered with delicate dark dots. Regularly, light-refracting granules without clear staining are deposited within them in larger accumulations.

...

Fairly remarkable is the observation that in the numerous tissue sections from many areas of the brain not a single cell with the peculiar fibrillary degeneration [neurofibrillary tangles] I had described [earlier] could be found.

The impressive clinical picture, the early age of onset and the characteristic neuropathological findings led Emil Kraepelin, pioneer psychiatrist and Alzheimer's teacher, to postulate a new disease entity, which he called "Alzheimer's disease." Only a few years later, however, it was recognized that the plaques and tangles thought to constitute a specific sign of Alzheimer's disease were also frequently found in brains of nondemented old people (Gellerstedt, 1932; Braunmühl, 1957). This made Alzheimer eventually conclude: that "*... the plaques are not the cause of senile dementia but only accompany the senile involution of the central nervous system ...*" (Alzheimer, 1911). Recent studies confirm that the presence of plaques and tangles correlates imperfectly with the development of the dementia syndrome. It is the actual quantitative loss of synapses that seems more closely related to the severity of cognitive dysfunction (DeKosky and Scheff, 1990).

Fig. 1 drawn after tubus 140, Fig. 2 after tubus 160, compensation ocular 4. gaz. ganglion cell, glz. glial cell, P central part (core) of the plaque, P_2 peripheral part, "Hof" [halo] of the plaque.

Fig. 1. Relationship of the fiber forming glial cell with the plaque. Right upper parietal lobe. In the core of the plaque [is] a very small, obviously darkly iodine-stained central part surrounded by a darker and than a brighter ring. The peripheral part is penetrated by numerous extraordinarily delicate glial fibres, which stem from the glial cells lying at the fringe of the halo.

Fig. 2. Huge fiber forming glial cells from deeper layers of the cortex of the right upper parietal lobe often embracing neighbouring ganglion cells.

Today, according to the U.S. Department of Health and Human Services, an estimated four million Americans suffer from Alzheimer's disease. This large number includes all those patients who develop dementia at a later age, that is, *senile dementia of the Alzheimer type* (Katzmann, 1976). It is a matter of controversy whether similar phenomenology alone is sufficient for grouping Alzheimer's disease and senile dementia of the Alzheimer type together. DSM-III-R bases the diagnosis of Alzheimer's disease and senile dementia of the Alzheimer type on specific criteria that render Alzheimer's disease/senile dementia of the Alzheimer type an exclusion diagnosis, only to be made if all other diseases that can cause mental impairment are absent. With the broadened definition now commonly used, age is the primary risk factor for Alzheimer's disease. The condition originally described as *presenile* dementia is thus a rare occurrence. Fewer than 5% of all Alzheimer patients belong to families where the early-onset disease seems to be inherited in an autosomal-dominant way (St. George-Hyslop et al., 1989). Among these families, a small subgroup has genetic mutations on chromosome 21 in the region that codes for the βA4-amyloid fragment of the amyloid precursor protein (APP), the protein containing the amyloid material of which the amyloid plaques are largely composed. Still, most of the families with familial Alzheimer's disease show no linkage to mutations in the APP gene. Further linkage evidence now implicates chromosome 19 (Roses et al., 1990) and chromosome 14 (Schellenberg et al., 1992). Degeneration of neurons and a neuropathological picture similar to Alzheimer's disease is seen in patients with trisomy 21 (Masters et al., 1985), supporting the importance of genetic factors. Nevertheless, most cases of Alzheimer's disease remain sporadic, and neither a known genetic cause nor a specific neuropathological marker exists.

NEUROPATHOLOGICAL CHARACTERISTICS OF ALZHEIMER'S DISEASE

Neurofibrillary Tangles

Neurofibrillary tangles (NFT) consist of ubiquitin-associated paired helical filaments of abnormally phosphorylated tau proteins (Grundke-Iqbal et al., 1986) reflecting the destruction of microtubules (Zhang et al., 1989) and neurofilaments (Matsuyama and Jarvik, 1989). These intraneuronal tangles appear to follow the formation of amyloid plaques and are likely to reflect neuronal damage, and eventually cell death (McKee et al., 1991). As reported by Alzheimer himself, the NFTs are not always present (Alzheimer, 1911). NFTs are regularly found in the pyramidal cells of the CA1 region of the hippocampus and in the superficial layers of the entorhinal cortex of nondemented elderly humans. In patients with fully developed Alzheimer's disease, the distribution of NFTs seems more widespread, including neurons of the layers III and V of the association cortex, the basal forebrain nuclei, and various brainstem nuclei. If extensive formation of NFTs has occurred, as in severe Alzheimer's disease, they can be found as extracellular residua. Since NFTs are present in various other diseases of the central nervous system, like progressive supranuclear palsy, Guam Parkinson dementia, and subacute sclerosing panencephalitis, they are not specific for Alzheimer's disease but rather the hallmark of neuronal cell death (for review see Mori and Ihara, 1991). Apart from NFTs, innumerable dystrophic neurites can be found in Alzheimer's disease tissue. They are often referred to as "curly fibers." Further exclusively neuronal hallmarks of nerve cell degeneration are the Hirano bodies and the granulovacuoles. Both structures are apparently remnants of condensed components of the destroyed neuronal cytoskeleton (Probst et al., 1991).

Senile Plaques

Senile plaques (Simchowicz, 1910) are spherical structures of 10 to 150 μm diameter. They lie in the extracellular space and are found in the brains of most elderly humans. The occurrence and density of senile plaques does not directly correlate with the degree of dementia (DeKosky and Scheff, 1990; Dickson et al., 1992). It seems that the clinically observed memory loss is correlated rather with the preferential localization of the neuropathological changes within the entorhinal cortex (Brodman area 28) of the ventrolateral temporal lobe and in areas of the hippocampal formation (Van Hoesen et al., 1991).

The main proteinaceous component of a senile plaque is the 4.2 kD βA4 amyloid protein that is part of a larger precursor, the amyloid precursor protein (Glenner and Wong, 1984; Masters et al., 1985; Kang et al., 1987; Müller-Hill and Beyreuther, 1989) (Figure 68-2). Apart from βA4, the senile plaques contain many proteins, like complement and the major histocompatibility complex (MHC) glycoproteins, that are otherwise characteristic for an inflammatory reaction. Senile plaques can be observed at various stages of their formation. Therefore, a number of morphological subtypes have been described.

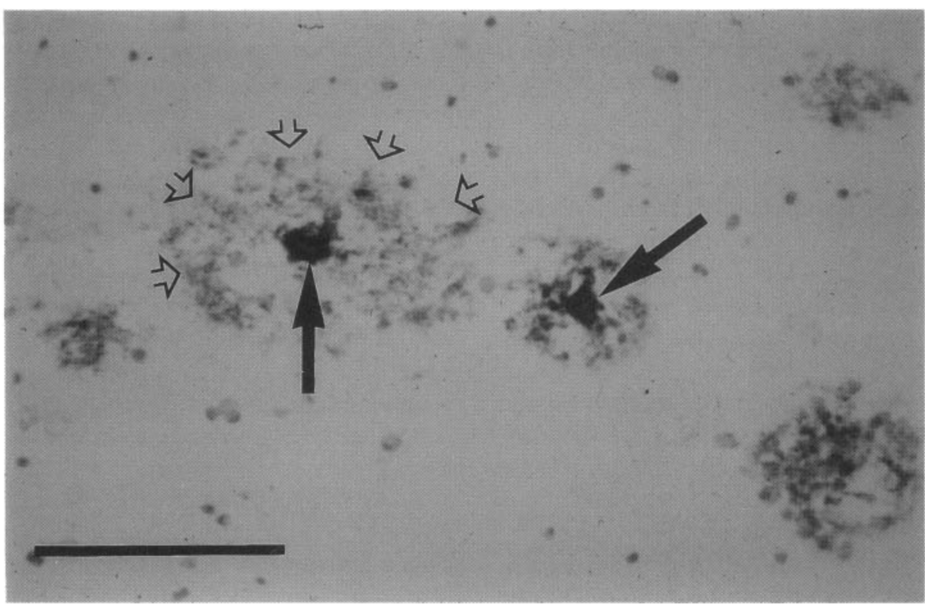

FIG. 68-2. Classical amyloid plaque. Staining with a monoclonal antibody against amyloid precursor protein (Weidemann et al., 1989) demonstrates that βA4 is the main proteinaceous component of the amyloid depositions in a classical amyloid plaque with its characteristic central core and the surrounding halo as described by A. Alzheimer. Scale bar = 150 μm.

According to Alzheimer's observation (Alzheimer, 1911), the formation of a plaque starts with a "Verdichtung des Grundgewebes" [condensation of tissue] leading to a "Hof ohne Kern" [halo of surrounding tissue without core]. Such a "Filzwerk" (meshwork]; (Braunmühl, 1957) constitutes a "Primitivplaque" [primitive plaque]; Braunmühl, 1957). This stage has also been designated "plaque A" (Probst et al., 1987) or "diffuse" (Yamaguchi et al., 1988) or "amorphous plaques" (Rozemuller et al., 1989). At this initial stage, no neuronal cell damage is observed, no amyloid or fibrillary structures are present, but the microglial cells as, "the early cellular response element of the brain" and "sensor to threat," already show the first signs of activation (McGeer et al., 1987; Probst et al., 1987; Streit et al., 1988; Gehrman et al., 1992; Gehrmann et al., 1993; Banati et al., 1993c). Upon careful examination, microglia are found to surround the pyramidal neurons that are about to die, a phenomenon Alzheimer and his pupils Simchowicz and Perusini referred to as building a microglial "Totenlade" [coffin] around the damaged neurons (Perusini, 1909; Simchowicz, 1910). With further disease progression, the next step is the formation of a primitive plaque (according to the definition of Wisnieski and Terry, 1973) in which the first fibrillary structures, composed of βA4 amyloid protein, appear. As an indicator of the severity of the pathological process, the activated microglial cells are now accompanied by reactive astrocytes with their characteristically enlarged cytoplasmic processes, originally described by Alzheimer as glial fibers. Very primitive plaques and diffuse plaques make up for the vast majority (>90%) of all plaques (Yamaguchi et al., 1988). Fewer than 10% have a dense amyloid core and are surrounded by a corona of swollen neurites which Alzheimer's described as "Höfe mit Kern" [halo with core]. They have now been designated "classical or typical plaques" (Wisniewski and Terry, 1973). A further very rarely seen variation consists entirely of compact amyloid (Alzheimer: "Kerne ohne Höfe," that is, core without halo) and is therefore called "compact plaque" (Wisniewski and Terry, 1973) (Figure 68-2).

MORPHOGENESIS OF SENILE PLAQUES AS AN EXAMPLE FOR NEUROGLIAL INTERACTION

From morphological observations, it has become clear that glial cells, namely, microglia and astrocytes, are actively involved in the formation of amyloid plaques. It is still an ongoing debate whether the origin of the amyloid is neuronal, vascular, i.e., from the bloodstream, or glial. The amyloid protein precursor (APP) can be produced by different cell types, including neurons, where it can be axonally transported (Shivers et al., 1988; Koo et al., 1990), astrocytes (Card et al., 1988; Neve et al., 1988; Banati et al., in press) and microglia (Wisniewski et al., 1989; Haass et al., 1991; LeBlanc et al., 1991; König

et al, 1992; Mönning et al., 1992). APP is now recognized to form a family of proteins. Its neuronal prototype, APP695, contains the structural domain of an integral transmembrane receptor (Kang et al., 1987). The different APP isoforms (Beyreuther and Masters, 1991; König et al., 1992) (Figure 68-3) are the result of differential splicing. The APP family falls into two categories: (1) the primarily neuronal isoforms (APP695) and (2) the primarily nonneuronal isoforms that contain a Kunitz protease inhibitor domain (Weidemann et al., 1989; Ohyagi et al., 1990).

Upon isolation of crude brain homogenate, the primarily neuronal APP695 is by far the most dominant of all APP isoforms in the central nervous system. In contrast to the relative abundance of the neuronal APP695, numerous investigations revealed that the APP isoforms increased in normal aging, Alzheimer's disease, and in experimental models, are mostly those containing the Kunitz protease inhibitor domain (Palmert et al., 1988; Tanzi et al., 1988; Siman et al., 1989; Tanaka et al., 1989; Golde et al., 1990, Johnson et al., 1990; Abe et al., 1991; König et al., 1991; Scott et al., 1991; Tanaka et al., 1992). This lends support to the hypothesis that either alternative splicing of APP in neurons is altered or that reactive glial cells contribute to the increased production of APP in aging and in the course of disease or experimental lesion. As a source for the amyloid deposited in close vicinity of blood vessels, specific cells of the mononuclear phagocyte system, the perivascular cells, seem to be a likely source (Graeber et al., 1989; Wegiel and Wisniewski, 1992) (Figure 68-6a). Oligodendrocytes, ependymal cells, mantle cells in spinal cord ganglia, and Schwann cells have also been reported to express APP (Karawabayashi et al., 1991).

As APP is principally a ubiquitous protein found in most cell types, the *sequence* in which different cells participate in different pathologies is of crucial importance in understanding the complex process of amyloid plaque formation. Based on the observation that microglia is usually the first cell to be activated in most pathologies of the central nervous system it

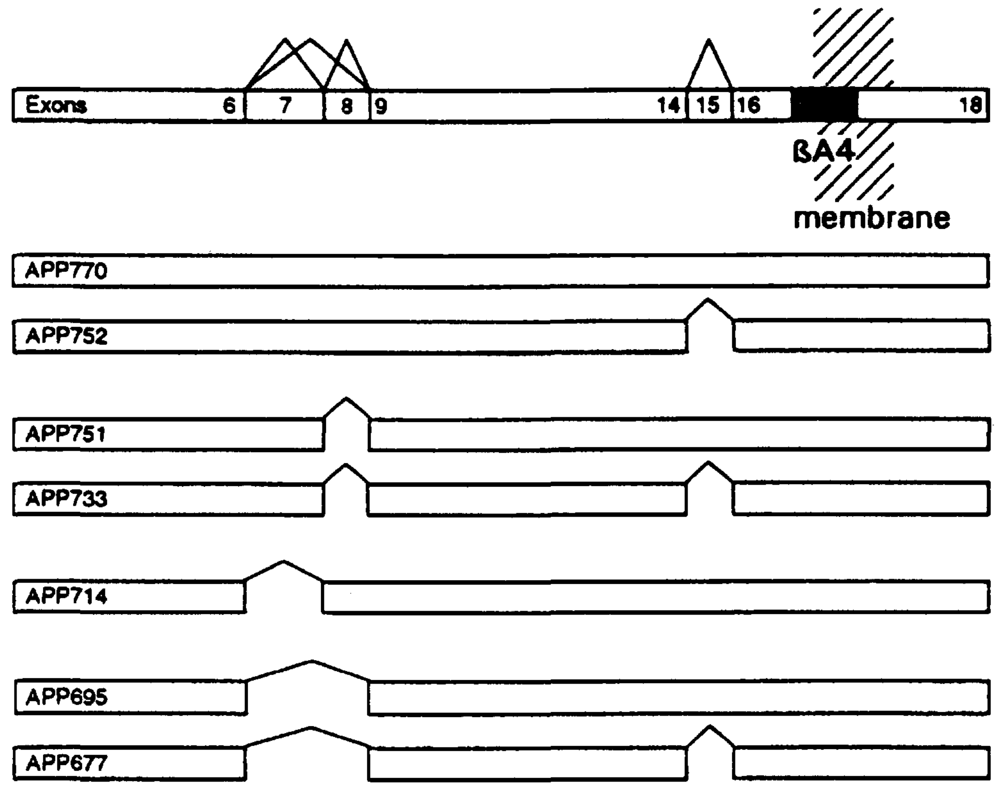

FIG. 68-3. Alternative splicing products of the *APP* gene. The amyloidogenic βA4 fragment lies near the C-terminal end of the amyloid precursor protein APP and is partly inserted into the cell membrane. The neuronal splicing forms lack the Kunitz protease inhibitor domain (i.e., Exon 7). In disease and experimental lesion the Kunitz protease inhibitor domain containing isoforms appear to be preferentially upregulated. (Exon 8 = OX 42).

has been suggested that the production of APP and subsequent amyloid deposition starts with an initial microglial response to neuronal dysfunction. Neuronal dysfunction might result either from external factors such as head trauma in the case of Morbus Alzheimer Pugilistica (Clinton et al., 1991), or intrinsic factors like increased neuronal vulnerability, possibly secondary to genetic factors. Once the production of APP is induced, its metabolic processing regularly leads to the release of βA4 (Haass et al., 1992), although it might represent only a minor portion among other APP cleavage products. Repeated and chronic induction, as might happen in the aging brain by a multitude of causes, could eventually lead to the accumulation of βA4 and by additional, yet to be clearly identified cofactors, to the formation of amyloid. Mutations in close proximity to the region encoding for βA4 in familial Alzheimer's disease have been taken as evidence that Alzheimer's disease is caused by an aberrant amyloidogenic processing of APP. Indeed, an increased production of βA4 has recently been reported for cell lines transfected with constructs bearing a mutation in the βA4 region (Citron et al., 1992; Cai et al., 1993). Whether the other known mutations in that region also cause an alteration of the metabolic pathway of APP remains to be shown. Cathepsin B is one of several enzymes that cleaves APP with high efficiency and is found in considerable amounts in activated microglia and within senile plaques (Cataldo and Nixon, 1990; Banati et al., 1993b). Free radicals are also regarded as important amyloidogenic cofactors promoting the aggregation of the βA4 amyloid (Dyrks et al., 1992). For proteolytic enzymes and free radicals activated microglia can be a potent source (Banati et al., 1991b, 1993b). Apart from proteolytic enzymes, microglia also contain protease inhibitors like cystatin C (Zucker-Franklin et al., 1987). A mutation of cystatin C is the cause of hereditary cerebral hemorrhage with amyloidosis (HCHWA) of Icelandic type (Ghiso et al., 1986). This example illustrates that glial cells are potentially important for the processing of APP. Amongst the proteins that have recently come into the focus of attention is apolipoprotein E (ApoE), certain isoforms of which appear to be associated with an increased risk for Alzheimer's disease. Interestingly, it is yet another protein that can be synthesised by cells of mononuclear-phagocyte lineage in response to nerve injury (Poirier, 1994). The early involvement of a cell type-like microglia that derives from mononuclear-phagocyte lineage (Banati et al., 1991a) would also explain the presence of the various inflammatory acute phase response proteins from the earliest stages of the disease (McGeer and Rogers, 1992; Strauss et al., 1992).

EXPERIMENTAL MODELS TO STUDY GLIAL AMYLOID PRECURSOR PROTEIN EXPRESSION

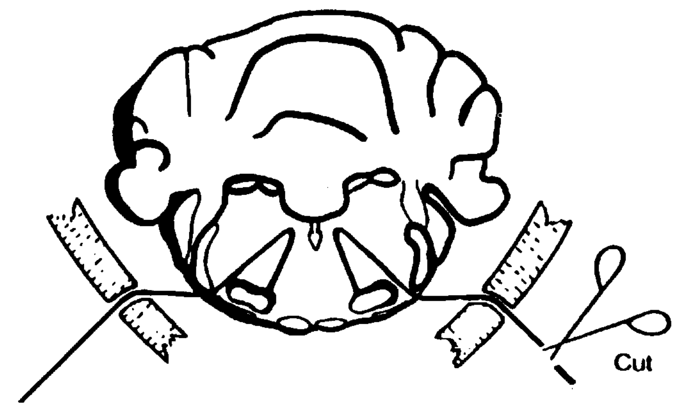
A number of models (for review see Beyreuther and Masters, 1991) have been established to study Alzheimer's disease under experimental conditions:

1. Aged nonhuman primates (Walker et al., 1990)
2. βA4 and APP mutant transgenics
3. Mouse ts16 transplant model (Richards et al., 1991)
4. PrP/scrapie Creutzfeld-Jakob disease, with plaques and perivascular amyloid (Prusiner et al., 1991)

The mechanism by which the amyloid precursor protein (APP) is converted to βA4, as well as its most relevant cellular source, is still mostly hypothetical. The following two subsections illustrate the regulation of APP in glial cells as one prerequisite for βA4 accumulation.

Peripheral Nerve Lesions

Acute activation of microglia can be stimulated in a graded fashion. One example is the transection of peripheral nerves such as the facial or sciatic nerve. Such nerve transections without damage to the blood-brain barrier cause a microglial reaction within hours in the nucleus of origin (Figure 68-4) or in projection areas in the central nervous system (Figure 68-7). Axotomy of the facial nerve prompts a rapid induction of APP immunoreactivity in microglial cells lying in close apposition to the injured neuron (Figures 68-4, 68-5, 68-6). Peripheral nerve lesions lead to a predominantly glial upregulation of APP mRNA and protein as early as 6 to 12 hours postlesion, not only at the site of affected neuronal cell bodies but also in corresponding projection areas (Banati et al., 1993a). The latter phenomenon can be observed after sciatic nerve transection when a glial APP induction can be seen in the nucleus gracilis, the projection area of the primary afferent fibers in the brainstem (Gehrmann et al., 1991) (Figure 68-7). Similarly, a lesion of the entorhinal cortex can induce glial APP-production in the dentate gyrus of the hippocampal formation (Banati et al., 1994a). The time course of APP-expression after sciatic nerve transection suggests a rapid transneuronal signaling to glial cells rather than axonal transport of APP to this area. In these experimental models light and electron microscopy demonstrates that microglia are a dominant source for nonneuronal APP expression.



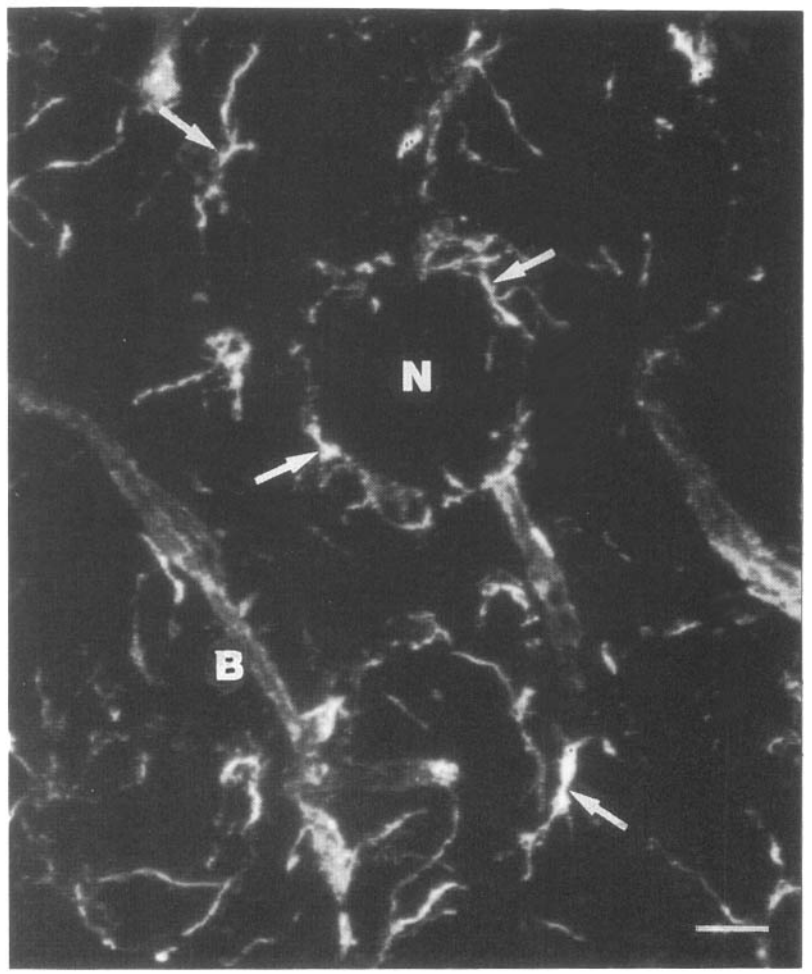


FIG. 68-4. APP immunoreactivity in microglia after facial nerve transection. Rat facial nerve axotomy is a lesion that leaves the blood-brain barrier intact and leads to a retrograde reaction in the motoneurons of the facial nucleus. Here, APP immunoreactivity in perineuronal microglia 4 days after lesion was detected with a monoclonal anti-APP antibody (Weidemann et al., 1989). The first APP immunoreactivity can be seen as early as 24 hours after lesion. APP is constitutively expressed on blood vessels. The picture was taken with a fluorescence confocal microscope (Leica; 40.0/1.3 oil, *xy*, 125 × 125 μm, extended focus). *N*, neuron; *B*, blood vessel. Scale bar = 25 μm.

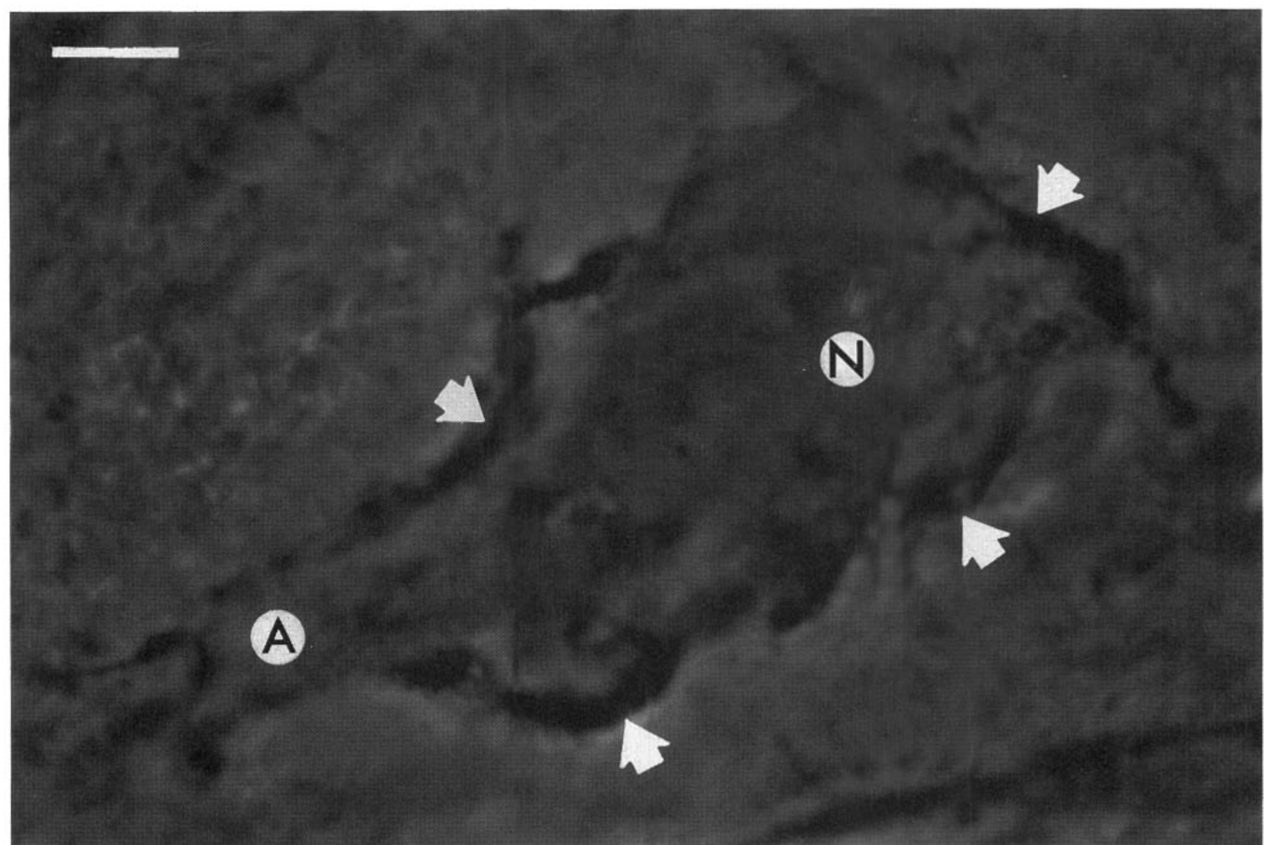

FIG. 68-5. APP immunoreactivity in perineuronal microglia. The axotomized motoneuron is closely ensheathed by strongly APP-immunoreactive microglia stained with a monoclonal anti-APP antibody (Weidemann et al., 1989). (Phase contrast picture taken 4 days after rat facial nerve axotomy.) *N*, neuron; *A*, axon. Scale bar = 10 μm.

Immune-Mediated Induction of Amyloid Precursor Protein

Microglia, which account for about 20% of all glial cells (Lawson et al., 1990), are capable of expressing marked levels of MHC class II. Upon activation, microglia rapidly upregulate the expression of MHC class II molecules (Gehrmann et al., 1992). Astrocytes can also express these immune molecules *in vitro* (Wekerle et al., 1986). Indicative of the involvement of immunocompetent cells in Alzheimer's disease is the presence of MHC class II molecules, which are regularly detected in amyloid plaques (Perlmutter et al., 1992).

A model that allows the study of glial APP synthesis in the context of a central nervous immune reaction is the experimental autoimmune encephalomyelitis (Banati et al., in press). Experimental autoimmune encephalomyelitis can be induced in naive syngeneic animals by the transfer of activated T cells, which recognize antigens of the central nervous system myelin sheath, such as myelin basic protein (Gehrmann et al., 1992). The disease is characterized at the histopathological level by the presence of inflammatory perivascular infiltrates, composed mainly of T lymphocytes, B lymphocytes, and macrophages. Glial cells, most conspicuously microglia, also respond to this inflammatory lesion by becoming activated. At an early preclinical stage (24 hours after T cell transfer) only very few glial cells newly express APP immunoreactivity. At the peak of clinical disease (6 days after T cell transfer), characteristic ramified cells are strongly positive for APP (Figure 68-8). Based on morphological criteria and double-labeling, the majority of these cells can be identified as microglia. Correlating with the course of clinical disease, the induction of APP in reactive microglia terminates in the postclinical stage, that is, 14 days after T cell transfer. These results indicate that APP can be induced in activated glial cells, particularly microglia, in immune-mediated disease.

CONCLUSIONS

The presence of many proteins related to the immune system and the dominant involvement of glial cells, particularly microglia, has led to various hy-

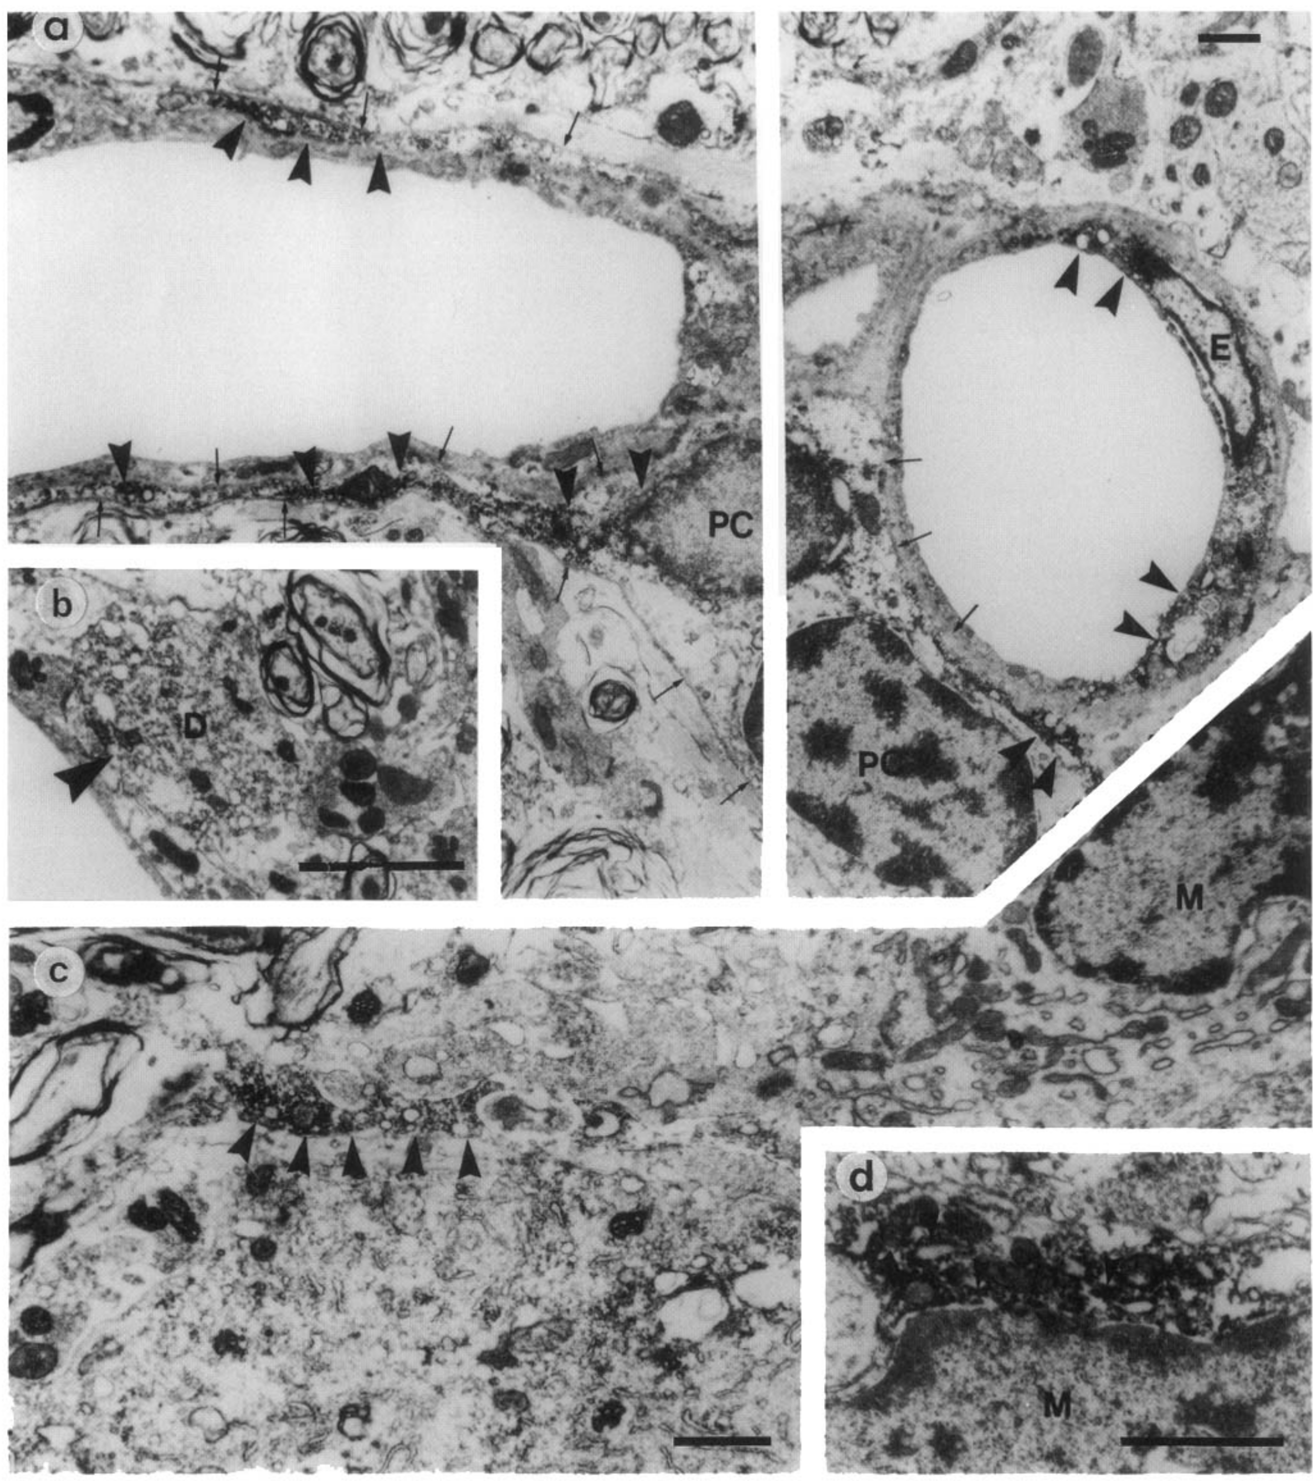

FIG. 68-6. Electron microscopic detection of APP. (A) In the control rat facial nucleus non-neuronal APP immunoreactivity (anti-APP antibody by Weidemann et al., 1989), as indicated by the dark DAB reaction product (*arrowheads*), is constitutively expressed in endothelial cells and in processes of perivascular cells, a cell type that lies within the basal lamina (*arrows*). *PC*, perivascular cell; *E*, endothelial cell. (B) The insert shows APP immunoreactivity in a dendrite (possibly bound to cytoskeletal proteins). *D*, dendrite. (C) 4 days after rat facial nerve axotomy-activated microglia show APP immunoreactivity in their cytoplasm (*c*) within the typically enlarged endoplasmatic reticulum (**d**). *M*, microglia. Scale bars = 1 μm.

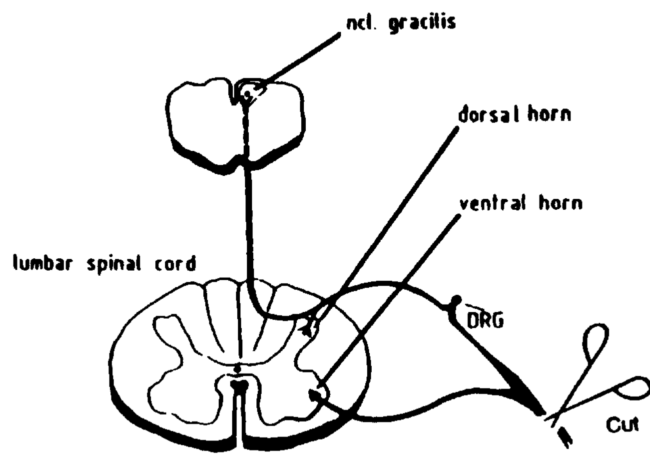

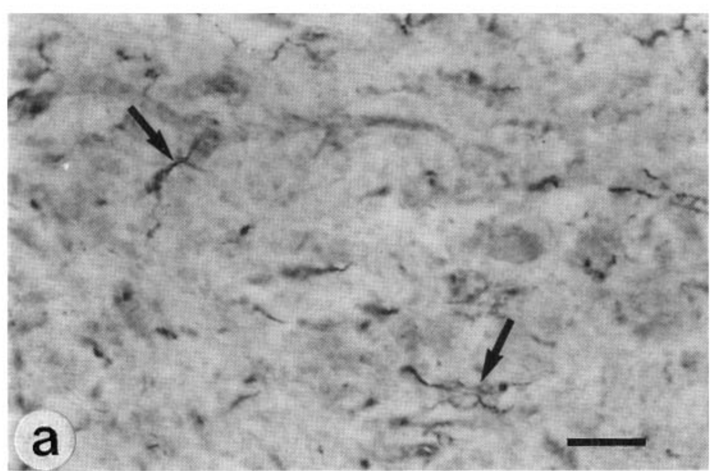

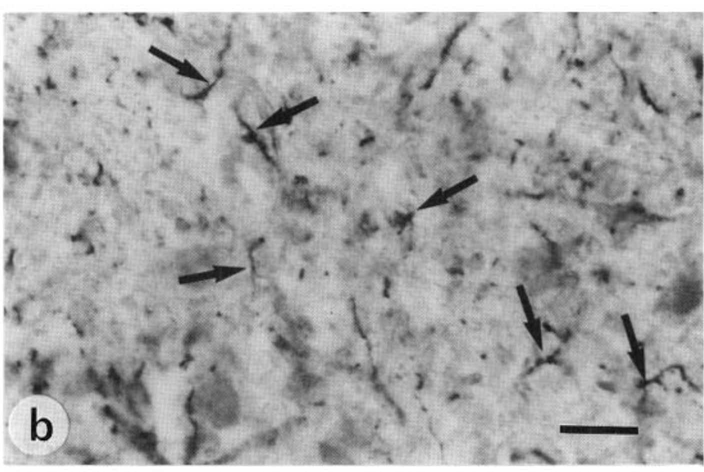

FIG. 68-7. Induction of APP immunoreactivity in microglia by anterograde neuronal reaction. The sciatic nerve sends primary afferent fibers into the nucleus gracilis. After induction by rat sciatic nerve transection APP immunoreactivity (anti-APP antibody by Weidemann et al., 1989) is light microscopically found in microglia as early as (A) 12 hours and more strongly after (B) 24 hours. Unlike after facial nerve axotomy, the microglial cells do not lie perineuronally, but are scattered in the sciatic projection area. The rapid appearance of microglial APP suggests that it has been *de novo*-synthesized in microglia rather than axonally transported and incorporated by phagocytosis. Scale bar = 25 μm.

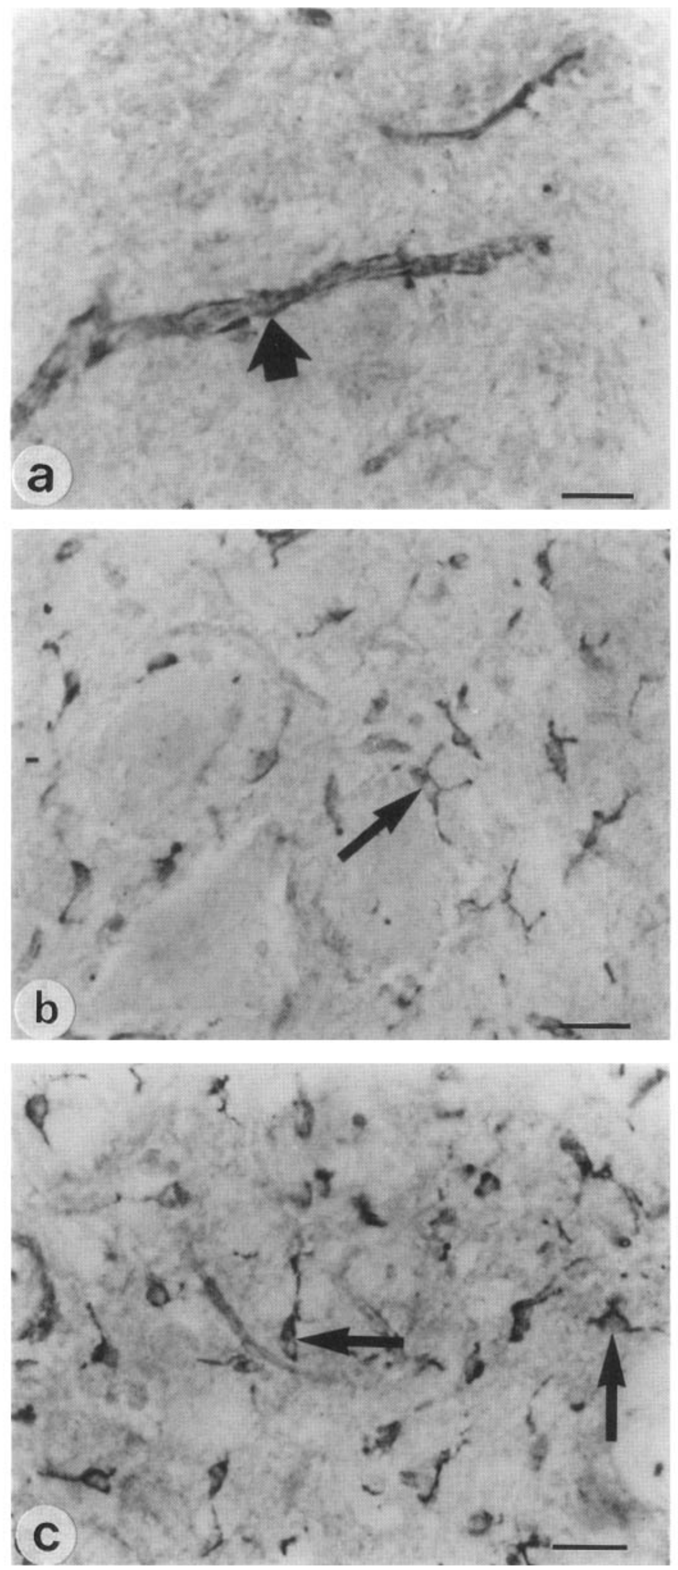

FIG. 68-8. Immune-mediated induction of APP. After transfer of activated T cells recognizing myelin basic protein into naive syngeneic rats, an experimental autoimmune encephalitis is induced. This causes an activation of microglia that goes along with a marked microglial expression of APP (as detected light microscopically by anti-APP antibody; Weidemann et al., 1989). The model indicates that also immune-mediated diseases can induce APP synthesis in glial cells. (**A**) Constitutive APP expression is seen in controls on blood vessels. The strongest APP immunoreactivity in microglia in the (**B**) anterior horn and the (**C**) dorsal horn of the spinal cord is seen between 6 and 7 days after T cell transfer, which correlates with the peak of clinical disease.

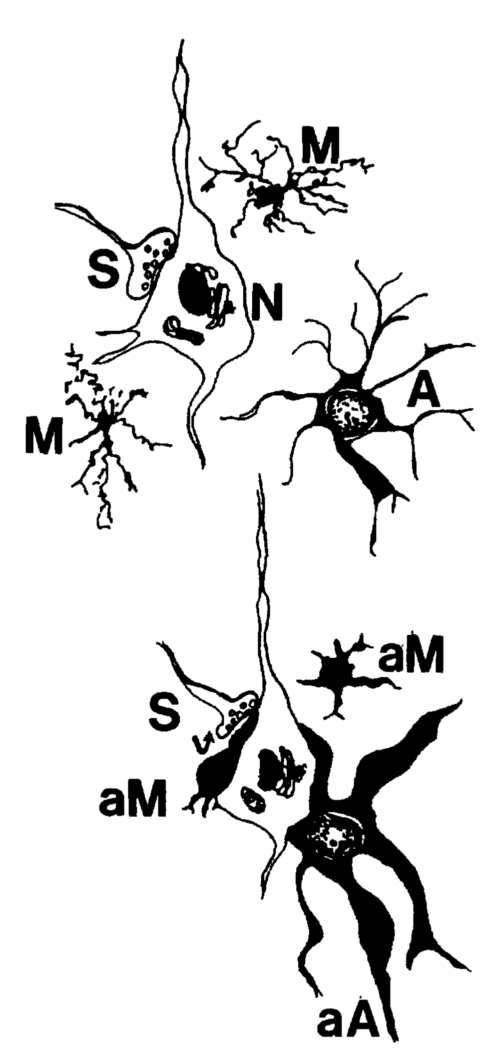

Gial reactions in response to neuronal lesion/dysfunction

A hypothetical model of amyloidogenesis

N	neuron	**S**	synapse
A	astrocyte	**aA**	activated astrocyte
fA	fibrous astrocyte	**rM**	resting microglia
aM	activated microglia	**pM**	phagocytic microglia
AP	amyloid plaque		

Early glial reactions

A variety of pathogenic stimuli can lead to neuronal reactions with subsequent glial activation. The cellular activation is accompanied by an up-regulation of APP expression in activated microglia and astrocytes. It is presently unclear in which cell type, neuron or glia, this stress-induced up-regulation of APP-synthesis mainly occurs. Activated microglia can perform ."synaptic stripping" leading to a de-afferentiation of the neuron (↯).

Chronic glial reactions

If the pathogenic stimulus persists microglia remain activated and the number of protoplasmatic astrocytes further increases. The dead neuron is eventually removed by brain macrophages/microglia. A continuously high synthesis of APP may overload the normal metabolic pathways and lead to the accumulation of ßA4-amyloid. In some cases of familiar Alzheimer's disease a mutation in the region coding for the ßA4 fraction might be instrumental in either increasing ßA4-amyloid production or altering its normal cleavage pathway.

Deposition of amyloid

With the cessation of the pathogenic stimulus microglia go back into their resting state and an astroglial scar remains. The amyloid plaque has formed during a chronic process that also led to the deposition of numerous other inflammatory proteins. It is an open question whether the diseased neuron itself could have produced the amyloid. In comparison, chronically activated glial cells do not only synthesise APP but also have a large repertoire of proteolytic enzymes and are capable of producing reactive oxygen intermediates, both pathophysiologically important amyloidogenic co-factors.

FIG. 68-9. Glial reactions in response to neuronal lesion or dysfunction.

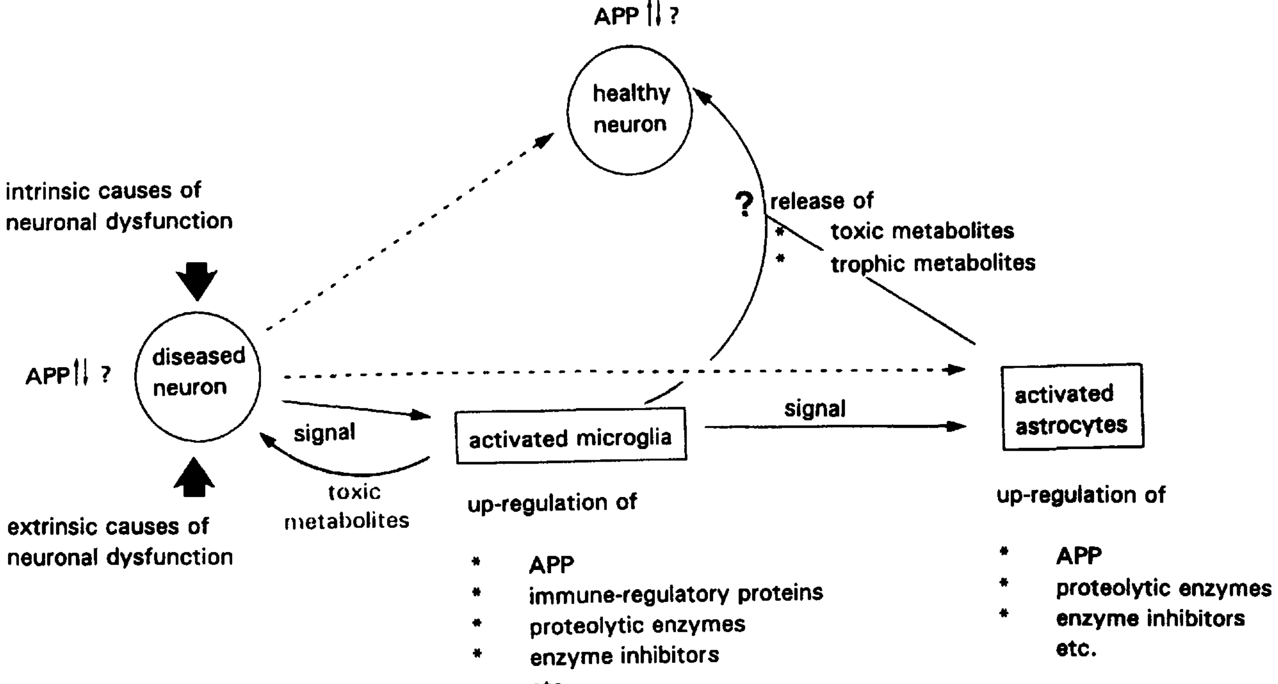

FIG. 68-10. Model of amyloidogenesis. The source of βA4 and how its precursor APP is regulated in neurons is still controversial. A number of studies, however, have shown that in Alzheimer's disease or in experimental lesions of the central nervous system the nonneuronal APP isoforms are increased. This implicates a dominant glial involvement in the formation of the amyloid plaque. Based on these observations, the model suggests that a dying or injured neuron acts on the local glia in its vicinity. The activation of glial cells goes along with the upregulation of APP. In the presence of other cofactors of amyloidogenesis, such as free radicals or APP proteolysis, βA4 might accumulate and eventually form the amyloid plaque. Such a glial activation might also have bystander effects on other neurons, for example, by the release of toxic (for review of cytotoxicity of microglia see Banati et al., 1993c) or trophic factors. The latter could explain the frequently seen sprouting of neurons into the plaque. The induction of APP in projection areas (as in the nucleus gracilis after sciatic nerve lesion, see Figure 68-7) might cause a cascade of similar events in areas of still healthy neurons. While the nature of the signal from neuron to microglia (and possibly also to astrocytes) is still open, the signal from microglia to astrocytes could be a member of the cytokine family (Giulian et al., 1988; Griffin et al., 1989).

potheses regarding the formation of senile plaques in Alzheimer's disease as part of an acute phase response (McGeer et al., 1987; Bauer et al., 1991; Nakajima et al., 1992). The function of APP in the immunopathology of Alzheimer's disease and related disorders is still largely unknown. Growth and differentiation factors like TGFβ can modulate the biosynthesis of APP in microglia depending on other factors like cell-cell or cell-extracellular matrix (Mönning et al., 1994). One hypothesis, therefore, is that APP could be important for the migratory behaviour of microglia, suggesting that the microglial APP synthesis is part of a physiological repair mechanism which under chronic stimulation might initiate the process of pre-clinical amyloid generation. As mentioned earlier, the number of senile plaques correlates imperfectly with the development of dementia. In contrast, decreased synaptic density gives a good measure for impaired cognitive functions (Masliah et al., 1989; DeKosky and Scheff, 1990). One characteristic function of activated microglia is neuronal deafferentiation by synaptic stripping (Blinzinger and Kreutzberg, 1968), a function they perform even after subtle neuronal injury. Chronic or repeated pathogenic stimuli acting upon the neurons, and the subsequent reactions of microglia and other glial cells, might thus eventually lead to a massive loss of synaptic connections (Figures 68-9 and 68-10). Such destruction/reconstruction of central nervous system tissue might involve toxic metabolites, like glutamate, nitric oxide or reactive oxygen intermediates, trophic factors, and tissue remodeling enzymes, that is, mechanisms that could be relevant for different therapeutic strategies (Abraham, 1989; Banati et al., 1993c).

Despite similar phenomenology of Alzheimer's disease and senile dementia of the Alzheimer type, it is still an open question whether these disorders belong to the same disease entity. Their etiology remains unknown. This chapter has therefore focused

on a description of the morphological changes seen in these conditions. The description of neuropathological phenomena evolving during the course of the human central nervous system disease or experimental models reveals that a variety of adverse noxious stimuli to the brain result in a common set of glial reactions. One of them is the rapid glial synthesis of APP, the protein that harbors the βA4, which itself is the main constituent of the senile plaque in Alzheimer's disease. Mutations of this protein in cases of familial Alzheimer's disease have underlined its importance. Therefore, these rare diseases now serve as models not only to study the pathophysiology of presenile dementia but also other forms of neuronal degeneration. The defining criteria of Alzheimer's disease, namely, clinical dementia and a certain neuropathology, have been questioned because of their limited specificity with respect to their cause. As happened with "schizophrenia" (Odegard, 1967; Frith, 1992), the perception and definition of "Alzheimer's disease" might therefore be subject to change.

69 | Gliomas

PAUL KLEIHUES, HIROKO OHGAKI, AND ADRIANO AGUZZI

Brain tumors amount to less than 2% of all malignant neoplasms and thus constitute a small fraction of the overall human cancer burden. However, they exert a wide spectrum of adverse effects, and for most of them, the prognosis is still poor. Furthermore, a significant proportion of central nervous system neoplasms affect children, in whom tumors of the nervous system (including retinoblastomas and peripheral neuroblastomas) rank second in incidence after leukemias. Brain tumor biology has for a long time been a *terra incognita*, but in recent years considerable progress has been made, particularly in the immunology and molecular genetics of gliomas. In addition, angiogenesis in human brain tumors and the biological basis of the migratory potential of neoplastic glial cells have become a focus of attention.

EPIDEMIOLOGY AND ETIOLOGY OF GLIOMAS

Analytical epidemiological studies show considerable geographical variation in the incidence of brain tumors, which generally tends to be higher in developed, industrial countries (Parkin et al., 1992). In Western Europe and North America, there are about 5 to 9 new cases of primary central nervous system tumors per 100,000 inhabitants each year. Approximately half of these are of glial origin. In multiracial countries, whites are more frequently affected than persons of African or Asian descent. In our study of 1330 patients (Figure 69-1), the ratio of male to female patients was 1.4:1, in accordance with other reports. This contrasts with the more benign meningiomas, which occur predominantly in women (Schiffer, 1993). There has been some controversy about a possible increase in the incidence of brain tumors over the past two decades, particularly in the elderly (Boyle et al., 1990; Greig et al., 1990; Davis et al., 1991). Most authors agree that, at least in part, this apparent increase is due to the introduction of high-resolution neuroimaging (computed tomography, magnetic resonance imaging), which has greatly improved the clinical diagnosis of neurological diseases (Desmeules et al., 1992; Modan et al., 1992).

With the exception of inherited neoplastic syndromes (e.g., neurofibromatosis, von Hippel-Lindau disease, tuberous sclerosis, germline mutations of the *p53* tumor suppressor gene), the etiology of human brain tumors is largely unknown (Schoenberg, 1982). Analytical epidemiological studies have revealed an increased risk of brain tumor development in association with certain occupations (T. Thomas and Waxweiler, 1986), for example, farmers, dentists, fire fighters, metal workers and rubber industry workers, but attempts to identify a specific exposure or causative environmental agent have been unsuccessful. The somewhat increased incidence of central nervous system neoplasms in anatomists (Stroup et al., 1986), pathologists (Harrington and Oakes, 1984) and embalmers (Walrath and Fraumeni, 1984) points to a possible role of formaldehyde, but it has emerged that in an industrial setting exposure to this weak carcinogen is not associated with an increased risk (Stroup et al., 1986). Similarly, multicenter cohort studies have not substantiated the hypothesis that occupational exposure to vinyl chloride carries an enhanced risk of brain tumor development (Simonato et al., 1991). This is also true for electromagnetic fields and environmental or medical (Schlehofer et al., 1992) radiation exposure. However, therapeutic irradiation of the brain, particularly in children, may lead to the development of malignant gliomas or primitive neuroectodermal tumors after an interval of usually 6 to 9 years (Brüstle et al., 1992b). A causative link between glioma development and previous neurological diseases (head trauma, epilepsy) has been suspected but remains unproven. This is also true for parental exposures to potential carcinogens and previous medical histories of various types during pregnancy (Schiffer, 1993).

PATHOLOGY AND CLINICAL ASPECTS

As in other tissues, the classification of tumors of the central nervous system is based on histogenetic principles, that is, the medical terminology relates to the

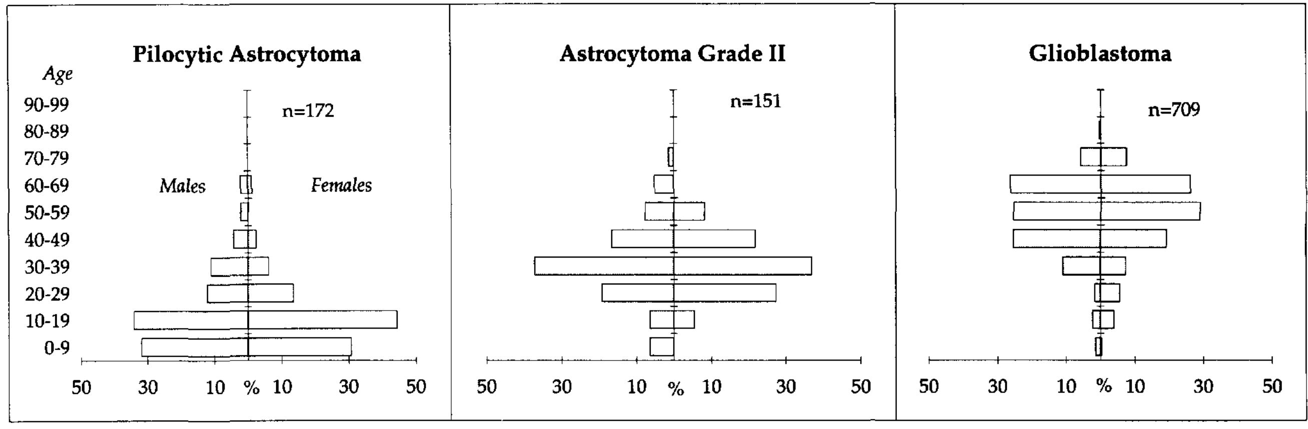

FIG. 69-1. Age and sex distribution of patients with gliomas (Institute of Neuropathology, University of Zürich, 1975–1993). Note that the age peak of malignant gliomas occurs much later than that of their benign counterparts.

cell of origin. Although gliomas are assumed to be derived from only three cell types, that is, differentiated astrocytes, oligodendrocytes and ependymal cells, the respective neoplasms display a large spectrum of different histopathological features, which in turn are associated with marked differences in incidence, location within the central nervous system, preferential age of affected patients and clinical course and outcome. It is now generally accepted that this variation in the phenotype and biological behavior of gliomas largely reflects the type of transformation-associated genes operative in neoplastic development.

Neurological symptoms resulting from glioma development depend primarily on the site of the tumor. However, the length of the patient's history and the chances for a long, remittance-free survival are more closely associated with the neoplasm's intrinsic biology, in particular, its proliferation potential, its inherent tendency for progression to anaplasia and its capacity to rapidly invade the surrounding brain tissue. For practical purposes, these characteristics are usually condensed into a grading scheme (Table 69-1). While the histogenesis of a neoplasm can often be derived from its morphological features and immunoreactivity profile, the biological correlates, in particular the clinical course and outcome, can only be estimated by comparisons with clinical data from patients with similar lesions. Therefore, in the grading of gliomas anaplasia is used as an operational term summarizing histopathological features typically associated with malignant biological behavior and may include nuclear atypia, increased mitotic activity, atypical mitoses, cellular pleomorphism, vascular proliferation, and necrosis. The significance of some of these features varies considerably in different tumor types. For example, nuclear atypia and extensive vascular profileration indicate anaplasia and a poor clinical prognosis in diffuse astrocytomas of the cerebral hemispheres but have no such implications in a pilocytic astrocytoma.

Astrocytic Tumors

Astrocytomas are tumors composed predominantly of neoplastic astrocytes. If not stated otherwise, this term applies to diffusely infiltrating neoplasms, which, according to their biological behavior, are subdivided into low-grade astrocytoma (WHO Grade II), anaplastic astrocytoma (WHO Grade III), and glioblastoma multiforme (WHO Grade IV) (Kleihues et al., 1993a,b).

Low-Grade Astrocytoma. Typically, low-grade astrocytomas occur in young adults, with a peak incidence in the fourth and fifth decades. They may be located in any region of the central nervous system, including the spinal cord but their preferential location is in the cerebral hemispheres, where they rep-

TABLE 69-1. *Grading of Astrocytic Tumors*

WHO definition	Grade	Features
Pilocytic astrocytoma	I	Rosenthal fibers, piloid cells
Low-grade astrocytoma	II	Nuclear atypia
Anaplastic astrocytoma	III	Mitotic activity
Glioblastoma multiforme	IV	Vascular proliferation/ necrosis

resent approximately 25% of all gliomas (Schiffer, 1993). Clinical symptoms may vary from several months to years according to location. Postoperative survival is typically from 3 to 5 years and depends largely on whether or not the tumor progresses to anaplasia and more rapid growth. Due to the infiltrative nature of these neoplasms, permanent cure through complete surgical resection is extremely rare. Macroscopically, low-grade astrocytomas are ill-defined, yellow-white, and homogeneous (Figure 69-2A). Single or multiple cysts containing a clear fluid may be seen. Diffuse infiltration often leads to enlargement and distortion, but not destruction, of the invaded anatomical structures, for example, cortex and compact myelinated pathways. Mitotic activity is absent. Microscopically, astrocytomas show a consistent tendency to diffusely infiltrate into the surrounding brain. Preexisting cell types, for example, neurons, are often entrapped. Phenotypically, neoplastic astrocytes may vary considerably in size, prominence, and disposition of cell processes, and abundance of cytoplasmic glial filaments. According to the prevailing cell type, the following variants can be distinguished.

Fibrillary Astrocytoma. By far the most frequently occurring astrocytoma is the fibrillary variant. Cell density is low to moderate. Nuclear atypia may be prominent. The cytoplasm is often scant and barely discernible. In more cellular lesions, numerous cell processes form a loose fibrillary matrix, often with microcyst formation (Figure 69-2B). Glial fibrillary acidic protein (GFAP) is consistently expressed in such areas.

Protoplasmic Astrocytoma. The protoplasmic astrocytoma is a rare variant characterized by neoplastic astrocytes with a small cell body and few flaccid processes with a low content of glial filaments. Accordingly, GFAP immunostaining is scant. Microcyst formation is common.

Gemistocytic Astrocytoma. Another variant of astrocytoma is predominantly composed of gemistocytic astrocytes. Tumor cells show large eosinophilic cell bodies, an angular shape, and stout, randomly oriented, GFAP-positive processes forming a coarse fibrillary network (Figure 69-2C). Nuclei are usually eccentric. Perivascular lymphocyte cuffing is frequent.

Anaplastic (Malignant) Astrocytoma. Focal or diffuse anaplasia, for example, increased cellularity, pleomorphism, nuclear atypia, and mitotic activity, characterizes the anaplastic or malignant astrocytoma. GFAP immunostaining may vary. Anaplastic astrocytomas show an inherent and often rapid tendency to progress to glioblastoma.

Glioblastoma. Glioblastoma is the most frequent and malignant brain tumor, and usually affects adults, with a peak incidence between 45 and 60 years. It is typically located in the cerebral hemispheres, most frequently involving the frontal and temporal lobe. The clinical history is usually short (less than 3 months) unless the neoplasm has developed from low-grade or anaplastic astrocytoma (secondary glioblastoma). Patients typically present with unspecific neurological symptoms, headache, and personality changes, but most threatening is the rapid development of raised intracranial pressure. After incomplete surgical resection and radiotherapy, the mean survival time is in the range of 6 to 9 months.

Macroscopically, glioblastomas are poorly defined, with varied coloration due to degeneration, necrosis, and occasional hemorrhage (Figure 69-3A). Histologically, they are composed of poorly differentiated, fusiform, round, or pleomorphic cells and occasional multinucleated giant cells. The presence of prominent vascular proliferation and/or necrosis is essential for the histological diagnosis (Figure 69-3B). The latter may comprise more than 80% of the total tumor mass. Mitotic activity and GFAP expression vary considerably. Many glioblastomas contain areas with differentiated neoplastic astrocytes, indicating their astrocytic nature and frequent evolution from low-grade or anaplastic astrocytoma (Burger and Kleihues, 1989). Two variants of glioblastoma are recognized. The giant cell glioblastoma is characterized by a predominance of bizarre, multinucleated giant cells and, on occasion, an abundant stromal reticulin network (Figure 69-3C). The gliosarcoma contains a neoplastic sarcomatous component, which is presumed to originate from a malignant transformation of the hyperplastic vascular elements typically observed in glioblastomas (see below).

Pilocytic Astrocytoma. After the embryonic central nervous system neoplasms, the pilocytic astrocytoma is the most frequent brain tumor in childhood, with a peak incidence around the age of 10 years. In contrast to the diffuse astrocytic tumors, the pilocytic astrocytoma is a more circumscribed, slowly expanding lesion, which very rarely shows a tendency to progress to anaplasia and therefore corresponds to WHO grade I (Kleihues et al., 1993a). Pilocytic astrocytomas are typically located in midline structures, that is, the optic nerve (optic glioma), the third ventricle, the thalamus, the median temporal lobe,

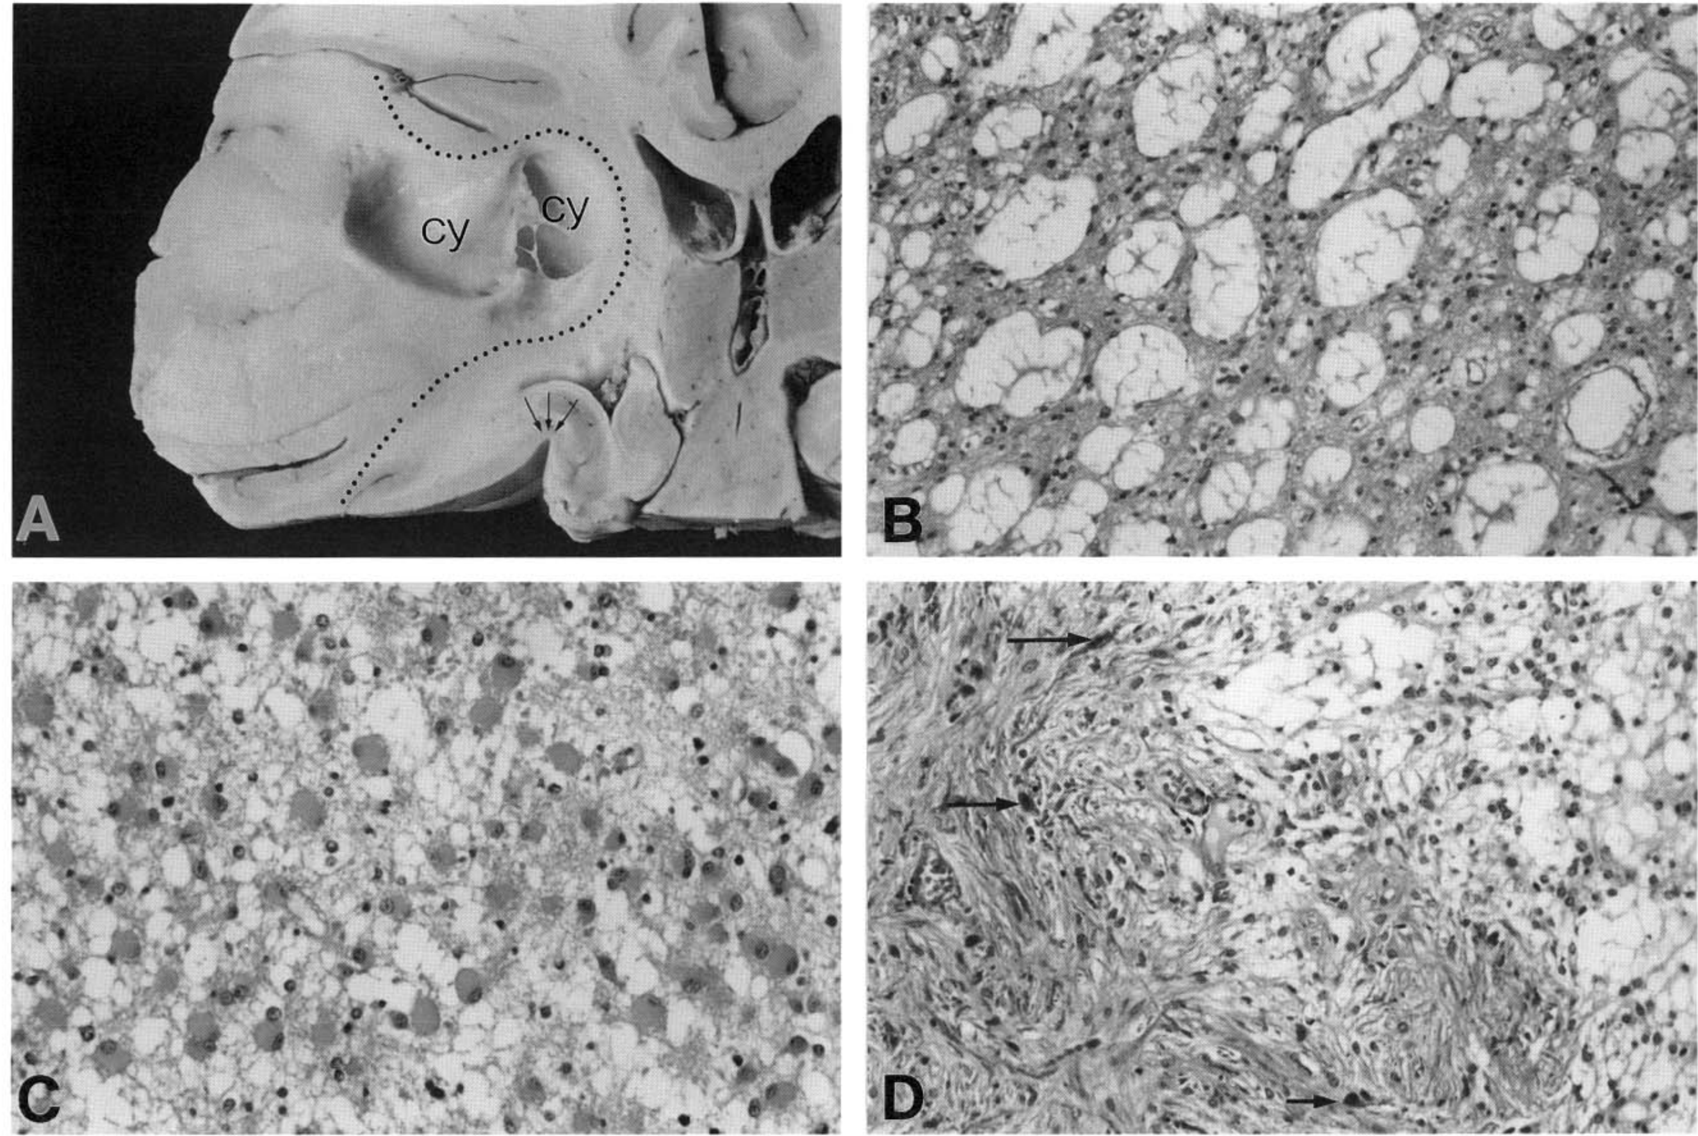

FIG. 69-2. Gross pathological and histological appearance of low grade astrocytomas. (**A**) Coronal section through the brain of a patient who died from astrocytoma of the left temporal lobe. The whitish tumor with large cysts [CY and ill-defined borders (*dotted line*)] diffusely infiltrates temporal gyri and the white matter. Although this neoplasm did not show histological signs of malignancy, it caused transtentorial herniation (*arrow*) and compression of the brainstem. (**B**) Typical histological appearance of a fibrillary astrocytoma with microcystic degeneration. (**C**) Gemistocytic astrocytoma with large cells showing a swollen cytoplasm, short thick processes, and eccentric nuclei. (**D**) Pilocytic astrocytoma featuring the typical biphasic pattern of fibrillary areas containing Rosenthal fibers (*arrows*) and loosely textured areas with microcystic degeneration.

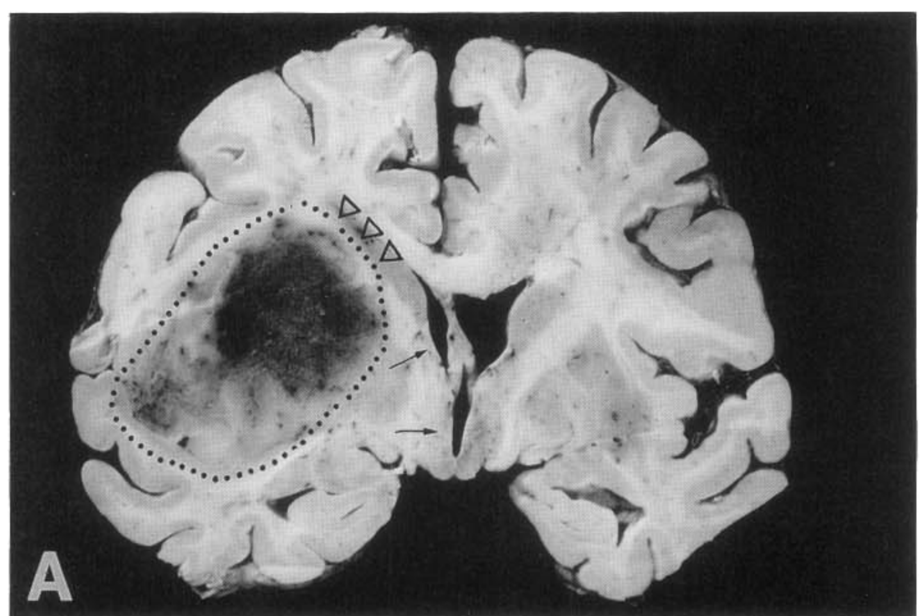

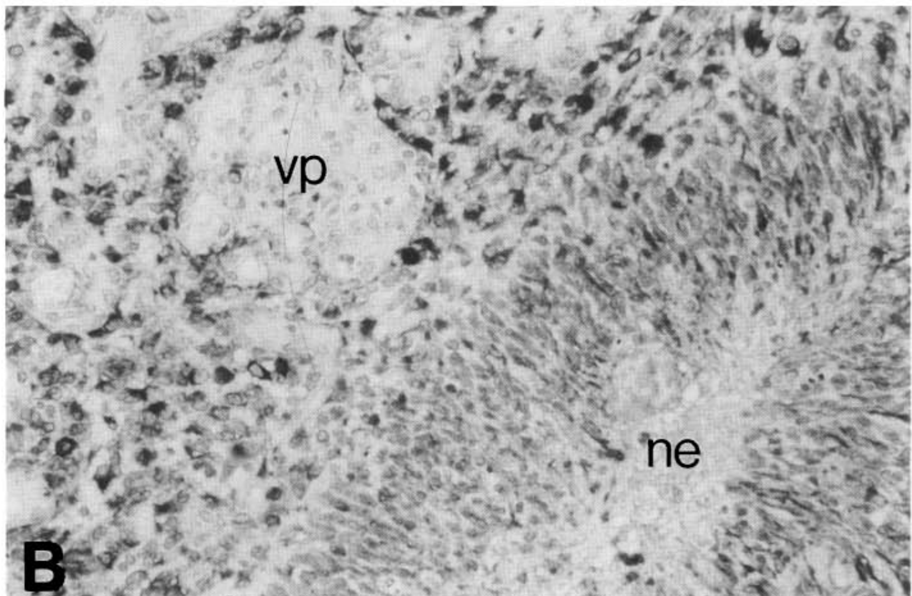

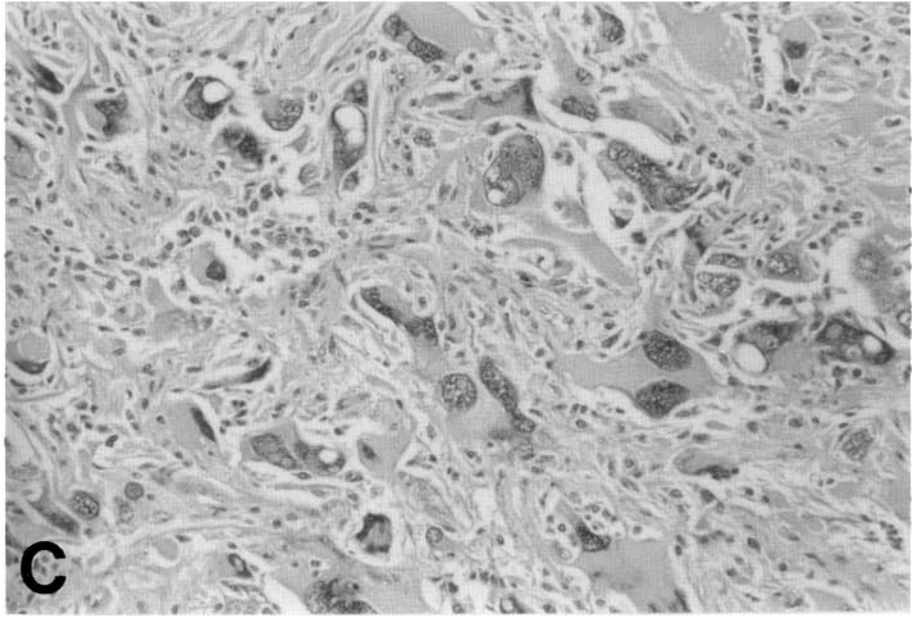

FIG. 69-3. Glioblastoma multiforme. (**A**) Coronal section showing a glioblastoma of the left cerebral hemisphere with hemorrhagic and necrotic components. The borders with the adjacent brain are ill defined (*dotted line*). Invasion of the capsula interna (*CI*) had caused hemiplegia. Note the compression of the ipsilateral ventricle (*arrow*). (**B**) Typical histological appearance of the glioblastoma with extensive vascular proliferations (*VP*) and necrosis (*NE*), surrounded by "pseudopalisading" tumor cells (GFAP immunostain). (**C**) Clusters of bizarre shaped, often multinucleated tumor cells in a giant cell glioblastoma.

the brainstem and the cerebellum. Total surgical resection is difficult, with the exception of cerebellar lesions. The clinical course often extends over many years, but eventually most tumors recur.

Macroscopically, the pilocytic astrocytoma is homogeneous, often cystic, and is well circumscribed. It is histologically characterized by bipolar, fusiform or "piloid" cells with dense fibrillation. It is particularly common to see a biphasic pattern in which pilocytic areas are intimately associated with a loosely structured microcystic component. Hyperchromatic bizarre nuclei, endothelial proliferation and invasion of the meninges are common but do not signify malignancy. Elongated eosinophilic, club-shaped structures (Rosenthal fibers) and eosinophilic intracytoplasmic protein droplets ("granular bodies") are histopathological hallmarks of this neoplasm (Figure 2D). GFAP expression is always demonstrable, although to a varying degree.

Pleomorphic Xanthoastrocytoma. The variant of astrocytoma known as pleomorphic xanthoastrocytoma occurs characteristically in children or young adults and affects the cerebral hemispheres, particularly the temporal lobe. It is typically superficial in location, shows an intimate relation to the meninges and may be associated with an underlying cyst. Histological hallmarks are pleomorphic tumor cells, which range from ordinary fibrillary astrocytes to giant, multinucleated forms. The latter typically contain lipid vacuoles; thus they are xanthomatous, but express GFAP. Pleomorphic xanthoastrocytomas are usually well demarcated and can often have a favorable prognosis (Kepes, 1993).

Subependymal Giant Cell Astrocytoma. The circumscribed, benign tumors known as subependymal giant cell astrocytomas often overlie the head of the caudate nucleus and typically occur in young patients as part of the tuberous sclerosis complex. They arise from the walls of the lateral ventricles, and are typically calcified. They are composed of large, plump cells that resemble astrocytes. GFAP expression is highly variable. These lesions grow very slowly and can be resected surgically when secondary complications, such as occlusion of the foramen of Monro, occur.

Oligodendroglial Tumors

Oligodendrogliomas usually affect adults and develop slowly over a period of years, often with seizures as the only clinical manifestation (WHO Grade II). They are preferentially located in the cerebral white matter and basal ganglia, are macroscopically pink and, in contrast to astrocytomas, tend to invade the leptomeninges. Tumor cells typically exhibit spherical, often hyperchromatic nuclei surrounded by artifactually swollen, clear cytoplasm. A well-defined plasma membrane lends them a so-called fried egg appearance. The stroma consists mainly of delicate, capillary-sized blood vessels. Focal calcifications in the peripheral zone of infiltration are a histopathological hallmark of oligodendrogliomas. No specific immunocytochemical marker is available for these tumors. A fraction of otherwise typical neoplastic oligodendrocytes expresses GFAP. Progression to anaplastic oligodendroglioma may occur, but is less frequent than in diffusely infiltrating astrocytomas.

Ependymal Tumors

Ependymomas develop from the ependymal or subependymal cells surrounding the ventricles and the central canal of the spinal cord, as well as from ependymal clusters in the filum terminale. Intracranial ependymomas occur predominantly in children and tend to fill the ventricular lumen. Clinical symptoms are usually due to blockage of cerebrospinal fluid flow, which may lead to a sudden increase in intracranial pressure. Slowly growing and usually well-delineated from adjacent brain structures, ependymomas correspond histologically to grade II. Spinal ependymomas are usually diagnosed in adults and are preferentially located in the lumbosacral region.

Histological hallmarks include perivascular pseudorosettes and ependymal rosettes. GFAP expression varies considerably and, if present, is usually restricted to the radiating cell processes of perivascular pseudorosettes. The more aggressively growing anaplastic ependymoma (WHO Grade III) is mainly characterized by brisk mitotic activity.

Among various histological variants only the *myxopapillary ependymoma* is of interest, as it occurs almost exclusively in the region of the cauda equina and originates from the filum terminale. Tumor cells may also surround pools of mucin, but their glial nature can usually be confirmed by immunoreactivity for GFAP. These neoplasms grow very slowly and correspond to WHO Grade I.

Subependymoma. The slowly growing benign tumors (WHO Grade I) called subependymomas appear as well-delineated, occasionally multiple firm nodules attached to the wall of the fourth or the lateral ventricles. They rarely obstruct cerebrospinal fluid pathways but are otherwise asymptomatic and typically detected at autopsy. Microscopically, sub-

ependymomas consist of clusters of ependymal cells with round nuclei, surrounded by broad swirls of glial processes. Despite their usually slow growth, a fraction of subependymomas causes symptoms by obstructing the cerebral aquaeduct.

PROLIFERATION AND GROWTH FRACTION

Growth and extension of a neoplasm depend on a variety of factors, the most important ones being their proliferation potential, the extent of cell loss and the ability of tumor cells to invade adjacent tissues and to metastasize. Gliomas have a considerable capacity to diffusely infiltrate the brain but penetration through the arachnoidal space is less common and metastasis to distant tissues is a very rare event. Most studies on the rate of proliferation of human gliomas have been carried out with BrdU immunostaining (Gratzner, 1982) or with the monoclonal antibody Ki-67 (Gerdes et al., 1984; Gerdes et al., 1992). The former method determines the fraction of tumor cells in the S-phase of the cell cycle (analogous to thymidine) but requires an infusion of BrdU in patients prior to or during surgical intervention (Hoshino et al., 1986). The monoclonal antibody Ki-67 can only be used on frozen sections while the more recently developed antibody MIB-1 can be applied to archival, formalin fixed, paraffin-embedded tissues (Cattoretti et al., 1992; Gerdes et al., 1992). These antibodies recognize a nuclear antigen expressed in all continuously cycling cells, that is, during G_1, S, G_2, and M phases of the cells cycle but not in resting cells (G_0 phase). Thus, the fraction of labeled cells directly reflects the size of the growth fraction. Accordingly, the BrdU labeling index (LI) is usually somewhat lower: LI BrdU = 0.34 × LI Ki-67 + 0.99 (Morimura et al., 1989). In gliomas, the labeling index generally agrees with histological grade and clinical behavior of the different tumors. In the benign, juvenile pilocytic astrocytoma, the LI is usually lower than 1%. For the diffuse infiltrating low-grade and anaplastic gliomas, the mean Ki-67 LI is typically 1 to 2% and 3 to 5%, respectively (Burger et al., 1986; Shibata et al., 1988; Zuber et al., 1988; Raghavan et al., 1990). Data for the glioblastoma vary considerably and can be higher than 30%. Since these neoplasms often show extensive necrosis, the proliferative fraction alone is not a valid criterion for tumor growth. The labeling index does not therefore correlate with individual patient survival in most studies (Bookwalter et al., 1986). More recent investigations seem to indicate that astrocytomas with a high Ki-67 LI, elevated *p53* protein and EGF receptor amplification are associated with malignant progression and poor prognosis (Jaros et al., 1992; Torp et al., 1992).

MIGRATION AND INVASION OF GLIOMA CELLS

It has long been realized that glioma cells migrate far beyond the apparent tumor border (Scherer, 1940a, 1940b). This tendency can be observed in low-grade as well as in high-grade astrocytomas, but is particularly noticeable in glioblastoma multiforme. Diffuse infiltration of the adjacent brain structures is the main reason that surgical resection is often incomplete, and even hemispherectomy may not prevent glioma recurrence (Burger et al., 1991). Anatomical structures vary in their susceptibility to glioma invasion. The glioblastoma extends very rapidly along compact myelin pathways, for example, corpus callosum, anterior commissure, fornix, optic radiation. Once tumor cells gain access to any of these structures, they rapidly migrate into the contralateral hemisphere. For this reason, glioblastomas frequently appear as multifocal tumors (Burger et al., 1988a). Rapid spread through the corpus callosum often leads to the macroscopic appearance of a lesion that unfolds symmetrically from the corpus callosum into the two hemispheres ("butterfly glioblastoma").

The migratory capacity of glioma cells can be reproduced in the rat brain, using either established rat glioma cells lines (Bernstein et al., 1990) or xenografted human glioma cells (Bernstein et al., 1989a, 1989b). As in the human brain, the corpus callosum has been identified as a major migration route. Further, grafted human astrocytes were found on the glia limitans at the outer surface of the brain, in the Virchow-Robin spaces and in the subependymal regions of the ventricles (Bernstein et al., 1989a). Another model system extensively investigated is the cocultivation of glioma spheroids and reaggregated fetal brain cells (Lund et al., 1990b). Of the various factors which are potentially involved in glioma invasion, extracellular matrix proteins have received particular attention. There is emerging evidence that integrin, fibronectin, and laminin modulate tumor spread (Letourneau et al., 1988; Bjerkvig et al., 1989). A comparative immunohistochemical study on human brain tumors indicates that the expression of tenascin, but not fibronectin, correlates with angiogenesis and the degree of invasion and malignancy (Higuchi et al., 1993). The question as to whether human glioma cells produce and secrete tenascin or whether they induce its synthesis by mesenchymal cells, is still unresolved. Of the cell adhesion molecules, neural cell adhesion molecule

(NCAM) expression was investigated in two rat glioma lines which differ greatly in their metastatic ability. It was found that failure of BT4Cn cells to synthesize NCAM is associated with an increased metastatic potential (Andersson et al., 1991).

Several proteinases have been implicated in the migration of transformed glial cells within the central nervous system, including collagenase type IV (Taylor et al., 1991; Vaithilingam et al., 1991; Reith and Rucklidge, 1992), endopeptidase (Monod et al., 1989) and progelatinase (Miazaki et al., 1992). As in other tissues, metalloproteinases are prime suspects among enzymes facilitating tumor invasion. Several of these have been partially identified (Paganetti et al., 1988; Apodaca et al., 1990; Lund et al., 1991). A motility factor produced by malignant glioma cells has been postulated and partially characterized by Ohnishi et al. (1990). Finally, it should be noted that growth factors typically expressed in malignant gliomas (e.g., epidermal growth factor) may also contribute to the spread of tumor cells within the central nervous system (Lund et al., 1990a, 1992; Engebraaten et al., 1993).

ANGIOGENESIS IN GLIAL TUMORS

A large body of anatomical observations and of experimental evidence points to the critical importance of an efficient blood supply for the growth of malignant tumors (Folkman, 1990; Weidner et al., 1991; Folkman, 1992). This fact is particularly obvious in the case of tumors belonging to the astrocytic lineage. Low-grade astrocytomas, which are associated with a protracted and relatively benign clinical course, invariably show vascular densities similar to that of normal cerebral tissue (Feigin et al., 1958). In contrast, disordered vascular hyperproliferation is one of the most prominent hallmarks of malignant astrocytic tumors, that is, anaplastic astrocytoma and glioblastoma multiforme (Kleihues et al., 1993). It has been shown that the presence of vascular proliferation correlates positively with an unfavorable clinical course (Daumas et al., 1988). Pathological angiogenesis in high-grade astrocytomas characteristically affects the endothelial compartment of the microvascular tree and leads to formation of kinky corkscrewlike capillaries with grotesquely thickened walls (Figure 69-3C).

The extent to which vascular proliferations colonize malignant astrocytomas is rarely seen in other human neoplasms and has prompted speculation that glioblastomas might produce angiogenic factors. Indeed, basic and acidic fibroblast growth factors (bFGF and aFGF) have been identified in glioblastomas (Zagzag et al., 1990; Stefanik et al., 1991). The demonstration within pathological vascular proliferations of the production of platelet-derived growth factor by glioma cells and of its cognate receptors by endothelial cells provided an elegant framework for the concept of an autocrine angiogenetic loop in gliomas (Heldin et al., 1988; Heldin and Westermark, 1991; Plate et al., 1992a,b).

Recently, an additional angiogenetic system has been discovered in gliomas: the vascular endothelial growth factor (VEGF) and its cognate receptors, the *flk*-1 and *flt* tyrosine kinases. VEGF is a heparin-binding growth factor with target-cell specificity restricted to vascular endothelial cells (Leung et al., 1989; Ferrara et al., 1991). What sets VEGF apart from related growth factors, such as basic and acidic FGF, is its exquisite specificity for vascular endothelia. The group of Werner Risau has demonstrated strong transcription of VEGF by glioblastoma cells (Plate et al., 1992). Most intriguingly, VEGF mRNA as detected by *in situ* hybridization was specifically expressed by "pseudopalisading" glioma cells, that is, those cells located in the immediate neighborhood of necrotic areas.

In an elegant, synchronous study, Shweiki et al. (1992) reported similar results and asked the additional question whether the dramatic upregulation of VEGF transcription in pseudopalisading cells might be the immediate consequence of hypoxia. Exposure to hypoxia of cultured astrocytoma cells resulted in strong induction of the VEGF message, and surprisingly it was found that this induction, far from being restricted to glioma cells, was detectable in cultured cells as diverse as skeletal muscle myoblasts and in fibroblastic cell lines. The physiological importance of the angiogenic stimulus elicited by VEGF is underlined by the recent finding that inhibition of VEGF production *in vivo* effectively reduces the tumorigenic potential of injected transformed cells (Kim et al., 1993).

In an effort to identify receptor tyrosine kinases potentially involved in angiogenetic signal transduction, Millauer et al. (1993) identified various candidate molecules using degenerated polymerase chain reaction cloning primers from early postimplantation embryos and cultured endothelial cells. This interesting cloning strategy resulted in the realization that a tyrosine receptor kinase which had been independently identified shortly before (Matthews et al., 1991) and had been termed *flk*-1 (fetal liver kinase), is strongly and widely expressed in the endothelial lining of budding capillaries during embryogenesis. *Flk*-1 binds to VEGF with high affinity and can therefore be regarded as a true receptor for this growth factor. The interaction between VEGF

and *flk*-1 is likely to be important for the vascular hyperplasia seen in gliomas. An additional receptor for VEGF is *flt*, a member of the platelet-derived growth factor receptor tyrosine kinase family.

One still poorly understood aspect is the histogenesis of secondary neoplastic transformation of the mesenchymal component occasionally seen in glioblastoma (so-called gliosarcoma). It has been proposed that the malignant mesenchymal component in gliosarcoma is derived from transformation of endothelial or pericytic cells, although derivation from fibrohistiocytic elements has also been discussed (Grant et al., 1989). In view of the extraordinarily concentrated efforts currently invested in the clarification of angiogenetic mechanisms of glial tumors, it seems likely that we will soon reach conclusive answers to these questions.

MOLECULAR GENETICS

It is now generically accepted that cancer cells evolve through a multistep process of malignant transformation, which genotypically is characterized by the sequential acquisition of genetic alterations. The latter includes the activation of protooncogenes and the inactivation of tumor suppressor genes. Several of these steps have recently been identified in human brain tumors.

p53 Tumor Suppressor Gene

The *p53* tumor suppressor gene is located on the short arm of chromosome 17 and encodes a nuclear phosphoprotein involved in the regulation of cell proliferation (Boyd, 1990). The wild-type *p53* gene acts as a tumor suppressor gene, whereas some *p53* mutations occurring within highly conserved regions not only cause loss of tumor suppressor function but may convert the *p53* protein into a dominant oncogene (Eiyahu, 1989; Finlay, 1989). Various human tumors show a loss either of both alleles of the *p53* gene, the loss of one *p53* allele with an associated point mutation, insertion, or deletion of the remaining allele, or an inactivation of the *p53* gene in one allel but a normal (wild-type) sequence in the other. The rapidly accumulating data on *p53* genetic alterations indicate that it may constitute the gene most frequently involved in human oncogenesis (Hollstein, 1991; Levine, 1991). The function of the *p53* gene product appears to lie in the stabilization of the genome after damage by carcinogens and irradiation. These environmental DNA damaging agents cause a nuclear accumulation of *p53*, which leads to cell cycle arrest or apoptosis (Lane, 1992). In contrast, interference with the *p53* pathway leads to continuous cell division in the presence of promutagenic DNA lesions and, thus, stable somatic mutations. Inactivation of the *p53* gene may occur by mutation or complex formation with viral or cellular oncoproteins (Levine, 1991).

***p53* Mutations in Human Gliomas.** The occurrence of *p53* mutations is largely restricted to diffusely infiltrating astrocytomas and to glioblastoma multiforme (Ohgaki et al., 1993). In low-grade astrocytomas (WHO Grade II) *p53* mutations, with or without loss of heterozygosity on chromosome 17p, are the only detectable genetic alteration and occur at an overall incidence of 24% (Fults et al., 1992; von Deimling et al., 1992; Ohgaki et al., 1993). Anaplastic astrocytomas contain p53 mutations at an incidence of 32% (Fults et al., 1992; von Deimling et al., 1992a). In three independent studies, 24 *p53* mutations were identified in a total of 72 glioblastomas, that is, in 33% of cases (Frankel et al., 1992; Fults et al., 1992; Louis et al., 1993). The observation that *p53* mutations are present at a similar incidence in low-grade astrocytoma, anaplastic astrocytoma, and glioblastoma multiforme may indicate that this gene is involved during a rather early stage of neoplastic transformation. One study suggests that the progression to glioblastoma is characterized by a clonal expansion of cells carrying a *p53* mutation, presumably due to selective growth advantage (Sidranski et al., 1992). This view is supported by a report by Hayashi et al. (1991) who found *p53* mutations only in progressive recurrent gliomas. However, both studies are based on relatively few cases and require confirmation in a larger series of tumors. *p53* Mutations in astrocytomas are often associated with loss of heterozygosity of chromosome 17p (Frankel et al., 1992; von Deimling et al., 1992).

p53 mutations in astrocytic human brain tumors are predominantly located at cytosine-guanine repeats (CpG sites) (55%), as in a variety of other human neoplasms (Levine, 1991), including colon carcinoma, sarcomas, lymphomas/leukemias, bladder carcinoma, and small-cell lung carcinoma. The *p53* mutations were located in highly conserved regions with slight clusters at codons 175 (7.5%), 248 (17.5%), and 273 (7.5%) (Ohgaki et al., 1993). These three codons have also been reported to be hot spots for mutations in colon cancer (Levine, 1991). Among the types of *p53* mutations in these astrocytic brain tumors, G:C → A:T transition mutations prevail (56%), followed by frameshift mutations (18%). G → A transitions are also the most frequent type of *p53* mu-

tation in small cell lung cancer, colon cancer, and lymphoid malignancies (Hollstein, 1991).

In some gliomas and extraneural tumors, the wild-type p53 protein accumulates in gliomas, probably through increased half-life rather than overexpression (Finlay et al., 1988). The mechanisms underlying this phenomenon are still poorly understood. Brain tumors occur in approximately 12% of patients affected by the Li-Fraumeni syndrome (Malkin et al., 1990; Srivastava et al., 1990). This inherited neoplastic disease is often, though not invariably, caused by *p53* germline mutations. Other neoplasms associated with this syndrome are soft tissue and bone sarcomas, breast cancer, leukemia, and adrenocortical carcinomas.

In contrast to diffusely infiltrating astrocytomas, the juvenile pilocytic astrocytoma does not contain mutations in the highly conserved regions of the *p53* gene, suggesting a different genetic basis for this benign childhood neoplasm (Ohgaki et al., 1993). This is also largely true for nonastrocytic gliomas, that is, oligodendrogliomas and ependymomas (Ohgaki et al., 1991).

p53 Inactivation by Complex Formation with Oncoproteins. The *p53* protein can be inactivated by complex formation with oncoproteins of DNA viruses, including the large T antigen of the SV40 and polyoma viruses, E1A of adenovirus 2 and 5, and E7 of human papilloma virus 16. In addition, inactivation may occur through binding to the murine double minute 2 gene (*mdm2*). The human homologue of this gene is frequently amplified in childhood sarcomas and a similar mechanism appears to be operative in less than 10% of human anaplastic gliomas and glioblastomas (Reifenberger et al., 1993). In these cases, *p53* mutations are typically absent.

Growth Factors and Growth Factor Receptors

Several growth factors have been implicated in the evolution of human gliomas, including platelet-derived growth factor and its receptor (Eva et al., 1982), tumor necrosis factor β (de Martin et al., 1987; Constam et al., 1992) and insulinlike growth factor (IGF-1) (Sandberg et al., 1993). Most prominent is the involvement of the epidermal growth factor receptor (EGFR), which occurs in up to 50% of glioblastomas but are very rare in low-grade astrocytomas (WHO Grade II), and in anaplastic astrocytomas. Almost two-thirds of the glioblastomas with amplified EGFR genes also show coamplification of rearranged EFGR genes and concomitant expression of mRNA species (Libermann et al., 1985; Bigner et al., 1988; Bigner and Vogelstein, 1990; Ekstrand et al., 1991). Expression of EGFR with an isolated extracellular truncation including the ligand binding domain can induce transformation *in vitro* (Haley et al., 1989).

Chromosomal Loss in the Pathogenesis of Gliomas

In isolated cases of low-grade and anaplastic astrocytomas, loss of heterozygosity on chromosomes 9p, 13, and 22 have been reported. In addition, more than 40% of anaplastic astrocytomas show loss of heterozygosity on chromosome 19q (von Deimling et al., 1992). Furthermore, the involvement of a second yet unidentified tumor suppressor gene on chromosome 17p distinct from the *p53* gene has been suggested for malignant astrocytomas (Frankel et al., 1992; Saxena et al., 1992). Loss of chromosome 10 was found in one-fifth of anaplastic astrocytomas and more than 70% of glioblastoma multiforme (Fults et al., 1992; von Deimling et al., 1992b). All glioblastomas with EGFR amplification also show loss of chromosome 10 (von Deimling et al., 1992b).

Genetic Models of Glioma Progression

The sequence of gene alterations acquired during glioma development is shown in Figure 69-4. However, this has to be considered provisional since only

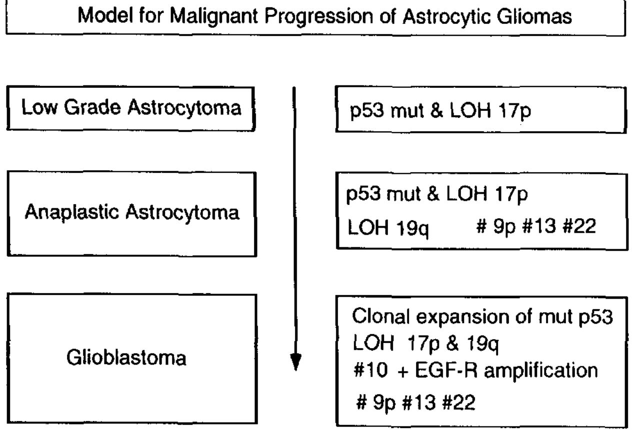

FIG. 69-4. Synopsis of genetic alterations associated with the evolution and progression of human gliomas. Mutations of the *p53* tumor suppressor gene, often in conjunction with loss of heterozygosity on chromosome 17, constitute the earliest detectable genetic change. Loss of chromosome 10 and amplification of the epidermal growth factor receptor (*EGF-R*) are largely restricted to the glioblastoma. [Modified from Ohgaki et al. (1993), with permission.]

a few transformation-associated genes have been identified so far. Nevertheless, there seems to be an emerging sequence of molecular events, with *p53* mutations being the first detectable alteration. The glioblastoma multiforme may develop *de novo* from differentiated astrocytes, usually with a short clinical history (primary glioblastoma). However, this lesion may also develop through progression from low grade and anaplastic astrocytoma (secondary glioblastoma). Based on molecular genetic analyses, von Deimling et al. (1993) have proposed two types of glioblastoma, one being characterized by loss of heterozygosity of chromosomes 17p and 10, the other by loss of heterozygosity of chromosome 10 and amplification of the EGFR gene. It remains to be shown whether this distinction correlates with differences in tumor phenotype and clinical behavior.

IMMUNOLOGY OF GLIOMAS

A large body of evidence indicates the existence of a complex network of interactions between neoplasms and the immune system of their hosts. In particular, the question has been pursued as to whether and to what extent tumors can trigger a cytotoxic immune reaction that may impair, with varying efficiency, their growth. It has also emerged that certain tumors may develop strategies aimed at paralyzing the immune system of the host, thereby optimizing their chances of expansion. Intriguingly, in glial tumors a good case can be made for both phenomena (Fontana et al., 1992). Several reports have pointed out that glioblastoma patients tend to suffer from a state of partial immune suppression. Downregulation of cutaneous immune reactivity, diminished numbers of T cells and marked depression of lymphocyte responses to lectins and antigens have been described and all point to impaired T cell-mediated immunity (Roszman et al., 1991). It remains to be ascertained whether this apparent downregulation of certain functions of the immune system modifies the biological behavior of the tumors in any clinically significant way.

Several exogenous factors and side effects of anticancer therapy might contribute to the decreased immunoreactivity. Treatment with antiepileptic drugs, especially hydantoins used to control tumor-related seizures, has been found to interfere with T cell immunity *in vivo* and *in vitro*. Corticosteroids used to reduce the glioma-associated brain edema are a well-established cause of decreased cellular immunity through the inhibition of cytokine secretion, of chemotaxis, and of expression of adhesion molecules involved in immune interactions. Furthermore, psychological stress, malnutrition, and, last but not least, specific tumor treatment with cytostatic agents and irradiation may contribute to impaired immunity in glioblastoma. As be discussed below, glioblastoma cells may even secrete immunosuppressive molecules that can hinder immune reactivity at the site of tumor growth.

Adriano Fontana and coworkers (1984) have shown that glioblastoma cells do not secrete a thymocyte-stimulatory factor, but rather inhibitory molecules blocking cytotoxic responses in primary mixed lymphocyte reactions. This factor, which has been termed glioblastoma-derived T cell suppressor factor (GTSF), was biochemically purified and shown to be a member of the family of transforming growth factor (TGF). In more recent studies, the same authors have characterized the elements controlling transcription of this factor in glioblastoma cells (Wrann et al., 1987; Schreiber et al., 1990). Anti-TGF-β2 antibodies neutralize the immunosuppressive activity detected in the supernatant of glioblastoma cells, indicating that at least *in vitro*, TGF-β2 is the only immunosuppressive factor that is released. TGF-β2 suppresses the secretion of TNF in mixed lymphocyte cultures, the production of H_2O_2 by macrophages stimulated with phorbol esters, the generation of lymphokine-activated killer cells, and the activation of natural killer cells. Furthermore, TGF-β2 influences the growth, differentiation, and immunoglobulin production of B lymphocytes (Wahl et al., 1989), although the molecular mechanisms leading to these effects are still poorly understood.

Although gemistocytic astrocytomas and glioblastomas are typically infiltrated to a varying extent by inflammatory cells, the efficiency of the immune response against gliomas might be compromised by the active inhibition of local immune responsiveness due to tumor-derived suppressor factors. Indeed, tumor-infiltrating T cells harvested from glioblastoma seem to be functionally arrested in a frozen state, and their expansion *in vitro* is almost impossible (Miescher et al., 1988). It has recently been suggested that escape from this type of negative control may be achieved by the loss of TGF-β binding sites on the surface of lymphocytes (Siepl et al., 1991).

One additional factor that may be rate-limiting in determining the biological effects of the above-mentioned system is the conversion of latent (L-) TGF-β to its active form. This process seems to be mediated by various cellular proteases and endoglycosidases (Huber et al., 1992). Treatment of glioblastoma cells with protease inhibitors may partially abolish the TGF-β-dependent inhibition of T cell growth (Huber et al., 1991) by interfering with the production of biologically active TGF-β. On the

other hand, a number of *in vitro* and *in vivo* findings point to the distinct possibility that glioma cells may have the potential to be a preferential target of immune surveillance.

Amid these contrasting viewpoints it is intriguing to note that neoplastic glial cells do share features typical of professional antigen presenting cells, such as expression of class I and II histocompatibility antigens (Carrel et al., 1982). Expression of histocompatibility antigens and of intercellular adhesion molecule (ICAM-1) is enhanced by interferon-γ, and such enhancement of expression seems to have functional importance as interferon-γ-treated glioma cells are efficient stimulators in the mixed lymphocyte reaction (Takiguchi et al., 1985). In addition, cultured glioma cells have been shown to express a wide variety of different cytokines, such as interleukin-1 and interleukin-6 (Takiguchi, et al., 1985; van Meir et al., 1990), granulocyte/macrophage colony stimulating factor (GM-CSF) and (G-CSF) (Tweardy et al., 1990; Frei et al., 1992). The significance of the expression of these growth factors and cytokines by the tumors *in situ*, however, has not yet been established with any certainty. Finally, glioblastoma cells may express immunologically important adhesion molecules such as ICAM-1, a cell adhesion molecule important for interaction with the leukocyte function associated antigen-1 (LFA-1, ICAM-1) (Kuppner et al., 1990).

The discovery of these peculiar immunological properties of neoplastic glial cells has triggered a wealth of studies aimed at their clinical exploitation. For example, Bigner and colleagues (1988) have characterized a monoclonal antibody termed Mel-14, which reacts with a chondroitin sulfate proteoglycan antigen in gliomas and other neoplasms. Intravenous administration of ^{131}I-labeled antibody significantly improved the survival of athymic mice transplanted intracerebrally with human glioma xenografts, thus suggesting the feasibility of radioimmunotherapy trials (Colapinto et al., 1990). In addition, the same group has shown that this antibody might be useful as a radioimaging reagent (Garg et al., 1992).

Generally, most attempts at using immunity to combat glial tumors had disappointing results (Apuzzo and Mitchell, 1981; Mahaley et al., 1983). A randomized clinical trial has shown no benefit from immunotherapy (Bloom et al., 1973). On the other hand, another clinical trial has suggested that survival can be increased if levamisole (an inhibitor of alkaline phosphatase) and BCG are added to irradiated homologous glial cells (Mahaley et al., 1983).

Recently, a very promising method has been developed, which exploits the combined antigenic properties and the requirements for autocrine growth factors for tumoral vaccination against gliomas. Initially, Trojan and colleagues (1992) reported that rat glioblastoma cells lose their tumorigenicity if production of insulinlike growth factor I (IGF-I) is inhibited by introducing antisense expression vectors. These results suggest that IGF-I is an important factor codetermining the malignant behavior of glioma cells *in vivo*. Based on the observation that histological sections revealed only a few glioma cells infiltrated by a large number of mononuclear cells in the challenged animals, the authors speculated that impairment of IGF-I production may render the glioma cells more susceptible to the immune response. Indeed, in a second study the same group was able to demonstrate that subcutaneous injection of IGF-I antisense-transfected glioma cells into rats prevented the formation of both subcutaneous and brain tumors induced by nontransfected cells (Trojan et al., 1993). Most intriguingly, administration of IGF-I antisense-transfected glioma cells was even able to cause regression of already established intracranial glioblastomas when injected ectopically. Although the mechanisms underlying these impressive results are still largely unknown, it appears that a glioma-specific immune response involving CD8$^+$ lymphocytes plays a key role. Trojan and colleagues (1993) have suggested that antisense blocking of IGF-I expression may reverse a phenotype that allows C6 glioma cells to evade the immune system.

ANIMAL MODELS OF GLIOMA INDUCTION

The highest incidence of spontaneous central nervous system tumors of nonhuman mammals is found in brachycephalic dogs. About 60% of these tumors are of neuroectodermal origin (McGrath, 1962). Over the past two decades, several animal models of glioma induction have been developed, using either chemical carcinogens or oncogenic viruses as causative agents. While the former were mainly used in the elucidation of basic mechanisms of tumor evolution in the central nervous system, the latter have become preferred systems in the evaluation of chemotherapeutic agents (Kleihues et al., 1976; Jänisch and Schreiber, 1977). More recently, tumors of the central nervous system have been induced in rodents by transfer of defined oncogenes or combination of oncogenes with or without concomitant carcinogen treatment (Kleihues et al., 1990).

Chemical Neurooncogenesis

The most effective neurooncogenic compounds are simple alkylating agents, particularly nitrosourea derivatives, which cause central nervous system neoplasms in rats after systemic administration (Druckrey et al., 1967). Dialkyl-aryltriazenes (Preussmann et al., 1974) and azo-, azoxy- and hydrazo compounds (Druckrey et al., 1968) are similarly effective. Ethylnitrosourea and related ethylating agents are particularly powerful when administered as a single (pulse) dose transplacentally or shortly after birth (Ivankovic and Druckrey, 1968). With these agents, the susceptibility of the rat central nervous system begins at the 10th prenatal day (E10), increases gradually and reaches its maximum at birth when a single dose is approximately 50 times more effective than in adult rats. After birth, the susceptibility of the central nervous system decreases and reaches that of adult rats at approximately 1 month (Ivankovic and Druckrey, 1968). *N*-Nitrosomethylurea and related methylating agents also induce brain tumors transplacentally, although—due to their higher toxicity—to a lesser extent. These agents produce a high incidence of central nervous system neoplasms when given as multiple small, weekly doses to adult rats. The tumors induced by alkylating agents have been classified as oligodendrogliomas, astrocytomas, ependymomas and mixed gliomas. In addition, transplacental and perinatal exposure to *N*-nitrosoethylurea (ENU) causes the induction of a high incidence of malignant schwannomas of the cranial and peripheral nerves (Wechsler et al., 1969). While the predominant tumor type, oligodendrogliomas, are thought to originate from the white matter, the other gliomas are more likely to originate from the subependymal matrix zone of the lateral ventricles (Schiffer et al., 1978; Burger et al., 1988). Recent immunohistochemical studies have shown that ENU-induced neoplasms previously classified as ependymomas express the neuronal marker synaptophysin and may thus be better termed primitive neuroectodermal tumors with neuronal differentiation (Vaquero et al., 1992).

Malignant transformation by alkylating agents is thought to result from interaction of the ultimate carcinogen, that is, a methyl or ethyl cation, with cellular DNA (Kleihues and Rajewsky, 1984). Of the various resulting base modifications produced, nucleophilic substitution at the extranuclear oxygen atoms of guanine, thymine, and cytosine has by far the greatest mutagenic efficiency and grossly correlates with the carcinogenic potential of the respective carcinogen (Singer and Grunberg, 1993). The major O-alkylated base is O^6-alkylguanine, which, during DNA replication mispairs with deoxythymidine, causing GC → AT transition mutations. O^6-methyl- and O^6-ethylguanine are repaired by the O^6-alkylguanine-DNA alkyltransferase (Pegg, 1990), and this occurs much less efficiently in the brain, that is, the target tissue, in comparison with the liver and other extraneural tissues (Goth and Rajewsky, 1974; Margison and Kleihues, 1975). This was thought to be the mechanism of preferential induction of nervous system tumors, but comparative studies in mice and gerbils showed that their central nervous system is similarly deficient in the repair of O^6-alkylguanines, although ENU and related agents do not have a significant neurooncogenic potential in these species (Kleihues and Rajewsky, 1984). So far, no transformation-associated gene has been identified to play a role in the evolution of ENU-induced central nervous system tumors. In particular, *ras* or *p53* mutations were not found in these neoplasms. In contrast, the genetic basis of ENU-induced schwannomas has been elucidated. These tumors invariably contain a T → A transversion in the transmembrane domain of the *neu* protooncogene (Bargmann et al., 1986; Perantoni et al., 1987).

The usefulness of these model systems for histogenic studies of central neuroectodermal tumors has been severely impaired by the unpredictability in location, number, and histological character of the induced neoplasms. To obviate these difficulties, we have used an organ reconstitution system in which the telencephalic anlage of ENU-primed rat embryos was transplanted into the basal ganglia of congenic recipients. The recipient animals were then challenged with a further dose of the carcinogenic agent (Burger et al., 1988b). Intriguingly, all neoplasms induced within the neural transplants had the typical histopathological features of differentiated oligodendrogliomas. They appeared to develop in a sequence similar to that observed in rats transplacentally exposed to ENU. When animals were allowed to survive for longer periods of time, a tendency to progress toward increased malignancy was observed with increasing histological dedifferentiation and invasion of adjacent brain structures.

Under the conditions of neural grafting, neoplastic transformation is restricted to oligodendrocytes or a precursor cell population already committed to oligodendrocytic differentiation. This is in marked contrast with the variety of neuroectodermal tumors induced by transplacental administration of the carcinogen. It seems, therefore, the ENU-induced brain tumors can arise by two histogenetic pathways: (1) transformation of embryonic matrix cells leading to the development of neoplasms which have retained the multipotent developmental capacity of their cells of origin. These neoplasms often originate

from the persistent subependymal matrix layer and can develop into a variety of histological subtypes, including oligodendrogliomas, astrocytomas, ependymomas, and mixed gliomas; (2) transformation of oligodendrocytes or of precursor cells committed to oligodendrocytic differentiation. This hypothesis is corroborated by the observation that ENU-induced oligodendrogliomas are frequently located in the hemispheric white matter, whereas astrocytic tumors and mixed gliomas tend to arise from the subependymal region (Schiffer, et al., 1978; Lantos and Pilkington, 1979). In fact, the absence of a persisting subependymal matrix layer might well explain the histological uniformity of the observed tumors in telencephalic rat transplants.

Direct Introduction of Oncogenes into Neuroectodermal Cells

In an effort to identify the specific molecular changes responsible for the induction of gliomas, we have exploited the grafting technology outlined above to directly introduce activated oncogenes into neuroectodermal precursor populations *in vivo*. Single-cell suspensions prepared from fetal rat brains were infected with replication-defective retroviral vectors encoding oncogenes and injected into the caudoputamen of adult rats using a stereotaxic frame. Given the frequent finding of activated, overexpressed or deregulated tyrosine kinase oncogenes, we reasoned that it might be interesting to study the consequence of widespread activation of oncogenes belonging to the "intimate" *SRC* family. These oncogenes share various structural and functional characteristics, and many of them are highly expressed in the developing nervous system and in some human and experimental neuroectodermal tumors. The members as yet recognized of this growing family of oncogenes are c-*src*, c-*fyn*, c-*yes*, and c-*yrk*. To deregulate the activity of these tyrosine kinase proteins we exploited a viral oncogene, the middle T antigen of polyomavirus (mT). Although mT lacks an enzymatic activity, it is capable of forming a protein complex with several members of the *src* family and of upregulating their tyrosine kinase activity (Courtneidge and Smith, 1983; Courtneidge, 1987; Kornbluth et al., 1987; Cheng et al., 1988; Kypta et al., 1990).

In rats carrying transplants expressing the polyoma middle T antigen we observed endothelial hemangiomas in the graft, which in 70% of the recipient animals led to fatal cerebral hemorrhage within 13 to 50 days after transplantation (Aguzzi et al., 1991). In the meantime it has been shown that endothelial cells constitute a prime target for the carcinogenic action of mT (Bautch et al., 1987; Williams et al., 1988, 1989; Montesano et al., 1990), and that tumors of other histological type than endothelial probably arise only in situations where neoplastic transformation of the endothelial compartment is blocked (Aguzzi et al., 1990; Rassoulzadegan et al., 1990; Guy et al., 1992). Most recently, we have shown that transformation of endothelial cells is possible even when either one of the kinases, c-*src*, c-*yes* or c-*fyn*, has been inactivated by homologous recombination (J. Thomas et al., 1993; Kiefer et al., 1994). Interestingly, rats that did not die from hemangiomas developed anaplastic gliomas after several months (Figure 69-5). It appears that the rapid induction of hemangiomas is induced by middle T alone, whereas delayed glioma induction requires additional genetic alterations.

As one of the most prominent biochemical effects of mT is the activation of the *SRC* kinase, we studied the consequences of the introduction of an activated moiety of *SRC*, that is, the v-*src* oncogene of the Rous sarcoma virus. Expression of the v-*src* gene caused a 70% incidence of astrocytic and mesenchymal tumors after latency periods of 2–6 months, but no endothelial lesions. It was found by *in situ* hybridization that these oncogenes are expressed in cells belonging to all types represented in the graft. This indicates that cell type-specific transformation is due to differential susceptibility of the respective target cell to the oncogenes, rather than to selective integration or expression of the retroviral construct (Aguzzi et al., 1991).

The highly efficient gene transfer by retroviral vectors into fetal brain transplants provides a challenging experimental strategy to study differentiation and oncogenesis in the central nervous system. In addition to the experiments detailed above, we have exploited this technology to study the action of various nuclear and cytoplasmic oncogenes in cells belonging to the central nervous system (Kleihues, et al., 1990; Brüstle et al., 1992a,b; Wiestler et al., 1992a, 1992b), as summarized in Figure 69-5. This model system may also become useful in assessing the organ-specific transforming activity of specific *p53* mutations observed in spontaneous and inherited human neuroectodermal neoplasms.

We would like to thank B. Pfister and D. Rüedi for technical help, and Dr. J. W. Grant for critical reading of the manuscript. The work of our laboratory is being supported by grants of the Swiss National Foundation and Swiss Cancer League to P.K. and to A.A., and by grants of the Sassella Stiftung, the Cancer League of the Kanton of Zürich, and the European Communities to A.A.

glutamate carriers and, 248
taurine, 252
Colchicine, in ischemic injury, 678
Collagenase, glioma invasion and, 1051
Colony-stimulating factor
biological action of, 706–707
in central nervous system, 453
general characteristics, 706
glial cell expression, 707
microglia and, 900
in mononuclear phagocyte system, 167
Connexins
amino acid sequences of, 301, 302f
in astrocytes, 308
in ependymal cells, 312
insertion into membranes, 302f, 303
in oligodendrocytes, 310
in Schwann cells, 312
structure of, 299–301, 301f
Coronaviruses, 1014–1016
Cortical injury, reactive gliosis and, 406
Cortical spreading depression, 901
Corticosteroids, in glioma therapy, 1054
Coupling
between astroglia, 361, 362f, 363f
gap junctions and
astrocytes, 305–309, 306f–308f
Bergmann glial cells, 312
ependymal cells, 312
Müller cells, 312
nonmammalian glial cells, 305
oligodendrocytes, 309–312, 310f, 311f
Schwann cells, 311–312
Creatine kinase, 495–496
Crosstalk, second-messenger, 284–285, 284f
CR3 receptors, 166
Crustacea, glial cells of, 99–103, 102f
CSF-1, microglial growth and, 174
C-type natriuretic peptide, 370
6-Cyano-2,3-dihydroxy-7-nitro-quinoxaline (CNQX), 817, 820
Cyclases, second messenger systems and, 502–503, 503f
Cyclic adenosine monophosphate
astrocytic swelling and, 930
gap junction conductance and, 304
glial fibrillary acidic protein levels and, 652
hepatic encephalopathy and, 956
as signal transduction system, 502
taurine effects on, 817
Cyclic guanosine monophosphate, 502–503
2′,3′-Cyclic nucleotide 3′-phosphodiesterase
myelin association, 542, 556t, 557t, 561–562, 562f
specificity of, 492–493
in X-linked mutants, 994
Cyclostomes, 107–110
Cysteic sulfinate, 246
Cysteine sulfinate decarboxylase, 496
Cytokines
cell adhesion molecules and, 688
in central nervous system, 453
chemoattractant, 708
colony-stimulating factors, 706–707
effects on astrocytes, 688
effects on experimental autoimmune encephalomyelitis, 691–692
effects on microglia, 690
effects on oligodendrocytes, 691
general features of, 701
interferon-gamma, 701–702
interleukin-1, 702–703
interleukin-6, 705–706
microglia cytotoxicity and, 900
transforming growth factor-beta, 707–708
tumor necrosis factors, 703–705
tumor necrosis factors and, 704
Cytoplasm
microfilaments, 638
sodium channels in, 205
Cytoskeletal proteins, 956
Cytoskeleton, and nodal formation, 626
Cytosolic transients, 278
Cytotactin/tenascin, 402
Cytotoxins, 674, 674t

Deiter's cells, 60
Delayed rectifier potassium channel, 187, 188f
Dendrites
in mononuclear phagocyte system, 166–167
swelling and brain edema, 921
Dentate gyrus degeneration, 891
2-Deoxyglucose, 795–797
Deoxyglucose-6-phosphate, 796–797
Depolarization, glial cells, 320–322, 320f
cell swelling and, 327
ligand-gated channels and, 328
patch-clamp recordings and, 326–327
Developmental plasticity, central nervous system. *See* Plasticity
Diacylglycerol, 500
Diffusion
extracellular potassium, 719–720
extracellular space and, 388
